Abstract

Bagging is a simple way to combine estimates in order to improve their performance. This method, suggested by Breiman in 1996, proceeds by resampling from the original data set, constructing a predictor from each subsample, and decide by combining. By bagging an n-sample, the crude nearest neighbor regression estimate is turned into a consistent weighted nearest neighbor regression estimate, which is amenable to statistical analysis. Letting the resampling size k_n grows appropriately with n, it is shown that this estimate may achieve optimal rate of convergence, independently from the fact that resampling is done with or without replacement. Since the estimate with the optimal rate of convergence depends on the unknown distribution of the observations, adaptation results by data-splitting are presented.

Keywords: bagging, resampling, nearest neighbor estimate, rates of convergence

1. Introduction

Ensemble methods are popular machine learning algorithms which train multiple learners and combine their predictions. The success of ensemble algorithms on many benchmark data sets has raised considerable interest in understanding why such methods succeed and identifying circumstances in which they can be expected to produce good results. It is now well known that the generalization ability of an ensemble can be significantly better than that of a single predictor, and ensemble learning has therefore been a hot topic during the past years. For a comprehensive review of the domain, we refer the reader to Dietterich (2000) and the references therein.

1.1 Bagging

One of the first and simplest ways to combine predictors in order to improve their performance is bagging (**b**ootstrap **agg**regat**ing**), suggested by Breiman (1996). This ensemble method proceeds by generating subsamples from the original data set, constructing a predictor from each resample, and decide by combining. It is one of the most effective computationally intensive procedures to improve on unstable estimates or classifiers, especially for large, high dimensional data set problems where finding a good model in one step is impossible because of the complexity and scale of the problem. Bagging has attracted much attention and is frequently applied, although its statistical mechanisms are not yet fully understood and are still under active investigation. Recent theoretical contributions to bagging and related methodologies include those of Friedman and Hall (2000), Bühlmann and Yu (2002), Hall and Samworth (2005), Buja and Stuetzle (2006) and Biau and Devroye (2008).

It turns out that Breiman's bagging principle has a simple application in the context of nearest neighbor methods. Nearest neighbor predictors are one of the oldest approaches to regression and classification (Fix and Hodges, 1951, 1952; Cover and Hart, 1967; Cover, 1968a,b; Györfi, 1978; Venkatesh et al., 1992; Psaltis et al., 1994). A major attraction of nearest neighbor procedures is their simplicity. For implementation, they require only a measure of distance in the sample space, along with samples of training data, hence their popularity as a starting point for refinement, improvement and adaptation to new settings (see for example Devroye et al., 1996, Chap. 19). Before we formalize the link between bagging and nearest neighbors, some definitions are in order. Throughout the paper, we suppose that we are given a sample $\mathcal{D}_n = \{(\mathbf{X}_1, Y_1), \ldots, (\mathbf{X}_n, Y_n)\}$ of i.i.d. $\mathbb{R}^d \times \mathbb{R}$-valued random variables with the same distribution as a generic pair $(\mathbf{X}, Y)$ satisfying $\mathbb{E}Y^2 < \infty$. The space $\mathbb{R}^d$ is equipped with the standard Euclidean metric. For fixed $\mathbf{x} \in \mathbb{R}^d$, our mission is to estimate the regression function $r(\mathbf{x}) = \mathbb{E}[Y|\mathbf{X} = \mathbf{x}]$ using the data $\mathcal{D}_n$. With this respect, we say that a regression function estimate $r_n(\mathbf{x})$ is consistent if $\mathbb{E}[r_n(\mathbf{X}) - r(\mathbf{X})]^2 \to 0$ as $n \to \infty$. It is universally consistent if this property is true for all distributions of $(\mathbf{X}, Y)$ with $\mathbb{E}Y^2 < \infty$.

1.2 Bagging and Nearest Neighbors

Recall that the 1-nearest neighbor (1-NN) regression estimate sets $r_n(\mathbf{x}) = Y_{(1)}(\mathbf{x})$ where $Y_{(1)}(\mathbf{x})$ is the observation of the feature vector $\mathbf{X}_{(1)}(\mathbf{x})$ whose Euclidean distance to $\mathbf{x}$ is minimal among all $\mathbf{X}_1, \ldots, \mathbf{X}_n$. Ties are broken in favor of smallest indices. It is clearly not, in general, a consistent estimate (Devroye et al., 1996, Chap. 5). However, by bagging, one may turn the 1-NN estimate into a consistent one, provided that the size of the resamples is sufficiently small.

We proceed as follows, via a randomized basic regression estimate r_{k_n} in which $1 \leq k_n \leq n$ is a parameter. The elementary predictor r_{k_n} is the 1-NN rule for a random subsample $\mathcal{S}_n$ drawn with (or without) replacement from $\{(\mathbf{X}_1, Y_1), \ldots, (\mathbf{X}_n, Y_n)\}$, with $\mathrm{Card}(\mathcal{S}_n) = k_n$. We apply bagging, that is, we repeat the random sampling an infinite number of times, and take the average of the individual outcomes. Thus, the bagged regression estimate $r_n^\star$ is defined by

$$r_n^\star(\mathbf{x}) = \mathbb{E}^\star\left[r_{k_n}(\mathbf{x})\right],$$

where $\mathbb{E}^\star$ denotes expectation with respect to the resampling distribution, conditionally on the data set $\mathcal{D}_n$.

The following result, proved in Biau and Devroye (2008), shows that for an appropriate choice of k_n, the bagged version of the 1-NN regression estimate is universally consistent:

Theorem 1 *If $k_n \to \infty$ and $k_n/n \to 0$, then $r_n^\star$ is universally consistent.*

In this theorem, the fact that resampling is done with or without replacement is irrelevant. Thus, by bagging, one may turn the crude 1-NN procedure into a consistent one, provided that the size of the resamples is sufficiently small. To understand the statistical forces driving Theorem 1, recall that if we let $V_1 \geq V_2 \geq \ldots \geq V_n \geq 0$ denote deterministic weights that sum to one, then the regression estimate

$$\sum_{i=1}^{n} V_i Y_{(i)}(\mathbf{x}),$$

with $(\mathbf{X}_{(1)}(\mathbf{x}), Y_{(1)}(\mathbf{x})), \ldots, (\mathbf{X}_{(n)}(\mathbf{x}), Y_{(n)}(\mathbf{x}))$ the reordering of the data such that

$$\|\mathbf{x} - \mathbf{X}_{(1)}(\mathbf{x})\| \leq \ldots \leq \|\mathbf{x} - \mathbf{X}_{(n)}(\mathbf{x})\|$$

is called a weighted nearest neighbor regression estimate. It is known to be universally consistent provided $V_1 \to 0$ and $\sum_{i>\varepsilon n} V_i \to 0$ for all $\varepsilon > 0$ as $n \to \infty$, see Stone (1977) and Devroye (1981) and Devroye et al. (1996, Problems 11.7, 11.8). The crux to prove Theorem 1 is to observe that $r_n^\star$ is in fact a weighted nearest neighbor estimate with

$$V_i = \mathbb{P}(i\text{-th nearest neighbor of } \mathbf{x} \text{ is the 1-NN in a random selection}).$$

Then, a moment's thought shows that for the "with replacement" sampling

$$V_i = \left(1 - \frac{i-1}{n}\right)^{k_n} - \left(1 - \frac{i}{n}\right)^{k_n},$$

whereas for sampling "without replacement", V_i is hypergeometric:

$$V_i = \begin{cases} \dfrac{\binom{n-i}{k_n - 1}}{\binom{n}{k_n}}, & i \leq n - k_n + 1 \\ 0, & i > n - k_n + 1. \end{cases}$$

The core of the proof of Theorem 1 is then to show that, in both cases, the weights V_i satisfy the conditions $V_1 \to 0$ and $\sum_{i>\varepsilon n} V_i \to 0$ for all $\varepsilon > 0$ as $n \to \infty$. These weights have been independently exhibited by Steele (2009), who also shows on practical examples that substantial reductions in prediction error are possible by bagging the 1-NN estimate. Note also that this new expression for the 1-NN bagged estimate makes any Monte-Carlo approach unnecessary to evaluate the estimate. Indeed, up to now, this predictor was implemented by Monte-Carlo, that is, by repeating the random sampling T times, and taking the average of the individual outcomes. Formally, if $Z_t = r_{k_n}(\mathbf{x})$ is the prediction in the t-th round of bagging, the bagged regression estimate was approximately evaluated as

$$r_n^\star(\mathbf{x}) \approx \frac{1}{T} \sum_{t=1}^{T} Z_t,$$

where $Z_1, \ldots, Z_T$ are the outcomes in the individual rounds. Clearly, writing the 1-NN bagged estimate as an (exact) weighted nearest neighbor predictor makes such calculations useless.

On the other hand, the fact that the bagged 1-NN estimate reduces to a weighted nearest neighbor estimate may seem at first sight somehow disappointing. Indeed, we get the ordinary k_n-NN rule back by the choice

$$V_i = \begin{cases} 1/k_n & \text{if } i \leq k_n \\ 0 & \text{otherwise,} \end{cases}$$

and, with an appropriate choice of the sequence (k_n), this regression estimate is known to have optimal asymptotic properties (see Györfi et al., 2002, Chap. 6, and the references therein). Thus, the question is: Why would one care about the bagged nearest neighbor rule then? The answer is twofold. First, bagging the 1-NN is a very popular technique for regression and classification in the machine learning community, and most—if not all—empirical studies report practical improvements over the traditional k_n-NN method. Secondly (and most importantly), analysing 1-NN bagging is part of a larger project trying to understand the driving forces behind the random forests estimates, which were defined in Breiman (2001). In short, random forests are some of the most successful ensemble methods that exhibit performance on the level of boosting and support vector machines. These learning procedures typically involve a resampling step, which may be interpreted as a particular 1-NN bagged procedure based on the so-called "layered nearest neighbor" proximities (Lin and Jeon, 2006; Biau and Devroye, 2008).

Thus, in the present paper, we go one step further in bagging investigation and study the rate of convergence of $\mathbb{E}[r_n^\star(\mathbf{X}) - r(\mathbf{X})]^2$ to 0 as $n \to \infty$. We will start our analysis by stating a comprehensive theorem on the rate of convergence of general weighted nearest neighbor estimates (Section 2.1). Then, this result will be particularized to 1-NN bagging, by distinguishing the "with replacement" (Section 2.2) and the "without replacement" (Section 2.3) cases. For the sake of clarity, technical proofs are postponed to Section 3.

Throughout the document, we will be interested in rate of convergence results for the class $\mathcal{F}$ of $(1, C, \rho, \sigma^2)$-smooth distributions $(\mathbf{X}, Y)$ such that $\mathbf{X}$ has compact support with diameter 2ρ, the regression function r is Lipschitz with constant C and, for all $\mathbf{x} \in \mathbb{R}^d$, $\sigma^2(\mathbf{x}) = \mathbb{V}[Y \,|\, \mathbf{X} = \mathbf{x}] \leq \sigma^2$ (the symbol $\mathbb{V}$ denotes variance). It is known (see, for example Ibragimov and Khasminskii, 1980, 1981, 1982) that for the class $\mathcal{F}$, the sequence $(n^{-\frac{2}{d+2}})$ is the optimal minimax rate of convergence. In particular,

$$\liminf_{n\to\infty} \inf_{r_n} \sup_{(\mathbf{X},Y)\in\mathcal{F}} \frac{\mathbb{E}[r_n(\mathbf{X}) - r(\mathbf{X})]^2}{\left((\rho C)^d \sigma^2\right)^{\frac{2}{d+2}} n^{-\frac{2}{d+2}}} \geq \Lambda$$

for some positive constant Λ independent of C, ρ and σ^2. Here the infimum is taken over all estimates r_n, that is, over all square integrable measurable functions of the data. As a striking result, we prove in Sections 2.2 and 2.3 that, irrespectively of the resampling type, for $d \geq 3$ and a suitable choice of the sequence (k_n), the estimate $r_n^\star$ is of optimum rate for the class $\mathcal{F}$, that is

$$\limsup_{n\to\infty} \sup_{(\mathbf{X},Y)\in\mathcal{F}} \frac{\mathbb{E}[r_n^\star(\mathbf{X}) - r(\mathbf{X})]^2}{\left((\rho C)^d \sigma^2\right)^{\frac{2}{d+2}} n^{-\frac{2}{d+2}}} \leq \Lambda$$

for some positive Λ independent of C, ρ and σ^2. Since the parameter k_n of the estimate with the optimal rate of convergence depends on the unknown distribution of $(\mathbf{X}, Y)$, especially on the smoothness of the regression function, we present in Section 2.4 adaptive (i.e., data-dependent) choices of k_n which preserve the minimax optimality of the estimate.

We wish to emphasize that all the results are obtained by letting the resampling size k_n grows with n in such a manner that $k_n \to \infty$ and $k_n/n \to 0$. These results are of interest because the majority of bagging experiments employ relatively large resample sizes. In fact, much of the evidence *against* the performance of bagged nearest neighbor methods is for full sample size resamples (see the discussion in Breiman, 1996, paragraph 6.4), except the notable results of Hall and Samworth (2005) and Steele (2009), who also report encouraging numerical results in the context of regression and classification.

2. Rates of Convergence

As an appetizer, we start our analysis of the 1-NN bagged regression estimate from a larger point of view, by offering a general theorem on the rate of convergence of weighted nearest neighbor estimates, that is, estimates of the form

$$r_n(\mathbf{x}) = \sum_{i=1}^{n} V_i Y_{(i)}(\mathbf{x})$$

with nonnegative weights satisfying the constraints $\sum_{i=1}^{n} V_i = 1$ and $V_1 \geq V_2 \geq \ldots \geq V_n \geq 0$.

2.1 Weighted Nearest Neighbor Estimates

Let us first recall various topological definitions that will be used in the paper. We first define the well-known notion of covering numbers which characterize the massiveness of a set (Kolmogorov and Tihomirov, 1961). As put forward in Kulkarni and Posner (1995), these quantities play a key role in the context of nearest neighbor analysis. Let $\mathcal{B}(\mathbf{x}, \varepsilon)$ denote the open Euclidean ball in $\mathbb{R}^d$ centered at $\mathbf{x}$ of radius ε.

Definition 2 *Let $\mathcal{A}$ be a subset of $\mathbb{R}^d$. The ε-covering number $\mathcal{N}(\varepsilon)$ $[= \mathcal{N}(\varepsilon, \mathcal{A})]$ is defined as the smallest number of open balls of radius ε that cover the set $\mathcal{A}$. That is*

$$\mathcal{N}(\varepsilon) = \inf \left\{ r \geq 1 : \exists \mathbf{x}_1, \ldots, \mathbf{x}_r \in \mathbb{R}^d \text{ such that } \mathcal{A} \subset \bigcup_{i=1}^{r} \mathcal{B}(\mathbf{x}_i, \varepsilon) \right\}.$$

A set $\mathcal{A} \subset \mathbb{R}^d$ is bounded if and only if $\mathcal{N}(\varepsilon) < \infty$ for all $\varepsilon > 0$. Note that as a function of ε, $\mathcal{N}(\varepsilon)$ is nonincreasing, piecewise-constant and right-continuous. The following discrete function, called the metric covering radius, can be interpreted as a pseudo-inverse of the function $\mathcal{N}(\varepsilon)$:

Definition 3 *The metric covering radius $\mathcal{N}^{-1}(r)$ $[= \mathcal{N}^{-1}(r, A)]$ is defined as the smallest radius such that there exist r balls of this radius which cover the set $\mathcal{A}$. That is*

$$\mathcal{N}^{-1}(r) = \inf \left\{ \varepsilon > 0 : \exists \mathbf{x}_1, \ldots, \mathbf{x}_r \in \mathbb{R}^d \text{ such that } \mathcal{A} \subset \bigcup_{i=1}^{r} \mathcal{B}(\mathbf{x}_i, \varepsilon) \right\}.$$

We note that $\mathcal{N}^{-1}(r)$ is a nonincreasing discrete function of r.

Throughout the paper, we will denote by μ the distribution of $\mathbf{X}$, which will be assumed to be a bounded random variable. Recall that the support $\mathcal{S}(\mu)$ of μ is defined as the collection of all $\mathbf{x}$ with $\mu(\mathcal{B}(\mathbf{x}, \varepsilon)) > 0$ for all $\varepsilon > 0$. Letting $\rho = \mathcal{N}^{-1}(1, \mathcal{S}(\mu))$, we observe that 2ρ is an upper bound on the diameter of $\mathcal{S}(\mu)$. We are now in a position to state the main result of this subsection. We let the symbol $\lfloor . \rfloor$ denote the integer part function.

Theorem 4 *Let $r_n(\mathbf{x}) = \sum_{i=1}^{n} V_i Y_{(i)}(\mathbf{x})$ be a weighted nearest neighbor estimate of $r(\mathbf{x})$. Suppose that $\mathbf{X}$ is bounded, and set $\rho = \mathcal{N}^{-1}(1, \mathcal{S}(\mu))$. Suppose in addition that, for all $\mathbf{x}$ and $\mathbf{x}' \in \mathbb{R}^d$,*

$$\sigma^2(\mathbf{x}) = \mathbb{V}[Y \,|\, \mathbf{X} = \mathbf{x}] \leq \sigma^2$$

and

$$\left| r(\mathbf{x}) - r(\mathbf{x}') \right| \leq C \|\mathbf{x} - \mathbf{x}'\|,$$

for some positive constants σ^2 and C. Then

(*i*) *If* $d = 1$,

$$\mathbb{E}\left[r_n(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq \sigma^2 \sum_{i=1}^{n} V_i^2 + 16\rho^2 C^2 \sum_{i=1}^{n} V_i \frac{i}{n}.$$

(*ii*) *If* $d = 2$,

$$\mathbb{E}\left[r_n(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq \sigma^2 \sum_{i=1}^{n} V_i^2 + 8\rho^2 C^2 \sum_{i=1}^{n} V_i \frac{i}{n} \left[1 + \ln\left(\frac{n}{i}\right)\right].$$

(*iii*) *If* $d \geq 3$,

$$\mathbb{E}\left[r_n(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq \sigma^2 \sum_{i=1}^{n} V_i^2 + \frac{8\rho^2 C^2}{1 - 2/d} \sum_{i=1}^{n} V_i \left\lfloor \frac{n}{i} \right\rfloor^{-2/d}.$$

Proof Setting

$$\tilde{r}_n(\mathbf{x}) = \sum_{i=1}^{n} V_i \, r(\mathbf{X}_{(i)}(\mathbf{x})),$$

the proof of Theorem 4 will rely on the variance/bias decomposition

$$\mathbb{E}\left[r_n(\mathbf{X}) - r(\mathbf{X})\right]^2 = \mathbb{E}\left[r_n(\mathbf{X}) - \tilde{r}_n(\mathbf{X})\right]^2 + \mathbb{E}\left[\tilde{r}_n(\mathbf{X}) - r(\mathbf{X})\right]^2. \tag{1}$$

The first term is easily bounded by noting that, for all $\mathbf{x} \in \mathbb{R}^d$,

$$\begin{aligned}
\mathbb{E}\left[r_n(\mathbf{x}) - \tilde{r}_n(\mathbf{x})\right]^2 &= \mathbb{E}\left[\sum_{i=1}^{n} V_i \left(Y_{(i)}(\mathbf{x}) - r(\mathbf{X}_{(i)}(\mathbf{x}))\right)\right]^2 \\
&= \mathbb{E}\left[\sum_{i=1}^{n} V_i^2 \left(Y_{(i)}(\mathbf{x}) - r(\mathbf{X}_{(i)}(\mathbf{x}))\right)^2\right] \\
&= \mathbb{E}\left[\sum_{i=1}^{n} V_i^2 \sigma^2 \left(\mathbf{X}_{(i)}(\mathbf{x})\right)\right] \\
&\leq \sigma^2 \sum_{i=1}^{n} V_i^2. \qquad (2)
\end{aligned}$$

To analyse the bias term in (1), we will need the following result, which bounds the convergence rate of the expected i-th nearest neighbor squared distance in terms of the metric covering radii of the support of the distribution μ of $\mathbf{X}$. Proposition 5 is a generalization of Theorem 1, page 1032 in Kulkarni and Posner (1995), which only reports results for the rate of convergence of *the* nearest neighbor. Therefore, this result is interesting by itself.

Proposition 5 *Suppose that* $\mathbf{X}$ *is bounded*. *Then*

$$\mathbb{E}\|\mathbf{X}_{(i)}(\mathbf{X}) - \mathbf{X}\|^2 \leq \frac{8i}{n} \sum_{j=1}^{\lfloor n/i \rfloor} \left[\mathcal{N}^{-1}\left(j, \mathcal{S}(\mu)\right)\right]^2.$$

For any bounded set $\mathcal{A}$ in the Euclidean d-space, the covering radius satisfies $\mathcal{N}^{-1}(r, \mathcal{A}) \leq \mathcal{N}^{-1}(1, \mathcal{A}) r^{-1/d}$ (see Kolmogorov and Tihomirov, 1961). Hence the following corollary:

Corollary 6 *Suppose that* $\mathbf{X}$ *is bounded, and set* $\rho = \mathcal{N}^{-1}(1, \mathcal{S}(\mu))$. *Then*

(*i*) *If* $d = 1$,

$$\mathbb{E}\|\mathbf{X}_{(i)}(\mathbf{X}) - \mathbf{X}\|^2 \leq \frac{16\rho^2 i}{n}.$$

(*ii*) *If* $d = 2$,

$$\mathbb{E}\|\mathbf{X}_{(i)}(\mathbf{X}) - \mathbf{X}\|^2 \leq \frac{8\rho^2 i}{n}\left[1 + \ln\left(\frac{n}{i}\right)\right].$$

(*iii*) *If* $d \geq 3$,

$$\mathbb{E}\|\mathbf{X}_{(i)}(\mathbf{X}) - \mathbf{X}\|^2 \leq \frac{8\rho^2 \lfloor n/i \rfloor^{-\frac{2}{d}}}{1 - 2/d}.$$

Thus, to prove Theorem 4, it suffices to note from (1) and (2) that

$$\mathbb{E}\left[r_n(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq \sigma^2 \sum_{i=1}^{n} V_i^2 + \mathbb{E}\left[\tilde{r}_n(\mathbf{X}) - r(\mathbf{X})\right]^2.$$

Next,

$$\begin{aligned}
\mathbb{E}\left[\tilde{r}_n(\mathbf{x}) - r(\mathbf{x})\right]^2 &= \mathbb{E}\left[\sum_{i=1}^{n} V_i \left(r(\mathbf{X}_{(i)}(\mathbf{x})) - r(\mathbf{x})\right)\right]^2 \\
&\leq \mathbb{E}\left[\sum_{i=1}^{n} V_i \left|r(\mathbf{X}_{(i)}(\mathbf{x})) - r(\mathbf{x})\right|\right]^2 \\
&\leq C^2\, \mathbb{E}\left[\sum_{i=1}^{n} V_i \left\|\mathbf{X}_{(i)}(\mathbf{x}) - \mathbf{x}\right\|\right]^2 \\
&\leq C^2 \left[\sum_{i=1}^{n} V_i\, \mathbb{E}\|\mathbf{X}_{(i)}(\mathbf{x}) - \mathbf{x}\|^2\right] \\
&\qquad \text{(by Jensen's inequality).}
\end{aligned}$$

Therefore, integrating with respect to the distribution of $\mathbf{X}$, we obtain

$$\mathbb{E}\left[\tilde{r}_n(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq C^2 \left[\sum_{i=1}^{n} V_i\, \mathbb{E}\|\mathbf{X}_{(i)}(\mathbf{X}) - \mathbf{X}\|^2\right],$$

and the conclusion follows by applying Corollary 6. ■

Theorem 4 offers a general result, which can be made more precise according to the weights definition. Taking for example

$$V_i = \begin{cases} 1/k_n & \text{if } i \leq k_n \\ 0 & \text{otherwise,} \end{cases}$$

we get the ordinary k_n-NN rule back. Here,

$$\sum_{i=1}^{n} V_i^2 = \frac{1}{k_n}$$

and

$$\begin{aligned}\sum_{i=1}^{n} V_i \left\lfloor \frac{n}{i} \right\rfloor^{-2/d} &= \frac{1}{k_n} \sum_{i=1}^{k_n} \left\lfloor \frac{n}{i} \right\rfloor^{-2/d} \\ &\leq \frac{1}{k_n} \sum_{i=1}^{k_n} \left\lfloor \frac{n}{k_n} \right\rfloor^{-2/d} \\ &= \left\lfloor \frac{n}{k_n} \right\rfloor^{-2/d} \\ &\leq \xi \left(\frac{n}{k_n} \right)^{-2/d}\end{aligned}$$

for some positive ξ. Therefore, in this context, according to Theorem 4, for $d \geq 3$, there exists a sequence (k_n) with $k_n \propto n^{\frac{2}{d+2}}$ such that

$$\mathbb{E}\left[r_n(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq \Lambda \left(\frac{(\rho C)^d \sigma^2}{n} \right)^{\frac{2}{d+2}},$$

for some positive constant Λ independent of ρ, C and σ^2. This is exactly Theorem 6.2, page 93 of Györfi et al. (2002), which states that the standard nearest neighbor estimate is of optimum rate for the class $\mathcal{F}$ of $(1, C, \rho, \sigma^2)$-smooth distributions $(\mathbf{X}, Y)$ such that $\mathbf{X}$ has compact support with covering radius ρ, the regression function r is Lipschitz with constant C and, for all $\mathbf{x} \in \mathbb{R}^d$, $\sigma^2(\mathbf{x}) = \mathbb{V}[Y \,|\, \mathbf{X} = \mathbf{x}] \leq \sigma^2$ (note however that the ordinary k_n-NN predictor is *not* optimal for higher smoothness, see Problem 6.2 in Györfi et al., 2002).

The adaptation of Theorem 4 to the 1-NN bagged regression estimate needs more careful attention. This will be the topic of the next two Sections.

2.2 Bagging with Replacement

This bagging-type is sometimes called moon-bagging, standing for **m o**ut **o**f **n b**ootstrap **agg**regat**ing**. As seen in the introduction, in this case, the weighted nearest neighbor regression estimate takes the form

$$r_n^\star(\mathbf{x}) = \sum_{i=1}^{n} V_i Y_{(i)}(\mathbf{x}),$$

where

$$V_i = \left(1 - \frac{i-1}{n}\right)^{k_n} - \left(1 - \frac{i}{n}\right)^{k_n}.$$

From now on, $\Gamma(t)$ will denote the Gamma function, that is,

$$\Gamma(t) = \int_0^\infty x^{t-1} e^{-x} \mathrm{d}x, \quad t > 0.$$

In order to make full use of Theorem 4, we first need a careful control of the term $\sum_{i=1}^n V_i^2$. This is done in the next proposition.

Proposition 7 *For $i = 1, \ldots, n$, let*

$$V_i = \left(1 - \frac{i-1}{n}\right)^{k_n} - \left(1 - \frac{i}{n}\right)^{k_n}.$$

Then

$$\sum_{i=1}^{n} V_i^2 \leq \frac{2k_n}{n}\left(1 + \frac{1}{n}\right)^{2k_n}.$$

The message of Proposition 7 is that, when resampling is done with replacement, the variance term of the bagged NN estimate is $\mathrm{O}(k_n/n)$. Let us now turn to the bias term analysis.

Proposition 8 *For $i = 1, \ldots, n$, let*

$$V_i = \left(1 - \frac{i-1}{n}\right)^{k_n} - \left(1 - \frac{i}{n}\right)^{k_n}.$$

Then

(*i*) *If $d = 1$,*

$$\sum_{i=1}^{n} V_i \frac{i}{n} \leq \frac{2}{k_n}\left(1 + \frac{1}{n}\right)^{k_n}.$$

(*ii*) *If $d = 2$,*

$$\sum_{i=1}^{n} V_i \frac{i}{n}\left[1 + \ln\left(\frac{n}{i}\right)\right] \leq \frac{2}{k_n}\left(1 + \frac{1}{n}\right)^{k_n}\left[1 + \ln(k_n + 1)\right].$$

(*iii*) *If $d \geq 3$,*

$$\sum_{i=1}^{n} V_i \left\lfloor \frac{n}{i} \right\rfloor^{-2/d} \leq \frac{1}{n^{k_n}} + \alpha_d \left(1 + \frac{1}{n}\right)^{k_n} {k_n}^{-\frac{2}{d}},$$

where

$$\alpha_d = 2\Gamma\left(\frac{d-2}{d}\right)\Gamma\left(\frac{d+2}{d}\right).$$

The take-home message here is that, for $d \geq 3$, the squared bias is $\mathrm{O}(k_n^{-2/d})$. Finally, putting all the pieces together, we obtain

Theorem 9 *Suppose that $\mathbf{X}$ is bounded, and set $\rho = \mathcal{N}^{-1}(1, \mathcal{S}(\mu))$. Suppose in addition that, for all $\mathbf{x}$ and $\mathbf{x}' \in \mathbb{R}^d$,*

$$\sigma^2(\mathbf{x}) = \mathbb{V}[Y \,|\, \mathbf{X} = \mathbf{x}] \leq \sigma^2$$

and

$$\left|r(\mathbf{x}) - r(\mathbf{x}')\right| \leq C\|\mathbf{x} - \mathbf{x}'\|,$$

for some positive constants σ^2 and C. Then

(*i*) *If $d = 1$,*

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq \frac{2\sigma^2 k_n}{n}\left(1 + \frac{1}{n}\right)^{2k_n} + \frac{32\rho^2 C^2}{k_n}\left(1 + \frac{1}{n}\right)^{k_n}.$$

(*ii*) *If* $d = 2$,

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq \frac{2\sigma^2 k_n}{n}\left(1+\frac{1}{n}\right)^{2k_n} + \frac{16\rho^2 C^2}{k_n}\left(1+\frac{1}{n}\right)^{k_n}\left[1+\ln(k_n+1)\right].$$

(*iii*) *If* $d \geq 3$,

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq \frac{2\sigma^2 k_n}{n}\left(1+\frac{1}{n}\right)^{2k_n} + \frac{8\rho^2 C^2}{1-2/d}\left[\frac{1}{n^{k_n}} + \alpha_d\left(1+\frac{1}{n}\right)^{k_n} k_n^{-\frac{2}{d}}\right],$$

where

$$\alpha_d = 2\Gamma\left(\frac{d-2}{d}\right)\Gamma\left(\frac{d+2}{d}\right).$$

By balancing the terms in Theorem 9, we are led to the following corollary:

Corollary 10 *Under the assumptions of Theorem 9,*

(*i*) *If* $d = 1$, *there exists a sequence* (k_n) *such that* $k_n \to \infty$, $k_n/n \to 0$, *and*

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq \Lambda \frac{\rho C \sigma}{\sqrt{n}},$$

for some positive constant Λ *independent of* ρ, C *and* σ^2.

(*ii*) *If* $d = 2$, *there exists a sequence* (k_n) *such that* $k_n \to \infty$, $k_n/n \to 0$, *and*

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq (\Lambda + o(1))\,\rho C \sigma \sqrt{\frac{\ln n}{n}},$$

for some positive constant Λ *independent of* ρ, C *and* σ^2.

(*iii*) *If* $d \geq 3$, *there exists a sequence* (k_n) *with* $k_n \propto n^{\frac{d}{d+2}}$ *such that*

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq \Lambda\left(\frac{(\rho C)^d \sigma^2}{n}\right)^{\frac{2}{d+2}},$$

for some positive constant Λ *independent of* ρ, C *and* σ^2.

Two important remarks are in order.

1. First, we note that, for $d \geq 3$ and a suitable choice of k_n, the bagged 1-NN estimate achieves both the minimax $n^{-2/(d+2)}$ rate and the optimal order of magnitude $((\rho C)^d \sigma^2)^{2/(d+2)}$ in the constant, for the class $\mathcal{F}$ of $(1, C, \rho, \sigma^2)$-smooth distributions $(\mathbf{X}, Y)$ such that $\mathbf{X}$ has compact support with covering radius ρ, the regression function r is Lipschitz with constant C and, for

all $\mathbf{x} \in \mathbb{R}^d$, $\sigma^2(\mathbf{x}) = \mathbb{V}[Y \,|\, \mathbf{X} = \mathbf{x}] \leq \sigma^2$. Seconds, the bound is valid for finite sample sizes, so that we are in fact able to approach the minimax lower bound not only asymptotically but even for finite sample sizes. On the other hand, the estimate with the optimal rate of convergence depends on the unknown distribution of $(\mathbf{X}, Y)$, and especially on the covering radius ρ and the smoothness of the regression function measured by the constant C. It is to correct this situation that we present adaptation results in Section 2.4.

2. For $d = 1$, the obtained rate is not optimal, whereas it is optimal up to a log term for $d = 2$. This low-dimensional phenomenon is also known to hold for the traditional k_n-NN regression estimate, which does not achieve the optimal rates in dimensions 1 and 2 (see Problems 6.1 and 6.7 in Györfi et al., 2002, Chap. 3).

2.3 Bagging Without Replacement

We briefly analyse in this subsection the rate of convergence of the bagged 1-NN regression estimate, assuming this time that, at each step, the k_n observations are distinctly chosen at random within the sample set $\mathcal{D}_n$. This alternative aggregation scheme is called subagging (for **sub**sample **agg**regat**ing**) in Bühlmann and Yu (2002). We know that, in this case, the weighted nearest neighbor regression estimate takes the form

$$r_n^\star(\mathbf{x}) = \sum_{i=1}^n V_i Y_{(i)}(\mathbf{x}),$$

where

$$V_i = \begin{cases} \dfrac{\binom{n-i}{k_n-1}}{\binom{n}{k_n}}, & i \leq n - k_n + 1 \\ 0, & i > n - k_n + 1. \end{cases}$$

Due to the fact that there is no repetition in the sampling process, the analysis turns out to be simpler. To prove Theorem 13 below, we start again by a control of the variance term $\sum_{i=1}^n V_i^2$.

Proposition 11 *For $i = 1, \ldots, n$, let*

$$V_i = \begin{cases} \dfrac{\binom{n-i}{k_n-1}}{\binom{n}{k_n}}, & i \leq n - k_n + 1 \\ 0, & i > n - k_n + 1. \end{cases}$$

Then

$$\sum_{i=1}^n V_i^2 \leq \frac{k_n}{n} \frac{1}{(1 - k_n/n + 1/n)^2}.$$

Thus, as for bagging with replacement, the variance term of the without replacement bagged 1-NN estimate is $O(k_n/n)$. The bias term may be treated by resorting to Theorem 4, via complex calculations due to the complicate form of the bagging weights. However, a much simpler route may be followed. Recall that

$$\tilde{r}_n^\star(\mathbf{x}) = \sum_{i=1}^n V_i \, r(\mathbf{X}_{(i)}(\mathbf{x})),$$

and observe that

$$\tilde{r}_n^\star(\mathbf{x}) = \mathbb{E}^\star\left[r(\mathbf{X}_{(1)}^\star(\mathbf{x}))\right],$$

where $\mathbf{X}_{(1)}^\star(\mathbf{x})$ is the nearest neighbor of $\mathbf{x}$ in a random subsample $\mathcal{S}_n$ drawn without replacement from $\{(\mathbf{X}_1,Y_1),\ldots,(\mathbf{X}_n,Y_n)\}$ with $\mathrm{Card}(\mathcal{S}_n)=k_n$, and $\mathbb{E}^\star$ denotes expectation with respect to the resampling distribution, conditionally on the data set $\mathcal{D}_n$. This is the basic ingredient for the proof of the next proposition.

Proposition 12 *Suppose that* $\mathbf{X}$ *is bounded, and set* $\rho = \mathcal{N}^{-1}(1,\mathcal{S}(\mu))$. *Suppose in addition that, for all* $\mathbf{x}$ *and* $\mathbf{x}' \in \mathbb{R}^d$,

$$\left|r(\mathbf{x}) - r(\mathbf{x}')\right| \le C\|\mathbf{x}-\mathbf{x}'\|,$$

for some positive constant C. *Then*

(*i*) *If* $d=1$,

$$\mathbb{E}\left[\tilde{r}_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \le \frac{16\rho^2C^2}{k_n}.$$

(*ii*) *If* $d=2$,

$$\mathbb{E}\left[\tilde{r}_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \le \frac{8\rho^2C^2}{k_n}(1+\ln k_n).$$

(*iii*) *If* $d\ge 3$,

$$\mathbb{E}\left[\tilde{r}_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \le \frac{8\rho^2C^2}{1-2/d}\,{k_n}^{-\frac{2}{d}}.$$

Thus, for $d\ge 3$, $\mathbb{E}\left[\tilde{r}_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 = \mathrm{O}(k_n^{-2/d})$. Combining Proposition 11 and Proposition 12 leads to the desired theorem:

Theorem 13 *Suppose that* $\mathbf{X}$ *is bounded, and set* $\rho = \mathcal{N}^{-1}(1,\mathcal{S}(\mu))$. *Suppose in addition that, for all* $\mathbf{x}$ *and* $\mathbf{x}' \in \mathbb{R}^d$,

$$\sigma^2(\mathbf{x}) = \mathbb{V}[Y\,|\,\mathbf{X}=\mathbf{x}] \le \sigma^2$$

and

$$\left|r(\mathbf{x}) - r(\mathbf{x}')\right| \le C\|\mathbf{x}-\mathbf{x}'\|,$$

for some positive constants σ^2 *and* C. *Then*

(*i*) *If* $d=1$,

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \le \frac{k_n}{n}\,\frac{\sigma^2}{(1-k_n/n+1/n)^2} + \frac{16\rho^2C^2}{k_n}.$$

(*ii*) *If* $d=2$,

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \le \frac{k_n}{n}\,\frac{\sigma^2}{(1-k_n/n+1/n)^2} + \frac{8\rho^2C^2}{k_n}(1+\ln k_n).$$

(*iii*) *If* $d\ge 3$,

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \le \frac{k_n}{n}\,\frac{\sigma^2}{(1-k_n/n+1/n)^2} + \frac{8\rho^2C^2}{1-2/d}\,k_n^{-\frac{2}{d}}.$$

By balancing the variance and bias terms, we obtain the following useful corollary:

Corollary 14 *Under the assumptions of Theorem 13,*

(*i*) *If $d = 1$, there exists a sequence (k_n) such that $k_n \to \infty$, $k_n/n \to 0$, and*

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq (\Lambda + o(1))\,\frac{\rho C \sigma}{\sqrt{n}},$$

for some positive constant Λ independent of ρ, C and σ^2.

(*ii*) *If $d = 2$, there exists a sequence (k_n) such that $k_n \to \infty$, $k_n/n \to 0$, and*

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq (\Lambda + o(1))\,\rho C \sigma \sqrt{\frac{\ln n}{n}},$$

for some positive constant Λ independent of ρ, C and σ^2.

(*iii*) *If $d \geq 3$, there exists a sequence (k_n) with $k_n \propto n^{\frac{d}{d+2}}$ such that*

$$\mathbb{E}\left[r_n^\star(\mathbf{X}) - r(\mathbf{X})\right]^2 \leq (\Lambda + o(1)) \left(\frac{(\rho C)^d \sigma^2}{n}\right)^{\frac{2}{d+2}},$$

for some positive constant Λ independent of ρ, C and σ^2.

As in bagging with replacement, Corollary 14 expresses the fact that, for $d \geq 3$, the without replacement bagged 1-NN estimate asymptotically achieves both the minimax $n^{-2/(d+2)}$ rate of convergence and the optimal order of magnitude $((\rho C)^d \sigma^2)^{d/(d+2)}$ in the constant, for the class $\mathcal{F}$ of $(1, C, \rho, \sigma^2)$-smooth distributions $(\mathbf{X}, Y)$.

2.4 Adaptation

In the previous subsections, the parameter k_n of the estimate with the optimal rate of convergence for the class $\mathcal{F}$ depends on the unknown distribution of $(\mathbf{X}, Y)$, especially on the smoothness of the regression function measured by the Lipschitz constant C. In this subsection, we present a data-dependent way of choosing the resampling size k_n and show that, for bounded Y, the estimate with parameter chosen in such an adaptive way achieves the optimal rate of convergence (irrespectively of the resampling type). To this aim, we split the sample $\mathcal{D}_n = \{(\mathbf{X}_1, Y_1), \ldots, (\mathbf{X}_n, Y_n)\}$ in two parts of size $\lfloor n/2 \rfloor$ and $n - \lfloor n/2 \rfloor$, respectively (assuming $n \geq 2$). The first half is denoted by $\mathcal{D}_n^\ell$ (learning set) and is used to construct the bagged 1-NN estimate $r^\star_{\lfloor n/2 \rfloor}(\mathbf{x}, \mathcal{D}_n^\ell) = r^\star_{k, \lfloor n/2 \rfloor}(\mathbf{x}, \mathcal{D}_n^\ell)$ (for the sake of clarity, we make the dependence of the estimate upon k explicit). The second half of the sample, denoted by $\mathcal{D}_n^t$ (testing set), is used to choose k by picking $\hat{k}_n \in K = \{1, \ldots, \lfloor n/2 \rfloor\}$ to minimize the empirical risk

$$\frac{1}{n - \lfloor n/2 \rfloor} \sum_{i = \lfloor n/2 \rfloor + 1}^{n} \left(Y_i - r^\star_{k, \lfloor n/2 \rfloor}(\mathbf{X}_i)\right)^2.$$

Define the estimate

$$r_n^\star(\mathbf{x}) = r^\star_{\hat{k}_n, \lfloor n/2 \rfloor}(\mathbf{x}, \mathcal{D}_n^\ell),$$

and note that $r_n^\star$ depends on the entire data $\mathcal{D}_n$. If $|Y| \leq L < \infty$ almost surely, a straightforward adaptation of Theorem 7.1 in Györfi et al. (2002) shows that, for any $\delta > 0$,

$$\mathbb{E}[r_n^\star(\mathbf{X}) - r(\mathbf{X})]^2 \leq (1+\delta) \inf_{k \in K} \mathbb{E}[r_{k,\lfloor n/2 \rfloor}^\star(\mathbf{X}) - r(\mathbf{X})]^2 + \Xi \frac{\ln n}{n},$$

for some positive constant Ξ depending only on L, d and δ. Immediately from Corollary 10 and Corollary 14 we can conclude:

Theorem 15 *Suppose that $|Y| \leq L$ almost surely, and let $r_n^\star$ be the bagged 1-NN estimate with $k \in K = \{1, \ldots, \lfloor n/2 \rfloor\}$ chosen by data-splitting, irrespectively of the resampling type. Then $(\ln n)^{(d+2)/(2d)} n^{-1/2} \leq \rho C$ together with $d \geq 3$ implies, for $n \geq 2$,*

$$\mathbb{E}[r_n^\star(\mathbf{X}) - r(\mathbf{X})]^2 \leq (\Lambda + o(1)) \left(\frac{(\rho C)^d}{n} \right)^{\frac{2}{d+2}},$$

for some positive constant Λ which depends only on L and d.

Thus, the expected error of the estimate obtained via data-splitting is bounded from above up to a constant by the corresponding minimax lower bound for the class $\mathcal{F}$ of regression functions, with the optimal dependence in C and ρ.

3. Proofs

Proofs of the main results are gathered in this section.

3.1 Proof of Proposition 5

All the covering and metric numbers we use in this proof are pertaining to the bounded set $\mathcal{S}(\mu)$. Therefore, to lighten notation a bit, we set $\mathcal{N}(\varepsilon) = \mathcal{N}(\varepsilon, \mathcal{S}(\mu))$ and $\mathcal{N}^{-1}(r) = \mathcal{N}^{-1}(r, \mathcal{S}(\mu))$.

Let $\mathbf{X}'$ be a random variable distributed as and independent of $\mathbf{X}$, and let, for $\varepsilon > 0$,

$$F_{\mathbf{X}}(\varepsilon) = \mathbb{P}\left(\|\mathbf{X} - \mathbf{X}'\| \leq \varepsilon \,|\, \mathbf{X} \right)$$

be the conditional cumulative distribution function of the Euclidean distance between $\mathbf{X}$ and $\mathbf{X}'$. Set finally

$$D_{(i)}(\mathbf{X}) = \|\mathbf{X}_{(i)}(\mathbf{X}) - \mathbf{X}\|.$$

Clearly,

$$\begin{aligned} \mathbb{P}\left(D_{(i)}^2(\mathbf{X}) > \varepsilon \right) &= \mathbb{E}\left[\mathbb{P}\left(D_{(i)}(\mathbf{X}) > \sqrt{\varepsilon} \,|\, \mathbf{X} \right) \right] \\ &= \mathbb{E}\left[\sum_{j=0}^{i-1} \binom{n}{j} \left[F_{\mathbf{X}}\left(\sqrt{\varepsilon}\right) \right]^j \left[1 - F_{\mathbf{X}}\left(\sqrt{\varepsilon}\right) \right]^{n-j} \right]. \end{aligned} \tag{3}$$

Take $\mathcal{B}_1, \ldots, \mathcal{B}_{\mathcal{N}(\sqrt{\varepsilon}/2)}$ a $\sqrt{\varepsilon}/2$-covering of $\mathcal{S}(\mu)$, and define an $\mathcal{N}(\sqrt{\varepsilon}/2)$-partition of $\mathcal{S}(\mu)$ as follows. For each $\ell = 1, \ldots, \mathcal{N}(\sqrt{\varepsilon}/2)$, let

$$\mathcal{P}_\ell = \mathcal{B}_\ell - \bigcup_{j=1}^{\ell-1} \mathcal{B}_j.$$

Then $\mathcal{P}_\ell \subset \mathcal{B}_\ell$ and

$$\bigcup_{\ell=1}^{\mathcal{N}(\sqrt{\varepsilon}/2)} \mathcal{B}_\ell = \bigcup_{\ell=1}^{\mathcal{N}(\sqrt{\varepsilon}/2)} \mathcal{P}_\ell,$$

with $\mathcal{P}_i \cap \mathcal{P}_m = \emptyset$. Also,

$$\sum_{\ell=1}^{\mathcal{N}(\sqrt{\varepsilon}/2)} \mu(\mathcal{P}_\ell) = 1.$$

Thus, letting $p_\ell = \mu(\mathcal{P}_\ell)$, we may write

$$\begin{aligned} F_{\mathbf{X}}\left(\sqrt{\varepsilon}\right) &\geq \mathbb{P}(\exists\, \ell = 1, \ldots, \mathcal{N}(\sqrt{\varepsilon}/2) : \mathbf{X} \in \mathcal{P}_\ell \text{ and } \mathbf{X}' \in \mathcal{P}_\ell \,|\, \mathbf{X}) \\ &= \mathbb{E}\left[\sum_{\ell=1}^{\mathcal{N}(\sqrt{\varepsilon}/2)} \mathbf{1}_{[\mathbf{X} \in \mathcal{P}_\ell]} \mathbf{1}_{[\mathbf{X}' \in \mathcal{P}_\ell]} \middle| \mathbf{X} \right] \\ &= \sum_{\ell=1}^{\mathcal{N}(\sqrt{\varepsilon}/2)} p_\ell \mathbf{1}_{[\mathbf{X} \in \mathcal{P}_\ell]}. \end{aligned}$$

As a by-product, we remark that, for all $\varepsilon > 0$, $F_{\mathbf{X}}\left(\sqrt{\varepsilon}\right) > 0$ almost surely. Moreover

$$\mathbb{E}\left[\frac{1}{F_{\mathbf{X}}\left(\sqrt{\varepsilon}\right)}\right] \leq \mathbb{E}\left[\frac{1}{\sum_{\ell=1}^{\mathcal{N}(\sqrt{\varepsilon}/2)} p_\ell \mathbf{1}_{[\mathbf{X} \in \mathcal{P}_\ell]}}\right] = \mathbb{E}\left[\sum_{\ell=1}^{\mathcal{N}(\sqrt{\varepsilon}/2)} \frac{1}{p_\ell} \mathbf{1}_{[\mathbf{X} \in \mathcal{P}_\ell]}\right],$$

leading to

$$\mathbb{E}\left[\frac{1}{F_{\mathbf{X}}\left(\sqrt{\varepsilon}\right)}\right] \leq \mathcal{N}\left(\frac{\sqrt{\varepsilon}}{2}\right). \tag{4}$$

Consequently, combining inequalities (3), (4) and technical Lemma 16, we obtain

$$\begin{aligned} \mathbb{P}\left(D^2_{(i)}(\mathbf{X}) > \varepsilon\right) &= \mathbb{E}\left[\frac{1}{F_{\mathbf{X}}\left(\sqrt{\varepsilon}\right)} \sum_{j=0}^{i-1} \binom{n}{j} \left[F_{\mathbf{X}}\left(\sqrt{\varepsilon}\right)\right]^{j+1} \left[1 - F_{\mathbf{X}}\left(\sqrt{\varepsilon}\right)\right]^{n-j}\right] \\ &\leq \frac{i}{n+1} \mathbb{E}\left[\frac{1}{F_{\mathbf{X}}\left(\sqrt{\varepsilon}\right)}\right] \\ &\leq \frac{i}{n} \mathcal{N}\left(\frac{\sqrt{\varepsilon}}{2}\right). \end{aligned}$$

Thus, since $\mathbb{P}(D^2_{(i)}(\mathbf{X}) > \varepsilon) = 0$ for $\varepsilon > 4[\mathcal{N}^{-1}(1)]^2$, we obtain

$$\begin{aligned} \mathbb{E}\left[D^2_{(i)}(\mathbf{X})\right] &= \int_0^\infty \mathbb{P}(D^2_{(i)}(\mathbf{X}) > \varepsilon) \mathrm{d}\varepsilon \\ &= \int_0^{4[\mathcal{N}^{-1}(1)]^2} \mathbb{P}(D^2_{(i)}(\mathbf{X}) > \varepsilon) \mathrm{d}\varepsilon \\ &\leq 4\left[\mathcal{N}^{-1}\left(\left\lfloor \frac{n}{i} \right\rfloor\right)\right]^2 + \frac{i}{n} \int_{4[\mathcal{N}^{-1}(\lfloor n/i \rfloor)]^2}^{4[\mathcal{N}^{-1}(1)]^2} \mathcal{N}(\sqrt{\varepsilon}/2) \mathrm{d}\varepsilon. \end{aligned}$$

Since $\mathcal{N}(\sqrt{\varepsilon}) = j$ for $\mathcal{N}^{-1}(j) \leq \sqrt{\varepsilon} < \mathcal{N}^{-1}(j-1)$, we get

$$\begin{aligned}
\mathbb{E}\left[D^2_{(i)}(\mathbf{X})\right] &\leq 4\left[\mathcal{N}^{-1}\left(\left\lfloor \frac{n}{i} \right\rfloor\right)\right]^2 + \frac{4i}{n}\int_{[\mathcal{N}^{-1}(\lfloor n/i \rfloor)]^2}^{[\mathcal{N}^{-1}(1)]^2} \mathcal{N}(\sqrt{\varepsilon})\mathrm{d}\varepsilon \\
&\leq 4\left[\mathcal{N}^{-1}\left(\left\lfloor \frac{n}{i} \right\rfloor\right)\right]^2 + \frac{4i}{n}\sum_{j=2}^{\lfloor n/i \rfloor}\int_{[\mathcal{N}^{-1}(j)]^2}^{[\mathcal{N}^{-1}(j-1)]^2} j\,\mathrm{d}\varepsilon \\
&= 4\left[\mathcal{N}^{-1}\left(\left\lfloor \frac{n}{i} \right\rfloor\right)\right]^2 \\
&\quad + \frac{4i}{n}\left[2\left[\mathcal{N}^{-1}(1)\right]^2 - \left\lfloor \frac{n}{i} \right\rfloor\left[\mathcal{N}^{-1}\left(\left\lfloor \frac{n}{i} \right\rfloor\right)\right]^2 + \sum_{j=2}^{\lfloor n/i \rfloor - 1}\left[\mathcal{N}^{-1}(j)\right]^2\right] \\
&\leq \frac{8i}{n}\left[\mathcal{N}^{-1}(1)\right]^2 + \frac{4i}{n}\left[\mathcal{N}^{-1}\left(\left\lfloor \frac{n}{i} \right\rfloor\right)\right]^2 + \frac{4i}{n}\sum_{j=2}^{\lfloor n/i \rfloor - 1}\left[\mathcal{N}^{-1}(j)\right]^2,
\end{aligned}$$

where the last statement follows from the inequality

$$-\frac{4i}{n}\left\lfloor \frac{n}{i} \right\rfloor + 4 \leq \frac{4i}{n}.$$

In conclusion, we are led to

$$\mathbb{E}\left[D^2_{(i)}(\mathbf{X})\right] \leq \frac{8i}{n}\sum_{j=1}^{\lfloor n/i \rfloor}\left[\mathcal{N}^{-1}(j)\right]^2,$$

as desired.

3.2 Proof of Corollary 6

For any bounded set $\mathcal{A}$ in the Euclidean d-space, the covering radius satisfies $\mathcal{N}^{-1}(r,\mathcal{A}) \leq \mathcal{N}^{-1}(1,\mathcal{A})r^{-1/d}$ (see Kolmogorov and Tihomirov, 1961). Consequently, using Proposition 5, we obtain

(*i*) For $d = 1$,

$$\begin{aligned}
\mathbb{E}\|\mathbf{X}_{(i)}(\mathbf{X}) - \mathbf{X}\|^2 &\leq \frac{8\rho^2 i}{n}\sum_{j=1}^{\lfloor n/i \rfloor} j^{-2} \\
&\leq \frac{8\rho^2 i}{n}\left[1 + \int_1^{\lfloor n/i \rfloor} x^{-2}\mathrm{d}x\right] \\
&\leq \frac{16\rho^2 i}{n}.
\end{aligned}$$

(*ii*) For $d = 2$,

$$\begin{aligned}
\mathbb{E}\|\mathbf{X}_{(i)}(\mathbf{X}) - \mathbf{X}\|^2 &\leq \frac{8\rho^2 i}{n}\sum_{j=1}^{\lfloor n/i \rfloor} j^{-1} \\
&\leq \frac{8\rho^2 i}{n}\left[1 + \int_1^{\lfloor n/i \rfloor} x^{-1}\mathrm{d}x\right] \\
&\leq \frac{8\rho^2 i}{n}\left[1 + \ln\left(\frac{n}{i}\right)\right].
\end{aligned}$$

(*iii*) For $d \geq 3$,

$$\begin{aligned}\mathbb{E}\|\mathbf{X}_{(i)}(\mathbf{X}) - \mathbf{X}\|^2 &\leq \frac{8\rho^2 i}{n} \sum_{j=1}^{\lfloor n/i \rfloor} j^{-\frac{2}{d}} \\ &\leq \frac{8\rho^2 i}{n} \int_0^{\lfloor n/i \rfloor} x^{-\frac{2}{d}} \mathrm{d}x \\ &= \frac{8\rho^2 \lfloor n/i \rfloor^{-\frac{2}{d}}}{1-2/d}.\end{aligned}$$

In the last statement, we used the inequality $i/n \leq 1/\lfloor n/i \rfloor$.

3.3 Proof of Proposition 7

An easy calculation shows that

$$\begin{aligned}\sum_{i=1}^n V_i^2 &= \sum_{i=1}^n \left[\left(1 - \frac{i-1}{n}\right)^{k_n} - \left(1 - \frac{i}{n}\right)^{k_n} \right]^2 \\ &= 2 \sum_{i=0}^{n-1} \left(1 - \frac{i}{n}\right)^{k_n} \left[\left(1 - \frac{i}{n}\right)^{k_n} - \left(1 - \frac{i+1}{n}\right)^{k_n} \right] - 1.\end{aligned}$$

Let the map $f : \mathbb{R} \to \mathbb{R}$ be defined by $f(x) = (1-x)^{k_n}$. Then, by the mean value theorem,

$$0 \leq \left(1 - \frac{i}{n}\right)^{k_n} - \left(1 - \frac{i+1}{n}\right)^{k_n} \leq -\frac{1}{n} f'\left(\frac{i}{n}\right) = \frac{k_n}{n} \left(1 - \frac{i}{n}\right)^{k_n - 1}.$$

Thus,

$$\sum_{i=1}^n V_i^2 \leq \frac{2k_n}{n} \sum_{i=0}^{n-1} \left(1 - \frac{i}{n}\right)^{2k_n - 1} - 1.$$

In addition, let the map $g : \mathbb{R} \to \mathbb{R}$ be defined by $g(x) = (1-x)^{2k_n - 1}$. Observing that

$$\int_0^1 g(x) \mathrm{d}x = \frac{1}{2k_n},$$

we obtain

$$\begin{aligned}\sum_{i=1}^n V_i^2 &\leq 2k_n \left[\frac{1}{n} \sum_{i=0}^{n-1} g\left(\frac{i}{n}\right) - \int_0^1 g(x) \mathrm{d}x \right] \\ &= 2k_n \sum_{i=0}^{n-1} \int_{i/n}^{(i+1)/n} \left[g\left(\frac{i}{n}\right) - g(x) \right] \mathrm{d}x.\end{aligned}$$

Invoking again the mean value theorem, we may write, for all $x \in [i/n, (i+1)/n]$,

$$0 \leq g\left(\frac{i}{n}\right) - g(x) \leq -\frac{1}{n} g'\left(\frac{i}{n}\right).$$

Therefore,

$$\sum_{i=1}^{n} V_i^2 \leq \frac{2k_n}{n^2} \sum_{i=0}^{n-1} \left[-g'\left(\frac{i}{n}\right) \right].$$

Clearly,

$$\frac{1}{n} \sum_{i=0}^{n-1} \left[-g'\left(\frac{i}{n}\right) \right] \leq -\int_{-1/n}^{1-1/n} g'(x)\mathrm{d}x = g\left(-\frac{1}{n}\right) - g\left(1-\frac{1}{n}\right).$$

Putting all the pieces together, we finally obtain

$$\begin{aligned}\sum_{i=1}^{n} V_i^2 &\leq \frac{2k_n}{n} \left[\left(1+\frac{1}{n}\right)^{2k_n-1} - \left(\frac{1}{n}\right)^{2k_n-1} \right] \\ &\leq \frac{2k_n}{n} \left(1+\frac{1}{n}\right)^{2k_n}.\end{aligned}$$

This concludes the proof of the proposition.

3.4 Proof of Proposition 8

We distinguish between the cases $d = 1$, $d = 2$ and $d \geq 3$.

(i) If $d = 1$, for $i = 1, \ldots, n$, by definition of the V_i's,

$$\sum_{i=1}^{n} V_i \frac{i}{n} = \sum_{i=1}^{n} \left[\left(1 - \frac{i-1}{n}\right)^{k_n} - \left(1-\frac{i}{n}\right)^{k_n} \right] \frac{i}{n}.$$

Thus

$$\begin{aligned}\sum_{i=1}^{n} V_i \frac{i}{n} &= \sum_{i=1}^{n} \left[\left(1 - \frac{i}{n} + \frac{1}{n}\right)^{k_n} - \left(1-\frac{i}{n}\right)^{k_n} \right] \frac{i}{n} \\ &= \sum_{i=1}^{n} \left[\sum_{j=1}^{k_n} \binom{k_n}{j} \frac{1}{n^j} \left(1-\frac{i}{n}\right)^{k_n-j} \right] \frac{i}{n} \\ &= \sum_{j=1}^{k_n} \binom{k_n}{j} \frac{1}{n^{j-1}} \left[\frac{1}{n} \sum_{i=1}^{n} \frac{i}{n} \left(1-\frac{i}{n}\right)^{k_n-j} \right].\end{aligned}$$

For all $j = 1, \ldots, k_n$, we use the inequality

$$\frac{1}{n} \sum_{i=1}^{n} \frac{i}{n} \left(1-\frac{i}{n}\right)^{k_n-j} \leq 2 \int_0^1 x(1-x)^{k_n-j}\mathrm{d}x,$$

which is clearly true for $j = k_n$, without the factor 2 in front of the integral. For $j < k_n$, it is illustrated in Figure 1, where we have plotted the function $f(x) = x(1-x)^{k_n-j}$. The factor 2 is necessary because f is not monotonic on $[0,1]$.

Consequently,

$$\sum_{i=1}^{n} V_i \frac{i}{n} \leq 2 \sum_{j=1}^{k_n} \binom{k_n}{j} \frac{1}{n^{j-1}} \int_0^1 x(1-x)^{k_n-j}\mathrm{d}x.$$

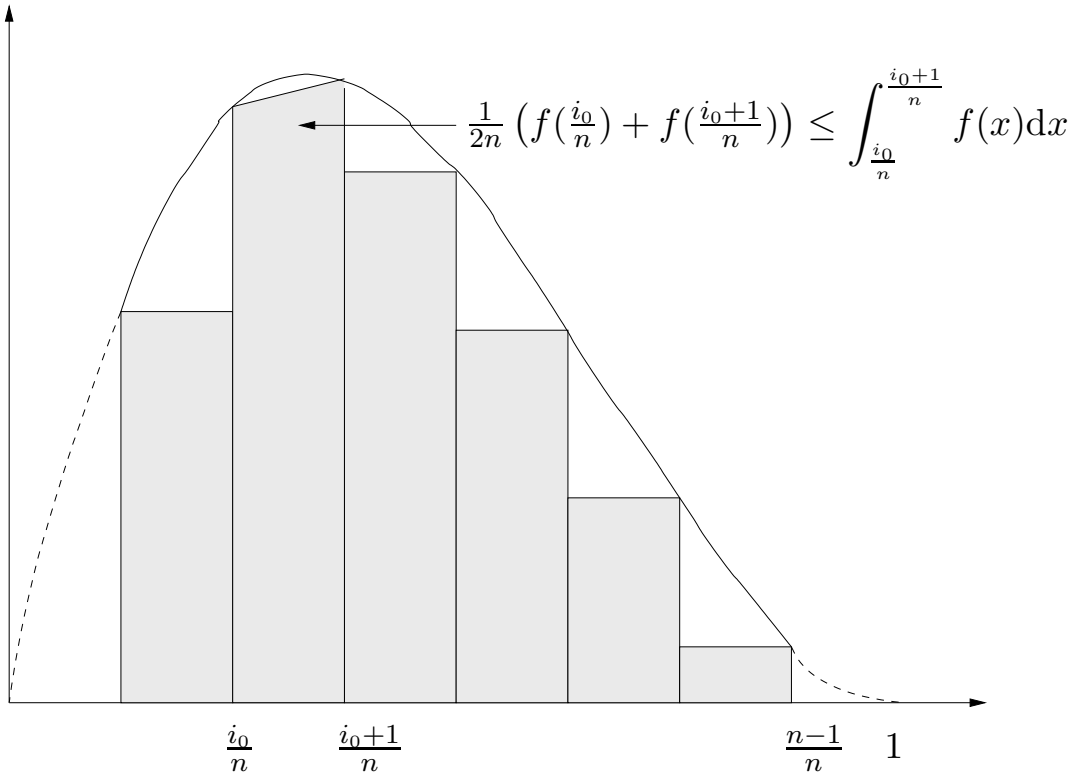

Figure 1: Illustration of $\frac{1}{n}\sum_{i=1}^{n}\frac{i}{n}\left(1-\frac{i}{n}\right)^{k_n-j} \le 2\int_0^1 x(1-x)^{k_n-j}\mathrm{d}x$.

Recalling the general formula

$$\int_0^1 x^{p-1}(1-x)^{q-1}\mathrm{d}x = \frac{\Gamma(p)\Gamma(q)}{\Gamma(p+q)}, \quad p,q>0, \tag{5}$$

we obtain

$$\begin{aligned}
\sum_{i=1}^n V_i \frac{i}{n} &\leq 2\sum_{j=1}^{k_n}\binom{k_n}{j}\frac{1}{n^{j-1}}\frac{\Gamma(2)\Gamma(k_n-j+1)}{\Gamma(k_n-j+3)} \\
&= 2\sum_{j=1}^{k_n}\binom{k_n}{j}\frac{1}{n^{j-1}}\frac{1}{(k_n-j+1)(k_n-j+2)} \\
&= 2\sum_{j=1}^{k_n}\binom{k_n}{j-1}\frac{1}{n^{j-1}}\frac{1}{j(k_n-j+2)} \\
&= 2\sum_{j=0}^{k_n-1}\binom{k_n}{j}\frac{1}{n^{j}}\frac{1}{(j+1)(k_n-j+1)}.
\end{aligned}$$

Observing finally that $(j+1)(k_n-j+1)\geq k_n$ for all $j=0,\ldots,k_n-1$, we conclude

$$\sum_{i=1}^n V_i \frac{i}{n} \leq \frac{2}{k_n}\sum_{j=0}^{k_n-1}\binom{k_n}{j}\frac{1}{n^j} \leq \frac{2}{k_n}\left(1+\frac{1}{n}\right)^{k_n}.$$

(ii) For $d=2$, a reasoning similar to the one reported in statement (i) above can be followed, to show that

$$\begin{aligned}
\sum_{i=1}^n V_i \frac{i}{n}\left[1+\ln\binom{n}{i}\right] \leq 2\Bigg[&\frac{1}{k_n}\left(1+\frac{1}{n}\right)^{k_n} \\
&-\sum_{j=1}^{k_n}\binom{k_n}{j}\frac{1}{n^{j-1}}\int_0^1 x(1-x)^{k_n-j}\ln x\,\mathrm{d}x\Bigg].
\end{aligned} \tag{6}$$

Denoting by H_n the n-th harmonic number, that is,

$$H_n = 1+\frac{1}{2}+\ldots+\frac{1}{n},$$

we have, for all $m\geq 0$ (see for example Gradshteyn and Ryzhik, 2007, Formula (4.253.1)),

$$-\int_0^1 x(1-x)^m\ln x\,\mathrm{d}x = \frac{H_{m+2}-1}{(m+1)(m+2)}.$$

Thus we may write

$$\begin{aligned}
&-\sum_{j=1}^{k_n}\binom{k_n}{j}\frac{1}{n^{j-1}}\int_0^1 x(1-x)^{k_n-j}\ln x\,\mathrm{d}x \\
&\quad=\sum_{j=1}^{k_n}\binom{k_n}{j}\frac{1}{n^{j-1}}\frac{H_{k_n-j+2}-1}{(k_n-j+1)(k_n-j+2)} \\
&\quad=\sum_{j=0}^{k_n-1}\binom{k_n}{j}\frac{1}{n^{j}}\frac{H_{k_n-j+1}-1}{(j+1)(k_n-j+1)}.
\end{aligned}$$

For all $j=0,\ldots,k_n-1$, we have $(j+1)(k_n-j+1)\geq k_n$, as well as

$$\begin{aligned} H_{k_n-j+1}-1 &= \frac{1}{2}+\ldots+\frac{1}{k_n-j+1} \\ &\leq \int_1^{k_n-j+1}\frac{\mathrm{d}x}{x} \\ &= \ln(k_n-j+1) \\ &\leq \ln(k_n+1). \end{aligned}$$

Therefore,

$$\begin{aligned} &-\sum_{j=1}^{k_n}\binom{k_n}{j}\frac{1}{n^{j-1}}\int_0^1 x(1-x)^{k_n-j}\ln x\,\mathrm{d}x \\ &\leq \frac{\ln(k_n+1)}{k_n}\sum_{j=0}^{k_n-1}\binom{k_n}{j}\frac{1}{n^j} \\ &\leq \frac{\ln(k_n+1)}{k_n}\left(1+\frac{1}{n}\right)^{k_n}. \end{aligned} \tag{7}$$

Combining inequalities (6) and (7) leads to the desired result.

(*iii*) For $d\geq 3$, we note that for all $i=1,\ldots,n-1$,

$$\left\lfloor\frac{n}{i}\right\rfloor^{-\frac{2}{d}}\leq\left(\frac{i/n}{1-i/n}\right)^{\frac{2}{d}},$$

and set consequently

$$S_n=\frac{1}{n^{k_n}}+\sum_{i=1}^{n-1}\left[\left(1-\frac{i-1}{n}\right)^{k_n}-\left(1-\frac{i}{n}\right)^{k_n}\right]\left(\frac{i/n}{1-i/n}\right)^{\frac{2}{d}}.$$

We obtain

$$\begin{aligned} S_n &= \frac{1}{n^{k_n}}+\sum_{i=1}^{n-1}\left[\sum_{j=1}^{k_n}\binom{k_n}{j}\frac{1}{n^j}\left(1-\frac{i}{n}\right)^{k_n-j}\right]\left(\frac{i/n}{1-i/n}\right)^{\frac{2}{d}} \\ &= \frac{1}{n^{k_n}}+\sum_{j=1}^{k_n}\binom{k_n}{j}\frac{1}{n^{j-1}}\left[\frac{1}{n}\sum_{i=1}^{n-1}\left(1-\frac{i}{n}\right)^{k_n-j-\frac{2}{d}}\left(\frac{i}{n}\right)^{\frac{2}{d}}\right] \\ &\leq \frac{1}{n^{k_n}}+2\sum_{j=1}^{k_n}\binom{k_n}{j}\frac{1}{n^{j-1}}\int_0^1 x^{\frac{2}{d}}(1-x)^{k_n-j-\frac{2}{d}}\,\mathrm{d}x. \end{aligned}$$

Applying formula (5) again, together with the identity

$$\Gamma\left(p+\frac{d-2}{d}\right)=\Gamma\left(\frac{d-2}{d}\right)\prod_{\ell=1}^{p}\left(\ell-\frac{2}{d}\right),$$

we obtain

$$\begin{aligned}
S_n &\leq \frac{1}{n^{k_n}} + \alpha_d \sum_{j=1}^{k_n} \binom{k_n}{j} \frac{1}{n^{j-1}} \frac{1}{(k_n - j + 1)} \prod_{\ell=1}^{k_n - j} \left(1 - \frac{2}{d\ell}\right) \\
&\quad \text{(with } \alpha_d = 2\Gamma((d-2)/d)\,\Gamma((d+2)/d)\text{)} \\
&= \frac{1}{n^{k_n}} + \alpha_d \sum_{j=1}^{k_n} \frac{k_n!}{j!(k_n - j + 1)!} \frac{1}{n^{j-1}} \prod_{\ell=1}^{k_n - j} \left(1 - \frac{2}{d\ell}\right) \\
&= \frac{1}{n^{k_n}} + \alpha_d \sum_{j=1}^{k_n} \frac{1}{n^{j-1}} \binom{k_n}{j-1} \frac{1}{j} \prod_{\ell=1}^{k_n - j} \left(1 - \frac{2}{d\ell}\right) \\
&= \frac{1}{n^{k_n}} + \alpha_d \sum_{j=0}^{k_n - 1} \frac{1}{n^j} \binom{k_n}{j} \frac{1}{j+1} \prod_{\ell=1}^{k_n - j - 1} \left(1 - \frac{2}{d\ell}\right).
\end{aligned}$$

Thus, by technical Lemma 17,

$$\begin{aligned}
S_n &\leq \frac{1}{n^{k_n}} + \alpha_d \sum_{j=0}^{k_n - 1} \binom{k_n}{j} \frac{k_n^{-\frac{2}{d}}}{n^j} \\
&\leq \frac{1}{n^{k_n}} + \alpha_d \left(1 + \frac{1}{n}\right)^{k_n} k_n^{-\frac{2}{d}}.
\end{aligned}$$

This concludes the proof of Proposition 8.

3.5 Proof of Proposition 11

We have, for $i = 1, \ldots, n - k_n + 1$,

$$\begin{aligned}
V_i &= \frac{\binom{n-i}{k_n - 1}}{\binom{n}{k_n}} \\
&= \frac{k_n}{n - k_n + 1} \prod_{j=0}^{k_n - 2} \left(1 - \frac{i}{n-j}\right) \\
&\leq \frac{k_n}{n - k_n + 1} \prod_{j=0}^{k_n - 2} \left(1 - \frac{i}{n}\right) \\
&= \frac{k_n}{n - k_n + 1} \left(1 - \frac{i}{n}\right)^{k_n - 1}.
\end{aligned}$$

This yields

$$\begin{aligned}
\sum_{i=1}^{n} V_i^2 &\leq \frac{k_n^2}{(n - k_n + 1)^2} \sum_{i=1}^{n - k_n + 1} \left(1 - \frac{i}{n}\right)^{2(k_n - 1)} \\
&\leq \frac{k_n^2 n}{(n - k_n + 1)^2} \frac{1}{n} \sum_{i=1}^{n} \left(1 - \frac{i}{n}\right)^{2(k_n - 1)}.
\end{aligned}$$

Observing finally that

$$\begin{aligned}\frac{1}{n}\sum_{i=1}^{n}\left(1-\frac{i}{n}\right)^{2(k_n-1)} &\le \int_0^1 (1-x)^{2(k_n-1)}\mathrm{d}x \\ &= \frac{1}{2k_n-1},\end{aligned}$$

we conclude that

$$\sum_{i=1}^{n} V_i^2 \le \frac{k_n^2 n}{(2k_n-1)(n-k_n+1)^2} \le \frac{k_n}{n}\,\frac{1}{(1-k_n/n+1/n)^2}.$$

3.6 Proof of Proposition 12

Recall that

$$\tilde{r}_n^\star(\mathbf{x}) = \sum_{i=1}^{n} V_i\, r(\mathbf{X}_{(i)}(\mathbf{x})),$$

and observe that

$$\tilde{r}_n^\star(\mathbf{x}) = \mathbb{E}^\star\left[r(\mathbf{X}_{(1)}^\star(\mathbf{x}))\right],$$

where $\mathbf{X}_{(1)}^\star(\mathbf{x})$ is the nearest neighbor of $\mathbf{x}$ in a random subsample $\mathcal{S}_n$ drawn without replacement from $\{(\mathbf{X}_1,Y_1),\ldots,(\mathbf{X}_n,Y_n)\}$ with $\mathrm{Card}(\mathcal{S}_n)=k_n$, and $\mathbb{E}^\star$ denotes expectation with respect to the resampling distribution, conditionally on the data set $\mathcal{D}_n$. Consequently, by Jensen's inequality,

$$\begin{aligned}\mathbb{E}\left[\tilde{r}_n^\star(\mathbf{x})-r(\mathbf{x})\right]^2 &= \mathbb{E}\left[\mathbb{E}^\star\left[r\left(\mathbf{X}_{(1)}^\star(\mathbf{x})\right)\mid\mathcal{D}_n\right]-r(\mathbf{x})\right]^2 \\ &= \mathbb{E}\left[\mathbb{E}^\star\left[r\left(\mathbf{X}_{(1)}^\star(\mathbf{x})\right)-r(\mathbf{x})\,|\,\mathcal{D}_n\right]\right]^2 \\ &\le \mathbb{E}\left[\mathbb{E}^\star\left[\left(r\left(\mathbf{X}_{(1)}^\star(\mathbf{x})\right)-r(\mathbf{x})\right)^2\mid\mathcal{D}_n\right]\right] \\ &= \mathbb{E}\left[r\left(\mathbf{X}_{(1)}^\star(\mathbf{x})\right)-r(\mathbf{x})\right]^2 \\ &\le C^2\,\mathbb{E}\|\mathbf{X}_{(1)}^\star(\mathbf{x})-\mathbf{x}\|^2.\end{aligned}$$

Since $\mathrm{Card}(\mathcal{S}_n)=k_n$, we conclude by applying Corollary 6, with $i=1$ and replacing n by k_n.

3.7 Two Technical Lemmas

Lemma 16 *For $j=0,\ldots,n-1$, let the map $\varphi_{n,j}(p)$ be defined by*

$$\varphi_{n,j}(p) = \binom{n}{j} p^{j+1}(1-p)^{n-j}, \quad 0\le p\le 1.$$

Then, for all $i=1,\ldots,n$,

$$\sup_{0\le p\le 1}\sum_{j=0}^{i-1}\varphi_{n,j}(p) \le \frac{i}{n+1}.$$

Proof Each map $\varphi_{n,j}$ is nonnegative, continuously increasing on the interval $[0,(j+1)/(n+1)]$ and decreasing on $[(j+1)/(n+1),1]$. Consequently, the supremum of the continuous function $\sum_{j=0}^{i-1}\varphi_{n,j}(p)$ is achieved at some point $p_\star$ of the interval $[1/(n+1),i/(n+1)]$. That is,

$$\begin{aligned}\sup_{0\le p\le 1}\sum_{j=0}^{i-1}\varphi_{n,j}(p) &= \sum_{j=0}^{i-1}\varphi_{n,j}(p_\star)\\ &= p_\star\sum_{j=0}^{i-1}\binom{n}{j}p_\star^j(1-p_\star)^{n-j}\\ &\le p_\star\sum_{j=0}^{n}\binom{n}{j}p_\star^j(1-p_\star)^{n-j}\\ &= p_\star \le \frac{i}{n+1}.\end{aligned}$$

■

Lemma 17 *For each $d\ge 3$, each $k_n\ge 1$, and $j=0,\dots,k_n-1$, we have*

$$\frac{1}{j+1}\prod_{\ell=1}^{k_n-j-1}\left(1-\frac{2}{d\ell}\right)\le k_n^{-\frac{2}{d}}.$$

Proof First, since $0\le 1-x\le e^{-x}$ for all $x\in[0,1]$,

$$\prod_{\ell=1}^{k_n-j-1}\left(1-\frac{2}{d\ell}\right)\le\exp\left(-\frac{2}{d}\sum_{\ell=1}^{k_n-j-1}\frac{1}{\ell}\right).$$

Thus, using $1+1/2+\ldots+1/p\ge\ln(p+1)$, we deduce

$$\prod_{\ell=1}^{k_n-j-1}\left(1-\frac{2}{d\ell}\right)\le(k_n-j)^{-\frac{2}{d}}.$$

To conclude, we use the fact that, for $j=0,\dots,k_n-1$,

$$\frac{1}{j+1}(k_n-j)^{-\frac{2}{d}}\le k_n^{-\frac{2}{d}}.$$

To see this, note that the inequality may be written under the equivalent form

$$\left(1-\frac{j}{k_n}\right)^{-\frac{2}{d}}\le 1+j=1+k_n\cdot\frac{j}{k_n}.$$

The result can easily be deduced from a comparison between the maps $\varphi:x\mapsto(1-x)^{-2/d}$ and $\psi:x\mapsto 1+k_nx$ on the interval $[0,1-1/k_n]$. Just note that $\varphi(0)=\psi(0)$, $\varphi(1-1/k_n)=k_n^{2/d}\le k_n=\psi(1-1/k_n)$ since $d\ge 3$, and φ is convex while ψ is affine. ■

Acknowledgments

The authors are greatly indebted to Luc Devroye for valuable comments and insightful suggestions on the first draft of the paper. They also thank two referees and the Acting Editor for their careful reading of the paper and thoughtful critical comments.

Abstract

ℓ_1-regularized logistic regression, also known as sparse logistic regression, is widely used in machine learning, computer vision, data mining, bioinformatics and neural signal processing. The use of ℓ_1 regularization attributes attractive properties to the classifier, such as feature selection, robustness to noise, and as a result, classifier generality in the context of supervised learning. When a sparse logistic regression problem has large-scale data in high dimensions, it is computationally expensive to minimize the non-differentiable ℓ_1-norm in the objective function. Motivated by recent work (Koh et al., 2007; Hale et al., 2008), we propose a novel hybrid algorithm based on combining two types of optimization iterations: one being very fast and memory friendly while the other being slower but more accurate. Called hybrid iterative shrinkage (HIS), the resulting algorithm is comprised of a fixed point continuation phase and an interior point phase. The first phase is based completely on memory efficient operations such as matrix-vector multiplications, while the second phase is based on a truncated Newton's method. Furthermore, we show that various optimization techniques, including line search and continuation, can significantly accelerate convergence. The algorithm has global convergence at a geometric rate (a Q-linear rate in optimization terminology). We present a numerical comparison with several existing algorithms, including an analysis using benchmark data from the UCI machine learning repository, and show our algorithm is the most computationally efficient without loss of accuracy.

Keywords: logistic regression, ℓ_1 regularization, fixed point continuation, supervised learning, large scale

1. Introduction

Logistic regression is an important linear classifier in machine learning and has been widely used in computer vision (Bishop, 2007), bioinformatics (Tsuruoka et al., 2007), gene classification (Liao and Chin, 2007), and neural signal processing (Parra et al., 2005; Gerson et al., 2005; Philiastides and Sajda, 2006). ℓ_1-regularized logistic regression or so-called sparse logistic regression (Tibshirani, 1996), where the weight vector of the classifier has a small number of nonzero values, has been shown to have attractive properties such as feature selection and robustness to noise. For supervised learning with many features but limited training samples, overfitting to the training data can be a problem in the absence of proper regularization (Vapnik, 1982, 1988). To reduce overfitting and obtain a robust classifier, one must find a sparse solution.

Minimizing or limiting the ℓ_1-norm of an unknown variable (the weight vector in logistic regression) has long been recognized as a practical avenue for obtaining a sparse solution. The use of ℓ_1 minimization is based on the assumption that the classifier parameters have, *a priori*, a Laplace distribution, and can be implemented using maximum-a-posteriori (MAP). The ℓ_2-norm is a result of penalizing the mean of a Gaussian prior, while a ℓ_1-norm models a Laplace prior, a distribution with heavier tails, and penalizes on its median. Such an assumption attributes important properties to ℓ_1-regularized logistic regression in that it tolerates outliers and, therefore, is robust to irrelevant features and noise in the data. Since the solution is sparse, the nonzero components in the solution correspond to useful features for classification; therefore, ℓ_1 minimization also performs feature selection (Littlestone, 1988; Ng, 1998), an important task for data mining and biomedical data analysis.

1.1 Logistic Regression

The basic form of logistic regression seeks a hyperplane that separates data belonging to two classes. The inputs are a set of training data $X = [x_1, \cdots, x_m]^\top \in \mathbb{R}^{m \times n}$, where each row of X is a sample and samples of either class are assumed to be independently identically distributed, and class labels $b \in \mathbb{R}^m$ are of $-1/+1$ elements. A linear classifier is a hyperplane $\{x : w^\top x + v = 0\}$, where $w \in \mathbb{R}^n$ is a set of weights and $v \in \mathbb{R}$ the intercept. The conditional probability for the classifier label b based on the data, according to the logistic model, takes the following form,

$$p(b_i|x_i) = \frac{\exp\big((w^T x_i + v)b_i\big)}{1 + \exp\big((w^T x_i + v)b_i\big)}, \quad i = 1, ..., m.$$

The average logistic loss function can be derived from the empirical logistic loss, computed from the negative log-likelihood of the logistic model associated with all the samples, divided by number of samples m,

$$l_{\text{avg}}(w, v) = \frac{1}{m} \sum_{i=1}^{m} \theta\big((w^T x_i + v)b_i\big),$$

where θ is the logistic transfer function: $\theta(z) := \log(1 + \exp(-z))$. The classifier parameters w and v can be determined by minimizing the average logistic loss function,

$$\arg\min_{w,v} \; l_{\text{avg}}(w, v).$$

Such an optimization can also be interpreted as a MAP estimate for classifier weights w and intercept v.

1.2 ℓ_1-Regularized Logistic Regression

The so-called *sparse logistic regression* has emerged as a popular linear decoder in the field of machine learning, adding the ℓ_1-penalty on the weights w:

$$\arg\min_{w,v} \; l_{\text{avg}}(w,v) + \lambda \|w\|_1, \tag{1}$$

where λ is a regularization parameter. It is well-known that ℓ_1 minimization tends to give sparse solutions. The ℓ_1 regularization results in logarithmic sample complexity bounds (number of training samples required to learn a function), making it an effective learner even under an exponential number of irrelevant features (Ng, 1998, 2004). Furthermore, ℓ_1 regularization also has appealing asymptotic sample-consistency for feature selection (Zhao and Yu, 2007).

Signals arising in the natural world tend to be sparse (Parra et al., 2001). Sparsity also arises in signals represented in a certain basis, such as the wavelet transform, the Krylov subspace, etc. Exploiting sparsity in a signal is therefore a natural constraint to employ in algorithm development. An exact form of sparsity can be sought using the ℓ_0 regularization, which explicitly penalizes the number of nonzero components,

$$\arg\min_{w,v} \; l_{\text{avg}}(w,v) + \lambda \|w\|_0. \tag{2}$$

Although theoretically attractive, problem (2) is in general NP-hard (Natarajan, 1995), requiring an exhaustive search. Due to this computational complexity, ℓ_1 regularization has become a popular alternative, and is subtly different than ℓ_0 regularization, in that the ℓ_1-norm penalizes large coefficients/parameters more than small ones.

The idea of adopting the ℓ_1 regularization for seeking sparse solutions to optimization problems has a long history. As early as the 1970's, Claerbout and Muir first proposed to use ℓ_1 to deconvolve seismic traces (Claerbout and Muir, 1973), where a sparse reflection function was sought from bandlimited data (Taylor et al., 1979). In the 1980's, Donoho et al. quantified the ability of ℓ_1 to recover sparse reflectivity functions (Donoho and Stark, 1989; Donoho and Logan, 1992). After the 1990s', there was a dramatic rise of applications using the sparsity-promoting property of the ℓ_1-norm. Sparse model selection was proposed in statistics using LASSO (Tibshirani, 1996), wherein the proposed soft thresholding is related to wavelet thresholding (Donoho et al., 1995). Basis pursuit, which aims to extract sparse signal representation from overcomplete dictionaries, also underwent great development during this time (Donoho and Stark, 1989; Donoho and Logan, 1992; Chen et al., 1998; Donoho and Huo, 2001; Donoho and Elad, 2003; Donoho, 2006). In recent years, minimization of the ℓ_1-norm has appeared as a key element in the emerging field of compressive sensing (Candés et al., 2006; Candés and Tao, 2006; Figueiredo et al., 2007; Hale et al., 2008). ℓ_1 minimization also has far reaching impact on various applications such as portfolio optimization (Lobo et al., 2007), sparse principle component analysis (d'Aspremont et al., 2005; Zou et al., 2006), sparse interconnect wiring design (Vandenberghe et al., 1997, 1998), sparse control system design (Hassibi et al., 1999), and optimization of well-connected sparse graphs (Ghosh and Boyd, 2006). Research on total variation based image processing also shows that minimizing the ℓ_1-norm of the intensity gradient can effectively remove random noise (Rudin et al., 1992). In the realm of machine learning, ℓ_1 regularization exists in various forms of classifiers, including ℓ_1-regularized logistic regression (Tibshirani, 1996), ℓ_1-regularized probit regression (Figueiredo and Jain, 2001; Figueiredo, 2003), ℓ_1-regularized support vector machines (Zhu et al., 2004), and ℓ_1-regularized multinomial logistic regression (Krishnapuram et al., 2005).

1.3 Existing Algorithms for ℓ_1-Regularized Logistic Regression

The ℓ_1-regularized logistic regression problem (1) is a convex and non-differentiable problem. A solution always exists but can be non-unique. These characteristics postulate some difficulties in solving the problem. Generic methods for nondifferentiable convex optimization, such as the ellipsoid method and various sub-gradient methods (Shor, 1985; Polyak, 1987), are not designed to handle instances of (1) with data of very large scale. There has been very active development on numerical algorithms for solving the ℓ_1-regularized logistic regression, including LASSO (Tibshirani, 1996), Gl1ce (Lokhorst, 1999), Grafting (Perkins and Theiler, 2003), GenLASSO (Roth, 2004), and SCGIS (Goodman, 2004). The IRLS-LARS (iteratively reweighted least squares least angle regression) algorithm uses a quadratic approximation for the average logistic loss function, which is consequently solved by the LARS (least angle regression) method (Efron et al., 2004; Lee et al., 2006). The BBR (Bayesian logistic regression) algorithm, described in Eyheramendy et al. (2003), Madigan et al. (2005), and Genkin et al. (2007), uses a cyclic coordinate descent method for the Bayesian logistic regression. Glmpath, a solver for ℓ_1-regularized generalized linear models using path following methods, can also handle the logistic regression problem (Park and Hastie, 2007). MOSEK is a general purpose primal-dual interior point solver, which can solve the ℓ_1-regularized logistic regression by formulating the dual problem, or treating it as a geometric program (Boyd et al., 2007). SMLR, algorithms for various sparse linear classifiers, can also solve sparse logistic regression (Krishnapuram et al., 2005). Recently, Koh, Kim, and Boyd proposed an interior-point method (Koh et al., 2007) for solving (1). Their algorithm takes truncated Newton steps and uses preconditioned conjugated gradient iterations. This interior-point solver is efficient and provides a highly accurate solution. The truncated Newton method has fast convergence, but forming and solving the underlying Newton systems require excessive amounts of memory for large-scale problems, making solving such large-scale problems prohibitive. A comparison of several of these different algorithms can be found in Schmidt et al. (2007).

1.4 Our Hybrid Algorithm

In this paper, we propose a hybrid algorithm that is comprised of two phases: the first phase is based on a new algorithm called iterative shrinkage, inspired by a fixed point continuation (FPC) (Hale et al., 2008), which is computationally fast and memory friendly; the second phase is a customized interior point method, devised by Koh et al. (2007).

Figure 1 shows a diagram of our hybrid algorithm, termed Hybrid Iterative Shrinkage (HIS) algorithm. Our algorithm requires less memory and, on mid/large-scale problems, runs faster than the interior point method. The iterative shrinkage phase only performs matrix-vector multiplications in size of X, as well as a very simple *shrinkage* operation (see (6) below), and therefore requires minimal memory consumption. By extending the results in Hale et al. (2008), we prove Q-linear convergence and show that the signs of w_{opt} (hence, the indices of nonzero elements) are obtained in a finite number of steps, typically much earlier than convergence. Based on the latter result, we propose a hybrid algorithm that is even faster and results in highly accurate solutions. Specifically, our algorithm predicts the sign changes in future shrinkage iterations, and when the signs of w^k are likely to be stable, switches to the interior point method and operates on a reduced problem that is much smaller than the original. The interior point method achieves high accuracy in the solution, making our hybrid algorithm equally accurate, as will be shown in the Section 4.

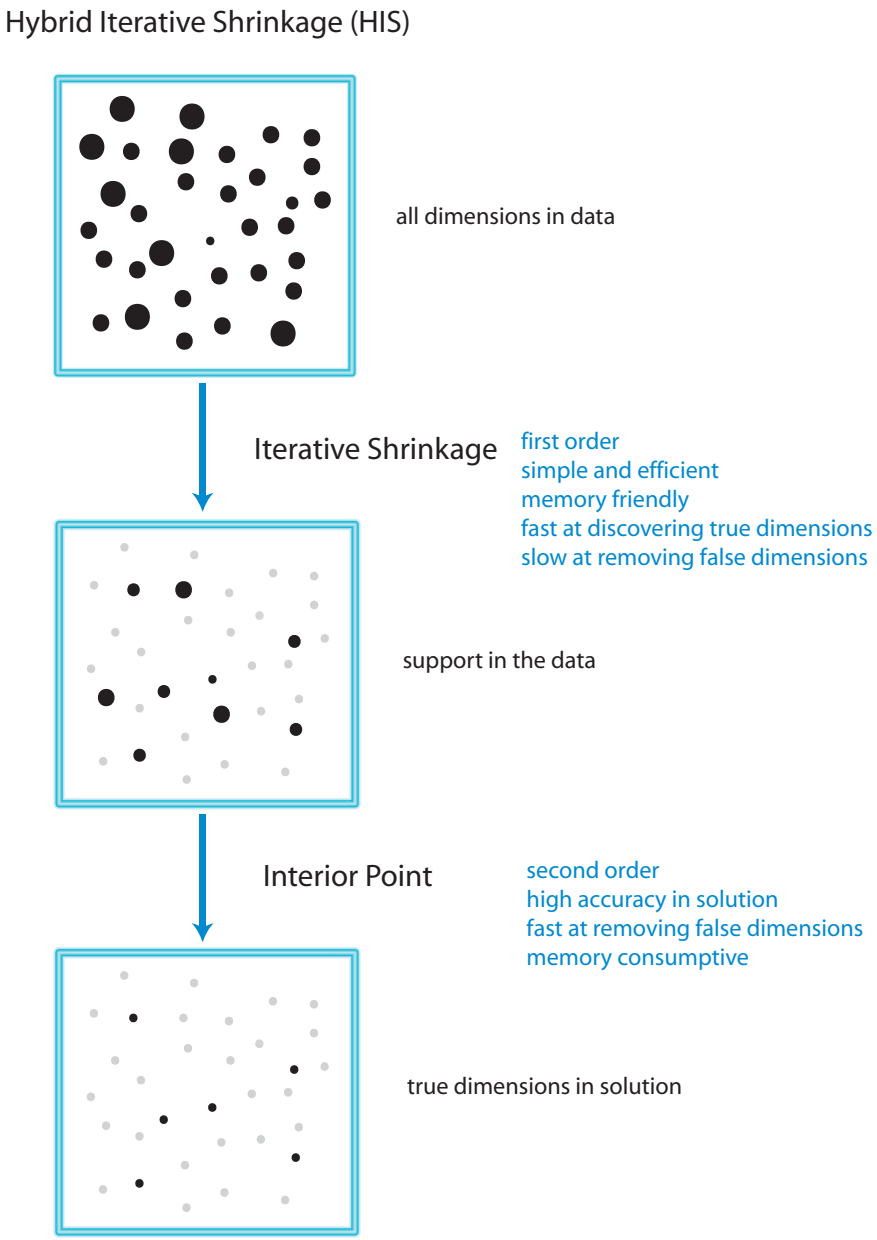

Figure 1: A diagram of our proposed hybrid iterative shrinkage (HIS) algorithm. The HIS algorithm is comprised of two phases: the iterative shrinkage phase and the interior point phase. The iterative shrinkage is inspired by a fixed point continuation method (Hale et al., 2008), which is computationally fast and memory friendly. The interior point method is based on a second-order truncated Newton method, devised by Koh et al. (2007). Our hybrid approach takes advantage of different computational strengths of the two methods and uses them for optimal algorithm acceleration while attaining high accuracy. Black dots indicate the nonzero dimensions, gray dots indicate dimensions that are eliminated, and the size of the dots show the error that each dimension contributes to the final solution. Note that the final solution is sparse with an overall small error.

There are several novel aspects of our hybrid approach. The rationale of the hybrid approach is based on the observation that the iterative shrinkage phase reduces the algorithm to gradient projection after a finite number of iterations, which will be described in Section 3.1. We build on this observation a hybrid approach to take advantage of the two phases of the computation using two types of numerical methods. In the first phase, inspired by the FPC by Hale et al. (2008), we customize the iterative shrinkage algorithm for the sparse logistic regression, whose objective function is not quadratic. In particular, the step length in the iterative shrinkage algorithm is not constant, unlike the compressive sensing problem. Therefore, we resort to a line search strategy to avoid computing the Hessian matrix (required for finding the step length for stability). In addition, the ℓ_1 regularization is only applied to the w component and not v in sparse logistic regression. This change in the model requires a different shrinkage step, as well as a careful treatment in the line search strategy.

The remainder of the paper is organized as follows. In Section 2, we present the iterative shrinkage algorithm for sparse logistic regression, and prove its global convergence and Q-linear convergence. In Section 3, we provide the rationale for the hybrid approach, together with a description of the hybrid algorithm. Numerical results are presented in Section 4. We conclude the paper in Section 5.

2. Sparse Logistic Regression using Iterative Shrinkage

The iterative shrinkage algorithm used in the first phase is inspired by a fixed point continuation algorithm by Hale et al. (2008).

2.1 Notation

For simplicity, we define $\|\cdot\| := \|\cdot\|_2$, as the Euclidean norm. The *support* of $x \in \mathbb{R}^n$ is denoted by $\mathrm{supp}(x) := \{i : x_i \neq 0\}$. We use g to denote the gradient of f, that is, $g(x) = \nabla f(x), \forall x$. For any index set $I \subseteq \{1,\ldots,n\}$ (later, we will use index sets E and L), $|I|$ is the cardinality of I and x_I is defined as the sub-vector of x of length $|I|$, consisting only of components x_i, $i \in I$. Similarly, for any vector-value mapping h, $h_I(x)$ denotes the sub-vector of $h(x)$ consisting of $h_i(x)$, $i \in I$.

To express the subdifferential of $\|\cdot\|_1$ we will use the signum function and multi-function (i.e., set-valued mapping). The signum function of $t \in \mathbb{R}$ is

$$\mathrm{sgn}(t) := \begin{cases} +1 & t > 0, \\ 0 & t = 0, \\ -1 & t < 0; \end{cases}$$

while the signum multi-function of $t \in \mathbb{R}$ is

$$\mathrm{SGN}(t) := \partial|t| = \begin{cases} \{+1\} & t > 0, \\ [-1,1] & t = 0, \\ \{-1\} & t < 0, \end{cases}$$

which is also the subdifferential of $|t|$.

For $x \in \mathbb{R}^n$, we define $\mathrm{sgn}(x) \in \mathbb{R}^n$ and $\mathrm{SGN}(x) \subset \mathbb{R}^n$ component-wise as $(\mathrm{sgn}(x))_i := \mathrm{sgn}(x_i)$ and $(\mathrm{SGN}(x))_i := \mathrm{SGN}(x_i)$, $i = 1,2,\cdots,n$, respectively. Furthermore, vector operators such as $|x|$

and $\max\{x,y\}$ are defined to operate component-wise, analogous with the definitions of sgn and SGN above. For $x,y \in \mathbb{R}^n$, let $x \odot y \in \mathbb{R}^n$ denote the component-wise product of x and y, that is, $(x \odot y)_i = x_i y_i$. Finally, we let X^* denote the set of all optimal solutions of problem (3).

2.2 Review of Fixed Point Continuation for ℓ_1-minimization

A fixed-point continuation algorithm was proposed in Hale et al. (2008) as a fast algorithm for large-scale ℓ_1-regularized convex optimization problems. The authors considered the following large-scale ℓ_1-regularized minimization problem,

$$\min_{x\in\mathbb{R}^n} f(x) + \lambda\|x\|_1, \tag{3}$$

where $f : \mathbb{R}^n \to \mathbb{R}$ is differentiable and convex, but not necessarily strictly convex, and $\lambda > 0$. They devised a fixed-point iterative algorithm and proved its global convergence, including finite convergence for some quantities, and a Q-linear (Quotient-linear) convergence rate without assuming strict convexity of f or solution uniqueness. Numerically they demonstrated Q-linear convergence in the quadratic case $f(x) = \|Ax-b\|_2^2$, where A is completely dense, and applied their algorithm to ℓ_1-regularized compressed sensing problems. As we will adopt this algorithm for solving our problem (1), we review some important and useful results here and develop some new insights in the context of ℓ_1-regularized logistic regression.

The rationale for FPC is based on the idea of operator splitting. It is well-known in convex analysis that minimizing a function in the form of $\phi(x) = \phi_1(x) + \phi_2(x)$, where both ϕ_1 and ϕ_2 are convex, is equivalent to finding a zero of the subdifferential $\partial\phi(x)$, that is, seeking x satisfying $\mathbf{0} \in T_1(x) + T_2(x)$ for $T_1 := \partial\phi_1$ and $T_2 := \partial\phi_2$. We say $(I+\tau T_1)$ is invertible if $y = x+\tau T_1(x)$ has a unique solution x for any given y. For $\tau > 0$, if $(I+\tau T_1)$ is invertible and T_2 is single-valued, then

$$\begin{aligned} \mathbf{0} \in T_1(x) + T_2(x) &\iff \mathbf{0} \in (x+\tau T_1(x)) - (x-\tau T_2(x)) \\ &\iff (I-\tau T_2)x \in (I+\tau T_1)x \\ &\iff x = (I+\tau T_1)^{-1}(I-\tau T_2)x. \end{aligned} \tag{4}$$

This gives rise to the forward-backward splitting algorithm in the form of a fixed-point iteration,

$$x^{k+1} := (I+\tau T_1)^{-1}(I-\tau T_2)x^k. \tag{5}$$

Applying (4) to problem (1), where $\phi_1(x) := \lambda\|x\|_1$ and $\phi_2(x) := f(x)$, the authors of Hale et al. (2008) obtained the following optimality condition of x^*:

$$x^* \in X^* \iff \mathbf{0} \in g(x^*) + \lambda \mathrm{SGN}(x^*) \Longleftrightarrow x^* = (I+\tau T_1)^{-1}(I-\tau T_2)x^*,$$

where $T_2(\cdot) = g(\cdot)$, the gradient of $f(\cdot)$, and $(I+\tau T_1)^{-1}(\cdot)$ is the shrinkage operator. Therefore, the fixed-point iteration (5) for solving (3) becomes

$$x^{k+1} = s \circ h(x^k),$$

which is a composition of two mappings s and h from $\mathbb{R}^n$ to $\mathbb{R}^n$.

The gradient descent operator is defined as

$$h(\cdot) := I(\cdot) - \tau\nabla f(\cdot).$$

The shrinkage operator, on the other hand, can be written as

$$s(\cdot) = \mathrm{sgn}(\cdot) \odot \max\{|\cdot| - \nu, 0\}, \tag{6}$$

where $\nu = \lambda\tau$. Shrinkage is also referred to soft-thresholding in the language of wavelet analysis:

$$(s(y))_i = \begin{cases} y_i - \nu, & y_i > \nu, \\ 0, & y_i \in [-\nu, \nu], \\ y_i + \nu, & y_i < -\nu. \end{cases}$$

In each iteration, the gradient descent step h reduces $f(x)$ by moving along the negative gradient direction of $f(x^k)$ and the shrinkage step s reduces the ℓ_1-norm by "shrinking" the magnitude of each nonzero component in the input vector.

2.3 Iterative Shrinkage for Sparse Logistic Regression

Recall that in the sparse logistic regression problem (1), the ℓ_1 regularization is only applied to w, not to v. Therefore, we propose a slightly different fixed point iteration. For simplicity of notation, we define column vectors $u = (w; v) \in \mathbb{R}^{n+1}$ and $c_i = (a_i; b_i) \in \mathbb{R}^{n+1}$, where $a_i = bx_i$, for $i = 1, 2, ..., m$. This reduces (1) to

$$\min_u \; l_{\mathrm{avg}}(u) + \lambda \|u_{1:n}\|_1,$$

where $l_{\mathrm{avg}} = \frac{1}{m}\sum_{i=1}^m \theta(c_i^T u)$, and θ denotes the logistic transfer function $\theta(z) = \log(1 + \exp(-z))$.

The gradient and Hessian of l_{avg} with respect to u is given by

$$\begin{aligned} g(u) &\equiv \nabla l_{\mathrm{avg}}(u) = \frac{1}{m}\sum_{i=1}^m \theta'(c_i^\top u) c_i, \\ H(u) &\equiv \nabla^2 l_{\mathrm{avg}}(u) = \frac{1}{m}\sum_{i=1}^m \theta''(c_i^\top u) c_i c_i^\top, \end{aligned}$$

where $\theta'(z) = -(1 + e^z)^{-1}$ and $\theta''(z) = (2 + e^{-z} + e^z)^{-1}$. To guarantee convergence, we require the step length be bounded by $2(\max_u \lambda_{\max} H(u))^{-1}$.

The iterative shrinkage algorithm for sparse logistic regression is

$$\begin{aligned} u^{k+1} &= s \circ h_{1:n}(u^k), \text{ for } w \text{ component}, \\ u^{k+1} &= h_{n+1}(u^k), \text{ for } v \text{ component}, \end{aligned} \tag{7}$$

which is a composition of two mappings h and s from $\mathbb{R}^n$ to $\mathbb{R}^n$, where the gradient operator is

$$h(\cdot) = \cdot - \tau g(\cdot) = \cdot - \tau \nabla l_{\mathrm{avg}}(\cdot).$$

While the authors in Hale et al. (2008) use a constant step length satisfying

$$0 < \tau < 2/\lambda_{\max}\{H_{EE}(u) : u \in \Omega\},$$

we employ line search to avoid the expensive calculation of maximum eigenvalues. We will present the convergence of the iterative shrinkage algorithm in Section 2.4. The details of the line search algorithm will be discussed in Section 2.5.

Algorithm 1 Fixed-Point Continuation Algorithm

Require: $A = [c_1^\top; c_2^\top; \cdots; c_m^\top] \in \mathbb{R}^{m\times(n+1)}$, $u = (w; v) \in \mathbb{R}^{n+1}$, $f(u) = m^{-1}\phi(Au)$, task: $\min_u l_{\text{avg}}(u) + \lambda\|u\|_1$
  Initialize u^0
  while "not converge" **do**
    Armijo-like line search algorithm (Algorithm 2)
    $k = k + 1$
  end while

2.4 Convergence

Global convergence and finite convergence on certain quantities were proven in Hale et al. (2008) when the following conditions are met: (i) the optimal solution set X^* is non-empty, (ii) $f \in C^2$ and its Hessian $H = \nabla^2 f$ is positive semi-definite in $\Omega = \{x : \|x - x^*\| \le \rho\} \subset \mathbb{R}^n$ for $\rho > 0$, and (iii) the maximum eigenvalue of H is bounded on Ω by a constant $\hat{\lambda}_{\max}$ and the step length τ is uniformly less than $2/\hat{\lambda}_{\max}$. These conditions are sufficient for the forward operator $h(\cdot)$ to be non-expansive.

Assumption 1 *Assume problem* (1) *has an optimal solution set $X^* \neq \emptyset$, and there exists a set*

$$\Omega = \{x : \|x - x^*\| \le \rho\} \subset \mathbb{R}^n$$

for some $x^* \in X^*$ and $\rho > 0$ such that $f \in C^2(\Omega)$, $H(x) := \nabla^2 f(x) \succeq 0$ for $x \in \Omega$ and

$$\hat{\lambda}_{\max} := \sup_{x\in\Omega} \lambda_{\max}(H(x)) < \infty.$$

For simplicity for the analysis, we choose a constant step length τ in the fixed-point iterations (7)*: $x^{k+1} = s(x^k - \tau g(x^k))$, where $\nu = \tau\lambda$, and*

$$\tau \in \left(0, 2/\hat{\lambda}_{\max}\right),$$

which guarantees that $h(\cdot) = I(\cdot) - \tau g(\cdot)$ is non-expansive in Ω.

Theorem 1 *Under Assumption, the sequence $\{u^k\}$ generated by the fixed-point iterations* (7) *applied to problem* (1) *from any starting point $x^0 \in \Omega$ converges to some $u^* \in U^* \cap \Omega$. In addition, for all but finitely many iterations, we have*

$$u_i^k = u_i^* = 0, \qquad \forall i \in L = \{i : |g_i^*| < \lambda, 1 \le i \le n\}, \tag{8}$$

$$\text{sgn}(h_i(u^k)) = \text{sgn}(h_i(u^*)) = -\frac{1}{\lambda} g_i^*, \qquad \forall i \in E = \{i : |g_i^*| = \lambda, 1 \le i \le n\}, \tag{9}$$

where as long as

$$\omega := \min\{\nu(1 - \frac{|g_i^*|}{\lambda}) : i \in L\} > 0.$$

The numbers of iterations not satisfying (8) *and* (9) *do not exceed $\|u^0 - u^*\|^2/\omega^2$ and $\|u^0 - u^*\|^2/\nu^2$, respectively.*

Proof We sketch the proof here. First, the iteration (7) is shown to be non-expansive in ℓ_2, that is, $\|u^k - u^*\|$ does not increase in k with the assumption on the step length τ. Specifically, in Assumption, the step length τ is chosen small enough to guarantee that $\|h(u^k) - h(u^*)\| \leq \|u^k - u^*\|$ (in practice, τ is determined, for example, by line search.) On the other hand, through a component-wise analysis, one can show that no matter what τ is, the shrinkage operator $s(\cdot)$ is always non-expansive, that is, $\|s(h_{1:n}(u^k)) - s(h_{1:n}(u^*))\| \leq \|h_{1:n}(u^k) - h_{1:n}(u^*)\|$. Therefore, from the definition of u^{k+1} in (7), we have

$$\|u^{k+1} - u^*\| \leq \|u^k - u^*\|, \tag{10}$$

using the fact that u^* is optimal if and only if u^* is a fixed point with respect to (7). However, this non-expansiveness of (7) does not directly give convergence.

Next, $\{u^k\}$ is shown to have a limit point $\bar{x}$, that is, a subsequence converging to $\bar{u}$, due to the compactness of Ω and (10). (7) can be proven to converge globally to $\bar{u}$. To show this, we first get

$$\|[s \circ h_{1:n}(\bar{u}); h_{n+1}(\bar{u})] - [s \circ h_{1:n}(u^*); h_{n+1}(u^*)]\| = \|\bar{u} - u^*\|,$$

from the fact that $\bar{u}$ is a limit point, and then use this equation to show that $\bar{u} = [s \circ h_{1:n}(\bar{u}); h_{n+1}(\bar{u})]$, that is, $\bar{u}$ is a fixed point with respect to (7), and thus an optimal solution. Repeating the first step above we have $\|u^{k+1} - \bar{u}\| \leq \|u^k - \bar{u}\|$, which extends $\bar{u}$ from being the limit of a subsequence to one of the entire sequence.

Finally, to obtain the finite convergence result, we need to take a closer look at the shrinkage operator $s(\cdot)$. When (8) does not hold for some iteration k at component i, we have $|u_i^{k+1} - u_i^*|^2 \leq |u_i^k - u_i^*|^2 - \omega^2$, and for (9), we have $|u_i^{k+1} - u_i^*|^2 \leq |u_i^k - u_i^*|^2 - \nu^2$. Obviously, there can be only a finite number of iterations k in which either (8) or (9) does not hold, and such numbers do not exceed $\|u^0 - u^*\|^2/\omega^2$ and $\|u^0 - u^*\|^2/\nu^2$, respectively. ■

A linear convergence result with a certain convergence rate can also be obtained. As long as $H_{EE}(x^*) := [H_{i,j}(x^*)]_{i,j \in E}$ has full rank *or* $f(x)$ is convex quadratic in x, the sequence $\{x^k\}$ converges to x^* *R*-linearly, and $\{\|x^k\|_1 + \mu f(x^k)\}$ converges to $\|x^*\|_1 + \mu f(x^*)$ *Q*-linearly. Furthermore, if $H_{EE}(x^*)$ has the full rank, then *R*-linear convergence can be strengthened to *Q*-linear convergence by using the fact that the minimal eigenvalue of H_{EE} at x^* is strictly greater than 0.

2.5 Line Search

An important element of the iterative shrinkage algorithm is the step length τ at each iteration. To ensure the stability of the algorithm, we require that the step length satisfy

$$0 < \tau < 2/\lambda_{\max}\{H_{EE}(u) : u \in \Omega\}.$$

In compressive sensing, where the smooth part of the objective function is quadratic, the step length is constant. In sparse logistic regression, however, the Hessian matrix changes at each iteration. If one has to dynamically compute the step length at each iteration, this requires an expensive computation for the Hessian matrix. Therefore, we resort to an "Armijo-like" line search algorithm to avoid such a computational burden. For large-scale problems, a line search method, if used appropriately, can save tremendous CPU time and memory. Convergence of the Armijo-like line search is not proven in our paper, however heuristic results are obtained through numerical experiments.

Algorithm 2 Armijo-like Line Search Algorithm

Compute heuristic step length α_0
Gradient step: $u^{k-} = u^k - \alpha_0 \nabla l_{\text{avg}}(u^k)$
Shrinkage step: $u^{k+} = s_{1:n}(u^{k-}, \lambda\alpha_0)$
Obtain search direction: $p^k = u^{k+} - u^k$
while "j $<$ max line search attempts" **do**
  if Armijo-like condition is met **then**
    Accept line search step, update $u^{k+1} = u^k + \alpha_j p^k$
  else
    Keep backtracking $\alpha_j = \mu\alpha_{j-1}$
  end if
  $j = j+1$
end while

Let's denote the objective function for the ℓ_1-regularized logistic regression as $\phi(u)$ for convenience:

$$\phi(u) = l_{\text{avg}}(u) + \lambda\|u_{1:n}\|_1,$$

where $l_{\text{avg}}(u) = \frac{1}{m}\sum_{i=1}^{m} \theta(c_i^T u)$ and θ is the logistic transfer function. A line search method, at each iteration, computes the step length α_k and the search direction p^k:

$$u^{k+1} = u^k + \alpha_k p^k.$$

The search direction will be described in Eqn. (12). For our sparse logistic regression, a sequence of step length candidates are identified, and a decision is made to accept one when certain conditions are satisfied. We compute a heuristic step length and gradually decrease it until a sufficient decrease condition is met.

Let's define the heuristic step length as α_0. Ideally the choice of step length α_0, would be a global minimizer of the smooth part of the objective function,

$$\varphi(\alpha) = l_{\text{avg}}(u^k + \alpha p^k), \;\; \alpha > 0,$$

which is too expensive to evaluate, unlike the quadratic case in compressive sensing. Therefore, an inexact line search strategy is usually performed in practice to identify a step length that achieves sufficient decrease in $\varphi(\alpha)$ at minimal cost. Motivated by a similar approach in GPSR (Figueiredo et al., 2007), we compute the heuristic step length through a minimizer of the quadratic approximation for $\varphi(\alpha)$,

$$l_{\text{avg}}(u^k - \alpha\nabla l_{\text{avg}}(u^k)) \approx l_{\text{avg}}(u^k) - \alpha\nabla l_{\text{avg}}(u^k)^T \nabla l_{\text{avg}}(u^k) + 0.5\alpha^2 \nabla l_{\text{avg}}(u^k)^T H(u^k) \nabla l_{\text{avg}}(u^k).$$

Differentiating the right-hand side with respect to α and setting the derivative to zero, we obtain

$$\alpha_0 = \frac{\nabla l_{\text{avg}}(\bar{u}^k)^T \nabla l_{\text{avg}}(\bar{u}^k)}{\nabla l_{\text{avg}}(\bar{u}^k)^T H(\bar{u}^k) \nabla l_{\text{avg}}(\bar{u}^k)}, \tag{11}$$

where $\bar{u}_i^k = 0$, if $u_i = 0$ or $|g_i| < \lambda$ and $\bar{u}^k = u^k$, otherwise. From (11) and the strict positiveness of θ'', we can see that the denominator is strictly positive as long as the gradient is nonzero. Computationally a very useful trick is not to compute the Hessian matrix directly, since we only use the vector-matrix product between the gradient vector $l_{\text{avg}}(\bar{u}^k)$ and the Hessian matrix $H(\bar{u}^k)$.

Based on the heuristic step length α_0, we can obtain the search direction p^k, which is a combination of the gradient descent step and the shrinkage step:

$$\begin{aligned} u^{k-} &= u^k - \alpha_0 \nabla l_{\text{avg}}(u^k), \\ u^{k+} &= s_{1:n}(u^{k-}, \lambda\alpha_0), \\ p^k &= u^{k+} - u^k. \end{aligned} \tag{12}$$

It is easy to verify that $s_\nu(y)$ is the solution to the non-smooth unconstrained minimization problem $\min \frac{1}{2}\|x-y\|_2^2 + \lambda\|x\|_1$. This minimization problem is equivalent to the following smooth constrained optimization problem,

$$\min \frac{1}{2}\|x-y\|_2^2 + \nu z, \text{ subject to } (x,z) \in \Omega := \{(x,z) \mid \|x\|_1 \le z\},$$

whose optimality condition is

$$(s(x,\nu)-x)^T(y-s(x,\nu)+\nu(z-\|s(x,\nu)\|_1) \ge 0,$$

for all $x \in \mathbb{R}^n$, $(y,z) \in \Omega$ and $\nu > 0$. Once we substitute $u-\tau g$ for x, u for y, $\|u_{1:n}\|_1$ for z and set $\nu = \lambda\tau$, the optimality condition becomes

$$(s_{1:n}(u-\tau g, \lambda\tau) - (u-\tau g))^T (u - s_{1:n}(u-\tau g, \lambda\tau)) + \lambda\tau(\|u_{1:n}\|_1 - \|s_{1:n}(u-\tau g, \lambda\tau)\|_1) \ge 0.$$

Using the fact $u^+ = s_{1:n}(u-\tau g, \lambda\tau)$, $p = u^+ - u$, we get

$$g^T p + \lambda(\|u^+_{1:n}\|_1 - \|u_{1:n}\|_1) \le -p^T p/\tau,$$

which means

$$\nabla l_{\text{avg}}(u^k)^T p^k + \lambda\|u^{k+}_{1:n}\|_1 - \lambda\|u^k_{1:n}\|_1 \le 0.$$

We then geometrically backtrack the step lengths, letting $\alpha_j = \alpha_0,\ \mu\alpha_0,\ \mu^2\alpha_0, \ldots$, until the following Armijo-like condition is satisfied:

$$\phi(u^k + \alpha_j p^k) \le C_k + \alpha_j \Delta_k.$$

Notice that the Armijo-like condition for line search stipulates that the step length α_j in the search direction p^k should produce a sufficient decrease of the objective function $\phi(u)$. C_k is a reference value with respect to the previous objective values, while the decrease in the objective function is described as

$$\Delta_k := \nabla l_{\text{avg}}(u^k)^T p^k + \lambda\|u^{k+}_{1:n}\|_1 - \lambda\|u^k_{1:n}\|_1 \le 0.$$

There are two types of Armijo-like conditions depending on the choice of C_k. One can choose $C_k = \phi(u^k)$, which makes the line search monotone. One can also derive a non-monotone line search, where C_k is a convex combination of the previous value C_{k-1} and the function value $\phi(u^k)$. We refer interested readers to Wen et al. (2009) for more details.

Figure 2 illustrates the computational speedup using the line search. The top panel shows the evolution of the objective function as a function of iterations. Tested on the benchmark data from the UCI repository, we see that our algorithm results in a speedup of 40 (6000 iterations without line search vs. 150 iterations with line search). The bottom panel shows the step length used in the algorithm. In the absence of the line search, we require that the step length satisfy $\tau < 2/\hat{\lambda}_{\max}$. For the Armijo-like line search, we illustrate both the heuristic step length α_0 (solid black curve) and the actual step length after backtracking (dashed red curve). Red asterisk labels the transition points on the continuation path, a concept we will discuss in the next section. Note that the step lengths can be on the order of 100 times larger for line search vs. no line search.

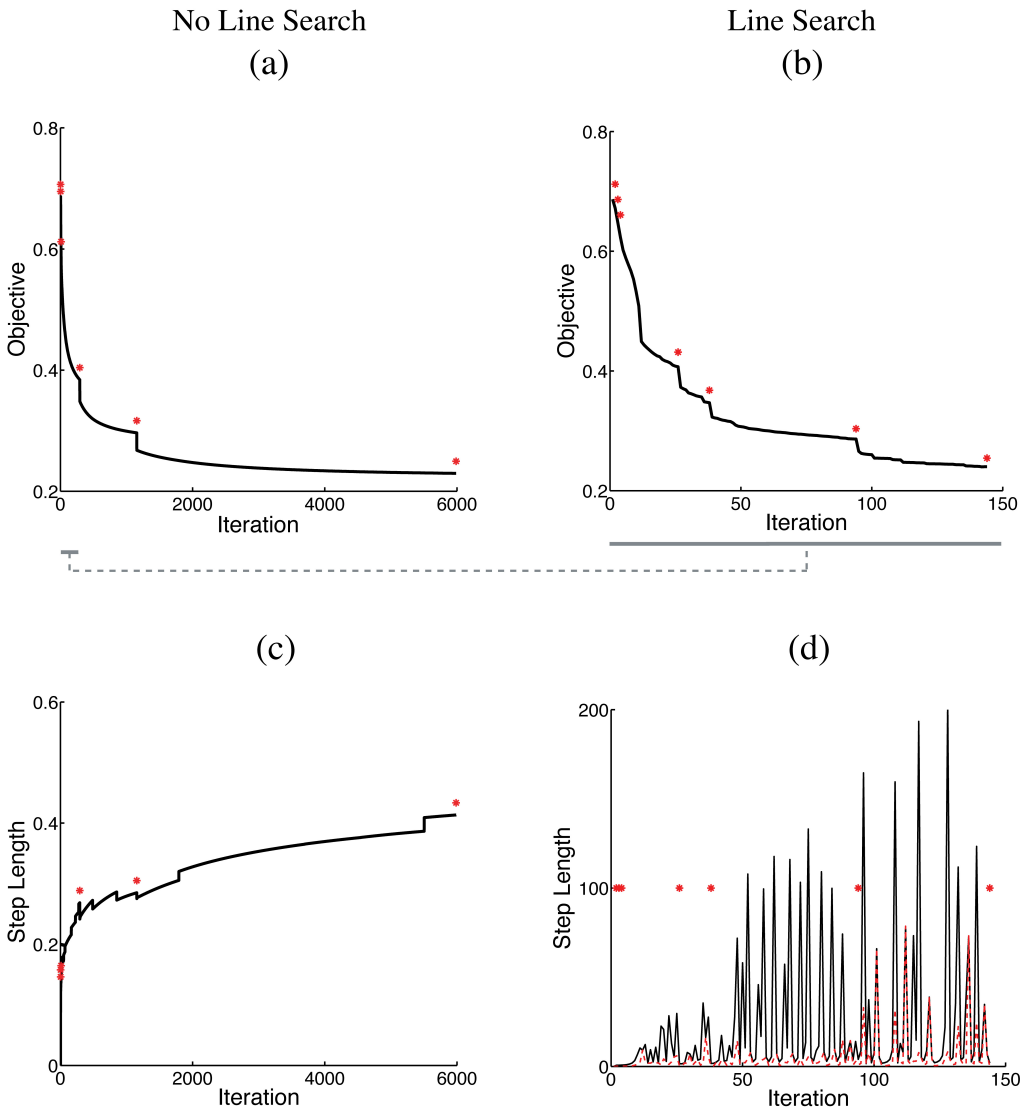

Figure 2: Illustration of the Armijo-like line search, comparing the iterative shrinkage algorithm with (right column) and without (left column) line search. (a) The objective function of the iterative shrinkage algorithm without line search, attaining convergence after 6000 iterations. (b) The objective of the iterative shrinkage algorithm with line search, converging at around 150 iterations. The gray bars under the "iteration" axes highlight the difference between the number of iterations—the gray bar in (a) represents the same number of iterations as the gray bar in (b). (c) The step length without line search is bounded by $2/\hat{\lambda}_{\max}$ to ensure convergence. (d) The step length used in the Armijo-like line search, (solid black curve) heuristic step length α_0 (Eqn. 11), (dashed red curve) actual time step after backtracking. The transition point on the continuation path is indicated in (red asterisk). Data used in this numerical experiment are the ionosphere data from the UCI machine learning data repository (http://archive.ics.uci.edu/ml/datasets/Ionosphere). Parameters used are $utol = 0.001$, $gtol = 0.01$, $\lambda_0 = 0.1$, $\lambda = 0.001$.

2.6 Continuation Path

A continuation strategy is adopted in our algorithm, by designing a regularization path similar to that is used in Hale et al. (2008),

$$\lambda_0 > \lambda_1 > ... > \lambda_{L-1} = \bar{\lambda}.$$

This idea is closely related to the homotopy algorithm in statistics, and has been successfully applied to the ℓ_1-regularized quadratic case, where the fidelity term is $f(x) = \|Ax-b\|_2^2$. The rationale of using such a continuation strategy is due to a fast rate of convergence for large λ. Therefore, by taking advantage of different convergence rate for a family of regularization parameter λ, if stopped appropriately, we can speed up the convergence rate of the full path. An intriguing discussion regarding the convergence rate of fixed-point algorithm with λ and ω, the spectral properties of Hessian, was presented in Hale et al. (2008). In the case of the logistic regression, we have decided to use the geometric progression for the continuation path. We define

$$\lambda_i = \lambda_0 \beta^{i-1}, \text{for } i = 0, ..., L-1,$$

where λ_0 can be calculated based on the ultimate $\bar{\lambda}$ we are interested in and the continuation path length L, that is, $\lambda_0 = \bar{\lambda}/\beta^{L-1}$.

As mentioned earlier, the goal of a continuation strategy is to construct a path with different rate of convergence, with which we can speed up the whole algorithm. The solution obtained from a previous subpath associated with λ_{i-1} is used as the initial condition for the next subpath for λ_i. Note that we design the path length L and the geometric progression rate β in such a way that the initial regularization λ_0 is fairly large, leading to a sparse solution for the initial path. Therefore, the initial condition for the whole path, considering the sparsity in solution, is a zero vector.

Another design issue regarding such a continuation strategy is we stop each subpath according to some criteria, in an endeavor to approximate the solution in the next λ as fast as possible. This means that a strong convergence is not required in subpath's except for the final one, and we can vary the stopping criteria to "tighten" such a convergence as we proceed. The following two stopping criteria are used:

$$\frac{\|u^{k+1} - u^k\|}{\max(\|u^k\|, 1)} < utol_i,$$
$$\frac{\|\nabla l_{\text{avg}}(u^k)\|_\infty}{\lambda_i} - 1 < gtol.$$

The first stopping criterion requires that relative change in u be small, while the second one is related to the optimality condition, defined in Eqn. (13). Theoretically, we would like to vary $utol_i$ to attain a seamless Q-linear convergence path. Such a choice seems to be problem dependent, and probably even data dependent in practice. It remains an important, yet difficult research topic to study the properties of different continuation strategies. We have chosen to use a geometric progression for the tolerance value, $utol_i = utol_0 * \gamma^{i-1}$, with $utol_0 = utol/\gamma^{L-1}$. In our numerical simulation, we use $utol = 10^{-4}$ and $gtol = 0.2$.

Figure 3 shows the continuation path using fixed $utol$ and a varying $utol$ following geometric progression. When we use a fixed $utol$ to ensure strong convergence each for λ along the path, the solver spends a lot of time evolving slowly. One can see in (a) that the objective function shows a

fairly flat reduction at earlier stages of the path. Clearly by relaxing the convergence at earlier stages of the path, we can accelerate the computation, shown in (b). The choice of *utol* and *gtol* seems to be data dependent in our experience, and the result we show in (b) might be suboptimal. Further optimization of the continuation path can potentially accelerate the computation even more, which remains an open question for future research.

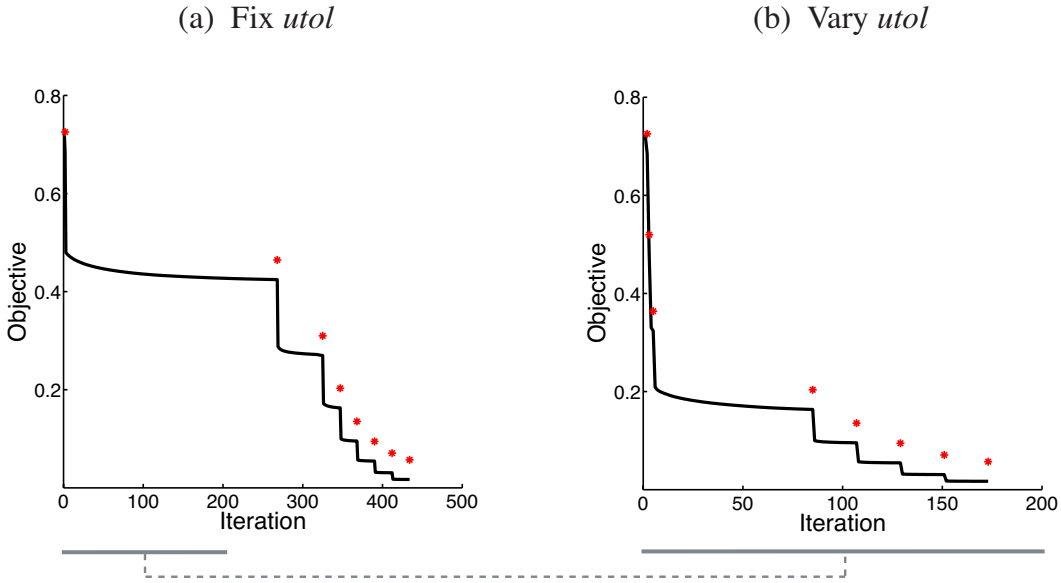

Figure 3: Illustration of the continuation strategy (a) using a fixed $utol = 0.0001$ is used for the stopping criterion, (b) using a varying *utol* according to geometric progression. Note that a stronger convergence is not necessary in earlier stages on the continuation path. By using a varying *utol*, especially tightening *utol* as we move along the path, we can accelerate the fixed point continuation algorithm. Shown is the objective value (black curve) as a function of iteration, where the transition point on the regularization path is labeled in (red asterisk). Data used in this experiment has 10000 dimension and 100 samples. A continuation path of length 8, starting from 0.128 and ending at 0.001.

3. Hybrid Iterative Shrinkage (HIS) Algorithm

In this section we describe a hybrid approach called HIS, which uses the iterative shrinkage algorithm described previously to enforce sparsity and identify the support in the data, followed by a subspace optimization via an interior point method.

3.1 Why A Hybrid Approach?

The hybrid approach is based on an interesting observation for the iterative shrinkage algorithm, regarding some finite convergence properties. The optimality condition for $\min f(x) + \lambda\|x\|_1$ is the following

$$g(x) + \lambda \mathrm{SGN}(x) \in \mathbf{0}, \tag{13}$$

which requires that $|g_i| \leq \lambda$, for $i = 1, ..., n$. We define two index sets

$$L := \{i : |g_i^*| < \lambda\} \text{ and } E := \{i : |g_i^*| = \lambda\},$$

where $g^* = g(u^*)$ is constant for all $u^* \in X^*$ and $|g_i^*| \leq \lambda$ for all i. Hence, $L \cap E = \emptyset$ and $L \cup E = \{1, \ldots, n\}$. The following holds true for all but a finite number of k:

$$\begin{aligned} u_i^k = u_i^* = 0, &\qquad \forall i \in L, \\ \operatorname{sgn}(h_i(u^k)) = \operatorname{sgn}(h_i(u^*)) = -\frac{1}{\lambda} g_i^*, &\qquad \forall i \in E. \end{aligned}$$

Assume that the underlying problem is nondegenerate, then L and E equal the sets of zero and nonzero components in x^*. According to the above finite convergence result, the iterative shrinkage algorithm obtains L and E, and thus the optimal support and signs of the optimal nonzero components, in a finite number of steps.

Corollary 2 *Under Assumption 1, after a finite number of iterations, the fixed-point iteration* (7) *reduces to gradient projection iterations for minimizing* $\phi(u_E)$ *over a constraint set* O_E*, where*

$$\phi(u_E) := -(g_E^*)^\top u_E + f((u_E; \mathbf{0})), \text{ and}$$

$$O_E = \{u_E \in \mathbb{R}^{|E|} : -\operatorname{sgn}(g_E^*) \odot u_E \geq 0\}.$$

Specifically, we have $u^{k+1} = (u_E^{k+1}; \mathbf{0})$ *in which*

$$u_E^{k+1} := P_{O_E}\left(u_E^k - \tau \nabla \phi(u_E^k)\right),$$

where P_{O_E} *is the orthogonal projection onto* O_E*, and* $\nabla \phi(u_E) = -g_E^* + g_E((u_E; \mathbf{0}))$.

This corollary, see Corollary 4.6 in Hale et al. (2008), can be directly applied to sparse logistic regression. The fixed point continuation reduces to the gradient projection after a finite number of iterations. The proof of this corollary is in general true for the $u_{1:n}$, that is, the w component in our problem.

Corollary 2 implies an important fact: there are two phases in the fixed point continuation algorithm. In the first phase, the number of nonzero elements in the x evolve rapidly, until after a finite number of iterations, when the support (non-zero elements in a vector) is found. Precisely, it means that for all $k > K$, the nonzero entries in u^k include all true nonzero entries in u^* with the matched signs. However, unless k is large, u^k typically also has extra nonzeros. At this point, the fixed point continuation reduces to the gradient projection, starting the second phase of the algorithm. In the second phase, the zero elements in the vector stay unaltered, while the magnitude of the nonzero elements (support) keeps evolving.

The above observation is a general statement for any f that is convex. Recall the quadratic case, where $f = \|y - Ax\|_2^2$, the second phase is very fast in terms of convergence rate. This is due to the quadratic function, and in an application to compressive sensing, the fixed point continuation algorithm alone has resulted in super-fast performance for large-scale problems (Hale et al., 2008). In the case of sparse logistic regression, we have a non-strictly convex f, the average logistic regression. This results in a fairly slow convergence rate when the algorithm reaches the second phase. In view of the continuation strategy we have, this greatly affects the speed of the last subpath, with the

regularization parameter $\bar{\lambda}$ of interest. In some sense, we have designed a continuation path that is super-fast until it reaches the second phase of the final subpath. This is not surprising given that the fixed point continuation algorithm is based on gradient descent and shrinkage operator. We envision that by switching to a Newton's method, we can accelerate the second phase.

Based on this intuition, we are now in a position to describe a hybrid algorithm: a fixed point continuation plus an interior point truncated Newton method. For the latter part we resort to the customized interior point in Koh et al. (2007). We modified the source code of the *l1logreg* software (written in C), and built an interface to our MATLAB code. This hybrid approach, based on our observation of the two phases, enables us to attain a good balance of speed and accuracy.

3.2 Interior Point Phase

The second phase of our HIS algorithm used an interior point method developed by Koh et al. (2007). We directly used a well-developed software package *l1logreg*[1] and modified the source code to build an interface to MATLAB. We review some key points for the interior point method here.

In Koh et al. (2007), the authors overcome the difficulty of non-differentiability of the objective function by transforming the original problem into an equivalent one with linear inequality constraints,

$$\begin{array}{ll} \min & \frac{1}{m}\sum_{i=1}^{m} l_{\text{avg}}(w^T a_i + v b_i) + \lambda \mathbf{1}^T u \\ \text{s.t.} & -u_i \leq w_i \leq u_i, \;\; i = 1, ..., n. \end{array}$$

A logarithmic barrier function, smooth and convex, is further constructed for the bound constraints,

$$\rho(w,u) = -\sum_{i=1}^{n} \log(u_i + w_i) - \sum_{i=1}^{n} \log(u_i - w_i),$$

defined on the domain $\{(w,u) \in \mathbb{R}^n \times \mathbb{R}^n | |w_i| < u_i, i = 1, ..., n\}$. The following optimization problem can be obtained by augmenting the logarithmic barrier,

$$\psi_t(v,w,u) = t l_{\text{avg}}(v,w) + t\lambda \mathbf{1}^T u + \rho(w,u),$$

where $t > 0$. The resulting objective function is smooth, strictly convex and bounded below, and therefore has a unique minimizer $(v^*(t), w^*(t), u^*(t))$. This defines a curve in $\mathbb{R} \times \mathbb{R}^n \times \mathbb{R}^n$, parameterized by t, called the central path. The optimal solution is also shown to be dual feasible. In addition, $(v^*(t), w^*(t))$ is $2n/t$-suboptimal.

As a primal interior-point method, the authors computed a sequence of points on the central path, for an increasing sequence of values of t, and minimized $\psi_t(v,w,u)$ for each t using a truncated Newton's method. The interior point method was customized by the authors in several ways: 1) the dual feasible point and the associated duality gap was computed in a cheap fashion, 2) the central path parameter t was updated to achieve a robust convergence when combined with the preconditioned conjugate gradient (PCG) algorithm, 3) an option for solving the Newton's system was given for problems of different scales, where small and medium dense problems were solved by direct methods (Cholesky factorization), while large problems were solved using iterative methods (conjugate gradients). Interested readers are referred to Koh et al. (2007) for more details.

1. Software can be downloaded at `http://www.stanford.edu/~boyd/papers/l1_logistic_reg.html`.

3.3 The Hybrid Algorithm

The hybrid algorithm leverages the computational strengths of both the iterative shrinkage solver and the interior point solver.

Algorithm 3 Hybrid Iterative Shrinkage (**HIS**) Algorithm

Require: $A = [c_1^\top; c_2^\top; \cdots; c_m^\top] \in \mathbb{R}^{m \times n+1}$, $u = (w; v) \in \mathbb{R}^{n+1}$, $f(u) = m^{-1}\phi(Au)$
  task: $\min_u l_{\text{avg}}(u) + \lambda\|u\|_1$
  Initialize u^0
  PHASE 1 : ITERATIVE SHRINKAGE
  Select λ_0 and $utol_0$
  while "not converge" **do**
    if "the last continuation path", $i == (L-1)$ and "transition condition" **then**
      "transit into PHASE 2"
    else
      Update $\lambda_i = \lambda_{i-1}\beta$, $utol_i = utol_{i-1}\gamma$
      Compute heuristic step length α_0
      Gradient descent step: $u^{k-} = u^k - \alpha_0 \nabla l_{\text{avg}}(u^k)$
      Shrinkage step: $u^{k+} = s_{1:n}(u^{k-}, \lambda\alpha_0)$
      Obtain line search direction: $p^k = u^{k+} - u^k$
      while "j $<$ max line search attempts" **do**
        if Armijo-like condition is met **then**
          Accept line search step, update $u^{k+1} = u^k + \alpha_j p^k$
        else
          Keep backtracking $\alpha_j = \mu\alpha_{j-1}$
        end if
        $j = j + 1$
      end while
    end if
  end while
  PHASE 2 : INTERIOR POINT
  Initialize $\tilde{w} = w_{nonzero}$ get subproblem $\min \psi_t(v, \tilde{w}, u)$
  while "not converged" $\eta > \varepsilon$ **do**
    Solve the Newton system : $\nabla^2\psi_t^k(v, \tilde{w}, u)[\Delta v, \Delta\tilde{w}, \Delta u] = -\nabla\psi_t^k(v, \tilde{w}, u)$
    Backtracking line search : find the smallest integer $j \geq 0$ that satisfies
    $\psi_t^k(v + \alpha_j\Delta v, \tilde{w} + \alpha_j\Delta\tilde{w}, u + \alpha_j\Delta u) \leq \psi_t^k(v, \tilde{w}, u) + c\alpha_j\nabla\psi_t^k(v, \tilde{w}, u)^T[\Delta v, \Delta\tilde{w}, \Delta u]$
    Update $\psi_t^{k+1}(v, \tilde{w}, u) = \psi_t^k(v, \tilde{w}, u) + \alpha_j(\Delta v, \Delta\tilde{w}, \Delta u)$
    Check dual feasibility
    Evaluate duality gap η
    $k = k + 1$
  end while

In the first phase, we use the iterative shrinkage solver, due to its computational efficiency and memory friendliness. It is especially beneficial to have a memory friendly solver for the initial phase when one is dealing with large-scale data sets. Recall that we use a continuation strategy for the iterative shrinkage phase, where a sequence of λ's is used along a regularization path. In the

last subpath where λ is the desired one, we transit to the interior point when the true support of the vector is found. The corollary in Section 3.1 states that iterative shrinkage recovers the true support in a finite number of steps. In addition, iterative shrinkage obtains all true nonzero components long before the true support is obtained. Therefore, as long as the iterative shrinkage seems to stagnate, which can be observed when the objective function evolves very slowly, it is highly likely that all true nonzero components are obtained. This indicates that the algorithm is ready for switching to the interior point.

In practice, we require the following transition condition,

$$\frac{\|u^{k+1} - u^k\|}{\max(\|u^k\|, 1)} < utol_t,$$

and extract the nonzero components in w as the input to the interior point solver. By doing so, we reduce the problem to a subproblem where the dimension is much smaller, and solve the subproblem using the interior point method.

The resulting hybrid algorithm achieves high computational speed while attaining the same numerical accuracy as the interior point method, as demonstrated with empirical results in the next section.

4. Numerical Results

In this section we present numerical results, on a variety of data sets, to demonstrate the benefits of our hybrid framework in terms of computational efficiency and accuracy.

4.1 Benchmark

We carried out a numerical comparison of the HIS algorithm with several existing algorithms in literature for ℓ_1-regularized logistic regression. Inspired by a comparison study on this topic by Schmidt et al. (2007),[2] we compared our algorithm with 10 algorithms, including a generalized version of Gauss-Seidel, Shooting, Grafting, Sub-Gradient, epsL1, Log-Barrier, Log-Norm, SmoothL1, EM, ProjectionL1 and Interior-Point method. In the numerical study, we replaced the interior point solver by the one written by Koh et al. (2007). Benchmark data were taken from the publicly available UCI machine learning repository.[3] We used 10 data sets of small to median size (internetad1, arrhythmia, glass, horsecolic, indiandiabetes, internetad2, ionosphere, madelon, pageblock, spambase, spectheart, wine).

All of the methods were run until the same convergence criteria was met, where appropriate, for instance the step length, change in function value, negative directional derivative, optimality condition, convergence tolerance is less than 10^{-6}. We treated each algorithm solver as a black box and evaluated both the computation time and the sparsity (measured by cardinality of solution). We set an upper limit of 250 iterations, meaning we stop the solver when the number of iteration exceeds 250. Since different algorithm has different speed for each iterate (usually a Newton step is more expensive than a gradient descent step), we think the computation time is a more appropriate evaluation criterion than number of iterations. The ability of the algorithm to find a sparse solution, measured by the cardinality, was also evaluated in this process.

2. Source code is available at `http://www.cs.wisc.edu/~gfung/GeneralL1`.
3. UCI machine learning repository is at `http://www.ics.uci.edu/~mlearn/MLRepository.html`.

Figure 4 shows the benchmark result using data from the UCI machine learning repository. All numerical results shown are averaged over a regularization path. The parameters for the regularization path are calculated according to each data set, where the maximal regularization parameter is calculated as follows:

$$\lambda_{max} = \frac{1}{m}\left\| \frac{m_-}{m} \sum_{b_i=+1} a_i + \frac{m_+}{m} \sum_{b_i=-1} a_i \right\|_\infty, \tag{14}$$

where m_- is the number of training samples with label -1 and m_+ is the number of training samples with label $+1$ (Koh et al., 2007). λ_{max} is an upper bound for the useful range of regularization parameter. When $\lambda \geq \lambda_{max}$, the cardinality of the solution will be zero. In this case, we test a regularization path of length 10, that is, $\lambda_{max}, 0.9\lambda_{max}, 0.8\lambda_{max}$ ... $0.1\lambda_{max}$. Among all the numerical solvers, our HIS algorithm is the most efficient. HIS achieves comparable cardinality in the solution, compared to the interior point solver.

We also evaluated the accuracy of the solution by looking at the classification performance using Kfold cross-validation. Table 1 summaries the accuracy of the solution using the HIS algorithm, compared to the interior point (IP) algorithm. Clearly, HIS algorithm achieves comparable accuracy compared to IP, an algorithm that is recognized for its high accuracy.

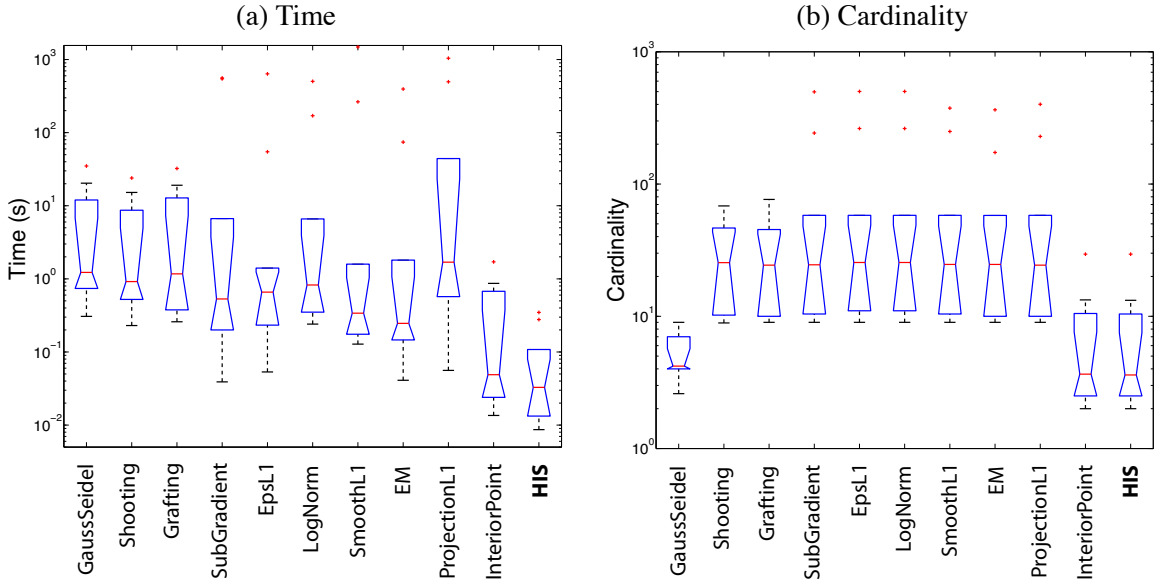

Figure 4: Comparison of our hybrid iterative shrinkage (HIS) method with several other existing methods in literature. Benchmark data were taken from the UCI machine learning repository, including 10 publicly available data sets. (a) Distribution of computation time across 10 data sets, (b) Distribution of cardinality for the solution across 10 data sets, averaged over a regularization path.

4.2 Scaling Result

Numerical experiments were carried out to study how our algorithm scales with the problem size. For the sake of generality, we used simulated data whose dimension ranges from 64 to 131072. The

Accuracy Comparison
($Az \in [0.5, 1.0]$)

dataname	accuracy(HIS)	accuarcy(IP)
arrhythmia	0.7363	0.7363
glass	0.6102	0.6102
horsecolic	0.5252	0.5252
ionosphere	0.5756	0.5756
madelon	0.6254	0.6254
spectheart	0.5350	0.5350
wine	0.6102	0.6102
internetad	0.8486	0.8486

Table 1: Comparison of solution accuracy for our hybrid iterative shrinkage (HIS) algorithm and the interior point (IP) algorithm. Accuracy of the solution was measured by Az value, resulted from Kfold cross-validation, where Kfold is 10. A regularization path of varying λ were computed to determine the maximum generalized Az value. The data sets were taken from the UCI machine learning repository.

data is drawn from a Normal distribution, where the mean of the distribution is shifted by a small amount for each class (0.1 for samples with label 1, and -0.1 for samples with label -1). The number of samples is the same for both classes and chosen to be smaller than the dimension of the data. Experiments for each dimension were carried out on 100 different sets of random data. We compared the mean and variances of the computation time, and compared our HIS algorithm to the IP algorithm.

Table 2 summarizes the computational speed for the HIS algorithm and the IP algorithm. It is noteworthy that the HIS algorithm improves the efficiency of computation, while maintaining comparable accuracy to the IP algorithm. Figure 5 plots the computation result as a function of dimension for better illustration. In (a) one can clearly see the speedup we gain from the HIS algorithm (red), compared to the IP algorithm (blue). We also show the solution quality in (b), where the weights we get from both solvers, is comparable.

4.3 Regularization Parameter

In general, the regularization parameter λ affects the number of iterations to converge for any solver. As λ becomes smaller, the cardinality of the solution increases, and the computation time needed for convergence also increases. Therefore when one seeks a solution with less sparsity (small λ), it is more computationally expensive.

In practice, when one carries out classification on a set of data, the optimal regularization parameter is often unknown. Speaking of optimality, we refer to a regularization parameter that results in the best classification result evaluated using Kfold cross-validation. One would run the algorithm along a regularization path, $\lambda_{max}, ..., \lambda_{min}$, where λ_{max} is computed by Eqn. (14) and where λ_{min} is supplied by the user.

Figure 6 shows the evolution of solution along the regularization path, using a small data set (ionosphere) from the UCI machine learning repository. This explores sparsity of different degrees

Speed Comparison

Table 2: Speed comparison of the HIS algorithm with the IP algorithm, based on simulated random benchmark data. Shown here is the computation speed as a function of dimension. Data used here are generated by sampling from two Gaussian distributions. Note that in the simulation, the continuation path used in the iterative shrinkage may or may not be optimal, which means that the speed profile for the HIS algorithm can be essentially accelerated even more.

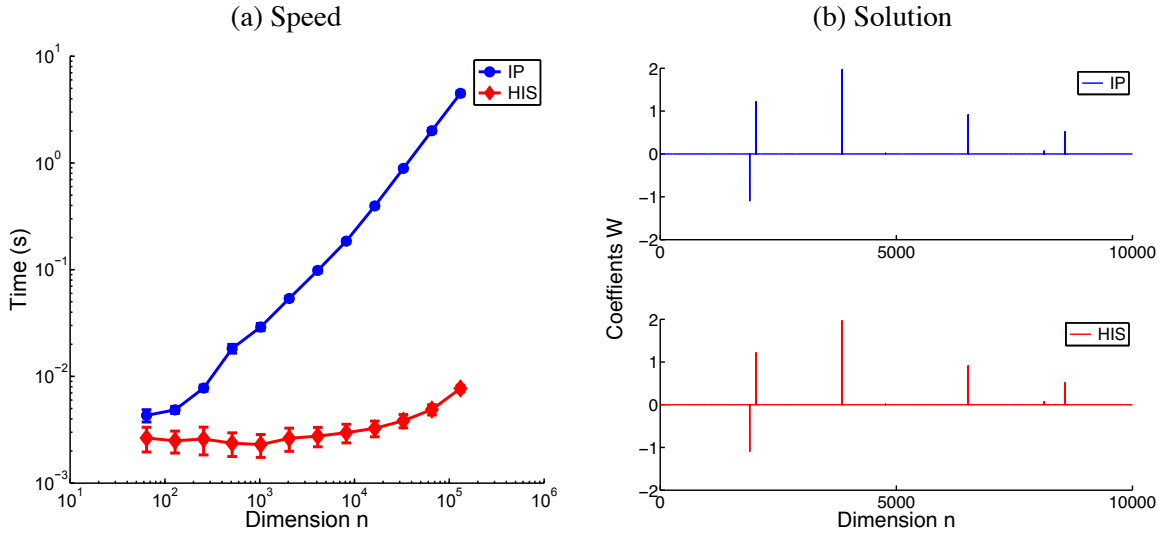

Figure 5: Comparison for the random benchmark data, between the HIS algorithm and the IP algorithm. (a) Speed profile for these two approaches: (blue curve) shows the speed profile for the IP algorithm, and (red curve) shows the speed profile for the HIS algorithm as a function of the data dimension. (b) An example of the solutions using the IP algorithm (blue) and the HIS algorithm (red).

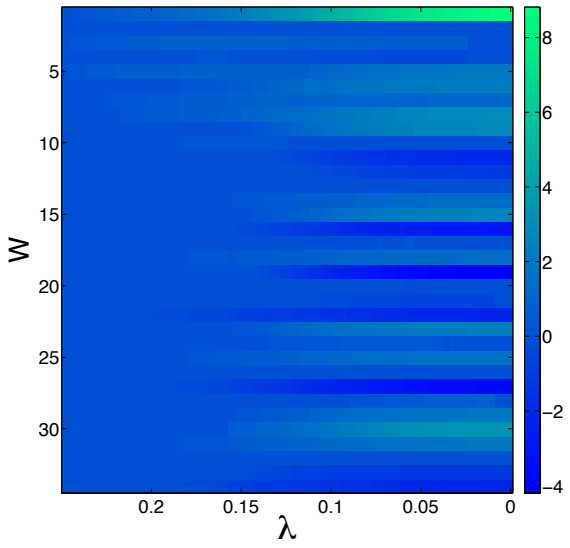

Figure 6: Solution w evolves along a regularization path, following a geometric progression from 10^{-1} to 10^{-4}. Data is ionosphere from UCI machine learning repository. As the λ becomes smaller, the cardinality of the solution goes up.

in the solution, and one can determine the optimal sparsity for the data. This is an attractive property of this model, where one can search in the feature space the most informative features about discrimination.

We illustrate the effect of the regularization parameter using real data of large scale. The data concerns a two alternative force choice task for face versus car discrimination. We used a spiking neuron model of primary visual cortex to map the input into cortical space, and decoded the resulting spike trains using sparse logistic regression (Shi et al., 2009). The data has 40960 dimensions and 360 samples for each of the two classes. Kfold cross-validation was used to evaluate the classification performance, where the number of Kfolds is 10 in our simulation.

The speedup of the HIS algorithm compared to the IP algorithm is shown in Figure 7(a), where blue indicates the computation time of the IP algorithm, and red shows the HIS algorithm. The HIS algorithm results in a significant speedup over the IP algorithm, without loss of accuracy. Note that there is an issue of model selection when we apply sparse logistic regression model to the data, in a sense there exists an optimal level of sparsity that achieves the best classification result. We ran the model with a sequence of regularization parameters, which resulted in classification result (evaluated by Az value from Kfold cross-validation). Figure 7(b) illustrates the classification result as a function of the cardinality of the solution. One can see the bell shape in the curve, which provides a route to select the optimal sparsity for the solution.

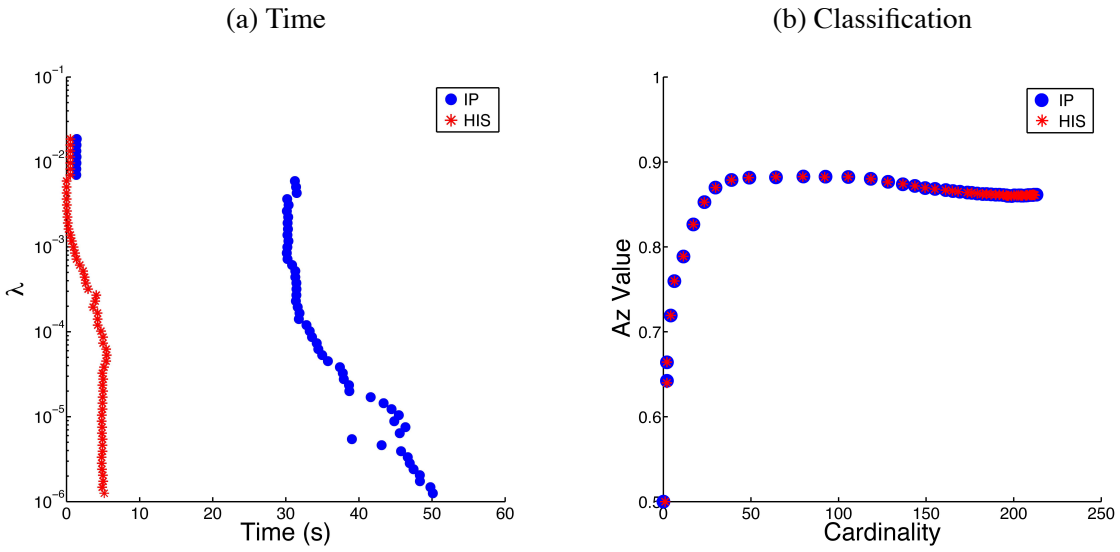

Figure 7: An example using real data of large scale, $n = 40960$, $m = 360$. (a) Computation time along such a regularization path, where the smaller λ requires more computation time. Note that the simulation is carried out for each λ separately. (b) Classification performance derived from ROC analysis based on Kfold cross-validation. Data used in this simulation are neural data for a visual discrimination task (Shi et al., 2009).

4.4 Data Sets with Large Dimensions and Samples

We applied the HIS algorithm to some examples of real-world data that have both large dimensions n and samples m. In this case, we considered text classification using the binary rcv1 data[4] (Lewis et al., 2004), and real-sim data.[5]

We ran the simulation on an Apple Mac Pro with two 3 GHz Quad-Core Intel processors, and 8 GB of memory. The timing of the simulation was calculated within the Matlab interface. All the operations were optimized for sparse matrix computation. Table 3 summarizes the numerical results. For both examples of text classification, we observed a speedup using the HIS algorithm while attaining the same numerical accuracy, compared with the IP algorithm. The regularization parameter does affect the computational efficiency, as we have observed in the previous section.

5. Conclusion

We have presented in this paper a computationally efficient algorithm for the ℓ_1-regularized logistic regression, also called the sparse logistic regression. The sparse logistic regression is a widely used model for binary classification in supervised learning. The ℓ_1 regularization leads to sparsity in the solution, making it a robust classifier for data whose dimensions are larger than the number of

4. Binary rcv1 data is available at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary.html#rcv1.binary`.
5. Real-sim data is available at `http://www.cs.umass.edu/~mccallum/code-data.html`.

Text Classification Application

	rcv1 $n = 20242$ $m = 47236$ nonzero = 1498952		real-sim $n = 72309$ $m = 20958$ nonzero = 3709083	
λ	Time(HIS)	Time(IP)	Time(HIS)	Time(IP)
10^{-1}	0.11	1.93	0.62	6.61
10^{-2}	0.27	1.93	0.62	6.61
10^{-3}	2.08	8.20	5.50	18.45
10^{-4}	5.80	8.66	13.12	19.36

Table 3: Illustration of performance on text classification, where both the dimensions n and samples m are large-scale. We compare the computational efficiency of the HIS and IP algorithms. In both cases, the solution accuracy is the same.

samples. Sparsity also provides an attractive avenue for feature selection, useful for various data mining tasks.

Solving the large-scale sparse logistic regression usually requires expensive computational resources, depending on the specific solver, memory and/or CPU time. The interior point method is so far the most efficient solver in the literature, but requires expensive memory consumption. We have presented the HIS algorithm, which couples a fast shrinkage method and a slower but more accurate interior point method. The iterative shrinkage algorithm has global convergence with a Q-linear rate. Various techniques such as line search and continuation strategy are used to accelerate the computation. The shrinkage solver only involves the gradient descent and the shrinkage operator, both of which are first-order. Based solely on efficient memory operations such as matrix-vector multiplication, the shrinkage solver serves as the first phase for the algorithm. This reduces the problem to a subspace whose dimension is smaller than the original problem. The HIS algorithm then transits into the second phase, using a more accurate interior point solver. We numerically compare the HIS algorithm with other popular algorithms in the literature, using benchmark data from the UCI machine learning repository. We show that the HIS algorithm is the most computationally efficient, while maintaining high accuracy. The HIS algorithm also scales very well with dimension of the problem, making it attractive for solving large-scale problems.

There are several ways to extend the HIS algorithm. One is to extend it beyond binary classification, allowing for multiple classes (Krishnapuram and Hartemink, 2005). The other is to further improve the regularization path. When applying the HIS algorithm, one will usually explore a range of sparsity by constructing a regularization path (λ_{max}, λ_1, ..., λ_{min}). Usually the smaller the λ, the more expensive it is to employ the shrinkage algorithm. One can accelerate the computation using the Bregman regularization, inspired by Yin et al. (2008). The Bregman iterative algorithm essentially boosts the solution by solving a sequence of optimizations, resulting in a different regularization path. Bregman has also been shown to improve solution quality in the presence of noise (Burger et al., 2006; Shi and Osher, 2008; Osher et al., 2010). We will discuss such a regularization path in a future paper.

Abstract

PyBrain is a versatile machine learning library for Python. Its goal is to provide flexible, easy-to-use yet still powerful algorithms for machine learning tasks, including a variety of predefined environments and benchmarks to test and compare algorithms. Implemented algorithms include Long Short-Term Memory (LSTM), policy gradient methods, (multidimensional) recurrent neural networks and deep belief networks.

Keywords: Python, neural networks, reinforcement learning, optimization

1. Introduction

PyBrain is a machine learning library written in Python designed to facilitate both the application of and research on premier learning algorithms such as LSTM (Hochreiter and Schmidhuber, 1997), deep belief networks, and policy gradient algorithms. Emphasizing both sequential and non-sequential data and tasks, PyBrain implements many recent learning algorithms and architectures ranging from areas such as supervised learning and reinforcement learning to direct search / optimization and evolutionary methods.

PyBrain is implemented in Python, with the scientific library SciPy being its only strict dependency. As is typical for programming in Python/SciPy, development time is greatly reduced as compared to languages such as Java/C++, at the cost of lower speed. PyBrain embodies a compositional setup, which means that it is designed to be able to connect various types of architectures and algorithms.

PyBrain goes beyond existing Python libraries in breadth in that it provides a toolbox for supervised, unsupervised and reinforcement learning as well as black-box and multi-objective optimization. In addition to standard algorithms (some of which, to the best of our knowledge, are not available as Python implementations elsewhere) for application-oriented users, it contains ref-

∗. Also at IDSIA, University of Lugano, Galleria 2, Manno-Lugano, 6900, Switzerland.

erence implementations of a number of algorithms at the bleeding edge of research. Furthermore, it sets itself apart by its flexibility for composing custom neural networks architectures, ranging from (multi-dimensional) recurrent networks to restricted Boltzmann machines or convolutional networks.

2. Library Overview

The library includes different types of training algorithms, trainable architectural components, specialized data sets and standardized benchmark tasks/environments. The available algorithms generally function both in sequential and non-sequential settings, and appropriate data handling tools have been developed for special applications, ranging from reinforcement learning to handwriting recognition applications. Implemented algorithms and methods come with unit tests in order to assure correctness and soundness.

In the following, we will provide a short overview of the different features of the library.

Supervised Learning Training algorithms include classical gradient-based methods and extensions both for non-sequential and sequential data. PyBrain also features Gaussian processes, the evolino algorithm and an SVM wrapper.

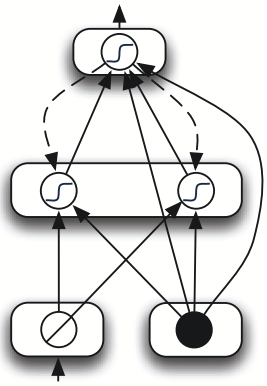
Black-Box Optimization / Evolutionary Methods Various black-box optimization algorithms have been implemented. In addition to traditional evolution strategies, covariance matrix adaptation, co-evolitionary and genetic algorithms (including NSGA-II for multi-objective optimization), we have included recent new algorithms (not available in other libraries) such as fitness expectation maximization, natural evolution strategies and policy gradients with parameter-based exploration.

Reinforcement Learning The reinforcement learning algorithms of PyBrain encompass basic methods such as Q-learning, SARSA and REINFORCE, but also natural actor-critic, neural-fitted Q-iteration, recurrent policy gradients, state-dependent exploration and reward-weighted regression.

Architectures Available architectures include standard feedforward neural networks, recurrent neural networks and LSTM, bi- and multidimensional recurrent neural networks and deep belief networks. The library puts emphasis on, but is not limited to, (recurrent) neural network structures arbitrarily structured as a directed acyclic graph of modules and connections.

Compositionality The basic structure of the library enables a compositional approach to machine learning. Different algorithms and architectures can be connected and composed, and then used and trained as desired. For example, arbitrarily structured recurrent neural network graphs can be trained using various different algorithms such as black-box search, policy gradients and supervised learning. For example, both an LSTM architecture and a deep belief network, though constituting wildly different architectures, can be trained using the same gradient implementation (e.g., RPROP).

Tasks and Benchmarks For black-box and multi-objective optimization, standard benchmarks are included in the library. For reinforcement learning settings, there are classical (PO)MDP mazes, (non-Markov) (double) pole balancing and various ODE environments based on physics simulations. In order to make data processing as easy as possible, PyBrain features functionality for constructing, serializing and deserializing data sets to files or over network connections.



```
# Load Data Set.
ds = SequentialDataSet.loadFromFile('parity.mat')

# Build a recurrent Network.
net = buildNetwork(1, 2, 1, bias=True,
                   hiddenclass=TanhLayer,
                   outclass=TanhLayer,
                   recurrent=True)
recCon = FullConnection(net['out'], net['hidden0'])
net.addRecurrentConnection(recCon)
net.sortModules()

# Create a trainer for backprop and train the net.
trainer = BackpropTrainer(net, ds, learningrate=0.05)
trainer.trainEpochs(1000)
```

Figure 1: Code example for solving the parity problem with a recurrent neural network.

Speed Optimization The development cycle of Python/SciPy is short, especially compared to languages such as Java/C/C++ and especially in scientific / machine learning settings. However, this comes at a cost-reduced speed. In order to partially mitigate this potential problem, we have implemented many parts of the library in C/C++ using SWIG as a bridge. Parallel implementations in both Python and C++ exist for crucial bottleneck elements of the library. The resulting speedup approaches an equivalent C++ implementation within an order of magnitude, and comes even closer for large architectures.

3. An Illustrative Example

In order to provide a useful example to a novice user, we construct a recurrent network that is able to solve the parity problem. The network is given a sequence of binary inputs and the corresponding objective is to determine whether the network has been provided an even or an odd number of 1s so far. The implemented topology and the corresponding code are shown in Figure 1.

We first construct a feed forward network consisting of a single linear input cell, a layer of two hidden cells and one output cell. The network also needs a bias, which is connected to the hidden and output layer. The layers are fully connected with one another.

The network is first created using a 'convenience' function. A recurrent connection from the output unit to the hidden layer is crucial to learn the problem and thus added afterwards.

It should be stressed that the clarity and shortness of this code example is representative for many algorithms and architectures used in actual problems. Constructing networks for classification, control or function approximation often requires even fewer lines of code.

4. Concluding Remarks

In PyBrain we emphasize simplicity, compositionality and the ability to combine various architectures and algorithm types. We believe this to be advantageous in the light of recent developments in sequence processing, deep belief networks, policy gradients and visual processing. Pybrain is easy to use, and is well-documented, both in code and in documents and tutorials explaining the use of the basic capabilities of the library. Among machine learning libraries written in Python,

PyBrain stands out for its combination of breadth, versatility and maturity of development. In order to further demonstrate its practical applicability to scientific research, we could emphasize that PyBrain, so far, has already been used in fourteen scientific peer-reviewed publications, for example, Sehnke et al. (2008), Rückstieß et al. (2008), Schaul and Schmidhuber (2009), Sun et al. (2009) and Wierstra et al. (2008).

5. Availability and Requirements

As of the time of writing, PyBrain has reached version 0.3 and both the entire source code and the documentation are available from the website, `www.pybrain.org`, under the BSD license. The available platforms are Mac OS X, Linux and Microsoft Windows. The only strict dependency is SciPy (`www.scipy.org`), highly recommended are matplotlib (required for most example scripts) and setuptools. The documentation includes a quickstart tutorial, installation instructions, tutorials on advanced topics, and an extensive API reference. Since PyBrain is under active development, we encourage researchers to contribute their work and provide guidelines for how they can do so.

Abstract

Leading classification methods such as support vector machines (SVMs) and their counterparts achieve strong generalization performance by maximizing the margin of separation between data classes. While the maximum margin approach has achieved promising performance, this article identifies its sensitivity to affine transformations of the data and to directions with large data spread. Maximum margin solutions may be misled by the spread of data and preferentially separate classes along large spread directions. This article corrects these weaknesses by measuring margin not in the absolute sense but rather only relative to the spread of data in any projection direction. Maximum relative margin corresponds to a data-dependent regularization on the classification function while maximum absolute margin corresponds to an ℓ_2 norm constraint on the classification function. Interestingly, the proposed improvements only require simple extensions to existing maximum margin formulations and preserve the computational efficiency of SVMs. Through the maximization of relative margin, surprising performance gains are achieved on real-world problems such as digit, text classification and on several other benchmark data sets. In addition, risk bounds are derived for the new formulation based on Rademacher averages.

Keywords: support vector machines, kernel methods, large margin, Rademacher complexity

1. Introduction

In classification problems, the aim is to learn a classifier that generalizes well on future data from a limited number of training examples. Support vector machines (SVMs) and maximum margin classifiers (Vapnik, 1995; Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004) have been a particularly successful approach both in theory and in practice. Given a labeled training set, these return a predictor that accurately labels previously unseen test examples. For simple binary classification in Euclidean spaces, this predictor is a function $f : \mathbb{R}^m \to \{\pm 1\}$ estimated from observed training data $(\mathbf{x}_i, y_i)_{i=1}^n$ consisting of inputs $\mathbf{x}_i \in \mathbb{R}^m$ and outputs $y_i \in \{\pm 1\}$. A linear function[1] $f(\mathbf{x}) := \text{sign}(\mathbf{w}^\top \mathbf{x} + b)$ where $\mathbf{w} \in \mathbb{R}^m, b \in \mathbb{R}$ serves as the decision rule throughout this article. The parameters of the hyperplane $(\mathbf{w}, b)$ are estimated by maximizing the margin (e.g., the distance between the hyperplanes defined by $\mathbf{w}^\top \mathbf{x} + b = 1$ and $\mathbf{w}^\top \mathbf{x} + b = -1$) while minimizing a weighted upper bound on the misclassification rate on training data (via so-called slack variables). In practice, the margin is maximized by minimizing $\frac{1}{2}\mathbf{w}^\top \mathbf{w}$ plus an upper bound on the misclassification rate.

1. In this article the dot product $\mathbf{w}^\top \mathbf{x}$ is used with the understanding that it can be replaced with a generalized inner product or by using a kernel for generic objects.

While maximum margin classification works well in practice, its solution can easily be perturbed by an (invertible) affine or scaling transformation of the input space. For instance, by transforming all training and testing inputs by an invertible linear transformation, the SVM solution and its resulting classification performance can be significantly varied. This is worrisome since an adversary could directly exploit this shortcoming and transform the data to drive performance down; a synthetic example showing this effect will be presented in Section 5. Moreover, this phenomenon is not limited to an explicit adversarial setting; it can naturally occur in many real world classification problems, especially in high dimensions. This article will explore such shortcomings in maximum margin solutions (or equivalently, SVMs in the context of this article) which exclusively measure margin by the points near the classification boundary regardless of how spread the remaining data is away from the separating hyperplane. An alternative approach will be followed based on controlling the spread while maximizing the margin. This helps overcome this bias and produces a formulation that is affine invariant. The key is to recover a large margin solution while normalizing the margin by the spread of the data. Thus, margin is measured in a *relative* sense rather than in the absolute sense. In addition, theoretical results using Rademacher averages support this intuition. The resulting classifier will be referred to as the relative margin machine (RMM) and was first introduced by Shivaswamy and Jebara (2009a) with this longer article serving to provide more details, more thorough empirical evaluation and more theoretical support.

Traditionally, controlling spread has been an important theme in classification problems. For instance, classical linear discriminant analysis (LDA) (Duda et al., 2000) finds projections of the data so that the inter-class separation is large while within-class scatter is small. However, the spread (or scatter in this context) is estimated by LDA using only simple first and the second order statistics of the data. While this is appropriate if class-conditional densities are Gaussian, second-order statistics are inappropriate for many real-world data sets and thus, the classification performance of LDA is typically weaker than that of SVMs. The estimation of spread should not make second-order assumptions about the data and should be tied to the margin criterion (Vapnik, 1995). A similar line of reasoning has been proposed to perform feature selection. Weston et al. (2000) showed that second order tests and filtering methods on features perform poorly compared to wrapper methods on SVMs which more reliably remove features that have low discriminative value. In this prior work, a feature's contribution to margin is compared to its effect on the radius of the data by computing bounding hyper-spheres rather than simple second-order statistics. Unfortunately, there, only axis-aligned feature selection was considered. Similarly, ellipsoidal kernel machines (Shivaswamy and Jebara, 2007) were proposed to normalize data in feature space by estimating bounding hyper-ellipsoids while avoiding second-order assumptions. Similarly, the radius-margin bound has been used as a criterion to tune the hyper-parameters of the SVM (Keerthi, 2002). Another criterion based jointly on ideas from the SVM method as well as Linear Discriminant Analysis has been studied by Zhang et al. (2005). This technique involves first solving the SVM and then solving an LDA problem based on the support vectors that were obtained. While these previous methods showed performance improvements, they relied on multiple-step locally optimal algorithms for interleaving spread information with margin estimation.

To overcome the limitations of local non-convex optimization schemes, the formulations derived here will remain convex, will be efficiently solvable and will admit helpful generalization bounds. A similar method to the RMM was described by Haffner (2001), yet that approach started from a different overall motivation. In contrast, this article starts with a novel intuition, produces a novel algorithm and provides novel empirical and theoretical support. Another interesting contact point

is the second order perceptron framework (Cesa-Bianchi et al., 2005) which parallels some of the intuitions underlying the RMM. In an on-line setting, the second order perceptron maintains both a decision rule and a covariance matrix to whiten the data. The mistake bounds it inherits were shown to be better than those of the classical perceptron algorithm. Alternatively, one may consider distributions over classifier solutions which provide a different estimate than the maximum margin setting and have also shown empirical improvements over SVMs (Jaakkola et al., 1999; Herbrich et al., 2001). In recent papers, Dredze et al. (2008) and Crammer et al. (2009a) consider a distribution on the perceptron hyperplane. These distribution assumptions permit update rules that resemble whitening of the data, thus alleviating adversarial affine transformations and producing changes to the basic maximum margin formulation that are similar in spirit to those the RMM provides. In addition, recently, a new batch algorithm called the Gaussian margin machine (GMM) (Crammer et al., 2009b) has been proposed. The GMM maintains a Gaussian distribution over weight vectors for binary classification and seeks the least informative distribution that correctly classifies training data. While the GMM is well motivated from a PAC-Bayesian perspective, the optimization problem itself is expensive involving a log-determinant optimization.

Another alternative route for improving SVM performance includes the use of additional examples. For instance, unlabeled or test examples may be available in semi-supervised or transductive formulations of the SVM (Joachims, 1999; Belkin et al., 2005). Alternatively, additional data that does not belong to any of the classification classes of interest may be available as in the so-called Universum approach (Weston et al., 2006; Sinz et al., 2008). In principle, these methods also change the way margin is measured and the way regularization is applied to the learning problem. While additional data can be helpful in overcoming limitations for many classifiers, this article will be interested in only the simple binary classification setting. The argument is that, without any additional assumptions beyond the simple classification problem, maximizing margin in the absolute sense may be suboptimal and that maximizing relative margin is a promising alternative.

Further, large margin methods have been successfully applied to a variety of tasks such as parsing (Collins and Roark, 2004; Taskar et al., 2004), matrix factorization (Srebro et al., 2005), structured prediction (Tsochantaridis et al., 2005), etc.; in fact, the RMM approach could be readily adapted to such problems. For instance, RMM has been successfully extended to structured prediction problems (Shivaswamy and Jebara, 2009b).

The organization of this article is as follows. Motivation from various perspectives are given in Section 2. The relative margin machine formulation is detailed in Section 3 and several variants and implementations are proposed. Generalization bounds for the various function classes are studied in Section 4. Experimental results are provided in Section 5. Finally, conclusions are presented in Section 6. Some proofs and otherwise standard results are provided in the Appendix.

1.1 Notation

Throughout this article, boldface letters indicate vectors/matrices. For two vectors $\mathbf{u} \in \mathbb{R}^m$ and $\mathbf{v} \in \mathbb{R}^m$, $\mathbf{u} \leq \mathbf{v}$ indicates that $u_i \leq v_i$ for all i from 1 to m. $\mathbf{1}$, $\mathbf{0}$ and $\mathbf{I}$ denote the vectors of all ones, all zeros and the identity matrix respectively; $\mathbf{0}$ also denotes a matrix of all zeros in some contexts. The dimensionality of vectors and matrices should be clear from the context.

2. Motivation

This section provides three different (an intuitive, a probabilistic and an affine transformation based) motivations for maximizing the margin relative to the data spread.

2.1 Intuitive Motivation with a Two Dimensional Example

Consider the simple two dimensional data set in Figure 1 where the goal is to separate the two classes of points: triangles and squares. The figure depicts three scaled versions of the two dimensional problem to illustrate potential problems with the large margin solution.

In the topmost plot in the left column of Figure 1, two possible linear decision boundaries separating the classes are shown. The red (or dark shade) solution is the SVM estimate while the green (or light shade) solution is the proposed maximum relative margin alternative. Clearly, the SVM solution achieves the largest margin possible while separating both classes, yet is this necessarily the best solution?

Next, consider the same set of points after a scaling transformation in the second and the third row of Figure 1. Note that all these three problems correspond to the same discrimination problem up to a scaling factor. With progressive scaling, the SVM increasingly deviates from the maximum relative margin solution (green), clearly indicating that the SVM decision boundary is sensitive to affine transformations of the data. Essentially, the SVM produces a family of different solutions as a result of the scaling. This sensitivity to scaling and affine transformations is worrisome. If the SVM solution and its generalization accuracy vary with scaling, an adversary may exploit such scaling to ensure that the SVM performs poorly. Meanwhile, an algorithm producing the maximum relative margin (green) decision boundary could remain resilient to adversarial scaling.

In the previous example, a direction with a small spread in the data produced a good and affine-invariant discriminator which maximized relative margin. Unlike the maximum margin solution, this solution accounts for the spread of the data in various directions. This permits it to recover a solution which has a large margin relative to the spread in that direction. Such a solution would otherwise be overlooked by a maximum margin criterion. A small margin in a correspondingly smaller spread of the data might be better than a large absolute margin with correspondingly larger data spread. This particular weakness in large margin estimation has only received limited attention in previous work.

It is helpful to consider the generative model for the above motivating example. Therein, each class was generated from a one dimensional line distribution with the two classes on two parallel lines. In this case, the maximum relative margin (green) decision boundary should obtain zero test error even if it is estimated from a finite number of examples. However, for finite training data, the SVM solution will make errors and will do so increasingly as the data is scaled further. While it is possible to anticipate these problems and choose kernels or nonlinear mappings to correct for them in advance, this is not necessarily practical. The right mapping or kernel is never provided in advance in realistic settings. Instead, one has to estimate kernels and nonlinear mappings, a difficult endeavor which can often exacerbate the learning problem. Similarly, simple data preprocessing (affine whitening to make the data set zero-mean and unit-covariance or scaling to place the data into a zero-one box) can also fail, possibly because of estimation problems in recovering the correct transformation (this will be shown in real-world experiments).

The above arguments show that large margin on its own is not enough; it is also necessary to control the spread of the data after projection. Therefore, maximum margin should be traded-off or

balanced with the goal of simultaneously minimizing the spread of the projected data, for instance, by bounding the spread $|\mathbf{w}^\top \mathbf{x} + b|$. This will allow the linear classifier to recover large margin solutions not in the absolute sense but rather *relative to* the spread of the data in that projection direction.

In the case of a kernel such as the RBF kernel, the points are first mapped to a space so that all the input examples are unit vectors (i.e., $\langle \phi(\mathbf{x}), \phi(\mathbf{x}) \rangle = 1$). Note that the intuitive motivation proposed here still applies in such cases. No matter how they are mapped initially, a large margin solution still projects these points to the real line where the margin of separation is maximized. However, the spread of the projection can still vary significantly among the different projection directions. Given the above motivation, it is important to achieve a large margin relative to the spread of the projections even in such situations. Furthermore, experiments will support this intuition with dramatic improvements on many real problems and with a variety of kernels (including radial basis function and polynomial kernels).

2.2 Probabilistic Motivation

In this subsection, an informal motivation is provided to illustrate why maximizing relative margin may be helpful. Suppose $(\mathbf{x}_i, y_i)_{i=1}^n$ are drawn independently and identically (*iid*) from a distribution $\mathcal{D}$. A classifier $\mathbf{w} \in \mathbb{R}^m$ is sought which will produce low error on future unseen examples according to the decision rule $\hat{y} = \text{sign}(\mathbf{w}^\top \mathbf{x})$. An alternative criterion is that the classifier should produce a large value of η according to the following expression:

$$\Pr_{(\mathbf{x},y)\sim\mathcal{D}} \left[y\mathbf{w}^\top \mathbf{x} \geq 0 \right] \geq \eta,$$

where $\mathbf{w} \in \mathbb{R}^m$ is the classifier. One way to ensure the above constraint is by requiring that the following inequality hold:

$$\mathbf{E}_{\mathcal{D}}[y\mathbf{w}^\top \mathbf{x}] \geq \sqrt{\frac{\eta}{1-\eta}} \sqrt{\mathbf{V}_{\mathcal{D}}[y\mathbf{w}^\top \mathbf{x}]}. \tag{1}$$

A proof of the above claim for a general distribution can be found in Shivaswamy et al. (2006). In fact, Gaussian margin machines (Crammer et al., 2009b) start with a similar motivation but assume a Gaussian distribution on the classifier.

According to (1), achieving a low probability of error requires the projections to have a large mean and a small variance. The mean and variance for the true distribution $\mathcal{D}$ may be unavailable, however, the empirical counterparts of these quantities are available and known to be concentrated. The above inequality is used as a loose motivation. Instead of precisely finding low variance and high mean projections, this paper implements this intuition by trading off between large margin and small projections of the data while correctly classifying most of the examples with a hinge loss.

2.3 Motivation From an Affine Invariance Perspective

Another motivation for maximum relative margin can be made by reformulating the classification problem altogether. Instead of learning a classifier from data, consider learning an affine transformation on data such that an a priori *fixed* classifier performs well. The data will be mapped by an affine transformation such that it is separated with large margin while it also produces a small radius. Recall that maximum margin classification and SVMs are motivated by generalization bounds based on Vapnik-Chervonenkis complexity arguments. These generalization bounds depend on the

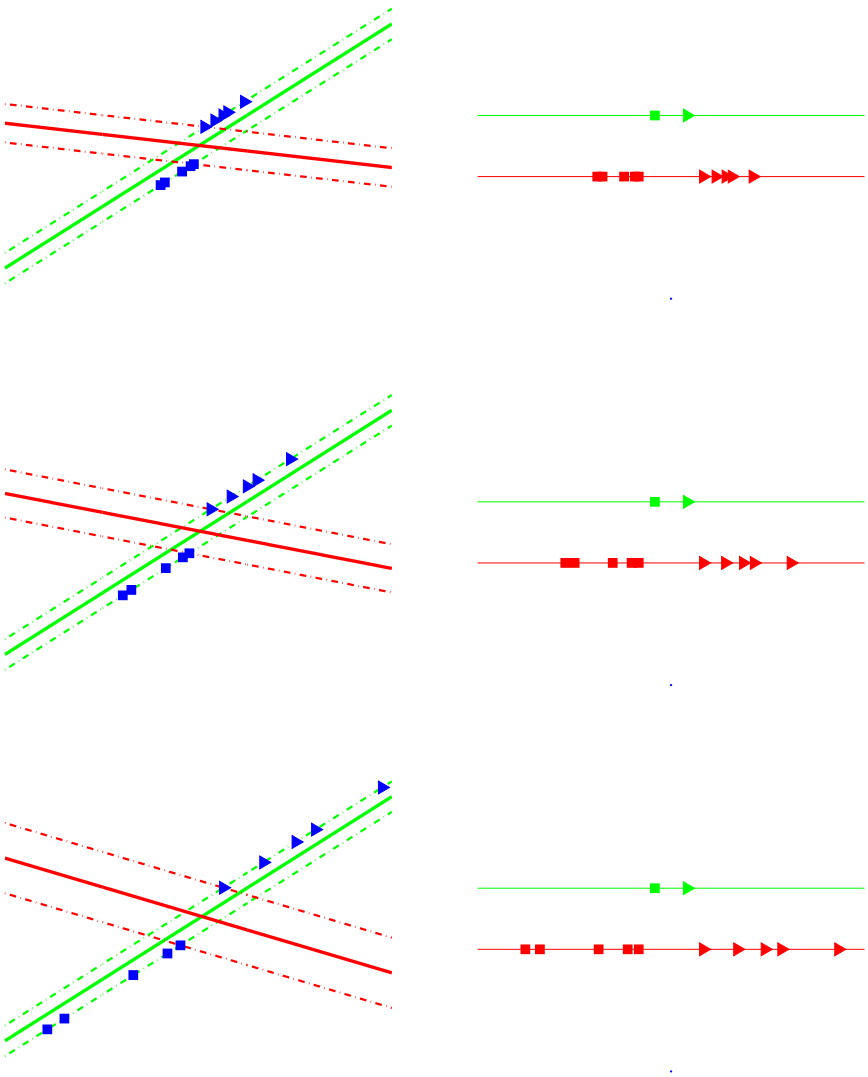

Figure 1: Left: As the data is scaled, the maximum margin SVM solution (red or dark shade) deviates from the maximum relative margin solution (green or light shade). Three different scaling scenarios are shown. Right: The projections of the examples (that is $\mathbf{w}^\top \mathbf{x} + b$) on the real line for the SVM solution (red or dark shade) and the proposed classifier (green or light shade) under each scaling scenario. These projections have been drawn on separated axes for clarity. The absolute margins for the maximum margin solution (red) are 1.24, 1.51 and 2.08 from top to bottom. For the maximum relative margin solution (green) the absolute margin is merely 0.71. However, the relative margin (the ratio of absolute margin to the spread of the projections) is 41%, 28%, and 21% for the maximum margin solution (red) and 100% for the relative margin solution (green). The scale of all axes is kept locked to permit direct visual comparison.

ratio of the margin to the radius of the data (Vapnik, 1995). Similarly, Rademacher generalization bounds (Shawe-Taylor and Cristianini, 2004) also consider the ratio of the trace of the kernel matrix to the margin. Here the radius of the data refers to an R such that $||\mathbf{x}|| \leq R$ for all $\mathbf{x}$ drawn from a distribution.

Instead of learning a classification rule, the optimization problem considered in this section will recover an affine transformation which achieves a large margin from a *fixed* decision rule while also achieving small radius. Assume the classification hyperplane is given a priori via the decision boundary $\mathbf{w}_0^\top \mathbf{x} + b_0 = 0$ with the two supporting margin hyperplanes $\mathbf{w}_0^\top \mathbf{x} + b_0 = \pm\rho$. Here, $\mathbf{w}_0 \in \mathbb{R}^m$ can be an arbitrary unit vector and b_0 is an arbitrary scalar. Consider the problem of mapping all the training points (by an affine transformation $\mathbf{x} \rightarrow \mathbf{A}\mathbf{x} + \mathbf{b}, \mathbf{A} \in \mathbb{R}^{m \times m}, \mathbf{b} \in \mathbb{R}^m$) so that the mapped points (i.e., $\mathbf{A}\mathbf{x}_i + \mathbf{b}$) satisfy the classification constraints $\mathbf{w}_0^\top \mathbf{x} + b_0 = \pm\rho$ while producing small radius, $\sqrt{R}$. The choice of $\mathbf{w}_0$ and b_0 is arbitrary since the affine transformation can completely compensate for it. For brevity, denote by $\tilde{\mathbf{A}} = [\mathbf{A}\ \mathbf{b}]$ and $\tilde{\mathbf{x}} = [\mathbf{x}^\top\ 1]^\top$. With this notation, the affine transformation learning problem is formalized by the following optimization:

$$\begin{aligned} \min_{\tilde{\mathbf{A}}, R, \rho} \quad & -\rho + ER & (2) \\ & y_i(\mathbf{w}_0^\top \tilde{\mathbf{A}} \tilde{\mathbf{x}}_i + b_0) \geq \rho, & \forall 1 \leq i \leq n \\ & \frac{1}{2}(\tilde{\mathbf{A}}\tilde{\mathbf{x}}_i)^\top (\tilde{\mathbf{A}}\tilde{\mathbf{x}}_i) \leq R & \forall 1 \leq i \leq n. \end{aligned}$$

The parameter E trades off between the radius of the affine transformed data and the margin[2] that will be obtained. The following Lemma shows that this affine transformation learning problem is basically equivalent to learning a large margin solution with a small spread.

Lemma 1 *The solution* $\tilde{\mathbf{A}}^*$ *to* (2) *is a rank one matrix*.

Proof Consider the Lagrangian of the above problem with Lagrange multipliers $\boldsymbol{\alpha}, \boldsymbol{\lambda}, \geq \mathbf{0}$:

$$\begin{aligned} \mathcal{L}(\tilde{\mathbf{A}}, \rho, R, \boldsymbol{\alpha}, \boldsymbol{\lambda}) = -\rho + ER - \sum_{i=1}^n \alpha_i (y_i(\mathbf{w}_0^\top \tilde{\mathbf{A}}\tilde{\mathbf{x}}_i + b_0) - \rho) \\ + \sum_{i=1}^n \lambda_i (\frac{1}{2}(\tilde{\mathbf{A}}\tilde{\mathbf{x}}_i)^\top (\tilde{\mathbf{A}}\tilde{\mathbf{x}}_i) - R). \end{aligned}$$

Differentiating the above Lagrangian with respect to $\mathbf{A}$ gives the following expression:

$$\frac{\partial \mathcal{L}(\tilde{\mathbf{A}}, \rho, R, \alpha, \lambda)}{\partial \tilde{\mathbf{A}}} = -\sum_{i=1}^n \alpha_i y_i \mathbf{w}_0 \tilde{\mathbf{x}}_i^\top + \tilde{\mathbf{A}} \sum_{i=1}^n \lambda_i \tilde{\mathbf{x}}_i \tilde{\mathbf{x}}_i^\top. \quad (3)$$

From (3), at optimum,

$$\tilde{\mathbf{A}}^* \sum_{i=1}^n \lambda_i \tilde{\mathbf{x}}_i \tilde{\mathbf{x}}_i^\top = -\sum_{i=1}^n \alpha_i y_i \mathbf{w}_0 \tilde{\mathbf{x}}_i^\top.$$

It is therefore clear that $\tilde{\mathbf{A}}^*$ can always be chosen to have rank one since the right hand side of the expression is just an outer product of two vectors. ■

2. For brevity, the so-called slack variables have been intentionally omitted since the proof holds in any case.

Lemma 1 gives further intuition on why one should limit the spread of the recovered classifier. Learning a transformation matrix $\tilde{\mathbf{A}}$ so as to maximize the margin while minimizing the radius given an a priori hyperplane $(\mathbf{w}_0, b_0)$ is no different from learning a classification hyperplane $(\mathbf{w}, b)$ with a large margin as well as a small spread. This is because the rank of the affine transformation $\tilde{\mathbf{A}}^*$ is one; thus, $\tilde{\mathbf{A}}^*$ merely maps all the points $\tilde{\mathbf{x}}_i$ onto a line achieving a certain margin ρ but also limiting the output or spread. This means that finding an affine transformation which achieves a large margin and small radius is equivalent to finding a $\mathbf{w}$ and b with a large margin and with projections constrained to remain close to the origin. Thus, the affine transformation learning problem complements the intuitive arguments in Section 2.1 and also suggests that the learning algorithm should bound the spread of the data.

3. From Absolute Margin to Relative Margin

This section will provide an upgrade path from the maximum margin classifier (or SVM) to a maximum relative margin formulation. Given independent identically distributed examples $(\mathbf{x}_i, y_i)_{i=1}^n$ where $\mathbf{x}_i \in \mathbb{R}^m$ and $y_i \in \{\pm 1\}$ are drawn from $\Pr(\mathbf{x}, y)$, the support vector machine primal formulation is as follows:

$$\begin{aligned} \min_{\mathbf{w},b,\xi} \ & \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{n}\xi_i \\ \text{s.t. } & y_i(\mathbf{w}^\top \mathbf{x}_i + b) \geq 1 - \xi_i, \ \ \xi_i \geq 0 \qquad\qquad \forall 1 \leq i \leq n. \end{aligned} \tag{4}$$

The above is an easily solvable quadratic program (QP) and maximizes the margin by minimizing $\|\mathbf{w}\|^2$. Since real data is seldom separable, slack variables (ξ_i) are used to relax the hard classification constraints. Thus, the above formulation maximizes the margin while minimizing an upper bound on the number of classification errors. The trade-off between the two quantities is controlled by the parameter C. Equivalently, the following dual of the formulation (4) can be solved:

$$\begin{aligned} \max_{\alpha} \ & \sum_{i=1}^{n}\alpha_i - \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n}\alpha_i\alpha_j y_i y_j \mathbf{x}_i^\top \mathbf{x}_j \\ \text{s.t. } & \sum_{i=1}^{n}\alpha_i y_i = 0 \\ & 0 \leq \alpha_i \leq C \qquad\qquad \forall 1 \leq i \leq n. \end{aligned} \tag{5}$$

Lemma 2 *The formulation in* (5) *is invariant to a rotation of the inputs*.

Proof Replace each $\mathbf{x}_i$ with $\mathbf{A}\mathbf{x}_i$ where $\mathbf{A}$ is a rotation matrix such that $\mathbf{A} \in \mathbb{R}^{m\times m}$ and $\mathbf{A}^\top\mathbf{A} = \mathbf{I}$. It is clear that the dual remains the same. ■

However, the dual is not the same if $\mathbf{A}$ is more general than a rotation matrix, for instance, if it is an arbitrary affine transformation.

The above classification framework can also handle non-linear classification readily by making use of Mercer kernels. A kernel function $k : \mathbb{R}^m \times \mathbb{R}^m \to \mathbb{R}$ replaces the dot products $\mathbf{x}_i^\top \mathbf{x}_j$ in (5). The kernel function k is such that $k(\mathbf{x}_i, \mathbf{x}_j) = \langle \phi(\mathbf{x}_i), \phi(\mathbf{x}_j) \rangle$, where $\phi : \mathbb{R}^m \to \mathcal{H}$ is a mapping to a Hilbert space. Thus, solving the SVM dual formulation (5) with a kernel function can give a

non-linear solution in the input space. In the rest of this article, $\mathbf{K} \in \mathbb{R}^{n \times n}$ denotes the Gram matrix whose individual entries are given by $K_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$. When applying Lemma 2 on a kernel defined feature space, the affine transformation is on $\phi(\mathbf{x}_i)$ and not on $\mathbf{x}_i$.

3.1 The Whitened SVM

One way of limiting sensitivity to affine transformations while recovering a large margin solution is to whiten the data with the covariance matrix prior to estimating the SVM solution. This may also reduce the bias towards regions of large data spread as discussed in Section 2. Denote by

$$\mathbf{\Sigma} = \frac{1}{n}\sum_{i=1}^{n} \mathbf{x}_i \mathbf{x}_i^\top - \frac{1}{n^2}\sum_{i=1}^{n} \mathbf{x}_i \sum_{j=1}^{n} \mathbf{x}_j^\top, \text{ and } \boldsymbol{\mu} = \frac{1}{n}\sum_{i=1}^{n} \mathbf{x}_i,$$

the sample covariance and sample mean, respectively. Now, consider the following formulation called $\mathbf{\Sigma}$-SVM:

$$\begin{aligned} \min_{\mathbf{w},b,\xi} \ & \frac{1-D}{2}\|\mathbf{w}\|^2 + \frac{D}{2}\|\mathbf{\Sigma}^{\frac{1}{2}}\mathbf{w}\|^2 + C\sum_{i=1}^{n}\xi_i \\ \text{s.t. } & y_i(\mathbf{w}^\top(\mathbf{x}_i - \boldsymbol{\mu}) + b) \geq 1 - \xi_i,\ \xi_i \geq 0 \qquad \forall 1 \leq i \leq n \end{aligned} \tag{6}$$

where $0 \leq D \leq 1$ is an additional parameter that trades off between the two regularization terms. When $D = 0$, (6) gives back the usual SVM primal (although on translated data). The dual of (6) can be shown to be:

$$\begin{aligned} \max_{\alpha} \ & \sum_{i=1}^{n}\alpha_i - \frac{1}{2}\sum_{i=1}^{n}\alpha_i y_i (\mathbf{x}_i - \boldsymbol{\mu})^\top ((1-D)\mathbf{I} + D\mathbf{\Sigma})^{-1} \sum_{j=1}^{n}\alpha_j y_j (\mathbf{x}_j - \boldsymbol{\mu}) \\ \text{s.t. } & \sum_{i=1}^{n}\alpha_i y_i = 0 \\ & 0 \leq \alpha_i \leq C \qquad \forall 1 \leq i \leq n. \end{aligned} \tag{7}$$

It is easy to see that the above formulation (7) is translation invariant and tends to an affine invariant solution when D tends to one. However, there are some problems with this formulation. First, the whitening process only considers second order statistics of the input data which may be inappropriate for non-Gaussian data sets. Furthermore, there are computational difficulties associated with whitening. Consider the following term:

$$(\mathbf{x}_i - \boldsymbol{\mu})^\top ((1-D)\mathbf{I} + D\mathbf{\Sigma})^{-1} (\mathbf{x}_j - \boldsymbol{\mu}).$$

When $0 < D < 1$, it can be shown, by using the Woodbury matrix inversion formula, that the above term can be kernelized as

$$\begin{aligned} \hat{k}(\mathbf{x}_i, \mathbf{x}_j) = & \frac{1}{1-D}\left(k(\mathbf{x}_i, \mathbf{x}_j) - \frac{\mathbf{K}_i^\top \mathbf{1}}{n} - \frac{\mathbf{K}_j^\top \mathbf{1}}{n} + \frac{\mathbf{1}^\top \mathbf{K} \mathbf{1}}{n^2} \right) \\ & - \frac{1}{1-D}\left(\left(\mathbf{K}_i - \frac{\mathbf{K}\mathbf{1}}{n} \right)^\top \left(\frac{\mathbf{I}}{n} - \frac{\mathbf{1}\mathbf{1}^\top}{n^2} \right) \left[\frac{1-D}{D}\mathbf{I} + \mathbf{K}\left(\frac{\mathbf{I}}{n} - \frac{\mathbf{1}\mathbf{1}^\top}{n^2} \right) \right]^{-1} \left(\mathbf{K}_j - \frac{\mathbf{K}\mathbf{1}}{n} \right) \right), \end{aligned}$$

where $\mathbf{K}_i$ is the i^{th} column of $\mathbf{K}$. This implies that the $\mathbf{\Sigma}$-SVM can be solved merely by solving (5) after replacing the kernel with $\hat{k}(\mathbf{x}_i, \mathbf{x}_j)$ as defined above. Note that the above formula involves a matrix inversion of size n, making the kernel computation alone $O(n^3)$. Even performing whitening as a preprocessing step in the feature space would involve this matrix inversion which is often computationally prohibitive.

3.2 Relative Margin Machines

While the above $\mathbf{\Sigma}$-SVM does address some of the issues of data spread, it made second order assumptions to recover $\mathbf{\Sigma}$ and involved a cumbersome matrix inversion. A more direct and efficient approach to control the spread is possible and will be proposed next.

The SVM will be modified such that the projections on the training examples remain bounded. A parameter will also be introduced that helps trade off between large margin and small spread of the projection of the data. This formulation will initially be solved by a quadratically constrained quadratic program (QCQP) in this section. The dual of this formulation will also be of interest and yield further geometric intuitions.

Consider the following formulation called the relative margin machine (RMM):

$$\begin{aligned} \min_{\mathbf{w},b} \ & \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{n}\xi_i & (8)\\ \text{s.t. } & y_i(\mathbf{w}^\top \mathbf{x}_i + b) \geq 1-\xi_i, \ \ \xi_i \geq 0 & \forall 1 \leq i \leq n \\ & \frac{1}{2}(\mathbf{w}^\top \mathbf{x}_i + b)^2 \leq \frac{B^2}{2} & \forall 1 \leq i \leq n. \end{aligned}$$

This formulation is similar to the SVM primal (4) except for the additional constraints $\frac{1}{2}(\mathbf{w}^\top \mathbf{x}_i + b)^2 \leq \frac{B^2}{2}$. The formulation has one extra parameter B in addition to the SVM parameter C. When B is large enough, the above QCQP gives the same solution as the SVM. Also note that only settings of $B > 1$ are meaningful since a value of B less than one would prevent any training examples from clearing the margin, that is, none of the examples could satisfy $y_i(\mathbf{w}^\top \mathbf{x}_i + b) \geq 1$ otherwise. Let $\mathbf{w}_C$ and b_C be the solutions obtained by solving the SVM (4) for a particular value of C. It is clear, then, that $B > \max_i |\mathbf{w}_C^\top \mathbf{x}_i + b_C|$, makes the constraint on the second line in the formulation (8) inactive for each i and the solution obtained is the same as the SVM estimate. This gives an upper threshold for the parameter B so that the RMM solution is not trivially identical to the SVM solution.

As B is decreased, the RMM solution increasingly differs from the SVM solution. Specifically, with a smaller B, the RMM still finds a large margin solution but with a smaller projection of the training examples. By trying different B values (within the aforementioned thresholds), different large relative margin solutions are explored. It is helpful to next consider the dual of the RMM problem.

The Lagrangian of (8) is given by:

$$\begin{aligned} \mathcal{L}(\mathbf{w}, b, \alpha, \lambda, \beta) = & \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{n}\xi_i - \sum_{i=1}^{n}\alpha_i\left(y_i(\mathbf{w}^\top \mathbf{x}_i + b) - 1 + \xi_i\right) - \sum_{i=1}^{n}\beta_i\xi_i \\ & + \sum_{i=1}^{n}\lambda_i\left(\frac{1}{2}(\mathbf{w}^\top \mathbf{x}_i + b)^2 - \frac{1}{2}B^2\right), \end{aligned}$$

where $\boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\lambda} \geq 0$ are the Lagrange multipliers corresponding to the constraints. Differentiating with respect to the primal variables and equating to zero produces:

$$
\begin{aligned}
(\mathbf{I} + \sum_{i=1}^{n} \lambda_i \mathbf{x}_i \mathbf{x}_i^\top)\mathbf{w} + b \sum_{i=1}^{n} \lambda_i \mathbf{x}_i &= \sum_{i=1}^{n} \alpha_i y_i \mathbf{x}_i, \\
\frac{1}{\boldsymbol{\lambda}^\top \mathbf{1}} (\sum_{i=1}^{n} \alpha_i y_i - \sum_{i=1}^{n} \lambda_i \mathbf{w}^\top \mathbf{x}_i) &= b, \\
\alpha_i + \beta_i &= C \qquad \forall 1 \leq i \leq n.
\end{aligned}
$$

Denoting by

$$
\boldsymbol{\Sigma}_{\boldsymbol{\lambda}} = \sum_{i=1}^{n} \lambda_i \mathbf{x}_i \mathbf{x}_i^\top - \frac{1}{\boldsymbol{\lambda}^\top \mathbf{1}} \sum_{i=1}^{n} \lambda_i \mathbf{x}_i \sum_{j=1}^{n} \lambda_j \mathbf{x}_j^\top, \text{ and } \boldsymbol{\mu}_{\boldsymbol{\lambda}} = \frac{1}{\boldsymbol{\lambda}^\top \mathbf{1}} \sum_{i=1}^{n} \lambda_i \mathbf{x}_i,
$$

the dual of (8) can be shown to be:

$$
\begin{aligned}
&\max_{\boldsymbol{\alpha}, \boldsymbol{\lambda}} \ \sum_{i=1}^{n} \alpha_i - \frac{1}{2} \sum_{i=1}^{n} \alpha_i y_i (\mathbf{x}_i - \boldsymbol{\mu}_{\boldsymbol{\lambda}})^\top (\mathbf{I} + \boldsymbol{\Sigma}_{\boldsymbol{\lambda}})^{-1} \sum_{j=1}^{n} \alpha_j y_j (\mathbf{x}_j - \boldsymbol{\mu}_{\boldsymbol{\lambda}}) + \frac{1}{2} B^2 \sum_{i=1}^{n} \lambda_i \qquad (9) \\
&\text{s.t. } 0 \leq \alpha_i \leq C \quad \lambda_i \geq 0 \qquad \forall 1 \leq i \leq n.
\end{aligned}
$$

Moreover, the optimal $\mathbf{w}$ can be shown to be:

$$
\mathbf{w} = (\mathbf{I} + \boldsymbol{\Sigma}_{\boldsymbol{\lambda}})^{-1} \sum_{i=1}^{n} \alpha_i y_i (\mathbf{x}_i - \boldsymbol{\mu}_{\boldsymbol{\lambda}}).
$$

Note that the above formulation is translation invariant since $\boldsymbol{\mu}_{\boldsymbol{\lambda}}$ is subtracted from each $\mathbf{x}_i$. $\boldsymbol{\Sigma}_{\boldsymbol{\lambda}}$ corresponds to a shape matrix (which is potentially low rank) determined by $\mathbf{x}_i$'s that have non-zero λ_i. From the Karush-Kuhn-Tucker (KKT) conditions of (8) it is clear that $\lambda_i (\frac{1}{2}(\mathbf{w}^\top \mathbf{x}_i + b)^2 - \frac{B^2}{2}) = 0$. Consequently $\lambda_i > 0$ implies $(\frac{1}{2}(\mathbf{w}^\top \mathbf{x}_i + b)^2 - \frac{B^2}{2}) = 0$. Notice the similarity in the two dual formulations in (7) and (9); both formulations look similar except for the choice of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ which transform the inputs. The RMM in (9) whitens data with the matrix $(\mathbf{I} + \boldsymbol{\Sigma}_{\boldsymbol{\lambda}})$ while simultaneously solving an SVM-like classification problem. While this is similar in spirit to the $\boldsymbol{\Sigma}$-SVM, the matrix $(\mathbf{I} + \boldsymbol{\Sigma}_{\boldsymbol{\lambda}})$ is being estimated directly to optimize the margin with a small data spread. The $\boldsymbol{\Sigma}$-SVM only whitens data as a preprocessing independently of the margin and the labels. The $\boldsymbol{\Sigma}$-SVM is equivalent to the RMM only in the rare situation when all $\lambda_i = t$ for some t which makes the $\boldsymbol{\mu}_{\boldsymbol{\lambda}}$ and $\boldsymbol{\Sigma}_{\boldsymbol{\lambda}}$ in the RMM and $\boldsymbol{\Sigma}$-SVM identical up to a scaling factor.

In practice, the above formulation will not be solved since it is computationally impractical. Solving (9) requires semi-definite programming (SDP) which prevents the method from scaling beyond a few hundred data points. Instead, an equivalent optimization will be used which gives the same solution but only requires quadratic programming. This is achieved by simply replacing the constraint $\frac{1}{2}(\mathbf{w}^\top \mathbf{x}_i + b)^2 \leq \frac{1}{2} B^2$ with the two equivalent linear constraints: $(\mathbf{w}^\top \mathbf{x}_i + b) \leq B$ and $-(\mathbf{w}^\top \mathbf{x}_i + b) \leq B$. With these linear constraints replacing the quadratic constraint, the problem is now merely a QP. In the primal, the QP has $4n$ constraints (including $\boldsymbol{\xi} \geq 0$) instead of the $2n$ constraints in the SVM. Thus, the RMM's quadratic program has the same order of complexity as the SVM. In the next section, an efficient implementation of the RMM problem is presented.

3.3 Fast Implementation

Once the quadratic constraints have been replaced with linear constraints, the RMM is merely a quadratic program which admits many fast implementation schemes. It is now possible to adapt previous fast SVM algorithms in the literature to the RMM. In this section, the *SVM*^{light} (Joachims, 1998) approach will be adapted to the following RMM optimization problem

$$\begin{aligned} \min_{\mathbf{w},b} \ & \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{n}\xi_i & (10)\\ \text{s.t. } & y_i(\mathbf{w}^\top \mathbf{x}_i + b) \geq 1-\xi_i, \ \ \xi_i \geq 0 & \forall 1 \leq i \leq n \\ & \mathbf{w}^\top \mathbf{x}_i + b \leq B & \forall 1 \leq i \leq n \\ & -\mathbf{w}^\top \mathbf{x}_i - b \leq B & \forall 1 \leq i \leq n. \end{aligned}$$

The dual of (10) can be shown to be the following:

$$\begin{aligned} \max_{\boldsymbol{\alpha},\boldsymbol{\lambda},\boldsymbol{\lambda}^*} \ & -\frac{1}{2}(\boldsymbol{\alpha}\bullet\mathbf{y}-\boldsymbol{\lambda}+\boldsymbol{\lambda}^*)^\top \mathbf{K}(\boldsymbol{\alpha}\bullet\mathbf{y}-\boldsymbol{\lambda}+\boldsymbol{\lambda}^*) + \boldsymbol{\alpha}^\top\mathbf{1} - B\boldsymbol{\lambda}^\top\mathbf{1} - B\boldsymbol{\lambda}^{*\top}\mathbf{1} & (11)\\ \text{s.t. } & \boldsymbol{\alpha}^\top\mathbf{y} - \boldsymbol{\lambda}^\top\mathbf{1} + \boldsymbol{\lambda}^{*\top}\mathbf{1} = 0 \\ & 0 \leq \boldsymbol{\alpha} \leq C\mathbf{1} \\ & \boldsymbol{\lambda}, \boldsymbol{\lambda}^* \geq \mathbf{0}, \end{aligned}$$

where the operator $\bullet$ denotes the element-wise product of two vectors.

The QP in (11) is solved in an iterative way. In each step, only a subset of the dual variables are optimized. For instance, in a particular iteration, take q, r and s ($\tilde{q}$, $\tilde{r}$ and $\tilde{s}$) to be indices of the free (fixed) variables in $\boldsymbol{\alpha}$, $\boldsymbol{\lambda}$ and $\boldsymbol{\lambda}^*$ respectively (ensuring that $q \cup \tilde{q} = \{1,2,\ldots n\}$ and $q \cap \tilde{q} = \emptyset$ and proceeding similarly for the other two indices). The optimization over the free variables in that step can then be expressed as:

$$\begin{aligned} \max_{\boldsymbol{\alpha}_q,\boldsymbol{\lambda}_r,\boldsymbol{\lambda}_s^*} \ & -\frac{1}{2}\begin{bmatrix} \boldsymbol{\alpha}_q\bullet\mathbf{y}_q \\ \boldsymbol{\lambda}_r \\ \boldsymbol{\lambda}_s^* \end{bmatrix}^\top \begin{bmatrix} \mathbf{K}_{qq} & -\mathbf{K}_{qr} & \mathbf{K}_{qs} \\ -\mathbf{K}_{rq} & \mathbf{K}_{rr} & -\mathbf{K}_{rs} \\ \mathbf{K}_{sq} & -\mathbf{K}_{sr} & \mathbf{K}_{ss} \end{bmatrix} \begin{bmatrix} \boldsymbol{\alpha}_q\bullet\mathbf{y}_q \\ \boldsymbol{\lambda}_r \\ \boldsymbol{\lambda}_s^* \end{bmatrix} & (12)\\ & -\frac{1}{2}\begin{bmatrix} \boldsymbol{\alpha}_q\bullet\mathbf{y}_q \\ \boldsymbol{\lambda}_r \\ \boldsymbol{\lambda}_s^* \end{bmatrix}^\top \begin{bmatrix} \mathbf{K}_{q\tilde{q}} & -\mathbf{K}_{q\tilde{r}} & \mathbf{K}_{q\tilde{s}} \\ -\mathbf{K}_{r\tilde{q}} & \mathbf{K}_{r\tilde{r}} & -\mathbf{K}_{r\tilde{s}} \\ \mathbf{K}_{s\tilde{q}} & -\mathbf{K}_{s\tilde{r}} & \mathbf{K}_{s\tilde{s}} \end{bmatrix} \begin{bmatrix} \boldsymbol{\alpha}_{\tilde{q}}\bullet\mathbf{y}_{\tilde{q}} \\ \boldsymbol{\lambda}_{\tilde{r}} \\ \boldsymbol{\lambda}_{\tilde{s}}^* \end{bmatrix} \\ & + \boldsymbol{\alpha}_q^\top\mathbf{1} - B\boldsymbol{\lambda}_r^\top\mathbf{1} - B\boldsymbol{\lambda}_s^{*\top}\mathbf{1} \\ \text{s.t. } & \boldsymbol{\alpha}_q^\top y_q - \boldsymbol{\lambda}_r^\top\mathbf{1} + \boldsymbol{\lambda}_s^{*\top}\mathbf{1} = -\boldsymbol{\alpha}_{\tilde{q}}^\top y_{\tilde{q}} + \boldsymbol{\lambda}_{\tilde{r}}^\top\mathbf{1} - \boldsymbol{\lambda}_{\tilde{s}}^{*\top}\mathbf{1}, \\ & \mathbf{0} \leq \boldsymbol{\alpha}_q \leq C\mathbf{1}, \\ & \boldsymbol{\lambda}_r, \ \boldsymbol{\lambda}_s^* \geq \mathbf{0}. \end{aligned}$$

While the first term in the above objective is quadratic in the free variables (over which it is optimized), the second term is merely linear. Essentially, the above is a working-set scheme which iteratively solves the QP over subsets of variables until some termination criteria are achieved. The following enumerates the termination criteria that will be used in this article. If $\boldsymbol{\alpha}, \boldsymbol{\lambda}, \boldsymbol{\lambda}^*$ and b are

the current solution (b is determined by the KKT conditions just as with SVMs), then:

$$\begin{aligned}
&\forall i \text{ s.t. } 0<\alpha_i<C: && b-\varepsilon \le y_i - (\sum_{j=1}^{n}(\alpha_j y_j - \lambda_j + \lambda_j^*)k(\mathbf{x}_i,\mathbf{x}_j)) \le b+\varepsilon \\
&\forall i \text{ s.t. } \alpha_i = 0: && y_i(\sum_{j=1}^{n}(\alpha_j y_j - \lambda_j + \lambda_j^*)k(\mathbf{x}_i,\mathbf{x}_j)+b) \ge 1-\varepsilon \\
&\forall i \text{ s.t. } \alpha_i = C: && y_i(\sum_{j=1}^{n}(\alpha_j y_j - \lambda_j + \lambda_j^*)k(\mathbf{x}_i,\mathbf{x}_j)+b) \le 1+\varepsilon \\
&\forall i \text{ s.t. } \lambda_i > 0: && B-\varepsilon \le (\sum_{j=1}^{n}(\alpha_j y_j - \lambda_j + \lambda_j^*)k(\mathbf{x}_i,\mathbf{x}_j)+b) \le B+\varepsilon \\
&\forall i \text{ s.t. } \lambda_i = 0: && (\sum_{j=1}^{n}(\alpha_j y_j - \lambda_j + \lambda_j^*)k(\mathbf{x}_i,\mathbf{x}_j)+b) \le B-\varepsilon \\
&\forall i \text{ s.t. } \lambda_i^* > 0: && B-\varepsilon \le -(\sum_{j=1}^{n}(\alpha_j y_j - \lambda_j + \lambda_j^*)k(\mathbf{x}_i,\mathbf{x}_j)+b) \le B+\varepsilon \\
&\forall i \text{ s.t. } \lambda_i^* = 0: && -(\sum_{j=1}^{n}(\alpha_j y_j - \lambda_j + \lambda_j^*)k(\mathbf{x}_i,\mathbf{x}_j)+b) \le B-\varepsilon.
\end{aligned}$$

In each step of the algorithm, a small sub-problem of the structure of (12) is solved. To select the free variables, these conditions are checked to find the worst violating variables both from the top of the violation list and from the bottom. The selected variables are optimized by solving (12) while keeping the other variables fixed. Since only a small QP is solved in each step, the cubic time scaling behavior is circumvented for improved efficiency. A few other book-keeping tricks have also been adapted from *SVM^{light}* to yield other minor improvements.

Denote by p the number of elements chosen in each step of the optimization (i.e., $p = |q| + |r| + |s|$). The QP in each step takes $O(p^3)$ and updating the prediction values to compute the KKT violations takes $O(nq)$ time. Sorting the output values to choose the most violated constraints takes $O(n\log(n))$ time. Thus, the total time taken in each iteration of the algorithm is $O(p^3 + n\log(n) + nq)$. Empirical running times are provided in Section 5 for a digit classification problem.

Many other fast SVM solvers could also be adapted to the RMM. Recent advances such as the cutting plane SVM algorithm (Joachims, 2006), Pegasos (Shalev-Shwartz et al., 2007) and so forth are also applicable and are deferred for future work.

3.4 Variants of the RMM

It is not always desirable to have a parameter in a formulation that would depend explicitly on the output from a previous computation as in (10). It is possible to overcome this issue via the following optimization problem:

$$\begin{aligned}
\min_{\mathbf{w},b,\xi,t\geq 1} \ & \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{n}\xi_i + Dt \qquad (13)\\
\text{s.t. } & y_i(\mathbf{w}^\top \mathbf{x}_i + b) \geq 1-\xi_i, \ \ \xi_i \geq 0 && \forall 1 \leq i \leq n,\\
& +(\mathbf{w}^\top \mathbf{x}_i + b) \leq t && \forall 1 \leq i \leq n,\\
& -(\mathbf{w}^\top \mathbf{x}_i + b) \leq t && \forall 1 \leq i \leq n.
\end{aligned}$$

Note that (13) has a parameter D instead of the parameter B in (10). The two optimization problems are equivalent in the sense that for every value of B in (10), it is possible to have a corresponding D such that both optimization problems give the same solution.

Further, in some situations, a hard constraint bounding the outputs as in (13) can be detrimental due to outliers. Thus, it might be required to have a relaxation on the bounding constraints as well. This motivates the following relaxed version of (13):

$$\begin{aligned}
\min_{\mathbf{w},b,\xi,t\geq 1} \ & \frac{1}{2}\|\mathbf{w}\|^2 + C\sum_{i=1}^{n}\xi_i + D(t + \frac{\nu}{n}\sum_{i=1}^{n}(\tau_i + \tau_i^*)) \qquad (14)\\
\text{s.t. } & y_i(\mathbf{w}^\top \mathbf{x}_i + b) \geq 1-\xi_i, \ \ \xi_i \geq 0 && \forall 1 \leq i \leq n,\\
& +(\mathbf{w}^\top \mathbf{x}_i + b) \leq t + \tau_i && \forall 1 \leq i \leq n,\\
& -(\mathbf{w}^\top \mathbf{x}_i + b) \leq t + \tau_i^* && \forall 1 \leq i \leq n.
\end{aligned}$$

In the above formulation, ν controls the fraction of outliers. It is not hard to derive the dual of the above to express it in kernelized form.

4. Risk Bounds

This section provides generalization guarantees for the classifiers of interest (the SVM, $\mathbf{\Sigma}$-SVM and RMM) which all produce decision[3] boundaries of the form $\mathbf{w}^\top \mathbf{x} = 0$ from a limited number of examples. In the SVM, the decision boundary is found by minimizing a combination of $\mathbf{w}^\top \mathbf{w}$ and an upper bound on the number of errors. This minimization is equivalent to choosing a function $g(\mathbf{x}) = \mathbf{w}^\top \mathbf{x}$ from a set of linear functions with bounded ℓ_2 norm. Therefore, with a suitable choice of E, the SVM solution chooses the function $g(\cdot)$ from the set $\{\mathbf{x} \rightarrow \mathbf{w}^\top \mathbf{x} | \frac{1}{2}\mathbf{w}^\top \mathbf{w} \leq E\}$.

By measuring the complexity of the function class being explored, it is possible to derive generalization guarantees and risk bounds. A natural measure of how complex a function class is the Rademacher complexity which has been fruitful in the derivation of generalization bounds. For SVMs, such results can be found in Shawe-Taylor and Cristianini (2004). This section continues in the same spirit and defines the function classes and their corresponding Rademacher complexities for slightly modified versions of the RMM as well as the $\mathbf{\Sigma}$-SVM. Furthermore, these will be used to provide generalization guarantees for both classifiers. The style and content of this section closely follows that of Shawe-Taylor and Cristianini (2004).

The function classes for the RMM and $\mathbf{\Sigma}$-SVM will depend on the data. Thus, these both entail so-called data-dependent regularization which is not quite as straightforward as the function classes explored by SVMs. In particular, the data involved in defining data-dependent function classes will

3. The bias term is suppressed in this section for brevity.

be treated differently and referred to as landmarks to distinguish them from the training data. Landmark data is used to define the function class while training data is used to select a specific function from the class. This distinction is important for the following theoretical derivations. However, in practical implementations, both the $\mathbf{\Sigma}$-SVM and the RMM may use the training data to both define the function class and to choose the best function within it. Thus, the distinction between landmark data and training data is merely a formality for deriving generalization bounds which require independent sets of examples for both stages. Ultimately, however, it will be possible to still provide generalization guarantees that are independent of the particular landmark examples. Details of this argument are provided in Section 4.6. For this section, however, it is assumed that, in parallel with the training data, a separate data set of landmarks is provided to define the function class for the RMM and the $\mathbf{\Sigma}$-SVM.

4.1 Function Class Definitions

Consider the training data set $(\mathbf{x}_i, y_i)_{i=1}^n$ with $\mathbf{x}_i \in \mathbb{R}^m$ and $y_i \in \{\pm 1\}$ which are drawn independently and identically distributed (*iid*) from an unknown underlying distribution $\mathbf{P}[(\mathbf{x}, y)]$ denoted as $\mathcal{D}$. The features of the training examples above are denoted by the set $\mathbf{S} = \{\mathbf{x}_1, \ldots, \mathbf{x}_n\}$.

Given a choice of the parameter E in the SVM (where E plays the role of the regularization parameter), the set of linear functions the SVM considers is:

Definition 3 $\mathcal{F}_E := \{\mathbf{x} \to \mathbf{w}^\top \mathbf{x} | \frac{1}{2}\mathbf{w}^\top \mathbf{w} \leq E\}$.

The RMM maximizes the margin while also limiting the spread of projections on the training data. It effectively considers the following function class:

Definition 4 $\mathcal{H}_{E,D}^S := \{\mathbf{x} \to \mathbf{w}^\top \mathbf{x} | \frac{\bar{D}}{2}\mathbf{w}^\top \mathbf{w} + \frac{D}{2}(\mathbf{w}^\top \mathbf{x}_i)^2 \leq E \ \forall 1 \leq i \leq n\}$.

Above, take $\bar{D} := 1 - D$ and $0 < D < 1$ trades off between large margin and small spread on the projections.[4] Since the above function class depends on the training examples, standard Rademacher analysis, which is straightforward for the SVM, is no longer applicable. Instead, define another function class for the RMM using a distinct set of landmark examples.

A set $\mathbf{V} = \{\mathbf{v}_1, \ldots, \mathbf{v}_{n_v}\}$ drawn *iid* from the same distribution $\mathbf{P}[\mathbf{x}]$, denoted as $\mathcal{D}_x$, is used as the landmark examples. With these landmark examples, the modified RMM function class can be written as:

Definition 5 $\mathcal{H}_{E,D}^V := \{\mathbf{x} \to \mathbf{w}^\top \mathbf{x} | \frac{\bar{D}}{2}\mathbf{w}^\top \mathbf{w} + \frac{D}{2}(\mathbf{w}^\top \mathbf{v}_i)^2 \leq E \ \forall 1 \leq i \leq n_v\}$.

Finally, function classes that are relevant for the $\mathbf{\Sigma}$-SVM are considered. These limit the average projection rather than the maximum projection. The data-dependent function class is defined as below:

Definition 6 $\mathcal{G}_{E,D}^S := \{\mathbf{x} \to \mathbf{w}^\top \mathbf{x} | \frac{\bar{D}}{2}\mathbf{w}^\top \mathbf{w} + \frac{D}{2n}\sum_{i=1}^n (\mathbf{w}^\top \mathbf{x}_i)^2 \leq E\}$.

A different landmark set $\mathbf{U} = \{\mathbf{u}_1, \ldots, \mathbf{u}_n\}$, again drawn *iid* from $\mathcal{D}_x$, is used in defining the corresponding landmark function class:

Definition 7 $\mathcal{G}_{B,D}^U := \{\mathbf{x} \to \mathbf{w}^\top \mathbf{x} | \frac{\bar{D}}{2}\mathbf{w}^\top \mathbf{w} + \frac{D}{2n}\sum_{i=1}^n (\mathbf{w}^\top \mathbf{u}_i)^2 \leq B\}$.

Note that the parameter E is fixed in $\mathcal{H}_{E,D}^V$ but n_v may be different from n. In the case of $\mathcal{G}_{B,D}^U$, the number of landmarks is the same (n) as the number of training examples but the parameter B is used instead of E. These distinctions are intentional and will be clarified in subsequent sections.

4. Zero and one are excluded from the range of D to avoid degenerate cases.

4.2 Rademacher Complexity

In this section the Rademacher complexity of the aforementioned function classes are quantified by bounding the empirical Rademacher complexity. Rademacher complexity measures the richness of a class of real-valued functions with respect to a probability distribution (Bartlett and Mendelson, 2002; Shawe-Taylor and Cristianini, 2004; Bousquet et al., 2004).

Definition 8 *For a sample* $\mathbf{S} = \{\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n\}$ *generated by a distribution on* $\mathbf{x}$ *and a real-valued function class* $\mathcal{F}$ *with domain* $\mathbf{x}$*, the empirical Rademacher complexity*[5] *of* $\mathcal{F}$ *is*

$$\hat{R}(\mathcal{F}) := \mathbf{E}_\sigma \left[\sup_{f \in \mathcal{F}} \left| \frac{2}{n} \sum_{i=1}^{n} \sigma_i f(\mathbf{x}_i) \right| \right]$$

where $\sigma = \{\sigma_1, \ldots \sigma_n\}$ *are independent random variables that take values* $+1$ *or* -1 *with equal probability. Moreover, the Rademacher complexity of* $\mathcal{F}$ *is:* $R(\mathcal{F}) := \mathbf{E}_\mathbf{S} \left[\hat{R}(\mathcal{F}) \right]$.

A stepping stone for quantifying the true Rademacher complexity is obtained by considering its empirical counterpart.

4.3 Empirical Rademacher Complexity

In this subsection, upper bounds on the empirical Rademacher complexities are derived for the previously defined function classes. These bounds provide insights on the regularization properties of the function classes for the sample $\mathbf{S} = \{\mathbf{x}_1, \mathbf{x}_2, \ldots \mathbf{x}_n\}$.

Theorem 9 $\hat{R}(\mathcal{F}_E) \leq T_0 := \frac{2\sqrt{2E}}{n} \sqrt{tr(\mathbf{K})}$, *where* $tr(\mathbf{K})$ *is the trace of the Gram matrix of the elements in* $\mathbf{S}$.

Proof

$$\begin{aligned}
\hat{R}(\mathcal{F}_E) &= \mathbf{E}_\sigma \left[\sup_{f \in \mathcal{F}_E} \left| \frac{2}{n} \sum_{i=1}^{n} \sigma_i f(\mathbf{x}_i) \right| \right] = \frac{2}{n} \mathbf{E}_\sigma \left[\max_{||\mathbf{w}|| \leq \sqrt{2E}} \left| \mathbf{w}^\top \sum_{i=1}^{n} \sigma_i \mathbf{x}_i \right| \right] \\
&\leq \frac{2\sqrt{2E}}{n} \mathbf{E}_\sigma \left[\left| \left| \sum_{i=1}^{n} \sigma_i \mathbf{x}_i \right| \right| \right] = \frac{2\sqrt{2E}}{n} \mathbf{E}_\sigma \left[\left(\sum_{i=1}^{n} \sigma_i \mathbf{x}_i^\top \sum_{j=1}^{n} \sigma_j \mathbf{x}_j \right)^{\frac{1}{2}} \right] \\
&\leq \frac{2\sqrt{2E}}{n} \left(\mathbf{E}_\sigma \left[\sum_{i,j=1}^{n} \sigma_i \sigma_j \mathbf{x}_i^\top \mathbf{x}_j \right] \right)^{\frac{1}{2}} = \frac{2\sqrt{2E}}{n} \sqrt{\mathrm{tr}(\mathbf{K})}.
\end{aligned}$$

The proof uses Jensen's inequality on the function $\sqrt{\cdot}$ and the fact that σ_i and σ_j are random variables taking values $+1$ or -1 with equal probability. Thus, when $i \neq j$, $\mathbf{E}_\sigma[\sigma_i \sigma_j \mathbf{x}_i^\top \mathbf{x}_i] = 0$ and, otherwise, $\mathbf{E}_\sigma[\sigma_i \sigma_i \mathbf{x}_i^\top \mathbf{x}_i] = \mathbf{E}_\sigma[\mathbf{x}_i^\top \mathbf{x}_i] = \mathbf{x}_i^\top \mathbf{x}_i$. The result follows from the linearity of the expectation operator. ■

5. The dependence of the empirical Rademacher complexity on n and $\mathbf{S}$ is suppressed by writing $\hat{R}(\mathcal{F})$ for brevity.

Roughly speaking, by keeping E small, the classifier's ability to fit arbitrary labels is reduced. This is one way to motivate a maximum margin strategy. Note that $\sqrt{\mathrm{tr}(\mathbf{K})}$ is a coarse measure of the spread of the data. However, most SVM formulations do not directly optimize this term. This motivates to next consider two new function classes.

Theorem 10 $\hat{R}(\mathcal{H}^V_{E,D}) \leq T_2(\mathbf{V},\mathbf{S})$, *where for any training set* $\mathcal{B}$ *and landmark*[6] *set* $\mathcal{A}$, $T_2(\mathcal{A},\mathcal{B}) := \min_{\lambda\geq 0}\ \frac{1}{|\mathcal{B}|}\sum_{\mathbf{x}\in\mathcal{B}}\mathbf{x}^\top\left(\bar{D}\mathbf{I}\sum_{\mathbf{u}\in\mathcal{A}}\lambda_{\mathbf{u}} + D\sum_{\mathbf{u}\in\mathcal{A}}\lambda_{\mathbf{u}}\mathbf{u}\mathbf{u}^\top\right)^{-1}\mathbf{x} + \frac{2E}{|\mathcal{B}|}\sum_{\mathbf{u}\in\mathcal{A}}\lambda_{\mathbf{u}}$.

Proof Start with the definition of the empirical Rademacher complexity:

$$\hat{R}(\mathcal{H}^V_{E,D}) = \mathbf{E}_\sigma\left[\sup_{\mathbf{w}:\frac{1}{2}(\bar{D}\mathbf{w}^\top\mathbf{w}+D(\mathbf{w}^\top\mathbf{v}_i)^2)\leq E}\left|\frac{2}{n}\sum_{i=1}^n\sigma_i(\mathbf{w}^\top\mathbf{x}_i)\right|\right].$$

Consider the supremum inside the expectation. Depending on the sign of the term inside $|\cdot|$, the above corresponds to either a maximization or a minimization. Without loss of generality, consider the case of maximization. When a minimization is involved, the value of the objective still remains the same. The supremum is recovered by solving the following optimization problem:

$$\max_{\mathbf{w}}\ \mathbf{w}^\top\sum_{i=1}^n\sigma_i\mathbf{x}_i\quad\text{s.t.}\qquad\frac{1}{2}(\bar{D}\mathbf{w}^\top\mathbf{w}+D(\mathbf{w}^\top\mathbf{v}_i)^2)\leq E\qquad\forall 1\leq i\leq n_v. \tag{15}$$

Using Lagrange multipliers $\lambda_1\geq 0,\ldots\lambda_{n_v}\geq 0$, the Lagrangian of (15) is: $\mathcal{L}(\mathbf{w},\lambda) = -\mathbf{w}^\top\sum_{i=1}^n\sigma_i\mathbf{x}_i + \sum_{i=1}^{n_v}\lambda_i\left(\frac{1}{2}\left(\bar{D}\mathbf{w}^\top\mathbf{w}+D(\mathbf{w}^\top\mathbf{v}_i)^2\right)-E\right)$. Differentiating this with respect to the primal variable $\mathbf{w}$ and equating it to zero gives: $\mathbf{w} = \boldsymbol{\Sigma}^{-1}_{\lambda,D}\sum_{i=1}^n\sigma_i\mathbf{x}_i$, where $\boldsymbol{\Sigma}_{\lambda,D} := \bar{D}\sum_{i=1}^{n_v}\lambda_i\mathbf{I} + D\sum_{i=1}^{n_v}\lambda_i\mathbf{v}_i\mathbf{v}_i^\top$. Substituting this $\mathbf{w}$ in $\mathcal{L}(\mathbf{w},\lambda)$ gives the dual of (15):

$$\min_{\lambda\geq 0}\ \frac{1}{2}\sum_{i=1}^n\sigma_i\mathbf{x}_i^\top\boldsymbol{\Sigma}^{-1}_{\lambda,D}\sum_{j=1}^n\sigma_j\mathbf{x}_j + E\sum_{i=1}^{n_v}\lambda_i.$$

This permits the following upper bound on the empirical Rademacher complexity since the primal and the dual objectives are equal at the optimum:

$$\begin{aligned}
\hat{R}(\mathcal{H}^V_{E,D}) &= \frac{2}{n}\mathbf{E}_\sigma\left[\min_{\lambda\geq 0}\ \frac{1}{2}\sum_{i=1}^n\sigma_i\mathbf{x}_i^\top\boldsymbol{\Sigma}^{-1}_{\lambda,D}\sum_{j=1}^n\sigma_j\mathbf{x}_j + E\sum_{i=1}^{n_v}\lambda_i\right]\\
&\leq \min_{\lambda\geq 0}\ \frac{2}{n}\mathbf{E}_\sigma\left[\frac{1}{2}\sum_{i=1}^n\sigma_i\mathbf{x}_i^\top\boldsymbol{\Sigma}^{-1}_{\lambda,D}\sum_{j=1}^n\sigma_j\mathbf{x}_j + E\sum_{i=1}^{n_v}\lambda_i\right]\\
&\leq \min_{\lambda\geq 0}\ \frac{1}{n}\sum_{i=1}^n\mathbf{x}_i^\top\boldsymbol{\Sigma}^{-1}_{\lambda,D}\mathbf{x}_i + \frac{2}{n}E\sum_{i=1}^{n_v}\lambda_i = T_2(\mathbf{V},\mathbf{S}).
\end{aligned}$$

On line one, the expectation is over the minimizers over λ; this is less than first taking the expectation and then minimizing over λ in line two. Then, simply recycle the arguments used in Theorem 9 to handle the expectation over σ. ■

6. $T_2(\mathcal{A},\mathcal{B})$ has been defined on generic sets. When an already defined set, such as $\mathbf{V}$ (with a known number n_v of elements) is an argument to T_2, λ will be subscripted with i or j.

Theorem 11 $\hat{R}(\mathcal{G}^U_{B,D}) \leq T_1(\mathbf{U},\mathbf{S})$, *where for any training set* $\mathcal{B}$ *and landmark set* $\mathcal{A}$, $T_1(\mathcal{A},\mathcal{B}) := \frac{2\sqrt{2B}}{|\mathcal{B}|}\left(\sum_{\mathbf{x}\in\mathcal{B}}\mathbf{x}^\top\left(\bar{D}\mathbf{I}+\frac{D}{|\mathcal{A}|}\sum_{\mathbf{u}\in\mathcal{A}}\mathbf{u}\mathbf{u}^\top\right)^{-1}\mathbf{x}\right)^{\frac{1}{2}}$.

Proof The proof is similar to the one for Theorem 10. ■

Thus, the empirical Rademacher complexities of the function classes of interest are bounded using the functions T_0, $T_1(\mathbf{U},\mathbf{S})$ and $T_2(\mathbf{V},\mathbf{S})$. For both $\mathcal{F}_E$ and $\mathcal{G}^U_{E,D}$, the empirical Rademacher complexity is bounded by a closed-form expression. For $\mathcal{H}^V_{E,D}$, optimizing over the Lagrange multipliers (i.e., the λ's) can further reduce the upper bound on empirical Rademacher complexity. This can yield advantages over both $\mathcal{F}_E$ and $\mathcal{G}^U_{E,D}$ in many situations and the overall shape of $\mathbf{\Sigma}_{\lambda,D}$ plays a key role in determining the overall bound; this will be discussed in Section 4.7. Note that the upper bound $T_2(\mathbf{V},\mathbf{S})$ is not a closed-form expression in general but can be evaluated in polynomial time using semi-definite programming by invoking Schur's complement lemma as shown by Boyd and Vandenberghe (2003).

4.4 From Empirical to True Rademacher Complexity

By definition 8, the empirical Rademacher complexity of a function class is dependent on the data sample, $\mathbf{S}$. In many cases, it is not possible to give exact expressions for the Rademacher complexity since the underlying distribution over the data is unknown. However, it is possible to give probabilistic upper bounds on the Rademacher complexity. Since the Rademacher complexity is the expectation of its empirical estimate over the data, by a straightforward application of McDiarmid's inequality (Appendix A), it is possible to show the following:

Lemma 12 *Fix* $\delta \in (0,1)$. *With probability at least* $1-\delta$ *over draws of the samples* $\mathbf{S}$ *the following holds for any function class* $\mathcal{F}$*:*

$$R(\mathcal{F}) \leq \hat{R}(\mathcal{F}) + 2\sqrt{\frac{\ln(2/\delta)}{2n}} \tag{16}$$

and,

$$\hat{R}(\mathcal{F}) \leq R(\mathcal{F}) + 2\sqrt{\frac{\ln(2/\delta)}{2n}}. \tag{17}$$

At this point, the motivation for introducing the landmark sets $\mathbf{U}$ and $\mathbf{V}$ becomes clear. The inequalities (16) and (17) do not hold when the function class $\mathcal{F}$ is dependent on the set $\mathbf{S}$. Specifically, using the sample $\mathbf{S}$ instead of the landmarks breaks the required *iid* assumptions in the derivation of (16) and (17). Thus neither Lemma 12, nor any of the results in Section 4.5 are sound for the function classes $\mathcal{G}^S_{B,D}$ and $\mathcal{H}^S_{E,D}$.

4.5 Generalization Bounds

This section presents generalization bounds for the three different function classes. The derivation largely follows the approach of Shawe-Taylor and Cristianini (2004) and, therefore, several details will be omitted in this article. Recall the theorem from Shawe-Taylor and Cristianini (2004) that leverages the empirical Rademacher complexity to provide a generalization bound.

Theorem 13 *Let $\mathcal{F}$ be a class of functions mapping Z to $[0,1]$; let $\{\mathbf{z}_1,\ldots,\mathbf{z}_n\}$ be drawn from the domain Z independently and identically distributed (*iid*) according to a probability distribution $\mathcal{D}$. Then, for any fixed $\delta \in (0,1)$, the following bound holds for any $f \in \mathcal{F}$ with probability at least $1-\delta$ over random draws of a set of examples of size n:*

$$\mathbf{E}_{\mathcal{D}}[f(\mathbf{z})] \leq \hat{\mathbf{E}}[f(\mathbf{z})] + \hat{R}(\mathcal{F}) + 3\sqrt{\frac{\ln(2/\delta)}{2n}}. \tag{18}$$

Similarly, under the same conditions as above, with probability at least $1-\delta$,

$$\hat{\mathbf{E}}[f(\mathbf{z})] \leq \mathbf{E}_{\mathcal{D}}[f(\mathbf{z})] + \hat{R}(\mathcal{F}) + 3\sqrt{\frac{\ln(2/\delta)}{2n}}. \tag{19}$$

Inequality (18) can be found in Shawe-Taylor and Cristianini (2004) and inequality (19) is obtained by a simple modification of the proof in Shawe-Taylor and Cristianini (2004). The following theorem, found in Shawe-Taylor and Cristianini (2004), gives a probabilistic upper bound on the future error rate based on the empirical error and the function class complexity.

Theorem 14 *Fix $\gamma > 0$. Let $\mathcal{F}$ be the class of functions from $\mathbb{R}^m \times \{\pm 1\} \to \mathbb{R}$ given by $f(\mathbf{x},y) = -yg(\mathbf{x})$. Let $\{(\mathbf{x}_1,y_1),\ldots,(\mathbf{x}_n,y_n)\}$ be drawn* iid *from a probability distribution $\mathcal{D}$. Then, with probability at least $1-\delta$ over the samples of size n, the following bound holds:*

$$\Pr_{\mathcal{D}}[y \neq \operatorname{sign}(g(\mathbf{x}))] \leq \frac{1}{n\gamma}\sum_{i=1}^{n}\xi_i + \frac{2}{\gamma}\hat{R}(\mathcal{F}) + 3\sqrt{\frac{\ln(2/\delta)}{2n}}, \tag{20}$$

where $\xi_i = \max(0, 1 - y_i g(\mathbf{x}_i))$ are the so-called slack variables.

The upper bounds that were derived in Section 4.2, namely: T_0, $T_1(\mathbf{U},\mathbf{S})$ and $T_2(\mathbf{V},\mathbf{S})$ can now be inserted into (20) to give generalization bounds for each class of interest. However, a caveat remains since a separate set of landmark data was necessary to provide such generalization bounds. The next section provides steps to eliminate the landmark data set from the bound.

4.6 Stating Bounds Independently of Landmarks

Note that the original function classes were defined using landmark examples. However, it is possible to eliminate these and state the generalization bounds independent of the landmark examples on function classes defined on the training data. Landmarks are eliminated from the generalization bounds in two steps. First, the empirical Rademacher complexities are shown to be concentrated and, second, the function classes defined using landmarks are shown to be supersets of the original function classes. One mild and standard assumption will be necessary, namely, that all examples from the distribution $\Pr([\mathbf{x}])$ have a norm bounded above by R with probability one.

4.6.1 CONCENTRATION OF EMPIRICAL RADEMACHER COMPLEXITY

Recall the upper bound $T_1(\mathbf{U},\mathbf{S})$ that was derived in Theorem 11. The following bounds show that these quantities are concentrated.

Theorem 15
i) With probability at least $1-\delta$*,*

$$T_1(\mathbf{U},\mathbf{S}) \leq \mathbf{E}_{\mathbf{U}}[T_1(\mathbf{U},\mathbf{S})] + O\left(\frac{1}{\sqrt{n}\sqrt{tr(\mathbf{K})}}\right).$$

ii) With probability at least $1-\delta$*,*

$$T_2(\mathbf{V},\mathbf{S}) \leq \mathbf{E}_{\mathbf{V}}[T_1(\mathbf{V},\mathbf{S})] + O\left(\frac{1}{\sqrt{n_v}\sqrt{tr(\mathbf{K})}}\right).$$

Proof McDiarmid's inequality from Appendix A can be applied to $T_1(\mathbf{U},\mathbf{S})$ since it is possible to compute Lipschitz constants $c_1, c_2, \ldots, c_n$ that correspond to each input of the function. These Lipschitz constants all share the same value c which is derived in Appendix B. With this Lipschitz constant, McDiarmid's inequality (32) is directly applicable and yields: $\Pr[T_1(\mathbf{U},\mathbf{S}) - \mathbf{E}_{\mathbf{U}}[T_1(\mathbf{U},\mathbf{S})] \geq \varepsilon] \leq \exp\left(-2\varepsilon^2/(nc^2)\right)$ Setting the upper bound on probability to δ, the following inequality holds with probability at least $1-\delta$:

$$T_1(\mathbf{U},\mathbf{S}) \leq \mathbf{E}_{\mathbf{U}}[T_1(\mathbf{U},\mathbf{S})] + \frac{2\sqrt{\ln(1/\delta)E}}{\bar{D}\sqrt{n}}\left(\sqrt{\sum_{i=1}^{n}\mathbf{x}_i^\top\mathbf{x}_i} - \sqrt{\sum_{i=1}^{n}\mathbf{x}_i^\top\mathbf{x}_i - \frac{DR^2\mu_{max}}{n\bar{D}+DR^2}}\right). \quad (21)$$

The second term above is:

$$\begin{aligned}
&\frac{2\sqrt{\ln(1/\delta)E}}{\bar{D}\sqrt{n}}\left(\sqrt{\sum_{i=1}^{n}\mathbf{x}_i^\top\mathbf{x}_i} - \sqrt{\sum_{i=1}^{n}\mathbf{x}_i^\top\mathbf{x}_i - \frac{DR^2\mu_{max}}{n\bar{D}+DR^2}}\right)\\
&= \frac{2\sqrt{\ln(1/\delta)E}}{\bar{D}\sqrt{n}}\frac{DR^2\mu_{max}/(n\bar{D}+DR^2)}{\sqrt{\sum_{i=1}^{n}\mathbf{x}_i^\top\mathbf{x}_i} + \sqrt{\sum_{i=1}^{n}\mathbf{x}_i^\top\mathbf{x}_i - \frac{DR^2\mu_{max}}{n\bar{D}+DR^2}}}\\
&\leq \frac{2\sqrt{\ln(1/\delta)E}}{\bar{D}\sqrt{n}}\frac{DR^2\mu_{max}/(n\bar{D}+DR^2)}{\sqrt{\sum_{i=1}^{n}\mathbf{x}_i^\top\mathbf{x}_i}}\\
&\leq \frac{2\sqrt{\ln(1/\delta)E}}{\bar{D}\sqrt{n}}\frac{DR^4 n}{(n\bar{D}+DR^2)\sqrt{\sum_{i=1}^{n}\mathbf{x}_i^\top\mathbf{x}_i}}\\
&\leq \frac{2\sqrt{\ln(1/\delta)E}}{\bar{D}\sqrt{n}}\frac{DR^4 n}{(n\bar{D})\sqrt{\sum_{i=1}^{n}\mathbf{x}_i^\top\mathbf{x}_i}} = O\left(\frac{1}{\sqrt{n}\sqrt{\mathrm{tr}(\mathbf{K})}}\right).
\end{aligned}$$

Here, $\mu_{max} \leq nR^2$ is the largest eigenvalue of the Gram matrix $\mathbf{K}$. The big oh notation refers to the asymptotic behavior in n. Note that $\mathrm{tr}(\mathbf{K})$ also grows with n. Thus, asymptotically, the above term is better than $O(1/\sqrt{n})$ which is the behavior of (20). So, from (21), with probability at least $1-\delta$: $T_1(\mathbf{U},\mathbf{S}) \leq \mathbf{E}_{\mathbf{U}}[T_1(\mathbf{U},\mathbf{S})] + O\left(1/\sqrt{n\,\mathrm{tr}(\mathbf{K})}\right)$.

The proof for the second claim is similar since $T_2(\mathbf{V},\mathbf{S})$ has the same Lipschitz constants (Appendix B). The only difference is in the number of elements in $\mathbf{V}$ which is reflected in the bound. ■

4.6.2 FUNCTION CLASS INCLUSION

At this point, using Equation 20 and Theorem 15, it is possible to state bounds that hold for functions in $\mathcal{G}^U_{B,D}$ and $\mathcal{H}^U_{B,D}$ but that are independent of $\mathbf{U}$ and $\mathbf{V}$ otherwise. However, the aim is to state uniform convergence bounds for functions in $\mathcal{G}^S_{B,D}$ and $\mathcal{H}^S_{B,D}$. This is achieved by showing the latter two sets are subsets of the former two with high probability. It is not enough to show that each element of one set is inside the other. Since uniform bounds are required for the initial function classes, one has to prove set-inclusion results.[7]

Theorem 16 *For $B = E + \varepsilon$ where $\varepsilon = O\left(\frac{1}{\sqrt{n}}\right)$, with probability at least $1 - 2\delta$ $\mathcal{G}^S_{E,D} \subseteq \mathcal{G}^U_{B,D}$.*

Proof First, note that $\mathcal{G}^S_{E,D} \subseteq \mathcal{F}_{E/\bar{D}}$. Thus, $\mathcal{F}_{E/\bar{D}}$ is a bigger class of functions than $\mathcal{G}^S_{E,D}$. Moreover, $\mathcal{F}_{E/\bar{D}}$ is not dependent on data. Now, consider $\frac{\bar{D}}{2}\mathbf{w}^\top\mathbf{w} + \frac{D}{2}(\mathbf{w}^\top\mathbf{x})^2$ where $\mathbf{w} \in \mathcal{F}_{E/\bar{D}}$. For $||\mathbf{x}|| \leq R^2$, the Cauchy-Schwarz inequality yields $\sup_{\mathbf{w}\in\mathcal{F}_{E/\bar{D}}} \frac{\bar{D}}{2}\mathbf{w}^\top\mathbf{w} + \frac{D}{2}(\mathbf{w}^\top\mathbf{x})^2 \leq \kappa$ where $\kappa = E/2 + DER^2/(2\bar{D})$. Now, define the function $h^{\mathbf{w}} : \mathcal{R}^m \to [0,1]$, as : $h^{\mathbf{w}}(\mathbf{x}) = (\frac{\bar{D}}{2}\mathbf{w}^\top\mathbf{w} + \frac{D}{2}(\mathbf{w}^\top\mathbf{x})^2)/\kappa$. Since the sets $\mathbf{S}$ and $\mathbf{U}$ are drawn *iid* from the distribution $\mathcal{D}_x$, it is now possible to apply (18) and (19) for any $\mathbf{w} \in \mathcal{F}_{E/\bar{D}}$. Applying (19) to $h^{\mathbf{w}}(\cdot)$ on $\mathbf{S}$, $\forall \mathbf{w} \in \mathcal{F}_{E/\bar{D}}$, with probability at least $1-\delta$, the following inequality holds:

$$\mathbf{E}_{\mathcal{D}_x}[h^{\mathbf{w}}(\mathbf{x})] \leq \frac{1}{n}\sum_{i=1}^{n} h^{\mathbf{w}}(\mathbf{x}_i) + 2\sqrt{\frac{2E}{n\bar{D}}}\sqrt{\frac{1}{n}\mathrm{tr}(\mathbf{K})} + 3\sqrt{\frac{\ln(2/\delta)}{2n}}, \tag{22}$$

where the value of $\hat{R}(\mathcal{F}_{E/\bar{D}})$ has been obtained from Theorem 9. The expectation is over the draw of $\mathbf{S}$. Similarly, applying (18) to $h^{\mathbf{w}}(\cdot)$ on $\mathbf{U}$, with probability at least $1-\delta$, $\forall \mathbf{w} \in \mathcal{F}_{E/\bar{D}}$, the following inequality holds:

$$\frac{1}{n}\sum_{i=1}^{n} h^{\mathbf{w}}(\mathbf{u}_i) \leq \mathbf{E}_{\mathcal{D}_x}[h^{\mathbf{w}}(\mathbf{u})] + 2\sqrt{\frac{2E}{n\bar{D}}}\sqrt{\frac{1}{n}\mathrm{tr}(\mathbf{K}_u)} + 3\sqrt{\frac{\ln(2/\delta)}{2n}} \tag{23}$$

where $\mathbf{K}_u$ is the Gram matrix of the landmark examples in $\mathbf{U}$. Using the fact that expectations in (22) and (23) are the same, $\mathrm{tr}(\mathbf{K}_u) \leq nR^2$, and the union bound, the following inequality holds $\forall \mathbf{w} \in \mathcal{F}_{E/\bar{D}}$ with probability at least $1-2\delta$:

$$\frac{1}{n}\sum_{i=1}^{n} h^{\mathbf{w}}(\mathbf{u}_i) \leq \frac{1}{n}\sum_{i=1}^{n} h^{\mathbf{w}}(\mathbf{x}_i) + 4R\sqrt{\frac{2E}{n\bar{D}}} + 6\sqrt{\frac{\ln(2/\delta)}{2n}}.$$

Using the definition of $h^{\mathbf{w}}(\cdot)$, with probability at least $1-2\delta$, $\forall \mathbf{w} \in \mathcal{F}_{E/\bar{D}}$,

$$\frac{\bar{D}}{2}\mathbf{w}^\top\mathbf{w} + \frac{D}{2n}\sum_{i=1}^{n}(\mathbf{w}^\top\mathbf{u}_i)^2 \leq \frac{\bar{D}}{2}\mathbf{w}^\top\mathbf{w} + \frac{D}{2n}\sum_{i=1}^{n}(\mathbf{w}^\top\mathbf{x}_i)^2 + O\left(\frac{1}{\sqrt{n}}\right).$$

Now, suppose, $\frac{\bar{D}}{2}\mathbf{w}^\top\mathbf{w} + \frac{D}{2n}\sum_{i=1}^{n}(\mathbf{w}^\top\mathbf{x}_i)^2 \leq E$, which describes the function class $\mathcal{G}^S_{E,D}$. If B is chosen to be $E+\varepsilon$ where $\varepsilon = O(\frac{1}{\sqrt{n}})$, then, $\forall \mathbf{w} \in \mathcal{F}_{E/\bar{D}}$, with probability at least $1-2\delta$, $\mathbf{w}^\top\mathbf{w} + \frac{D}{2n}\sum_{i=1}^{n}(\mathbf{w}^\top\mathbf{u}_i)^2 \leq B$. Since $\mathcal{F}_{E/\bar{D}}$ is a superset of $\mathcal{G}^S_{E,D}$, with probability at least $1-2\delta$, $\mathcal{G}^S_{E,D} \subseteq \mathcal{G}^U_{E,D}$. ■

7. The function classes will also be treated as sets of parameters $\mathbf{w}$ without introducing additional notation.

Theorem 17 *For $n_v = O(\sqrt{n})$, with probability at least $1-2\delta$, $\mathcal{H}^S_{E,D} \subseteq \mathcal{H}^V_{E,D}$.*

Proof First define the function, $g^{\mathbf{w}} : \mathbb{R}^m \to \mathbb{R}$, as $g^{\mathbf{w}}(\mathbf{v}) = \frac{\bar{D}}{2}\mathbf{w}^\top\mathbf{w} + \frac{D}{2}(\mathbf{w}^\top\mathbf{v})^2$. Define the indicator random variable $\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{v})>E]}$ which has a value 1 if $g^{\mathbf{w}}(\mathbf{v}) > E$ and a value 0 otherwise. By definition, $\forall \mathbf{w} \in \mathcal{H}^S_{E,D}$, $\forall \mathbf{x}_i \in \mathbf{S}$, $\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{x}_i)>E]} = 0$. Similarly, $\forall \mathbf{w} \in \mathcal{H}^V_{E,D}$, $\forall \mathbf{v}_i \in \mathbf{V}$, $\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{v}_i)>E]} = 0$. As before, consider a larger class of functions that is independent of $\mathbf{S}$, namely, $\mathcal{F}_{E/\bar{D}}$. For an *iid* sample $\mathbf{S}$ from the distribution $\mathcal{D}_x$, applying (18) to the indicator random variables $\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{x})>E]}$ on the set $\mathbf{S}$, with probability at least $1-\delta$,

$$\mathbf{E}_{\mathcal{D}_x}\left[\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{x})>E]}\right] \leq \frac{1}{n}\sum_{i=1}^{n}\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{x}_i)>E]} + 2\sqrt{\frac{2E}{n\bar{D}}}\sqrt{\frac{1}{n}\mathrm{tr}(\mathbf{K})} + 3\sqrt{\frac{\ln(2/\delta)}{2n}}. \tag{24}$$

Similarly, applying (19) on the set $\mathbf{V}$, with probability at least $1-\delta$,

$$\frac{1}{n_v}\sum_{i=1}^{n_v}\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{v}_i)>E]} \leq \mathbf{E}_{\mathcal{D}_x}\left[\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{x})>E]}\right] + 2\sqrt{\frac{2E}{n\bar{D}}}\sqrt{\frac{1}{n_v}\mathrm{tr}(\mathbf{K}_v)} + 3\sqrt{\frac{\ln(2/\delta)}{2n_v}}. \tag{25}$$

Performing a union bound on (24) and (25), using the fact that $\mathrm{tr}(\mathbf{K}) \leq nR^2$ and $\mathrm{tr}(\mathbf{K}_v) \leq n_v R^2$ with probability at least $1-2\delta$, $\forall \mathbf{w} \in \mathcal{F}_{E/\bar{D}}$,

$$\frac{1}{n_v}\sum_{i=1}^{n_v}\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{v}_i)>E]} - \frac{1}{n}\sum_{i=1}^{n}\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{x}_i)>E]} \leq 4R\sqrt{\frac{2E}{n\bar{D}}} + 3\sqrt{\frac{\ln(2/\delta)}{2}}\left(\frac{1}{\sqrt{n}} + \frac{1}{\sqrt{n_v}}\right). \tag{26}$$

Equating the right hand side of the above inequality to $\frac{1}{n_v}$, the above inequality can be written more succinctly as:

$$\begin{aligned}&\mathbf{P}\left[\exists \mathbf{w} \in \mathcal{F}_{E/\bar{D}} \frac{1}{n_v}\sum_{i=1}^{n_v}\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{v}_i)>E]} - \frac{1}{n}\sum_{i=1}^{n}\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{x}_i)>E]}) \geq \frac{1}{n_v}\right] \\ \leq & 2\exp\left(-\frac{2}{9}\left(\frac{1}{n_v} - 4R\sqrt{\frac{2E}{n\bar{D}}}\right)^2 / \left(\frac{1}{\sqrt{n}} + \frac{1}{\sqrt{n_v}}\right)^2\right)\end{aligned}$$

The left hand side of the equation above is the probability that there exists a $\mathbf{w}$ such that the difference in the fraction of the number of examples that fall outside $\frac{\bar{D}}{2}\mathbf{w}^\top\mathbf{w} + \frac{D}{2}(\mathbf{w}^\top\mathbf{x})^2 \leq E$ over the random draw of the sets $\mathbf{S}$ and $\mathbf{V}$ is at least $\frac{1}{n_v}$. Thus, it gives an upper bound on the probability that $\mathcal{H}^S_{E,D}$ is contained in $\mathcal{H}^V_{E,D}$. This is because, if there is a $\mathbf{w} \in \mathcal{H}^S_{E,D}$ that is not in $\mathcal{H}^V_{E,D}$, for such a $\mathbf{w}$, $\frac{1}{n_v}\sum_{i=1}^{n_v}\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{v}_i)>E]} > \frac{1}{n_v}$ and $\frac{1}{n}\sum_{i=1}^{n}\mathbf{I}_{[g^{\mathbf{w}}(\mathbf{x}_i)>E]} = 0$. Thus, equating the right hand side of (26) to $\frac{1}{n_v}$ and solving for n_v, the result follows. Both an exact value and the asymptotic behavior of n_v are derived in Appendix C. ■

It is straightforward to write the generalization bounds of Section 4.5 only in terms of $\mathbf{S}$, completely eliminating the landmark set $\mathbf{U}$ from the results in this section. However, the resulting bounds now have additional factors which further loosen them. In spite of this, in principle, using

a landmark set and compensating with McDiarmid's inequality can overcome the difficulties associated with a data-dependent hypothesis class and provide important generalization guarantees. In summary, the following overall bounds can now be provided for the function classes $\mathcal{F}_E$, $\mathcal{H}^S_{E,D}$ and $\mathcal{G}^S_{E,D}$. This result is obtained from a union bound of Theorem 14, Theorem 15, Theorem 16 and Theorem 17.

Theorem 18 *Fix $\gamma > 0$ and let $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)\}$ be drawn* iid *from a probability distribution $\mathcal{D}$ where $\|x\| \leq R$.*

i) For any g from the function class $\mathcal{F}_E$, the following holds with probability at least $1-\delta$,

$$\Pr_{\mathcal{D}}[y \neq \text{sign}(g(\mathbf{x}))] \leq \frac{1}{\gamma n}\sum_{i=1}^{n}\xi_i + 3\sqrt{\frac{\ln(2/\delta)}{2n}} + \frac{4\sqrt{2E}}{n\gamma}\sqrt{tr(\mathbf{K})}. \tag{27}$$

ii) For any g from the function class $\mathcal{H}^S_{E,D}$, the following inequality (a solution of a semi-definite program) holds for $n_v = O(\sqrt{n})$ with probability at least $1-\delta$,

$$\begin{aligned}\Pr_{\mathcal{D}}[y \neq \text{sign}(g(\mathbf{x}))] &\leq \frac{1}{n\gamma}\sum_{i=1}^{n}\xi_i + 3\sqrt{\frac{\ln(8/\delta)}{2n}} + O\left(\frac{1}{\sqrt{n_v}\sqrt{tr(\mathbf{K})}}\right)\\ &+ \frac{2}{\gamma}\mathbf{E}_{\mathbf{V}}\left(\min_{\lambda\geq 0}\frac{1}{n}\sum_{i=1}^{n}\mathbf{x}_i^\top\left(\bar{D}\sum_{j=1}^{n_v}\lambda_j\mathbf{I} + D\sum_{j=1}^{n_v}\lambda_j\mathbf{v}_j\mathbf{v}_j^\top\right)^{-1}\mathbf{x}_i + \frac{2E}{n}\sum_{i=1}^{n_v}\lambda_i\right).\end{aligned} \tag{28}$$

iii) Similarly, for any g from the function class $\mathcal{G}^S_{E,D}$, the following bound holds for $B = E + O(\frac{1}{\sqrt{n}})$ with probability at least $1-\delta$,

$$\begin{aligned}\Pr_{\mathcal{D}}[y \neq \text{sign}(g(\mathbf{x}))] &\leq \frac{1}{n\gamma}\sum_{i=1}^{n}\xi_i + 3\sqrt{\frac{\ln(8/\delta)}{2n}} + O\left(\frac{1}{\sqrt{n}\sqrt{tr(\mathbf{K})}}\right)\\ &+ \frac{4\sqrt{2B}}{n\gamma}\mathbf{E}_{\mathbf{U}}\left(\sum_{i=1}^{n}\mathbf{x}_i^\top\left(\bar{D}\mathbf{I} + \frac{D}{n}\sum_{j=1}^{n}\mathbf{u}_j\mathbf{u}_j^\top\right)^{-1}\mathbf{x}_i\right)^{\frac{1}{2}},\end{aligned} \tag{29}$$

where $\xi_i = \max(0, \gamma - y_i g(\mathbf{x}_i))$ are the so-called slack variables.

4.7 Discussion of the Bounds

Clearly, all the three bounds, namely (27), (28) and (29) in Theorem (18) have similar asymptotic behavior in n, so how do they differ? Simple, separable scenarios are considered in this section to examine these bounds (which will be referred to as the SVM bound, RMM bound and $\mathbf{\Sigma}$-SVM bound respectively). For the SVM bound, the quantity of interest is $4\frac{\sqrt{2E}}{n\gamma}\sqrt{\text{tr}(\mathbf{K})}$ and, for the $\mathbf{\Sigma}$-SVM bound, the quantity of interest is $\frac{4\sqrt{2E}}{n\hat{\gamma}}\sqrt{\left(\sum_{i=1}^{n}\mathbf{x}_i^\top\left(\bar{D}\mathbf{I} + \frac{D}{n}\sum_{j=1}^{n}\mathbf{u}_j\mathbf{u}_j^\top\right)^{-1}\mathbf{x}_i\right)}$. Similarly, for the RMM bound, the quantity of interest is:

$$\frac{2}{\hat{\gamma}}\left(\min_{\lambda\geq 0}\frac{1}{n}\sum_{i=1}^{n}\mathbf{x}_i^\top\left(\bar{D}\sum_{j=1}^{n_v}\lambda_j\mathbf{I} + D\sum_{j=1}^{n_v}\lambda_j\mathbf{v}_j\mathbf{v}_j^\top\right)^{-1}\mathbf{x}_i + \frac{2E}{n}\sum_{i=1}^{n_v}\lambda_i\right).$$

Here the expectations over $\mathbf{U}$ and $\mathbf{V}$ have been dropped for brevity; in fact, this is how these terms would have appeared without the concentration result (Theorem 15). Moreover, in the latter two cases, γ has been replaced by $\hat{\gamma}$ intentionally.

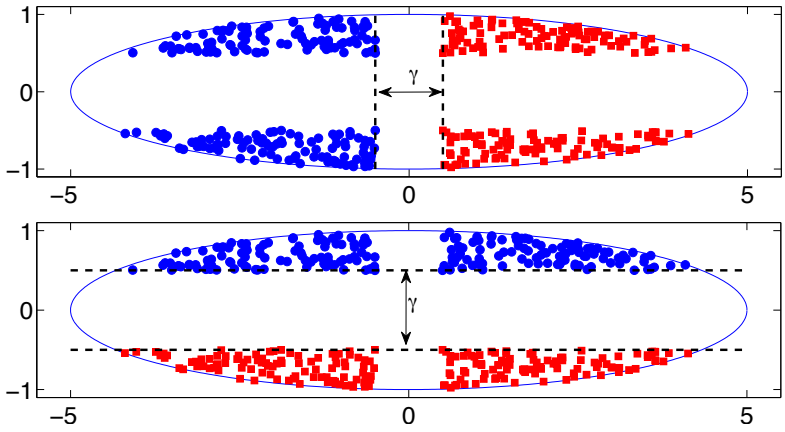

Figure 2: Two labellings of the same examples. Circles and squares denote the two classes (positive and negative). The top case is referred to as **toy example 1** and the bottom case is referred to as **toy example 2** in the sequel. The bound for the function class $\mathcal{F}_E$ does not distinguish between these two cases.

The differences between the three bounds will be illustrated with a toy example. In Figure 2, two different labellings of the same data set are shown. The two different labellings of the data produce completely different classification boundaries. However, in both the cases, the absolute margin of separation γ remains the same. A similar synthetic setting was explored in the context of second order perceptron bounds (Cesa-Bianchi et al., 2005).

The margin γ corresponding to the function class $\mathcal{F}$ is found by solving the following optimization problem:

$$\max_{\gamma,\mathbf{w}} \gamma, \quad \text{s.t. } y_i(\mathbf{w}^\top \mathbf{x}_i) \geq \gamma, \ \frac{1}{2}\mathbf{w}^\top \mathbf{w} \leq E.$$

This merely recovers the absolute margin γ which is shown in the figure. Similarly, for the function class $\mathcal{G}$, a margin $\hat{\gamma}$ is obtained by solving:

$$\max_{\gamma,\mathbf{w}} \gamma, \text{s.t. } y_i(\mathbf{w}^\top \mathbf{x}_i) \geq \gamma, \ \frac{1}{2}\mathbf{w}^\top \left(\bar{D}\mathbf{I} + \frac{D}{n} \sum_{j=1}^{n} \mathbf{x}_j \mathbf{x}_j^\top \right) \mathbf{w} \leq E.$$

Through a change of variable, $\mathbf{u} = \mathbf{\Sigma}^{\frac{1}{2}}\mathbf{w}$ where $\mathbf{\Sigma} = \left(\bar{D}\mathbf{I} + \frac{D}{n} \sum_{j=1}^{n} \mathbf{x}_j \mathbf{x}_j^\top \right)$ it is easy to see that the above optimization problem is equivalent to

$$\max_{\gamma,\mathbf{u}} \gamma, \ \text{s.t. } y_i \mathbf{u}^\top \mathbf{\Sigma}^{-\frac{1}{2}} \mathbf{x}_i \geq \gamma, \ \frac{1}{2}\mathbf{u}^\top \mathbf{u} \leq E.$$

	toy example 1	**toy example 2**
SVM bound	0.643	0.643
Σ-SVM bound, D=0	0.643	0.643
Σ-SVM bound, D=0.999	0.859	0.281
RMM bound, D=0	0.643	0.643
RMM bound, D=0.999	1.355	0.315

Table 1: The bound values for the two toy examples. The SVM bound does not distinguish between the two cases. By exploring D values, it is possible to obtain smaller bound values in both cases for Σ-SVM and RMM ($D = 0$ in **toy example 1** and D close to one in **toy example 2**).

Thus, when a linear function is selected from the function class $\mathcal{G}^S_{D,E}$, the margin $\hat{\gamma}$ is estimated from a whitened version of the data. Similarly, for function class $\mathcal{H}^S_{E,D}$, the margin is estimated from a whitened version of the data where the whitening matrix is modified by Lagrange multipliers.

Thus, in the finite sample case, the bounds differ as demonstrated in the above synthetic problem. The bound for the function class $\mathcal{G}^S_{E,D}$ explores a whitening of the data. Suppose $D = 0.999$, the result is a whitening which evens out the spread of the data in all directions. On this whitened data set, the margin $\hat{\gamma}$ appears much larger in **toy example 2** since it is large compared to the spread. This leads to an improvement in the Σ-SVM bound over the usual SVM bound. While such differences could be compensated for by appropriate a priori normalization of features, this is not always an easy preprocessing.

Similarly, the RMM bound also considers a whitening of the data however, it shapes the whitening matrix adaptively by estimating λ. This gives further flexibility and rescales data not only along principal eigen-directions but in any direction where the margin is large relative to the spread of the data. By exploring D values, margin can be measured relative to the spread of the data rather than in the absolute sense. Since Σ-SVM and RMM are strict generalizations of the SVM, through the use of a proper validation set, it is almost always possible to obtain improvements. The various bounds for the toy examples are shown in Table 1.

5. Experiments

In this section, a detailed investigation of the performance of the RMM[8] on several synthetic and real world data sets is provided.

5.1 Synthetic Data Set

First consider a simple two dimensional data set that illustrates the performance differences between the SVM and the RMM. Since this is a synthetic data set, the best classifier can be constructed and Bayes optimal results can be reported. Consider sampling data from two different Gaussian distributions[9] corresponding to two different classes. Samples are drawn from the two following

8. Code available at `http://www1.cs.columbia.edu/~pks2103/RMM`.
9. Due to such Gaussian assumptions, LDA or generative modeling would be appropriate contenders but are omitted to focus the discussion on margin-based approaches.

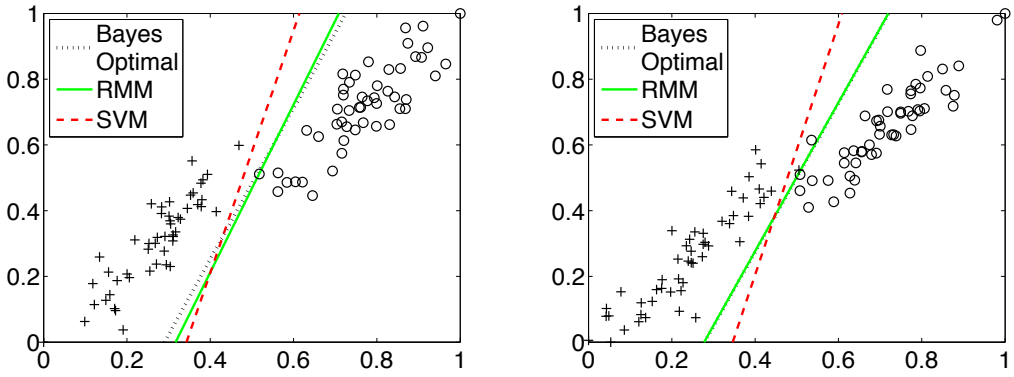

Figure 3: Two typical synthetic data sets (rescaled inside a 0-1 box) with corresponding SVM and RMM solutions are shown along with the Bayes optimal solution. The SVM (the RMM) solution uses the C (C and B) setting that minimized validation error. The RMM produces an estimate that is significantly closer to the Bayes optimal solution.

Gaussian distributions with equal prior probability:

$$\boldsymbol{\mu}_+ = \begin{bmatrix} 1 \\ 1 \end{bmatrix}, \ \boldsymbol{\mu}_- = \begin{bmatrix} 19 \\ 13 \end{bmatrix}, \ \boldsymbol{\Sigma} = \begin{bmatrix} 17 & 15 \\ 15 & 17 \end{bmatrix}.$$

The Gaussian distributions have different means, yet identical covariance. A total of 100,000 examples were drawn from each of the Gaussian distributions to create validation and test sets. Large validation and test sets were used to get accurate estimates of validation and test error.

Due to the synthetic nature of the problem, the Bayes optimal classifier is easily recovered (Duda et al., 2000) and is given by the following decision boundary

$$(\boldsymbol{\mu}_+ - \boldsymbol{\mu}_-)^\top \boldsymbol{\Sigma}^{-1}\mathbf{x} - 0.5(\boldsymbol{\mu}_+ - \boldsymbol{\mu}_-)^\top \boldsymbol{\Sigma}^{-1}(\boldsymbol{\mu}_+ + \boldsymbol{\mu}_-) = 0. \tag{30}$$

The above formula uses the true means and covariances of the Gaussian distributions (not empirical estimates). It is clear that the Bayes optimal solution is a linear decision boundary which is in the hypothesis class explored by both the RMM and the SVM. Note that the synthetic data was subsequently normalized to lie withing the zero-one box. This rescaling was taken into account while constructing the Bayes optimal classifier (30).

Various C values (and B values) were explored during SVM (RMM) training. The settings with minimum error rate on the validation set were used to compute test error rates. Furthermore, the test error rate for the Bayes optimal classifier was computed. Each experiment was repeated fifty times over random draws of train, test and validation sets. Figure 3 shows an example data set from this synthetic experiment along with the (cross-validated) SVM, RMM and Bayes optimal classification boundaries. The SVM decision boundary is biased to separate the data in a direction where it has large spread. The RMM is less biased by the spread and is visibly closer to the Bayes optimal solution.

Figure 4 shows the test error rates achieved for the SVM, the RMM and the Bayes optimal classifier. The SVM performs significantly worse than the RMM, particularly when training data

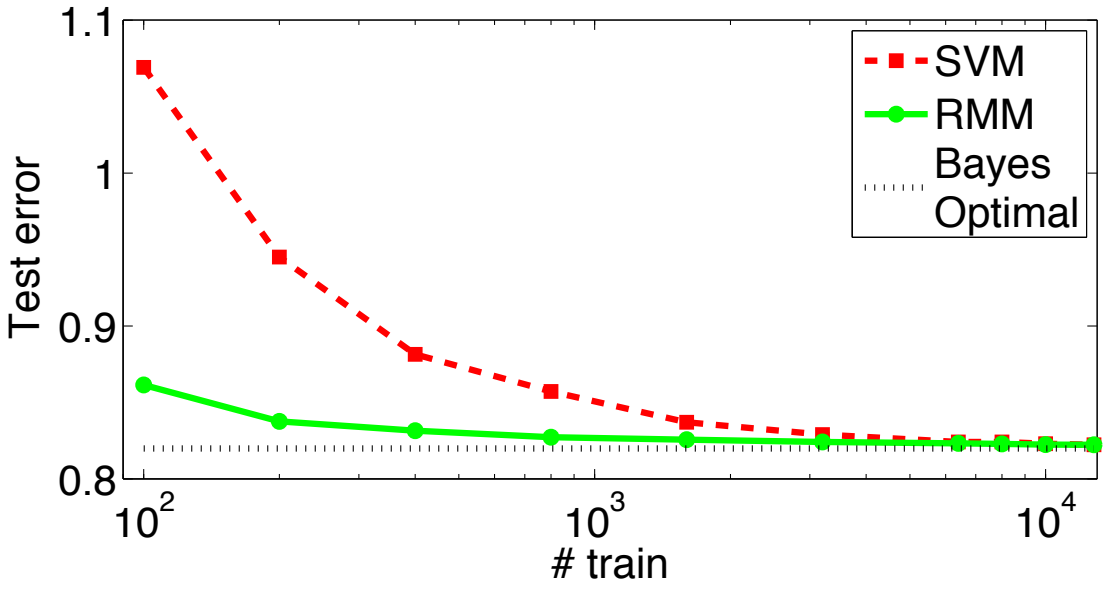

Figure 4: Percent test error rates for the SVM, RMM and Bayes optimal classifier as training data size is increased. The RMM has a statistically significant (at 5% level) advantage over the SVM until 6400 training examples. Subsequently, the advantage remains though with less statistical significance.

is scarce. The RMM maintains a statistically significant advantage over the SVM until the number of training examples grows beyond 6400. With larger training sample size n, regularization plays a smaller role in the future probability of error. This is clear, for instance, from the bound (27). The last term goes to zero at $O(1/\sqrt{n})$, the second term (which is the outcome of regularization) is $O(\sqrt{\mathrm{tr}(\mathbf{K})/n}\sqrt{1/n})$. Both have an $O(1/\sqrt{n})$ rate. However, the first term in the bound is the average slack variables divided by the margin which does not go to zero asymptotically with increasing n and eventually dominates the bound. Thus, the SVM and RMM have asymptotically similar performance but have significant differences in the small sample case.

The effect of scaling, which is a particular affine transformation, was explored next. To explore the effect of scaling in a controlled manner, first, the projection $\mathbf{w}$ recovered by the Bayes optimal classifier was obtained. An orthogonal vector $\mathbf{v}$ (such that $\mathbf{w}^\top \mathbf{v} = 0$) was then obtained. The examples (training, test and validation) were then projected onto the axes defined by $\mathbf{w}$ and $\mathbf{v}$. Each projection along $\mathbf{w}$ was preserved while the projection along $\mathbf{v}$ was scaled by a factor $s > 1$. This merely elongates the data further along directions orthogonal to $\mathbf{w}$ (i.e., along the Bayes optimal classification boundary). More concisely, given an example $\mathbf{x}$, the following scaling transformation was applied:

$$\begin{bmatrix} \mathbf{w} & \mathbf{v} \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & s \end{bmatrix} \begin{bmatrix} \mathbf{w} & \mathbf{v} \end{bmatrix}^{-1} \mathbf{x}. \tag{31}$$

Figure 5 shows the SVM and RMM test error rate across a range of scaling values s. Here, 100 examples were used to construct the training data. As s grows, the SVM further deviates from the

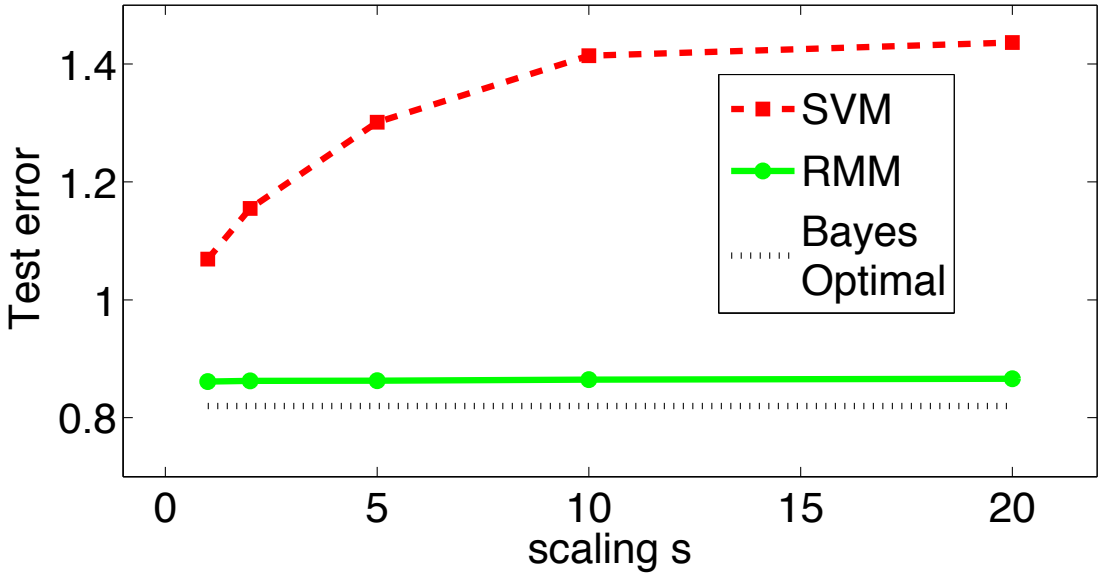

Figure 5: Percent test error rates for the SVM, RMM and Bayes optimal classifier as data is scaled according to (31). The RMM solution remains resilient to scaling while the SVM solution deteriorates significantly. The advantage of the RMM over the SVM is statistically significant (at the 1% level).

Bayes optimal classifier and attempts to separate the data along directions of large spread. Meanwhile, the RMM remains resilient to scaling and maintains a low error rate throughout.

To explore the effect of the B parameter, the average validation and test error rate were computed across many settings of C and B. The setting $C = 100$ was chosen since it obtained the minimum error rate on the validation set. The average test error rate of the RMM is shown in Figure 6 at $C = 100$ for multiple settings of the B parameter. Starting from the SVM solution on the right (i.e., large B) the error rate begins to fall until it attains a minimum and then starts to go increase. A similar behavior is seen in many real world data sets. Surprisingly, some data sets even exhibit monotonic reduction in test error as the value of B is decreased. The following section investigates such real world experiments in more detail.

5.2 Experiments on Digits

Experiments were carried out on three data sets of digits—optical digits from the UCI machine learning repository (Asuncion and Newman, 2007), USPS digits (LeCun et al., 1989) and MNIST digits (LeCun et al., 1998). These data sets vary considerably in terms of their number of features (64 in optical digits, 256 in USPS and 784 in MNIST) and their number of training examples (3823 in optical digits, 7291 in USPS and 60000 in MNIST). In all the multi-class experiments, the one versus one classification strategy was used. The one versus one strategy trains a classifier for every combination of two classes. The final prediction for an example is simply the class that is predicted most often. These results are directly comparable with various methods that have been applied on

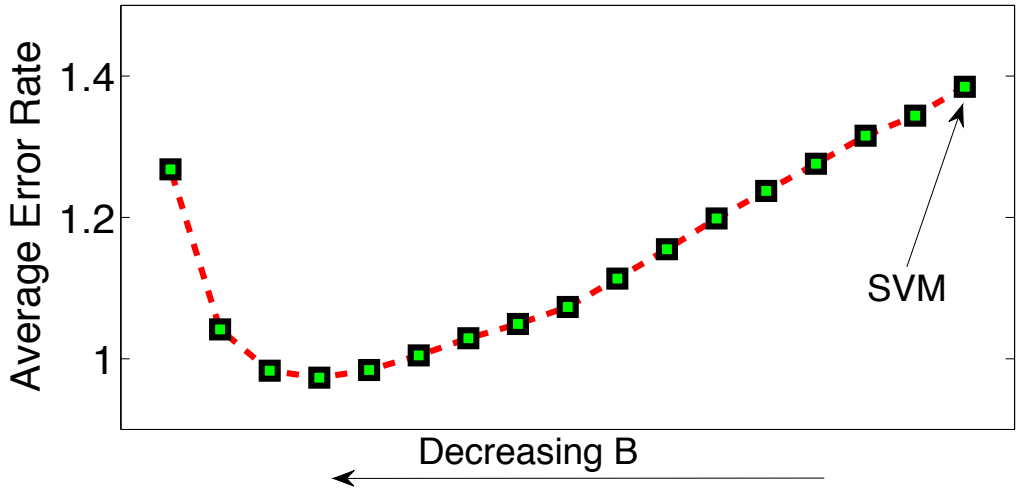

Figure 6: Behavior on the toy data set with $C = 100$. As the B value is decreased, the error rate decreases to a reasonably wide minimum before starting to increase.

Table 2: The number of misclassification in three different digit data sets. Various kernels are explored using the SVM, Σ-SVM, KLDA and RMM methods.

this data set. For a fair comparison, results from contender methods that use special preprocessing or domain knowledge are not explored in this article.[10]

10. Additional results are reported in `http://yann.lecun.com/exdb/mnist/`.

In all experiments, the digits were first normalized to have unit norm. This eliminates numerical problems that may arise in kernel functions such as the polynomial kernel $k(\mathbf{u},\mathbf{v}) = (1+\mathbf{u}^\top\mathbf{v})^d$. Classification results were then examined for various degrees of the polynomial kernel. In addition, kernel values were further normalized so that the trace of the training Gram matrix was equal to the number of training examples.

All parameters were tuned by splitting the training data according to an 80:20 ratio with the larger split being used for training and the smaller split for validation. The process was repeated five times over random splits to select hyper-parameters (C for the SVM, C and D for the $\mathbf{\Sigma}$-SVM and C and B for the RMM). A final classifier was trained for each of the 45 classification problems with the best parameters found by cross validation using all the training examples in its corresponding pair of classes.

For the MNIST digits experiment, the $\mathbf{\Sigma}$-SVM and kernel LDA (KLDA) methods were too computationally demanding due to their use of matrix inversion. To cater to these methods, a smaller experiment was conducted with 1000 examples per training. For the larger experiments, the $\mathbf{\Sigma}$-SVM and KLDA were excluded. The larger experiment on MNIST involved training on two thirds of the digits (i.e., training with an average of 8000 examples for each pair of digits) for each binary classification task. In both these experiments, the remaining training data was used as a validation set. The classifier that performed best on the validation set was used for testing.

After forming all 45 classifiers (corresponding to each pair of digits), testing was done on the standard separate test sets available for each of these three benchmark problems (1797 examples in the case of optical digits, 2007 examples in USPS and 10000 examples in MNIST). The final prediction for each test example was recovered based on the majority of predictions made by the 45 classifiers on the test example with ties broken uniformly at random.

It is important to note that, on the MNIST test set, an error rate improvement of 0.1% has been established as statistically significant (Bengio et al., 2007; Decoste and Schölkopf, 2002). This corresponds to 10 or more test examples being correctly classified by one method over an other.

Table 2 shows results on all three digits data sets for polynomial kernels under varying degrees as well as for RBF kernels. For each data set, the number of misclassified examples using the majority voting scheme above is reported. The $\mathbf{\Sigma}$-SVM typically outperforms the SVM yet the RMM outperforms both. Interestingly, with higher degree kernels, the $\mathbf{\Sigma}$-SVM seems to match the performance of the RMM while in most lower-degree kernels, the RMM outperforms both the SVM and the $\mathbf{\Sigma}$-SVM convincingly. Since the $\mathbf{\Sigma}$-SVM is prohibitive to run on large scale data sets due to the computationally cumbersome matrix inversion, the RMM was clearly the most competitive method in these experiments in terms of both accuracy and computational efficiency.

The best parameters found by validation in the previous experiments were used in a full-scale MNIST experiment which does not have a validation set of its own. All 45 pair-wise classifiers (both SVMs and RMMs) were trained with the previously cross-validated parameters using *all* the training examples for each class in MNIST for various kernels. The test results are reported in Table 2; the RMM advantages persist in this full-scale MNIST experiment.

5.3 Classifying MNIST Digits 3 vs 5

This section presents more detailed results on one particular binary classification problem in the MNIST digits data set: the classification of digit 3 versus 5. Therein, the RMM has a dramatically stronger performance than the SVM. The results reported in this section are with polynomial kernels

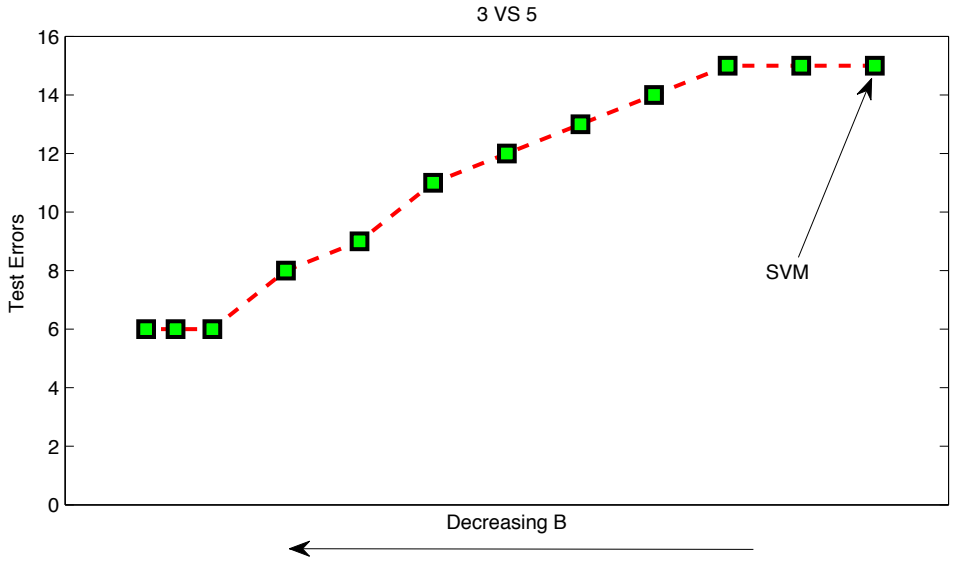

Figure 7: Performance on MNIST test set with digits 3 and 5. The number of errors decreases from 15 to 6 as B decreases from the right.

of degree 5. The parameter C was selected as mentioned above. With the selected C value, an SVM was first trained over the entire MNIST training set containing the digits 3 and 5. After noting the maximum absolute value of the output given on all the training examples, B value was reduced in steps. The number of test errors on the MNIST test set (3 versus 5) was noted. As the B value is reduced, the number of errors starts to diminish as shown in Figure 7. The number of errors produced by the SVM was 15. With the RMM, the number of errors dropped to 6 as the B value approached one. Clearly, as B decreases, the absolute margin is decreased however the test error rate drops drastically. This empirically suggests that maximizing the relative margin can have a beneficial effect on the performance of a classifier. Admittedly, this is only one example and is provided only for illustrative purposes. However, similar behavior was observed in most of the binary digit classification problems though in some cases the error rate did not go down significantly with decreasing B values. The generalization behavior on all 45 individual problems is explored in more detail in Section 5.4.

5.4 All 45 Binary MNIST Problems

This section explores RMM performance on the 45 pairwise digit classification problems in isolation. In these experiments, both C and B values were fixed using validation as in previous sections. A total of 45 binary classifiers were constructed using all MNIST training digits. The resulting error rates are shown in Figure 8. On most problems, the RMM obtains a significantly lower error rate than the SVM and, at times obtains half the error rate.

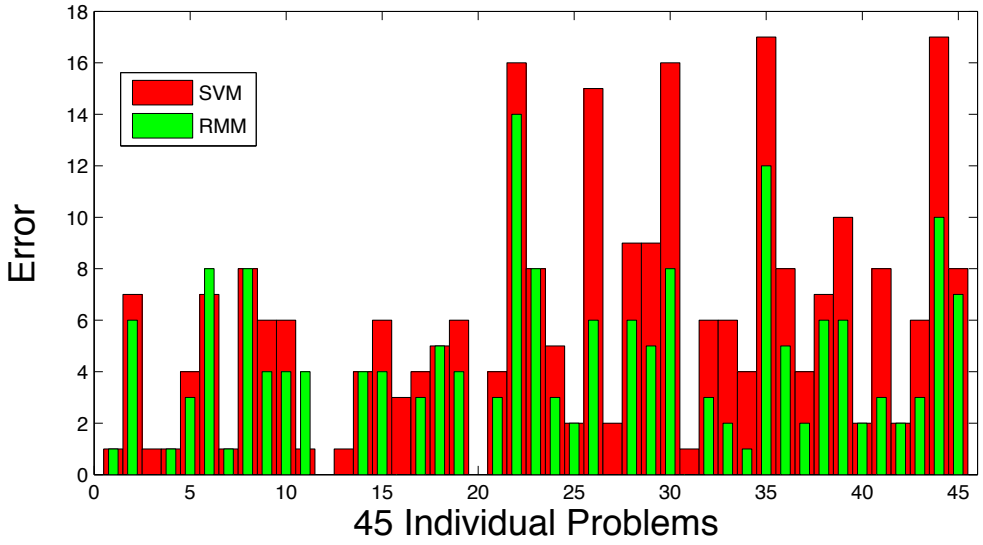

Figure 8: Total test errors on all 45 MNIST classification problems. Various classifiers were trained on the entire MNIST training data set and evaluated on a standardized separate test set.

Method	RMM	$\mathfrak{U}$-SVM		
# Universum	-	1000	3000	all
Error rate	1.081	1.059	1.037	1.020
Error Std Dev	0.138	0.142	0.149	0.159
p-value		0.402	0.148	0.031

Table 3: Percentage error rates for the RMM and the $\mathfrak{U}$-SVM. The rate for the SVM was 1.274 with a standard deviation of 0.179; this is significantly larger than all other results in the table (with a p-value of 0.000). The final row reports the p-value of a paired t-test between the RMM error rate and the $\mathfrak{U}$-SVM error rate (corresponding to the Universum size being considered in that column).

5.4.1 A COMPARISON WITH THE UNIVERSUM METHOD

A new framework known as the Universum (Weston et al., 2006; Sinz et al., 2008) was recently introduced which maximizes the margin while keeping classifier outputs low on an additional collection of non-examples that do not belong to either class of interest. These additional examples are known as Universum examples. Like landmarks, these are examples where a classifier's scalar predictions are forced to remain small. However, these Universum examples are obtained from any other distribution other than the one generating the training data. In the RMM, classification outputs on training examples are bounded; in the Universum, classification outputs on Universum examples are bounded (albeit with a different loss). The following experiments compare the Universum based framework with the RMM.

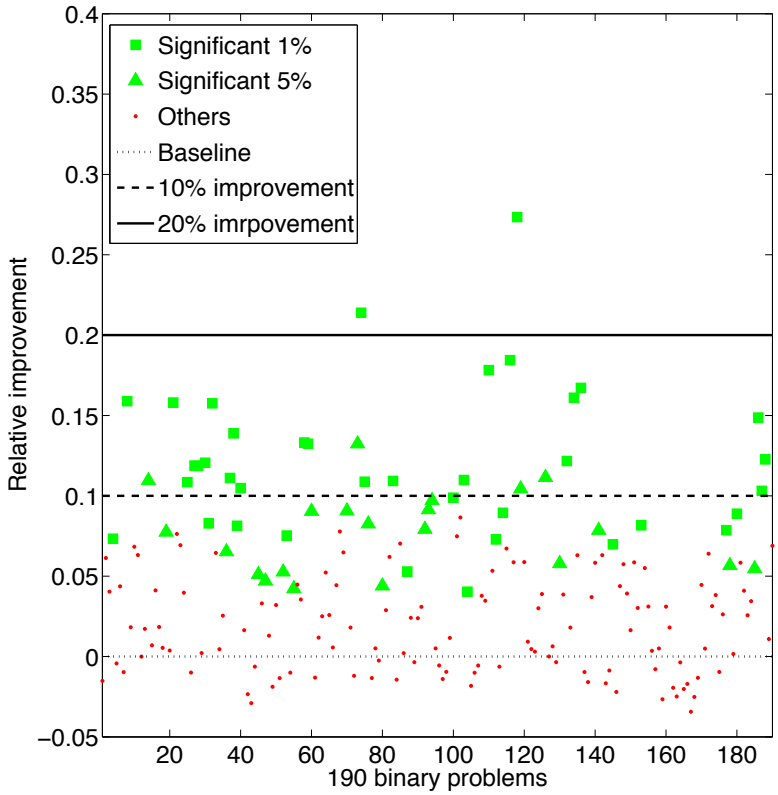

Figure 9: Percentage improvement of the RMM over the SVM on all 190 binary problems. Significance tests were performed using a paired t-test at the indicated levels of significance. On most problems, the RMM shows significant improvement over SVM.

An MNIST experiment was explored for classifying digits 5 vs 8 using 1000 labeled training examples under the RBF kernel. This setup is identical to the experimental conditions described in Weston et al. (2006). Examples of the digit 3 served as Universum examples since these were reported to be the *best* performing Universum examples in previous work (Weston et al., 2006). The experiments used the standard implementation of the Universum provided by the authors Weston et al. (2006) under the default parameter settings (for variables such as ε). The Universum was compared with the RMM which had access to the same 1000 training examples. Furthermore, 3500 examples were used as a test set and another 3500 examples as a validation set to perform model selection. All parameter settings for the RMM and the Universum SVM (or $\mathfrak{U}$-SVM) as well as the variance parameter of the RBF kernel were explored over a wide range of values. The parameter settings that achieved the smallest error on a validation set were then used to evaluate performance on the test set (and vice-versa). This entire experiment was repeated ten-fold over different random draws of the various sets. The average test error rates were compiled for both algorithms.

While the RMM only had access to the 1000 training examples, the $\mathfrak{U}$-SVM was also given a Universum of images of the digit 3. The Universum spanned three different sizes—1000, 3000 and 6131 examples (i.e., all available images of the digit 3 in the MNIST training set). The results are reported in Table 3. First, observe that both the RMM and the $\mathfrak{U}$-SVM improved the baseline SVM performance significantly (as measured by a paired t-test). With 1000 and 3000 Universum examples, even though the error rate of the $\mathfrak{U}$-SVM was slightly lower, a paired t-test revealed that it did not achieve statistically significant improvement over the RMM. Statistically significant advantages for the $\mathfrak{U}$-SVM only emerged when *all* the available images of the digit 3 were used in the Universum.

Note that there is a slight discrepancy between the errors reported here and those in Weston et al. (2006) even though both methods used the digit 3 to generate Universum examples. This may be because the previous authors (Weston et al., 2006) reported the *best test error* on 1865 examples. In this article, a more conservative approach is taken where a good model is first selected using the validation set and then errors are reported on an unseen test set without further tuning. Clearly, picking the minimum error rate on a test set will give more optimistic results but tuning to the test set can be potentially misleading. This makes it difficult to directly compare test error rates with those reported in the previous paper. While the error rate (using all digits 3 as the Universum examples) in our experiments varied from 0.74% to 1.35%, the authors in Weston et al. (2006) reported an error rate of 0.62%.

With 1000 training examples, the RMM (as in Equation (8)) has 1000 classification constraints and 1000 bounding constraints. With 1000 Universum examples, the $\mathfrak{U}$-SVM also has 1000 bounding constraints in addition to the classification constraints. It is interesting to note that the RMM, with no extra data, is not significantly worse than a $\mathfrak{U}$-SVM endowed with an additional 1000 or 3000 *best-possible* Universum examples.

The authors of Weston et al. (2006) observed that Universum examples help most when they are correlated with the training examples. This, coupled with the results in Table 3 and the fact that training examples are correlated most with themselves (or with examples from the same distribution as the training examples), raises the following question: How much of the performance gain with the $\mathfrak{U}$-SVM is due to the extra examples and how much of it is due to its implicit control of the spread (as with an RMM)? This is left as an open question in this article and as motivation for further theoretical work.

5.5 Text Classification

In this section, results are reported on the 20 Newsgroups [11] data set. This data set has posts from 20 different Usenet newsgroups. Each post was represented by a vector which counts the number of words that occurred in the document. In the text classification literature, this is commonly known as the bag of words representation. Each feature vector was divided by the total number of words in the document to normalize it.

All 190 binary pairwise classification problems were considered in this experiment. For each problem, 500 examples were used for training. The remaining examples were divided into a validation and test set of the same size. Both SVMs and RMMs were trained for various values of their parameters. After finding the parameter settings that achieved the lowest error on a validation set,

11. This data set is available online at `http://people.csail.mit.edu/jrennie/20Newsgroups/`.

the test error was evaluated (and vice-versa). This experiment was repeated ten times for random draws of the train, validation and test sets.

Figure 9 summarizes the results. For each binary classification problem, a paired t-test was performed and p-values were obtained. As can be seen from the plot, the RMM outperforms the SVM significantly in almost 30% of the problems. This experiment once again demonstrates that an absolute margin does not always result in a small test error.

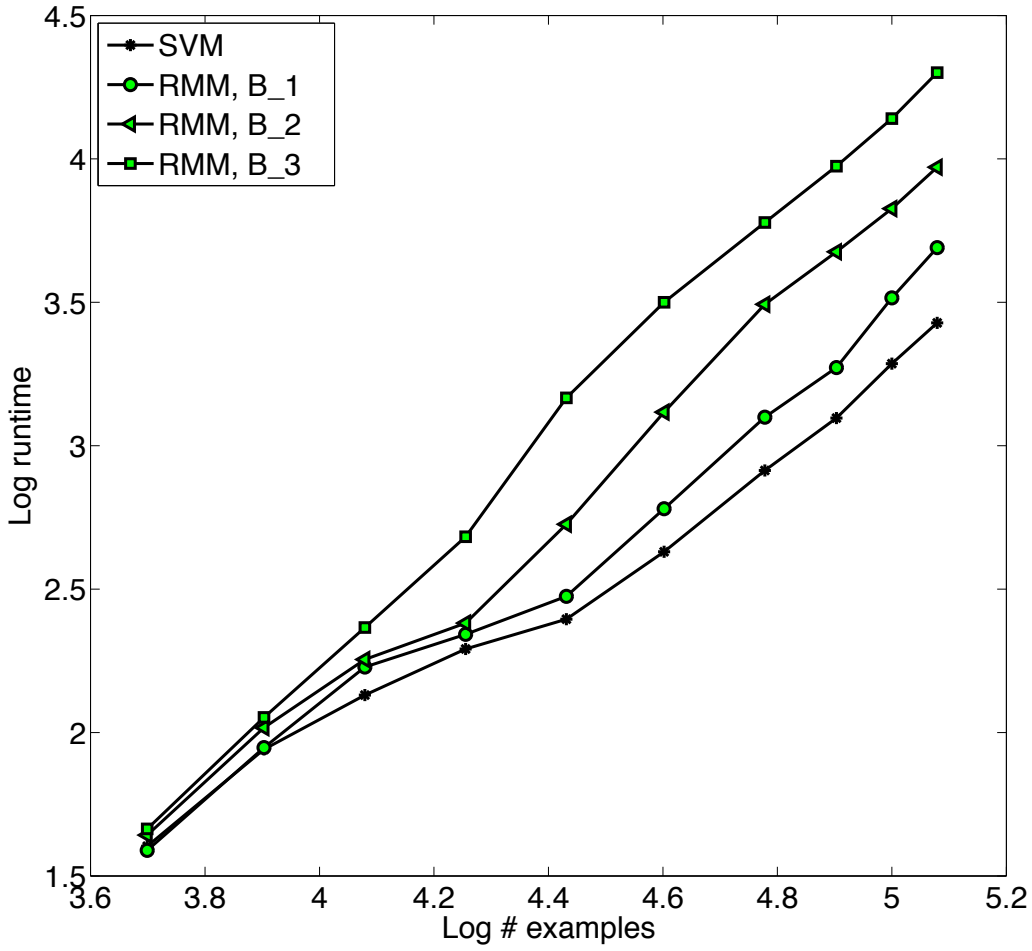

Figure 10: Log run time versus log number of examples. The figure shows that the SVM and the RMM have similar computational requirements overall.

Table 4: UCI results for a number of classification methods. Results are shown for the SVM, regularized kernel Linear Discriminant Analysis, the Σ-SVM, the RMM, an RBF network, Adaboost, LP-regularized Adaboost, QP-regularized Adaboost and Regularized Adaboost. The results have been split into two parts due to lack of space. For each data set, all methods could be placed on the same row in a larger table. For each data set, the algorithm which gave the minimum error rate is starred. All other algorithms that were not significantly different from (at the 5% significance level based on a paired t-test) the minimum error rate are in boldface.

5.6 Benchmark Data Sets

To compare the performance of the RMM with a number of other methods, experiments were performed on several benchmark data sets. In particular, 100 training and test splits of 13 of these data sets have been previously used in Raetsch et al. (2001); Mika et al. (1999); Cawley and Talbot (2003).[12] The RBF kernel was used in these experiments for all kernel-based methods. To handle the noisy nature of these data sets, the kernelized and relaxed version of the RMM (14) was used. All the parameters were tuned using cross-validation using a similar setup as in Raetsch et al. (2001).[13] With the chosen values of these parameters, the error rates were first obtained for all 100 test splits using the corresponding training splits. The results are reported in Table 4. Once again, the RMM exhibits clear performance advantages over other methods.

5.7 Scalability and Run-time

While the asymptotic run time behavior was analyzed in Section 3.3, the run time of the RMM is also studied empirically in this section. In particular, the classification of MNIST digits 0-4 versus 5-9 with a polynomial kernel of degree five was used to benchmark the algorithms. For both the RMM and the SVM, the tolerance parameter (ε mentioned in Section 3.3) was set to 0.001. The size of the sub-problem (12) solved was 800 in all the cases. To evaluate how the algorithms scale, the number of training examples was increased in steps and the training time was noted. Throughout all the experiments, the C value was set to 1. The SVM was first run on the training examples. The value of maximum absolute prediction θ was noted. Three different values of B were then tried for the RMM: $B_1 = 1 + (\theta - 1)/2$, $B_2 = 1 + (\theta - 1)/4$ and $B_3 = 1 + (\theta - 1)/10$. In all experiments, the run time was noted. The experiment was repeated ten times to get an average run time for each B value. A log-log plot comparing the number of examples to the average run time is shown in Figure 10. Both the SVM and the RMM run time exhibit similar asymptotic behavior.

6. Conclusions

The article showed that support vector machines and maximum margin classifiers can be sensitive to affine transformations of the input data and are biased in favor of separating data along directions with large spread. The relative margin machine was proposed to overcome such problems and optimizes the projection direction such that the margin is large only *relative to* the spread of the data. By deriving the dual with quadratic constraints, a geometric interpretation was also formulated for RMMs and led to risk bounds via Rademacher complexity arguments. In practice, the RMM implementation requires only additional linear constraints that complement the SVM quadratic program and maintain its efficient run time. Empirically, the RMM and maximum relative margin approach showed significant improvements in classification accuracy. In addition, an intermediate method known as Σ-SVM was shown that lies between the SVM and the RMM both conceptually and in terms of classification performance.

Generalization bounds with Rademacher averages were derived. The SVM's bound which involves the trace of the kernel matrix was replaced with a more general whitened version of the trace of the kernel matrix. A proof technique using landmark examples led to Rademacher bounds on an

13. The values of the selected parameters and the code for the RMM are available for download at `http://www.cs.columbia.edu/~pks2103/ucirmm/`.

empirical data-dependent hypothesis space. Furthermore, the bounds were stated independently of the particular sample of landmarks.

Directions of future work include exploring the connections between maximum relative margin and generalization bounds based on margin distributions (Schapire et al., 1998; Koltchinskii and Panchenko, 2002). By bounding outputs, the RMM is potentially finding a better margin distribution on the training examples. Previous arguments for such an approach were obtained in the context of voting methods (such as boosting) and may also be relevant here.

Furthermore, the maximization of relative margin is a fairly promising and general concept which may be compatible with other popular problems that have recently been tackled by the maximum margin paradigm. These include regression, ordinal regression, ranking and so forth. These are valuable and natural extensions for the RMM. Finally, since the constraints that bound the projections are unsupervised, RMMs can readily apply in semi-supervised and transductive settings. These are all promising directions for future work.

Appendix A. McDiarmid's Inequality

Assume $X_1, X_2, \ldots, X_n$ are independent random variables from a set $\mathcal{X}$ and $g : \mathcal{X}^n \to \mathbb{R}$. If the function g satisfies $\sup_{X_1,\ldots,X_n,\hat{X}_k} |g(X_1,\ldots,X_n) - g(X_1,\ldots,\hat{X}_k,\ldots,X_n)| \leq c_k$, for all $1 \leq k \leq n$ then, for any $\varepsilon > 0$:

$$\Pr\left[g(X_1,\ldots,X_n) - \mathbf{E}[g(X_1,\ldots,X_n)] \geq \varepsilon\right] \leq \exp\left(-\frac{2\varepsilon^2}{\sum_{i=1}^n c_i^2}\right), \tag{32}$$

$$\Pr\left[\mathbf{E}[g(X_1,\ldots,X_n)] - g(X_1,\ldots,X_n) \geq \varepsilon\right] \leq \exp\left(-\frac{2\varepsilon^2}{\sum_{i=1}^n c_i^2}\right),$$

where the expectations are over the random draws of $X_1,\ldots,X_n$. Here the constants $c_1, c_2, \cdots, c_n$ are called Lipschitz constants.

Appendix B. Lipschitz Constants for Section 4.6

Lemma 19 *The upper bound on $\hat{R}(\mathcal{G}^U_{B,D})$, namely $T_1(\mathbf{U},\mathbf{S})$, admits the Lipschitz constant:*

$$\frac{2\sqrt{2B}}{\bar{D}n}\left(\sqrt{\sum_{i=1}^n \mathbf{x}_i^\top \mathbf{x}_i} - \sqrt{\sum_{i=1}^n \mathbf{x}_i^\top \mathbf{x}_i - \frac{DR^2\mu_{max}}{n\bar{D}+DR^2}}\right).$$

Proof The quantity of interest is the worst change in

$$\frac{2\sqrt{2B}}{n}\sqrt{\sum_{i=1}^n \mathbf{x}_i(\bar{D}\mathbf{I} + \frac{D}{n}\sum_{j=1}^n \mathbf{u}_j\mathbf{u}_j^\top)^{-1}\mathbf{x}_i^\top}$$

when $\mathbf{u}_k$ is varied for any setting of $\mathbf{u}_1, \ldots, \mathbf{u}_{k-1}, \mathbf{u}_{k+1}, \ldots, \mathbf{u}_n$. Since $\sum_{j=1, j\neq k}^{n} \mathbf{u}_j \mathbf{u}_j^\top$ is positive semi-definite and inside the inverse operator, $\mathbf{u}_k$ will have the most extreme effect on the expression when $\sum_{j=1, j\neq k}^{n} \mathbf{u}_j \mathbf{u}_j^\top = \mathbf{0}$. Thus, consider:

$$\frac{2\sqrt{2B}}{n} \sqrt{\sum_{i=1}^{n} \mathbf{x}_i^\top \left(\bar{D}\mathbf{I} + \frac{D}{n} \mathbf{u}_k \mathbf{u}_k^\top \right)^{-1} \mathbf{x}_i}.$$

Apply the Woodbury matrix inversion identity to the term inside the square root:

$$\begin{aligned} \sum_{i=1}^{n} \mathbf{x}_i^\top \left(\bar{D}\mathbf{I} + \frac{D}{n} \mathbf{u}_k \mathbf{u}_k^\top \right)^{-1} \mathbf{x}_i &= \frac{1}{\bar{D}} \sum_{i=1}^{n} \mathbf{x}_i^\top \left(\mathbf{I} - \frac{\mathbf{u}_k \mathbf{u}_k^\top}{\frac{n\bar{D}}{D} + \mathbf{u}_k^\top \mathbf{u}_k} \right) \mathbf{x}_i \\ &= \frac{1}{\bar{D}} \left(\sum_{i=1}^{n} \mathbf{x}_i^\top \mathbf{x}_i - \frac{\sum_{i=1}^{n} (\mathbf{x}_i^\top \mathbf{u}_k)^2}{\frac{n\bar{D}}{D} + \mathbf{u}_k^\top \mathbf{u}_k} \right). \end{aligned}$$

The maximum value of this expression occurs when $\mathbf{u}_k = \mathbf{0}$. To find the minimum, write the second term inside the brackets in the above expression as below:

$$\left(\frac{\mathbf{u}_k^\top}{\|\mathbf{u}_k\|} \sum_{i=1}^{n} \mathbf{x}_i \mathbf{x}_i^\top \frac{\mathbf{u}_k}{\|\mathbf{u}_k\|} \right) / \left(\frac{n\bar{D}}{D\mathbf{u}_k^\top \mathbf{u}_k} + 1 \right).$$

Clearly, in the numerator, the magnitude of $\mathbf{u}_k$ does not matter. To maximize this expression, $\mathbf{u}_k$ should be set to a vector of maximal length and in the same direction as the maximum eigenvector of $\sum_{i=1}^{n} \mathbf{x}_i \mathbf{x}_i^\top$. Since all examples are assumed to have bounded norm no larger than R, the largest $\mathbf{u}_k$ vector has norm R. Denoting the maximum eigenvalue of $\sum_{i=1}^{n} \mathbf{x}_i \mathbf{x}_i^\top$ by μ_{max}, it is easy to show the claimed value of Lipschitz constant for any k. ■

Lemma 20 *The upper bound on $\hat{R}(\mathcal{H}_{E,D}^{V})$, namely $T_2(\mathbf{V}, \mathbf{S})$, admits the Lipschitz constant:*

$$\frac{2\sqrt{2E}}{\bar{D}n} \left(\sqrt{\sum_{i=1}^{n} \mathbf{x}_i^\top \mathbf{x}_i} - \sqrt{\sum_{i=1}^{n} \mathbf{x}_i^\top \mathbf{x}_i - \frac{DR^2 \mu_{max}}{n\bar{D} + DR^2}} \right).$$

Proof The quantity of interest is the maximum change in the following optimization problem over $\mathbf{u}_k$ for any setting of $\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_{k-1}, \mathbf{u}_{k+1}, \ldots, \mathbf{u}_{n_v}$:

$$\min_{\lambda \geq 0} \frac{1}{n} \sum_{i=1}^{n} \mathbf{x}_i^\top \left(\bar{D} \sum_{j=1}^{n_v} \lambda_j \mathbf{I} + D \sum_{j=1}^{n_v} \lambda_j \mathbf{u}_j \mathbf{u}_j^\top \right)^{-1} \mathbf{x}_i + \frac{2}{n} E \sum_{i=1}^{n_v} \lambda_i.$$

As before, this happens when all $\mathbf{u}$'s except $\mathbf{u}_k$ are $\mathbf{0}$. In such a scenario, the expression is minimized for the setting $\lambda_j = 0$ for all $j \neq k$. The minimization only needs to consider variable settings of λ_k. Since this minimization is over a single scalar, it is possible to obtain a closed-form expression for λ_k. The optimal λ_k is merely: $\frac{1}{\sqrt{2E}} \sum_{i=1}^{n} \mathbf{x}_i^\top \left(\bar{D}\mathbf{I} + D\mathbf{u}_k \mathbf{u}_k^\top \right)^{-1} \mathbf{x}_i$. Substituting this into the objective gives an expression which is independent of λ's:

$$\frac{2\sqrt{2E}}{n} \sqrt{\sum_{i=1}^{n} \mathbf{x}_i^\top \left(\bar{D}\mathbf{I} + \frac{D}{n} \mathbf{u}_k \mathbf{u}_k^\top \right)^{-1} \mathbf{x}_i}.$$

This expression is identical to the one obtained in Theorem 19 and the proof follows. ■

Appendix C. Solving for n_v

Let $x = \frac{1}{\sqrt{n_v}}$, $c = 4R\sqrt{\frac{2E}{D}}$ and $b = \frac{3}{2}\sqrt{\frac{\ln(2/\delta)}{2}}$. Consider solving for x in the expression $x^2 - 2bx = (c + 2b)/\sqrt{n}$. Equivalently, solve $(x-b)^2 = b^2 + (c+2b)/\sqrt{n}$. Taking the square root of both sides gives $x = b \pm \sqrt{b^2 + (c+2b)/\sqrt{n}}$. Since $x > 0$, only the positive root is considered. Thus, $\sqrt{n_v} = 1/(b + \sqrt{b^2 + (c+2b)/\sqrt{n}})$ which gives an exact expression for n_v. Dropping terms from the denominator produces the simpler expression: $\sqrt{n_v} \leq 1/\sqrt{(c+2b)/\sqrt{n}}$. Hence, $n_v \leq \frac{\sqrt{n}}{4R\sqrt{\frac{2E}{D}} + 3\sqrt{\frac{\ln(2/\delta)}{2}}}$.

Abstract

Most generalization bounds in learning theory are based on some measure of the complexity of the hypothesis class used, independently of any algorithm. In contrast, the notion of algorithmic stability can be used to derive tight generalization bounds that are tailored to specific learning algorithms by exploiting their particular properties. However, as in much of learning theory, existing stability analyses and bounds apply only in the scenario where the samples are independently and identically distributed. In many machine learning applications, however, this assumption does not hold. The observations received by the learning algorithm often have some inherent temporal dependence.

This paper studies the scenario where the observations are drawn from a stationary φ-mixing or β-mixing sequence, a widely adopted assumption in the study of non-i.i.d. processes that implies a dependence between observations weakening over time. We prove novel and distinct stability-based generalization bounds for stationary φ-mixing and β-mixing sequences. These bounds strictly generalize the bounds given in the i.i.d. case and apply to all stable learning algorithms, thereby extending the use of stability-bounds to non-i.i.d. scenarios.

We also illustrate the application of our φ-mixing generalization bounds to general classes of learning algorithms, including Support Vector Regression, Kernel Ridge Regression, and Support Vector Machines, and many other kernel regularization-based and relative entropy-based regularization algorithms. These novel bounds can thus be viewed as the first theoretical basis for the use of these algorithms in non-i.i.d. scenarios.

Keywords: learning in non-i.i.d. scenarios, weakly dependent observations, mixing distributions, algorithmic stability, generalization bounds, learning theory

1. Introduction

Most generalization bounds in learning theory are based on some measure of the complexity of the hypothesis class used, such as the VC-dimension, covering numbers, or Rademacher complexity. These measures characterize a class of hypotheses, independently of any algorithm. In contrast, the notion of algorithmic stability can be used to derive bounds that are tailored to specific learning algorithms and exploit their particular properties. A learning algorithm is stable if the hypothesis it

outputs varies in a limited way in response to small changes made to the training set. Algorithmic stability has been used effectively in the past to derive tight generalization bounds (Bousquet and Elisseeff, 2001, 2002; Kearns and Ron, 1997).

But, as in much of learning theory, existing stability analyses and bounds apply only in the scenario where the samples are independently and identically distributed (i.i.d.). In many machine learning applications, this assumption, however, does not hold; in fact, the i.i.d. assumption is not tested or derived from any data analysis. The observations received by the learning algorithm often have some inherent temporal dependence. This is clear in system diagnosis or time series prediction problems. Clearly, prices of different stocks on the same day, or of the same stock on different days, may be dependent. But, a less apparent time dependency may affect data sampled in many other tasks as well.

This paper studies the scenario where the observations are drawn from a stationary φ-mixing or β-mixing sequence, a widely adopted assumption in the study of non-i.i.d. processes that implies a dependence between observations weakening over time (Yu, 1994; Meir, 2000; Vidyasagar, 2003; Lozano et al., 2006; Mohri and Rostamizadeh, 2007). We prove novel and distinct stability-based generalization bounds for stationary φ-mixing and β-mixing sequences. These bounds strictly generalize the bounds given in the i.i.d. case and apply to all stable learning algorithms, thereby extending the usefulness of stability-bounds to non-i.i.d. scenarios. Our proofs are based on the independent block technique described by Yu (1994) and attributed to Bernstein (1927), which is commonly used in such contexts. However, our analysis somewhat differs from previous uses of this technique in that the blocks of points we consider are not necessarily of equal size.

For our analysis of stationary φ-mixing sequences, we make use of a generalized version of McDiarmid's inequality given by Kontorovich and Ramanan (2008) that holds for φ-mixing sequences. This leads to stability-based generalization bounds with the standard exponential form. Our generalization bounds for stationary β-mixing sequences cover a more general non-i.i.d. scenario and use the standard McDiarmid's inequality, however, unlike the φ-mixing case, the β-mixing bound presented here is not a purely exponential bound and contains an additive term depending on the mixing coefficient.

We also illustrate the application of our φ-mixing generalization bounds to general classes of learning algorithms, including Support Vector Regression (SVR) (Vapnik, 1998), Kernel Ridge Regression (Saunders et al., 1998), and Support Vector Machines (SVMs) (Cortes and Vapnik, 1995). Algorithms such as SVR have been used in the context of time series prediction in which the i.i.d. assumption does not hold, some with good experimental results (Müller et al., 1997; Mattera and Haykin, 1999). However, to our knowledge, the use of these algorithms in non-i.i.d. scenarios has not been previously supported by any theoretical analysis. The stability bounds we give for SVR, SVMs, and many other kernel regularization-based and relative entropy-based regularization algorithms can thus be viewed as the first theoretical basis for their use in such scenarios.

The following sections are organized as follows. In Section 2, we introduce the definitions relevant to the non-i.i.d. problems that we are considering and discuss the learning scenarios in that context. Section 3 gives our main generalization bounds for stationary φ-mixing sequences based on stability, as well as the illustration of its applications to general kernel regularization-based algorithms, including SVR, KRR, and SVMs, as well as to relative entropy-based regularization algorithms. Finally, Section 4 presents the first known stability bounds for the more general stationary β-mixing scenario.

2. Preliminaries

We first introduce some standard definitions for dependent observations in mixing theory (Doukhan, 1994) and then briefly discuss the learning scenarios in the non-i.i.d. case.

2.1 Non-i.i.d. Definitions

Definition 1 *A sequence of random variables $\mathbf{Z} = \{Z_t\}_{t=-\infty}^{\infty}$ is said to be* stationary *if for any t and non-negative integers m and k, the random vectors $(Z_t, \ldots, Z_{t+m})$ and $(Z_{t+k}, \ldots, Z_{t+m+k})$ have the same distribution.*

Thus, the index t or time, does not affect the distribution of a variable Z_t in a stationary sequence. This does not imply independence however. In particular, for $i < j < k$, $\Pr[Z_j \mid Z_i]$ may not equal $\Pr[Z_k \mid Z_i]$, that is, conditional probabilities may vary at different points in time. The following is a standard definition giving a measure of the dependence of the random variables Z_t within a stationary sequence. There are several equivalent definitions of these quantities, we are adopting here a version convenient for our analysis, as in Yu (1994).

Definition 2 *Let $\mathbf{Z} = \{Z_t\}_{t=-\infty}^{\infty}$ be a stationary sequence of random variables. For any $i, j \in \mathbb{Z} \cup \{-\infty, +\infty\}$, let σ_i^j denote the σ-algebra generated by the random variables Z_k, $i \leq k \leq j$. Then, for any positive integer k, the β-mixing and φ-mixing coefficients of the stochastic process $\mathbf{Z}$ are defined as*

$$\beta(k) = \sup_n \mathop{\mathrm{E}}_{B \in \sigma_{-\infty}^n} \Big[\sup_{A \in \sigma_{n+k}^{\infty}} \Big| \Pr[A \mid B] - \Pr[A] \Big| \Big] \quad \varphi(k) = \sup_{\substack{n \\ A \in \sigma_{n+k}^{\infty} \\ B \in \sigma_{-\infty}^n}} \Big| \Pr[A \mid B] - \Pr[A] \Big|.$$

$\mathbf{Z}$ is said to be β-mixing (φ-mixing) if $\beta(k) \to 0$ (resp. $\varphi(k) \to 0$) as $k \to \infty$. It is said to be algebraically β-mixing (algebraically φ-mixing*) if there exist real numbers $\beta_0 > 0$ (resp. $\varphi_0 > 0$) and $r > 0$ such that $\beta(k) \leq \beta_0 / k^r$ (resp. $\varphi(k) \leq \varphi_0 / k^r$) for all k,* exponentially mixing *if there exist real numbers β_0 (resp. $\varphi_0 > 0$), β_1 (resp. $\varphi_1 > 0$) and $r > 0$ such that $\beta(k) \leq \beta_0 \exp(-\beta_1 k^r)$ (resp. $\varphi(k) \leq \varphi_0 \exp(-\varphi_1 k^r)$) for all k.*

Both $\beta(k)$ and $\varphi(k)$ measure the dependence of an event on those that occurred more than k units of time in the past. β-mixing is a weaker assumption than φ-mixing and thus covers a more general non-i.i.d. scenario.

This paper gives stability-based generalization bounds both in the φ-mixing and β-mixing case. The β-mixing bounds cover a more general case of course, however, the φ-mixing bounds are simpler and admit the standard exponential form. The φ-mixing bounds are based on a concentration inequality that applies to φ-mixing processes only. Except for the use of this concentration bound and two lemmas 5 and 6, all of the intermediate proofs and results to derive a φ-mixing bound in Section 3 are given in the more general case of β-mixing sequences.

It has been argued by Vidyasagar (2003) that β-mixing is "just the right" assumption for the analysis of weakly-dependent sample points in machine learning, in particular because several PAC-learning results then carry over to the non-i.i.d. case. Our β-mixing generalization bounds further contribute to the analysis of this scenario.[1]

1. Some results have also been obtained in the more general context of α-mixing but they seem to require the stronger condition of exponential mixing (Modha and Masry, 1998).

We describe in several instances the application of our bounds in the case of algebraic mixing. Algebraic mixing is a standard assumption for mixing coefficients that has been adopted in previous studies of learning in the presence of dependent observations (Yu, 1994; Meir, 2000; Vidyasagar, 2003; Lozano et al., 2006). Let us also point out that mixing assumptions can be checked in some cases such as with Gaussian or Markov processes (Meir, 2000) and that mixing parameters can also be estimated in such cases.

Most previous studies use a technique originally introduced by Bernstein (1927) based on *independent blocks* of equal size (Yu, 1994; Meir, 2000; Lozano et al., 2006). This technique is particularly relevant when dealing with stationary β-mixing. We will need a related but somewhat different technique since the blocks we consider may not have the same size. The following lemma is a special case of Corollary 2.7 from Yu (1994).

Lemma 3 (Yu, 1994, Corollary 2.7) *Let $\mu \geq 1$ and suppose that h is measurable function, with absolute value bounded by M, on a product probability space $\left(\prod_{j=1}^{\mu} \Omega_j, \prod_{i=1}^{\mu} \sigma_{r_i}^{s_i}\right)$ where $r_i \leq s_i \leq r_{i+1}$ for all i. Let Q be a probability measure on the product space with marginal measures Q_i on $(\Omega_i, \sigma_{r_i}^{s_i})$, and let Q^{i+1} be the marginal measure of Q on $\left(\prod_{j=1}^{i+1} \Omega_j, \prod_{j=1}^{i+1} \sigma_{r_j}^{s_j}\right)$, $i = 1, \ldots, \mu-1$. Let $\beta(Q) = \sup_{1 \leq i \leq \mu-1} \beta(k_i)$, where $k_i = r_{i+1} - s_i$, and $P = \prod_{i=1}^{\mu} Q_i$. Then,*

$$|\mathop{\mathrm{E}}_{Q}[h] - \mathop{\mathrm{E}}_{P}[h]| \leq (\mu - 1) M \beta(Q).$$

The lemma gives a measure of the difference between the distribution of μ blocks where the blocks are independent in one case and dependent in the other case. The distribution within each block is assumed to be the same in both cases. For a monotonically decreasing function β, we have $\beta(Q) = \beta(k^*)$, where $k^* = \min_i(k_i)$ is the smallest gap between blocks.

2.2 Learning Scenarios

We consider the familiar supervised learning setting where the learning algorithm receives a sample of m labeled points $S = (z_1, \ldots, z_m) = ((x_1, y_1), \ldots, (x_m, y_m)) \in (X \times Y)^m$, where X is the input space and Y the set of labels ($Y \subseteq \mathbb{R}$ in the regression case), both assumed to be measurable.

For a fixed learning algorithm, we denote by h_S the hypothesis it returns when trained on the sample S. The error of a hypothesis on a pair $z \in X \times Y$ is measured in terms of a cost function $c : Y \times Y \to \mathbb{R}_+$. Thus, $c(h(x), y)$ measures the error of a hypothesis h on a pair (x, y), $c(h(x), y) = (h(x) - y)^2$ in the standard regression cases. We will often use the shorthand $c(h, z) := c(h(x), y)$ for a hypothesis h and $z = (x, y) \in X \times Y$ and will assume that c is upper bounded by a constant $M > 0$. We denote by $\widehat{R}(h)$ the empirical error of a hypothesis h for a training sample $S = (z_1, \ldots, z_m)$:

$$\widehat{R}(h) = \frac{1}{m} \sum_{i=1}^{m} c(h, z_i).$$

In the standard machine learning scenario, the sample pairs $z_1, \ldots, z_m$ are assumed to be i.i.d., a restrictive assumption that does not always hold in practice. We will consider here the more general case of dependent samples drawn from a stationary mixing sequence $\mathbf{Z}$ over $X \times Y$. As in the i.i.d. case, the objective of the learning algorithm is to select a hypothesis with small error over future samples. But, here, we must distinguish two versions of this problem.

In the most general version, future samples depend on the training sample S and thus the generalization error or true error of the hypothesis h_S trained on S must be measured by its expected error conditioned on the sample S:

$$R(h_S) = \mathop{\mathrm{E}}_{z}[c(h_S, z) \mid S]. \tag{1}$$

This is the most realistic setting in this context, which matches time series prediction problems. A somewhat less realistic version is one where the samples are dependent, but the test points are assumed to be independent of the training sample S. The generalization error of the hypothesis h_S trained on S is then:

$$R(h_S) = \mathop{\mathrm{E}}_{z}[c(h_S, z) \mid S] = \mathop{\mathrm{E}}_{z}[c(h_S, z)].$$

This setting seems less natural since, if samples are dependent, future test points must also depend on the training points, even if that dependence is relatively weak due to the time interval after which test points are drawn. Nevertheless, it is this somewhat less realistic setting that has been studied by all previous machine learning studies that we are aware of Yu (1994), Meir (2000), Vidyasagar (2003) and Lozano et al. (2006), even when examining specifically a time series prediction problem (Meir, 2000). Thus, the bounds derived in these studies cannot be directly applied to the more general setting. We will consider instead the most general setting with the definition of the generalization error based on Equation 1. Clearly, our analysis also applies to the less general setting just discussed as well.

Let us also briefly discuss the more general scenario of *non-stationary* mixing sequences, that is one where the distribution may change over time. Within that general case, the generalization error of a hypothesis h_S, defined straightforwardly by

$$R(h_S, t) = \mathop{\mathrm{E}}_{z_t \sim \sigma'_t}[c(h_S, z_t) \mid S],$$

would depend on the time t and it may be the case that $R(h_S,t) \neq R(h_S,t')$ for $t \neq t'$, making the definition of the generalization error a more subtle issue. To remove the dependence on time, one could define a weaker notion of the generalization error based on an expected loss over all time:

$$R(h_S) = \mathop{\mathrm{E}}_{t}[R(h_S, t)].$$

It is not clear however whether this term could be easily computed and be useful. A stronger condition would be to minimize the generalization error for any particular target time. Studies of this type have been conducted for smoothly changing distributions, such as in Zhou et al. (2008), however, to the best of our knowledge, the scenario of a both non-identical and non-independent sequences has not yet been studied.

3. φ-Mixing Generalization Bounds and Applications

This section gives generalization bounds for $\widehat{\beta}$-stable algorithms over a mixing stationary distribution.[2] The first two sections present our supporting lemmas which hold for either β-mixing or φ-mixing stationary distributions. In the third section, we will briefly discuss concentration inequalities that apply to φ-mixing processes only. Then, in the final section, we will present our main results.

2. The standard variable used for the stability coefficient is β. To avoid the confusion with the β-mixing coefficient, we will use $\widehat{\beta}$ instead.

The condition of $\widehat{\beta}$-stability is an algorithm-dependent property first introduced by Devroye and Wagner (1979) and Kearns and Ron (1997). It has been later used successfully by Bousquet and Elisseeff (2001, 2002) to show algorithm-specific stability bounds for i.i.d. samples. Roughly speaking, a learning algorithm is said to be *stable* if small changes to the training set do not cause large deviations in its output. The following gives the precise technical definition.

Definition 4 *A learning algorithm is said to be (uniformly)* $\widehat{\beta}$-stable *if the hypotheses it returns for any two training samples S and S' that differ by removing a single point satisfy*

$$\forall z \in X \times Y, \quad |c(h_S, z) - c(h_{S'}, z)| \leq \widehat{\beta}.$$

We note that a $\widehat{\beta}$-stable algorithm is also stable with respect to *replacing* a single point. Let S and S_i be two sequences differing in the ith coordinate, and $S_{/i}$ be equivalent to S and S_i but with the ith point removed. Then for a $\widehat{\beta}$-stable algorithm we have,

$$\begin{aligned} |c(h_S, z) - c(h_{S_i}, z)| &= |c(h_S, z) - c(h_{S_{/i}}) + c(h_{S_{/i}}) - c(h_{S_i}, z)| \\ &\leq |c(h_S, z) - c(h_{S_{/i}})| + |c(h_{S_{/i}}) - c(h_{S_i}, z)| \\ &\leq 2\widehat{\beta}. \end{aligned}$$

The use of stability in conjunction with McDiarmid's inequality will allow us to derive generalization bounds. McDiarmid's inequality is an exponential concentration bound of the form

$$\Pr[|\Phi - \mathrm{E}[\Phi]| \geq \varepsilon] \leq \exp\left(-\frac{m\varepsilon^2}{\tau^2}\right),$$

where the probability is over a sample of size m and where $\frac{\tau}{m}$ is the Lipschitz parameter of Φ, with τ a function of m. Unfortunately, this inequality cannot be applied when the sample points are not distributed in an i.i.d. fashion. We will use instead a result of Kontorovich and Ramanan (2008) that extends McDiarmid's inequality to φ-mixing distributions (Theorem 8). To obtain a stability-based generalization bound, we will apply this theorem to

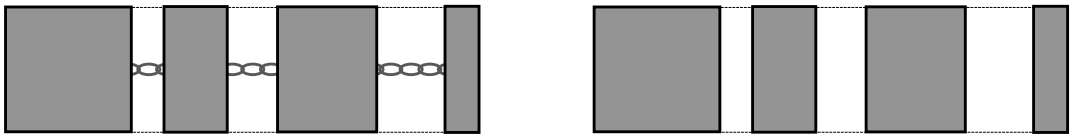
$$\Phi(S) = R(h_S) - \widehat{R}(h_S).$$

To do so, we need to show, as with the standard McDiarmid's inequality, that Φ is a Lipschitz function and, to make it useful, bound $\mathrm{E}[\Phi]$. The next two sections describe how we achieve both of these in this non-i.i.d. scenario.

Let us first take a brief look at the problem faced when attempting to give stability bounds for dependent sequences and give some idea of our solution for that problem. The stability proofs given by Bousquet and Elisseeff (2001) assume the i.i.d. property, thus replacing an element in a sequence with another does not affect the expected value of a random variable defined over that sequence. In other words, the following equality holds,

$$\mathop{\mathrm{E}}_{S}[V(Z_1, \ldots, Z_i, \ldots, Z_m)] = \mathop{\mathrm{E}}_{S, Z'}[V(Z_1, \ldots, Z', \ldots, Z_m)], \tag{2}$$

for a random variable V that is a function of the sequence of random variables $S = (Z_1, \ldots, Z_m)$. However, clearly, if the points in that sequence S are dependent, this equality may not hold anymore.



(a) (b)

Figure 1: Illustration of dependent (a) and independent (b) blocks. Although there is no dependence between blocks of points in (b), the distribution within each block remains the same as in (a) and thus points within a block remain dependent.

The main technique to cope with this problem is based on the so-called "independent block sequence" originally introduced by Bernstein (1927). This consists of eliminating from the original dependent sequence several blocks of contiguous points, leaving us with some remaining blocks of points. Instead of these dependent blocks, we then consider independent blocks of points, each with the same size and the same distribution (within each block) as the dependent ones. By Lemma 3, for a β-mixing distribution, the expected value of a random variable defined over the dependent blocks is close to the one based on these independent blocks. Working with these independent blocks brings us back to a situation similar to the i.i.d. case, with i.i.d. blocks replacing i.i.d. points. Figure 1 illustrates the two types of blocks just discussed.

Our use of this method somewhat differs from previous ones (see Yu, 1994; Meir, 2000) where many blocks of equal size are considered. We will be dealing with four blocks and with typically unequal sizes. More specifically, note that for Equation 2 to hold, we only need that the variable Z_i be independent of the other points in the sequence. To achieve this, roughly speaking, we will be "discarding" some of the points in the sequence surrounding Z_i. This results in a sequence of three blocks of contiguous points. If our algorithm is stable and we do not discard too many points, the hypothesis returned should not be greatly affected by this operation. In the next step, we apply the independent block lemma, which then allows us to assume each of these blocks as independent modulo the addition of a mixing term. In particular, Z_i becomes independent of all other points. Clearly, the number of points discarded is subject to a trade-off: removing too many points could excessively modify the hypothesis returned; removing too few would maintain the dependency between Z_i and the remaining points, thereby inducing a larger penalty when applying Lemma 3. This trade-off is made explicit in the following section where an optimal solution is sought.

3.1 Lipschitz Bound

As discussed in Section 2.2, in the most general scenario, test points depend on the training sample. We first present a lemma that relates the expected value of the generalization error in that scenario and the same expectation in the scenario where the test point is independent of the training sample. We denote by $R(h_S) = \mathrm{E}_z[c(h_S, z)|S]$ the expectation in the dependent case and by $\widetilde{R}(h_{S_b}) = \mathrm{E}_{\widetilde{z}}[c(h_{S_b}, \widetilde{z})]$ the expectation where the test points are assumed independent of the training, with S_b denoting a sequence similar to S but with the last b points removed. Figure 2(a) illustrates that sequence. The block S_b is assumed to have exactly the same distribution as the corresponding block of the same size in S.

Lemma 5 *Assume that the learning algorithm is $\widehat{\beta}$-stable and that the cost function c is bounded by M. Then, for any sample S of size m drawn from a φ-mixing stationary distribution and for any $b \in \{0,\ldots,m\}$, the following holds:*

$$|R(h_S) - \widetilde{R}(h_{S_b})| \leq b\widehat{\beta} + M\varphi(b)$$

Proof The $\widehat{\beta}$-stability of the learning algorithm implies that

$$|R(h_S) - R(h_{S_b})| = |\mathop{\mathrm{E}}_{z}[c(h_S,z)|S] - \mathop{\mathrm{E}}_{z}[c(h_{S_b},z)|S_b]| \leq b\widehat{\beta}. \tag{3}$$

Now, in order to remove the dependence on S_b we bound the following difference

$$\begin{aligned}
&|\mathop{\mathrm{E}}_{z}[c(h_{S_b},z)|S_b] - \mathop{\mathrm{E}}_{\widetilde{z}}[c(h_{S_b},\widetilde{z})]| \\
&\qquad = \Big|\sum_{z\in Z} c(h_{S_b},z)(\Pr[z|S_b] - \Pr[z])\Big| \\
&\qquad = \Big|\sum_{z\in Z^+} c(h_{S_b},z)(\Pr[z|S_b] - \Pr[z]) + \sum_{z\in Z^-} c(h_{S_b},z)(\Pr[z|S_b] - \Pr[z])\Big| \\
&\qquad = \Big|\sum_{z\in Z^+} c(h_{S_b},z)\Big|\Pr[z|S_b] - \Pr[z]\Big| - \sum_{z\in Z^-} c(h_{S_b},z)\Big|\Pr[z|S_b] - \Pr[z]\Big|\Big| \\
&\qquad \leq \max_{Z\in\{Z^-,Z^+\}} \sum_{z\in Z} c(h_{S_b},z)\Big|\Pr[z|S_b] - \Pr[z]\Big| \qquad (4) \\
&\qquad \leq \max_{Z\in\{Z^-,Z^+\}} M\sum_{z\in Z}\Big|\Pr[z|S_b] - \Pr[z]\Big| \\
&\qquad = \max_{Z\in\{Z^-,Z^+\}} M\Big|\sum_{z\in Z}\Pr[z|S_b] - \Pr[z]\Big| \\
&\qquad = \max_{Z\in\{Z^-,Z^+\}} M\Big|\Pr[Z|S_b] - \Pr[Z]\Big| \leq M\varphi(b),
\end{aligned}$$

where the sum has been separated over the set of zs Z^+ for which the difference $\Pr[z|S_b] - \Pr[z]$ is non-negative, and its complement Z^-. Using (3) and (4) and the triangle inequality yields the statement of the lemma. ■

Note that we assume that z immediately follows the sample S, which is the strongest dependent scenario. The following bounds can be improved in a straightforward manner if the test point z is assumed to be observed say k units of time after the sample S. The bound would then contain the mixing term $\varphi(k+b)$ instead of $\varphi(b)$.

We can now prove a Lipschitz bound for the function Φ.

Lemma 6 *Let $S = (z_1,\ldots,z_i,\ldots,z_m)$ and $S^i = (z_1,\ldots,z_i',\ldots,z_m)$ be two sequences drawn from a φ-mixing stationary process that differ only in point z_i for some $i \in \{1,\ldots,m\}$, and let h_S and h_{S^i} be the hypotheses returned by a $\widehat{\beta}$-stable algorithm when trained on each of these samples. Then, for any $i \in \{1,\ldots,m\}$, the following inequality holds:*

$$|\Phi(S) - \Phi(S^i)| \leq (b+2)2\widehat{\beta} + 2\varphi(b)M + \frac{M}{m}.$$

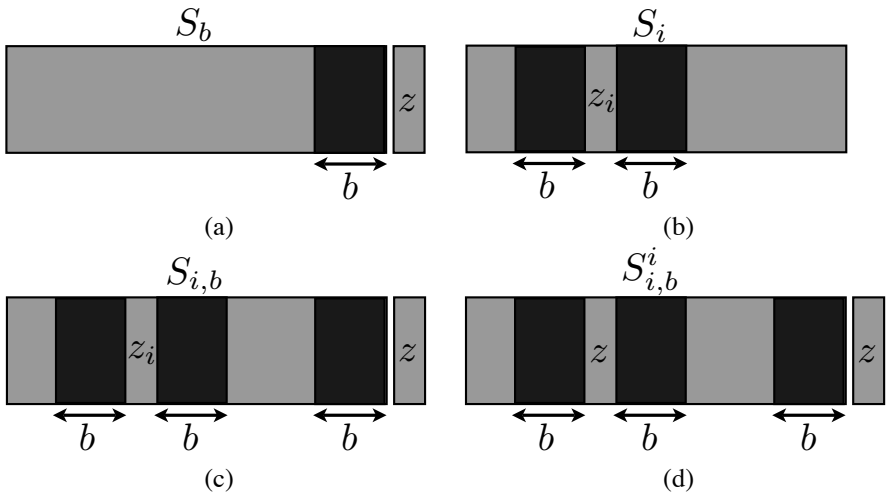


Figure 2: Illustration of the sequences derived from S that are considered in the proofs.

Proof To prove this inequality, we first bound the difference of the empirical errors as in Bousquet and Elisseeff (2002), then the difference of the generalization errors. Bounding the difference of costs on agreeing points with $\widehat{\beta}$ and the one that disagrees with M gives

$$\begin{aligned}|\widehat{R}(h_S) - \widehat{R}(h_{S^i})| &\leq \frac{1}{m}\sum_{j\neq i}|c(h_S, z_j) - c(h_{S^i}, z_j)| + \frac{1}{m}|c(h_S, z_i) - c(h_{S^i}, z_i')| \\ &\leq 2\widehat{\beta} + \frac{M}{m}. \end{aligned} \tag{5}$$

Since both $R(h_S)$ and $R(h_{S^i})$ are defined with respect to a (different) dependent point, we can apply Lemma 5 to both generalization error terms and use $\widehat{\beta}$-stability. Using this and the triangle inequality, we can write

$$\begin{aligned}|R(h_S) - R(h_{S^i})| &\leq |R(h_S) - \widetilde{R}(h_{S_b}) + \widetilde{R}(h_{S_b}) - \widetilde{R}(h_{S_b^i}) + \widetilde{R}(h_{S_b^i}) - R(h_{S^i})| \\ &\leq |\widetilde{R}(h_{S_b}) - \widetilde{R}(h_{S_b^i})| + 2b\widehat{\beta} + 2\varphi(b)M \\ &= \mathop{\mathrm{E}}_{\widetilde{z}}[c(h_{S_b}, \widetilde{z}) - c(h_{S_b^i}, \widetilde{z})] + 2b\widehat{\beta} + 2\varphi(b)M \\ &\leq 2\widehat{\beta} + 2b\widehat{\beta} + 2\varphi(b)M. \end{aligned} \tag{6}$$

The statement of the lemma is obtained by combining inequalities 5 and 6. ■

3.2 Bound on Expectation

As mentioned earlier, to obtain an explicit bound after application of a generalized McDiarmid's inequality, we also need to bound $\mathrm{E}_S[\Phi(S)]$. This is done by analyzing independent blocks using Lemma 3.

Lemma 7 *Let h_S be the hypothesis returned by a $\widehat{\beta}$-stable algorithm trained on a sample S drawn from a β-mixing stationary distribution. Then, for all $b \in [1,m]$, the following inequality holds:*

$$\mathop{\mathrm{E}}_{S}[|\Phi(S)|] \leq (6b+2)\widehat{\beta} + 3\beta(b)M.$$

Proof Let S_b be defined as in the proof of Lemma 5. To deal with independent block sequences defined with respect to the same hypothesis, we will consider the sequence $S_{i,b} = S_i \cap S_b$, which is illustrated by Figure 2(a-c). This can result in as many as four blocks. As before, we will consider a sequence $\widetilde{S}_{i,b}$ with a similar set of blocks each with the same distribution as the corresponding blocks in $S_{i,b}$, but such that the blocks are independent as seen in Figure 2(d).

Since three blocks of at most b points are removed from each hypothesis, by the $\widehat{\beta}$-stability of the learning algorithm, the following holds:

$$\begin{aligned}
\mathop{\mathrm{E}}_{S}[\Phi(S)] &= \mathop{\mathrm{E}}_{S}[\widehat{R}(h_S) - R(h_S)] \\
&= \mathop{\mathrm{E}}_{S,z}\left[\frac{1}{m}\sum_{i=1}^{m} c(h_S, z_i) - c(h_S, z)\right] \\
&\leq \mathop{\mathrm{E}}_{S_{i,b},z}\left[\frac{1}{m}\sum_{i=1}^{m} c(h_{S_{i,b}}, z_i) - c(h_{S_{i,b}}, z)\right] + 6b\widehat{\beta}.
\end{aligned}$$

The application of Lemma 3 to the difference of two cost functions also bounded by M as in the right-hand side leads to

$$\mathop{\mathrm{E}}_{S}[\Phi(S)] \leq \mathop{\mathrm{E}}_{\widetilde{S}_{i,b},\widetilde{z}}\left[\frac{1}{m}\sum_{i=1}^{m} c(h_{\widetilde{S}_{i,b}}, \widetilde{z}_i) - c(h_{\widetilde{S}_{i,b}}, \widetilde{z})\right] + 6b\widehat{\beta} + 3\beta(b)M.$$

Now, since the points $\widetilde{z}$ and $\widetilde{z}_i$ are independent and since the distribution is stationary, they have the same distribution and we can replace $\widetilde{z}_i$ with $\widetilde{z}$ in the empirical cost. Thus, we can write

$$\mathop{\mathrm{E}}_{S}[\Phi(S)] \leq \mathop{\mathrm{E}}_{\widetilde{S}_{i,b},\widetilde{z}}\left[\frac{1}{m}\sum_{i=1}^{m} c(h_{\widetilde{S}^i_{i,b}}, \widetilde{z}) - c(h_{\widetilde{S}_{i,b}}, \widetilde{z})\right] + 6b\widehat{\beta} + 3\beta(b)M \leq 2\widehat{\beta} + 6b\widehat{\beta} + 3\beta(b)M,$$

where $\widetilde{S}^i_{i,b}$ is the sequence derived from $\widetilde{S}_{i,b}$ by replacing $\widetilde{z}_i$ with $\widetilde{z}$. The last inequality holds by $\widehat{\beta}$-stability of the learning algorithm. The other side of the inequality in the statement of the lemma can be shown following the same steps. ■

3.3 φ-Mixing Concentration Bound

We are now prepared to make use of a concentration inequality to provide a generalization bound in the φ-mixing scenario. Several concentration inequalities have been shown in the φ-mixing case, for example, Marton (1998), Samson (2000), Chazottes et al. (2007) and Kontorovich and Ramanan (2008). We will use that of Kontorovich and Ramanan (2008), which is very similar to that of Chazottes et al. (2007), modulo the fact that the latter requires a finite sample space.

The following is a concentration inequality derived from that of Kontorovich and Ramanan (2008).[3]

Theorem 8 *Let $\Phi\colon Z^m \to \mathbb{R}$ be a measurable function that is c-Lipschitz with respect to the Hamming metric for some $c>0$ and let $Z_1,\ldots,Z_m$ be random variables distributed according to a φ-mixing distribution. Then, for any $\varepsilon>0$, the following inequality holds:*

$$\Pr\left[\left|\Phi(Z_1,\ldots,Z_m)-\mathrm{E}[\Phi(Z_1,\ldots,Z_m)]\right|\geq\varepsilon\right]\leq 2\exp\left(\frac{-2\varepsilon^2}{mc^2||\Delta_m||_\infty^2}\right),$$

where $||\Delta_m||_\infty \leq 1+2\sum_{k=1}^{m}\varphi(k)$.

It should be pointed out that the statement of the theorem in this paper is improved by a factor of 4 in the exponent with respect to that of Kontorovich and Ramanan (2008, Theorem 1.1). This can be achieved straightforwardly by following the same steps as in the proof of Kontorovich and Ramanan (2008), but by making use of the following general form of McDiarmid's inequality (Theorem 9) instead of Azuma's inequality. In particular, Theorem 5.1 of Kontorovich and Ramanan (2008) shows that for a φ-mixing distribution and a 1-Lipschitz function, the constants c_i can be bounded as follows in Theorem 9:

$$c_i \leq 1+2\sum_{k=1}^{m-i}\varphi(k).$$

Theorem 9 (McDiarmid, 1989, 6.10) *Let $Z_1,\ldots,Z_m$ be arbitrary random variables taking values in Z and let $\Phi\colon Z^m\to\mathbb{R}$ be a measurable function satisfying for all $z_i,z_i'\in Z$, $i=1,\ldots,m$, the following inequalities:*

$$\left|\mathrm{E}\left[\Phi(Z_1,\ldots,Z_m)\middle|Z_1=z_1,\ldots,Z_i=z_i\right]-\mathrm{E}\left[\Phi(Z_1,\ldots,Z_m)\middle|Z_1=z_1,\ldots,Z_i=z_i'\right]\right|\leq c_i,$$

where $c_i>0$, $i=1,\ldots,m$, are constants. Then, for any $\varepsilon>0$, the following inequality holds :

$$\Pr\left[\left|\Phi(Z_1,\ldots,Z_m)-\mathrm{E}[\Phi(Z_1,\ldots,Z_m)]\right|\geq\varepsilon\right]\leq 2\exp\left(\frac{-2\varepsilon^2}{\sum_{i=1}^m c_i^2}\right).$$

In the i.i.d. case, McDiarmid's theorem can be restated in the following simpler form that we shall use in Section 4.

Theorem 10 (McDiarmid, i.i.d. scenario) *Let $Z_1,\ldots,Z_m$ be independent random variables taking values in Z and let $\Phi\colon Z^m\to\mathbb{R}$ be a measurable function satisfying for all $z_i,z_i'\in Z$, $i=1,\ldots,m$, the following inequalities:*

$$\left|\Phi(z_1,\ldots,z_i,\ldots z_m)-\Phi(z_1,\ldots,z_i',\ldots z_m)\right|\leq c_i,$$

where $c_i>0$, $i=1,\ldots,m$, are constants. Then, for any $\varepsilon>0$, the following inequality holds:

$$\Pr\left[\left|\Phi(Z_1,\ldots,Z_m)-\mathrm{E}[\Phi(Z_1,\ldots,Z_m)]\right|\geq\varepsilon\right]\leq 2\exp\left(\frac{-2\varepsilon^2}{\sum_{i=1}^m c_i^2}\right).$$

3. We should note that original bound is expressed in terms of η-mixing coefficients. To simplify presentation, we are adapting it to the case of stationary φ-mixing sequences by using the following straightforward inequality for a stationary process: $2\varphi(j-i)\geq\eta_{ij}$. Furthermore, the bound presented in Kontorovich and Ramanan (2008) holds when the sample space is countable, it is extended to the continuous case in Kontorovich (2007).

3.4 φ-Mixing Generalization Bounds

This section presents several theorems that constitute the main results of this paper in the φ-mixing case. The following theorem is constructed from the bounds shown in the previous three sections.

Theorem 11 (General Non-i.i.d. Stability Bound) *Let h_S denote the hypothesis returned by a $\widehat{\beta}$-stable algorithm trained on a sample S drawn from a φ-mixing stationary distribution and let c be a measurable non-negative cost function upper bounded by $M>0$, then for any $b \in \{0,\ldots,m\}$ and any $\varepsilon>0$, the following generalization bound holds:*

$$\Pr_S\left[\left|R(h_S)-\widehat{R}(h_S)\right| > \varepsilon + (6b+2)\widehat{\beta} + 6M\varphi(b)\right] \leq 2\exp\left(\frac{-2\varepsilon^2(1+2\sum_{i=1}^{m}\varphi(i))^{-2}}{m((b+2)2\widehat{\beta}+2M\varphi(b)+M/m)^2}\right).$$

Proof The theorem follows directly the application of Lemma 6 and Lemma 7 to Theorem 8. ■

The theorem gives a general stability bound for φ-mixing stationary sequences. If we further assume that the sequence is algebraically φ-mixing, that is for all k, $\varphi(k)=\varphi_0 k^{-r}$ for some $r>1$, then we can solve for the value of b to optimize the bound.

Theorem 12 (Non-i.i.d. Stability Bound for Algebraically Mixing Sequences) *Let h_S denote the hypothesis returned by a $\widehat{\beta}$-stable algorithm trained on a sample S drawn from an algebraically φ-mixing stationary distribution, $\varphi(k)=\varphi_0 k^{-r}$ with $r>1$, and let c be a measurable non-negative cost function upper bounded by $M>0$, then, for any $\varepsilon>0$, the following generalization bound holds:*

$$\Pr_S\left[\left|R(h_S)-\widehat{R}(h_S)\right| > \varepsilon + 8\widehat{\beta} + (r+1)6M\varphi(b)\right] \leq 2\exp\left(\frac{-2\varepsilon^2(1+2\varphi_0 r/(r-1))^{-2}}{m(6\widehat{\beta}+(r+1)2M\varphi(b)+M/m)^2}\right),$$

where $b=\left(\frac{\widehat{\beta}}{r\varphi_0 M}\right)^{-1/(r+1)}$.

Proof For an algebraically mixing sequence, the value of b minimizing the bound of Theorem 11 satisfies the equation $\widehat{\beta}b^* = rM\varphi(b^*)$. Since b must be an integer, we use the approximation $b=\left\lceil\left(\frac{\widehat{\beta}}{r\varphi_0 M}\right)^{-1/(r+1)}\right\rceil$ when applying Theorem 11. However, observing the inequalities $\varphi(b^*)\geq\varphi(b)$ and $(b^*+1)\geq b$, allows us to write the statement of Theorem 12 in terms of the fractional choice b^*.

The term in the numerator can be bounded as

$$\begin{aligned}1+2\sum_{i=1}^{m}\varphi(i) &= 1+2\sum_{i=1}^{m}\varphi_0 i^{-r}\\ &\leq 1+2\varphi_0\left(1+\int_1^m x^{-r}dx\right)\\ &= 1+2\varphi_0\left(1+\frac{m^{1-r}-1}{1-r}\right).\end{aligned}$$

Using the assumption $r > 1$, we can upper bound m^{1-r} with 1 and obtain

$$1 + 2\varphi_0 \left(1 + \frac{m^{1-r} - 1}{1-r}\right) \leq 1 + 2\varphi_0 \left(1 + \frac{1}{r-1}\right) = 1 + \frac{2\varphi_0 r}{r-1}.$$

Plugging in this value and the minimizing value of b in the bound of Theorem 11 yields the statement of the theorem. ■

In the case of a zero mixing coefficient ($\varphi = 0$ and $b = 0$), the bounds of Theorem 11 coincide with the i.i.d. stability bound of Bousquet and Elisseeff (2002).

In the general case, in order for the right-hand side of these bounds to converge, we must have $\widehat{\beta} = o(1/\sqrt{m})$ and $\varphi(b) = o(1/\sqrt{m})$. The first condition holds for several families of algorithms with $\widehat{\beta} \leq O(1/m)$ (Bousquet and Elisseeff, 2002).

In the case of algebraically mixing sequences with $r > 1$, as assumed in Theorem 12, $\widehat{\beta} \leq O(1/m)$ implies $\varphi(b) \approx \varphi_0(\widehat{\beta}/(r\varphi_0 M))^{(r/(r+1))} < O(1/\sqrt{m})$. More specifically, for the scenario of algebraic mixing with $1/m$-stability, the following bound holds with probability at least $1 - \delta$:

$$\left|R(h_S) - \widehat{R}(h_S)\right| \leq O\left(\sqrt{\frac{\log(1/\delta)}{m^{\frac{r-1}{r+1}}}}\right).$$

This is obtained by setting the right-hand side of Theorem 12 equal to δ and solving for ε. Furthermore, if we choose $\varepsilon = \sqrt{\frac{C\log(m)}{m^{(r-1)/(r+1)}}}$ for a large enough constant $C > 0$, the right-hand side of Theorem 12 is summable over m and thus, by the Borel-Cantelli lemma, the following inequality holds almost surely:

$$\left|R(h_S) - \widehat{R}(h_S)\right| \leq O\left(\sqrt{\frac{\log(m)}{m^{\frac{r-1}{r+1}}}}\right).$$

Similar bounds can be given for the exponential mixing setting ($\varphi(k) = \varphi_0 \exp(-\varphi_1 k^r)$). If we choose $b = O(\sqrt{\log(m)^3/m})$ and assume $\widehat{\beta} = O(1/m)$, then, with probability at least $1 - \delta$,

$$\left|R(h_S) - \widehat{R}(h_S)\right| \leq O\left(\sqrt{\frac{\log(1/\delta)\log^2(m)}{m}}\right).$$

If we instead set $\varepsilon = C\sqrt{\frac{\log^3(m)}{m}}$ for a large enough constant C, the right-hand side of Theorem 12 is summable and again by the Borel-Cantelli lemma we have

$$\left|R(h_S) - \widehat{R}(h_S)\right| \leq O\left(\sqrt{\frac{\log^3(m)}{m}}\right),$$

almost surely.

3.5 Applications

We now present the application of our stability bounds for algebraically φ-mixing sequences to several algorithms, including the family of kernel-based regularization algorithms and that of relative entropy-based regularization algorithms. The application of our learning bounds will benefit from the previous analysis of the stability of these algorithms by Bousquet and Elisseeff (2002).

3.5.1 KERNEL-BASED REGULARIZATION ALGORITHMS

We first apply our bounds to a family of algorithms minimizing a regularized objective function based on the norm $\|\cdot\|_K$ in a reproducing kernel Hilbert space, where K is a positive definite symmetric kernel:

$$\operatorname*{argmin}_{h\in H} \frac{1}{m}\sum_{i=1}^{m} c(h,z_i) + \lambda\|h\|_K^2. \tag{7}$$

The application of our bound is possible, under some general conditions, since kernel regularized algorithms are stable with $\widehat{\beta} \leq O(1/m)$ (Bousquet and Elisseeff, 2002). For the sake of completeness, we briefly present the proof of this $\widehat{\beta}$-stability.

We will assume that the cost function c is σ-*admissible*, that is there exists $\sigma \in \mathbb{R}_+$ such that for any two hypotheses $h, h' \in H$ and for all $z = (x,y) \in X \times Y$,

$$|c(h,z) - c(h',z)| \leq \sigma|h(x) - h'(x)|.$$

This assumption holds for the quadratic cost and most other cost functions when the hypothesis set and the set of output labels are bounded by some $M \in \mathbb{R}_+$: $\forall h \in H, \forall x \in X, |h(x)| \leq M$ and $\forall y \in Y, |y| \leq M$. We will also assume that c is differentiable. This assumption is in fact not necessary and all of our results hold without it, but it makes the presentation simpler.

We denote by B_F the Bregman divergence associated to a convex function F: $B_F(f\|g) = F(f) - F(g) - \langle f - g, \nabla F(g)\rangle$. In what follows, it will be helpful to define F as the objective function of a general regularization based algorithm,

$$F_S(h) = \widehat{R}_S(h) + \lambda N(h),$$

where $\widehat{R}_S$ is the empirical error as measured on the sample S, $N : H \to \mathbb{R}^+$ is a regularization function and $\lambda > 0$ is the familiar trade-off parameter. Finally, we shall use the shorthand $\Delta h = h' - h$.

Lemma 13 (Bousquet and Elisseeff, 2002) *A kernel-based regularization algorithm of the form (7), with bounded kernel $K(x,x) \leq \kappa < \infty$ and σ-admissible cost function, is $\widehat{\beta}$-stable with coefficient*

$$\widehat{\beta} \leq \frac{\sigma^2\kappa^2}{m\lambda}.$$

Proof Let h and h' be the minimizers of F_S and F'_S respectively where S and S' differ in the first coordinate (choice of coordinate is without loss of generality), then,

$$B_N(h'\|h) + B_N(h\|h') \leq \frac{2\sigma}{m\lambda}\sup_{x\in S}|\Delta h(x)|. \tag{8}$$

To see this, we notice that since $B_F = B_{\widehat{R}} + \lambda B_N$, and since a Bregman divergence is non-negative,

$$\lambda\big(B_N(h'\|h) + B_N(h\|h')\big) \leq B_{F_S}(h'\|h) + B_{F_{S'}}(h\|h').$$

By the definition of h and h' as the minimizers of F_S and $F_{S'}$,

$$B_{F_S}(h'\|h) + B_{F_{S'}}(h\|h') = \widehat{R}_{F_S}(h') - \widehat{R}_{F_S}(h) + \widehat{R}_{F_{S'}}(h) - \widehat{R}_{F_{S'}}(h').$$

Finally, by the σ-admissibility of the cost function c and the definition of S and S',

$$\begin{aligned}\lambda\big(B_N(h'\|h)+B_N(h\|h')\big) &\leq \widehat{R}_{F_S}(h')-\widehat{R}_{F_S}(h)+\widehat{R}_{F_{S'}}(h)-\widehat{R}_{F_{S'}}(h')\\ &= \frac{1}{m}\Big[c(h',z_1)-c(h,z_1)+c(h,z_1')-c(h',z_1')\Big]\\ &\leq \frac{1}{m}\Big[\sigma|\Delta h(x_1)|+\sigma|\Delta h(x_1')|\Big]\\ &\leq \frac{2\sigma}{m}\sup_{x\in S}|\Delta h(x)|,\end{aligned}$$

which establishes (8).

Now, if we consider $N(\cdot)=\|\cdot\|_K^2$, we have $B_N(h'\|h)=\|h'-h\|_K^2$, thus $B_N(h'\|h)+B_N(h\|h')=2\|\Delta h\|_K^2$ and by (8) and the reproducing kernel property,

$$\begin{aligned}2\|\Delta h\|_K^2 &\leq \frac{2\sigma}{m\lambda}\sup_{x\in S}|\Delta h(x)|\\ &\leq \frac{2\sigma}{m\lambda}\kappa||\Delta h||_K.\end{aligned}$$

Thus $\|\Delta h\|_K \leq \frac{\sigma\kappa}{m\lambda}$. And using the σ-admissibility of c and the kernel reproducing property we obtain

$$\forall z\in X\times Y, |c(h',z)-c(h,z)|\leq \sigma|\Delta h(x)|\leq \kappa\sigma\|\Delta h\|_K.$$

Therefore,

$$\forall z\in X\times Y, |c(h',z)-c(h,z)|\leq \frac{\sigma^2\kappa^2}{m\lambda},$$

which completes the proof. ■

Three specific instances of kernel regularization algorithms are SVR, for which the cost function is based on the ε-insensitive cost:

$$c(h,z)=\begin{cases}0 & \text{if } |h(x)-y|\leq\varepsilon,\\ |h(x)-y|-\varepsilon & \text{otherwise.}\end{cases}$$

Kernel Ridge Regression (Saunders et al., 1998), for which

$$c(h,z)=(h(x)-y)^2\,,$$

and finally Support Vector Machines with the hinge-loss,

$$c(h,z)=\begin{cases}0 & \text{if } 1-yh(x)\leq 0,\\ 1-yh(x) & \text{if } yh(x)<1,\end{cases}$$

For kernel regularization algorithms, as pointed out in Bousquet and Elisseeff (2002, Lemma 23), a bound on the labels immediately implies a bound on the output of the hypothesis returned by the algorithm. We formally state this lemma below.

Lemma 14 *Let h^* be the solution of the optimization problem (7), let c be a cost function and let $B(\cdot)$ be a real-valued function such that for all $h \in H$, $x \in X$, and $y' \in Y$,*

$$c(h(x), y') \leq B(h(x)).$$

Then, the output of h^* is bounded as follows,

$$\forall x \in X, |h^*(x)| \leq \kappa \sqrt{\frac{B(0)}{\lambda}},$$

where λ is the regularization parameter, and $\kappa^2 \geq K(x,x)$ for all $x \in X$.

Proof Let $F(h) = \frac{1}{m} \sum_{i=1}^{m} c(h, z_i) + \lambda \|h\|_K^2$ and let $\mathbf{0}$ be the zero hypothesis, then by definition of F and h^*,

$$\lambda \|h^*\|_K^2 \leq F(h^*) \leq F(\mathbf{0}) \leq B(0).$$

Then, using the reproducing kernel property and the Cauchy-Schwarz inequality we note,

$$\forall x \in X, |h^*(x)| = \langle h^*, K(x, \cdot) \rangle \leq \|h^*\|_K \sqrt{K(x,x)} \leq \kappa \|h^*\|_K.$$

Combining the two inequalities proves the lemma. ■

We note that in Bousquet and Elisseeff (2002), the following bound is also stated: $c(h^*(x), y') \leq B(\kappa \sqrt{B(0)/\lambda})$. However, when later applied, it seems that the authors use an incorrect upper bound function $B(\cdot)$, which we remedy in the following.

Corollary 15 *Assume a bounded output $Y = [0, B]$, for some $B > 0$, and assume that $K(x,x) \leq \kappa^2$ for all x for some $\kappa > 0$. Let h_S denote the hypothesis returned by the algorithm when trained on a sample S drawn from an algebraically φ-mixing stationary distribution. Let $u = r/(r+1) \in [\frac{1}{2}, 1]$, $M' = 2(r+1)\varphi_0 M/(r\varphi_0 M)^u$, and $\varphi_0' = (1 + 2\varphi_0 r/(r-1))$. Then, with probability at least $1-\delta$, the following generalization bounds hold for*

a. Support Vector Machines (SVM, with hinge-loss)

$$R(h_S) \leq \widehat{R}(h_S) + \frac{8\kappa^2}{\lambda m} + \left(\frac{2\kappa^2}{\lambda}\right)^u \frac{3M'}{m^u} + \varphi_0' \left(M + \frac{3\kappa^2}{\lambda} + \left(\frac{2\kappa^2}{\lambda}\right)^u \frac{M'}{m^{u-1}}\right) \sqrt{\frac{2\log(2/\delta)}{m}},$$

where $M = \kappa \sqrt{\frac{1}{\lambda}} + B$.

b. Support Vector Regression (SVR):

$$R(h_S) \leq \widehat{R}(h_S) + \frac{8\kappa^2}{\lambda m} + \left(\frac{2\kappa^2}{\lambda}\right)^u \frac{3M'}{m^u} + \varphi_0' \left(M + \frac{3\kappa^2}{\lambda} + \left(\frac{2\kappa^2}{\lambda}\right)^u \frac{M'}{m^{u-1}}\right) \sqrt{\frac{2\log(2/\delta)}{m}},$$

where $M = \kappa \sqrt{\frac{2B}{\lambda}} + B$.

c. Kernel Ridge Regression (KRR):

$$R(h_S) \leq \widehat{R}(h_S) + \frac{32\kappa^2 B^2}{\lambda m} + \left(\frac{8\kappa^2 B^2}{\lambda}\right)^u \frac{3M'}{m^u} + \varphi_0'\left(M + \frac{12\kappa^2 B^2}{\lambda} + \left(\frac{8\kappa^2 B^2}{\lambda}\right)^u \frac{M'}{m^{u-1}}\right)\sqrt{\frac{2\log(2/\delta)}{m}},$$

where $M = 2\kappa^2 B^2/\lambda + B^2$.

Proof For SVM, the hinge-loss is 1-admissible giving $\widehat{\beta} \leq \kappa^2/(\lambda m)$. Using Lemma 14, with $B(0) = 1$, the loss can be bounded $\forall x \in X, y \in Y, 1 + |h^*(x)| \leq \kappa\sqrt{\frac{1}{\lambda}} + B$.

Similarly, SVR has a loss function that is 1-admissible, thus, applying Lemma 13 gives us $\widehat{\beta} \leq \kappa^2/(\lambda m)$. Using Lemma 14, with $B(0) = B$, we can bound the loss as follows, $\forall x \in X, y \in Y, |h^*(x) - y| \leq \kappa\sqrt{\frac{B}{\lambda}} + B$.

Finally for KRR, we have a loss function that is $2B$-admissible and again using Lemma 13 $\widehat{\beta} \leq 4\kappa^2 B^2/(\lambda m)$. Again, applying Lemma 14 with $B(0) = B^2$ and $\forall x \in X, y \in Y, (h^*(x) - y)^2 \leq \kappa^2 B^2/\lambda + B^2$.

Plugging these values into the bound of Theorem 12 and setting the right-hand side to δ yields the statement of the corollary. ■

3.5.2 RELATIVE ENTROPY-BASED REGULARIZATION ALGORITHMS

In this section, we apply the results of Theorem 12 to a family of learning algorithms based on relative entropy-regularization. These algorithms learn hypotheses h that are mixtures of base hypotheses in $\{h_\theta : \theta \in \Theta\}$, where Θ is measurable set. The output of these algorithms is a mixture $g : \Theta \to \mathbb{R}$, that is a distribution over Θ. Let G denote the set of all such distributions and let $g_0 \in G$ be a fixed distribution. Relative entropy based-regularization algorithms output the solution of a minimization problem of the following form:

$$\operatorname*{argmin}_{g \in G} \frac{1}{m}\sum_{i=1}^{m} c(g, z_i) + \lambda D(g\|g_0), \tag{9}$$

where the cost function $c : G \times Z \to \mathbb{R}$ is defined in terms of a second internal cost function $c' : H \times Z \to \mathbb{R}$:

$$c(g, z) = \int_\Theta c'(h_\theta, z) g(\theta) d\theta,$$

and where $D(g\|g_0)$ is the relative entropy between g and g_0:

$$D(g\|g_0) = \int_\Theta g(\theta) \log \frac{g(\theta)}{g_0(\theta)} d\theta.$$

As shown by Bousquet and Elisseeff (2002, Theorem 24), a relative entropy-based regularization algorithm defined by (9) with bounded loss $c'(\cdot) \leq M$, is $\widehat{\beta}$-stable with the following bound on the stability coefficient:

$$\widehat{\beta} \leq \frac{M^2}{\lambda m}.$$

Theorem 12 combined with this inequality immediately yields the following generalization bound.

Corollary 16 *Let h_S be the hypothesis solution of the optimization (9) trained on a sample S drawn from an algebraically φ-mixing stationary distribution with the internal cost function c' bounded by M. Then, with probability at least $1-\delta$, the following holds:*

$$R(h_S) \leq \widehat{R}(h_S) + \frac{8M^2}{\lambda m} + \frac{3M'}{\lambda^u m^u} + \varphi_0' \left(M + \frac{3M^2}{\lambda} + \frac{2^u M'}{\lambda^u m^{u-1}} \right) \sqrt{\frac{2\log(2/\delta)}{m}},$$

where $u = r/(r+1) \in [\frac{1}{2}, 1]$, $M' = 2(r+1)\varphi_0 M^{u+1}/(r\varphi_0)^u$, and $\varphi_0' = (1 + 2\varphi_0 r/(r-1))$.

3.6 Discussion

The results presented here are, to the best of our knowledge, the first stability-based generalization bounds for the class of algorithms just studied in a non-i.i.d. scenario. These bounds are non-trivial when the condition on the regularization parameter $\lambda \gg 1/m^{1/2-1/r}$ parameter holds for all large values of m. This condition coincides with the one obtained in the i.i.d. setting by Bousquet and Elisseeff (2002), in the limit, as r tends to infinity. The next section gives stability-based generalization bounds that hold even in the scenario of β-mixing sequences.

4. β-Mixing Generalization Bounds

In this section, we prove a stability-based generalization bound that only requires the training sequence to be drawn from a β-mixing stationary distribution. The bound is thus more general and covers the φ-mixing case analyzed in the previous section. However, unlike the φ-mixing case, the β-mixing bound presented here is not a purely exponential bound. It contains an additive term, which depends on the mixing coefficient.

As in the previous section, $\Phi(S)$ is defined by $\Phi(S) = R(h_S) - \widehat{R}(h_S)$. To simplify the presentation, here, we define the generalization error of h_S by $R(h_S) = \mathrm{E}_z[c(h_S, z)]$. Thus, test samples are assumed independent of S.[4] Note that for any block of points $Z = z_1 \ldots z_k$ drawn independently of S, the following equality holds:

$$\mathop{\mathrm{E}}_{Z}\left[\frac{1}{|Z|}\sum_{z\in Z} c(h_S, z)\right] = \frac{1}{k}\sum_{i=1}^{k} \mathop{\mathrm{E}}_{Z}[c(h_S, z_i)] = \frac{1}{k}\sum_{i=1}^{k} \mathop{\mathrm{E}}_{z_i}[c(h_S, z_i)] = \mathop{\mathrm{E}}_{z}[c(h_S, z)]$$

since, by stationarity, $\mathrm{E}_{z_i}[c(h_S, z_i)] = \mathrm{E}_{z_j}[c(h_S, z_j)]$ for all $1 \leq i, j \leq k$. Thus, for any such block Z, we can write $R(h_S) = \mathrm{E}_Z\left[\frac{1}{|Z|}\sum_{z\in Z} c(h_S, z)\right]$. For convenience, we extend the cost function c to blocks as follows:

$$c(h, Z) = \frac{1}{|Z|}\sum_{z\in Z} c(h, z).$$

With this notation, $R(h_S) = \mathrm{E}_Z[c(h_S, Z)]$ for any block drawn independently of S, regardless of the size of Z.

To derive a generalization bound for the β-mixing scenario, we apply McDiarmid's inequality (Theorem 10) to Φ defined over a sequence of independent blocks. The independent blocks we consider are non-symmetric and thus more general than those considered by previous authors (Yu, 1994; Meir, 2000).

4. In the β-mixing scenario, a result similar to that of Lemma 5 can be shown to hold in expectation with respect the sample S. Using Markov's inequality, the inequality can be shown to hold with high probability. Thus, the results that follow can all be be extended to the case where the test points depend on the training sample, at the expense of an an additional confidence term.

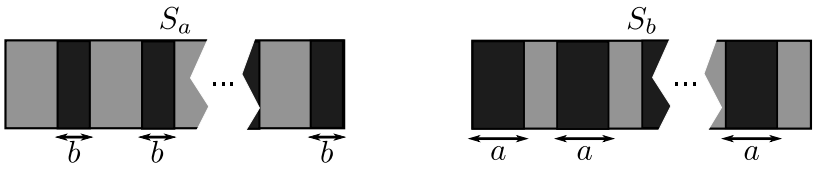

Figure 3: Illustration of the sequences S_a and S_b derived from S that are considered in the proofs. The darkened regions are considered as being removed from the sequence.

From a sample S made of a sequence of m points, we construct two sequences of blocks S_a and S_b, each containing μ blocks. Each block in S_a contains a points and each block in S_b contains b points (see Figure 3). S_a and S_b form a partitioning of S; for any $a,b \in \{0,\ldots,m\}$ such that $(a+b)\mu = m$, they are defined precisely as follows:

$$S_a = (Z_1^{(a)},\ldots,Z_\mu^{(a)}), \text{ with } Z_i^{(a)} = z_{(i-1)(a+b)+1},\ldots,z_{(i-1)(a+b)+a}$$
$$S_b = (Z_1^{(b)},\ldots,Z_\mu^{(b)}), \text{ with } Z_i^{(b)} = z_{(i-1)(a+b)+a+1},\ldots,z_{(i-1)(a+b)+a+b},$$

for all $i \in \{1,\ldots,\mu\}$. We shall consider similarly sequences of i.i.d. blocks $\widetilde{Z}_i^a$ and $\widetilde{Z}_i^b$, $i \in \{1,\ldots,\mu\}$, such that the points within each block are drawn according to the same original β-mixing distribution and shall denote by $\widetilde{S}_a$ the block sequence $(\widetilde{Z}_1^{(a)},\ldots,\widetilde{Z}_\mu^{(a)})$.

In preparation for the application of McDiarmid's inequality, we give a bound on the expectation of $\Phi(\widetilde{S}_a)$. Since the expectation is taken over a sequence of i.i.d. blocks, this brings us to a situation similar to the i.i.d. scenario analyzed by Bousquet and Elisseeff (2002), with the exception that we are dealing with i.i.d. blocks instead of i.i.d. points.

Lemma 17 *Let $\widetilde{S}_a$ be an independent block sequence as defined above, then the following bound holds for the expectation of $|\Phi(\widetilde{S}_a)|$:*

$$\mathop{\mathrm{E}}_{\widetilde{S}_a}[|\Phi(\widetilde{S}_a)|] \leq 2a\widehat{\beta}.$$

Proof Since the blocks $\widetilde{Z}^{(a)}$ are independent, we can replace any one of them with any other block Z drawn from the same distribution. However, changing the training set also changes the hypothesis, in a limited way. This is shown precisely below:

$$\begin{aligned}
\mathop{\mathrm{E}}_{\widetilde{S}_a}[|\Phi(\widetilde{S}_a)|] &= \mathop{\mathrm{E}}_{\widetilde{S}_a}\left[\left|\frac{1}{\mu}\sum_{i=1}^{\mu} c(h_{\widetilde{S}_a},\widetilde{Z}_i^{(a)}) - \mathop{\mathrm{E}}_{Z}[c(h_{\widetilde{S}_a},Z)]\right|\right] \\
&\leq \mathop{\mathrm{E}}_{\widetilde{S}_a,Z}\left[\left|\frac{1}{\mu}\sum_{i=1}^{\mu} c(h_{\widetilde{S}_a},\widetilde{Z}_i^{(a)}) - c(h_{\widetilde{S}_a},Z)\right|\right] \\
&= \mathop{\mathrm{E}}_{\widetilde{S}_a,Z}\left[\left|\frac{1}{\mu}\sum_{i=1}^{\mu} c(h_{\widetilde{S}_a^i},Z) - c(h_{\widetilde{S}_a},Z)\right|\right],
\end{aligned}$$

where $\widetilde{S}_a^i$ corresponds to the block sequence $\widetilde{S}_a$ obtained by replacing the ith block with Z. The $\widehat{\beta}$-stability of the learning algorithm gives

$$\mathop{\mathrm{E}}_{\widetilde{S}_a,Z}\left[\frac{1}{\mu}\Big|\sum_{i=1}^{\mu} c(h_{\widetilde{S}_a^i},Z) - c(h_{\widetilde{S}_a},Z)\Big|\right] \leq \mathop{\mathrm{E}}_{\widetilde{S}_a,Z}\left[\frac{1}{\mu}\sum_{i=1}^{\mu} 2a\widehat{\beta}\right] \leq 2a\widehat{\beta}.$$

■

We now relate the non-i.i.d. event $\Pr[\Phi(S) \geq \varepsilon]$ to an independent block sequence event to which we can apply McDiarmid's inequality.

Lemma 18 *Assume a $\widehat{\beta}$-stable algorithm. Then, for a sample S drawn from a β-mixing stationary distribution, the following bound holds:*

$$\Pr_S[|\Phi(S)| \geq \varepsilon] \leq \Pr_{\widetilde{S}_a}\left[|\Phi(\widetilde{S}_a)| - \mathrm{E}[|\Phi(\widetilde{S}_a)|] \geq \varepsilon_0'\right] + (\mu-1)\beta(b),$$

where $\varepsilon_0' = \varepsilon - \frac{\mu b M}{m} - 2\mu b\widehat{\beta} - \mathrm{E}_{\widetilde{S}_a'}[|\Phi(\widetilde{S}_a')|]$.

Proof The proof consists of first rewriting the event in terms of S_a and S_b and bounding the error on the points in S_b in a trivial manner. This can be afforded since b will be eventually chosen to be small. Since $|\mathrm{E}_{Z'}[c(h_S,Z')] - c(h_S,z')| \leq M$ for any $z' \in S_b$, we can write

$$\begin{aligned}
\Pr_S[|\Phi(S)| \geq \varepsilon] &= \Pr_S[|R(h_S) - \widehat{R}(h_S)| \geq \varepsilon] \\
&= \Pr_S\left[\frac{1}{m}\Big|\sum_{z\in S}\mathop{\mathrm{E}}_{Z}[c(h_S,Z)] - c(h_S,z)\Big| \geq \varepsilon\right] \\
&\leq \Pr_S\left[\frac{1}{m}\Big|\sum_{z\in S_a}\mathop{\mathrm{E}}_{Z}[c(h_S,Z)] - c(h_S,z)\Big| + \frac{1}{m}\Big|\sum_{z'\in S_b}\mathop{\mathrm{E}}_{Z'}[c(h_S,Z')] - c(h_S,z')\Big| \geq \varepsilon\right] \\
&\leq \Pr_S\left[\frac{1}{m}\Big|\sum_{z\in S_a}\mathop{\mathrm{E}}_{Z}[c(h_S,Z)] - c(h_S,z)\Big| + \frac{\mu b M}{m} \geq \varepsilon\right].
\end{aligned}$$

By $\widehat{\beta}$-stability and $\mu a/m \leq 1$, this last term can be bounded as follows

$$\begin{aligned}
&\Pr_S\left[\frac{1}{m}\Big|\sum_{z\in S_a}\mathop{\mathrm{E}}_{Z}[c(h_S,Z)] - c(h_S,z)\Big| + \frac{\mu b M}{m} \geq \varepsilon\right] \leq \\
&\qquad\qquad \Pr_{S_a}\left[\frac{1}{\mu a}\Big|\sum_{z\in S_a}\mathop{\mathrm{E}}_{Z}[c(h_{S_a},Z)] - c(h_{S_a},z)\Big| + \frac{\mu b M}{m} + 2\mu b\widehat{\beta} \geq \varepsilon\right].
\end{aligned}$$

The right-hand side can be rewritten in terms of Φ and bounded in terms of a β-mixing coefficient:

$$\begin{aligned}
&\Pr_{S_a}\left[\frac{1}{\mu a}\Big|\sum_{z\in S_a}\mathop{\mathrm{E}}_{Z}[c(h_{S_a},Z)] - c(h_{S_a},z)\Big| + \frac{\mu b M}{m} + 2\mu b\widehat{\beta} \geq \varepsilon\right] \\
&\qquad\qquad = \Pr_{S_a}\left[|\Phi(S_a)| + \frac{\mu b M}{m} + 2\mu b\widehat{\beta} \geq \varepsilon\right] \\
&\qquad\qquad \leq \Pr_{\widetilde{S}_a}\left[|\Phi(\widetilde{S}_a)| + \frac{\mu b M}{m} + 2\mu b\widehat{\beta} \geq \varepsilon\right] + (\mu-1)\beta(b),
\end{aligned}$$

by applying Lemma 3 to the indicator function of the event $\left\{|\Phi(S_a)| + \frac{\mu b M}{m} + 2\mu b\widehat{\beta} \geq \varepsilon\right\}$. Since $\mathrm{E}_{\widetilde{S}'_a}[|\Phi(\widetilde{S}'_a)|]$ is a constant, the probability in this last term can be rewritten as

$$\begin{aligned}
&\Pr_{\widetilde{S}_a}\left[|\Phi(\widetilde{S}_a)| + \frac{\mu b M}{m} + 2\mu b\widehat{\beta} \geq \varepsilon\right] \\
&\qquad = \Pr_{\widetilde{S}_a}\left[|\Phi(\widetilde{S}_a)| - \mathrm{E}_{\widetilde{S}'_a}[|\Phi(\widetilde{S}'_a)|] + \frac{\mu b M}{m} + 2\mu b\widehat{\beta} \geq \varepsilon - \mathrm{E}_{\widetilde{S}'_a}[|\Phi(\widetilde{S}'_a)|]\right] \\
&\qquad = \Pr_{\widetilde{S}_a}\left[|\Phi(\widetilde{S}_a)| - \mathrm{E}_{\widetilde{S}'_a}[|\Phi(\widetilde{S}'_a)|] \geq \varepsilon'_0\right],
\end{aligned}$$

which ends the proof of the lemma. ■

The last two lemmas will help us prove the main result of this section formulated in the following theorem.

Theorem 19 *Assume a $\widehat{\beta}$-stable algorithm and let ε' denote $\varepsilon - \frac{\mu b M}{m} - 2\mu b\widehat{\beta} - 2a\widehat{\beta}$ as in Lemma 18. Then, for any sample S of size m drawn according to a β-mixing stationary distribution, any choice of the parameters $a, b, \mu > 0$ such that $(a+b)\mu = m$, and $\varepsilon \geq 0$ such that $\varepsilon' \geq 0$, the following generalization bound holds:*

$$\Pr_{S}\left[|R(h_S) - \widehat{R}(h_S)| \geq \varepsilon\right] \leq \exp\left(\frac{-2\varepsilon'^2 m}{\left(4a\widehat{\beta}m + (a+b)M\right)^2}\right) + (\mu - 1)\beta(b).$$

Proof To prove the statement of theorem, it suffices to bound the probability term appearing in the right-hand side of Equation 18, $\Pr_{\widetilde{S}_a}\left[|\Phi(\widetilde{S}_a)| - \mathrm{E}[|\Phi(\widetilde{S}_a)|] \geq \varepsilon'_0\right]$, which is expressed only in terms of independent blocks. We can therefore apply McDiarmid's inequality by viewing the blocks as i.i.d. "points".

To do so, we must bound the quantity $\left||\Phi(\widetilde{S}_a)| - |\Phi(\widetilde{S}^i_a)|\right|$ where the sequence S_a and S^i_a differ in the ith block. We will bound separately the difference between the generalization errors and empirical errors.[5] The difference in empirical errors can be bounded as follows using the bound on the cost function c:

$$\begin{aligned}
|\widehat{R}(h_{S_a}) - \widehat{R}(h_{S^i_a})| &= \left|\frac{1}{\mu}\left[\sum_{j\neq i} c(h_{S_a}, Z_j) - c(h_{S^i_a}, Z_j)\right] + \frac{1}{\mu}\left[c(h_{S_a}, Z_i) - c(h_{S^i_a}, Z'_i)\right]\right| \\
&\leq 2a\widehat{\beta} + \frac{M}{\mu} = 2a\widehat{\beta} + \frac{(a+b)M}{m}.
\end{aligned}$$

The difference in generalization error can be straightforwardly bounded using $\widehat{\beta}$-stability:

$$|R(h_{S_a}) - R(h_{S^i_a})| = |\mathrm{E}_Z[c(h_{S_a}, Z)] - \mathrm{E}_Z[c(h_{S^i_a}, Z)]| = |\mathrm{E}_Z[c(h_{S_a}, Z) - c(h_{S^i_a}, Z)]| \leq 2a\widehat{\beta}.$$

5. We drop the superscripts on $Z^{(a)}$ since we will not be considering the sequence S_b in what follows.

Using these bounds in conjunction with McDiarmid's inequality yields

$$\Pr_{\widetilde{S}_a}[|\Phi(\widetilde{S}_a)| - \mathop{\mathrm{E}}_{\widetilde{S}'_a}[|\Phi(\widetilde{S}'_a)|] \geq \varepsilon'_0] \leq \exp\left(\frac{-2\varepsilon'^2_0 m}{\left(4a\widehat{\beta}m + (a+b)M\right)^2}\right)$$
$$\leq \exp\left(\frac{-2\varepsilon'^2 m}{\left(4a\widehat{\beta}m + (a+b)M\right)^2}\right).$$

Note that to show the second inequality we make use of Lemma 17 to establish the fact that

$$\varepsilon'_0 = \varepsilon - \frac{\mu b M}{m} - 2\mu b\widehat{\beta} - \mathop{\mathrm{E}}_{\widetilde{S}'_a}[|\Phi(\widetilde{S}'_a)|] \geq \varepsilon - \frac{\mu b M}{m} - 2\mu b\widehat{\beta} - 2a\widehat{\beta} = \varepsilon'.$$

Finally, we make use of Lemma 18 to establish the proof,

$$\Pr_S[|\Phi(S)| \geq \varepsilon] \leq \Pr_{\widetilde{S}_a}\left[|\Phi(\widetilde{S}_a)| - \mathrm{E}[|\Phi(\widetilde{S}_a)|] \geq \varepsilon'_0\right] + (\mu-1)\beta(b)$$
$$\leq \exp\left(\frac{-2\varepsilon'^2 m}{\left(4a\widehat{\beta}m + (a+b)M\right)^2}\right) + (\mu-1)\beta(b).$$

This concludes the proof of the theorem. ■

In order to make use of this bound, we must determine the values of parameters b and μ (a is then equal to $\mu/m - u$). There is a trade-off between selecting a large enough value for b to ensure that the mixing term decreases and choosing a large enough value of μ to minimize the remaining terms of the bound. The exact choice of parameters will depend on the type of mixing that is assumed (e.g., algebraic or exponential). In order to choose optimal parameters, it will be useful to view the bound as it holds with high probability, in the following corollary.

Corollary 20 *Assume a $\widehat{\beta}$-stable algorithm and let δ' denote $\delta - (\mu-1)\beta(b)$. Then, for any sample S of size m drawn according to a β-mixing stationary distribution, any choice of the parameters $a, b, \mu > 0$ such that $(a+b)\mu = m$, and $\delta \geq 0$ such that $\delta' \geq 0$, the following generalization bound holds with probability at least $(1-\delta)$:*

$$|R(h_S) - \widehat{R}(h_S)| < \mu b\left(\frac{M}{m} + 2\widehat{\beta}\right) + 2a\widehat{\beta}\left(4a\widehat{\beta}m + M\frac{m}{\mu}\right)\sqrt{\frac{\log(1/\delta')}{2m}}.$$

In the case of a fast mixing distribution, it is possible to select the values of the parameters to retrieve a bound as in the i.i.d. case, that is, $|R(h_S) - \widehat{R}(h_S)| = O\left(m^{-\frac{1}{2}}\sqrt{\log 1/\delta}\right)$. In particular, for $\beta(b) \equiv 0$, we can choose $a = 0$, $b = 1$, and $\mu = m$ to retrieve the i.i.d. bound of Bousquet and Elisseeff (2001).

In the following, we examine slower mixing algebraic β-mixing distributions, which are thus not close to the i.i.d. scenario. For algebraic mixing, the mixing parameter is defined as $\beta(b) = b^{-r}$. In that case, we wish to minimize the following function in terms of μ and b:

$$s(\mu, b) = \frac{\mu}{b^r} + \frac{m^{3/2}\widehat{\beta}}{\mu} + \frac{m^{1/2}}{\mu} + \mu b\left(\frac{1}{m} + \widehat{\beta}\right). \tag{10}$$

The first term of the function captures the condition $\delta > (\mu+1)\beta(b) \approx \mu/b^r$ and the remaining terms capture the shape of the bound in Corollary 20.

Setting the derivative with respect to each variable μ and b to zero and solving for each parameter results in the following expressions:

$$b = C_r \gamma^{-\frac{1}{r+1}} \qquad \mu = \frac{m^{3/4}\gamma^{\frac{1}{2(r+1)}}}{\sqrt{C_r(1+1/r)}},$$

where $\gamma = (m^{-1} + \widehat{\beta})$ and $C_r = r^{\frac{1}{r+1}}$ is a constant defined by the parameter r.

Now, assuming $\widehat{\beta} = O(m^{-\alpha})$ for some $0 < \alpha \leq 1$, we analyze the convergence behavior of Corollary 20. First, we observe that the terms b and μ have the following asymptotic behavior,

$$b = O\left(m^{\frac{\alpha}{r+1}}\right) \qquad \mu = O\left(m^{\frac{3}{4}-\frac{\alpha}{2(r+1)}}\right).$$

Next, we consider the condition $\delta' > 0$ which is equivalent to,

$$\delta > (\mu-1)\beta(b) = O\left(m^{\frac{3}{4}-\alpha\left(1-\frac{1}{2(r+1)}\right)}\right). \tag{11}$$

In order for the right-hand side of the inequality to converge, it must be the case that $\alpha > \frac{3r+3}{4r+2}$. In particular, if $\alpha = 1$, as is the case for several algorithms in Section 3.5, then it suffices that $r > 1$.

Finally, in order to see how the bound itself converges, we study the asymptotic behavior of the terms of Equation 10 (without the first term, which corresponds to the quantity already analyzed in Equation 11):

$$\underbrace{\frac{m^{3/2}\widehat{\beta}}{\mu} + \mu b\widehat{\beta}}_{(a)} + \underbrace{\frac{m^{1/2}}{\mu} + \frac{\mu b}{m}}_{(b)} = O\left(\underbrace{m^{\frac{3}{4}-\alpha\left(1-\frac{1}{2(r+1)}\right)}}_{(a)} \underbrace{+ m^{\frac{\alpha}{2(r+1)}-\frac{1}{4}}}_{(b)}\right).$$

This expression can be further simplified by noticing that $(b) \leq (a)$ for all $0 < \alpha \leq 1$ (with equality at $\alpha = 1$). Thus, both the bound and the condition on δ decrease asymptotically as the term in (a), resulting in the following corollary.

Corollary 21 *Assume a $\widehat{\beta}$-stable algorithm with $\widehat{\beta} = O(m^{-1})$ and let $\delta' = \delta - m^{\frac{1}{2(r+1)}-\frac{1}{4}}$. Then, for any sample S of size m drawn according to a algebraic β-mixing stationary distribution, and $\delta \geq 0$ such that $\delta' \geq 0$, the following generalization bound holds with probability at least $(1-\delta)$:*

$$|R(h_S) - \widehat{R}(h_S)| < O\left(m^{\frac{1}{2(r+1)}-\frac{1}{4}}\sqrt{\log(1/\delta')}\right).$$

As in previous bounds $r > 1$ is required for convergence. Furthermore, as expected, a larger mixing parameter r leads to a more favorable bound.

5. Conclusion

We presented stability bounds for both φ-mixing and β-mixing stationary sequences. Our bounds apply to large classes of algorithms, including common algorithms such as SVR, KRR, and SVMs, and extend to non-i.i.d. scenarios existing i.i.d. stability bounds. Since they are algorithm-specific, these bounds can often be tighter than other generalization bounds based on general complexity measures for families of hypotheses. As in the i.i.d. case, weaker notions of stability might help further improve and refine these bounds. These stability bounds complement general data-dependent learning bounds we have shown elsewhere for stationary β-mixing sequences using the notion of Rademacher complexity (Mohri and Rostamizadeh, 2009).

The stability bounds we presented can be used to analyze the properties of stable algorithms when used in the non-i.i.d settings studied. But, more importantly, they can serve as a tool for the design of novel and accurate learning algorithms. Of course, some mixing properties of the distributions need to be known to take advantage of the information supplied by our generalization bounds. In some problems, it is possible to estimate the shape of the mixing coefficients. This should help devising such algorithms.

Abstract

Maximum entropy (Maxent) is useful in natural language processing and many other areas. Iterative scaling (IS) methods are one of the most popular approaches to solve Maxent. With many variants of IS methods, it is difficult to understand them and see the differences. In this paper, we create a general and unified framework for iterative scaling methods. This framework also connects iterative scaling and coordinate descent methods. We prove general convergence results for IS methods and analyze their computational complexity. Based on the proposed framework, we extend a coordinate descent method for linear SVM to Maxent. Results show that it is faster than existing iterative scaling methods.

Keywords: maximum entropy, iterative scaling, coordinate descent, natural language processing, optimization

1. Introduction

Maximum entropy (Maxent) is widely used in many areas such as natural language processing (NLP) and document classification. It is suitable for problems needing probability interpretations. For many NLP tasks, given a word sequence, we can use Maxent models to predict the label sequence with the maximal probability (Berger et al., 1996). Such tasks are different from traditional classification problems, which assign label(s) to a single instance.

Maxent models the conditional probability as:

$$\begin{aligned} &P_{\mathbf{w}}(y|x) \equiv \frac{S_{\mathbf{w}}(x,y)}{T_{\mathbf{w}}(x)}, \\ &S_{\mathbf{w}}(x,y) \equiv e^{\sum_t w_t f_t(x,y)},\ T_{\mathbf{w}}(x) \equiv \sum_y S_{\mathbf{w}}(x,y), \end{aligned} \tag{1}$$

where x indicates a context, y is the label of the context, and $\mathbf{w} \in R^n$ is the weight vector. A real-valued function $f_t(x,y)$ denotes the t-th feature extracted from the context x and the label y. We assume a finite number of features. In some cases, $f_t(x,y)$ is 0/1 to indicate a particular property. $T_{\mathbf{w}}(x)$ is a normalization term applied to make $\sum_y P_{\mathbf{w}}(y|x) = 1$.

Given an empirical probability distribution $\tilde{P}(x,y)$ obtained from training samples, Maxent minimizes the following negative log-likelihood:

$$\min_{\mathbf{w}} \; -\sum_{x,y} \tilde{P}(x,y) \log P_{\mathbf{w}}(y|x),$$

or equivalently,

$$\min_{\mathbf{w}} \; \sum_{x} \tilde{P}(x) \log T_{\mathbf{w}}(x) - \sum_{t} w_t \tilde{P}(f_t), \tag{2}$$

where $\tilde{P}(x,y) = N_{x,y}/N$, $N_{x,y}$ is the number of times that (x,y) occurs in training data, and N is the total number of training samples. $\tilde{P}(x) = \sum_y \tilde{P}(x,y)$ is the marginal probability of x, and $\tilde{P}(f_t) = \sum_{x,y} \tilde{P}(x,y) f_t(x,y)$ is the expected value of $f_t(x,y)$. To avoid overfitting the training samples, some add a regularization term to (2) and solve:

$$\min_{\mathbf{w}} \; L(\mathbf{w}) \equiv \min_{\mathbf{w}} \; \sum_{x} \tilde{P}(x) \log T_{\mathbf{w}}(x) - \sum_{t} w_t \tilde{P}(f_t) + \frac{1}{2\sigma^2} \sum_{t} w_t^2, \tag{3}$$

where σ is a regularization parameter. More discussion about regularization terms for Maxent can be seen in, for example, Chen and Rosenfeld (2000). We focus on (3) in this paper because it is strictly convex. Note that (2) is convex, but may not be strictly convex. We can further prove that a unique global minimum of (3) exists. The proof, omitted here, is similar to Theorem 1 in Lin et al. (2008).

Iterative scaling (IS) methods are popular in training Maxent models. They all share the same property of *solving a one-variable sub-problem at a time*. Existing IS methods include generalized iterative scaling (GIS) by Darroch and Ratcliff (1972), improved iterative scaling (IIS) by Della Pietra et al. (1997), and sequential conditional generalized iterative scaling (SCGIS) by Goodman (2002). The approach by Jin et al. (2003) is also an IS method, but it assumes that every class uses the same set of features. As this assumption is not general, in this paper we do not include this approach for discussion. In optimization, coordinate descent (CD) is a popular method which also solves a one-variable sub-problem at a time. With these many IS and CD methods, it is difficult to see their differences. In Section 2, we propose a unified framework to describe IS and CD methods from an optimization viewpoint. We further analyze the theoretical convergence as well as computational complexity of IS and CD methods. In particular, general linear convergence is proved. In Section 3, based on a comparison between IS and CD methods, we propose a new and more efficient CD method. These two results (a unified framework and a faster CD method) are the main contributions of this paper.

Besides IS methods, numerous optimization methods have been applied to train Maxent. For example, Liu and Nocedal (1989), Bottou (2004), Daumé (2004), Keerthi et al. (2005), McDonald and Pereira (2006), Vishwanathan et al. (2006), Koh et al. (2007), Genkin et al. (2007), Andrew and Gao (2007), Schraudolph et al. (2007), Gao et al. (2007), Collins et al. (2008), Lin et al. (2008) and Friedman et al. (2008). They do not necessarily solve the optimization problem (3). Some handle more complicated log linear models such as Conditional Random Fields (CRF), but their approaches can be modified for Maxent. Some focus on logistic regression, which is a special form of Maxent if the number of labels is two. Moreover, some consider the L1 regularization term $\sum_t |w_t|$ in (3). Several papers have compared optimization methods for Maxent, though it is difficult to have a complete study. Malouf (2002) compares methods for NLP data, while Minka (2003) focuses on logistic regression for synthesis data. In this paper, we are interested in a detailed investigation of

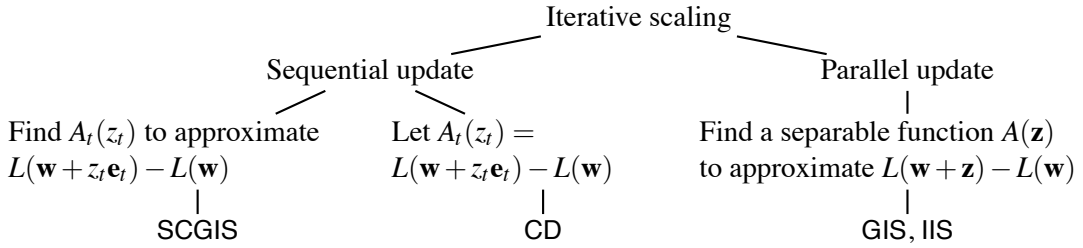

Figure 1: An illustration of various iterative scaling methods.

IS methods because they remain one of the most used approaches to train Maxent. This fact can be easily seen from popular NLP software. The Stanford Log-linear POS Tagger[1] supports two optimization methods, where one is IIS. The OpenNLP Maxent package (Baldridge et al., 2001) provides only one optimization method, which is GIS.

This paper is organized as follows. In Section 2, we present a unified framework for IS/CD methods and give theoretical results. Section 3 proposes a new CD method. Its advantages over existing IS/CD methods are discussed. In Section 4, we investigate some implementation issues for IS/CD methods. Section 5 presents experimental results. With a careful implementation, our CD outperforms IS and quasi-Newton techniques. Finally, Section 6 gives discussion and conclusions.

Part of this work appears in a short conference paper (Huang et al., 2009).

Notation X, Y, and n are the numbers of contexts, class labels, and features, respectively. The total number of nonzeros in training data and the average number of nonzeros per feature are respectively

$$\#\text{nz} \equiv \sum_{x,y} \sum_{t:f_t(x,y)\neq 0} 1 \quad \text{and} \quad \bar{l} \equiv \frac{\#\text{nz}}{n}. \tag{4}$$

In this paper, we assume non-negative feature values:

$$f_t(x,y) \geq 0,\ \forall t,x,y. \tag{5}$$

Most NLP applications have non-negative feature values. All existing IS methods use this property.

2. A Framework for Iterative Scaling and Coordinate Descent Methods

An important characteristic of IS and CD methods is that they solve a one-variable optimization problem and then modify the corresponding element in $\mathbf{w}$. Conceptually, the one-variable subproblem is related to the function reduction

$$L(\mathbf{w}+z_t\mathbf{e}_t)-L(\mathbf{w}),$$

where $\mathbf{e}_t \equiv [\underbrace{0,\ldots,0}_{t-1},1,0,\ldots,0]^T$. Then IS methods differ in how they approximate the function reduction. They can also be categorized according to whether $\mathbf{w}$'s components are updated in a sequential or parallel way. In this section, we create a framework for these methods. A hierarchical illustration of the framework is in Figure 1.

1. Stanford Log-linear POS Tagger can be found at `http://nlp.stanford.edu/software/tagger.shtml`.

2.1 The Framework

To introduce the framework, we separately discuss coordinate descent methods according to whether $\mathbf{w}$ is sequentially or parallely updated.

2.1.1 SEQUENTIAL UPDATE

For a sequential-update algorithm, once a one-variable sub-problem is solved, the corresponding element in $\mathbf{w}$ is updated. The new $\mathbf{w}$ is then used to construct the next sub-problem. The procedure is sketched in Algorithm 1. If the t-th component is selected for update, a sequential IS method solves the following one-variable sub-problem:

$$\min_{z_t} \; A_t(z_t),$$

where $A_t(z_t)$ is twice differentiable and bounds the function difference:

$$A_t(z_t) \geq L(\mathbf{w}+z_t\mathbf{e}_t) - L(\mathbf{w}), \; \forall z_t. \tag{6}$$

We hope that by minimizing $A_t(z_t)$, the resulting $L(\mathbf{w}+z_t\mathbf{e}_t)$ can be smaller than $L(\mathbf{w})$. However, (6) is not enough to ensure this property, so we impose an additional condition

$$A_t(0) = 0 \tag{7}$$

on the approximate function $A_t(z_t)$. The explanation below shows that we can strictly decrease the function value. If $A_t'(0) \neq 0$ and assume $\bar{z}_t \equiv \arg\min_{z_t} A_t(z_t)$ exists, with the condition $A_t(0) = 0$, we have $A_t(\bar{z}_t) < 0$. This property and (6) then imply $L(\mathbf{w}+\bar{z}_t\mathbf{e}_t) < L(\mathbf{w})$. If $A_t'(0) = 0$, we can prove that $\nabla_t L(\mathbf{w}) = 0$,[2] where $\nabla_t L(\mathbf{w}) = \partial L(\mathbf{w})/\partial w_t$. In this situation, the convexity of $L(\mathbf{w})$ and $\nabla_t L(\mathbf{w}) = 0$ imply that we cannot decrease the function value by modifying w_t, so we should move on to modify other components of $\mathbf{w}$.

A CD method can be viewed as a sequential-update IS method. Its approximate function $A_t(z_t)$ is simply the function difference:

$$A_t^{\mathsf{CD}}(z_t) = L(\mathbf{w}+z_t\mathbf{e}_t) - L(\mathbf{w}). \tag{8}$$

Other IS methods consider approximations so that $A_t(z_t)$ is simpler for minimization. More details are in Section 2.2. Note that the name "sequential" comes from the fact that each sub-problem $A_t(z_t)$ depends on $\mathbf{w}$ obtained from the previous update. Therefore, sub-problems must be sequentially solved.

2.1.2 PARALLEL UPDATE

A parallel-update IS method simultaneously constructs n independent one-variable sub-problems. After (approximately) solving all of them, the whole vector $\mathbf{w}$ is updated. Algorithm 2 gives the procedure. The function $A(\mathbf{z})$, $\mathbf{z} \in R^n$, is an approximation of $L(\mathbf{w}+\mathbf{z}) - L(\mathbf{w})$ satisfying

$$A(\mathbf{z}) \geq L(\mathbf{w}+\mathbf{z}) - L(\mathbf{w}), \; \forall \mathbf{z}, \quad A(\mathbf{0}) = 0, \quad \text{and} \quad A(\mathbf{z}) = \sum_{t=1}^{n} A_t(z_t). \tag{9}$$

2. Define a function $D(z_t) \equiv A(z_t) - (L(\mathbf{w}+z_t\mathbf{e}_t) - L(\mathbf{w}))$. We have $D'(0) = A'(0) - \nabla_t L(\mathbf{w})$. If $\nabla_t L(\mathbf{w}) \neq 0$ and $A_t'(0) = 0$, then $D'(0) \neq 0$. Since $D(0) = 0$, we can find a z_t such that $A(z_t) - (L(\mathbf{w}+z_t\mathbf{e}_t) - L(\mathbf{w})) < 0$, a contradiction to (6).

Algorithm 1 A sequential-update IS method

While $\mathbf{w}$ is not optimal

For $t = 1, \ldots, n$

1. Find an approximate function $A_t(z_t)$ satisfying (6)-(7).
2. Approximately solve $\min_{z_t} A_t(z_t)$ to get $\bar{z}_t$.
3. $w_t \leftarrow w_t + \bar{z}_t$.

Algorithm 2 A parallel-update IS method

While $\mathbf{w}$ is not optimal

1. Find approximate functions $A_t(z_t)\ \forall z_t$ satisfying (9).
2. For $t = 1, \ldots, n$

   Approximately solve $\min_{z_t} A_t(z_t)$ to get $\bar{z}_t$.
3. For $t = 1, \ldots, n$

   $w_t \leftarrow w_t + \bar{z}_t$.

The first two conditions are similar to (6) and (7). By a similar argument, we can ensure that the function value is strictly decreasing. The last condition indicates that $A(\mathbf{z})$ is separable, so

$$\min_{\mathbf{z}} A(\mathbf{z}) = \sum_{t=1}^{n} \min_{z_t} A_t(z_t).$$

That is, we can minimize $A_t(z_t),\ \forall z_t$ simultaneously, and then update $w_t\ \forall t$ together. We show in Section 4 that a parallel-update method possesses some nicer implementation properties than a sequential method. However, as sequential approaches update $\mathbf{w}$ as soon as a sub-problem is solved, they often converge faster than parallel methods.

If $A(\mathbf{z})$ satisfies (9), taking $\mathbf{z} = z_t \mathbf{e}_t$ implies that (6) and (7) hold for $A_t(z_t),\ \forall t = 1, \ldots, n$. A parallel-update method could thus be transformed to a sequential-update method using the same approximate function. Contrarily, a sequential-update algorithm cannot be directly transformed to a parallel-update method because the summation of the inequality in (6) does not imply (9).

2.2 Existing Iterative Scaling Methods

We introduce GIS, IIS and SCGIS via the proposed framework. GIS and IIS use a parallel update, but SCGIS is sequential. Their approximate functions aim to bound the change of the function values

$$L(\mathbf{w}+\mathbf{z}) - L(\mathbf{w}) = \sum_x \tilde{P}(x) \log \frac{T_{\mathbf{w}+\mathbf{z}}(x)}{T_{\mathbf{w}}(x)} + \sum_t Q_t(z_t), \tag{10}$$

where $T_{\mathbf{w}}(x)$ is defined in (1) and

$$Q_t(z_t) \equiv \frac{2w_t z_t + z_t^2}{2\sigma^2} - z_t \tilde{P}(f_t). \tag{11}$$

Then GIS, IIS and SCGIS use similar inequalities to get approximate functions. With

$$\begin{aligned} \frac{T_{\mathbf{w}+\mathbf{z}}(x)}{T_{\mathbf{w}}(x)} &= \frac{\sum_y S_{\mathbf{w}+\mathbf{z}}(x,y)}{T_{\mathbf{w}}(x)} = \frac{\sum_y S_{\mathbf{w}}(x,y)\left(e^{\sum_t z_t f_t(x,y)}\right)}{T_{\mathbf{w}}(x)} \\ &= \sum_y P_{\mathbf{w}}(y|x) e^{\sum_t z_t f_t(x,y)}, \end{aligned}$$

they apply $\log\alpha \le \alpha - 1\ \forall\alpha > 0$ and $\sum_y P_{\mathbf{w}}(y|x) = 1$ to get

$$\begin{aligned}(10) &\le \sum_t Q_t(z_t) + \sum_x \tilde{P}(x)\left(\sum_y P_{\mathbf{w}}(y|x)e^{\sum_t z_t f_t(x,y)} - 1\right)\\ &= \sum_t Q_t(z_t) + \sum_{x,y} \tilde{P}(x)P_{\mathbf{w}}(y|x)\left(e^{\sum_t z_t f_t(x,y)} - 1\right).\end{aligned} \tag{12}$$

GIS defines

$$f^{\#} \equiv \max_{x,y} f^{\#}(x,y), \quad f^{\#}(x,y) \equiv \sum_t f_t(x,y),$$

and adds a feature $f_{n+1}(x,y) \equiv f^{\#} - f^{\#}(x,y)$ with $z_{n+1} = 0$. Using Jensen's inequality and the assumption of non-negative feature values (5),

$$\begin{aligned}&e^{\sum_{t=1}^n z_t f_t(x,y)} = e^{\sum_{t=1}^{n+1} \frac{f_t(x,y)}{f^{\#}} z_t f^{\#}}\\ &\le \sum_{t=1}^{n+1} \frac{f_t(x,y)}{f^{\#}} e^{z_t f^{\#}} = \sum_{t=1}^{n} \frac{f_t(x,y)}{f^{\#}} e^{z_t f^{\#}} + \frac{f^{\#} - f^{\#}(x,y)}{f^{\#}} = \sum_{t=1}^{n}\left(\frac{e^{z_t f^{\#}} - 1}{f^{\#}} f_t(x,y)\right) + 1.\end{aligned} \tag{13}$$

Substituting (13) into (12), the approximate function of GIS is

$$A^{\mathsf{GIS}}(\mathbf{z}) = \sum_t Q_t(z_t) + \sum_{x,y} \tilde{P}(x)P_{\mathbf{w}}(y|x)\sum_t \left(\frac{e^{z_t f^{\#}} - 1}{f^{\#}} f_t(x,y)\right).$$

Then we obtain n independent one-variable functions:

$$A_t^{\mathsf{GIS}}(z_t) = Q_t(z_t) + \frac{e^{z_t f^{\#}} - 1}{f^{\#}} \sum_{x,y} \tilde{P}(x)P_{\mathbf{w}}(y|x) f_t(x,y).$$

IIS assumes $f_t(x,y) \ge 0$ and applies Jensen's inequality

$$e^{\sum_t z_t f_t(x,y)} = e^{\sum_t \frac{f_t(x,y)}{f^{\#}(x,y)} z_t f^{\#}(x,y)} \le \sum_t \frac{f_t(x,y)}{f^{\#}(x,y)} e^{z_t f^{\#}(x,y)}$$

on (12) to get the approximate function

$$A_t^{\mathsf{IIS}}(z_t) = Q_t(z_t) + \sum_{x,y} \tilde{P}(x)P_{\mathbf{w}}(y|x) f_t(x,y) \frac{e^{z_t f^{\#}(x,y)} - 1}{f^{\#}(x,y)}.$$

SCGIS is a sequential-update algorithm. It replaces $f^{\#}$ in GIS with

$$f_t^{\#} \equiv \max_{x,y} f_t(x,y). \tag{14}$$

Using $z_t\mathbf{e}_t$ as $\mathbf{z}$ in (10), a derivation similar to (13) gives

$$e^{z_t f_t(x,y)} \le \frac{f_t(x,y)}{f_t^{\#}} e^{z_t f_t^{\#}} + \frac{f_t^{\#} - f_t(x,y)}{f_t^{\#}}. \tag{15}$$

The approximate function of SCGIS is

$$A_t^{\mathsf{SCGIS}}(z_t) = Q_t(z_t) + \frac{e^{z_t f_t^\#} - 1}{f_t^\#} \sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y).$$

As a comparison, we expand $A_t^{\mathsf{CD}}(z_t)$ in (8) to the following form:

$$A_t^{\mathsf{CD}}(z_t) = Q_t(z_t) + \sum_x \tilde{P}(x) \log \frac{T_{\mathbf{w}+z_t\mathbf{e}_t}(x)}{T_{\mathbf{w}}(x)} \tag{16}$$

$$= Q_t(z_t) + \sum_x \tilde{P}(x) \log \left(1 + \sum_y P_{\mathbf{w}}(y|x)(e^{z_t f_t(x,y)} - 1)\right), \tag{17}$$

where (17) is from (1) and

$$S_{\mathbf{w}+z_t\mathbf{e}_t}(x,y) = S_{\mathbf{w}}(x,y) e^{z_t f_t(x,y)}, \tag{18}$$

$$T_{\mathbf{w}+z_t\mathbf{e}_t}(x) = T_{\mathbf{w}}(x) + \sum_y S_{\mathbf{w}}(x,y)(e^{z_t f_t(x,y)} - 1). \tag{19}$$

A summary of approximate functions of IS and CD methods is in Table 1.

2.3 Convergence of Iterative Scaling and Coordinate Descent Methods

The convergence of CD methods has been well studied (e.g., Bertsekas, 1999; Luo and Tseng, 1992). However, for methods like IS which use only an approximate function to bound the function difference, the convergence is less studied. In this section, we generalize the linear convergence proof in Chang et al. (2008) to show the convergence of IS and CD methods. To begin, we consider any convex and differentiable function L: $R^n \to R$ satisfying the following conditions in the set

$$U = \{\mathbf{w} \mid L(\mathbf{w}) \le L(\mathbf{w}^0)\}, \tag{20}$$

where $\mathbf{w}^0$ is the initial point of an IS/CD algorithm:

1. ∇L is bi-Lipschitz: there are two positive constants $\tau_{\max}$ and $\tau_{\min}$ such that for any $\mathbf{u}, \mathbf{v} \in U$,

$$\tau_{\min}\|\mathbf{u} - \mathbf{v}\| \le \|\nabla L(\mathbf{u}) - \nabla L(\mathbf{v})\| \le \tau_{\max}\|\mathbf{u} - \mathbf{v}\|. \tag{21}$$

2. Quadratic bound property: there is a constant $K > 0$ such that for any $\mathbf{u}, \mathbf{v} \in U$

$$|L(\mathbf{u}) - L(\mathbf{v}) - \nabla L(\mathbf{v})^T(\mathbf{u} - \mathbf{v})| \le K\|\mathbf{u} - \mathbf{v}\|^2. \tag{22}$$

The following theorem proves that (3) satisfies these two conditions.

Theorem 1 *$L(\mathbf{w})$ defined in* (3) *satisfies* (21) *and* (22).

The proof is in Section 7.1.

We denote $\mathbf{w}^k$ as the point after each iteration of the while loop in Algorithm 1 or 2. Hence from $\mathbf{w}^k$ to $\mathbf{w}^{k+1}$, n sub-problems are solved. The following theorem establishes our main linear convergence result for IS methods.

$$A_t^{\mathsf{GIS}}(z_t) = Q_t(z_t) + \frac{e^{z_t f^\#} - 1}{f^\#} \sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y)$$

$$A_t^{\mathsf{IIS}}(z_t) = Q_t(z_t) + \sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y) \frac{e^{z_t f^\#(x,y)} - 1}{f^\#(x,y)}$$

$$A_t^{\mathsf{SCGIS}}(z_t) = Q_t(z_t) + \frac{e^{z_t f_t^\#} - 1}{f_t^\#} \sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y)$$

$$A_t^{\mathsf{CD}}(z_t) = Q_t(z_t) + \sum_x \tilde{P}(x) \log\left(1 + \sum_y P_{\mathbf{w}}(y|x)(e^{z_t f_t(x,y)} - 1)\right)$$

Table 1: Approximate functions of IS and CD methods.

Theorem 2 *Consider Algorithm 1 or 2 to minimize a convex and twice differentiable function $L(\mathbf{w})$. Assume $L(\mathbf{w})$ attains a unique global minimum $\mathbf{w}^*$ and $L(\mathbf{w})$ satisfies* (21)-(22). *If the algorithm satisfies*

$$\|\mathbf{w}^{k+1} - \mathbf{w}^k\| \geq \eta \|\nabla L(\mathbf{w}^k)\|, \tag{23}$$

$$L(\mathbf{w}^{k+1}) - L(\mathbf{w}^k) \leq -\nu \|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2, \tag{24}$$

for some positive constants η and ν, then the sequence $\{\mathbf{w}^k\}$ generated by the algorithm linearly converges. That is, there is a constant $\mu \in (0,1)$ such that

$$L(\mathbf{w}^{k+1}) - L(\mathbf{w}^*) \leq (1-\mu)(L(\mathbf{w}^k) - L(\mathbf{w}^*)), \forall k.$$

The proof is in Section 7.2. Note that this theorem is not restricted to $L(\mathbf{w})$ in (3). Next, we show that IS/CD methods discussed in this paper satisfy (23)-(24), so they all possess the linear convergence property.

Theorem 3 *Consider $L(\mathbf{w})$ defined in* (3) *and assume $A_t(z_t)$ is exactly minimized in* GIS, IIS, SCGIS, *or* CD. *Then $\{\mathbf{w}^k\}$ satisfies* (23)-(24).

The proof is in Section 7.3.

2.4 Solving One-variable Sub-problems

After generating approximate functions, GIS, IIS, SCGIS and CD need to minimize one-variable sub-problems. In general, the approximate function possesses a unique global minimum. We do not discuss some rare situations where this property does not hold (for example, $\min_{z_t} A_t^{\mathsf{GIS}}(z_t)$ has an optimal solution $z_t = -\infty$ if $\tilde{P}(f_t) = 0$ and the regularization term is not considered).

Without the regularization term, by $A_t'(z_t) = 0$, GIS and SCGIS both have a simple closed-form solution of the sub-problem:

$$z_t = \frac{1}{f^s} \log\left(\frac{\tilde{P}(f_t)}{\sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y)}\right), \quad \text{where } f^s \equiv \begin{cases} f^\# \text{ if } s \text{ is GIS}, \\ f_t^\# \text{ if } s \text{ is SCGIS}. \end{cases} \tag{25}$$

For IIS, the term $e^{z_t f^\#(x,y)}$ in $A_t^{\mathsf{IIS}}(z_t)$ depends on x and y, so it does not have a closed-form solution. CD does not have a closed-form solution either.

With the regularization term, the sub-problems no longer have a closed-form solution. While many optimization methods can be applied, in this section we analyze the complexity of using the Newton method to solve one-variable sub-problems. The Newton method minimizes $A_t^s(z_t)$ by iteratively updating z_t:

$$z_t \leftarrow z_t - A_t^{s\prime}(z_t)/A_t^{s\prime\prime}(z_t), \tag{26}$$

where s indicates an IS or a CD method. This iterative procedure may diverge, so we often need a line search procedure to ensure the function value is decreasing (Fletcher, 1987, p. 47). Due to the many variants of line searches, here we discuss only the cost for finding the Newton direction. The Newton directions of GIS and SCGIS are similar:

$$-\frac{A_t^{s\prime}(z_t)}{A_t^{s\prime\prime}(z_t)} = -\frac{Q_t'(z_t) + e^{z_t f^s}\sum_{x,y}\tilde{P}(x)P_{\mathbf{w}}(y|x)f_t(x,y)}{Q_t''(z_t) + f^s e^{z_t f^s}\sum_{x,y}\tilde{P}(x)P_{\mathbf{w}}(y|x)f_t(x,y)}, \tag{27}$$

where f^s is defined in (25). For IIS, the Newton direction is:

$$-\frac{A_t^{\mathsf{IIS}\prime}(z_t)}{A_t^{\mathsf{IIS}\prime\prime}(z_t)} = -\frac{Q_t'(z_t) + \sum_{x,y}\tilde{P}(x)P_{\mathbf{w}}(y|x)f_t(x,y)e^{z_t f^\#(x,y)}}{Q_t''(z_t) + \sum_{x,y}\tilde{P}(x)P_{\mathbf{w}}(y|x)f_t(x,y)f^\#(x,y)e^{z_t f^\#(x,y)}}. \tag{28}$$

The Newton directions of CD is:

$$-\frac{A_t^{\mathsf{CD}\prime}(z_t)}{A_t^{\mathsf{CD}\prime\prime}(z_t)}, \tag{29}$$

where

$$A_t^{\mathsf{CD}\prime}(z_t) = Q_t'(z_t) + \sum_{x,y}\tilde{P}(x)P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x)f_t(x,y), \tag{30}$$

$$A_t^{\mathsf{CD}\prime\prime}(z_t) = Q_t''(z_t) + \sum_{x,y}\tilde{P}(x)P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x)f_t(x,y)^2 - \sum_x \tilde{P}(x)\left(\sum_y P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x)f_t(x,y)\right)^2. \tag{31}$$

Eqs. (27)-(28) can be easily obtained using formulas in Table 1. We show details of deriving (30)-(31) in Section 7.4.

We separate the complexity analysis to two parts. One is on calculating of $P_{\mathbf{w}}(y|x)\ \forall x,y$, and the other is on the remaining operations.

For $P_{\mathbf{w}}(y|x) = S_{\mathbf{w}}(x,y)/T_w(x)$, parallel-update approaches calculate it once every n sub-problems. To get $S_{\mathbf{w}}(x,y)\ \forall x,y$, the operation

$$\sum_t w_t f_t(x,y) \quad \forall x,y$$

needs $O(\#\text{nz})$ time. If $XY \le \#\text{nz}$, the cost for obtaining $P_{\mathbf{w}}(y|x),\ \forall x,y$ is $O(\#\text{nz})$, where X and Y are respectively the numbers of contexts and labels.[3] Therefore, on average each sub-problem shares $O(\#\text{nz}/n) = O(\bar{l})$ cost. For sequential-update methods, they expensively update $P_{\mathbf{w}}(y|x)$ after every

3. If $XY > \#\text{nz}$, one can calculate $e^{w_t f_t(x,y)},\ \forall f_t(x,y) \neq 0$ and then the product $\prod_{t:f_t(x,y)\neq 0} e^{w_t f_t(x,y)}$. The complexity is still $O(\#\text{nz})$.

	CD	GIS	SCGIS	IIS
1st Newton direction	$O(\bar{l})$	$O(\bar{l})$	$O(\bar{l})$	$O(\bar{l})$
Each subsequent Newton direction	$O(\bar{l})$	$O(1)$	$O(1)$	$O(\bar{l})$

Table 2: Cost for finding Newton directions if the Newton method is used to minimize $A_t(z_t)$.

sub-problem. A trick to trade memory for time is to store all $S_{\mathbf{w}}(x,y)$ and $T_{\mathbf{w}}(x)$, and use (18) and (19). Since $S_{\mathbf{w}+z_t\mathbf{e}_t}(x,y) = S_{\mathbf{w}}(x,y)$, if $f_t(x,y) = 0$, this procedure reduces the number of operations from the $O(\#\text{nz})$ operations to $O(\bar{l})$. However, it needs $O(XY)$ extra spaces to store all $S_{\mathbf{w}}(x,y)$ and $T_{\mathbf{w}}(x)$. This trick has been used in the SCGIS method (Goodman, 2002).

From (27) and (28), all remaining operations of GIS, IIS, and SCGIS involve the calculation of

$$\sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y) (\text{a function of } z_t), \tag{32}$$

which needs $O(\bar{l})$ under a fixed t. For GIS and SCGIS, since the function of z_t in (32) is independent of x, y, we can calculate and store $\sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y)$ in the first Newton iteration. Therefore, the overall cost (including calculating $P_{\mathbf{w}}(y|x)$) is $O(\bar{l})$ for the first Newton iteration and $O(1)$ for each subsequent iteration. For IIS, because $e^{z_t f^{\#}(x,y)}$ in (28) depends on x and y, we need $O(\bar{l})$ for every Newton direction. For CD, it calculates $P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x)$ for every z_t, so the cost per Newton direction is $O(\bar{l})$. We summarize the cost for solving sub-problems of GIS, SCGIS, IIS and CD in Table 2.

2.5 Related Work

Our framework for IS methods includes two important components:

1. Approximate $L(\mathbf{w} + z_t\mathbf{e}_t) - L(\mathbf{w})$ or $L(\mathbf{w} + \mathbf{z}) - L(\mathbf{w})$ to obtain functions $A_t(z_t)$.

2. Sequentially or parallely minimize approximate functions.

Each component has been well discussed in many places. However, ours may be the first to investigate IS methods in detail. Below we discuss some related work.

The closest work to our framework might be Lange et al. (2000) from the statistics community. They discuss "optimization transfer" algorithms which construct $A_t(z_t)$ or $A(\mathbf{z})$ satisfying conditions similar to (6)-(7) or (9). However, they do not require one-variable sub-problems, so $A(\mathbf{z})$ of a parallel-update method may be non-separable. They discuss that "optimization transfer" algorithms can be traced back to EM (Expectation Maximization). In their paper, the function $A_t(z_t)$ or $A(\mathbf{z})$ is called a "surrogate" function or a "majorizing" function. Some also call it an "auxiliary" function. Lange et al. (2000) further discuss several ways to construct $A(\mathbf{z})$, where Jensen's inequality used in (13) is one of them. An extension along this line of research is by Zhang et al. (2007).

The concept of sequential- and parallel-update algorithms is well known in many subjects. For example, these algorithms are used in iterative methods for solving linear systems (Jacobi and Gauss-Seidel methods). Some recent machine learning works which mention them include, for example, Collins et al. (2002) and Dudík et al. (2004). Dudík et al. (2004) propose a variant of IS methods for L1-regularized maximum entropy. They consider both sequential- and parallel-update

algorithms using certain approximate functions. Their sequential methods greedily choose coordinates minimizing $A_t(z_t)$, while ours in Section 2.1.1 chooses coordinates cyclicly.

Regarding the convergence, if the sub-problem has a closed-form solution like (25), it is easy to apply the result in Lange et al. (2000). However, the case with regularization is more complicated. For example, Dudík et al. (2004) point out that Goodman (2002) does not give a "complete proof of convergence." Note that the strict decrease of function values following conditions (6)-(7) or (9) does not imply the convergence to the optimal function value. In Section 2.3, we prove not only the global convergence but also the linear convergence for a general class of IS/CD methods.

3. Comparison and a New Coordinate Descent Method

Using the framework in Section 2, we compare CD and IS methods in this section. Based on the comparison, we propose a new and fast CD method.

3.1 Comparison of Iterative Scaling and Coordinate Descent Methods

An IS or CD method falls into a place between two extreme designs:

$$\begin{array}{l} A_t(z_t) \text{ a loose bound} \\ \text{Easy to minimize } A_t(z_t) \end{array} \iff \begin{array}{l} A_t(z_t) \text{ a tight bound} \\ \text{Hard to minimize } A_t(z_t) \end{array}$$

That is, there is a tradeoff between the tightness to bound the function difference and the hardness to solve the sub-problem. To check how IS and CD methods fit into this explanation, we obtain the following relationship of their approximate functions:

$$\begin{aligned} &A_t^{\mathsf{CD}}(z_t) \le A_t^{\mathsf{SCGIS}}(z_t) \le A_t^{\mathsf{GIS}}(z_t), \\ &A_t^{\mathsf{CD}}(z_t) \le A_t^{\mathsf{IIS}}(z_t) \le A_t^{\mathsf{GIS}}(z_t) \quad \forall\, z_t. \end{aligned} \tag{33}$$

The derivation is in Section 7.5. From (33), CD considers more accurate sub-problems than SCGIS and GIS. However, when solving the sub-problem, from Table 2, CD's each Newton step takes more time. The same situation occurs in comparing IIS and GIS.

The above discussion indicates that while a tight $A_t(z_t)$ can give faster convergence by handling fewer sub-problems, the total time may not be less due to the higher cost of each sub-problem.

3.2 A Fast Coordinate Descent Method

Based on the discussion in Section 3.1, we develop a CD method which is cheaper in solving each sub-problem but still enjoys fast final convergence. This method is modified from Chang et al. (2008), a CD approach for linear SVM. They approximately minimize $A_t^{\mathsf{CD}}(z_t)$ by applying only one Newton iteration. This approach is a truncated Newton method: In the early stage of the coordinate descent method, we roughly minimize $A_t^{\mathsf{CD}}(z_t)$ but in the final stage, one Newton update can quite accurately solve the sub-problem. The Newton direction at $z_t = 0$ is

$$d = -\frac{A_t^{\mathsf{CD}\prime}(0)}{A_t^{\mathsf{CD}\prime\prime}(0)}. \tag{34}$$

We discuss in Section 2.4 that the update rule (26) may not decrease the function value. Hence we need a line search procedure to find $\lambda \ge 0$ such that $z_t = \lambda d$ satisfies the following sufficient

Algorithm 3 A fast coordinate descent method for Maxent

- Choose $\beta \in (0,1)$ and $\gamma \in (0,1/2)$. Give initial $\mathbf{w}$ and calculate $S_{\mathbf{w}}(x,y)$, $T_{\mathbf{w}}(x)$, $\forall x,y$.
- While $\mathbf{w}$ is not optimal
  - For $t = 1,\ldots,n$
    1. Calculate the Newton direction

$$\begin{aligned} d &= -A_t^{\mathsf{CD}'}(0)/A_t^{\mathsf{CD}''}(0) \\ &= \frac{-\left(\sum_{x,y}\tilde{P}(x)P_{\mathbf{w}}(y|x)f_t(x,y)+\frac{w_t}{\sigma^2}\right)}{\sum_{x,y}\tilde{P}(x)P_{\mathbf{w}}(y|x)f_t(x,y)^2-\sum_x\tilde{P}(x)\left(\sum_y P_{\mathbf{w}}(y|x)f_t(x,y)\right)^2+\frac{1}{\sigma^2}}, \end{aligned}$$

       where

$$P_{\mathbf{w}}(y|x) = \frac{S_{\mathbf{w}}(x,y)}{T_{\mathbf{w}}(x)}.$$

    2. While $\lambda = 1,\beta,\beta^2,\ldots$
       (a) Let $z_t = \lambda d$
       (b) Calculate

$$A_t^{\mathsf{CD}}(z_t) = Q_t(z_t) + \sum_x \tilde{P}(x)\log\left(1+\sum_y \frac{S_{\mathbf{w}}(x,y)}{T_{\mathbf{w}}(x)}(e^{z_t f_t(x,y)}-1)\right)$$

       (c) If $A_t^{\mathsf{CD}}(z_t) \le \gamma z_t A_t^{\mathsf{CD}'}(0)$, then break.
    3. $w_t \leftarrow w_t + z_t$
    4. Update $S_{\mathbf{w}}(x,y)$ and $T_{\mathbf{w}}(x)$ $\forall x,y$ by (18)-(19)

decrease condition:

$$A_t^{\mathsf{CD}}(z_t) - A_t^{\mathsf{CD}}(0) = A_t^{\mathsf{CD}}(z_t) \le \gamma z_t A_t^{\mathsf{CD}'}(0) \le 0, \tag{35}$$

where γ is a constant in $(0,1/2)$. Note that $z_t A_t^{\mathsf{CD}'}(0)$ is negative under the definition of d in (34). Instead of (35), Grippo and Sciandrone (1999) and Chang et al. (2008) use

$$A_t^{\mathsf{CD}}(z_t) \le -\gamma z_t^2 \tag{36}$$

as the sufficient decrease condition. We prefer (35) as it is scale-invariant. That is, if A_t^{CD} is linearly scaled, then (35) holds under the same γ. In contrast, γ in (36) may need to be changed. To find λ for (35), a simple way is by sequentially checking $\lambda = 1,\beta,\beta^2,\ldots$, where $\beta \in (0,1)$. We choose β as 0.5 for experiments. The following theorem proves that the condition (35) can always be satisfied.

Theorem 4 *Given the Newton direction d as in* (34). *There is $\bar{\lambda} > 0$ such that $z_t = \lambda d$ satisfies* (35) *for all $0 \le \lambda < \bar{\lambda}$.*

The proof is in Section 7.6. The new CD procedure is in Algorithm 3. In the rest of this paper, we refer to CD as this new algorithm.

In Section 2.3 we prove the linear convergence of IS/CD methods. In Section 7.7, we use the same framework to prove that Algorithm 3 linearly converges:

Theorem 5 *Algorithm 3 satisfies* (23)-(24) *and linearly converges to the global optimum of* (3).

As evaluating $A_t^{\mathsf{CD}}(z_t)$ via (17)-(19) needs $O(\bar{l})$ time, the line search procedure takes

$$O(\bar{l}) \times (\#\text{ line search steps}).$$

This causes the cost of solving a sub-problem higher than that of GIS/SCGIS (see Table 2). Fortunately, we show that near the optimum, the line search procedure needs only one step:

Theorem 6 *In a neighborhood of the optimal solution, the Newton direction d defined in* (34) *satisfies the sufficient decrease condition* (35) *with* $\lambda = 1$.

The proof is in Section 7.8. If the line search procedure succeeds at $\lambda = 1$, then the cost for each sub-problem is similar to that of GIS and SCGIS.

Next we show that near the optimum, one Newton direction of CD's tight $A_t^{\mathsf{CD}}(z_t)$ already reduces the objective function $L(\mathbf{w})$ more rapidly than directions by exactly minimizing a loose $A_t(z_t)$ of GIS, IIS or SCGIS. Thus Algorithm 3 has faster final convergence than GIS, IIS, or SCGIS.

Theorem 7 *Assume* $\mathbf{w}^*$ *is the global optimum of* (3). *There is an* $\varepsilon > 0$ *such that the following result holds. For any* $\mathbf{w}$ *satisfying* $\|\mathbf{w} - \mathbf{w}^*\| \le \varepsilon$, *if we select an index t and generate directions*

$$d = -A_t^{\mathsf{CD}'}(0)/A_t^{\mathsf{CD}''}(0) \quad \textit{and} \quad d^s = \arg\min_{z_t} A_t^s(z_t), \quad s = \mathsf{GIS}, \mathsf{IIS} \textit{ or } \mathsf{SCGIS}, \tag{37}$$

then

$$\delta_t(d) < \min\left(\delta_t(d^{\mathsf{GIS}}), \delta_t(d^{\mathsf{IIS}}), \delta_t(d^{\mathsf{SCGIS}})\right),$$

where

$$\delta_t(z_t) \equiv L(\mathbf{w} + z_t \mathbf{e}_t) - L(\mathbf{w}).$$

The proof is in Section 7.9. Theorems 6 and 7 show that Algorithm 3 improves upon the traditional CD by approximately solving sub-problems, while still maintaining fast convergence. That is, it attempts to take both advantages of the two designs mentioned in Section 3.1.

3.2.1 EFFICIENT LINE SEARCH

We propose a technique to speed up the line search procedure. We derive a function $\bar{A}_t^{\mathsf{CD}}(z_t)$ so that it is cheaper to calculate than $A_t^{\mathsf{CD}}(z_t)$ and satisfies $\bar{A}_t^{\mathsf{CD}}(z_t) \ge A_t^{\mathsf{CD}}(z_t)\ \forall z_t$. Then,

$$\bar{A}_t^{\mathsf{CD}}(z_t) \le \gamma z_t A_t^{\mathsf{CD}'}(0) \tag{38}$$

implies (35), so we can save time by replacing step 2 of Algorithm 3 with

2'. While $\lambda = 1, \beta, \beta^2, \ldots$
   (a) Let $z_t = \lambda d$
   (b) Calculate $\bar{A}_t^{\mathsf{CD}}(z_t)$
   (c) If $\bar{A}_t^{\mathsf{CD}}(z_t) \le \gamma z_t A_t^{\mathsf{CD}'}(0)$, then break.
   (d) Calculate $A_t^{\mathsf{CD}}(z_t)$
   (e) If $A_t^{\mathsf{CD}}(z_t) \le \gamma z_t A_t^{\mathsf{CD}'}(0)$, then break.

We assume non-negative feature values and obtain

$$\bar{A}_t^{\mathsf{CD}}(z_t) \equiv Q_t(z_t) + \tilde{P}_t \log\left(1 + \frac{e^{z_t f_t^{\#}} - 1}{f_t^{\#} \tilde{P}_t} \sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y)\right), \tag{39}$$

where $f_t^{\#}$ is defined in (14),

$$\tilde{P}_t \equiv \sum_{\Omega_t} \tilde{P}(x), \quad \text{and} \quad \Omega_t \equiv \{x : \exists y \text{ such that } f_t(x,y) \neq 0\}. \tag{40}$$

The derivation is in Section 7.10. Because

$$\sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y),\ t = 1,\ldots,n \tag{41}$$

are available from finding $A_t^{\mathsf{CD}'}(0)$, getting $\bar{A}_t^{\mathsf{CD}}(z_t)$ and checking (38) take only $O(1)$, smaller than $O(\bar{l})$ for (35). Using $\log\alpha \leq \alpha - 1\ \forall \alpha > 0$, it is easy to see that

$$\bar{A}_t^{\mathsf{CD}}(z_t) \leq A_t^{\mathsf{SCGIS}}(z_t),\ \forall z_t.$$

Therefore, we can simply replace $A_t^{\mathsf{SCGIS}}(z_t)$ of the SCGIS method with $\bar{A}_t^{\mathsf{CD}}(z_t)$ to have a new IS method.

4. Implementation Issues

In this section we analyze some implementation issues of IS and CD methods.

4.1 Row Versus Column Format

In many Maxent applications, data are sparse with few nonzero $f_t(x,y)$. We store such data by a sparse matrix. Among many ways to implement sparse matrices, two common ones are "row format" and "column format." For the row format, each (x,y) corresponds to a list of nonzero $f_t(x,y)$, while for the column format, each feature t is associated with a list of (x,y). The loop to access data in the row format is $(x,y) \rightarrow t$, while for the column format it is $t \rightarrow (x,y)$. By $(x,y) \rightarrow t$ we mean that the outer loop goes through (x,y) values and for each (x,y), there is an inner loop for a list of feature values. For sequential-update algorithms such as SCGIS and CD, as we need to maintain $S_{\mathbf{w}}(x,y)\ \forall x,y$ via (18) after solving the t-th sub-problem, an easy access of t's corresponding (x,y) elements is essential. Therefore, the column format is more suitable. In contrast, parallel-update methods can use either row or column formats. For GIS, we can store all n elements of (41) before solving n sub-problems by (25) or (27). The calculation of (41) can be done by using the row format and a loop of $(x,y) \rightarrow t$. For IIS, an implementation by the row format is more complicated due to the $e^{z_t f^{\#}(x,y)}$ term in $A_t^{\mathsf{IIS}}(z_t)$. Take the Newton method to solve the sub-problem as an example. We can calculate and store (28) for all $t = 1,\ldots,n$ by a loop of $(x,y) \rightarrow t$. That is, n Newton directions are obtained together before conducting n updates.

4.2 Memory Requirement

For sequential-update methods, to save the computational time of calculating $P_{\mathbf{w}}(y|x)$, we use (18)-(19), so $S_{\mathbf{w}}(x,y)\ \forall x,y$ must be stored. Therefore, $O(XY)$ storage is needed. For parallel-update

Data set	X	Y	n	#nz
CoNLL2000-P	197,979	44	168,674	48,030,163
CoNLL2000-C	197,252	22	273,680	53,396,844
BROWN	935,137	185	626,726	601,216,661

Table 3: Statistics of NLP data (0/1 features). X: number of contexts, Y: number of class labels, n: number of features, and #nz: number of total non-zero feature values; see (4).

methods, they also need $O(XY)$ spaces if using the column format: To calculate $e^{\sum_t w_t f_t(x,y)}\ \forall x,y$ via a loop of $t \to (x,y)$, we need $O(XY)$ positions to store $\sum_t w_t f_t(x,y)\ \forall x,y$. In contrast, if using the row format, the loop is $x \to y \to t$, so for each fixed x, we need only $O(Y)$ spaces to store $S(x,y)\ \forall y$ and then obtain $T_{\mathbf{w}}(x)$. This advantage makes the parallel update a viable approach if Y (the number of labels) is very large.

4.3 Number of exp and log Operations

Many exp/log operations are needed in training a Maxent model. On most computers, exp/log operations are much more expensive than multiplications/divisions. It is important to analyze the number of exp/log operations in IS and CD methods.

We first discuss the number of exp operations. A simple check of (27)-(31) shows that the numbers are the same as those in Table 2. IIS and CD need $O(\bar{l})$ exp operations for every Newton direction because they calculate $e^{z_t f^{\#}(x,y)}$ in (28) and $e^{z_t f_t(x,y)}$ in (17), respectively. CD via Algorithm 3 takes only one Newton iteration, but each line search step also needs $O(\bar{l})$ exp operations. If feature values are binary, $e^{z_t f_t(x,y)}$ in (17) becomes e^{z_t}, a value independent of x,y. Thus the number of exp operations is significantly reduced from $O(\bar{l})$ to $O(1)$. This property implies that Algorithm 3 is more efficient if data are binary valued. In Section 5, we will confirm this result through experiments.

Regarding log operations, GIS, IIS and SCGIS need none as they remove the log function in $A_t(z_t)$. CD via Algorithm 3 keeps log in $A_t^{\mathsf{CD}}(z_t)$ and requires $O(|\Omega_t|)$ log operations at each line search step, where Ω_t is defined in (40).

4.4 Permutation of Indices in Solving Sub-problems

For sequential-update methods, one does not have to follow a cyclic way to update $w_1,\ldots,w_n$. Chang et al. (2008) report that in their CD method, a permutation of $\{1,\ldots,n\}$ as the order for solving n sub-problems leads to faster convergence. For sequential-update IS methods adopting this strategy, the linear convergence in Theorem 2 still holds.

5. Experiments

In this section, we compare IS/CD methods to reconfirm properties discussed in earlier sections. We consider two types of data for NLP (Natural Language Processing) applications. One is Maxent for 0/1-featured data and the other is Maxent (logistic regression) for document data with non-negative real-valued features. Programs used for experiments in this paper are online available at
`http://www.csie.ntu.edu.tw/~cjlin/liblinear/exp.html`.

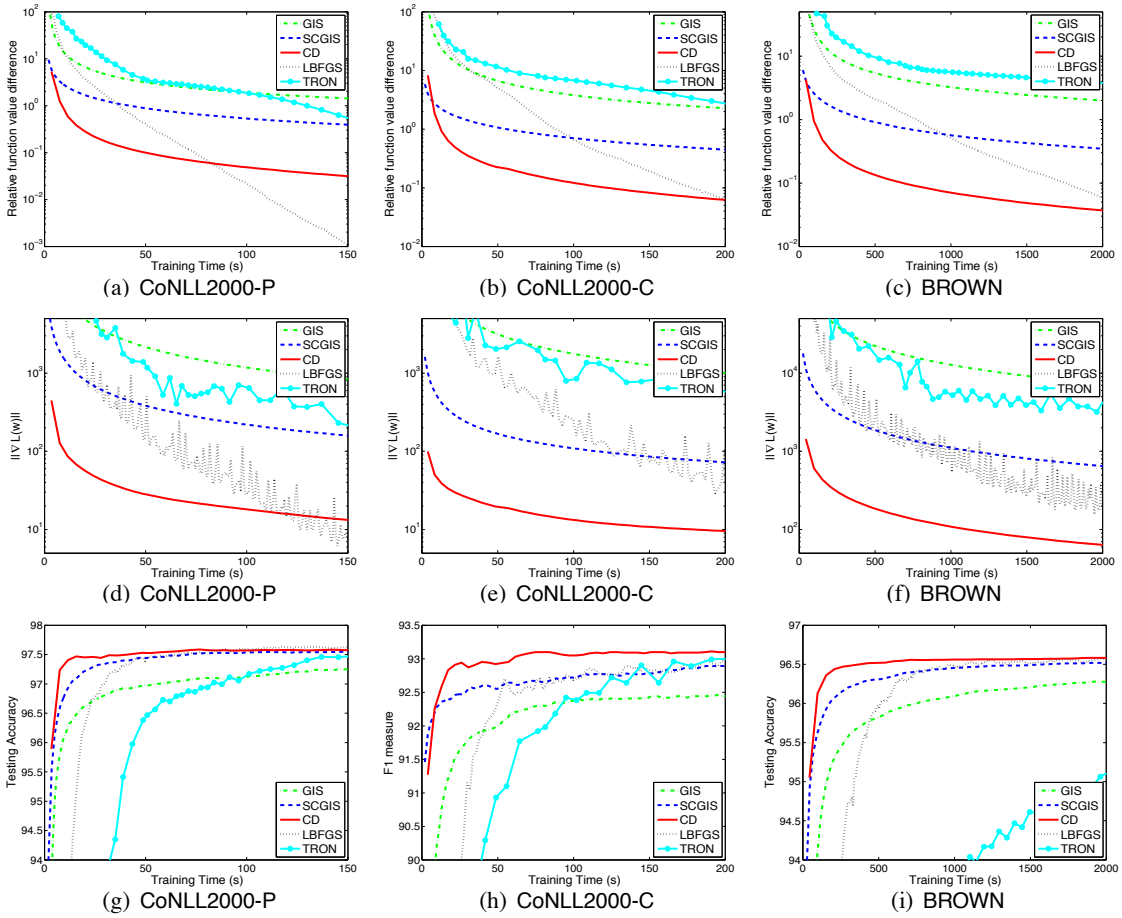

Figure 2: Results on 0/1-featured data. The first row shows time versus the relative function difference (42). The second and third rows show $\|\nabla L(\mathbf{w})\|$ and testing performances along time, respectively. Time is in seconds.

5.1 Maxent for 0/1-featured Data in NLP

We apply Maxent models to part of speech (POS) tagging and chunking tasks. In POS tagging, we mark a POS tag to the word in a text based on both its definition and context. In a chunking task, we divide a text into syntactically correlated parts of words. That is, given words in a sentence annotated with POS tags, we label each word with a chunk tag. Other learning models such as CRF (Conditional Random Fields) may outperform Maxent for these NLP applications. However, we do not consider other learning models as the focus of this paper is to study IS methods for Maxent.

We use CoNLL2000 shared task data[4] for chunking and POS tagging, and BROWN corpus[5] for POS tagging. CoNLL2000-P indicates CoNLL2000 for POS tagging, and CoNLL2000-C means CoNLL2000 for chunking. CoNLL2000 data consist of Sections 15-18 of the Wall Street Journal corpus as training data and Section 20 as testing data. For the BROWN corpus, we randomly se-

4. Data can be found at `http://www.cnts.ua.ac.be/conll2000/chunking`.
5. Corpus can be found at `http://www.nltk.org`.

lect four-fifth articles for training and use the rest for testing. We omit the stylistic tag modifiers "fw,""tl,""nc,"and "hl," so the number of labels is reduced from 472 to 185. Our implementation is built upon the OpenNLP package (Baldridge et al., 2001). We use the default setting of OpenNLP to extract binary features (0/1 values) suggested by Ratnaparkhi (1998). The OpenNLP implementation assumes that each feature index t corresponds to a unique label y. In prediction, we approximately maximize the probability of tag sequences to the word sequences by a beam search (Ratnaparkhi, 1998). Table 3 lists the statistics of data sets.

We implement the following methods for comparisons.

1. GIS and SCGIS: To minimize $A_t(z_t)$, we run Newton updates (without line search) until $|A'_t(z_t)| \leq 10^{-5}$. We can afford many Newton iterations because, according to Table 2, each Newton direction costs only $O(1)$ time.

2. CD: the coordinate descent method proposed in Section 3.2.

3. LBFGS: a limited memory quasi Newton method for general unconstrained optimization problems (Liu and Nocedal, 1989).

4. TRON: a trust region Newton method for logistic regression (Lin et al., 2008). We extend the method for Maxent.

We consider LBFGS as Malouf (2002) reports that it is better than other approaches including GIS and IIS. Lin et al. (2008) show that TRON is faster than LBFGS for document classification, so we include TRON for comparison. We exclude IIS because of its higher cost per Newton direction than GIS/SCGIS (see Table 2). Indeed Malouf (2002) reports that GIS outperforms IIS. Our implementation of all methods takes the property of 0/1 features. We use the regularization parameter $\sigma^2 = 10$ as under this value Maxent models achieve good testing performances. We set $\beta = 0.5$ and $\gamma = 0.001$ for the line search procedure (35) in CD. The initial $\mathbf{w}$ of all methods is $\mathbf{0}$.

We begin at checking time versus the relative difference of the function value to the optimum:

$$\frac{L(\mathbf{w}) - L(\mathbf{w}^*)}{L(\mathbf{w}^*)}, \tag{42}$$

where $\mathbf{w}^*$ is the optimal solution of (3). As $\mathbf{w}^*$ is not available, we obtain a reference point satisfying $\|\nabla L(\mathbf{w})\| \leq 0.01$. Results are in the first row of Figure 2. Next, we check these methods' gradient values. As $\|\nabla L(\mathbf{w})\| = 0$ implies that $\mathbf{w}$ is the global minimum, usually $\|\nabla L(\mathbf{w})\|$ is used in a stopping condition. The second row of Figure 2 shows time versus $\|\nabla L(\mathbf{w})\|$. We are also interested in the time needed to achieve a reasonable testing result. We measure the performance of POS tagging by accuracy and chunking by F1 measure. The third row of Figure 2 presents the testing accuracy/F1 versus training time. Note that (42) and $\|\nabla L(\mathbf{w})\|$ in Figure 2 are both log scaled.

We give some observations from Figure 2. Among the three IS/CD methods compared, the new CD approach discussed in Section 3.2 is the fastest. SCGIS comes the second, while GIS is the last. This result is consistent with the tightness of their approximate functions; see (33). Regarding IS/CD methods versus LBFGS/TRON, the three IS/CD methods more quickly decrease the function value in the beginning, but LBFGS has faster final convergence. In fact, if we draw figures with longer training time, TRON's final convergence is the fastest. This result is reasonable as LBFGS and TRON respectively have superlinear and quadratic convergence, higher than the linear rate proved in Theorem 2 for IS methods. The choice of methods thus relies on whether one prefers getting a

Problem	l	n	#nz	σ^2

Table 4: Statistics of document data (real-valued features). l: number of instances, n: number of features, #nz: number of total non-zero feature values, and σ^2: best regularization parameter from five-fold cross validation.

reasonable model quickly (IS/CD methods) or accurately minimizing the function (LBFGS/TRON). Practically CD/IS may be more useful as they reach the final testing accuracy rapidly. Finally, we compare LBFGS and TRON. Surprisingly, LBFGS outperforms TRON, a result opposite to that in Lin et al. (2008). We do not have a clear explanation yet. A difference is that Lin et al. (2008) deal with document data of real-valued features, but here we have 0/1-featured NLP applications. Therefore, one should always be careful that for the same approaches, observations made on one type of data may not extend to another.

In Section 4, we discussed a strategy of permuting n sub-problems to speed up the convergence of sequential-update IS methods. However, in training Maxent models for 0/1-featured NLP data, with/without permutation gives similar performances. We find that this strategy tends to work better if features are related. Hence we suspect that features used in POS tagging or chunking tasks are less correlated than those in documents and the order of sub-problems is not very important.

5.2 Maxent (Logistic Regression) for Document Classification

In this section, we experiment with logistic regression on document data with non-negative real-valued features. Chang et al. (2008) report that their CD method is very efficient for linear SVM, but is slightly less effective for logistic regression. They attribute the reason to that logistic regression requires expensive exp/log operations. In Section 4, we show that for 0/1 features, the number of IS methods' exp operations is smaller. Experiments here help to check if IS/CD methods are more suitable for 0/1 features than real values.

Logistic regression is a special case of maximum entropy with two labels $+1$ and -1. Consider training data $\{\bar{\mathbf{x}}_i, \bar{y}_i\}_{i=1}^{l}, \bar{\mathbf{x}}_i \in R^n, \bar{y}_i = \{1,-1\}$. Assume $\bar{x}_{it} \geq 0,\ \forall i,t$. We set the feature $f_t(x_i,y)$ as

$$f_t(x_i,y) = \begin{cases} \bar{x}_{it} & \text{if } y = 1, \\ 0 & \text{if } y = -1, \end{cases}$$

where x_i denotes the index of the i-th training instance $\bar{\mathbf{x}}_i$. Then

$$S_{\mathbf{w}}(x_i,y) = e^{\sum_t w_t f_t(x_i,y)} = \begin{cases} e^{\mathbf{w}^T \bar{\mathbf{x}}_i} & \text{if } y = 1, \\ 1 & \text{if } y = -1, \end{cases}$$

and

$$P_{\mathbf{w}}(y|x_i) = \frac{S_{\mathbf{w}}(x_i,y)}{T_{\mathbf{w}}(x_i)} = \frac{1}{1+e^{-y\mathbf{w}^T \bar{\mathbf{x}}_i}}. \tag{43}$$

From (2) and (43),

$$L(\mathbf{w}) \quad = \frac{1}{2\sigma^2}\sum_t w_t^2 + \frac{1}{l}\sum_i \log\left(1+e^{-\bar{y}_i \mathbf{w}^T \bar{\mathbf{x}}_i}\right)$$

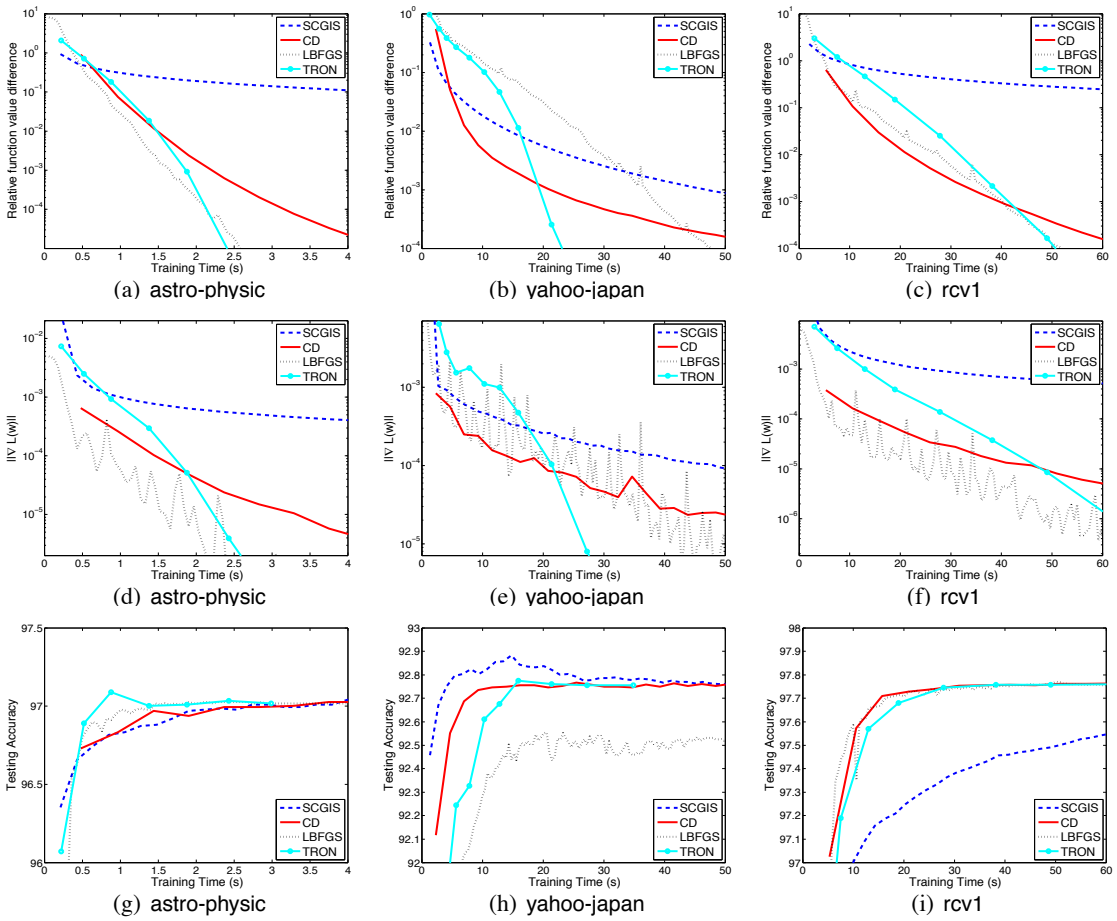

Figure 3: Results on real-valued document data. The first row shows time versus the relative function difference (42). The second and third rows show $\|\nabla L(\mathbf{w})\|$ and testing performances along time, respectively. Time is in seconds.

is the common form of regularized logistic regression. We give approximate functions of IS/CD methods in Section 7.11.

We compare the same methods: SCGIS, CD, LBFGS, and TRON. GIS is not included because of its slow convergence shown in Section 5.1. Our implementations are based on sources used in Chang et al. (2008).[6] We select three data sets considered in Chang et al. (2008). Each instance has been normalized to $\|\bar{\mathbf{x}}_i\| = 1$. Data statistics and σ^2 for each problem are in Table 4. We set $\beta = 0.5$ and $\gamma = 0.01$ for the line search procedure (35) in CD. Figure 3 shows the results of the relative function difference to the optimum, the gradient $\|\nabla L(\mathbf{w})\|$, and the testing accuracy.

From Figure 3, the relation between the two IS/CD methods is similar to that in Figure 2, where CD is faster than SCGIS. However, in contrast to Figure 2, here TRON/LBFGS may surpass IS/CD in an earlier stage. Some preliminary analysis on the cost per iteration seems to indicate that IS/CD

6. Source can be found at `http://www.csie.ntu.edu.tw/~cjlin/liblinear/exp.html`.

(c) CoNLL2000-P σ^2=1 (d) yahoo-japan σ^2=0.5l

Figure 4: This figure shows the effect of using (38) to do line search. The first and second rows show time versus the relative function difference with different σ^2. CDD indicates the CD method without using (38). Time is in seconds.

methods are more efficient on 0/1-featured data due to a smaller number of exp operations, but more experiments/data are needed to draw definitive conclusions.

In Figure 3, TRON is only similarly to or moderately better than LBFGS, but Lin et al. (2008) show that TRON is much better. The only difference between their setting and ours is that Lin et al. (2008) add one feature to each data instance. That is, they modify $\bar{\mathbf{x}}_i$ to $\begin{bmatrix} \bar{\mathbf{x}}_i \\ 1 \end{bmatrix}$, so weights of Maxent become $\begin{bmatrix} \mathbf{w} \\ b \end{bmatrix}$, where b is called the bias term. It is surprising that this difference affects LBFGS' performance that much.

6. Discussion and Conclusions

In (38), we propose a way to speed up the line search procedure of Algorithm 3. Figure 4 shows how effective this trick is by varying the value of σ^2. Clearly, the trick is more useful if σ^2 is small. In this situation, the function $L(\mathbf{w})$ is well conditioned (as it is closer to a quadratic function $\sum_t w_t^2$). Hence (38) more easily holds at $\lambda = 1$. Then the line search procedure costs only $O(1)$ time. However, a too small σ^2 may downgrade the testing accuracy. For example, the final accuracy for yahoo-japan is 92.75% with $\sigma^2 = 4l$, but is 92.31% with $\sigma^2 = 0.5l$.

Some work has concluded that approaches like LBFGS or nonlinear conjugate gradient are better than IS methods for training Maxent (e.g., Malouf, 2002; Daumé, 2004). However, experiments in this paper show that comparison results may vary under different circumstances. For example, comparison results can be affected by:

1. Data of the target application. IS/CD methods seem to perform better if features are 0/1 and if implementations have taken this property.

2. The IS method being compared. Our experiments indicate that GIS is inferior to many methods, but other IS/CD methods like SCGIS or CD (Algorithm 3) are more competitive.

In summary, we create a general framework for iterative scaling and coordinate descent methods for maximum entropy. Based on this framework, we discuss the convergence, computational complexity, and other properties of IS/CD methods. We further develop a new coordinate decent method for Maxent. It is more efficient than existing iterative scaling methods.

7. Proofs and Derivations

We define 1-norm and 2-norm of a vector $\mathbf{w} \in R^n$:

$$\|\mathbf{w}\|_1 \equiv \sum_{t=1}^{n} |w_t|, \quad \|\mathbf{w}\|_2 \equiv \sqrt{\sum_{t=1}^{n} w_t^2}.$$

The following inequality is useful in our proofs.

$$\|\mathbf{w}\|_2 \le \|\mathbf{w}\|_1 \le \sqrt{n}\|\mathbf{w}\|_2, \quad \forall \mathbf{w} \in R^n. \tag{44}$$

Subsequently we simplify $\|\mathbf{w}\|_2$ to $\|\mathbf{w}\|$.

7.1 Proof of Theorem 1

Due to the regularization term $\frac{1}{2\sigma^2}\mathbf{w}^T\mathbf{w}$, one can prove that the set U defined in (20) is bounded; see, for example, Theorem 1 of Lin et al. (2008). As $\nabla^2 L(\mathbf{w})$ is continuous in the bounded set U, the following $\tau_{\max}$ and $\tau_{\min}$ exist:

$$\tau_{\max} \equiv \max_{\mathbf{w}\in U} \lambda_{\max}(\nabla^2 L(\mathbf{w})) \quad \text{and} \quad \tau_{\min} \equiv \min_{\mathbf{w}\in U} \lambda_{\min}(\nabla^2 L(\mathbf{w})), \tag{45}$$

where $\lambda_{\max}(\cdot)$ and $\lambda_{\min}(\cdot)$ mean the largest and the smallest eigenvalues of a matrix, respectively. To show that $\tau_{\max}$ and $\tau_{\min}$ are positive, it is sufficient to prove $\tau_{\min} > 0$. As $\nabla^2 L(\mathbf{w})$ is I/σ^2 plus a positive semi-definite matrix, it is easy to see $\tau_{\min} \ge 1/(\sigma^2) > 0$.

To prove (21), we apply the multi-dimensional Mean-Value Theorem (Apostol, 1974, Theorem 12.9) to $\nabla L(\mathbf{w})$. If $\mathbf{u}, \mathbf{v} \in R^n$, then for any $\mathbf{a} \in R^n$, there is a $\mathbf{c} = \alpha\mathbf{u} + (1-\alpha)\mathbf{v}$ with $0 \le \alpha \le 1$ such that

$$\mathbf{a}^T(\nabla L(\mathbf{u}) - \nabla L(\mathbf{v})) = \mathbf{a}^T \nabla^2 L(\mathbf{c})(\mathbf{u}-\mathbf{v}). \tag{46}$$

Set

$$\mathbf{a} = \mathbf{u} - \mathbf{v}.$$

Then for any $\mathbf{u}, \mathbf{v} \in U$, there is a point $\mathbf{c}$ such that

$$(\mathbf{u}-\mathbf{v})^T(\nabla L(\mathbf{u}) - \nabla L(\mathbf{v})) = (\mathbf{u}-\mathbf{v})^T \nabla^2 L(\mathbf{c})(\mathbf{u}-\mathbf{v}). \tag{47}$$

Since U is a convex set from the convexity of $L(\mathbf{w})$, $\mathbf{c} \in U$. With (45) and (47),

$$\|\mathbf{u}-\mathbf{v}\|\|\nabla L(\mathbf{u}) - \nabla L(\mathbf{v})\| \ge (\mathbf{u}-\mathbf{v})^T(\nabla L(\mathbf{u}) - \nabla L(\mathbf{v})) \ge \tau_{\min}\|\mathbf{u}-\mathbf{v}\|^2.$$

Hence

$$\|\nabla L(\mathbf{u}) - \nabla L(\mathbf{v})\| \geq \tau_{\min}\|\mathbf{u}-\mathbf{v}\|. \tag{48}$$

By applying (46) again with $\mathbf{a} = \nabla L(\mathbf{u}) - \nabla L(\mathbf{v})$,

$$\begin{aligned}\|\nabla L(\mathbf{u}) - \nabla L(\mathbf{v})\|^2 \leq & \|\nabla L(\mathbf{u}) - \nabla L(\mathbf{v})\|\|\nabla^2 L(\mathbf{c})(\mathbf{u}-\mathbf{v})\| \\ \leq & \|\nabla L(\mathbf{u}) - \nabla L(\mathbf{v})\|\|\mathbf{u}-\mathbf{v}\|\tau_{\max}.\end{aligned}$$

Therefore,

$$\|\nabla L(\mathbf{u}) - \nabla L(\mathbf{v})\| \leq \tau_{\max}\|\mathbf{u}-\mathbf{v}\|. \tag{49}$$

Then (21) follows from (48) and (49)

To prove the second property (22), we write the Taylor expansion of $L(\mathbf{u})$:

$$L(\mathbf{u}) = L(\mathbf{v}) + \nabla L(\mathbf{v})^T(\mathbf{u}-\mathbf{v}) + \frac{1}{2}(\mathbf{u}-\mathbf{v})^T\nabla^2 L(\mathbf{c})(\mathbf{u}-\mathbf{v}),$$

where $\mathbf{c} \in U$. With (45), we have

$$\frac{\tau_{\min}}{2}\|\mathbf{u}-\mathbf{v}\|^2 \leq L(\mathbf{u}) - L(\mathbf{v}) - \nabla L(\mathbf{v})^T(\mathbf{u}-\mathbf{v}) \leq \frac{\tau_{\max}}{2}\|\mathbf{u}-\mathbf{v}\|^2.$$

Since $\tau_{\max} \geq \tau_{\min} > 0$, L satisfies (22) by choosing $K = \tau_{\max}/2$.

7.2 Proof of Theorem 2

The following proof is modified from Chang et al. (2008). Since $L(\mathbf{w})$ is convex and $\mathbf{w}^*$ is the unique solution, the optimality condition shows that

$$\nabla L(\mathbf{w}^*) = \mathbf{0}. \tag{50}$$

From (21) and (50),

$$\|\nabla L(\mathbf{w}^k)\| \geq \tau_{\min}\|\mathbf{w}^k - \mathbf{w}^*\|. \tag{51}$$

With (23) and (51),

$$\|\mathbf{w}^{k+1} - \mathbf{w}^k\| \geq \eta\tau_{\min}\|\mathbf{w}^k - \mathbf{w}^*\|. \tag{52}$$

From (24) and (52),

$$L(\mathbf{w}^k) - L(\mathbf{w}^{k+1}) \geq \nu\eta^2\tau_{\min}^2\|\mathbf{w}^k - \mathbf{w}^*\|^2. \tag{53}$$

Combining (22) and (50),

$$L(\mathbf{w}^k) - L(\mathbf{w}^*) \leq K\|\mathbf{w}^k - \mathbf{w}^*\|^2. \tag{54}$$

Using (53) and (54),

$$L(\mathbf{w}^k) - L(\mathbf{w}^{k+1}) \geq \frac{\nu\eta^2\tau_{\min}^2}{K}\left(L(\mathbf{w}^k) - L(\mathbf{w}^*)\right).$$

This is equivalent to

$$\left(L(\mathbf{w}^k) - L(\mathbf{w}^*)\right) + \left(L(\mathbf{w}^*) - L(\mathbf{w}^{k+1})\right) \geq \frac{\nu\eta^2\tau_{\min}^2}{K}\left(L(\mathbf{w}^k) - L(\mathbf{w}^*)\right).$$

Finally, we have

$$L(\mathbf{w}^{k+1}) - L(\mathbf{w}^*) \leq \left(1 - \frac{\nu\eta^2\tau_{\min}^2}{K}\right)\left(L(\mathbf{w}^k) - L(\mathbf{w}^*)\right). \tag{55}$$

Let $\mu \equiv \nu\eta^2\tau_{\min}^2/K$. As all constants are positive, $\mu > 0$. If $\mu > 1$, $L(\mathbf{w}^k) > L(\mathbf{w}^*)$ implies that $L(\mathbf{w}^{k+1}) < L(\mathbf{w}^*)$, a contradiction to the definition of $L(\mathbf{w}^*)$. Thus we have either $\mu \in (0,1)$ or $\mu = 1$, which suggests we get the optimum in finite steps.

7.3 Proof of Theorem 3

We prove the result for GIS and IIS first. Let $\bar{\mathbf{z}} = \arg\min_{\mathbf{z}} A^s(\mathbf{z})$, where s indicates GIS or IIS method.[7] From the definition of $A^s(\mathbf{z})$ and its convexity,[8]

$$\nabla A^s(\mathbf{0}) = \nabla L(\mathbf{w}^k) \text{ and } \nabla A^s(\bar{\mathbf{z}}) = \mathbf{0}.^{9} \tag{56}$$

Note that $\nabla A^s(\mathbf{z})$ is the gradient with respect to $\mathbf{z}$, but $\nabla L(\mathbf{w})$ is the gradient with respect to $\mathbf{w}$. Since U is bounded, the set $\{(\mathbf{w},\mathbf{z}) \mid \mathbf{w} \in U \text{ and } \mathbf{w}+\mathbf{z} \in U\}$ is also bounded. Thus we have that

$$\max_{\mathbf{w}\in U} \max_{\mathbf{z}:\mathbf{w}+\mathbf{z}\in U} \lambda_{\max}\left(\nabla^2 A^s(\mathbf{z})\right)$$

is bounded by a constant K. Here $\lambda_{\max}(\cdot)$ means the largest eigenvalue of a matrix. To prove (23), we use

$$\begin{aligned} &\|\mathbf{w}^{k+1} - \mathbf{w}^k\| = \|\bar{\mathbf{z}} - \mathbf{0}\| \\ \geq &\frac{1}{K}\|\nabla A^s(\bar{\mathbf{z}}) - \nabla A^s(\mathbf{0})\| = \frac{1}{K}\|\nabla A^s(\mathbf{0})\| = \frac{1}{K}\|\nabla L(\mathbf{w}^k)\|, \end{aligned} \tag{57}$$

where the inequality is from the same derivation for (49) in Theorem 1. The last two equalities follow from (56).

Next, we prove (24). By (56) and the fact that the minimal eigenvalue of $\nabla^2 A^s(\mathbf{z})$ is greater than or equal to $1/(\sigma^2)$, we have

$$A^s(\mathbf{0}) \geq A^s(\bar{\mathbf{z}}) - \nabla A^s(\bar{\mathbf{z}})^T\bar{\mathbf{z}} + \frac{1}{2\sigma^2}\bar{\mathbf{z}}^T\bar{\mathbf{z}} = A^s(\bar{\mathbf{z}}) + \frac{1}{2\sigma^2}\bar{\mathbf{z}}^T\bar{\mathbf{z}}. \tag{58}$$

From (9) and (58),

$$L(\mathbf{w}^k) - L(\mathbf{w}^{k+1}) = L(\mathbf{w}^k) - L(\mathbf{w}^k + \bar{\mathbf{z}}) \geq A^s(\mathbf{0}) - A^s(\bar{\mathbf{z}}) \geq \frac{1}{2\sigma^2}\bar{\mathbf{z}}^T\bar{\mathbf{z}} = \frac{1}{2\sigma^2}\|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2.$$

Let $\nu = 1/(2\sigma^2)$ and we obtain (24).

We then prove results for SCGIS and CD. For the convenience, we define some notation. A sequential algorithm starts from an initial point $\mathbf{w}^0$, and produces a sequence $\{\mathbf{w}^k\}_{k=0}^{\infty}$. At each iteration, $\mathbf{w}^{k+1}$ is constructed by sequentially updating each component of $\mathbf{w}^k$. This process generates vectors $\mathbf{w}^{k,t} \in R^n, t = 1,\ldots,n$, such that $\mathbf{w}^{k,1} = \mathbf{w}^k$, $\mathbf{w}^{k,n+1} = \mathbf{w}^{k+1}$, and

$$\mathbf{w}^{k,t} = [w_1^{k+1},\ldots,w_{t-1}^{k+1}, w_t^k,\ldots,w_n^k]^T \text{ for } t = 2,\ldots,n.$$

7. The existence of $\bar{z}$ follows from that U is bounded. See the explanation in the beginning of Section 7.1.
8. It is easy to see that all $A_t(z_t)$ in Table 1 are strictly convex.
9. Because $\nabla_t L(\mathbf{w}^k) = A_t^{\mathsf{CD}'}(0)$, we can easily obtain $\nabla A^s(\mathbf{0}) = \nabla L(\mathbf{w}^k)$ by checking $A_t^{s\prime}(0) = A_t^{\mathsf{CD}'}(0)$, where s is GIS or IIS. See formulas in Table 1.

By an argument similar to (57) and (58), we can prove that the one-variable function $A_t^s(z_t)$, where s is SCGIS or CD, satisfies

$$|w_t^{k,t+1} - w_t^{k,t}| \geq \bar{\eta}|A_t^{s\prime}(0)| = \bar{\eta}|\nabla L(\mathbf{w}^{k,t})_t| \text{ and} \tag{59}$$

$$L(\mathbf{w}^{k,t}) - L(\mathbf{w}^{k,t+1}) \geq \frac{1}{2\sigma^2}|w_t^{k,t+1} - w_t^{k,t}|^2. \tag{60}$$

Note that $\bar{\eta} > 0$ is a positive constant. To prove (23), taking the summation of (59) from $t = 1$ to n,

$$\begin{aligned}\|\mathbf{w}^{k+1} - \mathbf{w}^k\|_1 &\geq \bar{\eta}\sum_{t=1}^{n}|\nabla L(\mathbf{w}^{k,t})_t| \geq \bar{\eta}\sum_{t=1}^{n}\left(|\nabla L(\mathbf{w}^{k,1})_t| - |\nabla L(\mathbf{w}^{k,t})_t - \nabla L(\mathbf{w}^{k,1})_t|\right)\\ &= \bar{\eta}\left(\|\nabla L(\mathbf{w}^{k,1})\|_1 - \sum_{t=1}^{n}|\nabla L(\mathbf{w}^{k,t})_t - \nabla L(\mathbf{w}^{k,1})_t|\right).\end{aligned} \tag{61}$$

Since $L(\mathbf{w})$ satisfies (21), using (44),

$$\begin{aligned}&\sum_{t=1}^{n}|\nabla L(\mathbf{w}^{k,t})_t - \nabla L(\mathbf{w}^{k,1})_t| \leq \sum_{t=1}^{n}\|\nabla L(\mathbf{w}^{k,t}) - \nabla L(\mathbf{w}^{k,1})\|_1\\ \leq &\sum_{t=1}^{n}\sqrt{n}\tau_{\max}\|\mathbf{w}^{k,t} - \mathbf{w}^{k,1}\|_1 \leq n\sqrt{n}\tau_{\max}\|\mathbf{w}^{k+1} - \mathbf{w}^k\|_1.\end{aligned} \tag{62}$$

From (61) and (62), we have

$$\|\mathbf{w}^{k+1} - \mathbf{w}^k\|_1 \geq \frac{\bar{\eta}}{1 + \bar{\eta}n\sqrt{n}\tau_{\max}}\|\nabla L(\mathbf{w}^{k,1})\|_1.$$

This inequality and (44) imply

$$\|\mathbf{w}^{k+1} - \mathbf{w}^k\| \geq \tfrac{1}{\sqrt{n}}\|\mathbf{w}^{k+1} - \mathbf{w}^k\|_1 \geq \tfrac{\bar{\eta}}{\sqrt{n} + \bar{\eta}n^2\tau_{\max}}\|\nabla L(\mathbf{w}^k)\|.$$

Let $\eta = \bar{\eta}/(\sqrt{n} + \bar{\eta}n^2\tau_{\max})$. We then have (23).

Taking the summation of (60) from $t = 1$ to n, we get (24):

$$L(\mathbf{w}^k) - L(\mathbf{w}^{k+1}) \geq \frac{1}{2\sigma^2}\|\mathbf{w}^{k+1} - \mathbf{w}^k\|^2.$$

7.4 Derivation of (30)-(31)

Using (18)-(19), we have

$$\frac{dS_{\mathbf{w}+z_t\mathbf{e}_t}(x,y)}{dz_t} = S_{\mathbf{w}}(x,y)e^{z_t f_t(x,y)}f_t(x,y) = S_{\mathbf{w}+z_t\mathbf{e}_t}(x,y)f_t(x,y)$$

and

$$\frac{dT_{\mathbf{w}+z_t\mathbf{e}_t}(x)}{dz_t} = \sum_y S_{\mathbf{w}}(x,y)e^{z_t f_t(x,y)}f_t(x,y) = \sum_y S_{\mathbf{w}+z_t\mathbf{e}_t}(x,y)f_t(x,y).$$

Then (30) can be obtained from (16), the definition of $T_{\mathbf{w}+z_t\mathbf{e}_t}(x)$ in (1), and the following calculation:

$$\frac{d\log T_{\mathbf{w}+z_t\mathbf{e}_t}(x)}{dz_t} = \frac{\sum_y S_{\mathbf{w}+z_t\mathbf{e}_t}(x,y)f_t(x,y)}{T_{\mathbf{w}+z_t\mathbf{e}_t}(x)} = \sum_y P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x)f_t(x,y).$$

For (31), we use

$$\begin{aligned}
&\frac{d\sum_y P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x)f_t(x,y)}{dz_t} \\
&= \sum_y f_t(x,y)\frac{T_{\mathbf{w}+z_t\mathbf{e}_t}(x)\frac{dS_{\mathbf{w}+z_t\mathbf{e}_t}(x,y)}{dz_t} - \frac{dT_{\mathbf{w}+z_t\mathbf{e}_t}(x)}{dz_t}S_{\mathbf{w}+z_t\mathbf{e}_t}(x,y)}{T_{\mathbf{w}+z_t\mathbf{e}_t}(x)^2} \\
&= \sum_y f_t(x,y)\left(f_t(x,y)P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x) - \frac{S_{\mathbf{w}+z_t\mathbf{e}_t}(x,y)}{T_{\mathbf{w}+z_t\mathbf{e}_t}(x)}\sum_{y'} P_{\mathbf{w}+z_t\mathbf{e}_t}(y'|x)f_t(x,y')\right) \\
&= \sum_y P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x)f_t(x,y)^2 - \sum_y\left(P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x)f_t(x,y)\sum_{y'} P_{\mathbf{w}+z_t\mathbf{e}_t}(y'|x)f_t(x,y')\right) \\
&= \sum_y P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x)f_t(x,y)^2 - \left(\sum_y P_{\mathbf{w}+z_t\mathbf{e}_t}(y|x)f_t(x,y)\right)^2.
\end{aligned}$$

7.5 Derivation of (33)

From (6) and (9), we immediately have $A_t^{\mathsf{SCGIS}}(z_t) \geq A_t^{\mathsf{CD}}(z_t)$ and $A_t^{\mathsf{IIS}}(z_t) \geq A_t^{\mathsf{CD}}(z_t)$. Next we prove that $A_t^{\mathsf{GIS}}(z_t) \geq A_t^{\mathsf{SCGIS}}(z_t)$. Assume $D(z_t) \equiv A_t^{\mathsf{GIS}}(z_t) - A_t^{\mathsf{SCGIS}}(z_t)$. Then

$$D'(z_t) = \left(e^{z_t f^\#} - e^{z_t f_t^\#}\right)\sum_{x,y}\tilde{P}(x)P_{\mathbf{w}}(y|x)f_t(x,y).$$

Since $f^\# \geq f_t^\# \geq 0$,

$$\begin{aligned}
&D'(z_t) \geq 0 \text{ if } z_t > 0, \\
&D'(z_t) \leq 0 \text{ if } z_t < 0.
\end{aligned} \tag{63}$$

From Taylor expansion, there exists h between 0 and z_t such that

$$D(z_t) = D(0) + z_t D'(h).$$

From $A_t^{\mathsf{SCGIS}}(0) = A_t^{\mathsf{GIS}}(0) = 0$, we have $D(0) = 0$. By (63), $z_t D'(h) \geq 0$, so

$$A_t^{\mathsf{GIS}}(z_t) - A_t^{\mathsf{SCGIS}}(z_t) = D(z_t) \geq D(0) = 0.$$

We can use a similar method to prove $A_t^{\mathsf{GIS}}(z_t) \geq A_t^{\mathsf{IIS}}(z_t)$.

7.6 Proof of Theorem 4

From (31), we can define

$$H = \max_t\left(\frac{1}{\sigma^2} + \sum_{x,y}\tilde{P}(x)f_t(x,y)^2\right) \geq A_t^{\mathsf{CD}\prime\prime}(z_t),\ \forall z_t. \tag{64}$$

From the Taylor expansion of $A_t^{\mathsf{CD}}(z_t)$ at $z_t = 0$, there exists h between 0 and d such that $z_t = \lambda d$ satisfies

$$\begin{aligned}
& A_t^{\mathsf{CD}}(\lambda d) - \gamma\lambda d A_t^{\mathsf{CD}'}(0) \\
= \;& A_t^{\mathsf{CD}}(0) + A_t^{\mathsf{CD}'}(0)\lambda d + \frac{1}{2}A_t^{\mathsf{CD}''}(h)\lambda^2 d^2 - \gamma\lambda d A_t^{\mathsf{CD}'}(0) \\
\leq \;& A_t^{\mathsf{CD}'}(0)\lambda d + \frac{1}{2}H\lambda^2 d^2 - \gamma\lambda d A_t^{\mathsf{CD}'}(0) \\
= \;& -\lambda\frac{A_t^{\mathsf{CD}'}(0)^2}{A_t^{\mathsf{CD}''}(0)} + \frac{1}{2}H\lambda^2\frac{A_t^{\mathsf{CD}'}(0)^2}{A_t^{\mathsf{CD}''}(0)^2} + \gamma\lambda\frac{A_t^{\mathsf{CD}'}(0)^2}{A_t^{\mathsf{CD}''}(0)} \\
= \;& \lambda\frac{A_t^{\mathsf{CD}'}(0)^2}{A_t^{\mathsf{CD}''}(0)}\left(\lambda\left(\frac{H}{2A_t^{\mathsf{CD}''}(0)}\right) - 1 + \gamma\right). \qquad (65)
\end{aligned}$$

If we choose

$$\bar{\lambda} = \frac{2A_t^{\mathsf{CD}''}(0)(1-\gamma)}{H}, \qquad (66)$$

then for $\lambda \leq \bar{\lambda}$, (65) is non-positive. Therefore, (35) is satisfied for all $0 \leq \lambda \leq \bar{\lambda}$.

7.7 Proof of Theorem 5

Following the proof in Section 7.3, it is sufficient to prove inequalities in the same form as (59) and (60). By Theorem 4, any $\lambda \in [\beta\bar{\lambda}, \bar{\lambda}]$, where $\beta \in (0,1)$ and $\bar{\lambda}$ is defined in (66), satisfies the sufficient decrease condition (35). Since Algorithm 3 selects λ by trying $\{1, \beta, \beta^2, \dots\}$, with (64), the selected value λ satisfies

$$\lambda \geq \beta\bar{\lambda} = \beta\frac{2A_t^{\mathsf{CD}''}(0)(1-\gamma)}{H}.$$

This and (34) suggest that the step size $z_t = \lambda d$ in Algorithm 3 satisfies

$$|z_t| = \lambda\left|\frac{-A_t^{\mathsf{CD}'}(0)}{A_t^{\mathsf{CD}''}(0)}\right| \geq \frac{2\beta(1-\gamma)}{H}\left|A_t^{\mathsf{CD}'}(0)\right|. \qquad (67)$$

From (34), (35), $z_t = \lambda d$, $A_t^{\mathsf{CD}''}(0) \geq 1/\sigma^2$ and $\lambda \leq 1$, we have

$$A_t^{\mathsf{CD}}(z_t) - A_t^{\mathsf{CD}}(0) \leq \gamma z_t A_t^{\mathsf{CD}'}(0) = -\gamma z_t d A_t^{\mathsf{CD}''}(0) \leq -\frac{\gamma}{\lambda\sigma^2}z_t^2 \leq -\frac{\gamma}{\sigma^2}z_t^2. \qquad (68)$$

Note that z_t is the step taken for updating $w_t^{k,t}$ to $w_t^{k,t+1}$. With $A_t^{\mathsf{CD}}(z_t) = L(\mathbf{w}^{k,t+1}) - L(\mathbf{w}^{k,t})$, (67)-(68) are in the same form as (59)-(60). In Section 7.3, (59)-(60) are sufficient to prove the desired conditions (23)-(24) for the linear convergence (Theorem 2). Therefore, Algorithm 3 linearly converges.

7.8 Proof of Theorem 6

A direct calculation of $A_t^{\mathsf{CD}'''}(z_t)$ shows that it is bounded for all z_t and w_t^k. We assume that a bound is M. Using $A_t^{\mathsf{CD}}(0) = 0$, (34) and Taylor expansion, there exists h between 0 and d such that

$$\begin{aligned} A_t^{\mathsf{CD}}(d) &= A_t^{\mathsf{CD}'}(0)d + \frac{1}{2}A_t^{\mathsf{CD}''}(0)d^2 + \frac{1}{6}A_t^{\mathsf{CD}'''}(h)d^3 \\ &= -\frac{1}{2}\frac{A_t^{\mathsf{CD}'}(0)^2}{A_t^{\mathsf{CD}''}(0)} + \frac{1}{6}A_t^{\mathsf{CD}'''}(h)d^3 \\ &\le -\frac{1}{2}A_t^{\mathsf{CD}''}(0)d^2 + \frac{1}{6}M\left|d^3\right| \\ &= -\gamma d^2 A_t^{\mathsf{CD}''}(0) + \left(\gamma A_t^{\mathsf{CD}''}(0) - \frac{1}{2}A_t^{\mathsf{CD}''}(0) + \frac{1}{6}M|d|\right)d^2 \\ &= \gamma d A_t^{\mathsf{CD}'}(0) + \left(\gamma A_t^{\mathsf{CD}''}(0) - \frac{1}{2}A_t^{\mathsf{CD}''}(0) + \frac{1}{6}M|d|\right)d^2. \end{aligned} \tag{69}$$

Note that $\gamma < 1/2$. As $A_t^{\mathsf{CD}''}(0) \ge 1/\sigma^2$ and $|A_t^{\mathsf{CD}'}(0)| \to 0$ when $\mathbf{w}$ converges to the optimal solution $\mathbf{w}^*$, near the optimum, d is small enough so that

$$0 \le |d| \le \frac{6}{M}\left(\frac{1}{2} - \gamma\right)A_t^{\mathsf{CD}''}(0).$$

Then we obtain $A_t^{\mathsf{CD}}(d) \le \gamma d A_t^{\mathsf{CD}'}(0)$ and (35) is satisfied.

7.9 Proof of Theorem 7

The following lemma, needed for proving Theorem 7, shows that the direction taken by CD is bigger than that of GIS, IIS, or SCGIS.

Lemma 8 *There exists a positive constant* λ *such that in a neighborhood of* $\mathbf{w}^*$,

$$|d^s|(1+\lambda) \le |d| = \left|\frac{\delta_t'(0)}{\delta_t''(0)}\right|, \tag{70}$$

where d *and* d^s *are defined in* (37).

Proof. Since $d^s = \arg\min_{z_t} A_t^s(z_t)$ and $A_t^s(z_t)$ is strictly convex,

$$A_t^{s\prime}(d^s) = 0. \tag{71}$$

We separate the proof to two cases: $A_t^{s\prime}(0) > 0$ and $A_t^{s\prime}(0) < 0$. If $A_t^{s\prime}(0) = 0$, then $d^s = 0$, so (70) immediately holds.

If $A_t^{s\prime}(0) > 0$, from the strict convexity of $A_t^s(z_t)$ and (71), $d^s < 0$. It is sufficient to prove that there is λ such that $A_t^{s\prime}(d/(1+\lambda)) \le 0$. This result implies $d/(1+\lambda) \le d^s$, so we obtain (70) .

Using Taylor expansion, if $z_t f^s(x,y) < 0$, then

$$e^{z_t f^s(x,y)} \le 1 + z_t f^s(x,y) + \frac{1}{2}z_t^2 (f^s(x,y))^2, \tag{72}$$

where

$$f^s(x,y) \equiv \begin{cases} f^\# \text{ if } s \text{ is GIS}, \\ f_t^\# \text{ if } s \text{ is SCGIS}, \\ f^\#(x,y) \text{ if } s \text{ is IIS}. \end{cases}$$

From Table 1 and (72),

$$\begin{aligned} A_t^{s\prime}(z_t) &= \sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y) e^{z_t f^s(x,y)} + Q_t'(z_t) \\ &\le \left(\sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y) + \frac{w_t}{\sigma^2} - \tilde{P}(f_t) \right) + \left(R_1(\mathbf{w}) + \frac{1}{\sigma^2} \right) z_t + \frac{1}{2} z_t^2 R_2(\mathbf{w}) \\ &= A_t^{s\prime}(0) + \left(R_1(\mathbf{w}) + \frac{1}{\sigma^2} - \frac{1}{2}|z_t| R_2(\mathbf{w}) \right) z_t, \end{aligned} \tag{73}$$

where

$$\begin{aligned} R_1(\mathbf{w}) &\equiv \sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y) f^s(x,y) \quad \text{and} \\ R_2(\mathbf{w}) &\equiv \sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y) f^s(x,y)^2. \end{aligned}$$

Now the Newton direction is

$$d = -\frac{A_t^{\mathsf{CD}\prime}(0)}{A_t^{\mathsf{CD}\prime\prime}(0)} = -\frac{\delta_t'(0)}{\delta_t''(0)} = -\frac{A_t^{s\prime}(0)}{\delta_t''(0)} < 0. \tag{74}$$

From (31),

$$\begin{aligned} \delta_t''(0) &= \sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y)^2 - \sum_x \tilde{P}(x) \left(\sum_y P_{\mathbf{w}}(y|x) f_t(x,y) \right)^2 + \frac{1}{\sigma^2} \\ &\le R_1(\mathbf{w}) - R_3(\mathbf{w}) + \frac{1}{\sigma^2}, \end{aligned} \tag{75}$$

where

$$R_3(\mathbf{w}) \equiv \sum_x \tilde{P}(x) \left(\sum_y P_{\mathbf{w}}(y|x) f_t(x,y) \right)^2.$$

When $\mathbf{w} \to \mathbf{w}^*, R_1(\mathbf{w}), R_2(\mathbf{w}), R_3(\mathbf{w})$ respectively converge to $R_1(\mathbf{w}^*), R_2(\mathbf{w}^*), R_3(\mathbf{w}^*)$. Moreover, as $\mathbf{w} + d^s \mathbf{e}_t \in \{\bar{\mathbf{w}} \mid L(\bar{\mathbf{w}}) \le L(\mathbf{w})\}$, $d^s \to 0$ when $\mathbf{w} \to \mathbf{w}^*$. Therefore,

$$\lim_{\mathbf{w} \to \mathbf{w}^*} \frac{\delta_t''(0)}{R_1(\mathbf{w}) + \frac{1}{\sigma^2} - \frac{1}{2}|d^s| R_2(\mathbf{w})} = 1 - \frac{R_3(\mathbf{w}^*)}{R_1(\mathbf{w}^*) + \frac{1}{\sigma^2}}. \tag{76}$$

Here we can assume $R_3(\mathbf{w}^*) > 0$. If not, $f_t(x,y) = 0$ for all x, y. Then $w_t^* = 0$ is obtained in just one iteration. From (76), we can choose a positive λ such that

$$\frac{1}{1+\lambda} > 1 - \frac{R_3(\mathbf{w}^*)}{R_1(\mathbf{w}^*) + \frac{1}{\sigma^2}}. \tag{77}$$

From (76) and (77), for any $\mathbf{w}$ in a neighborhood of $\mathbf{w}^*$,

$$\delta_t''(0) \le \frac{R_1(\mathbf{w}) + \frac{1}{\sigma^2} - \frac{1}{2}|d^s| R_2(\mathbf{w})}{1+\lambda}.$$

From (74),

$$\frac{d}{1+\lambda} \le -\frac{A_t^{s\prime}(0)}{R_1(\mathbf{w}) + \frac{1}{\sigma^2} - \frac{1}{2}|d^s| R_2(\mathbf{w})}. \tag{78}$$

From (73) with $z_t = d/(1+\lambda)$ and (78),

$$A_t^{s\prime}\left(\frac{d}{1+\lambda}\right) \le A_t^{s\prime}(0) - A_t^{s\prime}(0) = 0.$$

Therefore, $d/(1+\lambda) \le d^s < 0$.

If $A_t^{s\prime}(0) < 0$, then $d^s > 0$. Using Taylor expansion, if $z_t f^s(x,y) > 0$, we have

$$e^{z_t f^s(x,y)} \ge 1 + z_t f^s(x,y).$$

Then (73) becomes

$$\begin{aligned} A_t^{s\prime}(z_t) &\ge \left(\sum_{x,y} \tilde{P}(x) P_{\mathbf{w}}(y|x) f_t(x,y) + \frac{w_t}{\sigma^2} - \tilde{P}(f_t)\right) + \left(R_1(\mathbf{w}) + \frac{1}{\sigma^2}\right) z_t \\ &= A_t^{s\prime}(0) + \left(R_1(\mathbf{w}) + \frac{1}{\sigma^2}\right) z_t. \end{aligned} \tag{79}$$

From (75) and a derivation similar to (76), there is a $\lambda > 0$ such that

$$\delta_t''(0)(1+\lambda) \le R_1(\mathbf{w}) + \frac{1}{\sigma^2}.$$

Let $z_t = d/(1+\lambda)$ in (79). With (74),

$$A_t^{s\prime}\left(\frac{d}{1+\lambda}\right) \ge A_t^{s\prime}(0) - A_t^{s\prime}(0) = 0.$$

Therefore, $0 < d^s \le d/(1+\lambda)$.

Proof of Theorem 7 We prove this theorem by calculating a lower bound of $\delta_t(d^s) - \delta_t(d)$. From (69),

$$\delta_t(d) \le -\frac{1}{2}\frac{\delta_t'(0)^2}{\delta_t''(0)} + \frac{1}{6} M d^3, \tag{80}$$

where M is an upper bound of $\delta_t'''(z_t)$. If $\mathbf{w}$ is sufficiently close to $\mathbf{w}^*$,

$$\begin{aligned} \delta_t(d^s) &= \delta_t'(0) d^s + \frac{1}{2}\delta_t''(0)(d^s)^2 + \frac{1}{6}\delta_t'''(h)(d^s)^3 \\ &= \frac{1}{2}\delta_t''(0)\left(\frac{\delta_t'(0)}{\delta_t''(0)} - d^s\right)^2 - \frac{1}{2}\frac{\delta_t'(0)^2}{\delta_t''(0)} + \frac{1}{6}\delta_t'''(h)(d^s)^3 \\ &\ge \frac{1}{2}\delta_t''(0)\left(\frac{\lambda}{1+\lambda}\right)\frac{\delta_t'(0)^2}{\delta_t''(0)^2} - \frac{1}{2}\frac{\delta_t'(0)^2}{\delta_t''(0)} - \frac{1}{6}M|d^3| \\ &= \frac{1}{2}\left(\frac{-1}{1+\lambda}\right)\frac{\delta_t'(0)^2}{\delta_t''(0)} - \frac{1}{6}M|d^3|, \end{aligned} \tag{81}$$

where h is between 0 and d^s and the inequality is from Lemma 8. Combining (80) and (81),

$$\begin{aligned}\delta_t(d^s)-\delta_t(d) &\geq \frac{1}{2}\left(1-\frac{1}{1+\lambda}\right)\frac{\delta_t'(0)^2}{\delta_t''(0)}-\frac{1}{3}M|d^3| \\ &= \left(\frac{1}{2}\left(\frac{\lambda}{1+\lambda}\right)-\frac{1}{3}M\frac{|\delta_t'(0)|}{\delta_t''(0)^2}\right)\frac{\delta_t'(0)^2}{\delta_t''(0)}.\end{aligned}$$

Since $\delta_t''(0)\geq 1/(\sigma^2)$ and $\delta_t'(0)\to\nabla_t L(\mathbf{w}^*)=0$, there is a neighborhood of $\mathbf{w}^*$ so that $\delta_t'(0)$ is small enough and

$$\frac{1}{2}\left(\frac{\lambda}{1+\lambda}\right)>\frac{1}{3}M\frac{|\delta_t'(0)|}{\delta_t''(0)^2}.$$

Therefore, $\delta_t(d^s)>\delta_t(d)$ in a neighborhood of $\mathbf{w}^*$.

7.10 Derivation of (39)

From Jensen's inequality and the fact that $\log(x)$ is a concave function,

$$\frac{\sum_{\Omega_t}\tilde{P}(x)\log\frac{T_{\mathbf{w}+z_t\mathbf{e}_t}(x)}{T_{\mathbf{w}}(x)}}{\sum_{\Omega_t}\tilde{P}(x)}\leq\log\left(\frac{\sum_{\Omega_t}\tilde{P}(x)\frac{T_{\mathbf{w}+z_t\mathbf{e}_t}(x)}{T_{\mathbf{w}}(x)}}{\sum_{\Omega_t}\tilde{P}(x)}\right).$$

With (16), (19) and (40), we have

$$A_t^{\mathsf{CD}}(z_t)\leq Q_t(z_t)+\tilde{P}_t\log\left(1+\frac{\sum_{\Omega_t}\tilde{P}(x)\sum_y P_{\mathbf{w}}(y|x)(e^{z_t f_t(x,y)}-1)}{\tilde{P}_t}\right).$$

By the inequality (15),

$$\begin{aligned}A_t^{\mathsf{CD}}(z_t) &\leq Q_t(z_t)+\tilde{P}_t\log\left(1+\frac{\sum_{\Omega_t}\tilde{P}(x)\sum_y P_{\mathbf{w}}(y|x)\left(\frac{f_t(x,y)e^{z_t f_t^\#}}{f_t^\#}+\frac{f_t^\#-f_t(x,y)}{f_t^\#}-1\right)}{\tilde{P}_t}\right) \\ &= Q_t(z_t)+\tilde{P}_t\log\left(1+\frac{\left(e^{z_t f_t^\#}-1\right)\sum_{\Omega_t}\tilde{P}(x)\sum_y P_{\mathbf{w}}(y|x)f_t(x,y)}{f_t^\#\tilde{P}_t}\right) \\ &= \bar{A}_t^{\mathsf{CD}}(z_t).\end{aligned}$$

Note that replacing $\tilde{P}_t$ with $\sum_x\tilde{P}(x)$ leads to another upper bound of $A_t^{\mathsf{CD}}(z_t)$. It is, however, looser than $\bar{A}_t^{\mathsf{CD}}(z_t)$.

7.11 Logistic Regression

We list approximate functions of IS/CD methods for logistic regression. Note that

$$\tilde{P}(x_i,y)=\begin{cases}\frac{1}{l} & \text{if } y=\bar{y}_i,\\ 0 & \text{otherwise,}\end{cases}\quad\text{and }\tilde{P}(f_t)=\sum_{i:\bar{y}_i=1}\frac{1}{l}\bar{x}_{it}. \tag{82}$$

For GIS, using the formula in Table 1 and (43),

$$A_t^{\mathsf{GIS}}(z_t) = Q_t(z_t) + \frac{1}{l}\left(\frac{e^{z_t f^\#} - 1}{f^\#} \sum_i \frac{\bar{x}_{it}}{1 + e^{-\mathbf{w}^T \bar{\mathbf{x}}_i}}\right),$$

where from (11) and (82),

$$Q_t(z_t) = \frac{2w_t z_t + z_t^2}{2\sigma^2} - \frac{z_t}{l} \sum_{i:\bar{y}_i = 1} \bar{x}_{it} \quad \text{and} \quad f^\# \equiv \max_j f^\#(i).$$

Similarly, IIS and SCGIS respectively solve

$$A_t^{\mathsf{IIS}}(z_t) = Q_t(z_t) + \frac{1}{l}\left(\sum_i \frac{\bar{x}_{it}}{1 + e^{-\mathbf{w}^T \mathbf{x}_i}} \frac{e^{z_t f^\#(i)} - 1}{f^\#(i)}\right),$$

$$A_t^{\mathsf{SCGIS}}(z_t) = Q_t(z_t) + \frac{1}{l}\left(\frac{e^{z_t f_t^\#} - 1}{f_t^\#} \sum_i \frac{\bar{x}_{it}}{1 + e^{-\mathbf{w}^T \mathbf{x}_i}}\right),$$

where $f_t^\# = \max_i \bar{x}_{it}$ and $f^\#(i) = \sum_t \bar{x}_{it}$. Finally, from (17), (30), and (31),

$$A_t^{\mathsf{CD}}(z_t) = Q_t(z_t) + \frac{1}{l} \sum_i \log\left(1 + \frac{e^{z_t \bar{x}_{it}} - 1}{1 + e^{-\mathbf{w}^T \bar{\mathbf{x}}_i}}\right),$$

$$A_t^{\mathsf{CD}\prime}(0) = \frac{w_t}{\sigma^2} + \frac{1}{l}\left(\sum_i \frac{\bar{x}_{it}}{1 + e^{-\mathbf{w}^T \bar{\mathbf{x}}_i}} - \sum_{i:\bar{y}_i = 1} \bar{x}_{it}\right),$$

$$A_t^{\mathsf{CD}\prime\prime}(0) = \frac{1}{\sigma^2} + \frac{1}{l}\left(\sum_i \frac{e^{-\mathbf{w}^T \bar{\mathbf{x}}_i} \bar{x}_{it}^2}{(1 + e^{-\mathbf{w}^T \bar{\mathbf{x}}_i})^2}\right).$$

Abstract

We propose a new algorithm for building decision tree classifiers. The algorithm is executed in a distributed environment and is especially designed for classifying large data sets and streaming data. It is empirically shown to be as accurate as a standard decision tree classifier, while being scalable for processing of streaming data on multiple processors. These findings are supported by a rigorous analysis of the algorithm's accuracy.

The essence of the algorithm is to quickly construct histograms at the processors, which compress the data to a fixed amount of memory. A master processor uses this information to find near-optimal split points to terminal tree nodes. Our analysis shows that guarantees on the local accuracy of split points imply guarantees on the overall tree accuracy.

Keywords: decision tree classifiers, distributed computing, streaming data, scalability

1. Introduction

We propose a new algorithm for building decision tree classifiers for classifying both large data sets and streaming data. As recently noted (Bottou and Bousquet, 2008), the challenge which distinguishes large-scale learning from small-scale learning is that training time is limited compared to the amount of available data. Thus, in our algorithm both training and testing are executed in a distributed environment, using only one pass on the data. We refer to the new algorithm as the Streaming Parallel Decision Tree (SPDT).

Decision trees are simple yet effective classification algorithms. One of their main advantages is that they provide human-readable rules of classification. Decision trees have several drawbacks, one of which is the need to sort all numerical attributes in order to decide where to split a node. This becomes costly in terms of running time and memory size, especially when decision trees are trained on large data. The various techniques for handling large data can be roughly grouped into two approaches: performing pre-sorting of the data, as in SLIQ (Mehta et al., 1996) and its successors SPRINT (Shafer et al., 1996) and ScalParC (Joshi et al., 1998), or replacing sorting with approximate representations of the data such as sampling and/or histogram building, for example, BOAT (Gehrke et al., 1999), CLOUDS (AlSabti et al., 1998), and SPIES (Jin and Agrawal, 2003). While pre-sorting techniques are more accurate, they cannot accommodate very large data sets or streaming data.

Faced with the challenge of handling large data, a large body of work has been dedicated to parallel decision tree algorithms (Shafer et al., 1996; Joshi et al., 1998; Narlikar, 1998; Jin and Agrawal,

2003; Srivastava et al., 1999; Sreenivas et al., 1999; Goil and Choudhary, 1999). There are several ways to parallelize decision trees, described in detail in Amado et al. (2001), Srivastava et al. (1999) and Narlikar (1998). Horizontal parallelism partitions the data so that different processors see different examples.[1] Vertical parallelism enables different processors to see different attributes. Task parallelism distributes the tree nodes among the processors. Finally, hybrid parallelism combines horizontal or vertical parallelism in the first stages of tree construction with task parallelism towards the end.

Like their serial counterparts, parallel decision trees overcome the sorting obstacle by applying pre-sorting, distributed sorting, and approximations. Following our interest in streaming data, we focus on approximate algorithms. Our proposed algorithm builds the decision tree in a breadth-first mode, using horizontal parallelism. The core of our algorithm is an on-line method for building histograms from streaming data at the processors. The histograms are essentially compressed representations of the data, so that each processor can transmit an approximate description of the data that it sees to a master processor, with low communication complexity. The master processor integrates the information received from all the processors and determines which terminal nodes to split and how.

This paper is organized as follows. In Section 2 we introduce the SPDT algorithm and the underlying histogram building algorithm. We dwell upon the advantages of SPDT over existing algorithms. In Section 3 we analyze the tree accuracy. In Section 4 we present experiments that compare the SPDT algorithm with the standard decision tree. The experiments show that the SPDT algorithm compares favorably with the traditional, single-processor algorithm. Moreover, it is scalable to streaming data and multiple processors. We conclude in Section 5.

2. Algorithm Description

Consider the following problem: given a (possibly infinite) series of training examples $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)\}$ where $\mathbf{x}_i \in \mathbb{R}^d$ and $y_i \in \{1, \ldots, c\}$, our goal is to construct a decision tree that will accurately classify test examples. The classifier is built using multiple processing nodes (i.e., CPUs), where each of the processing nodes observes approximately $1/W$ of the training examples (where W is the number of processing nodes). This partitioning happens for one of several reasons: for example, the data may not be stored in a single location, and may not arrive at a single location, or it may be too abundant to be handled by a single node in a timely manner.

Because of the large number of training examples, it is not feasible to store the examples (even in each separate processor). Therefore, a processor can either save a short buffer of examples and use them to improve (or construct) the classifier, or build a representative summary statistic from the examples, improving it over time, but never saving the examples themselves. In this paper we take the latter approach.

Although the setting described here is generally applicable to streams of data, it is also applicable to the classification of large data sets in batch mode, where memory and processing power constraints require the distribution of data across multiple processors and with limited memory for each processor.

We first present our histogram data structure and the methods related to it. We then describe the tree building process.

1. We refer to processing nodes as processors, to avoid confusion with tree nodes.

Algorithm 1 Update Procedure

input A histogram $h = \{(p_1, m_1), \ldots, (p_B, m_B)\}$, a point p.

output A histogram with B bins that represents the set $S \cup \{p\}$, where S is the set represented by h.

1: **if** $p = p_i$ for some i **then**

2: $m_i = m_i + 1$

3: **else**

4: Add the bin $(p, 1)$ to the histogram, resulting in a histogram of $B+1$ bins $h \cup \{(p,1)\}$. Denote $p_{B+1} = p$ and $m_{B+1} = 1$.

5: Sort the sequence $p_1, \ldots, p_{B+1}$. Denote by $q_1, \ldots, q_{B+1}$ the sorted sequence, and let π be a permutation on $1, \ldots, B+1$ such that $q_i = p_{\pi(i)}$ for all $i = 1, \ldots, B+1$. Denote $k_i = m_{\pi(i)}$, namely, the histogram $h \cup (p,1)$ is equivalent to $(q_1, k_1), \ldots, (q_{B+1}, k_{B+1})$, $q_1 < \ldots < q_{B+1}$.

6: Find a point q_i that minimizes $q_{i+1} - q_i$.

7: Replace the bins (q_i, k_i), (q_{i+1}, k_{i+1}) by the bin

$$\left(\frac{q_i k_i + q_{i+1} k_{i+1}}{k_i + k_{i+1}}, k_i + k_{i+1} \right).$$

8: **end if**

2.1 On-line Histogram Building

A histogram is a set of B pairs (called bins) of real numbers $\{(p_1, m_1), \ldots, (p_B, m_B)\}$, where B is a preset constant integer. The histogram is a compressed and approximate representation of a set S of real numbers. At any time we have $|S| = \sum_{i=1}^{B} m_i$, where $|S|$ is the number of points in S. The histogram data structure supports four procedures, named `update`, `merge`, `sum`, and `uniform`. The `update` procedure is based on an on-line clustering algorithm developed by Guedalia et al. (1999). A demonstration of the algorithms on actual input is given in the appendix.

Algorithm 1 presents the `update` procedure, which adds a new point to a set that is already represented by a given histogram. The `merge` procedure (Algorithm 2) creates a histogram that represents the union $S_1 \cup S_2$ of the sets S_1, S_2, whose representing histograms are given. The algorithm is similar to the update algorithm; in the first step, the two histograms form a single histogram with many bins. In the second step, bins which are closest are merged together (as in lines 5 and 6 in Algorithm 1) to form a single bin. The process repeats until the histogram has B bins.

The `sum` procedure estimates the number of points in a given interval $[a, b]$, that belong to a set whose histogram is given. Algorithm 3 describes how to calculate the sum for $[-\infty, b]$, and can be used to calculate the sum for $[a, b]$, since it is equal to the sum for $[-\infty, b]$ minus the sum for $[-\infty, a]$.

The algorithm assumes that for a bin (p, m), there are m points surrounding p, of which $m/2$ points are to the left of the bin and $m/2$ points are to the right. Consequently, the number of points in the interval $[p_i, p_{i+1}]$ is equal to $(m_i + m_{i+1})/2$, which is the area of the trapezoid $(p_i, 0), (p_i, m_i), (p_{i+1}, m_{i+1}), (p_{i+1}, 0)$, divided by $(p_{i+1} - p_i)$. To estimate the number of points in the interval $[p_i, b]$, for $p_i < b < p_{i+1}$, we draw a straight line from (p_i, m_i) to (p_{i+1}, m_{i+1}). We set $m_b = m_i + \frac{m_{i+1} - m_i}{p_{i+1} - p_i}(b - p_i)$, so that (b, m_b) is on this line. The estimated number of points in the interval $[p_i, b]$ is then the area of the trapezoid $(p_i, 0), (p_i, m_i), (b, m_b), (b, 0)$, divided again by $(p_{i+1} - p_i)$. The case where $b < p_1$ or $b > p_B$ requires special treatment. One possibility is to add two dummy bins $(p_0, 0)$ and $(p_{B+1}, 0)$, where p_0 and p_{B+1} are chosen using prior knowledge, according to which all

Algorithm 2 Merge Procedure

input Histograms $h_1 = \{(p_1^{(1)}, m_1^{(1)}), \ldots, (p_{B_1}^{(1)}, m_{B_1}^{(1)})\}$, $h_2 = \{(p_1^{(2)}, m_1^{(2)}), \ldots, (p_{B_2}^{(2)}, m_{B_2}^{(2)})\}$, an integer B .

output A histogram with B bins that represents the set $S_1 \cup S_2$, where S_1 and S_2 are the sets represented by h_1 and h_2, respectively.

1: For $i = 1, \ldots, B_1$, denote $p_i = p_i^{(1)}$ and $m_i = m_i^{(1)}$. For $i = 1, \ldots, B_2$, denote $p_{B_1+i} = p_i^{(2)}$ and $m_{B_1+i} = m_i^{(2)}$.

2: Sort the sequence $p_1, \ldots, p_{B_1+B_2}$. Denote by $q_1, \ldots, q_{B_1+B_2}$ the sorted sequence, and let π be a permutation on $1, \ldots, B_1+B_2$ such that $q_i = p_{\pi(i)}$ for all $i = 1, \ldots, B_1+B_2$. Denote $k_i = m_{\pi(i)}$, namely, the histogram $h_1 \cup h_2$ is equivalent to $(q_1, k_1), \ldots, (q_{B_1+B_2}, k_{B_1+B_2})$, $q_1 < \ldots < q_{B_1+B_2}$.

3: **repeat**

4: Find a point q_i that minimizes $q_{i+1} - q_i$.

5: Replace the bins (q_i, k_i), (q_{i+1}, k_{i+1}) by the bin

$$\left(\frac{q_i k_i + q_{i+1} k_{i+1}}{k_i + k_{i+1}}, k_i + k_{i+1} \right).$$

6: **until** The histogram has B bins

Algorithm 3 Sum Procedure

input A histogram $\{(p_1, m_1), \ldots, (p_B, m_B)\}$, a point b such that $p_1 < b < p_B$.

output Estimated number of points in the interval $[-\infty, b]$.

1: Find i such that $p_i \leq b < p_{i+1}$.

2: Set

$$s = \frac{m_i + m_b}{2} \cdot \frac{b - p_i}{p_{i+1} - p_i}$$

where

$$m_b = m_i + \frac{m_{i+1} - m_i}{p_{i+1} - p_i}(b - p_i).$$

3: **for all** $j < i$ **do**

4: $s = s + m_j$

5: **end for**

6: $s = s + m_i/2$

or almost all the points in S are in the interval $[p_0, p_{B+1}]$ (p_0 and p_{B+1} can be determined on the fly during the histogram's construction).

The `uniform` (Algorithm 4) procedure receives as input a histogram $\{(p_1, m_1), \ldots, (p_B, m_B)\}$ and an integer $\tilde{B}$ and outputs a set of real numbers $u_1 < \ldots < u_{\tilde{B}-1}$, with the property that the number of points between two consecutive numbers u_j, u_{j+1}, and the number of data points to the left of u_1 and to the right of $u_{\tilde{B}-1}$, is $\frac{|S|}{\tilde{B}}$. The algorithm works like the `sum` procedure in the inverse direction: After the point u_j was determined, we analytically find a point u_{j+1} such that the number of points in $[u_j, u_{j+1}]$ is estimated to be equal to $\frac{|S|}{\tilde{B}}$. This is very similar to the calculations performed in

Algorithm 4 Uniform Procedure

input A histogram $\{(p_1,m_1),\ldots,(p_B,m_B)\}$, an integer $\tilde{B}$.

output A set of real numbers $u_1 < \ldots < u_{\tilde{B}}$, with the property that the number of points between two consecutive numbers u_j, u_{j+1}, as well as the number of data points to the left of u_1 and to the right of $u_{\tilde{B}}$, is $\frac{1}{\tilde{B}}\sum_{i=1}^{B} m_i$.

1: **for all** $j = 1,\ldots,\tilde{B}-1$ **do**

2: Set $s = \frac{j}{\tilde{B}}\sum_{i=1}^{B} m_i$

3: Find i such that $\mathtt{sum}([-\infty,p_i]) < s < \mathtt{sum}([-\infty,p_{i+1}])$.

4: Set d to be the difference between s and $\mathtt{sum}([-\infty,p_i])$.

5: Search for u_j such that

$$d = \frac{m_i + m_{u_j}}{2} \cdot \frac{u_j - p_i}{p_{i+1} - p_i},$$

where

$$m_{u_j} = m_i + \frac{m_{i+1} - m_i}{p_{i+1} - p_i}(u_j - p_i).$$

Substituting

$$z = \frac{u_j - p_i}{p_{i+1} - p_i},$$

we obtain a quadratic equation $az^2 + bz + c = 0$ with $a = m_{i+1} - m_i$, $b = 2m_i$, and $c = -2d$. Hence set $u_j = p_i + (p_{i+1} - p_i)z$, where

$$z = \frac{-b + \sqrt{b^2 - 4ac}}{2a}.$$

6: **end for**

sum, where this time we are given the area of a trapezoid and have to compute the coordinates of its vertices (see line 5 in Algorithm 4).

2.2 Tree Growing Algorithm

We construct a decision tree based on a set of training examples $\{(\mathbf{x}_1,y_1),\ldots,(\mathbf{x}_n,y_n)\}$, where $\mathbf{x}_1,\ldots,\mathbf{x}_n \in \mathtt{R}^d$ are the feature vectors and $y_1,\ldots,y_n \in \{1,\ldots,c\}$ are the labels. Every internal node in the tree possesses two ordered child nodes and a decision rule of the form $\mathbf{x}^{(i)} < a$, where $\mathbf{x}^{(i)}$ is the ith attribute and a is a real number. Feature vectors that satisfy the decision rule are directed to the node's left child node, and the other vectors are directed to the right child node. Thus, every example $\mathbf{x}$ has a path from the root to one of the leaves, denoted $l(\mathbf{x})$. Every leaf has a label t, so that an example $\mathbf{x}$ is assigned the label $t(l(\mathbf{x}))$.

Algorithm 5 provides an overview of the tree construction algorithm. We note that this description fits standard decision trees as well. Each time that line 3 is executed, we say that a new iteration has begun. If there are too many samples (possibly infinite in number), we read a predefined number of samples; otherwise, we use the complete data set. A new level of nodes is appended to the tree in each iteration. In line 5 we decide whether a leaf v is to be split or labeled, according to a stopping criterion. Possible stopping criteria can be some threshold on the number of samples reaching the node, or on the node's impurity. A node's impurity is a function G that measures the homogeneity

Algorithm 5 Decision Tree

input Training set $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)\}$

1: Initialize T to be a single unlabeled node.
2: **while** there are unlabeled leaves in T **do**
3: Navigate data samples to their corresponding leaves.
4: **for all** unlabeled leaves v in T **do**
5: **if** v satisfies the stopping criterion **or** there are no samples reaching v **then**
6: Label v with the most frequent label among the samples reaching v
7: **else**
8: Choose candidate splits for v and estimate Δ for each of them.
9: Split v with the highest estimated Δ among all possible candidate splits.
10: **end if**
11: **end for**
12: **end while**

of labels in samples reaching the node. Its parameters are $q_1, \ldots, q_c$, where q_j is the probability that a sample reaching v has label j and c is the number of labels. The most popular impurity functions are the Gini criterion,

$$1 - \sum_j q_j^2$$

and the entropy function

$$-\sum_j q_j \ln q_j \text{ where } 0 \ln 0 \equiv 0 \,.$$

In our analysis in Section 3, we require G to be continuous and satisfy $G(\{q_j\}) \geq 1 - \max_j\{q_j\}$. These properties hold for the Gini and entropy functions.

The notation Δ, appearing in lines 8 and 9, represents the gap in the impurity function before and after splitting. Suppose that an attribute i and a threshold a are chosen, so that a node v is split according to the rule $\mathbf{x}^{(i)} < a$. Denote by τ the probability that a sample reaching v is directed to v's left child node. Denote further by $q_{L,j}$ and $q_{R,j}$ the probabilities of label j in the left and right child nodes, respectively. We define the function $\Delta(\tau, \{q_j\}, \{q_{L,j}\}, \{q_{R,j}\}) = \Delta(v, i, a)$ as

$$\Delta = G(\{q_j\}) - \tau G(\{q_{L,j}\}) - (1-\tau) G(\{q_{R,j}\}). \tag{1}$$

To complete the algorithm's description, we need to specify what are the candidate splits, mentioned in lines 8 and 9, and how the function Δ for each split is estimated in a distributed environment. We begin by providing an interpretation for these notions in the classical setting, that is, for the standard, serial algorithm. Most algorithms sort every attribute in the training set, and test splits of the form $\mathbf{x}^{(i)} < \frac{a+b}{2}$, where a and b are two consecutive numbers in the sorted sequence of the ith attribute. For every candidate split, Δ can be calculated precisely, as in (1).

In the parallel setting, we apply a distributed architecture that consists of W processors (also called workers). Each processor can observe $1/W$ of the data, but has a view of the complete classification tree built so far. We do not wish each processor to sort its share of the data set, because this operation is not scalable to extremely large data sets. Moreover, the communication complexity between the processors must be a constant that does not depend on the size of the data set. Our algorithm addresses these issues by trading time and communication complexity with

Algorithm 6 Compress Data Sets

input $1/W$ of the training set, where W is the number of processors
output histograms to be transmitted to the master processor

```
Initialize an empty histogram h(v,i,j) for every unlabeled leaf v, attribute i, and class j.
for all observed training samples (x_k, y_k), where x_k = (x_k^(1), ... x_k^(d)) do
    if the sample is directed to an unlabeled leaf v then
        for all attributes i do
            Update the histogram h(v,i,y_k) with the point x_k^(i), using the update procedure.
        end for
    end if
end for
```

classification accuracy. The processors build histograms describing the data they observed and send them to a master processor. Algorithm 6 specifies which histograms are built and how. The number of bins in the histograms is specified through a trade-off between accuracy and computational load: A large number of bins allows a more accurate description, whereas small histograms are beneficial for avoiding time, memory, and communications overloads.

For every unlabeled leaf v, attribute i, and class j, the master processor merges the W histograms $h(v,i,j)$ received from the processors. The master node now has an exact knowledge of the frequency of each label in each tree node, and hence the ability to calculate the impurity of all unlabeled leaves. Leaves that satisfy the stopping criterion are labeled. For the other leaves, the questions remain of how to choose candidate splits and how to estimate their Δ. They are answered as follows. Let v be an unlabeled leaf (that remains unlabeled after the application of the stopping criterion) and let i be an attribute. We first merge the histograms $h(v,i,1),\ldots,h(v,i,c)$ (c denotes the number of labels). The new histogram, denoted $h(v,i)$, represents the ith dimension of feature vectors that reach v, with no distinction between vectors of different labels. We now apply the `uniform` procedure on $h(v,i)$ with some chosen $\tilde{B}$. The resulting set $u_1 < \ldots < u_{\tilde{B}-1}$ constitutes the locations of the candidate splits for the ith attribute. Finally, Δ for each candidate split is estimated using the `sum` procedure and the histograms $h(v,i,j)$. We clarify the rationale behind this choice of split locations. Suppose that the best split is $\mathbf{x}^{(i)} < a$, where $u_k < a < u_{k+1}$. The number of points in the interval $[u_k, a]$ is bounded, implying a bound on the degree of change in Δ if one splits at u_k instead of a. This issue is discussed in more detail in Section 3.

Decision trees are frequently pruned during or after training to obtain smaller trees and better generalization. In the experiments presented in Section 4, we adapted the MDL-based pruning algorithm of Mehta et al. (1996), which is similar to the one used in CART (Breiman et al., 1984). This algorithm involves simple calculations during node splitting that reflect the node's purity. In a bottom-up pass on the complete tree, some subtrees are chosen to be pruned, based on estimates of the expected error rate before and after pruning. The distributed environment neither changes this pruning algorithm nor does it affect its output.

2.3 Complexity Analysis

Every iteration consists of an updating phase performed simultaneously by all the processors and a merging phase performed by the master processor. In the update phase, every processor makes one pass on the data batch assigned to it. The only memory allocation is for the histograms being

constructed. The number of bins in the histograms is constant; hence, operations on histograms take a constant amount of time. Every processor performs at most N/W histogram updates, where N is the size of the data batch and W is the number of processors. There are $W \times L \times c \times d$ histograms, where L is the number of leaves in the current iteration, c is the number of labels, and d is the number of attributes. Assuming that W, L, c, and d are all independent of N, it follows that the space complexity is $O(1)$. The histograms are communicated to the master processor, which merges them and applies the `sum` and `uniform` procedures. If the `uniform` procedure is applied with a constant parameter $\tilde{B}$, then the time complexity of the merging phase is $O(1)$.

To summarize, each iteration requires the following:

- At most N/W operations by each processor in the updating phase.
- Constant space and communication complexities.
- Constant time in the merging phase.

2.4 Related Work

In this section we discuss previous work on histogram and quantile approximations, as well as procedures for building decision trees on parallel platforms.

2.4.1 HISTOGRAMS AND QUANTILES APPROXIMATIONS

Data structures that summarize large sets are substantial components of a variety of algorithms in database management and data mining. Our histogram algorithms tackle two related problems: data compression and quantile approximations.[2] There is broad coverage of these topics in the literature, with an inclination towards one pass algorithms, see Gilbert et al. (2002), Guha et al. (2006), Ioannidis (2003) and Lin (2007) and references therein. Proposed solutions can be divided into two categories: The first category consists of algorithms with proven approximation guarantees (Cormode and Muthukrishnan, 2005; Gilbert et al., 2002; Greenwald and Khanna, 2001; Guha et al., 2006). The demand for a guaranteed accuracy level forces these algorithms to use large amounts of memory, that is, their space requirements are increasing functions of the data size. An exception is the probabilistic algorithm of Manku et al. (1998), which receives an input parameter δ and returns approximate quantiles whose guarantees hold with probability δ. The space complexity of this algorithm increases with δ but not with the data size. The second category, to which our algorithm belongs, consists of heuristics that work well empirically and demand low amounts of space, but lack any rigorous accuracy analysis (Agrawal and Swami, 1995; Jain and Chlamtac, 1985). To our knowledge, distributed environments are not addressed in either of the two categories, except for a brief mention by Manku et al. (1998).

Guaranteed accuracy at the cost of non-constant memory and increasing processing time are problematic because of the inherent nature of streaming data. For example, the algorithm proposed by Guha et al. (2006) requires roughly $O(B^2 \log n)$ memory, where n is the number of data points and B the number of bins. Thus, for example, a stream of 10^{10} data points (not a large number in today's data environments) requires more than 20 times the memory of a comparable fixed-memory algorithm.

2. For a sequence S of real numbers, the ϕ-quantile, $0 \leq \phi \leq 1$, is defined to be an element $x \in S$ such that $\lceil \phi |S| \rceil$ elements of S are smaller or equal to x.

The use of a fixed-memory algorithm, like the one proposed in this paper, naturally comes at a cost in accuracy. As we show, when the data distribution is highly skewed, the accuracy of the on-line histogram decays. Therefore, in cases where the data can be assumed to have originated in categorical distributions with a limited number of values or in distributions which are not highly skewed, the proposed algorithm is sufficiently accurate. In other cases, where distributions are known to be highly skewed, or memory sizes are not a major factor when executing the algorithm, practitioners may prefer to resort to guaranteed accuracy algorithms. This replaces the first part of the proposed algorithm, but keeps its higher levels intact.

2.4.2 PARALLEL DECISION TREES

The SPIES (Jin and Agrawal, 2003) and pCLOUDS (Sreenivas et al., 1999) algorithms build decision trees for streaming data and work in a distributed environment. They are similar to the SPDT algorithm in that they use histograms to process the data in constant time and memory. There are, however, three major differences between these algorithms and the SPDT algorithm and its analysis. The first difference is in the histogram building algorithm. Unlike SPDT, both SPIES and pCLOUDS sample the data. The second difference is in the need of a second pass. CLOUDS (AlSabti et al., 1998) has two versions, named SS and SSE.[3] SSE and SPIES may require several passes over the data, and therefore hold each data batch in memory. The purpose of the second pass is to locate exactly the best split location for every node, and hence eventually to construct the same tree as the standard algorithm. SS is more similar to SPDT, since both algorithms build histograms with an equal number of points in each bin and take the boundaries of the histograms to be the candidate splits. Since only a constant number of split locations is checked, it is possible that a suboptimal split is chosen, which may cause the entire tree to be different from the one constructed by the standard algorithm. The third difference between our work and previous works is our ability to analytically show that the error rate of the parallel tree approaches the error rate of the serial tree, even though the trees are not identical.

3. Bounding the Error of SPDT

In this section, we investigate the training error rate of SPDT. We adopt a simpler version of the framework set by Kearns and Mansour (1999), which views tree nodes as weak learners. This approach allows us to obtain an overall estimate of the tree by studying the local improvements in classification accuracy induced by the internal nodes.

3.1 Background

Let n be the number of training samples used to train a decision tree T. For a tree node v, denote by n_v the number of training samples that reach v, and by $q_{v,j}$ the probability that a sample reaching v has label j, for $j = 1, \ldots, c$. The training error rate of T is

$$e_T = \frac{1}{n} \sum_{v \text{ leaf in } T} n_v (1 - \max_j \{q_{v,j}\}).$$

3. pCLOUDS is a parallelization of the SSE version of CLOUDS. We mention the SS version as well because it can be similarly parallelized.

Henceforth, we require that the impurity function G is continuous and satisfies $G(\{q_j\}) \geq 1 - \max_j\{q_j\}$. The last inequality implies that we have $e_T \leq G_T$, where

$$G_T = \frac{1}{n} \sum_{v \text{ leaf in } T} n_v G(\{q_{v,j}\}). \tag{2}$$

For our analysis, we rewrite Algorithm 5 such that only one new leaf is added to the tree in each iteration (see Algorithm 7). The resulting full-grown tree is identical to the tree constructed by Algorithm 5. Let T_t be the tree produced by Algorithm 7 after the tth iteration. Suppose that the node v is split in the tth iteration and assigned the rule $\mathbf{x}^{(i)} < a$, and let v_L, v_R denote its left and right child nodes respectively. Then

$$\begin{aligned} &G_{T_{t-1}} - G_{T_t} \\ &= \frac{1}{n}(n_v G(\{q_{v,j}\}) - n_{v_L} G(\{q_{v_L,j}\}) - n_{v_R} G(\{q_{v_R,j}\})) \\ &= \frac{n_v}{n}\Delta(v,i,a). \end{aligned}$$

It follows that a lower bound on $\Delta(v,i,a)$ yields an upper bound on G_{T_t} and hence also on e_{T_t}.

Definition 1 *An internal node v, split by a rule $\mathbf{x}^{(i)} < a$, is said to perform locally well with respect to a function $f(\{q_j\})$ if it satisfies $\Delta(v,i,a) \geq f(\{q_{v,j}\})$. A tree T is said to perform locally well if every internal node v in it performs locally well. Finally, a decision tree building algorithm performs locally well if for every training set, the output tree performs locally well.*

Suppose that T_{t-1} has a leaf for which $\frac{n_v}{n} f(\{q_{v,j}\})$ can be lower-bounded by a quantity $h(t, G_{T_{t-1}})$ that depends only on t and $G_{T_{t-1}}$. Then a lower bound on the training error rate of an algorithm that performs locally well can be derived by solving the recurrence $G_{T_t} \leq G_{T_{t-1}} - h(t, G_{T_{t-1}})$. As a simple example, consider $f(\{q_j\}) = \alpha G(\{q_j\})$ for some positive constant α. By (2), and since the number of leaves in T_{t-1} is t, there exists a leaf v in T_{t-1} for which $\frac{n_v}{n} G(\{q_{v,j}\}) \geq G_{T_{t-1}}/t$, hence $\frac{n_v}{n} f(\{q_{v,j}\}) \geq \frac{\alpha}{t} G_{T_{t-1}}$. Let $\tilde{v}$ be the node which is split in the tth iteration. By definition (see line 10 in Algorithm 7), $\frac{n_{\tilde{v}}}{n}\Delta_{\tilde{v}} \geq \frac{n_v}{n}\Delta_v$, where Δ_v and $\Delta_{\tilde{v}}$ are the best splits for v and $\tilde{v}$. We have

$$G_{T_{t-1}} - G_{T_t} = \frac{n_{\tilde{v}}}{n}\Delta_{\tilde{v}} \geq \frac{n_v}{n}\Delta_v \geq \frac{n_v}{n} f(\{q_{v,j}\}) \geq \frac{\alpha}{t} G_{T_{t-1}}.$$

Let G_0 be an upper bound on G_{T_0}. Solving the recurrence $G_{T_t} \leq (1 - \alpha/t) G_{T_{t-1}}$ with initial value G_0, we obtain $G_{T_t} \leq G_0(t-1)^{-\alpha/2}$, therefore $e_{T_t} \leq G_0(t-1)^{-\alpha/2}$.

Kearns and Mansour (1999) made a stronger assumption, named the Weak Hypothesis Assumption, on the local performance of tree nodes. For binary classification and a finite feature space, it is shown that if $G(q_1, q_2)$ is the Gini index, the entropy function, or $G(q_1, q_2) = \sqrt{q_1 q_2}$, then the Weak Hypothesis Assumption implies good local performance (each splitting criterion with respect to its own $f(q_1, q_2)$). Lower bounds on the training error of trees with these splitting criteria are then derived, as described above. These bounds are subject to the validity of the Weak Hypothesis Assumption.

3.2 Main Result

To build an SPDT, we have to set the parameters B and $\tilde{B}$. Recall that B is the number of bins in the histograms constructed by the processors, and $\tilde{B}$ is the size of the output of `uniform`. Encouraged by empirical results concerning the histograms' accuracy, (see Section 4), we set $B = \tilde{B}$ and assume that all applications of the `uniform` and `sum` procedures during SPDT runtime provide us with exact information on the data set. For example, it is assumed that Δ is calculated exactly and not only "estimated" (see line 9 in Algorithm 5). We note that all our results remain intact also if we allow the calculations to be somewhat biased (the empirical evidence points to a bias of about 5%).

It follows that the only source for sub-optimality with respect to standard decision trees is in the choice of the candidate splits. We recall that for the standard decision tree, the number of candidate splits for a node v is equal to the number of training samples that reach v minus one. This luxury is out of the reach of the SPDT because of scalability requirements. The SPDT thus must test only a constant number of candidate splits before it announces the winning split. The following theorem asserts that Δ for the split chosen by the SPDT algorithm can be arbitrarily close to the optimal Δ (of the split chosen by the standard algorithm). The number of bins depends on how close to the real Δ we wish to be, and also on the shape of the training set, but not on its size.

Theorem 2 *Assume that the functions operating on histograms return exact answers. Let v be a leaf in a decision tree which is under construction, and let $\mathbf{x}^{(i)} < a$ be the best split for v according to the standard algorithm. Denote $\tau, q_j, q_{L,j}, q_{R,j}$ as in Section 2.2. Then for every $\delta > 0$ there exists B that depends on $\tau, \{q_j\}, \{q_{L,j}\}, \{q_{R,j}\}$, and δ, such that the split $\mathbf{x}^{(\tilde{i})} < \tilde{a}$ chosen by the SPDT algorithm with B bins satisfies $\Delta(v, \tilde{i}, \tilde{a}) \geq \Delta(v, i, a) - \delta$.*

Proof. Fix B and consider the split $\mathbf{x}^{(i)} < u_k$, where $u_k < a < u_{k+1}$ (take $u_k = u_1$ if $a < u_1$ or $u_k = u_r$ if $a > u_r$; in the sequel we assume without loss of generality that $a > u_1$). Denote by $\tilde{\tau}, \tilde{q}_L, \tilde{q}_R$ the quantities relevant to this split. Let ρ_j denote the probability that a training sample $\mathbf{x}$ that reaches v satisfies $u_k < \mathbf{x}^{(i)} < a$ and has label j. Then

$$\begin{aligned} \tilde{\tau} &= \tau - \rho_0 - \rho_1 \\ \tilde{q}_{L,j} &= \frac{\tau \cdot q_{L,j} - \rho_j}{\tilde{\tau}} \\ \tilde{q}_{R,j} &= \frac{(1-\tau) q_{R,j} + \rho_j}{1 - \tilde{\tau}}. \end{aligned}$$

By the continuity of $\Delta(\tau, \{q_j\}, \{q_{L,j}\}, \{q_{R,j}\})$, for every $\delta > 0$ there exists ε such that

$$\Delta(\tau, \{q_j\}, \{q_{L,j}\}, \{q_{R,j}\}) - \Delta(\tilde{\tau}, \{q_j\}, \{\tilde{q}_{L,j}\}, \{\tilde{q}_{R,j}\}) < \delta.$$

for all $\rho_j < \varepsilon$. Since $\rho_j \leq \frac{1}{B+1}$, we can guarantee that $\rho_j < \varepsilon$ for all j by setting $B = 1/\varepsilon$. We thus have $\Delta(v, \tilde{i}, \tilde{a}) \geq \Delta(v, i, u_k) \geq \Delta(v, i, a) - \delta$, as required.

Theorem 2 implies the following corollary.

Corollary 3 *Assume that the standard decision tree algorithm performs locally well with respect to a function $f(\{q_j\})$, and that the functions operating on histograms return exact answers. Then for every positive function $\delta(\{q_j\})$, the SPDT algorithm performs locally well with respect to $f(\{q_j\}) - \delta(\{q_j\})$, in the sense that for every training set there exists B such that the tree constructed by the SPDT algorithm with B bins performs locally well. Moreover, B does not depend on the size of the*

training set, implying constant memory and communication complexity and constant running time at the master processor.

We conclude this section with an example in which we explicitly derive an upper bound on the error rate of SPDT. Set $f(\{q_j\}) = \alpha G(\{q_j\})$ for a positive constant α, for which we have seen in Section 3.1 that $e_{T_t} \leq G_0(t-1)^{-\alpha/2}$. We note that Kearns and Mansour (1999) show that for $G(q_1, q_2) = \sqrt{q_1 q_2}$, the Weak Hypothesis Assumption implies good local performance with $f(q_1, q_2) = \alpha G(q_1, q_2)$. Applying Corollary 3 with $\delta(\{q_j\}) = \frac{\alpha}{2} G(\{q_j\}) = f(\{q_j\})/2$, we deduce that when using histograms with enough bins, the SPDT's error rate is guaranteed to be no more than $G_0(t-1)^{-\alpha/4}$.

4. Empirical Results

In the following section we empirically test the proposed algorithms. We first show the accuracy of the histogram building and merging procedures, and later compare the accuracy of SPDT compared to a standard decision tree algorithm.

4.1 Histogram Algorithms

We evaluated the accuracy of the histogram building and information extraction algorithms. We ran experiments on seven synthetic sets, generated via different kinds of probability distributions, summarized in Table 1. Each set S, consisting of 10^5 points, was partitioned into four equal parts, denoted $S_1 - S_4$. For each part S_k we built a histogram h_k with $B = 100$ bins, using the `update` procedure. We then ran the `uniform` procedure on h_k with $\tilde{B} = 100$, resulting in a sequence of points $u_1, \ldots, u_{99}$. For each pair of subsequent numbers u_i, u_{i+1}, we checked how many points of S_k are in the interval $[u_i, u_{i+1}]$. We expect to see $\frac{|S_k|}{\tilde{B}} = 25000/100 = 250$ points in each such interval. Our findings are summarized in Table 2. We observe that the mean absolute difference between 250 and the actual number of points in an interval is equal to 11.17 (4.47% of the expected quantity).

We repeat the same experiment on the histograms $h_{1,2}, h_{3,4}$, obtained after merging h_1 with h_2 and h_3 with h_4. The mean absolute difference between $50000/100 = 500$ and the number of points

Distribution	Probability density function
Normal	$f(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2}$
Uniform	$f(x) = 1,\ 0 \le x \le 1$
Exponential	$f(x) = \frac{1}{\mu} e^{-(x/\mu)},\ \mu = 0.5,\ x \le 0$
Beta	$f(x) = \frac{1}{\int_0^1 t^{a-1}(1-t)^{b-1}dt} x^{a-1}(1-x)^{b-1},\ a = 0.5,\ b = 0.5,\ 0 < x < 1$
Gamma	$f(x) = \frac{1}{b^a \Gamma(a)} x^{a-1} e^{-x/b},\ a = 3,\ b = 1,\ x \ge 0$
Lognormal	$f(x) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-(\ln(x)-\mu)^2/2\sigma^2},\ \mu = 1,\ \sigma = 0.5,\ x > 0$
Chi-square	$f(x) = \frac{1}{2^{v/2}\Gamma(v/2)} x^{(v-2)/2} e^{-x/2},\ v = 10,\ x \ge 0$

Table 2: Mean absolute difference between the number of points in $[u_i, u_{i+1}]$ and the desired number and standard deviation of the number of points in $[u_i, u_{i+1}]$. Details are in Section 4.1.

in $(S_k \cup S_{k+1}) \cap [u_i, u_{i+1}],\ k = 1,3$, is 25.87 (5.17% of the expected quantity). Finally, we merged $h_{1,2}$ with $h_{3,4}$. Applying the `uniform` procedure, the obtained mean absolute difference between 1000 and $S \cap [u_i, u_{i+1}]$ is 55.36 (5.54% of the expected quantity).

The `sum` and `uniform` procedures assume that there are $(m_i + m_{i+1})/2$ points in every interval $[p_i, p_{i+1}]$. We tested this assumption on the histograms $h_1 - h_4, h_{1,2}, h_{3,4}$ and $h_{1,2,3,4}$. For $h_{1,2,3,4}$, the mean absolute differences between $(m_i + m_{i+1})/2$ and the actual number of points in $[p_i, p_{i+1}]$ is 28.79. Recall that on average there are 1000 points in each interval, implying an error of 2.88%. Details are in Table 3.

Figure 1 shows how accuracy is affected by the distribution's skewness.[4] The figure was obtained by calculating the histograms $h_{1,2,3,4}$ and points $u_1, \ldots, u_{99}$ for different values of the param-

4. The skewness of a distribution is defined to be κ_3/σ^3, where κ_3 is the third moment and σ is the standard deviation.

4.2 Evaluation of the SPDT Algorithms

We ran our experiments on ten medium-sized data sets taken from the UCI repository (Blake et al., 1998) and two large data sets taken from the Pascal Large Scale Learning Challenge (Pascal, 2008). The characteristics of the data sets are summarized in Table 4. For the UCI data sets, we applied ten-fold cross validation when a train/test partition was not given. For the Pascal data sets, we extracted 10^5 examples to constitute a training set, and additional 10^4 examples to constitute a test set. We set the number of bins to 50, and limited the depth of the trees to no more than 100 for the UCI data sets and 10 for the Pascal data sets. We implemented our algorithm in the IBM Parallel Machine Learning toolbox (PML), which runs using MPICH2, and executed it on an 8-CPU Power5 machine with 16GB memory using a Linux operating system. We note that none of the experiments reported in previous works involved both a large number of examples and a large number of attributes.

We began by testing the assumption that splits chosen by the SPDT algorithm are close to optimal. To this end, we extracted four continuous attributes from the training sets (we chose the training set of the first fold if there was no train/test partition). For every attribute, we calculated the following three quantities: Δ of the optimal splitting point, Δ of the splitting point chosen by SPDT with 8 processors, and average Δ over all splitting points (chosen by random splitting). We then normalized by $G(\{q_j\})$, that is,

$$\tilde{\Delta} = \frac{\Delta}{G(\{q_j\})} = 1 - \frac{\tau G(\{q_{L,j}\}) + (1-\tau) G(\{q_{R,j}\})}{G(\{q_j\})}.$$

The normalized value $\tilde{\Delta}$ can be interpreted as the split's efficiency. Since $G(\{q_j\})$ is the maximum possible value of Δ, $\tilde{\Delta}$ represents the ratio between what is actually achieved and the maximum that can be achieved. Table 7 displays the gain of the various splitting algorithms.

Table 8: Percent error, areas under ROC curves, and tree sizes (number of tree nodes) before and after pruning, with eight processors.

We proceed to inspect the tree's accuracy. Tables 5 and 6 display the error rates and areas under the ROC curves of the standard decision tree and the SPDT algorithm with $1, 2, 4$, and 8 processors.[5] We note that it is infeasible to apply the standard algorithm on the Pascal data sets, due to their size. For the UCI data sets, we observe that the approximations undertaken by the SPDT algorithm do not necessarily have a detrimental effect on its error rate. The FF statistics combined with Holm's procedure (Demšar, 2006) with a confidence level of 95% shows that the SPDT algorithm exhibited accuracy that could not be detected as statistically significantly different from that of the standard algorithm.

It is also interesting to study the effect of pruning on the error rate and tree size. Using the procedure described in Section 2.2, we pruned the trees obtained by SPDT. Table 8 shows that pruning usually improves the error rate (though not to a statistically significant threshold, using sign test with $p < 0.05$) while reducing the tree size by 54% on average.

Figure 2 shows the speedup for different sized subsets of the face detection and OCR data sets. Referring to data set size as the number of examples multiplied by the number of dimensions, we found that data set size and speedup are highly correlated (Spearman correlation of 0.90). We further checked the running time as a function of the data set size. In a logarithmic scale, we obtain approximate regression curves (average $R^2 = 0.99$, see Figure 3). The slopes of the curves decrease as the number of processors increases, and drops below 1 for eight processors. In other words, if we multiply the data size by a factor of 10, the running time is multiplied by less than 10.

The results presented here fit the theoretical analysis of Section 2.3. For large data sets, the communication between the processors in the merging phase is negligible relative to the gain in the update phase. Therefore, increasing the number of processors is especially beneficial for large data sets.

5. The results for the OCR data set can be somewhat improved if we increase the tree depth to 25 instead of 10. For four processors, we obtain an error of 32.56% and AUC of 67.5%.

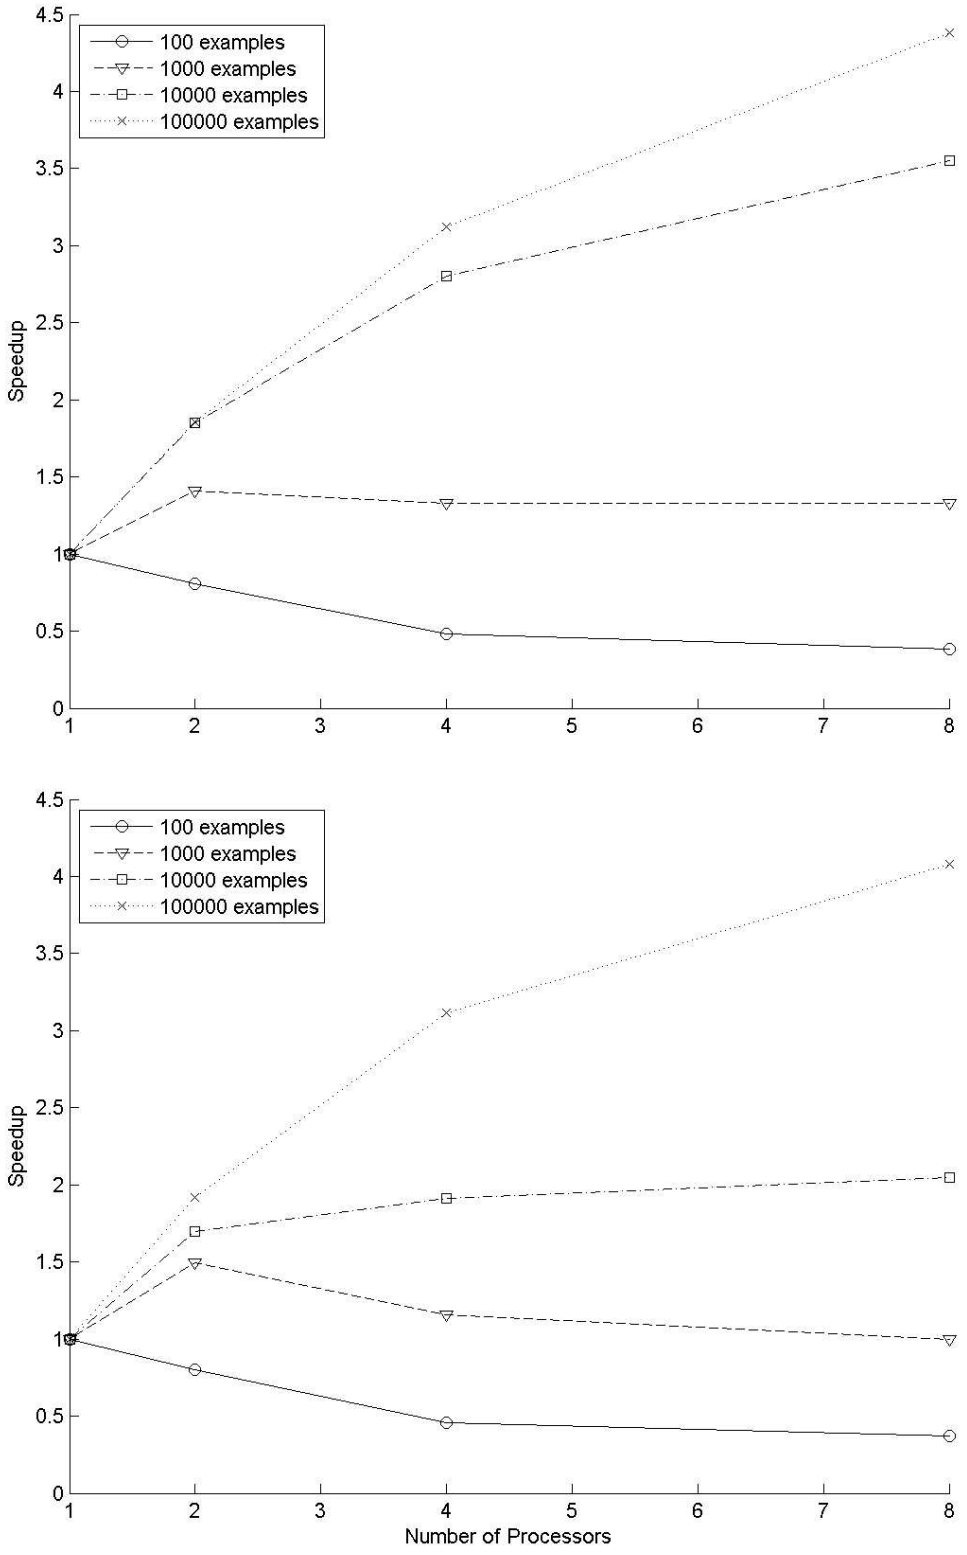

Figure 2: Speedup of the SPDT algorithm for the `face detection` (top) and `OCR` (bottom) data sets.

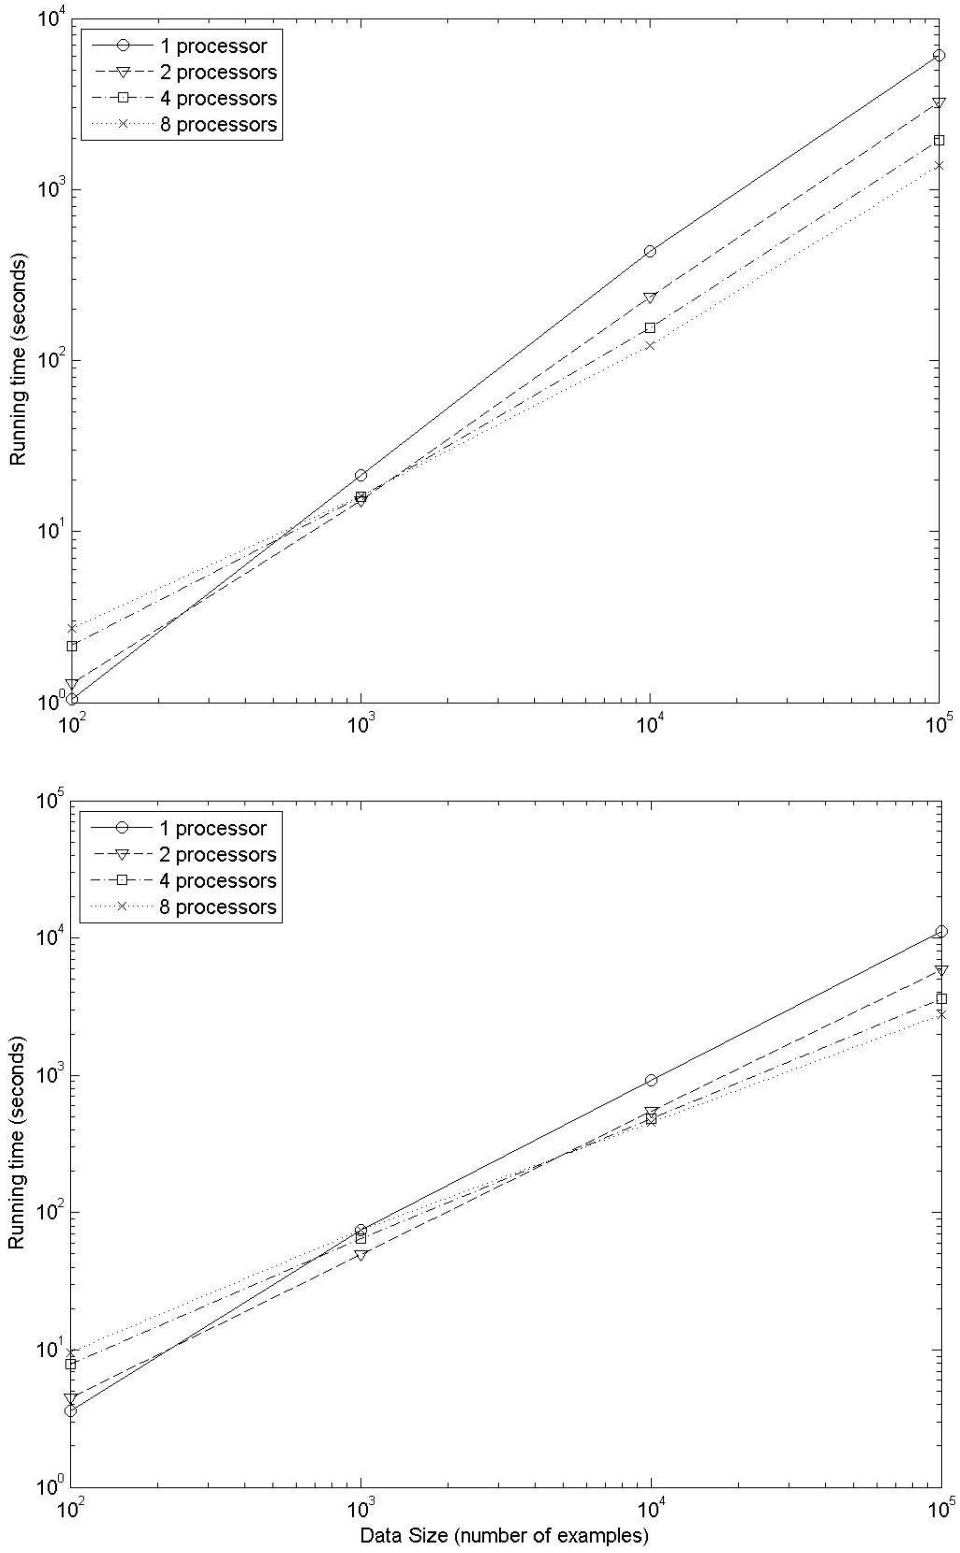

Figure 3: Running time vs. data size for the `face detection` (top) and `OCR` (bottom) data sets.

5. Conclusions

We propose a new algorithm for building decision trees, which we refer to as the Streaming Parallel Decision Tree (SPDT). The algorithm is specially designed for large data sets and streaming data, and is executed in a distributed environment. Our experiments reveal that the error rate of SPDT is approximately the same as for the serial algorithm. We also provide a way to analytically compare the error rate of trees constructed by serial and parallel algorithms without comparing similarities between the trees themselves.

Acknowledgments

We thank the referees for their valuable comments.

Appendix A.

We demonstrate how the histogram algorithms run on the following input sequence:

$$23, 19, 10, 16, 36, 2, 9, 32, 30, 45. \tag{3}$$

Suppose that we wish to build a histogram with five bins for the first seven elements. To this end, we perform seven executions of the `update` procedure. After reading the first five elements, we obtain the histogram

$$(23,1), (19,1), (10,1), (16,1), (36,1).$$

as depicted in Figure 4(a). We then add the bin $(2,1)$ and merge the two closest bins, $(16,1)$ and $(19,1)$, to a single bin $(17.5,2)$. This results in the following histogram, depicted in Figure 4(b):

$$(2,1), (10,1), (17.5,2), (23,1), (36,1).$$

We repeat this process for the seventh element: the bin $(9,1)$ is added, and the two closest bins, $(9,1)$ and $(10,1)$, form a new bin $(9.5,2)$. The resulting histogram is given in Figure 4(c):

$$(2,1), (9.5,2), (17.5,2), (23,1), (36,1).$$

Let us now merge the last histogram with the following one:

$$(32,1), (30,1), (45,1).$$

Figure 5 follows the changes in the histogram during the three iterations of the `merge` procedure. We omit details due to the similarity to the `update` examples given above. The final histogram is given in Figure 5(d):

$$(2,1), (9.5,2), (19.33,3), (32.67,3), (45,1).$$

This histogram represents the set in (3).

We now wish to estimate the number of points smaller than 15. The leftmost bin $(2,1)$ gives 1 point. The second bin, (9.5,2), has $2/2 = 1$ points to its left. The challenge is to estimate how many points to its right are smaller than 15. We first estimate that there are $(2+3)/2 = 2.5$ points inside the trapezoid whose vertices are $(9.5,0), (9.5,2), (19.33,3)$, and $(19.33,0)$ (see Figure 6). Assuming that the number of points inside a trapezoid is proportional to its area, the number of points

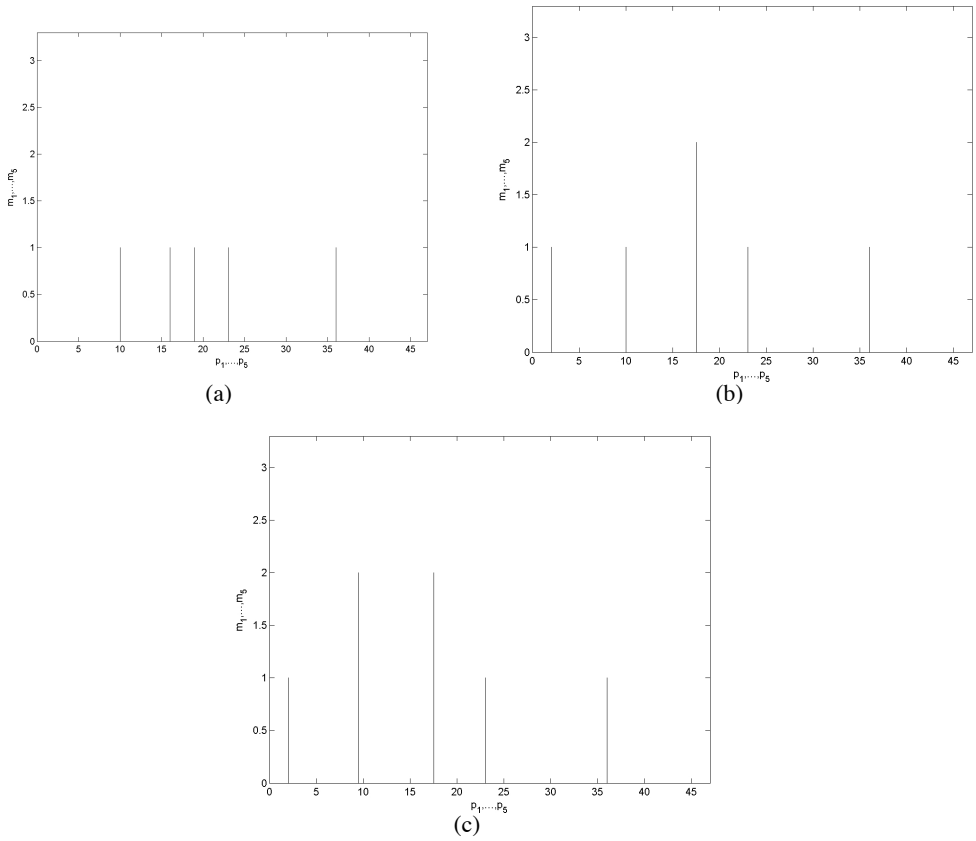

Figure 4: Examples of executions of the `update` procedure.

inside the trapezoid defined by the vertices $(9.5,0),(9.5,2),(15,2.56)$, and $(15,0)$ is estimated to be

$$\frac{2+2.56}{2} \times \frac{15-9.5}{19.33-9.5} = 1.28.$$

We thus estimate that there are in total $1+1+1.28 = 3.28$ points smaller than 15. The true answer, obtained by looking at the set represented by the histogram (see Equation (3)), is three points: $2, 9$, and 10.

The reader can readily verify that the `uniform` procedure with $\tilde{B} = 3$ returns the points 15.21 and 28.98. Each one of the intervals $[-\infty, 15.21], [15.21, 28.98]$, and $[28.98, \infty]$ is expected to contain 3.33 points. The true values are 3, 2, and 4, respectively.

Abstract

A successful class of image denoising methods is based on Bayesian approaches working in wavelet representations. The performance of these methods improves when relations among the local frequency coefficients are explicitly included. However, in these techniques, analytical estimates can be obtained *only* for particular combinations of analytical models of signal and noise, thus precluding its straightforward extension to deal with other arbitrary noise sources.

In this paper, we propose an alternative non-explicit way to take into account the relations among natural image wavelet coefficients for denoising: we use support vector regression (SVR) in the wavelet domain to enforce these relations in the estimated signal. Since relations among the coefficients are specific to the signal, the regularization property of SVR is exploited to remove the noise, which does not share this feature. The specific signal relations are encoded in an anisotropic kernel obtained from mutual information measures computed on a representative image database. In the proposed scheme, training considers minimizing the Kullback-Leibler divergence (KLD) between the estimated and actual probability functions (or histograms) of signal and noise in order to enforce similarity up to the higher (computationally estimable) order. Due to its non-parametric nature, the method can eventually cope with different noise sources without the need of an explicit re-formulation, as it is strictly necessary under parametric Bayesian formalisms.

Results under several noise levels and noise sources show that: (1) the proposed method outperforms conventional wavelet methods that assume coefficient independence, (2) it is similar to state-of-the-art methods that do explicitly include these relations when the noise source is Gaussian, and (3) it gives better numerical and visual performance when more complex, realistic noise sources are considered. Therefore, the proposed machine learning approach can be seen as a more flexible (model-free) alternative to the explicit description of wavelet coefficient relations for image denoising.

1. Introduction

Denoising requires representing the distorted signal in a domain where signal and noise display different enough behavior. In such a representation, noise is removed by imposing the known properties of the signal to the distorted samples. In image denoising, classical regularization techniques are used to impose smoothness in the spatial domain since noise is typically white (Banham and Katsaggelos, 1997). Smoothness in the spatial domain means predictability of the signal from the neighborhood, and thus classical approaches exploit the low-pass behavior of the power spectrum to rely on band-limitation or autoregressive models of the signal (Andrews and Hunt, 1977; Banham and Katsaggelos, 1997; Bertero et al., 1988). Several image denoising methods working in the spatial domain have been presented in the literature, either based on splines (Takeda et al., 2007), patch-based approximations (Kervrann and Boulanger, 2007), local auto-regressive models (Gutiérrez et al., 2006), or support vector regression (Kai Tick Chow and Lee, 2001; van Ginneken and Mendrik, 2006) to perform smooth (regularized) approximations of the noisy signal. Recently, successful methods use adaptive local basis representations (Dabov et al., 2007). Approaches to the problem using local basis is qualitatively related to wavelet descriptions. In fact, wavelet representations have been recognized as quite appropriate domains for image denoising.[1]

Wavelet representations are convenient in image denoising because natural image samples have a very specific statistical behavior in this domain. On the one hand, smoothness is represented by a strong energy compaction in coarse scales. On the other hand, the combination of smooth regions with local, high contrast features, such as edges, gives rise to sparse activation of wavelet sensors. This leads to very particular, heavy-tailed, marginal probability density functions (PDFs) of the wavelet coefficients (Burt and Adelson, 1983; Field, 1987; Simoncelli, 1997; Hyvärinen, 1999). These basic features were incorporated in the classical wavelet-based image denoising techniques (Donoho and Johnstone, 1995; Simoncelli, 1999; Figueiredo and Nowak, 2001). Classical techniques such as hard and soft thresholding (Donoho and Johnstone, 1995) have been derived by using Bayesian approaches in non-redundant wavelets, looking for either *Maximum a Posteriori* (MAP) or *Bayesian Least Squares* (BLS) estimators, in combination with simple marginal models and assuming statistical independence among coefficients (Simoncelli, 1999; Figueiredo and Nowak, 2001).

It is well-known, however, that marginal models in the wavelet domain are not enough for a proper signal characterization: relevant relations among coefficients still remain after wavelet transforms (Simoncelli, 1999). For instance, edges lead to strong coupling between the energy of neighboring wavelet coefficients of natural images. These relations among wavelet coefficients have proven to be a key issue in applications such as image coding (Malo et al., 2006; Camps-Valls et al., 2008), texture analysis and synthesis (Portilla and Simoncelli, 2000) or image quality metrics (Laparra et al., 2010). The use of these relations is in the roots of the most recent and successful image denoising approaches as well (Portilla et al., 2003; Siwei and Simoncelli, 2007; Goossens et al., 2009). In this case, more complex image models explicitly including the relations among coefficients have to be plugged and fitted into the Bayesian framework to obtain the image estimates.

Unfortunately, all these model-based Bayesian techniques have three common problems:

1. They critically depend on the accuracy of the image model, whose definition is not trivial;

1. In the 2007 IEEE International Symposium on Information Theory (ISIT2007), the tutorial "Recent Trends in Denoising" (`http://www.stanford.edu/~slansel/tutorial/summary.htm`) pointed out that state-of-the-art methodologies are usually defined in the wavelet domain.

2. MAP or LS estimations can only be derived analytically for particular, typically Gaussian, noise sources. For different noise sources, the whole technique has to be reformulated which may not be analytically tractable;

3. The estimation of the parameters of the image model from the noisy observation is difficult in general.

Conversely, non-parametric approaches can include the above qualitative properties in an indirect way without the restriction of being analytically attached to particular image or noise models. These approaches are based on *learning* the underlying model directly from the image samples.

In this work we apply support vector regression (SVR) in a redundant (overcomplete) wavelet domain to the noisy image. The proposed method has the following advantages in front of the Bayesian framework:

1. It does not use a particular parametric image model to be fitted, for example, no analytical PDF is required.

2. Its solution may be found for arbitrary noise sources even without knowing the functional form of the noise PDF since it can work with just noise histograms. Therefore, the procedure does not need to be reformulated for different noise sources.

3. It is capable to take into account the relations among wavelet coefficients of natural images through the use of a suitable kernel. In this way, the method preserves the relevant relations among the coefficients of the true signal and better removes the degradation.

The proposed method does not assume independence among the signal coefficients in the wavelet domain, as opposed to Simoncelli (1999) and Figueiredo and Nowak (2001), nor an explicit model of signal relations, as done in Portilla et al. (2003). Therefore, the proposed machine learning approach can be seen as a more flexible (model-free) alternative to the explicit description of wavelet coefficient relations for image denoising. Even though the selection of a particular SVR may be seen as a signal parametrization, the model is still non-parametric in the sense that no functional form of the signal (or noise) characteristics (e.g., the PDF) is assumed.

Non-explicit use of dependencies in local frequency domains for denoising was also introduced in Gutiérrez et al. (2006). In that case, relations were embedded into a perceptual model used for non-parametric spectrum estimation, and offered better results than local parametric autoregressive models not including these relations. Here we pursue the same goal (a model-free technique including local frequency relations), but with a completely different framework (SVR instead of perceptual information). The idea of using SVR regularization in the wavelet domain for image denoising has been recently introduced in Kai Tick Chow and Lee (2001), Cheng et al. (2004) and van Ginneken and Mendrik (2006). However, in these works, (1) the qualitative effect of the different parameters of the SVR was not analyzed, (2) these parameters were set without plausible justification of their values, and more importantly, (3) the relevance of the relations among the wavelet coefficients of the signal was not an issue, so the ability of SVR to take these relations into account in the kernel was neither assessed nor compared to other methods that do consider them. In fact, a trivial isotropic Gaussian kernel was used in all cases. On the contrary, in this paper we address the key following issues:

- **Natural images features in redundant wavelet domains.** Interesting insight about the problem can be obtained by analyzing the mutual information between the coefficients of wavelet representations (Buccigrossi and Simoncelli, 1999; Liu and Moulin, 2001). However, in redundant domains, it is strictly necessary to discern what are the relations specific to the signal and those due to the transform.
- **General constraints of the SVR parameters in image denoising.** Generic recommendations about the SVR parameters have been adapted to propose specific subband-dependent profiles for the insensitivity and the penalization parameters, and to propose a mutual information based kernel.
- **Effect of the SVR parameters.** We show the qualitative effect of varying the values of the parameters under the constrained parameter space.
- **Procedure to optimize the SVR parameters.** We propose an automatic procedure to select the SVR parameters based on the Kullback-Leibler divergence, under certain assumptions on signal and noise.

Even though this methodological framework is proposed in the context of achromatic image denoising, it can be readily extended to other denoising problems in which wavelet coefficients exhibit particular relations, such as in color or multispectral images, speech signals, etc.

The remainder of the paper is outlined as follows. In Section 2, we point out relevant signal features in redundant wavelet domains through mutual information measurements. These key properties will be used by the proposed algorithm presented in Section 3. In Section 4, the effect of SVR parameters and the validity of the proposed criterion for its selection is addressed experimentally. Section 5 shows the performance of the proposed method compared to standard denoising methods in the wavelet domain. Several experiments dealing with different amount and nature of noise illustrate the capabilities of our proposal. Finally, Section 6 draws some conclusions and outlines the further work.

2. Features of Natural Images in the Steerable Wavelet Domain

The starting hypothesis for image denoising is that signal and noise display different characteristics and thus it is possible to separate them in a certain domain. Natural images show non-trivial relationships among wavelet transform coefficients. In the following, we review the reported statistical properties of natural images in orthogonal wavelet domains, and then analyze them in the redundant steerable wavelet domain selected in our implementation. Specifically we will use mutual information (MI) to assess the statistical relations among wavelet coefficients of natural images as in Buccigrossi and Simoncelli (1999) and Liu and Moulin (2001).

2.1 Intraband Versus Interband Signal Relations in Orthogonal Wavelets

Dependencies among *orthogonal wavelet* coefficients were measured using mutual information in Liu and Moulin (2001). The dependencies were studied at interband and intraband levels, and the results suggested that the mutual information between intraband neighbors is typically *larger* than the interband relations for several models and types of interaction. In Buccigrossi and Simoncelli (1999), the authors analyzed the linear predictability of a coefficient's magnitude from a conditioning coefficient set, either its parent, neighbors (left and upper), cousins (coefficients at the same

location but in different orientation subbands), or aunts (cousins of the parent). After an exhaustive mutual information analysis, the parent provided less information content than the neighbors. These evidences suggest that the dependencies among spatial neighboring coefficients (intraband) in orthogonal wavelet descriptions are stronger than the interband dependencies.

2.2 Natural Images Relations in Steerable Wavelets

Redundant (non-orthogonal) wavelet representations may be more suited to image denoising applications since redundant representation of the image features may make the signal inherent relations clearer. Specifically, some redundant representations are designed to be translation or rotation invariant (Freeman and Adelson, 1991; Coifman and Donoho, 1995; Kingsbury, 2006). This behavior is convenient to ensure that a particular feature in different spatial regions (or with different orientations) gives rise to the same neighboring relations. Some translation invariant wavelets (Simoncelli and Freeman, 1995) have also a smoother rotation behavior than non-redundant transforms. This justifies applying the same processing all over a particular subband and dealing with the different orientations in similar ways. Besides, this prevents aliasing artifacts appearing in critically-sampled wavelets. In this work we choose a redundant steerable pyramid representation (Simoncelli and Freeman, 1995) to take advantage of these properties.

Despite the reported results on the relations of signal coefficients in orthogonal transforms, a number of questions have to be answered in the case of redundant representations, and in particular, in the steerable wavelet domain:

1. How relevant are the relations among coefficients of natural images in this domain?
2. How relatively important are interorientation, interscale and intraband signal relations?
3. How is the spatial arrangement of these signal relations?

The first question is particularly important since, even though the steerable transform may intensify the relations among signal coefficients, its redundant nature may also introduce relations which could be due to the transform but not to the signal. The second question allows us to focus on the most significant relations. Answering the third question is crucial to design suitable kernels for image denoising.

In the following, we get some insight on these concerns by performing two experiments on a representative database of 920 achromatic images of size 256×256 extracted from the McGill Calibrated Colour Image Database.[2]

2.2.1 SIGNAL RELATIONS ARE SPECIFIC TO THE SIGNAL

In our first test, following Liu and Moulin (2001), we computed the mutual information among steerable wavelet coefficients of the data set for different spatial, orientation, and scale distances. We used a steerable pyramid with 8 orientations and 4 scales. The mutual information was estimated from the uniformly binned empirical data (256 bins) by computing the histogram of all available sample pairs (721280 samples) for the three considered neighborhoods. In addition, as stated above, in redundant domains it is necessary to know whether these relations come from the images or they are due to the transform. Note that, considering i.i.d. signals, any relation among the coefficients

2. See `http://tabby.vision.mcgill.ca/`.

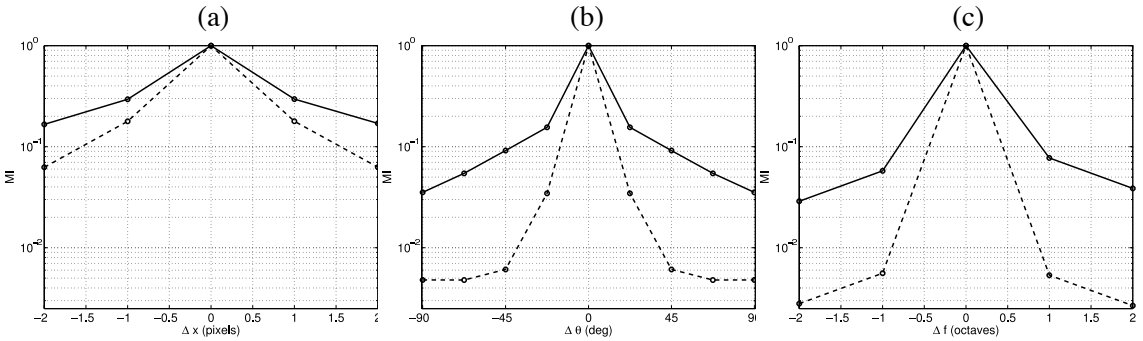

Figure 1: Comparison between redundancy of natural image coefficients in the steerable wavelet representation (solid), and the redundancy due to this representation (dashed). Redundancy is measured in terms of relative mutual information in logarithmic scale among (a) spatial (b) orientation and (c) scale neighbors.

after a linear transform will be due to the transform no matter their PDF in the original domain. Therefore, in order to assess the amount of relations due to the transform, we compared the MI among natural images coefficients, and the MI among the coefficients of an i.i.d. signal (Fig. 1). The relations displayed by i.i.d. signals in the transformed domain may be seen as a lower bound for the mutual information of signal coefficients. From Fig. 1, it can be noticed that, in every case, relations found in natural images are bigger than those introduced by the transform.

2.2.2 INTRABAND SIGNAL RELATIONS DOMINATE OVER INTERSCALE OR ORIENTATION

Besides, the results show that intraband relations in the signal are also more important than interorientation or interscale relations. Note that mutual information measures are defined to depend on logarithms of probability so that comparisons have to be done by subtraction, not by division. Beyond consistency with previously reported results for orthogonal wavelet transforms (Buccigrossi and Simoncelli, 1999; Liu and Moulin, 2001), it has been observed that the relations are specific to the signal and not just induced by the transform.

2.2.3 INTRABAND RELATIONS ARE STRONGLY ORIENTED

In our second test, we studied the spatial arrangement of the relations among intraband coefficients since they display the most relevant relations. To this end, we computed the mutual information in a 2D 5×5 neighborhood for the different orientations and scales. Figure 2[top] shows the above mentioned results for the set of natural images (finest scale). We also provide the relations introduced by the transform (i.i.d. signal, Fig. 2 [bottom]). Similar results were obtained for the other (coarser) scales. Again, the relations among the signal coefficients are higher than those introduced by the transform. Another key issue observed in Fig. 2 [top] is the specific spatial arrangement of these relations: the presence of oriented structures in natural images gives rise to strong anisotropic intraband relations in the different subbands. Coefficients following these relations are expected to be representative of natural features. These mutual information results match recently reported results on autocorrelation of intraband wavelet coefficients (Goossens et al., 2009). The results obtained in these experiments will be further used in Section 4 to design specific kernels that take into account the *observed* natural image relations.

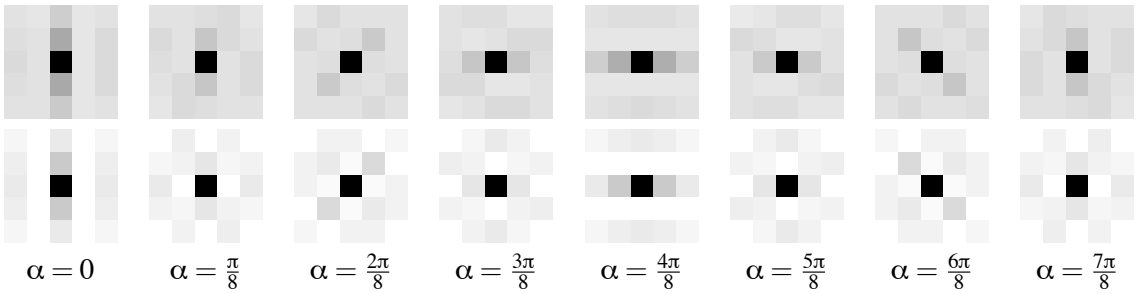

Figure 2: Mutual information among the central coefficient and its spatial neighbors in the same subband (intraband) in the steerable wavelet domain. Darker gray values indicate higher mutual information. Top row shows the results for the different orientations of the finest scale of the natural image database, and bottom row shows the equivalent results for Gaussian noise.

Summarizing, natural images have singular features in the steerable wavelet domain (Figs. 1 and 2): given a distorted image, enforcing these singular oriented relations among coefficients in every subband (with the appropriate kernels) will eventually preserve the natural signal relations and remove the noise. Of course, the bigger the difference between the shape of the intraband relations in signal and noise the better the results are expected to be.

3. Restoring Wavelet Relations with SVR

The effect of noise in the wavelet domain is introducing artificial deviations from the original signal and hiding the natural relations among the coefficients (see an illustrative example in Fig. 3). In the more general case, the degraded observation, $\mathbf{i_d}$, can be written as the result of the addition of a certain realization of noise, $\mathbf{n}$, to the original signal, $\mathbf{i}$:

$$\mathbf{i_d} = \mathbf{i} + \mathbf{n}. \tag{1}$$

Note that this (convenient) way to state the problem does not necessarily mean that the physical degradation has to be additive. In fact, the nature of the degradation should ideally be expressed through a probabilistic noise model that may depend on the original signal, $p(\mathbf{n}|\mathbf{i})$. The other desirable piece of information is a probabilistic model of the signal, $p(\mathbf{i})$. However, in most practical situations, the complete probabilistic description of the problem, that is, having $p(\mathbf{i})$ and $p(\mathbf{n}|\mathbf{i})$, is not available in analytical form.

In order to avoid this lack of information, we propose to use the regularization ability of SVRs. In this section, first we review the capabilities of the SVR for signal approximation. Afterwards, general constraints to the SVR parameter space are given for the particular problem of natural image denoising. Finally, we present an automatic procedure to choose the appropriate SVR parameters (from the above restricted space) to be used for any combination of image and noise.

3.1 Capabilities of SVR for Signal Estimation

Throughout this work, a wavelet transform, matrix T, is applied to the observed image, leading to a set of (noisy) coefficients, $\mathbf{y} = T \cdot \mathbf{i_d}$. The original set of wavelet coefficients, $\mathbf{x} = T \cdot \mathbf{i}$, has to be

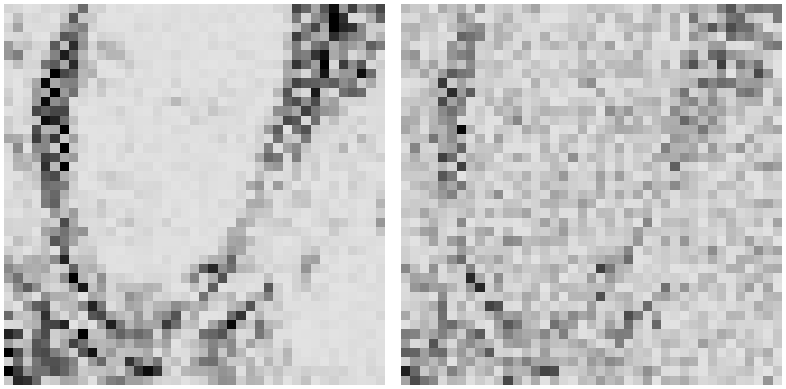

Figure 3: Effect of noise on the wavelet coefficients. Patch of a subband of a wavelet representation of the original image Barbara (left) and its noisy version (right). Darker values indicate higher amplitudes.

estimated from the distorted observation, $\mathbf{y}$. Due to the observed strong intraband relations, we will use the SVR in the wavelet domain in patches inside each subband. Subbands are decomposed into non-overlapping 16×16 patches, leading to sets of $N = 256$ samples. Now, given input-output pairs $\{p_i, y_i\}_{i=1}^{N}$, where p_i are the wavelet indices and y_i are the corresponding noisy wavelet coefficients in a patch, we train the *adaptive* SVR (Camps-Valls et al., 2001; Navia et al., 2001; Gómez et al., 2005) to approximate the signal.

Let ϕ be a non-linear mapping to a higher dimensional feature space, then the adaptive SVR computes the weights $\mathbf{w}$ to obtain the estimation, $\hat{x}_i = \phi^\top(p_i)\mathbf{w}$, by minimizing the following regularized functional:

$$\|\mathbf{w}\|^2 + \sum_i C_i \, \xi_i,$$

subject to $|y_i - \phi^\top(p_i)\mathbf{w}| \leq \varepsilon_i + \xi_i, \forall i = 1, \ldots, N$, where ξ_i are the magnitude of the deviations of the estimated signal from the observed noisy data outside the (sample-dependent) insensitivity zones ε_i. Sample-dependent penalization parameters, C_i, tune the trade-off between fitting the model to the observed noisy data (minimizing the deviations) and keeping model weights $\|\mathbf{w}\|$ small (enforcing flatness in the feature space).

This adaptive SVR differs from the standard formulation (Smola and Schölkopf, 2004), in two aspects: (1) the loss function given by (ε_i, C_i) is sample-dependent, which is convenient in wavelet domains where signal and noise variances strongly depend on the subband, and (2) the usual bias term in SVM formulations has been intentionally dropped to account for the fact that the expected value of wavelet coefficients is zero. The appropriate design of C_i and ε_i profiles is analyzed in Section 3.2.

Explicitly working with the non-linearity ϕ is no longer necessary since the whole formulation can be expressed in the form of dot products of the mapping functions called *kernels*, $K(p_i, p_j) = \phi(p_i)^\top \phi(p_j)$. In this case, the estimation is given by $\hat{\mathbf{x}} = K \cdot \alpha$, where α is the dual representation of weights $\mathbf{w}$ (Smola and Schölkopf, 2004). The kernel matrix can be seen as a similarity matrix between samples (or coefficients), and should reflect the relations between them. Many kernel functions have been proposed in the literature (Smola and Schölkopf, 2004). In the image denoising

case in wavelet domains, we focus on the basic structure of the generalized Radial Basis Functions (RBF) kernel since the relationship among the wavelet coefficients corresponding to spatial neighbors within a subband is local. However, as it will be analyzed in Section 3.2, the kernel will be adapted to incorporate the anisotropic signal relations studied in Section 2.2, see Fig. 2.

3.2 General Constraints on SVR Parameter Space in Image Denoising

As stated above, SVR signal approximation will depend on the penalization parameters, C_i, the insensitivities, ε_i, and the kernel K. In the following, we restrict the range of possible values of these parameters, $\theta = (C_i, \varepsilon_i, K)$, in the particular case of image denoising in wavelet domains:

Penalization factor. In general, the penalization factor of SVRs should be related to the standard deviation of the signal (Cherkassky, 2004). In the denoising problem considered here, the signal variance substantially differs in each wavelet scale. According to this, it is strictly necessary to set a different penalization factor *per* scale, $C_i = C\,k_i$, where k_i is a scale-dependent profile. This profile k_i was obtained by averaging the standard deviation of wavelet coefficients over 100 images from the database used in Section 2. This profile was multiplied by a factor, C, varied in the range $[10, 10^4]$, which did not show a strong impact on the results provided a sufficiently large value. This is consistent with the suggestions reported in Chalimourda et al. (2004) in a more general context. Note that, for instance, in the examples of the next section (Fig. 3), indistinguishable results are obtained for a large enough C. In our experiments, we found that a reasonable prescription for the global factor on the penalization profile is $C \approx 10^3$.

Adaptive insensitivity zone. In general, the insensitivity has to be related to the standard deviation of the noise (Kwok and Tsang, 2003). In transformed domains, the effect of the transform has to be taken into account in order to estimate the corresponding standard deviation. In redundant wavelet representations, this standard deviation is coefficient dependent. Thus it is strictly necessary to introduce a subband-dependent ε_i profile (Camps-Valls et al., 2001; Gómez et al., 2005). The transformed standard deviations can be estimated either (1) empirically from noise samples, or (2) computed from the noise covariance matrix if it is known. In the empirical case, noise samples can be experimentally obtained by applying the noise source to a large enough set of images, and writing the noise as in Eq. 1. In our experiments, we used the natural image database used in Section 2, and we obtained fairly stable results for the profile by considering 100 images. In the case that the noise covariance is known, the corresponding matrix in the selected wavelet domain can be obtained from the noise covariance matrix in the spatial domain, Σ_n, and the transform T (Stark and Woods, 1994). Therefore, the insensitivity profile can be computed as:

$$\varepsilon_i = \tau\, diag(T \cdot \Sigma_n \cdot T^\top)_i^{1/2}. \tag{2}$$

In the case of white noise, $\Sigma_n = \sigma_n^2 \cdot I$, and thus Eq. (2) reduces to:

$$\varepsilon_i = \tau\, \sigma_n\, diag(T \cdot T^\top)_i^{1/2}, \tag{3}$$

where σ_n^2 is the noise variance in the spatial domain, and τ is a scaling factor to be adapted for each particular image and noise combination. The scaling factor, τ, should be in the range

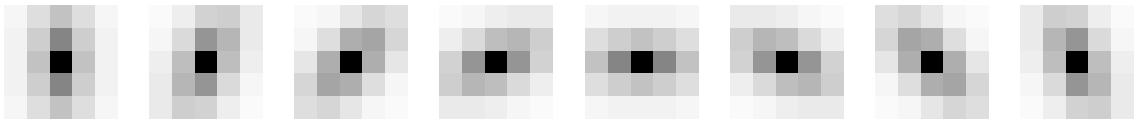

Figure 4: Anisotropic kernel functions used in the support vector regression method for the eight considered orientation subbands.

[0.5, 3] according to the known relationship between the ε-insensitivity zone and the noise standard deviation (Kwok and Tsang, 2003). Note that (2) may cope with colored noise. Considering the off-diagonal elements of the covariance matrix (neglected in (2) and (3)) would give rise to coupling ε-insensitivities among samples. This issue has been already considered and solved in the context of image coding by using an additional non-linear transform and a constant ε in the transformed domain (Camps-Valls et al., 2008). However, in this paper, we restrict ourselves to the approximated diagonal case.

Including signal relations in the kernel. In the kernel methods literature, the use of *prior* knowledge about the problem can be encoded through bagged, cluster, or probabilistic kernels (Jebara et al., 2004; Weston et al., 2004). In our case, we propose to take into account image coefficient relations by analyzing a large (representative) database and taking the (oriented) mutual information among samples as core distance measure. However, using these empirical measures to set the kernels is not straightforward since the kernels have to fulfill Mercer's Theorem (Mercer, 1905). According to this, we propose to use generalized Gaussian kernels. In particular, we fitted anisotropic Laplacian kernels to the MI measures to consider the intraband oriented relations within each subband:

$$K_\alpha(p_i, p_j) \quad = \quad \exp\big(-((p_i - p_j)^\top G(\alpha)^\top \Sigma^{-1} G(\alpha)(p_i - p_j))^{1/2}\big),$$

where $\Sigma = \begin{pmatrix} \sigma_1 & 0 \\ 0 & \sigma_2 \end{pmatrix}$, σ_1 and σ_2 are the widths of the kernels, $p_i \in \mathbb{R}^2$ denotes the spatial position of coefficient y_i within a subband, and $G(\alpha)$ is the 2D rotation matrix with rotation angle, α, corresponding to the orientation of each subband (see Fig. 4). Note that these set of oriented kernels describe the signal relationships that emerge from experiments in Section 2 (cf. Fig. 2[top]).

We obtained proper values for the widths σ_1 and σ_2 by fitting the above kernel to the MI measures among coefficients described in Section 2 ($\sigma_1 = 2\sigma_2$, and $\sigma_1 = 4.8$ in spatial coefficient units). The kernel was further normalized in the standard way. Since this width comes from direct measures from images, it describes a fundamental property of natural images so it can be kept fairly constant.

The conclusion of this section is that in the case of image denoising in wavelet domains, an appropriate analysis of the signal variance, the noise variance, and the relations among the wavelet coefficients of the signal can be used to strongly reduce the dimensionality of the SVR parameter space. After this analysis, the only SVR parameter that remains fixed is the global scaling, τ, to be applied to the insensitivity profile.

3.3 Procedure for Automatic SVR Selection

In the more general case, applying SVRs with a given set of parameters, θ, to a noisy image leads to a certain image estimate, $\hat{\mathbf{i}}_\theta = T^{-1} \cdot \hat{\mathbf{x}}_\theta$. From this image estimate, and the convenient additive notation for the noise (Eq. (1)), a noise estimate can be obtained: $\hat{\mathbf{n}}_\theta = \mathbf{i_d} - \hat{\mathbf{i}}_\theta$. In this section we propose a procedure to select the SVR parameters, θ, that better approximates the noise free image, using the available information.

In the more general situation the only available information is the noisy image. However, as stated above, denoising methods usually assume that additional probabilistic information on the signal and noise is available: $p(\mathbf{i})$ and $p(\mathbf{n}|\mathbf{i})$. Note that this knowledge is equivalent to the knowledge of the joint signal and noise distribution since $p(\mathbf{i},\mathbf{n}) = p(\mathbf{n}|\mathbf{i})\,p(\mathbf{i})$.

Let us momentarily assume that this information is available to propose the general procedure to set the SVR parameters. Afterwards, we will relax the requirements by considering an approximation that can be easily applied in practical situations.

In order to enforce solutions that closely follow the (assumed to be known) statistics of signal and noise, we propose to select the SVR that minimizes the k-th order Kullback-Leibler divergence (KLD) (Cover and Tomas, 1991) between the joint PDF of signal and noise, and the joint PDF of the estimated signal and the estimated noise:

$$\theta^* = \arg\ \min_\theta \left\{ D_{KL}\big[\, p(\hat{\mathbf{i}}_\theta, \hat{\mathbf{n}}_\theta) \parallel p(\mathbf{i},\mathbf{n}) \,\big] \right\}. \tag{4}$$

The underlying idea is that the SVR that minimizes the divergence between the above PDFs is the one that better captures the features of the true signal and better removes the degradation.

Although in ideal situations the application of this procedure would obtain the best results in statistical terms, in practical situations the full probabilistic description of the problem is not available. A number of approximations are done in practical situations. For instance, thermal noise in CCD cameras is not independent from the input signal since diffusion increase with the irradiance. However, thermal noise is usually assumed to be independent of the input signal. Additional assumptions as additivity or certain analytical marginal PDF of the noise are also widely used.

In our case, we assume independence between signal and noise:

$$p(\mathbf{i},\mathbf{n}) = p(\mathbf{i})\,p(\mathbf{n}).$$

However, no analytical model for these PDFs is assumed. Under this independence assumption, it is easy to see that Eq. 4 reduces to:

$$\theta^* = \arg\ \min_\theta \left\{ D_{KL}\big[\, p(\hat{\mathbf{i}}_\theta) \parallel p(\mathbf{i}) \,\big] + D_{KL}\big[\, p(\hat{\mathbf{n}}_\theta) \parallel p(\mathbf{n}) \,\big] \right\}. \tag{5}$$

This means that the selected SVR parameters are those that give rise to both signal and noise estimates probabilistically similar to the true signal and noise respectively. Note that this similarity does not require analytical models of the PDFs since it can be computed from histograms (or signal and noise samples).

Of course, the independence assumption does not hold in general, however, as it will be shown in Section 4.2, this is not a critical fact for a good behavior of the method even in non-additive cases in which the noise is clearly signal-dependent. Moreover, the independence assumption simplifies the practical application of the criterion for SVR selection since, for a limited number of samples,

histogram estimations of $p(\mathbf{i})$ and $p(\mathbf{n})$ are far more reliable than histogram estimations of $p(\mathbf{i},\mathbf{n})$, which implies the duplication of the dimensionality (in an already high dimensional situation).

In the examples throughout the paper we restricted ourselves to second order KLD measures due to the lack of samples, yet capturing the second order structure of signal and noise. The optimization in Eq. (5) was carried out by exhaustive search.

3.4 Summary of the Proposed Denoising Method

The proposed denoising method can be summarized as follows. First the noisy image is transformed by a steerable wavelet filter bank. Then, a set of SVRs is applied to the patches of the subbands of the transform. These SVRs use the profiles for the penalization factor and the insensitivity computed from signal and noise samples as described in Section 3.2. The SVRs use the kernel based on MI that captures signal relations in the wavelet domain as described in Section 3.2. While the scaling of the penalization profile and the kernels are kept fixed as indicated in Section 3.2, the scaling of the insensitivity profile is automatically selected following the procedure described in section 3.3.

4. Behavior of the Proposed Method

In this section, we show an illustrative example of how the SVR parameters affect the estimated solution. Moreover we validate the proposed automatic procedure for SVR selection considering examples with different noise sources including non-additive and signal dependent cases.

4.1 Impact of SVR Parameters in Image Denoising

As stated above, the regularization behavior of the SVR depends on $\theta = (C_i, \varepsilon_i, K)$. Here we show the qualitative effect of the global penalization scaling C, the global insensitivity scaling τ, and the kernel width σ assuming a generalized RBF kernel. Figure 5 shows the qualitative effect of SVR estimation as a function of these parameters. Compare the results with the original and noisy subbands shown in Fig. 3.

Increasing the kernel width, σ (vertical direction), introduces too strong relations among coefficients in such a way that spurious energy appears in the reconstruction. Increasing the insensitivity, τ (horizontal direction), a sparser solution is obtained, leading to information loss and thus relevant features of the signal are discarded. On the contrary, a too small insensitivity value gives rise to overfitting, and hence noise is not removed. Small values of the C parameter gives rise to over-regularized estimations. Large enough values of C give rise to similar behavior (see comments in Section 3.2).

Of course, interactions among these parameters occur, and have been studied in other contexts elsewhere (Chalimourda et al., 2004; Cherkassky and Ma, 2003; Cherkassky, 2004). In the image denoising case, the deviation from an *appropriate* solution in combined directions of the parameters gives rise to different solutions that combine the negative effect of the departure in each direction.

The above example suggests that *appropriate* SVRs can certainly recover the underlying structure of the original signal from the noisy observation, which is the rationale of the proposed method.

4.2 Validation of the Automatic Procedure for SVR Selection

In this section, we validate the previous SVR selection procedure in two different ways. Firstly, note that KLD values in the example of Fig. 3 *qualitatively* illustrate the usefulness of the proposed

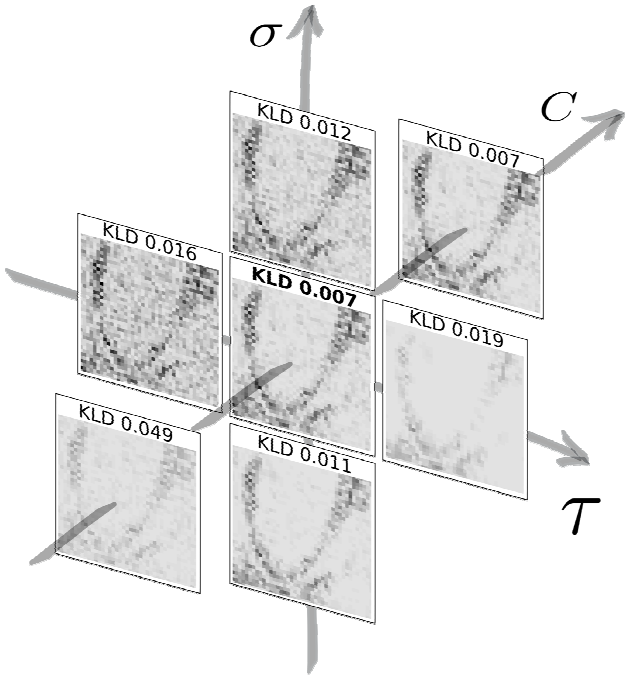

Figure 5: Effect of SVR parameters on the noisy wavelet patch of Fig. 3. The values of the KL-divergence criterion between the estimated and the actual PDFs of noise and signal are given in each case (see text in Section 3.3).

procedure: the minimum divergence solution (central subband patch) gives also a reasonable trade-off between smoothness and detail preservation of the original subband patch.

Secondly, we *quantitatively* show that the SVR that enforces the similarity between the estimated and actual signal and noise joint PDFs (in KLD terms) is not far from the SVR that maximizes the structural similarity between the estimated and the original image. In order to do so, we compare the KLD measures for different SVRs, with the corresponding distortion measured with the Structural SIMilarity (SSIM) index (Wang et al., 2004). The SSIM index is a widely used similarity measure, which is better related to human quality assessment than Euclidean measures, such as MSE or PSNR. Note that while KLD values are available in real situations (provided the noise histogram and a generic natural images histogram are known), distortion measures are not available since the original image is unknown. Consequently, the SSIM results next presented are for mere comparison purposes.

In this experiment, the SVM parameter space is reduced to the scaling factor on the insensitivity profile as recommended in Section 3.2. Accordingly, Fig. 6 shows the KLD and distortion (1-SSIM) results as a function of τ (see Eq. (3)). Curves are shown for different kinds of (Gaussian and non-Gaussian) noise sources corrupting a particular image (details on the noise sources are given in Section 5).

For the Gaussian noise case, two different variances are shown. It is worth noting that (1) the KLD criterion (solid) closely follows the actual distortion curve (dashed), and (2) the minima for low and high noise regime curves are very similar. These facts suggest that, in the Gaussian noise case, the proposed criterion is quite robust and provides consistent results: the higher the noise

(red curves) the higher the ε zone minima. Besides, the linear relation between ε and the noise standard deviation, reported in Kwok and Tsang (2003), is confirmed here: as expected, the scaling factor keeps fairly constant, $\tau \approx 2.5$, for both $\sigma_n^2 = 200$ and $\sigma_n^2 = 400$. Obviously, higher noise levels imply more distorted estimations. For other (non-Gaussian) noise sources, similar results are obtained. For the JPEG and JPEG2000 quantization noise sources, the KLD criterion also matches SSIM performance. For the case of more complex noise sources, such as vertical striping (VS) and Infra Red Imaging System (IRIS) noise, the criterion gives close-to-optimal solutions in SSIM terms. Note that, remarkably, the KLD criterion is better suited to the error minimization when the signal and noise independence assumption holds (Gaussian case). Therefore there is room to further improve the SVR selection criterion. The above results suggest that the proposed SVR selection procedure can be considered as a convenient approximation to distortion minimization (which is not possible in real situations).

5. Denoising Experiments and Discussion

In this section, we evaluate the performance of the proposed method in different scenarios for image denoising. Our algorithm is compared to several wavelet-based denoising methods using standard 256×256 images ('Barbara', 'Boats', 'Lena') with different levels and sources of degradation. In the following, we first give details on implementation issues of the considered algorithms. Then, we analyze their performance for several kinds of noise sources:

- Experiment 1. Additive Gaussian noise of different variances ($\sigma_n^2 = \{200, 400\}$).
- Experiment 2. Coding noise: JPEG and JPEG2000 at different quantization coarseness.
- Experiment 3. Acquisition noise: vertical striping and Infra Red Imaging System (IRIS) noise.

Note that the noise PDF is in general unknown, except for the academic case of Gaussian noise, but the histogram can be computed from samples in all cases.
All results are compared numerically by using the standard (yet not perceptually meaningful) RMSE, and the perceptually meaningful SSIM index (Wang et al., 2004). Moreover, representative examples are shown in every case for visual inspection. For proper visualization, all the results are equalized in the same way by truncating the values outside the $[0, 255]$ range.

5.1 Implementation Details

The algorithms that do not use information about the inter-coefficient relations (Donoho and Johnstone, 1995; Simoncelli, 1999; Figueiredo and Nowak, 2001) are straightforward to implement and have few parameters to tune. All these methods use orthogonal wavelet representations. In our particular implementation, we used 4-scale QMF wavelets from MatlabPyrTools.[3] In every case, we followed authors' prescriptions to choose these parameters for the best performance:

- *Hard Thresholding (HT)*. The key parameter is the threshold value λ. We use the noise variance to set the threshold, $\lambda = 3\sigma_n$, as suggested in Donoho and Johnstone (1995).

3. See `http://www.cns.nyu.edu/~eero/software.php`.

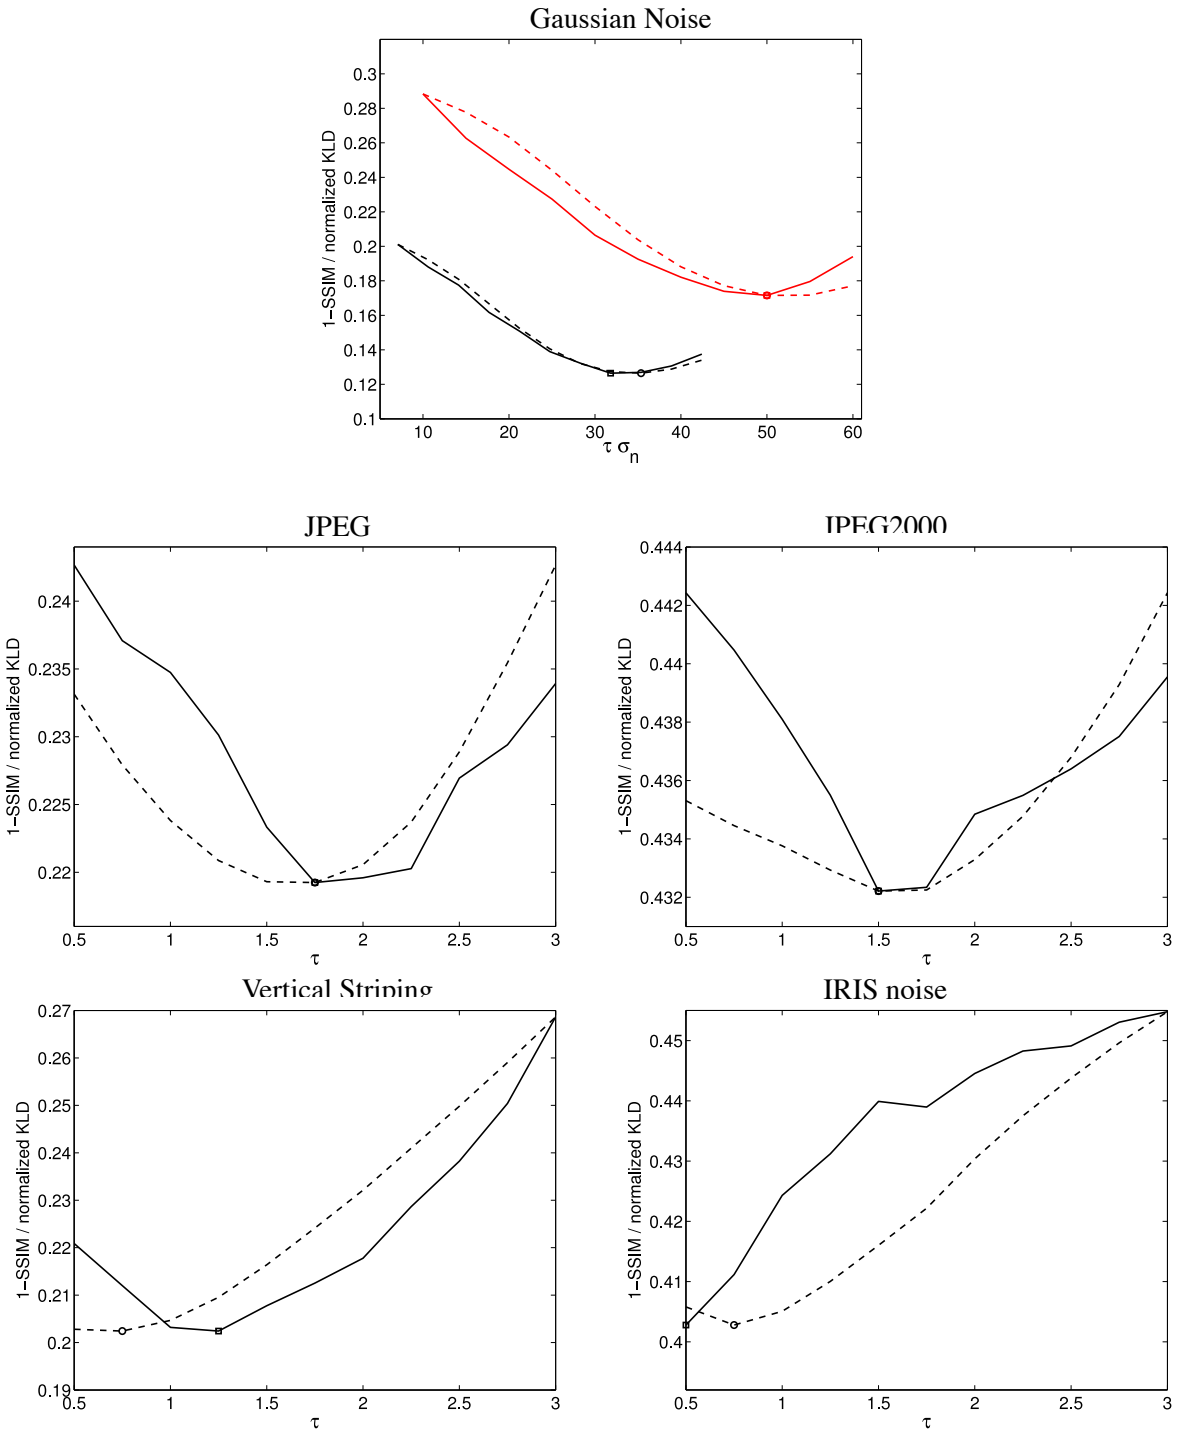

Figure 6: Validation of the proposed KLD criterion to adjust SVR parameter ε (or equivalently τ, see text). In every distortion case, solid lines represent the KLD criterion and dashed lines represent the distortion (1-SSIM). For proper visualization, KLD curves were normalized to fall in the same range as the distortion. In the Gaussian noise case, two different noise variances are considered: $\sigma_n^2 = 200$ (black lines) and $\sigma_n^2 = 400$ (red lines). As can be seen, the minima of the KL distance (squares) are always in the same region as the minima of the distortion (circles), thus giving rise to similar SSIM performance.

- *Soft Thresholding (ST)*. In our implementation, the threshold in each subband is derived from the standard deviation of the noise, σ_n, using optimized values to minimize the mean square error (MSE) in a set of 100 natural images. Threshold values were optimized for the σ_n^2 in the range [0,1600].

- *Bayesian Laplacian (BL)*. In this case, the parameters of the Laplacian distribution (s and p in Simoncelli, 1999) for the marginal PDFs in each subband are estimated by maximum likelihood (ML), as suggested by the author.

- *Bayesian Gaussian (BG)*. The threshold value was set according to the function of noise variance provided in Figueiredo and Nowak (2001).

On the other hand, in the case of the Gaussian Scale Mixture (GSM) (Portilla et al., 2003), which does consider inter-coefficient relations, we used the implementation provided by the authors.[4] We have used (1) the same representation as in the proposed method (4-scale, 8-orientation steerable pyramid), and (2) we also provided the average noise power spectral density (PSD) to achieve the best possible performance of the GSM method.

Details of the proposed SVR method are included in previous Section 3.2. A Matlab implementation of the algorithm is available online.[5] Since the C_i and ε_i profiles are computed off-line, the computational cost of the proposed method is mainly constrained by the SVR training. In our current implementation, we used the IRWLS algorithm in Matlab (Pérez-Cruz et al., 2000) in order to drop the bias term and incorporate the insensitivity and penalization profiles easily. These modifications are not trivial in faster implementations (Huang and Kecman, 2004; Kecman et al., 2004). As a result, our Matlab implementation takes about 30 seconds[6] for each image/noise estimation for a set of SVR parameters. Three strategies can be carried out for speeding up the optimization: (1) using faster SVR implementations (Platt, 1999; Chang and Lin, 2001; Tsang et al., 2005), (2) alternative procedures to exhaustive search on convex error surfaces (Torczon, 1997; Lewis and Torczon, 2002; Vishwanathan et al., 2006), and (3) restricting the dimension of the parameter space (as done in Section 3.2).

5.2 Experiment 1. Additive Gaussian Noise

Table 1 shows the distortion results for the three considered images and the two noise variances, $\sigma_n^2 = 200$ and $\sigma_n^2 = 400$.. The best SSIM values in each case are highlighted. In every case, we also provide the SVR^{opt} result, which is the best result the proposed method can get in SSIM terms. This is useful to assess the performance of the proposed divergence-based criterion and to give an upper bound of method's performance. Results show that our algorithm performs better than the methods that neglect signal relations (HT, ST, BG and BL), and obtains similar (yet slightly lower) numerical results than the one which incorporates them (GSM). It is not surprising that the GSM method achieves the best performance in this case, since it is analytically suited to deal with Gaussian noise. The SVR performance is consistent through all images and noise variances, thus suggesting that the guiding criterion is robust. Finally, it must be noted that, in the most difficult case of $\sigma_n^2 = 400$, GSM and SVR offer more similar results, and clearly outperform the rest of the methods.

Table 1: Results for the Gaussian noise: distortions for different images and methods are given at $\sigma_n^2 = 200$ (top) and $\sigma_n^2 = 400$ (bottom).

Figure 7 shows representative visual results in the challenging situation of $\sigma_n^2 = 400$. It can be noticed that thresholding methods (HT, ST) and Bayesian generalizations not including signal relations in the model (BG, BL) show poor performance, producing images either grained or corrupted by too salient wavelet functions. Even though SVR yields slightly lower numerical scores than GSM, global visual performance is comparable.

5.3 Experiment 2. Coding Noise: JPEG and JPEG2000

In this section, we focus on restoring grayscale images after JPEG or JPEG2000 compression, which induces non-Gaussian noise: it produces heavy tailed marginal error PDFs in the spatial domain with non-negligible relations among the pixels (see comments in Section 5.5). Quantization noise is an illustrative example of how the proposed method can cope with non-Gaussian, colored and signal-dependent noise. In order to obtain the necessary samples to build the noise histograms, we used 100 images from the database described in Section 2 encoded by JPEG and JPEG2000. In the first case, the Matlab implementation of the JPEG algorithm with quality factors $Q = 9$ (small distortion) and $Q = 7$ (large distortion) was used. In the second case, scalar quantization of the QMF wavelet domain using standard JPEG2000 bit allocation tables (Taubman and Marcellin, 2001) was used. Different values of quantization coarseness, that will be referred to as Δ_1 (small distortion) and Δ_2 (large distortion) were applied.

Table 2 shows the quantitative results for all considered methods for the three images at different quantization levels. It can be noticed that again the SVR method outperforms the thresholding methods (HT, ST) and those not including signal relations in the model (BG, BL). SVR yields similar numerical scores than GSM in JPEG (Fig. 8). However, in JPEG2000 better numerical (Table 2 [bottom]) and visual (Fig. 9) results are obtained with SVR. In general, high frequency details are better preserved by our method, while GSM yields over smoothed solutions, particularly in JPEG2000.

5.4 Experiment 3. Acquisition Noise: Vertical Striping and IRIS Noise

Real imaging systems introduce complex forms of noise depending on the acquisition process, so assuming a particular PDF for all cases is far from being realistic. For instance, variation of the intensity between neighboring elements of the CCD typically leads to vertical striping noise in pushbroom sensors (Mouroulis et al., 2000; Barducci and Pippi, 2001). Other typical acquisition noise source is observed in infrared imaging cameras, which is a complex mixture of different noise sources. In this section, we pay attention to these two particular non-Gaussian realistic acquisition noises through controlled experiments:

1. *Vertical striping noise*. We simulated this noise by modifying 4% of the image columns selected randomly. The luminance of the selected columns was modified by a random factor following a uniform distribution between 0.8 and 1. Spatial coherence was forced by attaching groups of contiguous 5 to 10 strips.

2. *InfraRed Imaging System (IRIS) noise*. Inspired in the observed characteristics of a representative number of acquired images by a commercial IR camera, the noise was modeled by a combination of four noise sources: low-variance Gaussian noise ($\sigma_n^2 \approx 50$), 'salt-and-pepper' noise (with a percentage of corrupted pixels about 0.05%), some spatially coherent missing pixels (black patches), and interlaced lines all over the image.

In both cases, we computed the contrast noise PDF, $p(\mathbf{n})$, from 100 noisy images. In the next Section 5.5, the non-Gaussian nature of these acquisition noise PDFs is shown.
Table 3 shows the obtained numerical results for all images and both acquisition noise sources. In both complex scenarios, the proposed SVR-based method outperforms GSM and the rest of

methods numerically. A noticeable gain in SSIM is observed, which is confirmed when looking at the restored images in Figs. 10 and 11. It is worth noting that in the vertical striping noise (Fig. 10), SVR yields a sharper (and more realistic) reconstruction while GSM produces an over-blurred solution. In the case of the IRIS noise, only SVR removes the interlacing noise contribution, producing better visual results. Including the average PSD information in GSM, as we do in the experiments, improves its performance. However, it is not enough to remove the interlacing artifact due to the particular nature of IRIS noise. IRIS noise is difficult because the PSD and variance of each particular realization of the noise may substantially differ from the (estimated) averages. On the contrary, the proposed SVR method uses an adaptive cost function learned from the noisy image. Here, nevertheless, the upper bound of performance is not met, suggesting that there is still room for improving the selection criterion proposed, possibly considering the joint density.

5.5 Analysis of the Residuals

Further qualitative insight in the obtained solutions can be achieved by comparing the estimated and actual PDFs of signal and noise with the different methods and noise sources. Since we are restricting ourselves to second order KLD criterion, this comparison reduces to assess the difference between 2D histograms (in the spatial domain).

It is widely known that the PDF of pairs of neighbor pixels in natural images is an oriented ellipsoid reflecting the strong correlation among luminance values in the spatial domain (Clarke, 1985). The corresponding restored images (even for the worse performing algorithms) also display such strong local correlation. Therefore, no relevant conclusion is gained by direct inspection of these histograms (results not shown). On the contrary, the 2D histograms of the noise are more

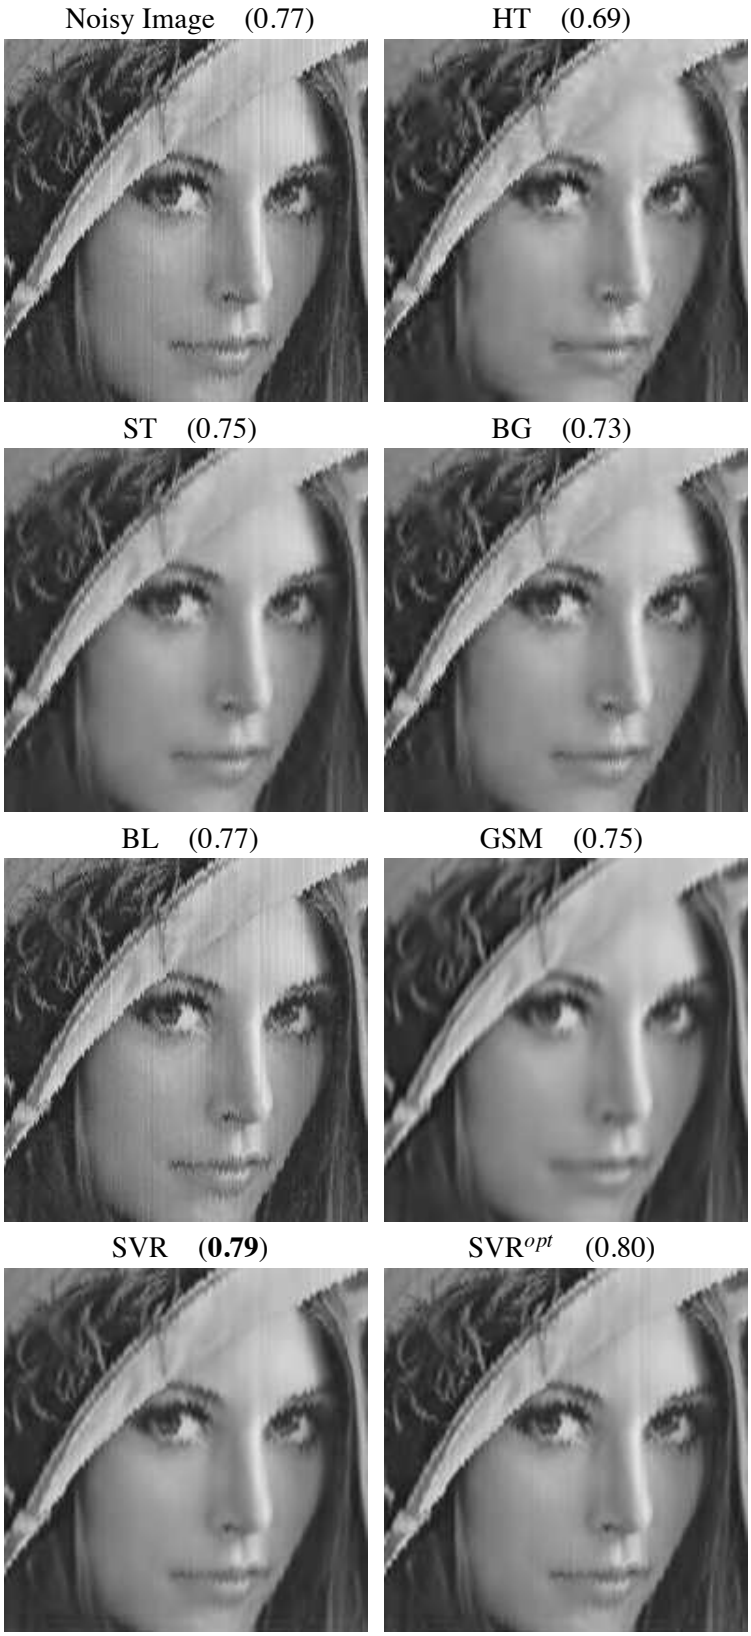

Figure 10: Visual results for the 'Lena' image with vertical striping noise. SSIM values are given in parentheses.

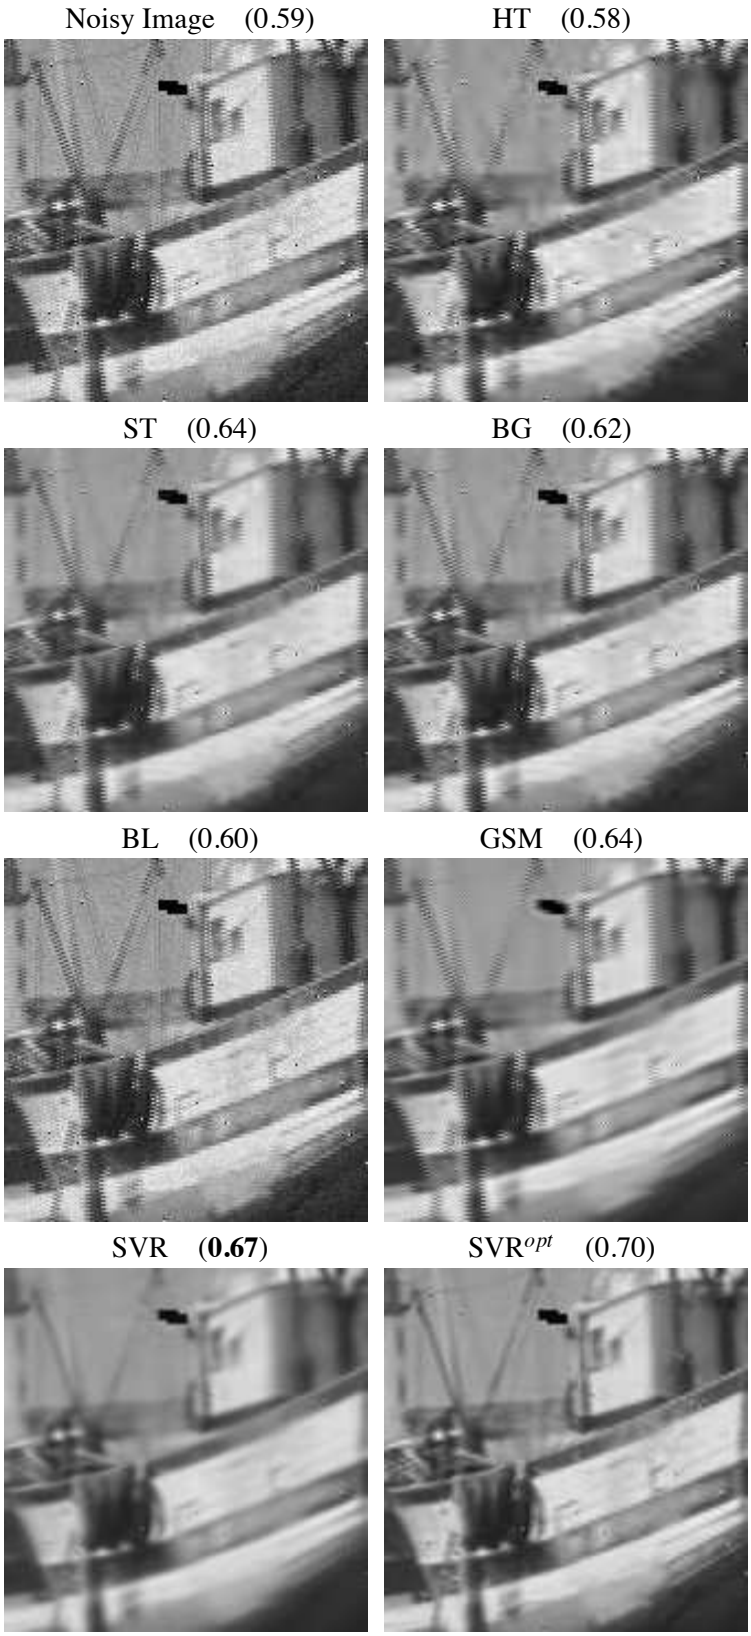

Figure 11: Visual results for the 'Boats' image with IRIS noise. SSIM values are given in parentheses.

suitable for direct inspection because (1) actual noise histograms are quite different for the different noise sources, and (2) the estimated histograms strongly depend on the denoising method.

Figure 4 represents the distribution of the actual and estimated noise PDFs by all the considered methods in the spatial domain. It can be noticed that, for the Gaussian noise, all methods reproduce quite well the shape and extent of the PDF, as expected for the parametric models, which use a proper Gaussian noise model. Note that the SVR method also succeeds in approximating the energy of the noise even without using the Gaussian assumption explicitly.

For non-Gaussian noise sources, the behavior of the methods markedly differ. For instance, the quantization noise induced by JPEG/JPEG2000 follows a non-Gaussian, oriented joint distribution (the central dark area is actually an oriented ellipsoid), indicating correlation among noise samples. In the case of JPEG, this central ellipsoid is better reproduced by hard thresholding and the proposed SVR method. The other methods slightly underestimate the variance of the noise. For the case of JPEG2000, methods not considering signal relations dramatically underestimate the noise variance. In the case of more complex noise sources, such as vertical striping or IRIS, none of the methods reproduce the low probability structure (light gray regions). However, the central peak is poorly reproduced by marginal methods, either overestimating (HT, ST, BG) or underestimating (BL) the width. On the contrary, GSM and SVR give more reasonable width estimation. To conclude, methods assuming an (inadequate) Gaussian noise model do not match, in general, the noise distribution, so they should be reformulated for each particular noise source, which may be complicated or even impossible. GSM constitutes an exception to this statement, since results suggest that the quality of the signal model compensates the unsuitability of the noise model. On the contrary, this is not necessary for the proposed method, which only needs examples of noisy images to *learn* from.

6. Conclusions

In this work, we proposed an alternative non-parametric way to take into account the relations among natural image wavelet coefficients for denoising: we used SVR in the wavelet domain to enforce these relations in the estimated signal. The specific signal relations, which proved to be more relevant in intraband coefficients, are encoded in an anisotropic kernel based on mutual information computed from a representative image database. An adaptive SVR with different cost function *per* subband was developed: the subband-dependent ε_i and C_i are modeled by analyzing the particular signal and noise variances in a representative image database. By following general recommendations for the design of the kernel, ε_i and C_i, and adapting them to the particular image denoising problem, we restricted the class of appropriate SVRs. A KLD-based criterion was proposed to automatically select the SVR that best recovers the relevant wavelet coefficient relations of the true signal. The criterion was quite consistent but there is still room for improvement, specially in the case of complex noise sources.

Results show that the performance of the proposed non-parametric method is (1) better than conventional wavelet methods that assume coefficient independence, (2) similar to state-of-the-art methods that do explicitly include these relations when the noise source is Gaussian, and (3) numerically and visually better results are obtained when more complex realistic noise sources are considered. Therefore, the proposed SVR approach can be seen as a more flexible (model-free) alternative to the explicit description of coefficient relations. The important thing here is that no reformulation is needed for dealing with any other kinds of noise. Moreover, these results are an

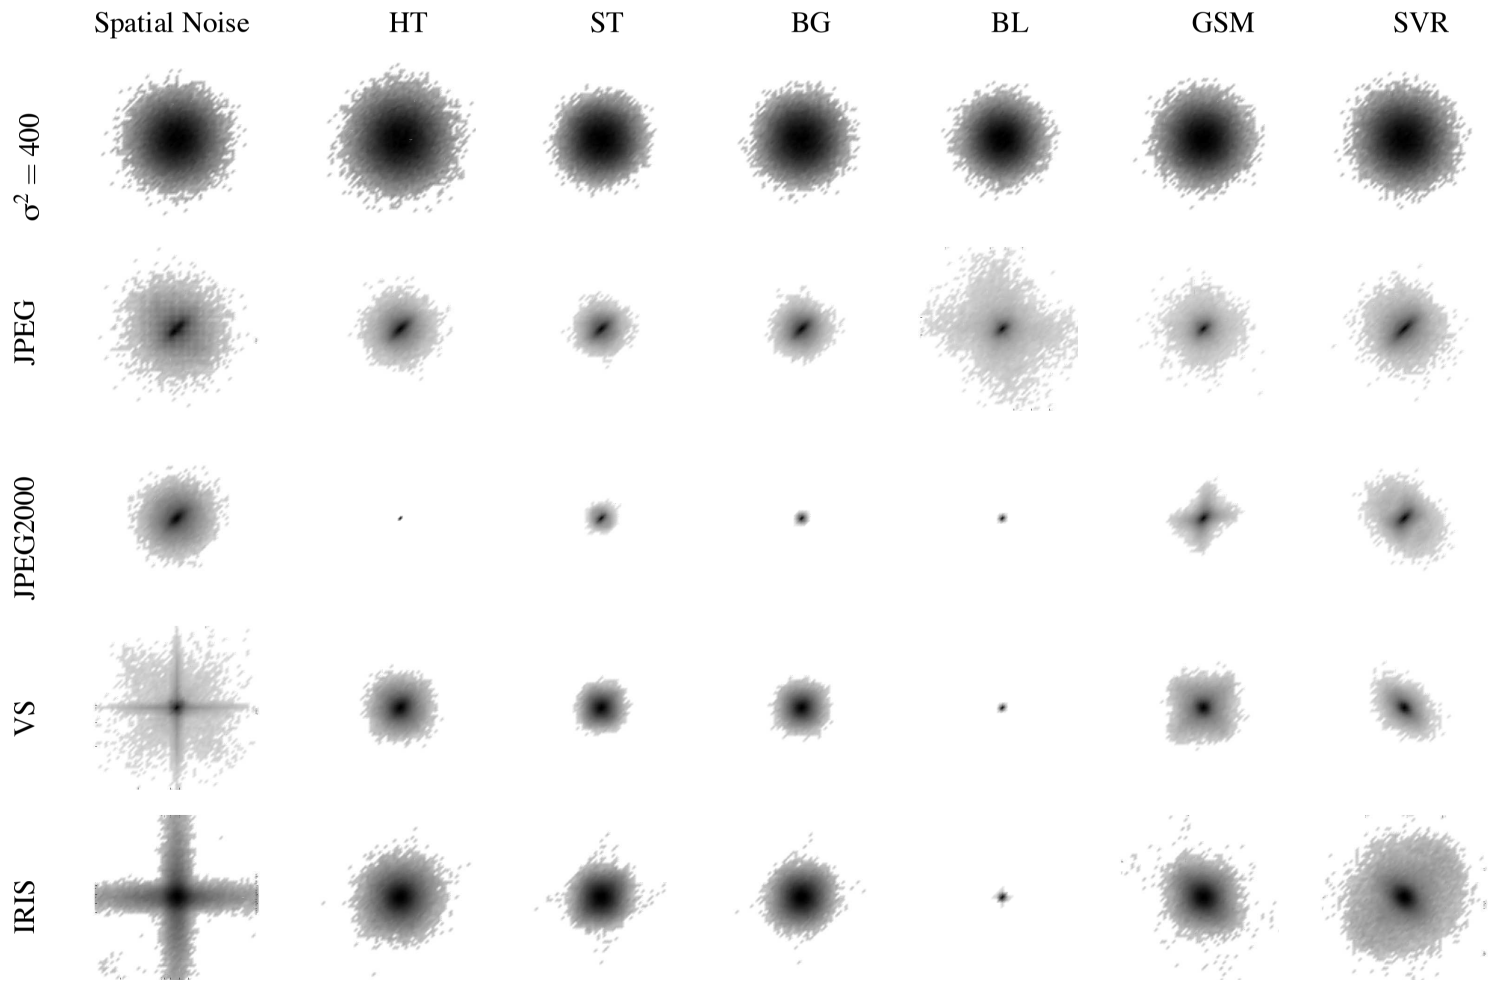

Table 4: 2D histograms of the residuals in the spatial domain for all methods and noise sources (darker regions indicate higher probability). In all cases, we considered a pixel and its right-hand neighbor (one pixel shift). All the histogram values have been exponentiated to 0.25 for better visualization.

additional indication that relation between local frequency coefficients is a salient natural image feature that should not be neglected in denoising applications.

Future work is tied to the incorporation of new information in the kernels: here we focused on the consideration of signal relations in the kernel, but the particular structure of the noise could be eventually incorporated. Note that the denoising procedure is quite general and admits any kind of non-parametric regression machine, such as Gaussian Processes.

Abstract

A large number of learning algorithms, for example, spectral clustering, kernel Principal Components Analysis and many manifold methods are based on estimating eigenvalues and eigenfunctions of operators defined by a similarity function or a kernel, given empirical data. Thus for the analysis of algorithms, it is an important problem to be able to assess the quality of such approximations. The contribution of our paper is two-fold:
1. We use a technique based on a concentration inequality for Hilbert spaces to provide new much simplified proofs for a number of results in spectral approximation.
2. Using these methods we provide several new results for estimating spectral properties of the graph Laplacian operator extending and strengthening results from von Luxburg et al. (2008).

Keywords: spectral convergence, empirical operators, learning integral operators, perturbation methods

1. Introduction

A broad variety of methods for machine learning and data analysis from Principal Components Analysis (PCA) to Kernel PCA, Laplacian-based spectral clustering and manifold methods, rely on estimating eigenvalues and eigenvectors of certain data-dependent matrices. In many cases these matrices can be interpreted as empirical versions of underlying integral operators or closely related objects, such as continuous Laplacian operators. Thus establishing connections between empirical operators and their continuous counterparts is essential to understanding these algorithms. In this paper, we propose a method for analyzing empirical operators based on concentration inequalities in Hilbert spaces. This technique together with perturbation theory results allows us to derive a number of results on spectral convergence in an exceptionally simple way. We note that the approach using concentration inequalities in a Hilbert space has already been proved useful for analyzing

supervised kernel algorithms, see De Vito et al. (2005b), Yao et al. (2007), Bauer et al. (2007) and Smale and Zhou (2007). Here we develop on this approach to provide a detailed and comprehensive study of perturbation results for empirical estimates of integral operators as well as empirical graph Laplacians.

In recent years several works started considering these connections. The first study of this problem appeared in Koltchinskii and Giné (2000) and Koltchinskii (1998), where the authors consider integral operators defined by a kernel. In Koltchinskii and Giné (2000) the authors study the relation between the spectrum of an integral operator with respect to a probability distribution and its (modified) empirical counterpart in the framework of U-statistics. In particular they prove that the ℓ_2 distance between the two (ordered) spectra goes to zero under the assumption that the kernel is symmetric and square integrable. Moreover, under some stronger conditions, rates of convergence and distributional limit theorems are obtained. The results are based on an inequality due to Lidskii and to Wielandt for finite dimensional matrices and the Marcinkiewicz law of large numbers. In Koltchinskii (1998) similar results were obtained for convergence of eigenfunctions and, using the triangle inequality, for spectral projections. These investigations were continued in Mendelson and Pajor (2005) and Mendelson and Pajor (2006), where it was shown that, under the assumption that the kernel is of positive type, the problem of eigenvalue convergence reduces to the study of how the random operator $\frac{1}{n}\sum_{i=1}^{n} X_i \otimes X_i$ deviates from its average $\mathbb{E}[X \otimes X]$, with respect to the operator norm, where $X, X_1, \ldots, X_n$ are i.i.d ℓ_2 random vectors. The result is based on a symmetrization technique and on the control of a suitable Radamacher complexity.
The above studies are related to the problem of consistency of kernel PCA considered in Shawe-Taylor et al. (2002) and Shawe-Taylor et al. (2005) and refined in Zwald et al. (2004) and Zwald and Blanchard (2006). In particular, Shawe-Taylor et al. (2002) and Shawe-Taylor et al. (2005) study the deviation of the sum of the all but the largest k eigenvalues of the empirical matrix to its mean using McDiarmid inequality. The above result is improved in Zwald et al. (2004) where fast rates are provided by means of a localized Rademacher complexities approach. The results in Zwald and Blanchard (2006) are a development of the results in Koltchinskii (1998). Using a new perturbation result the authors study directly the convergence of the whole subspace spanned by the first k eigenvectors and are able to show that only the gap between the k and $k+1$ eigenvalue affects the estimate. All the above results hold for symmetric, positive definite kernels.

A second related series of works considered convergence of the graph Laplacian in various settings , see for example, Belkin (2003), Lafon (2004), Belkin and Niyogi (2005), Hein et al. (2005), Hein (2006), Singer (2006) and Giné and Koltchinskii (2006). These papers discuss convergence of the graph Laplacian directly to the Laplace-Beltrami operator. Convergence of the normalized graph Laplacian applied to a fixed smooth function on the manifold is discussed in Hein et al. (2005), Singer (2006) and Lafon (2004). Results showing uniform convergence over some suitable class of test functions are presented in Hein (2006) and Giné and Koltchinskii (2006). Finally, convergence of eigenvalues and eigenfunctions for the case of the uniform distribution was shown in Belkin and Niyogi (2007).

Unlike these works, where the kernel function is chosen adaptively depending on the number of points, we will be primarily interested in convergence of the graph Laplacian to its continuous (population) counterpart for a *fixed* weight function. Von Luxburg et al. (2004) study the convergence of the second eigenvalue which is relevant in spectral clustering problems. These results are extended in von Luxburg et al. (2008), where operators are defined on the space of continuous functions. The analysis is performed in the context of perturbation theory in Banach spaces and bounds

on individual eigenfunctions are derived. The problem of out-of-sample extension is considered via a Nyström approximation argument. By working in Banach spaces the authors have only mild requirements for the weight function defining the graph Laplacian, at the price of having to do a fairly complicated analysis.

Our contribution is twofold. In the first part of the paper, we assume that the kernel K is symmetric and positive definite. We start considering the problem of out-of-sample extension of the kernel matrix and discuss a singular value decomposition perspective on Nyström-like extensions. More precisely, we show that a finite rank (extension) operator acting on the Reproducing Kernel Hilbert space $\mathcal{H}$ defined by K can be naturally associated with the empirical kernel matrix: the two operators have same eigenvalues and related eigenvectors/eigenfunctions. The kernel matrix and its extension can be seen as compositions of suitable restriction and extension operators that are explicitly defined by the kernel. A similar result holds true for the asymptotic integral operator, whose restriction to $\mathcal{H}$ is a Hilbert-Schmidt operator. We can use concentration inequalities for operator valued random variables and perturbation results to derive concentration results for eigenvalues (taking into account the multiplicity), as well as for the sums of eigenvalues. Moreover, using a perturbation result for spectral projections, we derive finite sample bounds for the deviation between the spectral projection associated with the k largest eigenvalues. We recover several known results with simplified proofs, and derive new results.

In the second part of the paper, we study the convergence of the asymmetric normalized graph Laplacian to its continuous counterpart. To this aim we consider a fixed positive symmetric weight function satisfying some smoothness conditions. These assumptions allow us to introduce a suitable intermediate Reproducing Kernel Hilbert space $\mathcal{H}$, which is, in fact, a Sobolev space. We describe explicitly restriction and extension operators and introduce a finite rank operator with spectral properties related to those of the graph Laplacian. Again we consider the law of large numbers for operator-valued random variables to derive concentration results for empirical operators. We study behavior of eigenvalues as well as the deviation of the corresponding spectral projections with respect to the Hilbert-Schmidt norm. To obtain explicit estimates for spectral projections we generalize the perturbation result in Zwald and Blanchard (2006) to deal with non-self-adjoint operators. From a technical point the main difficulty in studying the asymmetric graph Laplacian is that we no longer assume the weight function to be positive definite so that there is no longer a natural Reproducing Kernel Hilbert space space associated with it. In this case we have to deal with non-self-adjoint operators and the functional analysis becomes more involved. Comparing to von Luxburg et al. (2008), we note that the RKHS $\mathcal{H}$ replaces the Banach space of continuous functions. Assuming some regularity assumption on the weight functions we can exploit the Hilbert space structure to obtain more explicit results. Among other things, we derive explicit convergence rates for a large class of weight functions. Finally we note that for the case of positive definite weight functions results similar to those presented here have been independently derived by Smale and Zhou (2009).

The paper is organized as follows. We start by introducing the necessary mathematical objects in Section 2. We recall some facts about the properties of linear operators in Hilbert spaces, such as their spectral theory and some perturbation results, and discuss some concentration inequalities in Hilbert spaces. This technical summary section aims at making this paper self-contained and provide the reader with a (hopefully useful) overview of the needed tools and results. In Section 3, we study the spectral properties of kernel matrices generated from random data. We study concentration of operators obtained by an out-of-sample extension using the kernel function and obtain

considerably simplified derivations of several existing results on eigenvalues and eigenfunctions. We expect that these techniques will be useful in analyzing algorithms requiring spectral convergence. In fact, in Section 4, we apply these methods to prove convergence of eigenvalues and eigenvectors of the asymmetric graph Laplacian defined by a fixed weight function. We refine the results in von Luxburg et al. (2008), which, to the best of our knowledge, is the only other paper considering this problem so far.

2. Notation and Preliminaries

In this section we will discuss various preliminary results necessary for the further development.

2.1 Operator Theory

We first recall some basic notions in operator theory (see, for example, Lang, 1993). In the following we let $A : \mathcal{H} \to \mathcal{H}$ be a (linear) bounded operator, where $\mathcal{H}$ is a complex (separable) Hilbert space with scalar product[1] (norm) $\langle \cdot, \cdot \rangle$ ($\|\cdot\|$) and $(e_j)_{j\geq 1}$ a Hilbert basis in $\mathcal{H}$. We often use the notation $j \geq 1$ to denote a sequence or a sum from 1 to p where p can be infinite. The set of bounded operators on $\mathcal{H}$ is a Banach space with respect to the operator norm $\|A\|_{\mathcal{H},\mathcal{H}} = \|A\| = \sup_{\|f\|=1} \|Af\|$. If A is a bounded operator, we let A^* be its adjoint, which is a bounded operator with $\|A^*\| = \|A\|$.
A bounded operator A is Hilbert-Schmidt if $\sum_{j\geq 1} \|Ae_j\|^2 < \infty$ for some (any) Hilbert basis $(e_j)_{j\geq 1}$. The space of Hilbert-Schmidt operators is also a Hilbert space (a fact which will be a key in our development) endowed with the scalar product $\langle A, B \rangle_{HS} = \sum_j \langle Ae_j, Be_j \rangle$ and we denote by $\|\cdot\|_{HS}$ the corresponding norm. In particular, Hilbert-Schmidt operators are compact.

A closely related notion is that of a *trace class* operator. We say that a bounded operator A is trace class, if $\sum_{j\geq 1} \left\langle \sqrt{A^*A} e_j, e_j \right\rangle < \infty$ for some (any) Hilbert basis $(e_j)_{j\geq 1}$ (where $\sqrt{A^*A}$ is the square root of the positive operator A^*A defined by spectral theorem (see, for example, Lang, 1993). In particular, $\mathrm{Tr}(A) = \sum_{j\geq 1} \langle Ae_j, e_j \rangle < \infty$ and $\mathrm{Tr}(A)$ is called the trace of A. The space of trace class operators is a Banach space endowed with the norm $\|A\|_{TC} = \mathrm{Tr}(\sqrt{A^*A})$. Trace class operators are also Hilbert Schmidt (hence compact). The following inequalities relate the different operator norms:

$$\|A\| \leq \|A\|_{HS} \leq \|A\|_{TC}.$$

It can also be shown that for any Hilbert-Schmidt operator A and bounded operator B we have

$$\begin{aligned} \|AB\|_{HS} &\leq \|A\|_{HS}\|B\|, \\ \|BA\|_{HS} &\leq \|B\|\|A\|_{HS}. \end{aligned} \tag{1}$$

Remark 1 *If the context is clear we will simply denote the norm and the scalar product by $\|\cdot\|$ and $\langle \cdot, \cdot \rangle$ respectively. However, we will add a subscript when comparing norms in different spaces. When A is a bounded operator, $\|A\|$ always denotes the operator norm.*

2.2 Spectral Theory for Compact Operators

Recall that the spectrum of a matrix K can be defined as the set of eigenvalues $\lambda \in \mathbb{C}$, s.t. $\det(K - \lambda I) = 0$, or, equivalently, such that $\lambda I - K$ does not have a (bounded) inverse. This definition can be

1. We choose the convention for which the scalar product is linear in the first argument.

generalized to operators. Let $A : \mathcal{H} \to \mathcal{H}$ be a bounded operator, we say that $\lambda \in \mathbb{C}$ belongs to the spectrum $\sigma(A)$, if $(A - \lambda I)$ does not have a bounded inverse. For any $\lambda \notin \sigma(A)$, $R(\lambda) = (A - \lambda I)^{-1}$ is the *resolvent operator*, which is by definition a bounded operator. If A is a compact operator, then $\sigma(A) \setminus \{0\}$ consists of a countable family of isolated points with finite multiplicity $|\lambda_1| \geq |\lambda_2| \geq \cdots$ and either $\sigma(A)$ is finite or $\lim_{n\to\infty} \lambda_n = 0$ (see, for example, Lang, 1993).

If the bounded operator A is self-adjoint ($A = A^*$, analogous to a hermitian matrix in the finite-dimensional case), the eigenvalues are real. Each eigenvalue λ has an associated *eigenspace* which is the closed subspace of all eigenvectors with eigenvalue λ. A key result, known as the *Spectral Theorem*, ensures that

$$A = \sum_{i=1}^{\infty} \lambda_i P_{\lambda_i},$$

where P_λ is the *orthogonal projection operator* onto the eigenspace associated with λ. Moreover, it can be shown that the projection P_λ can be written explicitly in terms of the resolvent operator. Specifically, we have the following remarkable equality:

$$P_\lambda = \frac{1}{2\pi i} \int_\Gamma (\gamma I - A)^{-1} d\gamma,$$

where the integral can be taken over any closed simple rectifiable curve $\Gamma \subset \mathbb{C}$ (with positive direction) containing λ and no other eigenvalue. We note that while an integral of an operator-valued function may seem unfamiliar, it is defined along the same lines as an integral of an ordinary real-valued function. Despite the initial technicality, the above equation allows for far simpler analysis of eigenprojections than other seemingly more direct methods.

This analysis can be extended to operators, which are not self-adjoint, to obtain a decomposition parallel to the Jordan canonical form for matrices. To avoid overloading this section, we postpone the precise technical statements for that case to the Appendix B.

Remark 2 *Though in manifold and spectral learning we typically work with real valued functions, in this paper we will consider complex vector spaces to be able to use certain results from the spectral theory of (possibly non self-adjoint) operators. However, if the reproducing kernel and the weight function are both real valued, as usually is the case in machine learning, we will show that all functions of interest are real valued as well.*

2.3 Reproducing Kernel Hilbert Space (RKHS)

Let X be a subset of $\mathbb{R}^d$. A *Reproducing Kernel Hilbert space* is a Hilbert space $\mathcal{H}$ of functions $f : X \to \mathbb{C}$, such that all the evaluation functionals are bounded, that is

$$f(x) \leq C_x \|f\| \qquad \text{for some constant } C_x.$$

It can be shown that there is a unique conjugate symmetric positive definite kernel function $K : X \times X \to \mathbb{C}$, called *reproducing kernel*, associated with $\mathcal{H}$ and the following reproducing property holds

$$f(x) = \langle f, K_x \rangle,$$

where $K_x := K(\cdot, x)$. It is also well known (Aronszajn, 1950) that any conjugate symmetric positive definite kernel K uniquely defines a reproducing kernel Hilbert space whose reproducing kernel is

K. We will assume that the kernel is continuous and bounded, and we set

$$\kappa = \sup_{x \in X} K(x,x).$$

As a consequence, the elements of $\mathcal{H}$ are bounded continuous functions, the space $\mathcal{H}$ is separable and is compactly embedded in $\mathcal{C}(X)$ with the compact-open topology (Aronszajn, 1950).

Remark 3 *The set X can be taken to be any locally compact separable metric space and the assumption about continuity can be weakened. However, the above setting will simplify some technical considerations, in particular in Section* 4.2 *where Sobolev spaces are considered.*

2.4 Concentration Inequalities in Hilbert spaces

We recall that if $\xi_1, \ldots, \xi_n$ are independent (real-valued) random variables with zero mean and such that $|\xi_i| \leq C, \quad i = 1, \ldots, n$, then Hoeffding inequality ensures that $\forall \varepsilon > 0$,

$$\mathrm{P}\left[\left|\frac{1}{n}\sum_{i=1}^{n} \xi_i\right| \geq \varepsilon\right] \leq 2e^{-\frac{n\varepsilon^2}{2C^2}}.$$

If we set $\tau = \frac{n\varepsilon^2}{2C^2}$ then we can express the above inequality saying that with probability at least (with confidence) $1 - 2e^{-\tau}$,

$$\left|\frac{1}{n}\sum_{i=1}^{n} \xi_i\right| \leq \frac{C\sqrt{2\tau}}{\sqrt{n}}. \tag{2}$$

Similarly if $\xi_1, \ldots, \xi_n$ are zero mean independent random variables with values in a separable complex Hilbert space and such that $\|\xi_i\| \leq C, \quad i = 1, \ldots, n$, then the same inequality holds with the absolute value replaced by the norm in the Hilbert space, that is, the following bound

$$\left\|\frac{1}{n}\sum_{i=1}^{n} \xi_i\right\| \leq \frac{C\sqrt{2\tau}}{\sqrt{n}} \tag{3}$$

holds true with probability at least $1 - 2e^{-\tau}$ (Pinelis, 1992).

Remark 4 *In the cited reference the concentration inequality* (3) *is stated for real Hilbert spaces. However, a complex Hilbert space $\mathcal{H}$can be viewed as a real vector space with the scalar product given by $\langle f, g\rangle_{\mathcal{H}_\mathbb{R}} = (\langle f, g\rangle_{\mathcal{H}} + \langle g, f\rangle_{\mathcal{H}})/2$, so that $\|f\|_{\mathcal{H}_\mathbb{R}} = \|f\|_{\mathcal{H}}$. This last equality implies that* (3) *holds also for complex Hilbert spaces.*

2.5 Perturbation Theory

First we recall some results on perturbation of eigenvalues and eigenfunctions. About eigenvalues, we need to recall the notion of *extended enumeration* of discrete eigenvalues. We adapt the definition of Kato (1987), which is given for an arbitrary self-adjoint operator, to the compact operators. Let $A : \mathcal{H} \to \mathcal{H}$ be a compact operator, an extended enumeration is a sequence of real numbers where every nonzero eigenvalue of A appears as many times as its multiplicity and the other values (if any) are zero. An enumeration is an extended numeration where any element of the sequence is an

isolated eigenvalue with finite multiplicity. If the sequence is infinite, this last condition is equivalent to the fact that any element is nonzero.

The following result due to Kato (1987) is an extension to infinite dimensional operators of an inequality due to Lidskii for finite rank operator.

Theorem 5 (Kato 1987) *Let $\mathcal{H}$ be a separable Hilbert space with A, B self-adjoint compact operators. Let $(\gamma_j)_{j\geq 1}$, be an enumeration of discrete eigenvalues of $B-A$, then there exist extended enumerations $(\beta_j)_{j\geq 1}$ and $(\alpha_j)_{j\geq 1}$ of discrete eigenvalues of B and A respectively such that,*

$$\sum_{j\geq 1} \phi(\beta_j - \alpha_j) \leq \sum_{j\geq 1} \phi(\gamma_j),$$

where ϕ is any nonnegative convex function with $\phi(0) = 0$.

By choosing $\phi(t) = |t|^p$, $p \geq 1$, the above inequality becomes

$$\sum_{j\geq 1} |\beta_j - \alpha_j|^p \leq \sum_{j\geq 1} |\gamma_j|^p.$$

Letting $p = 2$ and recalling that $\|B-A\|_{HS}^2 = \sum_{j\geq 1} |\gamma_j|^2$, it follows that

$$\sum_{j\geq 1} |\beta_j - \alpha_j|^2 \leq \|B-A\|_{HS}^2.$$

Moreover, since $\lim_{p\to\infty} (\sum_{j\geq 1} |\gamma_j|^p)^{1/p} = \sup_{j\geq 1} |\gamma_j| = \|B-A\|$, we have that

$$\sup_{j\geq 1} |\beta_j - \alpha_j| \leq \|B-A\|.$$

Given an integer N, let m_N be the sum of the multiplicities of the first N nonzero top eigenvalues of A, it is possible to prove that the sequences $(\alpha_j)_{j\geq 1}$ and $(\beta_j)_{j\geq 1}$ in the above proposition can be chosen in such a way that

$$\begin{aligned} &\alpha_1 \geq \alpha_2 \geq \ldots \geq \alpha_{m_N} > \alpha_j && j > m_N, \\ &\beta_1 \geq \beta_2 \geq \ldots \geq \beta_{m_N} \geq \beta_j && j > m_N. \end{aligned}$$

However in general we need to consider extended enumerations, which are not necessarily decreasing sequence, in order to take into account the kernel spaces of A and B, which are potentially infinite dimensional vector spaces (also see the remark after Theorem II in Kato 1987).

To control the spectral projections associated with one or more eigenvalues we need the following perturbation result due to Zwald and Blanchard (2006) (see also Theorem 20 in Section 4.3). Let A be a positive compact operator such that the number of eigenvalues is infinite. Given $N \in \mathbb{N}$, let P_N^A be the orthogonal projection on the eigenvectors corresponding to the top N distinct eigenvalues $\alpha_1 > \ldots > \alpha_N$ and α_{N+1} the next one.

Proposition 6 *Let A be a compact positive operator. Given an integer N, if B is another compact positive operator such that $\|A-B\| \leq \frac{\alpha_N - \alpha_{N+1}}{4}$, then*

$$\|P_D^B - P_N^A\| \leq \frac{2}{\alpha_N - \alpha_{N+1}} \|A-B\|$$

where the integer D is such that the dimension of the range of P_D^B is equal to the dimension of the range of P_N^A. If A and B are Hilbert-Schmidt, in the above bound the operator norm can be replaced by the Hilbert-Schmidt norm.

We note that a bound on the projections associated with simple eigenvalues implies that the corresponding eigenvectors are close since, if u and v are taken to be normalized and such that $\langle u,v\rangle > 0$, then the following inequality holds

$$\|P_u - P_v\|_{HS}^2 = 2(1-\langle u,v\rangle^2) \geq 2(1-\langle u,v\rangle) = \|u-v\|_{\mathcal{H}}^2.$$

3. Integral Operators Defined by a Reproducing Kernel

Let X be a subset of $\mathbb{R}^d$ and $K : X \times X \to \mathbb{C}$ be a reproducing kernel satisfying the assumptions stated in Section 2.3. Let ρ be a probability measure on X and denote by $L^2(X,\rho)$ the space of square integrable (complex) functions with norm $\|f\|_\rho^2 = \langle f,f\rangle_\rho = \int_X |f(x)|^2 d\rho(x)$. Since $K(x,x) \leq \kappa$ by assumption, the corresponding integral operator $L_K : L^2(X,\rho) \to L^2(X,\rho)$

$$(L_K f)(x) = \int_X K(x,s) f(s) d\rho(s)$$

is a bounded operator.

Suppose we are now given a set of points $\mathbf{x} = (x_1,\ldots,x_n)$ sampled i.i.d. according to ρ. Many problems in statistical data analysis and machine learning deal with the empirical kernel $n \times n$-matrix $\mathbf{K}$ given by $\mathbf{K}_{ij} = \frac{1}{n} K(x_i,x_j)$. The question we want to discuss is to which extent we can use the kernel matrix $\mathbf{K}$ (and the corresponding eigenvalues, eigenvectors) to estimate L_K (and the corresponding eigenvalues, eigenfunctions). Answering this question is important as it guarantees that the computable empirical proxy is sufficiently close to the ideal infinite sample limit.
The first difficulty in relating L_K and $\mathbf{K}$ is that they operate on different spaces. By default, L_K is an operator on $L^2(X,\rho)$, while $\mathbf{K}$ is a finite dimensional matrix. To overcome this difficulty we let $\mathcal{H}$ be the RKHS associated with K and define the operators $T_{\mathcal{H}}, T_n : \mathcal{H} \to \mathcal{H}$ given by

$$T_{\mathcal{H}} = \int_X \langle \cdot, K_x\rangle K_x d\rho(x), \tag{4}$$

$$T_n = \frac{1}{n}\sum_{i=1}^n \langle \cdot, K_{x_i}\rangle K_{x_i}. \tag{5}$$

Note that $T_{\mathcal{H}}$ is the integral operator with kernel K with range and domain $\mathcal{H}$ rather than in $L^2(X,\rho)$. The reason for writing it in this seemingly complicated form is to make the parallel with (5) clear. To justify the "extension operator" in (5), consider the natural "restriction operator",[2] $R_n : \mathcal{H} \to \mathbb{C}^n$, $R_n f = (f(x_1),\ldots,f(x_n))$. It is not hard to check that the adjoint operator $R_n^* : \mathbb{C}^n \to \mathcal{H}$ can be written as $R_n^*(y_1,\ldots,y_n) = \frac{1}{n}\sum_{i=1}^n y_i K_{x_i}$. Indeed, we see that

$$\begin{aligned}\langle R_n^*(y_1,\ldots,y_n), f\rangle_{\mathcal{H}} &= \langle (y_1,\ldots,y_n), R_n f\rangle_{\mathbb{C}^n} \\ &= \frac{1}{n}\sum_{i=1}^n y_i \overline{f(x_i)} = \frac{1}{n}\sum_{i=1}^n y_i \langle K_{x_i}, f\rangle_{\mathcal{H}},\end{aligned}$$

2. R_n is also called sampling or evaluation operator. We prefer to call it the *restriction operator* since $R_n f$ is the restriction of the function $f : X \to \mathbb{R}$ to the set of points $\{x_1,\ldots,x_n\}$.

where $\mathbb{C}^n$ is endowed with $1/n$ times the canonical scalar product. Thus, we observe that $T_n = R_n^* R_n$ is the composition of the restriction operator and its adjoint. On the other hand for the matrix $\mathbf{K}$ we have that $\mathbf{K} = R_n R_n^*$, regarded as operator on $\mathbb{C}^n$. Similarly, if $R_{\mathcal{H}}$ denotes the inclusion $\mathcal{H} \hookrightarrow L^2(X,\rho)$, $T_{\mathcal{H}} = R_{\mathcal{H}}^* R_{\mathcal{H}}$ and $L_K = R_{\mathcal{H}} R_{\mathcal{H}}^*$.

In the next subsection, we discuss a parallel with the Singular Value Decomposition for matrices and show that $T_{\mathcal{H}}$ and L_K have the same eigenvalues (possibly, up to some zero eigenvalues) and the corresponding eigenfunctions are closely related. A similar relation holds for T_n and $\mathbf{K}$. Thus to establish a connection between the spectral properties of $\mathbf{K}$ and L_K, it is sufficient to bound the difference $T_{\mathcal{H}} - T_n$, which is done in the following theorem (De Vito et al., 2005b). While the proof can be found in De Vito et al. (2005b), we provide it for completeness and to emphasize its simplicity.

Theorem 7 *The operators $T_{\mathcal{H}}$ and T_n are Hilbert-Schmidt. Under the above assumption with confidence $1-2e^{-\tau}$*

$$\|T_{\mathcal{H}} - T_n\|_{HS} \leq \frac{2\sqrt{2}\kappa\sqrt{\tau}}{\sqrt{n}}.$$

Proof We introduce a sequence $(\xi_i)_{i=1}^n$ of random variables in the Hilbert space of Hilbert-Schmidt operators by

$$\xi_i = \langle \cdot, K_{x_i} \rangle K_{x_i} - T_{\mathcal{H}}.$$

From (4) follows that $E(\xi_i) = 0$. By a direct computation we have that $\|\langle \cdot, K_x \rangle K_x\|_{HS}^2 = \|K_x\|^4 \leq \kappa^2$. Hence, using (4), $\|T_{\mathcal{H}}\|_{HS} \leq \kappa$ and

$$\|\xi_i\|_{HS} \leq 2\kappa, \qquad i = 1, \ldots, n.$$

From inequality (3) we have with probability $1-2e^{-\tau}$

$$\|\frac{1}{n}\sum_{i=1}^n \xi_i\|_{HS} = \|T_{\mathcal{H}} - T_n\|_{HS} \leq \frac{2\sqrt{2}\kappa\sqrt{\tau}}{\sqrt{n}},$$

which establishes the result. ■

As a direct consequence of Theorem 7 we obtain several concentration inequalities for eigenvalues and eigenfunctions. These results will be discussed in subsection 3.2 and they are based on an interpretation of the Nyström extension in terms of Singular Value Decomposition of the empirical operator and its mean, as explained in the following subsection.

3.1 Extension Operators

We will now briefly revisit the Nyström extension and clarify some connections to the Singular Value Decomposition (SVD) for operators. Recall that applying SVD to a $p \times m$ matrix A produces a *singular system* consisting of singular (strictly positive) values $(\sigma_j)_{j=1}^k$ with k being the rank of A, vectors $(u_j)_{j=1}^m \in \mathbb{C}^m$ and $(v_j)_{j=1}^p \in \mathbb{C}^p$ such that they form orthonormal bases of $\mathbb{C}^m$ and $\mathbb{C}^p$ respectively, and

$$\begin{cases} A^* A u_j = \sigma_j u_j & j = 1, \ldots k \\ A^* A u_j = 0 & j = k+1, \ldots, m \\ A A^* v_j = \sigma_j v_j & j = 1, \ldots k \\ A A^* v_j = 0 & j = k+1, \ldots, p. \end{cases}$$

It is not hard to see that the matrix A can be written as $A = V\Sigma^{1/2}U^*$, where U and V are matrices obtained by "stacking" u's and v's in the columns, and Σ is a $p \times m$ matrix having the singular values σ_i on the first k-entries on the diagonal (and zero outside), so that

$$\begin{cases} Au_j = \sqrt{\sigma_j} v_j & j = 1, \dots k \\ Au_j = 0 & j = k+1, \dots, m \\ A^* v_j = \sqrt{\sigma_j} u_j & j = 1, \dots k \\ A^* v_j = 0 & j = k+1, \dots, p, \end{cases}$$

which is the formulation we will use in this paper. The same formalism applies more generally to operators and allows us to connect the spectral properties of L_K and $T_{\mathcal{H}}$ as well as the matrix $\mathbf{K}$ and the operator T_n. The basic idea is that each of these pairs (as shown in the previous subsection) corresponds to a singular system and thus share eigenvalues (up to some zero eigenvalues) and have eigenvectors related by a simple equation. Indeed the following result can be obtained considering the SVD decomposition associated with $R_{\mathcal{H}}$ (and Proposition 9 considering the SVD decomposition associated with R_n). The proof of the following proposition can be deduced from the results in De Vito et al. (2005b) and De Vito et al. (2006).[3]

Proposition 8 *The following facts hold true.*

1. *The operators L_K and $T_{\mathcal{H}}$ are positive, self-adjoint and trace class. In particular both $\sigma(L_K)$ and $\sigma(T_{\mathcal{H}})$ are contained in $[0, \kappa]$.*

2. *The spectra of L_K and $T_{\mathcal{H}}$ are the same, possibly up to the zero. If σ is a nonzero eigenvalue and u, v are the associated eigenfunctions of L_K and $T_{\mathcal{H}}$ (normalized to norm 1 in $L^2(X, \rho)$ and $\mathcal{H}$) respectively, then*

$$\begin{aligned} u(x) &= \frac{1}{\sqrt{\sigma_j}} v(x) \qquad \text{for } \rho\text{-almost all } x \in X, \\ v(x) &= \frac{1}{\sqrt{\sigma_j}} \int_X K(x,s) u(s) d\rho(s) \qquad \text{for all } x \in X. \end{aligned}$$

3. *The following decompositions hold:*

$$\begin{aligned} L_K g &= \sum_{j \geq 1} \sigma_j \langle g, u_j \rangle_\rho \, u_j \qquad g \in L^2(X, \rho), \\ T_{\mathcal{H}} f &= \sum_{j \geq 1} \sigma_j \langle f, v_j \rangle \, v_j \qquad f \in \mathcal{H}, \end{aligned}$$

where the eigenfunctions $(u_j)_{j \geq 1}$ of L_K form an orthonormal basis of $\ker L_K{}^{\perp}$ and the eigenfunctions $(v_j)_{j \geq 1}$ of $T_{\mathcal{H}}$ form an orthonormal basis for $\ker(T_{\mathcal{H}})^{\perp}$.

If K is real-valued, both the families $(u_j)_{j \geq 1}$ and $(v_j)_{j \geq 1}$ can be chosen as real valued functions.

3. In De Vito et al. (2005b) and De Vito et al. (2006) the results are stated for real kernels, however the proof does not change if K is complex valued. Moreover, if K is real and L_K is regarded as integral operator on the space of square integrable complex functions, one can easily check that the eigenvalues are positive and, if u is an eigenfunction with eigenvalue $\sigma \geq 0$, then the complex conjugate $\overline{u}$ is also an eigenfunction with the same eigenvalue, so that it is always possible to choose all the eigenfunctions to be real valued.

Note that the RKHS $\mathcal{H}$ does not depend on the measure ρ. If the support of the measure ρ is only a subset of X (e.g., a finite set of points or a submanifold), then functions in $L^2(X,\rho)$ are only defined on the support of ρ whereas functions in $\mathcal{H}$ are defined on the whole space is X. The eigenfunctions of L_K and $T_{\mathcal{H}}$ coincide (up-to a scaling factor) on the support of the measure, and v is an *extension*[4] of u outside of the support of ρ. Moreover, the extension/restriction operations preserve both the normalization and orthogonality of the eigenfunctions. In a slightly different context Coifman and Lafon (2006) showed the connection between the Nyström method and the set of eigenfunctions of L_K, which are called *geometric harmonics*. The main difference between our result and the cited paper is that we consider all the eigenfunctions, whereas Coifman and Lafon introduce a threshold on the spectrum to ensure stability since they do not consider a sampling procedure.

An analogous result relates the matrix $\mathbf{K}$ and the operator T_n .

Proposition 9 *The following facts hold.*

1. *The operator T_n is of finite rank, self-adjoint and positive, whereas the matrix $\mathbf{K}$ is conjugate symmetric and semi-positive definite. In particular the spectrum $\sigma(T_n)$ has only finitely many nonzero elements and is contained in $[0,\kappa]$.*

2. *The spectra of $\mathbf{K}$ and T_n are the same up to the zero, that is, $\sigma(\mathbf{K})\setminus\{0\} = \sigma(T_n)\setminus\{0\}$. Moreover, if $\hat{\sigma}$ is a nonzero eigenvalue and $\hat{u},\hat{v}$ are the corresponding eigenvector and eigenfunction of $\mathbf{K}$ and T_n (normalized to norm 1 in $\mathbb{C}^n$ and $\mathcal{H}$) respectively, then*

$$\begin{aligned} \hat{u} &= \frac{1}{\sqrt{\hat{\sigma}}}(\hat{v}(x_1),\ldots,\hat{v}(x_n)), \\ \hat{v} &= \frac{1}{\sqrt{\hat{\sigma}}}\left(\frac{1}{n}\sum_{i=1}^{n} K_{x_i}\hat{u}^i\right), \end{aligned}$$

   where $\hat{u}^i$ is the $i-$th component of the eigenvector $\hat{u}$.

3. *The following decompositions hold:*

$$\begin{aligned} \mathbf{K}w &= \sum_{j=1}^{k} \hat{\sigma}_j \langle w,\hat{u}_j\rangle \hat{u}_j \qquad w\in\mathbb{C}^n, \\ T_n f &= \sum_{j=1}^{k} \hat{\sigma}_j \langle f,\hat{v}_j\rangle_{\mathcal{H}} \hat{v}_j \qquad f\in\mathcal{H}, \end{aligned}$$

   where k is the rank of K and both sums run over the nonzero eigenvalues, the family $(\hat{u}_j)_{j\geq 1}$ is an orthonormal basis for $\ker\{\mathbf{K}\}^{\perp}\subset\mathbb{C}^n$ and the family $(\hat{v}_j)_{j\geq 1}$ of T_n forms an orthonormal basis for the space $\ker(T_n)^{\perp}\subset\mathcal{H}$, where

$$\ker(T_n) = \{f\in\mathcal{H} \mid f(x_i)=0\ \forall i=1,\ldots,n\}.$$

If K is real-valued, both the families $(\hat{u}_j)_{j\geq 1}$ and $(\hat{v}_j)_{j\geq 1}$ can be chosen as real valued vectors and functions, respectively.

4. However, the extension is *trivial* in the points $x\in X$ where $K(x,x)=0$, as it happens if the kernel is compactly supported.

Note that in this section L_K, T and T_n are self-adjoint operators and $\mathbf{K}$ is a conjugate symmetric matrix. If K is real, we can directly work with real Hilbert spaces. However since we need complex vector spaces in Section 4 for consistency we stated the above results for complex reproducing kernels.

3.2 Bounds on Eigenvalues and Spectral Projections

Using Theorem 7, we are able to bound the ℓ_2-distance between the spectrum of L_K and the spectrum of $\mathbf{K}$.

Proposition 10 *There exist an extended enumeration $(\sigma_j)_{j\geq 1}$ of discrete eigenvalues for L_K and an extended enumeration $(\hat{\sigma}_j)_{j\geq 1}$ of discrete eigenvalues for $\mathbf{K}$ such that*

$$\sum_{j\geq 1}(\sigma_j-\hat{\sigma}_j)^2 \leq \frac{8\kappa^2\tau}{n},$$

with confidence greater than $1-2e^{-\tau}$. In particular $\sup_{j\geq 1}|\sigma_j-\hat{\sigma}_j| \leq \frac{2\sqrt{2}\kappa\sqrt{\tau}}{\sqrt{n}}$.

Proof By Proposition 8, an extended enumeration $(\sigma_j)_{j\geq 1}$ of discrete eigenvalues for L_K is also an extended enumeration $(\sigma_j)_{j\geq 1}$ of discrete eigenvalues for $T_{\mathcal{H}}$, and a similar relation holds for $\mathbf{K}$ and T_n by Proposition 9. Theorem 5 with $A=T_n$ and $B=T_{\mathcal{H}}$ gives that

$$\sum_{j\geq 1}(\sigma_j-\hat{\sigma}_j)^2 \leq \|T_{\mathcal{H}}-T_n\|_{HS}^2$$

for a suitable extended enumerations $(\sigma_j)_{j\geq 1}$, $(\hat{\sigma}_j)_{j\geq 1}$ of discrete eigenvalues for T and T_n, respectively. Theorem 7 provides us with the claimed bound. ■

Theorem 4.2 and the following corollaries of Koltchinskii and Giné (2000) provide the same convergence rate (in expectation) under a different setting (the kernel K is only symmetric, but with some assumption on the decay of the eigenvalues of L_K).

The following result can be deduced by Theorem 5 with $p=1$ and Theorem 7, however a simpler direct proof is given below.

Proposition 11 *Under the assumption of Proposition 10 with confidence $1-2e^{-\tau}$*

$$|\sum_{j\geq 1}(\sigma_j-\hat{\sigma}_j)| = |\operatorname{Tr}(T_{\mathcal{H}})-\operatorname{Tr}(T_n)| \leq \frac{2\sqrt{2}\kappa\sqrt{\tau}}{\sqrt{n}}.$$

Proof Note that

$$\operatorname{Tr}(T_n)=\frac{1}{n}\sum_{i=1}^n K(x_i,x_i), \qquad \text{and} \qquad \operatorname{Tr}(T_{\mathcal{H}})=\int_X K(x,x)d\rho(x).$$

Then we can define a sequence $(\xi_i)_{i=1}{}^n$ of real-valued random variables by $\xi_i=K(x_i,x_i)-\operatorname{Tr}(T_{\mathcal{H}})$. Clearly $\mathbb{E}[\xi_i]=0$ and $|\xi_i|\leq 2\kappa$, $i=1,\ldots,n$ so that Hoeffding inequality (2) yields with confidence $1-2e^{-\tau}$

$$\left|\frac{1}{n}\sum_{i=1}^n \xi_i\right| = |\operatorname{Tr}(T_{\mathcal{H}})-\operatorname{Tr}(T_n)| \leq \frac{2\sqrt{2}\kappa\sqrt{\tau}}{\sqrt{n}}.$$

■

From Proposition 6 and Theorem 7 we directly derive the probabilistic bound on the eigenprojections given by Zwald and Blanchard (2006)—their proof is based on bounded difference inequality for real random variables—see also De Vito et al. (2005a). For the sake of simplicity, in the following result we assume that the number of eigenvalues of L_K is infinite.

Theorem 12 *Given an integer N, let m be the sum of the multiplicities of the first N distinct eigenvalues of L_K, so that*

$$\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_m > \sigma_{m+1},$$

and P_N be the orthogonal projection from $L^2(X,\rho)$ onto the span of the corresponding eigenfunctions. Let k be the rank of $\mathbf{K}$, and $\hat{u}_1 \ldots, \hat{u}_k$ the eigenvectors corresponding to the nonzero eigenvalues of $\mathbf{K}$ in a decreasing order. Denote by $\hat{v}_1 \ldots, \hat{v}_k \in \mathcal{H} \subset L^2(X,\rho)$ the corresponding Nyström extension given by item 2 of Proposition 9.

Given $\tau > 0$, if the number n of examples satisfies

$$n > \frac{128\,\kappa^2\tau}{(\sigma_m - \sigma_{m+1})^2},$$

then

$$\sum_{j=1}^{m} \|(I - P_N)\hat{v}_j\|_\rho^2 + \sum_{j=m+1}^{k} \|P_N \hat{v}_j\|_\rho^2 \leq \frac{32\kappa^2\tau}{(\sigma_m - \sigma_{m+1})^2\, n}\,, \tag{6}$$

with probability greater than $1 - 2e^{-\tau}$.

Proof Let $(u_j)_{j\geq 1}$ be an orthonormal family of eigenfunctions of L_K with strictly positive eigenvalues. Without loss of generality, we can assume that $u_1, \ldots, u_m$ are the eigenfunctions with eigenvalues $\sigma_1, \sigma_2, \ldots, \sigma_m$. Let $(v_j)_{j\geq 1}$ the corresponding family of eigenfunctions of $T_{\mathcal{H}}$ given by Proposition 8 and complete to an orthonormal basis of $\mathcal{H}$. Complete also the family $\hat{v}_1 \ldots, \hat{v}_k$ to an other orthonormal basis of $\mathcal{H}$.

Apply Proposition 6 with $A = T_{\mathcal{H}}$ and $B = T_n$ by taking into account Theorem 7. With high probability

$$\|P^{T_n} - P^{T_{\mathcal{H}}}\|_{\mathrm{HS}}^2 \leq \frac{8\kappa^2\tau}{(\sigma_m - \sigma_{m+1})^2\, n} \leq \frac{a_m - a_{m+1}}{2},$$

where

$$P^{T_{\mathcal{H}}} = \sum_{j=1}^{m} \langle f, v_j \rangle_{\mathcal{H}} v_j \qquad P^{T_n} = \sum_{j=1}^{m} \langle f, \hat{v}_j \rangle_{\mathcal{H}} \hat{v}_j$$

and the last bound follows from the condition on n. In particular, $\hat{\sigma}_m > \hat{\sigma}_{m+1}$.

Since both $(v_i)_{j\geq 1}$ and $(\hat{v}_i)_{j\geq 1}$ are orthonormal bases for $\mathcal{H}$

$$\begin{aligned}
\|P^{T_n} - P^{T_{\mathcal{H}}}\|_{\mathrm{HS}}^2 &= \sum_{i,j\geq 1} |\langle P^{T_n} v_i - P^{T_{\mathcal{H}}} v_i, \hat{v}_j \rangle_{\mathcal{H}}|^2 \\
&= \sum_{j=1}^{m} \sum_{i\geq m+1} |\langle v_i, \hat{v}_j \rangle_{\mathcal{H}}|^2 + \sum_{j\geq m+1} \sum_{i=1}^{m} |\langle v_i, \hat{v}_j \rangle_{\mathcal{H}}|^2 \\
&\geq \sum_{j=1}^{m} \sum_{\substack{i\geq m+1 \\ T_{\mathcal{H}} v_i \neq 0}} |\langle v_i, \hat{v}_j \rangle_{\mathcal{H}}|^2 + \sum_{j\geq m+1}^{k} \sum_{i=1}^{m} |\langle v_i, \hat{v}_j \rangle_{\mathcal{H}}|^2.
\end{aligned}$$

Since the sum on i is with respect to the eigenfunctions of $T_{\mathcal{H}}$ with nonzero eigenvalue, the Mercer theorem implies that $\langle v_i, \hat{v}_j \rangle_{\mathcal{H}} = \langle u_i, \hat{v}_j \rangle_\rho$. Finally, observe that

$$\sum_{i=1}^{m} |\langle u_i, \hat{v}_j \rangle_\rho|^2 = \|P_N \hat{v}_j\|_\rho^2$$
$$\sum_{\substack{i \geq m+1 \\ T_{\mathcal{H}} v_i \neq 0}} |\langle u_i, \hat{v}_j \rangle_\rho|^2 = \sum_{\substack{i \geq m+1 \\ L_K u_i \neq 0}} |\langle u_i, \hat{v}_j \rangle_\rho|^2 = \|(I - P_N)\hat{v}_j\|_\rho^2$$

where we used that $\ker T_{\mathcal{H}} \subset \ker T_n$, so that $\hat{v}_j \in \ker L_K{}^\perp$ with probability 1. ■

The first term on the left side of inequality (6) is the projection of the vector space spanned by the Nyström extension of the first top eigenvectors of the empirical matrix $\mathbf{K}$ onto the orthogonal of the vector space $\mathcal{M}_N$ spanned by the first top eigenfunctions of the integral operator L_K, the second term is the projection of the vector space spanned by the Nyström extensions of the other eigenvectors of $\mathbf{K}$ onto $\mathcal{M}_N$. Both differences are in $L^2(X, \rho)$ norm. A similar result is given in Zwald and Blanchard (2006), however, the role of the Nyström extensions is not considered—they study only the operators $T_{\mathcal{H}}$ and T_n (with our notation). Another result similar to ours is independently given in Smale and Zhou (2009), where the authors considered a single eigenfunction with multiplicity 1.

4. Asymmetric Graph Laplacian

In this section we will consider the case of the so-called asymmetric normalized graph Laplacian, which is the identity matrix minus the transition matrix for the natural random walk on a graph. In such a random walk, the probability of leaving a vertex along a given edge is proportional to the weight of that edge. As before, we will be interested in a specific class of graphs (matrices) associated with data.

Let $W : X \times X \to \mathbb{R}$ be a symmetric continuous weight function such that

$$0 < c \leq W(x,s) \leq C \qquad x, s \in X. \tag{7}$$

Note that we will not require W to be positive definite, but positive.

A set of data points $\mathbf{x} = (x_1, \ldots, x_n) \in X$ defines a weighted undirected graph with the weight matrix $\mathbf{W}$ given by $\mathbf{W}_{ij} = \frac{1}{n} W(x_i, x_j)$. The (asymmetric) normalized graph Laplacian $\mathbf{L} : \mathbb{C}^n \to \mathbb{C}^n$ is an $n \times n$ matrix given by

$$\mathbf{L} = \mathbf{I} - \mathbf{D}^{-1}\mathbf{W},$$

where the *degree* matrix $\mathbf{D}$ is diagonal with

$$\mathbf{D}_{ii} = \frac{1}{n} \sum_{j=1}^{n} W(x_i, x_j) = \sum_{j=1}^{n} \mathbf{W}_{ij},$$

which is invertible since $\mathbf{D} \geq cI$ by (7).

As in the previous section, X is a subset of $\mathbb{R}^d$ endowed with a probability measure ρ and $L^2(X, \rho)$ is the space of square integrable complex functions with respect to ρ.

Let $m(x) = \int_X W(x,s) d\rho(s)$ be the *degree function*, bound (7) implies that the operator $\mathbb{L} : L^2(X, \rho) \to L^2(X, \rho)$

$$(\mathbb{L}f)(x) = f(x) - \int_X \frac{W(x,s) f(s)}{m(x)} d\rho(s),$$

is well defined and continuous. The fact that W is bounded away from zero is essential to control the behavior of the degree function m, however it might be possible to replace this condition with the requirement that $m(x) \geq c$, to consider localized weight functions.

We see that when a set $\mathbf{x} = (x_1, \ldots, x_n) \in X$ is sampled i.i.d. according to ρ, the matrix $\mathbf{L}$ is an empirical version of the operator $\mathbb{L}$. We will view $\mathbf{L}$ as a perturbation of $\mathbb{L}$ due to finite sampling and will extend the approach developed in this paper to relate their spectral properties. Note that the methods described in the previous section are not directly applicable in this setting since W is not necessarily positive definite, so there is no RKHS associated with it. Moreover, even if W is positive definite, $\mathbb{L}$ involves division by a function, and may not be a map from the RKHS to itself. To overcome this difficulty in our theoretical analysis, we will rely on an auxiliary RKHS $\mathcal{H}$ with reproducing kernel K. Interestingly enough, this space will play no role from the algorithmic point of view, but only enters the theoretical analysis.

To state the properties of $\mathcal{H}$ we define the following functions

$$\begin{aligned} K_x &: X \to \mathbb{C} \qquad K_x(t) = K(t,x), \\ W_x &: X \to \mathbb{R} \qquad W_x(t) = W(t,x), \\ m_n &: X \to \mathbb{R} \qquad m_n = \frac{1}{n}\sum_{i=1}^{n} W_{x_i}, \end{aligned}$$

where m_n is the empirical counterpart of the function m and, in particular, $m_n(x_i) = \mathbf{D}_{ii}$.

To proceed we need the following assumption, which postulates that the functions $w_x, W_x/m, W_x/m_n$ belong to $\mathcal{H}$. However it is important to note that for W sufficiently smooth (as we expect it to be in most applications) these conditions can be satisfied by choosing $\mathcal{H}$ to be a Sobolev space of sufficiently high degree. This is made precise in the Section 4.2 (see Assumption 2).

Assumption 1 *Given a continuous weight function W satisfying* (7)*, we assume there exists a RKHS $\mathcal{H}$ with bounded continuous kernel K such that*

$$\begin{aligned} &W_x,\ \frac{1}{m}W_x,\ \frac{1}{m_n}W_x \in \mathcal{H} \\ &\|\frac{1}{m}W_x\|_{\mathcal{H}} \leq C, \end{aligned}$$

for all $x \in X$.

Assumption 1 allows to define the following bounded operators $\mathbb{L}_{\mathcal{H}}, A_{\mathcal{H}} : \mathcal{H} \to \mathcal{H}$

$$\begin{aligned} A_{\mathcal{H}} &= \int_X \langle \cdot, K_x \rangle_{\mathcal{H}} \frac{1}{m} W_x \, d\rho(x), \\ \mathbb{L}_{\mathcal{H}} &= I - A_{\mathcal{H}} \end{aligned}$$

and their empirical counterparts $\mathbb{L}_n, A_n : \mathcal{H} \to \mathcal{H}$

$$\begin{aligned} A_n &= \frac{1}{n}\sum_{i=1}^{n} \langle \cdot, K_{x_i} \rangle_{\mathcal{H}} \frac{1}{m_n} W_{x_i}, \\ \mathbb{L}_n &= I - A_n. \end{aligned}$$

Next result will show that $\mathbb{L}_{\mathcal{H}}$, $A_{\mathcal{H}}$ and $\mathbb{L}$ have related eigenvalues and eigenfunctions and that eigenvalues and eigenfunctions (eigenvectors) of $\mathbb{L}_n, A_n$ and $\mathbf{L}$ are also closely related. In particular

we will see in the following that to relate the spectral properties of $\mathbb{L}$ and $\mathbf{L}$ it suffices to control the deviation $A_{\mathcal{H}} - A_n$. However, before doing this, we make the above statements precise in the following subsection.

4.1 Extension Operators

In analogy to Section 3.1 we consider the relation between the operators we want to study and their extensions. We define the restriction operator $R_n : \mathcal{H} \to \mathbb{C}^n$ and the extension operator $E_n : \mathbb{C}^n \to \mathcal{H}$ as

$$\begin{aligned} R_n f &= (f(x_1), \ldots, f(x_n)) \qquad && f \in \mathcal{H}, \\ E_n(y_1, \ldots, y_n) &= \frac{1}{n} \sum_{i=1}^{n} y_i \frac{1}{m_n} W_{x_i} \qquad && (y_1, \ldots, y_n) \in \mathbb{C}^n. \end{aligned}$$

Clearly the extension operator is no longer the adjoint of R_n but the connection among the operators $\mathbf{L}$ to $\mathbb{L}_n$ and A_n can still be clarified by means of R_n and E_n. Indeed it is easy to check that $A_n = E_n R_n$ and $\mathbf{D}^{-1}\mathbf{W} = R_n E_n$. Similarly the infinite sample restrictions and extension operators can be defined to relate the operators $\mathbb{L}$, $A_{\mathcal{H}}$ and $\mathbb{L}_{\mathcal{H}}$. The next proposition considers such a connection.

Proposition 13 *The following facts hold true.*

1. *The operator $A_{\mathcal{H}}$ is Hilbert-Schmidt, the operators $\mathbb{L}$ and $\mathbb{L}_{\mathcal{H}}$ are bounded and have positive eigenvalues.*

2. *Given $\sigma \in [0, +\infty[$, $\sigma \in \sigma(\mathbb{L}_{\mathcal{H}})$ if and only if $1 - \sigma \in \sigma(A_{\mathcal{H}})$, with the same eigenfunction.*

3. *The spectra of $\mathbb{L}$ and $\mathbb{L}_{\mathcal{H}}$ are the same up to the eigenvalue 1. If $\sigma \neq 1$ is an eigenvalue and u, v associated eigenfunctions of $\mathbb{L}$ and $\mathbb{L}_{\mathcal{H}}$ respectively, then*

$$\begin{aligned} u(x) &= v(x) \qquad \text{for almost all } x \in X, \\ v(x) &= \frac{1}{1-\sigma} \int_X \frac{W(x,t)}{m(x)} u(t)\, d\rho(t) \qquad \text{for all } x \in X. \end{aligned}$$

4. *Finally the following decompositions hold*

$$\mathbb{L} = \sum_{\substack{j \geq 1 \\ \sigma_j \neq 1}} \sigma_j P_j + P_0, \tag{8}$$

$$\mathbb{L}_{\mathcal{H}} = I - \sum_{\substack{j \geq 1 \\ \sigma_j \neq 1}} (1 - \sigma_j) Q_j + D, \tag{9}$$

where the projections Q_j, P_j are the spectral projections of $\mathbb{L}$ and $\mathbb{L}_{\mathcal{H}}$ associated with the eigenvalue σ_j, P_0 is the spectral projection of $\mathbb{L}$ associated with the eigenvalue 1, and D is a quasi-nilpotent operator such that $\ker D = \ker(I - \mathbb{L}_{\mathcal{H}})$ and $Q_j D = D Q_j = 0$ for all $j \geq 1$.

Furthermore, all the eigenfunctions can be chosen as real-valued.

The proof of the above result is long and quite technical and can be found in Appendix A. Note that, with respect to Proposition 9, neither the normalization nor the orthogonality is preserved by the extension/restriction operations, so that we are free to normalize v with the factor $1/(1-\sigma)$, instead of $1/\sqrt{1-\sigma}$ as in Proposition 8. One can easily show that, if $u_1,\ldots,u_m$ is a linearly independent family of eigenfunctions of $\mathbb{L}$ with eigenvalues $\sigma_1,\ldots,\sigma_m \neq 1$, then the extension $v_1,\ldots,v_m$ is a linearly independent family of eigenfunctions of $\mathbb{L}_{\mathcal{H}}$ with eigenvalues $\sigma_1,\ldots,\sigma_m \neq 1$. Finally, we stress that in item 4 both series converge in the strong operator topology, however, though $\sum_{j\geq 1} P_i = I - P_0$, it is not true that $\sum_{j\geq 1} Q_i$ converges to $I - Q_0$, where Q_0 is the spectral projection of $\mathbb{L}_{\mathcal{H}}$ associated with the eigenvalue 1. This is the reason why we need to write the decomposition of $\mathbb{L}_{\mathcal{H}}$ as in (9) instead of (8). An analogous result allows us to relate $\mathbf{L}$ to $\mathbb{L}_n$ and A_n.

Proposition 14 *The following facts hold true.*

1. *The operator A_n is Hilbert-Schmidt, the matrix $\mathbf{L}$ and the operator $\mathbb{L}_n$ have positive eigenvalues.*

2. *Given $\sigma \in [0,+\infty[$, $\sigma \in \sigma(\mathbb{L}_n)$ if and only if $1-\sigma \in \sigma(A_n)$, with the same eigenfunction.*

3. *The spectra of $\mathbf{L}$ and $\mathbb{L}_n$ are the same up to the eigenvalue 1, moreover if $\hat{\sigma} \neq 1$ is an eigenvalue and the $\hat{u}, \hat{v}$ eigenvector and eigenfunction of $\mathbf{L}$ and $\mathbb{L}_n$, then*

$$\begin{aligned} \hat{u} &= (\hat{v}(x_1),\ldots,\hat{v}(x_1)), \\ \hat{v}(x) &= \frac{1}{1-\hat{\sigma}}\frac{1}{n}\sum_{i=1}^{n}\frac{W(x,x_i)}{m_n(x)}\hat{u}^i \end{aligned}$$

   where $\hat{u}^i$ is the $i-th$ component of the eigenvector $\hat{u}$.

4. *Finally the following decompositions hold*

$$\begin{aligned} \mathbf{L} &= \sum_{\substack{j\geq 1 \\ \hat{\sigma}_j \neq 1}} \hat{\sigma}_j \hat{P}_j + \hat{P}_0, \\ \mathbb{L}_n &= \sum_{\substack{j\geq 1 \\ \hat{\sigma}_j \neq 1}} \hat{\sigma}_j \hat{Q}_j + \hat{Q}_0 + \hat{D}, \end{aligned}$$

   where the projections Q_j, P_j are the spectral projections of $\mathbf{L}$ and $\mathbb{L}_n$ associated with the eigenvalue σ_j, $\hat{P}_0$ and $\hat{Q}_0$ are the spectral projections of $\mathbf{L}$ and $\mathbb{L}_n$ associated with the eigenvalue 1, and $\hat{D}$ is a quasi-nilpotent operator such that $\ker \hat{D} = \ker(I - \mathbb{L}_n)$ and $\hat{Q}_j \hat{D} = \hat{D}\hat{Q}_j = 0$ for all j with $\hat{\sigma}_j \neq 1$.

The last decomposition is parallel to the Jordan canonical form for (non-symmetric) matrices. Notice that, since the sum is finite, $\sum_{\substack{j\geq 1 \\ \hat{\sigma}_j \neq 1}} \hat{Q}_j + \hat{Q}_0 = I$.

4.2 Graph Laplacian Convergence for Smooth Weight Functions

If the weight function W is sufficiently differentiable, we can choose the RKHS $\mathcal{H}$ to be a suitable Sobolev space. For the sake of simplicity, we assume that X is a bounded open subset of $\mathbb{R}^d$ with a

nice boundary.[5] Given $s \in \mathbb{N}$, the Sobolev space $\mathcal{H}^s = \mathcal{H}^s(X)$ is

$$\mathcal{H}^s = \{f \in L^2(X,dx) \mid D^\alpha f \in L^2(X,dx)\ \forall |\alpha| = s\},$$

where $D^\alpha f$ is the (weak) derivative of f with respect to the multi-index $\alpha = (\alpha_1, \ldots, \alpha_d) \in \mathbb{N}^d$, $|\alpha| = \alpha_1 + \cdots + \alpha_d$ and $L^2(X,dx)$ is the space of square integrable complex functions with respect to the Lebesgue measure (Burenkov, 1998). The space $\mathcal{H}^s$ is a separable Hilbert space with respect to the scalar product

$$\langle f, g \rangle_{\mathcal{H}^s} = \langle f, g \rangle_{L^2(X,dx)} + \sum_{|\alpha|=s} \langle D^\alpha f, D^\alpha g \rangle_{L^2(X,dx)}.$$

Let $C_b^s(X)$ be the set of continuous bounded functions such that all the (standard) derivatives of order s exists and are continuous bounded functions. The space $C_b^s(X)$ is a Banach space with respect to the norm

$$\|f\|_{C_b^s} = \sup_{x \in X} |f(x)| + \sum_{|\alpha|=s} \sup_{x \in X} |(D^\alpha f)(x)|.$$

Since X is bounded, it is clear that $C_b^s(X) \subset \mathcal{H}^s$ and $\|f\|_{\mathcal{H}^s} \leq d \|f\|_{C_b^s}$, where d is a suitable constant depending only on s. A sort of converse also holds, which will be crucial in our approach, see Corollary 21 of Burenkov (1998). Let $l, m \in \mathbb{N}$ such that $l - m > \frac{d}{2}$, then

$$\mathcal{H}^l \subset C_b^m(X) \qquad \|f\|_{C_b^m} \leq d' \|f\|_{\mathcal{H}^l} \tag{10}$$

where d' is a constant depending only on l and m.

From Eq (10) with $l = s$ and $m = 0$, we see that the Sobolev space $\mathcal{H}^s$, where $s = \lfloor d/2 \rfloor + 1$, is a RKHS with a continuous[6] real valued bounded kernel K^s.

We are ready to state our assumption on the weight function, which implies Assumption 1.

Assumption 2 *We assume that $W : X \times X \to \mathbb{R}$ is a positive, symmetric function such that*

$$W(x,t) \geq c > 0 \qquad \forall x, t \in X, \tag{11}$$

$$W \in C_b^{d+1}(X \times X). \tag{12}$$

As we will see, condition (12) quantifies the regularity of W we need to use Sobolev spaces as RKHS and, as usual, it critically depends on the dimension of the input space, see also Remark 19 below. By inspecting our proofs, (12) can be replaced by the more technical condition $W \in \mathcal{H}^{d+1}(X \times X)$.

As a consequence of Assumption 2, we are able to control the deviation of $\mathbb{L}_n$ from $\mathbb{L}_{\mathcal{H}}$.

Theorem 15 *Under the conditions of Assumption 2, with confidence $1 - 2e^{-\tau}$ we have*

$$\|\mathbb{L}_n - \mathbb{L}_{\mathcal{H}}\|_{HS} = \|A_{\mathcal{H}} - A_n\|_{HS} \leq C \frac{\sqrt{\tau}}{\sqrt{n}}, \tag{13}$$

where $\|\cdot\|_{HS}$ is the Hilbert-Schimdt norm of an operator in the Sobolev space $\mathcal{H}^s$ with $s = \lfloor d/2 \rfloor + 1$, and C is a suitable constant.

5. The conditions, like quasi-resolved boundary open set, are very technical and we refer to Burenkov (1998) for the precise assumptions, see Section 4.3 of the cited reference.

6. The kernel K^s is continuous on $X \times X$ since the embedding of $\mathcal{H}^s$ into $C_b(X)$ is compact, see Schwartz (1964).

To prove this result we need some preliminary lemmas. In the following C will be a constant that could change from one statement to the other. The first result shows that Assumption 2 implies Assumption 1 with $\mathcal{H} = \mathcal{H}^s$ and that the multiplicative operators defined by the degree function, or its empirical estimate, are bounded.

Lemma 16 *There exists a suitable constant $C > 0$ such that*

1. *for all $x \in X$, $W_x, \frac{1}{m}W_x, \frac{1}{m_n}W_x \in \mathcal{H}^{d+1} \subset \mathcal{H}^s$ and $\|\frac{1}{m}W_x\|_{\mathcal{H}^s} \leq C$;*
2. *the multiplicative operators $M, M_n : \mathcal{H}^s \to \mathcal{H}^s$ defined by*

$$Mf = mf, \qquad M_n f = m_n f, \qquad\qquad f \in \mathcal{H}^s$$

are bounded invertible operators satisfying

$$\|M\|_{\mathcal{H}^s,\mathcal{H}^s}, \|M^{-1}\|_{\mathcal{H}^s,\mathcal{H}^s}, \|M_n\|_{\mathcal{H}^s,\mathcal{H}^s}, \|M_n^{-1}\|_{\mathcal{H}^s,\mathcal{H}^s} \leq C,$$
$$\|M - M_n\|_{\mathcal{H}^s,\mathcal{H}^s} \leq C\|m - m_n\|_{\mathcal{H}^{d+1}},$$

where $\|\cdot\|_{\mathcal{H}^s,\mathcal{H}^s}$ is the operator norm of an operator in the Sobolev space $\mathcal{H}^s$.

Proof Let $C_1 = \|W\|_{C_b^{d+1}(X\times X)}$. Given $x \in X$, clearly $W_x \in C_b^{d+1}(X)$ and, by standard results of differential calculus, both m and $m_n \in C_b^{d+1}(X)$ with

$$\|W_x\|_{C_b^{d+1}(X)}, \|m\|_{C_b^{d+1}(X)}, \|m_n\|_{C_b^{d+1}(X)} \leq C_1.$$

Leibniz rule for the quotient with bound (11) gives that $\frac{1}{m}$ and $\frac{1}{m_n} \in C_b^{d+1}(X)$ with

$$\|\frac{1}{m}\|_{C_b^{d+1}(X)}, \|\frac{1}{m_n}\|_{C_b^{d+1}(X)} \leq C_2,$$

where C_2 is independent both on n and on the sample $(x_1, \ldots, x_n)$. Claim in item 1 is a consequence of the fact that pointwise multiplication is a continuous bilinear map on $C_b^{d+1}(X)$, and $C_b^{d+1}(X) \subset \mathcal{H}^{d+1} \subset \mathcal{H}^s$ with

$$\|f\|_{\mathcal{H}^s} \leq C_3\|f\|_{\mathcal{H}^{d+1}} \leq C_4\|f\|_{C_b^{d+1}(X)}.$$

We claim that if $g \in C_b^{d+1}(X)$ and $f \in \mathcal{H}^s$, then $gf \in \mathcal{H}^s$ and

$$\|gf\|_{\mathcal{H}^s} \leq \|g\|_{\mathcal{H}^{d+1}}\|f\|_{\mathcal{H}^s}.$$

Indeed, Lemma 15 of Section 4 of Burenkov (1998) with $p = p_2 = 2$, $p_1 = \infty$, $l = s$ and $n = d$ ensures that

$$\|gf\|_{\mathcal{H}^s} \leq \|g\|_{C_b^s(X)}\|f\|_{\mathcal{H}^s}.$$

Eq. (10) with $m = s$ and $l = d + 1 > d/2 + s = d/2 + [d/2] + 1$ provides us with the claimed bound.

The content of item 2. is a consequence of the above result with $g = m, m_n, \frac{1}{m}, \frac{1}{m_n}$, and $m - m_n$, respectively, satisfying $\|g\|_{\mathcal{H}^{d+1}} \leq C_4 \max\{C_1, C_2\} = C_5$.
The constant C will be the maximum among the constants C_i. ■

Next lemma shows that the integral operator of kernel W and its empirical counterpart are Hilbert-Schmidt operators and it bounds their difference.

Lemma 17 *The operators $L_{W,\mathcal{H}}, L_{W,n} : \mathcal{H}^s \to \mathcal{H}^s$ defined by*

$$\begin{aligned} L_{W,\mathcal{H}} &= \int_X \langle \cdot, K_x^s \rangle_{\mathcal{H}^s} W_x d\rho(x), \\ L_{W,n} &= \frac{1}{n} \sum_{i=1}^n \langle \cdot, K_{x_i}^s \rangle_{\mathcal{H}^s} W_{x_i}, \end{aligned}$$

are Hilbert-Schmidt. Furthermore, with confidence $1 - 2e^{-\tau}$

$$\|L_{W,\mathcal{H}} - L_{W,n}\|_{HS} \leq C \frac{\sqrt{\tau}}{\sqrt{n}}.$$

for a suitable constant C.

Proof Note that $\|\langle \cdot, K_{x_i}^s \rangle_{\mathcal{H}^s} W_{x_i}\|_{HS} = \|K_{x_i}^s\|_{\mathcal{H}^s} \|W_{x_i}\|_{\mathcal{H}^s} \leq C_1$ for a suitable constant C_1, which is finite by item 1 of Lemma 16 and the fact that K^s is bounded. Hence $L_{W,n}, L_{W,\mathcal{H}}$ are Hilbert Schmidt operators on $\mathcal{H}^s$. The random variables $(\xi_i)_{i=1}^n$ defined by $\xi_i = \langle \cdot, K_{x_i}^s \rangle_{\mathcal{H}^s} W_{x_i} - L_{W,\mathcal{H}}$, taking value in the Hilbert space of Hilbert-Schmidt operators, are zero mean and bounded. Applying (3) we have with confidence $1 - 2e^{-\tau}$

$$\|L_{W,\mathcal{H}} - L_{W,n}\|_{HS} \leq C \frac{\sqrt{\tau}}{\sqrt{n}}, \tag{14}$$

for a suitable constant C. ■

We then consider multiplication operators defined by the degree functions.

Lemma 18 *With confidence $1 - 2e^{-\tau}$*

$$\|M - M_n\|_{\mathcal{H}^s, \mathcal{H}^s} \leq C \frac{\sqrt{\tau}}{\sqrt{n}}.$$

for a suitable constant C.

Proof Item 2 of Lemma 16 ensures that M and M_n are bounded operators on $\mathcal{H}^s$ with $\|M - M_n\|_{\mathcal{H}^s, \mathcal{H}^s} \leq C_1 \|m - m_n\|_{\mathcal{H}^{d+1}}$.
The random variables $(\xi_i)_{i=1}^n$, defined by $\xi_i = W_{x_i} - m \in \mathcal{H}^{d+1}$ are zero mean and bounded. Applying (3) we have with high probability

$$\|m - m_n\|_{\mathcal{H}^{d+1}} \leq \frac{C_2 \sqrt{\tau}}{\sqrt{n}},$$

so that the claim is proved with a suitable choice for C. ■

Remark 19 *In the above lemma we need to control $m - m_n$ in a suitable Hilbert space in order to use Hoeffding inequality* (3)*. Lemma* 15 *of Burenkov (1998) ensures that $\|M - M_n\|_{\mathcal{H}^s, \mathcal{H}^s}$ is bounded by $\|m - m_n\|_{C_b^s(X)}$. In order to control it with a Sobolev norm by means of* (10)*, we need to require that $m - m_n \in \mathcal{H}^l$ with $l > s + d/2$. Furthermore, the requirement that $\mathcal{H}^s$ is a RKHS with continuous bounded kernel implies that $s > d/2$ so that $l > d$. Hence a natural requirement on the weight function is that $W_x \in \mathcal{H}^l(X)$, which is closely related to Assumption 2 with the minimal choice $l = d + 1$.*

Finally, we can combine the above two lemmas to get the proof of Theorem 15.

Proof [Proof of Theorem 15] By Lemma 16, both M and M_n are invertible operators and

$$A_{\mathcal{H}} = M^{-1} L_{W,\mathcal{H}}, \qquad A_n = M_n^{-1} L_{W,n},$$

so that we can consider the following decomposition

$$\begin{aligned} A_n - A_{\mathcal{H}} &= M_n^{-1} L_{W,n} - M^{-1} L_{W,\mathcal{H}} \\ &= (M_n^{-1} - M^{-1}) L_{W,\mathcal{H}} + M_n^{-1}(L_{W,n} - L_{W,\mathcal{H}}) \\ &= M_n^{-1}(M - M_n) M^{-1} L_{W,\mathcal{H}} + \\ &\quad + M_n^{-1}(L_{W,n} - L_{W,\mathcal{H}}). \end{aligned} \tag{15}$$

By taking the Hilbert-Schmidt norm of the above expression and using (1) with the bounds provided by Lemma 16, we get

$$\|A_n - A_{\mathcal{H}}\|_{HS} \leq C^2 \|M - M_n\|_{\mathcal{H}^S, \mathcal{H}^S} \|L_{W,\mathcal{H}}\|_{HS} + C\|L_{W,n} - L_{W,\mathcal{H}}\|_{HS}.$$

The concentration inequalities (17) and (18) give (13), possibly redefining the constant C. ■

In the next section we discuss the implications of the above result in terms of concentration of eigenvalues and spectral projections.

4.3 Bounds on Eigenvalues and Spectral Projections

Since the operators are no longer self-adjoint the perturbation results in Section 3.2 cannot be used. See Appendix B for a short review about spectral theory for compact (not necessarily self-adjoint) operators. The following theorem is an adaptation of results in Anselone (1971), compare with Theorem 4.21.

Theorem 20 *Let A be a compact operator. Given a finite set Λ of non-zero eigenvalues of A, let Γ be any simple rectifiable closed curve (having positive direction) with Λ inside and $\sigma(A) \setminus \Lambda$ outside. Let P be the spectral projection associated with Λ, that is,*

$$P = \frac{1}{2\pi i} \int_\Gamma (\lambda - A)^{-1} \, d\lambda,$$

and define

$$\delta^{-1} = \sup_{\lambda \in \Gamma} \|(\lambda - A)^{-1}\|.$$

Let B be another compact operator such that

$$\|B - A\| \leq \frac{\delta^2}{\delta + \ell(\Gamma)/2\pi} < \delta,$$

where $\ell(\Gamma)$ is the length of Γ, then the following facts hold true.

1. *The curve Γ is a subset of the resolvent set of B enclosing a finite set $\widehat{\Lambda}$ of non-zero eigenvalues of B;*

2. *Denoting by $\widehat{P}$ the spectral projection of B associated with $\widehat{\Lambda}$, then*

$$\|\widehat{P}-P\| \leq \frac{\ell(\Gamma)}{2\pi\delta}\frac{\|B-A\|}{\delta-\|B-A\|};$$

3. *The dimension of the range of P is equal to the dimension of the range of $\hat{P}$.*

Moreover, if $B-A$ is a Hilbert-Schmidt operator, then

$$\|\widehat{P}-P\|_{HS} \leq \frac{\ell(\Gamma)}{2\pi\delta}\frac{\|B-A\|_{HS}}{\delta-\|B-A\|}.$$

We postpone the proof of the above result to Appendix A.

We note that, if A is self-adjoint, then the spectral theorem ensures that

$$\delta = \min_{\lambda\in\Gamma,\sigma\in\Lambda}|\lambda-\sigma|.$$

The above theorem together with the results obtained in the previous section allows to derive several results.

Proposition 21 *If Assumption 2 holds, let σ be an eigenvalue of $\mathbb{L}$, $\sigma\neq 1$, with multiplicity m. For any $\varepsilon>0$ and $\tau>0$, there exists an integer n_0 and a positive constant C such that, if the number of examples is greater than n_0, with probability greater than $1-2e^{-\tau}$,*

1. *there are $\hat{\sigma}_1,\ldots,\hat{\sigma}_m$ (possibly repeated) eigenvalues of the matrix $\mathbf{L}$ satisfying*

$$|\hat{\sigma}_i-\sigma|\leq\varepsilon \qquad \text{for all } i=1,\ldots,m.$$

2. *for any normalized eigenvector $\hat{u}\in\mathbb{C}^n$ of $\mathbf{L}$ with eigenvalue $\hat{\sigma}_i$ for some $i=1,\ldots,m$, there exists an eigenfunction $u\in\mathcal{H}^s\subset L^2(X,\rho)$ of $\mathbb{L}$ with eigenvalue σ, satisfying*

$$\|\hat{v}-u\|_{\mathcal{H}^s}\leq C\frac{\sqrt{\tau}}{\sqrt{n}},$$

where $\hat{v}$ is the Nyström extension of the vector $\hat{u}$ given in item 3 of Proposition 14.

If $\mathbb{L}_{\mathcal{H}}$ is self-adjoint, then $n_0\geq 4\frac{C^2\tau}{\varepsilon^2}$ provided that $\varepsilon<\min_{\sigma'\in\sigma(\mathbb{L}_{\mathcal{H}}),\sigma'\neq\sigma}|\sigma'-\sigma|$.

Proof Theorem 15 gives that, with probability greater than $1-2e^{-\tau}$,

$$\|A_n-A_{\mathcal{H}}\|\leq\|A_n-A_{\mathcal{H}}\|_{HS}\leq\frac{C_1\sqrt{\tau}}{\sqrt{n}}\leq\frac{\delta^2}{\delta+\varepsilon}. \tag{16}$$

for all $n\geq n_0$, where C_1 is a suitable constant, $n_0\in\mathbb{N}$ is such that $\frac{C_1\sqrt{\tau}}{\sqrt{n_0}}\leq\frac{\delta^2}{\delta+\varepsilon}$ and $\delta^{-1}=\sup_{\lambda\in\Gamma}\|(\lambda-A_{\mathcal{H}})^{-1}\|$. Under these conditions, we apply Theorem 20 with $A=A_{\mathcal{H}}$, $B=A_n$ and $\Gamma=\{\lambda\in\mathbb{C}\mid|\lambda-(1-\sigma)|=\varepsilon\}$, so that $\ell(\Gamma)=2\pi\varepsilon$. Since $A_{\mathcal{H}}$ is compact and assuming ε small enough, we have that $\Lambda=\{1-\sigma\}$.

Item 1 of Theorem 20 with Proposition 14 ensures that $\widehat{\Lambda}=\{1-\hat{\sigma}_1,\ldots,1-\hat{\sigma}_m\}$, so that $|\hat{\sigma}_i-\sigma|<\varepsilon$ for all $i=1,\ldots,m$. Let now $\hat{u}\in\mathbb{C}^n$ be a normalized vector such that $\mathbf{L}\hat{u}=\hat{\sigma}_i\hat{u}$ for some $i=1,\ldots,m$.

Proposition 14 ensures that $\hat{v}$ is an eigenfunction of A_n with eigenvalue $1-\hat{\sigma}$, so that $\hat{Q}\hat{v} = \hat{v}$ where $\hat{Q}$ is the spectral projection of A_n associated with $\hat{\Lambda}$. Let Q be the spectral projection of $A_{\mathcal{H}}$ associated with $1-\sigma$ and define $u = Q\hat{v} \in \mathcal{H}^s$. By definition of Q, $A_{\mathcal{H}}u = (1-\sigma)u$. Since $\mathcal{H}^s \subset L^2(X,\rho)$, Proposition 13 ensures that $\mathbb{L}u = \sigma u$. Item 2 of Theorem 20 gives that

$$\begin{aligned}\|\hat{v}-u\|_{\mathcal{H}^s} = \|\hat{Q}\hat{v}-Q\hat{v}\|_{\mathcal{H}^s} &\leq \|\hat{Q}-Q\|_{\mathcal{H}^s,\mathcal{H}^s}\|\hat{v}\|_{\mathcal{H}^s} \leq \|\hat{v}\|_{\mathcal{H}^s}\frac{\varepsilon}{\delta}\frac{\|A_n - A_{\mathcal{H}}\|_{HS}}{\delta - \|A_n - A_{\mathcal{H}}\|_{HS}} \\ &\leq \frac{C_2}{1-(\sigma+\varepsilon)}C_1\frac{\delta+\varepsilon}{\delta^2}\frac{\sqrt{\tau}}{\sqrt{n}},\end{aligned}$$

where we use (16), the fact that $\|A_n - A_{\mathcal{H}}\| \leq \frac{\delta^2}{\delta+\varepsilon}$ and

$$\|\hat{v}\|_{\mathcal{H}^s} \leq \frac{1}{1-\hat{\sigma}}\sup_{x\in X}\|\frac{1}{m_n}W_x\|_{\mathcal{H}^s} = \frac{C_2}{1-\hat{\sigma}} \leq \frac{C_2}{1-(\sigma+\varepsilon)}$$

with C_2 being the constant in item 1 of Lemma 16.
If $A_{\mathcal{H}}$ is self-adjoint, the spectral theorem ensures that $\delta = \varepsilon$, so that $n_0 \geq 4\frac{C^2\tau}{\varepsilon^2}$. ■

Next we consider convergence of the spectral projections of $A_{\mathcal{H}}$ and A_n associated with the first N-eigenvalues. For sake of simplicity, we assume that the cardinality of $\sigma(A_{\mathcal{H}})$ is infinite.

Proposition 22 *Consider the first N eigenvalues of $A_{\mathcal{H}}$. There exist an integer n_0 and a constant $C > 0$, depending on N and $\sigma(A_{\mathcal{H}})$, such that, with confidence $1-2e^{-\tau}$ and for any $n \geq n_0$,*

$$\|P_N - \hat{P}_D\|_{HS} \leq \frac{C\sqrt{\tau}}{\sqrt{n}},$$

where $P_N, \hat{P}_D$ are the eigenprojections corresponding to the first N eigenvalues of $A_{\mathcal{H}}$ and D eigenvalues of A_n, and D is such that the sum of the multiplicity of the first D eigenvalues of A_n is equal to the sum of the multiplicity of the first N eigenvalues of $A_{\mathcal{H}}$.

Proof The proof is close to the one of the previous proposition. We apply Theorem 20 with $A = A_{\mathcal{H}}$, $B = A_n$ and the curve Γ equal to the boundary of the rectangle

$$\{\lambda \in \mathbb{C} \mid \frac{\alpha_N + \alpha_{N+1}}{2} \leq \Re e(\lambda) \leq \|A\| + 2,\ |\Im m(\lambda)| \leq 1\},$$

where α_N is the N-largest eigenvalue of $A_{\mathcal{H}}$ and α_{N+1} the $N+1$-largest eigenvalue of $A_{\mathcal{H}}$. Clearly Γ encloses the first N largest eigenvalues of $A_{\mathcal{H}}$, but no other points of $\sigma(A)$. Define $\delta^{-1} = \sup_{\lambda\in\Gamma}\|(\lambda - A_{\mathcal{H}})^{-1}\|$ and $n_0 \in \mathbb{N}$ such that

$$\frac{C_1\sqrt{\tau}}{\sqrt{n_0}} \leq \frac{\delta^2}{\delta + \ell(\Gamma)/2\pi} \qquad \text{and} \qquad \frac{C_1\sqrt{\tau}}{\sqrt{n_0}} < 1,$$

where C_1 is the constant in Theorem 15. As in the above corollary, with probability greater than $1-2e^{-\tau}$, for all $n \geq n_0$

$$\|A_n - A_{\mathcal{H}}\| \leq \frac{\delta^2}{\delta + \ell(\Gamma)/2\pi} \qquad \text{and} \qquad \|A_n - A_{\mathcal{H}}\| < 1.$$

The last inequality ensures that the largest eigenvalues of A_n is smaller than $1 + \|A_{\mathcal{H}}\|$, so that by Theorem 20, the curve Γ encloses the first D-eigenvalues of A_n, where D is equal to the sum of the multiplicity of the first N eigenvalues of $A_{\mathcal{H}}$. The proof is finished letting $C = \frac{\delta + \ell(\Gamma)/2\pi}{\delta^2} C_1$. ■

Appendix A. Some Proofs

We start giving the proof of Proposition 13.

Proof [of Proposition 13]

We first need a preliminary fact. The function m is bounded from above and below by a positive constant by (7), so that the measure $\rho_W = m\rho$, having density m w.r.t. ρ, is equivalent[7] to ρ. This implies that the spaces $L^2(X,\rho)$ and $L^2(X,\rho_W)$ are the same vector space and the corresponding norm are equivalent. In this proof, we regard $\mathbb{L}$ as an operator from $L^2(X,\rho_W)$ into $L^2(X,\rho_W)$, observing that its eigenvalues and eigenfunctions are the same as the eigenvalues and eigenfunctions of $\mathbb{L}$, viewed as an operator from $L^2(X,\rho)$ into $L^2(X,\rho)$—however, functions that are orthogonal in $L^2(X,\rho_W)$ in general are not orthogonal in $L^2(X,\rho)$.

Note that the operator $I_K : \mathcal{H} \to L^2(X,\rho_W)$ defined by $I_K f(x) = \langle f, K_x \rangle$ is linear and Hilbert-Schmidt since

$$\begin{aligned}\|I_K\|_{HS}^2 &= \sum_{j\geq 1} \|I_K e_j\|_{\rho_W}^2 = \int_X \sum_{j\geq 1} \langle K_x, e_j \rangle^2 \, d\rho_W(x) \\ &= \int_X K(x,x) m(x) \, d\rho(x) \leq \kappa \|m\|_\infty,\end{aligned}$$

where $\kappa = \sup_{x\in X} K(x,x)$. The operator $I_W^* : L^2(X,\rho_W) \to \mathcal{H}$ defined by

$$I_W^* f = \int_X \frac{1}{m} W_x f(x) \, d\rho(x)$$

is linear and bounded since, by Assumption 1

$$\|\int_X \frac{1}{m} W_x f(x) \, d\rho(x)\|_{\mathcal{H}} \leq \int_X \|\frac{1}{m} W_x\|_{\mathcal{H}} |f(x)| \, d\rho(x) \leq C\|f\|_\rho \leq \frac{C}{c} \|f\|_{\rho_W}.$$

A direct computation shows that

$$I_W^* I_K = A_{\mathcal{H}} = I - \mathbb{L}_{\mathcal{H}}, \qquad \sigma(A_{\mathcal{H}}) = 1 - \sigma(\mathbb{L}_{\mathcal{H}})$$

and

$$I_K I_W^* = I - \mathbb{L}, \qquad \sigma(I_K I_W^*) = 1 - \sigma(\mathbb{L}).$$

7. Two measures are equivalent if they have the same null sets.

Both $I_W^* I_K$ and $I_K I_W^*$ are Hilbert-Schmidt operators since they are composition of a bounded operator and Hilbert-Schmidt operator. Moreover, let $\sigma \neq 1$ and $v \in \mathcal{H}$ with $v \neq 0$ such that $\mathbb{L}_{\mathcal{H}} v = \sigma v$. Letting $u = I_K v$, then

$$\mathbb{L}u = (I - I_K I_W^*) I_K v = I_K \mathbb{L}_{\mathcal{H}} v = \sigma u \quad \text{and} \quad I_W^* u = I_W^* I_K v = (1-\sigma) v \neq 0,$$

so that $u \neq 0$ and u is an eigenfunction of $\mathbb{L}$ with eigenvalue σ. Similarly we can prove that if $\sigma \neq 1$ and $u \in L^2(X, \rho), u \neq 0$ is such that $\mathbb{L}u = \sigma u$, then $v = \frac{1}{1-\sigma} I_W^* u$ is different from zero and is an eigenfunction of $\mathbb{L}_{\mathcal{H}}$ with eigenvalue σ.

We now show that $\mathbb{L}$ is a positive operator on $L^2(X, \rho_W)$, so that both $\mathbb{L}$ and $\mathbb{L}_{\mathcal{H}}$ have positive eigenvalues. Indeed, let $f \in L^2(X, \rho_W)$,

$$\begin{aligned}
\langle \mathbb{L} f, f \rangle_{\rho_W} &= \int_X |f(x)|^2 m(x) d\rho(x) - \int_X \left(\int_X \frac{W(x,s)}{m(x)} f(s) d\rho(s) \right) \overline{f(x)} m(x) d\rho(x) \\
&= \frac{1}{2} \int_X \int_X \left[|f(x)|^2 W(x,s) - 2W(x,s) f(x) \overline{f(s)} + |f(s)|^2 W(x,s) \right] d\rho(s) d\rho(x) \\
&= \frac{1}{2} \int_X \int_X W(x,s) |f(x) - f(s)|^2 d\rho(s) d\rho(x) \geq 0,
\end{aligned}$$

where we used that $W(x,s) = W(s,x) > 0$ and $m(x) = \int_X W(x,s)\, d\rho(s)$. Since W is real valued, it follows that we can always choose the eigenfunctions of $\mathbb{L}$ as real valued, and, as a consequence, the eigenfunctions of $\mathbb{L}_{\mathcal{H}}$.

Finally we prove that both $\mathbb{L}$ and $\mathbb{L}_{\mathcal{H}}$ admit a decomposition in terms of spectral projections— we stress that the spectral projection of $\mathbb{L}$ is orthogonal in $L^2(X, \rho_W)$, but not in $L^2(X, \rho)$.
Since $\mathbb{L}$ is a positive operator on $L^2(X, \rho_W)$, it is self-adjoint, as well as $I_K I_W^*$, hence the spectral theorem gives

$$I_K I_W^* = \sum_{j \geq 1} (1 - \sigma_j) P_j$$

where for all j, $P_j : L^2(X, \rho_W) \to L^2(X, \rho_W)$ is the spectral projection of $I_K I_W^*$ associated to the eigenvalue $1 - \sigma_j \neq 0$. Moreover note that P_j is also the spectral projection of $\mathbb{L}$ associated to the eigenvalue $\sigma_j \neq 1$. By definition P_j satisfies:

$$\begin{aligned}
P_j^2 &= P_j, \\
P_j^* &= P_j \qquad \text{the adjoint is in } L^2(X, \rho_W), \\
P_j P_i &= 0, \quad i \neq j, \\
P_j P_{ker(I_K I_W^*)} &= 0, \\
\sum_{j \geq 1} P_j &= I - P_{ker(I_K I_W^*)} = I - P_0
\end{aligned}$$

where $P_{ker(I_K I_W^*)}$ is the projection on the kernel of $I_K I_W^*$, that is, the projection P_0. Moreover the sum in the last equation converges in the strong operator topology. In particular we have

$$I_K I_W^* P_j = P_j I_K I_W^* = (1 - \sigma_j) P_j,$$

so that

$$\mathbb{L} = I - I_K I_W^* = \sum_{j \geq 1} \sigma_j P_j + P_0.$$

Let $Q_j : \mathcal{H} \to \mathcal{H}$ be defined by

$$Q_j = \frac{1}{1-\sigma_j} I_W^* P_j I_K.$$

Then from the properties of the projections P_j we have,

$$\begin{aligned} Q_j^2 &= \frac{1}{(1-\sigma_j)^2} I_W^* P_j I_K I_W^* P_j I_K = \frac{1}{1-\sigma_j} I_W^* P_j P_j I_K = Q_j, \\ Q_j Q_i &= \frac{1}{(1-\sigma_j)(1-\sigma_i)} I_W^* P_j I_K I_W^* P_i I_K = \frac{1}{1-\sigma_i} I_W^* P_j P_i I_K = 0, \quad i \neq j. \end{aligned}$$

Moreover,

$$\sum_{j\geq 1}(1-\sigma_j)Q_j = \sum_{j\geq 1}(1-\sigma_j)\frac{1}{1-\sigma_j} I_W^* P_j I_K = I_W^*(\sum_{j\geq 1} P_j) I_K = I_W^* I_K - I_W^* P_{ker(I_K I_W^*)} I_K$$

so that

$$I_K I_W^* = \sum_{j\geq 1}(1-\sigma_j)Q_j + I_W^* P_{ker(I_K I_W^*)} I_K,$$

where again all the sums are to be intended as converging in the strong operator topology. If we let $D = I_W^* P_{ker(I_K I_W^*)} I_K$ then

$$Q_j D = \frac{1}{1-\sigma_j} I_W^* P_j I_K I_W^* P_{ker(I_K I_W^*)} = I_W^* P_j P_{ker(I_K I_W^*)} = 0,$$

and, similarly $DQ_j = 0$. By construction $\sigma(D) = 0$, that is, D is a quasi-nilpotent operator. Equation (9) is now clear as well as the fact that $\ker D = \ker(I - \mathbb{L}_{\mathcal{H}})$. ■

Proof [Proof of Proposition 14] The proof is the same as the above proposition by replacing ρ with the empirical measure $\frac{1}{n}\sum_{i=1}^n \delta_{x_i}$. ■

Next we prove Theorem 20.

Proof [Proof of Theorem 20] We recall the following basic result. Let S and T two bounded operators acting on $\mathcal{H}$ and defined $C = I - ST$. If $\|C\| < 1$, then T has a bounded inverse and

$$T^{-1} - S = (I - C)^{-1} CS$$

where we note that $\|I - C\|^{-1} \leq \frac{1}{1-\|C\|}$ since $\|C\| < 1$, see Proposition 1.2 of Anselone (1971).

Let A and B two compact operators. Let Γ be a compact subset of the resolvent set of A and define

$$\delta^{-1} = \sup_{\lambda\in\Gamma} \|(\lambda - A)^{-1}\|,$$

which is finite since Γ is compact and the resolvent operator $(\lambda - A)^{-1}$ is norm continuous (see, for example, Anselone, 1971). Assume that

$$\|B - A\| < \delta,$$

then for any $\lambda \in \Gamma$

$$\|(\lambda - A)^{-1}(B-A)\| \leq \|(\lambda - A)^{-1}\|\|B-A\| \leq \delta^{-1}\|B-A\| < 1.$$

Hence we can apply the above result with $S = (\lambda - A)^{-1}, T = (\lambda - B)$, since

$$C = I - (\lambda - A)^{-1}(\lambda - B) = (\lambda - A)^{-1}(B-A).$$

It follows that $(\lambda - B)$ has a bounded inverse and

$$(\lambda - B)^{-1} - (\lambda - A)^{-1} = (I - (\lambda - A)^{-1}(B-A))^{-1}(\lambda - A)^{-1}(B-A)(\lambda - A)^{-1}.$$

In particular, Γ is a subset of the resolvent set of B and, if $B - A$ is a Hilbert-Schmidt operator, so is $(\lambda - B)^{-1} - (\lambda - A)^{-1}$.

Let Λ be a finite set of non-zero eigenvalues. Let Γ be any simple closed curve with Λ inside and $\sigma(A) \setminus \Lambda$ outside. Let P be the spectral projection associated with Λ, then

$$P = \frac{1}{2\pi i}\int_\Gamma (\lambda - A)^{-1}\, d\lambda.$$

Applying the above result, it follows that Γ is a subset of the resolvent set of B and we let $\widehat{\Lambda}$ be the subset of $\sigma(B)$ inside Γ and $\widehat{P}$ the corresponding spectral projection, then

$$\begin{aligned}\widehat{P} - P &= \frac{1}{2\pi i}\int_\Gamma (\lambda - B)^{-1} - (\lambda - A)^{-1}\, d\lambda \\ &= \frac{1}{2\pi i}\int_\Gamma (I - (\lambda - A)^{-1}(B-A))^{-1}(\lambda - A)^{-1}(B-A)(\lambda - A)^{-1}\, d\lambda.\end{aligned}$$

It follows that

$$\|\widehat{P} - P\| \leq \frac{\ell(\Gamma)}{2\pi}\frac{\delta^{-2}\|B-A\|}{1 - \delta^{-1}\|B-A\|} = \frac{\ell(\Gamma)}{2\pi\delta}\frac{\|B-A\|}{\delta - \|B-A\|}.$$

In particular if $\|B-A\| \leq \frac{\delta^2}{\delta + \ell(\Gamma)/2\pi} < \delta$, $\|\widehat{P} - P\| \leq 1$ so that the dimension of the range of P is equal to the dimension of the range of $\hat{P}$. It follows that $\widehat{\Lambda}$ is not empty.
If $B - A$ is a Hilbert-Schmidt operator, we can replace the operator norm with the Hilbert-Schmidt norm, and the corresponding inequality is a consequence of the fact that the Hilbert-Schmidt operator are an ideal. ■

Appendix B. Spectral Theorem for Non-self-adjoint Compact Operators

Let $A : \mathcal{H} \to \mathcal{H}$ be a compact operator. The spectrum $\sigma(A)$ of A is defined as the set of complex number such that the operator$(A - \lambda I)$ does not admit a bounded inverse, whereas the complement of $\sigma(A)$ is called the resolvent set and denoted by $\rho(A)$. For any $\lambda \in \rho(A)$, $R(\lambda) = (A - \lambda I)^{-1}$ is the resolvent operator, which is by definition a bounded operator. We recall the main results about the spectrum of a compact operator (Kato, 1966)

Proposition 23 *The spectrum of a compact operator A is a countable compact subset of* $\mathbb{C}$ *with no accumulation point different from zero, that is,*

$$\sigma(A) \setminus \{0\} = \{\lambda_i \mid i \geq 1,\ \lambda_i \neq \lambda_j \text{ if } i \neq j\}$$

with $\lim_{i\to\infty} \lambda_i = 0$ *if the cardinality of* $\sigma(A)$ *is infinite. For any* $i \geq 1$, λ_i *is an eigenvalue of A, that is, there exists a nonzero vector* $u \in \mathcal{H}$ *such that* $Au = \lambda_i u$. *Let* Γ_i *be a rectifiable closed simple curve (with positive direction) enclosing* λ_i, *but no other points of* $\sigma(A)$, *then the operator defined by*

$$P_{\lambda_i} = \frac{1}{2\pi i} \int_{\Gamma_i} (\lambda I - A)^{-1} d\lambda$$

satisfies

$$P_{\lambda_i} P_{\lambda_j} = \delta_{ij} P_{\lambda_i} \qquad \text{and} \qquad (A - \lambda_i) P_{\lambda_i} = D_{\lambda_i} \qquad \text{for all } i, j \geq 1,$$

where D_{λ_i} *is a nilpotent operator such that* $P_{\lambda_i} D_{\lambda_i} = D_{\lambda_i} P_{\lambda_i} = D_{\lambda_i}$. *In particular the dimension of the range of* P_{λ_i} *is always finite.*

We notice that P_{λ_i} is a projection onto a finite dimensional space $\mathcal{H}_{\lambda_i}$, which is left invariant by A. A nonzero vector u belongs to $\mathcal{H}_{\lambda_i}$ if and only if there exists an integer $m \leq \dim \mathcal{H}_{\lambda_i}$ such that $(A - \lambda)^m u = 0$, that is, u is a generalized eigenvector of A. However, if A is symmetric, for all $i \geq 1$, $\lambda_i \in \mathbb{R}$, P_{λ_i} is an orthogonal projection and $D_{\lambda_i} = 0$ and it holds that

$$A = \sum_{i \geq 1} \lambda_i P_{\lambda_i}$$

where the series converges in operator norm. Moreover, if $\mathcal{H}$ is infinite dimensional, $\lambda = 0$ is always in $\sigma(A)$, but it can be or not an eigenvalue of A.

If A be a compact operator with $\sigma(A) \subset [0, \|A\|]$, we introduce the following notation. Denoted by p_A the cardinality of $\sigma(A) \setminus \{0\}$ and given an integer $1 \leq N \leq p_A$, let $\lambda_1 > \lambda_2 > \ldots, \lambda_N > 0$ be the first N nonzero eigenvalues of A, sorted in a decreasing way. We denote by P_N^A the spectral projection onto all the generalized eigenvectors corresponding to the eigenvalues $\lambda_1, \ldots, \lambda_N$. The range of P_N^A is a finite-dimensional vector space, whose dimension is the sum of the algebraic multiplicity of the first N eigenvalues. Moreover

$$P_N^A = \sum_{j=1}^{N} P_{\lambda_j} = \frac{1}{2\pi i} \int_{\Gamma} (\lambda I - A)^{-1} d\lambda$$

where Γ is a rectifiable closed simple curve (with positive direction) enclosing $\lambda_1, \ldots, \lambda_N$, but no other points of $\sigma(A)$.

Abstract

In this paper, we study the problem of learning a matrix W from a set of linear measurements. Our formulation consists in solving an optimization problem which involves regularization with a spectral penalty term. That is, the penalty term is a function of the spectrum of the covariance of W. Instances of this problem in machine learning include multi-task learning, collaborative filtering and multi-view learning, among others. Our goal is to elucidate the form of the optimal solution of spectral learning. The theory of spectral learning relies on the von Neumann characterization of orthogonally invariant norms and their association with symmetric gauge functions. Using this tool we formulate a representer theorem for spectral regularization and specify it to several useful example, such as Schatten $p-$norms, trace norm and spectral norm, which should proved useful in applications.

Keywords: kernel methods, matrix learning, minimal norm interpolation, multi-task learning, orthogonally invariant norms, regularization

1. Introduction

In this paper, we study the problem of learning a matrix from a set of linear measurements. Our formulation consists in solving for the matrix

$$\hat{W} = \operatorname{argmin}\{E(I(W), y) + \gamma\Omega(W) : W \in M_{d,n}\}, \tag{1}$$

where $M_{d,n}$ is the set of $d \times n$ real matrices, y an $m-$dimensional real vector of observations and $I : M_{d,n} \to \mathbb{R}^m$ a linear operator, whose components are given by the Frobenius inner product between the matrix W and prescribed data matrices. The objective function in (1) combines a data term, $E(I(W), y)$, which measures the fit of W to available training data and a penalty term or regularizer, $\Omega(W)$. The positive constant γ controls the trade-off between the two terms and may be chosen

by prior information on the noise underlying the data. A typical example for the data term is $E(I(W),y) = \|I(W) - y\|_2^2$, where the subscript indicates the Euclidean norm.

In the design of learning algorithms from the point of view of regularization the choice of the penalty term is essential. To obtain insights into this issue, we shall investigate in this paper the form of matrices which solve the variational problem (1) when the penalty term is an *orthogonally invariant norm* (OI-norm). This means, for any pair of orthogonal matrices U and V, that

$$\Omega(UWV) = \Omega(W).$$

There are many important examples of OI-norms. Among them, the family of Schatten $p-$norms, $1 \leq p \leq \infty$, namely the ℓ_p-norm of the singular values of a matrix, are especially useful.

Our main motivation for studying the optimization problem (1) arises from its application to multi-task learning, see Argyriou et al. (2007a) and references therein. In this context, the matrix columns are interpreted as the parameters of different regression or classification tasks and the regularizer Ω is chosen in order to favor certain kinds of dependencies across the tasks. The operator I consists of inner products formed from the inputs of each task and the error term $E(I(W),y)$ is the sum of losses on the individual tasks. Collaborative filtering (Srebro et al., 2005) provides another interesting instance of problem (1), in which the operator I is formed from a subset of the matrix elements. Further examples in which OI-norm have been used include multi-class classification (Amit et al., 2007), multi-view learning (Cavallanti et al., 2008) and similarity learning (Maurer, 2008a).

A recent trend in regularization methods in machine learning is to use matrix regularizers which are orthogonally invariant (Argyriou et al., 2007a,b; Abernethy et al., 2009; Srebro et al., 2005). In particular, an important case is the Schatten one norm of W, which is often referred to as the *trace norm*. The general idea behind this methodology is that a small trace norm favors low-rank solution matrices to (1). This means that the tasks (the columns of W) are related in that they all lie in a low-dimensional subspace of $\mathbb{R}^d$. Indeed, if we choose the regularizer to be the rank of a matrix, we obtained a non-convex NP-hard problem. However, the trace norm provides a convex relaxation of this problem, which has been justified in various ways (see, for example, Fazel et al., 2001; Candès and Recht, 2008).

The main purpose of this paper is to characterize the form of the solutions to problem (1). Specifically, we provide what in machine learning is known as a *representer theorem*. Namely we show, for a wide variety of OI-norm regularizers, that it is possible to compute the inner product $\langle \hat{W}, X \rangle$ only in terms of the $m \times m$ Gram matrix I^*I and $I(X)$. A representer theorem is appealing from a practical point of view, because it ensures that the cost of solving the optimization problem (1) depends on the size m of the training sample, which can be much smaller than the number of elements of the matrix W. For example, in multi-task learning, the number of rows in the matrix W may be much larger than the number of data per task. More fundamentally, the task vectors (the columns of matrix W) may be elements of a reproducing kernel Hilbert Space.

Our point of view in developing these theorems is through the study of the *minimal norm interpolation* problem

$$\min\{\|W\| : I(W) = \hat{y},\ W \in M_{d,n}\}.$$

The reason for this is that the solution $\hat{W}$ of problem (1) also solves the above problem for an appropriately chosen $\hat{y} \in \mathbb{R}^m$. Specifically, this is the case if we choose $\hat{y} = I(\hat{W})$. In the development of these results, tools from convex analysis are needed. In particular, a key tool that we use in this

paper is a classical result of von Neumann (1962), which characterizes OI-norms in terms of the notion of *symmetric gauge function*; see also Lewis (1995) for a discussion of the von Neumann theorem in the context of convex analysis. We record some of these facts which we need in Section 4.

The paper is organized in the following manner. In Section 2 we introduce our notation and describe the connection between minimal norm interpolation and regularization. In Section 3 we describe the relationship between any solution of (1) and any solution of a dual problem, which involves a number of variables equal to the training set size. In Section 4 we specify this result to the class of OI-norms. In particular, we describe a special case of such norms, which contains the Schatten $p-$norms, and derive a linear representer theorem for this case. As we shall see, this computation in general involves a nonlinear function and a singular value decomposition of an appropriate matrix.

2. Background

Before proceeding, we introduce some of the notation used in the paper and review some basic facts.

2.1 Notation

We use $\mathbb{N}_d$ as a shorthand for the set of integers $\{1,\ldots,d\}$, $\mathbb{R}^d$ for the linear space of vectors with d real components and $M_{d,n}$ for the linear space of $d\times n$ real matrices. For any vector $a\in\mathbb{R}^d$ we use a_i to denote its i-th component and for any matrix $W\in M_{d,n}$ we use w_t to denote the t-th column of W, for $t\in\mathbb{N}_n$. For a vector $\lambda\in\mathbb{R}^d$, we let $\mathrm{Diag}(\lambda)$ or $\mathrm{Diag}(\lambda_i)_{i\in\mathbb{N}_d}$ to denote the $d\times d$ diagonal matrix having the elements of λ on the diagonal. We denote the trace of matrix W by $\mathrm{tr}(W)$. We use $\mathbf{S}^d$ to denote the set of $d\times d$ real symmetric matrices and $\mathbf{S}^d_+$ and $\mathbf{S}^d_{++}$ to denote the subsets of positive semidefinite and positive definite ones, respectively. We use $\succ$ and $\succeq$ for the positive definite and positive semidefinite partial orderings on $\mathbf{S}^d$, respectively. We also let O_d be the set of $d\times d$ orthogonal matrices and $\mathcal{P}_d$ the set of $d\times d$ permutation matrices. Finally, in this paper, the notation $\langle\cdot,\cdot\rangle$ denotes the standard inner products on $\mathbb{R}^d$ and $M_{d,n}$, that is, $\langle a,b\rangle=\sum_{i\in\mathbb{N}_d}a_ib_i$ for any vectors $a,b\in\mathbb{R}^d$ and $\langle W,V\rangle=\mathrm{tr}(W^\top V)$ for any matrices $W,V\in M_{d,n}$.

2.2 Regularization and Interpolation with Matrices

Let us first describe the type of optimization problems of interest in this paper. Our motivation comes from recent work in machine learning which deals with the problem of multi-task learning. Beyond these practical concerns, the matrix optimization problems we consider here have the property that the *matrix structure* is important.

We shall consider *regularization* problems of the type

$$\min\left\{E(I(W),y)+\gamma\,\Omega(W):W\in M_{d,n}\right\}, \tag{2}$$

where $E:\mathbb{R}^m\times\mathbb{R}^m\to\mathbb{R}$ is called a *loss function*, $\Omega:M_{d,n}\to\mathbb{R}$ a *regularizer*, $\gamma>0$ the *regularization parameter*, $I:M_{d,n}\to\mathbb{R}^m$ is a *linear operator* and $y\in\mathbb{R}^m$. Associated to the above regularization problem is the *interpolation problem*

$$\min\left\{\Omega(W):W\in M_{d,n},\ I(W)=y\right\}. \tag{3}$$

Unless otherwise stated, we always assume that the minima in problems (2) and (3) are attained.

Regularization enables one to trade off interpolation of the data against smoothness or simplicity of the model, whereas interpolation frequently suffers from *overfitting*. Note that the family of the former problems encompasses the latter ones. Indeed, an interpolation problem can be simply obtained in the limit as the regularization parameter γ goes to zero (see, for example, Micchelli and Pinkus, 1994).

For example, a special case of matrix regularization problems of the type (2) is obtained with the choice

$$I(W) = (\langle w_t, x_{ti} \rangle : t \in \mathbb{N}_n, i \in \mathbb{N}_{m_t}) \,,$$

where the x_{ti} are given input vectors in $\mathbb{R}^d$. This occurs, for example, in multi-task learning and problems closely related to it (Abernethy et al., 2009; Argyriou et al., 2007a,b; Candès and Recht, 2008; Cavallanti et al., 2008; Izenman, 1975; Maurer, 2006a,a; Srebro et al., 2005; Yuan et al., 2007, etc.). In learning multiple tasks jointly, each task may be represented by a vector of regression parameters which corresponds to the column w_t in our notation. There are n tasks and m_t data examples $\{(x_{ti}, y_{ti}) : i \in \mathbb{N}_{m_t}\}$ for the t-th task.

In multi-task learning, the error term E in (2) expresses the objective that the regression vector for each task should fit well the data for this particular task. The choice of the regularizer Ω is important in that it captures certain relationships between the tasks. For example, one such regularizer, considered in Evgeniou et al. (2005), is a specific quadratic form in W, namely

$$\Omega(W) = \sum_{s,t \in \mathbb{N}_n} \langle w_s, E_{st} w_t \rangle,$$

where the matrices $E_{st} \in \mathbf{S}^d$ are chosen to model cross-tasks interactions.

Another common choice for the regularizer is the *trace norm*, which is defined to be the sum of the singular values of a matrix,

$$\Omega(W) = \sum_{j \in \mathbb{N}_r} \sigma_j(W),$$

where $r = \min(d, m)$. Equivalently this regularizer can be expressed as $\Omega(W) = \mathrm{tr}(W^\top W)^{\frac{1}{2}}$. Regularization with the trace norm learns the tasks as one joint optimization problem, by favoring matrices with low rank (Argyriou et al., 2007a). In other words, the vectors w_t are related in that they are *all* linear combinations of a *small* set of basis vectors. It has been demonstrated that this approach allows for accurate estimation of related tasks even when there are only a *few* data points available for each task.

In general, the linear operator I can be written in the form

$$I(W) = (\langle W, X_i \rangle : i \in \mathbb{N}_m) \,, \tag{4}$$

where the inputs matrices X_i are in $M_{d,n}$. Recall that the *adjoint* operator, $I^* : \mathbb{R}^m \to M_{d,n}$, is defined by the property that

$$\langle I^*(c), W \rangle = \langle c, I(W) \rangle \,,$$

for all $c \in \mathbb{R}^m, W \in M_{d,n}$. Therefore, it follows that I^* is given at $c \in \mathbb{R}^m$, by

$$I^*(c) = \sum_{i \in \mathbb{N}_m} c_i X_i.$$

We denote by $\mathcal{R}(I)$ and $\mathcal{N}(I)$ the range and the null space of the operator I, respectively.

In this paper, we are interested in studying the form of the solution to matrix problems (2) or (3). For certain families of regularizers, the solutions can be expressed in terms of the given inputs X_i in (4). Such facts are known in machine learning as *representer theorems*, see Argyriou et al. (2009) and reference therein.

The line of attack we shall follow in this paper will go through *interpolation*. That is, our main concern will be to obtain representer theorems which hold for problems like (3). This in turn will imply representer theorems for the associated regularization problems. This is justified by the next lemma.

Lemma 1 *Let $E : \mathbb{R}^m \times \mathbb{R}^m \to \mathbb{R}$, a linear operator $I : M_{d,n} \to \mathbb{R}^m$, $\Omega : M_{d,n} \to \mathbb{R}$, $\gamma > 0$ such that the problems* (2) *and* (3) *admit a minimizer for every $y \in \mathbb{R}^m$. Then for every $y \in \mathbb{R}^m$ there exists $\hat{y} \in \mathbb{R}^m$ such that any solution of the interpolation problem* (3) *with $y = \hat{y}$ is a solution of the regularization problem* (2).

Proof If $\hat{W}$ solves (2), we may define $\hat{y} := I(\hat{W})$. It then readily follows that any solution of (3) with $\hat{y}$ in place of y is a solution of (2). ■

For some other results relating optimality conditions for regularization and interpolation problems, see Argyriou et al. (2009). We shall return to this issue in Section 4, where we study representer theorems of a particular type for regularizers which are OI-norms.

3. Duality and Minimal Norm Interpolation

In this section, we turn our attention to the study of the interpolation problem (3) when the function Ω is a *norm* on $M_{d,n}$. That is we prescribe a linear operator $I : M_{d,n} \to \mathbb{R}^m$, a vector $y \in \mathcal{R}(I) \setminus \{0\}$ and study the minimal norm interpolation problem

$$\phi := \min\{\|W\| : I(W) = y, W \in M_{d,n}\}. \tag{5}$$

The approach we take to analyze problem (5) makes use of a dual problem. To identify it, we recall the definition of the dual norm, given by

$$\|X\|_D = \max\{\langle X, W\rangle : W \in M_{d,n}, \|W\| \leq 1\}.$$

Consequently, it follows, for every $X, W \in M_{d,n}$, that

$$|\langle X, W\rangle| \leq \|X\|_D \|W\|. \tag{6}$$

Associated with this inequality is the notion of the *peak set* of the norm $\|\cdot\|$ at X, namely

$$\mathscr{D}\|X\| = \{W : \langle X, W\rangle = \|X\|_D, : W \in M_{d,n}, \|W\| = 1\}.$$

Note that, for each $X \in M_{d,n}\backslash\{0\}$ the peak set $\mathscr{D}\|X\|$ is a nonempty compact convex set which contains all $W \in M_{d,n}\backslash\{0\}$ that make the bound in (6) tight.

As we shall see in the theorem below, the dual norm leads to the following *dual problem*

$$\theta := \min\left\{\|I^*(c)\|_D : c \in \mathcal{R}(I),\ \langle c, y\rangle = 1\right\}. \tag{7}$$

Let us first observe that both the primal and dual problem have solutions. In the primal problem we minimize a norm which is a function which grows at infinity and, so, the existence of a solution is

assured. Similarly, the quantity $\|I^*(c)\|_D$ which is minimized in the dual problem is also norm on $c \in \mathcal{R}(I)$.

The main result of this section establishes the relationship between the solutions of the primal problem (5) and those of the dual problem (7).

Theorem 2 *A vector $\hat{c} \in \mathbb{R}^m$ solves the dual problem* (7) *if and only if there exists $\hat{W} \in \theta^{-1}\mathscr{D}\|I^*(\hat{c})\|$ such that $I(\hat{W}) = y$. Moreover, in this case $\hat{W}$ solves the primal problem* (5) *and $\phi\theta = 1$. Conversely, for every $\hat{W}$ solving the primal problem* (5) *and* any *solution $\hat{c}$ of the dual problem* (7)*, it holds that $\hat{W} \in \theta^{-1}\mathscr{D}\|I^*(\hat{c})\|$.*

Before we proceed with a proof, let us explain the rationale behind this result. The number of free parameters in the dual problem is at most $m-1$, while the primal problem involves $dn-m$ parameters. Typically, in applications, dn is much larger than m. Recalling the connection to multi-task learning in Section 2, this means that d is much larger than the number of data per task, $\frac{m}{n}$. Therefore, from the perspective of this parameter count, solving the dual problem may be advantageous. More importantly, any solution of the dual problem will provide us with a solution of the primal problem and conditions on the latter are obtained from a study of the peak set $\mathscr{D}\|I^*(\hat{c})\|$. For example, as we shall see in Section 4, in the case of OI-norms, this fact will be facilitated by fundamental matrix inequalities.

Proof of Theorem 2 First let us establish that

$$\frac{1}{\theta} \leq \phi. \tag{8}$$

To this end, consider any $c \in \mathbb{R}^m$ with $\langle c, y\rangle = 1$ and $W \in M_{d,n}$ with $I(W) = y$. Then

$$1 = \langle c, y\rangle = \langle c, I(W)\rangle = \langle I^*(c), W\rangle \leq \|I^*(c)\|_D \|W\|. \tag{9}$$

From this inequality we get the desired claim. To prove the reverse inequality in (8), we let $\hat{c} \in \mathcal{R}(I)$ be a solution of the dual problem (7) and conclude, for any $b \in \mathcal{R}(I)$ such that $\langle b, y\rangle = 0$, that

$$\lim_{\varepsilon \to 0^+} \frac{\|I^*(\hat{c} + \varepsilon b)\|_D - \|I^*(\hat{c})\|_D}{\varepsilon} \geq 0.$$

Since the dual norm is a maximum of linear functions over a compact set, we may apply Theorem 22 in the case that $\mathcal{X} = \{X : X \in M_{d,n}, \|X\| \leq 1\}$, $\mathcal{W} = M_{d,n}$, $f(W,X) = \langle W, X\rangle$, and evaluate Equation (16) for $W = I^*(\hat{c})$ and $\Delta = I^*(b)$ to obtain the inequality

$$\max\{\langle I^*(b), T\rangle \ : \ T \in \mathscr{D}\|I^*(\hat{c})\|\} \geq 0\,.$$

Using the fact that $b \in \mathcal{R}(I)$ and $\langle b, y\rangle = 0$, we can rephrase this inequality in the following fashion. For every $Z \in M_{d,n}$ such that $\langle Z, I^*(y)\rangle = 0$ we have that

$$\max\{\langle Z, I^*I(T)\rangle \ : \ T \in \mathscr{D}\|I^*(\hat{c})\|\} \geq 0.$$

To resolve this set of inequalities we use Lemma 21 in the appendix with $k = 1$, $J : M_{d,n} \to \mathbb{R}$ defined at $W \in M_{d,n}$ as $J(W) = \langle I^*(y), W\rangle$ and $\mathcal{W} := I^*I(\mathscr{D}\|I^*(\hat{c})\|)$. Since $J^* : \mathbb{R} \to M_{d,n}$ is given for $a \in \mathbb{R}$ as $J^*(a) = aI^*(y)$, we conclude that there exist $\lambda \in \mathbb{R}$ and $\tilde{W} \in \mathscr{D}\|I^*(\hat{c})\|$ such that

$$\lambda I^*(y) = I^*I(\tilde{W}).$$

This equation implies that $\lambda y - I(\tilde{W}) \in \mathcal{N}(I^*)$. However, recalling the fact that $y \in \mathcal{R}(I)$, we also have that $\lambda y - I(\tilde{W}) \in \mathcal{R}(I)$. Therefore, we have established that

$$\lambda y = I(\tilde{W}).$$

To identify the value of λ we use the fact that $\langle y, \hat{c} \rangle = 1$ and obtain that

$$\lambda = \langle \hat{c}, I(\tilde{W}) \rangle = \langle I^*(\hat{c}), \tilde{W} \rangle = \|I^*(\hat{c})\|_D = \theta.$$

Now, we define $\hat{W} = \frac{1}{\theta}\tilde{W}$ and note that $I(\hat{W}) = y$ and since $\|\tilde{W}\| = 1$ we obtain that

$$\phi \leq \|\hat{W}\| = \frac{1}{\theta}.$$

This inequality, combined with inequality (8) demonstrates that $\phi\theta = 1$ and that $\hat{W}$ is a solution to the primal problem (5).

To complete the proof, consider any $\hat{W}$ solving (5) and $\hat{c}$ solving (7) and it easily follows from inequality (9) and $\phi\theta = 1$ that $\hat{W} \in \theta^{-1}\mathscr{D}\|I^*(\hat{c})\|$. ■

Theorem 2 describes the relation between the set of solutions of the primal problem (5) and the dual problem (7). It also relates the set of solutions of the primal problem to the range of the adjoint operator I^*. This latter property, combined with Lemma 1, may be viewed as a general *representer theorem*, that is, the theorem implies that the solutions of the regularization problem (2) are matrices in the set $\mathscr{D}\|I^*(\tilde{c})\|$, for some $\tilde{c} \in \mathbb{R}^m$. However, additional effort is required to obtain a concrete representation of such solution. For example, for the Frobenius norm, $\mathscr{D}\|X\| = \{X/\|X\|\}$ and, so, the optimality condition becomes $\hat{W} = I^*(\tilde{c})$. We refer to this condition throughout the paper as the *standard representer theorem*, see Argyriou et al. (2009) and references therein. In other words, the standard representer theorem for $\hat{W}$ means that $\hat{W} \in \mathcal{R}(I^*)$.

We make no claim of originality for Theorem 2 as its proof uses well established tools of convex analysis. On the contrary, we emphasize the utility of this result for machine learning. Alternatively, we can approach the minimal norm interpolation problem by use of the Lagrangian, defined, for $W \in M_{d,n}$ and $\lambda \in \mathbb{R}^m$, as

$$\mathcal{L}(W, \lambda) = \|W\| + \langle W, I^*(\lambda) \rangle - \langle y, \lambda \rangle.$$

4. Representer Theorems for Orthogonally Invariant Norms

In this section, we focus our attention on matrix norms which are invariant under left and right multiplication by orthogonal matrices. As we shall see, for such norms, the representer theorem can be written in terms of the singular value decomposition. In addition, in Section 4.3, we shall describe a subclass of OI-norms for which representer theorems can be phrased in terms of matrix multiples of the adjoint operator value $I^*(\hat{c})$. This type of representer theorem arises in *multi-task learning* as described in Argyriou et al. (2009). That is, each of the columns of the optimal matrix lies in the span of the corresponding columns of the input matrices X_i.

4.1 Notation

Let $W \in M_{d,n}$ be a matrix and set $r = \min\{d,n\}$. We express the singular value decomposition of the matrix W in the form

$$W = U\Sigma V^\top,$$

where $U \in O_d, V \in O_n$ and $\Sigma \in M_{d,n}$ is a diagonal matrix with nonnegative elements, that is $\Sigma = \mathrm{diag}(\sigma(W))$, where $\sigma(W) = (\sigma_i(W) : i \in \mathbb{N}_r) \in \mathbb{R}^r_+$. We assume that the singular values are *ordered* in a non-increasing sense, that is,

$$\sigma_1(W) \geq \cdots \geq \sigma_r(W) \geq 0\,.$$

Note that $\sigma(W)$ is uniquely defined in this way. Sometimes we also use $\Sigma(W)$ to denote the diagonal matrix Σ. The components of $\sigma(W)$ are the *singular values* of W. They are equal to the square root of the largest r eigenvalues of $W^\top W$, which are the same as those of $WW^\top$. We shall call functions of the singular values of a matrix *spectral functions*.

In the case of a symmetric matrix $A \in \mathbf{S}^n$, we similarly write

$$A = U\Lambda U^\top$$

for a spectral decomposition of A, where $U \in O_n$, $\Lambda = \mathrm{Diag}(\lambda(A))$ and $\lambda(A) = (\lambda_j : j \in \mathbb{N}_n)$ has components ordered in non-decreasing sense

$$\lambda_1(A) \geq \cdots \geq \lambda_n(A)\,.$$

In addition, for $x \in \mathbb{R}^r$, we shall use $|x|$ to denote the vector of absolute values $(|x_i| : i \in \mathbb{N}_r)$. Finally, for two vectors $x, y \in \mathbb{R}^r$ we write $x \leq y$ whenever, for all $i \in \mathbb{N}_r$, $x_i \leq y_i$.

4.2 Orthogonally Invariant Norms

A norm $\|\cdot\|$ on $M_{d,n}$ is called *orthogonally invariant* whenever, for every $U \in O_d$, $V \in O_n$ and $W \in M_{d,n}$, we have that

$$\|UWV^\top\| = \|W\|\,.$$

It is clear from the definition that an OI-norm that $\|\cdot\|$ is a spectral function. That is, for some function f, we have that $\|W\| = f(\sigma(W))$.

The remaining conditions on f which characterize OI-norms were given by von Neumann (1962) (see also Horn and Johnson, 1991, Section 3.5). He established that OI-norms are exactly *symmetric gauge functions* (SG-functions) of the singular values. To this end, we let $\mathcal{P}_r$ be the subset of $r \times r$ permutation matrices.

Definition 3 *A function $f : \mathbb{R}^r \to \mathbb{R}_+$ is called an SG-function whenever the following properties hold:*

1. *f is a norm on $\mathbb{R}^r$;*
2. *$f(x) = f(|x|)$ for all $x \in \mathbb{R}^r$;*
3. *$f(Px) = f(x)$ for all $x \in \mathbb{R}^r$ and all permutation matrices $P \in \mathcal{P}_r$.*

Property 2 states that f is *absolutely* or *gauge invariant*. Property 3 states that f is *symmetric* or *permutation invariant*. Hence, an SG-function is an absolutely symmetric norm.

Von Neumann's result is stated in the following theorem.

Theorem 4 *If $\|\cdot\|$ is an OI-norm on $M_{d,n}$ then there exists an SG-function $f:\mathbb{R}^r\to\mathbb{R}_+$ such that $\|W\|=f(\sigma(W))$, for all $W\in M_{d,n}$. Conversely, if $f:\mathbb{R}^r\to\mathbb{R}$ is an SG-function then the norm defined at $W\in M_{d,n}$, as $\|W\|=f(\sigma(W))$ is orthogonally invariant.*

The best known example of OI-norms are the *Schatten p-norms*, where $p\geq 1$, They are defined, for every $W\in M_{d,n}$, as

$$\|W\|_p=\left(\sum_{i\in\mathbb{N}_r}(\sigma_i(W))^p\right)^{\frac{1}{p}}$$

and, for $p=\infty$, as

$$\|W\|_\infty=\sigma_1(W).$$

The Schatten $1-$norm is sometimes called the *trace norm* or *nuclear norm*. Other common values of p give rise to the *Frobenius norm* ($p=2$) and the *spectral norm* ($p=\infty$). The Frobenius norm can also be written as $\sqrt{\mathrm{tr}W^\top W}$ and the spectral norm is alternatively expressed as $\max\{\|Wx\|_2:\|x\|_2=1\}$, where the subscript on the vector norm indicates the Euclidean norm of that vector. Another well-known family of OI-norms are the *Ky Fan norms* defined, for every $W\in M_{d,n}$ as

$$\|W\|_{(k)}=\sum_{i\in\mathbb{N}_k}\sigma_i(W)$$

where $1\leq k\leq r$ (the cases $k=1$ and $k=r$ are the spectral and trace norms, respectively). For more examples and for many interesting results involving OI-norms, we refer the reader to (Bhatia, 1997, Sec. IV.2) and (Horn and Johnson, 1991, Sec. 3.5).

We also mention, in passing, a formula from Argyriou et al. (2007b) which is useful for algorithmic developments. Specifically, we recall, for $p\in(0,2]$, that

$$\|W\|_p=\inf\left\{\langle WW^\top,D^{-\frac{2-p}{p}}\rangle:D\in\mathbf{S}^d_{++},\mathrm{tr}D\leq 1\right\}. \tag{10}$$

When $p\in[1,2]$, the function

$$(W,D)\mapsto\langle WW^\top,D^{-\frac{2-p}{p}}\rangle$$

is jointly convex in W and D and, so, the infimum in (10) is convex in W, in agreement with the convexity of the norm of $\|W\|_p$. Furthermore, if $WW^\top$ is invertible and $p\in(0,2]$, then the infimum is uniquely attained by the matrix

$$D=\frac{(WW^\top)^{\frac{p}{2}}}{\mathrm{tr}(WW^\top)^{\frac{p}{2}}}.$$

In machine learning practice, regularization with the trace norm has been proposed for collaborative filtering and multi-task learning (Abernethy et al., 2009; Argyriou et al., 2007a,b; Maurer, 2006a; Srebro et al., 2005, and references therein) and related problems (Yuan et al., 2007). If $\Omega(W)=\mathrm{rank}(W)$ the regularization problem (1) is non-convex. However, a common technique that overcomes this issue is to replace the rank by the trace norm (Fazel et al., 2001). The trace norm is the ℓ_1 norm on the singular values and hence there is an analogy to regularization of a vector

variable with the ℓ_1 norm, which is often used to obtain sparse solutions, see Candès and Recht (2008) and reference therein. In analogy to ℓ_1 regularization, it has recently been shown that for certain configurations of the input data the low rank solution can be recovered using the trace norm approach (Candès and Recht, 2008; Recht et al., 2008). More generally, regardless of the rank of the solution, it has been demonstrated that this approach allows for accurate joint estimation of multiple related tasks even when there are only *few* data points available for each task (Srebro et al., 2005; Argyriou et al., 2007a). One motivation is to approximate a matrix with a (possibly low-rank) factorization (Srebro et al., 2005). Another is that fitting multiple learning tasks simultaneously, so that they share a small set of orthogonal features, leads to a trace norm problem (Argyriou et al., 2007a).

The spectral norm, $\|\cdot\|_\infty$, is also of interest in the context of filter design (Zames, 1981) in control theory. Moreover, Schatten p-norms in the range $p \in [1,2]$ can be used for trading off sparsity of the model against task independence in multi-task learning (Argyriou et al., 2007b). In general, OI-norms are a natural class of regularizers to consider, since many matrix optimization problems can be posed in terms of the spectrum of the matrix.

We now proceed by reviewing some facts on duals of OI-norms. To this end, we first state a useful inequality, which can be found, for example, in (Horn and Johnson, 1991, ex. 3.3.10). This inequality also originates from von Neumann (1962) and is sometimes called *von Neumann's trace theorem* or *Ky Fan inequality*.

Lemma 5 *For any $X, Y \in M_{d,n}$, we have that*

$$\langle X, Y \rangle \leq \langle \sigma(X), \sigma(Y) \rangle \tag{11}$$

and equality holds if and only if there are $U \in O_d$ and $V \in O_n$ such that $X = U\Sigma(X)V^\top$ and $Y = U\Sigma(Y)V^\top$.

We emphasize that equality in (11) implies that the matrices X and Y admit the same ordered system of singular vectors, where the ordering is given by *ordering of the singular values*. It is also important to note that this inequality is stronger than the Cauchy-Schwarz inequality for the Frobenius norm, $\langle X, Y \rangle \leq \|X\|_2 \|Y\|_2$. Moreover, in the case of diagonal matrices one obtains a vector inequality due to Hardy et al. (1988)

$$\langle x, y \rangle \leq \langle [x], [y] \rangle ,$$

where $x, y \in \mathbb{R}^d$ and $[x]$ denotes the vector consisting of the components of x in non-increasing order. Let us also mention that apart from norm duality, Lemma 5 underlies many analytical properties of spectral functions, such as convexity, Fenchel conjugacy, subgradients and differentiability (see, for example, Lewis, 1995 for a review).

For our purposes, inequality (11) can be used to compute the dual of an OI-norm in terms of the dual of the corresponding SG-function. This is expressed in the following lemmas, which follow easily from (11) (see also Bhatia, 1997, Secs. IV.1, IV.2).

Lemma 6 *If the norm $\|\cdot\|$ on $M_{d,n}$ is orthogonally invariant and f is the corresponding SG-function, then the dual norm is given, for $W \in M_{d,n}$, by*

$$\|W\|_D = f_D(\sigma(W))$$

where $f_D : \mathbb{R}^r \to \mathbb{R}_+$ is the dual norm of f.

Lemma 7 *$\|\cdot\|$ is an OI-norm on $M_{d,n}$ if and only if $\|\cdot\|_D$ is orthogonally invariant. Also, $f:\mathbb{R}^r\to\mathbb{R}$ is an SG-function if and only if f_D is an SG-function.*

The next useful formula describes the peak set for any OI-norm.

Lemma 8 *Let $W\in M_{d,n}\setminus\{0\}$ and $W=U\Sigma(W)V^\top$ its singular value decomposition. If the norm $\|\cdot\|$ is orthogonally invariant and f is the corresponding SG-function, then*

$$\mathscr{D}\|W\| = \{Z : Z = U\Sigma(Z)V^\top, \sigma(Z)\in\mathscr{D}f(\sigma(W))\}.$$

Lemma 9 *Let $W\in M_{d,n}\setminus\{0\}$ and $W=U\Sigma(X)V^\top$ its singular value decomposition. If the norm $\|\cdot\|$ is orthogonally invariant and the corresponding SG-function f is* differentiable *at $\sigma(W)$, then $\|\cdot\|$ is differentiable at W and*

$$\nabla\|W\| = U\,\nabla f(\sigma(W))\,V^\top.$$

Lemma 10 *If f is an SG-function, $x\in\mathbb{R}^r\setminus\{0\}$ and $w\in\mathscr{D}f(x)$, then $\overline{w}\in\mathscr{D}f(\bar{x})$, where $\overline{w},\bar{x}\in\mathbb{R}^r$ are the vectors with elements the absolute values of w,x, respectively, in decreasing order. Moreover, $|w|,|x|$ can yield $\overline{w},\bar{x}$ with a simultaneous permutation of their elements.*

In other words, duality of OI-norms translates to duality of SG-functions. Norm duality preserves orthogonal invariance as well as the symmetric gauge properties. And dual pairs of matrices with respect to OI-norms directly relate to dual pairs of vectors with respect to SG-functions. Similarly, (sub)gradients of OI-norms correspond to (sub)gradients of SG-functions. In fact, Lemmas 8 and 9 hold, more generally, for all symmetric functions of the singular values (Lewis, 1995).

As an example, the dual of a Schatten p-norm $\|\cdot\|_p$ is the norm $\|\cdot\|_q$, where $\frac{1}{p}+\frac{1}{q}=1$. For $p>1$ and every $W=U\Sigma(W)V^\top\in M_{d,n}\setminus\{0\}$, one can readily obtain the set of duals from the equality conditions in Hölder's inequality. These give that

$$\mathscr{D}\|W\|_p = \left\{Z : Z = U\Sigma(Z)V^\top, \sigma_i(Z) = \frac{(\sigma_i(W))^{q-1}}{\|\sigma(W)\|_q^{q-1}}, i\in\mathbb{N}_r\right\}.$$

Moreover, this norm is differentiable for $p>1$ and the gradient is given by

$$\nabla\|W\|_p = U\,\mathrm{Diag}(\lambda)V^\top\frac{1}{\|\sigma(X)\|_p^{p-1}},$$

where $\lambda_i=(\sigma_i(W))^{p-1}, i\in\mathbb{N}_r$.

Before continuing to the main result about OI-norms, we briefly review the relation between *regularization* and *interpolation* problems, mentioned at the end of Section 2. We are interested in obtaining representer theorems and optimality conditions, in general, for regularization problems of the form (2). We shall focus, however, on representer theorems for interpolation problems of the form (3).

Let $\Omega: M_{d,n}\to\mathbb{R}$ be a given regularizer and assume that, for every $y\in\mathbb{R}^m$ and linear operator $I: M_{d,n}\to\mathbb{R}^m$, there exists some solution of (3) satisfying a prescribed representer theorem. Then, by Lemma 1, for every $y\in\mathbb{R}^m$, $I: M_{d,n}\to\mathbb{R}^m$ and $E:\mathbb{R}^m\times\mathbb{R}^m\to\mathbb{R}$, the same representer theorem holds for some solution of problem (2). In the remainder of the paper we shall prove optimality conditions for interpolation problems, which thus equally apply to regularization problems.

Conversely, the representer theorem for the regularization problem (2) associated with certain choices of the function Ω and E , will also hold for the corresponding interpolation problems (3). To illustrate this idea, we adopt a result from Argyriou et al. (2009), which concerns the standard representer theorem,

$$\hat{W} \in \mathcal{R}(I^*)\,.$$

Theorem 11 *Let $E : \mathbb{R}^m \times \mathbb{R}^m \to \mathbb{R}$ and $\Omega : M_{d,n} \to \mathbb{R}$ be a function with the following properties:*

(i) *E is lower semicontinuous and bounded from below;*

(ii) *Ω is lower semicontinuous and has bounded sublevel sets, that is, for every $\lambda \in \mathbb{R}$, the set $\{W : W \in M_{d,n}, \Omega(W) \leq \lambda\}$ is bounded;*

(iii) *for some $v \in \mathbb{R}^m \setminus \{0\}, y \in \mathbb{R}^m$, there exists a* unique *minimizer of $\min\{E(av, y) : a \in \mathbb{R}\}$ and this minimizer does not equal zero.*

If, for all choices of I and y, there exists a solution $\hat{W} \in \mathcal{R}(I^*)$ of (2)*, then, for all choices of I and y such that $y \in \mathcal{R}(I)$, there exists a solution $\hat{W} \in \mathcal{R}(I^*)$ of* (3)*.*

As noted in Argyriou et al. (2009), the square loss, hinge loss or logistic loss are all valid error functions in this theorem. The above results allow us to focus on the interpolation problems, as a devise to study the regularization problem.

We are now ready to describe the main result of this section, which concerns the form of the solution of interpolation problems (5) for the class of OI-norms.

Theorem 12 *Assume that $\|\cdot\|$ is an OI-norm and let f be the corresponding SG-function. If the matrix $\hat{W} \in M_{d,n} \setminus \{0\}$ is a solution of* (5) *and the vector $\hat{c} \in \mathbb{R}^m$ is a solution of* (7)*, then*

$$\hat{W} = U\,\Sigma(\hat{W})\,V^\top\,,\; I^*(\hat{c}) = U\,\Sigma(I^*(\hat{c}))\,V^\top$$

for some $U \in O^d, V \in O^n$, and

$$\sigma(\hat{W}) \in \frac{1}{\|I^*(\hat{c})\|_D}\,\partial f(\sigma(I^*(\hat{c})))\,.$$

Proof By Theorem 2 we obtain that $\|I^*(\hat{c})\|_D \hat{W} \in \partial\|I^*(\hat{c})\|$. We can write $I^*(\hat{c})$ in terms of its singular value decomposition, $I^*(\hat{c}) = U\,\Sigma(I^*(\hat{c}))\,V^\top$ with $U \in O^d, V \in O^n$. Using Lemma 8 we conclude that

$$\|I^*(\hat{c})\|_D \hat{W} = U\,(\|I^*(\hat{c})\|_D \Sigma(\hat{W}))\,V^\top,$$

where $\|I^*(\hat{c})\|_D\,\sigma(\hat{W}) \in \partial f(\sigma(I^*(\hat{c})))$. ■

This theorem implies that, in order to solve the minimal norm interpolation problem (5), we may first solve the dual problem (7) and then find a matrix in the peak set of $I^*(\hat{c})$ scaled by $1/\|I^*(\hat{c})\|_D$, which interpolates the data. The latter step in turn requires computing a singular value decomposition of $I^*(\hat{c})$ and then solving a non-linear system of equations. However, when the SG-function is smooth, there is a unique elements in the peak set and, so, there is no need to solve the non-linear equations. For example, if $\|\cdot\|$ is the Frobenius norm, Theorem 12 readily yields the standard representer theorem.

4.3 Admissible Orthogonally Invariant Norms

In this section, we define a subclass of OI-norms, which obey an improved version of the representer theorem presented above.

We begin with a definition.

Definition 13 *A norm $\|\cdot\|$ on $\mathbb{R}^r$ is said to be* admissible *if for any $x \in \mathbb{R}^r$, any $k \in \mathbb{N}_r$ such that $x_k \neq 0$ we have that*

$$\|x^k\| < \|x\|$$

where x^k is the vector all of whose components agree with x, except the k-th component which is zero.

The simplest example of admissible norms are the ℓ_p norm on $\mathbb{R}^d$, $\|\cdot\|_p$, for $p \in [1,\infty)$. From this norm we can form other admissible norms in various ways. Specifically, for any $p_1, p_2 \in [1,\infty)$, we see that the norm $\|\cdot\|_{p_1} + \|\cdot\|_{p_2}$ or the norm $\max\{\|\cdot\|_{p_1}, \|\cdot\|_{p_2}\}$ are both admissible. Note that some of these norms are not strictly convex. Also compare this definition to that of weakly monotone norms (Horn and Johnson, 1985, Def. 5.5.13).

Lemma 14 *If $\|\cdot\|$ is an admissible norm on $\mathbb{R}^r$, $x \in \mathbb{R}^r \backslash \{0\}$ and $w \in \mathscr{D}\|x\|$, then for any $k \in \mathbb{N}_r$ with $x_k = 0$ it holds that $w_k = 0$.*

Conversely, assume that, for every $x \in \mathbb{R}^r \backslash \{0\}$, $w \in \mathscr{D}\|x\|$ and $k \in \mathbb{N}_r$, if $x_k = 0$ it holds that $w_k = 0$. Then $\|\cdot\|$ is admissible.

Proof Let $w \in \mathscr{D}\|x\|$, where $x \in \mathbb{R}^r \backslash \{0\}$, with $x_k = 0$. Suppose to the contrary that $w_k \neq 0$. Since $\|\cdot\|$ is admissible it follows that $\|w^k\| < \|w\|$, and so, we get that $\|w^k\| < 1$, because $\|w\| = 1$. However, we also have that

$$\|x\|_D = \langle w, x\rangle = \langle w^k, x\rangle \leq \|w^k\|\|x\|_D$$

from which it follows that $\|w^k\| \geq 1$. This proves the first part of the claim.

For the converse, we consider a $w \in \mathbb{R}^r \backslash \{0\}$ with $w_k \neq 0$. We shall show that $\|w^k\| < \|w\|$. To this end, we choose $x \in \mathscr{D}\|w^k\|_D$ and then we choose $y \in \mathscr{D}\|x^k\|$. By our hypothesis, we conclude that $y_k = 0$ and by our choice we have, in particular that $1 = \|y\| = \|x\|_D$. Consequently, it follows that

$$\|x^k\|_D = \langle y, x^k\rangle = \langle y, x\rangle \leq \|y\|\|x\|_D = 1$$

from which conclude that

$$\|w^k\| = \langle w^k, x\rangle = \langle w, x^k\rangle \leq \|w\|. \tag{12}$$

Moreover, if equality holds in this inequality it would follow that $\frac{w}{\|w\|} \in \mathscr{D}\|x^k\|$. But then, we can invoke our hypothesis once again and obtain a contradiction. That is, inequality (12) is strict and therefore $\|\cdot\|$ is an admissible norm, as asserted. ■

The above observation leads us to consider the following subclass of OI-norms.

Definition 15 *A norm $\|\cdot\|$ on $M_{d,n}$ is said to be* admissible orthogonally invariant *if there exists an admissible vector norm $\|\cdot\|$ on $\mathbb{R}^r$ such that, for every $W \in M_{d,n}$, we have that $\|W\| = \|\sigma(W)\|$.*

Examples of non-admissible OI-norms are the spectral norm, the Ky Fan norms $\|\cdot\|_{(k)}$ for $1 \leq k < r$ and the norm $\max\{\|\cdot\|_1, \alpha\|\cdot\|_\infty\}$ for $\alpha \in (1,\infty)$.

We have now accumulated sufficient information on admissible OI-norms to present an improved representer theorem for problem (5). We shall prove below, for any admissible OI-norm, $\hat{W}$ can be expressed as

$$\hat{W} = \sum_{i \in \mathbb{N}_m} \hat{c}_i X_i R.$$

In other words, $\hat{W}$ is obtained by first applying the standard representer theorem and then multiplying it from the right by the matrix R. In the case of the Frobenius norm $R = I_n$.

Theorem 16 *If $\|\cdot\|$ is admissible orthogonally invariant, the matrix $\hat{W} \in M_{d,n} \setminus \{0\}$ is a solution of* (5) *and the vector $\hat{c} \in \mathbb{R}^m$ is a solution of* (7)*, then there exists a matrix $R \in \mathbf{S}^n_+$ such that*

$$\hat{W} = I^*(\hat{c})R \tag{13}$$

and the eigenvectors of R are right singular vectors of $I^*(\hat{c})$.

Proof By Theorem 12, there exists $I^*(\hat{c}) = U\Sigma(I^*(\hat{c}))V^\top$, obtained from a dual solution $\hat{c}$ of (7), such that $\|I^*(\hat{c})\|_D \hat{W} = U\,\mathrm{Diag}(\lambda)V^\top$, where $\lambda \in \partial f(\sigma(I^*(\hat{c})))$ and f is the SG-function associated with $\|\cdot\|$. Since f is admissible, Lemma 14 implies that $\lambda_i = 0$ whenever $\sigma_i(I^*(\hat{c})) = 0$. Hence there exists $\mu \in \mathbb{R}^r_+$ such that $\lambda_i = \sigma_i(I^*(\hat{c}))\mu_i$, $i \in \mathbb{N}_r$, and $\mu_i = 0$ whenever $\sigma_i(I^*(\hat{c})) = 0$. Thus, $\|I^*(\hat{c})\|_D \hat{W} = U\Sigma(I^*(\hat{c}))V^\top V\,\mathrm{Diag}(\mu)V^\top$ and the corollary follows by selecting $R = \dfrac{1}{\|I^*(\hat{c})\|_D} V\,\mathrm{Diag}(\mu)V^\top$. ■

Note that, in the above theorem, the eigenvectors of R need not correspond to right singular vectors of $I^*(\hat{c})$ according to a simultaneous ordering of the eigenvalues / singular values.

We may also state a converse of Theorem 16, that is, the only OI-norms which satisfy property (13) are admissible.

Theorem 17 *If $\|\cdot\|$ is orthogonally invariant and condition* (13) *holds (without any conditions on $R \in M_{n,n}$), for every linear operator $I : M_{d,n} \to \mathbb{R}^m$, $y \in \mathcal{R}(I) \setminus \{0\}$, every solution $\hat{W}$ of* (5) *and every solution $\hat{c}$ of* (7)*, then the norm $\|\cdot\|$ is admissible orthogonally invariant.*

Proof Let f be the SG-function corresponding to $\|\cdot\|$. Let arbitrary $x \in \mathbb{R}^r \setminus \{0\}$ and $w \in \partial f(x)$. Define $\overline{x}, \overline{w} \in \mathbb{R}^r_+$ to be the vectors with elements the absolute values of x, w, respectively, in descending order. By Lemma 10, we obtain that $\overline{w} \in \partial f(\overline{x})$. Define also $X = \mathrm{Diag}(\overline{x}) \in M_{d,n}$ and $W = \mathrm{Diag}(\overline{w}) \in M_{d,n}$. By Lemma 8, we obtain that $W \in \partial\|X\|$. Now, consider the problem $\min\{\|Z\| : Z \in M_{d,n}, \langle Z, X\rangle = \|X\|_D\}$, whose set of solutions is $\partial\|X\|$. By hypothesis, $W = cXR$ for some $R \in M_{n,n}$ and for $c = \frac{1}{\|X\|_D}$ (the only solution of the dual problem). Therefore, $\mathrm{Diag}(\overline{w}) = c\,\mathrm{Diag}(\overline{x})R$ and hence $\overline{x}_k = 0$ implies $\overline{w}_k = 0$, for all $k \in \mathbb{N}_r$. By Lemma 10, this implies in turn that $w_k = 0$ if $x_k = 0$, for all $k \in \mathbb{N}_r$. Combining with Lemma 14, we deduce that f is admissible, as required. ■

We remark that there exist norms on $M_{d,n}$ which are not orthogonally invariant and satisfy condition (13). In fact, given two non-singular matrices $Q \in M_{d,d}$ and $M \in M_{n,n}$, the norm $W \mapsto \|QWM\|_2$ is not orthogonally invariant, but the representer theorem is easily seen to be

$$\hat{W} = (Q^\top Q)^{-1} I^*(\hat{c})(MM^\top)^{-1}.$$

Furthermore, concerning the converse of Theorem 16, it can be shown that if we restrict the eigenvectors of R to be right singular vectors of $I^*(\hat{c})$, then $\|\cdot\|$ has to be orthogonally invariant.

Moreover, if the norm $\|\cdot\|$ is not admissible, then it can be shown that for every solution $\hat{c}$ of the dual problem there exists a solution of the primal satisfying (13). As an example, see Corollary 20 below (spectral norm). For a characterization of functions yielding such representer theorems, see Argyriou et al. (2009).

Returning to Theorem 12, for the Schatten p-norms we have the following corollary. To state it, we use the notation A^{q-1} as a shorthand for the matrix $U \operatorname{Diag}(\sigma_i(A)^{q-1})_{i\in\mathbb{N}_r} V^\top$ when $A = U\Sigma(A)V^\top$.

Corollary 18 *If the matrix $\hat{W} \in M_{d,n} \setminus \{0\}$ is a solution of* (5) *for the Schatten $p-$norm, with $p \in (1,\infty)$, then there exists a vector $\hat{c} \in \mathbb{R}^m$ such that*

$$\hat{W} = \frac{I^*(\hat{c})^{q-1}}{\|I^*(\hat{c})\|_q^q},$$

where $\frac{1}{p} + \frac{1}{q} = 1$.

Proof The corollary follows directly from Theorem 12 and the description of $\partial\|\cdot\|_p$ in Section 4.2. ■

The above corollary does not cover the cases that $p = 1$ or $p = \infty$. We state them separately.

Corollary 19 *If $\hat{W} \in M_{d,n} \setminus \{0\}$ is a solution of* (5) *for the trace norm, $\hat{c} \in \mathbb{R}^m$ a solution of* (7) *and $I^*(\hat{c}) = \sum_{i\in\mathbb{N}_r} \sigma_i(I^*(\hat{c}))u_i v_i^\top$ is a singular value decomposition, then*

$$\hat{W} = \frac{1}{\sigma_1(I^*(\hat{c}))} \sum_{i\in\mathbb{N}_{r_{\max}}} \lambda_i u_i v_i^\top,$$

for some $\lambda_i \geq 0, i \in \mathbb{N}_{r_{\max}}$ such that $\sum_{i\in\mathbb{N}_{r_{\max}}} \lambda_i = 1$, where $r_{\max}$ is the multiplicity of the largest singular value $\sigma_1(I^*(\hat{c}))$. Moreover, $\hat{W} = I^*(\hat{c})R$, where

$$R = \frac{1}{\sigma_1^2(I^*(\hat{c}))} \sum_{i\in\mathbb{N}_{r_{\max}}} v_i v_i^\top.$$

Proof The corollary follows from Theorem 12 and the description of $\partial\|\cdot\|_1$. From the definition, it is easy to obtain that, for every $x \in \mathbb{R}^r_+$, $\partial\|x\|_1 = \{y \in \mathbb{R}^r_+ : y_i = 0, \text{ if } x_i < \|x\|_\infty, \sum_{i\in\mathbb{N}_r} y_i = 1\}$. Thus, $\sigma_1(I^*(\hat{c}))\hat{W} = \|I^*(\hat{c})\|_\infty \hat{W} = U\Lambda V^\top$, for $\Lambda = \operatorname{Diag}(\lambda)$ and $\lambda_i = 0$ for $i > r_{\max}$, $\sum_{i\in\mathbb{N}_{r_{\max}}} \lambda_i = 1$. Since $\Lambda = \frac{1}{\sigma_1(I^*(\hat{c}))}\Sigma(I^*(\hat{c}))\Lambda$, R can be selected as $\frac{1}{\sigma_1^2(I^*(\hat{c}))} V\Lambda V^\top$. ■

Corollary 20 *If the matrix $\hat{W} \in M_{d,n} \setminus \{0\}$ is a solution of* (5) *for the spectral norm, $\hat{c} \in \mathbb{R}^m$ a solution of* (7) *and $I^*(\hat{c}) = \sum_{i \in \mathbb{N}_r} \sigma_i(I^*(\hat{c}))u_i v_i^\top$ is a singular value decomposition, then*

$$\hat{W} = \frac{1}{\|I^*(\hat{c})\|_1} \sum_{i=1}^{\operatorname{rank}(I^*(\hat{c}))} u_i v_i^\top + \sum_{i=\operatorname{rank}(I^*(\hat{c}))+1}^{r} \alpha_i u_i v_i^\top , \tag{14}$$

for some $\alpha_i \in [0,1]$, $i = \operatorname{rank}(I^*(\hat{c})) + 1, \ldots, r$.

Proof The corollary follows from Theorem 12 and the fact that, for every $x \in \mathbb{R}^r_+$, $\mathscr{D}\|x\|_\infty = \{y \in [-1,1]^r : y_i = 1, \text{ if } x_i > 0\}$. ■

The above corollary also confirms that representation (13) does not apply to the spectral norm (which is not admissible orthogonally invariant). Indeed, from (14) it is clear that the range of $\hat{W}$ can be a superset of the range of $I^*(\hat{c})$.

To recapitulate the results presented in this section, Theorem 12 allows one to obtain the solutions of the primal minimum norm interpolation problem (5) from those of its dual problem (7), which involves m variables. This is true for *all OI-norms*, even though the representer theorem in the form (13) applies only to admissible OI-norms. Part of the appeal of OI-norms is that computing primal solutions from dual ones reduces to a vector norm optimization problem. Indeed, given a solution of the dual problem, one just needs to compute the *singular value decomposition* of the matrix $I^*(\hat{c})$ and *the peak set of the SG-function f at the singular values*. The associated primal solutions are then easily obtained by keeping the same row and column spaces and using elements of the peak set in place of the singular values. In fact, in many cases, the latter problem of computing the peak set of f may be straightforward. For example, if f_D is differentiable (except at zero), each dual solution is associated with a single primal one, which equals a multiple of the gradient of f_D at the dual solution.

4.4 Related Work

The results of Section 4 are related to other prior work, besides the already mentioned literature on representer theorems for the case of the vector L_2 norm (that is, for $n = 1$). In particular, the representer theorem for the trace norm (Corollary 19) has been stated in Srebro et al. (2005). Also, the representation (13) in Theorem 16 relates to the representer theorems proven in Argyriou et al. (2009); Abernethy et al. (2009). The results in Abernethy et al. (2009) apply to the case of the trace norm and when the X_i are rank one matrices. The results in Argyriou et al. (2009) give representer theorems for a broad class of functions, of which differentiable OI-norms are members. However, as mentioned before, Theorem 16 requires additional conditions on matrix R. In particular, the requirement on the eigenvectors of this matrix holds only for admissible OI-norms.

5. Conclusion and Future Work

We have characterized the form of the solution of regularization with an orthogonally invariant penalty term. Our result depends upon a detailed analysis of the corresponding minimal norm interpolation problem. In particular, we have derived a dual problem of the minimal norm interpolation problem and established the relationship between these two problems. The dual problem involves optimization over a vector of parameters whose size equals the number of data points. In practical circumstances, this number may be smaller than the dimension of the matrix we seek, thus our result

should prove useful in the development of optimization algorithms for orthogonally invariant norm regularization. For example, one could combine our result with Lemma 9 in order to implement gradient methods for solving the dual problem. Note however that the dual problem involves a singular value decomposition, and more effort is needed in elucidating the algorithmic implications of the results presented here.

Appendix A.

Here, we describe two results which we have used in the paper. Recall that for every linear operator $J : M_{d,n} \to \mathbb{R}^k$, the linear spaces $\mathcal{R}(J)$ and $\mathcal{N}(J)$ denote the range and the kernel of J, respectively.

Lemma 21 *Let $\mathcal{W}$ be a nonempty, convex and compact subset of $M_{d,n}$ and let $J : M_{d,n} \to \mathbb{R}^k$ be a linear operator. The set $\mathcal{R}(J^*)$ intersects $\mathcal{W}$ if and only if, for every $X \in \mathcal{N}(J)$ the following inequality holds*

$$\max\{\langle X, W\rangle : W \in \mathcal{W}\} \geq 0. \tag{15}$$

Proof Suppose that there exist $z \in \mathbb{R}^k$ and $T \in \mathcal{W}$ such that $J^*(z) = T$. Then for any $X \in M_{d,n}$ with $J(X) = 0$ we have that $\langle X, T\rangle = 0$ and, so, inequality (15) holds true.

Now, suppose that $\mathcal{R}(J^*) \cap \mathcal{W} = \emptyset$. Then, there is a hyperplane which strictly separates $\mathcal{R}(J^*)$ from $\mathcal{W}$ (see, for example, Rockafellar, 1970, Cor. 11.4.2). That is, there exist $W_0 \in M_{d,n}$ and $\mu \in \mathbb{R}$ such that, for all $z \in \mathbb{R}^k$,

$$\langle W_0, J^*(z)\rangle + \mu \geq 0,$$

while, for all $W \in \mathcal{W}$,

$$\langle W_0, W\rangle + \mu < 0.$$

The first inequality implies that $J(W_0) = 0$. To see this, we choose any $z_0 \in \mathbb{R}^k$ and $\lambda \in \mathbb{R}$ and let $z = \lambda z_0$ in the first inequality. Now, we allow $\lambda \to \pm\infty$, to obtain that $\langle W_0, J^*(z_0)\rangle = 0$. Therefore, the first inequality simplifies to the statement that $\mu \geq 0$.

The second inequality implies that

$$\max\{\langle W_0, W\rangle : W \in \mathcal{W}\} < -\mu \leq 0,$$

which contradicts (15) and proves the result. ■

Next, we state an important rule for taking directional derivatives of a convex function expressed as a maximum of a family of convex functions. For this purpose, recall that the right directional derivative of a function $g : \mathcal{W} \to \mathbb{R}$ in the direction Δ at $W \in \mathcal{W}$ is defined as

$$g'_+(W;\Delta) = \lim_{\lambda \to 0^+} \frac{g(W + \lambda\Delta) - g(W)}{\lambda}.$$

Theorem 22 *Let $\mathcal{W}$ be a convex subset and $\mathcal{X}$ a compact subset of $M_{d,n}$ and $f : \mathcal{W} \times \mathcal{X} \to \mathbb{R}$. If, for every $W \in \mathcal{W}$, the function $X \mapsto f(W,X)$ is continuous on $\mathcal{X}$ and, for every $X \in \mathcal{X}$ the function $W \mapsto f(W,X)$ is convex on $\mathcal{W}$, then the convex function $g : \mathcal{W} \to \mathbb{R}$ defined at $W \in \mathcal{W}$ as*

$$g(W) := \max\{f(W,X) : X \in \mathcal{X}\}$$

has a right directional derivative at W in the direction $\Delta \in M_{d,n}$, given as

$$g'_+(W;\Delta) = \max\{f'_+(W;\Delta,X) : X \in M(W)\}, \tag{16}$$

where $M(W) = \{X : X \in \mathcal{X}, f(W,X) = g(W)\}$.

Abstract

In this paper, we present an overview of *generalized expectation criteria (GE)*, a simple, robust, scalable method for semi-supervised training using weakly-labeled data. GE fits model parameters by favoring models that match certain expectation constraints, such as marginal label distributions, on the unlabeled data. This paper shows how to apply generalized expectation criteria to two classes of parametric models: maximum entropy models and conditional random fields. Experimental results demonstrate accuracy improvements over supervised training and a number of other state-of-the-art semi-supervised learning methods for these models.

Keywords: generalized expectation criteria, semi-supervised learning, logistic regression, conditional random fields

1. Introduction

Semi-supervised learning, where a small amount of human annotation is combined with a large amount of unlabeled data to yield an accurate classifier, has received a significant amount of attention from the research community. However, there are surprisingly few cases of its use in applications, where the emphasis is on solving a task, not on advancing theoretical understanding. This may be partially due to the natural time it takes for new machine learning ideas to propagate to practitioners, but we believe it is also due in large part to the inherent difficulty of the task and the unreliability of existing methods.

Instead of addressing the difficulties of semi-supervised learning head-on, we propose to use weakly labeled data ("side-information") in semi-supervised learning. To use this data, we present *generalized expectation critera (GE)*, a method initially described as *expectation regularization* in Mann and McCallum (2007). GE represents a new family of semi-supervised learning, where models are fit by minimizing model divergence from an input distribution. To calculate the divergence from the input distribution there is no need for additional training data, as the expected distribution on the unlabeled data can be used. These terms can be easily integrated with other terms, such as traditional log-likehood.

*. Gideon S. Mann is the corresponding author.

The experiments in this paper explore an illustrative special case of GE, *label regularization*, where a marginal distribution over output labels is applied as an expectation constraint. We investigate two parametric models: maximum entropy models and their structured output analog, conditional random fields. We demonstrate that for both of these models, label regularization is able to provide performance gains over other supervised and semi-supervised learning methods.

Generalized expectation criteria have a number of advantages over alternative semi-supervised learning techniques that make it suitable for use in practice. It is simple, making it easy to implement and use. It requires no additional processing such as constructing an inverted index for graph construction or pre-clustering unlabeled data. Since it can handle a wide spectrum of side-information, human intuitions about the problem can be explicitly communicated to the learning process, in contrast to other methods which can require opaque supervision, such as carefully tuned initialization, or specification of "contrastive examples" and other "auxiliary functions". We apply GE in this paper to discriminative models, and thus it is able to robustly handle overlapping, non-independent feature sets and yields transparent confidence estimates (in the form of probabilities). Additionally, GE has all of the advantages of parametric models, in particular scalability and a small memory footprint at test time.

2. Related Work

Traditional *supervised learning* takes as input fully labeled data, a set of tuples $\mathcal{D} = \{(x, y)\}$, where x is the input and y the desired output. The learner is a function which maps the input to a predictive function: $J(\mathcal{D}) = f$, where $f : x \rightarrow y$. Supervised learning is powerful, but the amount of labeled data needed can require significant human time and effort to create. In an effort to reduce the need for human effort, the machine learning community has explored semi-supervised learning. In *semi-supervised learning* approaches, a small amount of labeled data is augmented by unlabeled data, a set of elements $\mathcal{U} = \{x\}$, which it exploits to chose a similar function: $J(\mathcal{D} \cup \mathcal{U}) = f$. This section presents the main methods for semi-supervised learning from labeled and unlabeled data: 1) bootstrapping, 2) expectation maximization, 3) feature discovery, 4) decision boundaries in sparse region methods, and 5) graph-based methods.

In contrast to these methods, GE criteria exploit semi-supervised learning from weakly labeled data. With this scenario, there be no labeled data. Instead, in addition to unlabeled data there is side information that has been provided to the learner, for example, expectation constraints like marginal label distributions $\tilde{g}_y = p(y)$.[1] Section 2.2 reviews prior work in this area.

2.1 Semi-supervised Learning with Labeled and Unlabeled Instances

There are five main prior categories of semi-supervised learning approaches: bootstrapping, expectation maximization, feature discovery, decision boundaries in sparse regions, and graph-based methods.

2.1.1 BOOTSTRAPPING

In bootstrapping, or self-training approaches, a classifier is first trained on the fully labeled instances and then is applied to unlabeled instances. Some subset of those newly labeled instances are then used (in conjunction with the original labeled instances) to retrain the model.

1. Liang et al. (2009) presents a taxonomy of side-information.

Algorithm 1 Bootstrapping for semi-supervised learning

$f^{(0)} \leftarrow J(\mathcal{D})$
repeat
  $\mathcal{U}_B \leftarrow \cup_{x_i \in \mathcal{U}}(x_i, f^{(t-1)}(x_i))$
  $f^{(t)} \leftarrow J(\mathcal{D} \cup \mathcal{U}_B)$
until done

One of the most successful examples of this work is Yarowsky (1995), where a small 'seed set' of labeled instances is incrementally augmented. Co-training (Blum and Mitchell, 1998) looks at the case where two complementary classifiers can both be applied to a particular problem. Abney (2004) provides a deeper understanding of these methods by demonstrating that they optimize a natural objective function. However, these methods typically require continual human intervention in order to avoid performance loss during the bootstrapping process, such as in Riloff and Shepherd (2000).

2.1.2 EXPECTATION MAXIMIZATION

Generative models trained by expectation maximization (Dempster et al., 1977) have been widely studied for semi-supervised learning. EM consists of two steps: an expectation step $Q(\theta|\theta^{(t)}) = E_{p(y|x,\theta^{(t)}}[\log L(\theta;x,y)]$, and a maximization step, $\theta^{(t+1)} = \texttt{argmax}_\theta\, Q(\theta|\theta^{(t)})$. To apply EM to semi-supervised data, the log-likelihood function, $\log L(\theta;x,y)$, is set to be a composite of labeled and unlabeled data (possibly with a weighting factor to down-weight the contribution to the likelihood from the unlabeled data). One popular example of the use of EM for generative models is Nigam et al. (1998) which presents a naïve Bayes model for text classification trained using EM and semi-supervised data.

EM has also been applied to structured classification problems such as part-of-speech tagging (Klein and Manning, 2004), where EM can succeed after very careful and clever initialization. While these models can often be very effective, especially when used with "prototypes" (Haghighi and Klein, 2006b), they cannot efficiently accommodate non-independent features, for example, those that span multiple inputs. In these cases, the dynamic program required to compute the feature expectations over all input positions quickly becomes intractable, as building the lattice requires exponential space in the length of input features.

EM for discriminative models has also been explored. Wang et al. (2002) proposes a EM based model which instead of the likelihood, maximizes the entropy given the latent variables. Alternatively, Salakhutdinov et al. (2003) present an expected gradient method, which can be used for discriminative models which have some partially observed labels, and McCallum et al. (2005) uses this method for conditionally trained CRFs. While this method is appealing in the case of input data that consists of sequences with partially hidden variables, it cannot be applied to scenarios with fully unlabeled instances.

Another twist on this technique is to blend generative and discriminative models, by combining ML estimates over the labeled data with EM parameter estimates over the unlabeled data, for a joint model which combines a CRF and a HMM (Suzuki et al., 2007; Suzuki and Isozaki, 2008). In this formulation, the log-likelihood can be viewed as two separate log-likelihood functions $L_1(\theta)$ and $L_2(\theta)$ which respectively correspond to the CRF and HMM log-likelihood. When optimizing

$L_1(\theta)$ (using maximum likelihood), the HMM parameters are held constant, and the reverse when optimizing $L_2(\theta)$.

While EM can sometimes works well, it is often fragile and finds solutions that are worse than the equivalent supervised model. Merialdo (1994) gives a classic example where EM fails to help part-of-speech tagging. Cozman and Cohen (2006) discuss the risks of using EM and describe situations where it can fail. Additionally, the generative models on which EM depends often perform worse than discriminative models.

2.1.3 FEATURE DISCOVERY

As alternative to estimating a classifier directly with unlabeled data, a number of groups have explored using the unlabeled data for feature induction or feature discovery, and those features are then embedded into a traditional supervised learning problem. A latent clustering is applied over the unlabeled data, to learn a function f_l, which is used to provide additional features $f_l(x) = z$, these features are then used to augment the original labeled data: $\bar{\mathcal{D}} = \cup_{(x_d,y_d)\in\mathcal{D}}(x_d \cup z_d, y_d)$, and then supervised learning proceeds as usual. For example, Miller et al. (2004) and Ganchev et al. (2007) apply the method described in Brown et al. (1992) to cluster all of the word tokens in a large unsupervised corpus. Then for a given sentence, in addition to standard features, additional features corresponding to the latent clusters of the tokens in the sentence, are added. This technique, along with similar approachs (Freitag, 2004; Li and McCallum, 2005), have yielded small but consistent success. This method can be applied independently of the particular training method and in Section 6.3, we explore combining our method with those described by Miller et al. (2004).

Ando and Zhang (2005) use a similar method, but the clustering they explore is composed of auxiliary problems (e.g., predict a given token given the token context). In their method, they estimate the parameters for a linear classifier for each auxiliary problem, and then these parameters are embedded as a transformation of the parameters for a linear classifier for the original problem. Although this method has produced impressive gains, it is quite sensitive to the selection of auxiliary information, and making good selections requires significant insight. F. Pereira and J. Blitzer.[2] note that the list of tricks necessary to get the method of Ando and Zhang (2005) to work includes: oversampling positive instances, selecing the unlabeled data carefully, scaling real-valued features, and choosing the appropriate feature types.

Additionally, feature discovery as a semi-supervised learning technique relies on having a substantial amount of labeled data for training. It cannot be used in cases where only a limited amount of labeled data is available.

2.1.4 DECISION BOUNDARIES IN SPARSE REGIONS

Another family of methods uses the intuition that decision boundaries ought to fall in low-density regions (corresponding to an assumption of class separability) and thus fit discriminative models with this objective in mind. Clearly, if the cluster assumption is violated (i.e., the classes are not widely separable), assigning decision boundaries to low density regions is a poor choice. One illustrative example is entropy regularization (Grandvalet and Bengio, 2004), where a traditional conditional label log-likelihood objective function is augmented with an additional term that minimizes the

2. Conveyed in personal communication.

entropy of the label distribution on the unlabeled data:

$$O(\theta;\mathcal{D},\mathcal{U}) = L(\theta;\mathcal{D}) + H(\theta;\mathcal{U}) \\ = \sum_{d\in\mathcal{D}} \log p(y_d|x_d) - \lambda \sum_{u\in\mathcal{U}} \sum_{y} p(y|x_u) \log p(y|x_u) \,.$$

This objective function favors parameter settings where the model is certain of the labels on given unlabeled data. In entropy regularization, the hyper-parameter λ has a dramatic effect on the performance of the learner, since it must be tuned with regards to the amount of labeled and unlabeled data. Entropy regularization is particularly difficult to apply in cases of very small amounts of labeled data, since in one degenerate case, the model could select one output label for all possible inputs. Studies on structured output models in Jiao et al. (2006) experimentally demonstrate that careful tuning of λ is mandatory.

Transductive support vector machines (TSVMs) (Joachims, 1999) add a constraint to the SVM optimization function in order to preserve the margin over unknown test labels:

$$(\{y_u\},\theta) = \underset{\{y_u\},\theta}{\texttt{argmin}} \frac{1}{2}||\theta||^2 \quad \textit{subject to} \begin{cases} \forall_{x_i\in\mathcal{D}} & y_i[\theta\cdot x_i + b] \geq 1 \\ \forall_{x_u\in\mathcal{D}} & y_u[\theta\cdot x_u + b] \geq 1 \end{cases} .$$

It is combinatorially intractable to do a brute-force search over all possible labelings $\{y_u\}$, so an approximation search must be undertaken. Even with these approximations, the algorithm as originally proposed has running time $O(n^3)$. Sindhwani and Keerthi (2006) propose a method for speeding up training in some cases. In our experience, like entropy regularization, TSVMs also require extensive and delicate tuning of meta-parameters. We note that Sindhwani and Keerthi (2006) report results with meta-parameters tuned on test data. Benchmark tests have shown that entropy regularization performs as well as TSVMs (when the SVM is given a linear kernel) (Chapelle et al., 2006). Another related method is information regularization (Corduneanu and Jaakkola, 2003), which measures distance via the mutual information between a classifier and the marginal distribution $p(x)$.

2.1.5 GRAPH-BASED METHODS

Graph-based (manifold) methods can be very accurate when applied to semi-supervised learning. In these methods, a graph, typically with weighted edges, is constructed spanning the labeled and unlabeled instances. Thereafter, unlabeled instances are assigned labels according to their neighbors. Zhu and Ghahramani (2002) propose label propagation, where labels propagate from labeled instances to unlabeled instances (see Algorithm 2). In this formulation, there are two significant

Algorithm 2 Label propagation

repeat

$\forall_{x_u\in\mathcal{U}}:\ p(y_u^{(t)}|x_u^{(t)}) = \frac{1}{Z}\sum_{j\in\mathcal{N}(x_u)} q(j\rightarrow u) p(y_j^{(t-1)}|x_j)$

until $p(y_u^{(t)}|x_u^{(t)})$ converges

choices that must be made: the graph structure (the neighborhood $\mathcal{N}(x)$ for each instance) and the transition function $q(j\rightarrow i)$. Szummer and Jaakkola (2002) present a closely related approach which uses random walks through the graph to assign labels. More distantly related, Li and McCallum (2004) examine a method which performs an implicit clustering over points, as it simultaneously estimates pair-wise distance and classification boundaries.

As originally proposed, graph-based methods are slow, requiring time $O(n^3)$ or on average $O(kn^2)$ where k is the number of neighbors (similar to TSVMs). By sub-sampling unlabeled data, one can reduce run-time from $O(n^3)$ to $O(m^2n)$, where m is the subsampled number of unlabeled data points (Delalleau et al., 2006), but subsampling does not take full advantage of available unlabeled data. Zhu and Lafferty (2005) propose alternative methods for reducing the time compleity to $O(m^3), m < n$, but these may also impact performance. For structured output spaces, Lafferty et al. (2004) and Altun et al. (2005) have looked at approaches using these methods. However, the high running time of these methods has prevented wide-scale adoption, and they have been tested predominantly on synthetic or toy examples (e.g., with 5 labeled examples). Recently, Baluja et al. (2008) proposed a method for performing graph-based semi-supervised learning in parallel.

Since these are non-parametric models, they do not build a compact encoding of the model, and so it is not always clear how to apply them inductively (on new unlabeled data). At the very least, labeled and unlabeled data must be stored in order to classify new examples. In this paper we compare against a representative graph-based label propagation method called Quadratic Cost Criterion (QC) (Bengio et al., 2006) whose results are reported in Chapelle et al. (2006).

2.1.6 DIFFICULT APPLICATIONS

There are cases of semi-supervised learning being used in application settings, however, not without difficulty. In fact, a broad survey of semi-supervised learning methods (Chapelle et al., 2006) found that they do not uniformly beat supervised methods and that there is no clear winner from among the methods. This conclusion reflects the experimental evidence and theoretical support from a large span of work.

Expectation-maximization is notoriously fickle for semi-supervised learning. In a classic result (Merialdo, 1994) attempts semi-supervised learning to improve HMM part-of-speech tagging and finds that EM with unlabeled data reduces accuracy. Ng and Cardie (2003) also apply EM but finds that it fails to improve performance, as do Grenager et al. (2005) (without their tricky initialization). Cozman and Cohen (2006) discuss use cases where EM might fail to work.

Krogel and Scheffer (2004) use transductive SVMs for the functional genomics KDD Cup challenge and find that not only does it fails to improve performance but it even deteriorates performance. Ifrim and Weikum (2006) also find that TSVMs deteriorate performance. Kockelkorn et al. (2003) use transductive SVMs for text classification, but complain that it is computationally costly. Zhang and Oles (2000) discuss theoretical reasons why TSVMs might fail to work in various scenarios.

Macskassy and Provost (2006) apply harmonic mixing to classification of relational data, however the running time of harmonic mixing proves to be a barrier to its use. In the case of word sense disambiguation, Niu et al. (2005) has looked at label propagation, and found that the metric for graph construction has a dramatic effect on performance. Chen et al. (2005) look at combining manifold methods (e.g., ISOMAP) with semi-supervised learning, but finds that the methods are too fragile in their tuning parameters to be effective. Blum and Chawla (2001) also cite fragility in the tuning parameters as a problem for their graph-based method.

2.2 Semi-supervised Learning with Weakly Labeled Data

As an alternative to semi-supervised learning with labeled and unlabeled data, a number of methods have investigated semi-supervised learning with weakly labeled data or side information, though none with the expressiveness in labeling allowed by GE criteria.

Graph-based methods have used class proportions for post-processing to set thresholds on label propagation (Zhu et al., 2003). Schuurmans (1997) uses predicted label distributions on unlabeled data for model structure selection (as opposed to parameter estimation). More distantly, conditional harmonic mixing (Burges and Platt, 2006) minimizes over each point the KL-divergence between the currently predicted label distribution and the distribution predicted by its neighbors. Wang et al. (2004) also look at methods for incorporating class proportions into classification. In their model, they pseudolabel instances and provide them as constraints for the model to handle.

The use of side information to train a parametric classifier has been explored before by Schapire et al. (2002) who uses a boosted ensemble of weak learners set from human-generated expected distributions. There are significant differences between GE and this work, in particular, Schapire et al. (2002) match distributions on a per-instance basis, while generalized expectation criteria match a global distribution. Thus in the model proposed by Schapire et al. (2002), every example has to match the distribution given as input.[3] Graca et al. (2008) integrates similar types of instance-based constraints into EM learning, where the constraints restrict the space over which the model calculates the expectations of the hidden variables.

Like Schapire et al. (2002), Jin and Liu (2005) present a model for incorporating class proportions into discriminative models which places a expected class distribution over each instance. Unlike Schapire et al. (2002), these distributions start from a fixed point and then are allowed to change during training.

In contrastive estimation (Smith and Eisner, 2005), EM is performed over a restricted log-likelihood function, where instead of $L(\theta) = \sum_i \log p(x_i; \theta)$, the contrastive estimation log-likelihood function is $L_{CE}(\theta) = \sum_i \log p(x_i | \mathcal{N}(x_i); \theta)$. The neighborhood function $\mathcal{N}(x_i)$ must be highly tuned, and even slight variations in it can have significant impact on error. More crucially, the bias introduced by choosing $\mathcal{N}(x_i)$ is difficult to predict and unintuitive.

Haghighi and Klein (2006b) take prototypes as input to their method, and then uses SVD to link up words to prototypes with similar co-occurrence patterns (e.g., "Inner Richmond" has the label NEIGHBORHOOD). Haghighi and Klein (2006a) extends this framework to context-free grammar induction. Another group that has investigated integrating constraints into structure output learning is Chang et al. (2007) which integrates constraints into unsupervised learning with HMM. In their method, they reranking candidate labelings by constraint violations and then use a threshold set of these candidates for re-training in a Viterbi-like approximation to expectation maximization.

Generalized expectation criteria are unique in that it uses the expected distribution as the sole criterion for optimizing the model parameters on one set of unlabeled data (though it may also use labeled data). Most other methods do not try to directly fit these expectations, but use them instead as heuristics within a more complicated semi-supervised learning model. When we compare with techniques that use the label distribution (e.g., naïve Bayes with a fixed label prior), we find they do worse than GE, which demonstrates that GE is able to use these class distributions more effectively than other methods.

3. Label regularization is impossible under the Schapire et al. (2002) model, since if the model exactly matched the label expectation on a per-instance basis, in application it would assign all instances to the majority class.

3. Generalized Expectation Criteria

When a person is designing a classifier, they frequently have intuitions about the data they are trying to classify. For example, someone designing a part-of-speech tagger might know that 'nouns' are quite frequent, whereas 'conjunctions' are much less common. Manually labeling data can be a round-about way of providing this information to the machine learning model, and weak labeling provides another route for biasing the model with this information. It would be difficult to hypothesize priors over *model parameters* to capture this intuition. With GE the designer sets priors over *model expectations*, and since these expectations have a relatively transparent interpretation to the human designer, they provide an appealing route for injecting bias into the classifier. GE can effectively learn from a wide variety of side information, including expectation constraints which hold over global properties of the classifier (e.g., label marginals in label regularization), constraints over individual instances, and expectation constraints which are more expressive than the base model can model directly (e.g., a three label sequence in a markov order 1 CRF).

A **generalized expectation (GE) criterion** is a term in a parameter estimation objective function that assigns scores to values of a model expectation. First some standard notation: x is the input, y the output, and θ the parameters for a given model. Given a set of unlabeled data $\mathcal{U} = \{x\}$ and a conditional model $p(y|x;\theta)$, a GE criterion $G(\theta;\mathcal{U})$ is defined by a score function S and a constraint function $G(x,y)$:

$$G(\theta;\mathcal{U}) = S(E_{\mathcal{U}}[E_{p(y|x;\theta)}[G(x,y)]])\,.$$

In this light, GE criteria can be viewed as an replacement for a maximum likelihood estimator and can be maximized alone to yield a parameter estimate θ. For a particular choice of model family and parameterization, many different choices for score functions and constraint functions may be explored. In this paper we consider a subset of GE criteria which express a preference for a particular value of a constraint $\tilde{g}_{x,y}$, and apply the KL-divergence to compute model divergence from this constraint:

$$G(\theta;\mathcal{U}) = D(\tilde{g}_{x,y}||E_{\mathcal{U}}[p(y|x;\theta)G(x,y)])\,.$$

Other work has considered squared loss and constraint functions which are more and less expressive than the model parameterization (Druck et al., 2009a).

GE criteria can be used as a sole criterion for an objective function (e.g., Mann and McCallum 2008). In this work, we combine it the log-likelihood, $L(\theta)$ to form a composite objective function:

$$O(\theta;\mathcal{U},\mathcal{D}) = L(\theta;\mathcal{D}) + G(\theta;\mathcal{U})\,.$$

Alternatively, an entropy regularization term (Grandvalet and Bengio, 2004)[4] can be combined into the above objective function in the same manner:

$$O(\theta;\mathcal{U},\mathcal{D}) = L(\theta;\mathcal{D}) + G(\theta;\mathcal{U}) + H(\theta;\mathcal{U})\,.$$

GE criteria can be interpreted as a generalization of traditional maximum likelihood. First, GE allows a variety of scoring functions (e.g., KL-divergence or mean-squared error from a reference

4. Entropy regularization cannot be framed as a instance of GE, but a generalization could encompass both: $G(\theta;\mathcal{U}) = S(E_{\mathcal{U}}[E_{p(y|x;\theta)}[F(x,y)]])$, where F is an arbitrary function over a particular (x,y) tuple (e.g., for entropy regularization $F = \log p(y|x;\theta)$.

distribution) and thus can incorporate information from a source other than empirical feature counts derived from the training data (e.g., human intuition, empirical counts derived from alternative data sources). Second, there need not be a one-to-one relationship between GE terms and features. For example, we can express preferences on a subset of model features (and leave others unconstrained), or on marginal distributions larger than model factors. In this paper, we apply a constraint for only one feature obtained from human intuition about the problem.

We explore **label regularization**, where the constraints $\tilde{g}$ are expectations of model marginal distributions on the expected output labels. We look at functions $G(x,y) = \mathbf{1}(y)$, and use various estimated label marginal distributions:

$$\tilde{g}_{x,y} = \tilde{p}(y)\,.$$

The effect of adding this term is to ensure that the model applied to the unlabeled data matches the label proportions.[5] Note that this does not force the conditional label distribution for each instance to conform to this constraint, but rather it encourages the model to meet this constraint in aggregate over all instances.

Similar to label regularization, Quadrianto et al. (2008) uses label proportions to learn classifiers, though there are some interesting differences from our work. Their method relies on having multiple training subsets with very different class distributions, whereas we only use one data set with a single set of label proportions. Their work concentrates on non-structured classification, whereas we extend our method to the structured output case.

3.1 Recent Work on GE Criteria and Related Methods

Since the initial proposal of GE criteria (under the name *expectation regularization*) in Mann and McCallum (2007), there has been a flurry of recent work on generalized expectation criteria and related methods which apply expectation constraints for weak learning.

In a set of user experiments, Druck et al. (2008) compares traditional labeled data and *labeled features* (which can be used to build feature marginal distributions). That study finds that given the same amount of time, human annotation in the form of labeled features and classifiers trained using GE criteria outperform human annotation of traditional labeled instances and maximum likelihood training. For the structured output case, Mann and McCallum (2008) has shown that expectations over features for CRF learning, similar to the prototypes proposed in Haghighi and Klein (2006b), are more effective when used with GE than similar numbers of labeled tokens used to train a CRF. Druck et al. (2009a) extends these methods to conditional random field dependency parsing models, and shows that in that case as well feature marginal distributions can be effectively used to guide training.

A few groups have investigated related methods for incorporating expectation constraints. Ganchev et al. (2009) use expectation constraints over aligned sentences and a source-language parser induce dependency grammar on a target language, using a generative method related to expectation-maximization and a discriminative model closely related to GE criteria. Bellare et al. (2009) presents an alternative objective function to learn using expectation constraints over unlabeled data.

Since the emphasis is on reducing human annotation time, it is a clear question as to whether active learning can be applied to help choose labeled features or expectation constraints. Druck

5. The mathematics is unchanged for expectation constraints over any single features, but the experiments concern only this simple scenario.

et al. (2009b) pursues this question and uses active learning to choose which features to use with GE criteria. Along those lines, Liang et al. (2009) proposes a notion of 'measurements' to encapsulate the variety of weakly labeled data, and uses active learning to guide which measurements are provided from the human annotator to guide learning.

4. GE Criteria for Log-linear Models

In this section, we describe how to apply the GE criteria proposed above to conditionally trained log-linear models, starting with conditional maximum-entropy models, aka multinomial logistic regression models (Berger et al., 1996). In these models, there are k scalar feature functions $\psi_k(z,y)$, and the probability of the label y for input x is calculated by

$$p(y|x;\theta) = \frac{1}{Z(x)} \exp\left(\sum_k \theta_k \psi_k(x,y)\right),$$

where $Z(x) = \sum_{y'} \exp(\sum_k \theta_k \psi_k(x,y'))$ is the partition function. Given training data $\mathcal{D}$, the model is trained by maximizing the log-likelihood of the labels (with a Gaussian prior for regularization):

$$\begin{aligned} O(\theta;\mathcal{D}) &= \log L(\theta;\mathcal{D}) \\ &= \sum_{d\in\mathcal{D}} \log p(y_d|x_d;\theta) - \frac{\sum_k \theta_k^2}{2\sigma^2}. \end{aligned}$$

This can be done by gradient methods (Malouf, 2002), where the gradient of the likelihood is

$$\frac{\partial}{\partial\theta_k} O(\theta;\mathcal{D}) = \sum_d \left(\psi_k(x_d,y_d) - \sum_y p(y|x_d;\theta)\psi_k(x_d,y)\right) + \frac{\theta_k}{\sigma^2}.$$

For semi-supervised discriminative training, we augment the objective function by adding the generalized expectation criteria objective function terms.

$$\begin{aligned} O(\theta;D,U) &= L(\theta;\mathcal{D}) + G(\theta;\mathcal{U}) \\ &= \sum_d \log p(y_d|x_d);\theta) - \frac{\sum_k \theta_k^2}{2\sigma^2} - \lambda D(\tilde{g}_{x,y}||E_{\mathcal{U}}[E_{p(y|x;\theta)}[G(x,y)]]). \end{aligned}$$

Note that here the side information comes in the expectation constraints $\tilde{g}_{x,y}$ which specify particular priors for model marginal. In practice, we find that the hyper-parameters do not need to be extensively tuned. In particular, λ does not need tuning for each data set, and can be set simply to $\lambda = 10 \times$ # labeled examples.[6]

The form of the GE criteria lends itself to optimization by gradient based methods. After dropping terms which are constant with respect to the partial derivative, we are left with:

$$\begin{aligned} \frac{\partial}{\partial\theta_k} G(\theta;\mathcal{U}) &\propto \frac{\partial}{\partial\theta_k} \sum_y \tilde{g}_{x,y} \log \sum_{x\in\mathcal{U}} p(y|x;\theta) G(x,y) \\ &= \sum_y \left(\frac{\tilde{g}_{x,y}}{\sum_{x\in\mathcal{U}} p(y|x;\theta) G(x,y)}\right) \sum_{x\in\mathcal{U}} \frac{\partial}{\partial\theta_k} p(y|x;\theta) G(x,y) \\ &= \sum_y \left(\frac{\tilde{g}_{x,y}}{\sum_{x\in\mathcal{U}} p(y|x;\theta) G(x,y)}\right) \sum_{x\in U} p(y|x;\theta) G(x,y) \left(\psi_k(x,y) - \sum_{y'} p(y'|x;\theta)\psi_k(x)\right). \end{aligned}$$

6. As support for this value of λ, notice that the KL-divergence is significantly smaller than the likelihood as the likelihood is proportional to the number of examples, while the KL-divergence is not.

GE criteria aren't convex, and this can be shown by a contradictory example. Take a simple version of the GE criteria: $G(\theta;\mathcal{U}) = \sum_y \log \sum_x p(y|x;\theta)$. In this setting, for an arbitrary label y_i you can find parameter settings where $\forall x, p(y_i|x) = 1$, by having a parameter $\theta = \{\theta_k = \infty, \forall j \neq k, \theta_j = 0\}$ where $\psi_k(x,y) = \mathbf{1}\{y = y_i\}$. In this setting, it's pretty clear that multiple optima exist, and that other settings of θ yield smaller values of $G(\theta;\mathcal{U})$.

Label regularization can occasionally find a degenerate solution where, rather than the expectation of all instances matching the input distribution, instead, the distribution over labels for *each instance* will match the given distribution on every example. For example, given a three class classification task, if the labeled class distribution $\hat{p}_j(y) = \{.5,.35,.15\}$, it will find a solution such that $\tilde{p}(y;\theta) = \{.5,.35,.15\}$ for every instance. As a result, all the test instances will be assigned the same label.

One solution, appealing to 0/1 loss, would be to simply measure and match the expectation over winning class counts, but this is not differentiable. So instead, we make $p(y|x;\theta)$ more peaked using a less than 1.

$$p(y|x;\theta) \propto \exp\left(\frac{1}{T}\sum_k \theta_k \psi_k(x)\right).$$

This is differentiable and thus amenable to many gradient ascent methods. In practice we find that this meta-parameter does not require fine-tuning. Across all data sets we simply use $T = 0.1$ for multi-class problems and $T = 1$ for binary classification problems, and we find this to work well.

4.1 CRF Training

The previous section has shown the application of generalized expectation criteria to classification models. However, GE can additionally be applied to structured models. In this section, we examine the case of linear chain structured conditional random fields (Lafferty et al., 2001), and derive the GE gradient for this model.

Linear-chain CRFs are a discriminative probabilistic model over sequences $\mathbf{x} = \langle x_1..x_n\rangle$ of feature vectors and label sequences $\mathbf{y} = \langle y_1..y_n\rangle$, where $|\mathbf{x}| = |\mathbf{y}| = n$, and each label $y_i \in s$. This model is analogous to maximum entropy models for structured outputs, where expectations can be efficiently calculated by dynamic programming. For a linear-chain CRF of Markov order one

$$p(\mathbf{y}|\mathbf{x};\theta) = \frac{1}{Z(\mathbf{x})}\exp\left(\sum_k \theta_k \Psi_k(\mathbf{x},\mathbf{y})\right),$$

where $\Psi_k(\mathbf{x},\mathbf{y}) = \sum_i \psi_k(\mathbf{x}, y_i, y_{i+1}, i)$, and the partition function $Z(\mathbf{x}) = \sum_{\mathbf{y}'} \exp(\sum_k \theta_k \Psi_k(\mathbf{x},\mathbf{y}'))$. Given training data $\mathcal{D}$, the model is trained by maximizing the log-likelihood,

$$O(\theta;\mathcal{D}) = \sum_d \log p(\mathbf{y}_d|\mathbf{x}_d;\theta) - \frac{\sum_k \theta_k^2}{2\sigma^2},$$

by gradient-based methods where the gradient of the likelihood is (similar to the non-structured case):

$$\frac{\partial}{\partial\theta_k} O(\theta;D) = \sum_d \left(\Psi_k(\mathbf{x}_d,\mathbf{y}_d) - \sum_{\mathbf{y}} p(\mathbf{y}|\mathbf{x}_d;\theta)\Psi_k(\mathbf{x}_d,\mathbf{y})\right) + \frac{\theta_k}{\sigma^2}.$$

The second term (the expected counts of the features given the model) can be computed in a tractable amount of time, since according to the Markov assumption, the feature expectations can be rewritten:

$$\sum_{\mathbf{y}} p(\mathbf{y}|\mathbf{x};\theta)\Psi_k(\mathbf{x},\mathbf{y}) = \sum_i \sum_{y_i,y_{i+1}} p(y_i,y_{i+1}|\mathbf{x};\theta)\psi_k(\mathbf{x},y_i,y_{i+1},i)\,.$$

A dynamic program (the forward/backward algorithm) then computes in time $O(n|s|^2)$ all the needed probabilities $p_\theta(y_i,y_{i+1})$, where n is the sequence length, and $|s|$ is the number of labels.

4.2 Semi-supervised training with Generalized Expectation Criteria

To add unlabeled data regularization to the CRF training, just as with the maximum entropy model, we augment the objective function with the regularization term:

$$\begin{aligned} O(\theta;\mathcal{D},\mathcal{U}) =& L(\theta;\mathcal{D}) + G(\theta;\mathcal{U}) \\ =& \sum_d \log p(\mathbf{y}_d|\mathbf{x}_d;\theta) - \frac{\sum_k \theta_k^2}{2\sigma^2} - \lambda D(\tilde{g}_{x,y}||E_{\mathcal{U}}[E_{p(\mathbf{y}|\mathbf{x};\theta)}[\sum_i G(\mathbf{x},y_i)]])\,. \end{aligned}$$

Note that we restrict the constraint function to functions over one output label, $G(\mathbf{x},y_i)$. Druck et al. (2009a) has looked at extending the method to arbitrary constraint functions $G(\mathbf{x},\mathbf{y})$, but here we only consider constraint functions over functions of one label.

The derivation of the gradient for $G(\theta;\mathcal{U})$ is somewhat more complicated than in the unstructured case, but follows roughly the same line. s is the set of permissible output labels. $\mathbf{y}_{(m=s)} = \{\mathbf{y} : y_m = s\}$. The gradient is then:

$$\begin{aligned} \frac{\partial}{\partial\theta_k} G(\theta;\mathcal{U}) \propto& \frac{\partial}{\partial\theta_k} \sum_s \tilde{g}_{\mathbf{x},s} \log \sum_{\mathbf{x}\in\mathcal{U}} \sum_m \sum_{\mathbf{y}_{(m=s)}} p(\mathbf{y}_{(m=s)}|\mathbf{x}) G(\mathbf{x},s) \\ =& \sum_s \left(\frac{\tilde{g}_{\mathbf{x},s}}{\sum_{\mathbf{x}\in\mathcal{U},m,\mathbf{y}_{(m=s)}} p(\mathbf{y}_{(m=s)}|\mathbf{x}) G(\mathbf{x},s)} \right) \sum_{\mathbf{x}\in\mathcal{U}} \sum_m \sum_{\mathbf{y}_{(m=s)}} \frac{\partial}{\partial\theta_k} p(\mathbf{y}_{(m=s)}|\mathbf{x}) G(\mathbf{x},s) \\ \texttt{Now define:} \frac{\tilde{g}}{G} =& \left(\frac{\tilde{g}_{\mathbf{x},s}}{\sum_{\mathbf{x}\in\mathcal{U},m,\mathbf{y}_{(m=s)}} p(\mathbf{y}_{(m=s)}|\mathbf{x}) G(\mathbf{x},s)} \right) \\ =& \sum_s \frac{\tilde{g}}{G} \sum_{\mathbf{x}\in\mathcal{U}} \sum_m \sum_{\mathbf{y}_{(m=s)}} p(\mathbf{y}_{(m=s)}|\mathbf{x}) G(\mathbf{x},s) \left(\Psi_k(\mathbf{x},\mathbf{y}_{(m=s)}) - \sum_{\mathbf{y}'} p(\mathbf{y}'|\mathbf{x}) \Psi_k(\mathbf{x},\mathbf{y}) \right) \\ =& \sum_s \frac{\tilde{g}}{G} \sum_{\mathbf{x}\in\mathcal{U}} \sum_m \sum_{\mathbf{y}_{(m=s)}} p(\mathbf{y}_{(m=s)}|\mathbf{x}) G(x,s) \Psi_k(\mathbf{x},\mathbf{y}_{(m=s)}) \\ & - \sum_s \frac{\tilde{g}}{G} \sum_{\mathbf{x}\in\mathcal{U}} \sum_m \sum_{\mathbf{y}_{(m=s)}} p(\mathbf{y}_{(m=s)}|\mathbf{x}) G(\mathbf{x},s) \sum_{\mathbf{y}'} p(\mathbf{y}'|\mathbf{x}) \Psi_k(\mathbf{x},\mathbf{y}) \Bigg) \\ =& \sum_s \frac{\tilde{g}}{G} \sum_{\mathbf{x}\in\mathcal{U}} \left(\sum_i \sum_{y_i,y_{i+1}} \psi_k(\mathbf{x},y_i,y_{i+1},i) \sum_m p(y_i,y_{i+l},y_m=s|\mathbf{x}) G(\mathbf{x},s) \right) \\ & - \sum_s \frac{\tilde{g}}{G} \sum_{\mathbf{x}\in\mathcal{U}} \left(\sum_i \sum_{y_i,y_{i+1}} \psi_k(\mathbf{x},y_i,y_{i+1},i) \right) \left(\sum_m p(y_m=s|\mathbf{x}) G(\mathbf{x},s) \right)\,. \end{aligned}$$

After combining terms and rearranging we arrive at the final form of the gradient:

$$= \sum_{\mathbf{x}\in\mathbf{U}} \sum_{i} \sum_{y_i, y_{i+1}} \psi_k(\mathbf{x}, y_i, y_{i+1}, i) \times \sum_{s} \frac{\tilde{g}}{G} \left(\sum_{m} p(y_i, y_{i+1}, y_m = s|\mathbf{x};\theta) G(\mathbf{x}, s) - p(y_i, y_{i+1}|\mathbf{x};\theta) \sum_{m} p(y_m = s|\mathbf{x};\theta) G(\mathbf{x}, s) \right).$$

Here, the second term is easily obtainable from forward/backward, but the first term is a little more complicated to compute. Computing this term naively would require multiple runs of constrained forward/backward. Here we propose a more efficient method that requires only one run of forward/backward.[7] For the sake of simplicity, we omit the constraint function $G(\mathbf{x}, s)$; its addition is trivial. First we decompose the probability into two parts:

$$\sum_{m} p(y_i, y_{i+1}, y_m = s|\mathbf{x};\theta) = \sum_{m=1}^{i} p(y_i, y_{i+1}, y_m = s|\mathbf{x};\theta) + \sum_{m=i+1}^{n} p(y_i, y_{i+1}, y_m = s|\mathbf{x};\theta).$$

Similar to forward/backward we build a lattice of intermediate results that then can be used to calculate the quantity of interest:

$$\begin{aligned}
&\sum_{m=1}^{i} p(y_i, y_{i+1}, y_m = s|\mathbf{x};\theta) \\
&= p(y_i, y_{i+1}|\mathbf{x};\theta)\delta(y_i, s) + \sum_{m=1}^{i-1} p(y_i, y_{i+1}, y_m = s|\mathbf{x};\theta) \\
&= p(y_i, y_{i+1}|\mathbf{x};\theta)\delta(y_i, s) + \left(\sum_{y_{i-1}} \sum_{m=1}^{i-1} p(y_{i-1}, y_i, y_m = s|\mathbf{x};\theta) \right) p(y_{i+1}|y_i, \mathbf{x};\theta).
\end{aligned}$$

For each label s, it requires one pass to create a lattice with $\sum_{m=1}^{i-1} p(y_{i-1}, y_i, y_m = s|\mathbf{x};\theta)$ for all pairs (y_i, y_{i+1}). $\sum_{m=i+1}^{n} p(y_{i-1}, y_i, y_m = s|\mathbf{x};\theta)$ can be computed in the same fashion. To compute the lattices it takes time $O(n|s|^2)$, and one lattice must be computed for each label so the total time is $O(n|s|^3)$.

5. Experimental Results for Classifiers

We present two sets of experiments: experiments on maximum entropy models and conditional random fields for the special case of generalized expectation criteria, *label regularization*. For this set of experiments, we evaluate on five different data sets, and compare against seven different semi-supervised and supervised-only methods. We present learning curves, where the amount of labeled training data is gradually increased from one instance per class up to thousands of instances and demonstrate that generalized expectation criteria are able to show improvements for both types of scenarios. We present experiments with noisy expected distributions, and show that the method is robust with respect to a variety of settings for λ and temperature. We do not vary the gaussian regularizer, but leave a default value. Unpublished experiments by G. Druck[8] have suggested that

7. Kakade et al. (2002) present a related method that computes $p(y_{1..i} = s_{1..i}|y_{i+1} = s)$.

CoNLL03	100k	100k	114,264	9

Table 1: The data sets are complex: they have dramatic class skews, highly inter-dependent features, and large amounts of data. The SecStr data set has 315 atomic features, and 45k features when pairwise feature conjunctions are used.

while gaussian regularization can have an effect for label regularization, for more complicated GE variants it doesn't dramatically affect performance. We begin training with parameters set at 0 (even though the objective function may not be convex).

5.1 Experimental Set-up

First, we examine a protein secondary structure prediction task (**SecStr**), as extensively evaluated in Chapelle et al. (2006), compare with the published results and show that label regularization is able to outperform previous methods. Next, we examine three especially difficult natural language processing tasks: the CoNLL03 named-entity recognition task (**CoNLL03**), Part of speech tagging of the Wall Street Journal (**POS**), and the 2007 BiocreativeII evaluation (**BIOII**), using a sliding window classifier.[9] Finally, one of the main targets for semi-supervised learning is text classification (Nigam et al., 2006), and we evaluate on the simulated/real auto/aviation (**SRAA**) task. The tasks are large in scale, with up to hundreds of thousands of instances and features (see Table 1). They have complex characteristics such as heavily inter-dependent features and highly skewed class distributions.

Across all of the experiments, for supervised comparisons, we compare with naïve Bayes and maximum entropy models, for semi-supervised comparisons we compare with naïve Bayes trained with EM and maximum entropy models trained with entropy regularization. On some tasks, in particular the sliding window NLP tasks, the number of features per instance varied dramatically, and so we used document length normalization for the naïve Bayes approaches as we found it to significantly improve accuracy. On the secondary structure prediction (**SecStr**), we had access to published results for a supervised SVM using a radial-basis function (RBF) kernel, a Cluster Kernel (Weston et al., 2006) and a graph based-method, the Quadratic Cost Criterion with Class Mean Normalization (Bengio et al., 2006) trained using various data sub-sampling schemes (Delalleau et al., 2006): a random sampler and two smarter variations. Presumably, training a graph-based method on the entire unlabeled training set would have been technically infeasible.

For **CoNLL03**, **POS**, **BIOII**, and **SRAA**, we performed inductive learning, splitting the data randomly into two sections, training and test. From the training set, we randomly chose some instances to be labeled and set the remainder to be hidden. Out of those hidden, we then select a

9. The sliding window classifier makes independent decisions for each element in the sequence. While finite-state methods could also be applied in these cases, the cost of training label regularization would be prohibitive, and we found that these methods work well.

	# Labeled Instances		
	2	100	1000
SVM (supervised)		55.41	**66.29**
Cluster Kernel		57.05	65.97
QC randsub (CMN)		57.68	59.16
QC smartonly (CMN)		57.86	59.29
QC smartsub (CMN)		57.74	59.16
Naive Bayes (supervised)	52.42% (± 0.4)	57.12% (± 0.7)	64.47% (± 0.2)
Naive Bayes EM	50.79% (± 1.5)	57.34% (± 1.1)	57.60% (± .009)
MaxEnt (supervised)	52.42% (± 0.5)	56.74% (± 1.1)	65.43% (± 0.3)
MaxEnt + Ent. Min.	49.40% (± 2.1)	54.45% (± 1.8)	58.28% (± 0.1)
MaxEnt + GE	**57.08%** (± .03)	**58.51%** (± 0.4)	65.44% (± 0.3)

Table 2: Label regularization outperforms other semi-supervised learning methods at 100 labeled data points. At one instance per class, its performance is better than the *supervised* SVM and maximum entropy model at 100. Standard error is reported for experiments that were run locally. Other experimental performance is taken from the literature.

fixed number to use for unsupervised learning. We then evaluate the model on the hidden test data. We repeat this evaluation five times for each of the models.

The **SecStr** task was set up in what is commonly called transductive learning, where the model is evaluated on hidden training data. For this task, the labeled/unlabeled splits were provided with the data from Chapelle et al. (2006) and evaluation is on hidden training data. In order to provide a somewhat more fair comparison with the RBF kernels used by the other methods on this task, the feature set used by the maximum entropy model and naïve Bayes models is augmented by pairwise feature conjunctions.[10]

For the maximum entropy model trained with entropy regularization, after some experimentation, we weighted its contribution to the objective function with

$$\lambda = \text{\# labeled data points / \# unlabeled data points}.$$

This was shown to yield relatively good performance. For the first set of experiments, we use label proportions estimated from all of the data, corresponding to a use-case where a user gives this knowledge to the system during training. Section 5.3 presents experiments showing robustness to noisy label proportions both when smoothed towards a uniform distribution and when sampled from a limited number of training examples. Across the experiments, we observed that label regularization trains in time linear in the amount of unlabeled data, and since the resulting model is parametric, it is linear in the number of features for evaluation.

5.2 Learning Curves

For the first set of experiments, we experimented with varying the number of supervised training example, while keeping the unlabeled data set size the same (with sizes of the unlabeled data shown

10. Though, as one anonymous reviewer noted, this makes them strictly more expressive then kernel methods with quadratic features.

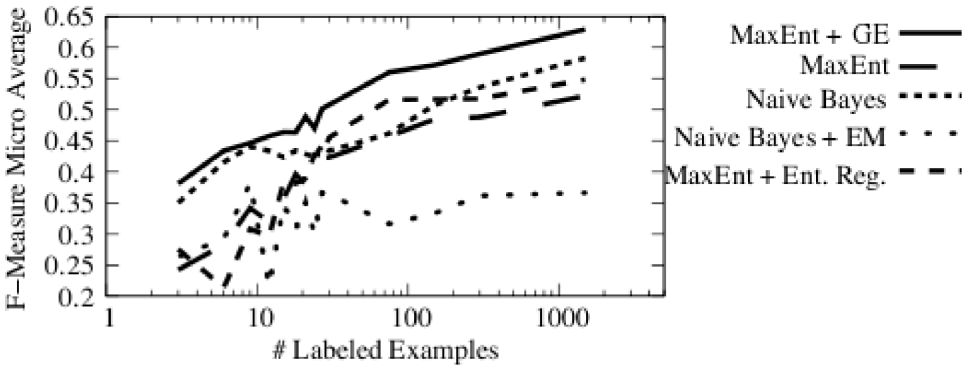

Figure 1: BIOII: Label regularization (GE) outperforms all other methods. The x-axis represents increasing numbers of labeled data instances. The y-axis is the F-measure micro average across all classes.

in Table 1). We added examples in a balanced way, going from 1 example per class up to 500 examples per class (when possible). For each data point we ran 5 trials, where the data was partitioned into training/test/unlabeled uniformly at random. The sole exception was for the **SecStr** data where the data splits and tests were pre-specified.

As Table 2 shows, for **SecStr**, label regularization outperforms the other methods at 100 labeled points, and approaches the cluster kernel method on 1000 points. While performance results were not available for the other methods for two instances per class, we ran label regularization for this case and found that it outperforms the *supervised* SVM and maximum entropy model when they are trained with 100 labeled points. In these experiments QC is not run over the complete data (presumably because of scalability problems), but operates on a subset, either selected randomly (randsub) or in a smarter fashion (smartonly and smartsub), while the label regularization method uses the complete data.

Figures 1, 2, 3, and 4 show classifier performance using a fixed amount of unlabeled data as greater amounts of labeled data is added. Label regularization yields significant benefits over the other methods for **POS**, **BIOII**, and **CoNLL03** for all amounts of labeled data. Label regularization on **SRAA** shows a benefit over the fully supervised maximum entropy model but its accuracy is not as high as that obtained by the EM-trained naïve Bayes learner. This may be partly explained by the fact that the baseline performance of the discriminative maximum entropy model is much lower than the generative naïve Bayes model, so that label regularization starts off at a considerable deficit.

While alternative methods often result in degredations of performance over their supervised counter parts (EM, entropy regularization, cluster kernels), in these experiments label regularization consistently yielded improved accuracy. Additionally, the benefit of label regularization is more apparent as the feature sets and numbers of unlabeled instances increase, with the least improvements on one of the simplest tasks, the **SRAA** text classification task.

These experiments demonstrate that label regularization can at least match, and in many cases beat, alternative methods of semi-supervised learning, given minimal additional information and access to large samples of unlabeled data. The successes of GE suggest more investigation of addi-

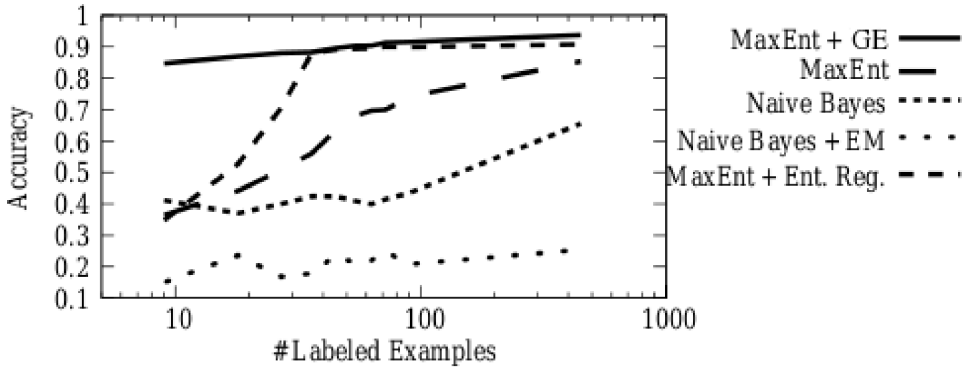

Figure 2: CoNLL03: Label regularization (GE) outperforms all other methods. The x-axis represents increasing numbers of labeled instances per class, and the y-axis is accuracy.

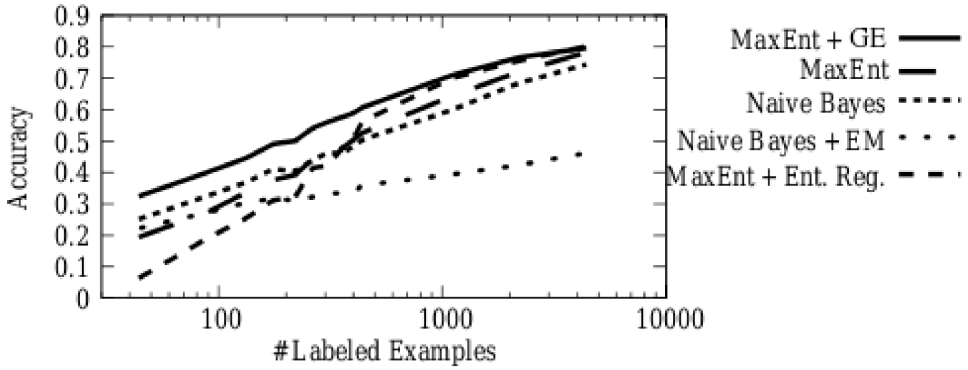

Figure 3: POS: Label regularization (GE) outperforms all other methods, though performance improvements over supervised maximum entropy methods appear to level off at 1300 labeled instances.

tional, alternative modalities of supervision which will generate data that can be added to supervised classifiers and combined with unlabeled data in order to improve performance.

5.3 Noisy Priors

The previous section assumes that the system has accurate knowledge of the distributions over the labels. In this section, we perform a sensitively analysis by gradually smoothing the class distribution until it reaches a uniform distribution. We add noisy counts ν to the true counts $c(y)$:

$$\hat{p}_j(\mathbf{y})(y) = \frac{c(y)+\nu}{\sum_{y'}(c(y')+\nu)}.$$

As more noise is added, the input distribution converges to uniform.

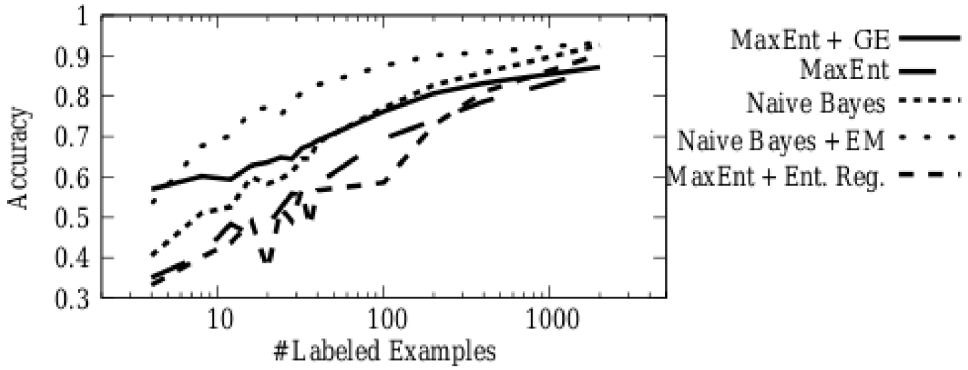

Figure 4: SRAA: Label regularization (GE) outperforms its supervised maximum entropy counterpart and entropy regularization and is the winner at one labeled instance per lass. After that, naïve Bayes EM is the clear winner.

Figure 5 demonstrates the effect of increasing noise in the system. At $\nu = 1{,}000$, the majority class probability drops from 84% to 80% and there is almost no loss of performance. At $\nu = 10{,}000$ are added, the majority class probability drops to 61% and there is only a slight loss of performance. At $\nu = 1e07$ the majority class probability has dropped to 11%, a virtually uniform distribution, and performance has leveled off. These results are encouraging as they suggest that relatively large changes (of 20% absolute, 27% relative) can be tolerated without major losses in accuracy. Even when the human has no domain knowledge to contribute, label distribution estimates of sufficient accuracy should be obtainable from a reasonably small number of labeled examples.

To test this assumption, we performed another set of experiments, where instead of smoothing the input distributions towards a uniform distribution, we sampled them from the data, varying the number of instances used in the sample. These points were sampled from the data, and then the data was partitioned into test/train/unlabel splits. Figure 6 and 7 demonstrate the effect of sampled distributions, as opposed to distributions smoothed towards a uniform distribution. For the **CoNLL3** data set, as can be seen in Figure 6, after sampling from 1000 points, the performance of the classifier doesn't get worse, suggesting that only a small amount of prior knowledge or labeling is necessary for determining accurate input distributions. With the **POS** data, it appears that as you increase the number of points used to compute the sample performance improves, though it appears to begin to level out at 1000 points. Because this data set is significantly smaller, we were unable to continue running experiments with larger numbers of sampled points to evaluate when the performance begins to level out.

5.4 Robustness

Along with robustness in the face of noise from the estimated label proportions, the model is robust to changes in λ and temperature. As can be seen in Figure 8, λ and temperature have a wide plateau over which their performance is stable. At some extreme values of λ and temperature, the performance degrades, and can drop below supervised performance. This trend was observed for 500 labeled examples (shown in the figure), as well as in cases when there as little as one

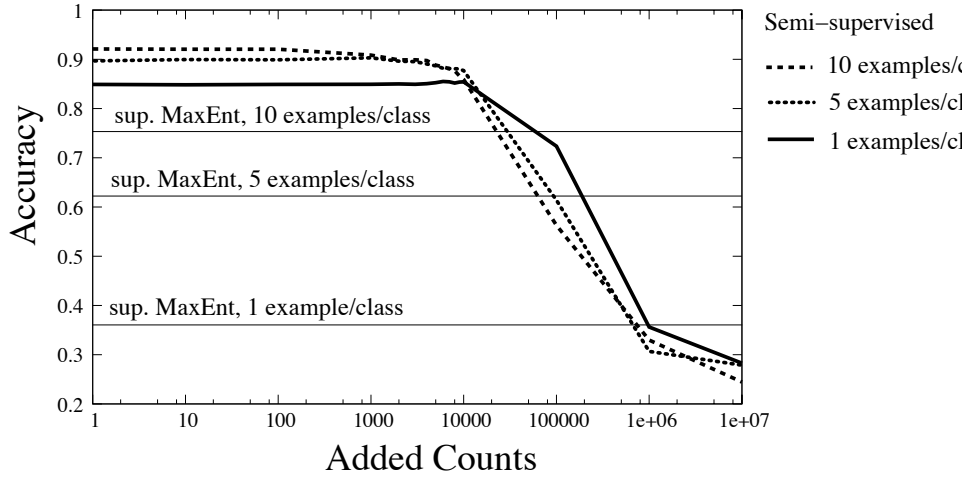

Figure 5: CoNLL03: The x-axis represents increasing amount of noise towards a uniform distribution. On this data set, the majority class is 84% of the instances, and so the uniform distribution is an extremely poor approximation. Performance suffers little when the majority class proportion is erroneously given as 61%($\nu = 10,000$)

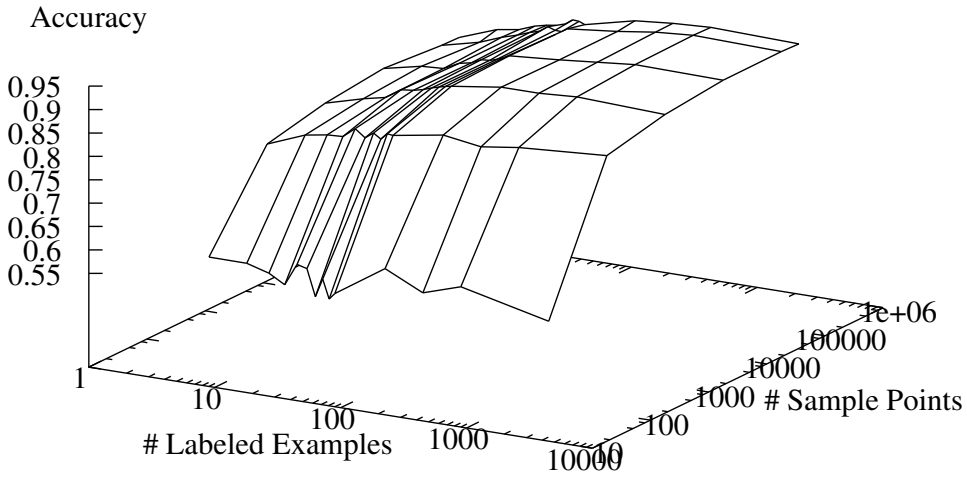

Figure 6: CoNLL03: An input label distribution with sampling noise. After 1000 points, sampling from more points doesn't appear to lead to performance improvements.

labeled example for a number of the data sets. For other semi-supervised techniques such as entropy regularization, extensive tuning is required across for each individual data set and labeled/unlabeled data set sizes in order to improve upon supervised-only performance (Jiao et al., 2006).

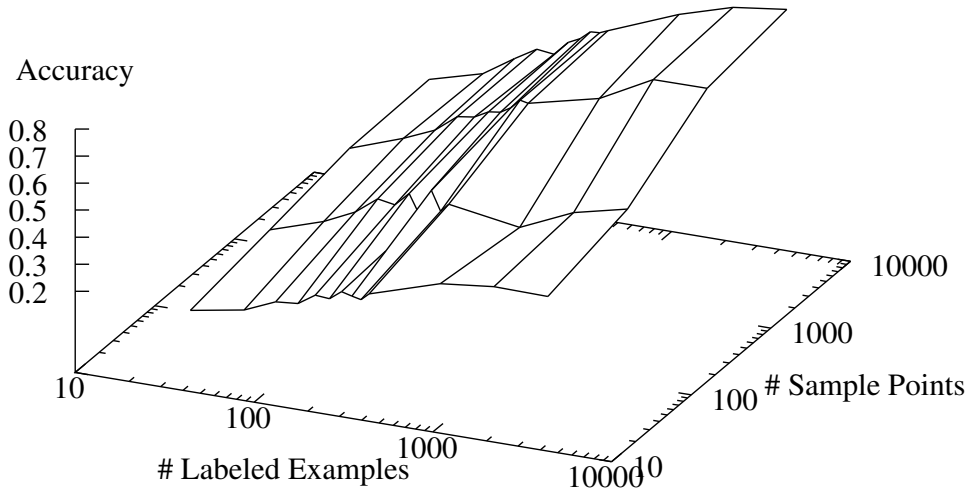

Figure 7: POS: An input label distribution with sampling noise. Since POS has many classes (44), access to an accurate sampling distribution has a larger impact on performance, and the graph suggests that even higher precision in sampling would lead to higher accuracy. Note that we were unable to sample as many points as in the previous example beause of limited amounts of available data.

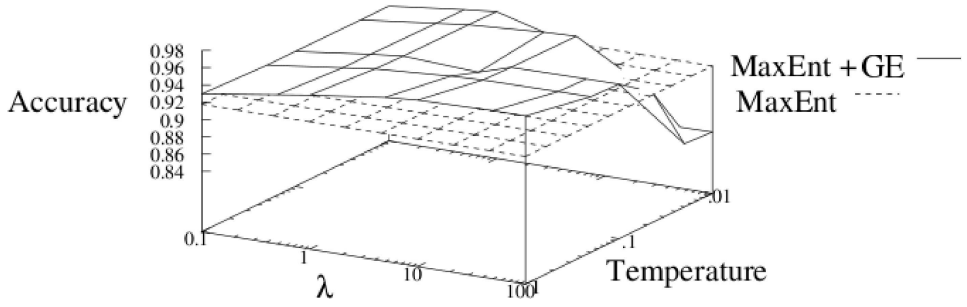

Figure 8: CoNLL03: For a wide range of λ and temperature the performance is similar and surpasses the purely supervised performance.

5.5 Running Time

Figure 9 shows the running time per optimization iteration for the two largest tasks, **CoNLL** and **BIOII**. The slope variation between the running times can be accounted for by the number of features in each of the data sets.

5.6 Mechanism of Effect

One question that needs to be addressed is whether label regularization is improving performance solely by adjusting the label proportions or operating in some other fashion. Though certainly correcting label proportions is one pathway for improved performance we have two pieces of evidence that additional learning is happening in the model. First, when we allow other classifiers access to

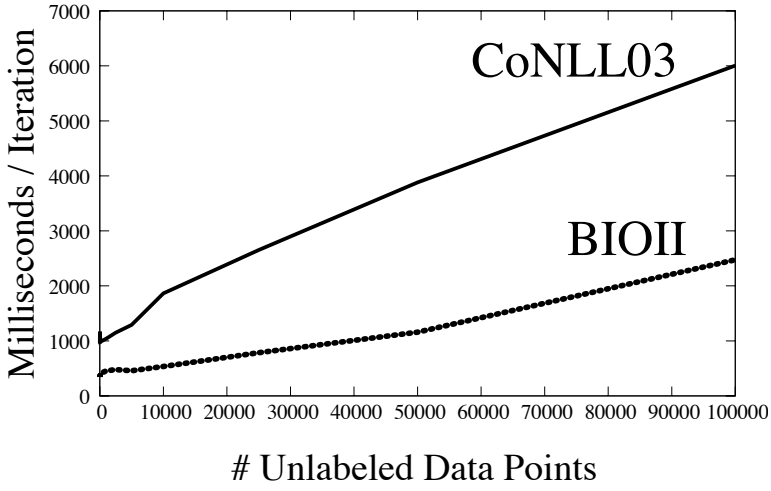

Figure 9: Label regularization is linear in the number of unlabeled examples, without requiring sub-sampling.

the label proportions, they are unable to reach the same gains as achieved with GE. For example, in all of the experiments the naïve Bayes classifier has its label prior fixed to the input distribution as it is subsequently trained with EM, yet it typically fails to reach the same level of performance as achieved with the GE methods. Second, Druck et al. (2008) reports results of experiments using GE criteria where the input distributions were only allowed to affect the features they were conditioned on (corresponding to only being able to adjust the label proportions). In these experiments, when GE could only adjust the features specified by the input distributions it achieved significantly worse results, thus indicating that learning parameter values for features not directly conditioned by the input distributions has a dramatic effect on classifier accuracy.

5.7 Combining Label Regularization and Entropy Regularization

Generalized expectation criteria can often be easily combined with other models. Any semi-supervised model in the parametric model family, such as expected gradient methods (Salakhutdinov et al., 2003), can be easily combined with GE, and certain generative models such as naïve MRFs (Druck et al., 2007) can be simply combined as well. More distantly, just as various models can be augmented with regularization terms (as in ridge regression for linear regression models), GE may be augmented in the same way. In this paper we used a Gaussian prior and minimized KL-divergence from input distributions with gradient methods here, in other cases it might require an alternative penalty term from the input distributions and a different minimization technique.

Here we examine combining label regularization with entropy regularization where the objective function is augmented with more than one regularization criterion. For many of the experiments, combining label regularization and entropy regularization does not lead to improvements. Two exceptions were experiments on **SRAA** and the **SecStr** data sets. Notably, on **SecStr**, combined entropy regularization and label regularization yields a performance of 66.30, a level which matches the performance of the supervised radial-basis SVM and beats all other unsupervised methods. For **SRAA**, Figure 10 shows that when entropy regularization is added to label regularization, there

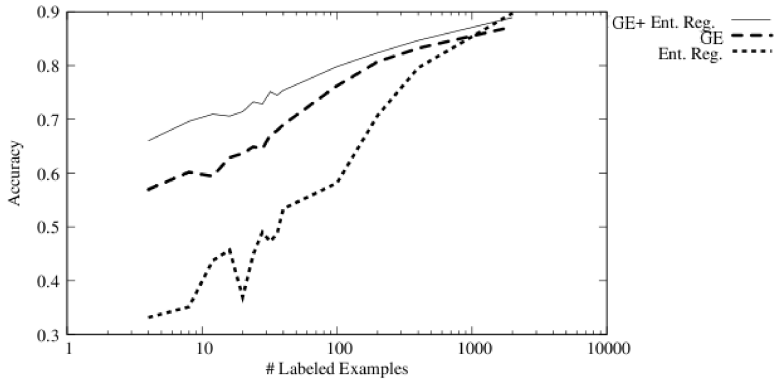

Figure 10: SRAA: Combining label regularization and entropy regularization can be easily accomplished, and yields improvements over label regularization alone for this data set.

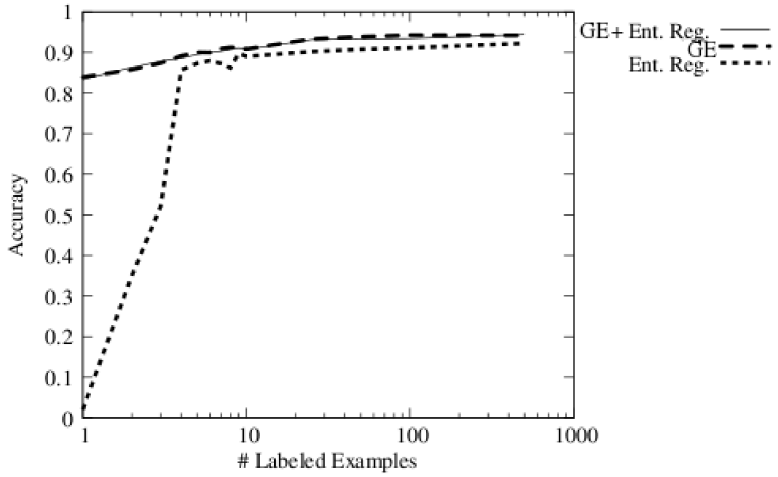

Figure 11: CoNLL03: On this data set, combining label regularization and entropy regularization does not lead to any benefit. The GE+Entropy regularization curve exactly overlaps the GE curve.

can sometimes be a benefit over the use of label regularization or entropy regularization alone. In comparison, Figure 11 shows that there is little or no difference in performance when entropy regularization is combined with label regularization in the case of **CoNLL03**.

6. Experimental Results for Conditional Random Fields

In this section, we examine the performance of label regularization for conditional random fields. We look at two data sets, Craigslist Apartment listings, and citation data. We compare against two previous methods for semi-supervised learning of conditional random fields, entropy regularization and the clustering method proposed by Miller et al. (2004) in Section 6.3. We demonstrate that label regularization can achieve higher accuracy than purely supervised training, and can beat or match

MRF (prototypes)	53.7%
MRF (prototypes) + cluster	71.5%
HMM supervised only (100)	74.4%
CRF supervised only (100)	75.8% ($\pm$ 0.3)
CRF supervised (100) + Ent. Reg. (2k)	76.7% ($\pm$ 0.4)
CRF supervised (100) + GE (2k)	77.1% ($\pm$ 0.3)

Table 3: APT: A CRF trained semi-supervised with 100 labeled examples and 2k unlabeled exampled has the highest performance, beating the strictly supervised CRF and the CRF trained semi-supervised with entropy regularization. Standard error is shown in parentheses for experiments run locally.

the performance of entropy regularization or clustering. We do not vary the gaussian regularizer, but leave a default value. We begin training with parameters set at 0 (even though the objective function may not be convex). Later experiments start from a model initialized by a non-structured classifier trained with GE, which we observed to yield higher accuracy (Mann and McCallum, 2008).

6.1 Apartment Listings

First we examine performance on the apartment data set (**APT**) initially presented by Grenager et al. (2005) and later examined by Haghighi and Klein (2006b), with label regularization. This data was collected in June 2004 from craigslist.com, and consists of 302 hand-labeled ads where each ad is labeled with 12 fields (e.g., SIZE, RENT, NEIGHBORHOOD, FEATURES). The average ad has 119 tokens in 8.7 fields.

For this task, sliding window models perform poorly as the fields are "sticky," (i.e., the best way to predict the next label is from the previous label). We set label regularization λ as before, but set the entropy regularization λ to 0.01 times the number of labeled examples divided by the number of unlabeled examples. For these experiments we used 2,000 unlabeled apartments listings.

We performed minimal feature engineering, using only standard capitalization and word class features (e.g., "digits"). We additionally used a feature that is the exact token string of the previous word. The use of flexible, non-independent features demonstrates the benefit of the greater expressive power of discriminatively trained CRFs; with these features alone, the CRF out-performs the supervised HMM.

Table 3 compares the performance of our system relative to previous supervised and semi-supervised systems,[11] where at the maximum amount of training data, label regularization achieves a 1.3% accuracy improvement over the purely supervised CRF, and a 0.4% accuracy improvement over semi-supervised learning via entropy regularization.

Table 4 shows learning curve performance for the CRF with a variety of different settings. With accurate input distributions, the CRF trained with label regularization achieves the highest performance, for all but with one example, where entropy regularization is the highest performer. Label regularization gives a 8% absolute accuracy improvement at the lower levels of training data and a 1.3% boost (a 5% relative error reduction) for a highly trained sequence model. Unlike entropy

11. We did not implement the ad-hoc boundary pre-processing and post-processing as is performed by the unsupervised MRF. These boundary features gave a 3% improvement for Haghighi and Klein (2006b).

# Supervised	Supervised	Entropy Regularization	GE: Estimated Priors	GE: Accurate Priors
1	41.2% (± 1.7)	44.3% (± 0.3)	41.3% (± 1.7)	**45.7%** (± 1.7)
5	48.4% (± 1.8)	45.8% (± 1.1)	51.9% (± 1.6)	**56.2%** (± 0.6)
10	55.9% (± 1.3)	58.0% (± 2.5)	57.5% (± 1.2)	**63.0 %** (± 0.2)
50	71.7% (± 0.5)	**74.1 %** (± 0.2)	73.7 % (± 0.4)	74.0 % (± 0.6)
100	75.8% (± 0.3)	76.7 % (± 0.4)	**77.4 %** (± 0.2)	77.1 % (± 0.3)

Table 4: APT: Use of input distributions estimated from limited labeled data yields smaller improvements over the true distributions, but still improves over the strictly supervised accuracy, and at large levels of training data, nearly matches the accuracy achieved by the true distributions. Standard error is shown in parentheses for the experiments.

# Supervised	Supervised	Entropy Regularization	GE: Estimated Priors	GE: Accurate Priors
1	24.9% (± 3.6)	17.5% (± 3.2)	25.5% (± 3.8)	**37.3%** (± 2.1)
5	52.4% (± 0.5)	27.0% (± 2.7)	52.4% (± 5.6)	**54.7%** (± 0.5)
10	56.1% (± 0.6)	35.2% (± 3.3)	55.5% (± 0.7)	**57.9%** (± 0.4)
50	67.8% (± 0.6)	66.5% (± 0.8)	67.5% (± 0.3)	**68.0%** (± 0.6)
100	72.7% (± 0.5)	**73.5%** (± 0.5)	72.4% (± 0.3)	72.0% (± 0.6)

Table 5: CITE: Label regularization (GE) is able to significantly improve on the purely supervised cases at very low levels of training data. At higher levels of training data, it makes less of an impact. Standard error is shown in parentheses for the experiments.

regularization, label regularization improves over supervised learning across all amounts of training data.

In addition to testing with accurate proportions, we also examined performance when input distributions were read directly off of the minimal training label sequence. When these noisy input distributions were used, the performance was less than with entropy regularization at lower levels of training data, but it still provided consistent gains in performance across all training settings.

6.2 Citation Data

In addition to experiments on apartment data, we also ran experiments on citation data (**CITE**) as given by Grenager et al. (2005). This data set consists of 500 hand-annotated citations taken from the reference sections of different computer science papers. Each citation is annotated with 13 fields (e.g., AUTHOR, TITLE, DATE, JOURNAL), and on average the citation has 35 tokens annotated with 5.5 fields. For this experiment we used 1,000 unlabeled examples, with $\lambda = 1$ times the number of unlabeled data points, and the entropy regularizer set as before. On this set of data, as shown in Table 5, label regularization gives a slight win at low levels of training data, but at higher levels, it does not provide any improvement. Entropy regularization unfortunately consistently decreases performance. Here, estimating the input distributions from the minimal training data leads to performance decreases beyond supervised training. The difference between the two data sets suggest that more work is needed to understand in what situations label regularization can be expected to work well.

# Supervised	Supervised	Supervised + Clustering	GE	GE + Clustering
1	41.2% (± 1.7)	44.5% (± 0.9)	45.7% (± 1.7)	**50.0%** (± 0.3)
5	48.4% (± 1.8)	54.3% (± 1.8)	56.2% (± 0.6)	**58.9%** (± 1.1)
10	55.9% (± 1.3)	61.2% (± 1.5)	63.0 % (± 0.2)	**64.4%** (± 0.9)
50	71.7% (± 0.5)	**74.1%** (± 0.5)	74.0 % (± 0.6)	**74.1%** (± 0.3)
100	75.8% (± 0.3)	**77.6%** (± 0.1)	77.1 % (± 0.3)	**77.6%** (± 0.2)

Table 6: APT: Using clustering features gives an additional gain to label regularization for low levels of training data, but it doesn't provide any additional benefit at higher levels of training data. Standard error is shown in parentheses for the experiments.

One thing to note from the experiments, is that as training data increases, the performance gap between the true distributions and estimated input distributions diminishes, until at 100 supervised examples, it almost matches the accuracy achieved by the true distributions. These results are at once encouraging and surprising, and suggest two possible reasons for improvement. First, perhaps the CRF isn't matching the proportions implicit in the labeled data, even though it has access to this information. Second, it suggests that the unlabeled data does have an effect beyond that of helping to readjust the classifier towards the input distributions. In particular, perhaps new features are being brought in by inclusion of the unlabeled examples.

The strengths of label regularization over entropy regularization are two-fold. First, GE gives an overall win in performance across many different levels of training data. Second, GE gives consistent gains. GE rarely performs worse than purely supervised training (when the input distributions are accurate), whereas the performance of entropy regularization is erratic, sometimes yielding a gain in performance, in other cases leading to a severe decrease in performance.

6.3 Clustering Features

Miller et al. (2004) proposes a method of using unsupervised clusters to improve performance. In his method, the unlabeled data undergoes word clustering, and then features corresponding to clusters are added during supervised training. A similar method can be applied here, in which features corresponding to unsupervised word clusters are added during semi-supervised training. We applied this method to the apartment data, and for very low level of training, found encouraging performance gains. Table 6 shows that for one labeled example, 2,000 unlabeled examples, and unsupervised clustering, the system achieves almost a 5% improvement by using these unsupervised cluster features (45.7% to 50.0%). At higher levels of training data, label regularization and clustering features interact poorly, and using them together lead to no improvement. While at lower levels of training data, label regularization is able to achieve more gains than the clustering method, at higher levels of performance, it only matches performance. We have also attempted to use sim features as proposed in Haghighi and Klein (2006b), but found these methods difficult to tune (e.g., what SVD rank to retain).

7. Conclusion

This paper has presented *generalized expectation criteria*, a simple, robust, scalable method for semi-supervised learning. This method penalizes models by divergence between the model's expectations over the unlabeled data and input conditional probabilities, which can be estimated from labeled data or given as a priori knowledge by a human annotator. An important special case, *label regularization* is empirically explored for the case of maximum entropy models where we find it to provide accuracy improvements over entropy regularization, naïve Bayes EM, Quadratic Cost Criterion (a representative graph-based method) and a cluster kernel SVM. We show that the method is robust to noise in the estimates of the input conditional probabilities, the meta-parameters need little or no tuning, and that it runs in linear time with increasing numbers of unlabeled examples.

We additionally present extensions of the method to conditional random fields. In this case, the gradient computation is complicated and requires the use of a specialized dynamic program which computes $\sum_j p(y_i, y_{i+1}, y_j = l|\mathbf{x};\theta)$. Conditional random fields trained with label regularization outperform alternative methods for semi-supervised training such as entropy regularization, and can achieve 1% to 8% improvement over supervised only approaches.

The simplicity of these methods, their robustness, and their high performance give promise that they may have a wide application and impact in use for semi-supervised machine learning.

Abstract

How can we generate realistic networks? In addition, how can we do so with a mathematically tractable model that allows for rigorous analysis of network properties? Real networks exhibit a long list of surprising properties: Heavy tails for the in- and out-degree distribution, heavy tails for the eigenvalues and eigenvectors, small diameters, and densification and shrinking diameters over time. Current network models and generators either fail to match several of the above properties, are complicated to analyze mathematically, or both. Here we propose a generative model for networks that is both mathematically tractable and can generate networks that have all the above mentioned structural properties. Our main idea here is to use a non-standard matrix operation, the *Kronecker product*, to generate graphs which we refer to as "Kronecker graphs".

First, we show that Kronecker graphs naturally obey common network properties. In fact, we rigorously *prove* that they do so. We also provide empirical evidence showing that Kronecker graphs can effectively model the structure of real networks.

We then present KRONFIT, a fast and scalable algorithm for fitting the Kronecker graph generation model to large real networks. A naive approach to fitting would take super-exponential time. In contrast, KRONFIT takes *linear* time, by exploiting the structure of Kronecker matrix multiplication and by using statistical simulation techniques.

Experiments on a wide range of large real and synthetic networks show that KRONFIT finds accurate parameters that very well mimic the properties of target networks. In fact, using just

four parameters we can accurately model several aspects of global network structure. Once fitted, the model parameters can be used to gain insights about the network structure, and the resulting synthetic graphs can be used for null-models, anonymization, extrapolations, and graph summarization.

Keywords: Kronecker graphs, network analysis, network models, social networks, graph generators, graph mining, network evolution

1. Introduction

What do real graphs look like? How do they evolve over time? How can we generate synthetic, but realistic looking, time-evolving graphs? Recently, network analysis has been attracting much interest, with an emphasis on finding patterns and abnormalities in social networks, computer networks, e-mail interactions, gene regulatory networks, and many more. Most of the work focuses on static snapshots of graphs, where fascinating "laws" have been discovered, including small diameters and heavy-tailed degree distributions.

In parallel with discoveries of such structural "laws" there has been effort to find mechanisms and models of network formation that generate networks with such structures. So, a good realistic network generation model is important for at least two reasons. The first is that it can generate graphs for extrapolations, hypothesis testing, "what-if" scenarios, and simulations, when real graphs are difficult or impossible to collect. For example, how well will a given protocol run on the Internet five years from now? Accurate network models can produce more realistic models for the future Internet, on which simulations can be run. The second reason is more subtle. It forces us to think about network properties that generative models should obey to be realistic.

In this paper we introduce Kronecker graphs, a generative network model which obeys all the main static network patterns that have appeared in the literature (Faloutsos et al., 1999; Albert et al., 1999; Chakrabarti et al., 2004; Farkas et al., 2001; Mihail and Papadimitriou, 2002; Watts and Strogatz, 1998). Our model also obeys recently discovered temporal evolution patterns (Leskovec et al., 2005b, 2007a). And, contrary to other models that match this combination of network properties (as for example, Bu and Towsley, 2002; Klemm and Eguíluz, 2002; Vázquez, 2003; Leskovec et al., 2005b; Zheleva et al., 2009), Kronecker graphs also lead to tractable analysis and rigorous proofs. Furthermore, the Kronecker graphs generative process also has a nice natural interpretation and justification.

Our model is based on a matrix operation, the *Kronecker product*. There are several known theorems on Kronecker products. They correspond exactly to a significant portion of what we want to prove: heavy-tailed distributions for in-degree, out-degree, eigenvalues, and eigenvectors. We also demonstrate how a Kronecker graphs can match the behavior of several real networks (social networks, citations, web, internet, and others). While Kronecker products have been studied by the algebraic combinatorics community (see, e.g., Chow, 1997; Imrich, 1998; Imrich and Klavžar, 2000; Hammack, 2009), the present work is the first to employ this operation in the design of network models to match real data.

Then we also make a step further and tackle the following problem: Given a large real network, we want to generate a synthetic graph, so that the resulting synthetic graph matches the properties of the real network as well as possible.

Ideally we would like: (a) A graph generation model that *naturally* produces networks where many properties that are also found in real networks naturally emerge. (b) The model parameter estimation should be fast and scalable, so that we can handle networks with millions of nodes. (c)

The resulting set of parameters should generate realistic-looking networks that match the statistical properties of the target, real networks.

In general the problem of modeling network structure presents several conceptual and engineering challenges: Which generative model should we choose, among the many in the literature? How do we measure the goodness of the fit? (Least squares don't work well for power laws, for subtle reasons!) If we use likelihood, how do we estimate it faster than in time quadratic on the number of nodes? How do we solve the node correspondence problem, that is, which node of the real network corresponds to what node of the synthetic one?

To answer the above questions we present KRONFIT, a fast and scalable algorithm for fitting Kronecker graphs by using the maximum likelihood principle. When calculating the likelihood there are two challenges: First, one needs to solve the node correspondence problem by matching the nodes of the real and the synthetic network. Essentially, one has to consider all mappings of nodes of the network to the rows and columns of the graph adjacency matrix. This becomes intractable for graphs with more than tens of nodes. Even when given the "true" node correspondences, just evaluating the likelihood is still prohibitively expensive for large graphs that we consider, as one needs to evaluate the probability of each possible edge. We present solutions to both of these problems: We develop a Metropolis sampling algorithm for sampling node correspondences, and approximate the likelihood to obtain a *linear* time algorithm for Kronecker graph model parameter estimation that scales to large networks with millions of nodes and edges. KRONFIT gives orders of magnitude speed-ups against older methods (20 minutes on a commodity PC, versus 2 days on a 50-machine cluster).

Our extensive experiments on synthetic and real networks show that Kronecker graphs can efficiently model statistical properties of networks, like degree distribution and diameter, while using only four parameters.

Once the model is fitted to the real network, there are several benefits and applications:

(a) *Network structure:* the parameters give us insight into the global structure of the network itself.

(b) *Null-model:* when working with network data we would often like to assess the significance or the extent to which a certain network property is expressed. We can use Kronecker graph as an accurate null-model.

(c) *Simulations:* given an algorithm working on a graph we would like to evaluate how its performance depends on various properties of the network. Using our model one can generate graphs that exhibit various combinations of such properties, and then evaluate the algorithm.

(d) *Extrapolations:* we can use the model to generate a larger graph, to help us understand how the network will look like in the future.

(e) *Sampling:* conversely, we can also generate a smaller graph, which may be useful for running simulation experiments (e.g., simulating routing algorithms in computer networks, or virus/worm propagation algorithms), when these algorithms may be too slow to run on large graphs.

(f) *Graph similarity:* to compare the similarity of the structure of different networks (even of different sizes) one can use the differences in estimated parameters as a similarity measure.

(g) *Graph visualization and compression:* we can compress the graph, by storing just the model parameters, and the deviations between the real and the synthetic graph. Similarly, for visualization purposes one can use the structure of the parameter matrix to visualize the backbone of the network, and then display the edges that deviate from the backbone structure.

(h) *Anonymization:* suppose that the real graph cannot be publicized, like, for example, corporate e-mail network or customer-product sales in a recommendation system. Yet, we would like to share our network. Our work gives ways to such a realistic, 'similar' network.

The current paper builds on our previous work on Kronecker graphs (Leskovec et al., 2005a; Leskovec and Faloutsos, 2007) and is organized as follows: Section 2 briefly surveys the related literature. In section 3 we introduce the Kronecker graph model, and give formal statements about the properties of networks it generates. We investigate the model using simulation in Section 4 and continue by introducing KRONFIT, the Kronecker graphs parameter estimation algorithm, in Section 5. We present experimental results on a wide range of real and synthetic networks in Section 6. We close with discussion and conclusions in Sections 7 and 8.

2. Relation to Previous Work on Network Modeling

Networks across a wide range of domains present surprising regularities, such as power laws, small diameters, communities, and so on. We use these patterns as sanity checks, that is, our synthetic graphs should match those properties of the real target graph.

Most of the related work in this field has concentrated on two aspects: properties and patterns found in real-world networks, and then ways to find models to build understanding about the emergence of these properties. First, we will discuss the commonly found patterns in (static and temporally evolving) graphs, and finally, the state of the art in graph generation methods.

2.1 Graph Patterns

Here we briefly introduce the network patterns (also referred to as properties or statistics) that we will later use to compare the similarity between the real networks and their synthetic counterparts produced by the Kronecker graphs model. While many patterns have been discovered, two of the principal ones are heavy-tailed degree distributions and small diameters.

Degree distribution: The degree-distribution of a graph is a power law if the number of nodes N_d with degree d is given by $N_d \propto d^{-\gamma} \quad (\gamma > 0)$ where γ is called the power law exponent. Power laws have been found in the Internet (Faloutsos et al., 1999), the Web (Kleinberg et al., 1999; Broder et al., 2000), citation graphs (Redner, 1998), online social networks (Chakrabarti et al., 2004) and many others.

Small diameter: Most real-world graphs exhibit relatively small diameter (the "small- world" phenomenon, or "six degrees of separation" Milgram, 1967): A graph has diameter D if every pair of nodes can be connected by a path of length at most D edges. The diameter D is susceptible to outliers. Thus, a more robust measure of the pair wise distances between nodes in a graph is the *integer effective diameter* (Tauro et al., 2001), which is the minimum number of links (steps/hops) in which some fraction (or quantile q, say $q = 0.9$) of all connected pairs of nodes can reach each other. Here we make use of *effective diameter* which we define as follows (Leskovec et al., 2005b). For each natural number h, let $g(h)$ denote the fraction of connected node pairs whose shortest

connecting path has length at most h, that is, at most h hops away. We then consider a function defined over all positive real numbers x by linearly interpolating between the points $(h, g(h))$ and $(h+1, g(h+1))$ for each x, where $h = \lfloor x \rfloor$, and we define the *effective diameter* of the network to be the value x at which the function $g(x)$ achieves the value 0.9. The effective diameter has been found to be small for large real-world graphs, like Internet, Web, and online social networks (Albert and Barabási, 2002; Milgram, 1967; Leskovec et al., 2005b).

Hop-plot: It extends the notion of diameter by plotting the number of reachable pairs $g(h)$ within h hops, as a function of the number of hops h (Palmer et al., 2002). It gives us a sense of how quickly nodes' neighborhoods expand with the number of hops.

Scree plot: This is a plot of the eigenvalues (or singular values) of the graph adjacency matrix, versus their rank, using the logarithmic scale. The scree plot is also often found to approximately obey a power law (Chakrabarti et al., 2004; Farkas et al., 2001). Moreover, this pattern was also found analytically for random power law graphs (Mihail and Papadimitriou, 2002; Chung et al., 2003).

Network values: The distribution of eigenvector components (indicators of "network value") associated to the largest eigenvalue of the graph adjacency matrix has also been found to be skewed (Chakrabarti et al., 2004).

Node triangle participation: Edges in real-world networks and especially in social networks tend to cluster (Watts and Strogatz, 1998) and form triads of connected nodes. Node triangle participation is a measure of transitivity in networks. It counts the number of triangles a node participates in, that is, the number of connections between the neighbors of a node. The plot of the number of triangles Δ versus the number of nodes that participate in Δ triangles has also been found to be skewed (Tsourakakis, 2008).

Densification power law: The relation between the number of edges $E(t)$ and the number of nodes $N(t)$ in evolving network at time t obeys the *densification power law* (DPL), which states that $E(t) \propto N(t)^a$. The *densification exponent* a is typically greater than 1, implying that the average degree of a node in the network is *increasing* over time (as the network gains more nodes and edges). This means that real networks tend to sprout many more edges than nodes, and thus densify as they grow (Leskovec et al., 2005b, 2007a).

Shrinking diameter: The effective diameter of graphs tends to shrink or stabilize as the number of nodes in a network grows over time (Leskovec et al., 2005b, 2007a). This is somewhat counterintuitive since from common experience as one would expect that as the volume of the object (a graph) grows, the size (i.e., the diameter) would also grow. But for real networks this does not hold as the diameter shrinks and then seems to stabilize as the network grows.

2.2 Generative Models of Network Structure

The earliest probabilistic generative model for graphs was the Erdős-Rényi (Erdős and Rényi, 1960) random graph model, where each pair of nodes has an identical, independent probability of being joined by an edge. The study of this model has led to a rich mathematical theory. However, as the model was not developed to model real-world networks it produces graphs that fail to match real networks in a number of respects (for example, it does not produce heavy-tailed degree distributions).

The vast majority of recent network models involve some form of *preferential attachment* (Barabási and Albert, 1999; Albert and Barabási, 2002; Winick and Jamin, 2002; Kleinberg et al.,

1999; Kumar et al., 1999; Flaxman et al., 2007) that employs a simple rule: new node joins the graph at each time step, and then creates a connection to an existing node u with the probability proportional to the degree of the node u. This leads to the "rich get richer" phenomena and to power law tails in degree distribution. However, the diameter in this model grows slowly with the number of nodes N, which violates the "shrinking diameter" property mentioned above.

There are also many variations of preferential attachment model, all somehow employing the "rich get richer" type mechanism, for example, the "copying model" (Kumar et al., 2000), the "winner does not take all" model (Pennock et al., 2002), the "forest fire" model (Leskovec et al., 2005b), the "random surfer model" (Blum et al., 2006), etc.

A different family of network methods strives for small diameter and local clustering in networks. Examples of such models include the *small-world* model (Watts and Strogatz, 1998) and the Waxman generator (Waxman, 1988). Another family of models shows that heavy tails emerge if nodes try to optimize their connectivity under resource constraints (Carlson and Doyle, 1999; Fabrikant et al., 2002).

In summary, most current models focus on modeling only one (static) network property, and neglect the others. In addition, it is usually hard to analytically analyze properties of the network model. On the other hand, the Kronecker graph model we describe in the next section addresses these issues as it matches multiple properties of real networks at the same time, while being analytically tractable and lending itself to rigorous analysis.

2.3 Parameter Estimation of Network Models

Until recently relatively little effort was made to fit the above network models to real data. One of the difficulties is that most of the above models usually define a mechanism or a principle by which a network is constructed, and thus parameter estimation is either trivial or almost impossible.

Most work in estimating network models comes from the area of social sciences, statistics and social network analysis where the *exponential random graphs*, also known as $p*$ model, were introduced (Wasserman and Pattison, 1996). The model essentially defines a log linear model over all possible graphs G, $p(G|\theta) \propto \exp(\theta^T s(G))$, where G is a graph, and s is a set of functions, that can be viewed as summary statistics for the structural features of the network. The $p*$ model usually focuses on "local" structural features of networks (like, for example, characteristics of nodes that determine a presence of an edge, link reciprocity, etc.). As exponential random graphs have been very useful for modeling small networks, and individual nodes and edges, our goal here is different in a sense that we aim to accurately model the structure of the network as a whole. Moreover, we aim to model and estimate parameters of networks with millions of nodes, while even for graphs of small size (> 100 nodes) the number of model parameters in exponential random graphs usually becomes too large, and estimation prohibitively expensive, both in terms of computational time and memory.

Regardless of a particular choice of a network model, a common theme when estimating the likelihood $P(G)$ of a graph G under some model is the challenge of finding the correspondence between the nodes of the true network and its synthetic counterpart. The node correspondence problem results in the factorially many possible matchings of nodes. One can think of the correspondence problem as a test of graph isomorphism. Two isomorphic graphs G and G' with differently assigned node IDs should have same likelihood $P(G) = P(G')$ so we aim to find an accurate mapping between the nodes of the two graphs.

SYMBOL	DESCRIPTION
G	Real network
N	Number of nodes in G
E	Number of edges in G
K	Kronecker graph (synthetic estimate of G)
K_1	Initiator of a Kronecker graphs
N_1	Number of nodes in initiator K_1
E_1	Number of edges in K_1 (the expected number of edges in $\mathcal{P}_1$, $E_1 = \sum \theta_{ij}$)
$G \otimes H$	Kronecker product of adjacency matrices of graphs G and H
$K_1^{[k]} = K_k = K$	k^{th} Kronecker power of K_1
$K_1[i,j]$	Entry at row i and column j of K_1
$\Theta = \mathcal{P}_1$	Stochastic Kronecker initiator
$\mathcal{P}_1^{[k]} = \mathcal{P}_k = \mathcal{P}$	k^{th} Kronecker power of $\mathcal{P}_1$
$\theta_{ij} = \mathcal{P}_1[i,j]$	Entry at row i and column j of $\mathcal{P}_1$
$p_{ij} = \mathcal{P}_k[i,j]$	Probability of an edge (i,j) in $\mathcal{P}_k$, that is, entry at row i and column j of $\mathcal{P}_k$
$K = R(\mathcal{P})$	Realization of a Stochastic Kronecker graph $\mathcal{P}$
$l(\Theta)$	Log-likelihood. Log-prob. that Θ generated real graph G, $\log P(G\|\Theta)$
$\hat{\Theta}$	Parameters at maximum likelihood, $\hat{\Theta} = \text{argmax}_\Theta P(G\|\Theta)$
σ	Permutation that maps node IDs of G to those of $\mathcal{P}$
a	Densification power law exponent, $E(t) \propto N(t)^a$
D	Diameter of a graph
N_c	Number of nodes in the largest weakly connected component of a graph
ω	Fraction of times `SwapNodes` permutation proposal distribution is used

Table 1: Table of symbols.

An ordering or a permutation defines the mapping of nodes in one network to nodes in the other network. For example, Butts (2005) used permutation sampling to determine similarity between two graph adjacency matrices, while Bezáková et al. (2006) used permutations for graph model selection. Recently, an approach for estimating parameters of the "copying" model was introduced (Wiuf et al., 2006), however authors also note that the class of "copying" models may not be rich enough to accurately model real networks. As we show later, Kronecker graph model seems to have the necessary expressive power to mimic real networks well.

3. Kronecker Graph Model

The Kronecker graph model we propose here is based on a recursive construction. Defining the recursion properly is somewhat subtle, as a number of standard, related graph construction methods fail to produce graphs that densify according to the patterns observed in real networks, and they also produce graphs whose diameters increase. To produce densifying graphs with constant/shrinking diameter, and thereby match the qualitative behavior of a real network, we develop a procedure that is best described in terms of the *Kronecker product* of matrices.

3.1 Main Idea

The main intuition behind the model is to create self-similar graphs, recursively. We begin with an *initiator* graph K_1, with N_1 nodes and E_1 edges, and by recursion we produce successively larger graphs $K_2, K_3, \ldots$ such that the k^{th} graph K_k is on $N_k = N_1^k$ nodes. If we want these graphs to exhibit a version of the Densification power law (Leskovec et al., 2005b), then K_k should have $E_k = E_1^k$ edges. This is a property that requires some care in order to get right, as standard recursive constructions (for example, the traditional Cartesian product or the construction of Barabási et al., 2001) do not yield graphs satisfying the densification power law.

It turns out that the *Kronecker product* of two matrices is the right tool for this goal. The Kronecker product is defined as follows:

Definition 1 (Kronecker product of matrices) *Given two matrices $\mathbf{A} = [a_{i,j}]$ and $\mathbf{B}$ of sizes $n \times m$ and $n' \times m'$ respectively, the Kronecker product matrix $\mathbf{C}$ of dimensions $(n \cdot n') \times (m \cdot m')$ is given by*

$$\mathbf{C} = \mathbf{A} \otimes \mathbf{B} \doteq \begin{pmatrix} a_{1,1}\mathbf{B} & a_{1,2}\mathbf{B} & \ldots & a_{1,m}\mathbf{B} \\ a_{2,1}\mathbf{B} & a_{2,2}\mathbf{B} & \ldots & a_{2,m}\mathbf{B} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n,1}\mathbf{B} & a_{n,2}\mathbf{B} & \ldots & a_{n,m}\mathbf{B} \end{pmatrix}.$$

We then define the Kronecker product of two graphs simply as the Kronecker product of their corresponding adjacency matrices.

Definition 2 (Kronecker product of graphs, Weichsel, 1962) *If G and H are graphs with adjacency matrices $A(G)$ and $A(H)$ respectively, then the Kronecker product $G \otimes H$ is defined as the graph with adjacency matrix $A(G) \otimes A(H)$.*

Observation 1 (Edges in Kronecker-multiplied graphs)

$$\textit{Edge } (X_{ij}, X_{kl}) \in G \otimes H \textit{ iff } (X_i, X_k) \in G \textit{ and } (X_j, X_l) \in H.$$

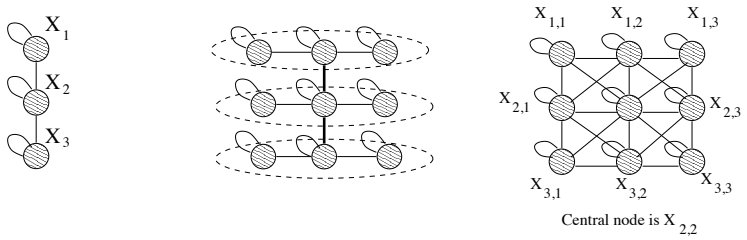
where X_{ij} and X_{kl} are nodes in $G \otimes H$, and X_i, X_j, X_k and X_l are the corresponding nodes in G and H, as in Figure 1.

The last observation is crucial, and deserves elaboration. Basically, each node in $G \otimes H$ can be represented as an ordered pair X_{ij}, with i a node of G and j a node of H, and with an edge joining X_{ij} and X_{kl} precisely when (X_i, X_k) is an edge of G and (X_j, X_l) is an edge of H. This is a direct consequence of the hierarchical nature of the Kronecker product. Figure 1(a–c) further illustrates this by showing the recursive construction of $G \otimes H$, when $G = H$ is a 3-node chain. Consider node $X_{1,2}$ in Figure 1(c): It belongs to the H graph that replaced node X_1 (see Figure 1(b)), and in fact is the X_2 node (i.e., the center) within this small H-graph.

We propose to produce a growing sequence of matrices by iterating the Kronecker product:

Definition 3 (Kronecker power) *The k^{th} power of K_1 is defined as the matrix $K_1^{[k]}$ (abbreviated to K_k), such that:*

$$K_1^{[k]} = K_k = \underbrace{K_1 \otimes K_1 \otimes \ldots K_1}_{k \text{ times}} = K_{k-1} \otimes K_1$$



(a) Graph K_1 (b) Intermediate stage (c) Graph $K_2 = K_1 \otimes K_1$

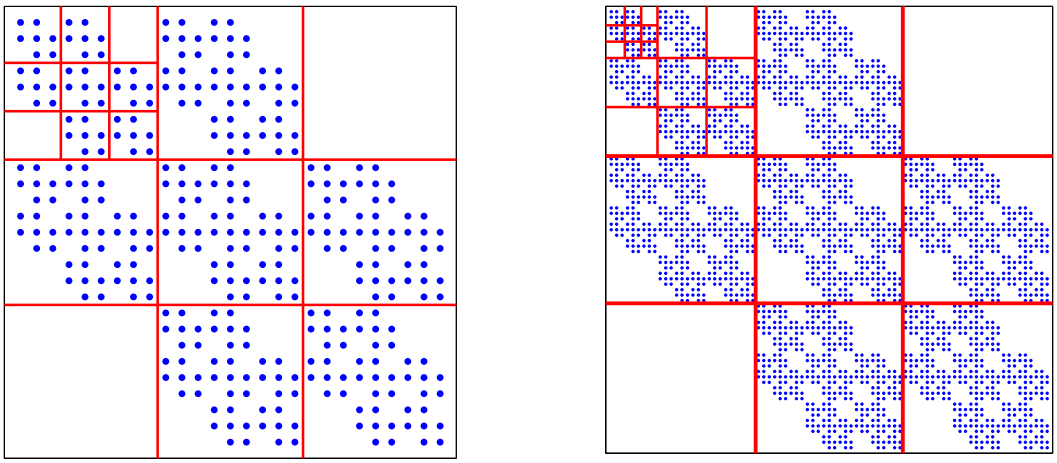
1	1	0
1	1	1
0	1	1

(d) Adjacency matrix of K_1

K_1	K_1	0
K_1	K_1	K_1
0	K_1	K_1

(e) Adjacency matrix of $K_2 = K_1 \otimes K_1$

Figure 1: *Example of Kronecker multiplication:* Top: a "3-chain" initiator graph and its Kronecker product with itself. Each of the X_i nodes gets expanded into 3 nodes, which are then linked using Observation 1. Bottom row: the corresponding adjacency matrices. See Figure 2 for adjacency matrices of K_3 and K_4.



(a) K_3 adjacency matrix (27×27) (b) K_4 adjacency matrix (81×81)

Figure 2: Adjacency matrices of K_3 and K_4, the 3^{rd} and 4^{th} Kronecker power of K_1 matrix as defined in Figure 1. Dots represent non-zero matrix entries, and white space represents zeros. Notice the recursive self-similar structure of the adjacency matrix.

Definition 4 (Kronecker graph) *Kronecker graph of order k is defined by the adjacency matrix* $K_1^{[k]}$*, where* K_1 *is the Kronecker initiator adjacency matrix.*

The self-similar nature of the Kronecker graph product is clear: To produce K_k from K_{k-1}, we "expand" (replace) each node of K_{k-1} by converting it into a copy of K_1, and we join these copies

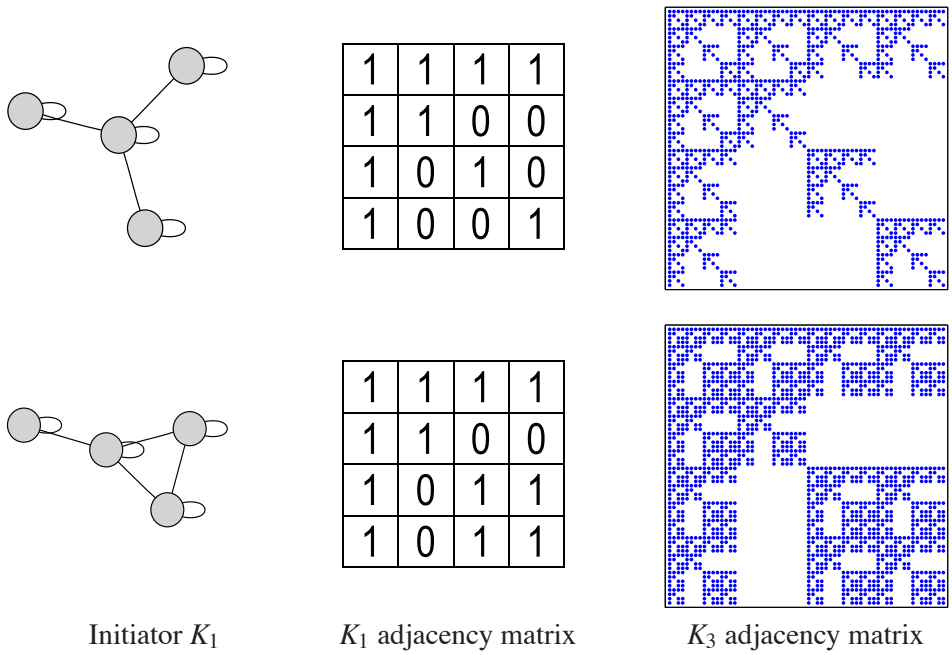


Figure 3: Two examples of Kronecker initiators on 4 nodes and the self-similar adjacency matrices they produce.

together according to the adjacencies in K_{k-1} (see Figure 1). This process is very natural: one can imagine it as positing that communities within the graph grow recursively, with nodes in the community recursively getting expanded into miniature copies of the community. Nodes in the sub-community then link among themselves and also to nodes from other communities.

Note that there are many different names to refer to Kronecker product of graphs. Other names for the Kronecker product are tensor product, categorical product, direct product, cardinal product, relational product, conjunction, weak direct product or just product, and even Cartesian product (Imrich and Klavžar, 2000).

3.2 Analysis of Kronecker Graphs

We shall now discuss the properties of Kronecker graphs, specifically, their degree distributions, diameters, eigenvalues, eigenvectors, and time-evolution. Our ability to prove analytical results about all of these properties is a major advantage of Kronecker graphs over other network models.

3.2.1 DEGREE DISTRIBUTION

The next few theorems prove that several distributions of interest are *multinomial* for our Kronecker graph model. This is important, because a careful choice of the initial graph K_1 makes the resulting multinomial distribution to behave like a power law or Discrete Gaussian Exponential (DGX) distribution (Bi et al., 2001; Clauset et al., 2007).

Theorem 5 (Multinomial degree distribution) *Kronecker graphs have multinomial degree distributions, for both in- and out-degrees.*

Proof Let the initiator K_1 have the degree sequence $d_1, d_2, \ldots, d_{N_1}$. Kronecker multiplication of a node with degree d expands it into N_1 nodes, with the corresponding degrees being $d \times d_1, d \times d_2, \ldots, d \times d_{N_1}$. After Kronecker powering, the degree of each node in graph K_k is of the form $d_{i_1} \times d_{i_2} \times \ldots d_{i_k}$, with $i_1, i_2, \ldots, i_k \in (1 \ldots N_1)$, and there is one node for each ordered combination. This gives us the multinomial distribution on the degrees of K_k. So, graph K_k will have multinomial degree distribution where the "events" (degrees) of the distribution will be combinations of degree products: $d_1^{i_1} d_2^{i_2} \ldots d_{N_1}^{i_{N_1}}$ (where $\sum_{j=1}^{N_1} i_j = k$) and event (degree) probabilities will be proportional to $\binom{k}{i_1 i_2 \ldots i_{N_1}}$. Note also that this is equivalent to noticing that the degrees of nodes in K_k can be expressed as the k^{th} Kronecker power of the vector $(d_1, d_2, \ldots, d_{N_1})$. ■

3.2.2 SPECTRAL PROPERTIES

Next we analyze the spectral properties of adjacency matrix of a Kronecker graph. We show that both the distribution of eigenvalues and the distribution of component values of eigenvectors of the graph adjacency matrix follow multinomial distributions.

Theorem 6 (Multinomial eigenvalue distribution) *The Kronecker graph K_k has a multinomial distribution for its eigenvalues.*

Proof Let K_1 have the eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_{N_1}$. By properties of the Kronecker multiplication (Loan, 2000; Langville and Stewart, 2004), the eigenvalues of K_k are the k^{th} Kronecker power of the vector of eigenvalues of the initiator matrix, $(\lambda_1, \lambda_2, \ldots, \lambda_{N_1})^{[k]}$. As in Theorem 5, the eigenvalue distribution is a multinomial. ■

A similar argument using properties of Kronecker matrix multiplication shows the following.

Theorem 7 (Multinomial eigenvector distribution) *The components of each eigenvector of the Kronecker graph K_k follow a multinomial distribution.*

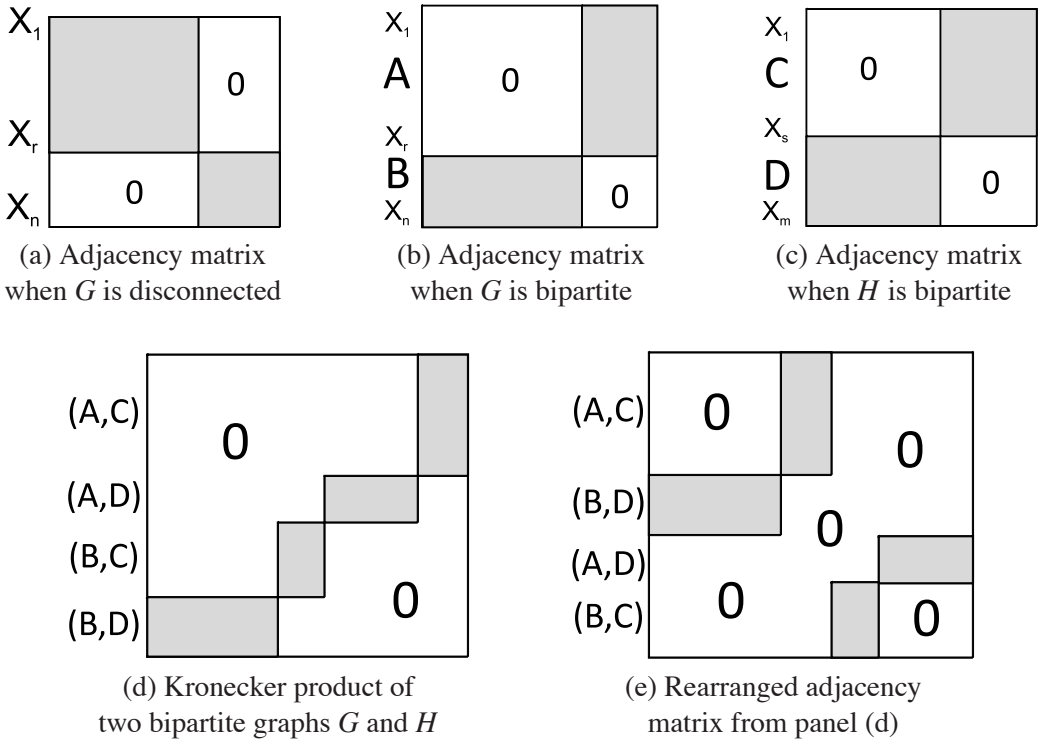
Proof Let K_1 have the eigenvectors $\vec{v}_1, \vec{v}_2, \ldots, \vec{v}_{N_1}$. By properties of the Kronecker multiplication (Loan, 2000; Langville and Stewart, 2004), the eigenvectors of K_k are given by the k^{th} Kronecker power of the vector: $(\vec{v}_1, \vec{v}_2, \ldots, \vec{v}_{N_1})$, which gives a multinomial distribution for the components of each eigenvector in K_k. ■

We have just covered several of the static graph patterns. Notice that the proofs were a direct consequences of the Kronecker multiplication properties.

3.2.3 CONNECTIVITY OF KRONECKER GRAPHS

We now present a series of results on the connectivity of Kronecker graphs. We show, maybe a bit surprisingly, that even if a Kronecker initiator graph is connected its Kronecker power can in fact be disconnected.

Lemma 8 *If at least one of G and H is a disconnected graph, then $G \otimes H$ is also disconnected.*



(a) Adjacency matrix when G is disconnected

(b) Adjacency matrix when G is bipartite

(c) Adjacency matrix when H is bipartite

(d) Kronecker product of two bipartite graphs G and H

(e) Rearranged adjacency matrix from panel (d)

Figure 4: Graph adjacency matrices. Dark parts represent connected (filled with ones) and white parts represent empty (filled with zeros) parts of the adjacency matrix. (a) When G is disconnected, Kronecker multiplication with any matrix H will result in $G \otimes H$ being disconnected. (b) Adjacency matrix of a connected bipartite graph G with node partitions A and B. (c) Adjacency matrix of a connected bipartite graph G with node partitions C and D. (e) Kronecker product of two bipartite graphs G and H. (d) After rearranging the adjacency matrix $G \otimes H$ we clearly see the resulting graph is disconnected.

Proof Without loss of generality we can assume that G has two connected components, while H is connected. Figure 4(a) illustrates the corresponding adjacency matrix for G. Using the notation from Observation 1 let graph let G have nodes $X_1, \ldots, X_n$, where nodes $\{X_1, \ldots X_r\}$ and $\{X_{r+1}, \ldots, X_n\}$ form the two connected components. Now, note that $(X_{ij}, X_{kl}) \notin G \otimes H$ for $i \in \{1, \ldots, r\}$, $k \in \{r+1, \ldots, n\}$, and all j, l. This follows directly from Observation 1 as (X_i, X_k) are not edges in G. Thus, $G \otimes H$ must at least two connected components. ■

Actually it turns out that both G and H can be connected while $G \otimes H$ is disconnected. The following theorem analyzes this case.

Theorem 9 *If both G and H are connected but bipartite, then $G \otimes H$ is disconnected, and each of the two connected components is again bipartite.*

Proof Again without loss of generality let G be bipartite with two partitions $A = \{X_1, \ldots X_r\}$ and $B = \{X_{r+1}, \ldots, X_n\}$, where edges exists only between the partitions, and no edges exist inside the

partition: $(X_i, X_k) \notin G$ for $i,k \in A$ or $i,k \in B$. Similarly, let H also be bipartite with two partitions $C = \{X_1, \ldots X_s\}$ and $D = \{X_{s+1}, \ldots, X_m\}$. Figures 4(b) and (c) illustrate the structure of the corresponding adjacency matrices.

Now, there will be two connected components in $G \otimes H$: 1^{st} component will be composed of nodes $\{X_{ij}\} \in G \otimes H$, where $(i \in A, j \in D)$ or $(i \in B, j \in C)$. And similarly, 2^{nd} component will be composed of nodes $\{X_{ij}\}$, where $(i \in A, j \in C)$ or $(i \in B, j \in D)$. Basically, there exist edges between node sets (A,D) and (B,C), and similarly between (A,C) and (B,D) but not across the sets. To see this we have to analyze the cases using Observation 1. For example, in $G \otimes H$ there exist edges between nodes (A,C) and (B,D) as there exist edges $(i,k) \in G$ for $i \in A, k \in B$, and $(j,l) \in H$ for $j \in C$ and $l \in D$. Similar is true for nodes (A,C) and (B,D). However, there are no edges cross the two sets, for example, nodes from (A,D) do not link to (A,C), as there are no edges between nodes in A (since G is bipartite). See Figures 4(d) and 4(e) for a visual proof. ■

Note that bipartite graphs are triangle free and have no self-loops. Stars, chains, trees and cycles of even length are all examples of bipartite graphs. In order to ensure that K_k is connected, for the remained of the paper we focus on initiator graphs K_1 with self loops on all of the vertices.

3.2.4 TEMPORAL PROPERTIES OF KRONECKER GRAPHS

We continue with the analysis of temporal patterns of evolution of Kronecker graphs: the densification power law, and shrinking/stabilizing diameter (Leskovec et al., 2005b, 2007a).

Theorem 10 (Densification power law) *Kronecker graphs follow the densification power law (DPL) with densification exponent* $a = \log(E_1)/\log(N_1)$.

Proof Since the k^{th} Kronecker power K_k has $N_k = N_1^k$ nodes and $E_k = E_1^k$ edges, it satisfies $E_k = N_k^a$, where $a = \log(E_1)/\log(N_1)$. The crucial point is that a is independent of k, and hence the sequence of Kronecker powers follows an exact version of the densification power law. ■

We now show how the Kronecker product also preserves the property of constant diameter, a crucial ingredient for matching the diameter properties of many real-world network data sets. In order to establish this, we will assume that the initiator graph K_1 has a self-loop on every node. Otherwise, its Kronecker powers may be disconnected.

Lemma 11 *If G and H each have diameter at most D and each has a self-loop on every node, then the Kronecker graph $G \otimes H$ also has diameter at most D.*

Proof Each node in $G \otimes H$ can be represented as an ordered pair (v,w), with v a node of G and w a node of H, and with an edge joining (v,w) and (x,y) precisely when (v,x) is an edge of G and (w,y) is an edge of H. (Note this exactly the Observation 1.) Now, for an arbitrary pair of nodes (v,w) and (v',w'), we must show that there is a path of length at most D connecting them. Since G has diameter at most D, there is a path $v = v_1, v_2, \ldots, v_r = v'$, where $r \leq D$. If $r < D$, we can convert this into a path $v = v_1, v_2, \ldots, v_D = v'$ of length exactly D, by simply repeating v' at the end for $D - r$ times. By an analogous argument, we have a path $w = w_1, w_2, \ldots, w_D = w'$. Now by the definition of the Kronecker product, there is an edge joining (v_i, w_i) and (v_{i+1}, w_{i+1}) for all $1 \leq i \leq D-1$, and so $(v,w) = (v_1,w_1), (v_2,w_2), \ldots, (v_D,w_D) = (v',w')$ is a path of length D connecting (v,w) to

(v', w'), as required. ■

Theorem 12 *If K_1 has diameter D and a self-loop on every node, then for every k, the graph K_k also has diameter D.*

Proof This follows directly from the previous lemma, combined with induction on k. ■

As defined in Section 2 we also consider the *effective diameter* D^*. We defined the q-effective diameter as the minimum D^* such that, for a q fraction of the reachable node pairs, the path length is at most D^*. The q-effective diameter is a more robust quantity than the diameter, the latter being prone to the effects of degenerate structures in the graph (e.g., very long chains). However, the q-effective diameter and diameter tend to exhibit qualitatively similar behavior. For reporting results in subsequent sections, we will generally consider the q-effective diameter with $q = 0.9$, and refer to this simply as the *effective diameter*.

Theorem 13 (Effective diameter) *If K_1 has diameter D and a self-loop on every node, then for every q, the q-effective diameter of K_k converges to D (from below) as k increases.*

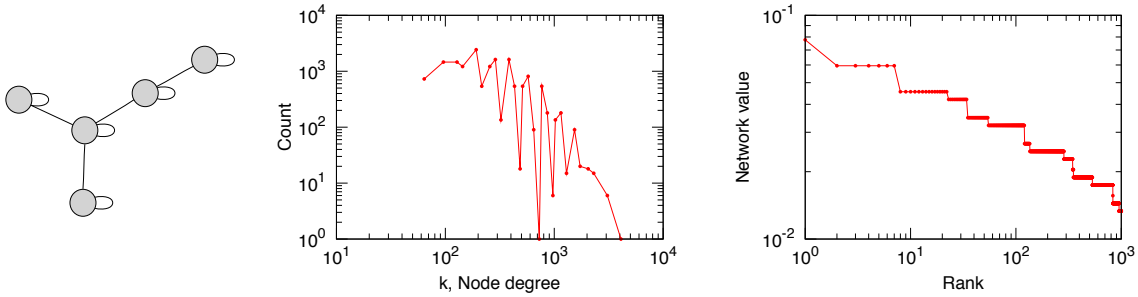
Proof To prove this, it is sufficient to show that for two randomly selected nodes of K_k, the probability that their distance is D converges to 1 as k goes to infinity.

We establish this as follows. Each node in K_k can be represented as an ordered sequence of k nodes from K_1, and we can view the random selection of a node in K_k as a sequence of k independent random node selections from K_1. Suppose that $v = (v_1, \ldots, v_k)$ and $w = (w_1, \ldots, w_k)$ are two such randomly selected nodes from K_k. Now, if x and y are two nodes in K_1 at distance D (such a pair (x, y) exists since K_1 has diameter D), then with probability $1 - (1 - \frac{1}{N_1^2})^k$, there is some index j for which $\{v_j, w_j\} = \{x, y\}$. If there is such an index, then the distance between v and w is D. As the expression $1 - (1 - \frac{1}{N_1^2})^k$ converges to 1 as k increases, it follows that the q-effective diameter is converging to D. ■

3.3 Stochastic Kronecker Graphs

While the Kronecker power construction discussed so far yields graphs with a range of desired properties, its discrete nature produces "staircase effects" in the degrees and spectral quantities, simply because individual values have large multiplicities. For example, degree distribution and distribution of eigenvalues of graph adjacency matrix and the distribution of the principal eigenvector components (i.e., the "network" value) are all impacted by this. These quantities are multinomially distributed which leads to individual values with large multiplicities. Figure 5 illustrates the staircase effect.

Here we propose a stochastic version of Kronecker graphs that eliminates this effect. There are many possible ways how one could introduce stochasticity into Kronecker graph model. Before introducing the proposed model, we introduce two simple ways of introducing randomness to Kronecker graphs and describe why they do not work.



(a) Kronecker initiator K_1 (b) Degree distribution of K_6 (6^{th} Kronecker power of K_1) (c) Network value of K_6 (6^{th} Kronecker power of K_1)

Figure 5: The "staircase" effect. Kronecker initiator and the degree distribution and network value plot for the 6^{th} Kronecker power of the initiator. Notice the non-smoothness of the curves.

Probably the simplest (but wrong) idea is to generate a large deterministic Kronecker graph K_k, and then uniformly at random flip some edges, that is, uniformly at random select entries of the graph adjacency matrix and flip them ($1 \rightarrow 0, 0 \rightarrow 1$). However, this will not work, as it will essentially superimpose an Erdős-Rényi random graph, which would, for example, corrupt the degree distribution—real networks usually have heavy tailed degree distributions, while random graphs have Binomial degree distributions. A second idea could be to allow a weighted initiator matrix, that is, values of entries of K_1 are not restricted to values $\{0,1\}$ but rather can be any non-negative real number. Using such K_1 one would generate K_k and then threshold the K_k matrix to obtain a binary adjacency matrix K, that is, for a chosen value of ε set $K[i,j] = 1$ if $K_k[i,j] > \varepsilon$ else $K[i,j] = 0$. This also would not work as the mechanism would selectively remove edges and thus the low degree nodes which would have low weight edges would get isolated first.

Now we define *Stochastic Kronecker graph model* which overcomes the above issues. A more natural way to introduce stochasticity to Kronecker graphs is to relax the assumption that entries of the initiator matrix take only binary values. Instead we allow entries of the initiator to take values on the interval $[0,1]$. This means now each entry of the initiator matrix encodes the probability of that particular edge appearing. We then Kronecker-power such initiator matrix to obtain a large stochastic adjacency matrix, where again each entry of the large matrix gives the probability of that particular edge appearing in a big graph. Such a stochastic adjacency matrix defines a probability distribution over all graphs. To obtain a graph we simply sample an instance from this distribution by sampling individual edges, where each edge appears independently with probability given by the entry of the large stochastic adjacency matrix. More formally, we define:

Definition 14 (Stochastic Kronecker graph) *Let $\mathcal{P}_1$ be a $N_1 \times N_1$* probability matrix*: the value $\theta_{ij} \in \mathcal{P}_1$ denotes the probability that edge (i,j) is present, $\theta_{ij} \in [0,1]$.*

Then k^{th} Kronecker power $\mathcal{P}_1^{[k]} = \mathcal{P}_k$, where each entry $p_{uv} \in \mathcal{P}_k$ encodes the probability of an edge (u,v).

To obtain a graph, an instance *(or* realization*), $K = R(\mathcal{P}_k)$ we include edge (u,v) in K with probability p_{uv}, $p_{uv} \in \mathcal{P}_k$.*

First, note that sum of the entries of $\mathcal{P}_1$, $\sum_{ij} \theta_{ij}$, can be greater than 1. Second, notice that in principle it takes $O(N_1^{2k})$ time to generate an instance K of a Stochastic Kronecker graph from the

probability matrix $\mathcal{P}_k$. This means the time to get a realization K is quadratic in the size of $\mathcal{P}_k$ as one has to flip a coin for each possible edge in the graph. Later we show how to generate Stochastic Kronecker graphs much faster, in the time *linear* in the expected number of edges in $\mathcal{P}_k$.

3.3.1 PROBABILITY OF AN EDGE

For the size of graphs we aim to model and generate here taking $\mathcal{P}_1$ (or K_1) and then explicitly performing the Kronecker product of the initiator matrix is infeasible. The reason for this is that $\mathcal{P}_1$ is usually dense, so $\mathcal{P}_k$ is also dense and one can not explicitly store it in memory to directly iterate the Kronecker product. However, due to the structure of Kronecker multiplication one can easily compute the probability of an edge in $\mathcal{P}_k$.

The probability p_{uv} of an edge (u,v) occurring in k-th Kronecker power $\mathcal{P} = \mathcal{P}_k$ can be calculated in $O(k)$ time as follows:

$$p_{uv} = \prod_{i=0}^{k-1} \mathcal{P}_1 \left[\left\lfloor \frac{u-1}{N_1^i} \right\rfloor (\mathrm{mod} N_1) + 1, \left\lfloor \frac{v-1}{N_1^i} \right\rfloor (\mathrm{mod} N_1) + 1 \right]. \quad (1)$$

The equation imitates recursive descent into the matrix $\mathcal{P}$, where at every level i the appropriate entry of $\mathcal{P}_1$ is chosen. Since $\mathcal{P}$ has N_1^k rows and columns it takes $O(k \log N_1)$ to evaluate the equation. Refer to Figure 6 for the illustration of the recursive structure of $\mathcal{P}$.

3.4 Additional Properties of Kronecker Graphs

Stochastic Kronecker graphs with initiator matrix of size $N_1 = 2$ were studied by Mahdian and Xu (2007). The authors showed a phase transition for the emergence of the giant component and another phase transition for connectivity, and proved that such graphs have constant diameters beyond the connectivity threshold, but are not searchable using a decentralized algorithm (Kleinberg, 1999).

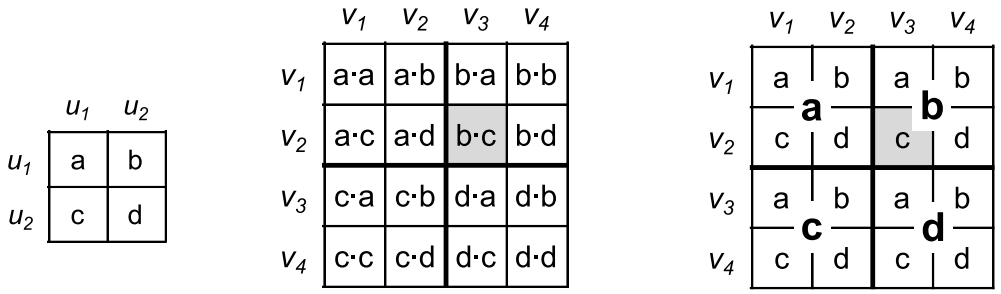
General overview of Kronecker product is given in Imrich and Klavžar (2000) and properties of Kronecker graphs related to graph minors, planarity, cut vertex and cut edge have been explored in Bottreau and Metivier (1998). Moreover, recently Tsourakakis (2008) gave a closed form expression for the number of triangles in a Kronecker graph that depends on the eigenvalues of the initiator graph K_1.

3.5 Two Interpretations of Kronecker Graphs

Next, we present two natural interpretations of the generative process behind the Kronecker graphs that go beyond the purely mathematical construction of Kronecker graphs as introduced so far.

We already mentioned the first interpretation when we first defined Kronecker graphs. One intuition is that networks are hierarchically organized into communities (clusters). Communities then grow recursively, creating miniature copies of themselves. Figure 1 depicts the process of the recursive community expansion. In fact, several researchers have argued that real networks are hierarchically organized (Ravasz et al., 2002; Ravasz and Barabási, 2003) and algorithms to extract the network hierarchical structure have also been developed (Sales-Pardo et al., 2007; Clauset et al., 2008). Moreover, especially web graphs (Dill et al., 2002; Dorogovtsev et al., 2002; Crovella and Bestavros, 1997) and biological networks (Ravasz and Barabási, 2003) were found to be self-similar and "fractal".

The second intuition comes from viewing every node of $\mathcal{P}_k$ as being described with an ordered sequence of k nodes from $\mathcal{P}_1$. (This is similar to the Observation 1 and the proof of Theorem 13.)



(a) 2×2 Stochastic Kronecker initiator $\mathcal{P}_1$

(b) Probability matrix $\mathcal{P}_2 = \mathcal{P}_1 \otimes \mathcal{P}_1$

(c) Alternative view of $\mathcal{P}_2 = \mathcal{P}_1 \otimes \mathcal{P}_1$

Figure 6: Stochastic Kronecker initiator $\mathcal{P}_1$ and the corresponding 2^{nd} Kronecker power $\mathcal{P}_2$. Notice the recursive nature of the Kronecker product, with edge probabilities in $\mathcal{P}_2$ simply being products of entries of $\mathcal{P}_1$.

Let's label nodes of the initiator matrix $\mathcal{P}_1$, $u_1, \ldots, u_{N_1}$, and nodes of $\mathcal{P}_k$ as $v_1, \ldots, v_{N_1^k}$. Then every node v_i of $\mathcal{P}_k$ is described with a sequence $(v_i(1), \ldots, v_i(k))$ of node labels of $\mathcal{P}_1$, where $v_i(l) \in \{u_1, \ldots, u_k\}$. Similarly, consider also a second node v_j with the label sequence $(v_j(1), \ldots, v_j(k))$. Then the probability p_e of an edge (v_i, v_j) in $\mathcal{P}_k$ is exactly:

$$p_e(v_i, v_j) = \mathcal{P}_k[v_i, v_j] = \prod_{l=1}^{k} \mathcal{P}_1[v_i(l), v_j(l)].$$

(Note this is exactly the Equation 1.)

Now one can look at the description sequence of node v_i as a k dimensional vector of attribute values $(v_i(1), \ldots, v_i(k))$. Then $p_e(v_i, v_j)$ is exactly the coordinate-wise product of appropriate entries of $\mathcal{P}_1$, where the node description sequence selects which entries of $\mathcal{P}_1$ to multiply. Thus, the $\mathcal{P}_1$ matrix can be thought of as the attribute similarity matrix, that is, it encodes the probability of linking given that two nodes agree/disagree on the attribute value. Then the probability of an edge is simply a product of individual attribute similarities over the k N_1-valued attributes that describe each of the two nodes.

This gives us a very natural interpretation of Stochastic Kronecker graphs: Each node is described by a sequence of categorical attribute values or features. And then the probability of two nodes linking depends on the product of individual attribute similarities. This way Kronecker graphs can effectively model homophily (nodes with similar attribute values are more likely to link) by $\mathcal{P}_1$ having high value entries on the diagonal. Or heterophily (nodes that differ are more likely to link) by $\mathcal{P}_1$ having high entries off the diagonal.

Figure 6 shows an example. Let's label nodes of $\mathcal{P}_1$ u_1, u_2 as in Figure 6(a). Then every node of $\mathcal{P}_k$ is described with an ordered sequence of k binary attributes. For example, Figure 6(b) shows an instance for $k = 2$ where node v_2 of $\mathcal{P}_2$ is described by (u_1, u_2), and similarly v_3 by (u_2, u_1). Then as shown in Figure 6(b), the probability of edge $p_e(v_2, v_3) = b \cdot c$, which is exactly $\mathcal{P}_1[u_2, u_1] \cdot \mathcal{P}_1[u_1, u_2] = b \cdot c$—the product of entries of $\mathcal{P}_1$, where the corresponding elements of the description of nodes v_2 and v_3 act as selectors of which entries of $\mathcal{P}_1$ to multiply.

Figure 6(c) further illustrates the recursive nature of Kronecker graphs. One can see Kronecker product as recursive descent into the big adjacency matrix where at each stage one of the entries

or blocks is chosen. For example, to get to entry (v_2, v_3) one first needs to dive into quadrant b following by the quadrant c. This intuition will help us in Section 3.6 to devise a fast algorithm for generating Kronecker graphs.

However, there are also two notes to make here. First, using a single initiator $\mathcal{P}_1$ we are implicitly assuming that there is one single and universal attribute similarity matrix that holds across all k N_1-ary attributes. One can easily relax this assumption by taking a different initiator matrix for each attribute (initiator matrices can even be of different sizes as attributes are of different arity), and then Kronecker multiplying them to obtain a large network. Here each initiator matrix plays the role of attribute similarity matrix for that particular attribute.

For simplicity and convenience we will work with a single initiator matrix but all our methods can be trivially extended to handle multiple initiator matrices. Moreover, as we will see later in Section 6 even a single 2×2 initiator matrix seems to be enough to capture large scale statistical properties of real-world networks.

The second assumption is harder to relax. When describing every node v_i with a sequence of attribute values we are implicitly assuming that the values of all attributes are uniformly distributed (have same proportions), and that every node has a unique combination of attribute values. So, all possible combinations of attribute values are taken. For example, node v_1 in a large matrix $\mathcal{P}_k$ has attribute sequence $(u_1, u_1, \ldots, u_1)$, and v_{N_1} has $(u_1, u_1, \ldots, u_1, u_{N_1})$, while the "last" node $v_{N_1^k}$ is has attribute values $(u_{N_1}, u_{N_1}, \ldots, u_{N_1})$. One can think of this as counting in N_1-ary number system, where node attribute descriptions range from 0 (i.e., "leftmost" node with attribute description $(u_1, u_1, \ldots, u_1)$) to N_1^k (i.e., "rightmost" node attribute description $(u_{N_1}, u_{N_1}, \ldots, u_{N_1})$).

A simple way to relax the above assumption is to take a larger initiator matrix with a smaller number of parameters than the number of entries. This means that multiple entries of $\mathcal{P}_1$ will share the same value (parameter). For example, if attribute u_1 takes one value 66% of the times, and the other value 33% of the times, then one can model this by taking a 3×3 initiator matrix with only four parameters. Adopting the naming convention of Figure 6 this means that parameter a now occupies a 2×2 block, which then also makes b and c occupy 2×1 and 1×2 blocks, and d a single cell. This way one gets a four parameter model with uneven feature value distribution.

We note that the view of Kronecker graphs where every node is described with a set of features and the initiator matrix encodes the probability of linking given the attribute values of two nodes somewhat resembles the Random dot product graph model (Young and Scheinerman, 2007; Nickel, 2008). The important difference here is that we multiply individual linking probabilities, while in Random dot product graphs one takes the sum of individual probabilities which seems somewhat less natural.

3.6 Fast Generation of Stochastic Kronecker Graphs

Generating a Stochastic Kronecker graph K on N nodes naively takes $O(N^2)$ time. Here we present a fast heuristic procedure that works well in practice and takes time *linear* in the number of edges to generate a graph. The intuition for fast generation of Stochastic Kronecker graphs comes from the recursive nature of the Kronecker product and is closely related to the R-MAT graph generator (Chakrabarti et al., 2004). In contrast to R-MAT Stochastic Kronecker graph initiator matrix encodes both the total number of edges in a graph and their structure. $\sum \theta_{ij}$ encodes the number of edges in the graph, while the proportions (ratios) of values θ_{ij} define how many edges each part of graph adjacency matrix will contain.

In order to illustrate the recursive nature of Kronecker graphs and to highlight the relation to R-MAT graph generator Figure 6 shows how probability matrix in panel (b) can be recursively decomposed as shown in panel (c) of Figure 6. To "arrive" to a particular edge (v_i, v_j) of $\mathcal{P}_k$ one has to make a sequence of k (in our case $k = 2$) decisions among the entries of $\mathcal{P}_1$, multiply the chosen entries of $\mathcal{P}_1$, and then placing the edge (v_i, v_j) with the obtained probability.

Thus, instead of flipping $O(N^2) = O(N_1^{2k})$ biased coins to determine the edges in a graph, we place E edges by directly simulating the recursion of the Kronecker product. Basically, we recursively choose sub-regions of matrix K with probability proportional to θ_{ij}, $\theta_{ij} \in \mathcal{P}_1$ until in k steps we descend to a single cell of the big adjacency matrix K and place an edge. For example, for (v_2, v_3) in Figure 6(c) we first have to choose b following by c.

More generally, the probability of each individual edge of $\mathcal{P}_k$ follows a Bernoulli distribution, as the edge occurrences are independent. By the Central Limit Theorem (Petrov, 1995) the number of edges in $\mathcal{P}_k$ tends to a normal distribution with mean $(\sum_{i,j=1}^{N_1} \theta_{ij})^k = E_1^k$, where $\theta_{ij} \in \mathcal{P}_1$. So, given a stochastic initiator matrix $\mathcal{P}_1$ we first sample the expected number of edges E in $\mathcal{P}_k$. Then we place E edges in a graph K, by applying the recursive descent for k steps where at each step we choose entry (i, j) with probability θ_{ij}/E_1 where $E_1 = \sum_{ij} \theta_{ij}$. Since we add $E = E_1^k$ edges, the probability that edge (v_i, v_j) appears in K is exactly $\mathcal{P}_k[v_i, v_j]$. However, in practice it can happen that more than one edge lands in the same (v_i, v_j) entry of big adjacency matrix K. If an edge lands in a already occupied cell we simply insert it again. Even though values of $\mathcal{P}_1$ are usually skewed, adjacency matrices of real networks are so sparse that collisions are not really a problem in practice as only around 1% of edges collide. It is due to these edge collisions the above procedure does not obtain exact samples from the graph distribution defined by the parameter matrix $\mathcal{P}$. However, in practice graphs generated by this fast linear time ($O(E)$) procedure are basically indistinguishable from graphs generated with the exact exponential time ($O(N^2)$) procedure.

Code for generating Kronecker graphs can be obtained at `http://snap.stanford.edu`.

3.7 Observations and Connections

Next, we describe several observations about the properties of Kronecker graphs and make connections to other network models.

- *Bipartite graphs:* Kronecker graphs can naturally model bipartite graphs. Instead of starting with a square $N_1 \times N_1$ initiator matrix, one can choose arbitrary $N_1 \times M_1$ initiator matrix, where rows define "left", and columns the "right" side of the bipartite graph. Kronecker multiplication will then generate bipartite graphs with partition sizes N_1^k and M_1^k.

- *Graph distributions:* $\mathcal{P}_k$ defines a distribution over all graphs, as it encodes the probability of all possible N_1^{2k} edges appearing in a graph by using an exponentially smaller number of parameters (just N_1^2). As we will later see, even a very small number of parameters, for example, 4 (2×2 initiator matrix) or 9 (3×3 initiator), is enough to accurately model the structure of large networks.

- *Extension of Erdős-Rényi random graph model:* Stochastic Kronecker graphs represent an extension of Erdős-Rényi (Erdős and Rényi, 1960) random graphs. If one takes $\mathcal{P}_1 = [\theta_{ij}]$, where every $\theta_{ij} = p$ then we obtain exactly the Erdős-Rényi model of random graphs $G_{n,p}$, where every edge appears independently with probability p.

- *Relation to the R-MAT model:* The recursive nature of Stochastic Kronecker graphs makes them related to the R-MAT generator (Chakrabarti et al., 2004). The difference between the two models is that in R-MAT one needs to separately specify the number of edges, while in Stochastic Kronecker graphs initiator matrix $\mathcal{P}_1$ also encodes the number of edges in the graph. Section 3.6 built on this similarity to devise a fast algorithm for generating Stochastic Kronecker graphs.

- *Densification:* Similarly as with deterministic Kronecker graphs the number of nodes in a Stochastic Kronecker graph grows as N_1^k, and the expected number of edges grows as $(\sum_{ij}\theta_{ij})^k$. This means one would want to choose values θ_{ij} of the initiator matrix $\mathcal{P}_1$ so that $\sum_{ij}\theta_{ij} > N_1$ in order for the resulting network to densify.

4. Simulations of Kronecker Graphs

Next we perform a set of simulation experiments to demonstrate the ability of Kronecker graphs to match the patterns of real-world networks. We will tackle the problem of estimating the Kronecker graph model from real data, that is, finding the most likely initiator $\mathcal{P}_1$, in the next section. Instead here we present simulation experiments using Kronecker graphs to explore the parameter space, and to compare properties of Kronecker graphs to those found in large real networks.

4.1 Comparison to Real Graphs

We observe two kinds of graph patterns—"static" and "temporal." As mentioned earlier, common static patterns include degree distribution, scree plot (eigenvalues of graph adjacency matrix vs. rank) and distribution of components of the principal eigenvector of graph adjacency matrix. Temporal patterns include the diameter over time, and the densification power law. For the diameter computation, we use the effective diameter as defined in Section 2.

For the purpose of this section consider the following setting. Given a real graph G we want to find Kronecker initiator that produces qualitatively similar graph. In principle one could try choosing each of the N_1^2 parameters for the matrix $\mathcal{P}_1$ separately. However, we reduce the number of parameters from N_1^2 to just two: α and β. Let K_1 be the initiator matrix (binary, deterministic). Then we create the corresponding stochastic initiator matrix $\mathcal{P}_1$ by replacing each "1" and "0" of K_1 with α and β respectively ($\beta \leq \alpha$). The resulting probability matrices maintain—with some random noise—the self-similar structure of the Kronecker graphs in the previous section (which, for clarity, we call *deterministic Kronecker graphs*). We defer the discussion of how to automatically estimate $\mathcal{P}_1$ from data G to the next section.

The data sets we use here are:

- CIT-HEP-TH: This is a citation graph for High-Energy Physics Theory research papers from pre-print archive ArXiv, with a total of N =29,555 papers and E =352,807 citations (Gehrke et al., 2003). We follow its evolution from January 1993 to April 2003, with one data-point per month.

- AS-ROUTEVIEWS: We also analyze a static data set consisting of a single snapshot of connectivity among Internet Autonomous Systems (RouteViews, 1997) from January 2000, with N =6,474 and E =26,467.

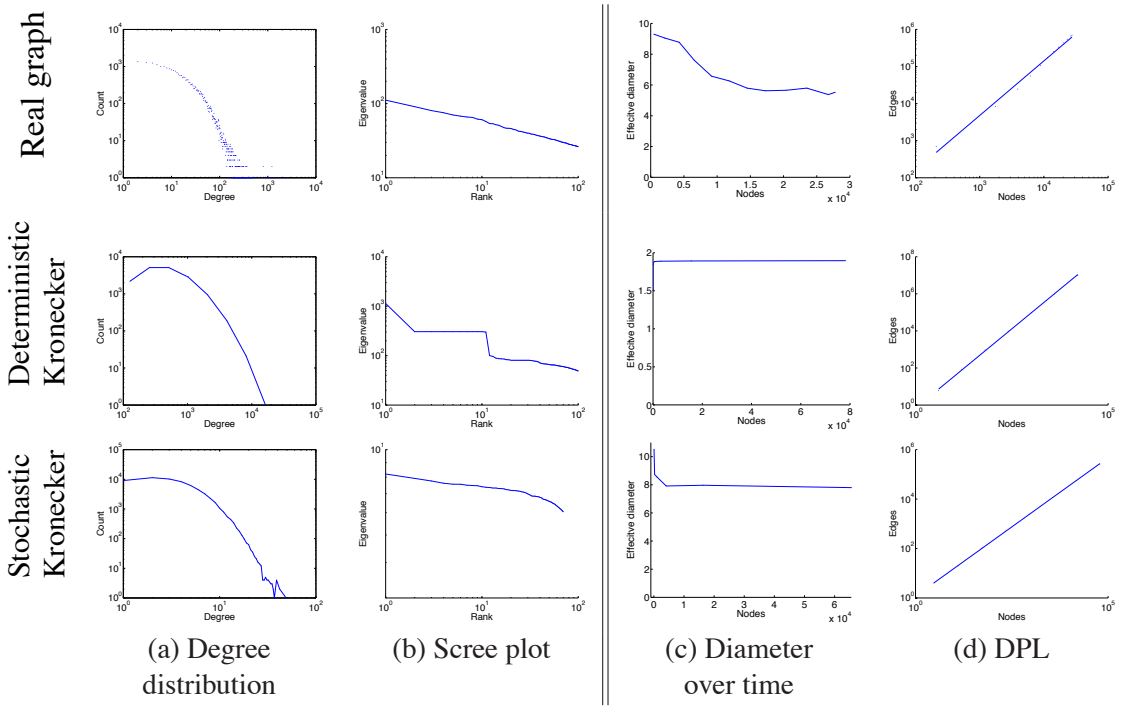


Figure 7: *Citation network (*CIT-HEP-TH*):* Patterns from the real graph (top row), the deterministic Kronecker graph with K_1 being a star graph on 4 nodes (center + 3 satellites) (middle row), and the Stochastic Kronecker graph ($\alpha = 0.41$, $\beta = 0.11$ – bottom row). *Static* patterns: (a) is the PDF of degrees in the graph (log-log scale), and (b) the distribution of eigenvalues (log-log scale). *Temporal* patterns: (c) gives the effective diameter over time (linear-linear scale), and (d) is the number of edges versus number of nodes over time (log-log scale). Notice that the Stochastic Kronecker graphs qualitatively matches all the patterns very well.

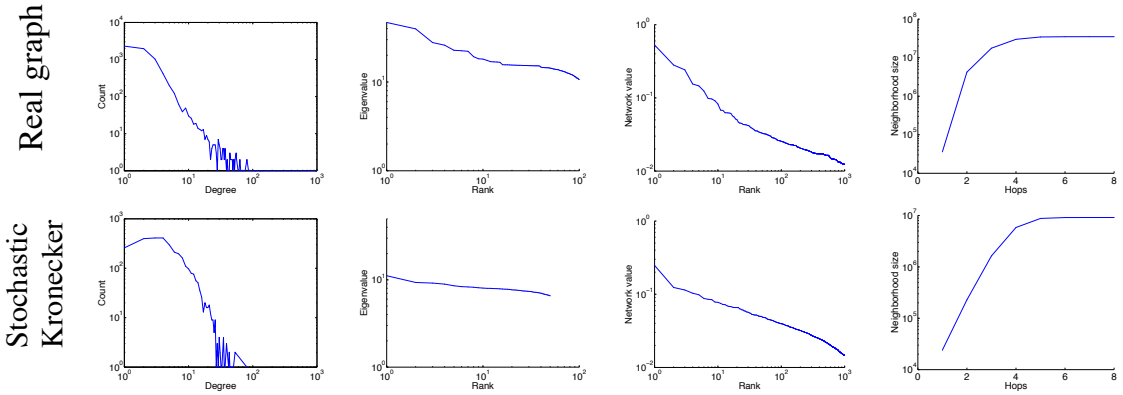
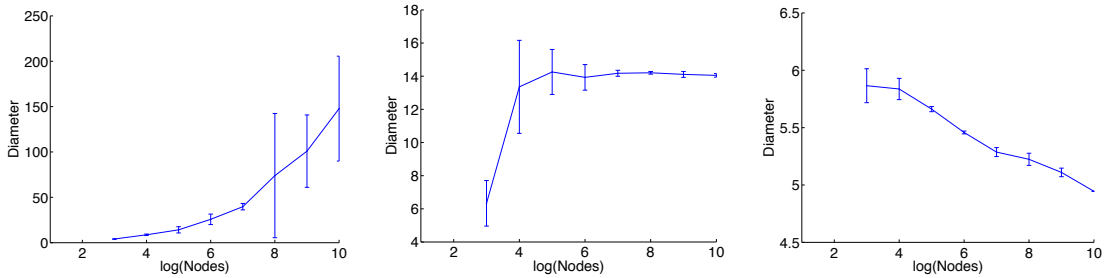
Results are shown in Figure 7 for the CIT-HEP-TH graph which evolves over time. We show the plots of two static and two temporal patterns. We see that the deterministic Kronecker model already to some degree captures the qualitative structure of the degree and eigenvalue distributions, as well as the temporal patterns represented by the densification power law and the stabilizing diameter. However, the deterministic nature of this model results in "staircase" behavior, as shown in scree plot for the deterministic Kronecker graph of Figure 7 (column (b), second row). We see that the Stochastic Kronecker graphs smooth out these distributions, further matching the qualitative structure of the real data, and they also match the shrinking-before-stabilization trend of the diameters of real graphs.

Similarly, Figure 8 shows plots for the static patterns in the *Autonomous systems* (AS-ROUTEVIEWS) graph. Recall that we analyze a single, static network snapshot in this case. In addition to the degree distribution and scree plot, we also show two typical plots (Chakrabarti et al., 2004): the distribution of *network values* (principal eigenvector components, sorted, versus rank) and the *hop-plot* (the number of reachable pairs $g(h)$ within h hops or less, as a function of the



(a) Degree distribution (b) Scree plot (c) "Network value" distribution (d) "Hop-plot"

Figure 8: *Autonomous systems (*AS-ROUTEVIEWS*):* Real (top) versus Kronecker (bottom). Columns (a) and (b) show the degree distribution and the scree plot, as before. Columns (c) and (d) show two more static patterns (see text). Notice that, again, the Stochastic Kronecker graph matches well the properties of the real graph.



(a) Increasing diameter $\alpha = 0.38, \beta = 0$ (b) Constant diameter $\alpha = 0.43, \beta = 0$ (c) Decreasing diameter $\alpha = 0.54, \beta = 0$

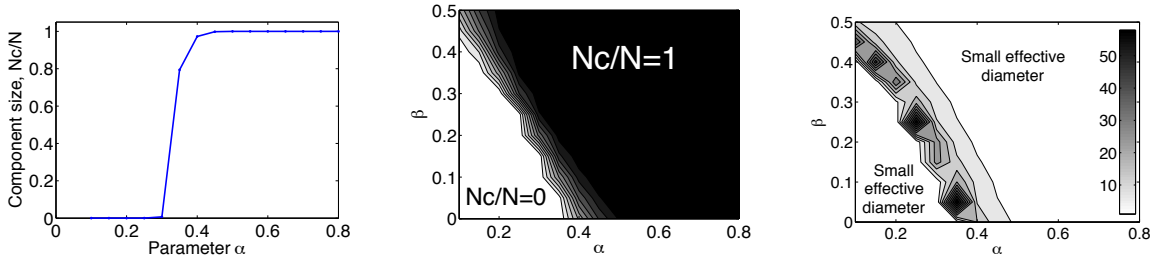
Figure 9: Effective diameter over time for a 4-node chain initiator graph. After each consecutive Kronecker power we measure the effective diameter. We use different settings of α parameter. $\alpha = 0.38, 0.43, 0.54$ and $\beta = 0$, respectively.

number of hops h). Notice that, again, the Stochastic Kronecker graph matches well the properties of the real graph.

4.2 Parameter Space of Kronecker Graphs

Last we present simulation experiments that investigate the parameter space of Stochastic Kronecker graphs.

First, in Figure 9 we show the ability of Kronecker Graphs to generate networks with increasing, constant and decreasing/stabilizing effective diameter. We start with a 4-node chain initiator graph (shown in top row of Figure 3), setting each "1" of K_1 to α and each "0" to $\beta = 0$ to obtain $\mathcal{P}_1$ that we then use to generate a growing sequence of graphs. We plot the effective diameter of each



(a) Largest component size (b) Largest component size (c) Effective diameter

Figure 10: Fraction of nodes in the largest weakly connected component (N_c/N) and the effective diameter for 4-star initiator graph. (a) We fix $\beta = 0.15$ and vary α. (b) We vary both α and β. (c) Effective diameter of the network, if network is disconnected or very dense path lengths are short, the diameter is large when the network is barely connected.

$R(\mathcal{P}_k)$ as we generate a sequence of growing graphs $R(\mathcal{P}_2), R(\mathcal{P}_3), \ldots, R(\mathcal{P}_{10})$. $R(\mathcal{P}_{10})$ has exactly 1,048,576 nodes. Notice Stochastic Kronecker graphs is a very flexible model. When the generated graph is very sparse (low value of α) we obtain graphs with slowly increasing effective diameter (Figure 9(a)). For intermediate values of α we get graphs with constant diameter (Figure 9(b)) and that in our case also slowly densify with densification exponent $a = 1.05$. Last, we see an example of a graph with shrinking/stabilizing effective diameter. Here we set the $\alpha = 0.54$ which results in a densification exponent of $a = 1.2$. Note that these observations are not contradicting Theorem 11. Actually, these simulations here agree well with the analysis of Mahdian and Xu (2007).

Next, we examine the parameter space of a Stochastic Kronecker graphs where we choose a star on 4 nodes as a initiator graph and parameterized with α and β as before. The initiator graph and the structure of the corresponding (deterministic) Kronecker graph adjacency matrix is shown in top row of Figure 3.

Figure 10(a) shows the sharp transition in the fraction of the number of nodes that belong to the largest weakly connected component as we fix $\beta = 0.15$ and slowly increase α. Such phase transitions on the size of the largest connected component also occur in Erdős-Rényi random graphs. Figure 10(b) further explores this by plotting the fraction of nodes in the largest connected component (N_c/N) over the full parameter space. Notice a sharp transition between disconnected (white area) and connected graphs (dark).

Last, Figure 10(c) shows the effective diameter over the parameter space (α, β) for the 4-node star initiator graph. Notice that when parameter values are small, the effective diameter is small, since the graph is disconnected and not many pairs of nodes can be reached. The shape of the transition between low-high diameter closely follows the shape of the emergence of the connected component. Similarly, when parameter values are large, the graph is very dense, and the diameter is small. There is a narrow band in parameter space where we get graphs with interesting diameters.

5. Kronecker Graph Model Estimation

In previous sections we investigated various properties of networks generated by the (Stochastic) Kronecker graphs model. Many of these properties were also observed in real networks. Moreover, we also gave closed form expressions (parametric forms) for values of these statistical network

properties, which allow us to calculate a property (e.g., diameter, eigenvalue spectrum) of a network directly from just the initiator matrix. So in principle, one could invert these equations and directly get from a property (e.g., shape of degree distribution) to the values of initiator matrix.

However, in previous sections we did not say anything about how various network properties of a Kronecker graph correlate and interdepend. For example, it could be the case that two network properties are mutually exclusive. For instance, perhaps only could only match the network diameter but not the degree distribution or vice versa. However, as we show later this is not the case.

Now we turn our attention to automatically estimating the Kronecker initiator graph. The setting is that we are given a real network G and would like to find a Stochastic Kronecker initiator $\mathcal{P}_1$ that produces a synthetic Kronecker graph K that is "similar" to G. One way to measure similarity is to compare statistical network properties, like diameter and degree distribution, of graphs G and K.

Comparing statistical properties already suggests a very direct approach to this problem: One could first identify the set of network properties (statistics) to match, then define a quality of fit metric and somehow optimize over it. For example, one could use the KL divergence (Kullback and Leibler, 1951), or the sum of squared differences between the degree distribution of the real network G and its synthetic counterpart K. Moreover, as we are interested in matching several such statistics between the networks one would have to meaningfully combine these individual error metrics into a global error metric. So, one would have to specify what kind of properties he or she cares about and then combine them accordingly. This would be a hard task as the patterns of interest have very different magnitudes and scales. Moreover, as new network patterns are discovered, the error functions would have to be changed and models re-estimated. And even then it is not clear how to define the optimization procedure to maximize the quality of fit and how to perform optimization over the parameter space.

Our approach here is different. Instead of committing to a set of network properties ahead of time, we try to directly match the adjacency matrices of the real network G and its synthetic counterpart K. The idea is that if the adjacency matrices are similar then the global statistical properties (statistics computed over K and G) will also match. Moreover, by directly working with the graph itself (and not summary statistics), we do not commit to any particular set of network statistics (network properties/patterns) and as new statistical properties of networks are discovered our models and estimated parameters will still hold.

5.1 Preliminaries

Stochastic graph models induce probability distributions over graphs. A generative model assigns a probability $P(G)$ to every graph G. $P(G)$ is the *likelihood* that a given model (with a given set of parameters) generates the graph G. We concentrate on the Stochastic Kronecker graphs model, and consider fitting it to a real graph G, our data. We use the maximum likelihood approach, that is, we aim to find parameter values, the initiator $\mathcal{P}_1$, that maximize $P(G)$ under the Stochastic Kronecker graph model.

This presents several challenges:

- **Model selection:** a graph is a single structure, and not a set of items drawn independently and identically-distributed (i.i.d.) from some distribution. So one cannot split it into independent training and test sets. The fitted parameters will thus be best to generate a *particular* instance of a graph. Also, overfitting could be an issue since a more complex model generally fits better.

- **Node correspondence:** The second challenge is the node correspondence or node labeling problem. The graph G has a set of N nodes, and each node has a unique label (index, ID). Labels do not carry any particular meaning, they just uniquely denote or identify the nodes. One can think of this as the graph is first generated and then the labels (node IDs) are randomly assigned. This means that two isomorphic graphs that have different node labels should have the same likelihood. A permutation σ is sufficient to describe the node correspondences as it maps labels (IDs) to nodes of the graph. To compute the likelihood $P(G)$ one has to consider all node correspondences $P(G) = \sum_\sigma P(G|\sigma)P(\sigma)$, where the sum is over all $N!$ permutations σ of N nodes. Calculating this *super-exponential* sum explicitly is infeasible for any graph with more than a handful of nodes. Intuitively, one can think of this summation as some kind of graph isomorphism test where we are searching for best correspondence (mapping) between nodes of G and $\mathcal{P}$.

- **Likelihood estimation:** Even if we assume one can efficiently solve the node correspondence problem, calculating $P(G|\sigma)$ naively takes $O(N^2)$ as one has to evaluate the probability of each of the N^2 possible edges in the graph adjacency matrix. Again, for graphs of size we want to model here, approaches with quadratic complexity are infeasible.

To develop our solution we use sampling to avoid the super-exponential sum over the node correspondences. By exploiting the structure of the Kronecker matrix multiplication we develop an algorithm to evaluate $P(G|\sigma)$ in *linear* time $O(E)$. Since real graphs are *sparse*, that is, the number of edges is roughly of the same order as the number of nodes, this makes fitting of Kronecker graphs to large networks feasible.

5.2 Problem Formulation

Suppose we are given a graph G on $N = N_1^k$ nodes (for some positive integer k), and an $N_1 \times N_1$ Stochastic Kronecker graphs initiator matrix $\mathcal{P}_1$. Here $\mathcal{P}_1$ is a parameter matrix, a set of parameters that we aim to estimate. For now also assume N_1, the size of the initiator matrix, is given. Later we will show how to automatically select it. Next, using $\mathcal{P}_1$ we create a Stochastic Kronecker graphs probability matrix $\mathcal{P}_k$, where every entry p_{uv} of $\mathcal{P}_k$ contains a probability that node u links to node v. We then evaluate the probability that G is a realization of $\mathcal{P}_k$. The task is to find such $\mathcal{P}_1$ that has the highest probability of realizing (generating) G.

Formally, we are solving:

$$\arg\max_{\mathcal{P}_1} P(G|\mathcal{P}_1). \tag{2}$$

To keep the notation simpler we use standard symbol Θ to denote the parameter matrix $\mathcal{P}_1$ that we are trying to estimate. We denote entries of $\Theta = \mathcal{P}_1 = [\theta_{ij}]$, and similarly we denote $\mathcal{P} = \mathcal{P}_k = [p_{ij}]$. Note that here we slightly simplified the notation: we use Θ to refer to $\mathcal{P}_1$, and θ_{ij} are elements of Θ. Similarly, p_{ij} are elements of $\mathcal{P}$ ($\equiv \mathcal{P}_k$). Moreover, we denote $K = R(\mathcal{P})$, that is, K is a realization of the Stochastic Kronecker graph sampled from probabilistic adjacency matrix $\mathcal{P}$.

As noted before, the node IDs are assigned arbitrarily and they carry no significant information, which means that we have to consider all the mappings of nodes from G to rows and columns of stochastic adjacency matrix $\mathcal{P}$. A priori all labelings are equally likely. A permutation σ of the set $\{1,\ldots,N\}$ defines this mapping of nodes from G to stochastic adjacency matrix $\mathcal{P}$. To evaluate the

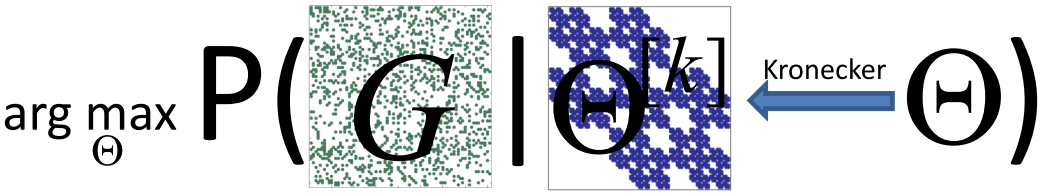


Figure 11: Kronecker parameter estimation as an optimization problem. We search over the initiator matrices Θ ($\equiv \mathcal{P}_1$). Using Kronecker multiplication we create probabilistic adjacency matrix $\Theta^{[k]}$ that is of same size as real network G. Now, we evaluate the likelihood by simultaneously traversing and multiplying entries of G and $\Theta^{[k]}$ (see Equation refeq:KronProbGPS). As shown by the figure permutation σ plays an important role, as permuting rows and columns of G could make it look more similar to $\Theta^{[k]}$ and thus increase the likelihood.

likelihood of G one needs to consider all possible mappings of N nodes of G to rows (columns) of $\mathcal{P}$. For convenience we work with *log-likelihood* $l(\Theta)$, and solve $\hat{\Theta} = \arg\max_\Theta l(\Theta)$, where $l(\Theta)$ is defined as:

$$\begin{aligned} l(\Theta) &= \log P(G|\Theta) = \log \sum_\sigma P(G|\Theta,\sigma)P(\sigma|\Theta) \\ &= \log \sum_\sigma P(G|\Theta,\sigma)P(\sigma). \end{aligned} \tag{3}$$

The likelihood that a given initiator matrix Θ and permutation σ gave rise to the real graph G, $P(G|\Theta,\sigma)$, is calculated naturally as follows. First, by using Θ we create the Stochastic Kronecker graph adjacency matrix $\mathcal{P} = \mathcal{P}_k = \Theta^{[k]}$. Permutation σ defines the mapping of nodes of G to the rows and columns of stochastic adjacency matrix $\mathcal{P}$. (See Figure 11 for the illustration.)

We then model edges as independent Bernoulli random variables parameterized by the parameter matrix Θ. So, each entry p_{uv} of $\mathcal{P}$ gives exactly the probability of edge (u,v) appearing.

We then define the likelihood:

$$P(G|\mathcal{P},\sigma) = \prod_{(u,v)\in G} \mathcal{P}[\sigma_u,\sigma_v] \prod_{(u,v)\notin G} (1-\mathcal{P}[\sigma_u,\sigma_v]), \tag{4}$$

where we denote σ_i as the i^{th} element of the permutation σ, and $\mathcal{P}[i,j]$ is the element at row i, and column j of matrix $\mathcal{P} = \Theta^{[k]}$.

The likelihood is defined very naturally. We traverse the entries of adjacency matrix G and then based on whether a particular edge appeared in G or not we take the probability of edge occurring (or not) as given by $\mathcal{P}$, and multiply these probabilities. As one has to touch all the entries of the stochastic adjacency matrix $\mathcal{P}$ evaluating Equation 4 takes $O(N^2)$ time.

We further illustrate the process of estimating Stochastic Kronecker initiator matrix Θ in Figure 11. We search over initiator matrices Θ to find the one that maximizes the likelihood $P(G|\Theta)$. To estimate $P(G|\Theta)$ we are given a concrete Θ and now we use Kronecker multiplication to create probabilistic adjacency matrix $\Theta^{[k]}$ that is of same size as real network G. Now, we evaluate the likelihood by traversing the corresponding entries of G and $\Theta^{[k]}$. Equation 4 basically traverses the

adjacency matrix of G, and maps every entry (u,v) of G to a corresponding entry (σ_u,σ_v) of $\mathcal{P}$. Then in case that edge (u,v) exists in G (i.e., $G[u,v]=1$) the likelihood that particular edge existing is $\mathcal{P}[\sigma_u,\sigma_v]$, and similarly, in case the edge (u,v) does not exist the likelihood is simply $1-\mathcal{P}[\sigma_u,\sigma_v]$. This also demonstrates the importance of permutation σ, as permuting rows and columns of G could make the adjacency matrix look more "similar" to $\Theta^{[k]}$, and would increase the likelihood.

So far we showed how to assess the quality (likelihood) of a particular Θ. So, naively one could perform some kind of grid search to find best Θ. However, this is very inefficient. A better way of doing it is to compute the gradient of the log-likelihood $\frac{\partial}{\partial\Theta}l(\Theta)$, and then use the gradient to update the current estimate of Θ and move towards a solution of higher likelihood. Algorithm 1 gives an outline of the optimization procedure.

However, there are several difficulties with this algorithm. First, we are assuming gradient descent type optimization will find a good solution, that is, the problem does not have (too many) local minima. Second, we are summing over exponentially many permutations in Equation 3. Third, the evaluation of Equation 4 as it is written now takes $O(N^2)$ time and needs to be evaluated $N!$ times. So, given a concrete Θ just naively calculating the likelihood takes $O(N!N^2)$ time, and then one also has to optimize over Θ.

Observation 2 *The complexity of calculating the likelihood $P(G|\Theta)$ of the graph G naively is $O(N!N^2)$, where N is the number of nodes in G.*

Next, we show that all this can be done in *linear time*.

5.3 Summing Over the Node Labelings

To maximize Equation 2 using algorithm 1 we need to obtain the gradient of the log-likelihood $\frac{\partial}{\partial\Theta}l(\Theta)$. We can write:

$$\begin{aligned}\frac{\partial}{\partial\Theta}l(\Theta) &= \frac{\sum_\sigma \frac{\partial}{\partial\Theta}P(G|\sigma,\Theta)P(\sigma)}{\sum_{\sigma'}P(G|\sigma',\Theta)P(\sigma')}\\ &= \frac{\sum_\sigma \frac{\partial \log P(G|\sigma,\Theta)}{\partial\Theta}P(G|\sigma,\Theta)P(\sigma)}{P(G|\Theta)}\\ &= \sum_\sigma \frac{\partial \log P(G|\sigma,\Theta)}{\partial\Theta}P(\sigma|G,\Theta). \qquad (5)\end{aligned}$$

Note we are still summing over all $N!$ permutations σ, so calculating Eq. 5 is computationally intractable for graphs with more than a handful of nodes. However, the equation has a nice form which allows for use of simulation techniques to avoid the summation over super-exponentially many node correspondences. Thus, we simulate draws from the permutation distribution $P(\sigma|G,\Theta)$, and then evaluate the quantities at the sampled permutations to obtain the expected values of log-likelihood and gradient. Algorithm 2 gives the details.

Note that we can also permute the rows and columns of the parameter matrix Θ to obtain equivalent estimates. Therefore Θ is not strictly identifiable exactly because of these permutations. Since the space of permutations on N nodes is very large (grows as $N!$) the permutation sampling algorithm will explore only a small fraction of the space of all permutations and may converge to one of the global maxima (but may not explore all $N_1!$ of them) of the parameter space. As we empirically

show later our results are not sensitive to this and multiple restarts result in equivalent (but often permuted) parameter estimates.

5.3.1 SAMPLING PERMUTATIONS

Next, we describe the Metropolis algorithm to simulate draws from the permutation distribution $P(\sigma|G,\Theta)$, which is given by

$$P(\sigma|G,\Theta) = \frac{P(\sigma,G,\Theta)}{\sum_\tau P(\tau,G,\Theta)} = \frac{P(\sigma,G,\Theta)}{Z}$$

where Z is the normalizing constant that is hard to compute since it involves the sum over $N!$ elements. However, if we compute the likelihood ratio between permutations σ and σ' (Equation 6) the normalizing constants nicely cancel out:

$$\frac{P(\sigma'|G,\Theta)}{P(\sigma|G,\Theta)} = \prod_{(u,v)\in G} \frac{\mathcal{P}[\sigma'_u,\sigma'_v]}{\mathcal{P}[\sigma_u,\sigma_v]} \prod_{(u,v)\notin G} \frac{(1-\mathcal{P}[\sigma'_u,\sigma'_v])}{(1-\mathcal{P}[\sigma_u,\sigma_v])} \tag{6}$$

$$= \prod_{\substack{(u,v)\in G \\ (\sigma_u,\sigma_v)\neq(\sigma'_u,\sigma'_v)}} \frac{\mathcal{P}[\sigma'_u,\sigma'_v]}{\mathcal{P}[\sigma_u,\sigma_v]} \prod_{\substack{(u,v)\notin G \\ (\sigma_u,\sigma_v)\neq(\sigma'_u,\sigma'_v)}} \frac{(1-\mathcal{P}[\sigma'_u,\sigma'_v])}{(1-\mathcal{P}[\sigma_u,\sigma_v])}. \tag{7}$$

This immediately suggests the use of a Metropolis sampling algorithm (Gamerman, 1997) to simulate draws from the permutation distribution since Metropolis is solely based on such ratios

return $\sigma^{(i)}$
Where $U(0,1)$ is a uniform distribution on $[0,1]$, and $\sigma' :=$ `SwapNodes(`σ, j, k`)` is the permutation σ' obtained from σ by swapping elements at positions j and k.

Algorithm 3: `SamplePermutation(`G,Θ`)`: Metropolis sampling of the node permutation.

(where normalizing constants cancel out). In particular, suppose that in the Metropolis algorithm (Algorithm 3) we consider a move from permutation σ to a new permutation σ'. Probability of accepting the move to σ' is given by Equation 6 (if $\frac{P(\sigma'|G,\Theta)}{P(\sigma|G,\Theta)} \leq 1$) or 1 otherwise.

Now we have to devise a way to sample permutations σ from the proposal distribution. One way to do this would be to simply generate a random permutation σ' and then check the acceptance condition. This would be very inefficient as we expect the distribution $P(\sigma|G,\Theta)$ to be heavily skewed, that is, there will be a relatively small number of good permutations (node mappings). Even more so as the degree distributions in real networks are skewed there will be many bad permutations with low likelihood, and few good ones that do a good job in matching nodes of high degree.

To make the sampling process "smoother", that is, sample permutations that are not that different (and thus are not randomly jumping across the permutation space) we design a Markov chain. The idea is to stay in high likelihood part of the permutation space longer. We do this by making samples dependent, that is, given σ' we want to generate next candidate permutation σ'' to then evaluate the likelihood ratio. When designing the Markov chain step one has to be careful so that the proposal distribution satisfies the detailed balance condition: $\pi(\sigma')P(\sigma'|\sigma'') = \pi(\sigma'')P(\sigma''|\sigma')$, where $P(\sigma'|\sigma'')$ is the transition probability of obtaining permutation σ' from σ'' and, $\pi(\sigma')$ is the stationary distribution.

In Algorithm 3 we use a simple proposal where given permutation σ' we generate σ'' by swapping elements at two uniformly at random chosen positions of σ'. We refer to this proposal as `SwapNodes`. While this is simple and clearly satisfies the detailed balance condition it is also inefficient in a way that most of the times low degree nodes will get swapped (a direct consequence of heavy tailed degree distributions). This has two consequences, (a) we will slowly converge to good permutations (accurate mappings of high degree nodes), and (b) once we reach a good permutation,

very few permutations will get accepted as most proposed permutations σ' will swap low degree nodes (as they form the majority of nodes).

A possibly more efficient way would be to swap elements of σ biased based on corresponding node degree, so that high degree nodes would get swapped more often. However, doing this directly does not satisfy the detailed balance condition. A way of sampling labels biased by node degrees that at the same time satisfies the detailed balance condition is the following: we pick an edge in G uniformly at random and swap the labels of the nodes at the edge endpoints. Notice this is biased towards swapping labels of nodes with high degrees simply as they have more edges. The detailed balance condition holds as edges are sampled uniformly at random. We refer to this proposal as `SwapEdgeEndpoints`.

However, the issue with this proposal is that if the graph G is disconnected, we will only be swapping labels of nodes that belong to the same connected component. This means that some parts of the permutation space will never get visited. To overcome this problem we execute `SwapNodes` with some probability ω and `SwapEdgeEndpoints` with probability $1-\omega$.

To summarize we consider the following two permutation proposal distributions:

- $\sigma'' = \texttt{SwapNodes}(\sigma')$: we obtain σ'' by taking σ', uniformly at random selecting a pair of elements and swapping their positions.

- $\sigma'' = \texttt{SwapEdgeEndpoints}(\sigma')$: we obtain σ'' from σ' by first sampling an edge (j,k) from G uniformly at random, then we take σ' and swap the labels at positions j and k.

5.3.2 SPEEDING UP THE LIKELIHOOD RATIO CALCULATION

We further speed up the algorithm by using the following observation. As written the Equation 6 takes $O(N^2)$ to evaluate since we have to consider N^2 possible edges. However, notice that permutations σ and σ' differ only at two positions, that is, elements at position j and k are swapped, that is, σ and σ' map all nodes except the two to the same locations. This means those elements of Equation 6 cancel out. Thus to update the likelihood we only need to traverse two rows and columns of matrix $\mathcal{P}$, namely rows and columns j and k, since everywhere else the mapping of the nodes to the adjacency matrix is the same for both permutations. This gives Equation 7 where the products now range only over the two rows/columns of $\mathcal{P}$ where σ and σ' differ.

Graphs we are working with here are too large to allow us to explicitly create and store the stochastic adjacency matrix $\mathcal{P}$ by Kronecker powering the initiator matrix Θ. Every time probability $\mathcal{P}[i,j]$ of edge (i,j) is needed the Equation 1 is evaluated, which takes $O(k)$. So a single iteration of Algorithm 3 takes $O(kN)$.

Observation 3 *Sampling a permutation* σ *from* $P(\sigma|G,\Theta)$ *takes* $O(kN)$.

This is gives us an improvement over the $O(N!)$ complexity of summing over all the permutations. So far we have shown how to obtain a permutation but we still need to evaluate the likelihood and find the gradients that will guide us in finding good initiator matrix. The problem here is that naively evaluating the network likelihood (gradient) as written in Equation 5 takes time $O(N^2)$. This is exactly what we investigate next and how to calculate the likelihood in *linear time*.

5.4 Efficiently Approximating Likelihood and Gradient

We just showed how to efficiently sample node permutations. Now, given a permutation we show how to efficiently evaluate the likelihood and it's gradient. Similarly as evaluating the likelihood ratio, naively calculating the log-likelihood $l(\Theta)$ or its gradient $\frac{\partial}{\partial\Theta}l(\Theta)$ takes time quadratic in the number of nodes. Next, we show how to compute this in linear time $O(E)$.

We begin with the observation that real graphs are sparse, which means that the number of edges is not quadratic but rather almost linear in the number of nodes, $E \ll N^2$. This means that majority of entries of graph adjacency matrix are zero, that is, most of the edges are not present. We exploit this fact. The idea is to first calculate the likelihood (gradient) of an empty graph, that is, a graph with zero edges, and then correct for the edges that actually appear in G.

To naively calculate the likelihood for an empty graph one needs to evaluate every cell of graph adjacency matrix. We consider Taylor approximation to the likelihood, and exploit the structure of matrix $\mathcal{P}$ to devise a constant time algorithm.

First, consider the second order Taylor approximation to log-likelihood of an edge that succeeds with probability x but does not appear in the graph:

$$\log(1-x) \approx -x - \frac{1}{2}x^2.$$

Calculating $l_e(\Theta)$, the log-likelihood of an empty graph, becomes:

$$l_e(\Theta) = \sum_{i=1}^{N}\sum_{j=1}^{N}\log(1-p_{ij}) \approx -\left(\sum_{i=1}^{N_1}\sum_{j=1}^{N_1}\theta_{ij}\right)^k - \frac{1}{2}\left(\sum_{i=1}^{N_1}\sum_{j=1}^{N_1}{\theta_{ij}}^2\right)^k. \tag{8}$$

Notice that while the first pair of sums ranges over N elements, the last pair only ranges over N_1 elements ($N_1 = \log_k N$). Equation 8 holds due to the recursive structure of matrix $\mathcal{P}$ generated by the Kronecker product. We substitute the $\log(1-p_{ij})$ with its Taylor approximation, which gives a sum over elements of $\mathcal{P}$ and their squares. Next, we notice the sum of elements of $\mathcal{P}$ forms a multinomial series, and thus $\sum_{i,j} p_{ij} = (\sum_{i,j}\theta_{ij})^k$, where θ_{ij} denotes an element of Θ, and p_{ij} element of $\Theta^{[k]}$.

Calculating log-likelihood of G now takes $O(E)$: First, we approximate the likelihood of an empty graph in constant time, and then account for the edges that are actually present in G, that is, we subtract "no-edge" likelihood and add the "edge" likelihoods:

$$l(\Theta) = l_e(\Theta) + \sum_{(u,v)\in G} -\log(1-\mathcal{P}[\sigma_u,\sigma_v]) + \log(\mathcal{P}[\sigma_u,\sigma_v]).$$

We note that by using the second order Taylor approximation to the log-likelihood of an empty graph, the error term of the approximation is $\frac{1}{3}(\sum_i {\theta_{ij}}^3)^k$, which can diverge for large k. For typical values of initiator matrix $\mathcal{P}_1$ (that we present in Section 6.5) we note that one needs about fourth or fifth order Taylor approximation for the error of the approximation actually go to zero as k approaches infinity, that is, $\sum_{ij}{\theta_{ij}}^{n+1} < 1$, where n is the order of Taylor approximation employed.

5.5 Calculating the Gradient

Calculation of the gradient of the log-likelihood follows exactly the same pattern as described above. First by using the Taylor approximation we calculate the gradient as if graph G would have no edges. Then we correct the gradient for the edges that are present in G. As in previous section we speed

up the calculations of the gradient by exploiting the fact that two consecutive permutations σ and σ' differ only at two positions, and thus given the gradient from previous step one only needs to account for the swap of the two rows and columns of the gradient matrix $\partial\mathcal{P}/\partial\Theta$ to update to the gradients of individual parameters.

5.6 Determining the Size of Initiator Matrix

The question we answer next is how to determine the right number of parameters, that is, what is the right size of matrix Θ? This is a classical question of model selection where there is a tradeoff between the complexity of the model, and the quality of the fit. Bigger model with more parameters usually fits better, however it is also more likely to overfit the data.

For model selection to find the appropriate value of N_1, the size of matrix Θ, and choose the right tradeoff between the complexity of the model and the quality of the fit, we propose to use the Bayes Information Criterion (BIC) (Schwarz, 1978). Stochastic Kronecker graph model the presence of edges with independent Bernoulli random variables, where the canonical number of parameters is N_1^{2k}, which is a function of a lower-dimensional parameter Θ. This is then a *curved exponential family* (Efron, 1975), and BIC naturally applies:

$$\mathrm{BIC}(N_1) = -l(\hat{\Theta}_{N_1}) + \frac{1}{2} N_1^2 \log(N^2)$$

where $\hat{\Theta}_{N_1}$ are the maximum likelihood parameters of the model with $N_1 \times N_1$ parameter matrix, and N is the number of nodes in G. Note that one could also additional term to the above formula to account for multiple global maxima of the likelihood space but as N_1 is small the additional term would make no real difference.

As an alternative to BIC one could also consider the Minimum Description Length (MDL) (Rissanen, 1978) principle where the model is scored by the quality of the fit plus the size of the description that encodes the model and the parameters.

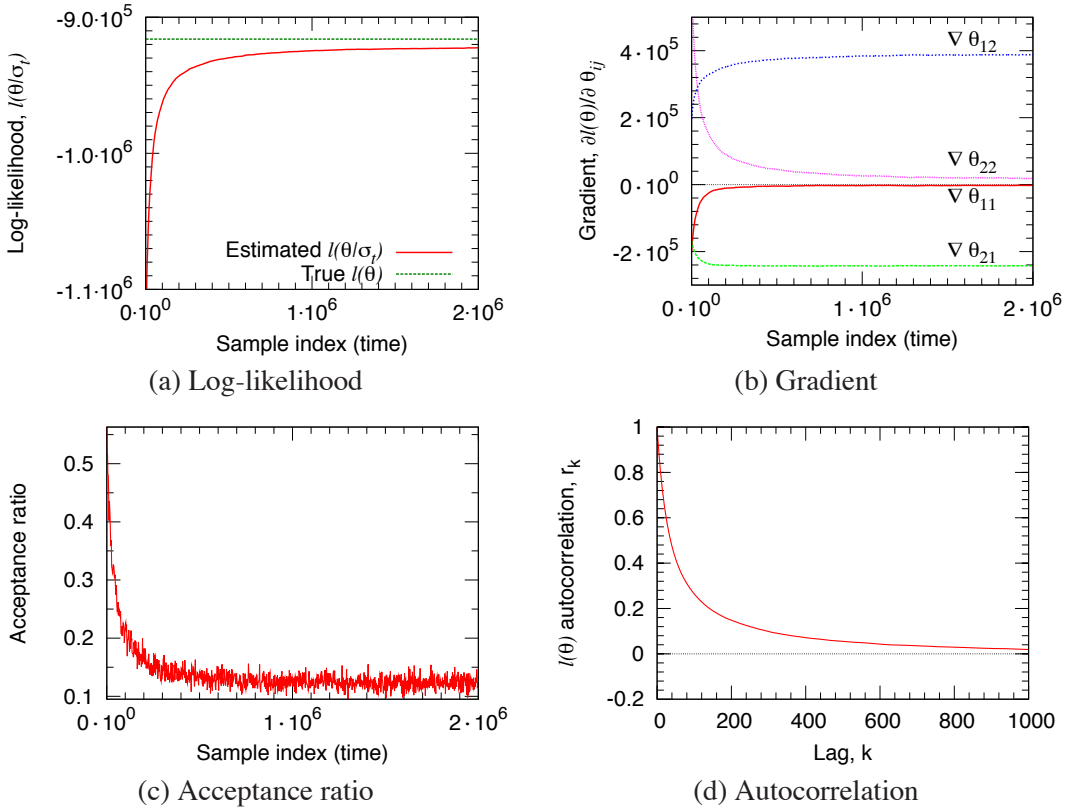
6. Experiments on Real and Synthetic Data

Next we described our experiments on a range of real and synthetic networks. We divide the experiments into several subsections. First we examine the convergence and mixing of the Markov chain of our permutation sampling scheme. Then we consider estimating the parameters of synthetic Kronecker graphs to see whether KRONFIT is able to recover the parameters used to generate the network. Last, we consider fitting Stochastic Kronecker graphs to large real world networks.

KRONFIT code for efficient Kronecker graph parameter estimation can be downloaded from `http://snap.stanford.edu`.

6.1 Permutation Sampling

In our experiments we considered both synthetic and real graphs. Unless mentioned otherwise all synthetic Kronecker graphs were generated using $\mathcal{P}_1^* = [0.8, 0.6; 0.5, 0.3]$, and $k = 14$ which gives us a graph G on N =16,384 nodes and E =115,741 edges. We chose this particular $\mathcal{P}_1^*$ as it resembles the typical initiator for real networks analyzed later in this section.



(a) Log-likelihood (b) Gradient

(c) Acceptance ratio (d) Autocorrelation

Figure 12: Convergence of the log-likelihood and components of the gradient towards their true values for Metropolis permutation sampling (Algorithm 3) with the number of samples.

6.1.1 CONVERGENCE OF THE LOG-LIKELIHOOD AND THE GRADIENT

First, we examine the convergence of Metropolis permutation sampling, where permutations are sampled sequentially. A new permutation is obtained by modifying the previous one which creates a Markov chain. We want to assess the convergence and mixing of the chain. We aim to determine how many permutations one needs to draw to reliably estimate the likelihood and the gradient, and also how long does it take until the samples converge to the stationary distribution. For the experiment we generated a synthetic Stochastic Kronecker graphs using $\mathcal{P}_1^*$ as defined above. Then, starting with a random permutation we run Algorithm 3, and measure how the likelihood and the gradients converge to their true values.

In this particular case, we first generated a Stochastic Kronecker graphs G as described above, but then calculated the likelihood and the parameter gradients for $\Theta' = [0.8, 0.75; 0.45, 0.3]$. We average the likelihoods and gradients over buckets of 1,000 consecutive samples, and plot how the log-likelihood calculated over the sampled permutations approaches the true log-likelihood (that we can compute since G is a Stochastic Kronecker graphs).

First, we present experiments that aim to answer how many samples (i.e., permutations) does one need to draw to obtain a reliable estimate of the gradient (see Equation 5). Figure 12(a) shows how the estimated log-likelihood approaches the true likelihood. Notice that estimated values

quickly converge to their true values, that is, Metropolis sampling quickly moves towards "good" permutations. Similarly, Figure 12(b) plots the convergence of the gradients. Notice that θ_{11} and θ_{22} of Θ' and $\mathcal{P}_1^*$ match, so gradients of these two parameters should converge to zero and indeed they do. On the other hand, θ_{12} and θ_{21} differ between Θ' and $\mathcal{P}_1^*$. Notice, the gradient for one is positive as the parameter θ_{12} of Θ' should be decreased, and similarly for θ_{21} the gradient is negative as the parameter value should be increased to match the Θ'. In summary, this shows that log-likelihood and gradients rather quickly converge to their true values.

In Figures 12(c) and (d) we also investigate the properties of the Markov Chain Monte Carlo sampling procedure, and assess convergence and mixing criteria. First, we plot the fraction of accepted proposals. It stabilizes at around 15%, which is quite close to the rule-of-a-thumb of 25%. Second, Figure 12(d) plots the autocorrelation of the log-likelihood as a function of the lag. Autocorrelation r_k of a signal X is a function of the lag k where r_k is defined as the correlation of signal X at time t with X at $t+k$, that is, correlation of the signal with itself at lag k. High autocorrelations within chains indicate slow mixing and, usually, slow convergence. On the other hand fast decay of autocorrelation implies better the mixing and thus one needs less samples to accurately estimate the gradient or the likelihood. Notice the rather fast autocorrelation decay.

All in all, these experiments show that one needs to sample on the order of tens of thousands of permutations for the estimates to converge. We also verified that the variance of the estimates is sufficiently small. In our experiments we start with a random permutation and use long burn-in time. Then when performing optimization we use the permutation from the previous step to initialize the permutation at the current step of the gradient descent. Intuitively, small changes in parameter space Θ also mean small changes in $P(\sigma|G,\Theta)$.

6.1.2 DIFFERENT PROPOSAL DISTRIBUTIONS

In Section 5.3.1 we defined two permutation sampling strategies: `SwapNodes` where we pick two nodes uniformly at random and swap their labels (node ids), and `SwapEdgeEndpoints` where we pick a random edge in a graph and then swap the labels of the edge endpoints. We also discussed that one can interpolate between the two strategies by executing `SwapNodes` with probability ω, and `SwapEdgeEndpoints` with probability $1-\omega$.

So, given a Stochastic Kronecker graphs G on N =16,384 and E =115,741 generated from $\mathcal{P}_1^* = [0.8, 0.7; 0.5, 0.3]$ we evaluate the likelihood of $\Theta' = [0.8, 0.75; 0.45, 0.3]$. As we sample permutations we observe how the estimated likelihood converges to the true likelihood. Moreover we also vary parameter ω which interpolates between the two permutation proposal distributions. The quicker the convergence towards the true log-likelihood the better the proposal distribution.

Figure 13 plots the convergence of the log-likelihood with the number of sampled permutations. We plot the average over non-overlapping buckets of 1,000 consecutive permutations. Faster convergence implies better permutation proposal distribution. When we use only `SwapNodes` ($\omega = 1$) or `SwapEdgeEndpoints` ($\omega = 0$) convergence is rather slow. We obtain best convergence for ω around 0.6.

Similarly, Figure 14(a) plots the autocorrelation as a function of the lag k for different choices of ω. Faster autocorrelation decay means better mixing of the Markov chain. Again, notice that we get best mixing for $\omega \approx 0.6$. (Notice logarithmic y-axis.)

Last, we diagnose how long the sampling procedure must be run before the generated samples can be considered to be drawn (approximately) from the stationary distribution. We call this the

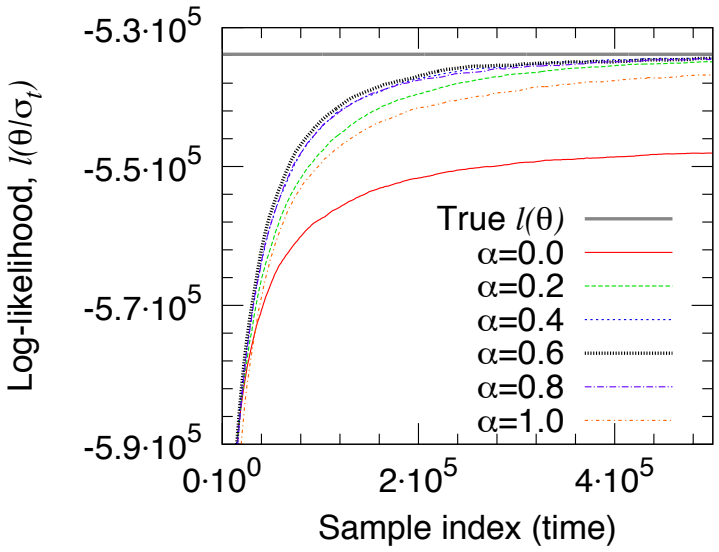


Figure 13: Convergence of the log-likelihood and gradients for Metropolis permutation sampling (Algorithm 3) for different choices of ω that interpolates between the `SwapNodes` ($\omega = 1$) and `SwapEdgeEndpoints` ($\omega = 0$) permutation proposal distributions. Notice fastest convergence of log-likelihood for $\omega = 0.6$.

burn-in time of the chain. There are various procedures for assessing convergence. Here we adopt the approach of Gelman et al. (2003), that is based on running multiple Markov chains each from a different starting point, and then comparing the variance within the chain and between the chains. The sooner the within- and between-chain variances become equal the shorter the burn-in time, that is, the sooner the samples are drawn from the stationary distribution.

Let l be the parameter that is being simulated with J different chains, and then let $l_j^{(k)}$ denote the k^{th} sample of the j^{th} chain, where $j = 1,\ldots,J$ and $k = 1,\ldots,K$. More specifically, in our case we run separate permutation sampling chains. So, we first sample permutation $\sigma_j^{(k)}$ and then calculate the corresponding log-likelihood $l_j^{(k)}$.

First, we compute between and within chain variances $\hat{\sigma}_B^2$ and $\hat{\sigma}_W^2$, where between-chain variance is obtained by

$$\hat{\sigma}_B^2 = \frac{K}{J-1}\sum_{j=1}^{J}(\bar{l}_{\cdot j} - \bar{l}_{\cdot\cdot})^2$$

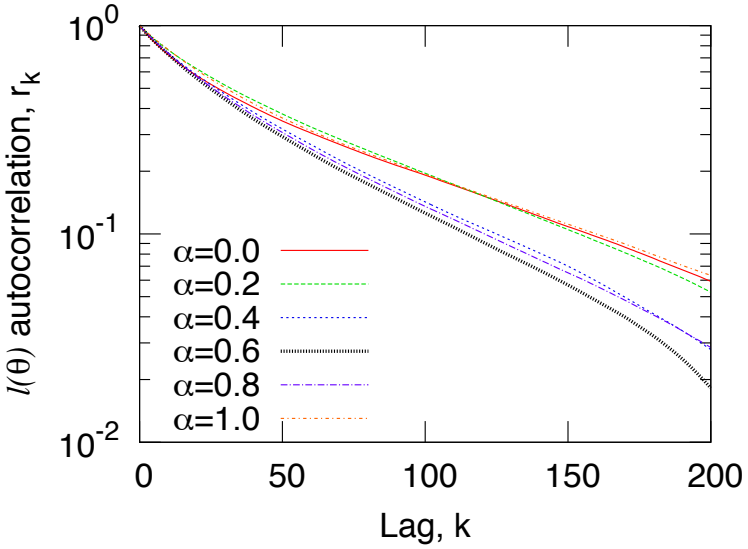
where $\bar{l}_{\cdot j} = \frac{1}{K}\sum_{k=1}^{K} l_j^{(k)}$ and $\bar{l}_{\cdot\cdot} = \frac{1}{J}\sum_{j=1}^{J}\bar{l}_{\cdot j}$.

Similarly the within-chain variance is defined by

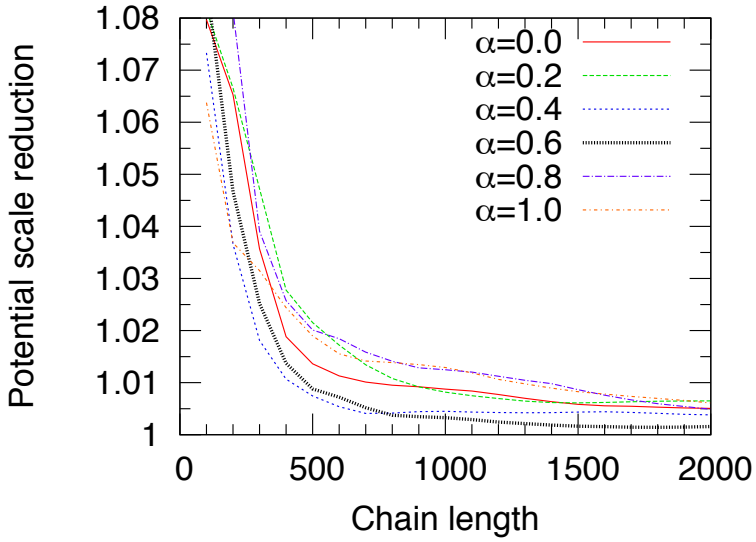
$$\hat{\sigma}_W^2 = \frac{1}{J(K-1)}\sum_{j=1}^{J}\sum_{k=1}^{K}(l_j^{(k)} - \bar{l}_{\cdot j})^2.$$

Then, the marginal posterior variance of $\hat{l}$ is calculated using

$$\hat{\sigma}^2 = \frac{K-1}{K}\hat{\sigma}_W^2 + \frac{1}{K}\hat{\sigma}_B^2.$$



(a) Autocorrelation

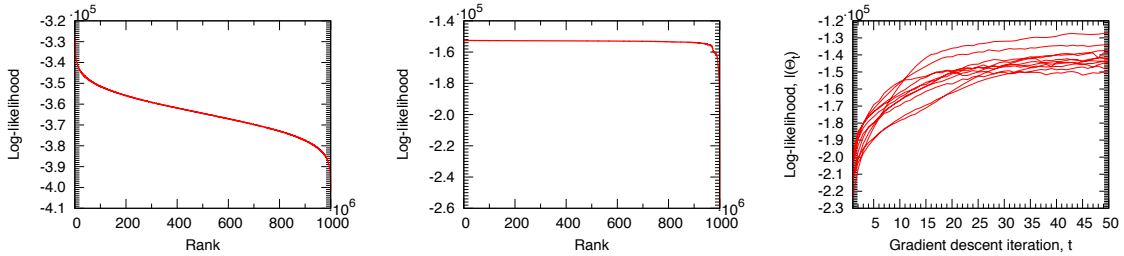


(b) Potential scale reduction

Figure 14: (a) Autocorrelation plot of the log-likelihood for the different choices of parameter ω. Notice we get best mixing with $\omega \approx 0.6$. (b) The potential scale reduction that compares the variance inside- and across- independent Markov chains for different values of parameter ω.

And, finally, we estimate the *potential scale reduction* (Gelman et al., 2003) of l by

$$\sqrt{\hat{R}} = \sqrt{\frac{\hat{\sigma}^2}{\hat{\sigma}_W^2}}.$$



(a) $l(\Theta|\sigma_i)$ where $\sigma_i \sim P(\sigma)$

(b) $l(\Theta|\sigma_i)$ where $\sigma_i \sim P(\sigma|\Theta, G)$

(c) $l(\Theta_t)$ for 10 random gradient descent runs

Figure 15: (a) Distribution of log-likelihood of permutations sampled uniformly at random, and (b) when sampled from $P(\sigma|\Theta, G)$. Notice the space of good permutations is rather small but our sampling quickly finds permutations of high likelihood. (c) Convergence of log-likelihood for 10 runs of gradient descent, each from a different random starting point.

Note that as the length of the chain $K \to \infty$, $\sqrt{\hat{R}}$ converges to 1 from above. The recommendation for convergence assessment from Gelman et al. (2003) is that the potential scale reduction is below 1.2.

Figure 14(b) gives the Gelman-Rubin-Brooks plot, where we plot the potential scale reduction $\sqrt{\hat{R}}$ over the increasing chain length K for different choices of parameter ω. Notice that the potential scale reduction quickly decays towards 1. Similarly as in Figure 14 the extreme values of ω give slow decay, while we obtain the fastest potential scale reduction when $\omega \approx 0.6$.

6.1.3 PROPERTIES OF THE PERMUTATION SPACE

Next we explore the properties of the permutation space. We would like to quantify what fraction of permutations are "good" (have high likelihood), and how quickly are they discovered. For the experiment we took a real network G (AS-ROUTEVIEWS network) and the MLE parameters $\hat{\Theta}$ for it that we estimated before hand ($l(\hat{\Theta}) \approx -150{,}000$). The network G has 6,474 nodes which means the space of all permutations has $\approx 10^{22{,}000}$ elements.

First, we sampled 1 billion (10^9) permutations σ_i uniformly at random, that is, $P(\sigma_i) = 1/(6{,}474!)$ and for each evaluated its log-likelihood $l(\sigma_i|\Theta) = \log P(\Theta|G, \sigma_i)$. We ordered the permutations in deceasing log-likelihood and plotted $l(\sigma_i|\Theta)$ vs. rank. Figure 15(a) gives the plot. Notice that very few random permutations are very bad (i.e., they give low likelihood), similarly few permutations are very good, while most of them are somewhere in between. Notice that best "random" permutation has log-likelihood of $\approx -320{,}000$, which is far below true likelihood $l(\hat{\Theta}) \approx -150{,}000$. This suggests that only a very small fraction of all permutations gives good node labelings.

On the other hand, we also repeated the same experiment but now using permutations sampled from the permutation distribution $\sigma_i \sim P(\sigma|\Theta, G)$ via our Metropolis sampling scheme. Figure 15(b) gives the plot. Notice the radical difference. Now the $l(\sigma|\Theta_i)$ very quickly converges to the true likelihood of $\approx -150{,}000$. This suggests that while the number of "good" permutations (accurate node mappings) is rather small, our sampling procedure quickly converges to the "good" part of the permutation space where node mappings are accurate, and spends the most time there.

6.2 Properties of the Optimization Space

In maximizing the likelihood we use a stochastic approximation to the gradient. This adds variance to the gradient and makes efficient optimization techniques, like conjugate gradient, highly unstable. Thus we use gradient descent, which is slower but easier to control. First, we make the following observation:

Observation 4 *Given a real graph G then finding the maximum likelihood Stochastic Kronecker initiator matrix $\hat{\Theta}$*

$$\hat{\Theta} = \arg\max_{\Theta} P(G|\Theta)$$

is a non-convex optimization problem.

Proof By definition permutations of the Kronecker graphs initiator matrix Θ all have the same log-likelihood. This means that we have several global minima that correspond to permutations of parameter matrix Θ, and then between them the log-likelihood drops. This means that the optimization problem is non-convex. ■

The above observation does not seem promising for estimating $\hat{\Theta}$ using gradient descent as it is prone to finding local minima. To test for this behavir we run the following experiment: we generated 100 synthetic Kronecker graphs on 16,384 (2^{14}) nodes and 1.4 million edges on the average, each with a randomly chosen 2×2 parameter matrix Θ^*. For each of the 100 graphs we run a single trial of gradient descent starting from a random parameter matrix Θ', and try to recover Θ^*. In 98% of the cases the gradient descent converged to the true parameters. Many times the algorithm converged to a different global minima, that is, $\hat{\Theta}$ is a permuted version of original parameter matrix Θ^*. Moreover, the median number of gradient descent iterations was only 52.

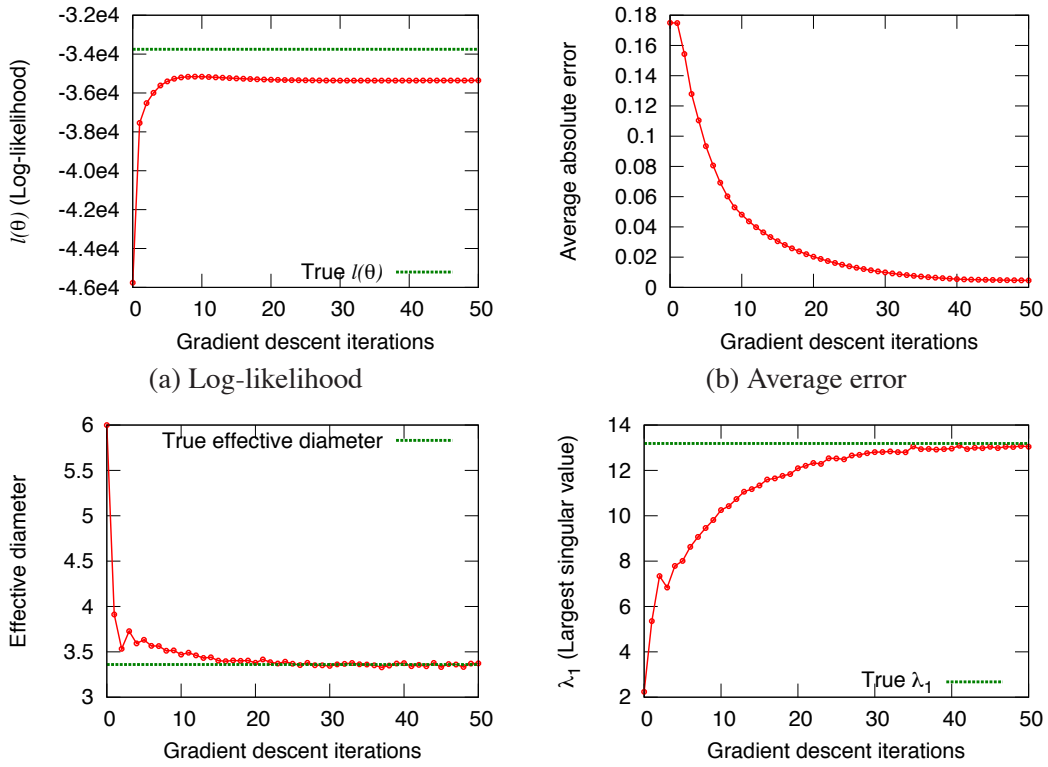
This suggests surprisingly nice structure of our optimization space: it seems to behave like a convex optimization problem with many equivalent global minima. Moreover, this experiment is also a good sanity check as it shows that given a Kronecker graph we can recover and identify the parameters that were used to generate it.

Moreover, Figure 15(c) plots the log-likelihood $l(\Theta_t)$ of the current parameter estimate Θ_t over the iterations t of the stochastic gradient descent. We plot the log-likelihood for 10 different runs of gradient descent, each time starting from a different random set of parameters Θ_0. Notice that in all runs gradient descent always converges towards the optimum, and none of the runs gets stuck in some local maxima.

6.3 Convergence of the Graph Properties

We approached the problem of estimating Stochastic Kronecker initiator matrix Θ by defining the likelihood over the individual entries of the graph adjacency matrix. However, what we would really like is to be given a real graph G and then generate a synthetic graph K that has similar properties as the real G. By properties we mean network statistics that can be computed from the graph, for example, diameter, degree distribution, clustering coefficient, etc. A priori it is not clear that our approach which tries to match individual entries of graph adjacency matrix will also be able to reproduce these global network statistics. However, as show next this is not the case.

To get some understanding of the convergence of the gradient descent in terms of the network properties we performed the following experiment. After every step t of stochastic gradient descent,



(a) Log-likelihood (b) Average error

(c) Effective diameter (d) Largest singular-value

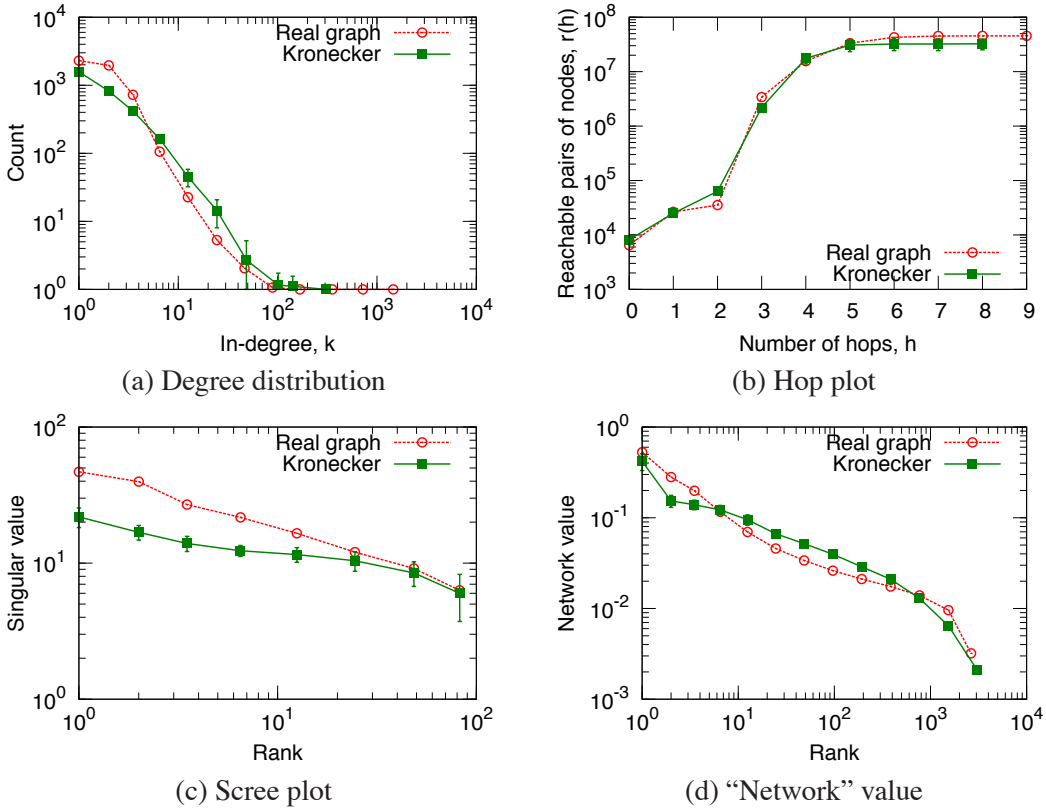
Figure 16: Convergence of graph properties with the number of iterations of gradient descent using the synthetic data set. We start with a random choice of parameters and with steps of gradient descent the Kronecker graph better and better matches network properties of the target graph.

we compare the true graph G with the synthetic Kronecker graph K_t generated using the current parameter estimates $\hat{\Theta}_t$. Figure 16(a) gives the convergence of log-likelihood, and (b) gives absolute error in parameter values ($\sum |\hat{\theta}_{ij} - \theta^*_{ij}|$, where $\hat{\theta}_{ij} \in \hat{\Theta}_t$, and $\theta^*_{ij} \in \Theta^*$). Similarly, Figure 16(c) plots the effective diameter, and (d) gives the largest singular value of graph adjacency matrix K as it converges to largest singular value of G.

Note how with progressing iterations of gradient descent properties of graph K_t quickly converge to those of G even though we are not directly optimizing the similarity in network properties: log-likelihood increases, absolute error of parameters decreases, diameter and largest singular value of K_t both converge to G. This is a nice result as it shows that through maximizing the likelihood the resulting graphs become more and more similar also in their structural properties (even though we are not directly optimizing over them).

6.4 Fitting to Real-world Networks

Next, we present experiments of fitting Kronecker graph model to real-world networks. Given a real network G we aim to discover the most likely parameters $\hat{\Theta}$ that ideally would generate a synthetic



(a) Degree distribution (b) Hop plot

(c) Scree plot (d) "Network" value

Figure 17: *Autonomous Systems (*AS-ROUTEVIEWS*):* Overlayed patterns of real graph and the fitted Kronecker graph. Notice that the fitted Kronecker graph matches patterns of the real graph while using only four parameters (2×2 initiator matrix).

graph K having similar properties as real G. This assumes that Kronecker graphs are a good model of the network structure, and that KRONFIT is able to find good parameters. In previous section we showed that KRONFIT can efficiently recover the parameters. Now we examine how well can Kronecker graph model the structure of real networks.

We consider several different networks, like a graph of connectivity among Internet Autonomous systems (AS-ROUTEVIEWS) with N =6,474 and E =26,467 a who-trusts-whom type social network from Epinions (Richardson et al., 2003) (EPINIONS) with N =75,879 and E =508,960 and many others. The largest network we consider for fitting is FLICKR photo-sharing online social network with 584,207 nodes and 3,555,115 edges.

For the purpose of this section we take a real network G, find parameters $\hat{\Theta}$ using KRONFIT, generate a synthetic graph K using $\hat{\Theta}$, and then compare G and K by comparing their properties that we introduced in Section 2. In all experiments we started from a random point (random initiator matrix) and run gradient descent for 100 steps. At each step we estimate the likelihood and the gradient based on 510,000 sampled permutations where we discard first 10,000 samples to allow the chain to burn-in.

6.4.1 FITTING TO AUTONOMOUS SYSTEMS NETWORK

First, we focus on the Autonomous Systems network obtained from the University of Oregon Route Views project (RouteViews, 1997). Given the AS network G we run KRONFIT to obtain parameter estimates $\hat{\Theta}$. Using the $\hat{\Theta}$ we then generate a synthetic Kronecker graph K, and compare the properties of G and K.

Figure 17 shows properties of AS-ROUTEVIEWS, and compares them with the properties of a synthetic Kronecker graph generated using the fitted parameters $\hat{\Theta}$ of size 2×2. Notice that properties of both graphs match really well. The estimated parameters are $\hat{\Theta} = [0.987, 0.571; 0.571, 0.049]$.

Figure 17(a) compares the degree distributions of the AS-ROUTEVIEWS network and its synthetic Kronecker estimate. In this and all other plots we use the exponential binning which is a standard procedure to de-noise the data when plotting on log-log scales. Notice a very close match in degree distribution between the real graph and its synthetic counterpart.

Figure 17(b) plots the cumulative number of pairs of nodes $g(h)$ that can be reached in $\leq h$ hops. The hop plot gives a sense about the distribution of the shortest path lengths in the network and about the network diameter. Last, Figures 17(c) and (d) plot the spectral properties of the graph adjacency matrix. Figure 17(c) plots largest singular values vs. rank, and (d) plots the components of left singular vector (the network value) vs. the rank. Again notice the good agreement with the real graph while using only four parameters.

Moreover, on all plots the error bars of two standard deviations show the variance of the graph properties for different realizations $R(\hat{\Theta}^{[k]})$. To obtain the error bars we took the same $\hat{\Theta}$, and generated 50 realizations of a Kronecker graph. As for the most of the plots the error bars are so small to be practically invisible, this shows that the variance of network properties when generating a Stochastic Kronecker graph is indeed very small.

Also notice that the AS-ROUTEVIEWS is an undirected graph, and that the fitted parameter matrix $\hat{\Theta}$ is in fact symmetric. This means that without a priori biasing the fitting towards undirected graphs, the recovered parameters obey this aspect of the network. Fitting AS-ROUTEVIEWS graph from a random set of parameters, performing gradient descent for 100 iterations and at each iteration sampling half a million permutations, took less than 10 minutes on a standard desktop PC. This is a significant speedup over Bezáková et al. (2006), where by using a similar permutation sampling approach for calculating the likelihood of a preferential attachment model on similar AS-ROUTEVIEWS graph took about two days on a cluster of 50 machines.

6.4.2 CHOICE OF THE INITIATOR MATRIX SIZE N_1

As mentioned earlier for finding the optimal number of parameters, that is, selecting the size of initiator matrix, BIC criterion naturally applies to the case of Kronecker graphs. Figure 23(b) shows BIC scores for the following experiment: We generated Kronecker graph with N =2,187 and E =8,736 using $N_1 = 3$ (9 parameters) and $k = 7$. For $1 \leq N_1 \leq 9$ we find the MLE parameters using gradient descent, and calculate the BIC scores. The model with the lowest score is chosen. As Figure 23(b) shows we recovered the true model, that is, BIC score is the lowest for the model with the true number of parameters, $N_1 = 3$.

Intuitively we expect a more complex model with more parameters to fit the data better. Thus we expect larger N_1 to generally give better likelihood. On the other hand the fit will also depend on the size of the graph G. Kronecker graphs can only generate graphs on N_1^k nodes, while real graphs do not necessarily have N_1^k nodes (for some, preferably small, integers N_1 and k). To solve this

N_1	$l(\hat{\Theta})$	N_1^k	E_1^k	$\lvert\{\deg(u) > 0\}\rvert$	BIC score
2	−152,499	8,192	25,023	5,675	152,506
3	−127,066	6,561	28,790	5,683	127,083
4	−153,260	16,384	24,925	8,222	153,290
5	−149,949	15,625	29,111	9,822	149,996
6	−128,241	7,776	26,557	6,623	128,309
AS-ROUTEVIEWS			26,467	6,474	

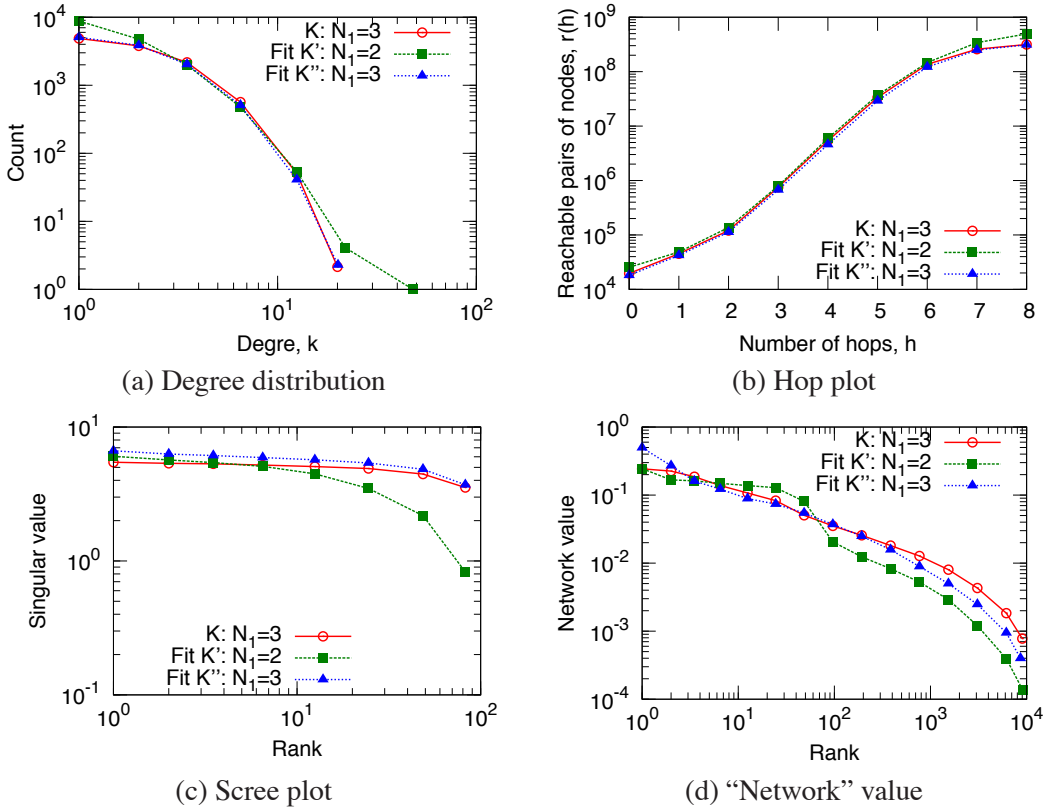
Table 2: Log-likelihood at MLE for different choices of the size of the initiator matrix N_1 for the AS-ROUTEVIEWS graph. Notice the log-likelihood $l(\hat{\theta})$ generally increases with the model complexity N_1. Also notice the effect of zero-padding, that is, for $N_1 = 4$ and $N_1 = 5$ the constraint of the number of nodes being an integer power of N_1 decreases the log-likelihood. However, the column $\lvert\{\deg(u) > 0\}\rvert$ gives the number of non-isolated nodes in the network which is much less than N_1^k and is in fact very close to the true number of nodes in the AS-ROUTEVIEWS. Using the BIC scores we see that $N_1 = 3$ or $N_1 = 6$ are best choices for the size of the initiator matrix.

problem we choose k so that $N_1^{k-1} < N(G) \leq N_1^k$, and then augment G by adding $N_1^k - N$ isolated nodes. Or equivalently, we pad the adjacency matrix of G with zeros until it is of the appropriate size, $N_1^k \times N_1^k$. While this solves the problem of requiring the integer power of the number of nodes it also makes the fitting problem harder as when $N \ll N_1^k$ we are basically fitting G plus a large number of isolated nodes.

Table 2 shows the results of fitting Kronecker graphs to AS-ROUTEVIEWS while varying the size of the initiator matrix N_1. First, notice that in general larger N_1 results in higher log-likelihood $l(\hat{\Theta})$ at MLE. Similarly, notice (column N_1^k) that while AS-ROUTEVIEWS has 6,474 nodes, Kronecker estimates have up to 16,384 nodes (16,384$= 4^7$, which is the first integer power of 4 greater than 6,474). However, we also show the number of non-zero degree (non-isolated) nodes in the Kronecker graph (column $\lvert\{\deg(u) > 0\}\rvert$). Notice that the number of non-isolated nodes well corresponds to the number of nodes in AS-ROUTEVIEWS network. This shows that KRONFIT is actually fitting the graph well and it successfully fits the structure of the graph plus a number of isolated nodes. Last, column E_1^k gives the number of edges in the corresponding Kronecker graph which is close to the true number of edges of the AS-ROUTEVIEWS graph.

Last, comparing the log-likelihood at the MLE and the BIC score in Table 2 we notice that the log-likelihood heavily dominates the BIC score. This means that the size of the initiator matrix (number of parameters) is so small that overfitting is not a concern. Thus we can just choose the initiator matrix that maximizes the likelihood. A simple calculation shows that one would need to take initiator matrices with thousands of entries before the model complexity part of BIC score would start to play a significant role.

We further examine the sensitivity of the choice of the initiator size by the following experiment. We generate a Stochastic Kronecker graphs K on 9 parameters ($N_1 = 3$), and then fit a Kronecker graph K' with a smaller number of parameters (4 instead of $9, N_1' = 2$). And also a Kronecker graph K'' of the same complexity as K ($N_1'' = 3$).



(a) Degree distribution (b) Hop plot

(c) Scree plot (d) "Network" value

Figure 18: *3 by 3 Stochastic Kronecker graphs:* Given a Stochastic Kronecker graphs G generated from $N_1 = 3$ (red curve), we fit a Kronecker graph K' with $N_1' = 2$ (green) and K'' with $N_1'' = 3$ (blue). Not surprisingly K'' fits the properties of K perfectly as the model is the of same complexity. On the other hand K' has only 4 parameters (instead of 9 as in K and K'') and still fits well.

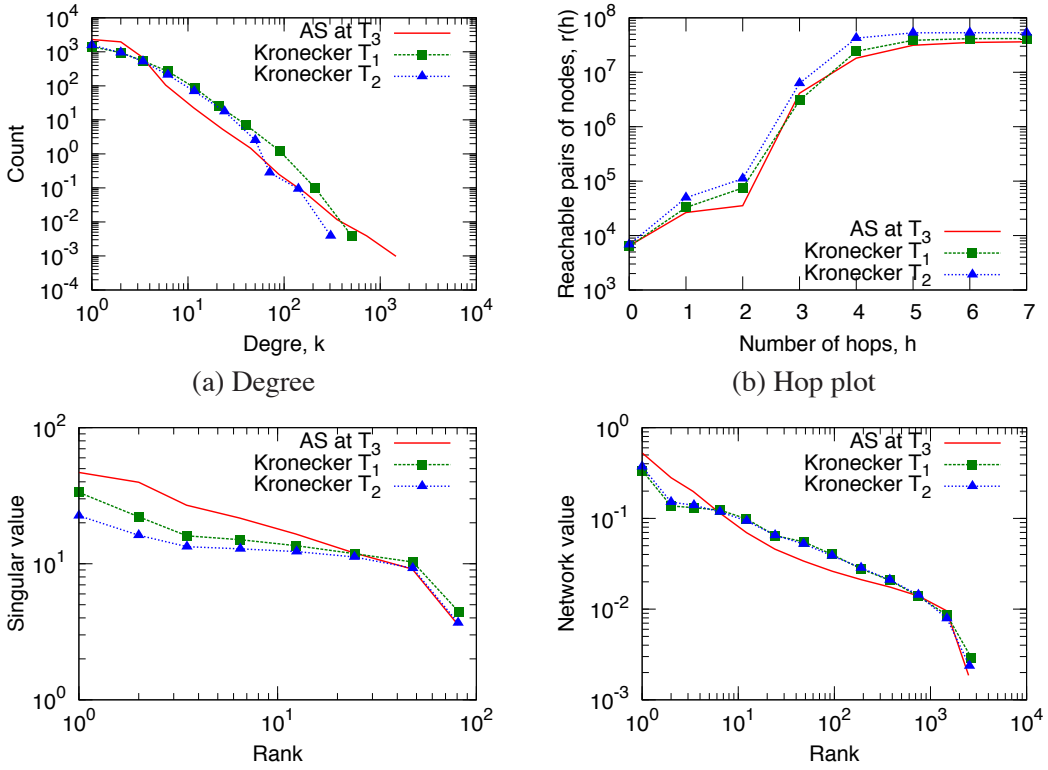
Figure 18 plots the properties of all three graphs. Not surprisingly K'' (blue) fits the properties of K (red) perfectly as the initiator is of the same size. On the other hand K' (green) is a simpler model with only 4 parameters (instead of 9 as in K and K'') and still generally fits well: hop plot and degree distribution match well, while spectral properties of graph adjacency matrix, especially scree plot, are not matched that well. This shows that nothing drastic happens and that even a bit too simple model still fits the data well. In general we observe empirically that by increasing the size of the initiator matrix one does not gain radically better fits for degree distribution and hop plot. On the other hand there is usually an improvement in the scree plot and the plot of network values when one increases the initiator size.

6.4.3 NETWORK PARAMETERS OVER TIME

Next we briefly examine the evolution of the Kronecker initiator for a temporally evolving graph. The idea is that given parameter estimates of a real-graph G_t at time t, we can forecast the future structure of the graph G_{t+x} at time $t+x$, that is, using parameters obtained from G_t we can generate a larger synthetic graph K that will be similar to G_{t+x}.

Snapshot at time	N	E	$l(\hat{\Theta})$	Estimates at MLE, $\hat{\Theta}$
T_1	2,048	8,794	−40,535	[0.981, 0.633; 0.633, 0.048]
T_2	4,088	15,711	−82,675	[0.934, 0.623; 0.622, 0.044]
T_3	6,474	26,467	−152,499	[0.987, 0.571; 0.571, 0.049]

Table 3: Parameter estimates of the three temporal snapshots of the AS-ROUTEVIEWS network. Notice that estimates stay remarkably stable over time.



(a) Degree (b) Hop plot

(c) Scree plot (d) "Network" value

Figure 19: *Autonomous systems network over time* (AS-ROUTEVIEWS): Overlayed patterns of real AS-ROUTEVIEWS network at time T_3 and the Kronecker graphs with parameters estimated from AS-ROUTEVIEWS at time T_1 and T_2. Notice good fits which means that parameters estimated on historic snapshots can be used to estimate the graph in the future.

As we have the information about the evolution of the AS-ROUTEVIEWS network, we estimated parameters for three snapshots of the network when it had about 2^k nodes. Table 3 gives the results of the fitting for the three temporal snapshots of the AS-ROUTEVIEWS network. Notice the parameter estimates $\hat{\Theta}$ remain remarkably stable over time. This means that Kronecker graphs can be used to estimate the structure of the networks in the future, that is, parameters estimated from the historic data can extrapolate the graph structure in the future.

Network	N	E	Estimated MLE parameters $\hat{\Theta}$	$l(\hat{\Theta})$	Time

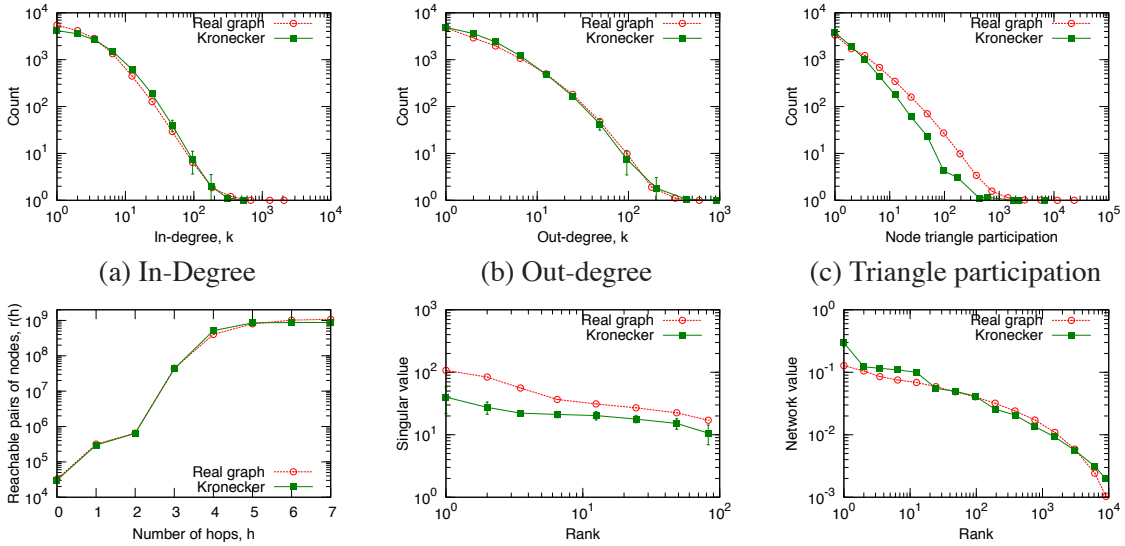
Table 4: Results of parameter estimation for 20 different networks. Table 5 gives the description and basic properties of the above network data sets. Networks and KRONFIT code are available for download at `http://snap.stanford.edu`.

Figure 19 further explores this. It overlays the graph properties of the real AS-ROUTEVIEWS network at time T_3 and the synthetic graphs for which we used the parameters obtained on historic snapshots of AS-ROUTEVIEWS at times T_1 and T_2. The agreements are good which demonstrates that Kronecker graphs can forecast the structure of the network in the future.

Moreover, this experiments also shows that parameter estimates do not suffer much from the zero padding of graph adjacency matrix (i.e., adding isolated nodes to make G have N_1^k nodes). Snapshots of AS-ROUTEVIEWS at T_1 and T_2 have close to 2^k nodes, while we had to add 26% (1,718) isolated nodes to the network at T_3 to make the number of nodes be 2^k. Regardless of this we see the parameter estimates $\hat{\Theta}$ remain basically constant over time, which seems to be independent of the number of isolated nodes added. This means that the estimated parameters are not biased too much from zero padding the adjacency matrix of G.

6.5 Fitting to Other Large Real-world Networks

Last, we present results of fitting Stochastic Kronecker graphs to 20 large real-world networks: large online social networks, like EPINIONS, FLICKR and DELICIOUS, web and blog graphs (WEB-NOTREDAME, BLOG-NAT05-6M, BLOG-NAT06ALL), internet and peer-to-peer networks (AS-NEWMAN, GNUTELLA-25, GNUTELLA-30), collaboration networks of co-authorships from DBLP (CA-DBLP) and various areas of physics (CA-HEP-TH, CA-HEP-PH, CA-GR-QC), physics citation networks (CIT-HEP-PH, CIT-HEP-TH), an email network (EMAIL-INSIDE), a protein inter-



(a) In-Degree (b) Out-degree (c) Triangle participation

(d) Hop plot (e) Scree plot (f) "Network" value

Figure 20: *Blog network* (BLOG-NAT06ALL): Overlayed patterns of real network and the estimated Kronecker graph using 4 parameters (2×2 initiator matrix). Notice that the Kronecker graph matches all properties of the real network.

action network BIO-PROTEINS, and a bipartite affiliation network (authors-to-papers, ATP-GR-QC). Refer to Table 5 in the appendix for the description and basic properties of these networks. They are available for download at `http://snap.stanford.edu`.

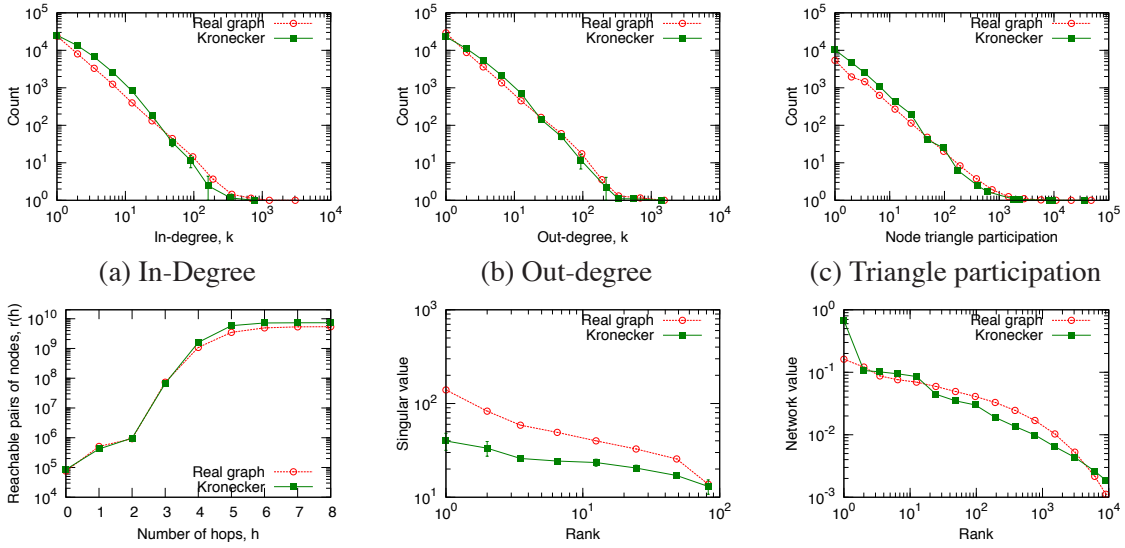
For each data set we started gradient descent from a random point (random initiator matrix) and ran it for 100 steps. At each step we estimate the likelihood and the gradient based on 510,000 sampled permutations where we discard first 10,000 samples to allow the chain to burn-in.

Table 4 gives the estimated parameters, the corresponding log-likelihoods and the wall clock times. All experiments were carried out on standard desktop computer. Notice that the estimated initiator matrices $\hat{\Theta}$ seem to have almost universal structure with a large value in the top left entry, a very small value at the bottom right corner and intermediate values in the other two corners. We further discuss the implications of such structure of Kronecker initiator matrix on the global network structure in next section.

Last, Figures 20 and 21 show overlays of various network properties of real and the estimated synthetic networks. In addition to the network properties we plotted in Figure 18, we also separately plot in- and out-degree distributions (as both networks are directed) and plot the node triangle participation in panel (c), where we plot the number of triangles a node participates in versus the number of such nodes. (Again the error bars show the variance of network properties over different realizations $R(\hat{\Theta}^{[k]})$ of a Stochastic Kronecker graph.)

Notice that for both networks and in all cases the properties of the real network and the synthetic Kronecker coincide really well. Using Stochastic Kronecker graphs with just 4 parameters we match the scree plot, degree distributions, triangle participation, hop plot and network values.

Given the previous experiments from the Autonomous systems graph we only present the results for the simplest model with initiator size $N_1 = 2$. Empirically we also observe that $N_1 = 2$ gives



(a) In-Degree (b) Out-degree (c) Triangle participation

(d) Hop plot (e) Scree plot (f) "Network" value

Figure 21: EPINIONS *who-trusts-whom social network:* Overlayed patterns of real network and the fitted Kronecker graph using only 4 parameters (2×2 initiator matrix). Again, the synthetic Kronecker graph matches all the properties of the real network.

surprisingly good fits and the estimation procedure is the most robust and converges the fastest. Using larger initiator matrices $N_1 > 2$ generally helps improve the likelihood but not dramatically. In terms of matching the network properties we also gent a slight improvement by making the model more complex. Figure 22 gives the percent improvement in log-likelihood as we make the model more complex. We use the log-likelihood of a 2×2 model as a baseline and estimate the log-likelihood at the MLE for larger initiator matrices. Again, models with more parameters tend to fit better. However, sometimes due to zero-padding of a graph adjacency matrix they actually have lower log-likelihood (as for example seen in Table 2).

6.6 Scalability

Last we also empirically evaluate the scalability of the KRONFIT. The experiment confirms that KRONFIT runtime scales linearly with the number of edges E in a graph G. More precisely, we performed the following experiment.

We generated a sequence of increasingly larger synthetic graphs on N nodes and $8N$ edges, and measured the time of one iteration of gradient descent, that is, sample 1 million permutations and evaluate the gradients. We started with a graph on 1,000 nodes, and finished with a graph on 8 million nodes, and 64 million edges. Figure 23(a) shows KRONFIT scales *linearly* with the size of the network. We plot wall-clock time vs. size of the graph. The dashed line gives a linear fit to the data points.

7. Discussion

Here we discuss several of the desirable properties of the proposed Kronecker graphs.

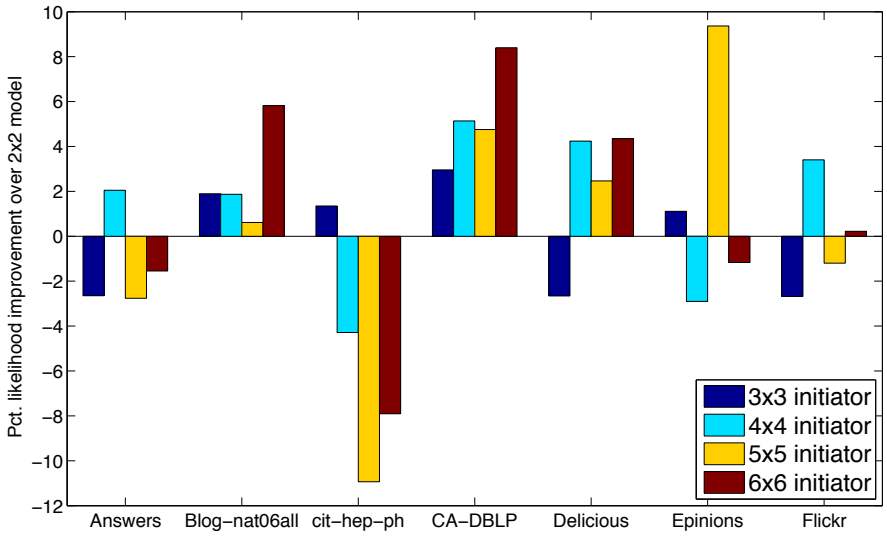


Figure 22: Percent improvement in log-likelihood over the 2×2 model as we increase the model complexity (size of initiator matrix). In general larger initiator matrices that have more degrees of freedom help improving the fit of the model.

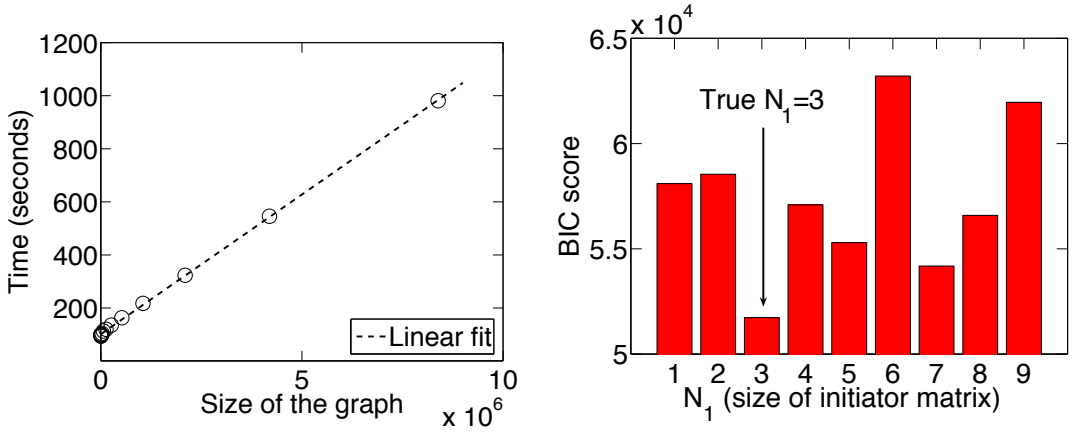
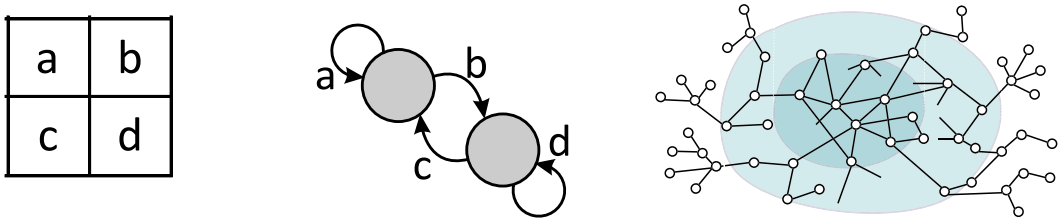


(a) Scalability (b) Model selection

Figure 23: (a) Processor time to sample 1 million gradients as the graph grows. Notice the algorithm scales linearly with the graph size. (b) BIC score for model selection.

Generality: Stochastic Kronecker graphs include several other generators as special cases: For $\theta_{ij} = c$, we obtain the classical Erdős-Rényi random graph model. For $\theta_{i,j} \in \{0,1\}$, we obtain a deterministic Kronecker graph. Setting the K_1 matrix to a 2×2 matrix, we obtain the R-MAT generator (Chakrabarti et al., 2004). In contrast to Kronecker graphs, the RMAT cannot extrapolate into the future, since it needs to know the number of edges to insert. Thus, it is incapable of obeying the densification power law.



(a) 2×2 initiator matrix (b) Two recursive communities (c) Core-periphery

Figure 24: 2×2 Kronecker initiator matrix (a) can be thought of as two communities where there are a and d edges inside each of the communities and b and c edges crossing the two communities as illustrated in (b). Each community can then be recursively divided using the same pattern. (c) The onion like core-periphery structure where the network gets denser and denser as we move towards the center of the network.

Phase transition phenomena: The Erdős-Rényi graphs exhibit phase transitions (Erdős and Rényi, 1960). Several researchers argue that real systems are "at the edge of chaos" or phase transition (Bak, 1996; Sole and Goodwin, 2000). Stochastic Kronecker graphs also exhibit phase transitions (Mahdian and Xu, 2007) for the emergence of the giant component and another phase transition for connectivity.

Implications to the structure of the large-real networks: Empirically we found that 2×2 initiator ($N_1 = 2$) fits well the properties of real-world networks. Moreover, given a 2×2 initiator matrix, one can look at it as a recursive expansion of two groups into sub-groups. We introduced this recursive view of Kronecker graphs back in Section 3. So, one can then interpret the diagonal values of Θ as the proportion of edges inside each of the groups, and the off-diagonal values give the fraction of edges connecting the groups. Figure 24 illustrates the setting for two groups.

For example, as shown in Figure 24, large a, d and small b, c would imply that the network is composed of hierarchically nested communities, where there are many edges inside each community and few edges crossing them (Leskovec, 2009). One could think of this structure as some kind of organizational or university hierarchy, where one expects the most friendships between people within same lab, a bit less between people in the same department, less across different departments, and the least friendships to be formed across people from different schools of the university.

However, parameter estimates for a wide range of networks presented in Table 4 suggests a very different picture of the network structure. Notice that for most networks $a \gg b > c \gg d$. Moreover, $a \approx 1, b \approx c \approx 0.6$ and $d \approx 0.2$. We empirically observed that the same structure of initiator matrix $\hat{\Theta}$ also holds when fitting 3×3 or 4×4 models. Always the top left element is the largest and then the values on the diagonal decay faster than off the diagonal (Leskovec, 2009).

This suggests a network structure which is also known as *core-periphery* (Borgatti and Everett, 2000; Holme, 2005), the *jellyfish* (Tauro et al., 2001; Siganos et al., 2006), or the *octopus* (Chung and Lu, 2006) structure of the network as illustrated in Figure 24(c).

All of the above basically say that the network is composed of a densely linked network core and the periphery. In our case this would imply the following structure of the initiator matrix. The core is modeled by parameter a and the periphery by d. Most edges are inside the core (large a), and very few between the nodes of periphery (small d). Then there are many more edges between the core and the periphery than inside the periphery ($b, c > d$) (Leskovec, 2009). This is exactly what

we see as well. And in spirit of Kronecker graphs the structure repeats recursively—the core again has the dense core and the periphery, and so on. And similarly the periphery itself has the core and the periphery.

This suggest an "onion" like *nested core-periphery* (Leskovec et al., 2008a,b) network structure as illustrated in Figure 24(c), where the network is composed of denser and denser layers as one moves towards the center of the network. We also observe similar structure of the Kronecker initiator when fitting 3×3 or 4×4 initiator matrix. The diagonal elements have large but decreasing values with off diagonal elements following same decreasing pattern.

One of the implications of this is that networks do not break nicely into hierarchically organized sets of communities that lend themselves to graph partitioning and community detection algorithms. On contrary, this suggests that large networks can be decomposed into a densely linked core with many small periphery pieces hanging off the core. This is in accordance with our recent results (Leskovec et al., 2008a,b), that make similar observation (but based on a completely different methodology based on graph partitioning) about the clustering and community structure of large real-world networks.

8. Conclusion

In conclusion, the main contribution of this work is a family of models of network structure that uses a non-traditional matrix operation, the *Kronecker product*. The resulting graphs (a) have all the static properties (heavy-tailed degree distribution, small diameter, etc.), (b) all the temporal properties (densification, shrinking diameter) that are found in real networks. And in addition, (c) we can formally prove all of these properties.

Several of the proofs are extremely simple, thanks to the rich theory of Kronecker multiplication. We also provide proofs about the diameter and effective diameter, and we show that Stochastic Kronecker graphs can mimic real graphs well.

Moreover, we also presented KRONFIT, a fast, scalable algorithm to estimate Stochastic Kronecker initiator, which can be then used to create a synthetic graph that mimics the properties of a given real network.

In contrast to earlier work, our work has the following novelties: (a) it is among the few that estimates the parameters of the chosen generator in a principled way, (b) it is among the few that has a concrete measure of goodness of the fit (namely, the likelihood), (c) it avoids the quadratic complexity of computing the likelihood by exploiting the properties of the Kronecker graphs, and (d) it avoids the factorial explosion of the node correspondence problem, by using the Metropolis sampling.

The resulting algorithm matches well all the known properties of real graphs, as we show with the Epinions graph and the AS graph, it scales linearly on the number of edges, and it is orders of magnitudes faster than earlier graph-fitting attempts: 20 minutes on a commodity PC, versus 2 days on a cluster of 50 workstations (Bezáková et al., 2006).

The benefits of fitting a Kronecker graph model into a real graph are several:

- *Extrapolation*: Once we have the Kronecker generator Θ for a given real matrix G (such that G is mimicked by $\Theta^{[k]}$), a larger version of G can be generated by $\Theta^{[k+1]}$.
- *Null-model*: When analyzing a real network G one often needs to asses the significance of the observation. $\Theta^{[k]}$ that mimics G can be used as an accurate model of G.

- *Network structure*: Estimated parameters give insight into the global network and community structure of the network.

- *Forecasting*: As we demonstrated one can obtain Θ from a graph G_t at time t such that G is mimicked by $\Theta^{[k]}$. Then Θ can be used to model the structure of G_{t+x} in the future.

- *Sampling*: Similarly, if we want a realistic sample of the real graph, we could use a smaller exponent in the Kronecker exponentiation, like $\Theta^{[k-1]}$.

- *Anonymization*: Since $\Theta^{[k]}$ mimics G, we can publish $\Theta^{[k]}$, without revealing information about the nodes of the real graph G.

Future work could include extensions of Kronecker graphs to evolving networks. We envision formulating a dynamic Bayesian network with first order Markov dependencies, where parameter matrix at time t depends on the graph G_t at current time t and the parameter matrix at time $t-1$. Given a series of network snapshots one would then aim to estimate initiator matrices at individual time steps and the parameters of the model governing the evolution of the initiator matrix. We expect that based on the evolution of initiator matrix one would gain greater insight in the evolution of large networks.

Second direction for future work is to explore connections between Kronecker graphs and Random Dot Product graphs (Young and Scheinerman, 2007; Nickel, 2008). This also nicely connects with the "attribute view" of Kronecker graphs as described in Section 3.5. It would be interesting to design methods to estimate the individual node attribute values as well as the attribute-attribute similarity matrix (i.e., the initiator matrix). As for some networks node attributes are already given one could then try to infer "hidden" or missing node attribute values and this way gain insight into individual nodes as well as individual edge formations. Moreover, this would be interesting as one could further evaluate how realistic is the "attribute view" of Kronecker graphs.

Last, we also mention possible extensions of Kronecker graphs for modeling weighted and labeled networks. Currently Stochastic Kronecker graphs use a Bernoulli edge generation model, that is, an entry of big matrix $\mathcal{P}$ encodes the parameter of a Bernoulli coin. In similar spirit one could consider entries of $\mathcal{P}$ to encode parameters of different edge generative processes. For example, to generate networks with weights on edges an entry of $\mathcal{P}$ could encode the parameter of an exponential distribution, or in case of labeled networks one could use several initiator matrices in parallel and this way encode parameters of a multinomial distribution over different node attribute values.

Abstract

The problem of computing a maximum a posteriori (MAP) configuration is a central computational challenge associated with Markov random fields. There has been some focus on "tree-based" linear programming (LP) relaxations for the MAP problem. This paper develops a family of super-linearly convergent algorithms for solving these LPs, based on proximal minimization schemes using Bregman divergences. As with standard message-passing on graphs, the algorithms are distributed and exploit the underlying graphical structure, and so scale well to large problems. Our algorithms have a double-loop character, with the outer loop corresponding to the proximal sequence, and an inner loop of cyclic Bregman projections used to compute each proximal update. We establish convergence guarantees for our algorithms, and illustrate their performance via some simulations. We also develop two classes of rounding schemes, deterministic and randomized, for obtaining integral configurations from the LP solutions. Our deterministic rounding schemes use a "re-parameterization" property of our algorithms so that when the LP solution is integral, the MAP solution can be obtained even before the LP-solver converges to the optimum. We also propose graph-structured randomized rounding schemes applicable to iterative LP-solving algorithms in general. We analyze the performance of and report simulations comparing these rounding schemes.

Keywords: graphical models, MAP Estimation, LP relaxation, proximal minimization, rounding schemes

1. Introduction

A key computational challenge that arises in applications of discrete graphical models is to compute the most probable configuration(s), often referred to as the *maximum a posteriori* (MAP) problem. Although the MAP problem can be solved exactly in polynomial time on trees (and more generally, graphs with bounded treewidth) using the max-product algorithm, it is computationally challenging

∗. Also in the Department of Electrical Engineering and Computer Sciences.

for general graphs. Indeed, the MAP problem for general discrete graphical models includes a large number of classical NP-complete problems as special cases, including MAX-CUT, independent set, and various satisfiability problems.

This intractability motivates the development and analysis of methods for obtaining approximate solutions, and there is a long history of approaches to the problem. One class of methods is based on simulated annealing (Geman and Geman, 1984), but the cooling schedules required for theoretical guarantees are often prohibitively slow. Besag (1986) proposed the iterated conditional modes algorithm, which performs a sequence of greedy local maximizations to approximate the MAP solution, but may be trapped by local maxima. Greig et al. (1989) observed that for binary problems with attractive pairwise interactions (the ferromagnetic Ising model in statistical physics terminology), the MAP configuration can be computed in polynomial-time by reduction to a max-flow problem. The ordinary max-product algorithm, a form of non-serial dynamic-programming (Bertele and Brioschi, 1972), computes the MAP configuration exactly for trees, and is also frequently applied to graphs with cycles. Despite some local optimality results (Freeman and Weiss, 2001; Wainwright et al., 2004), it has no general correctness guarantees for graph with cycles, and even worse, it can converge rapidly to non-MAP configurations (Wainwright et al., 2005), even for problems that are easily solved in polynomial time (e.g., ferromagnetic Ising models). For certain graphical models arising in computer vision, Boykov et al. (2001) proposed graph-cut based search algorithms that compute a local maximum over two classes of moves. A broad class of methods are based on the principle of convex relaxation, in which the discrete MAP problem is relaxed to a convex optimization problem over continuous variables. Examples of this convex relaxation problem include linear programming relaxations (Koval and Schlesinger, 1976; Chekuri et al., 2005; Wainwright et al., 2005), as well as quadratic, semidefinite and other conic programming relaxations (for instance, (Ravikumar and Lafferty, 2006; Kumar et al., 2006; Wainwright and Jordan, 2004)).

Among the family of conic programming relaxations, linear programming (LP) relaxation is the least expensive computationally, and also the best understood. The primary focus of this paper is a well-known LP relaxation of the MAP estimation problem for pairwise Markov random fields, one which has been independently proposed by several groups (Koval and Schlesinger, 1976; Chekuri et al., 2005; Wainwright et al., 2005). This LP relaxation is based on optimizing over a set of locally consistent pseudomarginals on edges and vertices of the graph. It is an exact method for any tree-structured graph, so that it can be viewed naturally as a tree-based LP relaxation.[1] The first connection between max-product message-passing and LP relaxation was made by Wainwright et al. (2005), who connected the tree-based LP relaxation to the class of tree-reweighted max-product (TRW-MP) algorithms, showing that TRW-MP fixed points satisfying a strong "tree agreement" condition specify optimal solutions to the LP relaxation.

For general graphs, this first-order LP relaxation could be solved—at least in principle—by various standard algorithms for linear programming, including the simplex and interior-point methods (Bertsimas and Tsitsikilis, 1997; Boyd and Vandenberghe, 2004). However, such generic methods fail to exploit the graph-structured nature of the LP, and hence do not scale favorably to large-scale problems (Yanover et al., 2006). A body of work has extended the connection between the LP relaxation and message-passing algorithms in various ways. Kolmogorov (2005) developed a serial form of TRW-MP updates with certain convergence guarantees; he also showed that there exist fixed points of the TRW-MP algorithm, not satisfying strong tree agreement, that do not cor-

1. In fact, this LP relaxation is the first in a hierarchy of relaxations, based on the treewidth of the graph (Wainwright et al., 2005).

respond to optimal solutions of the LP. This issue has a geometric interpretation, related to the fact that coordinate ascent schemes (to which TRW-MP is closely related), need not converge to the global optima for convex programs that are not strictly convex, but can become trapped in corners. Kolmogorov and Wainwright (2005) showed that this trapping phenomena does not arise for graphical models with binary variables and pairwise interactions, so that TRW-MP fixed points are always LP optimal. Globerson and Jaakkola (2007b) developed a related but different dual-ascent algorithm, which is guaranteed to converge but is not guaranteed to solve the LP. Weiss et al. (2007) established connections between convex forms of the sum-product algorithm, and exactness of reweighted max-product algorithms; Johnson et al. (2007) also proposed algorithms related to convex forms of sum-product. Various authors have connected the ordinary max-product algorithm to the LP relaxation for special classes of combinatorial problems, including matching (Bayati et al., 2005; Huang and Jebara, 2007; Bayati et al., 2007) and independent set (Sanghavi et al., 2007). For general problems, max-product does *not* solve the LP; Wainwright et al. (2005) describe a instance of the MIN-CUT problem on which max-product fails, even though LP relaxation is exact. Other authors (Feldman et al., 2002a; Komodakis et al., 2007) have implemented subgradient methods which are guaranteed to solve the linear program, but such methods typically have sub-linear convergence rates (Bertsimas and Tsitsikilis, 1997).

This paper makes two contributions to this line of work. Our first contribution is to develop and analyze a class of message-passing algorithms with the following properties: their only fixed points are LP-optimal solutions, they are provably convergent with at least a geometric rate, and they have a distributed nature, respecting the graphical structure of the problem. All of the algorithms in this paper are based on the well-established idea of *proximal minimization*: instead of directly solving the original linear program itself, we solve a sequence of so-called proximal problems, with the property that the sequence of associated solutions is guaranteed to converge to the LP solution. We describe different classes of algorithms, based on different choices of the proximal function: quadratic, entropic, and tree-reweighted entropies. For all choices, we show how the intermediate proximal problems can be solved by forms of message-passing on the graph that are similar to but distinct from the ordinary max-product or sum-product updates. An additional desirable feature, given the wide variety of lifting methods for further constraining LP relaxations (Wainwright and Jordan, 2003), is that new constraints can be incorporated in a relatively seamless manner, by introducing new messages to enforce them.

Our second contribution is to develop various types of rounding schemes that allow for early termination of LP-solving algorithms. There is a substantial body of past work (e.g., Raghavan and Thompson, 1987) on rounding fractional LP solutions so as to obtain integral solutions with approximation guarantees. Our use of rounding is rather different: instead, we consider rounding schemes applied to problems for which the LP solution is integral, so that rounding would be unnecessary if the LP were solved to optimality. In this setting, the benefit of certain rounding procedures (in particular, those that we develop) is allowing an LP-solving algorithm to be terminated *before* it has solved the LP, while still returning the MAP configuration, either with a deterministic or high probability guarantee. Our deterministic rounding schemes apply to a class of algorithms which, like the proximal minimization algorithms that we propose, maintain a certain invariant of the original problem. We also propose and analyze a class of graph-structured randomized rounding procedures that apply to any algorithm that approaches the optimal LP solution from the interior of the relaxed polytope. We analyze these rounding schemes, and give finite bounds on the number of iterations required for the rounding schemes to obtain an integral MAP solution.

The remainder of this paper is organized as follows. We begin in Section 2 with background on Markov random fields, and the first-order LP relaxation. In Section 3, we introduce the notions of proximal minimization and Bregman divergences, then derive various of message-passing algorithms based on these notions, and finally discuss their convergence properties. Section 4 is devoted to the development and analysis of rounding schemes, both for our proximal schemes as well as other classes of LP-solving algorithms. We provide experimental results in Section 5, and conclude with a discussion in Section 6.

2. Background

We begin by introducing some background on Markov random fields, and the LP relaxations that are the focus of this paper. Given a discrete space $\mathcal{X} = \{0, 1, 2, \ldots, m-1\}$, let $X = (X_1, \ldots, X_N) \in \mathcal{X}^N$ denote a N-dimensional discrete random vector. (While we have assumed the variables take values in the same set $\mathcal{X}$, we note that our results easily generalize to the case where the variables take values in different sets with differing cardinalities.) We assume that the distribution $\mathbb{P}$ of the random vector is a Markov random field, meaning that it factors according to the structure of an undirected graph $G = (V, E)$, with each variable X_s associated with one node $s \in V$, in the following way. Letting $\theta_s : \mathcal{X} \to \mathbb{R}$ and $\theta_{st} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ be singleton and edgewise potential functions respectively, we assume that the distribution takes the form

$$\mathbb{P}(x; \theta) \quad \propto \quad \exp\Big\{ \sum_{s \in V} \theta_s(x_s) + \sum_{(s,t) \in E} \theta_{st}(x_s, x_t) \Big\}.$$

The problem of *maximum a posteriori* (MAP) estimation is to compute a configuration with maximum probability—that is, an element

$$x^* \quad \in \quad \arg\max_{x \in \mathcal{X}^N} \Big\{ \sum_{s \in V} \theta_s(x_s) + \sum_{(s,t) \in E} \theta_{st}(x_s, x_t) \Big\}, \tag{1}$$

where the arg max operator extracts the configurations that achieve the maximal value. This problem is an integer program, since it involves optimizing over the discrete space $\mathcal{X}^N$. For future reference, we note that the functions $\theta_s(\cdot)$ and $\theta_{st}(\cdot)$ can always be represented in the form

$$\theta_s(x_s) = \sum_{j \in \mathcal{X}} \theta_{s;j} \mathbb{I}[x_s = j],$$
$$\theta_{st}(x_s, x_t) = \sum_{j,k \in \mathcal{X}} \theta_{st;jk} \mathbb{I}[x_s = j; x_t = k],$$

where the m-vectors $\{\theta_{s;j}, j \in \mathcal{X}\}$ and $m \times m$ matrices $\{\theta_{st;jk},\ (j,k) \in \mathcal{X} \times \mathcal{X}\}$ parameterize the problem.

The first-order linear programming (LP) relaxation (Koval and Schlesinger, 1976; Chekuri et al., 2005; Wainwright et al., 2005) of this problem is based on a set of pseudomarginals μ_s and μ_{st}, associated with the nodes and vertices of the graph. These pseudomarginals are constrained to be non-negative, as well to normalize and be locally consistent in the following sense:

$$\sum_{x_s \in \mathcal{X}} \mu_s(x_s) \quad = \quad 1, \qquad \text{for all } s \in V, \text{ and} \tag{2}$$

$$\sum_{x_t \in \mathcal{X}} \mu_{st}(x_s, x_t) \quad = \quad \mu_s(x_s) \qquad \text{for all } (s,t) \in E,\ x_s \in \mathcal{X}. \tag{3}$$

The polytope defined by the non-negativity constraints $\mu \geq 0$, the normalization constraints (2) and the marginalization constraints (3), is denoted by $\mathbb{L}(G)$. The LP relaxation is based on maximizing the linear function

$$\langle \theta, \mu \rangle \quad := \quad \sum_{s \in V} \sum_{x_s} \theta_s(x_s)\mu_s(x_s) + \sum_{(s,t) \in E} \sum_{x_s, x_t} \theta_{st}(x_s, x_t)\mu_{st}(x_s, x_t), \tag{4}$$

subject to the constraint $\mu \in \mathbb{L}(G)$.

In the sequel, we write the linear program (4) more compactly in the form $\max_{\mu \in \mathbb{L}(G)} \langle \theta, \mu \rangle$. By construction, this relaxation is guaranteed to be exact for any problem on a tree-structured graph (Wainwright et al., 2005), so that it can be viewed as a tree-based relaxation. The main goal of this paper is to develop efficient and distributed algorithms for solving this LP relaxation,[2] as well as strengthenings based on additional constraints. For instance, one natural strengthening is by "lifting": view the pairwise MRF as a particular case of a more general MRF with higher order cliques, define higher-order pseudomarginals on these cliques, and use them to impose higher-order consistency constraints. This particular progression of tighter relaxations underlies the Bethe to Kikuchi (sum-product to generalized sum-product) hierarchy (Yedidia et al., 2005); see Wainwright and Jordan (2003) for further discussion of such LP hierarchies.

3. Proximal Minimization Schemes

We begin by defining the notion of a proximal minimization scheme, and various types of divergences (among them Bregman) that we use to define our proximal sequences. Instead of dealing with the maximization problem $\max_{\mu \in \mathbb{L}(G)} \langle \theta, \mu \rangle$, it is convenient to consider the equivalent minimization problem,

$$\min_{\mu \in \mathbb{L}(G)} -\langle \theta, \mu \rangle.$$

3.1 Proximal Minimization

The class of methods that we develop are based on the notion of proximal minimization (Bertsekas and Tsitsiklis, 1997). Instead of attempting to solve the LP directly, we solve a sequence of problems of the form

$$\mu^{n+1} = \arg\min_{\mu \in \mathbb{L}(G)} \left\{ -\langle \theta, \mu \rangle + \frac{1}{\omega^n} D_f(\mu \,\|\, \mu^n) \right\}, \tag{5}$$

where for iteration numbers $n = 0, 1, 2, \ldots$, the vector μ^n denotes current iterate, the quantity ω^n is a positive weight, and D_f is a generalized distance function, known as the proximal function. (Note that we are using superscripts to represent the iteration number, *not* for the power operation.)

The purpose of introducing the proximal function is to convert the original LP—which is convex but not strictly so—into a strictly convex problem. The latter property is desirable for a number of reasons. First, for strictly convex programs, coordinate descent schemes are guaranteed to converge to the global optimum; note that they may become trapped for non-strictly convex problems, such as the piecewise linear surfaces that arise in linear programming. Moreover, the dual of a strictly convex problem is guaranteed to be differentiable (Bertsekas, 1995); a guarantee which need not hold

2. The relaxation could fail to be exact though, in which case the optimal solution to the relaxed problem will be suboptimal on the original MAP problem

for non-strictly convex problems. Note that differentiable dual functions can in general be solved more easily than non-differentiable dual functions. In the sequel, we show how for appropriately chosen generalized distances, the proximal sequence $\{\mu^n\}$ can be computed using message passing updates derived from cyclic projections.

We note that the proximal scheme (5) is similar to an annealing scheme, in that it involves perturbing the original cost function, with a choice of weights $\{\omega^n\}$. While the weights $\{\omega^n\}$ can be adjusted for faster convergence, they can also be set to a constant, unlike for standard annealing procedures in which the annealing weight is taken to 0. The reason is that $D_f(\mu \,\|\, \mu^{(n)})$, as a generalized distance, itself converges to zero as the algorithm approaches the optimum, thus providing an "adaptive" annealing. For appropriate choice of weights and proximal functions, these proximal minimization schemes converge to the LP optimum with at least geometric and possibly superlinear rates (Bertsekas and Tsitsiklis, 1997; Iusem and Teboulle, 1995).

In this paper, we focus primarily on proximal functions that are Bregman divergences (Censor and Zenios, 1997), a class that includes various well-known divergences, among them the squared ℓ_2-distance and norm, and the Kullback-Leibler divergence. We say that a function $f : S \mapsto \mathbb{R}$, with domain $S \subseteq \mathbb{R}^p$, is a *Bregman function* if int $S \neq \emptyset$ and it is continuously differentiable and strictly convex on int S. Any such function induces a *Bregman divergence* $D_f : S \times \text{int}S \mapsto \mathbb{R}$ as follows:

$$D_f(\mu' \,\|\, \nu) \quad := \quad f(\mu') - f(\nu) - \langle \nabla f(\nu), \mu' - \nu \rangle. \tag{6}$$

Figure 1 illustrates the geometric interpretation of this definition in terms of the tangent approximation. A Bregman divergence satisfies $D_f(\mu' \,\|\, \nu) \geq 0$ with equality if and only if $\mu' = \nu$, but need not be symmetric or satisfy the triangle inequality, so it is only a generalized distance. Further restrictions on the inducing function f are thus required for the divergence to be "well-behaved," for instance that it satisfy the property that for any sequence $\nu^n \to \nu^*$, where $\nu^n \in \text{int } S$, $\nu^* \in S$, then $D_f(\nu^* \,\|\, \nu^n) \to 0$. Censor and Zenios (1997) impose such technical conditions explicitly in their definition of a Bregman function; in this paper, we impose the stronger yet more easily stated condition that the Bregman function f (as defined above) be of Legendre type (Rockafellar, 1970). In this case, in addition to the Bregman function properties, it satisfies the following property: for any sequence $\mu^n \to \mu^*$ where $\mu^n \in \text{int } S$, $\mu^* \in \partial S$, it holds that $\|\nabla f(\mu^n)\| \to +\infty$. Further, we assume that the range $\nabla f(\text{int } S) = \mathbb{R}^p$.

Let us now look at some choices of divergences, proximal minimizations (5) based on which we will be studying in the sequel.

3.1.1 QUADRATIC DIVERGENCE

This choice is the simplest, and corresponds to setting the inducing Bregman function f in (6) to be the quadratic function

$$q(\mu) \quad := \quad \frac{1}{2}\Big\{ \sum_{s \in V} \sum_{x_s \in \mathcal{X}} \mu_s^2(x_s) + \sum_{(s,t) \in E} \sum_{(x_s, x_t) \in \mathcal{X} \times \mathcal{X}} \mu_{st}^2(x_s, x_t) \Big\},$$

defined over nodes and edges of the graph. The divergence is then simply the quadratic norm across nodes and edges

$$Q(\mu \,\|\, \nu) := \frac{1}{2} \sum_{s \in V} \|\mu_s - \nu_s\|^2 + \frac{1}{2} \sum_{(s,t) \in E} \|\mu_{st} - \nu_{st}\|^2, \tag{7}$$

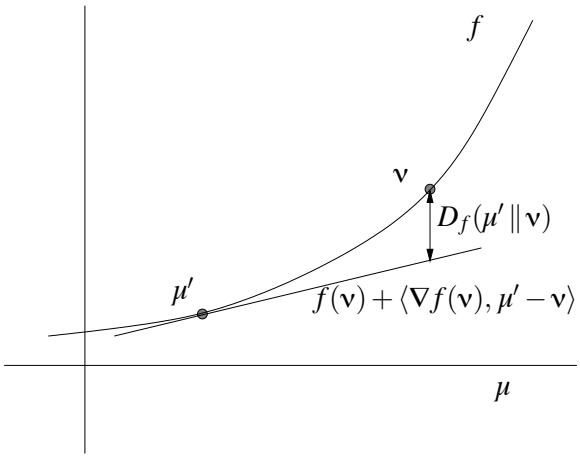

Figure 1: Graphical illustration of a Bregman divergence.

where we have used the shorthand $\|\mu_s - \nu_s\|^2 = \sum_{x_s \in \mathcal{X}} |\mu_s(x_s) - \nu_s(x_s)|^2$, with similar notation for the edges.

3.1.2 WEIGHTED ENTROPIC DIVERGENCE

Another choice for the inducing Bregman function is the weighted sum of negative entropies

$$\bar{H}_\alpha(\mu) = \sum_{s \in V} \alpha_s \bar{H}_s(\mu_s) + \sum_{(s,t) \in E} \alpha_{st} \bar{H}_{st}(\mu_{st}), \tag{8}$$

where $\bar{H}_s$ and $\bar{H}_{st}$ are defined by

$$\begin{aligned} \bar{H}_s(\mu_s) &:= \sum_{x_s \in \mathcal{X}} \mu_s(x_s) \log \mu_s(x_s), \text{ and} \\ \bar{H}_{st}(\mu_{st}) &:= \sum_{(x_s, x_t) \in \mathcal{X} \times \mathcal{X}} \mu_{st}(x_s, x_t) \log \mu_{st}(x_s, x_t), \end{aligned}$$

corresponding to the node-based and edge-based negative entropies, respectively. The corresponding Bregman divergence is a weighted sum of Kullback-Leibler (KL) divergences across the nodes and edges. In particular, letting $\alpha_s > 0$ and $\alpha_{st} > 0$ be positive weights associated with node s and edge (s,t) respectively, we define

$$D_\alpha(\mu \| \nu) \quad = \quad \sum_{s \in V} \alpha_s D(\mu_s \| \nu_s) + \sum_{(s,t) \in E} \alpha_{st} D(\mu_{st} \| \nu_{st}), \tag{9}$$

where $D(p \| q) := \sum_x \left(p(x) \log \frac{p(x)}{q(x)} - \left[p(x) - q(x) \right] \right)$ is the KL divergence. An advantage of the KL divergence, relative to the quadratic norm, is that it automatically acts to enforce non-negativity constraints on the pseudomarginals in the proximal minimization problem. (See Section 3.4 for a more detailed discussion of this issue.)

3.1.3 TREE-REWEIGHTED ENTROPIC DIVERGENCE

Our last example is based on a *tree-reweighted* entropy. The notion of a tree-reweighted entropy was first proposed by Wainwright et al. (2002). Their entropy function however while a Bregman

function is not of the Legendre type. Nonetheless let us first describe their proposed function. Given a set $\mathcal{T}$ of spanning trees $T = (V, E(T))$, and a probability distribution ρ over $\mathcal{T}$, we can obtain edge weights $\rho_{st} \in (0,1]$ for each edge (s,t) of the graph G as $\rho_{st} = \sum_{T \in \mathcal{T}} \mathbb{I}((s,t) \in E)$. Given such edge weights, define

$$f_{\text{trw}}(\mu) \quad := \quad \sum_{s \in V} \bar{H}_s(\mu_s) + \sum_{(s,t) \in E} \rho_{st} I_{st}(\mu_{st}), \tag{10}$$

where $\bar{H}$ is the negative entropy as defined earlier, while the quantity I_{st} defined as

$$I_{st}(\mu_{st}) \quad := \quad \sum_{(x_s, x_t) \in \mathcal{X} \times \mathcal{X}} \mu_{st}(x_s, x_t) \log \frac{\mu_{st}(x_s, x_t)}{[\sum_{x'_t} \mu_{st}(x_s, x'_t)][\sum_{x'_s} \mu_{st}(x'_s, x_t)]},$$

is the mutual information associated with edge (s,t). It can be shown that the function f_{trw} is strictly convex and continuously differentiable when restricted to $\mu \in \mathbb{L}(G)$; and in particular that it is a Bregman function with domain $\mathbb{L}(G)$. Within its domain $\mathbb{L}(G)$, the function can be re-expressed as a weighted negative entropy family (8),

$$f_{\text{trw}}(\mu) \quad = \quad \sum_{s \in V} (1 - \sum_{t:(s,t) \in E} \rho_{st}) \bar{H}_t(\mu_t) + \sum_{(s,t) \in E} \rho_{st} \bar{H}_{st}(\mu_{st}),$$

but where the node entropy weights $\alpha_s := 1 - \sum_{t:(s,t) \in E} \rho_{st}$ are not always positive. The corresponding Bregman divergence belongs to the weighted entropic family (9), with node weights α_s defined above, and edge-weights $\alpha_{st} = \rho_{st}$. However as stated above, this tree-reweighted entropy function is not of Legendre type, and hence is not admissible for our proximal minimization procedure (5).

However, Globerson and Jaakkola (2007a) proposed an alternative tree reweighted entropy that while equal to $f_{\text{trw}}(\mu)$ for $\mu \in \mathbb{L}(G)$ is yet convex for all μ (not just when restricted to $\mathbb{L}(G)$). Their proposed function is described as follows. For each undirected edge in E, construct two oriented edges in both directions; denote the set of these oriented edges by $\bar{E}$. Then given node weights $\rho_{os} \in (0,1]$ for each node $s \in V$, and edge weights $\rho_{s|t} \in (0,1]$ for oriented edges $(t \to s) \in \bar{E}$, define

$$f_{\text{otw}}(\mu) \quad := \quad \sum_{s \in V} \rho_{os} \bar{H}_s(\mu_s) + \sum_{(t \to s) \in \bar{E}} \rho_{s|t} \bar{H}_{s|t}(\mu_{st}), \tag{11}$$

where the quantity $\bar{H}_{s|t}$ defined as

$$\bar{H}_{s|t}(\mu_{st}) \quad := \quad \sum_{(x_s, x_t) \in \mathcal{X} \times \mathcal{X}} \mu_{st}(x_s, x_t) \log \frac{\mu_{st}(x_s, x_t)}{\sum_{x'_s} \mu_{st}(x'_s, x_t)},$$

is the conditional entropy of X_s given X_t with respect to the joint distribution μ_{st}. It can be shown that this oriented tree-reweighted entropy is not only a Bregman function with domain the non-negative orthant $\mathbb{R}^p_+$, but is also of Legendre type, so that it is indeed admissible for our proximal minimization procedure. The corresponding divergence is given as,

$$D_\rho(\mu \,\|\, \nu) \quad = \quad \sum_{s \in V} \rho_{os} D(\mu_s \,\|\, \nu_s) + \sum_{t \to s \in \bar{E}} \rho_{s|t} (D(\mu_{st} \,\|\, \nu_{st}) + \tilde{D}(\mu_{st} \,\|\, \nu_{st})),$$

where $D(p \,\|\, q)$ is the KL divergence, and $\tilde{D}(\cdot \,\|\, \cdot)$ is a KL divergence like term, defined as

$$\begin{aligned} \tilde{D}(\mu_{st} \,\|\, \nu_{st}) := & \sum_{(x_s, x_t) \in \mathcal{X} \times \mathcal{X}} \mu_{st}(x_s, x_t) \log \frac{[\sum_{x'_s} \nu_{st}(x'_s, x_t)]}{[\sum_{x'_s} \mu_{st}(x'_s, x_t)]} \\ & + \quad \frac{\nu_{st}(x_s, x_t)}{[\sum_{x'_s} \nu_{st}(x'_s, x_t)]} [\mu_{st}(x_s, x_t) - \nu_{st}(x_s, x_t)]. \end{aligned}$$

3.2 Proximal Sequences via Bregman Projection

The key in designing an efficient proximal minimization scheme is ensuring that the proximal sequence $\{\mu^n\}$ can be computed efficiently. In this section, we first describe how sequences of proximal minimizations (when the proximal function is a Bregman divergence) can be reformulated as a particular Bregman projection. We then describe how this Bregman projection can itself be computed iteratively, in terms of a sequence of cyclic Bregman projections (Censor and Zenios, 1997) based on a decomposition of the constraint set $\mathbb{L}(G)$. In the sequel, we then show how these cyclic Bregman projections reduce to very simple message-passing updates.

Given a Bregman divergence D, the *Bregman projection* of a vector ν onto a convex set C is given by

$$\widehat{\mu} \quad := \quad \arg\min_{\mu \in C} D_f(\mu \,\|\, \nu). \tag{12}$$

That this minimum is achieved and is unique follows from our assumption that the function f is of Legendre type and from Theorem 3.12 in Bauschke and Borwein (1997), so that the projection is well-defined. We define the projection operator

$$\Pi_C(\nu) := \arg\min_{\mu \in C} D_f(\mu \,\|\, \nu), \tag{13}$$

where we have suppressed the dependence on the Bregman function f in the notation. When the constraint set $C = \cap_{i=1}^{M} C_i$ is an intersection of simpler constraint sets, then a candidate algorithm for the Bregman projection is to compute it in a *cyclic manner*: by iteratively projecting onto the simple constraint sets $\{C_i\}$ (Censor and Zenios, 1997). Define the sequence

$$\mu^{t+1} = \Pi_{C_{i(t)}}(\mu^t),$$

for some control sequence parameter $i : \mathbb{N} \mapsto \{1, \ldots, M\}$ that takes each output value an infinite number of times, for instance $i(t) = t \bmod M$. It can be shown that *when the constraints are affine* then such cyclic Bregman projections μ^t converge to the projection $\widehat{\mu}$ onto the entire constraint set as defined in (12) so that $\mu^t \to \widehat{\mu}$ (Censor and Zenios, 1997). But when a constraint C_i is non-affine, the individual projection would have to be followed by a correction (Dykstra, 1985; Han, 1988; Censor and Zenios, 1997) in order for such convergence to hold. In Appendix A we have outlined these corrections briefly for the case where the constraints are linear inequalities. For ease of notation, we will now subsume these corrections into the iterative projection notation, $\mu^{t+1} = \Pi_{C_{i(t)}}(\mu^t)$, so that the notation assumes that the Bregman projections are suitably corrected when the constraints $C_{i(t)}$ are non-affine. In this paper, other than positivity constraints, we will be concerned only with affine constraints, for which no corrections are required.

Let us now look at the stationary condition characterizing the optimum $\widehat{\mu}$ of (12). As shown in for instance Bertsekas (1995), the optimum $\widehat{\mu}$ of any constrained optimization problem $\min_{\mu \in C} g(\mu)$ is given by the stationary condition,

$$\langle \nabla g(\widehat{\mu}), \mu - \widehat{\mu} \rangle \geq 0, \tag{14}$$

for all $\mu \in C$. For the projection problem (12), the gradient of the objective $D_f(\mu \,\|\, \nu) := f(\mu) - f(\nu) - \langle \nabla f(\nu), \mu - \nu \rangle$ with respect to the first argument μ is given by $\nabla f(\mu) - \nabla f(\nu)$, which when substituted in (14) yields the stationary condition of the optimum $\widehat{\mu}$ as

$$\langle \nabla f(\widehat{\mu}) - \nabla f(\nu), \mu - \widehat{\mu} \rangle \quad \geq \quad 0, \tag{15}$$

for all $\mu \in C$. Now consider the proximal minimization problem to be solved at step n, namely the strictly convex problem

$$\min_{\mu \in \mathbb{L}(G)} \Big\{ -\langle \theta, \mu \rangle + \frac{1}{\omega^n} D_f(\mu \| \mu^n) \Big\}. \tag{16}$$

Solving for the derivative of this objective with respect to μ as $-\theta + \frac{1}{\omega^n}(\nabla f(\mu) - \nabla f(\mu^n))$, and substituting in (14), we obtain the conditions defining the optimum μ^{n+1} as

$$\langle \nabla f(\mu^{n+1}) - \nabla f(\mu^n) - \omega^n \theta, \mu - \mu^{n+1} \rangle \quad \geq \quad 0,$$

for all $\mu \in \mathbb{L}(G)$. Comparing these with the conditions for Bregman projection (15), we see that if there exists a vector ν such that

$$\nabla f(\nu) = \nabla f(\mu^n) + \omega^n \theta, \tag{17}$$

then the proximal iterate μ^{n+1} is the Bregman projection of this vector ν onto the set $\mathbb{L}(G)$. As shown in Bauschke and Borwein (1997), for any function f of Legendre type with domain S, the gradient ∇f is a one-to-one function with domain int S, so that its inverse $(\nabla f)^{-1}$ is a well-defined function on the range $\nabla f(\text{int } S)$ of ∇f. Since we have assumed that this range is $\mathbb{R}^p$, we can thus obtain the unique ν which satisfies the condition in (17) as $\nu = (\nabla f)^{-1}(\nabla f(\mu) + \omega^n \theta)$ (Note that the range constraint could be relaxed to only require that the range of ∇f be a cone containing θ). Accordingly, we set up the following notation: for any Bregman function f, induced divergence D_f, and convex set C, we define the operator

$$\mathrm{J}_f(\mu, \nu) := (\nabla f)^{-1}(\nabla f(\mu) + \nu).$$

We can then write the proximal update (16) in a compact manner as the compounded operation

$$\mu^{n+1} \quad = \quad \Pi_{\mathbb{L}(G)}\Big(\mathrm{J}_f(\mu^n, \omega^n \theta)\Big).$$

Consequently, efficient algorithms for computing the Bregman projection (12) can be leveraged to compute the proximal update (16). In particular, we consider a decomposition of the constraint set as an intersection—$\mathbb{L}(G) = \cap_{k=1}^{M} \mathbb{L}_k(G)$—and then apply the method of cyclic Bregman projections discussed above. Initializing $\mu^{n,0} = \mu^n$ and updating from $\mu^{n,\tau} \mapsto \mu^{n,\tau+1}$ by projecting $\mu^{n,\tau}$ onto constraint set $\mathbb{L}_{i(\tau)}(G)$, where $i(\tau) = \tau \mod M$, for instance, we obtain the meta-algorithm summarized in Algorithm 1.

As shown in the following sections, by using a decomposition of $\mathbb{L}(G)$ over the edges of the graph, the inner loop steps correspond to local message-passing updates, slightly different in nature depending on the choice of Bregman distance. Iterating the inner and outer loops yields a provably convergent message-passing algorithm for the LP. Convergence follows from the convergence properties of proximal minimization (Bertsekas and Tsitsiklis, 1997), combined with convergence guarantees for cyclic Bregman projections (Censor and Zenios, 1997). In the following section, we derive the message-passing updates corresponding to various Bregman functions of interest.

3.3 Quadratic Projections

Consider the proximal sequence with the quadratic distance Q from Equation (7); the Bregman function inducing this distance is the quadratic function $q(y) = \frac{1}{2}y^2$, with gradient $\nabla q(y) = y$. A little calculation shows that the operator J_q takes the form

$$\mathrm{J}_q(\mu, \omega\theta) \quad = \quad \mu + \omega\theta,$$

Algorithm 1 Basic proximal-Bregman LP solver

Given a Bregman distance D, weight sequence $\{\omega^n\}$ and problem parameters θ:

- Initialize μ^0 to the uniform distribution: $\mu_s^{(0)}(x_s) = \frac{1}{m}, \mu_{st}^{(0)}(x_s, x_t) = \frac{1}{m^2}$.
- **Outer Loop:** For iterations $n = 0, 1, 2, \ldots$, update $\mu^{n+1} = \Pi_{\mathbb{L}(G)}\Big(\mathrm{J}_f(\mu^n, \omega^n\theta)\Big)$.
  - Solve Outer Loop via **Inner Loop:**
    (a) Inner initialization $\mu^{n,0} = \mathrm{J}_f(\mu^n, \omega^n\theta)$.
    (b) For $t = 0, 1, 2, \ldots$, set $i(t) = t \mod M$.
    (c) Update $\mu^{n,t+1} = \Pi_{\mathbb{L}_{i(t)}(G)}\big(\mu^{n,t}\big)$.

whence we obtain the initialization in Equation (19).

We now turn to the projections $\mu^{n,\tau+1} = \Pi_q(\mu^{n,\tau}, \mathbb{L}_i(G))$ onto the individual constraints $\mathbb{L}_i(G)$. For each such constraint, the local update is based on the solving the problem

$$\mu^{n,\tau+1} \quad = \quad \arg\min_{\nu \in \mathbb{L}_i(G)} \Big\{ q(\nu) - \langle \nu, \nabla q(\mu^{n,\tau}) \rangle \Big\}. \tag{18}$$

In Appendix B.1, we show how the solution to these inner updates takes the form (20) given in Algorithm 2. The $\{Z_s, Z_{st}\}$ variables correspond to the dual variables used to correct the Bregman projections for positivity (and hence inequality) constraints, as outlined in (33) in Section 3.2.

3.4 Entropic Projections

Consider the proximal sequence with the Kullback-Leibler distance $D(\mu \,\|\, \nu)$ defined in Equation (9). The Bregman function h_α inducing the distance is a sum of negative entropy functions $f(\mu) = \mu \log \mu$, and its gradient is given by $\nabla f(\mu) = \log(\mu) + \vec{1}$. In this case, some calculation shows that the map $\nu = \mathrm{J}_f(\mu, \omega\theta)$ is given by

$$\nu \quad = \quad \mu \exp(\omega\,\theta/\alpha),$$

whence we obtain the initialization Equation (21). In Appendix B.2, we derive the message-passing updates summarized in Algorithm 3.

3.5 Tree-reweighted Entropy Proximal Sequences

In the previous sections, we saw how to solve the proximal sequences following the algorithmic template 1 and using message passing updates derived from cyclic Bregman projections. In this section, we show that for the tree-reweighted entropic divergences (11), in addition to the cyclic Bregman projection recipe of the earlier sections, we can also use tree-reweighted sum-product or related methods (Globerson and Jaakkola, 2007b; Hazan and Shashua, 2008) to compute the proximal sequence.

end for

until convergence

equivalent over the constraint set $\mathbb{L}(G)$). The proximal optimization problem as stated above (24) reduces to,

$$\mu^{n+1} = \arg\min_{\nu\in\mathbb{L}(G)}\{\langle\theta^n,\nu\rangle + f_{\text{trw}}(\nu)\}.$$

But this is precisely the optimization problem solved by the tree-reweighted sum-product (Wainwright and Jordan, 2003), as well as other related methods (Globerson and Jaakkola, 2007b; Hazan and Shashua, 2008), for a graphical model with parameters θ^n.

Computing the gradient of the function f_{trw}, and performing some algebra yields the algorithmic template of Algorithm 4.

3.6 Convergence

We now turn to the convergence of the message-passing algorithms that we have proposed. At a high-level, for any Bregman proximal function, convergence follows from two sets of known results: (a) convergence of proximal algorithms; and (b) convergence of cyclic Bregman projections.

For completeness, we re-state the consequences of these results here. For any positive sequence $\omega^n > 0$, we say that it satisfies the *infinite travel condition* if $\sum_{n=1}^{\infty}(1/\omega^n) = +\infty$. We let $\mu^* \in \mathbb{L}(G)$ denote an optimal solution (not necessarily unique) of the LP, and use $f^* = f(\mu^*) = \langle\theta,\mu^*\rangle$ to denote

Algorithm 4 TRW proximal solver

- For outer iterations $n = 0, 1, 2, \ldots,$

  (a) Update the parameters:

$$\begin{aligned} \theta^n_s(x_s) &= \omega^n \theta_s(x_s) + \log(\mu^n(x_s)) + 1, \\ \theta^n_{st}(x_s, x_t) &= \omega^n \theta_{st}(x_s, x_t) + \rho_{st} \left(\log \frac{\mu^n_{st}(x_s, x_t)}{\sum_{x'_s} \mu^n_{st}(x'_s, x_t) \sum_{x'_t} \mu^n_{st}(x_s, x'_t)} - 1 \right). \end{aligned}$$

  (b) Run a convergent TRW-solver on a graphical model with parameters θ^n, so as to compute

$$\mu^{n+1} = \arg\min_{\nu \in \mathbb{L}(G)} \Big\{ -\langle \theta^n, \nu \rangle + f_{\mathrm{trw}}(\nu) \Big\}.$$

the LP optimal value. We say that the convergence rate is *superlinear* if

$$\lim_{n \to +\infty} \frac{|f(\mu^{n+1}) - f^*|}{|f(\mu^n) - f^*|} = 0,$$

and *linear* if

$$\lim_{n \to +\infty} \frac{|f(\mu^{n+1}) - f^*|}{|f(\mu^n) - f^*|} \leq \gamma,$$

for some $\gamma \in (0,1)$. We say the convergence is *geometric* if there exists some constant $C > 0$ and $\gamma \in (0,1)$ such that for all n,

$$|f(\mu^n) - f^*| \leq C\gamma^n.$$

Proposition 1 (Rate of outer loop convergence) *Consider the sequence of iterates produced by a proximal algorithm* (5) *for LP-solving.*

(a) Using the quadratic proximal function and positive weight sequence $\omega^n \to +\infty$ satisfying infinite travel, the proximal sequence $\{\mu^n\}$ converges superlinearly.

(b) Using the entropic proximal function and positive weight sequence ω^n satisfying infinite travel, the proximal sequence $\{\mu^n\}$ converges:

(i) superlinearly if $\omega^n \to 0$, and

(ii) at least linearly if $1/\omega^n \geq c$ for some constant $c > 0$.

The quadratic case is covered in Bertsekas and Tsitsiklis (1997), whereas the entropic case was analyzed by Tseng and Bertsekas (1993), and Iusem and Teboulle (1995).

Our inner loop message updates use cyclic Bregman projections, for which there is also a substantial literature on convergence. Censor and Zenios (1997) show that with dual feasibility correction, cyclic projections onto general convex sets are convergent. For Euclidean projections with

linear constraints, Deutsch and Hundal (2006) establish a linear rate of convergence, with the rate dependent on angles between the half-spaces defining the constraints. The intuition is that the more orthogonal the half-spaces, the faster the convergence; for instance, a single iteration suffices for completely orthogonal constraints. Our inner updates thus converge linearly to the solution within each outer proximal step.

We note that the rate-of-convergence results for the outer proximal loops assume that the proximal update (computed within each inner loop) has been performed exactly. In practice, the inner loop iterations do not converge finitely (though they have a linear rate of convergence), so that an early stopping entails that the solution to each proximal update would be computed only approximately, up to some accuracy ε. That is, if the proximal optimization function at outer iteration n is $h^n(\mu)$ with minimum μ^{n+1}, then the computed proximal update $\underline{\mu}^{n+1}$ is sub-optimal, with $h^n(\underline{\mu}^{n+1}) - h^n(\mu^{n+1}) \leq \varepsilon$. Some recent theory has addressed whether superlinear convergence can still be obtained in such a setting; for instance, Solodov and Svaiter (2001) shows that that under mild conditions superlinear rates still hold for proximal iterates with inner-loop solutions that are ε-suboptimal. In practice, we cannot directly use ε-suboptimality as the stopping criterion for the inner loop iterations since we do not have the optimal solution μ^{n+1}. However, since we are trying to solve a feasibility problem, it is quite natural to check for violation in the constraints defining $\mathbb{L}(G)$. We terminate our inner iterations when the violation in all the constraints below a tolerance ε. As we show in Section 5, our experiments show that setting this termination threshold to $\underline{\varepsilon} = 10^{-4}$ is small enough for sub-optimality to be practically irrelevant and that superlinear convergence still occurs.

3.6.1 REMARKS

The quadratic proximal updates turn out to be equivalent to solving the primal form of the LP by the projected subgradient method (Bertsekas, 1995) for constrained optimization. (This use of the subgradient method should be contrasted with other work Feldman et al. (2002b); Komodakis et al. (2007) which performed subgradient descent to the dual of the LP.) For any constrained optimization problem:

$$\begin{aligned} \min_{\mu} \quad & f_0(\mu) \\ s.t. \quad & f_j(\mu) \leq 0,\ j = 1,\ldots,m, \end{aligned} \tag{25}$$

the projected subgradient method performs subgradient descent iteratively on (i) the objective function f_0, as well as on (ii) the constraint functions $\{f_j\}_{j=1}^m$ till the constraints are satisfied. Casting it in the notation of Algorithm 1; over outer loop iterations $n = 1,\ldots,$ it sets

$$\mu^{n,0} = \mu^n - \alpha_n \nabla f_0(\mu^n),$$

and computes, over inner loop iterations $t = 1,\ldots,$

$$\begin{aligned} j(t) &= t \mod m, \\ \mu^{n,t+1} &= \mu^{n,t} - \alpha_{n,t} \nabla f_{j(t)}(\mu^{n,t}), \end{aligned}$$

and sets $\mu^{n+1} = \mu^{n,\infty}$, the converged estimate of the inner loops of outer iteration n. The constants $\{\alpha_n, \alpha_{n,t}\}$ are step-sizes for the corresponding subgradient descent steps.

The constraint set in our LP problem, $\mathbb{L}(G)$, has equality constraints so that it is not directly in the form of Equation (25). However any equality constraint $h(\mu) = 0$ can be rewritten equivalently as two inequality constraints $h(\mu) \leq 0$, and $-h(\mu) \leq 0$; so that one could cast our constrained LP in the form of (25) and solve it using the constrained subgradient descent method. As regards the step-sizes, suppose we set $\alpha_n = \omega^n$, and $\alpha_{n,t}$ according to Polyak's step-size (Bertsekas, 1995) so that $\alpha_{n,t} = \frac{f_{j(t)}(\mu^{n,t}) - f_{j(t)}(\mu^*)}{\|\nabla f_{j(t)}(\mu^{n,t})\|_2^2}$, where μ^* is the constrained optimum. Since μ^* is feasible by definition, $f_j(\mu^*) = 0$. Further, for the normalization constraints $C_{ss}(\mu) \gtreqless 1$ where $C_{ss}(\mu) := \sum_{x_s \in \mathcal{X}} \mu_s(x_s) - 1$, we have $\|\nabla C_{ss}(\mu)\|^2 = m$, while for the marginalization constraints $C_{st}(\mu) \gtreqless 0$, where $C_{st}(\mu) := \sum_{x_t \in \mathcal{X}} \mu_{st}(x_s, x_t) = \mu_s(x_s)$, we have $\|\nabla C_{st}(\mu)\|^2 = (m+1)$. It can then be seen that the subgradient method for constrained optimization applied to our constrained LP with the above step-sizes yields the same updates as our quadratic proximal scheme.

4. Rounding Schemes with Optimality Guarantees

The graph-structured LP in (4) was a relaxation of the MAP integer program (1), so that there are two possible outcomes to solving the LP: either an integral vertex is obtained, which is then guaranteed to be a MAP configuration, or a fractional vertex is obtained, in which case the relaxation is loose. In the latter case, a natural strategy is to "round" the fractional solution, so as to obtain an integral solution (Raghavan and Thompson, 1987). Such rounding schemes may either be randomized or deterministic. A natural measure of the quality of the rounded solution is in terms of its value relative to the optimal (MAP) value. There is now a substantial literature on performance guarantees of various rounding schemes, when applied to particular sub-classes of MAP problems (e.g., Raghavan and Thompson, 1987; Kleinberg and Tardos, 1999; Chekuri et al., 2005).

In this section, we show that rounding schemes can be useful even when the LP optimum is integral, since they may permit an LP-solving algorithm to be *finitely terminated*—that is, before it has actually solved the LP—while retaining the same optimality guarantees about the final output. An attractive feature of our proximal Bregman procedures is the existence of precisely such rounding schemes—namely, that under certain conditions, rounding pseudomarginals at intermediate iterations yields the integral LP optimum. We describe these rounding schemes in the following sections, and provide two kinds of results. We provide certificates under which the rounded solution is guaranteed to be MAP optimal; moreover, we provide upper bounds on the number of outer iterations required for the rounding scheme to obtain the LP optimum.

In the next Section 4.1, we describe and analyze deterministic rounding schemes that are specifically tailored to the proximal Bregman procedures that we have described. Then in the following Section 4.2, we propose and analyze a graph-structured randomized rounding scheme, which applies not only to our proximal Bregman procedures, but more broadly to any algorithm that generates a sequence of iterates contained within the local polytope $\mathbb{L}(G)$.

4.1 Deterministic Rounding Schemes

We begin by describing three deterministic rounding schemes that exploit the particular structure of the Bregman proximal updates.

4.1.1 NODE-BASED ROUNDING

This method is the simplest of the deterministic rounding procedures, and applies to the quadratic and entropic updates. It operates as follows: given the vector μ^n of pseudomarginals at iteration n, obtain an integral configuration $x^n(\mu^n) \in \mathcal{X}^N$ by choosing

$$x_s^n \quad \in \quad \arg\max_{x_s' \in \mathcal{X}} \mu^n(x_s'), \qquad \text{for each } s \in V.$$

We say that the node-rounded solution x^n is *edgewise-consistent* if

$$(x_s^n, x_t^n) \quad \in \quad \arg\max_{(x_s', x_t') \in \mathcal{X} \times \mathcal{X}} \mu_{st}^n(x_s', x_t') \qquad \text{for all edges } (s,t) \in E. \tag{26}$$

4.1.2 NEIGHBORHOOD-BASED ROUNDING

This rounding scheme applies to all three proximal schemes. For each node $s \in V$, denote its star-shaped neighborhood graph by $N_s = \{(s,t) | t \in N(s)\}$, consisting of edges between node s and its neighbors. Let $\{\text{QUA}, \text{ENT}, \text{TRW}\}$ refer to the quadratic, entropic, and tree-reweighted schemes respectively.

(a) Define the neighborhood-based energy function

$$F_s(x; \mu^n) \quad := \quad \begin{cases} 2\mu^n(x_s) + \sum_{t \in N(s)} \mu^n(x_s, x_t) & \text{for QUA} \\ 2\alpha_s \log \mu_s^n(x_s) + \sum_{t \in N(s)} \alpha_{st} \log \mu_{st}^n(x_s, x_t) & \text{for ENT} \\ 2 \log \mu^n(x_s) + \sum_{t \in N(s)} \rho_{st} \log \frac{\mu_{st}^n(x_s, x_t)}{\mu_s^n(x_s) \mu_t^n(x_t)} & \text{for TRW.} \end{cases} \tag{27}$$

(b) Compute a configuration $x^n(N_s)$ maximizing the function $F_s(x; \mu^n)$ by running two rounds of ordinary max-product on the star graph.

Say that such a rounding is *neighborhood-consistent* if the neighborhood MAP solutions $\{x^n(N_s), s \in V\}$ agree on their overlaps.

4.1.3 TREE-BASED ROUNDING

This method applies to all three proximal schemes, but most naturally to the TRW proximal method. Let $T_1, \ldots, T_K$ be a set of spanning trees that cover the graph (meaning that each edge appears in at least one tree), and let $\{\rho(T_i), i = 1, \ldots, K\}$ be a probability distribution over the trees. For each edge (s,t), define the *edge appearance probability* $\rho_{st} = \sum_{i=1}^K \rho(T_i)\, \mathbb{I}[(s,t) \in T_i]$. Then for each tree $i = 1, \ldots, K$:

(a) Define the tree-structured energy function

$$F_i(x; \mu^n) \quad := \quad \begin{cases} \sum_{s \in V} \log \mu^n(x_s) + \sum_{(s,t) \in E(T_i)} \frac{1}{\rho_{st}} \log \mu_{st}^n(x_s, x_t) & \text{for QUA} \\ \sum_{s \in V} \alpha_s \log \mu^n(x_s) + \sum_{(s,t) \in E(T_i)} \frac{\alpha_{st}}{\rho_{st}} \log \mu_{st}^n(x_s, x_t) & \text{for ENT} \\ \sum_{s \in V} \log \mu^n(x_s) + \sum_{(s,t) \in E(T_i)} \log \frac{\mu_{st}^n(x_s, x_t)}{\mu_s^n(x_s) \mu_t^n(x_t)} & \text{for TRW.} \end{cases} \tag{28}$$

(b) Run the ordinary max-product problem on energy $F_i(x;\mu^n)$ to find a MAP-optimal configuration $x^n(T_i)$.

Say that such a rounding is *tree-consistent* if the tree MAP solutions $\{x^n(T_i), i = 1,\ldots,M\}$ are all equal. This notion of tree-consistency is similar to the underlying motivation of the tree-reweighted max-product algorithm (Wainwright et al., 2005).

4.1.4 OPTIMALITY CERTIFICATES FOR DETERMINISTIC ROUNDING

The following result characterizes the optimality guarantees associated with these rounding schemes, when they are consistent respectively in the *edge-consistency*, *neighborhood-consistency* and *tree-consistency* senses defined earlier.

Theorem 2 (Deterministic rounding with MAP certificate) *Consider a sequence of iterates $\{\mu^n\}$ generated by the quadratic or entropic proximal schemes. For any $n = 1,2,3,\ldots$, any consistent rounded solution x^n obtained from μ^n via any of the node, neighborhood or tree-rounding schemes (when applicable) is guaranteed to be a MAP-optimal solution. For the iterates of TRW proximal scheme, the guarantee holds for both neighborhood and tree-rounding methods.*

We prove this claim in Section 4.1.6. It is important to note that such deterministic rounding guarantees do *not* apply to an arbitrary algorithm for solving the linear program. At a high-level, there are two key properties required to ensure guarantees in the rounding. First, the algorithm must maintain some representation of the cost function that (up to possible constant offsets) is equal to the cost function of the original problem, so that the set of maximizers of the invariance would be equivalent to the set of maximizers of the original cost function, and hence the MAP problem. Second, given a rounding scheme that maximizes tractable sub-parts of the reparameterized cost function, the rounding is said to be admissible if these partial solutions agree with one another. Our deterministic rounding schemes and optimality guarantees follow this approach, as we detail in the proof of Theorem 2.

We note that the invariances maintained by the proximal updates in this paper are closely related to the reparameterization condition satisfied by the sum-product and max-product algorithms (Wainwright et al., 2003). Indeed, each sum-product (or max-product) update can be shown to compute a new set of parameters for the Markov random field that preserves the probability distribution. A similar but slightly different notion of reparameterization underlies the tree-reweighted sum-product and max-product algorithms (Wainwright et al., 2005); for these algorithms, the invariance is preserved in terms of convex combinations over tree-structured graphs. The tree-reweighted max-product algorithm attempts to produce MAP optimality certificates that are based on verifying consistency of MAP solutions on certain tree-structured components whose convex combination is equal to the LP cost. The sequential TRW-S max-product algorithm of Kolmogorov (2006) is a version of tree-reweighted max-product using a clever scheduling of the messages to guarantee monotonic changes in a dual LP cost function. Finally, the elegant work of Weiss et al. (2007) exploits similar reparameterization arguments to derive conditions under which their convex free-energy based sum-product algorithms yield the optimal MAP solution.

An attractive feature of all the rounding schemes that we consider is their relatively low computational cost. The node-rounding scheme is trivial to implement. The neighborhood-based scheme requires running two iterations of max-product for each neighborhood of the graph. Finally, the tree-rounding scheme requires $O(KN)$ iterations of max-product, where K is the number of trees

that cover the graph, and N is the number of nodes. Many graphs with cycles can be covered with a small number K of trees; for instance, the lattice graph in 2-dimensions can be covered with two spanning trees, in which case the rounding cost is linear in the number of nodes.

4.1.5 BOUNDS ON ITERATIONS FOR DETERMINISTIC ROUNDING

Of course, the natural question is how many iterations are sufficient for a a given rounding scheme to succeed. The following result provides a way of deriving such upper bounds:

Corollary 3 *Suppose that the LP optimum is uniquely attained at an integral vertex μ^*, and consider algorithms generating sequence $\{\mu^n\}$ converging to μ^*. Then we have the following guarantees:*

(a) for quadratic and entropic schemes, all three types of rounding recover the MAP solution once $\|\mu^n - \mu\|_\infty \leq 1/2$.

(b) for the TRW-based proximal method, tree-based rounding recovers the MAP solution once $\|\mu^n - \mu\|_\infty \leq \frac{1}{4N}$.

Proof We first claim that if the ℓ_∞-bound $\|\mu^n - \mu^*\|_\infty < \frac{1}{2}$ is satisfied, then the node-based rounding returns the (unique) MAP configuration, and moreover this MAP configuration x^* is edge-consistent with respect to μ^n. To see these facts, note that the ℓ_∞ bound implies, in particular, that at every node $s \in V$, we have

$$|\mu_s^n(x_s^*) - \mu_s^*(x_s^*)| \;=\; |\mu_s^n(x_s^*) - 1| \;<\; \frac{1}{2},$$

which implies that $\mu_s^n(x_s^*) > 1/2$ as $\mu_s^*(x_s^*) = 1$. Due to the non-negativity constraints and marginalization constraint $\sum_{x_s \in \mathcal{X}} \mu^n(x_s) = 1$, at most one configuration can have mass above $1/2$. Thus, node-based rounding returns x_s^* at each node s, and hence overall, it returns the MAP configuration x^*. The same argument also shows that the inequality $\mu_{st}^n(x_s^*, x_t^*) > \frac{1}{2}$ holds, which implies that $(x_s^*, x_t^*) = \arg\max_{x_s, x_t} \mu^n(x_s, x_t)$ for all $(s,t) \in E$. Thus, we have shown x^* is edge-consistent for μ_{st}^n, according to the definition (26).

Next we turn to the performance of neighborhood and tree-rounding for the quadratic and entropic updates. For $n \geq n^*$, we know that x^* achieves the unique maximum of $\mu_s^n(x_s)$ at each node, and $\mu_{st}^n(x_s, x_t)$ on each edge. From the form of the neighborhood and tree energies (27),(28), this node- and edge-wise optimality implies that $x^*(N(s)) := \{x_t^*, t \in s \cup N(s)\}$ maximizes the neighborhood-based and tree-based cost functions as well, which implies success of neighborhood and tree-rounding. (Note that the positivity of the weights α_s and α_{st} is required to make this assertion.)

For the TRW algorithm in part (b), we note that when $\|\mu^n - \mu\|_\infty \leq 1/(4N)$, then we must have $\mu_s^n(x_s^*) \geq 1 - 1/(4N)$ for every node. We conclude that these inequalities imply that $x^* = (x_1^*, \ldots, x_N^*)$ must be the unique MAP on every tree. Indeed, consider the set $S = \{x \in \mathcal{X}^N \mid x \neq x^*\}$. By union bound, we have

$$\begin{aligned}
\mathbb{P}(S) &= \mathbb{P}[\exists s \in V \mid x_s \neq x_s^*] \\
&\leq \sum_{s=1}^N \mathbb{P}(x_s \neq x_s^*) \\
&= \sum_{s=1}^N (1 - \mu_s(x_s^*)) \leq \frac{1}{4},
\end{aligned}$$

showing that we have $\mathbb{P}(x^*) \geq 3/4$, so that x^* must be the MAP configuration.

To conclude the proof, note that the tree-rounding scheme computes the MAP configuration on each tree T_i, under a distribution with marginals μ_s and μ_{st}. Consequently, under the stated conditions, the configuration x^* must be the unique MAP configuration on each tree, so that tree rounding is guaranteed to find it. ■

Using this result, it is possible to bound the number of iterations required to achieve the ℓ_∞-bounds. In particular, suppose that the algorithm has a linear rate of convergence—say that $|f(\mu^n) - f(\mu^*)| \leq |f(\mu^0) - f(\mu^*)|\gamma^n$ for some $\gamma \in (0,1)$. For the quadratic or entropic methods, it suffices to show that $\|\mu^n - \mu^*\|_2 < 1/2$. For the entropic method, there exists some constant $C > 0$ such that $\|\mu^n - \mu^*\|_2 \leq \frac{1}{2C}|f(\mu^n) - f(\mu^*)|$ (cf. Prop. 8, Iusem and Teboulle, 1995). Consequently, we have

$$\|\mu^n - \mu^*\|_2 \quad \leq \quad \frac{|f(\mu^0) - f(\mu^*)|}{2C}\gamma^n.$$

Consequently, after $n^* := \frac{\log C|f(\mu^0)-f(\mu^*)|}{\log(1/\gamma)}$ iterations, the rounding scheme would be guaranteed to configuration for the entropic proximal method. Similar finite iteration bounds can also be obtained for the other proximal methods, showing finite convergence through use of our rounding schemes.

Note that we proved correctness of the neighborhood and tree-based rounding schemes by leveraging the correctness of the node-based rounding scheme. In practice, it is possible for neighborhood- or tree-based rounding to succeed even if node-based rounding fails; however, we currently do not have any sharper sufficient conditions for these rounding schemes.

4.1.6 PROOF OF THEOREM 2

We now turn to the proof of Theorem 2. At a high level, the proof consists of two main steps. First, we show that each proximal algorithm maintains a certain invariant of the original MAP cost function $F(x;\theta)$; in particular, the iterate μ^n induces a reparameterization $F(x;\mu^n)$ of the cost function such that the set of maximizers is preserved—viz.:

$$\arg\max_{x\in\mathcal{X}^N} F(x;\theta) := \arg\max_{x\in\mathcal{X}^N} \sum_{s\in V, x_s\in\mathcal{X}} \theta_s(x_s) + \sum_{(s,t)\in E, x_s, x_t\in\mathcal{X}} \theta_{st}(x_s,x_t) = \arg\max_{x\in\mathcal{X}^N} F(x;\mu^n). \tag{29}$$

Second, we show that the consistency conditions (edge, neighborhood or tree, respectively) guarantee that the rounded solution belongs to $\arg\max_{x\in\mathcal{X}^N} F(x;\mu^n)$

We begin with a lemma on the invariance property:

Lemma 4 (Invariance of maximizers) *Define the function*

$$F(x;\mu) \quad := \quad \begin{cases} \sum_{s\in V} \mu_s(x_s) + \sum_{(s,t)\in E} \mu_{st}(x_s,x_t) & \text{for QUA} \\ \sum_{s\in V} \alpha_s \log\mu_s(x_s) + \sum_{(s,t)\in E} \alpha_{st}\log\mu_{st}(x_s,x_t) & \text{for ENT} \\ \sum_{s\in V} \log\mu_s(x_s) + \sum_{(s,t)\in E} \rho_{st}\log\frac{\mu_{st}(x_s,x_t)}{\mu_s(x_s)\mu_t(x_t)} & \text{for TRW.} \end{cases} \tag{30}$$

At each iteration $n = 1,2,3,\ldots$ for which $\mu^n > 0$, the function $F(x;\mu^n)$ preserves the set of maximizers (29).

The proof of this claim, provided in Appendix C, is based on exploiting the necessary (Lagrangian) conditions defined by the optimization problems characterizing the sequence of iterations $\{\mu^n\}$.

For the second part of the proof, we show how a solution x^*, obtained by a rounding procedure, is guaranteed to maximize the function $F(x;\mu^n)$, and hence (by Lemma 4) the original cost function $F(x;\theta)$. In particular, we state the following simple lemma:

Lemma 5 *The rounding procedures have the following guarantees:*

(a) Any edge-consistent configuration from node rounding maximizes $F(x;\mu^n)$ for the quadratic and entropic schemes.

(b) Any neighborhood-consistent configuration from neighborhood rounding maximizes $F(x;\mu^n)$ for the quadratic and entropic schemes.

(c) Any tree-consistent configuration from tree rounding maximizes $F(x;\mu^n)$ for all three schemes.

Proof We begin by proving statement (a). Consider an edge-consistent integral configuration x^* obtained from node rounding. By definition, it maximizes $\mu^n(x_s)$ for all $s \in V$, and $\mu^n_{st}(x_s,x_t)$ for all $(s,t) \in E$, and so by inspection, also maximizes $F(x;\mu^n)$ for the quadratic and proximal cases.

We next prove statement (b) on neighborhood rounding. Suppose that neighborhood rounding outputs a single neighborhood-consistent integral configuration x^*. Since $x^*_{N(s)}$ maximizes the neighborhood energy (27) at each node $s \in V$, it must also maximize the sum $\sum_{s\in V} F_s(x;\mu^n)$. A little calculation shows that this sum is equal to $2F(x;\mu^n)$, the factor of two arising since the term on edge (s,t) arises twice, one for neighborhood rooted at s, and once for t.

Turning to claim (c), let x^* be a tree-consistent configuration obtained from tree rounding. Then for each $i = 1,\ldots,K$, the configuration x^* maximizes the tree-structured function $F_i(x;\mu^n)$, and hence also maximizes the convex combination $\sum_{i=1}^K \rho(T_i)F_i(x;\mu^n)$. By definition of the edge appearance probabilities ρ_{st}, this convex combination is equal to the function $F(x;\mu^n)$. ■

4.2 Randomized Rounding Schemes

The schemes considered in the previous section were all deterministic, since (disregarding any possible ties), the output of the rounding procedure was a deterministic function of the given pseudomarginals $\{\mu^n_s,\mu^n_{st}\}$. In this section, we consider randomized rounding procedures, in which the output is a random variable.

Perhaps the most naive randomized rounding scheme is the following: for each node $r \in V$, assign it value $x_r \in \mathcal{X}$ with probability $\mu^n_v(x_r)$. We propose a graph-structured generalization of this naive randomized rounding scheme, in which we perform the rounding in a dependent way across sub-groups of nodes, and establish guarantees for its success. In particular, we show that when the LP relaxation has a unique integral optimum that is well-separated from the second best configuration, then the rounding scheme succeeds with high probability after a pre-specified number of iterations.

4.2.1 THE RANDOMIZED ROUNDING SCHEME

Our randomized rounding scheme is based on any given subset E' of the edge set E. Consider the subgraph $G(E\backslash E')$, with vertex set V, and edge set $E\backslash E'$. We assume that E' is chosen such that

the subgraph $G(E\backslash E')$ is a forest. That is, we can decompose $G(E\backslash E')$ into a union of disjoint trees, $\{T_1,\ldots,T_K\}$, where $T_i = (V_i,E_i)$, such that the vertex subsets V_i are all disjoint and $V = V_1 \cup V_2 \cup \ldots \cup V_K$. We refer to the edge subset as *forest-inducing* when it has this property. Note that such a subset always exists, since $E' = E$ is trivially forest-inducing. In this case, the "trees" simply correspond to individual nodes, without any edges; $V_i = \{i\}$, $E_i = \emptyset$, $i = 1,\ldots,N$.

For any forest-inducing subset $E' \subseteq E$, Algorithm 5 defines our randomized rounding scheme.

Algorithm 5 RANDOMIZED ROUNDING SCHEME

for subtree indices $i = 1,\ldots,K$ **do**

Sample a sub-configuration X_{V_i} from the probability distribution

$$p(x_{V_i};\mu(T_i)) \quad = \quad \prod_{s\in V_i} \mu^n(x_s) \prod_{(s,t)\in E_i} \frac{\mu^n(x_s,x_t)}{\mu^n(x_s)\mu^n(x_t)}.$$

end for

Form the global configuration $X \in \mathcal{X}^N$ by concatenating all the local random samples:

$$X \quad := \quad \Big(X_{V_1},\ldots,X_{V_K}\Big).$$

To be clear, the randomized solution X is a function of both the pseudomarginals μ^n, and the choice of forest-inducing subset E', so that we occasionally use the notation $X(\mu^n;E')$ to reflect explicitly this dependence. Note that the simplest rounding scheme of this type is obtained by setting $E' = E$. Then the "trees" simply correspond to individual nodes without any edges, and the rounding scheme is the trivial node-based scheme.

The randomized rounding scheme can be "derandomized" so that we obtain a deterministic solution $x^d(\mu^n;E')$ that does at least well as the randomized scheme does in expectation. This derandomization scheme is shown in Algorithm 6, and its correctness is guaranteed in the following theorem, proved in Appendix D.

Theorem 6 *Let $(G = (V,E),\theta)$ be the given MAP problem instance, and let $\mu^n \in \mathbb{L}(G)$ be any set of pseudomarginals in the local polytope $\mathbb{L}(G)$. Then, for any subset $E' \subseteq E$ of the graph G, the (E',μ^n)-randomized rounding scheme in Algorithm 5, when derandomized as in Algorithm 6 satisfies,*

$$F(x^d(\mu^n;E');\theta) \geq \mathbb{E}\Big(F(X(\mu^n;E');\theta)\Big),$$

where $X(\mu^n;E')$ and $x^d(\mu^n;E')$ denote the outputs of the randomized and derandomized schemes respectively.

4.2.2 OSCILLATION AND GAPS

In order to state some theoretical guarantees on our randomized rounding schemes, we require some notation. For any edge $(s,t) \in E$, we define the *edge-based oscillation*

$$\delta_{st}(\theta) \quad := \quad \max_{x_s,x_t}[\theta_{st}(x_s,x_t)] - \min_{x_s,x_t}[\theta_{st}(x_s,x_t)].$$

Algorithm 6 DERANDOMIZED ROUNDING SCHEME

Initialize: $\bar{\mu} = \mu^n$.

for subtree indices $i = 1, \ldots, K$ **do**

Solve

$$x^d_{V_i} = \arg\max_{x_{V_i}} \sum_{s \in V_i} \left\{ \theta_s(x_s) + \sum_{t:(s,t)\in E'} \sum_{x_t} \bar{\mu}_t(x_t)\theta_{st}(x_s,x_t) \right\} + \sum_{(s,t)\in E_i} \theta_{st}(x_s,x_t).$$

Update $\bar{\mu}$:

$$\bar{\mu}_s(x_s) = \begin{cases} \bar{\mu}_s(x_s) & \text{if } s \notin V_i \\ 0 & \text{if } s \in V_i, x^d_s \neq x_s \\ 1 & \text{if } s \in V_i, x^d_s = x_s. \end{cases}$$

$$\bar{\mu}_{st}(x_s,x_t) = \begin{cases} \bar{\mu}_{st}(x_s,x_t) & \text{if } (s,t) \notin E_i \\ \bar{\mu}_s(x_s)\bar{\mu}_t(x_t) & \text{if } (s,t) \in E_i. \end{cases}$$

end for

Form the global configuration $x^d \in \mathcal{X}^N$ by concatenating all the subtree configurations:

$$x^d := \left(x^d_{V_1}, \ldots, x^d_{V_K} \right).$$

We define the *node-based oscillation* $\delta_s(\theta)$ in the analogous manner. The quantities $\delta_s(\theta)$ and $\delta_{st}(\theta)$ are measures of the strength of the potential functions.

We extend these measures of interaction strength to the full graph in the natural way

$$\delta_G(\theta) := \max\left\{ \max_{(s,t)\in E} \delta_{st}(\theta), \max_{s\in V} \delta_s(\theta) \right\}.$$

Using this oscillation function, we now define a measure of the quality of a unique MAP optimum, based on its separation from the second most probable configuration. In particular, letting $x^* \in \mathcal{X}^N$ denote a MAP configuration, and recalling the notation $F(x;\theta)$ for the LP objective, we define the *graph-based gap*

$$\Delta(\theta;G) := \frac{\min_{x\neq x^*} \left[F(x^*;\theta) - F(x;\theta) \right]}{\delta_G(\theta)}.$$

This gap function is a measure of how well-separated the MAP optimum x^* is from the remaining integral configurations. By definition, the gap $\Delta(\theta;G)$ is always non-negative, and it is strictly positive whenever the MAP configuration x^* is unique. Finally, note that the gap is invariant to the translations ($\theta \mapsto \theta' = \theta + C$) and rescalings ($\theta \mapsto \theta' = c\theta$) of the parameter vector θ. These invariances are appropriate for the MAP problem since the optima of the energy function $F(x;\theta)$ are not affected by either transformation (i.e., $\arg\max_x F(x;\theta) = \arg\max_x F(x;\theta')$ for both $\theta' = \theta + C$ and $\theta' = c\theta$).

Finally, for any forest-inducing subset, we let $d(E')$ be the maximum degree of any node with respect to edges in E'—namely,

$$d(E') \quad := \quad \max_{s \in V} |t \in V \ \mid \ (s,t) \in E'|.$$

4.2.3 OPTIMALITY GUARANTEES FOR RANDOMIZED ROUNDING

We show, in this section, that when the pseudomarginals μ^n are within a specified ℓ_1 norm ball around the unique MAP optimum μ^*, the randomized rounding scheme outputs the MAP configuration with high probability.

Theorem 7 *Consider a problem instance (G, θ) for which the MAP optimum x^* is unique, and let μ^* be the associated vertex of the polytope $\mathbb{L}(G)$. For any $\varepsilon \in (0,1)$, if at some iteration n, we have $\mu^n \in \mathbb{L}(G)$, and*

$$\|\mu^n - \mu^*\|_1 \ \leq \ \frac{\varepsilon \, \Delta(\theta; G)}{1 + d(E')}, \tag{31}$$

then (E', μ^n)-randomized rounding succeeds with probability greater than $1 - \varepsilon$,

$$\mathbb{P}[X(\mu^n; E') = x^*] \quad \geq \quad 1 - \varepsilon.$$

We provide the proof of this claim in Appendix E. It is worthwhile observing that the theorem applies to any algorithm that generates a sequence $\{\mu^n\}$ of iterates contained within the local polytope $\mathbb{L}(G)$. In addition to the proximal Bregman updates discussed in this paper, it also applies to interior-point methods (Boyd and Vandenberghe, 2004) for solving LPs. For the naive rounding based on $E' = E$, the sequence $\{\mu^n\}$ need not belong to $\mathbb{L}(G)$, but instead need only satisfy the milder conditions $\mu^n_s(x_s) \geq 0$ for all $s \in V$ and $x_s \in \mathcal{X}$, and $\sum_{x_s} \mu^n_s(x_s) = 1$ for all $s \in V$.

The derandomized rounding scheme enjoys a similar guarantee, as shown in the following theorem, proved in Appendix F.

Theorem 8 *Consider a problem instance (G, θ) for which the MAP optimum x^* is unique, and let μ^* be the associated vertex of the polytope $\mathbb{L}(G)$. If at some iteration n, we have $\mu^n \in \mathbb{L}(G)$, and*

$$\|\mu^n - \mu^*\|_1 \ \leq \ \frac{\Delta(\theta; G)}{1 + d(E')},$$

then the (E', μ^n)-derandomized rounding scheme in Algorithm 6 outputs the MAP solution,

$$x^d(\mu^n; E') = x^*.$$

4.2.4 BOUNDS ON ITERATIONS FOR RANDOMIZED ROUNDING

Although Theorems 7 and 8 apply even for sequences $\{\mu^n\}$ that need not converge to μ^*, it is most interesting when the LP relaxation is tight, so that the sequence $\{\mu^n\}$ generated by any LP-solver satisfies the condition $\mu^n \to \mu^*$. In this case, we are guaranteed that for any fixed $\varepsilon \in (0,1)$, the bound (31) will hold for an iteration number n that is "large enough". Of course, making this intuition precise requires control of convergence rates. Recall that N is the number of nodes in the graph, and m is cardinality of the set $\mathcal{X}$ from which all variables takes their values. With this notation, we have the following.

Corollary 9 *Under the conditions of Theorem 7, suppose that the sequence of iterates $\{\mu^n\}$ converge to the LP (and MAP) optimum at a linear rate: $\|\mu^n - \mu^*\|_2 \leq \gamma^n \|\mu^0 - \mu^*\|_2$. Then:*

(a) The randomized rounding in Algorithm 5 succeeds with probability at least $1-\varepsilon$ for all iterations greater than

$$n^* \quad := \quad \frac{\frac{1}{2}\log\left(Nm + N^2m^2\right) + \log\left(\|\mu^0 - \mu^*\|_2\right) + \log\left(\frac{1+d(E')}{\Delta(\theta;G)}\right) + \log(1/\varepsilon)}{\log(1/\gamma)}.$$

(b) The derandomized rounding in Algorithm 6 yields the MAP solution for all iterations greater than

$$n^* \quad := \quad \frac{\frac{1}{2}\log\left(Nm + N^2m^2\right) + \log\left(\|\mu^0 - \mu^*\|_2\right) + \log\left(\frac{1+d(E')}{\Delta(\theta;G)}\right)}{\log(1/\gamma)}.$$

This corollary follows by observing that the vector $(\mu^n - \mu^*)$ has less than $Nm + N^2m^2$ elements, so that $\|\mu^n - \mu^*\|_1 \leq \sqrt{Nm + N^2m^2}\,\|\mu^n - \mu^*\|_2$. Moreover, Theorems 7 and 8 provide an ℓ_1-ball radius such that the rounding schemes succeed (either with probability greater than $1-\varepsilon$, or deterministically) for all pseudomarginal vectors within these balls.

5. Experiments

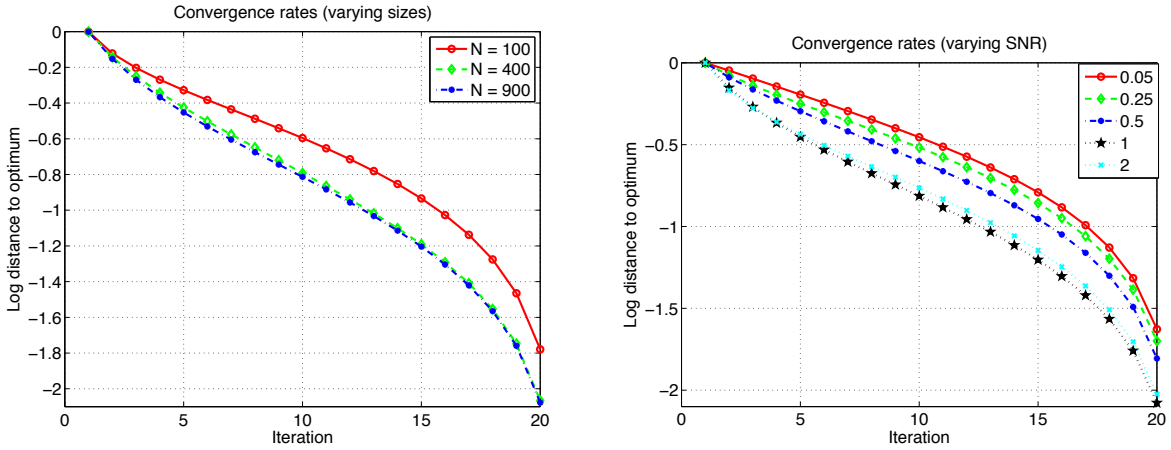
In this section, we provide the results of several experiments to illustrate the behavior of our methods on different problems. We performed experiments on 4-nearest neighbor grid graphs with sizes varying from $N = 100$ to $N = 900$, using models with either $m = 3$ or $m = 5$ labels. The edge potentials were set to Potts functions, of the form

$$\theta_{st}(x_s, x_t) = \begin{cases} \beta_{st} & \text{if } x_s = x_t \\ 0 & \text{otherwise.} \end{cases}$$

for a parameter $\beta_{st} \in \mathbb{R}$. These potential functions penalize disagreement of labels if $\beta_{st} > 0$, and penalize agreement if $\beta_{st} < 0$. The Potts weights on edges β_{st} were chosen randomly as $\text{Uniform}(-1,+1)$. We set the node potentials as $\theta_s(x_s) \sim \text{Uniform}(-\text{SNR}, \text{SNR})$, for some signal-to-noise parameter $\text{SNR} \geq 0$ that controls the ratio of node to edge strengths. In applying all of the proximal procedures, we set the proximal weights as $\omega^n = n$.

5.1 Rates of Convergence

We begin by reporting some results on the convergence rates of proximal updates. Figure 2(a) plots the logarithmic distance $\log\|\mu^n - \mu^*\|_2$ versus the number of iterations for grids of different sizes (node numbers $N \in \{100, 400, 900\}$). Here μ^n is the iterate at step n entropic proximal method and μ^* is the LP optimum. In all cases, note how the curves have an inverted quadratic shape, corresponding to a superlinear rate of convergence, which is consistent with Proposition 1. On other hand, Figure 2(b) provides plots of the logarithmic distance versus iteration number for problem sizes $N = 900$, and over a range of signal-to-noise ratios SNR (in particular, $\text{SNR} \in \{0.05, 0.25, 0.50, 1.0, 2.0\}$). Notice how the plots still show the same inverted quadratic shape, but that the rate of convergence slows down as the SNR decreases, as is to be expected.



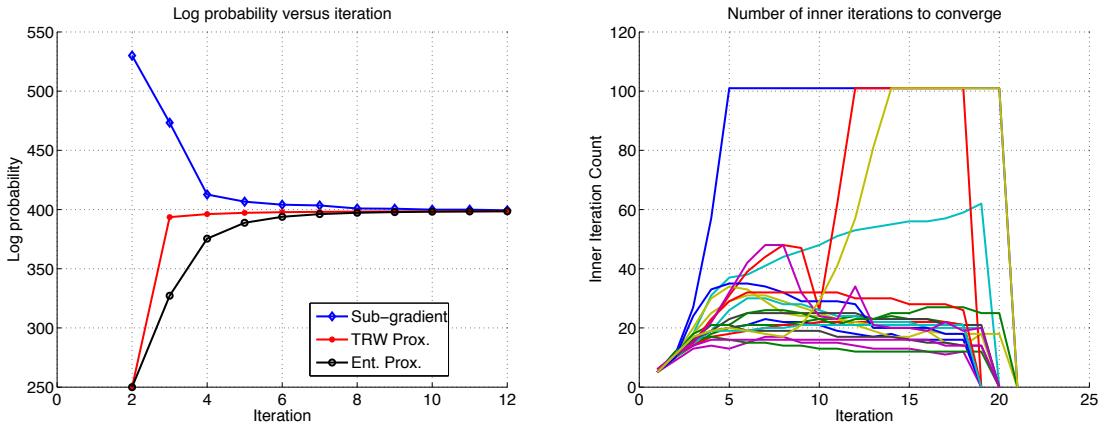
(a) (b)

Figure 2: (a) Plot of distance $\log_{10} \|\mu^n - \mu^*\|_2$ between the current entropic proximal iterate μ^n and the LP optimum μ^* versus iteration number for Potts models on grids with $N \in \{100, 400, 900\}$ vertices, $m = 5$ labels and SNR $= 1$. Note the superlinear rate of convergence, consistent with Proposition 1. (b) Plot of distance $\log_{10} \|\mu^n - \mu^*\|_2$ between the current entropic proximal iterate μ^n and the LP optimum μ^* versus iteration number for Potts models on grids with $m = 5$ labels, $N = 900$ vertices, and a range of signal-to-noise ratios SNR $\in \{0.05, 0.25, 0.50, 1.0, 2.0\}$. The rate of convergence remains superlinear but slows down as the SNR is decreased.

In Figure 3, we compare two of our proximal schemes—the entropic and the quadratic schemes—with a subgradient descent method, as previously proposed (Feldman et al., 2002a; Komodakis et al., 2007). For the comparison, we used a Potts model on a grid of 400 nodes, with each node taking three labels. The Potts weights were set as earlier, with SNR $= 2$. Plotted in Figure 3(a) are the log probabilities of the solutions from the TRW-proximal and entropic proximal methods, compared to the dual upper bound that is provided by the sub-gradient method. Each step on the horizontal axis is a single outer iteration for the proximal methods, and five steps of the subgradient method. (We note that it is slower to perform five subgradient steps than a single proximal outer iteration.) Both the primal proximal methods and the dual subgradient method converge to the same point. The TRW-based proximal scheme converges the fastest, essentially within four outer iterations, whereas the entropic scheme requires a few more iterations. The convergence rate of the subgradient ascent method is slower than both of these proximal schemes, even though we allowed it to take more steps per "iteration". In Figure 3(b), we plot a number of traces showing the number of inner iterations (vertical axis) required as a function of outer iteration (horizontal axis). The average number of inner iterations is around 20, and only rarely does the algorithm require substantially more.

5.2 Comparison of Rounding Schemes

In Figure 4, we compare five of our rounding schemes on a Potts model on grid graphs with $N = 400$, $m = 3$ labels and SNR $= 2$. For the graph-structured randomized rounding schemes, we used the node-based rounding scheme (so that $E \backslash E' = \emptyset$), and the chain-based rounding scheme (so that



(a) (b)

Figure 3: (a) Plots of the function value (for fractional iterates μ^n) versus number of iterations for a Potts model with $N = 400$ vertices, $m = 3$ labels and SNR $= 2$. Three methods are compared: a subgradient method (Feldman et al., 2002b; Komodakis et al., 2007), the entropic proximal method (Ent. Prox.), and the TRW-based proximal method (TRW Prox.). (b) Traces of different algorithm runs showing the number of inner iterations (vertical axis) versus the outer iteration number (horizontal axis). Typically around 20 inner iterations are required.

$E \backslash E'$ is the set of horizontal chains in the grid). For the deterministic rounding schemes, we used the node-based, neighborhood-based and the tree-based rounding schemes. Panel (a) of Figure 4 shows rounding schemes as applied to the entropic proximal algorithm, whereas panel (b) shows rounding schemes applied to the TRW proximal scheme. In both plots, the tree-based and star-based deterministic schemes are the first to return an optimal solution, whereas the node-based randomized scheme is the slowest in both plots. Of course, this type of ordering is to be expected, since the tree and star-based schemes look over larger neighborhoods of the graph, but incur larger computational cost.

6. Discussion

In this paper, we have developed distributed algorithms, based on the notion of proximal sequences, for solving graph-structured linear programming (LP) relaxations. Our methods respect the graph structure, and so can be scaled to large problems, and they exhibit a superlinear rate of convergence. We have also developed a series of graph-structured rounding schemes that can be used to generate integral solutions along with a certificate of optimality. These optimality certificates allow the algorithm to be terminated in a finite number of iterations.

The structure of our algorithms naturally lends itself to incorporating additional constraints, both linear and other types of conic constraints. It would be interesting to develop an adaptive version of our algorithm, which selectively incorporated new constraints as necessary, and then used the same proximal schemes to minimize the new conic program. Our algorithms for solving the LP are primal-based, so that the updates are in terms of the pseudo-marginals μ that are the primal parameters of the LP. This is contrast to typical message-passing algorithms such as tree-reweighted

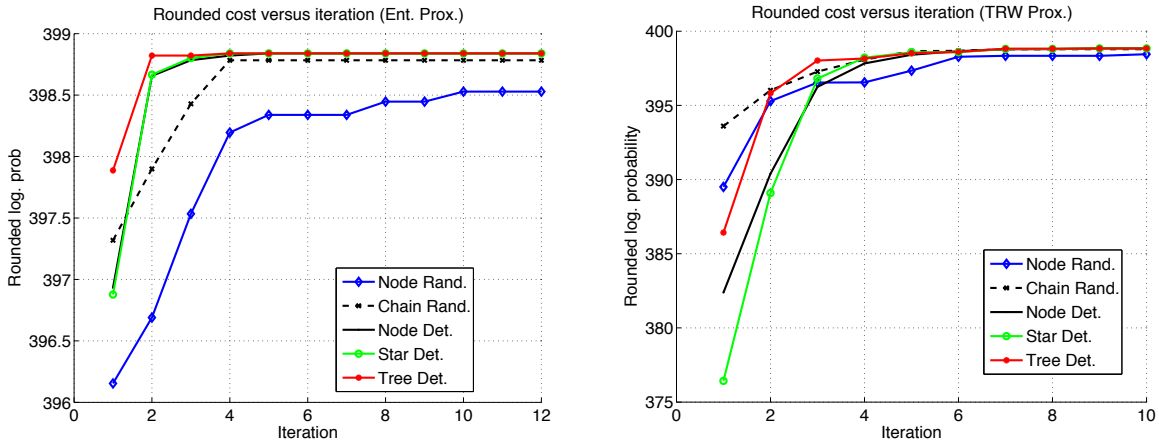


Figure 4: Plots of the log probability of rounded solutions versus the number of iterations for the entropic proximal scheme (panel (a)), and the TRW proximal scheme (panel (b)). In both cases, five different rounding schemes are compared: node-based randomized rounding (Node Rand.), chain-based randomized rounding (Chain Rand.), node-based deterministic rounding (Node. Det.), star-based deterministic rounding (Star Det.), and tree-based deterministic rounding (Tree Det.).

max-product, which are dual-based and where the updates are entirely in terms of *message* parameters that are the dual parameters of the LP. However, the dual of the LP is non-differentiable, so that these dual-based updates could either get trapped in local minima (dual co-ordinate ascent) or have sub-linear convergence rates (dual sub-gradient ascent). On the one hand, our primal-based algorithm converges to the LP minimum, and has at least linear convergence rates. On the other, it is more memory-intensive because of the need to maintain $O(|E|)$ edge pseudo-marginal parameters. It would be interesting to modify our algorithms so that maintaining these explicitly could be avoided; note that our derandomized rounding scheme (Algorithm 4.2.1) does not make use of the edge pseudo-marginal parameters.

Appendix A. Corrections to Bregman Projections

We briefly outline the corrections needed to cyclic Bregman projections for the case where the constraints are linear inequalities. It is useful, in order to characterize these needed corrections, to first note that these cyclic projections are equivalent to co-ordinate ascent steps on the dual of the Bregman projection problem (13). Let the linear constraint set for the Bregman projection

problem (13) be $C \equiv \cap_i \{\langle a_i, \mu \rangle \leq b_i\}$. Its Lagrangian can be written as

$$\mathcal{L}(\mu, z) = D_f(\mu \,\|\, \nu) + \sum_i z_i (\langle a_i, \mu \rangle - b_i),$$

where $z \geq 0$ are the Lagrangian or dual parameters. The dual function is given as $g(z) = \min_\mu \mathcal{L}(\mu, z)$, so that the dual problem can be written as

$$\min_{z \geq 0} \; g(z).$$

If the constraints were linear *equalities*, the dual variables $\{z\}$ would be unconstrained, and iterative co-ordinate ascent—which can be verified to be equivalent to cyclic projections of the primal variables onto individual constraints—would suffice to solve the dual problem. However, when the constraints have inequalities, the dual problem is no longer unconstrained: the dual variables are constrained to be positive. We would thus need to constrain the co-ordinate ascent steps. This can also be understood as the following primal-dual algorithmic scheme. Note that a necessary KKT condition for optimality of a primal-dual pair (μ, z) for (13) is

$$\nabla f(\mu) = \nabla f(\nu) - \sum_i z_i a_i. \tag{32}$$

The primal-dual algorithmic scheme then consists of maintaining primal-dual iterates (μ^t, z^t) which satisfy the equality (32), are dual feasible with $z^t \geq 0$, and which entail co-ordinate ascent on the dual problem, so that $g(z^{t+1}) \geq g(z^t)$ with at most one co-ordinate of μ^t updated in μ^{t+1}. We can now write down the corrected-projection update of μ^t given the single constraint $C_i \equiv \{\langle a_i, \mu \rangle \leq b_i\}$. According to the primal-dual algorithmic scheme this corresponds to co-ordinate ascent on the i-th co-ordinate of z^t so that (32) is maintained, whereby

$$\begin{aligned} \nabla f(\mu^{t+1}) &= \nabla f(\mu^t) + C\, a_i, \\ z^{t+1} &= z^t - C\, e_i, \\ C &:= \min\{z_i^t, \beta\}, \end{aligned} \tag{33}$$

where e_i is the co-ordinate vector with one in the i-th co-ordinate and zero elsewhere, and β is the i-th dual parameter setting corresponding to an unconstrained co-ordinate ascent update,

$$\begin{aligned} \nabla f(\mu) &= \nabla f(\mu^n) + \beta\, a_i, \\ \langle \mu, a_i \rangle &= b_i. \end{aligned} \tag{34}$$

One could derive such corrections corresponding to constrained dual ascent for general convex constraints (Dykstra, 1985; Han, 1988).

Appendix B. Detailed Derivation of Message-passing Updates

In this appendix, we provided detailed derivation of the message-passing updates for the inner loops of the algorithms.

B.1 Derivation of Algorithm 2

Consider the edge marginalization constraint for edge (s,t), $\mathbb{L}_i(G) \equiv \sum_{x_t} \mu_{st}(x_s,x_t) = \mu_s(x_s)$. Denoting the dual (Lagrange) parameter corresponding to the constraint by $\lambda_{st}(x_s)$, the Karush-Kuhn-Tucker conditions for the quadratic update (18) are given by

$$\begin{aligned}
\nabla q(\mu_{st}^{n,\tau+1}(x_s,x_t)) &= \nabla q(\mu_{st}^{n,\tau}(x_s,x_t)) + \lambda_{st}(x_s), \\
\nabla q(\mu_{s}^{n,\tau+1}(x_s)) &= \nabla q(\mu_{s}^{n,\tau}(x_s)) - \lambda_{st}(x_s), \\
\mu_{st}^{n,\tau+1}(x_s,x_t) &= \mu_{st}^{n,\tau}(x_s,x_t) + \lambda_{st}(x_s), \\
\mu_{s}^{n,\tau+1}(x_s) &= \mu_{s}^{n,\tau}(x_s) - \lambda_{st}(x_s),
\end{aligned}$$

while the constraint itself gives

$$\sum_{x_t} \mu_{st}^{n,\tau+1}(x_s,x_t) = \mu_s^{n,\tau}(x_s).$$

Solving for $\lambda_{st}(x_s)$ yields Equation (20). The node marginalization follows similarly.

The only inequalities are the positivity constraints, requiring that the node and edge pseudo-marginals be non-negative. Following the correction procedure for Bregman projections in (33), we maintain Lagrange dual variables corresponding to these constraints. We use $Z_s(x_s)$ as the Lagrange variables for the node positivity constraints $\mu_s(x_s) \geq 0$, and $Z_{st}(x_s,x_t)$ for the edge-positivity constraints $\mu_{st}(x_s,x_t) \geq 0$.

Consider the projection of $\{\mu^{n,\tau+1}\}$ onto the constraint $\mu_s(x_s) \geq 0$. Following (34), we first solve for $\beta_s(x_s)$ that satisfies

$$\begin{aligned}
\mu_s(x_s) &= \mu_s^{n,\tau+1}(x_s) - \beta_s(x_s), \\
\mu_s(x_s) &= 0,
\end{aligned}$$

so that $\beta_s(x_s) = \mu_s^{n,\tau+1}(x_s)$. Substituting in (33), we obtain the update

$$\begin{aligned}
C_s(x_s) &= \min\{Z_s(x_s), \mu_s^{(n,\tau+1)}(x_s)\}, \\
Z_s(x_s) &= Z_s(x_s) - C_s(x_s), \\
\mu_s^{(n,\tau+1)}(x_s) &= \mu_s^{(n,\tau+1)}(x_s) - C_s(x_s).
\end{aligned}$$

The edge positivity constraint updates follow similarly.

Thus overall, we obtain message-passing Algorithm 2 for the inner loop.

B.2 Derivation of Algorithm 3

Note that we do not need to explicitly impose positivity constraints in this case. Because the domain of the entropic Bregman function is the positive orthant, if we start from a positive point, any further Bregman projections would also result in a point in the positive orthant.

The projection $\mu^{n,\tau+1} = \Pi_h(\mu^{n,\tau}, \mathbb{L}_i(G))$ onto the individual constraint $\mathbb{L}_i(G)$ is defined by the optimization problem:

$$\mu^{n,\tau+1} = \min_{\mathbb{L}_i(G)} \{h(\mu) - \mu^\top \nabla h(\mu^{n,\tau})\}.$$

Consider the subset $\mathbb{L}_i(G)$ defined by the marginalization constraint along edge (s,t), namely $\sum_{x_t' \in \mathcal{X}} \mu_{st}(x_s, x_t') = \mu_s(x_s)$ for each $x_s \in \mathcal{X}$. Denoting the dual (Lagrange) parameters corresponding to these constraint by $\lambda_{st}(x_s)$, the KKT conditions are given by

$$\begin{aligned} \nabla h(\mu_{st}^{n,\tau+1}(x_s,x_t)) &= \nabla h(\mu_{st}^{n,\tau}(x_s,x_t)) + \lambda_{st}(x_s), \quad \text{and} \\ \nabla h(\mu_s^{n,\tau+1}(x_s)) &= \nabla h(\mu_s^{n,\tau}(x_s)) - \lambda_{st}(x_s). \end{aligned}$$

Computing the gradient ∇h and performing some algebra yields the relations

$$\begin{aligned} \mu_{st}^{(n,\tau+1)}(x_s,x_t) &= \mu_{st}^{(n,\tau)}(x_s,x_t)\exp(\lambda_{st}^{(n,\tau+1)}(x_s)), \\ \mu_s^{(n,\tau+1)}(x_s) &= \mu_s^{(n,\tau)}(x_s)\exp(-\lambda_{st}^{(n,\tau+1)}(x_s)), \quad \text{and} \\ \exp(2\lambda_{st}^{(n,\tau+1)}(x_s)) &= \frac{\mu_s^{(n,\tau)}(x_s)}{\sum_{x_t}\mu_{st}^{(n,\tau)}(x_s,x_t)}, \end{aligned}$$

from which the updates (22) follow.

Similarly, for the constraint set defined by the node marginalization constraint $\sum_{x_s \in \mathcal{X}} \mu_s(x_s) = 1$, we have $\nabla h(\mu_s^{(n,\tau+1)}(x_s)) = \nabla h(\mu_s^{(n,\tau)}(x_s)) + \lambda_s^{(n,\tau+1)}$, from which

$$\begin{aligned} \mu_s^{(n,\tau+1)}(x_s) &= \mu_s^{(n,\tau)}(x_s)\exp(\lambda_s^{(n,\tau+1)}), \qquad \text{and} \\ \exp(\lambda_s^{(n,\tau+1)}) &= 1/\sum_{x_s \in \mathcal{X}} \mu_s^{(n,\tau)}(x_s). \end{aligned}$$

The updates in Equation (23) follow.

Appendix C. Proof of Lemma 4

We provide a detailed proof for the entropic scheme; the arguments for other proximal algorithms are analogous. The key point is the following: regardless of how the proximal updates are computed, they must satisfy the necessary Lagrangian conditions for optimal points over the set $\mathbb{L}(G)$. Accordingly, we define the following sets of Lagrange multipliers:

$$\begin{aligned} \lambda_{ss} &\quad \text{for the normalization constraint } C_{ss}(\mu_s) = \textstyle\sum_{x_s'} \mu_s(x_s') - 1 = 0, \\ \lambda_{st}(x_s) &\quad \text{for the marginalization constraint } C_{ts}(x_s) = \textstyle\sum_{x_t'} \mu_{st}(x_s, x_t') - \mu_s(x_s) = 0, \\ \gamma_{st}(x_s,x_t) &\quad \text{for the non-negativity constraint } \mu_{st}(x_s,x_t) \geq 0. \end{aligned}$$

(There is no need to enforce the non-negativity constraint $\mu_s(x_s) \geq 0$ directly, since it is implied by the non-negativity of the joint pseudo-marginals and the marginalization constraints.)

With this notation, consider the Lagrangian associated with the entropic proximal update at step n:

$$L(x;\lambda,\gamma) = C(\mu;\theta,\mu^n) + \langle \gamma, \mu \rangle + \sum_{s \in V} \lambda_{ss} C_{ss}(x_s) + \sum_{(s,t) \in E} \left[\lambda_{ts}(x_s)C_{ts}(x_s) + \lambda_{st}(x_t)C_{st}(x_t)\right],$$

where $C(\mu;\theta,\mu^n)$ is shorthand for the cost component $-\langle \theta, \mu \rangle + \frac{1}{\omega^n} D_\alpha(\mu \,\|\, \mu^n)$. Using C, C' to denote constants (whose value can change from line to line), we now take derivatives to find the necessary

Lagrangian conditions:

$$\begin{aligned}
\frac{\partial L}{\partial \mu_s(x_s)} &= -\theta_s(x_s) + \frac{2\alpha_s}{\omega^n}\log\frac{\mu_s(x_s)}{\mu_s^n(x_s)} + C + \lambda_{ss} + \sum_{t\in N(s)} \lambda_{ts}(x_s), \qquad \text{and} \\
\frac{\partial L}{\partial \mu_{st}(x_s,x_t)} &= -\theta_{st}(x_s,x_t) + \frac{2\alpha_{st}}{\omega^n}\log\frac{\mu_{st}(x_s,x_t)}{\mu_{st}^n(x_s,x_t)} + C' + \gamma_{st}(x_s,x_t) - \lambda_{ts}(x_s) - \lambda_{st}(x_t).
\end{aligned}$$

Solving for the optimum $\mu = \mu^{n+1}$ yields

$$\begin{aligned}
\frac{2\alpha_s}{\omega^n}\log\mu_s^{n+1}(x_s) &= \theta_s(x_s) + \frac{2\alpha_s}{\omega^n}\log\mu_s^n(x_s) - \sum_{t\in N(s)} \lambda_{ts}(x_s) + C, \\
\frac{2\alpha_{st}}{\omega^n}\log\mu_{st}^{n+1}(x_s,x_t) &= \theta_{st}(x_s,x_t) + \frac{2\alpha_{st}}{\omega^n}\log\mu_{st}^n(x_s,x_t) - \gamma_{st}(x_s,x_t) \\
&\qquad + \lambda_{ts}(x_s) + \lambda_{st}(x_t) + C'.
\end{aligned}$$

From these conditions, we can compute the energy invariant (30):

$$\begin{aligned}
\frac{2}{\omega^n}F(x;\mu^{n+1}) &= \sum_{s\in V}\frac{2\alpha_s}{\omega^n}\log\mu_s^{n+1}(x_s) + \sum_{(s,t)\in E}\frac{2\alpha_{st}}{\omega^n}\log\mu_{st}^{n+1}(x_s,x_t) + C \\
&= F(x;\theta) + \frac{2}{\omega^n}\left\{\sum_{s\in V}\alpha_s\log\mu^n(x_s) + \sum_{(s,t)\in E}\alpha_{st}\log\mu_{st}^n(x_s,x_t)\right\} \\
&\qquad - \sum_{(s,t)\in E}\gamma_{st}(x_s,x_t) + C \\
&= F(x;\theta) + \frac{2}{\omega^n}F(x;\mu^n) - \sum_{(s,t)\in E}\gamma_{st}(x_s,x_t) + C.
\end{aligned}$$

Now since $\mu^n > 0$, by complementary slackness, we must have $\gamma_{st}(x_s,x_t) = 0$, which implies that

$$\frac{2}{\omega^n}F(x;\mu^{n+1}) = F(x;\theta) + \frac{2}{\omega^n}F(x;\mu^n) + C. \tag{35}$$

From this equation, it is a simple induction to show for some constants $\gamma_n > 0$ and $C_n \in \mathbb{R}$, we have $F(x;\mu^n) = \gamma_n F(x;\theta) + C_n$ for all iterations $n = 1,2,3,\ldots$, which implies preservation of the maximizers. If at iteration $n = 0$, we initialize $\mu^0 = 0$ to the all-uniform distribution, then we have $\frac{2}{\omega^1}F(x;\mu^1) = F(x;\theta) + C'$, so the statement follows for $n = 1$. Suppose that it holds at step n; then $\frac{2}{\omega^n}F(x;\mu^n) = \frac{2}{\omega^n}\gamma_n F(x;\theta) + \frac{2C_n}{\omega_n}$, and hence from the induction step (35), we have $F(x;\mu^{n+1}) = \gamma_{n+1}F(x;\theta) + C_{n+1}$, where $\gamma_{n+1} = \frac{\omega^n}{2}\gamma_n$.

Appendix D. Proof of Theorem 6

Consider the expected cost of the configuration $X(\mu^n;E')$ obtained from the randomized rounding procedure of Algorithm 5. A simple computation shows that

$$\mathbb{E}[F(X(\mu^n;E');\theta)] = G(\bar{\mu}) := \sum_{i=1}^{K} H(\mu^n;T_i) + H(\mu^n;E'),$$

where

$$\begin{aligned} H(\mu^n;T_i) &:= \sum_{s\in V_i}\sum_{x_s}\mu_s^n(x_s)\theta_s(x_s)+\sum_{(s,t)\in E_i}\sum_{x_s,x_t}\mu_{st}^n(x_s,x_t)\theta_{st}(x_s,x_t), \\ H(\mu^n;E') &:= \sum_{(u,v)\in E'}\sum_{x_s,x_t}\mu_u^n(x_u)\mu_v^n(x_v)\theta_{st}(x_u,x_v). \end{aligned} \tag{36}$$

We now show by induction that the de-randomized rounding scheme achieves cost at least as large as this expected value. Let $\bar{\mu}^{(i)}$ denote the updated pseudomarginals at the end of the i-th iteration. Since we initialize with $\bar{\mu}^{(0)}=\mu^n$, we have $G(\bar{\mu}^{(0)})=\mathbb{E}[F(X(\mu^n;E');\theta)]$. Consider the i-th step of the algorithm; the algorithm computes the portion of the de-randomized solution $x_{V_i}^d$ over the $i-$th tree. It will be convenient to use the decomposition $G=G_i+G_{\setminus i}$, where

$$\begin{aligned} G_i(\bar{\mu}) := \sum_{s\in V_i}\sum_{x_s}\bar{\mu}_s(x_s)\left\{\theta_s(x_s)+\sum_{\{t\,|\,(s,t)\in E'\}}\sum_{x_t}\bar{\mu}_t(x_t)\theta_{st}(x_s,x_t)\right\}+ \\ \sum_{(s,t)\in E_i}\sum_{x_s,x_t}\bar{\mu}_{st}(x_s,x_t)\,\theta_{st}(x_s,x_t), \end{aligned}$$

and $G_{\setminus i}=G-G_i$. If we define

$$\bar{F}_i(x_{V_i}) := \sum_{s\in V_i}\left\{\theta_s(x_s)+\sum_{t:(s,t)\in E'}\sum_{x_t}\bar{\mu}_t^{(i-1)}(x_t)\theta_{st}(x_s,x_t)\right\}+\sum_{(s,t)\in E_i}\theta_{st}(x_s,x_t),$$

it can be seen that $G_i(\bar{\mu}^{(i-1)})=\mathbb{E}[\bar{F}_i(x_{V_i})]$ where the expectation is under the tree-structured distribution over X_{V_i} given by

$$p(x_{V_i};\bar{\mu}^{(i-1)}(T_i)) = \prod_{s\in V_i}\bar{\mu}^{(i-1)}(x_s)\prod_{(s,t)\in E_i}\frac{\bar{\mu}^{(i-1)}(x_s,x_t)}{\bar{\mu}^{(i-1)}(x_s)\bar{\mu}^{(i-1)}(x_t)}.$$

Thus when the algorithm makes the choice $x_{V_i}^d=\arg\max_{x_{V_i}}\bar{F}_i(x_{V_i})$, it holds that

$$G_i(\bar{\mu}^{(i-1)}) \;=\; \mathbb{E}[\bar{F}_i(x_{V_i})] \;\leq\; \bar{F}_i(x_{V_i}^d).$$

The updated pseudomarginals $\bar{\mu}^{(i)}$ at the end the i-th step of the algorithm are given by,

$$\bar{\mu}_s^{(i)}(x_s) = \left\{\begin{array}{cc} \bar{\mu}_s^{(i-1)}(x_s) & \text{if } s\notin V_i \\ 0 & \text{if } s\in V_i, X_{d,s}\neq x_s \\ 1 & \text{if } s\in V_i, X_{d,s}=x_s. \end{array}\right\},$$

$$\bar{\mu}_{st}^{(i)}(x_s,x_t) = \left\{\begin{array}{ll} \bar{\mu}_{st}^{(i-1)}(x_s,x_t) & \text{if } (s,t)\notin E_i \\ \bar{\mu}_s^{(i)}(x_s)\bar{\mu}_t^{(i)}(x_t) & \text{if } (s,t)\in E_i. \end{array}\right.$$

In other words, $\bar{\mu}^{(i)}(T_i)$ is the indicator vector of the maximum energy sub-configuration $x_{V_i}^d$. Consequently, we have

$$G_i(\bar{\mu}^{(i)}) \;=\; \bar{F}_i(x_{V_i}^d) \;\geq\; G_i(\bar{\mu}^{(i-1)}),$$

and $G_{\setminus i}(\bar{\mu}^{(i)})=G_{\setminus i}(\bar{\mu}^{(i-1)})$, so that at the end of the i-th step, $G(\bar{\mu}^{(i)})\geq G(\bar{\mu}^{(i-1)})$. By induction, we conclude that $G(\bar{\mu}^{(K)})\geq G(\bar{\mu}^{(0)})$, where K is the total number of trees in the rounding scheme.

At the end of K steps, the quantity $\bar{\mu}^{(K)}$ is the indicator vector for $x^d(\mu^n;E')$ so that $G(\bar{\mu}^{(K)})=F(X_d(\mu^n;E');\theta)$. We have also shown that $G(\bar{\mu}^{(0)})=\mathbb{E}[F(X(\mu^n;E');\theta)]$. Combining these pieces, we conclude that $F(x^d(\mu^n;E');\theta)\geq\mathbb{E}[F(X(\mu^n;E');\theta)]$, thereby completing the proof.

Appendix E. Proof of Theorem 7

Let $p_{\text{succ}} = \mathbb{P}[X(\mu^n; E') = x^*]$, and let $R(\mu^n; E')$ denote the (random) integral vertex of $\mathbb{L}(G)$ that is specified by the random integral solution $X(\mu^n; E')$. (Since E' is some fixed forest-inducing subset, we frequently shorten this notation to $R(\mu^n)$.) We begin by computing the expected cost of the random solution, where the expectation is taken over the rounding procedure. A simple computation shows that $\mathbb{E}[\langle \theta, R(\mu^n)\rangle] := \sum_{i=1}^K H(\mu^n; T_i) + H(\mu^n; E')$, where $H(\mu^n; T_i)$ and $H(\mu^n; E')$ were defined previously (36).

We now upper bound the difference $\langle \theta, \mu^*\rangle - \mathbb{E}[\langle \theta, R(\mu^n)\rangle]$. For each subtree $i = 1, \ldots, K$, the quantity $D_i := H(\mu^*; T_i) - H(\mu^n; T_i)$ is upper bounded as

$$\begin{aligned} D_i &= \sum_{s \in V_i} \sum_{x_s} \Big[\mu_s^*(x_s) - \mu_s^n(x_s)\Big] \theta_s(x_s) + \sum_{(s,t) \in E_i} \sum_{x_s, x_t} \Big[\mu_s^*(x_s)\mu_t^*(x_t) - \mu_{st}^n(x_s, x_t)\Big] \theta_{st}(x_s, x_t) \\ &\leq \sum_{s \in V_i} \delta_s(\theta) \sum_{x_s} |\mu_s^*(x_s) - \mu_s^n(x_s)| + \sum_{(s,t) \in E_i} \delta_{st}(\theta) \sum_{x_s, x_t} |\mu_{st}^*(x_s, x_t) - \mu^n(x_s, x_t)|. \end{aligned}$$

In asserting this inequality, we have used the fact that that the matrix with entries given by $\mu_s^*(x_s)\mu_t^*(x_t) - \mu_{st}^n(x_s, x_t)$ is a difference of probability distributions, meaning that all its entries are between -1 and 1, and their sum is zero.

Similarly, we can upper bound the difference $D(E') = H(\mu^*; E') - H(\mu^n; E')$ associated with E':

$$\begin{aligned} D(E') &= \sum_{(u,v) \in E'} \sum_{x_u, x_v} \Big[\mu_u^*(x_u)\mu_v^*(x_v) - \mu_u^n(x_u)\mu_v^n(x_v)\Big] \theta_{uv}(x_u, x_v) \\ &\leq \sum_{(u,v) \in E'} \delta_{uv}(\theta) \sum_{x_u, x_v} \Big|\mu_u^*(x_u)\mu_v^*(x_v) - \mu_u^n(x_u)\mu_v^n(x_v)\Big| \\ &\leq \sum_{(u,v) \in E'} \delta_{uv}(\theta) \sum_{x_u, x_v} \Big\{ \Big|\mu_u^*(x_u)[\mu_v^*(x_v) - \mu_v^n(x_v)]\Big| + \Big|\mu_v^n(x_v)[\mu_u^*(x_u) - \mu_u^n(x_u)]\Big| \Big\} \\ &\leq \sum_{(u,v) \in E'} \delta_{uv}(\theta) \Big\{ \sum_{x_u} |\mu_u^n(x_u) - \mu_u^*(x_u)| + \sum_{x_u} |\mu_v^n(x_v) - \mu_v^*(x_v)| \Big\}. \end{aligned}$$

Combining the pieces, we obtain

$$\begin{aligned} \langle \theta, \mu^*\rangle - \mathbb{E}[\langle \theta, R(\mu^n)\rangle] &\leq \delta_G(\theta) \Big\{ \|\mu^n - \mu^*\|_1 + \sum_{s \in V} d(s; E') \sum_{x_s} |\mu_s^n(x_s) - \mu_s^*(x_s)| \Big\} \\ &\leq (1 + d(E'))\delta_G(\theta)\|\mu^n - \mu^*\|_1. \end{aligned} \tag{37}$$

In the other direction, we note that when the rounding fails, then we have

$$\langle \theta, \mu^*\rangle - \langle \theta, R(\mu^n)\rangle \geq \max_{x \neq x^*} [F(x^*; \theta) - F(x; \theta)].$$

Consequently, conditioning on whether the rounding succeeds or fails, we have

$$\begin{aligned} \langle \theta, \mu^*\rangle - \mathbb{E}[\langle \theta, R(\mu^n)\rangle] &\geq p_{\text{succ}} \big[\langle \theta, \mu^*\rangle - \langle \theta, \mu^*\rangle\big] + (1 - p_{\text{succ}}) \max_{x \neq x^*} [F(x^*; \theta) - F(x; \theta)] \\ &= (1 - p_{\text{succ}}) \max_{x \neq x^*} [F(x^*; \theta) - F(x; \theta)]. \end{aligned}$$

Combining this lower bound with the upper bound (37), performing some algebra, and using the definition of the gap $\Delta(\theta; G)$ yields that the probability of successful rounding is at least

$$p_{\text{succ}} \quad \geq \quad 1 - \frac{(1 + d(E'))}{\Delta(\theta; G)} \|\mu^n - \mu^*\|_1.$$

If the condition (31) holds, then this probability is at least $1 - \varepsilon$, as claimed.

Appendix F. Proof of Theorem 8

The proof follows that of Theorem 7 until Equation (37), which gives

$$\langle \theta, \mu^* \rangle - \mathbb{E}[\langle \theta, R(\mu^n) \rangle] \quad \leq (1 + d(E'))\, \delta_G(\theta)\, \|\mu^n - \mu^*\|_1.$$

Let $v^d(\mu^n; E')$ denote the integral vertex of $\mathbb{L}(G)$ that is specified by the de-randomized integral solution $x^d(\mu^n; E')$. Since E' is some fixed forest-inducing subset, we frequently shorten this notation to $v^d(\mu^n)$. Theorem 6 shows that

$$\mathbb{E}[\langle \theta, R(\mu^n) \rangle] \leq \langle \theta, v^d(\mu^n) \rangle.$$

Suppose the de-randomized solution is not optimal so that $v^d(\mu^n) \neq \mu^*$. Then, from the definition of the graph-based gap $\Delta(\theta; G)$, we obtain

$$\langle \theta, \mu^* \rangle - \langle \theta, v^d(\mu^n) \rangle \geq \delta_G(\theta)\, \Delta(\theta; G).$$

Combining the pieces, we obtain

$$\begin{aligned} \delta_G(\theta)\, \Delta(\theta; G) &\leq \langle \theta, \mu^* \rangle - \langle \theta, v^d(\mu^n) \rangle \\ &\leq \langle \theta, \mu^* \rangle - \mathbb{E}[\langle \theta, R(\mu^n) \rangle] \\ &\leq (1 + d(E'))\delta_G(\theta) \|\mu^n - \mu^*\|_1, \end{aligned}$$

which implies $\|\mu^n - \mu^*\|_1 \geq \frac{\Delta(\theta; G)}{1 + d(E')}$. However, this conclusion is a contradiction under the given assumption on $\|\mu^n - \mu^*\|_1$ in the theorem. It thus holds that the de-randomized solution $v^d(\mu^n)$ is equal to the MAP optimum μ^*, thereby completing the proof.

Abstract

We consider learning formulations with non-convex objective functions that often occur in practical applications. There are two approaches to this problem:

- Heuristic methods such as gradient descent that only find a local minimum. A drawback of this approach is the lack of theoretical guarantee showing that the local minimum gives a good solution.
- Convex relaxation such as L_1-regularization that solves the problem under some conditions. However it often leads to a sub-optimal solution in reality.

This paper tries to remedy the above gap between theory and practice. In particular, we present a multi-stage convex relaxation scheme for solving problems with non-convex objective functions. For learning formulations with sparse regularization, we analyze the behavior of a specific multi-stage relaxation scheme. Under appropriate conditions, we show that the local solution obtained by this procedure is superior to the global solution of the standard L_1 convex relaxation for learning sparse targets.

Keywords: sparsity, non-convex optimization, convex relaxation, multi-stage convex relaxation

1. Introduction

We consider the general regularization framework for machine learning, where a loss function is minimized, subject to a regularization condition on the model parameter. For many natural machine learning problems, either the loss function or the regularization condition can be non-convex. For example, the loss function is non-convex for classification problems, and the regularization condition is non-convex in problems with sparse parameters.

A major difficulty with nonconvex formulations is that the global optimal solution cannot be efficiently computed, and the behavior of a local solution is hard to analyze. In practice, convex relaxation (such as support vector machine for classification or L_1 regularization for sparse learning) has been adopted to remedy the problem. The choice of convex formulation makes the solution unique and efficient to compute. Moreover, the solution is easy to analyze theoretically. That is, it can be shown that the solution of the convex formulation approximately solves the original problem under appropriate assumptions. However, for many practical problems, such simple convex relaxation schemes can be sub-optimal.

Because of the above gap between practice and theory, it is important to study direct solutions of non-convex optimization problems beyond the standard convex relaxation. Our goal is to design a numerical procedure that leads to a *reproducible solution* which is better than the standard convex relaxation solution. In order to achieve this, we present a general framework of multi-stage convex relaxation, which iteratively refine the convex relaxation formulation to give better solutions. The method is derived from concave duality, and involves solving a sequence of convex relaxation problems, leading to better and better approximations to the original nonconvex formulation. It provides a unified framework that includes some previous approaches (such as LQA Jianqing Fan, 2001, LLA Zou and Li, 2008, CCCP Yuille and Rangarajan, 2003) as special cases. The procedure itself may be regarded as a special case of alternating optimization, which automatically ensures its convergence. Since each stage of multi-stage convex relaxation is a convex optimization problem, the approach is also computationally efficient. Although the method only leads to a local optimal solution for the original nonconvex problem, this local solution is a refinement of the global solution for the initial convex relaxation. Therefore intuitively one expects that the local solution is better than the standard one-stage convex relaxation. In order to prove this observation more rigorously, we consider least squares regression with nonconvex sparse regularization terms, for which we can analyze the effectiveness of the multi-stage convex relaxation. It is shown that under appropriate assumptions, the (local) solution computed by the multi-stage convex relaxation method using nonconvex regularization achieves better parameter estimation performance than the standard convex relaxation with L_1 regularization.

The main contribution of this paper is the analysis of sparse regularized least squares regression presented in Section 3, where we derive theoretical results showing that under appropriate conditions, it is beneficial to use multi-stage convex relaxation with nonconvex regularization as opposed to the standard convex L_1 regularization. This demonstrates the effectiveness of multi-stage convex relaxation for a specific but important problem. Although without theoretical analysis, we shall also present the general idea of multi-stage convex relaxation in Section 2, because it can be applied to other potential application examples as illustrated in Appendix C. The gist of our analysis can be applied to those examples (e.g., the multi-task learning problem in the setting of matrix completion, which has drawn significant attention recently) as well. However, the detailed derivation will be specific to each application and the analysis will not be trivial. Therefore while we shall present a rather general form of multi-stage convex relaxation formulation in order to unify various previous approaches, and put this work in a broader context, the detailed theoretical analysis (and empirical studies) for other important applications will be left to future work.

2. Multi-stage Convex Relaxation

This section presents the general idea of multi-stage convex relaxation which can be applied to various optimization problems. It integrates a number of existing ideas into a unified framework.

2.1 Regularized Learning Formulation

The multi-stage convex relaxation approach considered in the paper can be applied to the following optimization problem, which can be motivated from supervised learning formulation. As back-

ground information, its connection to regularized learning formula (15) is given in Appendix B.

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} R(\mathbf{w}),$$
$$R(\mathbf{w}) = R_0(\mathbf{w}) + \sum_{k=1}^{K} R_k(\mathbf{w}), \tag{1}$$

where $\mathbf{w} = [\mathbf{w}_1, \ldots, \mathbf{w}_d] \in \mathbb{R}^d$ is a d-dimensional parameter vector, and $R(\mathbf{w})$ is the general form of a regularized objective function. Moreover, for convenience, we assume that $R_0(\mathbf{w})$ is convex in $\mathbf{w}$, and each $R_k(\mathbf{w})$ is non-convex. In the proposed work, we shall employ convex/concave duality to derive convex relaxations of (1) that can be efficiently solved.

Related to (1), one may also consider the constrained formulation

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} R_0(\mathbf{w}) \quad \text{subject to } \sum_{k=1}^{K} R_k(\mathbf{w}) \le A, \tag{2}$$

where A is a constant. One may also mix (1) and (2).

2.2 Concave Duality

In the following discussion, we consider a single nonconvex component $R_k(\mathbf{w})$ in (1), which we shall rewrite using concave duality. Let $\mathbf{h}_k(\mathbf{w}) : R^d \to \Omega_k \subset R^{d_k}$ be a vector function with Ω_k being the convex hull of its range. It may not be a one-to-one map. However, we assume that there exists a function $\bar{R}_k$ defined on Ω_k so that we can express $R_k(\mathbf{w})$ as

$$R_k(\mathbf{w}) = \bar{R}_k(\mathbf{h}_k(\mathbf{w})).$$

Assume that we can find $\mathbf{h}_k$ so that the function $\bar{R}_k(\mathbf{u}_k)$ is concave on $\mathbf{u}_k \in \Omega_k$. Under this assumption, we can rewrite the regularization function $R_k(\mathbf{w})$ as:

$$R_k(\mathbf{w}) = \inf_{\mathbf{v}_k \in R^{d_k}} \left[\mathbf{v}_k^\top \mathbf{h}_k(\mathbf{w}) - R_k^*(\mathbf{v}_k) \right] \tag{3}$$

using concave duality (Rockafellar, 1970). In this case, $R_k^*(\mathbf{v}_k)$ is the concave dual of $\bar{R}_k(\mathbf{u}_k)$ given below

$$R_k^*(\mathbf{v}_k) = \inf_{\mathbf{u}_k \in \Omega_k} \left[\mathbf{v}_k^\top \mathbf{u}_k - \bar{R}_k(\mathbf{u}_k) \right].$$

Note that using the convention in convex analysis (Rockafellar, 1970), we may assume that $R_k^*(\mathbf{v}_k)$ is defined on R^{d_k} but may take $-\infty$ value. Equivalently, we may consider the subset $\{\mathbf{v}_k : R_k^*(\mathbf{v}_k) > -\infty\}$ as the feasible region of the optimization problem (3), and assume that $R_k^*(\mathbf{v}_k)$ is only defined on this feasible region.

It is well-known that the minimum of the right hand side of (3) is achieved at

$$\hat{\mathbf{v}}_k = \nabla_{\mathbf{u}} \bar{R}_k(\mathbf{u})|_{\mathbf{u}=\mathbf{h}_k(\mathbf{w})}. \tag{4}$$

This is the general framework we suggest in the paper. For illustration, some example non-convex problems encountered in machine learning are included in Appendix C.

2.3 Penalized Formulation

Let $\mathbf{h}_k(\mathbf{w})$ be a vector function with convex components, so that (3) holds. Given an appropriate vector $\mathbf{v}_k \in R^{d_k}$, a simple convex relaxation of (1) becomes

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}\in R^d} \left[R_0(\mathbf{w}) + \sum_{k=1}^{K} \mathbf{h}_k(\mathbf{w})^\top \mathbf{v}_k \right]. \tag{5}$$

This simple relaxation yields a solution that is different from the solution of (1). However, if each $\mathbf{h}_k$ satisfies the condition of Section 2.2, then it is possible to write $R_k(\mathbf{w})$ using (3). Now, with this new representation, we can rewrite (1) as

$$[\hat{\mathbf{w}}, \hat{\mathbf{v}}] = \arg\min_{\mathbf{w},\{\mathbf{v}_k\}} \left[R_0(\mathbf{w}) + \sum_{k=1}^{K} (\mathbf{h}_k(\mathbf{w})^\top \mathbf{v}_k - R_k^*(\mathbf{v}_k)) \right]. \tag{6}$$

This is clearly equivalent to (1) because of (3). If we can find a good approximation of $\hat{\mathbf{v}} = \{\hat{\mathbf{v}}_k\}$ that improves upon the initial value of $\hat{\mathbf{v}}_k = \mathbf{1}$, then the above formulation can lead to a refined convex problem in $\mathbf{w}$ that is a better convex relaxation than (5).

Our numerical procedure exploits the above fact, which tries to improve the estimation of $\mathbf{v}_k$ over the initial choice of $\mathbf{v}_k = \mathbf{1}$ in (5) using an iterative algorithm. This can be done using an alternating optimization procedure, which repeatedly applies the following two steps:

- First we optimize $\mathbf{w}$ with $\mathbf{v}$ fixed: this is a convex problem in $\mathbf{w}$ with appropriately chosen $\mathbf{h}(\mathbf{w})$.
- Second we optimize $\mathbf{v}$ with $\mathbf{w}$ fixed: although non-convex, it has a closed form solution that is given by (4).

Initialize $\hat{\mathbf{v}} = \mathbf{1}$
Repeat the following two steps until convergence:

- Let
$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left[R_0(\mathbf{w}) + \sum_{k=1}^{K} \mathbf{h}_k(\mathbf{w})^\top \hat{\mathbf{v}}_k \right]. \tag{7}$$
- Let $\hat{\mathbf{v}}_k = \nabla_{\mathbf{u}} \bar{R}_k(\mathbf{u})|_{\mathbf{u}=\mathbf{h}_k(\hat{\mathbf{w}})}$ $(k = 1, \ldots, K)$

Figure 1: Multi-stage Convex Relaxation Method

The general procedure for solving (6) is presented in Figure 1. It can be regarded as a generalization of CCCP (concave-convex programming) (Yuille and Rangarajan, 2003), which takes $\mathbf{h}(\mathbf{w}) = \mathbf{w}$. It is also more general than LQA (local quadratic approximation) (Jianqing Fan, 2001) or LLA (local linear approximation) (Zou and Li, 2008). Specifically LQA takes $\mathbf{h}_j(\hat{\mathbf{w}}) = \mathbf{w}_j^2$ and LLA takes $\mathbf{h}_j(\hat{\mathbf{w}}) = |\mathbf{w}_j|$. The justification of those procedures rely on the so-called MM (majorization-minimization) principle, where an upper bound of the objective function is minimized at each step (see Zou and Li, 2008 and references therein). However, in order to apply MM, for each particular choice of $\mathbf{h}$, one has to demonstrate that the convex relaxation is indeed an upper bound, which is

necessary to show convergence. In the concave relaxation formulation adopted in this work, the justification of convergence is automatically embedded in (6), which becomes a joint optimization problem. Figure 1 is simply an alternating optimization procedure for solving (6), which is equivalent to (1). Since convex duality of many interesting objective functions (including matrix functions) are familiar to many machine learning researchers, the concave duality derivation presented here can be automatically applied to various applications without the need to worry about convergence justification. This will be especially useful for complex formulations such as structured or matrix regularization, where the more traditional MM idea cannot be easily applied. One may also regard our framework as a principled method to design a class of algorithms that may be interpreted as MM procedures. Some examples illustrate its applications are presented in Appendix C.

Note that by repeatedly refining the parameter $\mathbf{v}$, we can potentially obtain better and better convex relaxation in Figure 1, leading to a solution superior to that of the initial convex relaxation. Since at each step the procedure decreases the objective function in (6), its convergence to a local minimum is easy to show. In fact, in order to achieve convergence, one only needs to approximately minimize (7) and reasonably decrease the objective value at each step. We skip the detailed analysis here, because in the general case, a local solution is not necessarily a good solution, and there are other approaches (such as gradient descent) that can compute a local solution. In order to demonstrate the effectiveness of multi-stage convex relaxation, we shall include a more careful analysis for the special case of sparse regularization in Section 3.1. Our theory shows that the local solution of multi-stage relaxation with a nonconvex sparse regularizer is superior to the convex L_1 regularization solution (under appropriate conditions).

2.4 Constrained Formulation

The multi-stage convex relaxation idea can also be used to solve the constrained formulation (2). The one-stage convex relaxation of (2), given fixed relaxation parameter $\mathbf{v}_k$, becomes

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}\in R^d} R_0(\mathbf{w}) \quad \text{subject to } \sum_{k=1}^{K} \mathbf{h}_k(\mathbf{w})^\top \mathbf{v}_k \le A + \sum_{k=1}^{K} R_k^*(\mathbf{v}_k).$$

Because of (3), the above formulation is equivalent to (2) if we optimize over $\mathbf{v}$. This means that by optimizing $\mathbf{v}$ in addition to $\mathbf{w}$, we obtain the following algorithm:

- Initialize $\hat{\mathbf{v}} = \mathbf{1}$
- Repeat the following two steps until convergence:
  - Let
$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} R_0(\mathbf{w}) \quad \text{subject to } \sum_{k=1}^{K} \mathbf{h}_k(\mathbf{w})^\top \hat{\mathbf{v}}_k \le A + \sum_{k=1}^{K} R_k^*(\hat{\mathbf{v}}_k).$$
  - Let $\hat{\mathbf{v}}_k = \nabla_{\mathbf{u}} \bar{R}_k(\mathbf{u})|_{\mathbf{u}=\mathbf{h}_k(\hat{\mathbf{w}})}$ $(k = 1,\ldots,K)$

If an optimization problem includes both nonconvex penalization and nonconvex constrains, then one may use the above algorithm with Figure 1.

3. Multi-stage Convex Relaxation for Sparse Regularization

The multi-stage convex relaxation method described in the previous section tries to obtain better approximations of the original nonconvex problem by refining the convex relaxation formulation. Since the local solution found by the algorithm is the global solution of a refined convex relaxation formulation, it should be closer to the desired solution than that of the standard one-stage convex relaxation method. Although this high level intuition is appealing, it is still necessarily to present a more rigorous theoretical result which can precisely demonstrate the advantage of the multi-stage approach over the standard single stage method. Unless we can develop a theory to show the effectiveness of the multi-stage procedure in Figure 1, our proposal is yet another local minimum finding scheme that may potentially get stuck at a bad local solution.

In order to obtain some strong theoretical results that can demonstrate the advantage of the multi-stage approach, we consider the special case of sparse learning. This is because this problem has been well-studied in recent years, and the behavior of convex relaxation (L_1 regularization) is well-understood.

3.1 Theory of Sparse Regularization

For a non-convex but smooth regularization condition such as capped-L_1 or smoothed-L_p with $p \in (0,1)$, standard numerical techniques such as gradient descent lead to a local minimum solution. Unfortunately, it is difficult to find the global optimum, and it is also difficult to analyze the quality of the local minimum. Although in practice, such a local minimum solution may outperform the Lasso solution, the lack of theoretical (and practical) performance guarantee prevents the more wide-spread applications of such algorithms. As a matter of fact, results with non-convex regularization are difficult to reproduce because different numerical optimization procedures can lead to different local minima. Therefore the quality of the solution heavily depend on the numerical procedure used.

The situation is very different for a convex relaxation formulation such as L_1-regularization (Lasso). The global optimum can be easily computed using standard convex programming techniques. It is known that in practice, 1-norm regularization often leads to sparse solutions (although often suboptimal). Moreover, its performance has been theoretically analyzed recently. For example, it is known from the compressed sensing literature that under certain conditions, the solution of L_1 relaxation may be equivalent to L_0 regularization asymptotically (e.g., Candes and Tao, 2005). If the target is truly sparse, then it was shown in Zhao and Yu (2006) that under some restrictive conditions referred to as *irrepresentable conditions*, 1-norm regularization solves the feature selection problem. The prediction performance of this method has been considered in Koltchinskii (2008), Zhang (2009a), Bickel et al. (2009) and Bunea et al. (2007).

In spite of its success, L_1-regularization often leads to suboptimal solutions because it is not a good approximation to L_0 regularization. Statistically, this means that even though it converges to the true sparse target when $n \to \infty$ (consistency), the rate of convergence can be suboptimal. The only way to fix this problem is to employ a non-convex regularization condition that is closer to L_0 regularization. In the following, we formally prove a result for multi-stage convex relaxation with non-convex sparse regularization that is superior to the Lasso result. In essence, we establish a performance guarantee for non-convex formulations when they are solved by using the multi-stage convex relaxation approach which is more sophisticated than the standard one-stage convex relaxation.

In supervised learning, we observe a set of input vectors $\mathbf{x}_1,\ldots,\mathbf{x}_n \in R^d$, with corresponding desired output variables $y_1,\ldots,y_n$. In general, we may assume that there exists a target $\bar{\mathbf{w}} \in R^d$ such that

$$y_i = \bar{\mathbf{w}}^\top \mathbf{x}_i + \varepsilon_i \qquad (i = 1,\ldots,n), \tag{8}$$

where ε_i are zero-mean independent random noises (but not necessarily identically distributed). Moreover, we assume that the target vector $\bar{\mathbf{w}}$ is sparse. That is, there exists $\bar{k} = \|\bar{\mathbf{w}}\|_0$ is small. This is the standard statistical model for sparse learning.

Let $\mathbf{y}$ denote the vector of $[y_i]$ and X be the $n \times d$ matrix with each row a vector $\mathbf{x}_i$. We are interested in recovering $\bar{\mathbf{w}}$ from noisy observations using the following sparse regression method:

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left[\frac{1}{n}\|X\mathbf{w} - \mathbf{y}\|_2^2 + \lambda \sum_{j=1}^{d} g(|\mathbf{w}_j|) \right], \tag{9}$$

where $g(|\mathbf{w}_j|)$ is a regularization function. Here we require that $g'(u)$ is non-negative which means we penalize larger u more significantly. Moreover, we assume $u^{1-q}g'(u)$ is a non-increasing function when $u > 0$, which means that $[g(|\mathbf{w}_1|),\ldots,g(|\mathbf{w}_d|)]$ is concave with respect to $\mathbf{h}(\mathbf{w}) = [|\mathbf{w}_1|^q,\ldots,|\mathbf{w}_d|^q]$ for some $q \geq 1$. It follows that (9) can be solved using the multi-stage convex relaxation algorithm in Figure 2, which we will analyze. Although this algorithm was mentioned in Zou and Li (2008) as LLA when $q = 1$, they only presented a one-step low-dimensional asymptotic analysis. We present a true multi-stage analysis in high dimension. Our analysis also focuses on $q = 1$ (LLA) for convenience because the Lasso analysis in Zhang (2009a) can be directly adapted; however in principle, one can also analyze the more general case of $q > 1$.

Initialize $\lambda_j^{(0)} = \lambda$ for $j = 1,\ldots,d$
For $\ell = 1, 2, \ldots$

- Let
$$\hat{\mathbf{w}}^{(\ell)} = \arg\min_{\mathbf{w}\in R^d} \left[\frac{1}{n}\|X\mathbf{w} - \mathbf{y}\|_2^2 + \sum_{j=1}^{d} \lambda_j^{(\ell-1)} |\mathbf{w}_j|^q \right]. \tag{10}$$
- Let $\lambda_j^{(\ell)} = \lambda q^{-1} |\hat{\mathbf{w}}_j|^{1-q} g'(|\hat{\mathbf{w}}_j^{(\ell)}|)$ $(j = 1,\ldots,d)$

Figure 2: Multi-stage Convex Relaxation for Sparse Regularization

For convenience, we consider fixed design only, where X is fixed and the randomness is with respect to $\mathbf{y}$ only. We require some technical conditions for our analysis. First we assume sub-Gaussian noise as follows.

Assumption 3.1 *Assume that $\{\varepsilon_i\}_{i=1,\ldots,n}$ in (8) are independent (but not necessarily identically distributed) sub-Gaussians: there exists $\sigma \geq 0$ such that $\forall i$ and $\forall t \in R$,*

$$\mathbf{E}_{\varepsilon_i} e^{t\varepsilon_i} \leq e^{\sigma^2 t^2/2}.$$

Both Gaussian and bounded random variables are sub-Gaussian using the above definition. For example, if a random variable $\xi \in [a,b]$, then $\mathbf{E}_\xi e^{t(\xi - \mathbf{E}\xi)} \leq e^{(b-a)^2 t^2/8}$. If a random variable is Gaussian: $\xi \sim N(0,\sigma^2)$, then $\mathbf{E}_\xi e^{t\xi} \leq e^{\sigma^2 t^2/2}$.

We also introduce the concept of sparse eigenvalue, which is standard in the analysis of L_1 regularization.

Definition 1 *Given k, define*

$$\rho_+(k) = \sup\left\{\frac{1}{n}\|X\mathbf{w}\|_2^2/\|\mathbf{w}\|_2^2 : \|\mathbf{w}\|_0 \le k\right\},$$
$$\rho_-(k) = \inf\left\{\frac{1}{n}\|X\mathbf{w}\|_2^2/\|\mathbf{w}\|_2^2 : \|\mathbf{w}\|_0 \le k\right\}.$$

Our main result is stated as follows. The proof is in the appendix.

Theorem 2 *Let Assumption 3.1 hold. Assume also that the target $\bar{\mathbf{w}}$ is sparse, with $\mathbf{E}y_i = \bar{\mathbf{w}}^\top \mathbf{x}_i$, and $\bar{k} = \|\bar{\mathbf{w}}\|_0$. Choose λ such that*

$$\lambda \ge 20\sigma\sqrt{2\rho_+(1)\ln(2d/\eta)/n}.$$

Assume that $g'(z) \ge 0$ is a non-increasing function such that $g'(z) = 1$ when $z \le 0$. Moreover, we require that $g'(\theta) \ge 0.9$ with $\theta = 9\lambda/\rho_-(2\bar{k}+s)$. Assume that $\rho_+(s)/\rho_-(2\bar{k}+2s) \le 1 + 0.5s/\bar{k}$ for some $s \ge 2\bar{k}$, then with probability larger than $1-\eta$:

$$\|\hat{\mathbf{w}}^{(\ell)} - \bar{\mathbf{w}}\|_2 \le \frac{17}{\rho_-(2\bar{k}+s)}\left[2\sigma\sqrt{\rho_+(\bar{k})}\left(\sqrt{7.4\bar{k}/n} + \sqrt{2.7\ln(2/\eta)/n}\right)\right.$$
$$\left. + \lambda\left(\sum_{j:\bar{\mathbf{w}}_j \ne 0} g'(|\bar{\mathbf{w}}_j| - \theta)^2\right)^{1/2}\right] + 0.7^\ell \frac{10}{\rho_-(2\bar{k}+s)}\sqrt{\bar{k}}\lambda,$$

where $\hat{\mathbf{w}}^{(\ell)}$ is the solution of (10) with $q = 1$.

Note that the theorem allows the situation $d \gg n$, which is what we are interested in. This is the first general analysis of multi-stage convex relaxation for high dimensional sparse learning, although some simpler asymptotic results for low dimensional two-stage procedures were obtained in Zou (2006) and Zou and Li (2008), they are not comparable to ours.

Results most comparable to what we have obtained here are that of the FoBa procedure in Zhang (2009b) and that of the MC+ procedure in Zhang (2010). The former is a forward backward greedy algorithm, which does not optimize (9), while the latter is a path-following algorithm for solving (9). Although results in Zhang (2010) are comparable to ours, we should note that efficient path-following computation in MC+ requires specialized regularizers $g(\cdot)$. Moreover, unlike our procedure, which is efficient because of convex optimization, there is no proof showing that the path-following strategy in Zhang (2010) is always efficient (in the sense that there may be exponentially many switching points). However, empirical experience in Zhang (2010) does indicate its efficiency for a class of regularizers that can be relatively easily handled by path-following. Therefore we are not claiming here that our approach will always be superior to Zhang (2010) in practice. Nevertheless, our result suggests that different local solution procedures can be used to solve the same nonconvex formulation with valid theoretical guarantees. This opens the door for additional theoretical studies of other numerical procedures.

The condition $\rho_+(s)/\rho_-(2\bar{k}+2s) \le 1 + 0.5s/\bar{k}$ requires the eigenvalue ratio $\rho_+(s)/\rho_-(s)$ to grow sub-linearly in s. Such a condition, referred to as *sparse eigenvalue condition*, is also needed in

the standard analysis of L_1 regularization (Zhang and Huang, 2008; Zhang, 2009a). It is related but weaker than the *restricted isometry property* (RIP) in compressive sensing (Candes and Tao, 2005). Note that in the traditional low-dimensional statistical analysis, one assumes that $\rho_+(s)/\rho_-(2\bar{k}+2s) < \infty$ as $s \to \infty$, which is significantly stronger than the condition we use here. Although in practice it is often difficult to verify the sparse eigenvalue condition for real problems, Theorem 2 nevertheless provides important theoretical insights for multi-stage convex relaxation.

Since in standard Lasso, $g'(|\mathbf{w}_j|) \equiv 1$, we obtain the following bound from Theorem 2

$$\|\hat{\mathbf{w}}_{L_1} - \bar{\mathbf{w}}\|_2 = O(\sqrt{k}\lambda),$$

where $\hat{\mathbf{w}}_{L_1}$ is the solution of the standard L_1 regularization. This bound is tight for Lasso, in the sense that the right hand side cannot be improved except for the constant—this can be easily verified with an orthogonal design matrix. It is known that in order for Lasso to be effective, one has to pick λ no smaller than the order $\sigma\sqrt{\ln d/n}$. Therefore, the parameter estimation error of the standard Lasso is of the order $\sigma\sqrt{\bar{k}\ln d/n}$, which cannot be improved.

In comparison, if we consider an appropriate regularization condition $g(|\mathbf{w}_j|)$ that is concave in $|\mathbf{w}_j|$. Since $g'(|\mathbf{w}_j|) \approx 0$ when $|\mathbf{w}_j|$ is large, the bound in Theorem 2 can be significantly better when most non-zero coefficients of $\bar{\mathbf{w}}$ are relatively large in magnitude. For example, consider the capped-L_1 regularizer $g(|\mathbf{w}_j|) = \min(\alpha, |\mathbf{w}_j|)$ with $\alpha \geq \theta$; in the extreme case where $\min_j |\mathbf{w}_j| > \alpha + \theta$ (which can be achieved when all nonzero components of $\bar{\mathbf{w}}$ are larger than the order $\sigma\sqrt{\ln d/n}$), we obtain the better bound

$$\|\hat{\mathbf{w}}^{(\ell)} - \bar{\mathbf{w}}\|_2 = O(\sqrt{\bar{k}/n} + \sqrt{\ln(1/\eta)/n})$$

for the multi-stage procedure for a sufficiently large ℓ at the order of $\ln\ln d$. This bound is superior to the standard one-stage L_1 regularization bound $\|\hat{\mathbf{w}}_{L_1} - \bar{\mathbf{w}}\|_2 = O(\sqrt{\bar{k}\ln(d/\eta)/n})$, which is tight for Lasso. The difference can be significant when $\ln d$ is large.

Generally speaking, with a regularization condition $g(|\mathbf{w}_j|)$ that is concave in $|\mathbf{w}_j|$, the dependency on λ is through $g'(|\bar{\mathbf{w}}_j|)$ which decreases as $|\bar{\mathbf{w}}_j|$ increases. This removes the bias of the Lasso and leads to improved performance. Specifically, if $\bar{\mathbf{w}}_j$ is large, then $g'(|\bar{\mathbf{w}}_j|) \approx 0$. In comparison, the Lasso bias is due to the fact that $g'(|\bar{\mathbf{w}}_j|) \equiv 1$. For illustration, the derivative $g'(\cdot)$ of some sparse regularizers are plotted in Figure 3.

Note that our theorem only applies to regularizers with finite derivative at zero. That is, $g'(0) < \infty$. The result doesn't apply to L_p regularization with $p < 1$ because $g'(0) = \infty$. Although a weaker result can be obtained for such regularizers, we do not include it here. We only include an intuitive example below to illustrate why the condition $g'(0) < \infty$ is necessary for stronger results presented in the paper. Observe that the multi-stage convex relaxation method only computes a local minimum, and the regularization update rule is given by $\lambda_j^{(\ell-1)} = g'(\hat{\mathbf{w}}_j^{(\ell-1)})$. If $g'(0) = \infty$, then $\lambda_j^{(\ell-1)} = \infty$ when $\hat{\mathbf{w}}_j^{(\ell-1)} = 0$. This means that if a feature accidentally becomes zero in some stage, it will always remain zero. This is why only weaker results can be obtained for L_p regularizers ($p < 1$): we need to further assume that $\hat{\mathbf{w}}_j^{(\ell)}$ never becomes close to zero when $\bar{\mathbf{w}}_j \neq 0$. A toy example is presented in Table 1 to demonstrate this point. The example is a simulated regression problem with $d = 500$ variables and $n = 100$ training data. The first five variables of the target $\bar{\mathbf{w}}$ are non-zeros, and the remaining variables are zeros. For both capped-L_1 and L_p regularizers, the first stage is the standard L_1 regularization, which misses the correct feature #2 and wrongly selects some incorrect ones. For capped-L_1 regularization, in the second stage, because most correct features are identified,

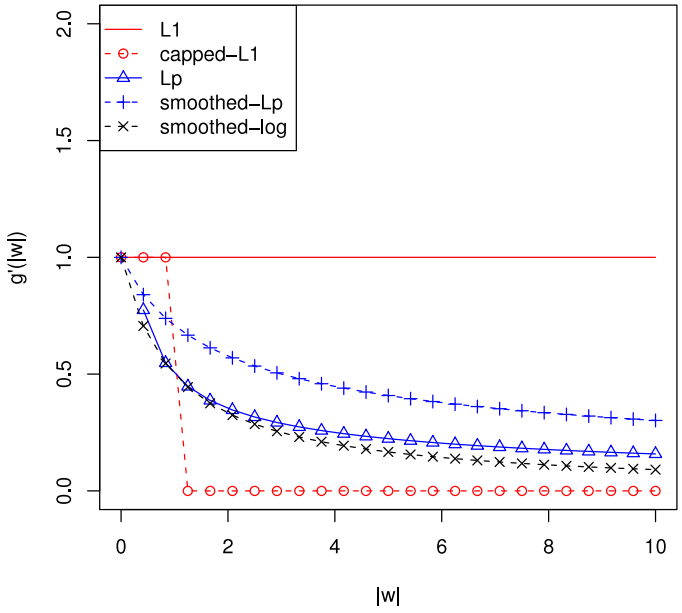

Figure 3: Derivative $g'(|\mathbf{w}_j|)$ of some sparse regularizers

Stage ℓ	coefficients	$\|\hat{\mathbf{w}}^{(\ell)} - \bar{\mathbf{w}}\|_2$
multi-stage capped-L_1

Table 1: An Illustrative Example for Multi-stage Sparse Regularization

the corresponding "bias" is reduced by not penalizing the corresponding variables. This leads to improved performance. Since the correct feature #2 shows up in stage 2, we are able to identify it and further improve the convex relaxation in stage 3. After stage 3, the procedure stabilizes because it computes exactly the same relaxation. For L_p regularization, since feature #2 becomes zero in stage 1, it will remain zero thereafter because $\lambda_2^{(\ell)} = \infty$ when $\ell \geq 1$. In order to remedy this problem, one has to use a regularizer with $g'(0) < \infty$ such as the smoothed L_p regularizer.

3.2 Empirical Study

Although this paper focuses on the development of the general multi-stage convex relaxation framework as well as its theoretical understanding (in particular the major result given in Theorem 2), we include two simple numerical examples to verify our theory. More comprehensive empirical comparisons can be found in other related work such as Candes et al. (2008), Zou (2006) and Zou and Li (2008).

In order to avoid cluttering, we only present results with capped-L_1 and L_p ($p = 0.5$) regularization methods. Note that based on Theorem 2, we may tune α in capped-L_1 by using a formula $\alpha = \alpha_0\lambda$ where λ is the regularization parameter. We choose $\alpha_0 = 10$ and $\alpha_0 = 100$.

In the first experiment, we generate an $n \times d$ random matrix with its column j corresponding to $[\mathbf{x}_{1,j}, \ldots, \mathbf{x}_{n,j}]$, and each element of the matrix is an independent standard Gaussian $N(0,1)$. We then normalize its columns so that $\sum_{i=1}^{n} \mathbf{x}_{i,j}^2 = n$. A truly sparse target $\bar{\beta}$, is generated with k nonzero elements that are uniformly distributed from $[-10, 10]$. The observation $\mathbf{y}_i = \bar{\beta}^\top \mathbf{x}_i + \varepsilon_i$, where each $\varepsilon_i \sim N(0, \sigma^2)$. In this experiment, we take $n = 50, d = 200, k = 5, \sigma = 1$, and repeat the experiment 100 times. The average training error and 2-norm parameter estimation error are reported in Figure 4. We compare the performance of multi-stage methods with different regularization parameter λ. As expected, the training error for the multi-stage algorithms are smaller than that of L_1, due to the smaller bias. Moreover, substantially smaller parameter estimation error is achieved by the multi-stage procedures, which is consistent with Theorem 2. This can be regarded as an empirical verification of the theoretical result.

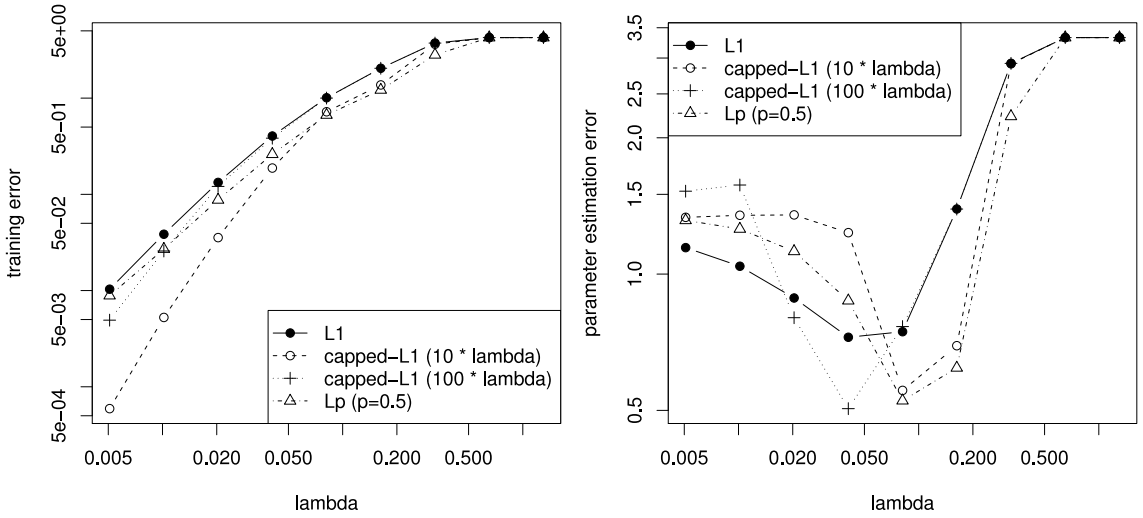

Figure 4: Performance of multi-stage convex relaxation on simulation data. Left: average training squared error versus λ; Right: parameter estimation error versus λ.

In the second experiment, we use the *Boston Housing* data to illustrate the effectiveness of multi-stage convex relaxation. This data set contains 506 census tracts of Boston from the 1970 census, available from the *UCI Machine Learning Database Repository*: `http://archive.ics.`

uci.edu/ml/. Each census tract is a data-point, with 13 features (we add a constant offset on e as the 14th feature), and the desired output is the housing price. In this example, we randomly partition the data into 20 training plus 486 test points. We perform the experiments 100 times, and report training and test squared error versus the regularization parameter λ for different q. The results are plotted in Figure 5. In this case, $L_{0.5}$ is not effective, while capped-L_1 regularization with $\alpha = 100\lambda$ is slightly better than Lasso. Note that this data set contains only a small number ($d = 14$) features, which is not the case where we can expect significant benefit from the multi-stage approach (most of other UCI data similarly contain only small number of features). In order to illustrate the advantage of the multi-stage method more clearly, we also report results on a modified Boston Housing data, where we append 20 random features (similar to the simulation experiments) to the original Boston Housing data, and rerun the experiments. The results are shown in Figure 6. As expected from Theorem 2 and the discussion thereafter, since d becomes large, the multi-stage convex relaxation approach with capped-L_1 regularization and $L_{0.5}$ regularization perform significantly better than the standard Lasso.

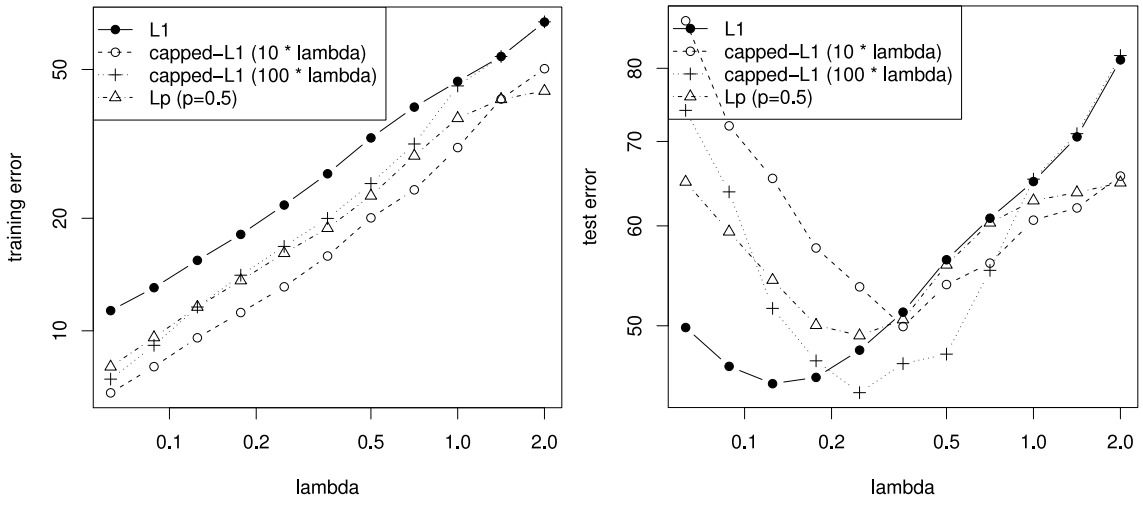

Figure 5: Performance of multi-stage convex relaxation on the original Boston Housing data. Left: average training squared error versus λ; Right: test squared error versus λ.

4. Discussion

Many machine learning applications require solving nonconvex optimization problems. There are two approaches to this problem:

- Heuristic methods such as gradient descent that only find a local minimum. A drawback of this approach is the lack of theoretical guarantee showing that the local minimum gives a good solution.

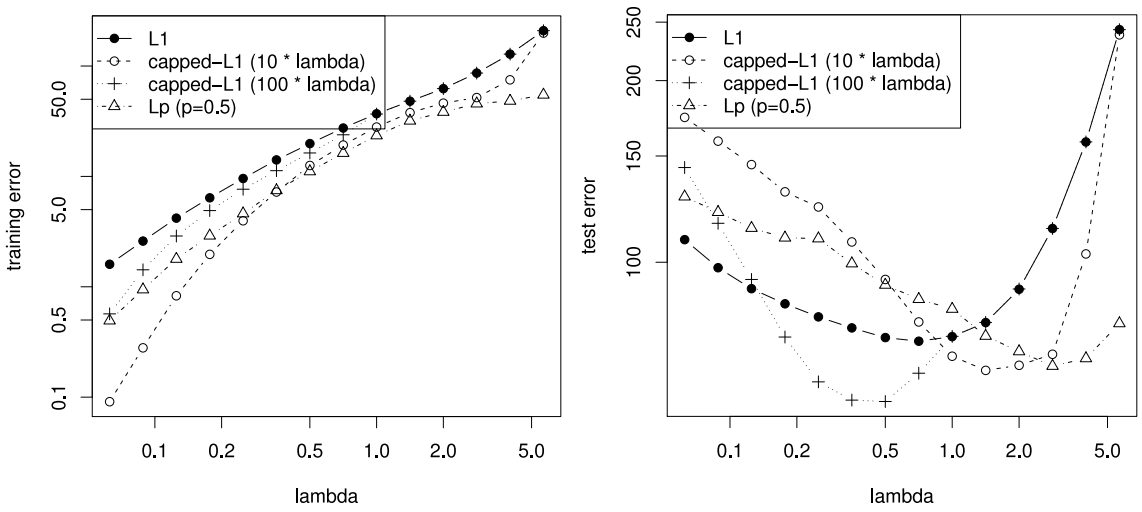

Figure 6: Performance of multi-stage convex relaxation on the modified Boston Housing data. Left: average training squared error versus λ; Right: test squared error versus λ.

- Convex relaxation such as L_1-regularization that solves the problem under some conditions. However it often leads to a sub-optimal solution in reality.

The goal of this paper is to remedy the above gap between theory and practice. In particular, we investigated a multi-stage convex relaxation scheme for solving problems with non-convex objective functions. The general algorithmic technique is presented first, which can be applied to a wide range of problems. It unifies a number of earlier approaches. The intuition is to refine convex relaxation iteratively by using solutions obtained from earlier stages. This leads to better and better convex relaxation formulations, and thus better and better solutions.

Although the scheme only finds a local minimum, the above argument indicates that the local minimum it finds should be closer to the original nonconvex problem than the standard convex relaxation solution. In order to prove the effectiveness of this approach theoretically, we considered the sparse learning problem where the behavior of convex relaxation (Lasso) has been well studied in recent years. We showed that under appropriate conditions, the local solution from the multi-stage convex relaxation algorithm is superior to the global solution of the standard L_1 convex relaxation for learning sparse targets. Experiments confirmed the effectiveness of this method.

We shall mention that our theory only shows that nonconvex regularization behaves better than Lasso under appropriate sparse eigenvalue conditions. When such conditions hold, multi-stage convex relaxation is superior. On the other hand, when such conditions fail, neither Lasso nor (the local solution of) multi-stage convex relaxation can be shown to work well. However, in such case, some features will become highly correlated, and local solutions of non-convex formulations may become unstable. In order to improve stability, it may be helpful to employ ensemble methods such as bagging. Our empirical experience suggests that when features are highly correlated, convex formulations may perform better than (non-bagged) nonconvex formulations due to the added sta-

bility. However, since our analysis doesn't yield any insights in this scenario, further investigation is necessary to theoretically compare convex formulations to bagged nonconvex formulations.

Finally, multi-stage convex relaxation is not the only numerical method that can solve nonconvex formulations with strong theoretical guarantee. For example, the MC+ procedure in Zhang (2010) offers a different method with similar guarantee. This opens the possibility of investigating other local solution methods for nonconvex optimization such as modified gradient descent algorithms that may be potentially more efficient.

Appendix A. Proof of Theorem 2

The analysis is an adaptation of Zhang (2009a). We first introduce some definitions. Consider the positive semi-definite matrix $A = n^{-1}X^\top X \in \mathbb{R}^{d\times d}$. Given $s,k \geq 1$ such that $s+k \leq d$. Let I,J be disjoint subsets of $\{1,\ldots,d\}$ with k and s elements respectively. Let $A_{I,I} \in R^{k\times k}$ be the restriction of A to indices I, $A_{I,J} \in R^{k\times s}$ be the restriction of A to indices I on the left and J on the right. Similarly we define restriction $\mathbf{w}_I$ of a vector $\mathbf{w} \in R^d$ on I; and for convenience, we allow either $\mathbf{w}_I \in R^k$ or $\mathbf{w}_I \in R^d$ (where components not in I are zeros) depending on the context.

We also need the following quantity in our analysis:

$$\pi(k,s) = \sup_{\mathbf{v}\in R^k, \mathbf{u}\in R^s, I, J} \frac{\mathbf{v}^\top A_{I,J}\mathbf{u}\|\mathbf{v}\|_2}{\mathbf{v}^\top A_{I,I}\mathbf{v}\|\mathbf{u}\|_\infty}.$$

The following two lemmas are taken from Zhang (2009a). We skip the proof.

Lemma 3 *The following inequality holds:*

$$\pi(k,s) \leq \frac{s^{1/2}}{2}\sqrt{\rho_+(s)/\rho_-(k+s)-1},$$

Lemma 4 *Consider $k,s>0$ and $G \subset \{1,\ldots,d\}$ such that $|G^c| = k$. Given any $\mathbf{w} \in R^d$. Let J be the indices of the s largest components of $\mathbf{w}_G$ (in absolute values), and $I = G^c \cup J$. Then*

$$\max(0, \mathbf{w}_I^\top A\mathbf{w}) \geq \rho_-(k+s)(\|\mathbf{w}_I\|_2 - \pi(k+s,s)\|\mathbf{w}_G\|_1/s)\|\mathbf{w}_I\|_2.$$

The following lemma gives bounds for sub-Gaussian noise needed in our analysis.

Lemma 5 *Define $\hat{\varepsilon} = \frac{1}{n}\sum_{i=1}^n(\bar{\mathbf{w}}^\top\mathbf{x}_i - \mathbf{y}_i)\mathbf{x}_i$. Under the conditions of Assumption 3.1, with probability larger than $1-\eta$:*

$$\|\hat{\varepsilon}\|_\infty^2 \leq 2\sigma^2\rho_+(1)\ln(2d/\eta)/n. \tag{11}$$

Moreover, for any fixed F, with probability larger than $1-\eta$:

$$\|\hat{\varepsilon}_F\|_2^2 \leq \rho_+(|F|)\sigma^2[7.4|F| + 2.7\ln(2/\eta)]/n. \tag{12}$$

Proof The proof relies on two propositions. The first proposition is a simple application of large deviation bound for sub-Gaussian random variables.

Proposition 6 *Consider a fixed vector $\mathbf{u} = [\mathbf{u}_1,\ldots,\mathbf{u}_n] \in \mathbb{R}^n$, and a random vector $\mathbf{y} = [\mathbf{y}_1,\ldots,\mathbf{y}_n] \in \mathbb{R}^n$ with independent sub-Gaussian components: $\mathbf{E}e^{t(\mathbf{y}_i - \mathbf{E}\mathbf{y}_i)} \leq e^{\sigma^2t^2/2}$ for all t and i, then $\forall\varepsilon>0$:*

$$\Pr\left(\left|\mathbf{u}^\top(\mathbf{y}-\mathbf{E}\mathbf{y})\right| \geq \varepsilon\right) \leq 2e^{-\varepsilon^2/(2\sigma^2\|\mathbf{u}\|_2^2)}.$$

Proof (of Proposition 6). Let $s_n = \sum_{i=1}^n \mathbf{u}_i(\mathbf{y}_i - \mathbf{E}\mathbf{y}_i)$; then by assumption, $\mathbf{E}(e^{ts_n} + e^{-ts_n}) \leq 2e^{\sum_i \mathbf{u}_i^2\sigma^2 t^2/2}$, which implies that $\Pr(|s_n| \geq \varepsilon)e^{t\varepsilon} \leq 2e^{\sum_i \mathbf{u}_i^2\sigma^2 t^2/2}$. Now let $t = \varepsilon/(\sum_i \mathbf{u}_i^2\sigma^2)$, we obtain the desired bound. ■

The second proposition is taken from Pisier (1989).

Proposition 7 *Consider the unit sphere $S^{k-1} = \{\mathbf{u} : \|\mathbf{u}\|_2 = 1\}$ in $\mathbb{R}^k$ ($k \geq 1$). Given any $\varepsilon > 0$, there exists an ε-cover $Q \subset S^{k-1}$ such that $\min_{q\in Q} \|\mathbf{u} - q\|_2 \leq \varepsilon$ for all $\|\mathbf{u}\|_2 = 1$, with $|Q| \leq (1+2/\varepsilon)^k$.*

Now are are ready to prove (11). Let $\mathbf{x}_{i,j}$ be the j-th component of $\mathbf{x}_i$, then by definition, we have $\sum_{i=1}^n \mathbf{x}_{i,j}^2 \leq n\rho_+(1)$ for all $j = 1,\ldots,d$. It follows from Proposition 6 that for all $\varepsilon > 0$ and j: $\Pr(|\hat{\varepsilon}_j| \geq \varepsilon) \leq 2e^{-n\varepsilon^2/(2\sigma^2\rho_+(1))}$. Taking union bound for $j = 1,\ldots,d$, we obtain $\Pr(\|\hat{\varepsilon}\|_\infty \geq \varepsilon) \leq 2de^{-n\varepsilon^2/(2\sigma^2\rho_+(1))}$, which is equivalent to (11).

Next we are ready to prove (12). Let P be the projection matrix to the column spanned by X_F, and let k be the dimension of P, then $k \leq |F|$.

According to Proposition 7, given $\varepsilon_1 > 0$, there exists a finite set $Q = \{q_i\}$ with $|Q| \leq (1+2/\varepsilon_1)^k$ such that $\|Pq_i\|_2 = 1$ for all i, and $\min_i \|P\mathbf{z} - Pq_i\|_2 \leq \varepsilon_1$ for all $\|P\mathbf{z}\|_2 = 1$. To see the existence of Q, we consider a rotation of the coordinate system (which does not change 2-norm) so that $P\mathbf{z}$ is the projection of $\mathbf{z} \in \mathbb{R}^n$ to its first k coordinates in the new coordinate system. Proposition 7 can now be directly applied to the first k coordinates in the new system, implying that we can pick q_i such that $Pq_i = q_i$.

For each i, Proposition 6 implies that $\forall \varepsilon_2 > 0$:

$$\Pr\left(\left|q_i^\top P(\mathbf{y} - \mathbf{E}\mathbf{y})\right| \geq \varepsilon_2\right) \leq 2e^{-\varepsilon_2^2/(2\sigma^2)}.$$

Taking union bound for all $q_i \in Q$, we obtain with probability exceeding $1 - 2(1+2/\varepsilon_1)^k e^{-\varepsilon_2^2/2\sigma^2}$:

$$\left|q_i^\top P(\mathbf{y} - \mathbf{E}\mathbf{y})\right| \leq \varepsilon_2$$

for all i.

Let $\mathbf{z} = P(\mathbf{y} - \mathbf{E}\mathbf{y})/\|P(\mathbf{y} - \mathbf{E}\mathbf{y})\|_2$, then there exists i such that $\|P\mathbf{z} - Pq_i\|_2 \leq \varepsilon_1$. We have

$$\begin{aligned}\|P(\mathbf{y} - \mathbf{E}\mathbf{y})\|_2 =& \mathbf{z}^\top P(\mathbf{y} - \mathbf{E}\mathbf{y}) \\ \leq& \|P\mathbf{z} - Pq_i\|_2 \|P(\mathbf{y} - \mathbf{E}\mathbf{y})\|_2 + |q_i^\top P(\mathbf{y} - \mathbf{E}\mathbf{y})| \\ \leq& \varepsilon_1 \|P(\mathbf{y} - \mathbf{E}\mathbf{y})\|_2 + \varepsilon_2.\end{aligned}$$

Therefore

$$\|P(\mathbf{y} - \mathbf{E}\mathbf{y})\|_2 \leq \varepsilon_2/(1 - \varepsilon_1).$$

Let $\varepsilon_1 = 2/15$, and $\eta = 2(1+2/\varepsilon_1)^k e^{-\varepsilon_2^2/2\sigma^2}$, we have

$$\varepsilon_2^2 = 2\sigma^2[(4k+1)\ln 2 - \ln\eta],$$

and thus

$$\begin{aligned}\rho_+(|F|)^{-1/2}\|\hat{\varepsilon}_F\|_2 =& \rho_+(|F|)^{-1/2}\|X_F^\top(\mathbf{y} - \mathbf{E}\mathbf{y})\|_2 \\ \leq& \|P(\mathbf{y} - \mathbf{E}\mathbf{y})\|_2 \leq \frac{15}{13}\sigma\sqrt{2(4k+1)\ln 2 - 2\ln\eta}.\end{aligned}$$

This simplifies to the desired bound.

■

Lemma 8 *Consider $\bar{\mathbf{w}}$ such that $\{j : \bar{\mathbf{w}}_j \neq 0\} \subset F$ and $F \cap G = \emptyset$. Let $\hat{\mathbf{w}} = \hat{\mathbf{w}}^{(\ell)}$ be the solution of (10) with $q = 1$, and let $\Delta\hat{\mathbf{w}} = \hat{\mathbf{w}} - \bar{\mathbf{w}}$. Let $\lambda_G = \min_{j\in G}\lambda_j^{(\ell-1)}$ and $\lambda_0 = \max_j \lambda_j^{(\ell-1)}$. Then*

$$\sum_{j\in G}|\hat{\mathbf{w}}_j| \leq \frac{2\|\hat{\varepsilon}\|_\infty}{\lambda_G - 2\|\hat{\varepsilon}\|_\infty}\sum_{j\notin F\cup G}|\hat{\mathbf{w}}_j| + \frac{2\|\hat{\varepsilon}\|_\infty + \lambda_0}{\lambda_G - 2\|\hat{\varepsilon}\|_\infty}\sum_{j\in F}|\Delta\hat{\mathbf{w}}_j|.$$

Proof For simplicity, let $\lambda_j = \lambda_j^{(\ell-1)}$. The first order equation implies that

$$\frac{1}{n}\sum_{i=1}^n 2(\mathbf{x}_i^\top \mathbf{w} - y_i)\mathbf{x}_{i,j} + \lambda_j \mathrm{sgn}(\mathbf{w}_j) = 0,$$

where $\mathrm{sgn}(\mathbf{w}_j) = 1$ when $\mathbf{w}_j > 0$, $\mathrm{sgn}(\mathbf{w}_j) = -1$ when $\mathbf{w}_j < 0$, and $\mathrm{sgn}(\mathbf{w}_j) \in [-1,1]$ when $\mathbf{w}_j = 0$. This implies that for all $\mathbf{v} \in \mathbb{R}^d$, we have

$$2\mathbf{v}^\top A\Delta\hat{\mathbf{w}} \leq -2\mathbf{v}^\top\hat{\varepsilon} - \sum_{j=1}^d \lambda_j \mathbf{v}_j \mathrm{sgn}(\hat{\mathbf{w}}_j). \tag{13}$$

Now, let $\mathbf{v} = \Delta\hat{\mathbf{w}}$ in (13), we obtain

$$\begin{aligned}
0 \leq & 2\Delta\hat{\mathbf{w}}^\top A\Delta\hat{\mathbf{w}} \leq 2|\Delta\hat{\mathbf{w}}^\top\hat{\varepsilon}| - \sum_{j=1}^d \lambda_j\Delta\hat{\mathbf{w}}_j\mathrm{sgn}(\hat{\mathbf{w}}_j)\\
\leq & 2\|\Delta\hat{\mathbf{w}}\|_1\|\hat{\varepsilon}\|_\infty - \sum_{j\in F}\lambda_j\Delta\hat{\mathbf{w}}_j\mathrm{sgn}(\hat{\mathbf{w}}_j) - \sum_{j\notin F}\lambda_j\Delta\hat{\mathbf{w}}_j\mathrm{sgn}(\hat{\mathbf{w}}_j)\\
\leq & 2\|\Delta\hat{\mathbf{w}}\|_1\|\hat{\varepsilon}\|_\infty + \sum_{j\in F}\lambda_j|\Delta\hat{\mathbf{w}}_j| - \sum_{j\notin F}\lambda_j|\hat{\mathbf{w}}_j|\\
\leq & \sum_{j\in G}(2\|\hat{\varepsilon}\|_\infty - \lambda_G)|\hat{\mathbf{w}}_j| + \sum_{j\notin G\cup F} 2\|\hat{\varepsilon}\|_\infty|\hat{\mathbf{w}}_j| + \sum_{j\in F}(2\|\hat{\varepsilon}\|_\infty + \lambda_0)|\Delta\hat{\mathbf{w}}_j|.
\end{aligned}$$

By rearranging the above inequality, we obtain the desired bound. ■

Lemma 9 *Using the notations of Lemma 8, and let J be the indices of the largest s coefficients (in absolute value) of $\hat{\mathbf{w}}_G$. Let $I = G^c \cup J$ and $k = |G^c|$. If $(\lambda_0 + 2\|\hat{\varepsilon}\|_\infty)/(\lambda_G - 2\|\hat{\varepsilon}\|_\infty) \leq 3$, then*

$$\|\Delta\hat{\mathbf{w}}\|_2 \leq (1 + (3k/s)^{0.5})\|\Delta\hat{\mathbf{w}}_I\|_2.$$

Proof Using $(\lambda_0 + 2\|\hat{\varepsilon}\|_\infty)/(\lambda_G - 2\|\hat{\varepsilon}\|_\infty) \leq 3$, we obtain from Lemma 8

$$\|\hat{\mathbf{w}}_G\|_1 \leq 3\|\Delta\hat{\mathbf{w}} - \hat{\mathbf{w}}_G\|_1.$$

Therefore $\|\Delta\hat{\mathbf{w}} - \Delta\hat{\mathbf{w}}_I\|_\infty \leq \|\Delta\hat{\mathbf{w}}_G\|_1/s \leq 3\|\Delta\hat{\mathbf{w}} - \hat{\mathbf{w}}_G\|_1/s$, which implies that

$$\begin{aligned}
\|\Delta\hat{\mathbf{w}} - \Delta\hat{\mathbf{w}}_I\|_2 \leq & (\|\Delta\hat{\mathbf{w}} - \Delta\hat{\mathbf{w}}_I\|_1\|\Delta\hat{\mathbf{w}} - \Delta\hat{\mathbf{w}}_I\|_\infty)^{1/2}\\
\leq & 3^{1/2}\|\Delta\hat{\mathbf{w}} - \hat{\mathbf{w}}_G\|_1 s^{-1/2} \leq (3k/s)^{1/2}\|\Delta\hat{\mathbf{w}}_I\|_2.
\end{aligned}$$

By rearranging this inequality, we obtain the desired bound. ■

Lemma 10 *Let the conditions of Lemma 8 hold, and let $k = |G^c|$. If $t = 1 - \pi(k+s,s)k^{1/2}s^{-1} > 0$, and $(\lambda_0 + 2\|\hat{\varepsilon}\|_\infty)/(\lambda_G - 2\|\hat{\varepsilon}\|_\infty) \leq (4-t)/(4-3t)$, then*

$$\|\Delta\hat{\mathbf{w}}\|_2 \leq \frac{1+(3k/s)^{0.5}}{t\rho_-(k+s)}\left[2\|\hat{\varepsilon}_{G^c}\|_2 + \left(\sum_{j\in F}(\lambda_j^{(\ell-1)})^2\right)^{1/2}\right].$$

Proof Let J be the indices of the largest s coefficients (in absolute value) of $\hat{\mathbf{w}}_G$, and $I = G^c \cup J$. The conditions of the lemma imply that

$$\begin{aligned}\max(0, \Delta\hat{\mathbf{w}}_I^\top A\Delta\hat{\mathbf{w}}) \geq& \rho_-(k+s)[\|\Delta\hat{\mathbf{w}}_I\|_2 - \pi(k+s,s)\|\hat{\mathbf{w}}_G\|_1/s]\|\Delta\hat{\mathbf{w}}_I\|_2 \\ \geq& \rho_-(k+s)[1-(1-t)(4-t)(4-3t)^{-1}]\|\Delta\hat{\mathbf{w}}_I\|_2^2 \\ \geq& 0.5t\rho_-(k+s)\|\Delta\hat{\mathbf{w}}_I\|_2^2.\end{aligned}$$

In the above derivation, the first inequality is due to Lemma 4; the second inequality is due to the conditions of this lemma plus Lemma 8, which implies that

$$\|\hat{\mathbf{w}}_G\|_1 \leq 2\frac{\|\hat{\varepsilon}\|_\infty + \lambda_0}{\lambda_G - 2\|\hat{\varepsilon}\|_\infty}\|\hat{\mathbf{w}}_{G^c}\|_1 \leq \frac{\|\hat{\varepsilon}\|_\infty + \lambda_0}{\lambda_G - 2\|\hat{\varepsilon}\|_\infty}\sqrt{k}\|\hat{\mathbf{w}}_I\|_2;$$

and the last inequality follows from $1-(1-t)(4-t)(4-3t)^{-1} \geq 0.5t$.

If $\Delta\hat{\mathbf{w}}_I^\top \hat{A}\Delta\hat{\mathbf{w}} \leq 0$, then the above inequality, together with Lemma 9, imply the lemma. Therefore in the following, we can assume that

$$\Delta\hat{\mathbf{w}}_I^\top A\Delta\hat{\mathbf{w}} \geq 0.5t\rho_-(k+s)\|\Delta\hat{\mathbf{w}}_I\|_2^2.$$

Moreover, let $\lambda_j = \lambda_j^{(\ell-1)}$. We obtain from (13) with $\mathbf{v} = \Delta\hat{\mathbf{w}}_I$ the following:

$$\begin{aligned}2\Delta\hat{\mathbf{w}}_I^\top \hat{A}\Delta\hat{\mathbf{w}} \leq& -2\Delta\hat{\mathbf{w}}_I^\top\hat{\varepsilon} - \sum_{j\in I}\lambda_j\Delta\hat{\mathbf{w}}_j\mathrm{sgn}(\hat{\mathbf{w}}_j) \\ \leq& 2\|\Delta\hat{\mathbf{w}}_I\|_2\|\hat{\varepsilon}_{G^c}\|_2 + 2\|\hat{\varepsilon}_G\|_\infty\sum_{j\in G}|\Delta\hat{\mathbf{w}}_j| + \sum_{j\in F}\lambda_j|\Delta\hat{\mathbf{w}}_j| - \sum_{j\in G}\lambda_j|\Delta\hat{\mathbf{w}}_j| \\ \leq& 2\|\Delta\hat{\mathbf{w}}_I\|_2\|\hat{\varepsilon}_{G^c}\|_2 + (\sum_{j\in F}\lambda_j^2)^{1/2}\|\Delta\hat{\mathbf{w}}_I\|_2,\end{aligned}$$

where $\lambda_j \geq \lambda_G \geq 2\|\hat{\varepsilon}_G\|_\infty$ is used to derive the last inequality. Now by combining the above two estimates, we obtain

$$\|\Delta\hat{\mathbf{w}}_I\|_2 \leq \frac{1}{t\rho_-(k+s)}\left[2\|\hat{\varepsilon}_{G^c}\|_2 + (\sum_{j\in F}\lambda_j^2)^{1/2}\right].$$

The desired bound now follows from Lemma 9. ■

Lemma 11 *Consider $g(\cdot)$ that satisfies the conditions of Theorem 2. Let $\lambda_j = \lambda g'(|\tilde{\mathbf{w}}_j|)$ for some $\tilde{\mathbf{w}} \in R^d$, then*

$$\left(\sum_{j\in F}\lambda_j^2\right)^{1/2} \le \lambda\left(\sum_{j\in F} g'(|\bar{\mathbf{w}}_j|-\theta)^2\right)^{1/2} + \lambda\theta^{-1}\left(\sum_{j\in F}|\bar{\mathbf{w}}_j-\tilde{\mathbf{w}}_j|^2\right)^{1/2}.$$

Proof By assumption, if $|\bar{\mathbf{w}}_j - \tilde{\mathbf{w}}_j| \ge \theta$, then

$$g'(|\tilde{\mathbf{w}}_j|) \le 1 \le \theta^{-1}|\bar{\mathbf{w}}_j - \tilde{\mathbf{w}}_j|;$$

otherwise, $g'(|\tilde{\mathbf{w}}_j|) \le g'(|\bar{\mathbf{w}}_j|-\theta)$. It follows that the following inequality always holds:

$$g'(|\tilde{\mathbf{w}}_j|) \le g'(|\bar{\mathbf{w}}_j|-\theta) + \theta^{-1}|\bar{\mathbf{w}}_j - \tilde{\mathbf{w}}_j|.$$

The desired bound is a direct consequence of the above result and the 2-norm triangle inequality $(\sum_j (x_j+\Delta x_j)^2)^{1/2} \le (\sum_j x_j^2)^{1/2} + (\sum_j \Delta x_j^2)^{1/2}$. ■

Lemma 12 *Under the conditions of Theorem 2, we have for all $s \ge 2\bar{k}$:*

$$\|\hat{\mathbf{w}}^{(\ell)} - \bar{\mathbf{w}}\|_2 \le \frac{7}{\rho_-(2\bar{k}+s)}\sqrt{|F|}\lambda.$$

Proof Let $t = 0.5$, then using Lemma 5, the condition of the theorem implies that

$$\frac{\lambda + 2\|\hat{\varepsilon}\|_\infty}{\lambda g'(\theta) - 2\|\hat{\varepsilon}\|_\infty} \le \frac{4-t}{4-3t}.$$

Moreover, Lemma 3 implies that the condition

$$t = 0.5 \le 1 - \pi(2\bar{k}+s, s)(2\bar{k})^{0.5}/s$$

is also satisfied.

Now, if we assume that at some $\ell \ge 1$ that

$$|G_\ell^c| \le 2\bar{k}, \quad \text{where } G_\ell = \{j \notin F : \lambda_j^{(\ell-1)} \ge \lambda g'(\theta)\}, \tag{14}$$

then we can obtain from Lemma 10 that

$$\|\hat{\mathbf{w}}^{(\ell)} - \bar{\mathbf{w}}\|_2 \le \frac{1+\sqrt{3}}{t\rho_-(2\bar{k}+s)}\left[2\sqrt{|G_\ell^c|}\|\hat{\varepsilon}\|_\infty + \sqrt{|F|}\lambda\right] \le \frac{3.2}{t\rho_-(2\bar{k}+s)}\sqrt{|F|}\lambda,$$

where we have used the fact that $|G_\ell^c| \le 2\bar{k} \le 2|F|$ and $\lambda \ge 20\|\hat{\varepsilon}\|_\infty$ in the derivation of the second inequality. This shows that (14) implies the lemma.

Therefore next we only need to prove by induction on ℓ that (14) holds for all $\ell = 1, 2, \ldots$. When $\ell = 1$, we have $G_1 = F^c$, which implies that (14) holds.

Now assume that (14) holds at $\ell-1$ for some $\ell>1$. Since $j\in G_\ell^c-F$ implies that $j\notin F$ and $\lambda g'(|\hat{\mathbf{w}}_j^{(\ell-1)}|)=\lambda_j^{(\ell)}<\lambda g'(\theta)$ by definition, and since $g'(z)$ is non-increasing when $z\geq 0$ (theorem assumption), we know that $|\hat{\mathbf{w}}_j^{(\ell-1)}|\geq\theta$. Therefore by induction hypothesis we obtain

$$\begin{aligned}\sqrt{|G_\ell^c-F|}\leq&\sqrt{\sum_{j\in G_\ell^c-F}|\hat{\mathbf{w}}_j^{(\ell-1)}|^2/\theta^2}\leq\frac{\|\hat{\mathbf{w}}^{(\ell-1)}-\bar{\mathbf{w}}\|_2}{\theta}\\ \leq&\frac{7\lambda}{\rho_-(2\bar{k}+s)\theta}\sqrt{|F|}\leq\sqrt{|F|},\end{aligned}$$

where the second to the last inequality is due to the fact that (14) implies the lemma at $\ell-1$. The last inequality uses the definition of θ in the theorem. This inequality implies that $|G_\ell^c|\leq 2|F|\leq 2\bar{k}$, which completes the induction step. ■

A.1 Proof of Theorem 2

As in the proof of Lemma 12, if we let $t=0.5$, then using Lemma 5, the condition of the theorem implies that

$$\frac{\lambda+2\|\hat{\varepsilon}\|_\infty}{\lambda g'(\theta)-2\|\hat{\varepsilon}\|_\infty}\leq\frac{4-t}{4-3t}.$$

Moreover, Lemma 3 implies that the condition

$$t=0.5\leq 1-\pi(2\bar{k}+s,s)(2\bar{k})^{0.5}/s$$

is also satisfied.

We prove by induction: for $\ell=1$, the result follows from Lemma 12. For $\ell>1$, we let $G^c=F\cup\{j:|\hat{\mathbf{w}}_j^{(\ell-1)}|\geq\theta\}$. From the proof of Lemma 12, we know that

$$k=|G^c|\leq 2\bar{k}.$$

Let $u=\sqrt{\rho_+(\bar{k})}\sigma[\sqrt{7.4\bar{k}/n}+\sqrt{2.7\ln(2/\eta)/n}]$. We know from Lemma 5, and $\lambda\geq 20\|\hat{\varepsilon}\|_\infty$ that with probability $1-2\eta$,

$$\begin{aligned}\|\hat{\varepsilon}_{G^c}\|_2\leq&\|\hat{\varepsilon}_F\|_2+\sqrt{|G^c-F|}\|\hat{\varepsilon}\|_\infty\\ \leq&u+\sqrt{|G^c-F|}\lambda/20\\ \leq&u+(\lambda/20)\sqrt{\sum_{j\in G^c-F}|\hat{\mathbf{w}}_j^{(\ell-1)}|^2/\theta^2}\\ \leq&u+\lambda(20\theta)^{-1}\|\hat{\mathbf{w}}^{(\ell-1)}-\bar{\mathbf{w}}\|_2.\end{aligned}$$

Now, using Lemma 10 and Lemma 11, we obtain

$$\begin{aligned}
&\|\Delta\hat{\mathbf{w}}^{(\ell)}\|_2 \\
\leq&\frac{1+\sqrt{3}}{t\rho_-(k+s)}\left[2\|\hat{\varepsilon}_{G^c}\|_2+(\sum_{j\in F}(\lambda_j^{(\ell-1)})^2)^{1/2}\right] \\
\leq&\frac{1+\sqrt{3}}{t\rho_-(k+s)}\left[2\|\hat{\varepsilon}_{G^c}\|_2+\lambda\left(\sum_{j\in F}g'(|\bar{\mathbf{w}}_j|-\theta)^2\right)^{1/2}+\lambda\theta^{-1}\left(\sum_{j\in F}|\bar{\mathbf{w}}_j-\hat{\mathbf{w}}_j^{(\ell-1)}|^2\right)^{1/2}\right] \\
\leq&\frac{1+\sqrt{3}}{t\rho_-(k+s)}\left[2u+\lambda\left(\sum_{j\in F}g'(|\bar{\mathbf{w}}_j|-\theta)^2\right)^{1/2}+1.1\lambda\theta^{-1}\|\bar{\mathbf{w}}-\hat{\mathbf{w}}^{(\ell-1)}\|_2\right] \\
\leq&\frac{1+\sqrt{3}}{t\rho_-(k+s)}\left[2u+\lambda\left(\sum_{j\in F}g'(|\bar{\mathbf{w}}_j|-\theta)^2\right)^{1/2}\right]+0.67\|\bar{\mathbf{w}}-\hat{\mathbf{w}}^{(\ell-1)}\|_2.
\end{aligned}$$

The desired bound can now be obtained by solving this recursion with respect to

$$\|\Delta\hat{\mathbf{w}}^{(\ell)}\|_2=\|\bar{\mathbf{w}}-\hat{\mathbf{w}}^{(\ell)}\|_2$$

for $\ell=2,3,\ldots$, where $\|\Delta\hat{\mathbf{w}}^{(1)}\|_2$ is given by Lemma 12.

Appendix B. Some Non-convex Formulations in Machine Learning

Consider a set of input vectors $\mathbf{x}_1,\ldots,\mathbf{x}_n\in R^d$, with corresponding desired output variables $y_1,\ldots,y_n$. The task of supervised learning is to estimate the functional relationship $y\approx f(\mathbf{x})$ between the input $\mathbf{x}$ and the output variable y from the training examples $\{(\mathbf{x}_1,y_1),\ldots,(\mathbf{x}_n,y_n)\}$. The quality of prediction is often measured through a loss function $\phi(f(\mathbf{x}),y)$.

Now, consider linear prediction model $f(\mathbf{x})=\mathbf{w}^\top\mathbf{x}$. As in boosting or kernel methods, nonlinearity can be introduced by including nonlinear features in $\mathbf{x}$. For linear models, we are mainly interested in the scenario that $d\gg n$. That is, there are many more features than the number of samples. In this case, an unconstrained empirical risk minimization is inadequate because the solution overfits the data. The standard remedy for this problem is to impose a constraint on $\mathbf{w}$ to obtain a *regularized* problem. This leads to the following regularized empirical risk minimization method:

$$\hat{\mathbf{w}}=\arg\min_{\mathbf{w}\in R^d}\left[\sum_{i=1}^n\phi(\mathbf{w}^\top\mathbf{x}_i,y_i)+\lambda g(\mathbf{w})\right], \tag{15}$$

where $\lambda>0$ is an appropriately chosen regularization condition. This is the motivation for the general problem formulation (1) in Section 2.

B.1 Loss Function

Examples of loss function $\phi(\mathbf{w}^\top\mathbf{x},y)$ in (15) include least squares for regression: $\phi(\mathbf{w}^\top\mathbf{x},y)=(\mathbf{w}^\top\mathbf{x}-y)^2$, and 0-1 binary classification error: $\phi(\mathbf{w}^\top\mathbf{x},y)=I(\mathbf{w}^\top\mathbf{x}y\leq 0)$, where $y\in\{\pm 1\}$ are the class labels, and $I(\cdot)$ is the set indicator function. The latter is nonconvex. In practice, for computational reasons, a convex relaxation such as the SVM loss $\phi(\mathbf{w}^\top\mathbf{x},y)=\max(0,1-\mathbf{w}^\top\mathbf{x}y)$

is often used to substitute the classification error loss. Such a convex loss is often referred to as a surrogate loss function, and the resulting method becomes a convex relaxation method for solving binary classification. This class of methods have been theoretically analyzed in Bartlett et al. (2006) and Zhang (2004). While asymptotically, convex surrogate methods are consistent (that is, they can be used to obtain Bayes optimal classifiers when the sample size approaches infinity), for finite data, these methods can be more sensitive to outliers. In order to alleviate the effect of outliers, one may consider the smoothed classification error loss function $\phi(\mathbf{w}^\top \mathbf{x}, y) = \min(\alpha, \max(0, 1 - \mathbf{w}^\top \mathbf{x} y))$ ($\alpha \geq 1$). This loss function is bounded, and thus more robust to outliers than SVMs under finite sample size; moreover, it is piece-wise differentiable, and thus easier to handle than the discontinuous classification error loss. For comparison purpose, the three loss functions are plotted in Figure 7.

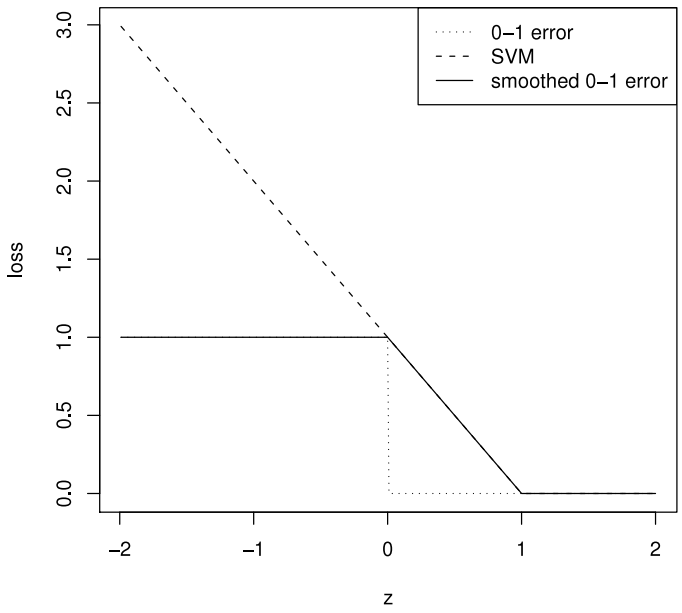

Figure 7: Loss Functions: classification error versus smoothed classification error ($\alpha = 1$) and SVM

B.2 Regularization Condition

Some examples of regularization conditions in (15) include squared regularization $g(\mathbf{w}) = \mathbf{w}^\top \mathbf{w}$, and 1-norm regularization $g(\mathbf{w}) = \|\mathbf{w}\|_1$. The former can be generalized to kernel methods, and the latter leads to sparse solutions. Sparsity is an important regularization condition, which corresponds to the (non-convex) L_0 regularization, defined as $\|\mathbf{w}\|_0 = |\{j : \mathbf{w}_j \neq 0\}| = k$. That is, the measure of complexity is the number of none zero coefficients. If we know the sparsity parameter k for the target vector, then a good learning method is L_0 regularization:

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w} \in R^d} \frac{1}{n} \sum_{i=1}^{n} \phi(\mathbf{w}^\top \mathbf{x}_i, y_i) \quad \text{subject to } \|\mathbf{w}\|_0 \leq k, \tag{16}$$

which applies the standard empirical risk minimization formulation to learning L_0 constrained sparse targets.

If k is not known, then one may regard k as a tuning parameter, which can be selected through cross-validation. This method is often referred to as *subset selection* in the literature. Sparse learning is an essential topic in machine learning, which has attracted considerable interests recently. It can be shown that the solution of the L_0 regularization problem in (16) achieves good prediction accuracy if the target function can be approximated by a sparse $\bar{\mathbf{w}}$. However, a fundamental difficulty with this method is the computational cost, because the number of subsets of $\{1,\ldots,d\}$ of cardinality k (corresponding to the nonzero components of $\mathbf{w}$) is exponential in k.

Due to the computational difficult, in practice, it is necessary to replace (16) by some easier to solve formulations in (15). Specifically, L_0 regularization is equivalent to (15) by choosing the regularization function as $g(\mathbf{w}) = \|\mathbf{w}\|_0$. However, this function is discontinuous. For computational reasons, it is helpful to consider a continuous approximation with $g(\mathbf{w}) = \|\mathbf{w}\|_p^p$, where $p > 0$. If $p \geq 1$, the resulting formulation is convex. In particular, by choosing the closest approximation with $p = 1$, one obtain *Lasso*, which is the standard convex relaxation formulation for sparse learning. With $p \in (0,1)$, the L_p regularizer $\|\mathbf{w}\|_p^p$ is non-convex but continuous.

Supervised learning can be solved using general empirical risk minimization formulation in (15). Both ϕ and g can be non-convex in application problems. The traditional approach is to use convex relaxation to approximate it, leading to a single stage convex formulation. In this paper, we try to extend the idea by looking at a more general multi-stage convex relaxation method, which leads to more accurate approximations.

For illustration, we consider the following examples which will be used in our later discussion.

- Smoothed classification error loss: formulation (15) with convex regularization $g(\mathbf{w})$ and nonconvex loss function (with $\alpha \geq 1$)

$$\phi(\mathbf{w}^\top \mathbf{x}, y) = \min(\alpha, \max(0, 1 - \mathbf{w}^\top \mathbf{x} y)).$$

  This corresponds to $R_0(\mathbf{w}) = \lambda g(\mathbf{w})$, and $R_k(\mathbf{w}) = \phi(\hat{\mathbf{w}}^\top \mathbf{x}_k, y_k)$ for $k = 1,\ldots,n$ in (1).

- L_p regularization ($0 \leq p \leq 1$): formulation (15) with nonconvex regularization $g(\mathbf{w}) = \|\mathbf{w}\|_p^p$ and a loss function $\phi(\cdot,\cdot)$ that is convex in $\mathbf{w}$. This corresponds to $R_0(\mathbf{w}) = n^{-1}\sum_{i=1}^n \phi(\mathbf{w}^\top \mathbf{x}_i, y_i)$, and $R_k(\mathbf{w}) = \lambda |\mathbf{w}_k|^p$ for $k = 1,\ldots,d$ in (1).

- Smoothed L_p regularization (with parameters $\alpha > 0$ and $0 \leq p \leq 1$): formulation (15) with nonconvex regularization $g(\mathbf{w}) = \sum_k [(\alpha + |\mathbf{w}_k|)^p - \alpha^p]/(p\alpha^{p-1})$, and a loss function $\phi(\cdot,\cdot)$ that is convex in $\mathbf{w}$. This corresponds to $R_0(\mathbf{w}) = n^{-1}\sum_{i=1}^n \phi(\mathbf{w}^\top \mathbf{x}_i, y_i)$, and $R_k(\mathbf{w}) = \lambda[(\alpha + |\mathbf{w}_k|)^p - \alpha^p]/(p\alpha^{p-1})$ for $k = 1,\ldots,d$ in (1). The main difference between standard L_p and smoothed L_p is at $|\mathbf{w}_k| = 0$, where the smoothed L_p regularization is differentiable, with derivative 1. This difference is theoretically important as discussed in Section 3.1.

- Smoothed log regularization (with parameter $\alpha > 0$): formulation (15) with nonconvex regularization $g(\mathbf{w}) = \sum_k \alpha \ln(\alpha + |\mathbf{w}_k|)$, and a loss function $\phi(\cdot,\cdot)$ that is convex in $\mathbf{w}$. This corresponds to $R_0(\mathbf{w}) = n^{-1}\sum_{i=1}^n \phi(\mathbf{w}^\top \mathbf{x}_i, y_i)$, and $R_k(\mathbf{w}) = \lambda\alpha \ln(\alpha + |\mathbf{w}_k|)$ for $k = 1,\ldots,d$ in (1). Similar to the smoothed L_p regularization, the smoothed log-loss has derivative 1 at $|\mathbf{w}_k| = 0$.

- Capped-L_1 regularization (with parameter $\alpha > 0$): formulation (15) with nonconvex regularization $g(\mathbf{w}) = \sum_{j=1}^{d} \min(|\mathbf{w}_j|, \alpha)$, and a loss function $\phi(\cdot,\cdot)$ that is convex in $\mathbf{w}$. This corresponds to $R_0(\mathbf{w}) = n^{-1}\sum_{i=1}^{n}\phi(\mathbf{w}^\top \mathbf{x}_i, y_i)$, and $R_k(\mathbf{w}) = \lambda \min(|\mathbf{w}_k|, \alpha)$ for $k = 1,\ldots,d$ in (1). The capped-L_1 regularization is a good approximation to L_0 because as $\alpha \to 0$, $\sum_k \min(|\mathbf{w}_k|,\alpha)/\alpha \to \|\mathbf{w}\|_0$. Therefore when $\alpha \to 0$, this regularization condition is equivalent to the sparse L_0 regularization up to a rescaling of λ. Capped-L_1 regularization is a simpler but less smooth version of the SCAD regularization (Jianqing Fan, 2001). SCAD is more complicated, but its advantage cannot be shown through our analysis.

Appendix C. Some Examples of Multi-stage Convex Relaxation Methods

The multi-stage convex relaxation method can be used with examples in Section 2.2 to obtain concrete algorithms for various formulations. We describe some examples here.

C.1 Smoothed Classification Loss

We consider a loss term of the form $R_k(\mathbf{w}) = \min(\alpha, \max(0, 1 - \mathbf{w}^\top \mathbf{x}_k y_k))$ for $k = 1,\ldots,n$ (with $\alpha \geq 1$), and relax it to the SVM loss $\mathbf{h}_k(\mathbf{w}) = \max(0, 1 - \mathbf{w}^\top \mathbf{x}_k y_k)$.

The optimization problem is

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left[\sum_{i=1}^{n} \min(\alpha, \max(0, 1 - \mathbf{w}^\top \mathbf{x}_i y_i)) + \lambda g(\mathbf{w}) \right],$$

where we assume that $g(\mathbf{w})$ is a convex regularization condition such as $g(\mathbf{w}) = \lambda\|\mathbf{w}\|_2^2$.

Consider concave duality in Section 2.2. Each $\mathbf{u}_k$ is a scalar in the range $\Omega_k = [0,\infty)$, and $\bar{R}_k(\mathbf{u}_k) = \min(\alpha, \mathbf{u}_k)$. We have $R_k^*(\mathbf{v}_k) = \alpha(\mathbf{v}_k - 1)I(\mathbf{v}_k \in [0,1])$, defined on the domain $\mathbf{v}_k \geq 0$. The solution in (4) is given by $\hat{\mathbf{v}}_k = I(\mathbf{w}^\top \mathbf{x}_k y_k \geq 1 - \alpha)$ for $k = 1,\ldots,n$. Therefore Section 2.2 implies that the multi-stage convex relaxation solves the weighted SVM formulation

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left[\sum_{i=1}^{n} \hat{\mathbf{v}}_i \max(0, 1 - \mathbf{w}^\top \mathbf{x}_i y_i) + \lambda g(\mathbf{w}) \right],$$

where the relaxation parameter $\mathbf{v}$ is updated as

$$\hat{\mathbf{v}}_i = I(\hat{\mathbf{w}}^\top \mathbf{x}_i y_i \geq 1 - \alpha) \quad (i = 1,\ldots,n).$$

Intuitively, the mis-classified points $\hat{\mathbf{w}}^\top \mathbf{x}_i y_i < 1 - \alpha$ are considered as outliers, and ignored.

C.2 L_p and Smoothed L_p Regularization

In sparse regularization, we may consider a regularization term $R_k(\mathbf{w}) = \lambda|\mathbf{w}_k|^p/p$ ($k = 1,\ldots,d$) for some $p \in (0,1)$. Given any $q > p$, (3) holds with $\mathbf{u}_k = \mathbf{h}_k(\mathbf{w}) = |\mathbf{w}_k|^q \in [0,\infty)$, and $\bar{R}_k(\mathbf{u}_k) = \lambda|\mathbf{u}_k|^{p/q}/p$, where $\mathbf{u}_k \in \Omega_k = [0,\infty)$. The dual is $R_k^*(\mathbf{v}_k) = -\lambda c(p,q)(\mathbf{v}_k/\lambda)^{p/(p-q)}$, defined on the domain $\mathbf{v}_k \geq 0$, where $c(p,q) = (q-p)p^{-1}q^{q/(p-q)}$. The solution in (4) is given by $\hat{\mathbf{v}}_k = (\lambda/q)|\mathbf{w}_k|^{p-q}$.

An extension is to consider a regularization term $R_k(\mathbf{w}) = \lambda[(\alpha + |\mathbf{w}_k|)^p - \alpha^p]/(p\alpha^{p-1})$ ($k = 1,\ldots,d$) for some $p \in (0,1)$ and $\alpha > 0$. Given any $q > p$, (3) holds with $\mathbf{u}_k = \mathbf{h}_k(\mathbf{w}) = (\alpha +$

$|\mathbf{w}_k|)^q \in [\alpha^q, \infty)$, and $\bar{R}_k(\mathbf{u}_k) = \lambda[\mathbf{u}_k^{p/q} - \alpha^p]/(p\alpha^{p-1})$, where $\mathbf{u}_k \in \Omega_k = [0,\infty)$. The dual is $R_k^*(\mathbf{v}_k) = -\lambda c(p,q)\alpha^{p/(p-q)}(\mathbf{v}_k/\lambda)^{p/(p-q)} + \lambda\alpha/p$, defined on the domain $\mathbf{v}_k \geq 0$, where $c(p,q) = (q-p)p^{p/(q-p)}q^{q/(p-q)}$. The solution in (4) is given by $\hat{\mathbf{v}}_k = \lambda/(q\alpha^{p-1})(\alpha + |\mathbf{w}_k|)^{p-q}$.

An alternative is to relax smoothed L_p regularization ($p \in (0,1)$) directly to L_q regularization for $q \geq 1$ (one usually takes either $q = 1$ or $q = 2$). In this case, $\mathbf{u}_k = \mathbf{h}_k(\mathbf{w}) = |\mathbf{w}_k|^q \in [0,\infty)$, and $\bar{R}_k(\mathbf{u}_k) = \lambda[(\alpha + \mathbf{u}_k^{1/q})^p - \alpha^p]/(p\alpha^{p-1})$. Although it is not difficult to verify that $\bar{R}_k(\mathbf{u}_k)$ is concave, we do not have a simple closed form for $R_k^*(\mathbf{v}_k)$. However, it is easy to check that the solution in (4) is given by $\hat{\mathbf{v}}_k = \lambda/(q\alpha^{p-1})(\alpha + |\mathbf{w}_k|)^{p-1}|\mathbf{w}_k|^{1-q}$.

In summary, for L_p and smoothed L_p, we consider the following optimization formulation for some $\alpha \geq 0$ and $p \in (0,1]$:

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left[R_0(\mathbf{w}) + \lambda \sum_{j=1}^{d} (\alpha + |\mathbf{w}_j|)^p \right],$$

where we assume that $R_0(\mathbf{w})$ is a convex function of $\mathbf{w}$.

From previous discussion, the multi-stage convex relaxation method in Section 2.2 becomes a weighted L_q regularization formulation for $q \geq 1$:

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left[R_0(\mathbf{w}) + \sum_{j=1}^{d} \hat{\mathbf{v}}_j |\mathbf{w}_j|^q \right],$$

where the relaxation parameter $\mathbf{v}$ is updated as

$$\hat{\mathbf{v}}_j = \lambda(p/q)(\alpha + |\hat{\mathbf{w}}_j|)^{p-1}|\hat{\mathbf{w}}_j|^{1-q} \quad (j = 1,\ldots,d).$$

The typical choices of q are $q = 1$ or $q = 2$. That is, we relax L_p regularization to L_1 or L_2 regularization.

Finally, we note that the two stage version of L_p regularization, relaxed to L_q with $q = 1$, is referred to Adaptive-Lasso (Zou, 2006).

C.3 Smoothed log Regularization

This is a different sparse regularization condition, where we consider a regularization term $R_k(\mathbf{w}) = \lambda\alpha\ln(\alpha + |\mathbf{w}_k|)$ for some $\alpha > 0$. Given any $q > 0$, (3) holds with $\mathbf{u}_k = \mathbf{h}_k(\mathbf{w}) = (\alpha + |\mathbf{w}_k|)^q \in [\alpha^q, \infty)$, and $\bar{R}_k(\mathbf{u}_k) = \lambda(\alpha/q)\ln(\mathbf{u}_k)$, where $\mathbf{u}_k \in \Omega_k = [0,\infty)$. The dual is $R_k^*(\mathbf{v}_k) = \lambda(\alpha/q)[\ln\mathbf{v}_k + 1 - \ln(\lambda\alpha/q)]$, defined on the domain $\mathbf{v}_k \geq 0$. The solution in (4) is given by $\hat{\mathbf{v}}_k = \lambda(\alpha/q)(\alpha + |\mathbf{w}_k|)^{-q}$.

Similar to smoothed L_p, we may relax directly to L_q, with $\mathbf{u}_k = \mathbf{h}_k(\mathbf{w}) = |\mathbf{w}_k|^q \in [0,\infty)$. $\bar{R}_k(\mathbf{u}_k) = \lambda\alpha\ln(\alpha + \mathbf{u}_k^{1/q})$, where The solution in (4) is given by $\hat{\mathbf{v}}_k = \lambda(\alpha/q)(\alpha + |\mathbf{w}_k|)^{-1}|\mathbf{w}_k|^{1-q}$.

Similar to smoothed log regularization, the multi-stage convex relaxation method in Section 2.2 becomes a weighted L_q regularization formulation for $q \geq 1$:

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left[R_0(\mathbf{w}) + \sum_{j=1}^{d} \hat{\mathbf{v}}_j |\mathbf{w}_j|^q \right],$$

where the relaxation parameter $\mathbf{v}$ is updated as

$$\hat{\mathbf{v}}_j = \lambda(\alpha/q)(\alpha + |\mathbf{w}_j|)^{-1}|\mathbf{w}_j|^{1-q} \quad (j = 1,\ldots,d).$$

This resulting procedure is the same as the one empirically studied in Candes et al. (2008).

C.3.1 CAPPED L_1 REGULARIZATION

We consider another sparse regularization term with $R_k(\mathbf{w}) = \lambda \min(|\mathbf{w}_k|, \alpha)$ ($k = 1, \ldots, d$) for some $\alpha > 0$. In this case, (3) holds with $\mathbf{u}_k = \mathbf{h}_k(\mathbf{w}) = |\mathbf{w}_k| \in [0, \infty)$, and $\bar{R}_k(\mathbf{u}_k) = \lambda \min(\mathbf{u}_k, \alpha)$, where $\mathbf{u}_k \in \Omega_k = [0, \infty)$. The dual is $R_k^*(\mathbf{v}_k) = \lambda\alpha(-1 + \mathbf{v}_k/\lambda) I(\mathbf{v}_k \in [0, \lambda])$ defined $[0, \infty)$, where $I(\cdot)$ is the set indicator function. The solution in (4) is given by $\hat{\mathbf{v}}_k = \lambda I(|\mathbf{w}_k| \leq \alpha)$.

In capped L_1 regularization, we consider the optimization problem

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left[R_0(\mathbf{w}) + \lambda \sum_{j=1}^{d} \min(\alpha, |\mathbf{w}_j|) \right],$$

where we assume that $R_0(\mathbf{w})$ is a convex function of $\mathbf{w}$.

From Section 2.2, the multi-stage convex relaxation becomes a weighted L_1 regularization formulation:

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w}} \left[R_0(\mathbf{w}) + \sum_{j=1}^{d} \hat{\mathbf{v}}_j |\mathbf{w}_j| \right],$$

where the relaxation parameter $\mathbf{v}$ is updated as

$$\hat{\mathbf{v}}_j = \lambda I(|\hat{\mathbf{w}}_j| \leq \alpha) \quad (j = 1, \ldots, d).$$

This method has an intuitive interpretation: in order to achieve sparsity, the standard L_1 regularization not only shrinks small coefficients to zero, but also shrinks large coefficients. This causes a bias. The capped-L_1 formulation removes the bias by adaptively adjusting the relaxation parameter $\hat{\mathbf{v}}_j$ so that if $|\hat{\mathbf{w}}_j|$ is large, then we do not penalize the corresponding variable j.

C.3.2 SPARSE EIGENVALUE PROBLEM

We use a simple example to illustrate that the multi-stage convex relaxation idea does not only apply to formulations with convex risks. Consider the sparse eigenvalue problem, where we are interested in finding the largest eigenvalue of a positive semi-definite matrix A. One formulation is

$$\hat{\mathbf{w}} = \arg\max_{\|\mathbf{w}\|_2 \leq 1} \left[\mathbf{w}^\top A \mathbf{w} - \lambda \sum_{j=1}^{d} (\alpha + |\mathbf{w}_j|)^p \right],$$

with parameter $p \in (0, 1)$ and a small parameter $\alpha > 0$ to encourage sparsity. If $\lambda = 0$, then it is the standard eigenvalue problem without sparsity constraints. Although the standard eigenvalue problem is not convex in $\mathbf{w}$, it has a convex relaxation to a semi-definite programming problem, and thus can be efficiently solved. For convenience, we think of the standard eigenvalue problem as "convex" for the purpose of this paper. The multi-stage convex relaxation becomes:

$$\hat{\mathbf{w}} = \arg\max_{\|\mathbf{w}\|_2 \leq 1} \left[\mathbf{w}^\top A \mathbf{w} - \sum_{j=1}^{d} \mathbf{v}_j \mathbf{w}_j^2 \right],$$

which is a standard eigenvalue problem. The relaxation parameter is updated as

$$\hat{\mathbf{v}}_j = \lambda(p/2)(\alpha + |\hat{\mathbf{w}}_j|)^{p-1} |\hat{\mathbf{w}}_j|^{-1} \quad (j = 1, \ldots, d).$$

C.3.3 MATRIX REGULARIZATION

Our final example is multi-task learning with matrix regularization, also considered in Argyriou et al. (2008). In this case, $\mathbf{w}$ is not a vector, but a matrix, with columns (tasks) $\mathbf{w}^\ell$. We solve a problem of the following form:

$$\mathbf{w} = \arg\min_{\mathbf{w}} \left[\sum_{\ell=1}^{m} R^\ell(\mathbf{w}^\ell) + \lambda \mathrm{tr}((\alpha I + \mathbf{w}\mathbf{w}^\top)^{p/2}) \right].$$

In the above formulation, R^ℓ is the risk function for task ℓ. The matrix regularization used here is the counterpart of L_p regularization for vectors. It encourages low-rank if $p < 2$. In particular, the case of $p = 1$ is often called trace norm (or nuclear norm). It is convex and frequently used in the literature. The parameter $\alpha > 0$ gives some smoothness, similar to the vector case.

The case of $p < 1$ gives better low-rank approximation, similar to the vector regularization case. Again, this problem can be solved with multi-stage convex relaxation method. In this case, the relaxation parameter $\mathbf{v}$ is a positive semi-definite matrix, and we relax the regularization term to $\mathbf{h}(\mathbf{w}) = (\alpha I + \mathbf{w}\mathbf{w}^\top)$ as a matrix. Thus the relaxed regularization term becomes $\mathrm{tr}(\mathbf{v}(\alpha I + \mathbf{w}\mathbf{w}^\top))$. This regularization decouples the problems as follows, which allows us to solve each task ℓ separately:

$$\hat{\mathbf{w}}^\ell = \arg\min_{\mathbf{w}^\ell} \left[R^\ell(\mathbf{w}^\ell) + (\mathbf{w}^\ell)^\top \hat{\mathbf{v}} \mathbf{w}^\ell \right] \qquad (\ell = 1, 2, \ldots, m).$$

This is a key advantage of the method. Similar to the vector case, we have the following update formula for the relaxation parameter:

$$\hat{\mathbf{v}} = \lambda(p/2)(\alpha I + \hat{\mathbf{w}}\hat{\mathbf{w}}^\top)^{(p-2)/2}.$$

Abstract

Learning a measure of similarity between pairs of objects is an important generic problem in machine learning. It is particularly useful in large scale applications like searching for an image that is similar to a given image or finding videos that are relevant to a given video. In these tasks, users look for objects that are not only visually similar but also semantically related to a given object. Unfortunately, the approaches that exist today for learning such semantic similarity do not scale to large data sets. This is both because typically their CPU and storage requirements grow quadratically with the sample size, and because many methods impose complex positivity constraints on the space of learned similarity functions.

The current paper presents OASIS, an *Online Algorithm for Scalable Image Similarity* learning that learns a bilinear similarity measure over sparse representations. OASIS is an online dual approach using the passive-aggressive family of learning algorithms with a large margin criterion and an efficient hinge loss cost. Our experiments show that OASIS is both fast and accurate at a wide range of scales: for a data set with thousands of images, it achieves better results than existing state-of-the-art methods, while being an order of magnitude faster. For large, web scale, data sets, OASIS can be trained on more than two million images from 150K text queries within 3 days on a single CPU. On this large scale data set, human evaluations showed that 35% of the ten nearest neighbors of a given test image, as found by OASIS, were semantically relevant to that image. This suggests that query independent similarity could be accurately learned even for large scale data sets that could not be handled before.

Keywords: large scale, metric learning, image similarity, online learning

1. Introduction

Large scale learning is sometimes defined as the regime where learning is limited by computational resources rather than by availability of data (Bottou, 2008). Learning a pairwise similarity measure is a particularly challenging large scale task: since pairs of samples have to be considered, the large scale regime is reached even for fairly small data sets, and learning similarity for large data sets becomes exceptionally hard to handle.

At the same time, similarity learning is a well studied problem with multiple real world applications. It is particularly useful for applications that aim to discover new and relevant data for a user. For instance, a user browsing a photo in her album may ask to find similar or related images. Another user may search for additional data while viewing an online video or browsing text documents. In all these applications, similarity could have different flavors: a user may search for images that are similar visually, or semantically, or anywhere in between.

Many similarity learning algorithms assume that the available training data contains real-valued pairwise similarities or distances. However, in all the above examples, the precise numerical value of pairwise similarity between objects is usually not available. Fortunately, one can often obtain information about the *relative* similarity of different pairs (Frome et al., 2007), for instance, by presenting people with several object pairs and asking them to select the pair that is most similar. For large scale data, where man-in-the-loop experiments are prohibitively costly, relative similarities can be extracted from analyzing pairs of images that are returned in response to the same text query (Schultz and Joachims, 2004). For instance, the images that are ranked highly by one of the image search engines for the query "cute kitty" are likely to be semantically more similar than a random pair of images. The current paper focuses on this setting: similarity information is extracted from pairs of images that share a common label or are retrieved in response to a common text query.

Similarity learning has an interesting reciprocal relation with classification. On one hand, pairwise similarity can be used in classification algorithms like nearest neighbors or kernel methods. On the other hand, when objects can be classified into (possibly overlapping) classes, the inferred labels induce a notion of similarity across object pairs. Importantly however, similarity learning assumes a form of supervision that is weaker than in classification, since no labels are provided. OASIS is designed to learn a *class-independent* similarity measure with no need for class labels.

A large number of previous studies have focused on learning a similarity measure that is also a metric, like in the case of a positive semidefinite matrix that defines a Mahalanobis distance (Yang, 2006). However, similarity learning algorithms are often evaluated in a context of ranking. For instance, the learned metric is typically used together with a nearest-neighbor classifier (Weinberger et al., 2006; Globerson and Roweis, 2006). When the amount of training data available is very small, adding positivity constraints for enforcing metric properties is useful for reducing over fitting and improving generalization. However, when sufficient data is available, as in many modern applications, adding positive semi-definitiveness constraints consumes considerable computation time, and its benefit in terms of generalization are limited. With this view, we take here an approach that avoids imposing positivity or symmetry constraints on the learned similarity measure.

The current paper presents an approach for learning semantic similarity that scales up to an order of magnitude larger than current published approaches. Three components are combined to make this approach fast and scalable: First, our approach uses an unconstrained bilinear similarity. Given two images p_1 and p_2 we measure similarity through a bilinear form $p_1^T \mathbf{W} p_2$, where the matrix $\mathbf{W}$ is not required to be positive, or even symmetric. Second we use a sparse representation

of the images, which allows to compute similarities very fast. Finally, the training algorithm that we developed, OASIS, *Online Algorithm for Scalable Image Similarity learning*, is an online dual approach based on the passive-aggressive algorithm (Crammer et al., 2006). It minimizes a large margin target function based on the hinge loss, and already converges to high quality similarity measures after being presented with a small fraction of the training pairs.

We find that OASIS is both fast and accurate at a wide range of scales: for a standard benchmark with thousands of images, it achieves better (but comparable) results than existing state-of-the-art methods, with computation times that are shorter by orders of magnitude. For web-scale data sets, OASIS can be trained on more than two million images within three days on a single CPU, and its training time grows linearly with the size of the data. On this large scale data set, human evaluations of OASIS learned similarity show that 35% of the ten nearest neighbors of a given image are semantically relevant to that image.

The paper is organized as follows. We first present our online algorithm, OASIS, based on the Passive-aggressive family of algorithms. We then present the sparse feature extraction technique used in the experiments. We continue by describing experiments with OASIS on problems of image similarity, at two different scales: a large scale academic benchmark with tens of thousands of images, and a web-scale problem with millions of images. The paper ends with a discussion on properties of OASIS.

2. Learning Relative Similarity

We consider the problem of learning a pairwise similarity function S, given data on the relative similarity of pairs of images.

Formally, let $\mathcal{P}$ be a set of images, and $r_{ij} = r(p_i, p_j) \in \mathbb{R}$ be a pairwise relevance measure which states how strongly $p_j \in \mathcal{P}$ is related to $p_i \in \mathcal{P}$. This relevance measure could encode the fact that two images belong to the same category or were appropriate for the same query. We do not assume that we have full access to all the values of r. Instead, we assume that we can compare some pairwise relevance scores (for instance $r(p_i, p_j)$ and $r(p_i, p_k)$) and decide which pair is more relevant. We also assume that when $r(p_i, p_j)$ is not available, its value is zero (since the vast majority of images are not related to each other). Our goal is to learn a similarity function $S(p_i, p_j)$ that assigns higher similarity scores to pairs of more relevant images,

$$S(p_i, p_i^+) > S(p_i, p_i^-)\ , \quad \forall p_i, p_i^+, p_i^- \in \mathcal{P} \text{ such that } r(p_i, p_i^+) > r(p_i, p_i^-). \tag{1}$$

In this paper we overload notation by using p_i to denote both the image and its representation as a column vector $p_i \in \mathbb{R}^d$. We consider a parametric similarity function that has a bi-linear form,

$$S_{\mathbf{W}}(p_i, p_j) \equiv p_i^T\ \mathbf{W}\ p_j \tag{2}$$

with $\mathbf{W} \in \mathbb{R}^{d \times d}$. Importantly, if the images p_i are represented as sparse vectors, namely, only a number $k_i \ll d$ of the d entries in the vector p_i are non-zeroes, then the value of Equation (2) can be computed very efficiently even when d is large. Specifically, $S_{\mathbf{W}}$ can be computed with complexity of $O(k_i k_j)$ regardless of the dimensionality d.

2.1 An Online Algorithm

We propose an online algorithm based on the Passive-Aggressive (PA) family of learning algorithms introduced by Crammer et al. (2006). Here we consider an algorithm that uses triplets of images $p_i, p_i^+, p_i^- \in \mathcal{P}$ such that $r(p_i, p_i^+) > r(p_i, p_i^-)$.

We aim to find a parametric similarity function S such that all triplets obey

$$S_{\mathbf{W}}(p_i, p_i^+) > S_{\mathbf{W}}(p_i, p_i^-) + 1 \tag{3}$$

which means that it fulfills Equation (1) with a safety margin of 1. We define the following hinge loss function for the triplet:

$$l_{\mathbf{W}}(p_i, p_i^+, p_i^-) = \max\left\{0, 1 - S_{\mathbf{W}}(p_i, p_i^+) + S_{\mathbf{W}}(p_i, p_i^-)\right\}. \tag{4}$$

Our goal is to minimize a global loss $L_{\mathbf{W}}$ that accumulates hinge losses (4) over all possible triplets in the training set:

$$L_{\mathbf{W}} = \sum_{(p_i, p_i^+, p_i^-) \in \mathcal{P}} l_{\mathbf{W}}(p_i, p_i^+, p_i^-)\ .$$

In order to minimize this loss, we apply the Passive-Aggressive algorithm iteratively over triplets to optimize $\mathbf{W}$. First, $\mathbf{W}$ is initialized to some value $\mathbf{W}^0$. Then, at each training iteration i, we randomly select a triplet (p_i, p_i^+, p_i^-), and solve the following convex problem with soft margin:

$$\begin{aligned} \mathbf{W}^i &= \operatorname{argmin}_{\mathbf{W}} \frac{1}{2}\|\mathbf{W} - \mathbf{W}^{i-1}\|_{Fro}^2 + C\xi \\ \text{s.t.} \quad & l_{\mathbf{W}}(p_i, p_i^+, p_i^-) \le \xi \quad \text{and} \quad \xi \ge 0 \end{aligned} \tag{5}$$

where $\|\cdot\|_{Fro}$ is the Frobenius norm (point-wise L_2 norm). Therefore, at each iteration i, $\mathbf{W}^i$ is selected to optimize a trade-off between remaining close to the previous parameters $\mathbf{W}^{i-1}$ and minimizing the loss on the current triplet $l_{\mathbf{W}}(p_i, p_i^+, p_i^-)$. The *aggressiveness* parameter C controls this trade-off.

OASIS

Initialization:

Initialize $\mathbf{W}^0 = I$

Iterations

repeat

Sample three images p, p_i^+, p_i^-, such that $r(p_i, p_i^+) > r(p_i, p_i^-)$.

Update $\mathbf{W}^i = \mathbf{W}^{i-1} + \tau_i \mathbf{V}^i$

where $\tau_i = \min\left\{C, \frac{l_{\mathbf{W}^{i-1}}(p_i, p_i^+, p_i^-)}{\|\mathbf{V}^i\|^2}\right\}$

and $\mathbf{V}^i = [p_i^1(p_k^+ - p_k^-), \ldots, p_i^d(p_k^+ - p_k^-)]^T$

until (stopping criterion)

Figure 1: Pseudo-code of the OASIS algorithm.

We follow Crammer et al. (2006) to solve the problem in Equation (5). When $l_{\mathbf{W}}(p_i, p_i^+, p_i^-) = 0$, it is clear that $\mathbf{W}^i = \mathbf{W}^{i-1}$ satisfies Equation (5) directly. Otherwise, we define the Lagrangian

$$\mathcal{L}(\mathbf{W}, \tau, \xi, \lambda) = \frac{1}{2}\|\mathbf{W} - \mathbf{W}^{i-1}\|^2 + C\xi + \tau(1 - \xi - p_i^T \mathbf{W}(p_i^+ - p_i^-)) - \lambda\xi \tag{6}$$

where $\tau \geq 0$ and $\lambda \geq 0$ are Lagrange multipliers. The optimal solution is such that the gradient vanishes $\frac{\partial \mathcal{L}(\mathbf{W}, \tau, \xi, \lambda)}{\partial \mathbf{W}} = 0$, hence

$$\frac{\partial \mathcal{L}(\mathbf{W}, \tau, \xi, \lambda)}{\partial \mathbf{W}} = \mathbf{W} - \mathbf{W}^{i-1} - \tau \mathbf{V}_i = 0$$

where the gradient matrix $\mathbf{V}_i = \frac{\partial \mathcal{L}_W}{\partial \mathbf{W}} = [p_i^1(p_i^+ - p_i^-), \ldots, p_i^d(p_i^+ - p_i^-)]^T$. The optimal new $\mathbf{W}$ is therefore

$$\mathbf{W} = \mathbf{W}^{i-1} + \tau \mathbf{V}_i \tag{7}$$

where we still need to estimate τ. Differentiating the Lagrangian with respect to ξ and setting it to zero also yields:

$$\frac{\partial \mathcal{L}(\mathbf{W}, \tau, \xi, \lambda)}{\partial \xi} = C - \tau - \lambda = 0 \tag{8}$$

which, knowing that $\lambda \geq 0$, means that $\tau \leq C$. Plugging Equations (7) and (8) back into the Lagrangian in Equation (6), we obtain

$$\mathcal{L}(\tau) = \frac{1}{2}\tau^2 \|\mathbf{V}_i\|^2 + \tau(1 - p_i^T(\mathbf{W}^{i-1} + \tau \mathbf{V}_i)(p_i^+ - p_i^-)) \,.$$

Regrouping the terms we obtain

$$\mathcal{L}(\tau) = -\frac{1}{2}\tau^2 \|\mathbf{V}_i\|^2 + \tau(1 - p_i^T \mathbf{W}^{i-1}(p_i^+ - p_i^-)) \,.$$

Taking the derivative of this second Lagrangian with respect to τ and setting it to 0, we have

$$\frac{\partial \mathcal{L}(\tau)}{\partial \tau} = -\tau \|\mathbf{V}_i\|^2 + (1 - p_i^T \mathbf{W}^{i-1}(p_i^+ - p_i^-)) = 0$$

which yields

$$\tau = \frac{1 - p_i^T \mathbf{W}^{i-1}(p_i^+ - p_i^-)}{\|\mathbf{V}_i\|^2} = \frac{l_{\mathbf{W}^{i-1}}(p_i, p_i^+, p_i^-)}{\|\mathbf{V}_i\|^2} \,.$$

Finally, Since $\tau \leq C$, we obtain

$$\tau = \min\left\{C, \frac{l_{\mathbf{W}^{i-1}}(p_i, p_i^+, p_i^-)}{\|\mathbf{V}_i\|^2}\right\} \,. \tag{9}$$

Equations (7) and (9) summarize the update needed for every triplets (p_i, p_i^+, p_i^-). It has been shown (Crammer et al., 2006) that applying such an iterative algorithm yields a cumulative online loss that is likely to be small. It was furthermore shown that selecting the best $\mathbf{W}_i$ during training using a hold-out validation set achieves good generalization. We also show below that multiple runs of the algorithm converge to provide similar precision (see Figure 7).

2.2 Loss Bounds

Following closely the analysis of loss bounds for passive aggressive (PA) algorithms developed by Crammer et al. (2006) we state similar *relative* bounds for the OASIS framework. We do this by rewriting OASIS as a straightforward linear classification problem. Denote by $\overrightarrow{w_i}$ the vector obtained by"unfolding" the matrix $\mathbf{W}$ (concatenating all its columns into a single vector) and similarly $\overrightarrow{x_i}$ the unfolded matrix $p_i(p_i^+ - p_i^-)^T$. Using this notation, the constraint in Equation (3) becomes

$$\overrightarrow{w_i} \cdot \overrightarrow{x_i} > 1 \quad ,$$

with $\cdot$ denoting the standard inner product. This is equivalent to the formulation of PA when the label y_i is always 1. The introduction of slack variables in Equation (5) brings us to the variant denoted by Crammer et al. (2006) as PA-I.

The loss bounds in Crammer et al. (2006) rely on $\overrightarrow{w_0}$ being the zero vector. Since here we initialize with $W^0 = I$ (the identity matrix) we need to adapt the analysis slightly. Let $\overrightarrow{u}$ be a vector in $\mathbb{R}^{d^2}$ obtained by unfolding an arbitrary matrix $\mathbf{U}$. We define

$$l_i = 1 - \overrightarrow{w_i} \cdot \overrightarrow{x_i} \quad \text{and} \quad l_i^* = 1 - \overrightarrow{u} \cdot \overrightarrow{x_i} \quad ,$$

where l_i is the instantaneous loss at round i, and l_i^* is the loss suffered by the arbitrary vector $\overrightarrow{u}$. The following two theorems rely on Lemma 1 of Crammer et al. (2006), which we restate without proof:

$$\sum \tau_i (2l_i - \tau_i \|x_i\|^2 - 2l_i^*) \leq \|\overrightarrow{u} - \overrightarrow{w_0}\|^2 \, .$$

While in Crammer et al. (2006) $\overrightarrow{w_0}$ is the zero vector, in our case $\overrightarrow{w_0}$ is the unfolded *identity matrix*. We therefore have

$$\|\overrightarrow{u} - \overrightarrow{w_0}\|^2 = \|\mathbf{U}\|_{Fro}^2 - 2trace(\mathbf{U}) + n \, .$$

Using this modified lemma we can restate the relevant bound:

Theorem 1 *Let $(\overrightarrow{x_1}),...,(\overrightarrow{x_M})$ be a sequence of examples where $\overrightarrow{x_i} \in \mathbb{R}^{d^2}$, $\|\overrightarrow{x_i}\| \leq R$ for all $i = 1...M$. Then, for any matrix $\mathbf{U} \in \mathbb{R}^{n^2}$, the number of prediction mistakes made by OASIS on this sequence of examples is bounded from above by,*

$$\max\{R^2, 1/C\}\left(\|\mathbf{U}\|_{Fro}^2 - 2trace(\mathbf{U}) + n + 2C\sum_{i=1}^{M} l_i^*\right)$$

where C is the aggressiveness parameter provided to OASIS.

2.3 Sampling Strategy

For real world data sets, the actual number of triplets (p_i, p_i^+, p_i^-) is typically very large and cannot be stored in memory. Instead, we use the fact that the number of relevant images for a category or a query is typically small, and keep a list of relevant images for each query or category. For the case of single-labeled images, we can efficiently retrieve an image that is relevant to a given image, by first finding its class, and then finding another image from that class. The case of multi-labeled images is described in Section 5.2.

Specifically, to sample a triplet (p_i, p_i^+, p_i^-) during training, we first uniformly sample an image p_i from $\mathcal{P}$. Then we uniformly sample an image p_i^+ from the images sharing the same categories

or queries as p_i. Finally, we uniformly sample an image p_i^- from the images that share no category or query with p_i. When the set $\mathcal{P}$ is very large and the number of categories or queries is also very large, one does not need to maintain the set of non-relevant images for each image: sampling directly from $\mathcal{P}$ instead only adds a small amount of noise to the training procedure and is not really harmful.

When relevance feedbacks $r(p_i, p_j)$ are provided as real numbers and not just $\in \{0,1\}$, one could use these number to bias training towards those pairs that have a higher relevance feedback value. This can be done by considering $r(p_i, p_j)$ as frequencies of appearance, and sampling pairs according to the distribution of these frequencies.

3. Image Representation

The problem of selecting an informative representation of images is still an unsolved computer vision challenge, and an ongoing research topic. Different approaches for image representation have been proposed including by Feng et al. (2004); Takala et al. (2005) and Tieu and Viola (2004). In the information retrieval community there is wide agreement that a bag-of-words representation is a very useful representation for handling text documents in a wide range of applications. For image representation, there is still no such approach that would be adequate for a wide variety of image processing problems. However, among the proposed representations, a consensus is emerging on using *local descriptors* for various tasks, for example, Lowe (2004); Quelhas et al. (2005). This type of representation segments the image into *regions of interest*, and extracts visual features from each region. The segmentation algorithm as well as the region features vary among approaches, but, in all cases, the image is then represented as a set of feature vectors describing the regions of interest. Such a set is often called a *bag-of-local-descriptors*.

In this paper we take the approach of creating a sparse representation based on the framework of local descriptors. Our features are extracted by dividing each image into overlapping square blocks, and each block is then described with edge and color histograms. For edge histograms, we rely on *uniform Local Binary Patterns* (uLBPs) proposed by Ojala et al. (2002). These texture descriptors have shown to be effective on various tasks in the computer vision literature (Ojala et al., 2002; Takala et al., 2005), certainly due to their robustness with respect to changes in illumination and other photometric transformations (Ojala et al., 2002). Local Binary Patterns estimate a texture histogram of a block by considering differences in intensity at circular neighborhoods centered on each pixel. Precisely, we use $LBP_{8,2}$ patterns, which means that a circle of radius 2 is considered centered on each block. For each circle, the intensity of the center pixel is compared to the interpolated intensities located at 8 equally-spaced locations on the circle, as shown on Figure 2, left. These eight binary tests (lower or greater intensity) result in an 8-bit sequence, see Figure 2, right. Hence, each block pixel is mapped to a sequence among $2^8 = 256$ possible sequences and each block can therefore be represented as a 256-bin histogram. In fact, it has been observed that the bins corresponding to non-uniform sequences (sequences with more than 2 transitions $1 \rightarrow 0$ or $0 \rightarrow 1$) can be merged, yielding more compact 59-bin histograms without performance loss (Ojala et al., 2002).

Color histograms are obtained by K-means clustering. We first select a palette or typical colors by training a color codebook from the Red-Green-Blue pixels of a large training set of images using K-means. The color histogram of a block is then obtained by mapping each block pixel to the closest color in the codebook palette.

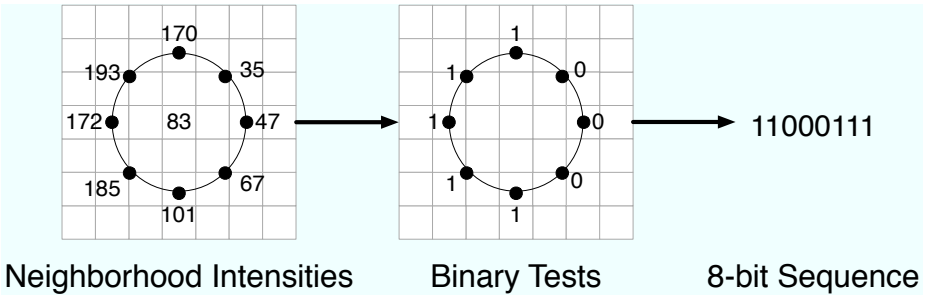

Figure 2: An example of Local Binary Pattern ($LBP_{8,2}$). For a given pixel, the Local Binary Pattern is an 8-bit code obtained by verifying whether the intensity of the pixel is greater or lower than its 8 neighbors.

Finally, the histograms describing color and edge statistics of each block are concatenated, which yields a single vector descriptor per block. Our local descriptor representation is therefore simple, relying on both a basic segmentation approach and simple features. Naturally, alternative representations could also be used with OASIS, (Feng et al., 2004; Grangier et al., 2006; Tieu and Viola, 2004) However, this paper focuses on the learning model, and a benchmark of image representations is beyond the scope of the current paper.

As a final step, we use the representation of blocks to obtain a representation for an image. For computation efficiency we aim at a high dimensional and sparse vector space. For this purpose, each local descriptor of an image p is represented as a discrete index, called *visual term* or *visterm*, and, like for text data, the image is represented as a *bag-of-visterms* vector, in which each component p_i is related to the presence or absence of visterm i in p.

The mapping of the descriptors to discrete indexes is performed according to a codebook C, which is typically learned from the local descriptors of the training images through k-means clustering (Duygulu et al., 2002; Jeon and Manmatha, 2004; Quelhas et al., 2005). The assignment of the weight p_i of visterm i in image p is as follows:

$$p_i = \frac{f_i \, d_i}{\sqrt{\sum_{j=1}^{d} (f_j \, d_j)^2}} \, ,$$

where f_i is the term frequency of i in p, which refers to the number of occurrences of i in p, while d_j is the inverse document frequency of j, which is defined as $-log(r_j)$, r_j being the fraction of training images containing at least one occurrence of visterm j. This approach has been found successful for the task of content based image ranking described by Grangier and Bengio (2008).

In the experiments described below, we used a large set of images collected from the web to train the features. This set is described in more detail in Section 5.2. We used a set of 20 typical RGB colors (hence the number of clusters used in the k-means for colors was 20), the block vocabulary size $d = 10000$ and our image blocks were of size 64x64 pixels, overlapping every 32 pixels. Furthermore, in order to be robust to scale, we extracted blocks at various scales by successively down scaling images by a factor of 1.25 and extracting the features at each level, until there were less than 10 blocks in the resulting image. There was on average around 70 non-zero

values (out of 10000) describing a single image. Note that no other information (such as meta-data) was added in the input vector representation each image.

4. Related Work

Similarity learning can be considered in two main setups, depending on the type of available training labels. First, a regression setup, where the training set consists of pairs of objects x_i^1, x_i^2 and their pairwise similarity $y_i \in \mathbf{R}$. In many cases however, precise similarities are not available, but rather a weaker notion of similarity order. In one such setup, the training set consists of triplets of objects x_i^1, x_i^2, x_i^3 and a ranking similarity function, that can tell which of the two pairs (x^1, x^2) or (x^1, x^3) is more similar. Finally, multiple similarity learning studies assume that a binary measure of similarity is available $y_i \in \{+1, -1\}$, indicating whether a pair of objects is similar or not.

For small-scale data, there are two main groups of similarity learning approaches. The first approach, learning Mahalanobis distances, can be viewed as learning a linear projection of the data into another space (often of lower dimensionality), where a Euclidean distance is defined among pairs of objects. Such approaches include Fisher's Linear Discriminant Analysis (LDA), relevant component analysis (RCA) (Bar-Hillel et al., 2003), supervised global metric learning (Xing et al., 2003), large margin nearest neighbor (LMNN) (Weinberger et al., 2006) and Metric Learning by Collapsing Classes (Globerson and Roweis, 2006). A Mahalanobis distance learning algorithm which uses a supervision signal identical to the one we employ in OASIS is Rosales and Fung (2006), which learns a special kind of PSD matrix via linear programming. See also a review by Yang (2006) for more details.

The second family of approaches, learning kernels, is used to improve performance of kernel based classifiers. Learning a full kernel matrix in a non parametric way is prohibitive except for very small data. As an alternative, several studies suggested to learn a weighted sum of pre-defined kernels (Lanckriet et al., 2004) where the weights are being learned from data. In some applications this was shown to be inferior to uniform weighting of the kernels (Noble, 2008). The work of Frome et al. (2007) further learns a weighting over local distance function for every image in the training set. Non linear image similarity learning was also studied in the context of dimensionality reduction, as in Hadsell et al. (2006).

Finally, Jain et al. (2008a,b), based on work by Davis et al. (2007), aim to learn metrics in an online setting. This work is one of the closest work with respect to OASIS: it learns a linear model of a [dis-]similarity function between documents in an online way. The main difference is that the work of Jain et al. (2008a) learn a true distance throughout the learning process, imposing positive definiteness constraints, and is slightly less efficient computationally. We argue in this paper that in the large scale regime, such a constraint is not necessary given the amount of available training examples.

Another work closely related to OASIS is that of Rasiwasia and Vasconcelos (2008), which also tries to learn a semantic similarity function between images. In their case, however, semantic similarity is learned by representing each image by the posterior probability distribution over a pre-defined set of semantic tags, and then computing the distance between two images as the distance between the two underlying posterior distributions. The representation size of images in this approach is therefore equal to the number of semantic classes, hence it will not scale when the number of semantic classes is very large as in free text search.

5. Experiments

Evaluating large scale learning algorithms poses special challenges. First, current available benchmarks are limited either in their scale, like 30K images in Caltech256 as described by Griffin et al. (2007), or in their resolution, such as the tiny images data set of Torralba et al. (2007). Large scale methods are not expected to perform particularly well on small data sets, since they are designed to extract limited information from each sample. Second, many images on the web cannot be used without explicit permission, hence they cannot be collected and packed into a single database. Large, proprietary collections of images do exist, but are not available freely for academic research. Finally, except for very few cases, similarity learning approaches in current literature do not scale to handle large data sets effectively, which makes it hard to compare a new large scale method with the existing methods.

To address these issues, this paper takes the approach of conducting experiments at two different scales. First, to demonstrate the scalability of OASIS we applied OASIS to a web-scale data with 2.7 million images. Second, to investigate the properties of OASIS more deeply, we compare OASIS with small-scale methods using the standard Caltech256 benchmark.

5.1 Evaluation Measures

We evaluated the performance of all algorithms using standard ranking precision measures based on nearest neighbors. For each query image in the test set, all other test images were ranked according to their similarity to the query image. The number of same-class images among the top k images (the k nearest neighbors) was computed. When averaged across test images (either within or across classes), this yields a measure known as precision-at-top-k, providing a precision curve as a function of the rank k.

We also calculated the *mean average precision* (mAP), a measure that is widely used in the information retrieval community. To compute average precision, the precision-at-top-k is first calculated for each test image. Then, it is averaged over all positions k that have a positive sample. For example, if all positives are ranked highest, the average-precision is 1. The average-precision measure is then further averaged across all test image queries, yielding the *mean average precision* (mAP).

5.2 Web-Scale Experiment

Our first set of experiments is based on Google proprietary data that is two orders of magnitude larger than current standard benchmarks. We collected a set of $\sim$150K text queries submitted to the Google Image Search system. For each of these queries, we had access to a set of relevant images, each of which is associated with a numerical relevance score. This yielded a total of $\sim$2.7 million images, which we split into a training set of 2.3 million images and a test set of 0.4 million images (see Table 1).

Set	Number of Queries	Number of Images
Training	139944	2292259
Test	41877	402164

Table 1: Statistics of the Web data set.

5.2.1 EXPERIMENTAL SETUP

We used the query-image relevance information to create an image-image relevance as follows. Denote the set of text queries by $\mathcal{Q}$ and the set of images by $\mathcal{P}$. For each $q \in \mathcal{Q}$, let $\mathcal{P}_q^+$ denote the set of images that are relevant to the query q, and let $\mathcal{P}_q^-$ denote the set of irrelevant images. The query-image relevance is defined by the matrix $\mathbf{R}_{QI} : \mathcal{Q} \times \mathcal{P} \to \mathbb{R}^+$, and obeys $\mathbf{R}_{QI}(q, p_q^+) > 0$ and $\mathbf{R}_{QI}(q, p_q^-) = 0$ for all $q \in \mathcal{Q}$, $p_q^+ \in \mathcal{P}_q^+$, $p_q^- \in \mathcal{P}_q^-$. We also computed a normalized version of $\mathbf{R}_{QI}$, which can be interpreted as a joint distribution matrix, or the probability to observe a query q and an image p for that query,

$$Pr(q,p) = \frac{\mathbf{R}_{QI}(q,p)}{\sum_{q',p'} \mathbf{R}_{QI}(q',p')} \quad .$$

In order to compute the image-image relevance matrix $\mathbf{R}_{II} : \mathcal{P} \times \mathcal{P} \to \mathbb{R}^+$, we treated images as being conditionally independent given the queries, $Pr(p_1, p_2|q) = Pr(p_1|q)Pr(p_2|q)$, and computed the joint image-image probability as a relevance measure

$$Pr(p_1,p_2) = \sum_{q \in \mathcal{Q}} Pr(p_1,p_2|q)\, Pr(q) = \sum_{q \in \mathcal{Q}} Pr(p_1 \mid q) Pr(p_2 \mid q) Pr(q) \; .$$

To improve scalability, we used a threshold over this joint distribution, and considered two images to be related only if their joint distribution exceeded a cutoff value θ

$$\mathbf{R}_{II}(p_1,p_2) = [Pr(p_1,p_2)]_\theta \tag{10}$$

where $[x]_\theta = x$ for $x > \theta$ and is zero otherwise. To set the value of θ we have manually inspected a small subset of pairs of related images taken from the training set. We selected the largest θ such that most of those related pairs had scores above the threshold, while minimizing noise in $\mathbf{R}_{II}$.

Equation 10 is written as if one needs to calculate the full joint matrix $\mathbf{R}_{II}$, but this matrix grows quadratically with the number of images. In practice, we can use the fact that $\mathbf{R}_{QI}$ is very sparse, to quickly create a list with images that are relevant to a given image. To do this given an image p_i, we go over all the queries for which it is relevant $\mathbf{R}_{QI}(q, p_i)$, and for each of these queries, collect the list of all images that are relevant to that query. The average number of queries relevant for an image in our data is small (about 100), and so is the number of images relevant for a given query. As a result, $\mathbf{R}_{II}$ can be calculated efficiently even for large image sets.

We trained OASIS over 2.3 million images in the training set using the sampling mechanism based on the relevance of each image, as described in Section 2.3. To select the number of training iterations, we used as a validation set a small subset of the training set to trace the mean average precision of the model at regular intervals during the training process. Training was stopped when the mean average precision had saturated, which happened after 160 million iterations (triplets). Overall, training took a total of $\sim$4000 minutes on a single CPU of a standard modern machine. Finally, we evaluated the trained model on the 400 thousand images of the test set.

5.2.2 RESULTS

We start with specific examples illustrating the behavior of OASIS, and continue with a quantitative analysis of precision and speed. Table 2 shows the top five images as ranked by OASIS on four examples of query-images in the test set. The relevant text queries for each image are shown beneath the image. The first example (top row), shows a query-image that was originally retrieved

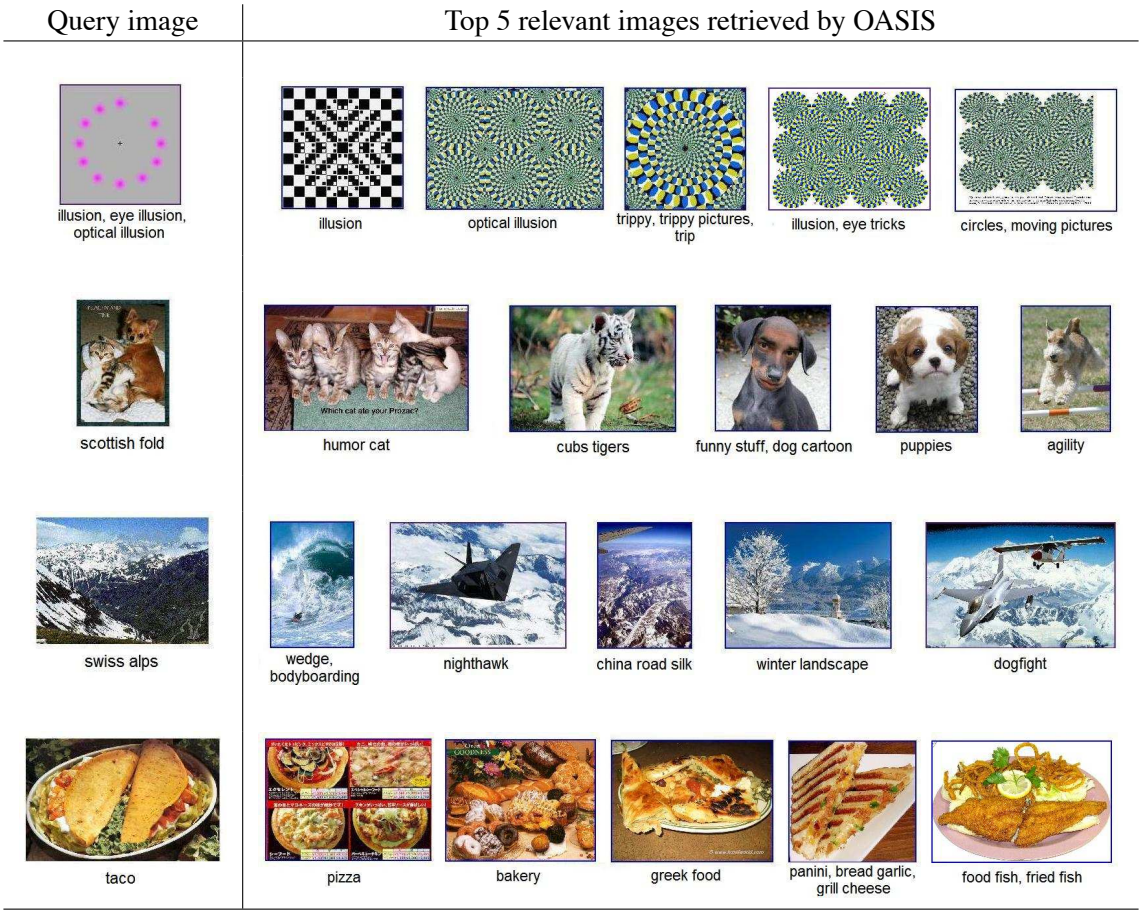

Table 2: OASIS: Successful cases from the Web data set

in response to the text query "illusion". All five images ranked highly by OASIS are semantically related, showing other types of visual illusions. Similar results can be observed for the three remaining examples on this table, where OASIS captures well the semantics of animal photos (cats and dogs), mountains and different food items.

In all these cases, OASIS captures similarity that is both semantic and visual, since the raw visual similarity of these images is not high. A different behavior is demonstrated in Table 3. It shows three cases where OASIS was biased by visual similarity and provided high rankings to images that were semantically non relevant. In the first example, the assortment of flowers is confused with assortments of food items and a thigh section (5th nearest neighbor) which has visually similar shape. The second example presents a query image which in itself has no definite semantic element. The results retrieved are those that merely match texture of the query image and bear no semantic similarity. In the third example, OASIS fails to capture the butterfly in the query image.

To obtain a quantitative evaluation of OASIS we computed the precision at top k, using a threshold $\theta = 0$, which means that an image in the test set is considered relevant to a query image, if there exists at least one text query to which they were both relevant to.

The obtained precision values were quite low, achieving 1.5% precision at the top ranked image. This is drastically lower than the precision described below for Caltech256, and could be the result

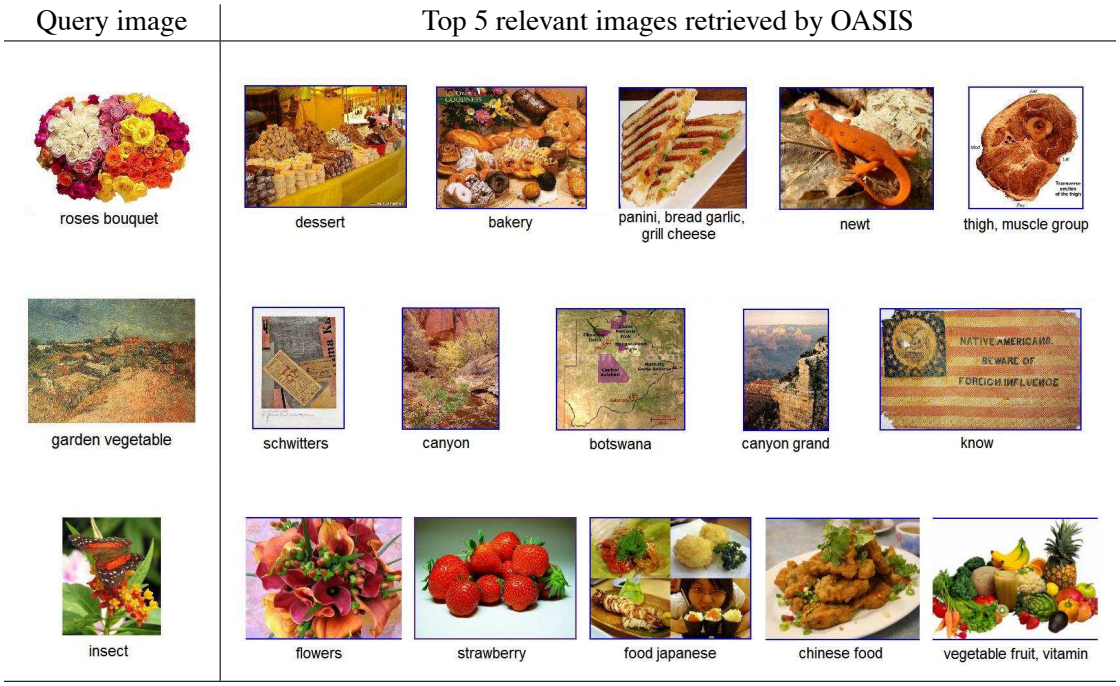

Table 3: OASIS: Failure cases from the Web data set

of multiple reasons. First, the number of unique textual queries in our data is very large (around 150K), hence the images in this data set were significantly more heterogeneous than images in the Caltech256 data.

Second, and most importantly, our labels that measure pairwise relevance are very partial. This means that many pairs of images that are semantically related are not labeled as such. A clear demonstration of this effect is observed in Tables 2 and 3. The query images (like "*scottish fold*") have labels that are usually very different from the labels of the retrieved images (as in "*humor cat*", "*agility*") even if their semantic content is very similar. This is a common problem in content-based analysis, since similar content can be described in many different ways. In the case discussed here, the partial data on the query-image relevance $\mathbf{R}_{QI}$ is further propagated to the image-image relevance measure $\mathbf{R}_{II}$.

5.2.3 HUMAN EVALUATION EXPERIMENTS

In order to obtain a more accurate estimate of the real semantic precision, we performed a rating experiment with human evaluators. We chose the 25 most relevant images[1] from the test set and retrieved their 10 nearest neighbors as determined by OASIS. We excluded query-images which contained porn, racy or duplicates in their 10 nearest neighbors. We also selected randomly a set of 10 negative images p^- that were chosen for each of the query images p such that $\mathbf{R}_{II}(p,p^-)=0$. These negatives were then randomly mixed with the 10 nearest neighbors.

All 25 query images were presented to twenty human evaluators, asking them to mark which of the 20 candidate images are *semantically relevant* to the query image.[2] Evaluators were volunteers

1. The overall relevance of an image was estimated as the sum of relevances of the image with respect to all queries.
2. The description of the task as given to the evaluators is provided in Appendix A.

selected from a pool of friends and colleagues, many of which had experience with search or machine vision problems. We collected the ratings on the positive images and calculated the precision at top k.

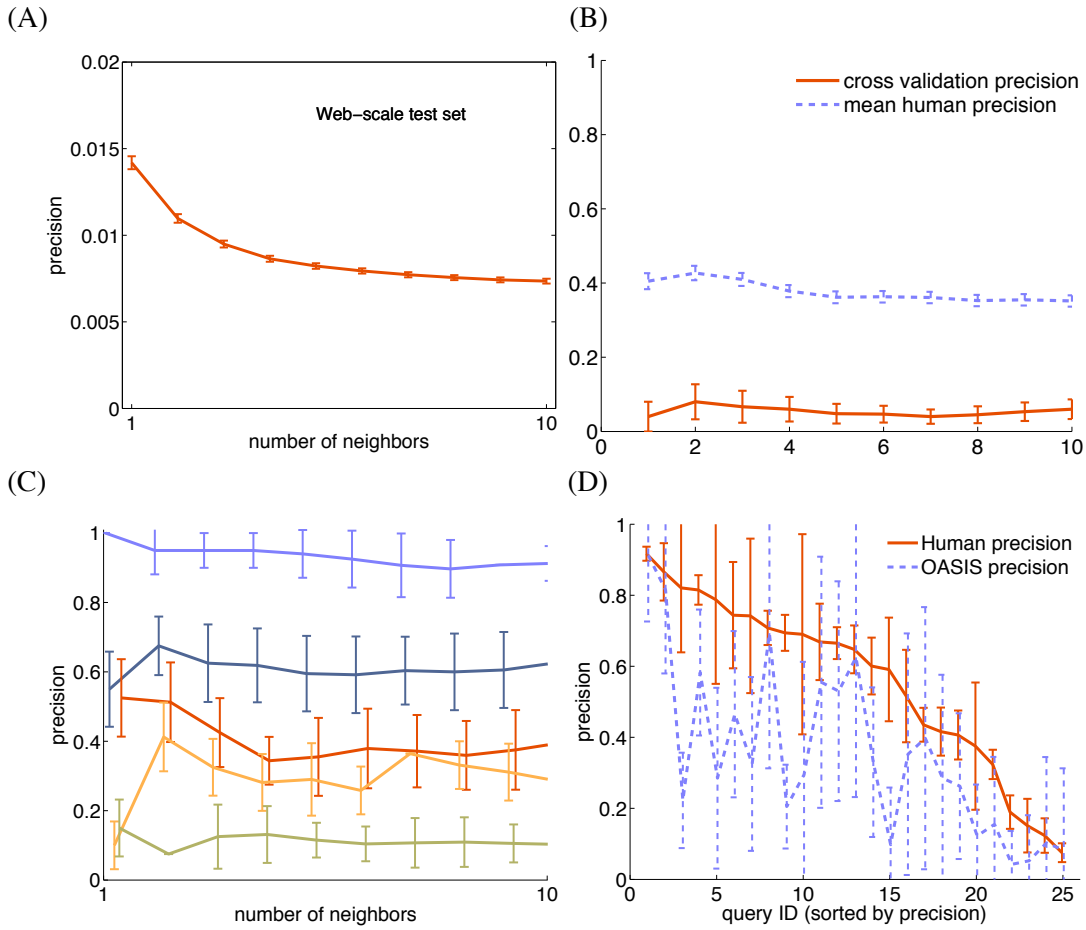

Figure 3: **(A)** Precision at top k as a function of k neighbors computed against $\mathbf{R}_{II}$ ($\theta = 0$) for the web-scale test set. **(B)** Precision at top k as a function of k neighbors for the human evaluation subset. **(C)** Mean precision for 5 selected queries. Error bars denote the standard error of the mean. To select the queries for this plot, we first calculated the mean-average precision per query, sorted the queries by their mAP, and selected the queries ranked at position 1, 6, 11, 16, and 21. **(D)** Precision of OASIS and human evaluators, per query, using rankings of all (remaining) human evaluators as a ground truth.

Figure 3(B) shows the average precision across all queries and evaluators. Precision peaks at 42% and reaches 35% at the top 10 ranked image, being significantly higher than the values calculated automatically using $\mathbf{R}_{II}$.

We observed that the variability across different query images was also very high. Figure 3(C) shows the precision for 5 different queries, selected to span the range of average-precision values. The error bars at each curve show the variability in the responses of different evaluators. The

precision of OASIS varies greatly across different queries. Some query images were "easy" for OASIS, yielding high scores from most evaluators, while other queries retrieved images that were consistently found to be irrelevant by most evaluators.

We also compared the magnitude of variability across human evaluators, with variability across queries. We first calculated the mAP from the precision curves of every query and evaluator, and then calculated the standard deviation in the mAP of every evaluator and of every query. The mean standard deviation over queries was 0.33, suggesting a large variability in the difficulty of image queries, as observed in Figure 3(C) . The mean standard deviation over evaluators was 0.25, suggesting that different evaluators had very different notions of what images should be regarded as "semantically similar" to a query image.

Finally, to estimate an "upper bound" on the difficulty of the task, we also computed the precision of the human evaluators themselves. For every evaluator, we used the rankings of all other evaluators as ground truth, to compute his precision. As with the ranks of OASIS, we computed the fraction of evaluators that marked an image as relevant, and repeated this separately for every query and human evaluator, providing a measure of "coherence" per query. Figure 3(D) shows the mean precision obtained by OASIS and human evaluators for every query in our data. For some queries OASIS achieves precision that is very close to that of the mean human evaluator. In many cases OASIS achieves precision that is as good or better than some evaluators.

5.2.4 SPEED AND SCALABILITY

We further studied how the runtime of OASIS scales with the size of the training set. Figure 4 shows that the runtime of OASIS, as found by early stopping on a separate validation set, grows linearly with the train set size. We compare this to the fastest result we found in the literature, based on a fast implementation of LMNN by Weinberger and Saul (2008). LMNN learns a Mahalanobis distance for k-nearest neighbor classification, aiming to have the nearest neighbors of a sample belong to the same class, and samples from different classes separated by a large margin. The LMNN algorithm is known to scale quadratically with the number of objects, although their experiments with MNIST data show that the active set of constraints grows linearly. This could be because MNIST has 10 classes only. In many real world data however, the number of classes typically grows almost linearly with the number of samples.

5.3 Caltech256 Data Set

To compare OASIS with small-scale methods we used the *Caltech256* data set (Griffin et al., 2007). This data set consists of 30607 images that were obtained from Google image search and from *PicSearch.com*. Images were assigned to 257 categories and evaluated by humans in order to ensure image quality and relevance. After we have pre-processed the images as described in Section 3 and filtered images that were too small, we were left with 29461 images in 256 categories. To allow comparisons with other methods in the literature that were not optimized for sparse representation, we also reduced the block vocabulary size d from 10000 to 1000. This processed data is available online at *http://ai.stanford.edu/∼gal/Research/OASIS*.

Using the Caltech256 data set allows us to compare OASIS with existing similarity learning methods. For OASIS, we treated images that have the same labels as similar. The same labels were used for comparing with methods that learn a metric for classification, as described below.

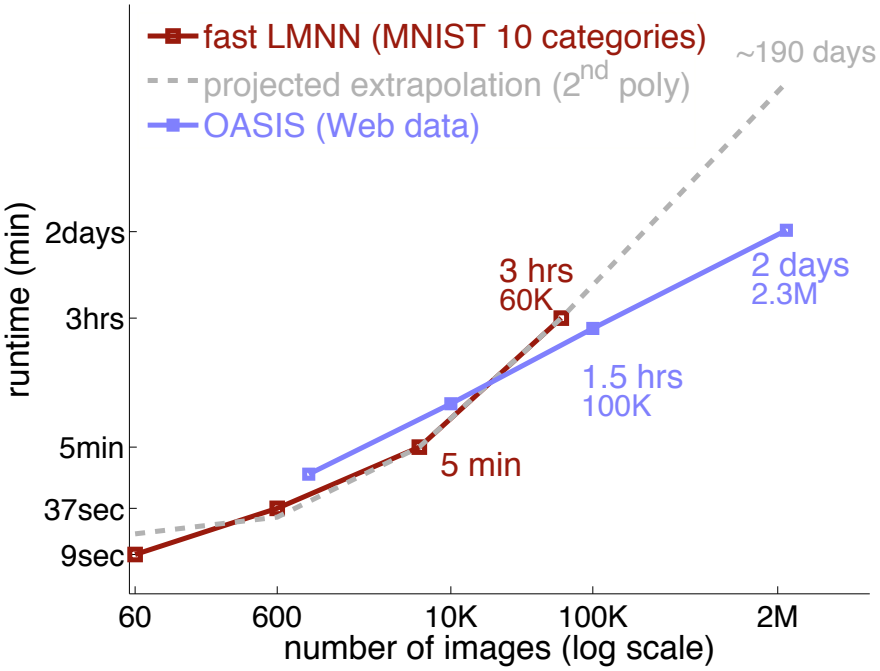

Figure 4: Comparison of the runtime of OASIS and fast-LMNN by Weinberger and Saul (2008), over a wide range of scales. LMNN results (on MNIST data) are faster than OASIS results on subsets of the web data. However LMNN scales quadratically with the number of samples, hence is three times slower on 60K images, and may be infeasible for handling 2.3 million images.

5.3.1 COMPARED METHODS

We compared the following approaches:

1. **OASIS.** - The algorithm described above in Section 2.1.

2. **Euclidean.** - The standard Euclidean distance in feature space. The initialization of OASIS using the identity matrix is equivalent to this distance measure.

3. **MCML** - Metric Learning by Collapsing Classes (Globerson and Roweis, 2006). This approach learns a Mahalanobis distance such that samples from the same class are mapped to the same point. The problem is written as a convex optimization problem, and we have used the gradient-descent implementation provided by the authors.

4. **LMNN** - Large Margin Nearest Neighbor Classification (Weinberger et al., 2006). This approach learns a Mahalanobis distance for k-nearest neighbor classification, aiming to have the k-nearest neighbors of a given sample belong to the same class while examples from different classes are separated by a large margin. As a preprocessing phase, images were projected to a basis of the principal components (PCA) of the data, with no dimensionality reduction, since

this improved the precision results. We also compared with a fast implementation of LMNN, that uses a clever scheme of maintaining a set of active constraints (Weinberger and Saul, 2008). We used the web data discussed above to compare with previously published results obtained with fast-LMNN on MNIST data (see Figure 4).

5. **LEGO** - Online metric learning (Jain et al., 2008a). LEGO learns a Mahalanobis distance in an online fashion using a regularized per instance loss, yielding a positive semidefinite matrix. The main variant of LEGO aims to fit a given set of pairwise distances. We used another variant of LEGO that, like OASIS, learns from relative distances. In our experimental setting, the loss is incurred for same-class examples being more than a certain distance away, and different class examples being less than a certain distance away. LEGO uses the LogDet divergence for regularization, as opposed to the Frobenius norm used in OASIS.

For all these approaches, we used an implementation provided by the authors. Algorithms were implemented in Matlab, with runtime bottlenecks implemented in C for speedup (except LEGO). We test below two variants of OASIS applied to the Caltech256 data set: a pure Matlab implementation, and one that has a *C* components. We used a C^{++} implementation of OASIS for the web-scale experiments described below.

We have also experimented with the methods of Xing et al. (2003) and RCA (Bar-Hillel et al., 2003). We found the method of Xing et al. (2003) to be too slow for the sets in our experiments. RCA is based on a per-class eigen decomposition that is not well defined when the number of samples is smaller than the feature dimensionality. We therefore experimented with a preprocessing phase of dimensionality reduction followed by RCA, but results were inferior to other methods and were not included in the evaluations below. RCA also did not perform well when tested on the full data, where dimensionality was not a problem, possibly because it is not designed to handle well sparse data.

5.3.2 EXPERIMENTAL PROTOCOL

We tested all methods on subsets of classes taken from the Caltech256 repository. Each subset was built such that it included semantically diverse categories, spanning the full range of classification difficulty, as measured by Griffin et al. (2007). We used subsets of sizes 10, 20, 50 and 249 classes (we used 249 classes since classes 251-256 are strongly correlated with other classes, and since class 129 did not contain enough large images). The full lists of categories in each set are given in Appendix B. For each set, images from each class were split into a training set of 40 images and a test set of 25 images, as proposed by Griffin et al. (2007).

We used cross-validation to select the values of hyper parameters for all algorithms except MCML. Models were learned on 80% of the training set (32 images), and evaluated on the remaining 20%. Cross validation was used for setting the following hyper parameters: the early stopping time for OASIS; the ω parameter for LMNN ($\omega \in \{0.125, 0.25, 0.5\}$), and the regularization parameter η for LEGO ($\eta \in \{0.02, 0.08, 0.32\}$). We found that LEGO was usually not sensitive to the choice of η, yielding a variance that was smaller than the variance over different cross-validation splits. Results reported below were obtained by selecting the best value of the hyper parameter and then training again on the full training set (40 images). For MCML, we used the default parameters supplied with the code from the authors, since its very long run time and multiple parameters made it non-feasible to tune hyper parameters on this data.

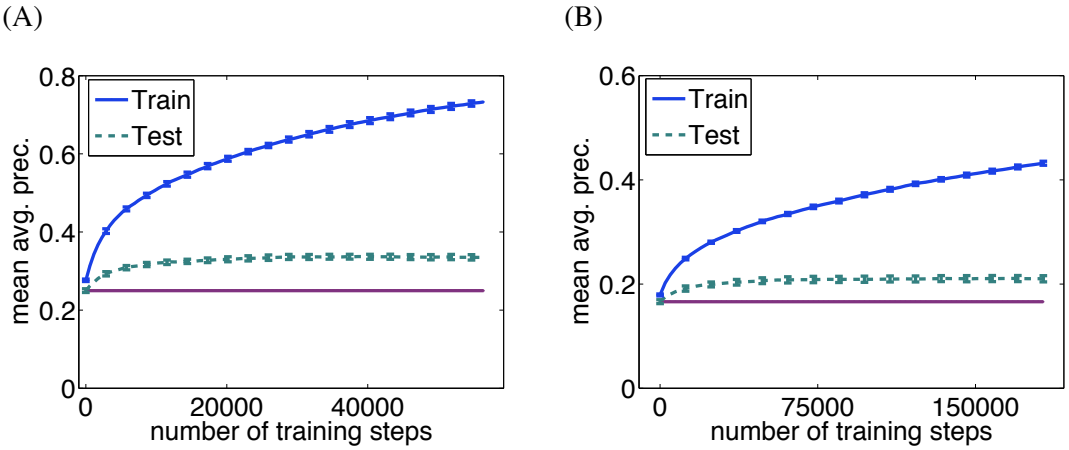

Figure 5: Mean average precision of OASIS as a function of the number of training steps. Error bars represent standard error of the mean over 5 selections of training (40 images) and test (25 images) sets. Performance is compared with a baseline obtained using the naïve Euclidean metric on the feature vector. C=0.1 **(A)** 10 classes. Test performance saturates around 30K training steps, while going over all triplets would require 2.8 million steps. **(B)** 20 classes.

5.3.3 RESULTS

Figure 5 traces the mean average precision over the training and the test sets as it progresses during learning. For the 10 classes task, precision on the test set saturates early (around 35K training steps), and then decreases very slowly.

Figure 6 and Table 4 compare the precision obtained with OASIS, with four competing approaches, as described above (Section 5.3.1). OASIS achieved consistently superior results throughout the full range of k (number of neighbors) tested, and on all four sets studied. Interestingly, we found that LMNN performance on the training set was often high, suggesting that it overfits the training set. This behavior was also noted by Weinberger et al. (2006) in some of their experiments.

OASIS achieves superior or equal performance, with a runtime that is faster by about two orders of magnitudes than MCML, and about one order of magnitude faster than LMNN. The run time of OASIS and LEGO was measured until the point of early stopping.

Table 5 shows the total CPU time in minutes for training each of the algorithms compared (measured on a standard 1.8GHz Intel Xeon CPU). For the purpose of a fair comparison with competing approaches, we tested two implementations of OASIS: The first was fully implemented Matlab. The second had the core of the algorithm implemented in C and called from Matlab.[3] LMNN code and MCML code were supplied by the authors and implemented in Matlab, with core parts implemented in C. LEGO code was supplied by the authors and fully implemented in Matlab.

Importantly, we found that Matlab does not make full use of the speedup that can be gained by sparse image representation. As a result, the C/C^{++} implementation of OASIS that we tested is significantly faster.

5.4 Parallel Training

We presented OASIS as optimizing an objective function at each step. Since OASIS is based on the PA framework, it is also known to minimize a global objective of the form

$$\|\mathbf{W}\|_{Fro}^2 + C \sum_i l_i$$

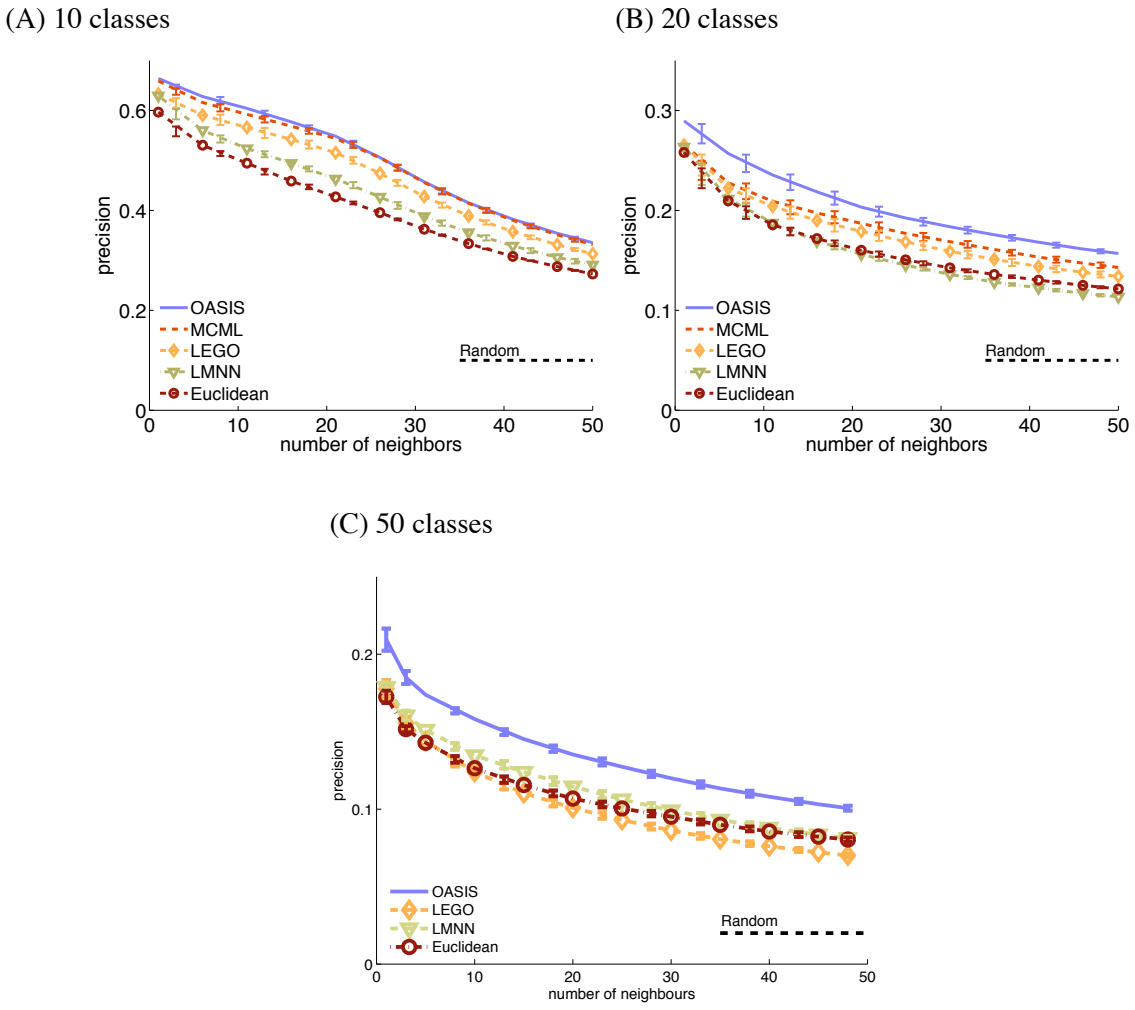

Figure 6: Comparison of the performance of OASIS, LMNN, MCML, LEGO and the Euclidean metric in feature space. Each curve shows the precision at top k as a function of k neighbors. The results are averaged across 5 train/test partitions (40 training images, 25 test images), error bars are standard error of the means (s.e.m.), black dashed line denotes chance performance. **(A)** 10 classes. **(B)** 20 classes. **(C)** 50 classes.

as shown by Crammer et al. (2006) This objective is convex since the losses l_i are linear in $\mathbf{W}$. For such convex functions, it is guaranteed that any linear combination of solutions is superior than each of the individual solutions. This property suggests another way to speed up training, by training multiple rankers in parallel and averaging the resulting models. Each of the individual models can be trained with a smaller number of iterations. Note however that there is no guarantee that the total CPU time is improved.

Figure 7 demonstrates this approach; we trained 5 or 10 rankers in parallel and plot the test set mean average precision as a function of the number of training iterations.

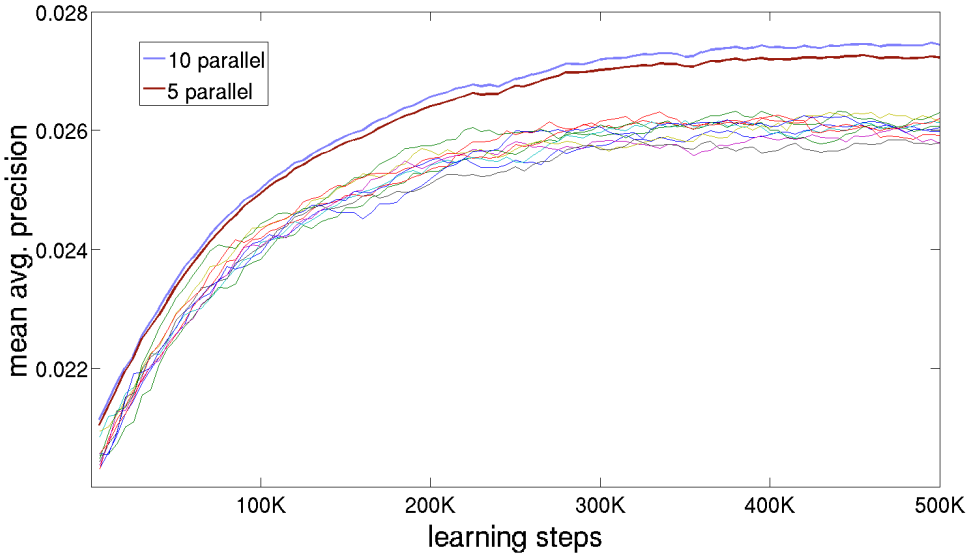

Figure 7: Comparing individual rankers and a linear combination of 5 and 10 rankers. Results are for an experiment with 249 classes of the Caltech256 data set.

.

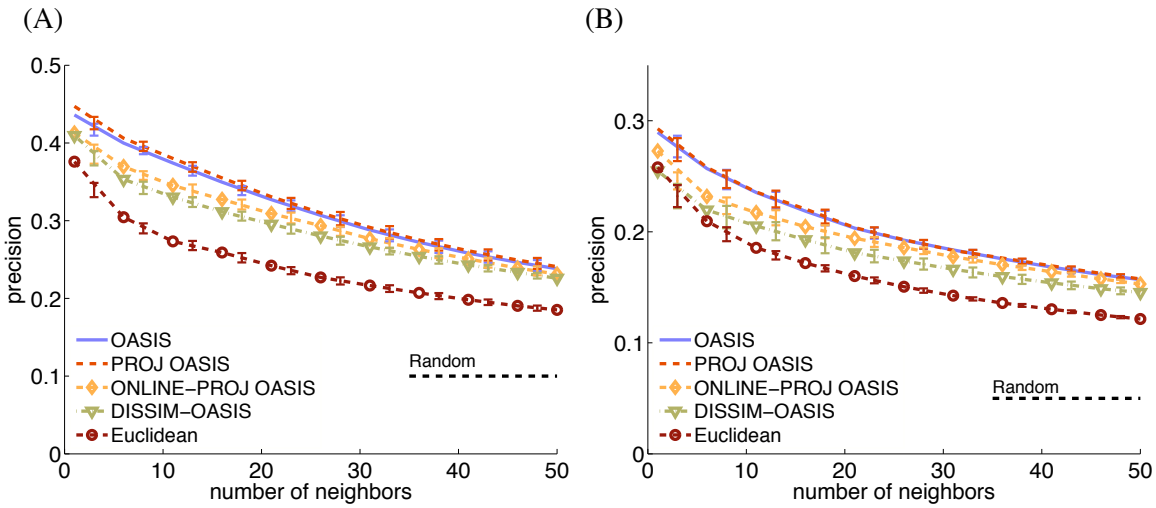

Figure 8: Comparison of Symmetric variants of OASIS. **(A)** 10 classes. **(B)** 20 classes.

6. Symmetry and Positivity

The similarity matrix **W** learned by OASIS is not guaranteed to be positive or even symmetric. Some applications, like ranking images by semantic relevance to a given image query are known to be non-symmetric when based on human judgement (Tversky, 1977). However, in some applications symmetry or positivity constraints reflect a prior knowledge that may help avoiding overfitting.

Furthermore positive $\mathbf{W}$ impose a Mahalanobis metric over the data, that can be further factorized to extract a linear projection of the data into a Euclidean space: $\mathbf{x}^T\mathbf{W}\mathbf{y} = (\mathbf{A}\mathbf{x})^T(\mathbf{A}\mathbf{y})$ such that $\mathbf{A}^T\mathbf{A} = \mathbf{W}$. Such projection $\mathbf{A}$ of the data can be useful for visualization and exploratory analysis of data for example in scientific applications. We now discuss variants of OASIS that learn a symmetric or positive matrices.

6.1 Symmetric Similarities

A simple approach to enforce symmetry is to project the OASIS model $\mathbf{W}$ onto the set of symmetric matrices $\mathbf{W}' = sym(\mathbf{W}) = \frac{1}{2}\left(\mathbf{W}^T + \mathbf{W}\right)$. The update procedure then consists of a series of gradient steps followed by projection to the feasible set (of symmetric matrices). This approach is sometimes called projected gradient, and we denote it here *Online-Proj-Oasis*. Alternatively, projection can also be applied after learning is completed (denoted here *Proj-Oasis*).

Alternatively, the asymmetric score function $S_{\mathbf{W}}(p_i, p_j)$ in the loss l_W can be replaced with a symmetric score

$$S'_{\mathbf{W}}(p_i, p_j) \equiv -(p_i - p_j)^T \mathbf{W} (p_i - p_j) .$$

and derive an OASIS-like algorithm (which we call *Dissim-Oasis*). The optimal update for this loss has a symmetric gradient $\mathbf{V}'^i = (p_i - p_i^+)(p_i - p_i^+)^T - (p_i - p_i^-)(p_i - p_i^-)^T$. Therefore, if $\mathbf{W}^0$ is initialized with a symmetric matrix (for example, the identity matrix) all $\mathbf{W}^i$ are guaranteed to remain symmetric. *Dissim-Oasis* is closely related to LMNN (Weinberger et al., 2006). This can be seen be casting the batch objective of LMNN, into an online setup, which has the form $err(W) = -\omega \cdot S'_{\mathbf{W}}(p_i, p_i^+) + (1-\omega) \cdot l'_{\mathbf{W}}(p_i, p_i^+, p_i^-)$. This online version of LMNN becomes equivalent to *D*issim-Oasis for $\omega = 0$.

Figure 8 compares the precision of the different symmetric methods with the original OASIS. All symmetric variants performed slightly worse, or equal to the original asymmetric OASIS. Asymmetric OASIS is also twice faster than DISSIM-OASIS. The precision of *Proj-Oasis* was equivalent to that of OASIS. This was because the asymmetric OASIS learning rule actually converged to an almost-symmetric model (as measured by a symmetry index $\rho(\mathbf{W}) = \frac{\|sym(\mathbf{W})\|_2}{\|\mathbf{W}\|_2} = 0.94$).

6.2 Positive Similarity

Most similarity learning approaches focus on learning metrics. In the context of OASIS, when $\mathbf{W}$ is positive semi definite (PSD), it defines a Mahalanobis distance over the images. The matrix square-root of $\mathbf{W}$, $\mathbf{A}^T\mathbf{A} = \mathbf{W}$ can then be used to project the data into a new space in which the Euclidean distance is equivalent to the $\mathbf{W}$ distance in the original space.

We experimented with positive variants of OASIS, where we repeatedly projected the learned model onto the set of PSD matrices, once every t iterations. Projection is done by taking the eigen decomposition $\mathbf{W} = \mathbf{V} \cdot \mathbf{D} \cdot \mathbf{V}^T$ where $\mathbf{V}$ is the eigenvector matrix and $\mathbf{D}$ is the diagonal eigenvalues matrix limited to positive eigenvalues. Figure 9 traces precision on the test set throughout learning for various values of t.

The effect of positive projections is complex. First, continuously projecting once every few steps helps to reduce overfitting, as can be observed by the slower decline of the blue curve (upper smooth curve) compared to the orange curve (lowest curve). However, when projection is performed after many steps (instead of continuously), performance of the projected model actually outperforms the continuous-projection model (upper jittery curve). The reason for this effect is likely to be that the

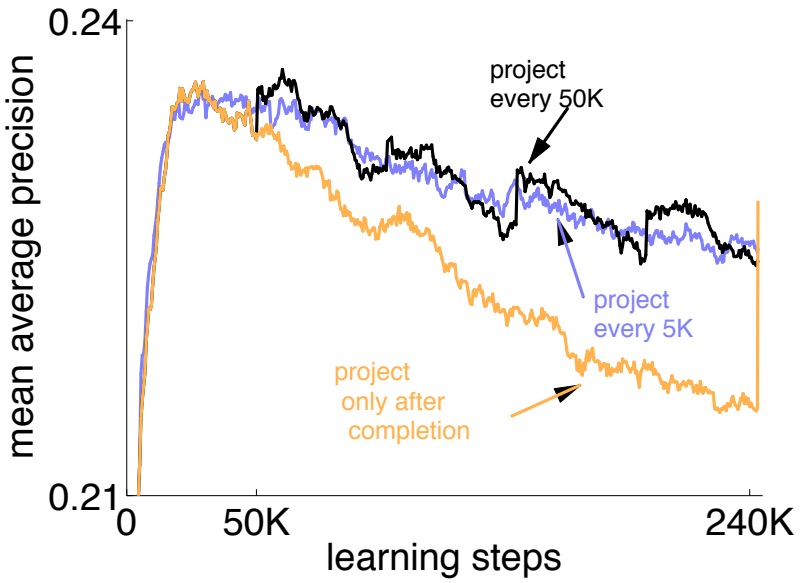

Figure 9: Mean average precision (mAP) during training for three PSD projection schemes, using the set of 20 classes from caltech256.

estimates of the positive sub-space are very noisy when only based on a few samples (see also Chen et al. 2009, Section 2.1). Indeed, accurate estimation of the negative subspace is known to be a hard problem, because small perturbations can turn a negative but small eigenvalue, into a small but positive one. As a result, the set of vectors selected based on having positive eigenvalues, is highly variable. We found that this effect was so strong, that the optimal projection strategy is to avoid projection throughout learning completely. Instead, projecting into PSD after learning (namely, after a model was chosen using early stopping) provided the best performance in our experiments.

An interesting alternative to obtain a PSD matrix was explored by Kulis et al. (2009) and Jain et al. (2008a). Using a LogDet divergence between two matrices $D_{ld}(X,Y) = tr(XY^{-1}) - log(det(XY^{-1}))$ ensures that, given an initial PSD matrix, all subsequent matrices will be PSD as well. It would be interesting to test the effect of using LogDet regularization in the OASIS setup.

7. Discussion

We have presented OASIS, a scalable algorithm for learning image similarity that captures both semantic and visual aspects of image similarity. Three key factors contribute to the scalability of OASIS. First, using a large margin online approach allows training to converge even after seeing a small fraction of potential pairs. Second, the objective function of OASIS does not require the similarity measure to be necessarily a metric during training, although it appears to naturally converge to a symmetric solution. Finally, we use a sparse representation of low level features which allows computing scores very efficiently.

We found that OASIS performs well in a wide range of scales: from problems with thousands of images, where it slightly outperforms existing metric-learning approaches, to large web-scale problems, where it achieves high accuracy, as estimated by human evaluators.

OASIS differs from previous methods in that the similarity measure that it learns is not forced to be a metric, or even symmetric. When the number of available samples is small, it is useful to add constraints that reflect prior knowledge on the type of similarity measure expected to be learned. However, we found that these constraints were not helpful even for problems with a few hundreds of samples. Interestingly, human judgements of pairwise similarity are known to be asymmetric, a property that can be easily captured by an OASIS model.

OASIS learns a class-independent model: it is not aware of which queries or categories were shared by two similar images. As such, it is more limited in its descriptive power and it is likely that class-dependent similarity models could improve precision. On the other hand, class-independent models could generalize to handle classes that were not observed during training, as in transfer learning. Large scale similarity learning, applied to images from a large variety of classes, could therefore be a useful tool to address real-world problems with a large number of classes.

Appendix A. Human Evaluation

The following text was given as instructions to human evaluators when judging the relevance of images to a query image.

```
Scenario:
     A user is searching images to use in a presentation he/she plans to
  give.  The user runs a standard image search, and selects an image,
  the ''query image''.  The user then wishes to refine the search and
  look for images that are SEMANTICALLY similar to the query image.
     The difficulty lies, in the definition of ''SEMANTICALLY''. This can
  have many interpretations, and you should take that into account.
     So for instance, if you see an image of a big red truck, you can
  interpret the user intent (the notion of semantically similar) in
  various ways:
    - any big red truck
    - any red truck
    - any big truck
    - any truck
    - any vehicle
  You should interpret ''SEMANTICALLY'' in a broad sense rather than
  in a strict sense but feel free to draw the line yourself (although
```

```
  be consistent).

Your task:
     You will see a set of query images on the left side of the screen,
  and a set of potential candidate matches, 5 per row, on the
  right. Your job is to decide for each of the candidate images if it
  is a good semantic match to the query image or not. The default is
  that it is NOT a good match. Furthermore, if for some reason you
  cannot make-up your mind, then answer ''can't say''.
```

Appendix B. Caltech256 Class Sets

- **10 classes**: *bear, skyscraper, billiards, yo-yo, minotaur, roulette-wheel, hamburger, laptop-101, hummingbird, blimp*.
- **20 classes***: airplanes-101, mars, homer-simpson, hourglass, waterfall, helicopter-101, mountain-bike starfish-101, teapot, pyramid, refrigerator, cowboy-hat, giraffe, joy-stick, crab-101, bird-bath, fighter-jet tuning-fork, iguana, dog*.
- **50 classes***: car-side-101, tower-pisa, hibiscus, saturn, menorah-101, rainbow, cartman, chandelier-101, backpack, grapes, laptop-101, telephone-box, binoculars, helicopter-101, paper-shredder, eiffel-tower, top-hat, tomato, star-fish-101, hot-air-balloon, tweezer, picnic-table, elk, kangaroo-101, mattress, toaster, electric-guitar-101, bathtub, gorilla, jesus-christ, cormorant, mandolin, light-house, cake, tricycle, speed-boat, computer-mouse, superman, chimp, pram, fried-egg, fighter-jet, unicorn, greyhound, grasshopper, goose, iguana, drinking-straw, snake, hot-dog*.
- **249 classes***: classes 1-250, excluding class 129 (leopards-101), which had less than 65 large enough images*.

Abstract

We present a continuous time Bayesian network reasoning and learning engine (CTBN-RLE). A continuous time Bayesian network (CTBN) provides a compact (factored) description of a continuous-time Markov process. This software provides libraries and programs for most of the algorithms developed for CTBNs. For learning, CTBN-RLE implements structure and parameter learning for both complete and partial data. For inference, it implements exact inference and Gibbs and importance sampling approximate inference for any type of evidence pattern. Additionally, the library supplies visualization methods for graphically displaying CTBNs or trajectories of evidence.

Keywords: continuous time Bayesian networks, C++, open source software

1. Introduction

Continuous time Bayesian networks (CTBNs) represent a continuous-time finite-state Markov process compactly factored according to a graph (Nodelman et al., 2002). The initial distribution of the process is represented as a Bayesian network. The dynamics of the process is also factorized according to a directed graph, but this graph may contain cycles. The edges in this second graph represent causal influence between variables of the system.

CTBNs compactly represent the dynamics differently than models in queueing theory (Bolch et al., 1998), Petri nets (Petri, 1962), or matrix diagrams (Ciardo and Miner, 1999). The representation and algorithms developed so far for CTBNs emphasize reasoning about the transient properties over the steady-state of the system. Unfortunately, previously there were no commonly available software packages implementing CTBN algorithms. Their implementation requires a few critical numerical algorithms, thus making it difficult to quickly try the representation without prior experience.

This software package aims to reduce this barrier to entry by supplying our implementations of these methods in a complete object-oriented design. The software does not require any external libraries. It is implemented in C++ with demonstration programs for common functionality and a documented interface for users to develop their own programs. The class hierarchy was designed with extensions to allow for further innovation.

2. Continuous Time Bayesian Networks

The dynamics of a continuous-time n-state Markov process are often described with an n-by-n intensity (or rate) matrix, Q with elements q_{ij}. The diagonal elements are non-positive and correspond to the parameters of the exponential distributions describing the duration of time the process stays in each state. Therefore the expected duration in state i is $\frac{1}{-q_{ii}}$. All other elements are non-negative and each row sums to zero. The probability of transitioning from state i to state j is proportional to q_{ij}.

A continuous time Bayesian network (CTBN) consists of a set of variables, $\mathcal{X}$, an initial distribution P_0 over $\mathcal{X}$ specified as a Bayesian network, and a graph-factored model of the dynamics of the system which is composed of two parts: (1) a directed (possibly cyclic) graph $\mathcal{G}$ over $\mathcal{X}$ and (2) conditional intensities $\mathbf{Q}_{X|\mathbf{U}}$ for each variable $X \in \mathcal{X}$ with parent set $\mathbf{U}$ in the graph $\mathcal{G}$. $\mathbf{Q}_{X|\mathbf{U}}$ is defined as a set of intensity matrices $\mathbf{Q}_{X|\mathbf{u}}$ for each assignment $\mathbf{u}$ to the variables $\mathbf{U}$. At any instant, the evolution of variable X is governed by the intensity matrix $\mathbf{Q}_{X|\mathbf{u}}$ if $\mathbf{u}$ is the current assignment to the parents of X.

3. Engine Components

In terms of data structures, the library supplies classes for storing and efficiently scanning multivariate trajectories, for representing both the initial distribution (as a Bayesian network) and the dynamics (as a directed graph with associated conditional rate matrices) of a CTBN, for representing the associated sufficient statistics, and for drawing samples from the CTBN process.

3.1 Inference Methods

Inference for CTBNs can take a number of forms. The common three types of queries are all implemented and additional query types can be added (through subclassing) without knowledge of the details of the inference algorithms. In particular, code is supplied for

- querying the marginal distribution of a variable at a particular time (filtering or smoothing),
- querying the expected number of transitions for a variable during an interval of time, and
- querying the expected amount of time a variable stayed in a particular state during an interval.

All are conditioned on a (possibly incomplete) trajectory of events (transitions of the states of the variables of the process). The latter two represent the calculations necessary to compute expected sufficient statistics.

Exact inference (which takes exponential time in terms of the number of variables) is implemented. Additionally, two approximate inference methods based on sampling are also implemented: Gibbs sampling (El-Hay et al., 2008) and importance sampling (Fan and Shelton, 2008).

3.2 Learning

All learning methods estimate both the dynamics graph and the Bayesian network of the initial distribution. For the latter, this is just standard Bayesian network learning which exists in other packages; however, we supply our implementation here for simplicity and to avoid relying on other software packages.

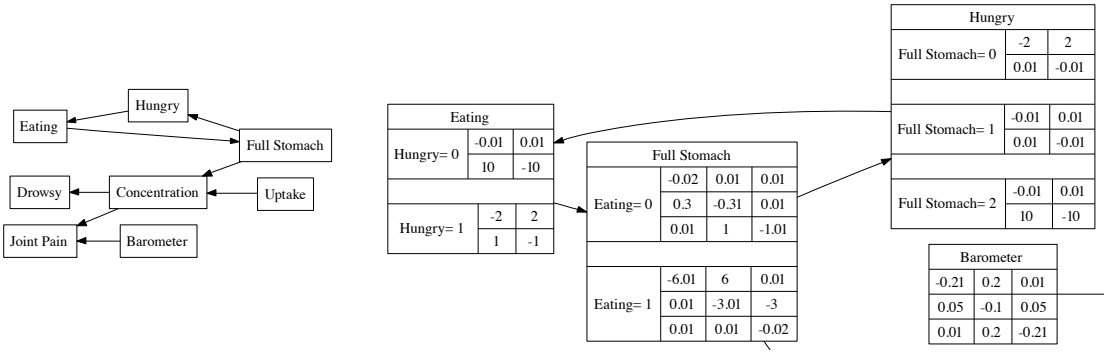

Figure 1: (Left) Automatic layout of the drug effect network without parameters. (Right) Portion of automatic layout with parameters.

Maximum likelihood parameter learning is implemented both for complete data (Nodelman et al., 2003) and for incomplete data (Nodelman et al., 2005) via the expectation-maximization algorithm. Structure learning is also implemented for both complete and incomplete data. The latter represents an implementation of structural expectation maximization. Two structure searches are available: a brute force search that tries all parent sets up to a certain size (not possible for the initial distribution due to acyclic constraints) and a graph edit search that makes local changes to the graph.

3.3 Modularity

Any supplied (or user-defined) inference method can be used in expectation-maximization and structural expectation maximization. Different proposal distributions for importance sampling can be added through simple subclassing. Similarly, the code allows for the construction of CTBNs from any underlying process type. As an example, we define "toggle" variables (only the *change* of state has meaning) through a very short subclass that implements the necessary parameter tieing. This new process can be mixed freely with other processes to create CTBNs of mixed node types.

3.4 Visualization

Two visualization tools are supplied. The first converts a CTBN into a text file suitable to be read by the open source package `graphviz` which can then layout the CTBN in a variety of formats. Figure 1 shows the output of this automatic visualization on the drug effect network from Nodelman et al. (2002). Additionally, either an postscript or text visualization of a trajectory can be automatically generated. Figure 2 shows these outputs for a partially observed trajectory drawn from the same drug effect network.

Abstract

In recent years, a fundamental problem structure has emerged as very useful in a variety of machine learning applications: Submodularity is an intuitive diminishing returns property, stating that adding an element to a smaller set helps more than adding it to a larger set. Similarly to convexity, submodularity allows one to efficiently find provably (near-) optimal solutions for large problems. We present SFO, a toolbox for use in MATLAB or Octave that implements algorithms for minimization and maximization of submodular functions. A tutorial script illustrates the application of submodularity to machine learning and AI problems such as feature selection, clustering, inference and optimized information gathering.

1. Introduction

Convex optimization has become a powerful tool in machine learning: Surprisingly, many problems that intuitively require the optimization of highly multi-modal objectives, such as clustering and non-linear classification, can be reduced to convex programs, allowing efficient and optimal solution. More formally, they require finding a solution $\mathbf{x}^* \in \mathbb{R}^d$:

$$\mathbf{x}^* = \operatorname*{argmin}_{\mathbf{x}} g(\mathbf{x}) \text{ s.t. } \mathbf{x} \in \mathfrak{F},$$

where g is a convex function, and $\mathfrak{F} \subseteq \mathbb{R}^d$ is a (convex) set of feasible solutions.

However, many optimization problems in machine learning, such as feature selection, structure learning and inference in discrete graphical models, require finding solutions to *combinatorial* optimization problems: They can be reduced to the problem

$$\mathcal{A}^* = \operatorname*{argmin}_{\mathcal{A} \subseteq \mathcal{V}} F(\mathcal{A}) \text{ s.t. } \mathcal{A} \in \mathfrak{F},$$

where F is a set function $F : 2^{\mathcal{V}} \to \mathbb{R}$ defined over a finite set $\mathcal{V}$, and $\mathfrak{F} \subseteq 2^{\mathcal{V}}$ is a collection of feasible subsets of $\mathcal{V}$, for example, all sets of size at most k, $\mathfrak{F} = \{\mathcal{A} \subseteq \mathcal{V} : |\mathcal{A}| \leq k\}$.

In many machine learning problems, the function F satisfies *submodularity*, an intuitive diminishing returns property, stating that adding an element to a smaller set helps more than adding it to a larger set. Formally, for all $\mathcal{A} \subseteq \mathcal{B} \subseteq \mathcal{V}$ and $s \in \mathcal{V} \setminus \mathcal{B}$ it must hold that $F(\mathcal{A} \cup \{s\}) - F(\mathcal{A}) \geq F(\mathcal{B} \cup \{s\}) - F(B)$. Similarly to convexity, submodularity allows one to efficiently find provably (near-) optimal solutions for large problems. Interestingly, for submodular functions, guarantees can be obtained both for minimization and for maximization problems. This is important, since applications require both minimization (e.g., in clustering, inference and structure learning) and maximization (e.g., in feature selection and optimized information gathering). We present SFO, a

toolbox[1] for use in MATLAB or Octave that implements various algorithms for *minimization and maximization* of submodular functions. Examples illustrate the application of submodularity to machine learning and AI problems such as clustering (Narasimhan et al., 2005), inference in graphical models (Kolmogorov and Zabih, 2004) and optimized information gathering (Krause et al., 2006).

2. Implementation of Submodular Functions

The SFO toolbox includes several examples of submodular functions. It is also easily extendable with additional functions. The ground set $\mathcal{V}$ is implemented as a MATLAB array. Submodular functions are implemented as MATLAB objects, inheriting from sfo_fn. The following shows example code defining the submodular function

$$F(\mathcal{A}) = I(\mathcal{X}_\mathcal{A}; \mathcal{X}_{\mathcal{V}\setminus\mathcal{A}}) = H(\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}}) - H(\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}} \mid \mathcal{X}_\mathcal{A}),$$

that is, the mutual information between a set of random variables $\mathcal{X}_\mathcal{A}$ and its complement $\mathcal{X}_{\mathcal{V}\setminus\mathcal{A}}$, based on a joint multivariate normal distribution $P(\mathcal{X}_\mathcal{V} = \mathbf{x}_\mathcal{V}) = \mathcal{N}(\mathbf{x}_\mathcal{V}; 0, \Sigma)$ with covariance matrix $\Sigma \in \mathbb{R}^{100\times 100}$:

```
V = 1:100;
F = sfo_fn_mi(Sigma,V);
F(1:3) % evaluate F on set A=[1,2,3]
```

This objective function has been used for experimental design in Gaussian processes (Krause et al., 2008), structure learning (Narasimhan and Bilmes, 2004) and clustering (Narasimhan et al., 2005). Often, algorithms require computing marginal increments

$$\delta_s^+(\mathcal{A}) = F(\mathcal{A}\cup\{s\}) - F(\mathcal{A}) \text{ and } \delta_s^-(\mathcal{A}) = F(\mathcal{A}\setminus\{s\}) - F(\mathcal{A}),$$

that is, computing the change in submodular value by adding (removing) an element s from a set $\mathcal{A}$. Often, computing $F(\mathcal{A}\cup\{s\})$ (or $F(\mathcal{A}\setminus\{s\})$) is more efficient when $F(\mathcal{A})$ has already been computed. E.g., for mutual information, incrementally computing $F(\mathcal{A}\cup\{s\})$ requires up-/downdating of the Cholesky decomposition of covariance matrix $\Sigma_{\mathcal{A}\mathcal{A}}$. To speed up computation, the submodular function objects in SFO support methods inc and dec:

```
F = init(F,1:5); % cache computation of F(1:5)
inc(F,1:5,9) % efficient evaluation of F([1:5 9])
dec(F,1:5,3) % efficient evaluation of F([1:2 4:5])
```

The SFO toolbox implements several other examples of submodular functions, including

sfo_fn_entropy	Entropy of multivariate Gaussians
sfo_fn_infogain	Information gain for multivariate Gaussians
sfo_fn_mi	Mutual information in multivariate Gaussians
sfo_fn_varred	Variance reduction in multivariate Gaussians
sfo_fn_detect	Improvement in detection performance
sfo_fn_cutfun	Cut function in graphs
sfo_fn_ising	Energy in ising models with attractive potentials

1. The toolbox is available at `http://www.submodularity.org`.

Creating submodular functions from other submodular functions is also possible, using sfo_fn_lincomb for nonnegative linear combinations, and sfo_fn_trunc for truncation. Custom submodular functions can be used either by inheriting from sfo_fn, or by using the sfo_fn_wrapper function, which wraps a pointer to an anonymous function in a submodular function object. The following example wraps an anonymous function fn which computes, for any set of integers $\mathcal{A}$, the number of distinct remainders modulo 5:

```
fn = @(A) length(unique(mod(A,5)));
F = sfo_fn_wrapper(fn);
F([1 6]) % returns 1
F([1:10]) % returns 5
```

3. Implemented Algorithms for Submodular Function Optimization

SFO implements various algorithms for (constrained) maximization and minimization of submodular functions. Their use is demonstrated in sfo_tutorial and sfo_tutorial_octave.

Minimization of Submodular Functions

- sfo_min_norm_point: The minimum norm point algorithm of Fujishige (2005) for solving $\mathcal{A}^* = \operatorname{argmin}_{\mathcal{A}\subseteq\mathcal{V}} F(\mathcal{A})$ for general submodular functions.
- sfo_queyranne: Algorithm of Queyranne (1995) solving $\mathcal{A}^* = \operatorname{argmin}_{\mathcal{A}\subseteq\mathcal{V}:0<|\mathcal{A}|<|\mathcal{V}|} F(\mathcal{A})$ for symmetric submodular functions (i.e., $F(\mathcal{A}) = F(\mathcal{V}\setminus\mathcal{A})$ for all sets $\mathcal{A}$).
- sfo_ssp: The submodular-supermodular procedure of Narasimhan and Bilmes (2006) for (heuristically) minimizing the difference between two submodular functions $\mathcal{A}^* = \operatorname{argmin}_{\mathcal{A}\subseteq\mathcal{V}} F_1(\mathcal{A}) - F_2(\mathcal{A})$.
- sfo_s_t_min_cut: Solves $\mathcal{A}^* = \operatorname{argmin}_{\mathcal{A}\subseteq\mathcal{V}} F(\mathcal{A})$ s.t. $s \in \mathcal{A}, t \notin \mathcal{A}$.
- sfo_greedy_splitting: The algorithm of Zhao et al. (2005) for submodular clustering

Maximization of Submodular Functions

- sfo_greedy_lazy: The greedy algorithm of Nemhauser et al. (1978) for constrained maximization / coverage, using the lazy evaluation technique of Minoux (1978).
- sfo_cover: Greedy coverage algorithm using lazy evaluations.
- sfo_celf: The CELF algorithm for approximately solving $\mathcal{A}^* = \operatorname{argmax}_{\mathcal{A}} F(\mathcal{A})$ s.t. $C(\mathcal{A}) \leq B$, for linear cost function C (Leskovec et al., 2007).
- sfo_ls_lazy: The (deterministic) local search algorithm of Feige et al. (2007) for unconstrained maximization of nonnegative submodular functions, using lazy evaluations.
- sfo_pspiel: The PSPIEL algorithm of Krause et al. (2006). PSPIEL approximately solves $\mathcal{A}^* = \operatorname{argmax}_{\mathcal{A}} F(\mathcal{A})$ s.t. $C(\mathcal{A}) \leq B$, where $C(\mathcal{A})$ is the cost of a cheapest path connecting the nodes $\mathcal{A}$ in a graph.
- sfo_saturate: The SATURATE algorithm of Krause et al. (2008) for approximately solving the robust optimization problem $\mathcal{A}^* = \operatorname{argmax}_{|\mathcal{A}|\leq k} \min_i F_i(\mathcal{A})$.
- sfo_balance: The ESPASS algorithm for approximately solving the optimization problem $\max_{|\mathcal{A}_1\cup\cdots\cup\mathcal{A}_k|\leq m} \min_i F(\mathcal{A}_i)$ (Krause et al., 2009).
- sfo_max_dca_lazy: The Data Correcting algorithm for maximizing general (not necessarily nondecreasing) submodular functions (Goldengorin et al., 1999).

Abstract

We extend the well-known BFGS quasi-Newton method and its memory-limited variant LBFGS to the optimization of nonsmooth convex objectives. This is done in a rigorous fashion by generalizing three components of BFGS to subdifferentials: the local quadratic model, the identification of a descent direction, and the Wolfe line search conditions. We prove that under some technical conditions, the resulting subBFGS algorithm is globally convergent in objective function value. We apply its memory-limited variant (subLBFGS) to L_2-regularized risk minimization with the binary hinge loss. To extend our algorithm to the multiclass and multilabel settings, we develop a new, efficient, exact line search algorithm. We prove its worst-case time complexity bounds, and show that our line search can also be used to extend a recently developed bundle method to the multiclass and multilabel settings. We also apply the direction-finding component of our algorithm to L_1-regularized risk minimization with logistic loss. In all these contexts our methods perform comparable to or better than specialized state-of-the-art solvers on a number of publicly available data sets. An open source implementation of our algorithms is freely available.

Keywords: BFGS, variable metric methods, Wolfe conditions, subgradient, risk minimization, hinge loss, multiclass, multilabel, bundle methods, BMRM, OCAS, OWL-QN

1. Introduction

The BFGS quasi-Newton method (Nocedal and Wright, 1999) and its memory-limited LBFGS variant are widely regarded as the workhorses of smooth nonlinear optimization due to their combination of computational efficiency and good asymptotic convergence. Given a smooth objective

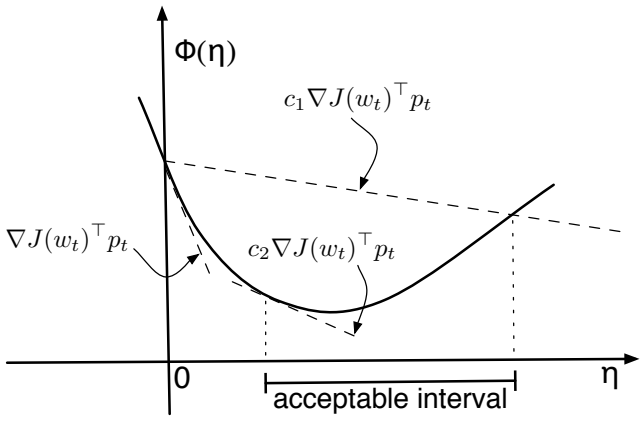

Figure 1: Geometric illustration of the Wolfe conditions (4) and (5).

function $J : \mathbb{R}^d \to \mathbb{R}$ and a current iterate $\boldsymbol{w}_t \in \mathbb{R}^d$, BFGS forms a local quadratic model of J:

$$Q_t(\boldsymbol{p}) \;:=\; J(\boldsymbol{w}_t) + \tfrac{1}{2}\boldsymbol{p}^\top \boldsymbol{B}_t^{-1}\boldsymbol{p} + \nabla J(\boldsymbol{w}_t)^\top \boldsymbol{p}, \tag{1}$$

where $\boldsymbol{B}_t \succ 0$ is a positive-definite estimate of the inverse Hessian of J, and ∇J denotes the gradient. Minimizing $Q_t(\boldsymbol{p})$ gives the quasi-Newton direction

$$\boldsymbol{p}_t := -\boldsymbol{B}_t \nabla J(\boldsymbol{w}_t), \tag{2}$$

which is used for the parameter update:

$$\boldsymbol{w}_{t+1} = \boldsymbol{w}_t + \eta_t \boldsymbol{p}_t. \tag{3}$$

The step size $\eta_t > 0$ is normally determined by a line search obeying the Wolfe (1969) conditions:

$$J(\boldsymbol{w}_{t+1}) \;\le\; J(\boldsymbol{w}_t) + c_1\eta_t \nabla J(\boldsymbol{w}_t)^\top \boldsymbol{p}_t \qquad \text{(sufficient decrease)} \tag{4}$$

$$\text{and} \quad \nabla J(\boldsymbol{w}_{t+1})^\top \boldsymbol{p}_t \;\ge\; c_2 \nabla J(\boldsymbol{w}_t)^\top \boldsymbol{p}_t \qquad \text{(curvature)} \tag{5}$$

with $0 < c_1 < c_2 < 1$. Figure 1 illustrates these conditions geometrically. The matrix $\boldsymbol{B}_t$ is then modified via the incremental rank-two update

$$\boldsymbol{B}_{t+1} = (\boldsymbol{I} - \rho_t \boldsymbol{s}_t \boldsymbol{y}_t^\top)\boldsymbol{B}_t(\boldsymbol{I} - \rho_t \boldsymbol{y}_t \boldsymbol{s}_t^\top) + \rho_t \boldsymbol{s}_t \boldsymbol{s}_t^\top, \tag{6}$$

where $\boldsymbol{s}_t := \boldsymbol{w}_{t+1} - \boldsymbol{w}_t$ and $\boldsymbol{y}_t := \nabla J(\boldsymbol{w}_{t+1}) - \nabla J(\boldsymbol{w}_t)$ denote the most recent step along the optimization trajectory in parameter and gradient space, respectively, and $\rho_t := (\boldsymbol{y}_t{}^\top \boldsymbol{s}_t)^{-1}$. The BFGS update (6) enforces the secant equation $\boldsymbol{B}_{t+1}\boldsymbol{y}_t = \boldsymbol{s}_t$. Given a descent direction $\boldsymbol{p}_t$, the Wolfe conditions ensure that $(\forall t)\ \boldsymbol{s}_t^\top \boldsymbol{y}_t > 0$ and hence $\boldsymbol{B}_0 \succ 0 \implies (\forall t)\ \boldsymbol{B}_t \succ 0$.

Limited-memory BFGS (LBFGS, Liu and Nocedal, 1989) is a variant of BFGS designed for high-dimensional optimization problems where the $O(d^2)$ cost of storing and updating $\boldsymbol{B}_t$ would be prohibitive. LBFGS approximates the quasi-Newton direction (2) directly from the last m pairs of

$\boldsymbol{s}_t$ and $\boldsymbol{y}_t$ via a matrix-free approach, reducing the cost to $O(md)$ space and time per iteration, with m freely chosen.

There have been some attempts to apply (L)BFGS directly to nonsmooth optimization problems, in the hope that they would perform well on nonsmooth functions that are convex and differentiable almost everywhere. Indeed, it has been noted that in cases where BFGS (resp., LBFGS) does not encounter any nonsmooth point, it often converges to the optimum (Lemarechal, 1982; Lewis and Overton, 2008a). However, Lukšan and Vlček (1999), Haarala (2004), and Lewis and Overton (2008b) also report catastrophic failures of (L)BFGS on nonsmooth functions. Various fixes can be used to avoid this problem, but only in an ad-hoc manner. Therefore, subgradient-based approaches such as subgradient descent (Nedić and Bertsekas, 2000) or bundle methods (Joachims, 2006; Franc and Sonnenburg, 2008; Teo et al., 2010) have gained considerable attention for minimizing nonsmooth objectives.

Although a convex function might not be differentiable everywhere, a subgradient always exists (Hiriart-Urruty and Lemaréchal, 1993). Let $\boldsymbol{w}$ be a point where a convex function J is finite. Then a subgradient is the normal vector of any tangential supporting hyperplane of J at $\boldsymbol{w}$. Formally, $\boldsymbol{g}$ is called a subgradient of J at $\boldsymbol{w}$ if and only if (Hiriart-Urruty and Lemaréchal, 1993, Definition VI.1.2.1)

$$(\forall \boldsymbol{w}') \;\; J(\boldsymbol{w}') \;\geq\; J(\boldsymbol{w}) + (\boldsymbol{w}' - \boldsymbol{w})^\top \boldsymbol{g}. \tag{7}$$

The set of all subgradients at a point is called the subdifferential, and is denoted $\partial J(\boldsymbol{w})$. If this set is not empty then J is said to be *subdifferentiable at* $\boldsymbol{w}$. If it contains exactly one element, that is, $\partial J(\boldsymbol{w}) = \{\nabla J(\boldsymbol{w})\}$, then J is *differentiable* at $\boldsymbol{w}$. Figure 2 provides the geometric interpretation of (7).

The aim of this paper is to develop principled and robust quasi-Newton methods that are amenable to subgradients. This results in subBFGS and its memory-limited variant subLBFGS, two new subgradient quasi-Newton methods that are applicable to nonsmooth convex optimization problems. In particular, we apply our algorithms to a variety of machine learning problems, exploiting knowledge about the subdifferential of the binary hinge loss and its generalizations to the multiclass and multilabel settings.

In the next section we motivate our work by illustrating the difficulties of LBFGS on nonsmooth functions, and the advantage of incorporating BFGS' curvature estimate into the parameter update. In Section 3 we develop our optimization algorithms generically, before discussing their application to L_2-regularized risk minimization with the hinge loss in Section 4. We describe a new efficient algorithm to identify the nonsmooth points of a one-dimensional pointwise maximum of linear functions in Section 5, then use it to develop an exact line search that extends our optimization algorithms to the multiclass and multilabel settings (Section 6). Section 7 compares and contrasts our work with other recent efforts in this area. We report our experimental results on a number of public data sets in Section 8, and conclude with a discussion and outlook in Section 9.

2. Motivation

The application of standard (L)BFGS to nonsmooth optimization is problematic since the quasi-Newton direction generated at a nonsmooth point is not necessarily a descent direction. Nevertheless, BFGS' inverse Hessian estimate can provide an effective model of the overall shape of a nonsmooth objective; incorporating it into the parameter update can therefore be beneficial. We

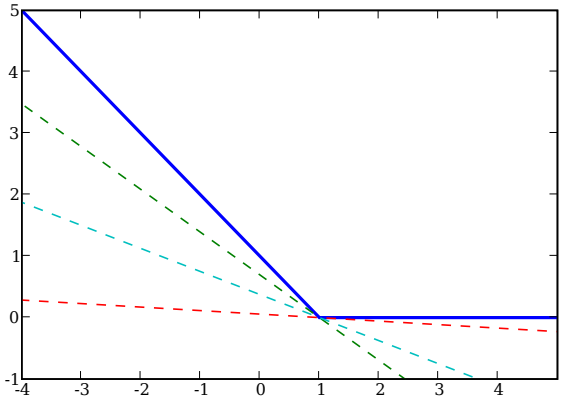

Figure 2: Geometric interpretation of subgradients. The dashed lines are tangential to the hinge function (solid blue line); the slopes of these lines are subgradients.

discuss these two aspects of (L)BFGS to motivate our work on developing new quasi-Newton methods that are amenable to subgradients while preserving the fast convergence properties of standard (L)BFGS.

2.1 Problems of (L)BFGS on Nonsmooth Objectives

Smoothness of the objective function is essential for classical (L)BFGS because both the local quadratic model (1) and the Wolfe conditions (4, 5) require the existence of the gradient ∇J at every point. As pointed out by Hiriart-Urruty and Lemaréchal (1993, Remark VIII.2.1.3), even though nonsmooth convex functions are differentiable everywhere except on a set of Lebesgue measure zero, it is unwise to just use a smooth optimizer on a nonsmooth convex problem under the assumption that "it should work almost surely." Below we illustrate this on both a toy example and real-world machine learning problems.

2.1.1 A TOY EXAMPLE

The following simple example demonstrates the problems faced by BFGS when working with a nonsmooth objective function, and how our subgradient BFGS (subBFGS) method (to be introduced in Section 3) with exact line search overcomes these problems. Consider the task of minimizing

$$f(x,y) = 10\,|x| + |y| \tag{8}$$

with respect to x and y. Clearly, $f(x,y)$ is convex but nonsmooth, with the minimum located at $(0,0)$ (Figure 3, left). It is subdifferentiable whenever x or y is zero:

$$\partial_x f(0,\cdot) = [-10,10] \;\text{ and }\; \partial_y f(\cdot,0) = [-1,1].$$

We call such lines of subdifferentiability in parameter space *hinges*.

We can minimize (8) with the standard BFGS algorithm, employing a backtracking line search (Nocedal and Wright, 1999, Procedure 3.1) that starts with a step size that obeys the curvature

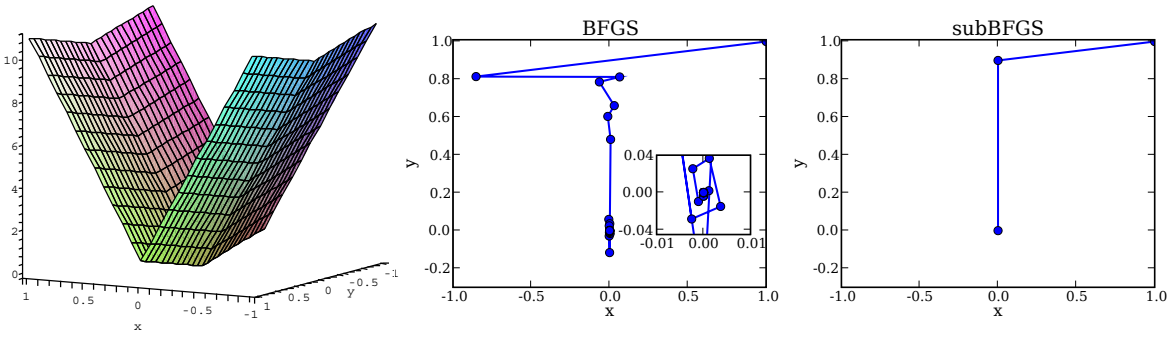

Figure 3: Left: the nonsmooth convex function (8); optimization trajectory of BFGS with inexact line search (center) and subBFGS (right) on this function.

condition (5), then exponentially decays it until both Wolfe conditions (4,5) are satisfied.[1] The curvature condition forces BFGS to jump across at least one hinge, thus ensuring that the gradient displacement vector $\boldsymbol{y}_t$ in (6) is non-zero; this prevents BFGS from diverging. Moreover, with such an *inexact* line search BFGS will generally not step on any hinges directly, thus avoiding (in an ad-hoc manner) the problem of non-differentiability. Although this algorithm quickly decreases the objective from the starting point $(1,1)$, it is then slowed down by heavy oscillations around the optimum (Figure 3, center), caused by the utter mismatch between BFGS' quadratic model and the actual function.

A generally sensible strategy is to use an exact line search that finds the optimum along a given descent direction (cf. Section 4.2.1). However, this line optimum will often lie on a hinge (as it does in our toy example), where the function is not differentiable. If an arbitrary subgradient is supplied instead, the BFGS update (6) can produce a search direction which is not a descent direction, causing the next line search to fail. In our toy example, standard BFGS with exact line search consistently fails after the first step, which takes it to the hinge at $x = 0$.

Unlike standard BFGS, our subBFGS method can handle hinges and thus reap the benefits of an exact line search. As Figure 3 (right) shows, once the first iteration of subBFGS lands it on the hinge at $x = 0$, its direction-finding routine (Algorithm 2) finds a descent direction for the next step. In fact, on this simple example Algorithm 2 yields a vector with zero x component, which takes subBFGS straight to the optimum at the second step.[2]

2.1.2 TYPICAL NONSMOOTH OPTIMIZATION PROBLEMS IN MACHINE LEARNING

The problems faced by smooth quasi-Newton methods on nonsmooth objectives are not only encountered in cleverly constructed toy examples, but also in real-world applications. To show this, we apply LBFGS to L_2-regularized risk minimization problems (30) with binary hinge loss (31), a typical nonsmooth optimization problem encountered in machine learning. For this particular objective function, an exact line search is cheap and easy to compute (see Section 4.2.1 for details). Figure 4 (left & center) shows the behavior of LBFGS with this exact line search (LBFGS-LS)

1. We set $c_1 = 10^{-3}$ in (4) and $c_2 = 0.8$ in (5), and used a decay factor of 0.9.
2. This is achieved for any choice of initial subgradient $\boldsymbol{g}^{(1)}$ (Line 3 of Algorithm 2).

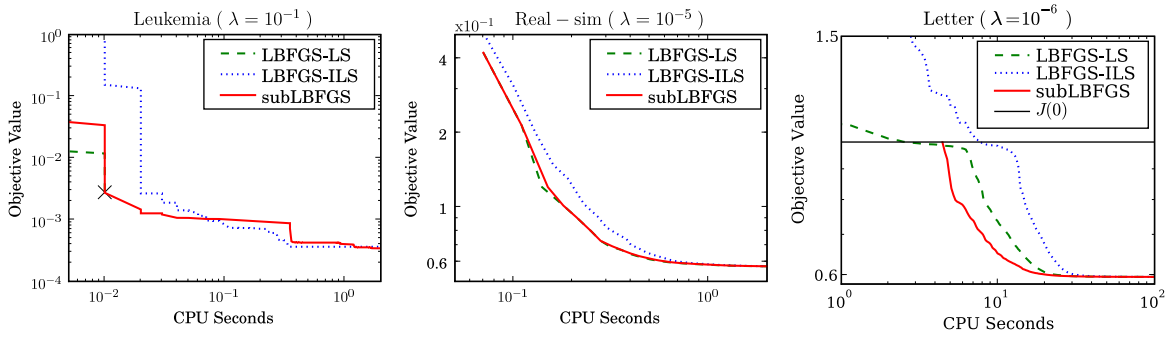

Figure 4: Performance of subLBFGS (solid) and standard LBFGS with exact (dashed) and inexact (dotted) line search methods on sample L_2-regularized risk minimization problems with the binary (left and center) and multiclass hinge losses (right). LBFGS with exact line search (dashed) fails after 3 iterations (marked as $\times$) on the Leukemia data set (left).

on two data sets, namely Leukemia and Real-sim.[3] It can be seen that LBFGS-LS converges on Real-sim but diverges on the Leukemia data set. This is because using an exact line search on a nonsmooth objective function increases the chance of landing on nonsmooth points, a situation that standard BFGS (resp., LBFGS) is not designed to deal with. To prevent (L)BFGS' sudden breakdown, a scheme that actively avoids nonsmooth points must be used. One such possibility is to use an inexact line search that obeys the Wolfe conditions. Here we used an efficient inexact line search that uses a caching scheme specifically designed for L_2-regularized hinge loss (cf. end of Section 4.2). This implementation of LBFGS (LBFGS-ILS) converges on both data sets shown here but may fail on others. It is also slower, due to the inexactness of its line search.

For the multiclass hinge loss (42) we encounter another problem: if we follow the usual practice of initializing $\boldsymbol{w} = \mathbf{0}$, which happens to be a non-differentiable point, then LBFGS stalls. One way to get around this is to force LBFGS to take a unit step along its search direction to escape this nonsmooth point. However, as can be seen on the Letter data set[3] in Figure 4 (right), such an ad-hoc fix increases the value of the objective above $J(\mathbf{0})$ (solid horizontal line), and it takes several CPU seconds for the optimizers to recover from this. In all cases shown in Figure 4, our subgradient LBFGS (subLBFGS) method (as will be introduced later) performs comparable to or better than the best implementation of LBFGS.

2.2 Advantage of Incorporating BFGS' Curvature Estimate

In machine learning one often encounters L_2-regularized risk minimization problems (30) with various hinge losses (31, 42, 55). Since the Hessian of those objective functions at differentiable points equals $\lambda \boldsymbol{I}$ (where λ is the regularization constant), one might be tempted to argue that for such problems, BFGS' approximation $\boldsymbol{B}_t$ to the inverse Hessian should be simply set to $\lambda^{-1}\boldsymbol{I}$. This would reduce the quasi-Newton direction $\boldsymbol{p}_t = -\boldsymbol{B}_t \boldsymbol{g}_t$, $\boldsymbol{g}_t \in \partial J(\boldsymbol{w}_t)$ to simply a scaled subgradient direction.

To check if doing so is beneficial, we compared the performance of our subLBFGS method with two implementations of subgradient descent: a vanilla gradient descent method (denoted GD) that

3. Descriptions of these data sets can be found in Section 8.

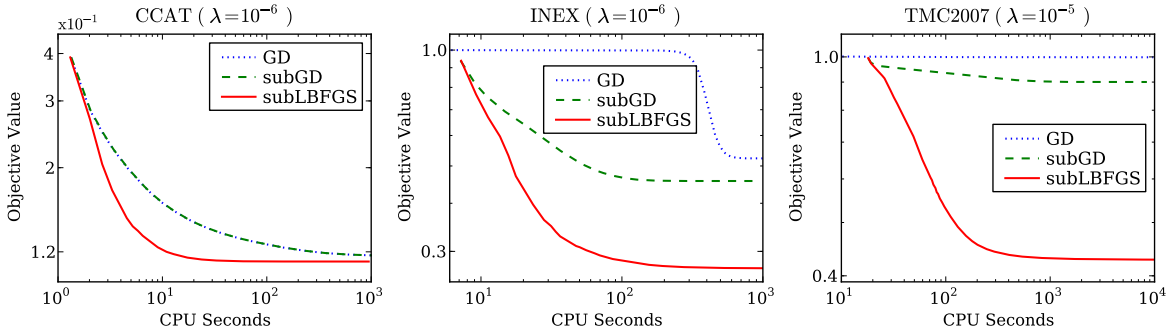

Figure 5: Performance of subLBFGS, GD, and subGD on sample L_2-regularized risk minimization problems with binary (left), multiclass (center), and multilabel (right) hinge losses.

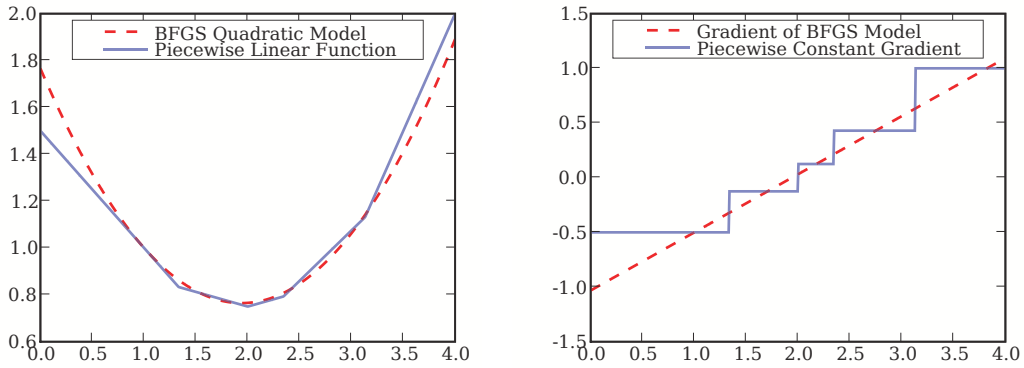

Figure 6: BFGS' quadratic approximation to a piecewise linear function (left), and its estimate of the gradient of this function (right).

uses a random subgradient for its parameter update, and an improved subgradient descent method (denoted subGD) whose parameter is updated in the direction produced by our direction-finding routine (Algorithm 2) with $\boldsymbol{B}_t = \boldsymbol{I}$. All algorithms used exact line search, except that GD took a unit step for the first update in order to avoid the nonsmooth point $\boldsymbol{w}_0 = \boldsymbol{0}$ (cf. the discussion in Section 2.1). As can be seen in Figure 5, on all sample L_2-regularized hinge loss minimization problems, subLBFGS (solid) converges significantly faster than GD (dotted) and subGD (dashed). This indicates that BFGS' $\boldsymbol{B}_t$ matrix is able to model the objective function, including its hinges, better than simply setting $\boldsymbol{B}_t$ to a scaled identity matrix.

We believe that BFGS' curvature update (6) plays an important role in the performance of subLBFGS seen in Figure 5. Recall that (6) satisfies the secant condition $\boldsymbol{B}_{t+1}\boldsymbol{y}_t = \boldsymbol{s}_t$, where $\boldsymbol{s}_t$ and $\boldsymbol{y}_t$ are displacement vectors in parameter and gradient space, respectively. The secant condition in fact implements a *finite differencing* scheme: for a one-dimensional objective function $J : \mathbb{R} \to \mathbb{R}$,

we have

$$\boldsymbol{B}_{t+1} = \frac{(w+p)-w}{\nabla J(w+p) - \nabla J(w)}. \tag{9}$$

Although the original motivation behind the secant condition was to approximate the inverse Hessian, the finite differencing scheme (9) allows BFGS to model the global curvature (i.e., overall shape) of the objective function from first-order information. For instance, Figure 6 (left) shows that the BFGS quadratic model[4] (1) fits a piecewise linear function quite well despite the fact that the actual Hessian in this case is zero almost everywhere, and infinite (in the limit) at nonsmooth points. Figure 6 (right) reveals that BFGS captures the global trend of the gradient rather than its infinitesimal variation, that is, the Hessian. This is beneficial for nonsmooth problems, where Hessian does not fully represent the overall curvature of the objective function.

3. Subgradient BFGS Method

We modify the standard BFGS algorithm to derive our new algorithm (subBFGS, Algorithm 1) for nonsmooth convex optimization, and its memory-limited variant (subLBFGS). Our modifications can be grouped into three areas, which we elaborate on in turn: generalizing the local quadratic model, finding a descent direction, and finding a step size that obeys a subgradient reformulation of the Wolfe conditions. We then show that our algorithm's estimate of the inverse Hessian has a bounded spectrum, which allows us to prove its convergence.

Algorithm 1 Subgradient BFGS (subBFGS)

Initialize: $t := 0, \boldsymbol{w}_0 = \boldsymbol{0}, \boldsymbol{B}_0 = \boldsymbol{I}$
Set: direction-finding tolerance $\varepsilon \geq 0$, iteration limit $k_{\max} > 0$,
    lower bound $h > 0$ on $\frac{\boldsymbol{s}_t^\top \boldsymbol{y}_t}{\boldsymbol{y}_t^\top \boldsymbol{y}_t}$ (cf. discussion in Section 3.4)
Compute subgradient $\boldsymbol{g}_0 \in \partial J(\boldsymbol{w}_0)$
while not converged **do**
  $\boldsymbol{p}_t = \texttt{descentDirection}(\boldsymbol{g}_t, \varepsilon, k_{\max})$ (Algorithm 2)
  if $\boldsymbol{p}_t =$ failure **then**
    Return $\boldsymbol{w}_t$
  end if
  Find η_t that obeys (23) and (24) (e.g., Algorithm 3 or 5)
  $\boldsymbol{s}_t = \eta_t \boldsymbol{p}_t$
  $\boldsymbol{w}_{t+1} = \boldsymbol{w}_t + \boldsymbol{s}_t$
  Choose subgradient $\boldsymbol{g}_{t+1} \in \partial J(\boldsymbol{w}_{t+1}) : \boldsymbol{s}_t^\top (\boldsymbol{g}_{t+1} - \boldsymbol{g}_t) > 0$
  $\boldsymbol{y}_t := \boldsymbol{g}_{t+1} - \boldsymbol{g}_t$
  $\boldsymbol{s}_t := \boldsymbol{s}_t + \max\left(0,\ h - \frac{\boldsymbol{s}_t^\top \boldsymbol{y}_t}{\boldsymbol{y}_t^\top \boldsymbol{y}_t}\right) \boldsymbol{y}_t$ (ensure $\frac{\boldsymbol{s}_t^\top \boldsymbol{y}_t}{\boldsymbol{y}_t^\top \boldsymbol{y}_t} \geq h$)
  Update $\boldsymbol{B}_{t+1}$ via (6)
  $t := t + 1$
end while

4. For ease of exposition, the model was constructed at a differentiable point.

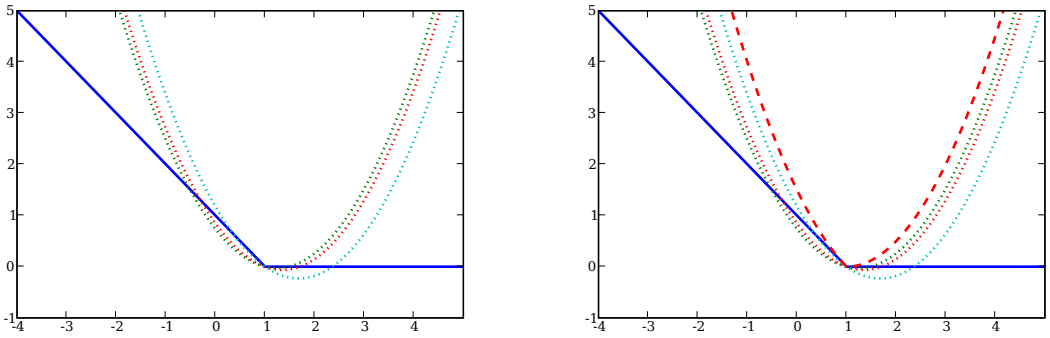

Figure 7: Left: selecting arbitrary subgradients yields many possible quadratic models (dotted lines) for the objective (solid blue line) at a subdifferentiable point. The models were built by keeping $\boldsymbol{B}_t$ fixed, but selecting random subgradients. Right: the tightest pseudo-quadratic fit (10) (bold red dashes); note that it is not a quadratic.

3.1 Generalizing the Local Quadratic Model

Recall that BFGS assumes that the objective function J is differentiable everywhere so that at the current iterate $\boldsymbol{w}_t$ it can construct a local quadratic model (1) of $J(\boldsymbol{w}_t)$. For a nonsmooth objective function, such a model becomes ambiguous at non-differentiable points (Figure 7, left). To resolve the ambiguity, we could simply replace the gradient $\nabla J(\boldsymbol{w}_t)$ in (1) with an arbitrary subgradient $\boldsymbol{g}_t \in \partial J(\boldsymbol{w}_t)$. However, as will be discussed later, the resulting quasi-Newton direction $\boldsymbol{p}_t := -\boldsymbol{B}_t \boldsymbol{g}_t$ is not necessarily a descent direction. To address this fundamental modeling problem, we first generalize the local quadratic model (1) as follows:

$$\begin{aligned} Q_t(\boldsymbol{p}) &:= J(\boldsymbol{w}_t) + M_t(\boldsymbol{p}), \quad \text{where} \\ M_t(\boldsymbol{p}) &:= \tfrac{1}{2}\boldsymbol{p}^\top \boldsymbol{B}_t^{-1}\boldsymbol{p} + \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}. \end{aligned} \tag{10}$$

Note that where J is differentiable, (10) reduces to the familiar BFGS quadratic model (1). At non-differentiable points, however, the model is no longer quadratic, as the supremum may be attained at different elements of $\partial J(\boldsymbol{w}_t)$ for different directions $\boldsymbol{p}$. Instead it can be viewed as the tightest pseudo-quadratic fit to J at $\boldsymbol{w}_t$ (Figure 7, right). Although the local model (10) of subBFGS is nonsmooth, it only incorporates non-differential points present at the current location; all others are smoothly approximated by the quasi-Newton mechanism.

Having constructed the model (10), we can minimize $Q_t(\boldsymbol{p})$, or equivalently $M_t(\boldsymbol{p})$:

$$\min_{\boldsymbol{p}\in\mathbb{R}^d} \left(\tfrac{1}{2}\boldsymbol{p}^\top \boldsymbol{B}_t^{-1}\boldsymbol{p} + \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p} \right) \tag{11}$$

to obtain a search direction. We now show that solving (11) is closely related to the problem of finding a *normalized steepest descent* direction. A normalized steepest descent direction is defined

as the solution to the following problem (Hiriart-Urruty and Lemaréchal, 1993, Chapter VIII):

$$\min_{\boldsymbol{p}\in\mathbb{R}^d} \; J'(\boldsymbol{w}_t,\, \boldsymbol{p}) \;\text{ s.t. }\; |||\boldsymbol{p}||| \leq 1, \tag{12}$$

where

$$J'(\boldsymbol{w}_t,\, \boldsymbol{p}) := \lim_{\eta\downarrow 0} \frac{J(\boldsymbol{w}_t + \eta\boldsymbol{p}) - J(\boldsymbol{w}_t)}{\eta}$$

is the directional derivative of J at $\boldsymbol{w}_t$ in direction $\boldsymbol{p}$, and $|||\cdot|||$ is a norm defined on $\mathbb{R}^d$. In other words, the normalized steepest descent direction is the direction of bounded norm along which the maximum rate of decrease in the objective function value is achieved. Using the property: $J'(\boldsymbol{w}_t,\, \boldsymbol{p}) = \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}$ (Bertsekas, 1999, Proposition B.24.b), we can rewrite (12) as:

$$\min_{\boldsymbol{p}\in\mathbb{R}^d} \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p} \quad \text{s.t. } |||\boldsymbol{p}||| \leq 1. \tag{13}$$

If the matrix $\boldsymbol{B}_t \succ 0$ as in (11) is used to define the norm $|||\cdot|||$ as

$$|||\boldsymbol{p}|||^2 := \boldsymbol{p}^\top \boldsymbol{B}_t^{-1} \boldsymbol{p}, \tag{14}$$

then the solution to (13) points to the same direction as that obtained by minimizing our pseudo-quadratic model (11). To see this, we write the Lagrangian of the constrained minimization problem (13):

$$\begin{aligned} L(\boldsymbol{p},\alpha) \;&:= \alpha\, \boldsymbol{p}^\top \boldsymbol{B}_t^{-1} \boldsymbol{p} \;-\alpha\; + \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p} \\ &= \tfrac{1}{2}\, \boldsymbol{p}^\top (2\alpha \boldsymbol{B}_t^{-1}) \boldsymbol{p} \;-\alpha\; + \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}, \end{aligned} \tag{15}$$

where $\alpha > 0$ is a Lagrangian multiplier. It is easy to see from (15) that minimizing the Lagrangian function L with respect to $\boldsymbol{p}$ is equivalent to solving (11) with $\boldsymbol{B}_t^{-1}$ scaled by a scalar 2α, implying that the steepest descent direction obtained by solving (13) with the weighted norm (14) only differs in length from the search direction obtained by solving (11). Therefore, our search direction is essentially an unnomalized steepest descent direction with respect to the weighted norm (14).

Ideally, we would like to solve (11) to obtain the best search direction. This is generally intractable due to the presence a supremum over the entire subdifferential set $\partial J(\boldsymbol{w}_t)$. In many machine learning problems, however, $\partial J(\boldsymbol{w}_t)$ has some special structure that simplifies the calculation of that supremum. In particular, the subdifferential of all the problems considered in this paper is a convex and compact polyhedron characterised as the convex hull of its extreme points. This dramatically reduces the cost of calculating $\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}$ since the supremum can only be attained at an extreme point of the polyhedral set $\partial J(\boldsymbol{w}_t)$ (Bertsekas, 1999, Proposition B.21c). In what follows, we develop an iterative procedure that is guaranteed to find a quasi-Newton descent direction, assuming an oracle that supplies $\arg\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}$ for a given direction $\boldsymbol{p} \in \mathbb{R}^d$. Efficient oracles for this purpose can be derived for many machine learning settings; we provides such oracles for L_2-regularized risk minimization with the binary hinge loss (Section 4.1), multiclass and multilabel hinge losses (Section 6), and L_1-regularized logistic loss (Section 8.4).

Algorithm 2 $\boldsymbol{p}_t = \texttt{descentDirection}(\boldsymbol{g}^{(1)}, \varepsilon, k_{\max})$

input (sub)gradient $\boldsymbol{g}^{(1)} \in \partial J(\boldsymbol{w}_t)$, tolerance $\varepsilon \geq 0$, iteration limit $k_{\max} > 0$,
and an oracle to calculate $\arg\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}$ for any given $\boldsymbol{w}$ and $\boldsymbol{p}$
output descent direction $\boldsymbol{p}_t$
Initialize: $i = 1$, $\bar{\boldsymbol{g}}^{(1)} = \boldsymbol{g}^{(1)}$, $\boldsymbol{p}^{(1)} = -\boldsymbol{B}_t \boldsymbol{g}^{(1)}$
$\boldsymbol{g}^{(2)} = \arg\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}^{(1)}$
$\varepsilon^{(1)} := \boldsymbol{p}^{(1)\top} \boldsymbol{g}^{(2)} - \boldsymbol{p}^{(1)\top} \bar{\boldsymbol{g}}^{(1)}$
while $(\boldsymbol{g}^{(i+1)\top} \boldsymbol{p}^{(i)} > 0$ or $\varepsilon^{(i)} > \varepsilon)$ and $\varepsilon^{(i)} > 0$ and $i < k_{\max}$ **do**
  $\mu^* := \min\left[1, \frac{(\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)})^\top \boldsymbol{B}_t \bar{\boldsymbol{g}}^{(i)}}{(\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)})^\top \boldsymbol{B}_t (\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)})}\right]$; see (97)
  $\bar{\boldsymbol{g}}^{(i+1)} = (1-\mu^*)\bar{\boldsymbol{g}}^{(i)} + \mu^* \boldsymbol{g}^{(i+1)}$
  $\boldsymbol{p}^{(i+1)} = (1-\mu^*)\boldsymbol{p}^{(i)} - \mu^* \boldsymbol{B}_t \boldsymbol{g}^{(i+1)}$; see (76)
  $\boldsymbol{g}^{(i+2)} = \arg\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}^{(i+1)}$
  $\varepsilon^{(i+1)} := \min_{j\leq(i+1)} \left[\boldsymbol{p}^{(j)\top} \boldsymbol{g}^{(j+1)} - \frac{1}{2}(\boldsymbol{p}^{(j)\top} \bar{\boldsymbol{g}}^{(j)} + \boldsymbol{p}^{(i+1)\top} \bar{\boldsymbol{g}}^{(i+1)})\right]$
  $i := i + 1$
end while
$\boldsymbol{p}_t = \operatorname{argmin}_{j\leq i} M_t(\boldsymbol{p}^{(j)})$
if $\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}_t \geq 0$ **then**
  return failure;
else
  return $\boldsymbol{p}_t$.
end if

3.2 Finding a Descent Direction

A direction $\boldsymbol{p}_t$ is a descent direction if and only if $\boldsymbol{g}^\top \boldsymbol{p}_t < 0 \quad \forall \boldsymbol{g} \in \partial J(\boldsymbol{w}_t)$ (Hiriart-Urruty and Lemaréchal, 1993, Theorem VIII.1.1.2), or equivalently

$$\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}_t \;<\; 0. \tag{16}$$

For a smooth convex function, the quasi-Newton direction (2) is always a descent direction because

$$\nabla J(\boldsymbol{w}_t)^\top \boldsymbol{p}_t \;=\; -\nabla J(\boldsymbol{w}_t)^\top \boldsymbol{B}_t \nabla J(\boldsymbol{w}_t) \;<\; 0$$

holds due to the positivity of $\boldsymbol{B}_t$.

For nonsmooth functions, however, the quasi-Newton direction $\boldsymbol{p}_t := -\boldsymbol{B}_t \boldsymbol{g}_t$ for a given $\boldsymbol{g}_t \in \partial J(\boldsymbol{w}_t)$ may not fulfill the descent condition (16), making it impossible to find a step size $\eta > 0$ that obeys the Wolfe conditions (4, 5), thus causing a failure of the line search. We now present an iterative approach to finding a quasi-Newton *descent* direction.

Our goal is to minimize the pseudo-quadratic model (10), or equivalently minimize $M_t(\boldsymbol{p})$. Inspired by bundle methods (Teo et al., 2010), we achieve this by minimizing convex lower bounds of $M_t(\boldsymbol{p})$ that are designed to progressively approach $M_t(\boldsymbol{p})$ over iterations. At iteration i we build the following convex lower bound on $M_t(\boldsymbol{p})$:

$$M_t^{(i)}(\boldsymbol{p}) \;:=\; \tfrac{1}{2}\boldsymbol{p}^\top \boldsymbol{B}_t^{-1} \boldsymbol{p} + \sup_{j\leq i} \boldsymbol{g}^{(j)\top} \boldsymbol{p}, \tag{17}$$

where $i, j \in \mathbb{N}$ and $\boldsymbol{g}^{(j)} \in \partial J(\boldsymbol{w}_t)\ \forall j \leq i$. Given a $\boldsymbol{p}^{(i)} \in \mathbb{R}^d$ the lower bound (17) is successively tightened by computing

$$\boldsymbol{g}^{(i+1)} := \operatorname*{arg\,sup}_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}^{(i)}, \tag{18}$$

such that $M_t^{(i)}(\boldsymbol{p}) \leq M_t^{(i+1)}(\boldsymbol{p}) \leq M_t(\boldsymbol{p})\ \forall \boldsymbol{p} \in \mathbb{R}^d$. Here we set $\boldsymbol{g}^{(1)} \in \partial J(\boldsymbol{w}_t)$ arbitrarily, and assume that (18) is provided by an oracle (e.g., as described in Section 4.1). To solve $\min_{\boldsymbol{p} \in \mathbb{R}^d} M_t^{(i)}(\boldsymbol{p})$, we rewrite it as a constrained optimization problem:

$$\min_{\boldsymbol{p}, \xi} \left(\tfrac{1}{2} \boldsymbol{p}^\top \boldsymbol{B}_t^{-1} \boldsymbol{p} + \xi \right) \ \text{ s.t. } \ \boldsymbol{g}^{(j)\top} \boldsymbol{p} \leq \xi \ \ \forall j \leq i. \tag{19}$$

This problem can be solved exactly via quadratic programming, but doing so may incur substantial computational expense. Instead we adopt an alternative approach (Algorithm 2) which does not solve (19) to optimality. The key idea is to write the proposed descent direction at iteration $i+1$ as a convex combination of $\boldsymbol{p}^{(i)}$ and $-\boldsymbol{B}_t \boldsymbol{g}^{(i+1)}$ (Line 9 of Algorithm 2); and as will be shown in Appendix B, the returned search direction takes the form

$$\boldsymbol{p}_t = -\boldsymbol{B}_t \bar{\boldsymbol{g}}_t,$$

where $\bar{\boldsymbol{g}}_t$ is a subgradient in $\partial J(\boldsymbol{w}_t)$ that allows $\boldsymbol{p}_t$ to satisfy the descent condition (16). The optimal convex combination coefficient μ^* can be computed exactly (Line 7 of Algorithm 2) using an argument based on maximizing the dual objective of $M_t(\boldsymbol{p})$; see Appendix A for details.

The weak duality theorem (Hiriart-Urruty and Lemaréchal, 1993, Theorem XII.2.1.5) states that the optimal primal value is no less than any dual value, that is, if $D_t(\boldsymbol{\alpha})$ is the dual of $M_t(\boldsymbol{p})$, then $\min_{\boldsymbol{p} \in \mathbb{R}^d} M_t(\boldsymbol{p}) \geq D_t(\boldsymbol{\alpha})$ holds for all feasible dual solutions $\boldsymbol{\alpha}$. Therefore, by iteratively increasing the value of the dual objective we close the gap to optimality in the primal. Based on this argument, we use the following upper bound on the duality gap as our measure of progress:

$$\varepsilon^{(i)} := \min_{j \leq i} \left[\boldsymbol{p}^{(j)\top} \boldsymbol{g}^{(j+1)} - \tfrac{1}{2} (\boldsymbol{p}^{(j)\top} \bar{\boldsymbol{g}}^{(j)} + \boldsymbol{p}^{(i)\top} \bar{\boldsymbol{g}}^{(i)}) \right] \geq \min_{\boldsymbol{p} \in \mathbb{R}^d} M_t(\boldsymbol{p}) - D_t(\boldsymbol{\alpha}^*), \tag{20}$$

where $\bar{\boldsymbol{g}}^{(i)}$ is an aggregated subgradient (Line 8 of Algorithm 2) which lies in the convex hull of $\boldsymbol{g}^{(j)} \in \partial J(\boldsymbol{w}_t)\ \forall j \leq i$, and $\boldsymbol{\alpha}^*$ is the optimal dual solution; Equations 77–79 in Appendix A provide intermediate steps that lead to the inequality in (20). Theorem 7 (Appendix B) shows that $\varepsilon^{(i)}$ is monotonically decreasing, leading us to a practical stopping criterion (Line 6 of Algorithm 2) for our direction-finding procedure.

A detailed derivation of Algorithm 2 is given in Appendix A, where we also prove that at a non-optimal iterate a direction-finding tolerance $\varepsilon \geq 0$ exists such that the search direction produced by Algorithm 2 is a descent direction; in Appendix B we prove that Algorithm 2 converges to a solution with precision ε in $O(1/\varepsilon)$ iterations. Our proofs are based on the assumption that the spectrum (eigenvalues) of BFGS' approximation $\boldsymbol{B}_t$ to the inverse Hessian is bounded from above and below. This is a reasonable assumption if simple safeguards such as those described in Section 3.4 are employed in the practical implementation.

3.3 Subgradient Line Search

Given the current iterate $\boldsymbol{w}_t$ and a search direction $\boldsymbol{p}_t$, the task of a line search is to find a step size $\eta > 0$ which reduces the objective function value along the line $\boldsymbol{w}_t + \eta \boldsymbol{p}_t$:

$$\text{minimize } \Phi(\eta) := J(\boldsymbol{w}_t + \eta \boldsymbol{p}_t). \tag{21}$$

Using the chain rule, we can write

$$\partial \Phi(\eta) := \{\boldsymbol{g}^\top \boldsymbol{p}_t : \boldsymbol{g} \in \partial J(\boldsymbol{w}_t + \eta \boldsymbol{p}_t)\}. \tag{22}$$

Exact line search finds the optimal step size η^* by minimizing $\Phi(\eta)$, such that $0 \in \partial\Phi(\eta^*)$; inexact line searches solve (21) approximately while enforcing conditions designed to ensure convergence. The Wolfe conditions (4) and (5), for instance, achieve this by guaranteeing a sufficient decrease in the value of the objective and excluding pathologically small step sizes, respectively (Wolfe, 1969; Nocedal and Wright, 1999). The original Wolfe conditions, however, require the objective function to be smooth; to extend them to nonsmooth convex problems, we propose the following subgradient reformulation:

$$J(\boldsymbol{w}_{t+1}) \leq J(\boldsymbol{w}_t) + c_1 \eta_t \sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}_t \qquad \text{(sufficient decrease)} \tag{23}$$

$$\text{and} \quad \sup_{\boldsymbol{g}' \in \partial J(\boldsymbol{w}_{t+1})} \boldsymbol{g}'^\top \boldsymbol{p}_t \geq c_2 \sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}_t, \qquad \text{(curvature)} \tag{24}$$

where $0 < c_1 < c_2 < 1$. Figure 8 illustrates how these conditions enforce acceptance of non-trivial step sizes that decrease the objective function value. In Appendix C we formally show that for any given descent direction we can always find a positive step size that satisfies (23) and (24). Moreover, Appendix D shows that the sufficient decrease condition (23) provides a necessary condition for the global convergence of subBFGS.

Employing an exact line search is a common strategy to speed up convergence, but it drastically increases the probability of landing on a non-differentiable point (as in Figure 4, left). In order to leverage the fast convergence provided by an exact line search, one must therefore use an optimizer that can handle subgradients, like our subBFGS.

A natural question to ask is whether the optimal step size η^* obtained by an exact line search satisfies the reformulated Wolfe conditions (resp., the standard Wolfe conditions when J is smooth). The answer is no: depending on the choice of c_1, η^* may violate the sufficient decrease condition (23). For the function shown in Figure 8, for instance, we can increase the value of c_1 such that the acceptable interval for the step size excludes η^*. In practice one can set c_1 to a small value, for example, 10^{-4}, to prevent this from happening.

The curvature condition (24), on the other hand, is always satisfied by η^*, as long as $\boldsymbol{p}_t$ is a descent direction (16):

$$\sup_{\boldsymbol{g}' \in J(\boldsymbol{w}_t + \eta^* \boldsymbol{p}_t)} \boldsymbol{g}'^\top \boldsymbol{p}_t = \sup_{g \in \partial\Phi(\eta^*)} g \geq 0 > \sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}_t$$

because $0 \in \partial\Phi(\eta^*)$.

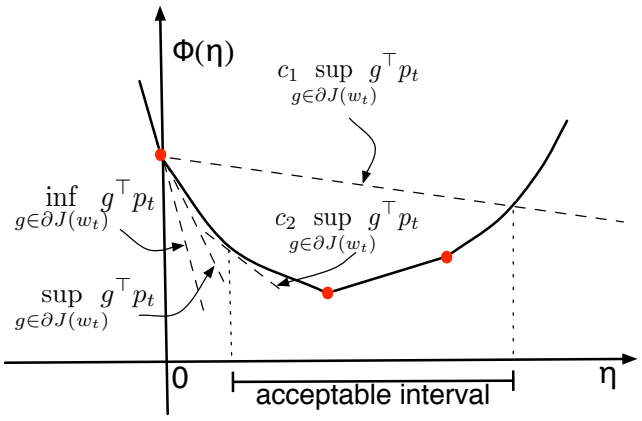

Figure 8: Geometric illustration of the subgradient Wolfe conditions (23) and (24). Solid disks are subdifferentiable points; the slopes of dashed lines are indicated.

3.4 Bounded Spectrum of SubBFGS' Inverse Hessian Estimate

Recall from Section 1 that to ensure positivity of BFGS' estimate $\boldsymbol{B}_t$ of the inverse Hessian, we must have $(\forall t)\ \boldsymbol{s}_t^\top \boldsymbol{y}_t > 0$. Extending this condition to nonsmooth functions, we require

$$(\boldsymbol{w}_{t+1} - \boldsymbol{w}_t)^\top (\boldsymbol{g}_{t+1} - \boldsymbol{g}_t) > 0, \ \text{ where } \ \boldsymbol{g}_{t+1} \in \partial J(\boldsymbol{w}_{t+1}) \ \text{ and } \ \boldsymbol{g}_t \in \partial J(\boldsymbol{w}_t). \tag{25}$$

If J is strongly convex,[5] and $\boldsymbol{w}_{t+1} \neq \boldsymbol{w}_t$, then (25) holds for any choice of $\boldsymbol{g}_{t+1}$ and $\boldsymbol{g}_t$.[6] For general convex functions, $\boldsymbol{g}_{t+1}$ need to be chosen (Line 12 of Algorithm 1) to satisfy (25). The existence of such a subgradient is guaranteed by the convexity of the objective function. To see this, we first use the fact that $\eta_t \boldsymbol{p}_t = \boldsymbol{w}_{t+1} - \boldsymbol{w}_t$ and $\eta_t > 0$ to rewrite (25) as

$$\boldsymbol{p}_t^\top \boldsymbol{g}_{t+1} > \boldsymbol{p}_t^\top \boldsymbol{g}_t, \ \text{ where } \ \boldsymbol{g}_{t+1} \in \partial J(\boldsymbol{w}_{t+1}) \ \text{ and } \ \boldsymbol{g}_t \in \partial J(\boldsymbol{w}_t). \tag{26}$$

It follows from (22) that both sides of inequality (26) are subgradients of $\Phi(\eta)$ at η_t and 0, respectively. The monotonic property of $\partial\Phi(\eta)$ given in Theorem 1 (below) ensures that $\boldsymbol{p}_t^\top \boldsymbol{g}_{t+1}$ is no less than $\boldsymbol{p}_t^\top \boldsymbol{g}_t$ for any choice of $\boldsymbol{g}_{t+1}$ and $\boldsymbol{g}_t$, that is,

$$\inf_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_{t+1})} \boldsymbol{p}_t^\top \boldsymbol{g} \ \geq \ \sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{p}_t^\top \boldsymbol{g}. \tag{27}$$

This means that the only case where inequality (26) is violated is when both terms of (27) are equal, and

$$\boldsymbol{g}_{t+1} = \operatorname*{arg\,inf}_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_{t+1})} \boldsymbol{g}^\top \boldsymbol{p}_t \ \text{ and } \ \boldsymbol{g}_t = \operatorname*{arg\,sup}_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}_t,$$

that is, in this case $\boldsymbol{p}_t^\top \boldsymbol{g}_{t+1} = \boldsymbol{p}_t^\top \boldsymbol{g}_t$. To avoid this, we simply need to set $\boldsymbol{g}_{t+1}$ to a different subgradient in $\partial J(\boldsymbol{w}_{t+1})$.

5. If J is strongly convex, then $(\boldsymbol{g}_2 - \boldsymbol{g}_1)^\top (\boldsymbol{w}_2 - \boldsymbol{w}_1) \geq c \|\boldsymbol{w}_2 - \boldsymbol{w}_1\|^2$, with $c > 0$, $\boldsymbol{g}_i \in \partial J(\boldsymbol{w}_i)$, $i = 1, 2$.
6. We found empirically that no qualitative difference between using random subgradients versus choosing a particular subgradient when updating the $\boldsymbol{B}_t$ matrix.

Theorem 1 (Hiriart-Urruty and Lemaréchal, 1993, Theorem I.4.2.1)
Let Φ be a one-dimensional convex function on its domain, then $\partial\Phi(\eta)$ is increasing in the sense that $g_1 \leq g_2$ whenever $g_1 \in \partial\Phi(\eta_1)$, $g_2 \in \partial\Phi(\eta_2)$, and $\eta_1 < \eta_2$.

Our convergence analysis for the direction-finding procedure (Algorithm 2) as well as the global convergence proof of subBFGS in Appendix D require the spectrum of $\boldsymbol{B}_t$ to be bounded from above and below by a positive scalar:

$$\exists (h, H : 0 < h \leq H < \infty) : (\forall t)\ h \preceq \boldsymbol{B}_t \preceq H. \tag{28}$$

From a theoretical point of view it is difficult to guarantee (28) (Nocedal and Wright, 1999, page 212), but based on the fact that $\boldsymbol{B}_t$ is an approximation to the inverse Hessian $\boldsymbol{H}_t^{-1}$, it is reasonable to expect (28) to be true if

$$(\forall t)\ 1/H \preceq \boldsymbol{H}_t \preceq 1/h.$$

Since BFGS "senses" the Hessian via (6) only through the parameter and gradient displacements $\boldsymbol{s}_t$ and $\boldsymbol{y}_t$, we can translate the bounds on the spectrum of $\boldsymbol{H}_t$ into conditions that only involve $\boldsymbol{s}_t$ and $\boldsymbol{y}_t$:

$$(\forall t)\ \ \frac{\boldsymbol{s}_t^\top \boldsymbol{y}_t}{\boldsymbol{s}_t^\top \boldsymbol{s}_t} \geq \frac{1}{H} \ \text{ and } \ \frac{\boldsymbol{y}_t^\top \boldsymbol{y}_t}{\boldsymbol{s}_t^\top \boldsymbol{y}_t} \leq \frac{1}{h}, \ \text{ with } \ 0 < h \leq H < \infty. \tag{29}$$

This technique is used in Nocedal and Wright (1999, Theorem 8.5). If J is strongly convex[5] and $\boldsymbol{s}_t \neq \boldsymbol{0}$, then there exists an H such that the left inequality in (29) holds. On general convex functions, one can skip BFGS' curvature update if $(\boldsymbol{s}_t^\top \boldsymbol{y}_t / \boldsymbol{s}_t^\top \boldsymbol{s}_t)$ falls below a threshold. To establish the second inequality, we add a fraction of $\boldsymbol{y}_t$ to $\boldsymbol{s}_t$ at Line 14 of Algorithm 1 (though this modification is never actually invoked in our experiments of Section 8, where we set $h = 10^{-8}$).

3.5 Limited-Memory Subgradient BFGS

It is straightforward to implement an LBFGS variant of our subBFGS algorithm: we simply modify Algorithms 1 and 2 to compute all products between $\boldsymbol{B}_t$ and a vector by means of the standard LBFGS matrix-free scheme (Nocedal and Wright, 1999, Algorithm 9.1). We call the resulting algorithm subLBFGS.

3.6 Convergence of Subgradient (L)BFGS

In Section 3.4 we have shown that the spectrum of subBFGS' inverse Hessian estimate is bounded. From this and other technical assumptions, we prove in Appendix D that subBFGS is globally convergent in objective function value, that is, $J(\boldsymbol{w}) \to \inf_{\boldsymbol{w}} J(\boldsymbol{w})$. Moreover, in Appendix E we show that subBFGS converges for all counterexamples we could find in the literature used to illustrate the non-convergence of existing optimization methods on nonsmooth problems.

We have also examined the convergence of subLBFGS empirically. In most of our experiments of Section 8, we observe that after an initial transient, subLBFGS observes a period of linear convergence, until close to the optimum it exhibits superlinear convergence behavior. This is illustrated

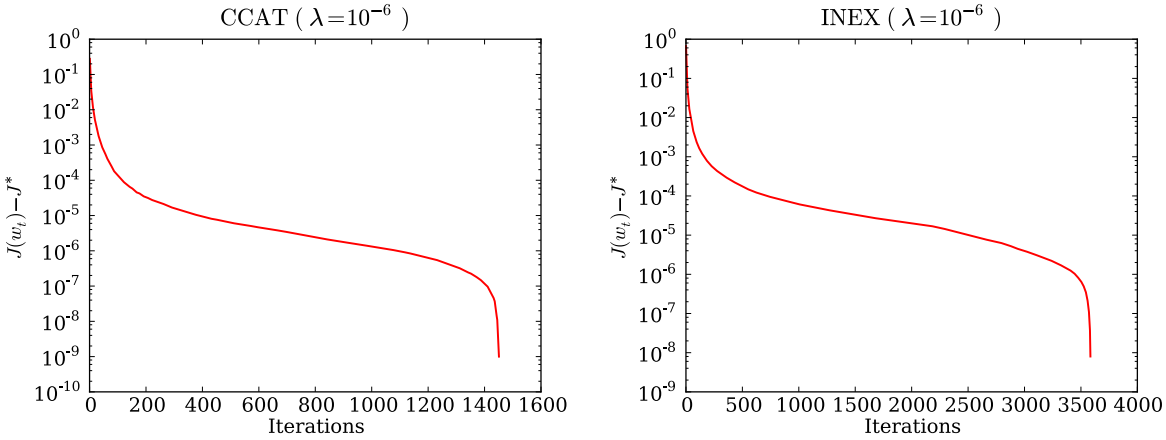

Figure 9: Convergence of subLBFGS in objective function value on sample L_2-regularized risk minimization problems with binary (left) and multiclass (right) hinge losses.

in Figure 9, where we plot (on a log scale) the excess objective function value $J(\boldsymbol{w}_t)$ over its "optimum" J^*[7] against the iteration number in two typical runs. The same kind of convergence behavior was observed by Lewis and Overton (2008a, Figure 5.7), who applied the classical BFGS algorithm with a specially designed line search to nonsmooth functions. They caution that the apparent superlinear convergence may be an artifact caused by the inaccuracy of the estimated optimal value of the objective.

4. SubBFGS for L_2-Regularized Binary Hinge Loss

Many machine learning algorithms can be viewed as minimizing the L_2-regularized risk

$$J(\boldsymbol{w}) := \frac{\lambda}{2}\|\boldsymbol{w}\|^2 + \frac{1}{n}\sum_{i=1}^{n} l(\boldsymbol{x}_i, z_i, \boldsymbol{w}), \tag{30}$$

where $\lambda > 0$ is a regularization constant, $\boldsymbol{x}_i \in \mathcal{X} \subseteq \mathbb{R}^d$ are the input features, $z_i \in \mathcal{Z} \subseteq \mathbb{Z}$ the corresponding labels, and the loss l is a non-negative convex function of $\boldsymbol{w}$ which measures the discrepancy between z_i and the predictions arising from using $\boldsymbol{w}$. A loss function commonly used for binary classification is the binary hinge loss

$$l(\boldsymbol{x}, z, \boldsymbol{w}) := \max(0, 1 - z\boldsymbol{w}^\top \boldsymbol{x}), \tag{31}$$

where $z \in \{\pm 1\}$. L_2-regularized risk minimization with the binary hinge loss is a convex but nonsmooth optimization problem; in this section we show how subBFGS (Algorithm 1) can be applied to this problem.

7. Estimated empirically by running subLBFGS for 10^4 seconds, or until the relative improvement over 5 iterations was less than 10^{-8}.

Let $\mathcal{E}$, $\mathcal{M}$, and $\mathcal{W}$ index the set of points which are in error, on the margin, and well-classified, respectively:

$$\begin{aligned}\mathcal{E} &:= \{i \in \{1,2,\ldots,n\} : 1 - z_i \boldsymbol{w}^\top \boldsymbol{x}_i > 0\},\\ \mathcal{M} &:= \{i \in \{1,2,\ldots,n\} : 1 - z_i \boldsymbol{w}^\top \boldsymbol{x}_i = 0\},\\ \mathcal{W} &:= \{i \in \{1,2,\ldots,n\} : 1 - z_i \boldsymbol{w}^\top \boldsymbol{x}_i < 0\}.\end{aligned}$$

Differentiating (30) after plugging in (31) then yields

$$\partial J(\boldsymbol{w}) \;=\; \lambda \boldsymbol{w} - \frac{1}{n}\sum_{i=1}^{n} \beta_i z_i \boldsymbol{x}_i \;=\; \bar{\boldsymbol{w}} - \frac{1}{n}\sum_{i \in \mathcal{M}} \beta_i z_i \boldsymbol{x}_i, \tag{32}$$

$$\text{where} \quad \bar{\boldsymbol{w}} := \lambda \boldsymbol{w} - \frac{1}{n}\sum_{i \in \mathcal{E}} z_i \boldsymbol{x}_i \quad \text{and} \quad \beta_i := \begin{cases} 1 & \text{if} \quad i \in \mathcal{E}, \\ [0,1] & \text{if} \quad i \in \mathcal{M}, \\ 0 & \text{if} \quad i \in \mathcal{W}. \end{cases}$$

4.1 Efficient Oracle for the Direction-Finding Method

Recall that subBFGS requires an oracle that provides $\arg\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}$ for a given direction $\boldsymbol{p}$. For L_2-regularized risk minimization with the binary hinge loss we can implement such an oracle at a computational cost of $O(d\,|\,\mathcal{M}_t\,|)$, where d is the dimensionality of $\boldsymbol{p}$ and $|\,\mathcal{M}_t\,|$ the number of current margin points, which is normally much less than n. Towards this end, we use (32) to obtain

$$\begin{aligned}\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p} \;&=\; \sup_{\beta_i, i \in \mathcal{M}_t} \left(\bar{\boldsymbol{w}}_t - \frac{1}{n}\sum_{i \in \mathcal{M}_t} \beta_i z_i \boldsymbol{x}_i \right)^\top \boldsymbol{p} \\ &=\; \bar{\boldsymbol{w}}_t^\top \boldsymbol{p} - \frac{1}{n}\sum_{i \in \mathcal{M}_t} \inf_{\beta_i \in [0,1]} (\beta_i z_i \boldsymbol{x}_i^\top \boldsymbol{p}).\end{aligned} \tag{33}$$

Since for a given $\boldsymbol{p}$ the first term of the right-hand side of (33) is a constant, the supremum is attained when we set $\beta_i \; \forall i \in \mathcal{M}_t$ via the following strategy:

$$\beta_i := \begin{cases} 0 & \text{if } \; z_i \boldsymbol{x}_i^\top \boldsymbol{p}_t \geq 0, \\ 1 & \text{if } \; z_i \boldsymbol{x}_i^\top \boldsymbol{p}_t < 0. \end{cases}$$

4.2 Implementing the Line Search

The one-dimensional convex function $\Phi(\eta) := J(\boldsymbol{w} + \eta \boldsymbol{p})$ (Figure 10, left) obtained by restricting (30) to a line can be evaluated efficiently. To see this, rewrite (30) as

$$J(\boldsymbol{w}) \;:=\; \frac{\lambda}{2}\|\boldsymbol{w}\|^2 + \frac{1}{n}\mathbf{1}^\top \max(\mathbf{0},\, \mathbf{1} - \boldsymbol{z} \cdot \boldsymbol{X}\boldsymbol{w}), \tag{34}$$

where $\mathbf{0}$ and $\mathbf{1}$ are column vectors of zeros and ones, respectively, $\cdot$ denotes the Hadamard (component-wise) product, and $\boldsymbol{z} \in \mathbb{R}^n$ collects correct labels corresponding to each row of data in $\boldsymbol{X} := [\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_n]^\top \in \mathbb{R}^{n \times d}$. Given a search direction $\boldsymbol{p}$ at a point $\boldsymbol{w}$, (34) allows us to write

$$\Phi(\eta) = \frac{\lambda}{2}\|\boldsymbol{w}\|^2 + \lambda \eta\, \boldsymbol{w}^\top \boldsymbol{p} + \frac{\lambda \eta^2}{2}\|\boldsymbol{p}\|^2 + \frac{1}{n}\mathbf{1}^\top \max\left[0,\, (\mathbf{1} - (\boldsymbol{f} + \eta \Delta \boldsymbol{f}))\right], \tag{35}$$

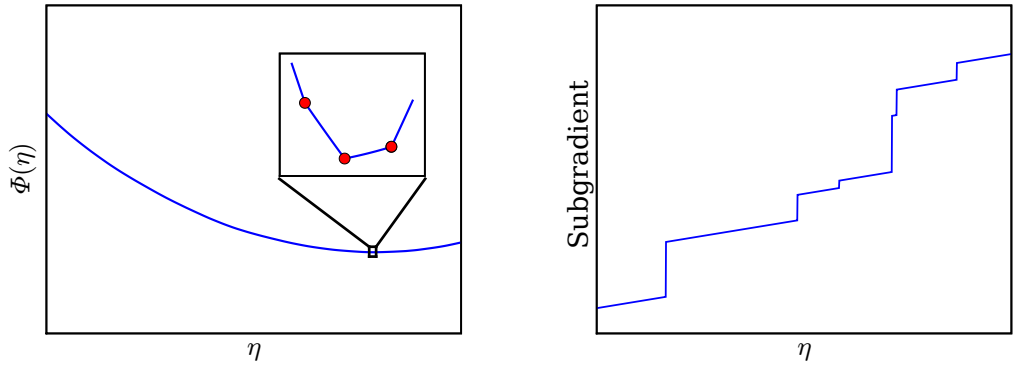

Figure 10: Left: Piecewise quadratic convex function Φ of step size η; solid disks in the zoomed inset are subdifferentiable points. Right: The subgradient of $\Phi(\eta)$ increases monotonically with η, and jumps discontinuously at subdifferentiable points.

where $\boldsymbol{f} := \boldsymbol{z} \cdot \boldsymbol{X}\boldsymbol{w}$ and $\Delta\boldsymbol{f} := \boldsymbol{z} \cdot \boldsymbol{X}\boldsymbol{p}$. Differentiating (35) with respect to η gives the subdifferential of Φ:

$$\partial\Phi(\eta) = \lambda \boldsymbol{w}^\top \boldsymbol{p} + \eta\lambda\|\boldsymbol{p}\|^2 - \frac{1}{n}\boldsymbol{\delta}(\eta)^\top \Delta\boldsymbol{f}, \tag{36}$$

where $\boldsymbol{\delta} : \mathbb{R} \to \mathbb{R}^n$ outputs a column vector $[\delta_1(\eta), \delta_2(\eta), \cdots, \delta_n(\eta)]^\top$ with

$$\delta_i(\eta) := \begin{cases} 1 & \text{if} \quad f_i + \eta\Delta f_i < 1, \\ [0,1] & \text{if} \quad f_i + \eta\Delta f_i = 1, \\ 0 & \text{if} \quad f_i + \eta\Delta f_i > 1. \end{cases} \tag{37}$$

We cache $\boldsymbol{f}$ and $\Delta\boldsymbol{f}$, expending $O(nd)$ computational effort and using $O(n)$ storage. We also cache the scalars $\frac{\lambda}{2}\|\boldsymbol{w}\|^2$, $\lambda\boldsymbol{w}^\top\boldsymbol{p}$, and $\frac{\lambda}{2}\|\boldsymbol{p}\|^2$, each of which requires $O(d)$ work. The evaluation of $\boldsymbol{1} - (\boldsymbol{f} + \eta\Delta\boldsymbol{f})$, $\boldsymbol{\delta}(\eta)$, and the inner products in the final terms of (35) and (36) all take $O(n)$ effort. Given the cached terms, all other terms in (35) can be computed in constant time, thus reducing the cost of evaluating $\Phi(\eta)$ (resp., its subgradient) to $O(n)$. Furthermore, from (37) we see that $\Phi(\eta)$ is differentiable everywhere except at

$$\eta_i := (1 - f_i)/\Delta f_i \;\text{ with }\; \Delta f_i \neq 0, \tag{38}$$

where it becomes subdifferentiable. At these points an element of the indicator vector (37) changes from 0 to 1 or vice versa (causing the subgradient to jump, as shown in Figure 10, right); otherwise $\boldsymbol{\delta}(\eta)$ remains constant. Using this property of $\boldsymbol{\delta}(\eta)$, we can update the last term of (36) in constant time when passing a hinge point (Line 25 of Algorithm 3). We are now in a position to introduce an exact line search which takes advantage of this scheme.

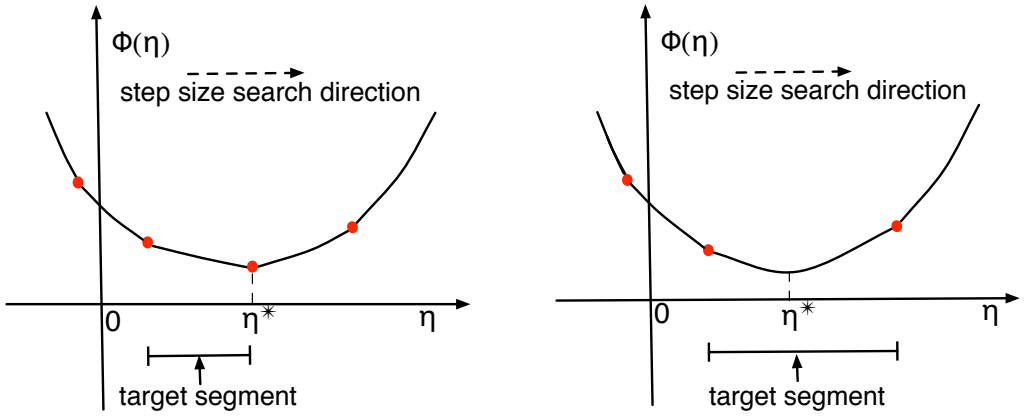

Figure 11: Nonsmooth convex function Φ of step size η. Solid disks are subdifferentiable points; the optimal step η^* either falls on such a point (left), or lies between two such points (right).

4.2.1 EXACT LINE SEARCH

Given a direction $\boldsymbol{p}$, exact line search finds the optimal step size $\eta^* := \operatorname{argmin}_{\eta \geq 0} \Phi(\eta)$ that satisfies $0 \in \partial \Phi(\eta^*)$, or equivalently

$$\inf \partial \Phi(\eta^*) \leq 0 \leq \sup \partial \Phi(\eta^*).$$

By Theorem 1, $\sup \partial \Phi(\eta)$ is monotonically increasing with η. Based on this property, our algorithm first builds a list of all possible subdifferentiable points and $\eta = 0$, sorted by non-descending value of η (Lines 4–5 of Algorithm 3). Then, it starts with $\eta = 0$, and walks through the sorted list until it locates the "target segment", an interval $[\eta_a, \eta_b]$ between two subdifferential points with $\sup \partial \Phi(\eta_a) \leq 0$ and $\sup \partial \Phi(\eta_b) \geq 0$. We now know that the optimal step size either coincides with η_b (Figure 11, left), or lies in (η_a, η_b) (Figure 11, right). If η^* lies in the smooth interval (η_a, η_b), then setting (36) to zero gives

$$\eta^* = \frac{\boldsymbol{\delta}(\eta')^\top \Delta \boldsymbol{f}/n - \lambda \boldsymbol{w}^\top \boldsymbol{p}}{\lambda \|\boldsymbol{p}\|^2}, \quad \forall \eta' \in (\eta_a, \eta_b). \tag{39}$$

Otherwise, $\eta^* = \eta_b$. See Algorithm 3 for the detailed implementation.

5. Segmenting the Pointwise Maximum of 1-D Linear Functions

The line search of Algorithm 3 requires a vector $\boldsymbol{\eta}$ listing the subdifferentiable points along the line $\boldsymbol{w} + \eta \boldsymbol{p}$, and sorts it in non-descending order (Line 5). For an objective function like (30) whose nonsmooth component is just a sum of hinge losses (31), this vector is very easy to compute (cf. (38)). In order to apply our line search approach to multiclass and multilabel losses, however, we must solve a more general problem: we need to efficiently find the subdifferentiable points of a

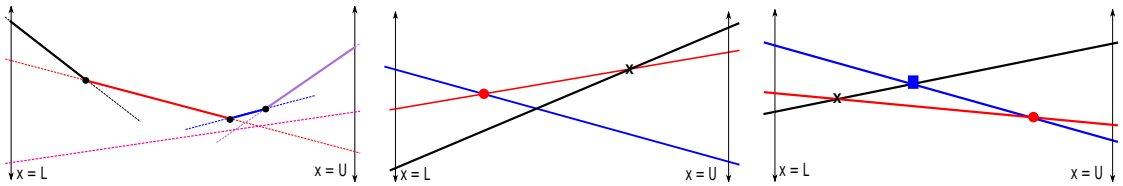
Algorithm 3 Exact Line Search for L_2-Regularized Binary Hinge Loss

input $\boldsymbol{w}, \boldsymbol{p}, \lambda, \boldsymbol{f}$, and $\Delta\boldsymbol{f}$ as in (35)
output optimal step size
$h = \lambda\|\boldsymbol{p}\|^2,\ j := 1$
$\boldsymbol{\eta} := [(\mathbf{1} - \boldsymbol{f})./\Delta\boldsymbol{f}, 0]$ (vector of subdifferentiable points & zero)
$\boldsymbol{\pi} = \texttt{argsort}(\boldsymbol{\eta})$ (indices sorted by non-descending value of $\boldsymbol{\eta}$)
while $\eta_{\pi_j} \leq 0$ **do**
  $j := j + 1$
end while
$\eta := \eta_{\pi_j}/2$
for $i := 1$ to $\boldsymbol{f}.\texttt{size}$ **do**
  $\delta_i := \begin{cases} 1 & \text{if } f_i + \eta\,\Delta f_i < 1 \\ 0 & \text{otherwise} \end{cases}$ (value of $\boldsymbol{\delta}(\eta)$ (37) for any $\eta \in (0, \eta_{\pi_j})$)
end for
$\rho := \boldsymbol{\delta}^\top \Delta\boldsymbol{f}/n - \lambda \boldsymbol{w}^\top \boldsymbol{p}$
$\eta := 0,\ \rho' := 0$
$g := -\rho$ (value of $\sup \partial\Phi(0)$)
while $g < 0$ **do**
  $\rho' := \rho$
  if $j > \boldsymbol{\pi}.\texttt{size}$ **then**
    $\eta := \infty$ (no more subdifferentiable points)
    break
  else
    $\eta := \eta_{\pi_j}$
  end if
  repeat
    $\rho := \begin{cases} \rho - \Delta f_{\pi_j}/n & \text{if } \delta_{\pi_j} = 1 \\ \rho + \Delta f_{\pi_j}/n & \text{otherwise} \end{cases}$ (move to next subdifferentiable point and update ρ accordingly)
    $j := j + 1$
  until $\eta_{\pi_j} \neq \eta_{\pi_{j-1}}$ and $j \leq \boldsymbol{\pi}.\texttt{size}$
  $g := \eta h - \rho$ (value of $\sup \partial\Phi(\eta_{\pi_{j-1}})$)
end while
return $\min(\eta,\ \rho'/h)$ (cf. equation 39)

one-dimensional piecewise linear function $\rho : \mathbb{R} \to \mathbb{R}$ defined to be the pointwise maximum of r lines:

$$\rho(\eta) = \max_{1 \leq p \leq r} (b_p + \eta\, a_p), \tag{40}$$

where a_p and b_p denote the slope and offset of the p^{th} line, respectively. Clearly, ρ is convex since it is the pointwise maximum of linear functions (Boyd and Vandenberghe, 2004, Section 3.2.3), see Figure 12(a). The difficulty here is that although ρ consists of at most r line segments bounded by at most $r-1$ subdifferentiable points, there are $r(r-1)/2$ candidates for these points, namely all intersections between any two of the r lines. A naive algorithm to find the subdifferentiable points of ρ would therefore take $O(r^2)$ time. In what follows, however, we show how this can be done in just $O(r \log r)$ time. In Section 6 we will then use this technique (Algorithm 4) to perform efficient exact line search in the multiclass and multilabel settings.



(a) Pointwise maximum of lines (b) Case 1 (c) Case 2

Figure 12: (a) Convex piecewise linear function defined as the maximum of 5 lines, but comprising only 4 active line segments (bold) separated by 3 subdifferentiable points (black dots). (b, c) Two cases encountered by our algorithm: (b) The new intersection (black cross) lies to the right of the previous one (red dot) and is therefore pushed onto the stack; (c) The new intersection lies to the left of the previous one. In this case the latter is popped from the stack, and a third intersection (blue square) is computed and pushed onto it.

Algorithm 4 Segmenting a Pointwise Maximum of 1-D Linear Functions

  while not S.`empty` **do**
    $(\eta, \xi) := S$.`top`
    $\eta' := \dfrac{b_{\pi_q} - b_\xi}{a_\xi - a_{\pi_q}}$ (intersection of two lines)
    if $L < \eta' \le \eta$ or ($\eta' = L$ and $a_{\pi_q} > a_\xi$) **then**
      S.`pop` (cf. Figure 12(c))
    else
      break
    end if
  end while
  if $L < \eta' \le U$ or ($\eta' = L$ and $a_{\pi_q} > a_\xi$) **then**
    S.`push` (η', π_q) (cf. Figure 12(b))
  end if
end for
return S

We begin by specifying an interval $[L,U]$ $(0 \le L < U < \infty)$ in which to find the subdifferentiable points of ρ, and set $\mathbf{y} := \boldsymbol{b} + L\boldsymbol{a}$, where $\boldsymbol{a} = [a_1, a_2, \cdots, a_r]$ and $\boldsymbol{b} = [b_1, b_2, \cdots, b_r]$. In other words, $\mathbf{y}$ contains the intersections of the r lines defining $\rho(\eta)$ with the vertical line $\eta = L$. Let $\boldsymbol{\pi}$ denote the permutation that sorts $\mathbf{y}$ in non-ascending order, that is, $p < q \implies y_{\pi_p} \ge y_{\pi_q}$, and let $\rho^{(q)}$ be the

function obtained by considering only the top $q \leq r$ lines at $\eta = L$, that is, the first q lines in $\boldsymbol{\pi}$:

$$\rho^{(q)}(\eta) = \max_{1 \leq p \leq q} (b_{\pi_p} + \eta\, a_{\pi_p}). \tag{41}$$

It is clear that $\rho^{(r)} = \rho$. Let $\boldsymbol{\eta}$ contain all $q' \leq q-1$ subdifferentiable points of $\rho^{(q)}$ in $[L,U]$ in ascending order, and $\boldsymbol{\xi}$ the indices of the corresponding *active* lines, that is, the maximum in (41) is attained for line ξ_{j-1} over the interval $[\eta_{j-1}, \eta_j]$: $\xi_{j-1} := \pi_{p^*}$, where $p^* = \operatorname{argmax}_{1 \leq p \leq q}(b_{\pi_p} + \eta a_{\pi_p})$ for $\eta \in [\eta_{j-1}, \eta_j]$, and lines ξ_{j-1} and ξ_j intersect at η_j.

Initially we set $\eta_0 := L$ and $\xi_0 := \pi_1$, the leftmost bold segment in Figure 12(a). Algorithm 4 goes through lines in $\boldsymbol{\pi}$ sequentially, and maintains a Last-In-First-Out stack S which at the end of the q^{th} iteration consists of the tuples

$$(\eta_0, \xi_0), (\eta_1, \xi_1), \ldots, (\eta_{q'}, \xi_{q'})$$

in order of ascending η_i, with $(\eta_{q'}, \xi_{q'})$ at the top. After r iterations S contains a sorted list of all subdifferentiable points (and the corresponding active lines) of $\rho = \rho^{(r)}$ in $[L,U]$, as required by our line searches.

In iteration $q+1$ Algorithm 4 examines the intersection η' between lines $\xi_{q'}$ and π_{q+1}: If $\eta' > U$, line π_{q+1} is irrelevant, and we proceed to the next iteration. If $\eta_{q'} < \eta' \leq U$ as in Figure 12(b), then line π_{q+1} is becoming active at η', and we simply push (η', π_{q+1}) onto the stack. If $\eta' \leq \eta_{q'}$ as in Figure 12(c), on the other hand, then line π_{q+1} dominates line $\xi_{q'}$ over the interval (η', ∞) and hence over $(\eta_{q'}, U] \subset (\eta', \infty)$, so we pop $(\eta_{q'}, \xi_{q'})$ from the stack (deactivating line $\xi_{q'}$), decrement q', and repeat the comparison.

Theorem 2 *The total running time of Algorithm 4 is $O(r \log r)$.*

Proof Computing intersections of lines as well as pushing and popping from the stack require $O(1)$ time. Each of the r lines can be pushed onto and popped from the stack at most once; amortized over r iterations the running time is therefore $O(r)$. The time complexity of Algorithm 4 is thus dominated by the initial sorting of $\mathbf{y}$ (i.e., the computation of $\boldsymbol{\pi}$), which takes $O(r \log r)$ time. ■

6. SubBFGS for Multiclass and Multilabel Hinge Losses

We now use the algorithm developed in Section 5 to generalize the subBFGS method of Section 4 to the multiclass and multilabel settings with finite label set $\mathcal{Z}$. We assume that given a feature vector $\boldsymbol{x}$ our classifier predicts the label

$$z^* = \operatorname*{argmax}_{z \in \mathcal{Z}} f(\boldsymbol{w}, \boldsymbol{x}, z),$$

where f is a linear function of $\boldsymbol{w}$, that is, $f(\boldsymbol{w}, \boldsymbol{x}, z) = \boldsymbol{w}^\top \phi(\boldsymbol{x}, z)$ for some feature map $\phi(\boldsymbol{x}, z)$.

6.1 Multiclass Hinge Loss

A variety of multiclass hinge losses have been proposed in the literature that generalize the binary hinge loss, and enforce a margin of separation between the true label z_i and every other label. We

focus on the following rather general variant (Taskar et al., 2004):[8]

$$l(\boldsymbol{x}_i, z_i, \boldsymbol{w}) \;:=\; \max_{z \in \mathcal{Z}} [\Delta(z, z_i) + f(\boldsymbol{w}, \boldsymbol{x}_i, z) - f(\boldsymbol{w}, \boldsymbol{x}_i, z_i)], \tag{42}$$

where $\Delta(z, z_i) \geq 0$ is the *label loss* specifying the margin required between labels z and z_i. For instance, a uniform margin of separation is achieved by setting $\Delta(z, z') := \tau > 0 \; \forall z \neq z'$ (Crammer and Singer, 2003a). By requiring that $\forall z \in \mathcal{Z} : \Delta(z, z) = 0$ we ensure that (42) always remains non-negative. Adapting (30) to the multiclass hinge loss (42) we obtain

$$J(\boldsymbol{w}) \;:=\; \frac{\lambda}{2}\|\boldsymbol{w}\|^2 + \frac{1}{n}\sum_{i=1}^{n} \max_{z \in \mathcal{Z}} [\Delta(z, z_i) + f(\boldsymbol{w}, \boldsymbol{x}_i, z) - f(\boldsymbol{w}, \boldsymbol{x}_i, z_i)]. \tag{43}$$

For a given $\boldsymbol{w}$, consider the set

$$\mathcal{Z}_i^* := \operatorname*{argmax}_{z \in \mathcal{Z}} [\Delta(z, z_i) + f(\boldsymbol{w}, \boldsymbol{x}_i, z) - f(\boldsymbol{w}, \boldsymbol{x}_i, z_i)]$$

of maximum-loss labels (possibly more than one) for the i^{th} training instance. Since $f(\boldsymbol{w}, \boldsymbol{x}, z) = \boldsymbol{w}^\top \phi(\boldsymbol{x}, z)$, the subdifferential of (43) can then be written as

$$\partial J(\boldsymbol{w}) \;=\; \lambda \boldsymbol{w} + \frac{1}{n}\sum_{i=1}^{n} \sum_{z \in \mathcal{Z}} \beta_{i,z}\, \phi(\boldsymbol{x}_i, z) \tag{44}$$

$$\text{with} \quad \beta_{i,z} \;=\; \left\{ \begin{array}{cc} [0,1] & \text{if } z \in \mathcal{Z}_i^* \\ 0 & \text{otherwise} \end{array} \right\} - \delta_{z,z_i} \;\; \text{s.t.} \;\; \sum_{z \in \mathcal{Z}} \beta_{i,z} = 0, \tag{45}$$

where δ is the Kronecker delta: $\delta_{a,b} = 1$ if $a = b$, and 0 otherwise.[9]

6.2 Efficient Multiclass Direction-Finding Oracle

For L_2-regularized risk minimization with multiclass hinge loss, we can use a similar scheme as described in Section 4.1 to implement an efficient oracle that provides $\arg\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}$ for the direction-finding procedure (Algorithm 2). Using (44), we can write

$$\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p} \;=\; \lambda \boldsymbol{w}^\top \boldsymbol{p} + \frac{1}{n}\sum_{i=1}^{n} \sum_{z \in \mathcal{Z}} \sup_{\beta_{i,z}} \left(\beta_{i,z}\, \phi(\boldsymbol{x}_i, z)^\top \boldsymbol{p} \right). \tag{46}$$

The supremum in (46) is attained when we pick, from the choices offered by (45),

$$\beta_{i,z} := \delta_{z,z_i^*} - \delta_{z,z_i}, \;\; \text{where} \;\; z_i^* := \operatorname*{argmax}_{z \in \mathcal{Z}_i^*} \phi(\boldsymbol{x}_i, z)^\top \boldsymbol{p}.$$

8. Our algorithm can also deal with the slack-rescaled variant of Tsochantaridis et al. (2005).

9. Let $l_i^* := \max_{z \neq z_i} [\Delta(z, z_i) + f(\boldsymbol{w}, \boldsymbol{x}_i, z) - f(\boldsymbol{w}, \boldsymbol{x}_i, z_i)]$. Definition (45) allows the following values of $\beta_{i,z}$:

$$\left\{ \begin{array}{c|ccc} & z = z_i & z \in \mathcal{Z}_i^* \setminus \{z_i\} & \text{otherwise} \\ \hline l_i^* < 0 & 0 & 0 & 0 \\ l_i^* = 0 & [-1, 0] & [0, 1] & 0 \\ l_i^* > 0 & -1 & [0, 1] & 0 \end{array} \right\} \;\; \text{s.t.} \;\; \sum_{z \in \mathcal{Z}} \beta_{i,z} = 0.$$

6.3 Implementing the Multiclass Line Search

Let $\Phi(\eta) := J(\boldsymbol{w} + \eta \boldsymbol{p})$ be the one-dimensional convex function obtained by restricting (43) to a line along direction $\boldsymbol{p}$. Letting $\rho_i(\eta) := l(\boldsymbol{x}_i, z_i, \boldsymbol{w} + \eta \boldsymbol{p})$, we can write

$$\Phi(\eta) \;=\; \frac{\lambda}{2}\|\boldsymbol{w}\|^2 + \lambda\eta \boldsymbol{w}^\top \boldsymbol{p} + \frac{\lambda\eta^2}{2}\|\boldsymbol{p}\|^2 + \frac{1}{n}\sum_{i=1}^{n} \rho_i(\eta). \tag{47}$$

Each $\rho_i(\eta)$ is a piecewise linear convex function. To see this, observe that

$$f(\boldsymbol{w} + \eta \boldsymbol{p}, \boldsymbol{x}, z) := (\boldsymbol{w} + \eta \boldsymbol{p})^\top \phi(\boldsymbol{x}, z) = f(\boldsymbol{w}, \boldsymbol{x}, z) + \eta f(\boldsymbol{p}, \boldsymbol{x}, z)$$

and hence

$$\rho_i(\eta) := \max_{z \in \mathcal{Z}} [\underbrace{\Delta(z, z_i) + f(\boldsymbol{w}, \boldsymbol{x}_i, z) - f(\boldsymbol{w}, \boldsymbol{x}_i, z_i)}_{=: b_z^{(i)}} + \eta \underbrace{(f(\boldsymbol{p}, \boldsymbol{x}_i, z) - f(\boldsymbol{p}, \boldsymbol{x}_i, z_i))}_{=: a_z^{(i)}}], \tag{48}$$

which has the functional form of (40) with $r = |\mathcal{Z}|$. Algorithm 4 can therefore be used to compute a sorted vector $\boldsymbol{\eta}^{(i)}$ of all subdifferentiable points of $\rho_i(\eta)$ and corresponding active lines $\boldsymbol{\xi}^{(i)}$ in the interval $[0, \infty)$ in $O(|\mathcal{Z}| \log |\mathcal{Z}|)$ time. With some abuse of notation, we now have

$$\eta \in [\eta_j^{(i)}, \eta_{j+1}^{(i)}] \implies \rho_i(\eta) = b_{\xi_j^{(i)}} + \eta\, a_{\xi_j^{(i)}}. \tag{49}$$

The first three terms of (47) are constant, linear, and quadratic (with non-negative coefficient) in η, respectively. The remaining sum of piecewise linear convex functions $\rho_i(\eta)$ is also piecewise linear and convex, and so $\Phi(\eta)$ is a piecewise quadratic convex function.

6.3.1 EXACT MULTICLASS LINE SEARCH

Our exact line search employs a similar two-stage strategy as discussed in Section 4.2.1 for locating its minimum $\eta^* := \operatorname{argmin}_{\eta > 0} \Phi(\eta)$: we first find the first *subdifferentiable* point $\check{\eta}$ past the minimum, then locate η^* within the differentiable region to its left. We precompute and cache a vector $\boldsymbol{a}^{(i)}$ of all the slopes $a_z^{(i)}$ (offsets $b_z^{(i)}$ are not needed), the subdifferentiable points $\boldsymbol{\eta}^{(i)}$ (sorted in ascending order via Algorithm 4), and the corresponding indices $\boldsymbol{\xi}^{(i)}$ of active lines of ρ_i for all training instances i, as well as $\|\boldsymbol{w}\|^2$, $\boldsymbol{w}^\top \boldsymbol{p}$, and $\lambda\|\boldsymbol{p}\|^2$.

Since $\Phi(\eta)$ is convex, any point $\eta < \eta^*$ cannot have a non-negative subgradient.[10] The first subdifferentiable point $\check{\eta} \geq \eta^*$ therefore obeys

$$\begin{aligned} \check{\eta} \;&:=\; \min \eta \in \{\boldsymbol{\eta}^{(i)}, i = 1, 2, \ldots, n\} : \eta \geq \eta^* \\ &=\; \min \eta \in \{\boldsymbol{\eta}^{(i)}, i = 1, 2, \ldots, n\} : \sup \partial \Phi(\eta) \geq 0. \end{aligned} \tag{50}$$

We solve (50) via a simple linear search: Starting from $\eta = 0$, we walk from one subdifferentiable point to the next until $\sup \partial \Phi(\eta) \geq 0$. To perform this walk efficiently, define a vector $\boldsymbol{\psi} \in \mathbb{N}^n$ of indices into the sorted vector $\boldsymbol{\eta}^{(i)}$ *resp.* $\boldsymbol{\xi}^{(i)}$; initially $\boldsymbol{\psi} := \mathbf{0}$, indicating that $(\forall i)\ \eta_0^{(i)} = 0$. Given the current index vector $\boldsymbol{\psi}$, the next subdifferentiable point is then

$$\eta' := \eta_{(\psi_{i'}+1)}^{(i')}, \;\; \text{where} \;\; i' = \operatorname*{argmin}_{1 \leq i \leq n} \eta_{(\psi_i+1)}^{(i)}; \tag{51}$$

10. If $\Phi(\eta)$ has a flat optimal region, we define η^* to be the infimum of that region.

Algorithm 5 Exact Line Search for L_2-Regularized Multiclass Hinge Loss

1: **input** base point $\boldsymbol{w}$, descent direction $\boldsymbol{p}$, regularization parameter λ, vector $\boldsymbol{a}$ of all slopes as defined in (48), for each training instance i: sorted stack S_i of subdifferentiable points and active lines, as produced by Algorithm 4
2: **output** optimal step size
3: $\boldsymbol{a} := \boldsymbol{a}/n,\ h := \lambda\|\boldsymbol{p}\|^2$
4: $\rho := \lambda \boldsymbol{w}^\top \boldsymbol{p}$
5: **for** $i := 1$ to n **do**
6: **while** not S_i.`empty` **do**
7: R_i.`push` S_i.`pop` (reverse the stacks)
8: **end while**
9: $(\cdot, \xi_i) := R_i$.`pop`
10: $\rho := \rho + a_{\xi_i}$
11: **end for**
12: $\eta := 0,\ \rho' = 0$
13: $g := \rho$ (value of $\sup \partial\Phi(0)$)
14: **while** $g < 0$ **do**
15: $\rho' := \rho$
16: **if** $\forall i : R_i$.`empty` **then**
17: $\eta := \infty$ (no more subdifferentiable points)
18: **break**
19: **end if**
20: $I := \operatorname{argmin}_{1 \le i \le n}\ \eta' :\ (\eta', \cdot) = R_i$.`top` (find the next subdifferentiable point)
21: $\rho := \rho - \sum_{i \in I} a_{\xi_i}$
22: $\Xi := \{\xi_i : (\eta, \xi_i) := R_i.\texttt{pop},\ \ i \in I\}$
23: $\rho := \rho + \sum_{\xi_i \in \Xi} a_{\xi_i}$
24: $g := \rho + \eta h$ (value of $\sup \partial\Phi(\eta)$)
25: **end while**
26: **return** $\min(\eta, -\rho'/h)$

the step is completed by incrementing $\psi_{i'}$, that is, $\psi_{i'} := \psi_{i'} + 1$ so as to remove $\eta^{(i')}_{\psi_{i'}}$ from future consideration.[11] Note that computing the argmin in (51) takes $O(\log n)$ time (e.g., using a priority queue). Inserting (49) into (47) and differentiating, we find that

$$\sup \partial\Phi(\eta') \ = \ \lambda \boldsymbol{w}^\top \boldsymbol{p} + \lambda \eta' \|\boldsymbol{p}\|^2 + \frac{1}{n} \sum_{i=1}^{n} a_{\xi^{(i)}_{\psi_i}}. \tag{52}$$

The key observation here is that after the initial calculation of $\sup \partial\Phi(0) = \lambda \boldsymbol{w}^\top \boldsymbol{p} + \frac{1}{n}\sum_{i=1}^{n} a_{\xi^{(i)}_0}$ for $\eta = 0$, the sum in (52) can be updated incrementally in constant time through the addition of $a_{\xi^{(i')}_{\psi_{i'}}} - a_{\xi^{(i')}_{(\psi_{i'}-1)}}$ (Lines 20–23 of Algorithm 5).

Suppose we find $\check{\eta} = \eta^{(i')}_{\psi_{i'}}$ for some i'. We then know that the minimum η^* is either equal to $\check{\eta}$ (Figure 11, left), or found within the quadratic segment immediately to its left (Figure 11, right).

11. For ease of exposition, we assume i' in (51) is unique, and deal with multiple choices of i' in Algorithm 5.

We thus decrement $\psi_{i'}$ (i.e., take one step back) so as to index the segment in question, set the right-hand side of (52) to zero, and solve for η' to obtain

$$\eta^* \;=\; \min\left(\check{\eta},\; \frac{\lambda \boldsymbol{w}^\top \boldsymbol{p} + \frac{1}{n}\sum_{i=1}^n a_{\xi^{(i)}_{\psi_i}}}{-\lambda\|\boldsymbol{p}\|^2}\right). \tag{53}$$

This only takes constant time: we have cached $\boldsymbol{w}^\top \boldsymbol{p}$ and $\lambda\|\boldsymbol{p}\|^2$, and the sum in (53) can be obtained incrementally by adding $a_{\xi^{(i')}_{\psi_{i'}}} - a_{\xi^{(i')}_{(\psi_{i'}+1)}}$ to its last value in (52).

To locate $\check{\eta}$ we have to walk at most $O(n|\mathcal{Z}|)$ steps, each requiring $O(\log n)$ computation of argmin as in (51). Given $\check{\eta}$, the exact minimum η^* can be obtained in $O(1)$. Including the preprocessing cost of $O(n|\mathcal{Z}|\log|\mathcal{Z}|)$ (for invoking Algorithm 4), our exact multiclass line search therefore takes $O(n|\mathcal{Z}|(\log n|\mathcal{Z}|))$ time in the worst case. Algorithm 5 provides an implementation which instead of an index vector $\boldsymbol{\psi}$ directly uses the sorted stacks of subdifferentiable points and active lines produced by Algorithm 4. (The cost of reversing those stacks in Lines 6–8 of Algorithm 5 can easily be avoided through the use of double-ended queues.)

6.4 Multilabel Hinge Loss

Recently, there has been interest in extending the concept of the hinge loss to multilabel problems. Multilabel problems generalize the multiclass setting in that each training instance $\boldsymbol{x}_i$ is associated with a set of labels $\mathcal{Z}_i \subseteq \mathcal{Z}$ (Crammer and Singer, 2003b). For a uniform margin of separation τ, a hinge loss can be defined in this setting as follows:

$$l(\boldsymbol{x}_i, \mathcal{Z}_i, \boldsymbol{w}) := \max[0,\; \tau + \max_{z' \notin \mathcal{Z}_i} f(\boldsymbol{w}, \boldsymbol{x}_i, z') - \min_{z \in \mathcal{Z}_i} f(\boldsymbol{w}, \boldsymbol{x}_i, z)]. \tag{54}$$

We can generalize this to a not necessarily uniform label loss $\Delta(z', z) \geq 0$ as follows:

$$l(\boldsymbol{x}_i, \mathcal{Z}_i, \boldsymbol{w}) := \max_{\substack{(z,z'):\, z \in \mathcal{Z}_i \\ z' \notin \mathcal{Z}_i \setminus \{z\}}} [\Delta(z', z) + f(\boldsymbol{w}, \boldsymbol{x}_i, z') - f(\boldsymbol{w}, \boldsymbol{x}_i, z)], \tag{55}$$

where as before we require that $\Delta(z, z) = 0\ \forall z \in \mathcal{Z}$ so that by explicitly allowing $z' = z$ we can ensure that (55) remains non-negative. For a uniform margin $\Delta(z', z) = \tau\ \ \forall z' \neq z$ our multilabel hinge loss (55) reduces to the decoupled version (54), which in turn reduces to the multiclass hinge loss (42) if $\mathcal{Z}_i := \{z_i\}$ for all i.

For a given $\boldsymbol{w}$, let

$$\mathcal{Z}_i^* := \operatorname*{argmax}_{\substack{(z,z'):\, z \in \mathcal{Z}_i \\ z' \notin \mathcal{Z}_i \setminus \{z\}}} [\Delta(z', z) + f(\boldsymbol{w}, \boldsymbol{x}_i, z') - f(\boldsymbol{w}, \boldsymbol{x}_i, z)]$$

be the set of worst label pairs (possibly more than one) for the i^{th} training instance. The subdifferential of the multilabel analogue of L_2-regularized multiclass objective (43) can then be written just as in (44), with coefficients

$$\beta_{i,z} := \sum_{z':\,(z',z) \in \mathcal{Z}_i^*} \gamma^{(i)}_{z',z} - \sum_{z':\,(z,z') \in \mathcal{Z}_i^*} \gamma^{(i)}_{z,z'}, \;\text{ where }\; (\forall i) \sum_{(z,z') \in \mathcal{Z}_i^*} \gamma^{(i)}_{z,z'} = 1 \;\text{ and }\; \gamma^{(i)}_{z,z'} \geq 0. \tag{56}$$

Now let $(z_i, z_i') := \operatorname{argmax}_{(z,z')\in\mathcal{Z}_i^*} [\phi(\boldsymbol{x}_i, z') - \phi(\boldsymbol{x}_i, z)]^\top \boldsymbol{p}$ be a single steepest worst label pair in direction $\boldsymbol{p}$. We obtain $\arg\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}$ for our direction-finding procedure by picking, from the choices offered by (56), $\gamma^{(i)}_{z,z'} := \delta_{z,z_i}\delta_{z',z_i'}$.

Finally, the line search we described in Section 6.3 for the multiclass hinge loss can be extended in a straightforward manner to our multilabel setting. The only caveat is that now $\rho_i(\eta) := l(\boldsymbol{x}_i, \mathcal{Z}_i, \boldsymbol{w} + \eta\boldsymbol{p})$ must be written as

$$\rho_i(\eta) := \max_{\substack{(z,z'):\, z\in\mathcal{Z}_i \\ z'\notin\mathcal{Z}_i\setminus\{z\}}} [\underbrace{\Delta(z', z) + f(\boldsymbol{w}, \boldsymbol{x}_i, z') - f(\boldsymbol{w}, \boldsymbol{x}_i, z)}_{=: b^{(i)}_{z,z'}} + \eta \underbrace{(f(\boldsymbol{p}, \boldsymbol{x}_i, z') - f(\boldsymbol{p}, \boldsymbol{x}_i, z))}_{=: a^{(i)}_{z,z'}}]. \tag{57}$$

In the worst case, (57) could be the piecewise maximum of $O(|\mathcal{Z}|^2)$ lines, thus increasing the overall complexity of the line search. In practice, however, the set of true labels $\mathcal{Z}_i$ is usually small, typically of size 2 or 3 (cf. Crammer and Singer, 2003b, Figure 3). As long as $\forall i : |\mathcal{Z}_i| = O(1)$, our complexity estimates of Section 6.3.1 still apply.

7. Related Work

We discuss related work in two areas: nonsmooth convex optimization, and the problem of segmenting the pointwise maximum of a set of one-dimensional linear functions.

7.1 Nonsmooth Convex Optimization

There are four main approaches to nonsmooth convex optimization: quasi-Newton methods, bundle methods, stochastic dual methods, and smooth approximation. We discuss each of these briefly, and compare and contrast our work with the state of the art.

7.1.1 NONSMOOTH QUASI-NEWTON METHODS

These methods try to find a descent quasi-Newton direction at every iteration, and invoke a line search to minimize the one-dimensional convex function along that direction. We note that the line search routines we describe in Sections 4–6 are applicable to all such methods. An example of this class of algorithms is the work of Lukšan and Vlček (1999), who propose an extension of BFGS to nonsmooth convex problems. Their algorithm samples subgradients around non-differentiable points in order to obtain a descent direction. In many machine learning problems evaluating the objective function and its (sub)gradient is very expensive, making such an approach inefficient. In contrast, given a current iterate $\boldsymbol{w}_t$, our direction-finding routine (Algorithm 2) samples subgradients from the set $\partial J(\boldsymbol{w}_t)$ via the oracle. Since this avoids the cost of explicitly evaluating new (sub)gradients, it is computationally more efficient.

Recently, Andrew and Gao (2007) introduced a variant of LBFGS, the Orthant-Wise Limited-memory Quasi-Newton (OWL-QN) algorithm, suitable for optimizing L_1-regularized log-linear models:

$$J(\boldsymbol{w}) := \lambda\|\boldsymbol{w}\|_1 + \underbrace{\frac{1}{n}\sum_{i=1}^{n} \ln(1 + e^{-z_i \boldsymbol{w}^\top \boldsymbol{x}_i})}_{\text{logistic loss}}, \tag{58}$$

where the logistic loss is smooth, but the regularizer is only subdifferentiable at points where $\boldsymbol{w}$ has zero elements. From the optimization viewpoint this objective is very similar to L_2-regularized hinge loss; the direction finding and line search methods that we discussed in Sections 3.2 and 3.3, respectively, can be applied to this problem with slight modifications.

OWL-QN is based on the observation that the L_1 regularizer is linear within any given orthant. Therefore, it maintains an approximation $\boldsymbol{B}^{\text{ow}}$ to the inverse Hessian of the logistic loss, and uses an efficient scheme to select orthants for optimization. In fact, its success greatly depends on its direction-finding subroutine, which demands a specially chosen subgradient $\boldsymbol{g}^{\text{ow}}$ (Andrew and Gao, 2007, Equation 4) to produce the quasi-Newton direction, $\boldsymbol{p}^{\text{ow}} = \pi(\boldsymbol{p}, \boldsymbol{g}^{\text{ow}})$, where $\boldsymbol{p} := -\boldsymbol{B}^{\text{ow}}\boldsymbol{g}^{\text{ow}}$ and the projection π returns a search direction by setting the i^{th} element of $\boldsymbol{p}$ to zero whenever $p_i g_i^{\text{ow}} > 0$. As shown in Section 8.4, the direction-finding subroutine of OWL-QN can be replaced by our Algorithm 2, which makes OWL-QN more robust to the choice of subgradients.

7.1.2 BUNDLE METHODS

Bundle method solvers (Hiriart-Urruty and Lemaréchal, 1993) use past (sub)gradients to build a model of the objective function. The (sub)gradients are used to lower-bound the objective by a piecewise linear function which is minimized to obtain the next iterate. This fundamentally differs from the BFGS approach of using past gradients to approximate the (inverse) Hessian, hence building a quadratic model of the objective function.

Bundle methods have recently been adapted to the machine learning context, where they are known as SVMStruct (Tsochantaridis et al., 2005) *resp*. BMRM (Smola et al., 2007). One notable feature of these variants is that they do not employ a line search. This is justified by noting that a line search involves computing the value of the objective function multiple times, a potentially expensive operation in machine learning applications.

Franc and Sonnenburg (2008) speed up the convergence of SVMStruct for L_2-regularized binary hinge loss. The main idea of their optimized cutting plane algorithm, OCAS, is to perform a line search along the line connecting two successive iterates of a bundle method solver. Recently they have extended OCAS to multiclass classification (Franc and Sonnenburg, 2009). Although developed independently, their line search methods for both settings are very similar to the methods we describe in Sections 4.2.1 and 6.3.1, respectively. In particular, their line search for multiclass classification also involves segmenting the pointwise maximum of r 1-D linear functions (cf. Section 5), though the $O(r^2)$ time complexity of their method is worse than our $O(r \log r)$.

7.1.3 STOCHASTIC DUAL METHODS

Distinct from the above two classes of primal algorithms are methods which work in the dual domain. A prominent member of this class is the LaRank algorithm of Bordes et al. (2007), which achieves state-of-the-art results on multiclass classification problems. While dual algorithms are very competitive on clean data sets, they tend to be slow when given noisy data.

7.1.4 SMOOTH APPROXIMATION

Another possible way to bypass the complications caused by the nonsmoothness of an objective function is to work on a smooth approximation instead—see for instance the recent work of Nesterov (2005) and Nemirovski (2005). Some machine learning applications have also been pursued along these lines (Lee and Mangasarian, 2001; Zhang and Oles, 2001). Although this approach can

be effective, it is unclear how to build a smooth approximation in general. Furthermore, smooth approximations often sacrifice dual sparsity, which often leads to better generalization performance on the test data, and also may be needed to prove generalization bounds.

7.2 Segmenting the Pointwise Maximum of 1-D Linear Functions

The problem of computing the line segments that comprise the pointwise maximum of a given set of line segments has received attention in the area of computational geometry; see Agarwal and Sharir (2000) for a survey. Hershberger (1989) for instance proposed a divide-and-conquer algorithm for this problem with the same time complexity as our Algorithm 4. The Hershberger (1989) algorithm solves a slightly harder problem—his function is the pointwise maximum of line segments, as opposed to our lines—but our algorithm is conceptually simpler and easier to implement.

A similar problem has also been studied under the banner of kinetic data structures by Basch (1999), who proposed a heap-based algorithm for this problem and proved a worst-case $O(r \log^2 r)$ bound, where r is the number of line segments. Basch (1999) also claims that the lower bound is $O(r \log r)$; our Algorithm 4 achieves this bound.

8. Experiments

We evaluated the performance of our subLBFGS algorithm with, and compared it to other state-of-the-art nonsmooth optimization methods on L_2-regularized binary, multiclass, and multilabel hinge loss minimization problems. We also compared OWL-QN with a variant that uses our direction-finding routine on L_1-regularized logistic loss minimization tasks. On strictly convex problems such as these every convergent optimizer will reach the same solution; comparing generalisation performance is therefore pointless. Hence we concentrate on empirically evaluating the convergence behavior (objective function value *vs*. CPU seconds). All experiments were carried out on a Linux machine with dual 2.4 GHz Intel Core 2 processors and 4 GB of RAM.

In all experiments the regularization parameter was chosen from the set $10^{\{-6,-5,\cdots,-1\}}$ so as to achieve the highest prediction accuracy on the test data set, while convergence behavior (objective function value *vs*. CPU seconds) is reported on the training data set. To see the influence of the regularization parameter λ, we also compared the time required by each algorithm to reduce the objective function value to within 2% of the optimal value.[12] For all algorithms the initial iterate $\boldsymbol{w}_0$ was set to $\mathbf{0}$. Open source C++ code implementing our algorithms and experiments is available for download from `http://www.cs.adelaide.edu.au/~jinyu/Code/nonsmoothOpt.tar.gz`.

The subgradient for the construction of the subLBFGS search direction (cf. Line 12 of Algorithm 1) was chosen arbitrarily from the subdifferential. For the binary hinge loss minimization (Section 8.3), for instance, we picked an arbitrary subgradient by randomly setting the coefficient $\beta_i \ \forall i \in \mathcal{M}$ in (32) to either 0 or 1.

8.1 Convergence Tolerance of the Direction-Finding Procedure

The convergence tolerance ε of Algorithm 2 controls the precision of the solution to the direction-finding problem (11): lower tolerance may yield a better search direction. Figure 13 (left) shows

12. For L_1-regularized logistic loss minimization, the "optimal" value was the final objective function value achieved by the OWL-QN* algorithm (cf. Section 8.4). In all other experiments, it was found by running subLBFGS for 10^4 seconds, or until its relative improvement over 5 iterations was less than 10^{-8}.

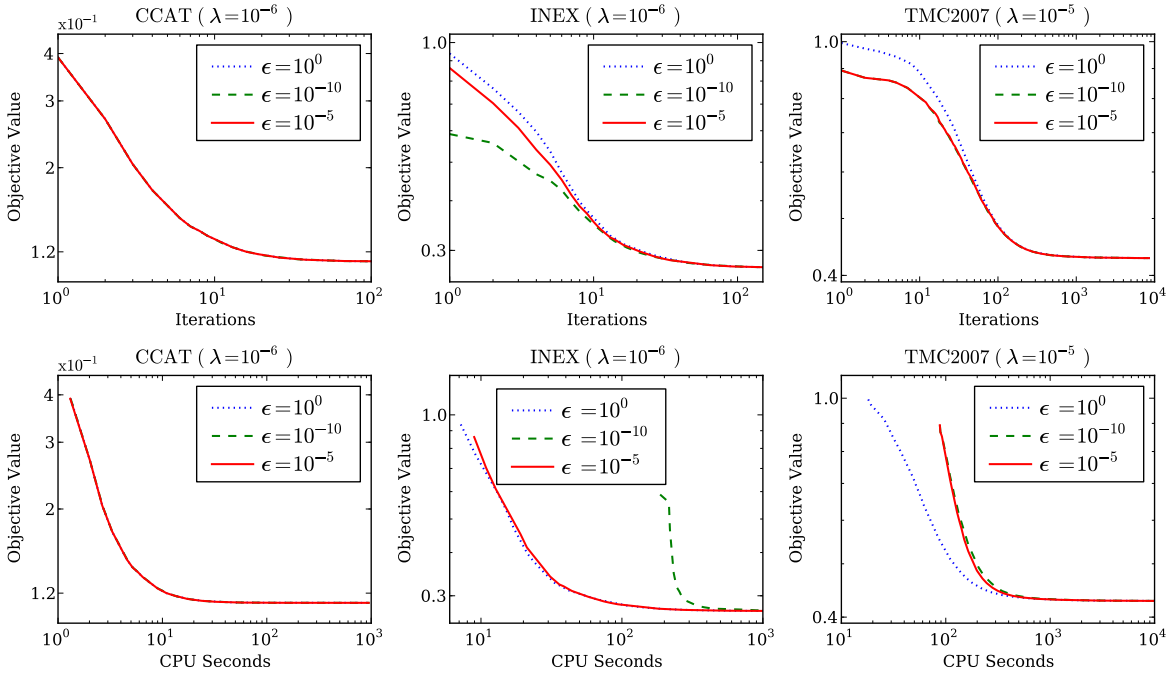

Figure 13: Performance of subLBFGS with varying direction-finding tolerance ε in terms of objective function value *vs*. number of iterations (top row) *resp*. CPU seconds (bottom row) on sample L_2-regularized risk minimization problems with binary (left), multiclass (center), and multilabel (right) hinge losses.

that on binary classification problems, subLBFGS is not sensitive to the choice of ε (i.e., the quality of the search direction). This is due to the fact that $\partial J(\boldsymbol{w})$ as defined in (32) is usually dominated by its constant component $\bar{\boldsymbol{w}}$; search directions that correspond to different choices of ε therefore can not differ too much from each other. In the case of multiclass and multilabel classification, where the structure of $\partial J(\boldsymbol{w})$ is more complicated, we can see from Figure 13 (top center and right) that a better search direction can lead to faster convergence in terms of iteration numbers. However, this is achieved at the cost of more CPU time spent in the direction-finding routine. As shown in Figure 13 (bottom center and right), extensively optimizing the search direction actually slows down convergence in terms of CPU seconds. We therefore used an intermediate value of $\varepsilon = 10^{-5}$ for all our experiments, except that for multiclass and multilabel classification problems we relaxed the tolerance to 1.0 at the initial iterate $\boldsymbol{w} = \boldsymbol{0}$, where the direction-finding oracle $\arg\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{0})} \boldsymbol{g}^\top \boldsymbol{p}$ is expensive to compute, due to the large number of extreme points in $\partial J(\boldsymbol{0})$.

8.2 Size of SubLBFGS Buffer

The size m of the subLBFGS buffer determines the number of parameter and gradient displacement vectors $\boldsymbol{s}_t$ and $\boldsymbol{y}_t$ used in the construction of the quasi-Newton direction. Figure 14 shows that the performance of subLBFGS is not sensitive to the particular value of m within the range $5 \leq m \leq 25$.

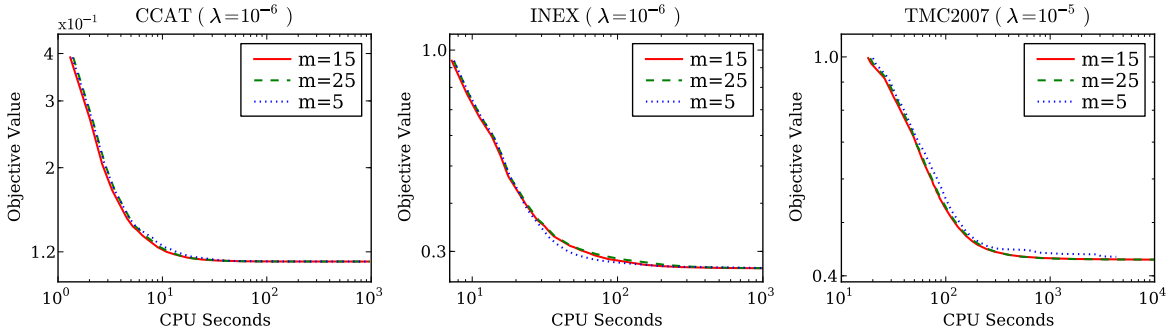

Figure 14: Performance of subLBFGS with varying buffer size on sample L_2-regularized risk minimization problems with binary (left), multiclass (center), and multilabel hinge losses (right).

Data Set	Train/Test Set Size	Dimensionality	Sparsity
Covertype	522911/58101	54	77.8%
CCAT	781265/23149	47236	99.8%
Astro-physics	29882/32487	99757	99.9%
MNIST-binary	60000/10000	780	80.8%
Adult9	32561/16281	123	88.7%
Real-sim	57763/14438	20958	99.8%
Leukemia	38/34	7129	00.0%

Table 1: The binary data sets used in our experiments of Sections 2, 8.3, and 8.4.

We therefore simply set $m = 15$ *a priori* for all subsequent experiments; this is a typical value for LBFGS (Nocedal and Wright, 1999).

8.3 L_2-Regularized Binary Hinge Loss

For our first set of experiments, we applied subLBFGS with exact line search (Algorithm 3) to the task of L_2-regularized binary hinge loss minimization. Our control methods are the bundle method solver BMRM (Teo et al., 2010) and the optimized cutting plane algorithm OCAS (Franc and Sonnenburg, 2008),[13] both of which were shown to perform competitively on this task. SVMStruct (Tsochantaridis et al., 2005) is another well-known bundle method solver that is widely used in the machine learning community. For L_2-regularized optimization problems BMRM is identical to SVMStruct, hence we omit comparisons with SVMStruct.

Table 1 lists the six data sets we used: The Covertype data set of Blackard, Jock & Dean,[14] CCAT from the Reuters RCV1 collection,[15] the Astro-physics data set of abstracts of scientific papers from the Physics ArXiv (Joachims, 2006), the MNIST data set of handwritten digits[16] with

13. The source code of OCAS (version 0.6.0) was obtained from `http://www.shogun-toolbox.org`.
14. Data set can be found at `http://kdd.ics.uci.edu/databases/covertype/covertype.html`.
15. Data set can be found at `http://www.daviddlewis.com/resources/testcollections/rcv1`.
16. Data set can be found at `http://yann.lecun.com/exdb/mnist`.

Data Set	L_1-reg. logistic loss			L_2-reg. binary loss	
	λ_{L_1}	k_{L_1}	$k_{L_1 r}$	λ_{L_2}	k_{L_2}
Covertype	10^{-5}	1	2	10^{-6}	0
CCAT	10^{-6}	284	406	10^{-6}	0
Astro-physics	10^{-5}	1702	1902	10^{-4}	0

Adult9	10^{-4}	2	6	10^{-5}	1
Real-sim	10^{-6}	1017	1274	10^{-5}	1

Table 2: Regularization parameter λ and overall number k of direction-finding iterations in our experiments of Sections 8.3 and 8.4, respectively.

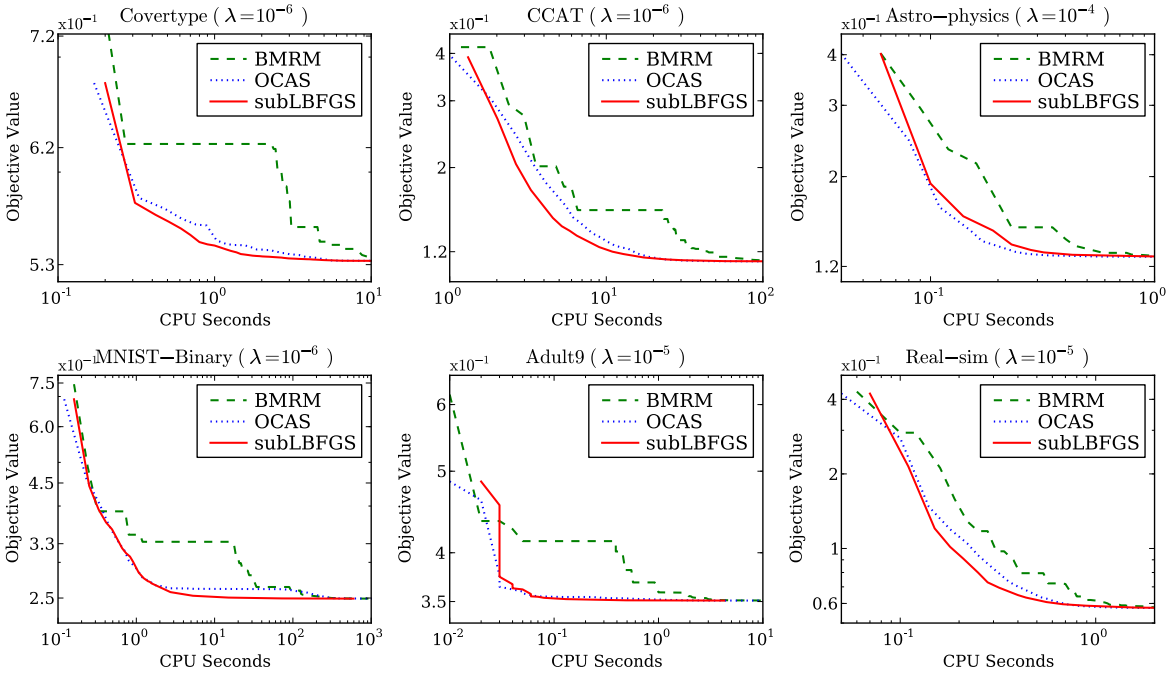

Figure 15: Objective function value *vs*. CPU seconds on L_2-regularized binary hinge loss minimization tasks.

two classes: even and odd digits, the Adult9 data set of census income data,[17] and the Real-sim data set of real *vs*. simulated data.[17] Table 2 lists our parameter settings, and reports the overall number k_{L_2} of iterations through the direction-finding loop (Lines 6–13 of Algorithm 2) for each data set. The very small values of k_{L_2} indicate that on these problems subLBFGS only rarely needs to correct its initial guess of a descent direction.

It can be seen from Figure 15 that subLBFGS (solid) reduces the value of the objective considerably faster than BMRM (dashed). On the binary MNIST data set, for instance, the objective

17. Data set can be found at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary.html`.

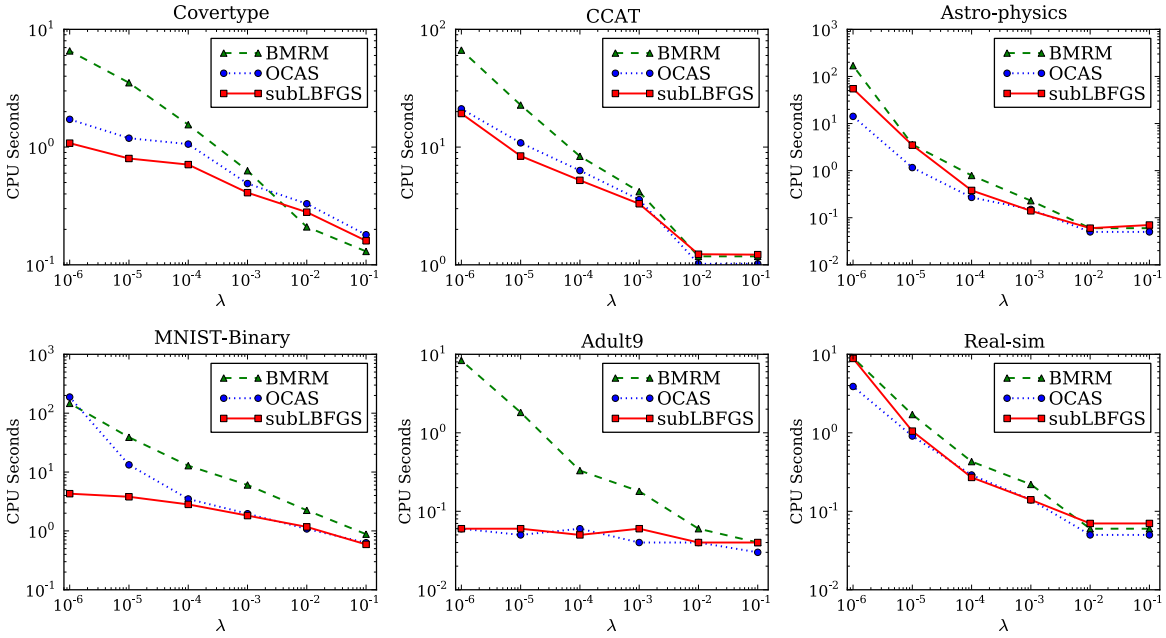

Figure 16: Regularization parameter $\lambda \in \{10^{-6}, \cdots, 10^{-1}\}$ *vs*. CPU seconds taken to reduce the objective function to within 2% of the optimal value on L_2-regularized binary hinge loss minimization tasks.

function value of subLBFGS after 10 CPU seconds is 25% lower than that of BMRM. In this set of experiments the performance of subLBFGS and OCAS (dotted) is very similar.

Figure 16 shows that all algorithms generally converge faster for larger values of the regularization constant λ. However, in most cases subLBFGS converges faster than BMRM across a wide range of λ values, exhibiting a speedup of up to more than two orders of magnitude. SubLBFGS and OCAS show similar performance here: for small values of λ, OCAS converges slightly faster than subLBFGS on the Astro-physics and Real-sim data sets but is outperformed by subLBFGS on the Covertype, CCAT, and binary MNIST data sets.

8.4 L_1-Regularized Logistic Loss

To demonstrate the utility of our direction-finding routine (Algorithm 2) in its own right, we plugged it into the OWL-QN algorithm (Andrew and Gao, 2007)[18] as an alternative direction-finding method such that $\boldsymbol{p}^{\text{ow}} = \texttt{descentDirection}(\boldsymbol{g}^{\text{ow}}, \varepsilon, k_{\max})$, and compared this variant (denoted OWL-QN*) with the original (cf. Section 7.1) on L_1-regularized minimization of the logistic loss (58), on the same data sets as in Section 8.3.

An oracle that supplies $\arg\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}$ for this objective is easily constructed by noting that (58) is nonsmooth whenever at least one component of the parameter vector $\boldsymbol{w}$ is zero. Let $w_i = 0$ be such a component; the corresponding component of the subdifferential $\partial \lambda \|\boldsymbol{w}\|_1$ of the L_1

18. The source code of OWL-QN (original release) was obtained from Microsoft Research through `http://tinyurl.com/p774cx`.

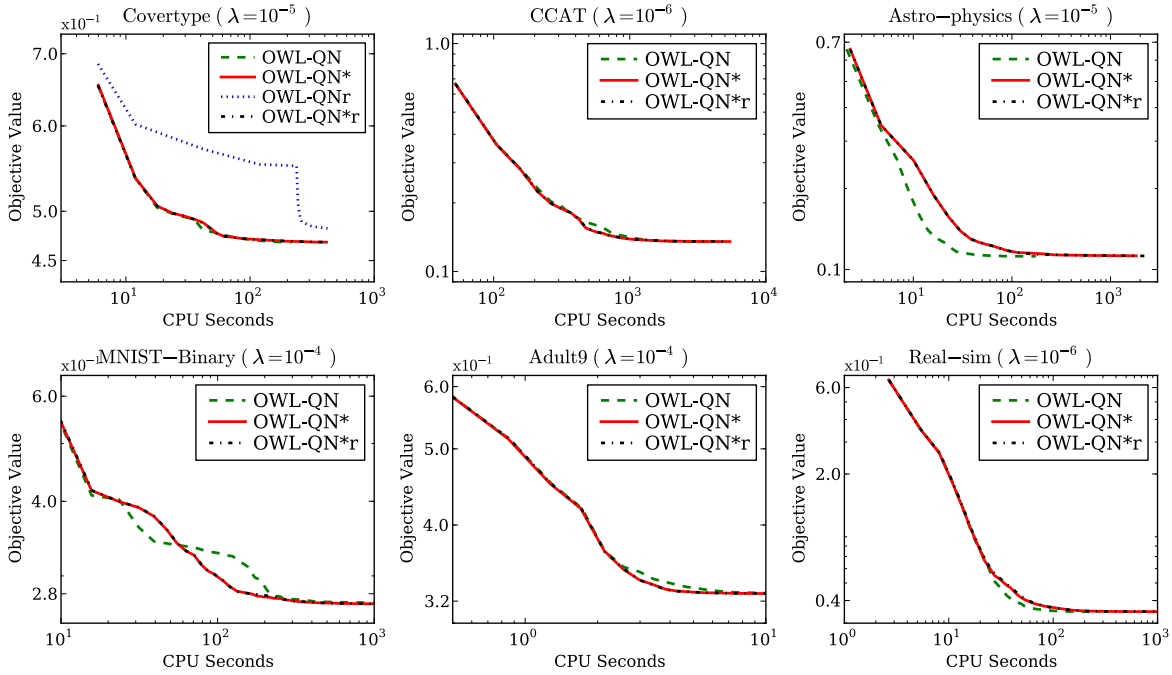

Figure 17: Objective function value *vs*. CPU seconds on L_1-regularized logistic loss minimization tasks.

regularizer is the interval $[-\lambda, \lambda]$. The supremum of $\boldsymbol{g}^\top \boldsymbol{p}$ is attained at the interval boundary whose sign matches that of the corresponding component of the direction vector $\boldsymbol{p}$, that is, at $\lambda \operatorname{sign}(p_i)$.

Using the stopping criterion suggested by Andrew and Gao (2007), we ran experiments until the averaged relative change in objective function value over the previous 5 iterations fell below 10^{-5}. As shown in Figure 17, the only clear difference in convergence between the two algorithms is found on the Astro-physics data set where OWL-QN* is outperformed by the original OWL-QN method. This is because finding a descent direction via Algorithm 2 is particularly difficult on the Astro-physics data set (as indicated by the large inner loop iteration number k_{L_1} in Table 2); the slowdown on this data set can also be found in Figure 18 for other values of λ. Although finding a descent direction can be challenging for the generic direction-finding routine of OWL-QN*, in the following experiment we show that this routine is very robust to the choice of initial subgradients.

To examine the algorithms' sensitivity to the choice of subgradients, we also ran them with subgradients randomly chosen from the set $\partial J(\boldsymbol{w})$ (as opposed to the specially chosen subgradient $\boldsymbol{g}^{\text{ow}}$ used in the previous set of experiments) fed to their corresponding direction-finding routines. OWL-QN relies heavily on its particular choice of subgradients, hence breaks down completely under these conditions: the only data set where we could even plot its (poor) performance was Covertype (dotted "OWL-QNr" line in Figure 17). Our direction-finding routine, by contrast, is self-correcting and thus not affected by this manipulation: the curves for OWL-QN*r lie on top of those for OWL-QN*. Table 2 shows that in this case more direction-finding iterations are needed though: $k_{L_1 r} > k_{L_1}$. This empirically confirms that as long as $\arg\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}$ is given, Algorithm 2 can

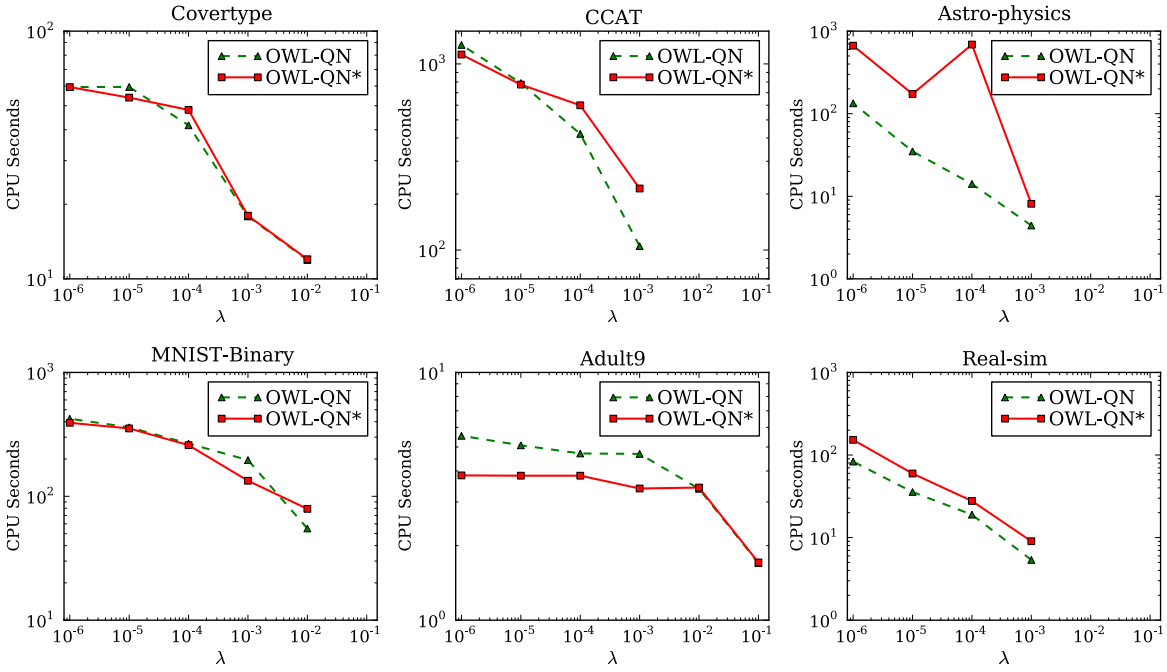

Figure 18: Regularization parameter $\lambda \in \{10^{-6}, \cdots, 10^{-1}\}$ *vs*. CPU seconds taken to reduce the objective function to within 2% of the optimal value on L_1-regularized logistic loss minimization tasks. (No point is plotted if the initial parameter $\boldsymbol{w}_0 = \mathbf{0}$ is already optimal.)

indeed be used as a generic quasi-Newton direction-finding routine that is able to recover from a poor initial choice of subgradients.

8.5 L_2-Regularized Multiclass and Multilabel Hinge Loss

We incorporated our exact line search of Section 6.3.1 into both subLBFGS and OCAS (Franc and Sonnenburg, 2008), thus enabling them to deal with multiclass and multilabel losses. We refer to our generalized version of OCAS as line search BMRM (ls-BMRM). Using the variant of the multiclass and multilabel hinge loss which enforces a uniform margin of separation ($\Delta(z, z') = 1 \; \forall z \neq z'$), we experimentally evaluated both algorithms on a number of publicly available data sets (Table 3). All multiclass data sets except INEX were downloaded from `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/multiclass.html`, while the multilabel data sets were obtained from `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/multilabel.html`. INEX (Maes et al., 2007) is available from `http://webia.lip6.fr/~bordes/mywiki/doku.php?id=multiclass_data`. The original RCV1 data set consists of 23149 training instances, of which we used 21149 instances for training and the remaining 2000 for testing.

8.5.1 PERFORMANCE ON MULTICLASS PROBLEMS

This set of experiments is designed to demonstrate the convergence properties of multiclass subLBFGS, compared to the BMRM bundle method (Teo et al., 2010) and ls-BMRM. Figure 19 shows

Data Set	Train/Test Set Size	Dimensionality	$\lvert\mathcal{Z}\rvert$	Sparsity	λ	k
Letter	16000/4000	16	26	0.0%	10^{-6}	65
USPS	7291/2007	256	10	3.3%	10^{-3}	14
Protein	14895/6621	357	3	70.7%	10^{-2}	1
MNIST	60000/10000	780	10	80.8%	10^{-3}	1
INEX	6053/6054	167295	18	99.5%	10^{-6}	5
News20	15935/3993	62061	20	99.9%	10^{-2}	12
Scene	1211/1196	294	6	0.0%	10^{-1}	14
TMC2007	21519/7077	30438	22	99.7%	10^{-5}	19
RCV1	21149/2000	47236	103	99.8%	10^{-5}	4

Table 3: The multiclass (top 6 rows) and multilabel (bottom 3 rows) data sets used, values of the regularization parameter, and overall number k of direction-finding iterations in our experiments of Section 8.5.

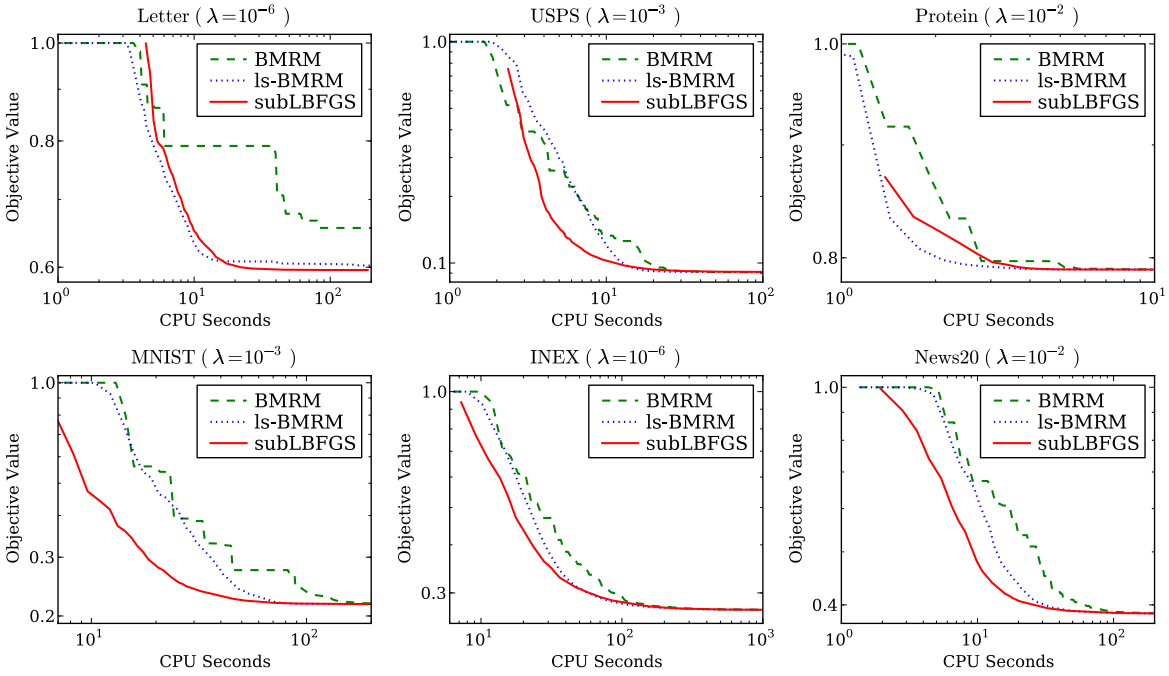

Figure 19: Objective function value *vs.* CPU seconds on L_2-regularized multiclass hinge loss minimization tasks.

that subLBFGS outperforms BMRM on all data sets. On 4 out of 6 data sets, subLBFGS outperforms ls-BMRM as well early on but slows down later, for an overall performance comparable to ls-BMRM. On the MNIST data set, for instance, subLBFGS takes only about half as much CPU time as ls-BMRM to reduce the objective function value to 0.3 (about 50% above the optimal value),

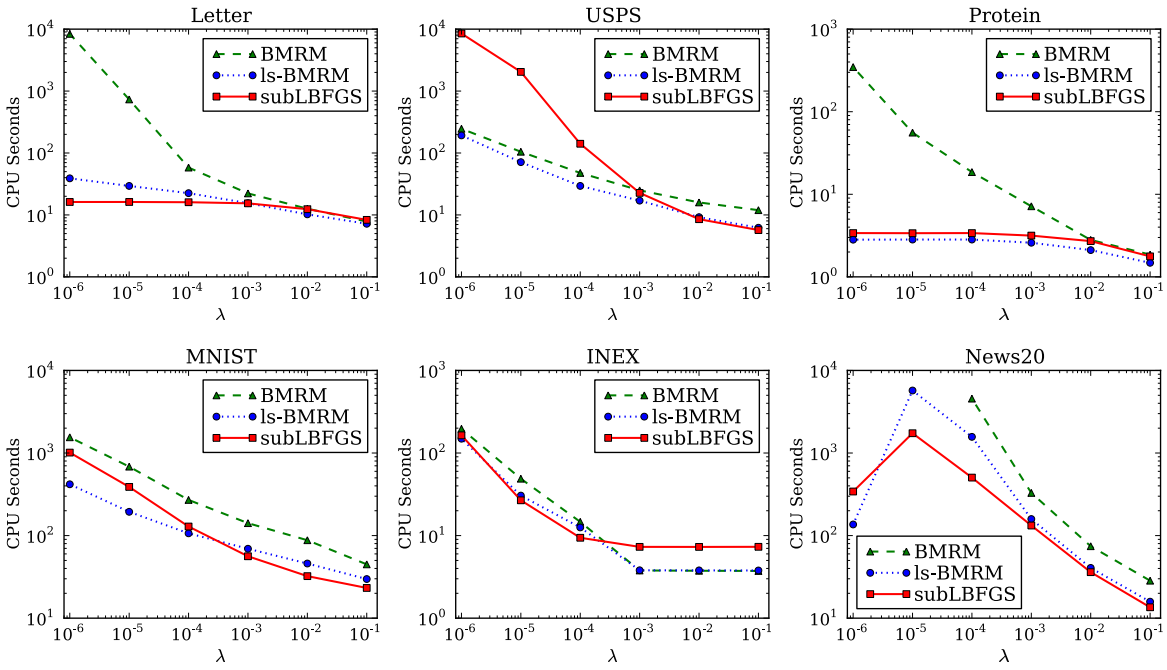

Figure 20: Regularization parameter $\lambda \in \{10^{-6}, \cdots, 10^{-1}\}$ *vs*. CPU seconds taken to reduce the objective function to within 2% of the optimal value. (No point is plotted if an algorithm failed to reach the threshold value within 10^4 seconds.)

yet both algorithms reach within 2% of the optimal value at about the same time (Figure 20, bottom left). We hypothesize that subLBFGS' local model (10) of the objective function facilitates rapid early improvement but is less appropriate for final convergence to the optimum (cf. the discussion in Section 9). Bundle methods, on the other hand, are slower initially because they need to accumulate a sufficient number of gradients to build a faithful piecewise linear model of the objective function. These results suggest that a hybrid approach that first runs subLBFGS then switches to ls-BMRM may be promising.

Similar to what we saw in the binary setting (Figure 16), Figure 20 shows that all algorithms tend to converge faster for large values of λ. Generally, subLBFGS converges faster than BMRM across a wide range of λ values; for small values of λ it can greatly outperform BMRM (as seen on Letter, Protein, and News20). The performance of subLBFGS is worse than that of BMRM in two instances: on USPS for small values of λ, and on INEX for large values of λ. The poor performance on USPS may be caused by a limitation of subLBFGS' local model (10) that causes it to slow down on final convergence. On the INEX data set, the initial point $\boldsymbol{w}_0 = \mathbf{0}$ is nearly optimal for large values of λ; in this situation there is no advantage in using subLBFGS.

Leveraging its exact line search (Algorithm 5), ls-BMRM is competitive on all data sets and across all λ values, exhibiting performance comparable to subLBFGS in many cases. From Figure 20 we find that BMRM never outperforms both subLBFGS and ls-BMRM.

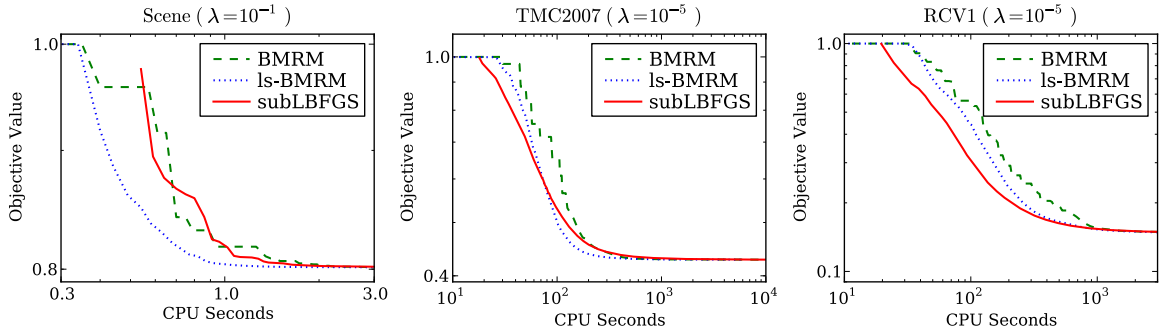

Figure 21: Objective function value *vs*. CPU seconds in L_2-regularized multilabel hinge loss minimization tasks.

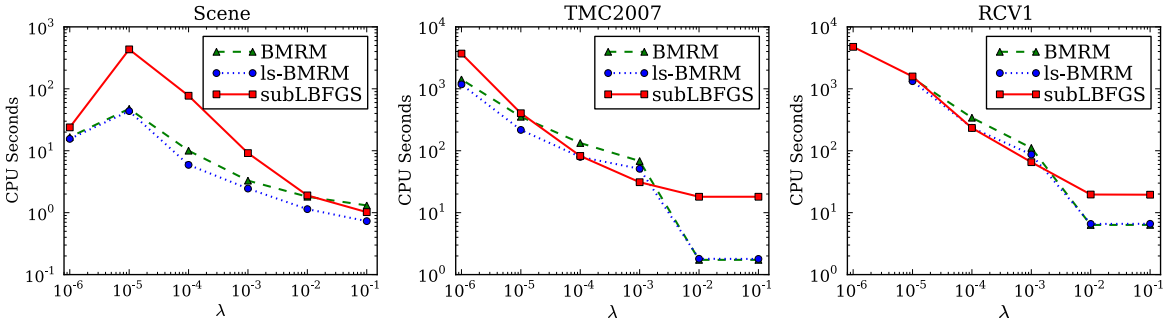

Figure 22: Regularization parameter $\lambda \in \{10^{-6}, \cdots, 10^{-1}\}$ *vs*. CPU seconds taken to reduce the objective function to within 2% of the optimal value. (No point is plotted if an algorithm failed to reach the threshold value within 10^4 seconds.)

8.5.2 PERFORMANCE ON MULTILABEL PROBLEMS

For our final set of experiments we turn to the multilabel setting. Figure 21 shows that on the Scene data set the performance of subLBFGS is similar to that of BMRM, while on the larger TMC2007 and RCV1 sets, subLBFGS outperforms both of its competitors initially but slows down later on, resulting in performance no better than BMRM. Comparing performance across different values of λ (Figure 22), we find that in many cases subLBFGS requires more time than its competitors to reach within 2% of the optimal value, and in contrast to the multiclass setting, here ls-BMRM only performs marginally better than BMRM. The primary reason for this is that the exact line search used by ls-BMRM and subLBFGS requires substantially more computational effort in the multilabel than in the multiclass setting. There is an inherent trade-off here: subLBFGS and ls-BMRM expend computation in an exact line search, while BMRM focuses on improving its local model of the objective function instead. In situations where the line search is very expensive, the latter strategy seems to pay off.

9. Discussion and Outlook

We proposed subBFGS (resp., subLBFGS), an extension of the BFGS quasi-Newton method (resp., its limited-memory variant), for handling nonsmooth convex optimization problems, and proved its global convergence in objective function value. We applied our algorithm to a variety of machine learning problems employing the L_2-regularized binary hinge loss and its multiclass and multilabel generalizations, as well as L_1-regularized risk minimization with logistic loss. Our experiments show that our algorithm is versatile, applicable to many problems, and often outperforms specialized solvers.

Our solver is easy to parallelize: The master node computes the search direction and transmits it to the slaves. The slaves compute the (sub)gradient and loss value on subsets of data, which is aggregated at the master node. This information is used to compute the next search direction, and the process repeats. Similarly, the line search, which is the expensive part of the computation on multiclass and multilabel problems, is easy to parallelize: The slaves run Algorithm 4 on subsets of the data; the results are fed back to the master which can then run Algorithm 5 to compute the step size.

In many of our experiments we observe that subLBFGS decreases the objective function rapidly at the beginning but slows down closer to the optimum. We hypothesize that this is due to an averaging effect: Initially (i.e., when sampled sparsely at a coarse scale) a superposition of many hinges looks sufficiently similar to a smooth function for optimization of a quadratic local model to work well (cf. Figure 6). Later on, when the objective is sampled at finer resolution near the optimum, the few nearest hinges begin to dominate the picture, making a smooth local model less appropriate.

Even though the local model (10) of sub(L)BFGS is nonsmooth, it only explicitly models the hinges at its present location—all others are subject to smooth quadratic approximation. Apparently this strategy works sufficiently well during early iterations to provide for rapid improvement on multiclass problems, which typically comprise a large number of hinges. The exact location of the optimum, however, may depend on individual nearby hinges which are not represented in (10), resulting in the observed slowdown.

Bundle method solvers, by contrast, exhibit slow initial progress but tend to be competitive asymptotically. This is because they build a piecewise linear lower bound of the objective function, which initially is not very good but through successive tightening eventually becomes a faithful model. To take advantage of this we are contemplating hybrid solvers that switch over from sub(L)BFGS to a bundle method as appropriate.

While bundle methods like BMRM have an exact, implementable stopping criterion based on the duality gap, no such stopping criterion exists for BFGS and other quasi-Newton algorithms. Therefore, it is customary to use the relative change in function value as an implementable stopping criterion. Developing a stopping criterion for sub(L)BFGS based on duality arguments remains an important open question.

sub(L)BFGS relies on an efficient exact line search. We proposed such line searches for the multiclass hinge loss and its extension to the multilabel setting, based on a conceptually simple yet optimal algorithm to segment the pointwise maximum of lines. A crucial assumption we had to make is that the number $|\mathcal{Z}|$ of labels is manageable, as it takes $O(|\mathcal{Z}|\log|\mathcal{Z}|)$ time to identify the hinges associated with each training instance. In certain structured prediction problems (Tsochantaridis et al., 2005) which have recently gained prominence in machine learning, the set $\mathcal{Z}$ could

be exponentially large—for instance, predicting binary labels on a chain of length n produces 2^n possible labellings. Clearly our line searches are not efficient in such cases; we are investigating trust region variants of sub(L)BFGS to bridge this gap.

Finally, to put our contributions in perspective, recall that we modified three aspects of the standard BFGS algorithm, namely the quadratic model (Section 3.1), the descent direction finding (Section 3.2), and the Wolfe conditions (Section 3.3). Each of these modifications is versatile enough to be used as a component in other nonsmooth optimization algorithms. This not only offers the promise of improving existing algorithms, but may also help clarify connections between them. We hope that our research will focus attention on the core subroutines that need to be made more efficient in order to handle larger and larger data sets.

Acknowledgments

A short version of this paper was presented at the 2008 ICML conference (Yu et al., 2008). We thank Choon Hui Teo for many useful discussions and help with implementation issues, Xinhua Zhang for proofreading our manuscript, and the anonymous reviewers of both ICML and JMLR for their useful feedback which helped improve this paper. We thank John R. Birge for pointing us to his work (Birge et al., 1998) which led us to the convergence proof in Appendix D.

Appendix A. Bundle Search for a Descent Direction

Recall from Section 3.2 that at a subdifferential point $\boldsymbol{w}$ our goal is to find a descent direction $\boldsymbol{p}^*$ which minimizes the pseudo-quadratic model:[19]

$$M(\boldsymbol{p}) := \tfrac{1}{2}\boldsymbol{p}^\top \boldsymbol{B}^{-1}\boldsymbol{p} + \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}. \tag{59}$$

This is generally intractable due to the presence of a supremum over the entire subdifferential $\partial J(\boldsymbol{w})$. We therefore propose a bundle-based descent direction finding procedure (Algorithm 2) which progressively approaches $M(\boldsymbol{p})$ from below via a series of convex functions $M^{(1)}(\boldsymbol{p}), \cdots, M^{(i)}(\boldsymbol{p})$, each taking the same form as $M(\boldsymbol{p})$ but with the supremum defined over a countable subset of $\partial J(\boldsymbol{w})$. At iteration i our convex lower bound $M^{(i)}(\boldsymbol{p})$ takes the form

$$\begin{aligned} M^{(i)}(\boldsymbol{p}) &:= \tfrac{1}{2}\boldsymbol{p}^\top \boldsymbol{B}^{-1}\boldsymbol{p} + \sup_{\boldsymbol{g}\in\mathcal{V}^{(i)}} \boldsymbol{g}^\top \boldsymbol{p}, \text{ where} \\ \mathcal{V}^{(i)} &:= \{\boldsymbol{g}^{(j)} : j \le i,\ i, j\ \in \mathbb{N}\} \subseteq \partial J(\boldsymbol{w}). \end{aligned} \tag{60}$$

Given an iterate $\boldsymbol{p}^{(j-1)} \in \mathbb{R}^d$ we find a *violating subgradient* $\boldsymbol{g}^{(j)}$ via

$$\boldsymbol{g}^{(j)} := \operatorname*{arg\,sup}_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}^{(j-1)}. \tag{61}$$

19. For ease of exposition we are suppressing the iteration index t here.

Violating subgradients recover the true objective $M(\boldsymbol{p})$ at the iterates $\boldsymbol{p}^{(j-1)}$:

$$M(\boldsymbol{p}^{(j-1)}) = M^{(j)}(\boldsymbol{p}^{(j-1)}) = \tfrac{1}{2}\boldsymbol{p}^{(j-1)\top}\boldsymbol{B}^{-1}\boldsymbol{p}^{(j-1)} + \boldsymbol{g}^{(j)\top}\boldsymbol{p}^{(j-1)}. \tag{62}$$

To produce the iterates $\boldsymbol{p}^{(i)}$, we rewrite $\min_{\boldsymbol{p}\in\mathbb{R}^d} M^{(i)}(\boldsymbol{p})$ as a constrained optimization problem (19), which allows us to write the Lagrangian of (60) as

$$L^{(i)}(\boldsymbol{p},\xi,\boldsymbol{\alpha}) := \tfrac{1}{2}\boldsymbol{p}^\top\boldsymbol{B}^{-1}\boldsymbol{p} + \xi - \boldsymbol{\alpha}^\top(\xi\mathbf{1} - \boldsymbol{G}^{(i)^\top}\boldsymbol{p}), \tag{63}$$

where $\boldsymbol{G}^{(i)} := [\boldsymbol{g}^{(1)}, \boldsymbol{g}^{(2)}, \ldots, \boldsymbol{g}^{(i)}] \in \mathbb{R}^{d\times i}$ collects past violating subgradients, and $\boldsymbol{\alpha}$ is a column vector of non-negative Lagrange multipliers. Setting the derivative of (63) with respect to the primal variables ξ and $\boldsymbol{p}$ to zero yields, respectively,

$$\boldsymbol{\alpha}^\top\mathbf{1} = 1 \quad \text{and} \tag{64}$$

$$\boldsymbol{p} = -\boldsymbol{B}\boldsymbol{G}^{(i)}\boldsymbol{\alpha}. \tag{65}$$

The primal variable $\boldsymbol{p}$ and the dual variable $\boldsymbol{\alpha}$ are related via the dual connection (65). To eliminate the primal variables ξ and $\boldsymbol{p}$, we plug (64) and (65) back into the Lagrangian to obtain the dual of $M^{(i)}(\boldsymbol{p})$:

$$\begin{aligned} D^{(i)}(\boldsymbol{\alpha}) &:= -\tfrac{1}{2}(\boldsymbol{G}^{(i)}\boldsymbol{\alpha})^\top\boldsymbol{B}(\boldsymbol{G}^{(i)}\boldsymbol{\alpha}), \\ &\text{s.t. } \boldsymbol{\alpha}\in[0,1]^i,\ \|\boldsymbol{\alpha}\|_1 = 1. \end{aligned} \tag{66}$$

The dual objective $D^{(i)}(\boldsymbol{\alpha})$ (resp., primal objective $M^{(i)}(\boldsymbol{p})$) can be maximized (resp., minimized) exactly via quadratic programming. However, doing so may incur substantial computational expense. Instead we adopt an iterative scheme which is cheap and easy to implement yet guarantees dual improvement.

Let $\boldsymbol{\alpha}^{(i)} \in [0,1]^i$ be a feasible solution for $D^{(i)}(\boldsymbol{\alpha})$.[20] The corresponding primal solution $\boldsymbol{p}^{(i)}$ can be found by using (65). This in turn allows us to compute the next violating subgradient $\boldsymbol{g}^{(i+1)}$ via (61). With the new violating subgradient the dual becomes

$$\begin{aligned} D^{(i+1)}(\boldsymbol{\alpha}) &:= -\tfrac{1}{2}(\boldsymbol{G}^{(i+1)}\boldsymbol{\alpha})^\top\boldsymbol{B}(\boldsymbol{G}^{(i+1)}\boldsymbol{\alpha}), \\ &\text{s.t. } \boldsymbol{\alpha}\in[0,1]^{i+1},\ \|\boldsymbol{\alpha}\|_1 = 1, \end{aligned} \tag{67}$$

where the subgradient matrix is now extended:

$$\boldsymbol{G}^{(i+1)} = [\boldsymbol{G}^{(i)}, \boldsymbol{g}^{(i+1)}]. \tag{68}$$

Our iterative strategy constructs a new feasible solution $\boldsymbol{\alpha}\in[0,1]^{i+1}$ for (67) by constraining it to take the following form:

$$\boldsymbol{\alpha} = \begin{bmatrix} (1-\mu)\boldsymbol{\alpha}^{(i)} \\ \mu \end{bmatrix}, \quad \text{where } \mu\in[0,1]. \tag{69}$$

20. Note that $\boldsymbol{\alpha}^{(1)} = \mathbf{1}$ is a feasible solution for $D^{(1)}(\boldsymbol{\alpha})$.

In other words, we maximize a one-dimensional function $\bar{D}^{(i+1)} : [0,1] \to \mathbb{R}$:

$$\begin{aligned} \bar{D}^{(i+1)}(\mu) &:= -\tfrac{1}{2}\left(\boldsymbol{G}^{(i+1)}\boldsymbol{\alpha}\right)^\top \boldsymbol{B}\left(\boldsymbol{G}^{(i+1)}\boldsymbol{\alpha}\right) \\ &= -\tfrac{1}{2}\left((1-\mu)\bar{\boldsymbol{g}}^{(i)} + \mu \boldsymbol{g}^{(i+1)}\right)^\top \boldsymbol{B}\left((1-\mu)\bar{\boldsymbol{g}}^{(i)} + \mu \boldsymbol{g}^{(i+1)}\right), \end{aligned} \tag{70}$$

where

$$\bar{\boldsymbol{g}}^{(i)} := \boldsymbol{G}^{(i)}\boldsymbol{\alpha}^{(i)} \in \partial J(\boldsymbol{w}) \tag{71}$$

lies in the convex hull of $\boldsymbol{g}^{(j)} \in \partial J(\boldsymbol{w})\ \forall j \leq i$ (and hence in the convex set $\partial J(\boldsymbol{w})$) because $\boldsymbol{\alpha}^{(i)} \in [0,1]^i$ and $\|\boldsymbol{\alpha}^{(i)}\|_1 = 1$. Moreover, $\mu \in [0,1]$ ensures the feasibility of the dual solution. Noting that $\bar{D}^{(i+1)}(\mu)$ is a concave quadratic function, we set

$$\partial \bar{D}^{(i+1)}(\mu) = \left(\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)}\right)^\top \boldsymbol{B}\left((1-\eta)\bar{\boldsymbol{g}}^{(i)} + \eta \boldsymbol{g}^{(i+1)}\right) = 0 \tag{72}$$

to obtain the optimum

$$\mu^* := \operatorname*{argmax}_{\mu \in [0,1]} \bar{D}^{(i+1)}(\mu) = \min\left(1, \max\left(0, \frac{(\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)})^\top \boldsymbol{B}\bar{\boldsymbol{g}}^{(i)}}{(\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)})^\top \boldsymbol{B}(\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)})}\right)\right). \tag{73}$$

Our dual solution at step $i+1$ then becomes

$$\boldsymbol{\alpha}^{(i+1)} := \begin{bmatrix} (1-\mu^*)\boldsymbol{\alpha}^{(i)} \\ \mu^* \end{bmatrix}. \tag{74}$$

Furthermore, from (68), (69), and (71) it follows that $\bar{\boldsymbol{g}}^{(i)}$ can be maintained via an incremental update (Line 8 of Algorithm 2):

$$\bar{\boldsymbol{g}}^{(i+1)} := \boldsymbol{G}^{(i+1)}\boldsymbol{\alpha}^{(i+1)} = (1-\mu^*)\bar{\boldsymbol{g}}^{(i)} + \mu^* \boldsymbol{g}^{(i+1)}, \tag{75}$$

which combined with the dual connection (65) yields an incremental update for the primal solution (Line 9 of Algorithm 2):

$$\begin{aligned} \boldsymbol{p}^{(i+1)} := -\boldsymbol{B}\bar{\boldsymbol{g}}^{(i+1)} &= -(1-\mu^*)\boldsymbol{B}\bar{\boldsymbol{g}}^{(i)} - \mu^* \boldsymbol{B}\boldsymbol{g}^{(i+1)} \\ &= (1-\mu^*)\boldsymbol{p}^{(i)} - \mu^* \boldsymbol{B}\boldsymbol{g}^{(i+1)}. \end{aligned} \tag{76}$$

Using (75) and (76), computing a primal solution (Lines 7–9 of Algorithm 2) costs a total of $O(d^2)$ time (resp., $O(md)$ time for LBFGS with buffer size m), where d is the dimensionality of the optimization problem. Note that maximizing $D^{(i+1)}(\boldsymbol{\alpha})$ directly via quadratic programming generally results in a larger progress than that obtained by our approach.

In order to measure the quality of our solution at iteration i, we define the quantity

$$\varepsilon^{(i)} := \min_{j \leq i} M^{(j+1)}(\boldsymbol{p}^{(j)}) - D^{(i)}(\boldsymbol{\alpha}^{(i)}) = \min_{j \leq i} M(\boldsymbol{p}^{(j)}) - D^{(i)}(\boldsymbol{\alpha}^{(i)}), \tag{77}$$

where the second equality follows directly from (62). Let $D(\boldsymbol{\alpha})$ be the corresponding dual problem of $M(\boldsymbol{p})$, with the property $D\left(\begin{bmatrix} \boldsymbol{\alpha}^{(i)} \\ \mathbf{0} \end{bmatrix}\right) = D^{(i)}(\boldsymbol{\alpha}^{(i)})$, and let $\boldsymbol{\alpha}^*$ be the optimal solution to

$\operatorname{argmax}_{\boldsymbol{\alpha}\in\mathcal{A}} D(\boldsymbol{\alpha})$ in some domain $\mathcal{A}$ of interest. As a consequence of the weak duality theorem (Hiriart-Urruty and Lemaréchal, 1993, Theorem XII.2.1.5), $\min_{\boldsymbol{p}\in\mathbb{R}^d} M(\boldsymbol{p}) \geq D(\boldsymbol{\alpha}^*)$. Therefore (77) implies that

$$\varepsilon^{(i)} \;\geq\; \min_{\boldsymbol{p}\in\mathbb{R}^d} M(\boldsymbol{p}) - D^{(i)}(\boldsymbol{\alpha}^{(i)}) \;\geq\; \min_{\boldsymbol{p}\in\mathbb{R}^d} M(\boldsymbol{p}) - D(\boldsymbol{\alpha}^*) \;\geq\; 0. \tag{78}$$

The second inequality essentially says that $\varepsilon^{(i)}$ is an upper bound on the duality gap. In fact, Theorem 7 below shows that $(\varepsilon^{(i)} - \varepsilon^{(i+1)})$ is bounded away from 0, that is, $\varepsilon^{(i)}$ is monotonically decreasing. This guides us to design a practical stopping criterion (Line 6 of Algorithm 2) for our direction-finding procedure. Furthermore, using the dual connection (65), we can derive an implementable formula for $\varepsilon^{(i)}$:

$$\begin{aligned}
\varepsilon^{(i)} &= \min_{j\leq i} \left[\tfrac{1}{2}\boldsymbol{p}^{(j)\top}\boldsymbol{B}^{-1}\boldsymbol{p}^{(j)} + \boldsymbol{p}^{(j)\top}\boldsymbol{g}^{(j+1)} + \tfrac{1}{2}(\boldsymbol{G}^{(i)}\boldsymbol{\alpha}^{(i)})^\top \boldsymbol{B}(\boldsymbol{G}^{(i)}\boldsymbol{\alpha}^{(i)}) \right] \\
&= \min_{j\leq i} \left[-\tfrac{1}{2}\boldsymbol{p}^{(j)\top}\bar{\boldsymbol{g}}^{(j)} + \boldsymbol{p}^{(j)\top}\boldsymbol{g}^{(j+1)} - \tfrac{1}{2}\boldsymbol{p}^{(i)\top}\bar{\boldsymbol{g}}^{(i)} \right] \\
&= \min_{j\leq i} \left[\boldsymbol{p}^{(j)\top}\boldsymbol{g}^{(j+1)} - \tfrac{1}{2}(\boldsymbol{p}^{(j)\top}\bar{\boldsymbol{g}}^{(j)} + \boldsymbol{p}^{(i)^\top}\bar{\boldsymbol{g}}^{(i)}) \right], \\
&\quad \text{where } \boldsymbol{g}^{(j+1)} := \operatorname*{arg\,sup}_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}^{(j)} \text{ and } \bar{\boldsymbol{g}}^{(j)} := \boldsymbol{G}^{(j)}\boldsymbol{\alpha}^{(j)} \;\; \forall j \leq i.
\end{aligned} \tag{79}$$

It is worth noting that continuous progress in the dual objective value does not necessarily prevent an increase in the primal objective value, that is, it is possible that $M(\boldsymbol{p}^{(i+1)}) \geq M(\boldsymbol{p}^{(i)})$. Therefore, we choose the best primal solution so far,

$$\boldsymbol{p} := \operatorname*{argmin}_{j\leq i} M(\boldsymbol{p}^{(j)}), \tag{80}$$

as the search direction (Line 18 of Algorithm 2) for the parameter update (3). This direction is a direction of descent as long as the last iterate $\boldsymbol{p}^{(i)}$ fulfills the descent condition (16). To see this, we use (88–90) below to get $\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}^{(i)} = M(\boldsymbol{p}^{(i)}) + D^{(i)}(\boldsymbol{\alpha}^{(i)})$, and since

$$M(\boldsymbol{p}^{(i)}) \geq \min_{j\leq i} M(\boldsymbol{p}^{(j)}) \text{ and } D^{(i)}(\boldsymbol{\alpha}^{(i)}) \geq D^{(j)}(\boldsymbol{\alpha}^{(j)}) \;\; \forall j \leq i,$$

definition (80) immediately gives $\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}^{(i)} \;\geq\; \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p}$. Hence if $\boldsymbol{p}^{(i)}$ is a descent direction, then so is $\boldsymbol{p}$.

We now show that if the current parameter vector $\boldsymbol{w}$ is not optimal, then a direction-finding tolerance $\varepsilon \geq 0$ exists for Algorithm 2 such that the returned search direction $\boldsymbol{p}$ is a descent direction, that is, $\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p} < 0$.

Lemma 3 *Let $\boldsymbol{B}$ be the current approximation to the inverse Hessian maintained by Algorithm 1, and $h > 0$ a lower bound on the eigenvalues of $\boldsymbol{B}$. If the current iterate $\boldsymbol{w}$ is not optimal: $\mathbf{0} \notin \partial J(\boldsymbol{w})$, and the number of direction-finding iterations is unlimited ($k_{max} = \infty$), then there exists a direction-finding tolerance $\varepsilon \geq 0$ such that the descent direction $\boldsymbol{p} = -\boldsymbol{B}\bar{\boldsymbol{g}}$, $\bar{\boldsymbol{g}} \in \partial J(\boldsymbol{w})$ returned by Algorithm 2 at $\boldsymbol{w}$ satisfies $\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top \boldsymbol{p} < 0$.*

Proof Algorithm 2 returns $\boldsymbol{p}$ after i iterations when $\varepsilon^{(i)} \leq \varepsilon$, where $\varepsilon^{(i)} = M(\boldsymbol{p}) - D^{(i)}(\boldsymbol{\alpha}^{(i)})$ by definitions (77) and (80). Using definition (66) of $D^{(i)}(\boldsymbol{\alpha}^{(i)})$, we have

$$-D^{(i)}(\boldsymbol{\alpha}^{(i)}) \;=\; \tfrac{1}{2}(\boldsymbol{G}^{(i)}\boldsymbol{\alpha}^{(i)})^\top \boldsymbol{B}(\boldsymbol{G}^{(i)}\boldsymbol{\alpha}^{(i)}) \;=\; \tfrac{1}{2}\bar{\boldsymbol{g}}^{(i)\top}\boldsymbol{B}\bar{\boldsymbol{g}}^{(i)}, \tag{81}$$

where $\bar{\boldsymbol{g}}^{(i)} = \boldsymbol{G}^{(i)}\boldsymbol{\alpha}^{(i)}$ is a subgradient in $\partial J(\boldsymbol{w})$. On the other hand, using (59) and (76), one can write

$$\begin{aligned} M(\boldsymbol{p}) \;&=\; \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p} + \tfrac{1}{2}\boldsymbol{p}^\top\boldsymbol{B}^{-1}\boldsymbol{p} \\ &=\; \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p} + \tfrac{1}{2}\bar{\boldsymbol{g}}^\top\boldsymbol{B}\bar{\boldsymbol{g}}, \quad \text{where} \quad \bar{\boldsymbol{g}} \in \partial J(\boldsymbol{w}). \end{aligned} \tag{82}$$

Putting together (81) and (82), and using $\boldsymbol{B} \succ h$, one obtains

$$\varepsilon^{(i)} = \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p} + \tfrac{1}{2}\bar{\boldsymbol{g}}^\top\boldsymbol{B}\bar{\boldsymbol{g}} + \tfrac{1}{2}\bar{\boldsymbol{g}}^{(i)\top}\boldsymbol{B}\bar{\boldsymbol{g}}^{(i)} \geq \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p} + \frac{h}{2}\|\bar{\boldsymbol{g}}\|^2 + \frac{h}{2}\|\bar{\boldsymbol{g}}^{(i)}\|^2. \tag{83}$$

Since $\mathbf{0} \notin \partial J(\boldsymbol{w})$, the last two terms of (83) are strictly positive; and by (78), $\varepsilon^{(i)} \geq 0$. The claim follows by choosing an ε such that $(\forall i)\;\; \frac{h}{2}(\|\bar{\boldsymbol{g}}\|^2 + \|\bar{\boldsymbol{g}}^{(i)}\|^2) > \varepsilon \geq \varepsilon^{(i)} \geq 0$. ■

Using the notation from Lemma 3, we show in the following corollary that a stricter upper bound on ε allows us to bound $\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p}$ in terms of $\bar{\boldsymbol{g}}^\top\boldsymbol{B}\bar{\boldsymbol{g}}$ and $\|\bar{\boldsymbol{g}}\|$. This will be used in Appendix D to establish the global convergence of the subBFGS algorithm.

Corollary 4 *Under the conditions of Lemma 3, there exists an* $\varepsilon \geq 0$ *for Algorithm 2 such that the search direction* $\boldsymbol{p}$ *generated by Algorithm 2 satisfies*

$$\sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p} \leq -\tfrac{1}{2}\bar{\boldsymbol{g}}^\top\boldsymbol{B}\bar{\boldsymbol{g}} \leq -\frac{h}{2}\|\bar{\boldsymbol{g}}\|^2 < 0. \tag{84}$$

Proof Using (83), we have

$$(\forall i)\;\; \varepsilon^{(i)} \geq \sup_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p} + \tfrac{1}{2}\bar{\boldsymbol{g}}^\top\boldsymbol{B}\bar{\boldsymbol{g}} + \frac{h}{2}\|\bar{\boldsymbol{g}}^{(i)}\|^2.$$

The first inequality in (84) results from choosing an ε such that

$$(\forall i)\;\; \frac{h}{2}\|\bar{\boldsymbol{g}}^{(i)}\|^2 \geq \varepsilon \geq \varepsilon^{(i)} \geq 0. \tag{85}$$

The lower bound $h > 0$ on the spectrum of $\boldsymbol{B}$ yields the second inequality in (84), and the third follows from the fact that $\|\bar{\boldsymbol{g}}\| > 0$ at non-optimal iterates. ■

Appendix B. Convergence of the Descent Direction Search

Using the notation established in Appendix A, we now prove the convergence of Algorithm 2 via several technical intermediate steps. The proof shares similarities with the proofs found in Smola et al. (2007), Shalev-Shwartz and Singer (2008), and Warmuth et al. (2008). The key idea is that at each iterate Algorithm 2 decreases the upper bound $\varepsilon^{(i)}$ on the distance from the optimality, and the decrease in $\varepsilon^{(i)}$ is characterized by the recurrence $\varepsilon^{(i)} - \varepsilon^{(i+1)} \geq c(\varepsilon^{(i)})^2$ with $c > 0$ (Theorem 7). Analysing this recurrence then gives the convergence rate of the algorithm (Theorem 9).

We first provide two technical lemmas (Lemma 5 and 6) that are needed to prove Theorem 7.

Lemma 5 *Let $\bar{D}^{(i+1)}(\mu)$ be the one-dimensional function defined in* (70)*, and $\varepsilon^{(i)}$ the positive measure defined in* (77)*. Then $\varepsilon^{(i)} \leq \partial\bar{D}^{(i+1)}(0)$.*

Proof Let $\boldsymbol{p}^{(i)}$ be our primal solution at iteration i, derived from the dual solution $\boldsymbol{\alpha}^{(i)}$ using the dual connection (65). We then have

$$\boldsymbol{p}^{(i)} = -\boldsymbol{B}\bar{\boldsymbol{g}}^{(i)}, \quad \text{where} \quad \bar{\boldsymbol{g}}^{(i)} := \boldsymbol{G}^{(i)}\boldsymbol{\alpha}^{(i)}. \tag{86}$$

Definition (59) of $M(\boldsymbol{p})$ implies that

$$M(\boldsymbol{p}^{(i)}) \;=\; \tfrac{1}{2}{\boldsymbol{p}^{(i)}}^{\top}\boldsymbol{B}^{-1}\boldsymbol{p}^{(i)} + {\boldsymbol{p}^{(i)}}^{\top}\boldsymbol{g}^{(i+1)}, \tag{87}$$

where

$$\boldsymbol{g}^{(i+1)} := \operatorname*{arg\,sup}_{\boldsymbol{g}\in\partial J(\boldsymbol{w})} \boldsymbol{g}^{\top}\boldsymbol{p}^{(i)}. \tag{88}$$

Using (86), we have $\boldsymbol{B}^{-1}\boldsymbol{p}^{(i)} = -\boldsymbol{B}^{-1}\boldsymbol{B}\bar{\boldsymbol{g}}^{(i)} = -\bar{\boldsymbol{g}}^{(i)}$, and hence (87) becomes

$$M(\boldsymbol{p}^{(i)}) \;=\; {\boldsymbol{p}^{(i)}}^{\top}\boldsymbol{g}^{(i+1)} - \tfrac{1}{2}{\boldsymbol{p}^{(i)}}^{\top}\bar{\boldsymbol{g}}^{(i)}. \tag{89}$$

Similarly, we have

$$D^{(i)}(\boldsymbol{\alpha}^{(i)}) \;=\; -\tfrac{1}{2}(\boldsymbol{G}^{(i)}\boldsymbol{\alpha}^{(i)})^{\top}\boldsymbol{B}(\boldsymbol{G}^{(i)}\boldsymbol{\alpha}^{(i)}) \;=\; \tfrac{1}{2}{\boldsymbol{p}^{(i)}}^{\top}\bar{\boldsymbol{g}}^{(i)}. \tag{90}$$

From (72) and (86) it follows that

$$\partial\bar{D}^{(i+1)}(0) \;=\; (\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)})^{\top}\boldsymbol{B}\bar{\boldsymbol{g}}^{(i)} \;=\; (\boldsymbol{g}^{(i+1)} - \bar{\boldsymbol{g}}^{(i)})^{\top}\boldsymbol{p}^{(i)}, \tag{91}$$

where $\boldsymbol{g}^{(i+1)}$ is a violating subgradient chosen via (61), and hence coincides with (88). Using (89)–(91), we obtain

$$M(\boldsymbol{p}^{(i)}) - D^{(i)}(\boldsymbol{\alpha}^{(i)}) \;=\; \left(\boldsymbol{g}^{(i+1)} - \bar{\boldsymbol{g}}^{(i)}\right)^{\top}\boldsymbol{p}^{(i)} \;=\; \partial\bar{D}^{(i+1)}(0). \tag{92}$$

Together with definition (77) of $\varepsilon^{(i)}$, (92) implies that

$$\begin{aligned}\varepsilon^{(i)} \;&=\; \min_{j\leq i} M(\boldsymbol{p}^{(j)}) - D^{(i)}\left(\boldsymbol{\alpha}^{(i)}\right)\\ &\leq\; M(\boldsymbol{p}^{(i)}) - D^{(i)}(\boldsymbol{\alpha}^{(i)}) \;=\; \partial\bar{D}^{(i+1)}(0).\end{aligned}$$

■

Lemma 6 *Let $f : [0,1] \to \mathbb{R}$ be a concave quadratic function with $f(0) = 0$, $\partial f(0) \in [0,a]$, and $\partial f^2(x) \geq -a$ for some $a \geq 0$. Then $\max_{x\in[0,1]} f(x) \geq \frac{(\partial f(0))^2}{2a}$.*

Proof Using a second-order Taylor expansion around 0, we have $f(x) \geq \partial f(0)x - \frac{a}{2}x^2$. $x^* = \partial f(0)/a$ is the unconstrained maximum of the lower bound. Since $\partial f(0) \in [0,a]$, we have $x^* \in [0,1]$. Plugging x^* into the lower bound yields $(\partial f(0))^2/(2a)$. ■

Theorem 7 *Assume that at $\boldsymbol{w}$ the convex objective function $J : \mathbb{R}^d \to \mathbb{R}$ has bounded subgradient: $\|\partial J(\boldsymbol{w})\| \leq G$, and that the approximation $\boldsymbol{B}$ to the inverse Hessian has bounded eigenvalues: $\boldsymbol{B} \preceq H$. Then*

$$\varepsilon^{(i)} - \varepsilon^{(i+1)} \;\geq\; \frac{(\varepsilon^{(i)})^2}{8G^2H}.$$

Proof Recall that we constrain the form of feasible dual solutions for $D^{(i+1)}(\boldsymbol{\alpha})$ as in (69). Instead of $D^{(i+1)}(\boldsymbol{\alpha})$, we thus work with the one-dimensional concave quadratic function $\bar{D}^{(i+1)}(\mu)$ (70). It is obvious that $\begin{bmatrix} \boldsymbol{\alpha}^{(i)} \\ 0 \end{bmatrix}$ is a feasible solution for $D^{(i+1)}(\boldsymbol{\alpha})$. In this case, $\bar{D}^{(i+1)}(0) = D^{(i)}(\boldsymbol{\alpha}^{(i)})$. (74) implies that $\bar{D}^{(i+1)}(\mu^*) = D^{(i+1)}(\boldsymbol{\alpha}^{(i+1)})$. Using the definition (77) of $\varepsilon^{(i)}$, we thus have

$$\varepsilon^{(i)} - \varepsilon^{(i+1)} \;\geq\; D^{(i+1)}(\boldsymbol{\alpha}^{(i+1)}) - D^{(i)}(\boldsymbol{\alpha}^{(i)}) \;=\; \bar{D}^{(i+1)}(\mu^*) - \bar{D}^{(i+1)}(0). \tag{93}$$

It is easy to see from (93) that $\varepsilon^{(i)} - \varepsilon^{(i+1)}$ are upper bounds on the maximal value of the concave quadratic function $f(\mu) := \bar{D}^{(i+1)}(\mu) - \bar{D}^{(i+1)}(0)$ with $\mu \in [0,1]$ and $f(0) = 0$. Furthermore, the definitions of $\bar{D}^{(i+1)}(\mu)$ and $f(\mu)$ imply that

$$\begin{aligned} \partial f(0) \;&=\; \partial \bar{D}^{(i+1)}(0) \;=\; (\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)})^\top \boldsymbol{B} \bar{\boldsymbol{g}}^{(i)} \quad \text{and} \\ \partial^2 f(\mu) \;&=\; \partial^2 \bar{D}^{(i+1)}(\mu) \;=\; -(\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)})^\top \boldsymbol{B} (\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)}). \end{aligned} \tag{94}$$

Since $\|\partial J(\boldsymbol{w})\| \leq G$ and $\bar{\boldsymbol{g}}^{(i)} \in \partial J(\boldsymbol{w})$ (71), we have $\|\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)}\| \leq 2G$. Our upper bound on the spectrum of $\boldsymbol{B}$ then gives $|\partial f(0)| \leq 2G^2H$ and $\left|\partial^2 f(\mu)\right| \leq 4G^2H$. Additionally, Lemma 5 and the fact that $\boldsymbol{B} \succeq 0$ imply that

$$\partial f(0) \;=\; \partial \bar{D}^{(i+1)}(0) \geq 0 \quad \text{and} \quad \partial^2 f(\mu) \;=\; \partial^2 \bar{D}^{(i+1)}(\mu) \leq 0, \tag{95}$$

which means that

$$\partial f(0) \;\in\; [0, 2G^2H] \subset [0, 4G^2H] \quad \text{and} \quad \partial^2 f(\mu) \;\geq\; -4G^2H.$$

Invoking Lemma 6, we immediately get

$$\varepsilon^{(i)} - \varepsilon^{(i+1)} \;\geq\; \frac{(\partial f(0))^2}{8G^2H} \;=\; \frac{(\partial \bar{D}^{(i+1)}(0))^2}{8G^2H}. \tag{96}$$

Since $\varepsilon^{(i)} \leq \partial \bar{D}^{(i+1)}(0)$ by Lemma 5, the inequality (96) still holds when $\partial \bar{D}^{(i+1)}(0)$ is replaced with $\varepsilon^{(i)}$. ■

(94) and (95) imply that the optimal combination coefficient μ^* (73) has the property

$$\mu^* = \min\left[1, \frac{\partial \bar{D}^{(i+1)}(0)}{-\partial^2 \bar{D}^{(i+1)}(\mu)}\right].$$

Moreover, we can use (65) to reduce the cost of computing μ^* by setting $\boldsymbol{B}\bar{\boldsymbol{g}}^{(i)}$ in (73) to be $-\boldsymbol{p}^{(i)}$ (Line 7 of Algorithm 2), and calculate

$$\mu^* = \min\left[1, \frac{\boldsymbol{g}^{(i+1)\top}\boldsymbol{p}^{(i)} - \bar{\boldsymbol{g}}^{(i)\top}\boldsymbol{p}^{(i)}}{\boldsymbol{g}^{(i+1)\top}\boldsymbol{B}_t\boldsymbol{g}^{(i+1)} + 2\,\boldsymbol{g}^{(i+1)\top}\boldsymbol{p}^{(i)} - \bar{\boldsymbol{g}}^{(i)\top}\boldsymbol{p}^{(i)}}\right], \tag{97}$$

where $\boldsymbol{B}_t\boldsymbol{g}^{(i+1)}$ can be cached for the update of the primal solution at Line 9 of Algorithm 2.

To prove Theorem 9, we use the following lemma proven by induction by Abe et al. (2001, Sublemma 5.4):

Lemma 8 *Let* $\{\varepsilon^{(1)}, \varepsilon^{(2)}, \cdots\}$ *be a sequence of non-negative numbers satisfying* $\forall i \in \mathbb{N}$ *the recurrence*

$$\varepsilon^{(i)} - \varepsilon^{(i+1)} \;\geq\; c\,(\varepsilon^{(i)})^2,$$

where $c \in \mathbb{R}_+$ *is a positive constant. Then* $\forall i \in \mathbb{N}$ *we have*

$$\varepsilon^{(i)} \;\leq\; \frac{1}{c\left(i + \frac{1}{\varepsilon^{(1)}c}\right)}.$$

We now show that Algorithm 2 decreases $\varepsilon^{(i)}$ to a pre-defined tolerance ε in $O(1/\varepsilon)$ steps:

Theorem 9 *Under the assumptions of Theorem 7, Algorithm 2 converges to the desired precision* ε *after*

$$1 \;\leq\; t \;\leq\; \frac{8G^2H}{\varepsilon} - 4$$

steps for any $\varepsilon < 2G^2H$.

Proof Theorem 7 states that

$$\varepsilon^{(i)} - \varepsilon^{(i+1)} \;\geq\; \frac{(\varepsilon^{(i)})^2}{8G^2H},$$

where $\varepsilon^{(i)}$ is non-negative $\forall i \in \mathbb{N}$ by (78). Applying Lemma 8 we thus obtain

$$\varepsilon^{(i)} \;\leq\; \frac{1}{c\left(i + \frac{1}{\varepsilon^{(1)}c}\right)}, \quad \text{where} \quad c := \frac{1}{8G^2H}. \tag{98}$$

Our assumptions on $\|\partial J(\boldsymbol{w})\|$ and the spectrum of $\boldsymbol{B}$ imply that

$$\bar{D}^{(i+1)}(0) \;=\; (\bar{\boldsymbol{g}}^{(i)} - \boldsymbol{g}^{(i+1)})^\top \boldsymbol{B}\bar{\boldsymbol{g}}^{(i)} \;\leq\; 2G^2H.$$

Hence $\varepsilon^{(i)} \leq 2G^2H$ by Lemma 5. This means that (98) holds with $\varepsilon^{(1)} = 2G^2H$. Therefore we can solve

$$\varepsilon \leq \frac{1}{c\left(t + \frac{1}{\varepsilon^{(1)}c}\right)} \quad \text{with} \quad c := \frac{1}{8G^2H} \;\text{ and }\; \varepsilon^{(1)} := 2G^2H \tag{99}$$

to obtain an upper bound on t such that $(\forall i \geq t)\ \varepsilon^{(i)} \leq \varepsilon < 2G^2H$. The solution to (99) is $t \leq \frac{8G^2H}{\varepsilon} - 4$. ■

Appendix C. Satisfiability of the Subgradient Wolfe Conditions

To formally show that there always is a positive step size that satisfies the subgradient Wolfe conditions (23, 24), we restate a result of Hiriart-Urruty and Lemaréchal (1993, Theorem VI.2.3.3) in slightly modified form:

Lemma 10 *Given two points $\boldsymbol{w} \neq \boldsymbol{w}'$ in $\mathbb{R}^d$, define $\boldsymbol{w}_\eta = \eta\boldsymbol{w}' + (1-\eta)\boldsymbol{w}$. Let $J : \mathbb{R}^d \to \mathbb{R}$ be convex. There exists $\eta \in (0,1)$ and $\tilde{\boldsymbol{g}} \in \partial J(\boldsymbol{w}_\eta)$ such that*

$$J(\boldsymbol{w}') - J(\boldsymbol{w}) \;=\; \tilde{\boldsymbol{g}}^\top(\boldsymbol{w}' - \boldsymbol{w}) \;\leq\; \hat{\boldsymbol{g}}^\top(\boldsymbol{w}' - \boldsymbol{w}),$$

where $\hat{\boldsymbol{g}} := \arg\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_\eta)} \boldsymbol{g}^\top(\boldsymbol{w}' - \boldsymbol{w})$.

Theorem 11 *Let $\boldsymbol{p}$ be a descent direction at an iterate $\boldsymbol{w}$. If $\Phi(\eta) := J(\boldsymbol{w} + \eta\boldsymbol{p})$ is bounded below, then there exists a step size $\eta > 0$ which satisfies the subgradient Wolfe conditions (23, 24).*

Proof Since $\boldsymbol{p}$ is a descent direction, the line $J(\boldsymbol{w}) + c_1\eta \sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p}$ with $c_1 \in (0,1)$ must intersect $\Phi(\eta)$ at least once at some $\eta > 0$ (see Figure 1 for geometric intuition). Let η' be the smallest such intersection point; then

$$J(\boldsymbol{w} + \eta'\boldsymbol{p}) \;=\; J(\boldsymbol{w}) \;+\; c_1\eta' \sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p}. \tag{100}$$

Since $\Phi(\eta)$ is lower bounded, the sufficient decrease condition (23) holds for all $\eta'' \in [0, \eta']$. Setting $\boldsymbol{w}' = \boldsymbol{w} + \eta'\boldsymbol{p}$ in Lemma 10 implies that there exists an $\eta'' \in (0, \eta')$ such that

$$J(\boldsymbol{w} + \eta'\boldsymbol{p}) - J(\boldsymbol{w}) \;\leq\; \eta' \sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w} + \eta''\boldsymbol{p})} \boldsymbol{g}^\top\boldsymbol{p}. \tag{101}$$

Plugging (100) into (101) and simplifying it yields

$$c_1 \sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p} \;\leq \sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w} + \eta''\boldsymbol{p})} \boldsymbol{g}^\top\boldsymbol{p}. \tag{102}$$

Since $\boldsymbol{p}$ is a descent direction, $\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w})} \boldsymbol{g}^\top\boldsymbol{p} < 0$, and thus (102) also holds when c_1 is replaced by $c_2 \in (c_1, 1)$. ■

Algorithm 6 Algorithm 1 of Birge et al. (1998)

1: Initialize: $t := 0$ and $\boldsymbol{w}_0$
2: **while** not converged **do**
3: Find $\boldsymbol{w}_{t+1}$ that obeys

$$J(\boldsymbol{w}_{t+1}) \leq J(\boldsymbol{w}_t) - a_t \|\boldsymbol{g}_{\varepsilon'_t}\|^2 + \varepsilon_t \quad \text{where } \boldsymbol{g}_{\varepsilon'_t} \in \partial_{\varepsilon'_t} J(\boldsymbol{w}_{t+1}),\ a_t > 0,\ \varepsilon_t, \varepsilon'_t \geq 0\,. \tag{104}$$

4: $t := t + 1$
5: **end while**

Appendix D. Global Convergence of SubBFGS

There are technical difficulties in extending the classical BFGS convergence proof to the nonsmooth case. This route was taken by Andrew and Gao (2007), which unfortunately left their proof critically flawed: In a key step (Andrew and Gao, 2007, Equation 7) they seek to establish the non-negativity of the directional derivative $f'(\bar{x};\bar{q})$ of a convex function f at a point $\bar{x}$ in the direction $\bar{q}$, where $\bar{x}$ and $\bar{q}$ are the limit points of convergent sequences $\{x^k\}$ and $\{\hat{q}^k\}_\kappa$, respectively. They do so by taking the limit for $k \in \kappa$ of

$$f'(x^k + \tilde{\alpha}^k \hat{q}^k; \hat{q}^k) \ > \ \gamma f'(x^k; \hat{q}^k), \ \text{ where } \ \{\tilde{\alpha}^k\} \to 0 \ \text{ and } \ \gamma \in (0,1)\,,$$

which leads them to claim that

$$f'(\bar{x};\bar{q}) \ \geq \ \gamma f'(\bar{x};\bar{q})\,, \tag{103}$$

which would imply $f'(\bar{x};\bar{q}) \geq 0$ because $\gamma \in (0,1)$. However, $f'(x^k, \hat{q}^k)$ does not necessarily converge to $f'(\bar{x};\bar{q})$ because the directional derivative of a nonsmooth convex function is not continuous, only *upper semi-continuous* (Bertsekas, 1999, Proposition B.23). Instead of (103) we thus only have

$$f'(\bar{x};\bar{q}) \ \geq \ \gamma \limsup_{k\to\infty, k\in\kappa} f'(x^k;\hat{q}^k)\,,$$

which does not suffice to establish the desired result: $f'(\bar{x};\bar{q}) \geq 0$. A similar mistake is also found in the reasoning of Andrew and Gao (2007) just after Equation 7.

Instead of this flawed approach, we use the technique introduced by Birge et al. (1998) to prove the global convergence of subBFGS (Algorithm 1) in objective function value, that is, $J(\boldsymbol{w}_t) \to \inf_{\boldsymbol{w}} J(\boldsymbol{w})$, provided that the spectrum of BFGS' inverse Hessian approximation $\boldsymbol{B}_t$ is bounded from above and below for all t, and the step size η_t (obtained at Line 9) is not summable: $\sum_{t=0}^{\infty} \eta_t = \infty$.

Birge et al. (1998) provide a unified framework for convergence analysis of optimization algorithms for nonsmooth convex optimization, based on the notion of ε-*subgradients*. Formally, $\boldsymbol{g}$ is called an ε-subgradient of J at $\boldsymbol{w}$ iff (Hiriart-Urruty and Lemaréchal, 1993, Definition XI.1.1.1)

$$(\forall \boldsymbol{w}') \ J(\boldsymbol{w}') \ \geq \ J(\boldsymbol{w}) + (\boldsymbol{w}' - \boldsymbol{w})^\top \boldsymbol{g} - \varepsilon, \ \text{ where } \ \varepsilon \geq 0. \tag{105}$$

The set of all ε-subgradients at a point $\boldsymbol{w}$ is called the ε-subdifferential, and denoted $\partial_\varepsilon J(\boldsymbol{w})$. From the definition of subgradient (7), it is easy to see that $\partial J(\boldsymbol{w}) = \partial_0 J(\boldsymbol{w}) \subseteq \partial_\varepsilon J(\boldsymbol{w})$. Birge et al. (1998) propose an ε-subgradient-based algorithm (Algorithm 6) and provide sufficient conditions for its global convergence:

Theorem 12 (Birge et al., 1998, Theorem 2.1(iv), first sentence)
Let $J : \mathbb{R}^d \to \mathbb{R} \cup \{\infty\}$ be a proper lower semi-continuous[21] *extended-valued convex function, and let $\{(\varepsilon_t, \varepsilon'_t, a_t, \boldsymbol{w}_{t+1}, \boldsymbol{g}_{\varepsilon'_t})\}$ be any sequence generated by Algorithm 6 satisfying*

$$\sum_{t=0}^{\infty} \varepsilon_t < \infty \;\; \text{and} \;\; \sum_{t=0}^{\infty} a_t = \infty. \tag{106}$$

If $\varepsilon'_t \to 0$, and there exists a positive number $\beta > 0$ such that, for all large t,

$$\beta \, \|\boldsymbol{w}_{t+1} - \boldsymbol{w}_t\| \;\leq\; a_t \|\boldsymbol{g}_{\varepsilon'_t}\|, \tag{107}$$

then $J(\boldsymbol{w}_t) \to \inf_{\boldsymbol{w}} J(\boldsymbol{w})$.

We will use this result to establish the global convergence of subBFGS in Theorem 14. Towards this end, we first show that subBFGS is a special case of Algorithm 6:

Lemma 13 *Let $\boldsymbol{p}_t = -\boldsymbol{B}_t \bar{\boldsymbol{g}}_t$ be the descent direction produced by Algorithm 2 at a non-optimal iterate $\boldsymbol{w}_t$, where $\boldsymbol{B}_t \succeq h > 0$ and $\bar{\boldsymbol{g}}_t \in \partial J(\boldsymbol{w}_t)$, and let $\boldsymbol{w}_{t+1} = \boldsymbol{w}_t + \eta_t \boldsymbol{p}_t$, where $\eta_t > 0$ satisfies sufficient decrease* (23) *with free parameter $c_1 \in (0,1)$. Then $\boldsymbol{w}_{t+1}$ obeys* (104) *of Algorithm 6 for $a_t := \frac{c_1 \eta_t h}{2}$, $\varepsilon_t = 0$, and $\varepsilon'_t := \eta_t (1 - \frac{c_1}{2}) \, \bar{\boldsymbol{g}}_t^\top \boldsymbol{B}_t \bar{\boldsymbol{g}}_t$.*

Proof Our sufficient decrease condition (23) and Corollary 4 imply that

$$\begin{aligned} J(\boldsymbol{w}_{t+1}) \;&\leq\; J(\boldsymbol{w}_t) - \frac{c_1 \eta_t}{2} \, \bar{\boldsymbol{g}}_t^\top \boldsymbol{B}_t \bar{\boldsymbol{g}}_t \\ &\leq\; J(\boldsymbol{w}_t) - a_t \|\bar{\boldsymbol{g}}_t\|^2, \;\; \text{where} \;\; a_t := \frac{c_1 \eta_t h}{2}. \end{aligned} \tag{108}$$

What is left to prove is that $\bar{\boldsymbol{g}}_t \in \partial_{\varepsilon'_t} J(\boldsymbol{w}_{t+1})$ for an $\varepsilon'_t \geq 0$. Using $\bar{\boldsymbol{g}}_t \in \partial J(\boldsymbol{w}_t)$ and the definition (7) of subgradient, we have

$$\begin{aligned} (\forall \boldsymbol{w}) \;\; J(\boldsymbol{w}) \;&\geq\; J(\boldsymbol{w}_t) + (\boldsymbol{w} - \boldsymbol{w}_t)^\top \bar{\boldsymbol{g}}_t \\ &=\; J(\boldsymbol{w}_{t+1}) + (\boldsymbol{w} - \boldsymbol{w}_{t+1})^\top \bar{\boldsymbol{g}}_t + J(\boldsymbol{w}_t) - J(\boldsymbol{w}_{t+1}) + (\boldsymbol{w}_{t+1} - \boldsymbol{w}_t)^\top \bar{\boldsymbol{g}}_t \, . \end{aligned}$$

Using $\boldsymbol{w}_{t+1} - \boldsymbol{w}_t = -\eta_t \boldsymbol{B}_t \bar{\boldsymbol{g}}_t$ and (108) gives

$$\begin{aligned} (\forall \boldsymbol{w}) \;\; J(\boldsymbol{w}) \;&\geq\; J(\boldsymbol{w}_{t+1}) + (\boldsymbol{w} - \boldsymbol{w}_{t+1})^\top \bar{\boldsymbol{g}}_t + \frac{c_1 \eta_t}{2} \, \bar{\boldsymbol{g}}_t^\top \boldsymbol{B}_t \bar{\boldsymbol{g}}_t - \eta_t \, \bar{\boldsymbol{g}}_t^\top \boldsymbol{B}_t \bar{\boldsymbol{g}}_t \\ &=\; J(\boldsymbol{w}_{t+1}) + (\boldsymbol{w} - \boldsymbol{w}_{t+1})^\top \bar{\boldsymbol{g}}_t - \varepsilon'_t \, , \end{aligned}$$

where $\varepsilon'_t := \eta_t (1 - \frac{c_1}{2}) \, \bar{\boldsymbol{g}}_t^\top \boldsymbol{B}_t \bar{\boldsymbol{g}}_t$. Since $\eta_t > 0$, $c_1 < 1$, and $\boldsymbol{B}_t \succeq h > 0$, ε'_t is non-negative. By the definition (105) of ε-subgradient, $\bar{\boldsymbol{g}}_t \in \partial_{\varepsilon'_t} J(\boldsymbol{w}_{t+1})$. ■

21. This means that there exists at least one $\boldsymbol{w} \in \mathbb{R}^d$ such that $J(\boldsymbol{w}) < \infty$, and that for all $\boldsymbol{w} \in \mathbb{R}^d$, $J(\boldsymbol{w}) > -\infty$ and $J(\boldsymbol{w}) \leq \liminf_{t \to \infty} J(\boldsymbol{w}_t)$ for any sequence $\{\boldsymbol{w}_t\}$ converging to $\boldsymbol{w}$. All objective functions considered in this paper fulfill these conditions.

Theorem 14 *Let $J : \mathbb{R}^d \to \mathbb{R} \cup \{\infty\}$ be a proper lower semi-continuous*[21] *extended-valued convex function. Algorithm 1 with a line search that satisfies the sufficient decrease condition* (23) *with $c_1 \in (0,1)$ converges globally to the minimal value of J, provided that:*

1. *the spectrum of its approximation to the inverse Hessian is bounded above and below: $\exists\,(h, H : 0 < h \le H < \infty) : (\forall t)\ h \preceq \boldsymbol{B}_t \preceq H$*
2. *the step size $\eta_t > 0$ satisfies $\sum_{t=0}^{\infty} \eta_t = \infty$, and*
3. *the direction-finding tolerance ε for Algorithm 2 satisfies* (85).

Proof We have already shown in Lemma 13 that subBFGS is a special case of Algorithm 6. Thus if we can show that the technical conditions of Theorem 12 are met, it directly establishes the global convergence of subBFGS.

Recall that for subBFGS $a_t := \frac{c_1 \eta_t h}{2}$, $\varepsilon_t = 0$, $\varepsilon'_t := \eta_t (1 - \frac{c_1}{2})\, \bar{\boldsymbol{g}}_t^\top \boldsymbol{B}_t \bar{\boldsymbol{g}}_t$, and $\bar{\boldsymbol{g}}_t = \boldsymbol{g}_{\varepsilon'_t}$. Our assumption on η_t implies that $\sum_{t=0}^{\infty} a_t = \frac{c_1 h}{2} \sum_{t=0}^{\infty} \eta_t = \infty$, thus establishing (106). We now show that $\varepsilon'_t \to 0$. Under the third condition of Theorem 14, it follows from the first inequality in (84) in Corollary 4 that

$$\sup_{\boldsymbol{g} \in \partial J(\boldsymbol{w}_t)} \boldsymbol{g}^\top \boldsymbol{p}_t \ \le\ -\tfrac{1}{2}\, \bar{\boldsymbol{g}}_t^\top \boldsymbol{B}_t \bar{\boldsymbol{g}}_t\,, \tag{109}$$

where $\boldsymbol{p}_t = -\boldsymbol{B}_t \bar{\boldsymbol{g}}_t$, $\bar{\boldsymbol{g}}_t \in \partial J(\boldsymbol{w}_t)$ is the search direction returned by Algorithm 2. Together with the sufficient decrease condition (23), (109) implies (108). Now use (108) recursively to obtain

$$J(\boldsymbol{w}_{t+1}) \ \le\ J(\boldsymbol{w}_0) - \frac{c_1}{2} \sum_{i=0}^{t} \eta_i\, \bar{\boldsymbol{g}}_i^\top \boldsymbol{B}_i \bar{\boldsymbol{g}}_i\,.$$

Since J is proper (hence bounded from below), we have

$$\sum_{t=0}^{\infty} \eta_i\, \bar{\boldsymbol{g}}_i^\top \boldsymbol{B}_i \bar{\boldsymbol{g}}_i \ =\ \frac{1}{1 - \frac{c_1}{2}} \sum_{t=0}^{\infty} \varepsilon'_i \ <\ \infty\,. \tag{110}$$

Recall that $\varepsilon'_i \ge 0$. The bounded sum of non-negative terms in (110) implies that the terms in the sum must converge to zero.

Finally, to show (107) we use $\boldsymbol{w}_{t+1} - \boldsymbol{w}_t = -\eta_t \boldsymbol{B}_t \bar{\boldsymbol{g}}_t$, the definition of the matrix norm: $\|\boldsymbol{B}\| := \max_{\boldsymbol{x} \neq 0} \frac{\|\boldsymbol{B}\boldsymbol{x}\|}{\|\boldsymbol{x}\|}$, and the upper bound on the spectrum of $\boldsymbol{B}_t$ to write:

$$\|\boldsymbol{w}_{t+1} - \boldsymbol{w}_t\| \ =\ \eta_t \|\boldsymbol{B}_t \bar{\boldsymbol{g}}_t\| \ \le\ \eta_t \|\boldsymbol{B}_t\| \|\bar{\boldsymbol{g}}_t\| \ \le\ \eta_t H \|\bar{\boldsymbol{g}}_t\|. \tag{111}$$

Recall that $\bar{\boldsymbol{g}}_t = \boldsymbol{g}_{\varepsilon'_t}$ and $a_t = \frac{c_1 \eta_t h}{2}$, and multiply both sides of (111) by $\frac{c_1 h}{2H}$ to obtain (107) with $\beta := \frac{c_1 h}{2H}$. ■

Appendix E. SubBFGS Converges on Various Counterexamples

We demonstrate the global convergence of subBFGS[22] with an exact line search on various counterexamples from the literature, designed to show the failure to converge of other gradient-based algorithms.

22. We run Algorithm 1 with $h = 10^{-8}$ and $\varepsilon = 10^{-5}$.

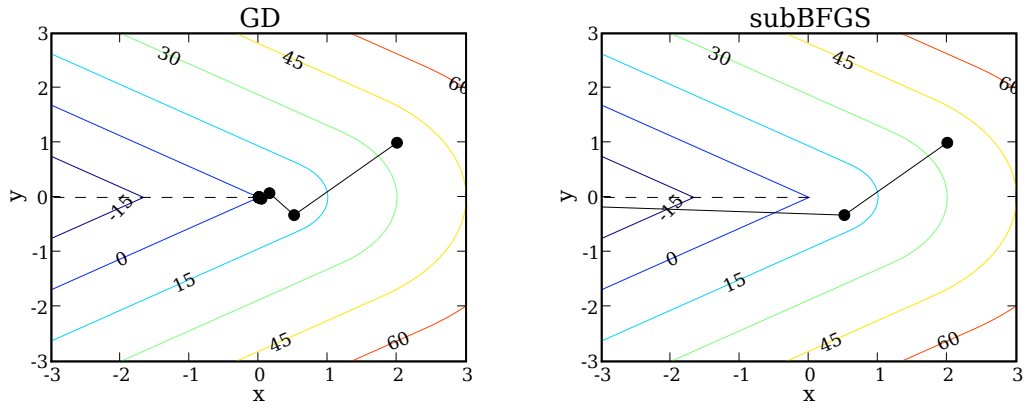

Figure 23: Optimization trajectory of steepest descent (left) and subBFGS (right) on counterexample (112).

E.1 Counterexample for Steepest Descent

The first counterexample (112) is given by Wolfe (1975) to show the non-convergent behaviour of the steepest descent method with an exact line search (denoted GD):

$$f(x,y) := \begin{cases} 5\sqrt{(9x^2+16y^2)} & \text{if} \quad x \geq |y|, \\ 9x+16|y| & \text{otherwise.} \end{cases} \tag{112}$$

This function is subdifferentiable along $x \leq 0,\ y = 0$ (dashed line in Figure 23); its minimal value $(-\infty)$ is attained for $x = -\infty$. As can be seen in Figure 23 (left), starting from a differentiable point $(2,1)$, GD follows successively orthogonal directions, that is, $-\nabla f(x,y)$, and converges to the non-optimal point $(0,0)$. As pointed out by Wolfe (1975), the failure of GD here is due to the fact that GD does not have a global view of f, specifically, it is because the gradient evaluated at each iterate (solid disk) is not informative about $\partial f(0,0)$, which contains subgradients (e.g., $(9,0)$), whose negative directions point toward the minimum. SubBFGS overcomes this "short-sightedness" by incorporating into the parameter update (3) an estimate $\boldsymbol{B}_t$ of the inverse Hessian, whose information about the shape of f prevents subBFGS from zigzagging to a non-optimal point. Figure 23 (right) shows that subBFGS moves to the correct region ($x < 0$) at the second step. In fact, the second step of subBFGS lands exactly on the hinge $x \leq 0, y = 0$, where a subgradient pointing to the optimum is available.

E.2 Counterexample for Steepest Subgradient Descent

The second counterexample (113), due to Hiriart-Urruty and Lemaréchal (1993, Section VIII.2.2), is a piecewise linear function which is subdifferentiable along $0 \leq y = \pm 3x$ and $x = 0$ (dashed lines in Figure 24):

$$f(x,y) := \max\{-100,\ \pm 2x+3y,\ \pm 5x+2y\}. \tag{113}$$

This example shows that steepest subgradient descent with an exact line search (denoted subGD) may not converge to the optimum of a nonsmooth function. Steepest subgradient descent updates

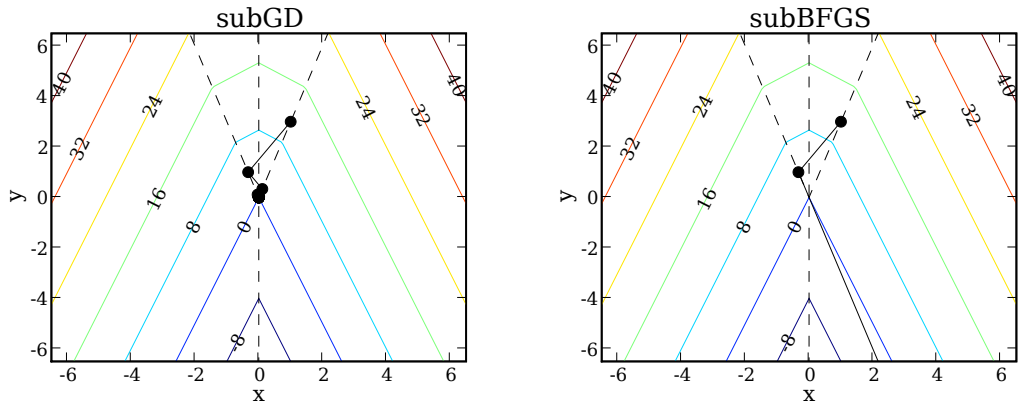

Figure 24: Optimization trajectory of steepest subgradient descent (left) and subBFGS (right) on counterexample (113).

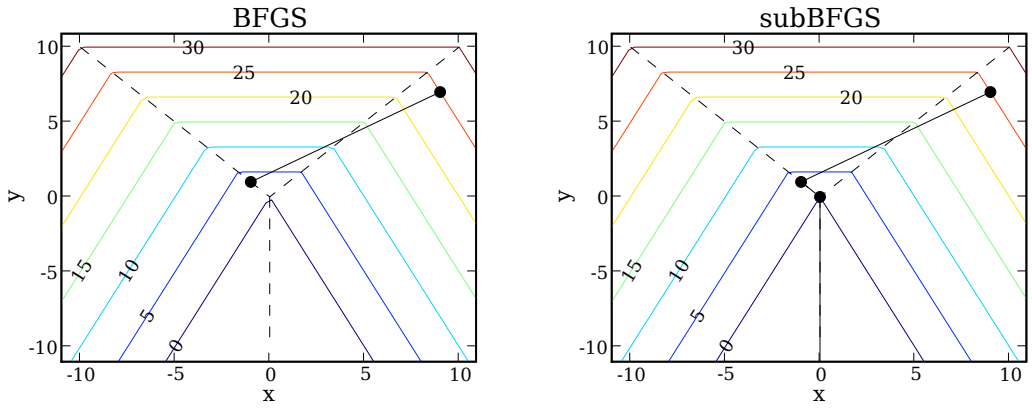

Figure 25: Optimization trajectory of standard BFGS (left) and subBFGS (right) on counterexample (114).

parameters along the *steepest descent* subgradient direction, which is obtained by solving the min-sup problem (13) with respect to the Euclidean norm. Clearly, the minimal value of f (-100) is attained for sufficiently negative values of y. However, subGD oscillates between two hinges $0 \leq y = \pm 3x$, converging to the non-optimal point $(0,0)$, as shown in Figure 24 (left). The zigzagging optimization trajectory of subGD does not allow it to land on any informative position such as the hinge $y = 0$, where the steepest subgradient descent direction points to the desired region $(y < 0)$; Hiriart-Urruty and Lemaréchal (1993, Section VIII.2.2) provide a detailed discussion. By contrast, subBFGS moves to the $y < 0$ region at the second step (Figure 24, right), which ends at the point $(100, -300)$ (not shown in the figure) where the minimal value of f is attained .

E.3 Counterexample for BFGS

The final counterexample (114) is given by Lewis and Overton (2008b) to show that the standard BFGS algorithm with an exact line search can break down when encountering a nonsmooth point:

$$f(x,y) := \max\{2|x| + y,\ 3y\}. \tag{114}$$

This function is subdifferentiable along $x = 0,\ y \leq 0$ and $y = |x|$ (dashed lines in Figure 25). Figure 25 (left) shows that after the first step, BFGS lands on a nonsmooth point, where it fails to find a descent direction. This is not surprising because at a nonsmooth point $\boldsymbol{w}$ the quasi-Newton direction $\boldsymbol{p} := -\boldsymbol{B}\boldsymbol{g}$ for a given subgradient $\boldsymbol{g} \in \partial J(\boldsymbol{w})$ is not necessarily a direction of descent. SubBFGS fixes this problem by using a direction-finding procedure (Algorithm 2), which is guaranteed to generate a descent quasi-Newton direction. Here subBFGS converges to $f = -\infty$ in three iterations (Figure 25, right).

Abstract

We present a unified framework to study graph kernels, special cases of which include the random walk (Gärtner et al., 2003; Borgwardt et al., 2005) and marginalized (Kashima et al., 2003, 2004; Mahé et al., 2004) graph kernels. Through reduction to a Sylvester equation we improve the time complexity of kernel computation between unlabeled graphs with n vertices from $O(n^6)$ to $O(n^3)$. We find a spectral decomposition approach even more efficient when computing entire kernel matrices. For labeled graphs we develop conjugate gradient and fixed-point methods that take $O(dn^3)$ time per iteration, where d is the size of the label set. By extending the necessary linear algebra to Reproducing Kernel Hilbert Spaces (RKHS) we obtain the same result for d-dimensional edge kernels, and $O(n^4)$ in the infinite-dimensional case; on sparse graphs these algorithms only take $O(n^2)$ time per iteration in all cases. Experiments on graphs from bioinformatics and other application domains show that these techniques can speed up computation of the kernel by an order of magnitude or more. We also show that certain rational kernels (Cortes et al., 2002, 2003, 2004) when specialized to graphs reduce to our random walk graph kernel. Finally, we relate our framework to R-convolution kernels (Haussler, 1999) and provide a kernel that is close to the optimal assignment kernel of Fröhlich et al. (2006) yet provably positive semi-definite.

Keywords: linear algebra in RKHS, Sylvester equations, spectral decomposition, bioinformatics, rational kernels, transducers, semirings, random walks

1. Introduction

Machine learning in domains such as bioinformatics (Sharan and Ideker, 2006), chemoinformatics (Bonchev and Rouvray, 1991), drug discovery (Kubinyi, 2003), web data mining

∗. Also at the Max Planck Institute for Biological Cybernetics.

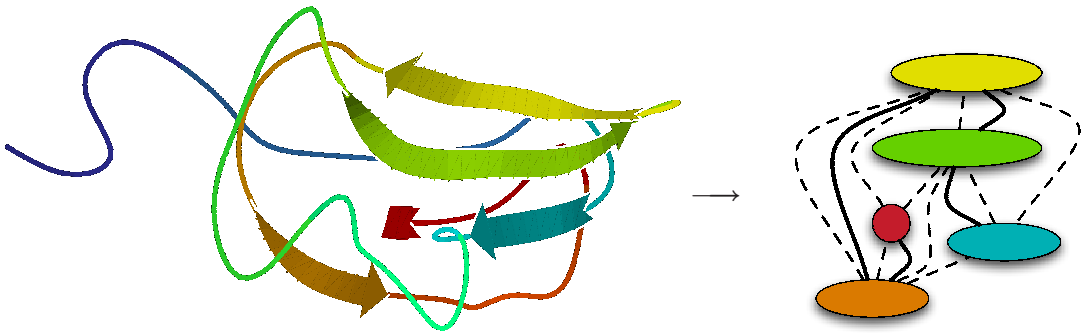

Figure 1: Left: Structure of *E. coli* protein fragment APO-BCCP87 (Yao et al., 1997), ID 1a6x in the Protein Data Bank (Berman et al., 2000). Right: Borgwardt et al.'s (2005) graph representation for this protein fragment. Nodes represent secondary structure elements, and edges encode neighborhood along the amino acid chain (solid) resp. in Euclidean 3D space (dashed).

(Washio and Motoda, 2003), and social networks (Kumar et al., 2006) involves the study of relationships between structured objects. Graphs are natural data structures to model such structures, with nodes representing objects and edges the relations between them. In this context, one often encounters two questions: "How similar are two nodes in a given graph?" and "How similar are two graphs to each other?"

In protein function prediction, for instance, one might want to predict whether a given protein is an enzyme or not. Computational approaches infer protein function by finding proteins with similar sequence, structure, or chemical properties. A very successful recent method is to model the protein as a graph (see Figure 1), and assign similar functions to similar graphs (Borgwardt et al., 2005). In Section 5.2 we compute graph kernels to measure the similarity between proteins and enzymes represented in this fashion.

Another application featured in Section 5.2 involves predicting the toxicity of chemical molecules by comparing their three-dimensional structure. Here the molecular structure is modeled as a graph, and the challenge is to compute the similarity between molecules of known and unknown toxicity.

Finally, consider the task of finding web pages with related content. Since documents on the web link to each other, one can model each web page as the node of a graph, and each link as an edge. Now the problem becomes that of computing similarities between the nodes of a graph. Taking this one step further, detecting mirrored sets of web pages requires computing the similarity between the graphs representing them.

Kernel methods (Schölkopf and Smola, 2002) offer a natural framework to study these questions. Roughly speaking, a kernel $k(x,x')$ is a measure of similarity between objects x and x'. It must satisfy two mathematical requirements: it must be symmetric, that is, $k(x,x') = k(x',x)$, and positive semi-definite (p.s.d.). Comparing nodes in a graph involves constructing a kernel between nodes, while comparing graphs involves constructing a kernel between graphs. In both cases, the challenge is to define a kernel that captures the semantics inherent in the graph structure and is reasonably efficient to evaluate.

The idea of constructing kernels *on* graphs (i.e., between the nodes of a single graph) was first proposed by Kondor and Lafferty (2002), and extended by Smola and Kondor (2003). In con-

trast, in this paper we focus on kernels *between* graphs. The first such kernels were proposed by Gärtner et al. (2003) and later extended by Borgwardt et al. (2005). Much at the same time, the idea of marginalized kernels (Tsuda et al., 2002) was extended to graphs by Kashima et al. (2003, 2004), then further refined by Mahé et al. (2004). Another algebraic approach to graph kernels has appeared recently (Kondor and Borgwardt, 2008). A seemingly independent line of research investigates the so-called rational kernels, which are kernels between finite state automata based on the algebra of abstract semirings (Cortes et al., 2002, 2003, 2004).

The aim of this paper is twofold: on the one hand we present theoretical results showing that all the above graph kernels are in fact closely related, on the other hand we present new algorithms for efficiently computing such kernels. We begin by establishing some notation and reviewing pertinent concepts from linear algebra and graph theory.

1.1 Paper Outline

The first part of this paper (Sections 2–5) elaborates and updates a conference publication of Vishwanathan et al. (2007) to present a unifying framework for graph kernels encompassing many known kernels as special cases, and to discuss connections to yet others. After defining some basic concepts in Section 2, we describe the framework in Section 3, prove that it leads to p.s.d. kernels, and discuss the random walk and marginalized graph kernels as special cases. For ease of exposition we will work with real matrices in the main body of the paper and relegate the RKHS extensions to Appendix A. In Section 4 we present four efficient ways to compute random walk graph kernels, namely: 1. via reduction to a Sylvester equation, 2. with a conjugate gradient solver, 3. using fixed-point iterations, and 4. via spectral decompositions. Experiments on a variety of real and synthetic data sets in Section 5 illustrate the computational advantages of our methods, which generally reduce the time complexity of kernel computation from $O(n^6)$ to $O(n^3)$. The experiments of Section 5.3 were previously presented at a bioinformatics symposium (Borgwardt et al., 2007).

The second part of the paper (Sections 6–7) draws further connections to existing kernels on structured objects. In Section 6 we present a simple proof that rational kernels (Cortes et al., 2002, 2003, 2004) are p.s.d., and show that specializing them to graphs yields random walk graph kernels. In Section 7 we discuss the relation between R-convolution kernels (Haussler, 1999) and various graph kernels, all of which can in fact be shown to be instances of R-convolution kernels. Extending the framework through the use of semirings does not always result in a p.s.d. kernel though; a case in point is the optimal assignment kernel of Fröhlich et al. (2006). We establish sufficient conditions for R-convolution kernels in semirings to be p.s.d., and provide a "mostly optimal assignment kernel" that is provably p.s.d. We conclude in Section 8 with an outlook and discussion.

2. Preliminaries

Here we define the basic concepts and notation from linear algebra and graph theory that will be used in the remainder of the paper.

2.1 Linear Algebra Concepts

We use $\mathbf{e}_i$ to denote the i^{th} standard basis vector (that is, a vector of all zeros with the i^{th} entry set to one), $\mathbf{e}$ to denote a vector with all entries set to one, $\mathbf{0}$ to denote the vector of all zeros, and $\mathbf{I}$ to

denote the identity matrix. When it is clear from the context we will not mention the dimensions of these vectors and matrices.

Definition 1 *Given real matrices $A \in \mathbb{R}^{n\times m}$ and $B \in \mathbb{R}^{p\times q}$, the Kronecker product $A \otimes B \in \mathbb{R}^{np\times mq}$ and column-stacking operator* $\mathrm{vec}(A) \in \mathbb{R}^{nm}$ *are defined as*

$$A \otimes B := \begin{bmatrix} A_{11}B & A_{12}B & \dots & A_{1m}B \\ \vdots & \vdots & \vdots & \vdots \\ A_{n1}B & A_{n2}B & \dots & A_{nm}B \end{bmatrix}, \quad \mathrm{vec}(A) := \begin{bmatrix} A_{*1} \\ \vdots \\ A_{*m} \end{bmatrix},$$

where A_{*j} denotes the j^{th} column of A.

The Kronecker product and vec operator are linked by the well-known property (e.g., Bernstein, 2005, Proposition 7.1.9):

$$\mathrm{vec}(ABC) = (C^\top \otimes A)\,\mathrm{vec}(B). \tag{1}$$

Another well-known property of the Kronecker product which we make use of is (Bernstein, 2005, Proposition 7.1.6):

$$(A \otimes B)(C \otimes D) = AC \otimes BD. \tag{2}$$

Finally, the Hadamard product of two real matrices $A, B \in \mathbb{R}^{n\times m}$, denoted by $A \odot B \in \mathbb{R}^{n\times m}$, is obtained by element-wise multiplication. It interacts with the Kronecker product via

$$(A \otimes B) \odot (C \otimes D) = (A \odot C) \otimes (B \odot D). \tag{3}$$

All the above concepts can be extended to a Reproducing Kernel Hilbert Space (RKHS) (See Appendix A for details).

2.2 Graph Concepts

A graph G consists of an ordered set of n vertices $V = \{v_1, v_2, \dots, v_n\}$, and a set of directed edges $E \subset V \times V$. A vertex v_i is said to be a neighbor of another vertex v_j if they are connected by an edge, that is, if $(v_i, v_j) \in E$; this is also denoted $v_i \sim v_j$. We do not allow self-loops, that is, $(v_i, v_i) \notin E$ for any i. A walk of length k on G is a sequence of indices $i_0, i_1, \dots i_k$ such that $v_{i_{r-1}} \sim v_{i_r}$ for all $1 \le r \le k$. A graph is said to be strongly connected if any two pairs of vertices can be connected by a walk. In this paper we will always work with strongly connected graphs. A graph is said to be undirected if $(v_i, v_j) \in E \iff (v_j, v_i) \in E$.

In much of the following we will be dealing with weighted graphs, which are a slight generalization of the above. In a weighted graph, each edge (v_i, v_j) has an associated weight $w_{ij} > 0$ signifying its "strength". If v_i and v_j are not neighbors, then $w_{ij} = 0$. In an undirected weighted graph $w_{ij} = w_{ji}$.

When G is unweighted, we define its adjacency matrix as the $n \times n$ matrix $\widetilde{\mathrm{A}}$ with $\widetilde{\mathrm{A}}_{ij} = 1$ if $v_j \sim v_i$, and 0 otherwise. For weighted graphs, $\widetilde{\mathrm{A}}_{ij} = w_{ji}$. While some authors would call these matrices the transpose of the adjacency matrix, for our purposes the present definitions will be more convenient. For undirected graphs $\widetilde{\mathrm{A}}$ is symmetric, and the two definitions coincide. The diagonal entries of $\widetilde{\mathrm{A}}$ are always zero.

The adjacency matrix has a normalized cousin, defined $A := \widetilde{\mathrm{A}} D^{-1}$, which has the property that each of its columns sums to one, and it can therefore serve as the transition matrix for a stochastic process. Here, D is a diagonal matrix of node degrees, that is, $D_{ii} = d_i = \sum_j \widetilde{\mathrm{A}}_{ij}$. A random walk on G is a process generating sequences of vertices $v_{i_1}, v_{i_2}, v_{i_3}, \ldots$ according to $\mathbb{P}(i_{k+1}|i_1, \ldots i_k) = A_{i_{k+1},i_k}$, that is, the probability at v_{i_k} of picking $v_{i_{k+1}}$ next is proportional to the weight of the edge $(v_{i_k}, v_{i_{k+1}})$. The t^{th} power of A thus describes t-length walks, that is, $(A^t)_{ij}$ is the probability of a transition from vertex v_j to vertex v_i via a walk of length t. If p_0 is an initial probability distribution over vertices, then the probability distribution p_t describing the location of our random walker at time t is $p_t = A^t p_0$. The j^{th} component of p_t denotes the probability of finishing a t-length walk at vertex v_j.

A random walk need not continue indefinitely; to model this, we associate every node v_{i_k} in the graph with a stopping probability q_{i_k}. Our generalized random walk graph kernels then use the overall probability of stopping after t steps, given by $q^\top p_t$. Like p_0, the vector q of stopping probabilities is a place to embed prior knowledge into the kernel design. Since p_t as a probability distribution sums to one, a *uniform* vector q (as might be chosen in the absence of prior knowledge) would yield the same overall stopping probability for all p_t, thus leading to a kernel that is invariant with respect to the graph structure it is meant to measure. In this case, the unnormalized adjacency matrix $\widetilde{\mathrm{A}}$ (which simply counts random walks instead of measuring their probability) should be used instead.

Let $\mathcal{X}$ be a set of labels which includes the special label ζ. Every edge-labeled graph G is associated with a label matrix $X \in \mathcal{X}^{n \times n}$ in which X_{ij} is the label of the edge (v_j, v_i) and $X_{ij} = \zeta$ if $(v_j, v_i) \notin E$. Let $\mathcal{H}$ be the RKHS induced by a p.s.d. kernel $\kappa : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, and let $\phi : \mathcal{X} \to \mathcal{H}$ denote the corresponding feature map, which we assume maps ζ to the zero element of $\mathcal{H}$. We use $\Phi(X)$ to denote the feature matrix of G (see Appendix A for details). For ease of exposition we do not consider labels on vertices here, though our results hold for that case as well. Henceforth we use the term labeled graph to denote an edge-labeled graph.

Two graphs $G = (V, E)$ and $G' = (V', E')$ are *isomorphic* (denoted by $G \cong G'$) if there exists a bijective mapping $g : V \to V'$ (called the isomorphism function) such that $(v_i, v_j) \in E$ iff $(g(v_i), g(v_j)) \in E'$.

3. Random Walk Graph Kernels

Our generalized random walk graph kernels are based on a simple idea: given a pair of graphs, perform random walks on both, and count the number of matching walks. We show that this simple concept underlies both random walk and marginalized graph kernels. In order to do this, we first need to introduce direct product graphs.

3.1 Direct Product Graphs

Given two graphs $G(V, E)$ and $G'(V', E')$, their direct product $G_\times$ is a graph with vertex set

$$V_\times = \{(v_i, v'_r) : v_i \in V,\ v'_r \in V'\}, \tag{4}$$

and edge set

$$E_\times = \{((v_i, v'_r), (v_j, v'_s)) : (v_i, v_j) \in E \wedge (v'_r, v'_s) \in E'\}. \tag{5}$$

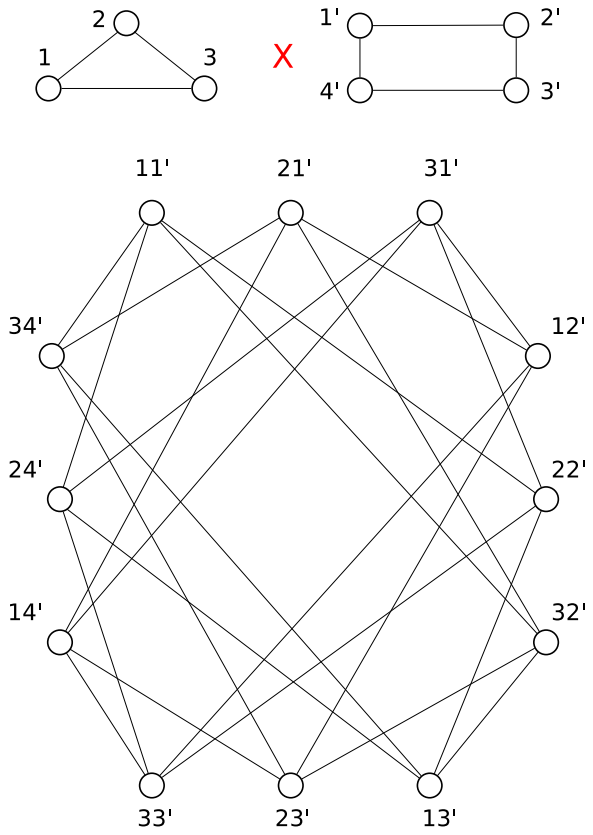

Figure 2: Two graphs (top left & right) and their direct product (bottom). Each node of the direct product graph is labeled with a pair of nodes (4); an edge exists in the direct product if and only if the corresponding nodes are adjacent in both original graphs (5). For instance, nodes $11'$ and $32'$ are adjacent because there is an edge between nodes 1 and 3 in the first, and $1'$ and $2'$ in the second graph.

In other words, $G_\times$ is a graph over pairs of vertices from G and G', and two vertices in $G_\times$ are neighbors if and only if the corresponding vertices in G and G' are both neighbors; see Figure 2 for an illustration. If $\widetilde{\mathrm{A}}$ and $\widetilde{\mathrm{A}}'$ are the respective adjacency matrices of G and G', then the adjacency matrix of $G_\times$ is $\widetilde{\mathrm{A}}_\times = \widetilde{\mathrm{A}} \otimes \widetilde{\mathrm{A}}'$. Similarly, $A_\times = A \otimes A'$.

Performing a random walk on the direct product graph is equivalent to performing a simultaneous random walk on G and G' (Imrich and Klavžar, 2000). If p and p' denote initial probability distributions over the vertices of G and G', then the corresponding initial probability distribution on the direct product graph is $p_\times := p \otimes p'$. Likewise, if q and q' are stopping probabilities (that is, the probability that a random walk ends at a given vertex), then the stopping probability on the direct product graph is $q_\times := q \otimes q'$.

Let $|V| =: n$ and $|V'| =: n'$. If G and G' are edge-labeled, we can associate a weight matrix $W_\times \in \mathbb{R}^{nn' \times nn'}$ with $G_\times$ using our extension of the Kronecker product (Definition 1) into RKHS (Definition 11 in Appendix A):

$$W_\times = \Phi(X) \otimes \Phi(X'). \tag{6}$$

As a consequence of the definition of $\Phi(X)$ and $\Phi(X')$, the entries of $W_\times$ are non-zero only if the corresponding edge exists in the direct product graph. If we simply let $\mathcal{H} = \mathbb{R}$, $\Phi(X) = \widetilde{\mathrm{A}}$, and $\Phi(X') = \widetilde{\mathrm{A}}'$ then (6) reduces to $\widetilde{\mathrm{A}}_\times$, the adjacency matrix of the direct product graph. Normalization can be incorporated by letting $\phi(X_{ij}) = 1/d_i$ if $(v_j, v_i) \in E$, and zero otherwise.[1] Then $\Phi(X) = A$ and $\Phi(X') = A'$, and consequently $W_\times = A_\times$.

If the edges of our graphs take on labels from a finite set, without loss of generality $\{1, 2, \ldots, d\}$, we can let $\mathcal{H}$ be $\mathbb{R}^d$ endowed with the usual inner product. For each edge $(v_j, v_i) \in E$ we set $\phi(X_{ij}) = \mathbf{e}_l / d_i$ if the edge (v_j, v_i) is labeled l; all other entries of $\Phi(X)$ are $\mathbf{0}$. Thus the weight matrix (6) has a non-zero entry iff an edge exists in the direct product graph and the corresponding edges in G and G' have the same label. Let ${}^lA$ denote the normalized adjacency matrix of the graph filtered by the label l, that is, ${}^lA_{ij} = A_{ij}$ if $X_{ij} = l$, and zero otherwise. Some simple algebra (omitted for the sake of brevity) shows that the weight matrix of the direct product graph can then be written as

$$W_\times = \sum_{l=1}^{d} {}^lA \otimes {}^lA'. \tag{7}$$

In Section 4 we will develop efficient methods to compute kernels defined using the weight matrix of the direct product graph. The applicability and time complexity of a particular method will depend on whether the graphs are unlabeled though possibly edge-weighted ($W_\times = A_\times$), have discrete edge labels (7), or—in the most general case—employ an arbitrary edge kernel (6); see Table 1 for a summary.

3.2 Kernel Definition

As stated above, performing a random walk on the direct product graph $G_\times$ is equivalent to performing a simultaneous random walk on the graphs G and G' (Imrich and Klavžar, 2000). Therefore, the $((i-1)n' + r, (j-1)n' + s)^{\text{th}}$ entry of $A_\times^k$ represents the probability of simultaneous length k random walks on G (starting from vertex v_j and ending in vertex v_i) and G' (starting from vertex v'_s and ending in vertex v'_r). The entries of $W_\times$ (6) represent similarity between edges: The $((i-1)n' + r, (j-1)n' + s)$ entry of $W_\times^k$ represents the similarity between simultaneous length k random walks on G and G', measured via the kernel function κ. Given initial and stopping probability distributions $p_\times$ and $q_\times$ one can compute $q_\times^\top W_\times^k p_\times$, which is the expected similarity between simultaneous length k random walks on G and G'.

To define a kernel which computes the similarity between G and G', one natural idea is to simply sum up $q_\times^\top W_\times^k p_\times$ for all values of k. However, this sum might not converge, leaving the kernel value undefined. To overcome this problem, we introduce appropriately chosen non-negative coefficients $\mu(k)$, and define the kernel between G and G' as

$$k(G, G') := \sum_{k=0}^{\infty} \mu(k)\, q_\times^\top W_\times^k p_\times. \tag{8}$$

This definition is very flexible and offers the kernel designer many parameters to adjust in an application-specific manner: Appropriately choosing $\mu(k)$ allows one to (de-)emphasize walks of different lengths; if initial and stopping probabilities are known for a particular application, then

1. The technical problem that now $\phi(X_{ij})$ depends on d_i can be addressed by making d_i a feature of all edges $(v_j, v_i) \in E$.

this knowledge can be incorporated into the kernel; and finally, appropriate kernels or similarity measures between edges can be incorporated via the weight matrix $W_\times$. Despite its flexibility, this kernel is guaranteed to be p.s.d. and—as we will see in Section 4—can be computed efficiently by exploiting the special structure of $W_\times$. To show that (8) is a valid p.s.d. kernel we need the following technical lemma:

Lemma 2 $\forall\, k \in \mathbb{N}:\ W_\times^k p_\times = \mathrm{vec}[\Phi(X')^k p' (\Phi(X)^k p)^\top]$.

Proof By induction over k. Base case: $k = 0$. Using (1) we find

$$W_\times^0 p_\times = p_\times = (p \otimes p')\,\mathrm{vec}(1) = \mathrm{vec}(p'\,1\,p^\top) = \mathrm{vec}[\Phi(X')^0 p' (\Phi(X)^0 p)^\top]. \tag{9}$$

Induction from k to $k+1$: Using the induction assumption $W_\times^k p_\times = \mathrm{vec}[\Phi(X')^k p' (\Phi(X)^k p)^\top]$ and Lemma 12 we obtain

$$\begin{aligned} W_\times^{k+1} p_\times = W_\times W_\times^k p_\times &= (\Phi(X) \otimes \Phi(X'))\,\mathrm{vec}[\Phi(X')^k p' (\Phi(X)^k p)^\top] \\ &= \mathrm{vec}[\Phi(X')\Phi(X')^k p' (\Phi(X)^k p)^\top \Phi(X)^\top] \\ &= \mathrm{vec}[\Phi(X')^{k+1} p' (\Phi(X)^{k+1} p)^\top]. \end{aligned} \tag{10}$$

Base case (9) and induction (10) together imply Lemma 2 $\forall\, k \in \mathbb{N}_0$. ■

Theorem 3 *If the coefficients $\mu(k)$ are such that* (8) *converges, then* (8) *defines a valid p.s.d. kernel.*

Proof Using Lemmas 12 and 2 we can write

$$\begin{aligned} q_\times^\top W_\times^k p_\times &= (q \otimes q')^\top\,\mathrm{vec}[\Phi(X')^k p' (\Phi(X)^k p)^\top] \\ &= \mathrm{vec}[q'^\top \Phi(X')^k p' (\Phi(X)^k p)^\top q] \\ &= \underbrace{(q^\top \Phi(X)^k p)^\top}_{\rho_k(G)^\top} \underbrace{(q'^\top \Phi(X')^k p')}_{\rho_k(G')}. \end{aligned} \tag{11}$$

Each individual term of (11) equals $\rho_k(G)^\top \rho_k(G')$ for some function ρ_k, and is therefore a valid p.s.d. kernel. The theorem follows because the class of p.s.d. kernels is closed under non-negative linear combinations and pointwise limits (Berg et al., 1984). ■

3.3 Special Cases

Kashima et al. (2004) define a kernel between labeled graphs via walks and their label sequences. Recall that a walk of length t on G is a sequence of indices $i_1, i_2, \ldots i_{t+1}$ such that $v_{i_k} \sim v_{i_{k+1}}$ for all $1 \le k \le t$. In our setting (where we do not consider node labels), the label sequence $h = h_1, \ldots, h_t$ associated with a walk is simply the sequence of edge labels encountered during the walk. Let P denote a transition probability matrix, where P_{ij} denotes the probability of transition from node v_i to node v_j. For instance, P might be the normalized adjacency matrix of G. Furthermore, let p

and q denote starting and stopping probabilities. Then one can compute the probability of a walk $i_1, i_2, \ldots i_{t+1}$ and hence the label sequence h associated with it as

$$p(h|G) := q_{i_{t+1}} \prod_{j=1}^{t} P_{i_j,i_{j+1}} p_{i_1}. \tag{12}$$

Now let $\hat{\phi}$ denote a feature map on edge labels, and define a kernel between label sequences of length t by

$$\kappa(h,h') := \prod_{i=1}^{t} \kappa(h_i,h'_i) = \prod_{i=1}^{t} \left\langle \hat{\phi}(h_i), \hat{\phi}(h'_i) \right\rangle \tag{13}$$

if h and h' have the same length t, and zero otherwise. Using (12) and (13) we can define a kernel between graphs via marginalization:

$$k(G,G') := \sum_{h} \sum_{h'} \kappa(h,h')\, p(h|G)\, p(h|G'). \tag{14}$$

Kashima et al. (2004, Eq. 1.19) show that (14) can be written as

$$k(G,G') = q_\times^\top (\mathbf{I} - T_\times)^{-1} p_\times, \tag{15}$$

where $T_\times = [\mathrm{vec}(P)\,\mathrm{vec}(P')^\top] \odot [\hat{\Phi}(X) \otimes \hat{\Phi}(X')]$. (As usual, X and X' denote the edge label matrices of G and G', respectively, and $\hat{\Phi}$ the corresponding feature matrices.)

Although this kernel is differently motivated, it can be obtained as a special case of our framework. Towards this end, assume $\mu(k) = \lambda^k$ for some $\lambda > 0$. We can then write

$$k(G,G') \;=\; \sum_{k=0}^{\infty} \lambda^k q_\times^\top W_\times^k p_\times \;=\; q_\times^\top (\mathbf{I} - \lambda W_\times)^{-1} p_\times. \tag{16}$$

To recover the marginalized graph kernels let $\lambda = 1$, and define $\Phi(X_{ij}) = P_{ij} \hat{\Phi}(X_{ij})$, in which case $W_\times = T_\times$, thus recovering (15).

Given a pair of graphs, Gärtner et al. (2003) also perform random walks on both, but then *count* the number of matching walks. Their kernel is defined as (Gärtner et al., 2003, Definition 6):

$$k(G,G') = \sum_{i=1}^{n} \sum_{j=1}^{n'} \sum_{k=0}^{\infty} \lambda_k \left[\widetilde{\mathrm{A}}_\times^k \right]_{ij}. \tag{17}$$

To obtain (17) in our framework, set $\mu(k) := \lambda_k$, assume uniform distributions for the starting and stopping probabilities over the vertices of G and G' (i.e., $p_i = q_i = 1/n$ and $p'_i = q'_i = 1/n'$), and let $\Phi(X) := \widetilde{\mathrm{A}}$ and $\Phi(X') = \widetilde{\mathrm{A}}'$. Consequently, $p_\times = q_\times = \mathbf{e}/(nn')$, and $W_\times = \widetilde{\mathrm{A}}_\times$, the unnormalized adjacency matrix of the direct product graph. This allows us to rewrite (8) to obtain

$$k(G,G') \;=\; \sum_{k=0}^{\infty} \mu(k)\, q_\times^\top W_\times^k p_\times \;=\; \frac{1}{n^2 n'^2} \sum_{i=1}^{n} \sum_{j=1}^{n'} \sum_{k=0}^{\infty} \lambda_k \left[\widetilde{\mathrm{A}}_\times^k \right]_{ij}, \tag{18}$$

which recovers (17) to within a constant factor. Gärtner et al. (2003) also extend their kernels to graphs with labels from a finite set by replacing $\widetilde{\mathrm{A}}_\times$ in (17) with a sum $\widetilde{\mathrm{W}}_\times$ of label-filtered (but

sparsity	dense				sparse

Table 1: Worst-case time complexity (in $O(\cdot)$ notation) of our methods for an $m \times m$ graph kernel matrix, where $n =$ size of the graphs (number of nodes), $d =$ size of label set *resp*. dimensionality of feature map, $r =$ effective rank of $W_\times$, $k =$ number of fixed-point iterations (31), and $k' =$ number of power iterations (37).

unnormalized) adjacency matrices, analogous to our (7). The reduction to our framework extends to this setting in a straightforward manner.

Gärtner et al. (2003) discuss two cases of special interest: First, their *geometric* kernel employs a fixed decay factor λ to down-weight the contribution of long walks to the kernel, setting $\lambda_k := \lambda^k$ as in our (16). The choice of λ is critical here: It must be small enough for the sum in (17) to converge, depending on the spectrum of $W_\times$ (Vishwanathan, 2002, Chapter 6). Second, their *exponential* kernel is defined as

$$k(G,G') = \sum_{i=1}^{n}\sum_{j=1}^{n'} [e^{\lambda\widetilde{A}_\times}]_{ij} = \mathbf{e}^\top e^{\lambda\widetilde{A}_\times}\mathbf{e}, \tag{19}$$

using the matrix exponential. This is obtained in our framework by setting $\lambda_k := \lambda^k/k!$, so that the right-most sum in (18) becomes the series expansion of $e^{\lambda\widetilde{A}_\times}$.

The kernels of Gärtner et al. (2003) differ from our definition (8) in that they do not explicitly model starting or stopping probabilities, and employ unnormalized adjacency matrices instead of our more general weight matrix (6) which allows for normalization and arbitrary kernels on edges.

4. Efficient Computation

Computing a geometric random walk graph kernel with $\mu(k) = \lambda^k$ amounts to inverting $(\mathbf{I} - \lambda W_\times)$, an $n^2 \times n^2$ matrix if G and G' have n vertices each. Since the complexity of inverting a matrix is essentially cubic in its dimensions, direct computation of (16) would require $O(n^6)$ time. Below we develop methods based on Sylvester equations (Section 4.1), conjugate gradients (Section 4.2), fixed-point iterations (Section 4.3), and spectral decompositions (Section 4.4) that greatly accelerate this computation. Section 4.5 introduces an approximation that can further speed up the kernel computation for labeled graphs.

Table 1 summarizes our results, listing the worst-case time complexity of our methods as a function of graph density and labeling. Exact computation of the full kernel matrix between m dense, unlabeled (but possibly edge-weighted) graphs of n nodes each (leftmost column) is generally quadratic in the number of graphs and cubic in their size; for the iterative methods this must be multiplied by the number of iterations, which is given by the effective rank r of the weight matrix $W_\times$

for conjugate gradient, and by (31) for fixed-point iterations. The spectral decomposition approach (Section 4.4) is exceptional here in that it can be linear in m *resp*. quadratic in n (but not both) if precomputation of the m spectral graph decompositions dominates (*resp*. is dominated by) the actual kernel computations.

The cost of the iterative algorithms increases by another factor of d for graphs with edge labels from a finite set of d symbols or an edge kernel with d-dimensional feature map; for an arbitrary edge kernel (whose feature map may be infinite-dimensional) this factor becomes n. On labeled graphs our spectral decomposition approach offers no savings, and the Sylvester equation method applies only if the labels come from a finite set of symbols, and then with unknown time complexity. A nearest Kronecker product approximation can be used, however, to approximate the direct product of labeled graphs with a weight matrix that can be handled by any of our methods for unlabeled graphs. This approximation requires k' (37) iterations, each costing $O(dn^2)$ time when the labels come from a finite set of d symbols, and $O(n^4)$ in general.

Finally, when the graphs are sparse (i.e., only have $O(n)$ edges each; rightmost column in Table 1) our iterative methods (conjugate gradient, fixed-point, and nearest Kronecker product) take only $O(n^2)$ time per iteration, regardless of how the graphs are labeled. We cannot authoritatively state the time complexity for sparse graphs of solving Sylvester equations or performing spectral decompositions. Spielman and Teng (2008) have shown that graphs can be sparsified (i.e., approximated by sparse graphs) in nearly linear time, although the constants involved are quite large.

4.1 Sylvester Equation Methods

Consider the following equation, commonly known as the Sylvester or Lyapunov equation:

$$M = SMT + M_0. \tag{20}$$

Here, $S, T, M_0 \in \mathbb{R}^{n\times n}$ are given and we need to solve for $M \in \mathbb{R}^{n\times n}$. These equations can be readily solved in $O(n^3)$ time with freely available code (Gardiner et al., 1992), such as Matlab's `dlyap` method. Solving the generalized Sylvester equation

$$M = \sum_{i=1}^{d} S_i M T_i + M_0 \tag{21}$$

involves computing generalized simultaneous Schur factorizations of d symmetric matrices (Lathauwer et al., 2004). Although technically involved, (21) can also be solved efficiently, albeit at a higher computational cost. The computational complexity of this generalized factorization is at present unknown.

We now show that for graphs with discrete edge labels, whose weight matrix $W_\times$ can be written as (7), the problem of computing the graph kernel (16) can be reduced to solving the following generalized Sylvester equation:

$$M = \sum_{i=1}^{d} \lambda {}^iA' M {}^iA^\top + M_0, \tag{22}$$

where $\mathrm{vec}(M_0) = p_\times$. We begin by *flattening* (22):

$$\mathrm{vec}(M) = \lambda \sum_{i=1}^{d} \mathrm{vec}({}^iA' M {}^iA^\top) + p_\times. \tag{23}$$

Using Lemma 12 (which extends (1) into an RKHS) we can rewrite (23) as

$$(\mathbf{I} - \lambda \sum_{i=1}^{d} {}^{i}A \otimes {}^{i}A') \operatorname{vec}(M) = p_\times, \tag{24}$$

use (7), and solve (24) for $\operatorname{vec}(M)$:

$$\operatorname{vec}(M) = (\mathbf{I} - \lambda W_\times)^{-1} p_\times. \tag{25}$$

Multiplying both sides of (25) by $q_\times^\top$ yields

$$q_\times^\top \operatorname{vec}(M) = q_\times^\top (\mathbf{I} - \lambda W_\times)^{-1} p_\times. \tag{26}$$

The right-hand side of (26) is the graph kernel (16). Given the solution M of the Sylvester equation (22), the graph kernel can be obtained as $q_\times^\top \operatorname{vec}(M)$ in $O(n^2)$ time. The same argument applies for unlabeled graphs by simply setting $d = 1$, which turns (22) into a simple Sylvester equation. Since solving that only takes $O(n^3)$ time, computing the random walk graph kernel in this fashion is much faster than the $O(n^6)$ time required by the direct approach.

One drawback of this strategy is that Sylvester equation solvers are quite sophisticated and typically available only as black-box library routines, which limits their applicability. Matlab's `dlyap` solver, for instance, does not exploit sparsity, and only handles the cases $d = 1$ and $d = 2$. A solver for the simple Sylvester equation (20) can still be used to efficiently compute kernels between labeled graphs though by employing the nearest Kronecker product approximation (Section 4.5).

4.2 Conjugate Gradient Methods

Given a matrix M and a vector b, conjugate gradient (CG) methods solve the system of equations $Mx = b$ efficiently (Nocedal and Wright, 1999). While they are designed for symmetric p.s.d. matrices, CG solvers can also be used to solve other linear systems efficiently. They are particularly efficient if the matrix is rank deficient, or has a small *effective rank*, that is, number of distinct eigenvalues. Furthermore, if computing matrix-vector products is cheap—because M is sparse, for instance—the CG solver can be sped up significantly (Nocedal and Wright, 1999). Specifically, if computing Mv for an arbitrary vector v requires $O(m)$ time, and the effective rank of M is r, then a CG solver takes $O(r)$ iterations, and hence only $O(rm)$ time, to solve $Mx = b$.

The graph kernel (16) can be computed by a two-step procedure: First we solve the linear system

$$(\mathbf{I} - \lambda W_\times) x = p_\times, \tag{27}$$

for x, then we compute $q_\times^\top x$. We now focus on efficient ways to solve (27) with a CG solver. Recall that if G and G' contain n vertices each then $W_\times$ is an $n^2 \times n^2$ matrix. Naively, multiplying W by some vector y inside the CG algorithm requires $O(n^4)$ operations. However, by our extension of the vec-ABC formula (1) into RKHS (Lemma 12), introducing the matrix $Y \in \mathbb{R}^{n \times n}$ with $y = \operatorname{vec}(Y)$, and recalling that $W_\times = \Phi(X) \otimes \Phi(X')$, by Lemma 12 we can write

$$W_\times y = (\Phi(X) \otimes \Phi(X')) \operatorname{vec}(Y) = \operatorname{vec}(\Phi(X') Y \Phi(X)^\top). \tag{28}$$

If $\phi(\cdot) \in \mathbb{R}^d$ then the above matrix-vector product can be computed in $O(dn^3)$ time. If $\Phi(X)$ and $\Phi(X')$ are sparse, then $\Phi(X') Y \Phi(X)^\top$ can be computed yet more efficiently: If there are $O(n)$ non-ζ entries in $\Phi(X)$ and $\Phi(X')$, then computing (28) takes only $O(n^2)$ time.

4.3 Fixed-Point Iterations

Fixed-point methods begin by rewriting (27) as

$$x = p_\times + \lambda W_\times x. \tag{29}$$

Now, solving for x is equivalent to finding a fixed point of (29) taken as an iteration (Nocedal and Wright, 1999). Letting x_t denote the value of x at iteration t, we set $x_0 := p_\times$, then compute

$$x_{t+1} = p_\times + \lambda W_\times x_t \tag{30}$$

repeatedly until $\|x_{t+1} - x_t\| < \varepsilon$, where $\|\cdot\|$ denotes the Euclidean norm and ε some pre-defined tolerance. This is guaranteed to converge if all eigenvalues of $\lambda W_\times$ lie inside the unit disk; this can be ensured by setting $\lambda < |\xi_1|^{-1}$, where ξ_1 is the largest-magnitude eigenvalue of $W_\times$. Assuming that each iteration of (30) contracts x to the fixpoint by a factor of $\lambda\xi_1$, we converge to within ε of the fixpoint in k iterations, where

$$k = O\left(\frac{\ln \varepsilon}{\ln \lambda + \ln |\xi_1|}\right). \tag{31}$$

The above is closely related to the power method used to compute the largest eigenvalue of a matrix (Golub and Van Loan, 1996); efficient preconditioners can also be used to speed up convergence (Golub and Van Loan, 1996). Since each iteration of (30) involves computation of the matrix-vector product $W_\times x_t$, all speed-ups for computing the matrix-vector product discussed in Section 4.2 are applicable here. In particular, we exploit the fact that $W_\times$ is a sum of Kronecker products to reduce the worst-case time complexity to $O(dn^3)$ per iteration in our experiments, in contrast to Kashima et al. (2004) who computed the matrix-vector product explicitly.

4.4 Spectral Decomposition Method

In the previous two sections we have introduced methods that are efficient for both unlabeled and labeled graphs, but specifically computed the geometric kernel (16), that is, assumed that $\mu(k) = \lambda^k$. We now turn to a method based on spectral decompositions that can compute the general random walk kernel (8) for any convergent choice of $\mu(k)$, but is only efficient for unlabeled graphs. (In fact, it will turn out to be our *most* efficient method for computing an entire kernel matrix between unlabeled graphs.)

Let $W_\times = P_\times D_\times P_\times^{-1}$ denote the spectral decomposition of $W_\times$, that is, the columns of $P_\times$ are its eigenvectors, and $D_\times$ is a diagonal matrix of corresponding eigenvalues. The random walk graph kernel (8) can then be written as

$$k(G,G') := \sum_{k=0}^{\infty} \mu(k)\, q_\times^\top (P_\times D_\times P_\times^{-1})^k p_\times = q_\times^\top P_\times \left(\sum_{k=0}^{\infty} \mu(k) D_\times^k\right) P_\times^{-1} p_\times. \tag{32}$$

This simplifies matters in that (32) only takes weighted powers of a diagonal matrix, which decouple into scalar powers of its entries. An implementable graph kernel can then be obtained by employing a power series that is known to converge to a given nonlinear function. The geometric kernel (16), for instance, uses the fact that $\sum_{k=0}^{\infty} x^k = \frac{1}{1-x}$; setting $\mu(k) := \lambda^k$ in (32) we thus obtain

$$k(G,G') := q_\times^\top P_\times (\mathbf{I} - \lambda D_\times)^{-1} P_\times^{-1} p_\times. \tag{33}$$

The crucial difference to (16) is that the inverse in (33) is of a diagonal matrix, hence trivial to compute: just take the reciprocal of each entry. To give another example, setting $\mu(k) := \lambda^k/k!$ in (32) yields the exponential kernel (19) by way of spectral decomposition:

$$k(G,G') := q_\times^\top P_\times e^{\lambda D_\times} P_\times^{-1} p_\times, \tag{34}$$

because $e^x = \sum_{k=0}^\infty x^k/k!$. Again, unlike in (19) the matrix exponential here is trivial to compute because $\lambda D_\times$ is diagonal: simply exponentiate each entry.

Thus by diagonalizing the nonlinearity central to a random walk graph kernel, spectral decomposition can greatly expedite its computation. As described above, however, it is computationally unattractive: Computing the spectral decomposition of a dense matrix takes time cubic in its size (Golub and Van Loan, 1996); since $W_\times$ is an $n^2 \times n^2$ matrix this would result in $O(n^6)$ time complexity per kernel computation.[2] By leveraging the properties of the Kronecker product, however, we can obtain a far better result for unlabeled (though possibly edge-weighted) graphs:

Theorem 4 *The kernel matrix for any random walk kernel* (8) *between m unlabeled, possibly edge-weighted graphs with n nodes can be computed in $O((mp+n)mn^2)$ time via spectral decompositions, where computing the corresponding scalar power series takes $O(p)$ time.*

Proof Because the graphs are unlabeled, we have $W_\times := A_\times = A_i \otimes A_j$, where A_i and A_j ($i, j \in \{1,2,\ldots,m\}$) are the adjacency matrices (normalized or not) of individual graphs. Begin by precomputing the spectral decomposition of each graph: $(\forall i)\, A_i = P_i D_i P_i^{-1}$. Using Propositions 7.1.6, 7.1.7 of Bernstein (2005) we have

$$A_i \otimes A_j \;=\; (P_i D_i P_i^{-1}) \otimes (P_j D_j P_j^{-1}) \;=\; (P_i \otimes P_j)(D_i \otimes D_j)(P_i \otimes P_j)^{-1}. \tag{35}$$

Proposition 7.1.10 of Bernstein (2005) tells us that in fact $D_i \otimes D_j = D_\times$, which implies that also $P_i \otimes P_j = P_\times$ and that indeed the spectral decomposition of a Kronecker product decomposes into those of its constituents, as seen in (35). We can therefore use Propositions 7.1.6, 7.1.7 of Bernstein (2005) again to rewrite (32) as

$$k(G_i, G_j) \;=\; (q_i^\top P_i \otimes q_j^\top P_j) \left(\sum_{k=0}^\infty \mu(k) (D_i \otimes D_j)^k \right) (P_i^{-1} p_i \otimes P_j^{-1} p_j). \tag{36}$$

Computing the central power series here takes $O(n^2 p)$ time just as in (32), but the cost of calculating the two flanking factors has been reduced from $O(n^4)$ to $O(n^2)$ in (36). The entire $m \times m$ kernel matrix can thus be obtained in $O(m^2 n^2 p)$ time, plus the $O(mn^3)$ time it takes to precompute spectral decompositions of the m individual adjacency matrices. ■

Note that in practice we will always pick a power series with known limit that is trivial to evaluate (i.e., $p = 1$), as exemplified by the geometric (33) and exponential (34) kernels. Theorem 4 then gives us a very efficient method to compute entire kernel matrices, albeit only between unlabeled graphs. (It is tempting to try to extend the spectral approach for the exponential kernel to labeled graphs, but this runs into a key technical difficulty: a sum of (label-filtered adjacency) matrices in the exponent cannot be separated unless those matrices commute, that is, generally $e^{A+B} \neq e^A e^B$ unless $AB = BA$.)

2. Thus Gärtner et al. (2003) give a time complexity cubic in the $O(n^2)$ size of the product graph.

4.5 Nearest Kronecker Product Approximation

As we have seen above, some of our fast methods for computing random walk graph kernels may become computationally expensive, or not even be available, for labeled graphs, in particular when the number d of distinct labels is large or a general edge kernel is employed. In such cases we can find the *nearest Kronecker product* to $W_\times$, that is, compute matrices S and T such that $W_\times \approx S \otimes T$, then use any of our methods on $S \otimes T$ as if it were the adjacency matrix of a direct product of *unlabeled* graphs.

Finding the nearest Kronecker product approximating a matrix such as $W_\times$ is a well-studied problem in numerical linear algebra, and efficient algorithms which can exploit the sparsity of $W_\times$ are available (Pitsianis, 1992; Van Loan, 2000). Formally, these methods minimize the Frobenius norm $\|W_\times - S \otimes T\|_F$ by computing the largest singular value of $\hat{W}_\times$, a permuted version of $W_\times$. We employ the power method[3] for this purpose, each iteration of which entails computing the matrix-vector product $\hat{W}_\times \mathrm{vec}(T')$, where $T' \in \mathbb{R}^{n \times n}$ is the current approximation of T. The result of the matrix-vector product is then reshaped into an $n \times n$ matrix to form T' for the next iteration (Pitsianis, 1992). It is easy to see that computing $\hat{W}_\times \mathrm{vec}(T')$ requires $O(n^4)$ time.

If $W_\times$ can be written as a sum of d Kronecker products (7), then so can $\hat{W}_\times$ (Pitsianis, 1992; Van Loan, 2000), and the cost per iteration hence drops to $O(dn^2)$. Furthermore, if the two graphs are sparse with $O(n)$ edges each, then $W_\times$ will have $O(n^2)$ non-zero entries, and each iteration only takes $O(n^2)$ time. The number k' of iterations required is

$$k' = O\left(\frac{\ln n}{\ln|\xi_1| - \ln|\xi_2|}\right), \tag{37}$$

where ξ_1 and ξ_2 are the eigenvalues of $W_\times$ with largest *resp*. second-largest magnitude.

As described above, the nearest Kronecker product approximation is calculated separately for each entry of an $m \times m$ kernel matrix. This causes two problems: First, the spectral decomposition method will now take $O(m^2 n^3)$ time, as it is no longer possible to precompute the m graph spectra. Second, like the optimal assignment kernel (Section 7.2) the resulting kernel matrix may have negative eigenvalues, and hence fail to be p.s.d. In future work, it may be possible to address these shortcomings by computing a *simultaneous* nearest Kronecker product approximation for the entire kernel matrix. For now, we verified empirically on the MUTAG and PTC data sets (cf. Section 5.2) that the most negative eigenvalue is relatively small: its magnitude was 4.4% *resp*. 0.1% of ξ_2. We also found the nearest Kronecker product to provide a better approximation than simply ignoring the graph labels: the angle between $\mathrm{vec}(W_\times)$ and its unlabeled variant was 2.2 *resp*. 4.7 times greater than that between $\mathrm{vec}(W_\times)$ and $\mathrm{vec}(S \otimes T)$.

5. Experiments

Numerous studies have applied random walk graph kernels to problems such as protein function prediction (Borgwardt et al., 2005) and chemoinformatics (Kashima et al., 2004). In our experiments we therefore focus on the runtime of computing the kernels, rather than their utility in any given application. We present three sets of experiments: First, we study the scaling behaviour of our algorithms on unlabeled random graphs. Second, we assess the practical impact of our algorithmic improvement on four real-world data sets whose size mandates fast kernel computation. Third, we

3. Lanczos iterations are typically faster but more difficult to handle numerically.

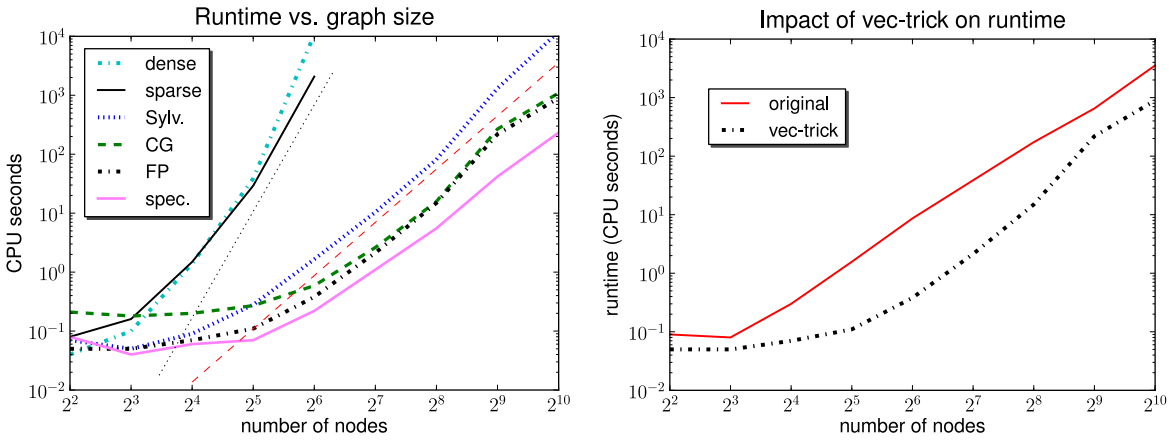

Figure 3: Time to compute a 10×10 kernel matrix on random graphs with n nodes and $3n$ edges as a function of the graph size n. Left: The Sylvester equation (Sylv.), conjugate gradient (CG), fixed-point iteration (FP), and spectral decomposition (spec.) approaches, compared to the dense and sparse direct method. Thin straight lines indicate $O(n^6)$ (black dots) *resp*. $O(n^3)$ (red dashes) scaling. Right: Kashima et al.'s (2004) fixed-point iteration (original) compared to our version, which exploits Lemma 12 (vec-trick).

devise novel methods for protein-protein interaction (PPI) network comparison using graph kernels. The algorithmic challenge here is to efficiently compute kernels on large sparse graphs.

The baseline for comparison in all our experiments is the direct approach of Gärtner et al. (2003), implemented via a sparse LU factorization; this already runs orders of magnitude faster on our data sets than a dense (i.e., non-sparse) implementation. Our code was written in Matlab Release 2008a, and all experiments were run under Mac OS X 10.5.5 on an Apple Mac Pro with a 3.0 GHz Intel 8-Core processor and 16 GB of main memory. We employed Lemma 12 to speed up matrix-vector multiplication for both CG and fixed-point methods (cf. Section 4.2), and used the function `dlyap` from Matlab's control toolbox to solve the Sylvester equation. By default, we used a value of $\lambda = 10^{-4}$, and set the convergence tolerance for both CG solver and fixed-point iteration to 10^{-6}. For the real-world data sets, the value of λ was chosen to ensure that the random walk graph kernel converges. Since our methods are exact and produce the same kernel values (to numerical precision), we only report the CPU time of each algorithm.

5.1 Unlabeled Random Graphs

The aim here is to study the scaling behaviour of our algorithms as a function of graph size and sparsity. We generated several sets of unlabeled random graphs. For the first set we began with an empty graph of $n = 2^k$ nodes, where $k = 2, 3, \ldots, 10$, randomly added $3n$ edges, then checked the graph's connectivity. For each k we repeated this process until we had collected 10 strongly connected random graphs.

The time required to compute the 10×10 kernel matrix between these graphs for each value of n is shown in Figure 3 (left). We see that the direct approach scales asymptotically as $O(n^6)$ in both the dense and the sparse implementation. For a graph of 64 nodes the direct approach already takes over half an hour (sparse) *resp*. 3 hours (dense) of CPU time. Our Sylvester equation (Sylv.),

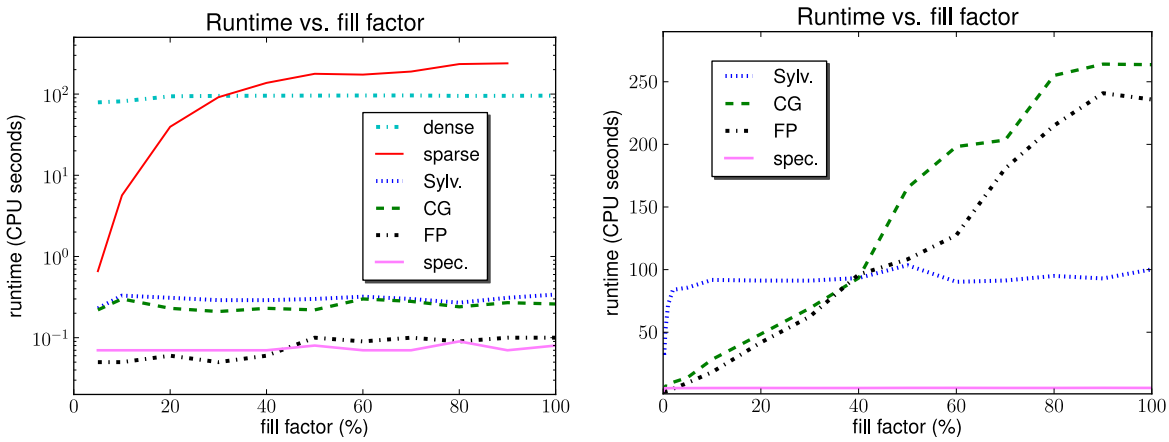

Figure 4: Time to compute a 10×10 kernel matrix on random graphs as a function of their fill factor. Left: The dense and sparse direct method on 32-node graphs, compared to our Sylvester equation (Sylv.), conjugate gradient (CG), fixed point iteration (FP), and spectral decomposition (spec.) approaches. Right: Our approaches on larger graphs with 256 nodes, where the direct method is infeasible.

conjugate gradient (CG) and fixed-point iteration (FP) methods, by contrast, all scale as $O(n^3)$, and can thus be applied to far larger graphs. Our spectral decomposition approach (spec.) is the fastest method here; it too scales as $O(n^3)$ as n asymptotically dominates over the fixed kernel matrix size $m = 10$.

We also examined the impact of Lemma 12 on enhancing the runtime performance of the fixed-point iteration approach as originally proposed by Kashima et al. (2004). For this experiment, we again computed the 10×10 kernel matrix on the above random graphs, once using the original fixed-point iteration, and once using fixed-point iteration enhanced by Lemma 12. As Figure 3 (right) shows, our approach consistently outperforms the original version, sometimes by over an order of magnitude.

For the next set of experiments we fixed the graph size at 32 nodes (the largest size that the direct method could handle comfortably), and randomly added edges until the fill factor (i.e., the number of non-zero entries in the adjacency matrix) reached $x\%$, where $x = 5, 10, 20, 30, \ldots, 100$. For each x, we generated 10 such graphs and computed the 10×10 kernel matrix between them. Figure 4 (left) shows that as expected, the sparse direct method is faster than its dense counterpart for small fill factors but slower for larger ones. Both however are consistently outperformed by our four methods, which are up to three orders of magnitude faster, with fixed-point iterations (FP) and spectral decompositions (spec.) the most efficient.

To better understand how our algorithms take advantage of sparsity, we generated a set of larger random graphs (with 256 nodes) by the same procedure as before, but with a geometric progression of fill factors: $x = 0.1, 0.2, 0.5, 1, 2, 5, 10, 20, 50, 100$. The direct methods are infeasible here. The CPU times taken by our algorithms to compute a 10×10 kernel matrix is shown in Figure 4 (right). Both conjugate gradient and fixed point iteration methods have runtimes roughly proportional to the fill factor. The runtime of the Sylvester equation solver, by contrast, is largely independent of the fill factor because our black-box `dlyap` solver does not aggressively exploit sparsity in the adja-

cency matrices. The same holds for our spectral decomposition approach, which however exhibits impressive performance here: although it does not exploit sparsity at all, it is the fastest method by far on all but the sparsest ($\leq 2\%$ filled) graphs. Clearly, well-designed *sparse* implementations of Sylvester equation solvers, and in particular spectral decomposition, could facilitate substantial further gains in efficiency here.

5.2 Real-World Data Sets

Our next set of experiments used four real-world data sets: Two sets of molecular compounds (MUTAG and PTC), and two data sets describing protein tertiary structure (Protein and Enzyme). Graph kernels provide useful measures of similarity for all of these.

5.2.1 THE DATA SETS

We now briefly describe each data set, and discuss how graph kernels are applicable.

Chemical Molecules. Toxicity of chemical molecules can be predicted to some degree by comparing their three-dimensional structure. We employed graph kernels to measure similarity between molecules from the MUTAG and PTC data sets (Toivonen et al., 2003). The average number of nodes per graph in these data sets is 17.72 *resp*. 26.70; the average number of edges is 38.76 *resp*. 52.06.

Protein Graphs. A standard approach to protein function prediction involves classifying proteins into enzymes and non-enzymes, then further assigning enzymes to one of the six top-level classes of the Enzyme Commission (EC) hierarchy. Towards this end, Borgwardt et al. (2005) modeled a data set of 1128 proteins as graphs in which vertices represent secondary structure elements, and edges represent neighborhood within the 3-D structure or along the amino acid chain, as illustrated in Figure 1.

Comparing these graphs via a modified random walk graph kernel and classifying them with a Support Vector Machine (SVM) led to function prediction accuracies competitive with state-of-the-art approaches (Borgwardt et al., 2005). We used Borgwardt et al.'s (2005) data to test the efficacy of our methods on a large data set. The average number of nodes and edges per graph in this data is 38.57 *resp*. 143.75. We used a single label on the edges, and the delta kernel to define similarity between edges.

Enzyme Graphs. We repeated the above experiment on an enzyme graph data set, also due to Borgwardt et al. (2005). This data set contains 600 graphs, with 32.63 nodes and 124.27 edges on average. Graphs in this data set represent enzymes from the BRENDA enzyme database (Schomburg et al., 2004). The biological challenge on this data is to correctly assign the enzymes to one of the EC top-level classes.

5.2.2 UNLABELED GRAPHS

For this experiment, we computed kernels taking into account only the topology of the graph, that is, we did not consider node or edge labels. Table 2 lists the CPU time required to compute the full kernel matrix for each data set, as well as—for comparison purposes—a 100×100 submatrix. The latter is also shown graphically in Figure 5 (left).

data set	MUTAG		PTC		Enzyme		Protein	
nodes/graph	17.7		26.7		32.6		38.6	
edges/node	2.2		1.9		3.8		3.7	
#graphs	100	230	100	417	100	600	100	1128
Sparse	31”	1’45”	45”	7’23”	1’52”	1h21’	23’23”	2.1d*
Sylvester	10”	54”	28”	7’33”	31”	23’28”	5’25”	11h29’

Fixed-Point	8”	43”	15”	2’38”	5”	5’44”	43”	22’09”
Spectral	5”	27”	7”	1’54”	7”	4’32”	27”	23’52”

*extrapolated number of days; run did not finish in time available.

Table 2: Time to compute kernel matrix for unlabeled graphs from various data sets.

On these unlabeled graphs, conjugate gradient, fixed-point iterations, and spectral decompositions—sped up via Lemma 12—are consistently faster than the sparse direct method. The Sylvester equation approach is very competitive on smaller graphs (outperforming CG on MUTAG) but slows down with increasing number of nodes per graph. Even so, it still outperforms the sparse direct method. Overall, spectral decomposition is the most efficient approach, followed by fixed-point iterations.

5.2.3 LABELED GRAPHS

For this experiment, we compared graphs with edge labels. Note that node labels can be dealt with by concatenating them to the edge labels of adjacent edges. On the two protein data sets we employed a linear kernel to measure similarity between edge weights representing distances (in Ångströms) between secondary structure elements; since $d = 1$ we can use all our methods for unlabeled graphs here. On the two chemical data sets we used a delta kernel to compare edge labels reflecting types of bonds in molecules; for the Sylvester equation and spectral decomposition approaches we then employed the nearest Kronecker product approximation. We report CPU times for the full kernel matrix as well as a 100×100 submatrix in Table 3; the latter is also shown graphically in Figure 5 (right).

On labeled graphs, the conjugate gradient and the fixed-point iteration always outperform the sparse direct approach, more so on the larger graphs and with the linear kernel. As expected, spectral decompositions are inefficient in combination with the nearest Kronecker product approximation,

kernel	delta, $d=7$		delta, $d=22$		linear, $d=1$			
data set	MUTAG		PTC		Enzyme		Protein	
#graphs	100	230	100	417	100	600	100	1128

Spectral	1’20”	7’08”	1’40”	26’54”	8”	4’22”	26”	21’23”

*extrapolated number of days; run did not finish in time available.

Table 3: Time to compute kernel matrix for labeled graphs from various data sets.

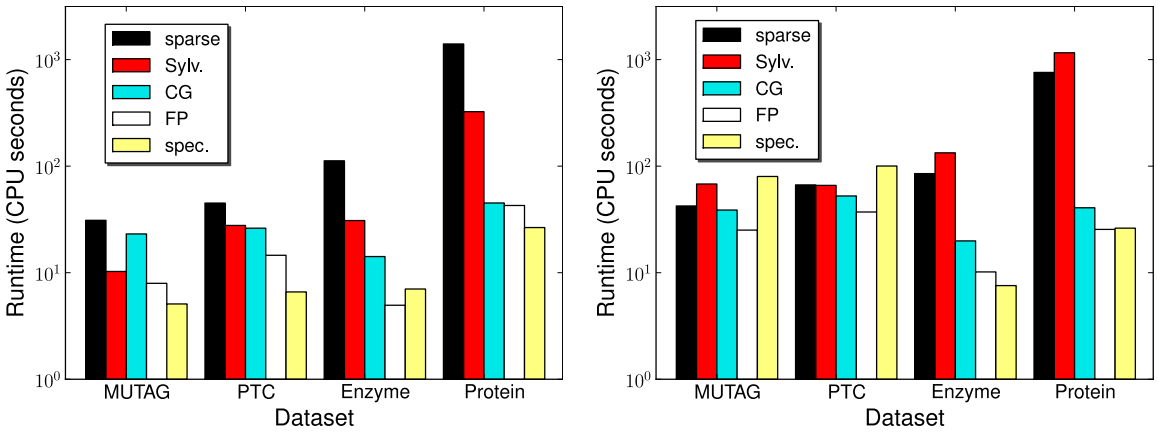

Figure 5: Time (in seconds on a log-scale) to compute 100×100 kernel matrix for unlabeled (left) *resp*. labeled (right) graphs from several data sets, comparing the conventional sparse method to our fast Sylvester equation, conjugate gradient (CG), fixed-point iteration (FP), and spectral approaches.

but with the linear kernel they perform as well as fixed-point iterations for $m = 100$, and better yet on the large kernel matrices. The Sylvester equation approach (at least with the Sylvester solver we used) cannot take advantage of sparsity, but still manages to perform almost as well as the sparse direct method.

5.3 Protein-Protein Interaction Networks

In our third experiment, we used random walk graph kernels to tackle a large-scale problem in bioinformatics involving the comparison of fairly large protein-protein interaction (PPI) networks. Using a combination of human PPI and clinical microarray gene expression data, the task is to predict the disease outcome (dead or alive, relapse or no relapse) of cancer patients. As before, we set $\lambda = 0.001$ and the convergence tolerance to 10^{-6} for all our experiments reported below.

5.3.1 CO-INTEGRATION OF GENE EXPRESSION AND PPI DATA

We co-integrated clinical microarray gene expression data for cancer patients with known human PPI from Rual et al. (2005). Specifically, a patient's gene expression profile was transformed into a graph as follows: A node was created for every protein which—according to Rual et al. (2005)—participates in an interaction, and whose corresponding gene expression level was measured on this patient's microarray. We connect two proteins in this graph by an edge if Rual et al. (2005) list these proteins as interacting, and both genes are up- *resp*. downregulated with respect to a reference measurement. Each node bears the name of the corresponding protein as its label.

This approach of co-integrating PPI and gene expression data is built on the assumption that genes with similar gene expression levels are translated into proteins that are more likely to interact. Recent studies confirm that this assumption holds significantly more often for co-expressed than for random pairs of proteins (Fraser et al., 2004; Bhardwaj and Lu, 2005). To measure similarity between these networks in a biologically meaningful manner, we compare which groups of proteins interact and are co-regulated in each patient. For this purpose, a random walk graph kernel is the

data set	Leukemia		Breast Cancer	
kernel	vanilla	composite	vanilla	composite
Sparse	24”	52”	39”	1’19”
Conj. Grad.	6”	13”	12”	26”
Fixed-Point	4”	7”	7”	13”

Table 4: Average time to compute kernel matrix on protein-protein interaction networks.

natural choice, as a random walk in this graph represents a group of proteins in which consecutive proteins along the walk are co-expressed and interact. As each node bears the name of its corresponding protein as its node label, the size of the product graph is at most that of the smaller of the two input graphs.

5.3.2 COMPOSITE GRAPH KERNEL

The presence of an edge in a graph signifies an interaction between the corresponding nodes. In chemoinformatics, for instance, edges indicate chemical bonds between two atoms; in PPI networks, edges indicate interactions between proteins. When studying protein interactions in disease, however, the *absence* of a given interaction can be as significant as its presence. Since existing graph kernels cannot take this into account, we propose to modify them appropriately. Key to our approach is the notion of a complement graph:

Definition 5 *Let $G = (V, E)$ be a graph with vertex set V and edge set E. Its complement $\bar{G} = (V, \bar{E})$ is a graph over the same vertices but with complementary edges $\bar{E} := (V \times V) \setminus E$.*

In other words, the complement graph consists of exactly those edges *not* present in the original graph. Using this notion we define the *composite* graph kernel

$$k_{comp}(G, G') := k(G, G') + k(\bar{G}, \bar{G}'). \tag{38}$$

This deceptively simple kernel leads to substantial gains in performance in our experiments comparing co-integrated gene expression/protein-protein interaction networks.

5.3.3 DATA SETS

Leukemia. Bullinger et al. (2004) provide a data set of microarrays of 119 leukemia patients. Since 50 patients survived after a median follow-up time of 334 days, always predicting a lethal outcome here would result in a baseline prediction accuracy of 1 - 50/119 = 58.0%. Co-integrating this data with human PPI, we found 2,167 proteins from Rual et al. (2005) for which Bullinger et al. (2004) report expression levels among the 26,260 genes they examined.
Breast Cancer. This data set consists of microarrays of 78 breast cancer patients, of which 44 had shown no relapse of metastases within 5 years after initial treatment (van’t Veer et al., 2002). Always predicting survival thus gives a baseline prediction accuracy of 44/78 = 56.4% on this data. When generating co-integrated graphs, we found 2,429 proteins from Rual et al. (2005) for which van’t Veer et al. (2002) measure gene expression out of the 24,479 genes they studied.

5.3.4 RESULTS

In Table 4 we contrast the CPU runtimes of our conjugate gradient and fixed-point approaches to graph kernel computation on the cancer patients modeled as labeled graphs with that of the direct

sparse method. On both data sets, our fast graph kernel computation methods yield an impressive gain in speed.

Using either the "vanilla" graph kernel (16) or our composite graph kernel (38), we predict the survivors by means of a support vector machine (SVM) in 10-fold cross-validation. The vanilla random walk graph kernel offers slightly higher prediction accuracy than the baseline classifier on one task (Leukemia: 59.2 % vs 58.0 %), and gives identical results on the other (Breast Cancer: both 56.4 %). Our composite graph kernel attains 5 percentage points above baseline in both experiments (Leukemia: 63.3 %; Breast cancer: 61.5 %).

The vanilla kernel suffers from its inability to measure network discrepancies, the paucity of the graph model employed, and the fact that only a small minority of genes could be mapped to interacting proteins; due to these problems, its accuracy remains close to the baseline. The composite kernel, by contrast, also models missing interactions. With it, even our simple graph model, which only considers 10% of the genes examined in both studies, is able to capture some relevant biological information, which in turn leads to better classification accuracy on these challenging data sets (Warnat et al., 2005).

6. Rational Kernels

Rational kernels (Cortes et al., 2004) were conceived to compute similarity between variable-length sequences and, more generally, weighted automata. For instance, the output of a large-vocabulary speech recognizer for a particular input speech utterance is typically a weighted automaton compactly representing a large set of alternative sequences. The weights assigned by the system to each sequence are used to rank different alternatives according to the models the system is based on. It is therefore natural to compare two weighted automata by defining a kernel.

As discussed in Section 3, random walk graph kernels have a very different basis: They compute the similarity between two random graphs by matching random walks. Here the graph itself is the object to be compared, and we want to find a semantically meaningful kernel. Contrast this with a weighted automaton, whose graph is merely a compact representation of the set of variable-length sequences which we wish to compare. Despite these differences we find rational kernels and random walk graph kernels to be closely related.

To understand the connection recall that every random walk on a labeled graph produces a sequence of edge labels encountered during the walk. Viewing the set of all label sequences generated by random walks on a graph as a language, one can design a weighted transducer which accepts this language, with the weight assigned to each label sequence being the probability of a random walk generating this sequence. (This transducer can be represented by a graph whose adjacency matrix is the normalized weight matrix of the original graph.)

In this section we formalize this observation and thus establish connections between rational kernels on transducers (Cortes et al., 2004) and random walk graph kernels. In particular, we show that composition of transducers is analogous to computing product graphs, and that rational kernels on weighted transducers may be viewed as generalizations of random walk graph kernels to weighted automata. In order to make these connections explicit we adopt notation commonly used for describing *algebraic path problems*, wherein disparate problems related to graphs, automata, and transducers are described in a common framework using matrices and tensors (Eilenberg, 1974; Lehmann, 1977; Berstel, 1979; Kuich and Salomaa, 1986).

6.1 Semirings

At the most general level, weighted transducers are defined over semirings. In a semiring addition and multiplication are generalized to abstract operations $\bar{\oplus}$ and $\bar{\odot}$ with the same distributive properties:

Definition 6 (Mohri, 2002) *A semiring is a system* $(\mathbb{K}, \bar{\oplus}, \bar{\odot}, \bar{0}, \bar{1})$ *such that*

1. $(\mathbb{K}, \bar{\oplus}, \bar{0})$ *is a commutative monoid in which* $\bar{0} \in \mathbb{K}$ *is the identity element for* $\bar{\oplus}$ *(i.e., for any* $x, y, z \in \mathbb{K}$*, we have* $x \bar{\oplus} y \in \mathbb{K}$*,* $(x \bar{\oplus} y) \bar{\oplus} z = x \bar{\oplus} (y \bar{\oplus} z)$*,* $x \bar{\oplus} \bar{0} = \bar{0} \bar{\oplus} x = x$ *and* $x \bar{\oplus} y = y \bar{\oplus} x$*);*

2. $(\mathbb{K}, \bar{\odot}, \bar{1})$ *is a monoid in which* $\bar{1}$ *is the identity operator for* $\bar{\odot}$ *(i.e., for any* $x, y, z \in \mathbb{K}$*, we have* $x \bar{\odot} y \in \mathbb{K}$*,* $(x \bar{\odot} y) \bar{\odot} z = x \bar{\odot} (y \bar{\odot} z)$*, and* $x \bar{\odot} \bar{1} = \bar{1} \bar{\odot} x = x$*);*

3. $\bar{\odot}$ *distributes over* $\bar{\oplus}$*, that is, for any* $x, y, z \in \mathbb{K}$*,*

$$\begin{aligned} (x \bar{\oplus} y) \bar{\odot} z &= (x \bar{\odot} z) \bar{\oplus} (y \bar{\odot} z) \\ \textit{and}\ \ z \bar{\odot} (x \bar{\oplus} y) &= (z \bar{\odot} x) \bar{\oplus} (z \bar{\odot} y); \end{aligned}$$

4. $\bar{0}$ *is an annihilator for* $\bar{\odot}$*:* $\forall x \in \mathbb{K}$*,* $x \bar{\odot} \bar{0} = \bar{0} \bar{\odot} x = \bar{0}$.

Thus, a semiring is a ring that may lack negation. $(\mathbb{R}, +, \cdot, 0, 1)$ is the familiar semiring of real numbers. Other examples include

Boolean: $(\{\text{FALSE}, \text{TRUE}\}, \vee, \wedge, \text{FALSE}, \text{TRUE})$;

Logarithmic: $(\mathbb{R} \cup \{-\infty\}, \bar{\oplus}_{\ln}, +, -\infty, 0)$, where $\forall x, y \in \mathbb{K}: \ x \bar{\oplus}_{\ln} y := \ln(e^x + e^y)$;

Tropical: $(\mathbb{R} \cup \{-\infty\}, \max, +, -\infty, 0)$.

Linear algebra operations such as matrix addition and multiplication as well as Kronecker products can be carried over to a semiring in a straightforward manner. For instance, for $M, M' \in \mathbb{K}^{n \times n}$ we have

$$[M \bar{\odot} M']_{i,j} = \bigoplus_{k=1}^{n} M_{ik} \bar{\odot} M'_{kj}. \tag{39}$$

The $(\bar{\oplus}, \bar{\odot})$ operations in some semirings can be mapped into ordinary $(+, \cdot)$ operations by applying an appropriate *morphism*:

Definition 7 *Let* $(\mathbb{K}, \bar{\oplus}, \bar{\odot}, \bar{0}, \bar{1})$ *be a semiring. A function* $\psi : \mathbb{K} \to \mathbb{R}$ *is a morphism if*

$$\begin{aligned} \psi(x \bar{\oplus} y) &= \psi(x) + \psi(y); \\ \psi(x \bar{\odot} y) &= \psi(x) \cdot \psi(y); \\ \psi(\bar{0}) = 0 \ \ &\textit{and} \ \ \psi(\bar{1}) = 1. \end{aligned}$$

In the following, by 'morphism' we will always mean a morphism from a semiring to the real numbers. Not all semirings have such morphisms: For instance, the logarithmic semiring has a morphism—namely, the exponential function—but the tropical semiring does not have one. If the semiring has a morphism ψ, applying it to the matrix product (39), for instance, yields

$$\begin{aligned}\psi([M \bar{\odot} M']_{i,j}) &= \psi\left(\overline{\bigoplus_{k=1}^{n}} M_{ik} \bar{\odot} M'_{kj}\right) \\ &= \sum_{k=1}^{n} \psi(M_{ik} \bar{\odot} M'_{kj}) = \sum_{k=1}^{n} \psi(M_{ik}) \cdot \psi(M'_{kj}). \end{aligned} \tag{40}$$

As in Appendix A, we can extend the morphism ψ to matrices (and analogously to vectors) by defining $[\Psi(M)]_{ij} := \psi(M_{ij})$. We can then write (40) concisely as

$$\Psi(M \bar{\odot} M') = \Psi(M)\Psi(M'). \tag{41}$$

6.2 Weighted Transducers

Loosely speaking, a transducer is a weighted automaton with an input and an output alphabet. We will work with the following slightly specialized definition:[4]

Definition 8 *A weighted finite-state transducer T over a semiring $(\mathbb{K}, \bar{\oplus}, \bar{\odot}, \bar{0}, \bar{1})$ is a 5-tuple $T = (\Sigma, Q, H, p, q)$, where Σ is a finite input-output alphabet, Q is a finite set of n states, $p \in \mathbb{K}^n$ is a vector of initial weights, $q \in \mathbb{K}^n$ is a vector of final weights, and H is a four-dimensional tensor in $\mathbb{K}^{n \times |\Sigma| \times |\Sigma| \times n}$ which encodes transitions and their corresponding weights.*

For $a, b \in \Sigma$ we will use the shorthand H_{ab} to denote the $n \times n$ slice H_{*ab*} of the transition tensor, which represents all valid transitions on input symbol a emitting the output symbol b. The output weight assigned by T to a pair of strings $\alpha = a_1 a_2 \ldots a_l$ and $\beta = b_1 b_2 \ldots b_l$ is

$$[\![T]\!](\alpha, \beta) = q^\top \bar{\odot} H_{a_1 b_1} \bar{\odot} H_{a_2 b_2} \bar{\odot} \ldots \bar{\odot} H_{a_l b_l} \bar{\odot} p. \tag{42}$$

A transducer is said to accept a pair of strings (α, β) if it assigns non-zero output weight to them, that is, $[\![T]\!](\alpha, \beta) \neq \bar{0}$. A transducer is said to be regulated if the output weight it assigns to any pair of strings is well-defined in $\mathbb{K}$. Since we disallow ε transitions, our transducers are always regulated.

The inverse of $T = (\Sigma, Q, H, p, q)$, denoted by T^{-1}, is obtained by transposing the input and output labels of each transition. Formally, $T^{-1} = (\Sigma, Q, H^\top, p, q)$ where $H^\top_{ab} := H_{ba}$. The composition of two transducers $T = (\Sigma, Q, H, p, q)$ and $T' = (\Sigma, Q', H', p', q')$ is a transducer $T_\times = T \circ T' = (\Sigma, Q_\times, H_\times, p_\times, q_\times)$, where $Q_\times = Q \times Q'$, $p_\times = p \bar{\otimes} p'$,[5] $q_\times := q \bar{\otimes} q'$, and $(H_\times)_{ab} = \bar{\bigoplus}_{c \in \Sigma} H_{ac} \bar{\otimes} H'_{cb}$. It can be shown that

$$[\![T_\times]\!](\alpha, \beta) = [\![T \circ T']\!](\alpha, \beta) = \overline{\bigoplus_{\gamma}} [\![T]\!](\alpha, \gamma) \bar{\odot} [\![T']\!](\gamma, \beta). \tag{43}$$

4. We disallow ε transitions, and use the same alphabet for both input and output. Furthermore, in a departure from tradition, we represent the transition function as a four-dimensional tensor.
5. We use $\bar{\otimes}$ to denote the Kronecker product using the semiring operation $\bar{\odot}$, in order to distinguish it from the regular Kronecker product $\otimes$.

Composing T with its inverse yields $T \circ T^{-1} = (\Sigma, Q \times Q, H^*, p \bar{\otimes} p, q \bar{\otimes} q)$, where $H^*_{ab} = \bar{\bigoplus}_{c \in \Sigma} H_{ac} \bar{\otimes} H_{bc}$. There exists a general and efficient algorithm for composing transducers as in (43) which takes advantage of the sparseness of the input transducers (Mohri et al., 1996; Pereira and Riley, 1997).

6.3 Weighted Automata

A weighted automaton is a transducer with identical input and output symbols. The transition matrix of a weighted automaton is therefore a three-dimensional tensor in $\mathbb{K}^{n \times |\Sigma| \times n}$. As before, we will use the shorthand H_a to denote the $n \times n$ slice H_{*a*} of the transition tensor, which represents all valid transitions on the input symbol a emitting output symbolx a. If Σ contains d symbols, then by specializing (42) it is easy to see that a weighted automaton accepts a string $\alpha = a_1 a_2 \ldots a_l$ with weight

$$[\![T]\!](\alpha) = q^\top \bar{\odot} H_{a_1} \bar{\odot} H_{a_2} \bar{\odot} \ldots \bar{\odot} H_{a_l} \bar{\odot} p. \tag{44}$$

The composition of two weighted automata $T = (\Sigma, Q, H, p, q)$ and $T' = (\Sigma, Q', H', p', q')$ is an automaton $T_\times = T \circ T' = (\Sigma, Q_\times, H_\times, p_\times, q_\times)$, where $Q_\times = Q \times Q'$, $p_\times = p \bar{\otimes} p'$, $q_\times := q \bar{\otimes} q'$, and $(H_\times)_a = H_a \bar{\otimes} H'_a$. The composition operation is also defined for a weighted automaton W and a transducer T:

$$[\![W \circ T]\!](\alpha, \beta) = [\![W]\!](\alpha) \bar{\odot} [\![T]\!](\alpha, \beta). \tag{45}$$

Every random walk on a labeled graph results in a sequence of edge labels encountered during the walk. The set of all label sequences generated by random walks on a given graph is a language. One can construct a weighted automaton which accepts this language as follows: Use the standard semiring $(\mathbb{R}, +, \cdot, 0, 1)$, let the alphabet Σ consist of the labels $\{1, \ldots, d\}$ of the graph, and identify the nodes of the graph with the states of the weighted automaton. Let the starting and stopping probabilities p and q on the graph equal those of the weighted automaton, and complete the construction by identifying for each $l \in \Sigma$ the label-filtered adjacency matrix ${}^l\!A$ of the graph with H_l, the transition tensor of the weighted automaton for that symbol.

Under the above mapping (44) has a natural interpretation: The weight assigned by the automaton to a string of symbols is the probability of encountering the corresponding labels while performing a random walk on the corresponding labeled graph. The composition of weighted automata, when specialized to labeled graphs, is equivalent to computing a direct product graph.

An unlabeled graph corresponds to a weighted automaton whose input-output alphabet contains exactly one symbol, and which therefore only accepts strings of the form $a^k = aa \ldots a$. The transition matrix of such a graph (equivalently, its adjacency matrix) is a 2-dimensional tensor in $\mathbb{K}^{n \times n}$. If A denotes the adjacency matrix of a graph G, then the output weight assigned by G to a^k is $[\![G]\!](a^k) = q^\top AA \ldots Ap = q^\top A^k p$.

6.4 The Rational Kernel for Strings

Given a weighted transducer T and a function $\psi : \mathbb{K} \to \mathbb{R}$, the rational kernel between two strings $\alpha = a_1 a_2 \ldots a_l$ and $\beta = b_1 b_2 \ldots b_l$ is defined as (Cortes et al., 2004):

$$k(\alpha, \beta) := \psi\left([\![T]\!](\alpha, \beta)\right). \tag{46}$$

Cortes et al. (2004) show that a generic way to obtain p.s.d. rational kernels is to replace T in (46) by $T \circ T^{-1}$, and let ψ be a semiring morphism. We now present an alternate proof which uses properties of the Kronecker product. Since ψ is a semiring morphism, by specializing (42) to $T \circ T^{-1}$, we can write $k(\alpha,\beta) = \psi\left([\![T \circ T^{-1}]\!](\alpha,\beta)\right)$ as

$$\Psi(q \bar{\otimes} q)^\top \Psi\left(\overline{\bigoplus_{c_1}} H_{a_1 c_1} \bar{\otimes} H_{b_1 c_1}\right) \ldots \Psi\left(\overline{\bigoplus_{c_l}} H_{a_l c_l} \bar{\otimes} H_{b_l c_l}\right) \Psi(p \bar{\otimes} p). \tag{47}$$

Rules analogous to (41) give us

$$\Psi\left(\overline{\bigoplus_{c \in \Sigma}} H_{ac} \bar{\otimes} H_{bc}\right) = \sum_{c \in \Sigma} \Psi(H_{ac}) \otimes \Psi(H_{bc}). \tag{48}$$

Using (48) we can rewrite (47) as

$$\sum_{c_1 c_2 \ldots c_l} \Psi(q)^\top \otimes \Psi(q)^\top \left(\Psi(H_{a_1 c_1}) \otimes \Psi(H_{b_1 c_1})\right) \ldots \left(\Psi(H_{a_l c_l}) \otimes \Psi(H_{b_l c_l})\right) \Psi(p) \otimes \Psi(p). \tag{49}$$

Finally, successively applying (2) to (49) yields

$$k(\alpha,\beta) = \sum_{c_1 c_2 \ldots c_l} \underbrace{\left(\Psi(q)^\top \Psi(H_{a_1 c_1}) \ldots \Psi(H_{a_l c_l}) \Psi(p)\right)}_{\rho(\alpha)} \underbrace{\left(\Psi(q)^\top \Psi(H_{b_1 c_1}) \ldots \Psi(H_{b_l c_l}) \Psi(p)\right)}_{\rho(\beta)}, \tag{50}$$

Each term of (50) equals $\rho(\alpha)\rho(\beta)$ for some scalar function ρ, and is therefore a valid p.s.d. kernel. Since p.s.d. kernels are closed under addition and pointwise limits (Berg et al., 1984), $k(\alpha,\beta)$ is a valid p.s.d. kernel.

6.5 The Rational Kernel for Weighted Automata

Rational kernels on strings can be naturally extended to weighted automata S and U via (Cortes et al., 2004):

$$\begin{aligned} k(S,U) &= \psi\left(\overline{\bigoplus_{\alpha,\beta}} [\![S]\!](\alpha) \bar{\odot} [\![T]\!](\alpha,\beta) \bar{\odot} [\![U]\!](\beta)\right) \\ &= \psi\left(\overline{\bigoplus_{\alpha,\beta}} [\![S \circ T \circ U]\!](\alpha,\beta)\right), \end{aligned} \tag{51}$$

where we obtained (51) by using (45) twice. If ψ is a semiring morphism, then we can use Definition 7 to rewrite (51) as

$$k(S,U) = \sum_{\alpha,\beta} \psi\left([\![S \circ T \circ U]\!](\alpha,\beta)\right). \tag{52}$$

Since p.s.d. kernels are closed under addition and pointwise limits, if $\psi\left([\![S \circ T \circ U]\!](\alpha,\beta)\right)$ is a p.s.d. kernel for any given α and β, then so is (52).

6.6 Recovering Random Walk Graph Kernels

In order to recover random walk graph kernels we use the standard $(\mathbb{R},+,\cdot,0,1)$ ring as our semiring, and hence set ψ to be the identity function. Next we set the transducer T to simply transform any input string of length k into an identical output string with weight $\mu(k) \geq 0$. With these restrictions (52) can be written as

$$k(S,U) = \sum_{\alpha} \mu(|\alpha|)[\![S \circ U]\!](\alpha), \tag{53}$$

where $|\alpha|$ denotes the length of α. Let us rearrange (53) to

$$k(S,U) = \sum_{k} \mu(k) \left(\sum_{a_1,a_2,\ldots,a_k} [\![S \circ U]\!](a_1,a_2,\ldots,a_k) \right). \tag{54}$$

Specializing the definition of $\circ$ to weighted automata, and letting H_a (resp. H'_a) denote the transition tensor of S (resp. U), we can rewrite (54) as

$$\begin{aligned}
k(S,U) &= \sum_{k} \mu(k) \left(\sum_{a_1,a_2,\ldots,a_k \in \Sigma^k} (q \otimes q')^\top (H_{a_1} \otimes H'_{a_1}) \ldots (H_{a_k} \otimes H'_{a_k})(p \otimes p') \right) \\
&= \sum_{k} \mu(k) (q \otimes q')^\top \left(\sum_{a_1,a_2,\ldots,a_k \in \Sigma^k} (H_{a_1} \otimes H'_{a_1}) \ldots (H_{a_k} \otimes H'_{a_k}) \right) (p \otimes p') \\
&= \sum_{k} \mu(k) (q \otimes q')^\top \left(\sum_{a \in \Sigma} H_a \otimes H'_a \right) \ldots \left(\sum_{a \in \Sigma} H_a \otimes H'_a \right) (p \otimes p') \\
&= \sum_{k} \mu(k) (q \otimes q')^\top \left(\sum_{a} H_a \otimes H'_a \right)^k (p \otimes p').
\end{aligned} \tag{55}$$

Next, we identify H_a (resp. H'_a) with the label-filtered adjacency matrix ${}^aA$ (resp. ${}^aA'$) of a graph G (resp. G') with discrete edge labels. It easy to see that $H_\times := \sum_a H_a \otimes H'_a$ is the weight matrix (7) of the direct product of G and G'. Letting $p_\times = p \otimes p'$ and $q_\times = q \otimes q'$, (55) reduces to

$$k(G,G') = \sum_{k} \mu(k)\, q_\times^\top H_\times^k\, p_\times, \tag{56}$$

which recovers the random walk graph kernel (8) with $W_\times = H_\times$.

The generality of the rational kernel comes at a computational cost: Even when restricted as in (53), it requires the composition $S \circ U$ of two transducers, which takes up to $O((|Q_S|+|E_S|)(|Q_U|+|E_U|))$ time, where $|Q|$ is the number of states and $|E|$ the number of transitions (Cortes et al., 2004, Section 4.1). In our setting $|Q| = n$, the number of nodes in the graph, and $|E|$ is the number of its edges, which can be of $O(n^2)$; the worst-case time complexity of the composition operation is therefore $O(n^4)$. Cortes et al. (2004) showed that the sum in (53) can be computed via a single-source shortest distance algorithm over a semiring. If $S \circ U$ is acyclic, then this is linear in the size of $S \circ U$, which in the worst case is $O(n^2)$. In general, however, an all-pairs shortest-distance algorithm must be employed, such as the generalization of the Floyd-Warshall algorithm due to Lehmann (1977). This algorithm is cubic in the size of $S \circ U$, thus leading to an $O(n^6)$ worst-case time complexity. Since computing $S \circ U$ is the same as computing $W_\times$, and the Lehmann

(1977) algorithm is a way to compute $(I - W_\times)^{-1}$ (the *transitive closure* of $W_\times$), our linear algebra techniques to speed up computation of random walk graph kernels can also be applied to rational kernels.[6] The key insight here is that we never explicitly construct the composition (i.e., direct product graph) in order to compute the kernel.

For ease of exposition we derived (56) by setting T to be an identity transducer. Instead, one can use a weighted transducer which allows for more flexible matching between strings in the alphabet. Basically, the transducer now plays the role of the kernel function κ, and this in turn leads to a more flexible similarity matrix $W_\times$.

There is one important difference between graph kernels and rational kernels. Graph kernels can handle arbitrary edge kernels, including continuous edge labels via the weight matrix $W_\times$. In contrast, rational kernels, which were designed to work with strings and automata, assume that the alphabet (set of labels) is finite. As we saw above, they can incorporate flexible similarity matrices $W_\times$ in this setting, but cannot handle continuous edge labels. Furthermore, to date rational kernels have not been extended to deal with labels mapped to an RKHS.

7. R-convolution Kernels

Haussler's (1999) R-convolution kernels provide a generic way to construct kernels for discrete compound objects. Let $x \in \mathcal{X}$ be such an object, and $\vec{x} := (x_1, x_2, \ldots, x_D)$ denote a decomposition of x, with each $x_i \in \mathcal{X}_i$. We can define a boolean predicate

$$R : \mathcal{X} \times \mathcal{X} \to \{\text{TRUE}, \text{FALSE}\}, \tag{57}$$

where $\mathcal{X} := \mathcal{X}_1 \times \ldots \times \mathcal{X}_D$ and $R(x, \vec{x})$ is TRUE whenever $\vec{x}$ is a valid decomposition of x. Now consider the inverse of (57), the set of all valid decompositions of an object:

$$R^{-1}(x) := \{\vec{x} | R(x, \vec{x}) = \text{TRUE}\}. \tag{58}$$

Like Haussler (1999) we assume that (58) is countable. We define the R-convolution $\star$ of the kernels $\kappa_1, \kappa_2, \ldots, \kappa_D$ with $\kappa_i : \mathcal{X}_i \times \mathcal{X}_i \to \mathbb{R}$ to be

$$k(x, x') = \kappa_1 \star \kappa_2 \star \ldots \star \kappa_D(x, x') := \sum_{\substack{\vec{x} \in R^{-1}(x) \\ \vec{x}' \in R^{-1}(x')}} \mu(\vec{x}, \vec{x}') \prod_{i=1}^{D} \kappa_i(x_i, x_i'), \tag{59}$$

where μ denotes a set of non-negative coefficients on $\mathcal{X} \times \mathcal{X}$, which ensures that the sum in (59) converges.[7] Haussler (1999) showed that $k(x, x')$ is p.s.d. and hence admissible as a kernel (Schölkopf and Smola, 2002), provided that all the individual κ_i are. The deliberate vagueness of this setup in regard to the nature of the underlying decomposition leads to a rich framework: Many different kernels can be obtained by simply changing the decomposition.

7.1 Graph Kernels as R-Convolutions

To apply R-convolution kernels to graphs, one decomposes the graph into smaller substructures, and builds the kernel based on similarities between those components. Most graph kernels are—knowingly or not—based on R-convolutions; they mainly differ in the way they decompose the graph for comparison and the similarity measure they use to compare the components.

6. We thank an anonymous reviewer for pointing this out.
7. Haussler (1999) implicitly assumed this sum to be well-defined, hence did not use μ in his definition.

Gärtner et al. (2003) observed that any graph kernel whose feature map is injective could be used to determine whether two graphs G and G' are isomorphic: Simply compute $d(G,G') := k(G,G) - 2k(G,G') + k(G',G')$; since by definition *any* structural difference between the graphs would yield a non-zero $d(G,G')$, they are isomorphic iff $d(G,G') = 0$. The graph isomorphism problem, however, is widely believed to be not solvable in polynomial time (Garey and Johnson, 1979). Gärtner et al. (2003) also showed that computing inner products in a feature space constructed over all subgraphs of a graph is NP-hard. One must therefore choose which substructures to distinguish in defining a practical graph kernel, and this choice is generally motivated by runtime considerations.

Random walks provide a straightforward graph decomposition that—as we have seen in Section 4—leads to kernels that can be computed efficiently. To see that our random walk graph kernel (8) is indeed an R-convolution kernel, note that the definition of our weight matrix (6) and the RKHS Kronecker product (Definition 11) imply

$$\begin{aligned}[W_\times]_{(i-1)n'+r,\,(j-1)n'+s} &= [\Phi(X) \otimes \Phi(X')]_{(i-1)n'+r,\,(j-1)n'+s} \\ &= \left\langle \phi(v_i, v_j), \phi(v'_r, v'_s) \right\rangle_{\mathcal{H}} =: \kappa((v_i, v_j), (v'_r, v'_s)),\end{aligned}$$

where κ is our edge kernel. We can thus expand (8) by explicitly taking all paths through the repeated matrix products, giving

$$\begin{aligned}k(G,G') &:= \sum_{k=1}^{\infty} \mu(k)\, q_\times^\top W_\times^k p_\times = \sum_{k=1}^{\infty} \mu(k)\, q_\times^\top \left(\prod_{i=1}^{k} W_\times \right) p_\times \\ &= \sum_{k=1}^{\infty} \mu(k) \sum_{\substack{v_0, v_1, \ldots v_k \in V \\ v'_0, v'_1, \ldots v'_k \in V'}} q_{v_k} q'_{v'_k} \left(\prod_{i=1}^{k} \kappa((v_{i-1}, v_i), (v'_{i-1}, v'_i)) \right) p_{v_0}\, p'_{v'_0}. \end{aligned} \tag{60}$$

This is easily identified as an instance of the R-convolution kernel (59), where the decomposition is into all equal-length sequences $\vec{v}, \vec{v}'$ of nodes from V and V', respectively, and

$$\mu(\vec{v}, \vec{v}') := \mu(|\vec{v}|)\, q_{v_{|\vec{v}|}} q'_{v'_{|\vec{v}|}} p_{v_0}\, p'_{v'_0}, \tag{61}$$

where $|\cdot|$ in (61) denotes the length of a sequence. Finally, note that by definition of our edge kernel κ, only pairs of sequences that are both actual walks on their respective graphs will make a non-zero contribution to (60).

Random walk graph kernels as proposed by Gärtner et al. (2003) likewise decompose a graph into random walks, but then employ a delta kernel between nodes. Borgwardt et al. (2005), on the other hand, use a kernel defined on both nodes and edges. The marginalized graph kernels of Kashima et al. (2004) are closely related but subtly different in that they decompose the graph into all possible *label* sequences generated by a walk. Mahé et al. (2004) extend this approach in two ways: They enrich the labels via the so-called Morgan index, and modify the kernel definition to prevent *tottering*, that is, the generation of high similarity scores by multiple, similar, small substructures. Both these extensions are particularly relevant for chemoinformatics applications.

Further afield, Horváth et al. (2004) decompose a graph into cyclic patterns, then count the number of common cyclic patterns which occur in both graphs. Their kernel is plagued by computational issues; in fact they show that computing the cyclic pattern kernel of a general graph is NP-hard. They consequently restrict their attention to practical problem classes where the number of simple cycles is bounded.

Ramon and Gärtner (2003) consider subtree patterns to define graph kernels. Starting from a given node v, a tree is created by adding all the nodes that can be reached from v in $1,\ldots,h$ steps, where h is the height of the tree. If more than one walk connects two nodes, then each one of these is used to define a distinct subtree. This means that the same node is counted several times, thus leading to tottering. Furthermore, the number of candidate trees grows exponentially with the height of the subtree under consideration, thus severely limiting the depth of graph structure one can probe at reasonable computational cost.

Borgwardt and Kriegel (2005) define a kernel (62) based on shortest paths. They represent a graph $G = (V,E)$ by a complete graph $S = (V,\bar{E})$ over the same vertices, wherein the weight of each edge in $\bar{E}$ equals the length of the shortest path between the corresponding nodes in G. Their shortest path kernel is then defined as

$$k_{\mathrm{sp}}(G,G') = \sum_{e\in\bar{E}} \sum_{e'\in\bar{E}'} \kappa(e,e'), \tag{62}$$

where κ is any kernel defined on the edges of S and S'.

Shervashidze et al. (2009) use subgraphs of fixed size to define kernels. Their key idea is to represent the graph by a normalized frequency vector which counts the frequency of occurrence of various fixed-size subgraphs. The kernel is then simply computed as the dot product between these vectors.

Other decompositions of graphs which are well suited for particular application domains include molecular fingerprints based on various types of depth-first searches (Ralaivola et al., 2005) and structural elements such as rings or functional groups (Fröhlich et al., 2006).

7.2 R-Convolutions in Abstract Semirings

There have been a few attempts to extend the R-convolution kernel (59) to abstract semirings, by defining:

$$k(x,x') := \bigoplus_{\substack{\vec{x}\in R^{-1}(x)\\ \vec{x}'\in R^{-1}(x')}} \mu(\vec{x},\vec{x}') \,\bar{\odot} \bigodot_{i=1}^{D} \kappa_i(x_i,x_i'). \tag{63}$$

The optimal assignment graph kernel of Fröhlich et al. (2006) is motivated along these lines, using the tropical semiring. It can be defined as

$$k(x,x') = \max_{\substack{\vec{x}\in R^{-1}(x)\\ \vec{x}'\in R^{-1}(x')}} \left(\mu(\vec{x},\vec{x}') + \sum_{i=1}^{D} \kappa_i(x_i,x_i') \right). \tag{64}$$

Unfortunately (64) is not always p.s.d. (Vert, 2008). The problem is that the class of p.s.d. kernels is not closed under the max operation (Berg et al., 1984).

For semirings that have a morphism ψ to the reals, however, we can rewrite (63) as

$$\psi(k(x,x')) = \sum_{\substack{\vec{x}\in R^{-1}(x)\\ \vec{x}'\in R^{-1}(x')}} \mu(\vec{x},\vec{x}') \prod_{i=1}^{D} \psi(\kappa_i(x_i,x_i')). \tag{65}$$

Comparing (65) with (59) makes it clear that $\psi \circ k$ is p.s.d. and hence admissible if all $\psi \circ \kappa_i$ are. This can be used to construct p.s.d. R-convolution kernels in such semirings.

For instance, take the logarithmic semiring $(\mathbb{R} \cup \{-\infty\}, \bar{\oplus}_{\ln}, +, -\infty, 0)$ augmented with an inverse temperature parameter $\beta > 0$, so that $x \bar{\oplus}_{\ln} y := \ln(e^{\beta x} + e^{\beta y})/\beta$. This has the morphism $\psi(x) = e^{\beta x}$. We can thus specialize (65) to define

$$k(x,x') := \sum_{\substack{\vec{x} \in R^{-1}(x) \\ \vec{x}' \in R^{-1}(x')}} e^{\beta \kappa(\vec{x},\vec{x}')}, \quad \text{where} \quad \kappa(\vec{x},\vec{x}') := \mu(\vec{x},\vec{x}') + \sum_{i=1}^{D} \kappa_i(x_i,x_i'), \tag{66}$$

which is a valid p.s.d. kernel if all $e^{\beta \kappa_i}$ are. Note that if κ_i is a p.s.d. kernel, then since $\beta > 0$ so is $\beta \kappa_i$, and since p.s.d. kernels are closed under exponentiation (Genton, 2001, Equation 5) so is $e^{\beta \kappa_i}$.

What makes (66) interesting is that when the temperature approaches zero ($\beta \to \infty$), the augmented logarithmic semiring approaches the tropical semiring, as $x \bar{\oplus}_{\ln} y \to \max(x,y)$. We thus obtain a kernel that approximates (an exponentiated version of) the optimal assignment kernel (64) yet is provably p.s.d. Since at low temperatures the value of (66) is dominated by the optimal assignment, one might call it the "mostly optimal assignment kernel."

The finite range of floating-point computer arithmetic unfortunately limits how low a temperature (66) can be used with in practice, though this can be greatly extended via suitable software, such as the `extnum` C++ class.[8]

8. Discussion and Outlook

As evidenced by the large number of recent papers, random walk and marginalized graph kernels have received considerable research attention. Although the connections between these two kernels were hinted at by Kashima et al. (2004), no effort was made to pursue this further. Our aim in presenting a unified framework for random walk and marginalized graph kernels that combines the best features of previous formulations is to highlight the similarities as well as the differences between these approaches. Furthermore, it allows us to use extended linear algebra in an RKHS to efficiently compute all these kernels by exploiting common structure inherent in these problems.

As more and more graph-structured data (e.g., molecular structures and protein interaction networks) becomes available in fields such as biology, web data mining, *etc*., graph classification will gain importance over the coming years. Hence there is a pressing need to speed up the computation of similarity metrics on graphs. We have shown that sparsity, low effective rank, and Kronecker product structure can be exploited to greatly reduce the computational cost of graph kernels; taking advantage of other forms of structure in $W_\times$ remains a computational challenge. Now that the computation of random walk graph kernels is viable for practical problem sizes, it will open the doors for their application in hitherto unexplored domains.

A major deficiency of geometric random walk graph kernels is that the admissible range of values of the decay parameter λ in (16) depends on the spectrum of the weight matrix $W_\times$. Since this is typically unknown, in practice one often resorts to very low values of λ—but this makes the contributions of higher-order terms (corresponding to long walks) to the kernel negligible. In fact in many applications a naive kernel which simply computes the average kernel between all pairs of edges in the two graphs has performance comparable to the random walk graph kernel.

8. `extnum` can be found at `http://darwin.nmsu.edu/molb_resources/bioinformatics/extnum/extnum.html`.

Trying to remedy this situation by normalizing the matrices involved leads to another phenomenon called *tottering* (Mahé et al., 2004). Roughly speaking tottering occurs when short self-repeating walks make a disproportionately large contribution to the kernel value. Consider two adjacent vertices v and v' in a graph. Because of tottering, contributions due to walks of the form $v \to v' \to v \to \ldots$ dominate the kernel value. Unfortunately a kernel using self-avoiding walks (walks which do not visit the same vertex twice) cannot be computed in polynomial time.

A natural question to ask is the following: Since diffusion can be viewed as a continuous time limit of random walks, can the ideas behind the random walk kernel be extended to diffusion? Unfortunately, the Laplacian of the product graph does not decompose into the Kronecker product of the Laplacian matrices of the constituent graphs; this rules out a straightforward extension.

Although rational kernels have always been viewed as distinct from graph kernels, we have shown that in fact these two research areas are closely related. It is our hope that this will facilitate cross-pollination of ideas such as the use of semirings and transducers in defining graph kernels. A return to the tensor and matrix notation which was commonly used to describe algebraic path problems would help make these connections explicit.

It is fair to say that R-convolution kernels are the mother of all kernels on structured data. It is enlightening to view various graph kernels as instances of R-convolution kernels since this brings into focus the relevant decomposition used to define a given kernel, and the similarities and differences between various kernels. Extending R-convolutions to abstract semirings, however, does not always result in a valid p.s.d. kernel. We have shown that a morphism to the reals is sufficient to successfully transport an R-convolution kernel into a semiring; whether it is necessary remains an open problem.

We do not believe that the last word on graph comparison has been said yet. Thus far, simple decompositions like random walks have been used to compare graphs. This is mainly driven by computational considerations and not by the application domain at hand. The algorithmic challenge of the future is to integrate higher-order structures such as spanning trees in graph comparisons, and to compute such kernels efficiently.

Acknowledgments

We thank Markus Hegland and Tim Sears for enlightening discussions, Alex Smola for pointing out to us that the optimal assignment kernel may fail to be p.s.d., and the anonymous reviewers for their detailed comments and suggestions which greatly helped improve this paper.

Appendix A. Extending Linear Algebra to RKHS

It is well known that any continuous, symmetric, positive definite kernel $\kappa\colon \mathcal{X}\times\mathcal{X}\to\mathbb{R}$ has a corresponding Hilbert space $\mathcal{H}$, called the Reproducing Kernel Hilbert Space or RKHS, which induces a feature map $\phi : \mathcal{X}\to\mathcal{H}$ satisfying $\kappa(x,x') = \langle\phi(x),\phi(x')\rangle_{\mathcal{H}}$. The natural extension of this so-called feature map to matrices is $\Phi\colon \mathcal{X}^{n\times m}\to\mathcal{H}^{n\times m}$ defined $[\Phi(A)]_{ij} := \phi(A_{ij})$. In what follows, we use Φ to lift tensor algebra from $\mathcal{X}$ to $\mathcal{H}$, extending various matrix products to the RKHS, and proving some of their their useful properties. Straightforward extensions via the commutativity properties of the operators have been omitted for the sake of brevity.

A.1 Matrix Product

Definition 9 *Let $A\in\mathcal{X}^{n\times m}$, $B\in\mathcal{X}^{m\times p}$, and $C\in\mathbb{R}^{m\times p}$. The matrix products $\Phi(A)\Phi(B)\in\mathbb{R}^{n\times p}$ and $\Phi(A)C\in\mathcal{H}^{n\times p}$ are given by*

$$[\Phi(A)\Phi(B)]_{ik} := \sum_j \big\langle\phi(A_{ij}),\phi(B_{jk})\big\rangle_{\mathcal{H}} \quad \textit{and} \quad [\Phi(A)C]_{ik} := \sum_j \phi(A_{ij})C_{jk}.$$

It is straightforward to show that the usual properties of matrix multiplication—namely associativity, transpose-commutativity, and distributivity with addition—hold for Definition 9 above, with one exception: associativity does *not* hold if the elements of all three matrices involved belong to the RKHS. In other words, given $A\in\mathcal{X}^{n\times m}$, $B\in\mathcal{X}^{m\times p}$, and $C\in\mathcal{X}^{p\times q}$, generally $[\Phi(A)\Phi(B)]\Phi(C)\neq\Phi(A)[\Phi(B)\Phi(C)]$. The technical difficulty is that in general

$$\big\langle\phi(A_{ij}),\phi(B_{jk})\big\rangle_{\mathcal{H}}\phi(C_{kl}) \neq \phi(A_{ij})\big\langle\phi(B_{jk}),\phi(C_{kl})\big\rangle_{\mathcal{H}}. \tag{67}$$

Further examples of statements like (67), involving properties which do not hold when extended to an RKHS, can be found for the other matrix products at (69) and (76) below.

Definition 9 allows us to state a first RKHS extension of the vec(ABC) formula (1):

Lemma 10 *If $A\in\mathbb{R}^{n\times m}$, $B\in\mathcal{X}^{m\times p}$, and $C\in\mathbb{R}^{p\times q}$, then*

$$\operatorname{vec}(A\Phi(B)C)) = (C^\top\otimes A)\operatorname{vec}(\Phi(B)) \ \in\mathcal{X}^{nq\times 1}.$$

Proof Analogous to Lemma 12 below. ■

A.2 Kronecker Product

Definition 11 *Let $A\in\mathcal{X}^{n\times m}$ and $B\in\mathcal{X}^{p\times q}$. The Kronecker product $\Phi(A)\otimes\Phi(B)\in\mathbb{R}^{np\times mq}$ is defined as*

$$[\Phi(A)\otimes\Phi(B)]_{(i-1)p+k,(j-1)q+l} := \big\langle\phi(A_{ij}),\phi(B_{kl})\big\rangle_{\mathcal{H}}.$$

Similarly to (67) above, for matrices in an RKHS

$$* \qquad (\Phi(A)\otimes\Phi(B))(\Phi(C)\otimes\Phi(D)) = (\Phi(A)\,\Phi(C))\otimes(\Phi(B)\,\Phi(D)) \tag{68}$$

does *not* necessarily hold. The technical problem with (68) is that generally

$$\langle \phi(A_{ir}), \phi(B_{ks}) \rangle_{\mathcal{H}} \langle \phi(C_{rj}), \phi(D_{sl}) \rangle_{\mathcal{H}} \neq \langle \phi(A_{ir}), \phi(C_{rj}) \rangle_{\mathcal{H}} \langle \phi(B_{ks}), \phi(D_{sl}) \rangle_{\mathcal{H}}. \tag{69}$$

In Section A.3 we show that analogous properties (Lemmas 14 and 15) do hold for the *heterogeneous* Kronecker product between RKHS and real matrices.

Definition 11 gives us a second extension of the vec(ABC) formula (1) to RKHS:

Lemma 12 *If $A \in \mathcal{X}^{n\times m}$, $B \in \mathbb{R}^{m\times p}$, and $C \in \mathcal{X}^{p\times q}$, then*

$$\operatorname{vec}(\Phi(A)\, B\, \Phi(C)) = (\Phi(C)^\top \otimes \Phi(A)) \operatorname{vec}(B) \ \in \mathbb{R}^{nq\times 1}.$$

Proof We begin by rewriting the k^{th} column of $\Phi(A)B\Phi(C)$ as

$$\begin{aligned}
[\Phi(A)B\Phi(C)]_{*k} = \Phi(A) \sum_j B_{*j}\, \phi(C_{jk}) &= \sum_j \phi(C_{jk}) \Phi(A) B_{*j} \\
&= [\phi(C_{1k})\Phi(A), \phi(C_{2k})\Phi(A), \ldots \phi(C_{nk})\Phi(A)] \underbrace{\begin{bmatrix} B_{*1} \\ B_{*2} \\ \vdots \\ B_{*n} \end{bmatrix}}_{\operatorname{vec}(B)} \\
&= ([\phi(C_{1k}), \phi(C_{2k}), \ldots \phi(C_{nk})] \otimes \Phi(A)) \operatorname{vec}(B). \qquad (70)
\end{aligned}$$

To obtain Lemma 12 we stack up the columns of (70):

$$\begin{aligned}
\operatorname{vec}(\Phi(A)\, B\, \Phi(C)) &= \left(\begin{bmatrix} \phi(C_{11}) & \phi(C_{21}) & \ldots & \phi(C_{n1}) \\ \vdots & \vdots & \ddots & \vdots \\ \phi(C_{1n}) & \phi(C_{2n}) & \ldots & \phi(C_{nn}) \end{bmatrix} \otimes \Phi(A) \right) \operatorname{vec}(B) \\
&= (\Phi(C)^\top \otimes \Phi(A)) \operatorname{vec}(B).
\end{aligned}$$

■

Direct computation of the right-hand side of Lemma 12 requires $nmpq$ kernel evaluations; when m, p, and q are all $O(n)$ this is $O(n^4)$. If $\mathcal{H}$ is finite-dimensional, however—in other words, if the feature map can be taken to be $\phi\colon \mathcal{X} \to \mathbb{R}^d$ with $d < \infty$—then the left-hand side of Lemma 12 can be obtained in $O(n^3 d)$ operations. Our efficient computation schemes in Section 4 exploit this observation.

A.3 Heterogeneous Kronecker Product

Definition 13 *Let $A \in \mathcal{X}^{n\times m}$ and $B \in \mathbb{R}^{p\times q}$. The heterogeneous Kronecker product $\Phi(A) \otimes B \in \mathcal{X}^{np\times mq}$ is given by*

$$[\Phi(A) \otimes B]_{(i-1)p+k,(j-1)q+l} = \phi(A_{ij})\, B_{kl}.$$

Recall that the standard Kronecker product obeys (2); here we prove two extensions:

Lemma 14 *If $A \in \mathcal{X}^{n\times m}$, $B \in \mathcal{X}^{p\times q}$, $C \in \mathbb{R}^{m\times o}$, and $D \in \mathbb{R}^{q\times r}$, then*

$$(\Phi(A)\otimes\Phi(B))(C\otimes D) = (\Phi(A)C)\otimes(\Phi(B)D).$$

Proof Using the linearity of the inner product we directly verify

$$\begin{aligned}
[(\Phi(A)\otimes\Phi(B))(C\otimes D)]_{(i-1)p+k,(j-1)q+l} &= \sum_{r,s}\langle\phi(A_{ir}),\phi(B_{ks})\rangle_{\mathcal{H}} C_{rj}D_{sl} \\
&= \left\langle \sum_r \phi(A_{ir})C_{rj}, \sum_s \phi(B_{ks})D_{sl} \right\rangle_{\mathcal{H}} \\
&= \left\langle [\Phi(A)C]_{ij}, [\Phi(B)D]_{kl} \right\rangle_{\mathcal{H}} \\
&= [(\Phi(A)C)\otimes(\Phi(B)D)]_{(i-1)p+k,(j-1)q+l}
\end{aligned}$$

■

Lemma 15 *If $A \in \mathcal{X}^{n\times m}$, $B \in \mathbb{R}^{p\times q}$, $C \in \mathcal{X}^{m\times o}$, and $D \in \mathbb{R}^{q\times r}$, then*

$$(\Phi(A)\otimes B)(\Phi(C)\otimes D) = (\Phi(A)\,\Phi(C))\otimes(BD).$$

Proof Using the linearity of the inner product we directly verify

$$\begin{aligned}
[(\Phi(A)\otimes B)(\Phi(C)\otimes D)]_{(i-1)p+k,(j-1)q+l} &= \sum_{r,s}\left\langle \phi(A_{ir})B_{ks}, \phi(C_{rj})D_{sl}\right\rangle_{\mathcal{H}} \\
&= \sum_r \left\langle \phi(A_{ir}),\phi(C_{rj})\right\rangle_{\mathcal{H}} \sum_s B_{ks}D_{sl} \\
&= [\Phi(A)\,\Phi(C)]_{ij}\,[BD]_{kl} \\
&= [(\Phi(A)\,\Phi(C))\otimes(BD)]_{(i-1)p+k,(j-1)q+l}
\end{aligned}$$

■

Using the heterogeneous Kronecker product, we can state four more RKHS extensions of the vec-ABC formula (1):

Lemma 16 *If $A \in \mathcal{X}^{n\times m}$, $B \in \mathbb{R}^{m\times p}$, and $C \in \mathbb{R}^{p\times q}$, then*

$$\operatorname{vec}(\Phi(A)\,BC) = (C^\top\otimes\Phi(A))\operatorname{vec}(B) \ \in \mathcal{X}^{nq\times 1}.$$

Proof Analogous to Lemma 12. ■

Lemma 17 *If $A \in \mathbb{R}^{n\times m}$, $B \in \mathbb{R}^{m\times p}$, and $C \in \mathcal{X}^{p\times q}$, then*

$$\operatorname{vec}(AB\,\Phi(C)) = (\Phi(C)^\top\otimes A)\operatorname{vec}(B) \ \in \mathcal{X}^{nq\times 1}.$$

Proof Analogous to Lemma 12. ■

Lemma 18 *If $A \in \mathcal{X}^{n\times m}$, $B \in \mathcal{X}^{m\times p}$, and $C \in \mathbb{R}^{p\times q}$, then*

$$\operatorname{vec}(\Phi(A)\,\Phi(B)C) = (C^\top \otimes \Phi(A))\operatorname{vec}(\Phi(B)) \;\in \mathbb{R}^{nq\times 1}.$$

Proof Analogous to Lemma 12. ■

Lemma 19 *If $A \in \mathbb{R}^{n\times m}$, $B \in \mathcal{X}^{m\times p}$, and $C \in \mathcal{X}^{p\times q}$, then*

$$\operatorname{vec}(A\,\Phi(B)\,\Phi(C)) = (\Phi(C)^\top \otimes A)\operatorname{vec}(\Phi(B)) \;\in \mathbb{R}^{nq\times 1}.$$

Proof Analogous to Lemma 12. ■

Note that there is no analogous lemma for $\operatorname{vec}(\Phi(A)\,\Phi(B)\,\Phi(C))$ since this term is not well-defined due to non-associativity (67).

A.4 Kronecker Sum

A concept closely related to the Kronecker product is that of the Kronecker sum, which is defined for real matrices $A \in \mathbb{R}^{n\times m}$ and $B \in \mathbb{R}^{p\times q}$ as

$$A \oplus B := A \otimes \mathbf{I}_{pq} + \mathbf{I}_{nm} \otimes B, \tag{71}$$

with $\mathbf{I}_{nm}$ (resp. $\mathbf{I}_{pq}$) denoting the $n \times m$ (resp. $p \times q$) identity matrix. Many of its properties can be derived from those of the Kronecker product. Unlike the Kronecker product, however, the Kronecker sum of two matrices in an RKHS is a matrix in the RKHS. From Definition 1 and (71) we find that

$$[A \oplus B]_{(i-1)p+k,(j-1)q+l} := A_{ij}\delta_{kl} + \delta_{ij}B_{kl}. \tag{72}$$

We can extend (72) to RKHS, defining analogously:

Definition 20 *Let $A \in \mathcal{X}^{n\times m}$ and $B \in \mathcal{X}^{p\times q}$. The Kronecker sum $\Phi(A) \oplus \Phi(B) \in \mathcal{X}^{np\times mq}$ is defined as*

$$[\Phi(A) \oplus \Phi(B)]_{(i-1)p+k,(j-1)q+l} := \phi(A_{ij})\delta_{kl} + \delta_{ij}\phi(B_{kl}).$$

In other words, in an RKHS the Kronecker sum is defined just as in (71):

$$\Phi(A) \oplus \Phi(B) \;=\; \Phi(A) \otimes \mathbf{I}_B + \mathbf{I}_A \otimes \Phi(B), \tag{73}$$

where $\mathbf{I}_M$ denotes the real-valued identity matrix of the same dimensions (not necessarily square) as matrix M. In accordance with Definition 13, the result of (73) is an RKHS matrix.

The equivalent of the vec-ABC formula (1) for Kronecker sums is:

$$\begin{aligned}(A \oplus B)\operatorname{vec}(C) &= (A \otimes \mathbf{I}_B + \mathbf{I}_A \otimes B)\operatorname{vec}(C)\\ &= (A \otimes \mathbf{I}_B)\operatorname{vec}(C) + (\mathbf{I}_A \otimes B)\operatorname{vec}(C)\\ &= \operatorname{vec}(\mathbf{I}_B C A^\top) + \operatorname{vec}(BC\mathbf{I}_A^\top)\\ &= \operatorname{vec}(\mathbf{I}_B C A^\top + BC\mathbf{I}_A^\top).\end{aligned} \tag{74}$$

This also works for matrices in an RKHS:

Lemma 21 *If $A \in \mathcal{X}^{n\times m}$, $B \in \mathcal{X}^{p\times q}$, and $C \in \mathcal{X}^{q\times m}$, then*

$$(\Phi(A) \oplus \Phi(B))\,\mathrm{vec}(\Phi(C)) = \mathrm{vec}(\mathbf{I}_B\,\Phi(C)\,\Phi(A)^\top + \Phi(B)\,\Phi(C)\,\mathbf{I}_A^\top) \in \mathbb{R}^{np\times 1}.$$

Proof Analogous to (74), using Lemmas 18 and 19. ■

Furthermore, we have two valid heterogeneous forms that map into the RKHS:

Lemma 22 *If $A \in \mathcal{X}^{n\times m}$, $B \in \mathcal{X}^{p\times q}$, and $C \in \mathbb{R}^{q\times m}$, then*

$$(\Phi(A) \oplus \Phi(B))\,\mathrm{vec}(C) = \mathrm{vec}(\mathbf{I}_B\,C\,\Phi(A)^\top + \Phi(B)\,C\,\mathbf{I}_A^\top) \in \mathcal{X}^{np\times 1}.$$

Proof Analogous to (74), using Lemmas 16 and 17. ■

Lemma 23 *If $A \in \mathbb{R}^{n\times m}$, $B \in \mathbb{R}^{p\times q}$, and $C \in \mathcal{X}^{q\times m}$, then*

$$(A \oplus B)\,\mathrm{vec}(\Phi(C)) = \mathrm{vec}(\mathbf{I}_B\,\Phi(C)\,A^\top + B\,\Phi(C)\,\mathbf{I}_A^\top) \in \mathcal{X}^{np\times 1}.$$

Proof Analogous to (74), using Lemma 10. ■

A.5 Hadamard Product

While the extension of the Hadamard (element-wise) product to an RKHS is not required to implement our fast graph kernels, the reader may find it interesting in its own right.

Definition 24 *Let $A, B \in \mathcal{X}^{n\times m}$ and $C \in \mathbb{R}^{n\times m}$. The Hadamard products $\Phi(A) \odot \Phi(B) \in \mathbb{R}^{n\times m}$ and $\Phi(A) \odot C \in \mathcal{H}^{n\times m}$ are given by*

$$[\Phi(A) \odot \Phi(B)]_{ij} = \big\langle \phi(A_{ij}), \phi(B_{ij}) \big\rangle_{\mathcal{H}} \quad \text{and} \quad [\Phi(A) \odot C]_{ij} = \phi(A_{ij})\,C_{ij}.$$

We prove two extensions of (3):

Lemma 25 *If $A \in \mathcal{X}^{n\times m}$, $B \in \mathcal{X}^{p\times q}$, $C \in \mathbb{R}^{n\times m}$, and $D \in \mathbb{R}^{p\times q}$, then*

$$(\Phi(A) \otimes \Phi(B)) \odot (C \otimes D) = (\Phi(A) \odot C) \otimes (\Phi(B) \odot D).$$

Proof Using the linearity of the inner product we directly verify

$$\begin{aligned}
[(\Phi(A) \otimes \Phi(B)) \odot (C \otimes D)]_{(i-1)p+k,(j-1)q+l} &= \big\langle \phi(A_{ij}), \phi(B_{kl}) \big\rangle_{\mathcal{H}} C_{ij} D_{kl} \\
&= \big\langle \phi(A_{ij})C_{ij}, \phi(B_{kl})D_{kl} \big\rangle_{\mathcal{H}} \\
&= \big\langle [\Phi(A) \odot C]_{ij}, [\Phi(B) \odot D]_{kl} \big\rangle_{\mathcal{H}} \\
&= [(\Phi(A) \odot C) \otimes (\Phi(B) \odot D)]_{(i-1)p+k,(j-1)q+l}
\end{aligned}$$

■

Lemma 26 *If $A \in \mathcal{X}^{n\times m}$, $B \in \mathbb{R}^{p\times q}$, $C \in \mathcal{X}^{n\times m}$, and $D \in \mathbb{R}^{p\times q}$, then*

$$(\Phi(A) \otimes B) \odot (\Phi(C) \otimes D) = (\Phi(A) \odot \Phi(C)) \otimes (B \odot D).$$

Proof Using the linearity of the inner product we directly verify

$$\begin{aligned}
[(\Phi(A) \otimes B) \odot (\Phi(C) \otimes D)]_{(i-1)p+k,(j-1)q+l} &= \left\langle \phi(A_{ij})B_{kl}, \phi(C_{ij})D_{kl} \right\rangle_{\mathcal{H}} \\
&= \left\langle \phi(A_{ij}), \phi(C_{ij}) \right\rangle_{\mathcal{H}} B_{kl}D_{kl} \\
&= [\Phi(A) \odot \Phi(C)]_{ij}[B \odot D]_{kl} \\
&= [(\Phi(A) \odot \Phi(C)) \otimes (B \odot D)]_{(i-1)p+k,(j-1)q+l}
\end{aligned}$$

■

As before,

$$* \qquad (\Phi(A) \otimes \Phi(B)) \odot (\Phi(C) \otimes \Phi(D)) = (\Phi(A) \odot \Phi(C)) \otimes (\Phi(B) \odot \Phi(D)) \tag{75}$$

does *not* necessarily hold, the difficulty with (75) being that in general,

$$\left\langle \phi(A_{ij}), \phi(B_{kl}) \right\rangle_{\mathcal{H}} \left\langle \phi(C_{ij}), \phi(D_{kl}) \right\rangle_{\mathcal{H}} \neq \left\langle \phi(A_{ij}), \phi(C_{ij}) \right\rangle_{\mathcal{H}} \left\langle \phi(B_{kl}), \phi(D_{kl}) \right\rangle_{\mathcal{H}}. \tag{76}$$

Abstract

In this paper, we consider the asymptotic form of the generalization error for the restricted Boltzmann machine in Bayesian estimation. It has been shown that obtaining the maximum pole of zeta functions is related to the asymptotic form of the generalization error for hierarchical learning models (Watanabe, 2001a,b). The zeta function is defined by using a Kullback function. We use two methods to obtain the maximum pole: a new eigenvalue analysis method and a recursive blowing up process. We show that these methods are effective for obtaining the asymptotic form of the generalization error of hierarchical learning models.

Keywords: Boltzmann machine, non-regular learning machine, resolution of singularities, zeta function

1. Introduction

A learning system consists of data, a learning model and a learning algorithm. The purpose of such a system is to estimate an unknown true density function from data distributed by the true density function. The data associated with image or speech recognition, artificial intelligence, the control of a robot, genetic analysis, data mining, time series prediction, and so on, are very complicated and usually not generated by a simple normal distribution, as they are influenced by many factors. Learning models for analyzing such data should likewise have complicated structures. Hierarchical learning models such as the Boltzmann machine, layered neural network, reduced rank regression and the normal mixture model are known to be effective learning models. They are, however, non-regular statistical models, which cannot be analyzed using the classic theories of regular statistical models (Hartigan, 1985; Sussmann, 1992; Hagiwara, Toda, and Usui, 1993; Fukumizu, 1996).

For example, consider a simple restricted Boltzmann machine that has two observable units and one hidden unit with binary variables (Fig. 1). The model is expressed by the probability form of two observable units $x=(x_1,x_2)\in\{1,-1\}^2$ with a parameter $a=(a_1,a_2)\in\mathbb{R}^2$:

$$p(x|a)=\sum_{y=\pm 1}p(x,y|a)=\frac{\exp(a_1x_1+a_2x_2)+\exp(-a_1x_1-a_2x_2)}{Z(a)},$$

where $y\in\{1,-1\}$ is the hidden variable,

$$p(x,y|a)=\frac{\exp(a_1x_1y+a_2x_2y)}{Z(a)},\ \text{and}\ Z(a)=\sum_{x_i=\pm 1,y=\pm 1,}\exp(a_1x_1y+a_2x_2y).$$

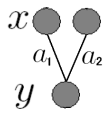

Figure 1: Simple restricted Boltzmann machine model: Two observable units and one hidden unit. The learning model is $p(x|a) \approx \exp(a_1x_1 + a_2x_2) + \exp(-a_1x_1 - a_2x_2)$.

We have

$$p(x|a) = \{(\prod_{i=1}^{2}(1 + x_i \tanh(a_i)) + \prod_{i=1}^{2}(1 - x_i \tanh(a_i)))\} \frac{\prod_{i=1}^{2} \cosh(a_i)}{Z(a)}$$

$$= \frac{\prod_{i=1}^{2} \cosh(a_i)}{Z(a)}(2 + 2x_1x_2 \tanh(a_1)\tanh(a_2)) = \frac{1 + x_1x_2 \tanh(a_1)\tanh(a_2)}{4}.$$

Assume that the true density function is $p(x|a^*)$ with $a^* = 0$. Then the true parameter set is $\{a = (a_1, a_2) \in \mathbb{R}^2 | p(x|a^*) = p(x|a)\} = \{a_1 = 0\} \cup \{a_2 = 0\}$. This set does not consist of only one point, resulting in a non-positive definite Fisher matrix function. On the other hand, the true parameter set of regular models should be one point and its Fisher matrix function is positive definite. Usually, the true parameter set of non-regular models is an analytic set with complicated singularities. Consequently, the many theoretical problems, such as clarifying generalization errors in learning theory, have remained unsolved.

The generalization error measures the difference between the true density function $q(x)$ and the predictive density function $p(x|x^n)$ obtained using n distributed training samples $x^n = (x_1, \ldots, x_n)$ of x from the true density function $q(x)$. We define it as the average Kullback distance between $q(x)$ and $p(x|x^n)$:

$$G(n) = E_n\{\sum_x q(x) \log \frac{q(x)}{p(x|x^n)}\},$$

where E_n is the expectation value over n training samples. This function clarifies precisely how $p(x|x^n)$ can approximate $q(x)$. Thus, $G(n)$ is also called a learning curve or a learning efficiency. For an arbitrary fixed parameter w^* in a parameter space W, we have

$$G(n) = \sum_x q(x) \log \frac{q(x)}{p(x|w^*)} + E_n\{\sum_x q(x) \log \frac{p(x|w^*)}{p(x|x^n)}\}.$$

The first and second terms are called the function approximation error and the statistical estimation error, respectively. The asymptotic form of the generalization error is important for model selection methods. The optimal model balances the function approximation error with the statistical estimation error. Since the Fisher matrix function is singular, non-regular models cannot be analyzed using the classic model selection methods of regular statistical models such as AIC (Akaike, 1974), TIC (Takeuchi, 1976), HQ (Hannan and Quinn, 1979), NIC (Murata, Yoshizawa, and Amari, 1994), BIC (Schwarz, 1978), and MDL (Rissanen, 1984). Therefore, it is important to construct a mathematical foundation for clarifying the generalization error of non-regular models.

In this paper, we clarify the generalization error of certain restricted Boltzmann machines, explicitly (Theorem 2 and Theorem 3), and give new bounds for the generalization error of the other types (Theorem 4), using both a new method of eigenvalue analysis and a recursive blowing up process. The restricted Boltzmann machine is one of the non-regular models and a complete bipartite graph type model that does not allow connections between hidden units (Hinton, 2004; Salakhutdinov, Mnih, and Hinton, 2007). It has been applied efficiently in recognizing hand-written digits and faces.

Several papers (Yamazaki and Watanabe, 2005; Nishiyama and Watanabe, 2006) have reported upper bounds for the asymptotic form of the generalization error for the Boltzmann machine model, but not the exact main terms.

We usually consider the generalization error in terms of a direct and an inverse problem. The direct problem involves solving the generalization error with a known true density function. The inverse problem is finding proper learning models and learning algorithms to minimize the generalization error under the condition of an unknown true density function. The inverse problem is important for practical usage, but in order to solve it, we first need to solve the direct problem. In this paper, we consider the direct problem of the restricted Boltzmann machine model.

We have already obtained the exact asymptotic forms of the generalization errors for the three layered neural network (Aoyagi and Watanabe, 2005a; Aoyagi, 2006), and for the reduced rank regression (Aoyagi and Watanabe, 2005b). In addition, Rusakov and Geiger (2005) obtained the same for Naive Bayesian networks (cf. Remark 1).

This paper consists of four sections. In Section 2, we summarize the framework of Bayesian learning models. In Section 3, we explain the restricted Boltzmann machine and show our main results, and we give our conclusions in Section 4.

2. Stochastic Complexity and Generalization Error in Bayesian Estimation

It is well known that Bayesian estimation is more appropriate than the maximum likelihood method when a learning machine is non-regular (Akaike, 1980; Mackay, 1992). In this paper, we consider the stochastic complexity and the generalization error in Bayesian estimation.

Let $q(x)$ be a true probability density function and $x^n := \{x_i\}_{i=1}^n$ be n training samples randomly selected from $q(x)$. Consider a learning model which is written by a probability form $p(x|w)$, where w is a parameter. The purpose of the learning system is to estimate $q(x)$ from x^n by using $p(x|w)$.

Let $p(w|x^n)$ be the *a posteriori* probability density function:

$$p(w|x^n) = \frac{1}{Z_n}\psi(w)\prod_{i=1}^{n} p(x_i|w),$$

where $\psi(w)$ is an *a priori* probability density function on the parameter set W and

$$Z_n = \int_W \psi(w)\prod_{i=1}^{n} p(x_i|w)\mathrm{d}w.$$

So the average inference $p(x|x^n)$ of the Bayesian density function is given by

$$p(x|x^n) = \int p(x|w)p(w|x^n)\mathrm{d}w,$$

which is the predictive density function.

Set

$$K(q||p) = \sum_x q(x) \log \frac{q(x)}{p(x|x^n)}.$$

This function always has a positive value and satisfies $K(q||p) = 0$ if and only if $q(x) = p(x|x^n)$.

The generalization error $G(n)$ is its expectation value E_n over n training samples:

$$G(n) = E_n\{\sum_x q(x) \log \frac{q(x)}{p(x|x^n)}\}.$$

Let

$$K_n(w) = \frac{1}{n} \sum_{i=1}^{n} \log \frac{q(x)}{p(x^n|w)}.$$

The average stochastic complexity or the free energy is defined by

$$F(n) = -E_n\{\log \int \exp(-nK_n(w))\psi(w)dw\}.$$

Then we have $G(n) = F(n+1) - F(n)$ for an arbitrary natural number n (Levin, Tishby, and Solla, 1990; Amari, Fujita, and Shinomoto, 1992; Amari and Murata, 1993). $F(n)$ is known as the Bayesian criterion in Bayesian model selection (Schwarz, 1978), stochastic complexity in universal coding (Rissanen, 1986; Yamanishi, 1998), Akaike's Bayesian criterion in optimization of hyper-parameters (Akaike, 1980) and evidence in neural network learning (Mackay, 1992). In addition, $F(n)$ is an important function for analyzing the generalization error.

It has recently been proved that the maximum pole of a zeta function gives the generalization error of hierarchical learning models asymptotically, assuming that the function approximation error is negligible compared to the statistical estimation error (Watanabe, 2001a,b). This assumption is natural for the model selection problem. To compare various models of different parameter's dimension, we assume that the true distribution is a certain dimensional model. If the parameter's dimension of the true distribution is larger than that of the learning model, clarifying the behavior of the generalization error is rather easy. We assume, therefore, that the true density distribution $q(x)$ is included in the learning model, that is, $q(x) = p(x|w^*)$ for $w^* \in W$, where W is the parameter space.

Define the zeta function $J(z)$ of a complex variable z for the learning model by

$$J(z) = \int K(w)^z \psi(w) \mathrm{d}w,$$

where $K(w)$ is the Kullback function:

$$K(w) = \sum_x p(x|w^*) \log \frac{p(x|w^*)}{p(x|w)}.$$

Then, for the maximum pole $-\lambda$ of $J(z)$ and its order θ, we have

$$F(n) = \lambda \log n - (\theta - 1) \log \log n + O(1), \tag{1}$$

where $O(1)$ is a bounded function of n, and if $G(n)$ has an asymptotic expansion,

$$G(n) \cong \lambda/n - (\theta - 1)/(n \log n) \text{ as } n \to \infty. \tag{2}$$

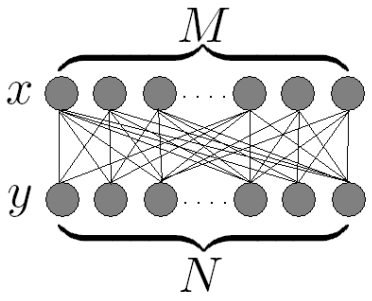

Figure 2: A restricted Boltzmann machine: M is the number of binary observable units x and N is the number of binary hidden units y. The learning model is $p(x,y|a) \propto \exp(\sum_{i=1}^{M}\sum_{j=1}^{N} a_{ij}x_iy_j)$, where a_{ij} is a parameter between x_i and y_j.

Therefore, our aim in this paper is to obtain λ and θ.

To assist in achieving this aim, we use the desingularization in algebraic geometry (Watanabe, 2009). It is, however, a new problem, even in mathematics, to obtain the desingularization of Kullback functions, since the singularities of these functions are very complicated and as such most of them have not yet been investigated (Appendix A). We, therefore, need a new method of eigenvalue analysis and a recursive blowing up process.

3. Restricted Boltzmann Machine

From now on, for simplicity, we denote

$$\{\{n\}\} = \begin{cases} 0, & \text{if } n = 0 \mod 2, \\ 1, & \text{if } n = 1 \mod 2, \end{cases} \quad \{\{(n_1,\cdots,n_m)\}\} = (\{\{n_1\}\},\cdots,\{\{n_m\}\}),$$

and we use the notation $\mathrm{d}a$ instead of $\prod_{i=1}^{H}\prod_{j=1}^{H'} \mathrm{d}a_{ij}$ for $a = (a_{ij})$.

Let $2 \leq M \in \mathbb{N}$ and $N \in \mathbb{N}$. Set

$$p(x,y|a) = \frac{\exp(\sum_{i=1}^{M}\sum_{j=1}^{N} a_{ij}x_iy_j)}{Z(a)},$$

where

$$Z(a) = \sum_{x_i=\pm 1, y_j=\pm 1,} \exp(\sum_{i=1}^{M}\sum_{j=1}^{N} a_{ij}x_iy_j),$$

$x = (x_i) \in \{1,-1\}^M$ and $y = (y_j) \in \{1,-1\}^N$ (Fig. 2).

Consider a restricted Boltzmann machine

$$\begin{aligned} p(x|a) &= \sum_{y_j=\pm 1} p(x,y|a) = \frac{\prod_{j=1}^N (\prod_{i=1}^M \exp(a_{ij}x_i) + \prod_{i=1}^M \exp(-a_{ij}x_i))}{Z(a)} \\ &= \{\prod_{j=1}^N (\prod_{i=1}^M (1+x_i \tanh(a_{ij})) + \prod_{i=1}^M (1-x_i \tanh(a_{ij})))\} \frac{\prod_{j=1}^N \prod_{i=1}^M \cosh(a_{ij})}{Z(a)} \\ &= \frac{\prod_{j=1}^N \prod_{i=1}^M \cosh(a_{ij})}{Z(a)} \\ &\times \prod_{j=1}^N (2 \sum_{0 \le p \le M/2} \sum_{i_1 < \cdots < i_{2p}} x_{i_1} x_{i_2} \cdots x_{i_{2p}} \tanh(a_{i_1 j}) \tanh(a_{i_2 j}) \cdots \tanh(a_{i_{2p} j})). \end{aligned}$$

Let $B = (b_{ij}) = (\tanh(a_{ij}))$. Denote $B^J = \prod_{i=1}^M \prod_{j=1}^N b_{ij}^{J_{ij}}$ and $x^J = \prod_{i=1}^M x_i^{\sum_{j=1}^N J_{ij}}$, where $J = (J_{ij})$ is an $M \times N$ matrix with $J_{ij} \in \{0,1\}$. Then we have

$$p(x|a) = \frac{2^N \prod_{j=1}^N \prod_{i=1}^M \cosh(a_{ij})}{Z(a)} \sum_{J:\{\{\sum_{i=1}^M J_{ij}\}\}=0 \text{ for all } j} B^J x^J.$$

Let

$$Z(b) = \frac{Z(a)}{2^N \prod_{j=1}^N \prod_{i=1}^M \cosh(a_{ij})}.$$

Set $I = \{I = (I_i) \in \{0,1\}^M | \{\{\sum_{i=1}^M I_i\}\} = 0\}$, and $B^I = \sum_{\substack{J:\{\{\sum_{i=1}^M J_{ij}\}\}=0 \\ \{\{\sum_{j=1}^N J_{ij}\}\}=I_i}} B^J$ for $I \in I$. Then we have

$$p(x|a) = \frac{1}{Z(b)} \sum_{I \in I} B^I x^I$$

and $Z(b) = 2^N B^0$. Since $\sum_{0 \le i \le M/2} \begin{pmatrix} M \\ 2i \end{pmatrix} = ((1+1)^M + (1-1)^M)/2 = 2^{M-1}$, the number of elements in I is 2^{M-1}.

Remark 1 Rusakov and Geiger (2005) obtained λ and θ for the following class of Naive Bayesian networks with two hidden states and binary features:

$$p(x|c,d,t) = t \prod_{i=1}^M c_i^{(1+x_i)/2} (1-c_i)^{(1-x_i)/2} + (1-t) \prod_{i=1}^N d_i^{(1+x_i)/2} (1-d_i)^{(1-x_i)/2}.$$

where $x \in \{1,-1\}^M$, $c = \{c_i\}_{i=1}^M \in \mathbb{R}^M$, $d = \{d_i\}_{i=1}^M \in \mathbb{R}^M$ and $0 \le t \le 1$. Our models with one hidden unit ($N = 1$) are obtained by setting $t = 1/2$, $\tanh(a_i) = 2c_i - 1$ and $d_i = -c_i$. The relation $d_i = -c_i$ creates a parameter space different from that of our models.

Assume that the true distribution is $p(x|a^*)$ with $a^* = (a_{ij}^*)$ and set $B^* = b^* = (b_{ij}^*) = (\tanh(a_{ij}^*))$. Then the Kullback function $K(a)$ is

$$\begin{aligned} &\sum_{x_i=\pm 1} p(x|a^*)(\log p(x|a^*) - \log p(x|a)) = \sum_{x_i=\pm 1} p(x|a^*) \sum_{k=2}^\infty \frac{(-1)^k}{k} (\frac{p(x|a)}{p(x|a^*)} - 1)^k \\ = &\sum_{x_i=\pm 1} \frac{(p(x|a) - p(x|a^*))^2}{p(x|a^*)} (1 + \sum_{k=1}^\infty \frac{(-1)^k}{k+2} (\frac{p(x|a)}{p(x|a^*)} - 1)^k). \end{aligned}$$

Lemma 1 Watanabe, 2001c *If analytic functions K_1, K_2 satisfy $\gamma_1|K_2| \leq |K_1| \leq \gamma_2|K_2|$ for some positive constants γ_1 and γ_2, then the maximum pole and its order of $\int |K_1|^z dw$ are those of $\int |K_2|^z dw$.*

By Lemma 1, since we consider a neighborhood of $\frac{p(x|a)}{p(x|a^*)} = 1$, we only need to obtain the maximum pole of $J(z) = \int \Psi_0^z \mathrm{d}b$, where

$$\Psi_0 = \sum_{x_i=\pm 1} (p(x|a) - p(x|a^*))^2 = \sum_{x_i=\pm 1} (\frac{\sum_{I\in I} B^I x^I}{Z(b)} - \frac{\sum_{I\in I} B^{*I} x^I}{Z(b^*)})^2$$

$$= \sum_{x_i=\pm 1} (\sum_{I\in I} \left(\frac{B^I}{Z(b)} - \frac{B^{*I}}{Z(b^*)} \right) x^I)^2 = 2^M \sum_{I\in I} \left(\frac{B^I}{Z(b)} - \frac{B^{*I}}{Z(b^*)} \right)^2.$$

By Lemma 1 again, we can replace Ψ_0 by

$$\Psi = \sum_{I\in\{0,1\}^M} 2^{2N} (\frac{B^I}{Z(b)} - \frac{B^{*I}}{Z(b^*)})^2 = \sum_{I\in\{0,1\}^M} (\frac{B^I}{B^0} - \frac{B^{*I}}{B^{*0}})^2. \tag{3}$$

4. Main Results

Consider the zeta function $J(z) = \int_V \Psi^z \mathrm{d}b$, where V is a sufficiently small neighborhood of a^*.

From the eigenvalue analysis method, we obtain the following theorem.

Theorem 2 *The average stochastic complexity $F(n)$ in Eq. (1) and the generalization error $G(n)$ in Eq. (2) are given by using the following maximum pole $-\lambda$ of $J(z)$ and its order θ.*

(Case 1)*: If $M = 2$ then $\lambda = 1/2$ and* $\theta = \begin{cases} 2, & \text{if } N = 1, b^* = 0 \\ 1, & \text{otherwise.} \end{cases}$

(Case 2)*: If $M = 3$ then* $\lambda = \begin{cases} 3/4, & \text{if } N = 1, b^* = 0 \\ 1/2, & \text{if } N = 1, b^* \neq 0, \prod_{i=1}^3 b_{i1}^* = 0 \\ 3/2, & \text{if } N = 1, \prod_{i=1}^3 b_{i1}^* \neq 0 \\ 3/2, & \text{if } N \geq 2, \end{cases}$

and $\theta = \begin{cases} 3, & \text{if } N = 2, b^* = 0, \\ 2, & \text{if } N = 2, b^* \neq 0, b_{i_0 j}^* = b_{i_1 j}^* = 0 \text{ for } 1 \leq j \leq N, \\ 2, & \text{if } N = 2, b_{i_0 j_0}^* b_{i_1 j_0}^* \neq 0, b_{i_2 j_0} = b_{ij}^* = 0 \text{ for } 1 \leq i \leq 3, 1 \leq j \leq N, j \neq j_0, \\ 1, & \text{otherwise}, \end{cases}$ *where* $i_0, i_1, i_2 \in \{1,2,3\}$ *are different from each other and* $1 \leq j_0 \leq N$.

For its proof, we use the eigenvalues and the eigenvectors of the matrix $C_j = (c_j^{I,I'})$ where $b_j^I = \prod_{i=1}^M b_{ij}^{I_i}$, and $c_j^{I,I'} = b_j^{I''}$ with $\{\{I' + I''\}\} = I$, for $I, I', I'' \in I$. Its proof appears in Appendix B.

We obtain λ and θ in Eqs. (1) and (2) for $M > N$ using a recursive blowing up.

Theorem 3 *Assume that $M > N$ and $a^* = 0$. The average stochastic complexity $F(n)$ in Eq. (1) and the generalization error $G(n)$ in Eq. (2) are given by using the maximum pole $-\lambda = -\frac{MN}{4}$ of $J(z)$ and its order* $\theta = \begin{cases} 1, & \text{if } M > N+1, \\ M, & \text{if } M = N+1. \end{cases}$

We also bound values of λ for other cases.

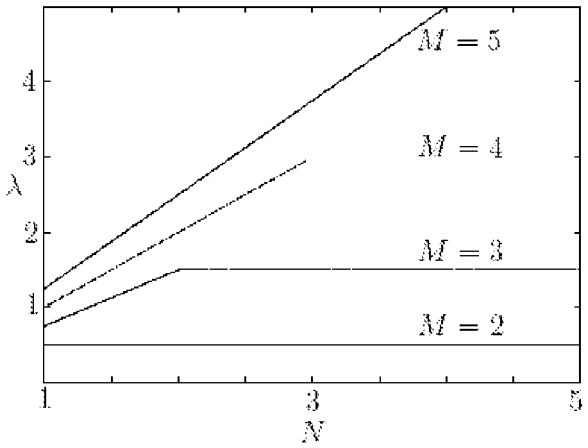

Figure 3: The curve of λ along the y-axis and N along the x-axis, when $M = 2,3,4,5$ and $a^* = 0$.

Theorem 4 *Let* $(a_{1j}, a_{2j}, \cdots, a_{Mj}) \neq 0$ *for* $j = 1, \ldots, N_0$ *and* $(a_{1j}, a_{2j}, \cdots, a_{Mj}) = 0$ *for* $j = N_0 + 1, \ldots, N$ *in* V*, where* V *is a sufficiently small neighborhood of* a^*.

Then we have

$$\begin{aligned} &\frac{M(N-N_0)}{4} \leq \lambda \leq \frac{M(N-N_0)}{4} + \frac{MN_0}{2}, && \text{if } M > N - N_0 \\ \frac{M(M-1)}{4} + \frac{MN_0}{2} \leq \lambda &\leq \frac{2N_0+(M-1)(M-2)}{4} + \frac{MN_0}{2} \left(< \frac{MN_0}{2} + \frac{M(N-N_0)}{4} \right), && \text{if } M \leq N - N_0. \end{aligned}$$

The proofs for these two theorems appear in Appendix C.

5. Conclusion

In this paper, we obtain the generalization error of restricted Boltzmann machines asymptotically (Fig. 3).

We use a new method of eigenvalue analysis and a recursive blowing up in algebraic geometry and show that these are effective for solving the problem in learning theory.

We have not used the eigenvalue analysis method where $M > N$, which is usually the case in applications. Eigenvalue analysis seems to be necessary for solving the behavior of the restricted Boltzmann machine model's generalization error for $M \leq N$.

In this paper, we clarify the generalization error for (i) $M = 3$ (Theorem 2) and (ii) $M > N$, $a^* = 0$ (Theorem 3) explicitly and give new bounds for the generalization error of the other types (Theorem 4). The case (i) shows that λ is independent of a^* for $M - 1 = 2 \leq N$, and so implies that we need more careful consideration for obtaining the exact values λ for the case of Theorem 4.

Our future research aims to improve our methods, and to apply them to the case of Theorem 4 and to obtain the generalization error of the general Boltzmann machine, which is also known as the Bayesian network, the graphical model and the spin model, as such models are widely used in many fields. We believe that extending our results would provide a mathematical foundation for the analysis of various graphical models.

This study involves applying techniques of algebraic geometry to learning theory and it seems that we can contribute to the development of both these fields in the future.

The application of our results is as follows. The results of this paper introduce a mathematical measure of preciseness for numerical calculations such as the Markov Chain Monte Carlo. Using the Markov Chain Monte Carlo (MCMC) method, estimated values for marginal likelihoods had previously been calculated for hyper-parameter estimations and model selection methods of complex learning models, but the theoretical values were not known. The theoretical values of marginal likelihoods have been given in this paper. This enables us to construct a mathematical foundation for analyzing and developing the precision of the MCMC method (Nagata and Watanabe, 2005). Moreover, Nagata and Watanabe (2007) studied the setting of temperatures for the exchange MCMC method and proved the mathematical relation between the symmetrized Kullback function and the exchange ratio, from which an optimal setting of temperatures could be devised. Our theoretical results will be helpful in these numerical experiments. Furthermore, these values have been compared with those of the generalization error of a localized Bayes estimation (Takamatsu, Nakajima, and Watanabe, 2005).

Appendix A. Hironaka's Theorem

We introduce Hironaka's Theorem about the desingularization.

Theorem 5 [Desingularization (Fig. 4)] (Hironaka, 1964)
Let f be a real analytic function in a neighborhood of $w = (w_1, \cdots, w_d) \in \mathbb{R}^d$ with $f(w) = 0$. There exist an open set $V \ni w$, a real analytic manifold U, and a proper analytic map μ from U to V such that
(1) $\mu : U - \mathcal{E} \to V - f^{-1}(0)$ is an isomorphism, where $\mathcal{E} = \mu^{-1}(f^{-1}(0))$,
(2) for each $u \in U$, there is a local analytic coordinate system $(u_1, \cdots, u_n)$ such that $f(\mu(u)) = \pm u_1^{s_1} u_2^{s_2} \cdots u_n^{s_n}$, where $s_1, \cdots, s_n$ are non-negative integers.

Applying Hironaka's theorem to the Kullback function $K(w)$, for each $w \in K^{-1}(0) \cap W$, we have a proper analytic map μ_w from an analytic manifold U_w to a neighborhood V_w of w satisfying Hironaka's Theorem (1) and (2). Then the local integration on V_w of the zeta function $J(z)$ of the learning model is

$$\begin{aligned} J_w(z) &= \int_{V_w} K(w)^z \psi(w) dw \\ &= \int_{U_w} \sum_u (u_1^{2s_1} u_2^{2s_2} \cdots u_d^{2s_d})^z \psi(\mu_w(u)) |\mu_w'(u)| du. \end{aligned} \tag{4}$$

Therefore, the poles of $J_w(z)$ can be obtained. For example, the function

$$\int_{U_0} (u_1^{2s_1} u_2^{2s_2} \cdots u_d^{2s_d})^z u_1^{t_1} u_1^{t_2} \cdots u_1^{t_d} du$$

has the poles $-(t_1+1)/(2s_1), \cdots, -(t_d+1)/(2s_d)$, where U_0 is a small neighborhood of 0. For each $w \in W \setminus K^{-1}(0)$, there exists a neighborhood V_w such that $K(w') \neq 0$, for all $w' \in V_w$. So

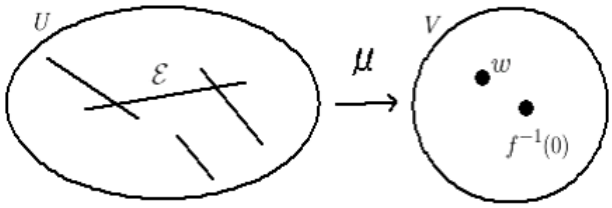

Figure 4: Hironaka's Theorem: This is the picture of a desingularization μ of $f : \mathcal{E}$ maps to $f^{-1}(0)$. $U - \mathcal{E}$ is isomorphic to $V - f^{-1}(0)$ by μ, where V is a small neighborhood of w with $f(w) = 0$.

$J_w(z) = \int_{V_w} K(w)^z \psi(w) dw$ has no poles. It is known that μ of an arbitrary polynomial in Hironaka's Theorem can be obtained by using a blowing up process. Note that the exponents in the integral are $2s_i$ instead of s_i as shown in Eq. (4), since the Kullback function is positive.

In spite of such results, it is still difficult to obtain the generalization error mainly for the following two reasons. (a) The desingularization of any polynomial is in general very difficult, although it is known to be a finite process. Furthermore, most of the Kullback functions of non-regular statistical models are degenerate (over $\mathbb{R}$) with respect to their Newton polyhedrons, which is the condition for using a toric resolution (Fulton, 1993; Watanabe, Hagiwara, Akaho, Motomura, Fukumizu, Okada, and Aoyagi, 2005). Also, points in the singularity set $\{K = \partial K/\partial w = 0\}$ of Kullback functions $K(w)$ are not isolated, and Kullback functions are not simple polynomials, as their number of variables and number of terms grow with parameters, for example, M and N in Eq. (3). It is therefore, a new problem, even in mathematics, to obtain desingularizations of such Kullback functions, since their singularities are very complicated and as such most of them have not yet been investigated. (b) Since our main purpose is to obtain the maximum pole, obtaining a desingularization is not enough. We need techniques for choosing the maximum one from all poles. However, to the best of our knowledge, no theorems for such a purpose have been developed.

We give below Lemmas 2 and 3 in (Aoyagi and Watanabe, 2005b), as they are frequently used in this paper. Define the norm of a matrix $C = (c_{ij})$ by $\|C\| = \sqrt{\sum_{i,j} |c_{ij}|^2}$.

Lemma 6 (Aoyagi and Watanabe, 2005b) *Let U be a neighborhood of $w_0 \in \mathbb{R}^d$, $C(w)$ be an analytic $H \times H'$ matrix function from U, $\psi(w)$ be a C^∞ function from U with compact support, and P and Q be any regular $H \times H$ and $H' \times H'$ matrices, respectively. Then the maximum pole of $\int_U \|C(w)\|^{2z} \psi(w) dw$ and its order are those of $\int_U \|PC(w)Q\|^{2z} \psi(w) dw$.*

Lemma 7 *Assume that $p(x|a) = \frac{\prod_{j=1}^N W_j(x,a)}{\sum_x \prod_{j=1}^N W_j(x,a)}$ for $x \in X$. Then the maximum pole of $\int_U \{\sum_{x \in X} (p(x|a) - p(x|a^*))^2\}^z \psi(w) da$ and its order are those of*

$$\int_U \{ \sum_{x,x' \in X} (\sum_j^N (\log W_j(x,a) - \log W_j(x,a^*) - \log W_j(x',a) + \log W_j(x',a^*))\}^2 \psi(w) dw.$$

(Proof)

Consider the ideal I generated by $p(x|a)-p(x|a^*)$ for $x\in X$.

Then I is generated by $\frac{\prod_{j=1}^N W_j(x,a)}{\prod_{j=1}^N W_j(x,a^*)}-\frac{\sum_x\prod_{j=1}^N W_j(x,a)}{\sum_x\prod_{j=1}^N W_j(x,a^*)}$, and so by $\frac{\prod_{j=1}^N W_j(x,a)}{\prod_{j=1}^N W_j(x,a^*)}-\frac{\prod_{j=1}^N W_j(x',a)}{\prod_{j=1}^N W_j(x',a^*)}$ for $x,x'\in X$.

Since $|x-1|/2\le|\log x|\le 2|x-1|$ for $|x-1|<1/2$, we have

$$\sum_{x,x'\in X}(\frac{\prod_{j=1}^N W_j(x,a)}{\prod_{j=1}^N W_j(x,a^*)}\frac{\prod_{j=1}^N W_j(x',a^*)}{\prod_{j=1}^N W_j(x',a)}-1)^2/4$$

$$\le\sum_{x,x'\in X}(\sum_j^N(\log(W_j(x,a))-\log(W_j(x,a^*))+\log(W_j(x',a^*))-\log(W_j(x',a))))^2$$

$$\le\sum_{x,x'\in X}(\frac{\prod_{j=1}^N W_i(x,a)}{\prod_{j=1}^N W_j(x,a^*)}\frac{\prod_{j=1}^N W_j(x',a^*)}{\prod_{j=1}^N W_j(x',a)}-1)^2 4$$

Q.E.D.

Appendix B. Eigenvalue Analysis

The purpose of eigenvalue analysis is to simplify the blowing up process.

Hierarchical learning machines often have Kullback functions involving a matrix product such as $K(w)=\|D_1D_2\cdots D_N\|^2$, where D_i is a parameter matrix. Therefore, analyzing the eigenvalues of these matrices and applying Lemma 6 sometimes results in an easier function to handle. For example, the restricted Boltzmann machine has a Kullback function $\|\tilde{B}_N\|^2=\|\begin{pmatrix}\mathbf{0} & E\end{pmatrix}C_N\cdots C_2C_1(1,0,\ldots,0)^t\|^2$, where E is the identity matrix (t denotes the transpose). Theorem 9 (4) below shows that analyzing the eigenvalues of C_N makes an easier function $\|R\tilde{B}_N\|^2$ to blow up, where R is a certain regular matrix. This is the main point of this method.

Let $I,I',I''\in I$. We set $B_N^I=B^I$, $b_j^I=\prod_{i=1}^M b_{ij}^{I_i}$, and

$$B_N=(B_N^I)=(B_N^{(0,\ldots,0)},B_N^{(1,1,0,\ldots,0)},B_N^{(1,0,1,0,\ldots,0)},\ldots).$$

We now have $B_N^I=\sum_{\{\{I'+I''\}\}=I}b_N^{I''}B_{N-1}^{I'}$.

For convenience, we denote the "(I,I')th" element of a $2^{M-1}\times 2^{M-1}$ matrix C by $c^{I,I'}$.

Now consider the eigenvalues of the matrix $C_N=(c_N^{I,I'})$ where $c_N^{I,I'}=b_N^{I''}$ with $\{\{I'+I''\}\}=I$.

Note that $B_N=C_NB_{N-1}$.

Let $\ell=(\ell_1,\ldots,\ell_{2^{M-1}})=(\ell_I)\in\{-1,1\}^{2^{M-1}}$ with $\ell_{(0,\ldots,0)}=1$. ℓ is an eigenvector, if and only if

$$\sum_{I'\in I}c_N^{I,I'}\ell_{I'}=\ell_I\sum_{I'\in I}c_N^{(0,\ldots,0),I'}\ell_{I'}=\ell_I\sum_{I'\in I}b_N^{I'}\ell_{I'},\ \text{for all } I\in I.$$

That is,

$$\ell\text{ is an eigenvector}\iff\begin{array}{l}\text{if }\{\{I+I'\}\}=I''\ (\{\{I+I'+I''\}\}=0)\\ \text{then }\ell_{I''}=\ell_I\ell_{I'}\ (\ \ell_I\ell_{I'}\ell_{I''}=1).\end{array}$$

Denote the number of all elements in a set K by $\#K$.

Theorem 8 *Let* $K_1 \subset \{2,\ldots,M\}$. *Set* $\ell_I = \begin{cases} -1, & \text{if } \#\{i \in K_1 : I_i = 1\} \text{ is odd,} \\ 1, & \text{otherwise.} \end{cases}$ *Then* $\ell = (\ell_I)$ *is an eigenvector of* C_N *and its eigenvalue is*

$$\sum_{I \in I} \ell_I b_N^I = \frac{\prod_{i=1}^M (1+x_i b_i) + \prod_{i=1}^M (1-x_i b_i)}{2}, \text{ where } x_i = -1 \text{ if } i \in K_1, \text{ and } x_i = 1 \text{ if } i \notin K_1.$$

Note that $\sum_{I \in I} \ell_I b_N^I > 0$ *since* $b_i = \tanh(a_i)$.

(Proof)

Assume that $\{\{I' + I'' + I'''\}\} = 0$. If all $\#\{i \in K_1 : I'_i = 1\}$, $\#\{i \in K_1 : I''_i = 1\}$ and $\#\{i \in K_1 : I'''_i = 1\}$ are even, then $\ell_{I'}\ell_{I''}\ell_{I'''} = 1$.

If $\#\{i \in K_1 : I'_i = 1\}$ is odd, then $\#\{i \in K_1 : I''_i = 1\}$ or $\#\{i \in K_1 : I'''_i = 1\}$ is odd, since $\{\{I' + I'' + I'''\}\} = 0$.

If $\#\{i \in K_1 : I'_i = 1\}$ and $\#\{i \in K_1 : I''_i = 1\}$ are odd, then $\#\{i \in K_1 : I'''_i = 1\}$ is even and $\ell_{I'}\ell_{I''}\ell_{I'''} = 1$ since $\{\{I' + I'' + I'''\}\} = 0$.

Q.E.D.

We have 2^{M-1} eigenvectors ℓ. Moreover, they are orthogonal to each other, since the eigenvectors of a symmetric matrix are orthogonal. These eigenvectors ℓ's, therefore, span the whole space $\mathbb{R}^{2^{M-1}}$.

Set $\mathbf{1} = (1,\ldots,1)^t \in \mathbb{Z}^{2^{M-1}-1}$ (t denotes the transpose). Let $D = (D^{I,I'})$ be a symmetric matrix formed by arranging the eigenvectors ℓ's such that $D = \begin{pmatrix} 1 & \mathbf{1}^t \\ \mathbf{1} & D' \end{pmatrix}$ and $DD = 2^{M-1}E$, where E is the identity matrix and $D^{I,I'}$ is "(I,I')th" element of D.

Since $DD = \begin{pmatrix} 2^{M-1} & \mathbf{1}^t D' \\ \mathbf{1} + D'\mathbf{1} & \mathbf{1}\mathbf{1}^t + D'D' \end{pmatrix} = 2^{M-1}E$, we have $D'\mathbf{1} = -\mathbf{1}$.

Let $C'_N = DC_N D/2^{M-1} = DC_N D^{-1} = \begin{pmatrix} s_N^0 & 0 & 0 & \cdots & 0 \\ 0 & s_N^1 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & s_N^{2^{M-1}-1} \end{pmatrix}$.

We use s_N^i or s_N^I ($I \in I$), depending on the situation.

Since $C_N = D^{-1}C'_N D$, we have $b_N^{\{\{I+K\}\}} = \sum_{J \in I} D^{I,J} s_N^J D^{J,K}/2^{M-1}$.

B.1 Example

Let $M = 4$.

We have the matrix by arranging the eigenvectors of C_N,

$$D = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & -1 & -1 & -1 & 1 & 1 & 1 & -1 \\ 1 & -1 & 1 & 1 & -1 & -1 & 1 & -1 \\ 1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\ 1 & 1 & -1 & 1 & -1 & 1 & -1 & -1 \\ 1 & 1 & 1 & -1 & 1 & -1 & -1 & -1 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \end{pmatrix}$$ and the eigenvalues

$$\begin{aligned}
s_N^0 &= 1 + b_{1N}b_{2N} + b_{1N}b_{3N} + b_{1N}b_{4N} + b_{2N}b_{3N} + b_{2N}b_{4N} + b_{3N}b_{4N} + b_{1N}b_{2N}b_{3N}b_{4N}, \\
s_N^1 &= 1 + b_{2N}b_{3N} + b_{2N}b_{4N} + b_{3N}b_{4N} - b_{1N}(b_{2N} + b_{3N} + b_{4N} + b_{2N}b_{3N}b_{4N}), \\
s_N^2 &= 1 + b_{1N}b_{3N} + b_{1N}b_{4N} + b_{3N}b_{4N} - b_{2N}(b_{1N} + b_{3N} + b_{4N} + b_{1N}b_{3N}b_{4N}), \\
s_N^3 &= 1 + b_{1N}b_{3N} + b_{2N}b_{4N} + b_{1N}b_{2N}b_{3N}b_{4N} - (b_{1N} + b_{3N})(b_{2N} + b_{4N}), \\
s_N^4 &= 1 + b_{1N}b_{2N} + b_{3N}b_{4N} + b_{1N}b_{2N}b_{3N}b_{4N} - (b_{1N} + b_{2N})(b_{3N} + b_{4N}), \\
s_N^5 &= 1 + b_{1N}b_{2N} + b_{1N}b_{4N} + b_{2N}b_{4N} - b_{3N}(b_{1N} + b_{2N} + b_{4N} + b_{1N}b_{2N}b_{4N}), \\
s_N^6 &= 1 + b_{1N}b_{2N} + b_{1N}b_{3N} + b_{2N}b_{3N} - b_{4N}(b_{1N} + b_{2N} + b_{3N} + b_{1N}b_{2N}b_{3N}), \\
s_N^7 &= 1 + b_{1N}b_{4N} + b_{2N}b_{3N} + b_{1N}b_{2N}b_{3N}b_{4N} - (b_{1N} + b_{4N})(b_{2N} + b_{3N}).
\end{aligned}$$

Theorem 9 *Let $H = 2^{M-1} - 1$.*

(1) *Let* $d_{ij} = \begin{cases} 1, & \text{if } i = 1 \text{ or } j = 1, \\ D^{I,J}, & \text{if } I = (1, 0, \ldots, 0, \overset{i}{1}, 0, \ldots, 0) \\ & \text{and } J = (1, 0, \ldots, 0, \overset{j}{1}, 0, \ldots, 0). \end{cases}$

Then $D^{I,J} = \prod_{i,j:I_i=1,J_j=1} d_{ij}$ for all $I, J \in \mathcal{I}$.

(2) $B_N = C_N B_{N-1} = C_N \cdots C_2 B_1 = DC'_N \cdots C'_2 D^{-1} B_1 = \dfrac{DC'_N \cdots C'_1 \mathbf{1}}{2^{M-1}}$.

(3) *We have* $2^{M-1} D'^{-1} = D' - \mathbf{1}\mathbf{1}^t$.

(4) *Let* $\tilde{B}_1 = (B_1^I)_{I \neq 0}$, $\tilde{B}_N = (B_N^I)_{I \neq 0}$ *and*

$$S = -\frac{1}{H+1} \begin{pmatrix} \prod_{j=1}^N s^{*1}_j - \prod_{j=1}^N s^{*0}_j \\ \vdots \\ \prod_{j=1}^N s^{*H}_j - \prod_{j=1}^N s^{*0}_j \end{pmatrix} \begin{pmatrix} \prod_{j=2}^N s^1_j - \prod_{j=2}^N s^0_j & \cdots & \prod_{j=2}^N s^H_j - \prod_{j=2}^N s^0_j \end{pmatrix}$$
$$+ B^{*0}_N \prod_{j=2}^N s^0_j \begin{pmatrix} 1 & \cdots & 1 \\ \vdots & \vdots & \vdots \\ 1 & \cdots & 1 \end{pmatrix} + B^{*0}_N \begin{pmatrix} \prod_{j=2}^N s^1_j & 0 & 0 & \cdots & 0 \\ 0 & \prod_{j=2}^N s^2_j & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \cdots & \prod_{j=2}^N s^H_j \end{pmatrix}.$$

We have

$$(\det S) D'^{-1} S^{-1} D'^{-1} 2^{M-1} (\tilde{B}_N B^{*0}_N - \tilde{B}^*_N B^0_N)$$

$$= (\det S)\tilde{B}_1 - (B^{*0}_N)^{H-1}(\mathbf{1}\ D')\begin{pmatrix} \prod_{j=1}^N s^{*0}_j \prod_{i\neq 0}\prod_{j=2}^N s^i_j \\ \vdots \\ \prod_{j=1}^N s^{*H}_j \prod_{i\neq H}\prod_{j=2}^N s^i_j \end{pmatrix}.$$

(5) *The corresponding element to* I *of* $(\mathbf{1}\ D')\begin{pmatrix} \prod_{i\neq 0}\prod_{j=2}^N s^i_j \\ \vdots \\ \prod_{i\neq H}\prod_{j=2}^N s^i_j \end{pmatrix}$ *consists of monomials* $c_J \prod_{i=1}^M \prod_{j=2}^N b_{ij}^{J_{ij}}$, *where* $c_J \in \mathbb{R}, 0 \leq J_{ij} \in \mathbb{Z}$ *and* $\{\{\sum_{j=1}^N J_{ij}\}\} = I_i$.

(Proof)
(1) Fix $K_1 \subset \{2,\ldots,M\}$.
Consider the eigenvector ℓ defined by using K_1.
Set $d'_1 = 1$ and $d'_i = \ell_I$ for $I = (1,\ 0,\ \ldots,\ 0,\ \overset{i}{1},\ 0,\ \ldots,\ 0)$, $i \geq 2$.
Since $\ell_I = \prod_{i\in K_1 : I_i = 1}(-1) = \prod_{i:I_i=1} d'_i$ and D is symmetric, we have statement (1).
(2) is obvious.
(3) Since $DD = \begin{pmatrix} 2^{M-1} & \mathbf{1}^t D' \\ \mathbf{1}+D'\mathbf{1} & \mathbf{1}\mathbf{1}^t + D'D' \end{pmatrix} = 2^{M-1}E$, we have $D'D' = 2^{M-1}E' - \mathbf{1}\mathbf{1}^t$ and $D'(D' - \mathbf{1}\mathbf{1}^t) = 2^{M-1}E' - \mathbf{1}\mathbf{1}^t - D'\mathbf{1}\mathbf{1}^t = 2^{M-1}E' - \mathbf{1}\mathbf{1}^t + \mathbf{1}\mathbf{1}^t = 2^{M-1}E'$, where E' is the identity matrix.
(4)

$$2^{M-1}(\tilde{B}_N B^{*0}_N - \tilde{B}^*_N B^0_N) = 2^{M-1}\begin{pmatrix} -\tilde{B}^*_N & B^{*0}_N E \end{pmatrix} B_N$$
$$= \begin{pmatrix} -\tilde{B}^*_N & B^{*0}_N E \end{pmatrix} D \begin{pmatrix} \prod_{j=2}^N s^0_j & 0 & 0 & \cdots & 0 \\ 0 & \prod_{j=2}^N s^1_j & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \cdots & \prod_{j=2}^N s^H_j \end{pmatrix} DB_1$$

$$= (-\tilde{B}^*_N \begin{pmatrix} 1 & \mathbf{1}^t \end{pmatrix} + B^{*0}_N \begin{pmatrix} \mathbf{1} & D' \end{pmatrix})$$
$$\begin{pmatrix} \prod_{j=2}^N s^0_j & 0 & 0 & \cdots & 0 \\ 0 & \prod_{j=2}^N s^1_j & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \cdots & \prod_{j=2}^N s^H_j \end{pmatrix} DB_1$$

$$= (\frac{-\begin{pmatrix} \mathbf{1} & D' \end{pmatrix}}{H+1} \begin{pmatrix} \prod_{j=1}^N s^{*0}_j \\ \prod_{j=1}^N s^{*1}_j \\ \vdots \\ \prod_{j=1}^N s^{*H}_j \end{pmatrix} \begin{pmatrix} 1 & \mathbf{1}^t \end{pmatrix} + B^{*0}_N \begin{pmatrix} \mathbf{1} & D' \end{pmatrix})$$
$$\begin{pmatrix} \prod_{j=2}^N s^0_j & 0 & 0 & \cdots & 0 \\ 0 & \prod_{j=2}^N s^1_j & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \cdots & \prod_{j=2}^N s^H_j \end{pmatrix} DB_1$$

$$= \begin{pmatrix} \mathbf{1} & D' \end{pmatrix} (-\frac{1}{H+1} \begin{pmatrix} \prod_{j=1}^N s^{*0}_j \\ \prod_{j=1}^N s^{*1}_j \\ \vdots \\ \prod_{j=1}^N s^{*H}_j \end{pmatrix} \begin{pmatrix} \prod_{j=2}^N s^0_j & \cdots & \prod_{j=2}^N s^H_j \end{pmatrix}$$
$$+ B^{*0}_N \begin{pmatrix} \prod_{j=2}^N s^0_j & 0 & 0 & \cdots & 0 \\ 0 & \prod_{j=2}^N s^1_j & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \cdots & \prod_{j=2}^N s^H_j \end{pmatrix}) (\begin{pmatrix} 1 \\ \mathbf{1} \end{pmatrix} + \begin{pmatrix} \mathbf{1}^t \\ D' \end{pmatrix} \tilde{B}_1)$$

$$= D' (-T^0 \begin{pmatrix} \prod_{j=1}^N s^{*1}_j - \prod_{j=1}^N s^{*0}_j \\ \vdots \\ \prod_{j=1}^N s^{*H}_j - \prod_{j=1}^N s^{*0}_j \end{pmatrix} + B^{*0}_N \begin{pmatrix} \prod_{j=2}^N s^1_j - \prod_{j=2}^N s^0_j \\ \vdots \\ \prod_{j=2}^N s^H_j - \prod_{j=2}^N s^0_j \end{pmatrix}) + D' S D' \tilde{B}_1,$$

where $T^0 = \frac{\prod_{j=2}^N s^0_j + \cdots + \prod_{j=2}^N s^H_j}{H+1}$.

Also we have $S^{-1}_{i_1 j_1} = (\det S)^{-1} \times$

$$\begin{cases} \frac{(B^{*0}_N)^{H-2}}{H+1} \sum_{i_2=0, i_2 \neq i_1}^H (\prod_{j=1}^N s^{*i_1}_j + H \prod_{j=1}^N s^{*i_2}_j) \prod_{0 \leq i \leq H, i \neq i_1, i_2} \prod_{j=2}^N s^i_j, & \text{if } i_1 = j_1, \\ \frac{(B^{*0}_N)^{H-2}}{H+1} \sum_{0 \leq i_2 \leq H, i_2 \neq i_1, j_1} (\prod_{j=1}^N s^{*i_1}_j - \prod_{j=1}^N s^{*i_2}_j) \prod_{0 \leq i \leq H, i \neq i_1, i_2} \prod_{j=2}^N s^i_j & \\ -\frac{(B^{*0}_N)^{H-2}}{H+1} (H \prod_{j=1}^N s^{*i_1}_j + \prod_{j=1}^N s^{*j_1}_j) \prod_{0 \leq i \leq H, i \neq i_1, j_1} \prod_{j=2}^N s^i_j, & \text{if } i_1 \neq j_1 \end{cases}$$

and $\det S = (B^{*0}_N)^{H-1} \sum_{i_2=0}^H \prod_{j=1}^N s^{*i_2}_j \prod_{i \neq i_2} \prod_{j=2}^N s^i_j$.

Let $\mathbf{s} = \begin{pmatrix} \prod_{j=1}^N s^{*0}_j \prod_{i \neq 0} \prod_{j=2}^N s^i_j \\ \vdots \\ \prod_{j=1}^N s^{*H}_j \prod_{i \neq H} \prod_{j=2}^N s^i_j \end{pmatrix}$ and $\tilde{\mathbf{s}} = \begin{pmatrix} \prod_{j=1}^N s^{*1}_j \prod_{i \neq 1} \prod_{j=2}^N s^i_j \\ \vdots \\ \prod_{j=1}^N s^{*H}_j \prod_{i \neq H} \prod_{j=2}^N s^i_j \end{pmatrix}$.

Since $(\det S) S^{-1} (-T^0 \begin{pmatrix} \prod_{j=1}^N s^{*1}_j - \prod_{j=1}^N s^{*0}_j \\ \vdots \\ \prod_{j=1}^N s^{*H}_j - \prod_{j=1}^N s^{*0}_j \end{pmatrix} + B^{*0}_N \begin{pmatrix} \prod_{j=2}^N s^1_j - \prod_{j=2}^N s^0_j \\ \vdots \\ \prod_{j=2}^N s^H_j - \prod_{j=2}^N s^0_j \end{pmatrix})$

$$= (B^{*0}_N)^{H-1} \{ \sum_{i_2=0}^H \prod_{j=1}^N s^{*i_2}_j \prod_{i \neq i_2} \prod_{j=2}^N s^i_j \mathbf{1} - (H+1) \begin{pmatrix} \prod_{j=1}^N s^{*1}_j \prod_{i \neq 1} \prod_{j=2}^N s^i_j \\ \vdots \\ \prod_{j=1}^N s^{*H}_j \prod_{i \neq H} \prod_{j=2}^N s^i_j \end{pmatrix} \},$$

we have

$$\begin{aligned} & D'^{-1} S^{-1} D'^{-1} 2^{M-1} (\tilde{B}_N B^{*0}_N - \tilde{B}^*_N B^0_N) \\ &= (\det S) \tilde{B}_1 - (B^{*0}_N)^{H-1} \sum_{i_2=0}^H \prod_{j=1}^N s^{*i_2}_j \prod_{i \neq i_2} \prod_{j=2}^N s^i_j \mathbf{1} - (H+1)(B^{*0}_N)^{H-1} D'^{-1} \tilde{\mathbf{s}} \\ &= (\det S) \tilde{B}_1 - (B^{*0}_N)^{H-1} \sum_{i_2=0}^H \prod_{j=1}^N s^{*i_2}_j \prod_{i \neq i_2} \prod_{j=2}^N s^i_j \mathbf{1} - (B^{*0}_N)^{H-1} (D' - \mathbf{1}\mathbf{1}^t) \tilde{\mathbf{s}} \\ &= (\det S) \tilde{B}_1 - (B^{*0}_N)^{H-1} \prod_{j=1}^N s^{*0}_j \prod_{i \neq 0} \prod_{j=2}^N s^i_j \mathbf{1} - (B^{*0}_N)^{H-1} D' \tilde{\mathbf{s}} \\ &= (\det S) \tilde{B}_1 - (B^{*0}_N)^{H-1} (\mathbf{1}, D') \mathbf{s}, \end{aligned}$$

by using (3).
(5) Since $b_j^{\{\{I+K\}\}} = \sum_{J\in I} D^{I,J} s_j^J D^{J,K}/2^{M-1}$, we have for $I' \in I$,

$$\begin{aligned}
&\sum_{J\in I} D^{I,J} s_j^{\{\{J+I'\}\}} D^{J,K} = D^{I,I'} D^{I',K} \sum_{J\in I} D^{I,\{\{J+I'\}\}} s_j^{\{\{J+I'\}\}} D^{\{\{J+I'\}\},K} \\
= \;& 2^{M-1} D^{I,I'} D^{I',K} b_j^{\{\{I+K\}\}},
\end{aligned}$$

by using (1).

Let $I_0 = (0,\ldots,0), I_1 = (1,1,0,\ldots,0), I_2 = (1,0,1,0,\ldots,0),\ldots$.

The fact that

$$\begin{aligned}
& D \begin{pmatrix} \prod_{i\neq 0}\prod_{j=2}^N s_j^i \\ \prod_{i\neq 1}\prod_{j=2}^N s_j^i \\ \vdots \\ \prod_{i\neq H}\prod_{j=2}^N s_j^i \end{pmatrix} \\
= \;& -D \begin{pmatrix} \prod_{i\neq 0}\prod_{j=2}^N s_j^i & 0 & 0 & \cdots & 0 \\ 0 & \prod_{i\neq 1}\prod_{j=2}^N s_j^i & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & \prod_{i\neq H}\prod_{j=2}^N s_j^i \end{pmatrix} D^{-1} 2^{M-1} \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix} \\
= \;& -\left\{ \prod_{j=2}^N \prod_{0\neq I'\in I} D \begin{pmatrix} s_j^{\{\{I_0+I'\}\}} & 0 & 0 & \cdots & 0 \\ 0 & s_j^{\{\{I_1+I'\}\}} & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & s_j^{\{\{I_H+I'\}\}} \end{pmatrix} D^{-1} \right\} 2^{M-1} \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix},
\end{aligned}$$

and $\sum_{J\in I} D^{I,J} s_j^{\{\{J+I'\}\}} D^{J,K} = 2^{M-1} D^{I,I'} D^{I',K} b_j^{\{\{I+K\}\}}$ yields statement (5).

Q.E.D.

Proof of Theorem 2

By Theorem 9 (4) and Lemma 6, we only need to consider the maximum pole of $J(z) = \int \|\Psi'\|^{2z} \mathrm{d}b$, where $\Psi' = (\det S)\tilde{B}_1 - (B^{*0}_N)^{H-1}(\mathbf{1}\ D') \begin{pmatrix} \prod_{j=1}^N s^{*0}_j \prod_{i\neq 0}\prod_{j=2}^N s_j^i \\ \vdots \\ \prod_{j=1}^N s^{*H}_j \prod_{i\neq H}\prod_{j=2}^N s_j^i \end{pmatrix}$.

(Case 1): The fact that $B^{11} = \sum_{k=1}^N b_{1k}b_{2k} + \cdots$ provides Case 1.

(Case 2): Assume that $M = 3$.

We have $D' = \begin{pmatrix} 1 & -1 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & 1 \end{pmatrix}$, $\begin{cases} s_j^0 = 1 + b_{1j}b_{2j} + b_{1j}b_{3j} + b_{2j}b_{3j}, \\ s_j^1 = 1 + b_{1j}b_{2j} - b_{1j}b_{3j} - b_{2j}b_{3j}, \\ s_j^2 = 1 - b_{1j}b_{2j} + b_{1j}b_{3j} - b_{2j}b_{3j}, \\ s_j^3 = 1 - b_{1j}b_{2j} - b_{1j}b_{3j} + b_{2j}b_{3j}, \end{cases}$

and $\Psi' = (\det S) \begin{pmatrix} b_{11}b_{21} \\ b_{11}b_{31} \\ b_{21}b_{31} \end{pmatrix} - \prod_{i=0}^3 \prod_{j=2}^N s_j^i (B^{*0}_N)^2 (1, D') \begin{pmatrix} \prod_{j=1}^N s^{*0}_j / \prod_{j=2}^N s_j^0 \\ \prod_{j=1}^N s^{*1}_j / \prod_{j=2}^N s_j^1 \\ \prod_{j=1}^N s^{*2}_j / \prod_{j=2}^N s_j^2 \\ \prod_{j=1}^N s^{*3}_j / \prod_{j=2}^N s_j^3 \end{pmatrix}$.

Let $N=1$. The fact that $\Psi' = 4(B^{*0}_N)^2\tilde{B}_1 - 4(B^{*0}_N)^2 \begin{pmatrix} b^*_{11}b^*_{21} \\ b^*_{11}b^*_{31} \\ b^*_{21}b^*_{31} \end{pmatrix}$ yields the statement for $N=1$.

Assume that $N \geq 2$, $b^* \neq 0$ and $b^*_{11} \neq 0, b^*_{21} \neq 0, b^*_{31} \neq 0$. Set $b'_{21} = b_{11}b_{21}$, $b'_{31} = b_{11}b_{31}$ and $b'_{11} = b_{21}b_{31} = b'_{21}b'_{31}/b^2_{11}$. Then

$$\Psi' = (\det S)\begin{pmatrix} b'_{21} \\ b'_{31} \\ b'_{11} \end{pmatrix} - \prod_{i=0}^{3}\prod_{j=2}^{N} s^i_j (B^{*0}_N)^2 (\mathbf{1}, D') \begin{pmatrix} \prod_{j=1}^N s^{*0}_j / \prod_{j=2}^N s^0_j \\ \prod_{j=1}^N s^{*1}_j / \prod_{j=2}^N s^1_j \\ \prod_{j=1}^N s^{*2}_j / \prod_{j=2}^N s^2_j \\ \prod_{j=1}^N s^{*3}_j / \prod_{j=2}^N s^3_j \end{pmatrix}$$

and its maximum pole is $3/2$ and its order is 1.

Assume that $N \geq 2$, $b^* \neq 0$, $b^*_{11} \neq 0$ and $\prod_{i=1}^3 b^*_{ij} = 0$ for all j. Let $\psi = \begin{pmatrix} \psi_1 \\ \psi_2 \\ \psi_3 \end{pmatrix} = (\mathbf{1}, D') \begin{pmatrix} \prod_{j=1}^N s^{*0}_j / \prod_{j=2}^N s^0_j \\ \prod_{j=1}^N s^{*1}_j / \prod_{j=2}^N s^1_j \\ \prod_{j=1}^N s^{*2}_j / \prod_{j=2}^N s^2_j \\ \prod_{j=1}^N s^{*3}_j / \prod_{j=2}^N s^3_j \end{pmatrix}$. By setting $\begin{pmatrix} b'_{21} \\ b'_{31} \end{pmatrix} = (\det S)\begin{pmatrix} b_{11}b_{21} \\ b_{11}b_{31} \end{pmatrix}$

$$-\prod_{i=0}^3 \prod_{j=2}^N s^i_j (B^{*0}_N)^2 \begin{pmatrix} 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \end{pmatrix} \begin{pmatrix} \prod_{j=1}^N s^{*0}_j / \prod_{j=2}^N s^0_j \\ \prod_{j=1}^N s^{*1}_j / \prod_{j=2}^N s^1_j \\ \prod_{j=1}^N s^{*2}_j / \prod_{j=2}^N s^2_j \\ \prod_{j=1}^N s^{*3}_j / \prod_{j=2}^N s^3_j \end{pmatrix} \text{ and}$$

$$\Psi'' = \begin{pmatrix} \Psi''_1 \\ \Psi''_2 \\ \Psi''_3 \end{pmatrix} = \begin{pmatrix} b'_{21} \\ b'_{31} \\ \frac{(\prod_{i=0}^3 \prod_{j=2}^N s^i_j (B^{*0}_N)^2)^2 \psi_1 \psi_2}{b^2_{11} \det S} - (B^{*0}_N)^2 \prod_{i=0}^3 \prod_{j=2}^N s^i_j \psi_3 \end{pmatrix},$$

and by using Lemma 6, we need the maximum pole of $\int \|\Psi''\|^{2z} db$. Ψ'' is singular in the following cases: (i) $b^*_{11}b^*_{21} = b^*_{2j} = b^*_{3j} = 0$ for all j, (ii) $b^*_{11}b^*_{21} \neq 0$, $b^*_{1j} = b^*_{2j} = b^*_{3j} = 0$ for all j, since we have $\frac{\partial \psi}{\partial b_j}|_{b^*}$

$$= -(\mathbf{1}, D') \begin{pmatrix} s^{*0}_1/s^{*0}_j & 0 & 0 & 0 \\ 0 & s^{*1}_1/s^{*1}_j & 0 & 0 \\ 0 & 0 & s^{*2}_1/s^{*2}_j & 0 \\ 0 & 0 & 0 & s^{*3}_1/s^{*3}_j \end{pmatrix} \begin{pmatrix} b^*_{2j}+b^*_{3j} & b^*_{1j}+b^*_{3j} & b^*_{1j}+b^*_{2j} \\ b^*_{2j}-b^*_{3j} & b^*_{1j}-b^*_{3j} & -b^*_{1j}-b^*_{2j} \\ -b^*_{2j}+b^*_{3j} & -b^*_{1j}-b^*_{3j} & b^*_{1j}-b^*_{2j} \\ -b^*_{2j}-b^*_{3j} & -b^*_{1j}+b^*_{3j} & -b^*_{1j}+b^*_{2j} \end{pmatrix}.$$ If

Ψ'' is not singular, its maximum pole is $3/2$ and its order is 1. Assume that Ψ'' is singular that is, (i) $b^*_{11}b^*_{21} = b^*_{2j} = b^*_{3j} = 0$ for all j and (ii) $b^*_{11}b^*_{21} \neq 0, b^*_{1j} = b^*_{2j} = b^*_{3j} = 0$ for all j. Construct the blow-up of Ψ'' along the submanifold $\{b_{3j} = 0, 2 \leq j \leq N\}$. Let $b_{32} = u$ and $b_{3j} = ub'_{3j}$ for $j \geq 2$. In the case (i), the coefficient of b_{2j_0} is around $4ub_{1j_0}\sum_{j=2}^N b_{1j}b'_{3j}(1/b^2_{11} - 1) + 4ub'_{3j_0}(1 - b^2_{1j_0})$, since $\prod_{i\neq 0}\prod_{j=2}^N s^i_j \cong \prod_{j=2}^N (1 - b_{1j}b_{2j} - ub_{1j}b'_{3j} - ub_{2j}b'_{3j} + 2ub^2_{1j}b_{2j}b'_{3j}) \cong 1 + \sum_{j=2}^N (-b_{1j}b_{2j} - ub_{1j}b'_{3j} - ub_{2j}b'_{3j} + 2ub^2_{1j}b_{2j}b'_{3j}) + \sum_{j\neq j'} ub_{1j}b_{1j'}b_{2j}b'_{3j'}$, $\prod_{i=0}\prod_{j=2}^N s^i_j \psi_1 \cong -4\sum_{j=2}^N b_{1j}b_{2j}$, $\prod_{i=0}\prod_{j=2}^N s^i_j \psi_2 \cong -4u\sum_{j=2}^N b_{1j}b'_{3j}$, and $\prod_{i=0}\prod_{j=2}^N s^i_j \psi_3 \cong 4\sum_{j=2}^N (-ub_{2j}b'_{3j} + 2ub^2_{1j}b_{2j}b'_{3j}) + 4\sum_{j\neq j'} ub_{1j}b_{1j'}b_{2j}b'_{3j'}$. If $4ub_{1j_0}\sum_{j=2}^N b_{1j}b'_{3j}(1/b^2_{11} - 1) +$

$4ub'_{3j_0}(1-b_{1j_0}^2)=0$ for all j_0 then $b'_{3j_0}=0$ for all j_0 since $|b_{1j}|<1$. It contradicts $b'_{32}=1$. So $(\frac{(\prod_{i=0}^{3}\prod_{j=2}^{N}s_j^i(B^{*0}_N)^2)^2\psi_1\psi_2}{b_{11}^2\det S}-(B^{*0}_N)^2\prod_{i=0}^{3}\prod_{j=2}^{N}s_j^i\psi_3)/u$ is smooth.

In the case (ii), the coefficient b_{2j_0} is around $4u(1-{b^*_{21}}^2)b'_{3j_0}$ since ${s^*}^0_1\prod_{i\neq 0}\prod_{j=2}^{N}s_j^i\cong 4(1+b^*_{11}b^*_{21})\prod_{j=2}^{N}(1-ub_{2j}b'_{3j})\cong 4(1+b^*_{11}b^*_{21})(1-u\sum_{j=2}^{N}b_{2j}b'_{3j})$, $(1+b^*_{11}b^*_{21})\prod_{i=0}\prod_{j=2}^{N}s_j^i\psi_1\cong 4b^*_{11}b^*_{21}$, $\prod_{i=0}\prod_{j=2}^{N}s_j^i\psi_2\cong -4ub^*_{11}b^*_{21}\sum_{j=2}^{N}b_{2j}b'_{3j}$, and $\prod_{i=0}\prod_{j=2}^{N}s_j^i\psi_3\cong -4u\sum_{j=2}^{N}b_{2j}b'_{3j}$. So $(\frac{(\prod_{i=0}^{3}\prod_{j=2}^{N}s_j^i(B^{*0}_N)^2)^2\psi_1\psi_2}{b_{11}^2\det S}-(B^{*0}_N)^2\prod_{i=0}^{3}\prod_{j=2}^{N}s_j^i\psi_3)/u$ is smooth.

We have $\Psi''=\begin{pmatrix} b'_{21}\\ b'_{31}\\ ub'_{22}\end{pmatrix}$, for a variable b'_{22} for both cases (i) and (ii) and we have the statement for $N\geq 2$, $b^*\neq 0$, $b^*_{11}\neq 0$ and $\prod_{i=1}^{3}b^*_{ij}=0$ for all j.

Let $N\geq 2$ and $b^*=0$.

Construct the blow-up of Ψ' along the submanifold $\{b_{ij}=0, 1\leq i\leq M, 1\leq j\leq N\}$.

Let $b_{11}=u$ and $b_{ij}=ub'_{ij}$ for $(i,j)\neq(1,1)$.

We have $\Psi''=u^2(\det S)\begin{pmatrix} b'_{21}\\ b'_{31}\\ b'_{21}b'_{31}\end{pmatrix}+4u^2\begin{pmatrix} \sum_{k=2}^{N}b'_{1k}b'_{2k}+u^2f_1\\ \sum_{k=2}^{N}b'_{1k}b'_{3k}+u^2f_2\\ \sum_{k=2}^{N}b'_{2k}b'_{3k}+u^2f_3\end{pmatrix}$, where f_1, f_2 and f_3 are polynomials of b'_{ij} of at least degree two.

By setting $\begin{pmatrix} b''_{21}\\ b''_{31}\end{pmatrix}=\begin{pmatrix} b'_{21}\\ b'_{31}\end{pmatrix}+4\begin{pmatrix} \sum_{k=2}^{N}b'_{1k}b'_{2k}+u^2f_1\\ \sum_{k=2}^{N}b'_{1k}b'_{3k}+u^2f_2\end{pmatrix}/(\det S)$, we have

$$\begin{aligned}\Psi''=&\frac{u^2}{\det S}\\ &\times\begin{pmatrix} (\det S)^2b''_{21}\\ (\det S)^2b''_{31}\\ (b''_{21}\det S-4\sum_{k=2}^{N}b'_{1k}b'_{2k}-4u^2f_1)(b''_{31}\det S-4\sum_{k=2}^{N}b'_{1k}b'_{3k}-4u^2f_2)\end{pmatrix}\\ &+u^2\begin{pmatrix} 0\\ 0\\ 4\sum_{k=2}^{N}b'_{2k}b'_{3k}+4u^2f_3\end{pmatrix}.\end{aligned}$$

By using Lemma 6 again, the maximum pole of $\int\|\Psi''\|^{2z}u^{3N}db$ is that of $J(z)=\int\|\Psi'''\|^{2z}u^{3N}\mathrm{d}b$, where $\Psi'''=u^2\begin{pmatrix} b''_{21}\\ b''_{31}\\ g_1\end{pmatrix}$, and

$$g_1=(\sum_{k=2}^{N}b'_{1k}b'_{2k}+u^2f_1)(\sum_{k=2}^{N}b'_{1k}b'_{3k}+u^2f_2)+\frac{\det S}{4}(\sum_{k=2}^{N}b'_{2k}b'_{3k}+u^2f_3).$$

Construct the blow-up of Ψ''' along the submanifold $\{b''_{21}=0, b''_{31}=0, b'_{3k}=0, 2\leq k\leq N\}$. Then we have cases (I) and (II).

(I) Let $b'_{32}=v$, $b''_{21}=vb'''_{21}$, $b''_{31}=vb'''_{21}$ and $b'_{3k}=vb''_{3k}$ for $3\leq k\leq N$. Then $\Psi'''=u^2v\begin{pmatrix} b'''_{21}\\ b'''_{31}\\ g'_1\end{pmatrix}$, where $g'_1=(\sum_{k=2}^{N}b'_{1k}b'_{2k}+u^2f_1)(b'_{12}+\sum_{k=3}^{N}b'_{1k}b''_{3k}+u^2f_2/v)+\frac{\det S}{4}(b'_{22}+\sum_{k=3}^{N}b'_{2k}b''_{3k}+u^2f_3/v)$.

By Theorem 9 (5), we can set $f_2 = vf_2'$ and $f_3 = vf_3'$, where f_2' and f_3' are polynomials.
We have

$$(\sum_{k=2}^{N} b'_{1k}b'_{2k})(b'_{12}+\sum_{k=3}^{N} b'_{1k}b''_{3k})+\frac{\det S}{4}(b'_{22}+\sum_{k=3}^{N} b'_{2k}b''_{3k})$$

$$=(b'_{2,2},b'_{2,3},\cdots,b'_{2,N})\left(\begin{pmatrix} b'_{1,2}\\ b'_{1,3}\\ \vdots\\ b'_{1,N}\end{pmatrix}(b'_{1,2},b'_{1,3},\cdots,b'_{1,N})+\frac{\det S}{4}E\right)\begin{pmatrix} 1\\ b''_{3,3}\\ \vdots\\ b''_{3,N}\end{pmatrix}.$$

Since $\begin{pmatrix} b'_{1,2}\\ b'_{1,3}\\ \vdots\\ b'_{1,N}\end{pmatrix}(b'_{1,2},b'_{1,3},\cdots,b'_{1,N})+\frac{\det S}{4}E$ is regular, we can change variables from $(b'_{2,2},b'_{2,3},\cdots,b'_{2,N})$ to $(b''_{2,2},b''_{2,3},\cdots,b''_{2,N})$ by

$$(b''_{2,2},b''_{2,3},\cdots,b''_{2,N})=(b'_{2,2},b'_{2,3},\cdots,b'_{2,N})\left(\begin{pmatrix} b'_{1,2}\\ b'_{1,3}\\ \vdots\\ b'_{1,N}\end{pmatrix}(b'_{1,2},b'_{1,3},\cdots,b'_{1,N})+\frac{\det S}{4}E\right).$$

Moreover, let $b'''_{22}=b''_{2,2}+b''_{2,3}b''_{3,3}+\cdots+b''_{2,N}b''_{3,N}$.

Then, we have

$$\Psi''' = u^2 v\begin{pmatrix} b'''_{21}\\ b'''_{31}\\ b'''_{22}+u^2 f_4\end{pmatrix},$$

where f_4 is a polynomial. Therefore, we have the poles $-\frac{3N}{4}, -\frac{N+1}{2}$ and $-\frac{3}{2}$.
(II) Let $b''_{21}=v$, $b''_{31}=vb'''_{21}$ and $b'_{3k}=vb''_{3k}$ for $2\le k\le N$. Then we have the poles $-\frac{3N}{4}$ and $-\frac{N+1}{2}$.
Q.E.D.

Appendix C.

Definition 10 *(1) Let $R=(r_{ij})$ be an $H\times H'$ matrix, I an element of $\{0,1\}^H$, and $f(R,r')$ an analytic function of $r_{11},r_{21},\ldots,r_{HH'},r'_1,\ldots,r'_k$, where $r'=(r'_1,\ldots,r'_k)$. $f(R,r')$ is an I-type function of $(r_{ij})_{i'\le i\le H,1\le j\le H'}$, if for any $I_{i_0}=1$ with $i_0\ge i'$,*

$$f(r_{11},\cdots,r_{1N},r_{21},\cdots,r_{i_0-1,N},ur_{i_0,1},\cdots,ur_{i_0,N},r_{i_0+1,1},\cdots,r_{M,N},r')/u,$$

is an analytic function of u, where u is a variable.
(2) Let $I,I'\in\{0,1\}^H$. We denote $I\le I'$ if $I_i\le I'_i$ for all $i=1,\ldots,H$, and denote $I<I'$ if $I\le I'$ and $I\ne I'$.

For example, $B^I = B^I_N$ is an I'-type function of B for all $I' \le I$ ($I' \in \{0,1\}^M$).

Let $I_{ij} = (0, \ldots, 0, \overset{i}{1}, 0, \ldots, 0, \overset{j}{1}, 0, \ldots, 0)$, for $i < j$.

Proof of Theorem 3

Assume that $a^* = 0$.

Let $B'^{I_{ij}} = B^{I_{ij}} - \sum_{k=1}^N b_{ik} b_{jk}$, which is a polynomial of at least degree four.

For $I \in I$, let $I^{(s)} \in \{0,1\}^M$ be $I^{(s)}_i = \begin{cases} 0, & \text{if } i \le s, \\ I_i, & \text{if } i > s. \end{cases}$

We set $I' = I - \{I_{ij} : 1 \le i < j \le M\}$.

By using a blowing up process together with an inductive method of s, we have functions (5) and (6) below.

$$\int \{ \sum_{1 \le i < j \le M} (B^{I_{ij}}_{(s)})^2 + \sum_{I \in I'} (B^I_{(s)})^2 \}^z \\ u_1^{MN-1} u_2^{(M-1)N-1} \cdots u_s^{(M-s+1)N-1} \prod_{i=1}^s v_i^{N-i-1} \mathrm{d}u \mathrm{d}b^{(s)} \mathrm{d}v, \tag{5}$$

where

$$B^{I_{ij}}_{(s)} = \begin{cases} u_1^2 u_2^2 \cdots u_i^2 u_{i+1} \cdots u_j \{ f^{(s)}_{ij} + b^{(s)}_{ji} + u_1^2 B'^{I_{ij}}_{(s)} \}, & i < j \le s, \\ u_1^2 u_2^2 \cdots u_i^2 u_{i+1} \cdots u_s \{ f^{(s)}_{ij} + b^{(s)}_{ji} + u_1^2 B'^{I_{ij}}_{(s)} \}, & i \le s < j, \\ u_1^2 u_2^2 \cdots u_s^2 \{ f^{(s)}_{ij} + \sum_{k=s+1}^N b^{(s)}_{ik} b^{(s)}_{jk} + u_1^2 B'^{I_{ij}}_{(s)} \}, & s < i < j, \end{cases}$$

$$B^I_{(s)} = \prod_{k=1}^s u_k^{\sum_{k'=k}^M I_i} B'^I_{(s)}, \text{ for } I \in I',$$

$f^{(s)}_{ij}$ is an $I^{(s)}_{ij}$-type function of $(b^{(s)}_{kl})_{s+1 \le k \le M, 1 \le l \le N}$,

$$f^{(s)}_{ij}|_{b^{(s)}_{i1} = \cdots = b^{(s)}_{i,\min\{i-1,s\}} = b^{(s)}_{j1} = \cdots = b^{(s)}_{j,\min\{i-1,s\}} = 0} = 0,$$

$B'^{I_{ij}}_{(s)}$ is an $I^{(s)}_{ij}$-type function of $(b^{(s)}_{kl})_{s+1 \le k \le M, 1 \le l \le N}$, and $B'^I_{(s)}$ ($I \in I'$) is an $I^{(s)}$-type function of $(b^{(s)}_{kl})_{s+1 \le k \le M, 1 \le l \le N}$.

For $s+1 \le \ell \le M$ and $1 \le \ell' \le s$,

$$\int \{ \sum_{\{i<j\le s\} \cup \{i \le s < j, i < \ell'\} \cup \{i = \ell', j = \ell\}} (B^{I_{ij}}_{(s)})^2 \}^z u_1^{MN-1} u_2^{(M-1)N-1} \cdots u_s^{(M-s+1)N-1} u_{s+1}^{(M-s)N-1} \mathrm{d}u \mathrm{d}\tilde{b}, \tag{6}$$

where

$$B^{I_{ij}}_{(s)} = \begin{cases} u_1^2 u_2^2 \cdots u_i^2 u_{i+1} \cdots u_j \tilde{b}_{ji}, & \text{if } i < j \le s, \\ u_1^2 u_2^2 \cdots u_i^2 u_{i+1} \cdots u_{s+1} \tilde{b}_{ji}, & \text{if } i \le s < j, i < \ell', \\ u_1^2 u_2^2 \cdots u_{\ell'}^2 u_{\ell'+1} \cdots u_{s+1}, & \text{if } i = \ell', j = \ell. \end{cases}$$

C.1 Step 1

Construct the blow-up of function (3) along the submanifold $\{b_{ij}=0, 1\leq i\leq M, 1\leq j\leq N\}$.

Let $b_{11}=u_1, b_{ij}=u_1 b'_{ij}, (i,j)\neq(1,1)$.

Then we have $B^{I_{1j}}=u_1^2(b'_{j1}+\sum_{k=2}^N b'_{1k}b'_{jk}+B'^{I_{1j}}/u_1^2)$ for $j\geq 2$ and $B^{I_{ij}}=u_1^2(\sum_{k=1}^N b'_{ik}b'_{jk}+B'^{I_{ij}}/u_1^2)$ for $2\leq i<j$.

Let $b''_{j1}=b'_{j1}+\sum_{k=2}^N b'_{1k}b'_{jk}$ for $j\geq 2$.

Then for $2\leq i<j$,

$$
\begin{aligned}
&\sum_{k=1}^N b'_{ik}b'_{jk}=(b''_{i1}-\sum_{k=2}^N b'_{1k}b'_{ik})(b''_{j1}-\sum_{k=2}^N b'_{1k}b'_{jk})+\sum_{k=2}^N b'_{ik}b'_{jk}\\
=\;& b''_{i1}(b''_{j1}-\sum_{k=2}^N b'_{1k}b'_{jk})-(\sum_{k=2}^N b'_{1k}b'_{ik})b''_{j1}+(\sum_{k=2}^N b'_{1k}b'_{ik})(\sum_{k=2}^N b'_{1k}b'_{jk})+\sum_{k=2}^N b'_{ik}b'_{jk}\\
=\;& f_{ij}^{(1)}+(b'_{i2},\ldots,b'_{iN})\begin{pmatrix} b'_{12}\\ b'_{13}\\ \vdots\\ b'_{1N}\end{pmatrix}(b'_{12},\ldots,b'_{1N})\begin{pmatrix} b'_{j2}\\ b'_{j3}\\ \vdots\\ b'_{jN}\end{pmatrix}\\
&+(b'_{i2},\ldots,b'_{iN})\begin{pmatrix} b'_{j2}\\ b'_{j3}\\ \vdots\\ b'_{jN}\end{pmatrix},
\end{aligned}
$$

where $f_{ij}^{(1)}=b''_{i1}(b''_{j1}-\sum_{k=2}^N b'_{1k}b'_{jk})-(\sum_{k=2}^N b'_{1k}b'_{ik})b''_{j1}$ is an $I_{ij}^{(1)}$-type function of $\begin{pmatrix} b''_{21} & b'_{22} & \cdots & b'_{2N}\\ b''_{31} & b'_{32} & \cdots & b'_{3N}\\ \vdots & \vdots & \vdots & \vdots\\ b''_{M1} & b'_{M2} & \cdots & b'_{MN}\end{pmatrix}$ with $f_{ij}^{(1)}|_{b''_{i1}=b''_{j1}=0}=0$.

Next, construct the blow-up along the submanifold $\{b'_{12}=b'_{13}=\cdots=b'_{1N}=0\}$.

Let $b'_{12}=v_1, b'_{13}=v_1 b''_{13}, \cdots, b'_{1N}=v_1 b''_{1N}$.

Then we have, for $2\leq i<j$,

$$
\begin{aligned}
&(b'_{i2},\ldots,b'_{iN})\begin{pmatrix} b'_{12}\\ b'_{13}\\ \vdots\\ b'_{1N}\end{pmatrix}(b'_{12},\ldots,b'_{1N})\begin{pmatrix} b'_{j2}\\ b'_{j3}\\ \vdots\\ b'_{jN}\end{pmatrix}+(b'_{i2},\ldots,b'_{iN})\begin{pmatrix} b'_{j2}\\ b'_{j3}\\ \vdots\\ b'_{jN}\end{pmatrix}\\
=\;&(b'_{i2},\ldots,b'_{iN})\left(v_1^2\begin{pmatrix} 1\\ b''_{13}\\ \vdots\\ b''_{1N}\end{pmatrix}(1,b''_{13},\cdots,b''_{1N})+\begin{pmatrix} 1 & 0 & \cdots & 0\\ 0 & 1 & \cdots & 0\\ \vdots & \vdots & \vdots & \vdots\\ 0 & 0 & \cdots & 1\end{pmatrix}\right)\begin{pmatrix} b'_{j2}\\ b'_{j3}\\ \vdots\\ b'_{jN}\end{pmatrix}.
\end{aligned}
$$

Let $Q_i = \sqrt{1+b''^2_{13}+\cdots+b''^2_{1i}}$ and

$$G = \begin{pmatrix} \frac{1}{Q_N} & \frac{-b''_{13}}{Q_3} & \cdots & \frac{-b''_{1i}}{Q_{i-1}Q_i} & \cdots & \frac{-b''_{1N}}{Q_{N-1}Q_N} \\ \frac{b''_{13}}{Q_N} & \frac{1}{Q_3} & \cdots & \frac{-b''_{13}b''_{1i}}{Q_{i-1}Q_i} & \cdots & \frac{-b''_{13}b''_{1N}}{Q_{N-1}Q_N} \\ \frac{b''_{14}}{Q_N} & 0 & \cdots & \frac{-b''_{14}b''_{1i}}{Q_{i-1}Q_i} & \cdots & \frac{-b''_{14}b''_{1N}}{Q_{N-1}Q_N} \\ \vdots & \vdots & & \vdots & & \vdots \\ & & & \frac{-b''_{1,i-1}b''_{1i}}{Q_{i-1}Q_i} & & \\ & & & \frac{Q_{i-1}}{Q_i} & & \\ & & & 0 & & \\ \vdots & \vdots & \cdots & \vdots & \cdots & \vdots \\ \frac{b''_{1N}}{Q_N} & 0 & \cdots & 0 & \cdots & \frac{Q_{N-1}}{Q_N} \end{pmatrix}.$$

Then we have

$$\begin{aligned} & v_1^2 \begin{pmatrix} 1 \\ b''_{13} \\ \vdots \\ b''_{1N} \end{pmatrix} (1, b''_{13}, \cdots, b''_{1N}) + \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 \end{pmatrix} \\ = \; & v_1^2 G \begin{pmatrix} 1+b''^2_{13}+\cdots+b''^2_{1N} & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & 0 \end{pmatrix} G^t + \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 \end{pmatrix} \\ = \; & G \left(v_1^2 \begin{pmatrix} 1+b''^2_{13}+\cdots+b''^2_{1N} & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & 0 \end{pmatrix} + \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 \end{pmatrix} \right) G^t \\ = \; & G \begin{pmatrix} 1+v_1^2(1+b''^2_{13}+\cdots+b''^2_{1N}) & 0 & \cdots & 0 \\ 0 & 1 & 0\cdots & 0 \\ \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & 1 \end{pmatrix} G^t. \end{aligned}$$

Therefore, we can change the variables from $(b'_{i2}, b'_{i3}, \cdots, b'_{iN})$ to $(b''_{i2}, b''_{i3}, \cdots, b''_{iN})$ by

$$\begin{pmatrix} b''_{i2} \\ b''_{i3} \\ \vdots \\ b''_{iN} \end{pmatrix} = \begin{pmatrix} \sqrt{1+v_1^2(1+b''^2_{13}+\cdots+b''^2_{1N})} & 0 & \cdots & 0 \\ 0 & 1 & 0\cdots & 0 \\ \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & 1 \end{pmatrix} G^t \begin{pmatrix} b'_{i2} \\ b'_{i3} \\ \vdots \\ b'_{iN} \end{pmatrix}.$$

We have

$$(b'_{i2},b'_{i3},\cdots,b'_{iN})\left(v_1^2\begin{pmatrix}1\\ b'_{13}\\ \vdots\\ b'_{1N}\end{pmatrix}(1,b'_{13},\cdots,b'_{1N})+\begin{pmatrix}1&0&\cdots&0\\ 0&1&\cdots&0\\ \vdots&\vdots&\vdots&\vdots\\ 0&0&\cdots&1\end{pmatrix}\right)\begin{pmatrix}b'_{j2}\\ b'_{j3}\\ \vdots\\ b'_{jN}\end{pmatrix}$$
$$= \sum_{k=2}^{N} b''_{ik}b''_{jk}.$$

Let $b^{(1)}_{ik} = b''_{ik}$ for $1 \le i \le M, 1 \le k \le N$ and $(i,k) \ne (1,1)$, $B^{\prime I_{ij}}_{(1)} = B^{\prime I_{ij}}/u_1^4$ for $1 \le i < j \le M$ and $B^{I}_{(1)} = B^{I}/u_1^{\sum_{k=1}^{M} I_i}$ for $I \in I'$.

We have $B^{I_{1j}} = u_1^2(b^{(1)}_{j1} + u_1^2 B^{\prime I_{1j}}_{(1)})$ for $1 < j$, $B^{I_{ij}} = u_1^2(f^{(1)}_{ij} + \sum_{k=2}^{N} b^{(1)}_{ik}b^{(1)}_{jk} + u_1^2 B^{\prime I_{ij}}_{(1)})$ for $1 < i < j$ and $B^{I} = u_1^{\sum_{k=1}^{M} I_i} B^{I}_{(1)}$ for $I \in I'$, where $f^{(1)}_{ij}$ is an $I^{(1)}_{ij}$-type function of $(b^{(1)}_{kl})_{2\le k\le M, 1\le l\le N}$ with $f^{(1)}_{ij}|_{b^{(1)}_{i1}=b^{(1)}_{j1}=0} = 0$, $B^{\prime I_{ij}}_{(1)}$ is an $I^{(1)}_{ij}$-type function of $(b^{(1)}_{kl})_{2\le k\le M, 1\le l\le N}$, and $B^{\prime I}_{(1)}$ is an $I^{(1)}$-type function of $(b^{(1)}_{kl})_{2\le k\le M, 1\le l\le N}$.

C.2 Step 2

Assume Eq. (5). Construct the blow-up of function (5) along the submanifold $\{b^{(s)}_{ij} = 0, s+1 \le i \le M, 1 \le j \le N\}$.

Let $b^{(s)}_{ij} = u_{s+1} b'^{(s)}_{ij}$.

We have

$$B^{I_{ij}}_{(s)} = \begin{cases} u_1^2u_2^2\cdots u_i^2u_{i+1}\cdots u_j\{f^{(s)}_{ij} + b^{(s)}_{ji} + u_1^2 B^{\prime I_{ij}}_{(s)}\}, & i < j \le s, \\ u_1^2u_2^2\cdots u_i^2u_{i+1}\cdots u_su_{s+1}\{f^{(s)}_{ij}/u_{s+1} + b'^{(s)}_{ji} + u_1^2 B^{\prime I_{ij}}_{(s)}/u_{s+1}\}, & i \le s < j, \\ u_1^2u_2^2\cdots u_s^2u_{s+1}^2\{f^{(s)}_{ij}/u_{s+1}^2 + \sum_{k=s+1}^{N} b'^{(s)}_{ik}b'^{(s)}_{jk} + u_1^2 B^{\prime I_{ij}}_{(s)}/u_{s+1}^2\}, & s < i < j, \end{cases}$$

and

$$B^{I}_{(s)} = \prod_{k=1}^{s+1} u_k^{\sum_{k'=k}^{N} I_i} B'^{I}_{(s)}/u_{s+1}^{\sum_{k'=s+1}^{N} I_i}, I \in I'.$$

We may consider $b'^{(s)}_{s+1,s+1} = 1$ or $b'^{(s)}_{\ell,\ell'} = 1$ for some $s+1 \le \ell \le M$ and $1 \le \ell' \le s$.

If $b'^{(s)}_{\ell,\ell'} = 1$ for some $s+1 \le \ell \le M$ and $1 \le \ell' \le s$, then we have function (6) by using

$$f^{(s)}_{ij}|_{b^{(s)}_{i1}=\cdots=b^{(s)}_{i,\min\{i-1,s\}}=b^{(s)}_{j1}=\cdots=b^{(s)}_{j,\min\{i-1,s\}}=0} = 0,$$

and Lemma 6.

Let $b'^{(s)}_{s+1,s+1} = 1$.

Set $b''^{(s)}_{j,s+1} = b'^{(s)}_{j,s+1} + \sum_{k=s+2}^{N} b'^{(s)}_{s+1,k}b'^{(s)}_{jk}$ for $j \ge s+2$.

Then for $s+2 \leq i < j$,

$$\begin{aligned}
& f_{ij}^{(s)}/u_{s+1}^2 + \sum_{k=s+1}^{N} b'^{(s)}_{ik} b'^{(s)}_{jk} \\
= \; & f_{ij}^{(s)}/u_{s+1}^2 + (b''^{(s)}_{i,s+1} - \sum_{k=s+2}^{N} b'^{(s)}_{s+1,k} b'^{(s)}_{ik})(b''^{(s)}_{j,s+1} - \sum_{k=s+2}^{N} b'^{(s)}_{s+1,k} b'^{(s)}_{jk}) + \sum_{k=s+2}^{N} b'^{(s)}_{ik} b'^{(s)}_{jk} \\
= \; & f_{ij}^{(s)}/u_{s+1}^2 + b''^{(s)}_{j,s+1}(b''^{(s)}_{i,s+1} - \sum_{k=s+2}^{N} b'^{(s)}_{s+1,k} b'^{(s)}_{ik}) - b''^{(s)}_{i,s+1}(\sum_{k=s+2}^{N} b'^{(s)}_{s+1,k} b'^{(s)}_{jk}) \\
& + (\sum_{k=s+2}^{N} b'^{(s)}_{s+1,k} b'^{(s)}_{ik})(\sum_{k=s+2}^{N} b'^{(s)}_{s+1,k} b'^{(s)}_{jk}) + \sum_{k=s+2}^{N} b'^{(s)}_{ik} b'^{(s)}_{jk}.
\end{aligned}$$

Let $f_{ij}^{(s+1)} = f_{ij}^{(s)}/u_{s+1}^2 + b''^{(s)}_{j,s+1}(b''^{(s)}_{i,s+1} - \sum_{k=s+2}^{N} b'^{(s)}_{s+1,k} b'^{(s)}_{ik}) - b''^{(s)}_{i,s+1}(\sum_{k=s+2}^{N} b'^{(s)}_{s+1,k} b'^{(s)}_{jk})$. Then $f_{ij}^{(s+1)}$ is an $I_{ij}^{(s+1)}$-type function of $\begin{pmatrix} b''^{(s)}_{s+2,1} & b'^{(s)}_{s+2,2} & \cdots & b'^{(s)}_{s+2,N} \\ \vdots & \vdots & \vdots & \vdots \\ b''^{(s)}_{M1} & b'^{(s)}_{M2} & \cdots & b'^{(s)}_{MN} \end{pmatrix}$ with

$$f_{ij}^{(s+1)}|_{b''^{(s)}_{i1} = \cdots = b''^{(s)}_{i,s+1} = b''^{(s)}_{j1} = \cdots = b''^{(s)}_{j,s+1} = 0} = 0.$$

Next, construct the blow-up along the submanifold $\{b'^{(s)}_{s+1,s+2} = b'^{(s)}_{s+1,s+3} = \cdots = b'^{(s)}_{s+1,N} = 0\}$.
Let $b'^{(s)}_{s+1,s+2} = v_s$, $b'^{(s)}_{s+1,s+3} = v_s b''^{(s)}_{s+1,s+3}, \cdots,$
$b'^{(s)}_{s+1,N} = v_s b''^{(s)}_{s+1,N}$.
Let $Q_i^{(s)} = \sqrt{1 + {b''^{(s)}_{s+1,s+3}}^2 + \cdots + {b''^{(s)}_{s+1,i}}^2}$ and

$$G^{(s)} = \begin{pmatrix}
\frac{1}{Q_N} & \frac{-b''^{(s)}_{s+1,s+3}}{Q_{s+3}^{(s)}} & \cdots & \frac{-b''^{(s)}_{s+1,i}}{Q_{i-1}^{(s)} Q_i^{(s)}} & \cdots & \frac{-b''^{(s)}_{s+1,N}}{Q_{N-1}^{(s)} Q_N^{(s)}} \\
\frac{b''^{(s)}_{s+1,s+3}}{Q_N^{(s)}} & \frac{1}{Q_{s+3}^{(s)}} & \cdots & \frac{-b''^{(s)}_{s+1,s+3} b''^{(s)}_{s+1,i}}{Q_{i-1}^{(s)} Q_i^{(s)}} & \cdots & \frac{-b''^{(s)}_{s+1,s+3} b''^{(s)}_{s+1,N}}{Q_{N-1}^{(s)} Q_N^{(s)}} \\
\frac{b''^{(s)}_{s+1,s+4}}{Q_N^{(s)}} & 0 & \cdots & \frac{-b''^{(s)}_{s+1,s+4} b''^{(s)}_{s+1,i}}{Q_{i-1}^{(s)} Q_i^{(s)}} & \cdots & \frac{-b''^{(s)}_{s+1,s+4} b''^{(s)}_{s+1,N}}{Q_{N-1}^{(s)} Q_N^{(s)}} \\
\vdots & \vdots & & \vdots & & \vdots \\
 & & & \frac{-b''^{(s)}_{s+1,i-1} b''^{(s)}_{s+1,i}}{Q_{i-1}^{(s)} Q_i^{(s)}} & & \\
 & & & \frac{Q_{i-1}^{(s)}}{Q_i^{(s)}} & & \\
 & & & 0 & & \\
\vdots & \vdots & \cdots & \vdots & \cdots & \vdots \\
\frac{b''^{(s)}_{s+1,N}}{Q_N^{(s)}} & 0 & \cdots & 0 & \cdots & \frac{Q_{N-1}^{(s)}}{Q_N^{(s)}}
\end{pmatrix}.$$

Change variables from $(b'^{(s)}_{i,s+2}, b'^{(s)}_{i,s+3}, \cdots, b'^{(s)}_{iN})$ to $(b''^{(s)}_{i,s+2}, b''^{(s)}_{i,s+3}, \cdots, b''^{(s)}_{iN})$ by

$$\begin{pmatrix} b''^{(s)}_{i,s+2} \\ b''^{(s)}_{i,s+3} \\ \vdots \\ b''^{(s)}_{iN} \end{pmatrix} = \begin{pmatrix} \sqrt{1+v^2(1+{b''^{(s)}_{s+1,s+3}}^2+\cdots+{b''^{(s)}_{s+1,N}}^2)} & 0 & \cdots & 0 \\ 0 & & 1 & 0\cdots 0 \\ \vdots & & \vdots & \cdots \vdots \\ 0 & & 0 & \cdots 1 \end{pmatrix} G^{(s)^t} \begin{pmatrix} b'^{(s)}_{i,s+2} \\ b'^{(s)}_{i,s+3} \\ \vdots \\ b'^{(s)}_{iN} \end{pmatrix}.$$

We have

$$\begin{aligned} & (\sum_{k=s+2}^{N} b'^{(s)}_{s+1,k} b'^{(s)}_{ik})(\sum_{k=s+2}^{N} b'^{(s)}_{s+1,k} b'^{(s)}_{jk}) + \sum_{k=s+2}^{N} b^{(s)}_{ik} b^{(s)}_{jk} \\ = & \sum_{k=s+2}^{N} b''^{(s)}_{ik} b''^{(s)}_{jk}. \end{aligned}$$

Let $b^{(s+1)}_{ji} = b^{(s)}_{ji}$ for $i, j \leq s$ and $b^{(s+1)}_{ji} = b''^{(s)}_{ji}$ for $i, j > s$ and $(i, j) \neq (s+1, s+1)$. Also let $f^{(s+1)}_{ij} = f^{(s)}_{ij}$ for $i < j \leq s$, $f^{(s+1)}_{ij} = f^{(s)}_{ij}/u_{s+1}$ for $i \leq s < j$, $f^{(s+1)}_{s+1,j} = f^{(s)}_{s+1,j}/u^2_{s+1}$ for $j > s+1$, $B'^{I_{ij}}_{(s+1)} = B'^{I_{ij}}_{(s)}$ for $i < j \leq s$, $B'^{I_{ij}}_{(s+1)} = B'^{I_{ij}}_{(s)}/u_{s+1}$ for $i \leq s < j$, $B'^{I_{ij}}_{(s+1)} = B'^{I_{ij}}_{(s)}/u^2_{s+1}$ for $s < i < j$ and $B'^{I}_{(s+1)} = B'^{I}_{(s)}/u^{\sum_{k'=s+1}^{N} I_i}_{s+1}$ for $I \in I'$. Then we have Eq. (5) with $s+1$.

C.3 Step 3

From the above induction ($1 \leq s \leq N+1$), we finally have Eq. (6) since we assume that $N < M$.

Note that we have the same inductive results for

$$\int \{ \sum_{1 \leq i < j \leq M} (\sum_{k=1}^{N} b_{ik} b_{jk})^2 \}^z \mathrm{d}b, \tag{7}$$

instead of the function in Eq. (3). This means that the maximum pole, and its order, of the function in Eq. (3) are those of the function in Eq. (7).

Now we again consider the maximum pole of the function in Eq. (7) and its order.

In Step3, we use the same symbol b rather than $b^{(s)}$ for the sake of simplicity.

We need to consider the following function with the inductive method with s.

$$\begin{aligned} \int \{ u_1^4 u_2^4 \cdots u_s^4 \sum_{1 \leq i < j \leq M, i \leq s} b^2_{ji} + u_1^4 u_2^4 \cdots u_s^4 \sum_{s+1 \leq i < j \leq M} (\sum_{k=s+1}^{N} b_{ik} b_{jk})^2 \}^z \\ \prod_{k=1}^{s} u_k^{(M-k+1)(N-k+1)+(2M-k)(k-1)-1} \mathrm{d}u \mathrm{d}b. \end{aligned} \tag{8}$$

First, we set the variables the same as in Step 1. Then we have

$$\int \{ u_1^4 \sum_{2 \leq j \leq M} b^2_{j1} + u_1^4 \sum_{2 \leq i < j \leq M} (f^{(1)}_{ij} + \sum_{k=2}^{N} b_{ik} b_{jk})^2 \}^z u_1^{MN-1} \mathrm{d}u \mathrm{d}b.$$

By using Lemma 6 again, we need to consider

$$\int \{u_1^4 \sum_{2\le j\le M} b_{j1}^2 + u_1^4 \sum_{2\le i<j\le M} (\sum_{k=2}^{N} b_{ik}b_{jk})^2\}^z u_1^{MN-1} \mathrm{d}u\mathrm{d}b.$$

Assume Eq. (8). Construct the blow-up of function (8) along the submanifold $\{b_{ji} = 0, 1 \le i < j \le M, i \le s, b_{kl} = 0, s+1 \le k \le M, s+1 \le l \le N\}$.

Then we have

$$\int \{u_1^4 u_2^4 \cdots u_s^4 u_{s+1}^2 \sum_{1\le i<j\le M, i\le s} b_{ji}^2 + u_1^4 u_2^4 \cdots u_s^4 u_{s+1}^4 \sum_{s+1\le i<j\le M} (\sum_{k=s+1}^{N} b_{ik}b_{jk})^2\}^z$$
$$u_{s+1}^{(M-s)(N-s)+(2M-1-s)s/2-1} \prod_{k=1}^{s} u_k^{(M-k+1)(N-k+1)+(2M-k)(k-1)-1} \mathrm{d}u\mathrm{d}b,$$

where we can set $b_{21} = 1$ or $b_{s+1,s+1} = 1$.

If $b_{21} = 1$, we have the poles

$$\frac{(M-k+1)(N-k+1)+(2M-k)(k-1)}{4}, k = 1, \ldots, s$$

and

$$\frac{(M-s)(N-s)+(2M-1-s)s/2}{2}.$$

If $b_{s+1,s+1} = 1$, then by setting the variables the same as in Step 2 and by using Lemma 6, we have

$$\int \{u_1^4 u_2^4 \cdots u_s^4 u_{s+1}^2 \sum_{1\le i<j\le M, i\le s} b_{ji}^2$$
$$+ u_1^4 u_2^4 \cdots u_s^4 u_{s+1}^4 (\sum_{s+1<j\le M} b_{j,s+1}^2 + \sum_{s+2\le i<j\le M} (\sum_{k=s+2}^{N} b_{ik}b_{jk})^2)\}^z$$
$$u_{s+1}^{(M-s)(N-s)+(2M-1-s)s/2-1} \prod_{k=1}^{s} u_k^{(M-k+1)(N-k+1)+(2M-k)(k-1)-1} \mathrm{d}u\mathrm{d}b. \tag{9}$$

Construct the blow-up of function (9) along the submanifold $\{b_{ji} = 0, 1 \le i < j \le M, i \le s, u_{s+1} = 0\}$.

Then we have Eq. (8) with $s+1$, that is,

$$\int \{u_1^4 u_2^4 \cdots u_s^4 u_{s+1}^4 \sum_{1\le i<j\le M, i\le s} b_{ji}^2$$
$$+ u_1^4 u_2^4 \cdots u_s^4 u_{s+1}^4 (\sum_{s+1<j\le M} b_{j,s+1}^2 + \sum_{s+2\le i<j\le M} (\sum_{k=s+2}^{N} b_{ik}b_{jk})^2)\}^z$$
$$u_{s+1}^{(M-s)(N-s)+(2M-1-s)s-1} \prod_{k=1}^{s} u_k^{(M-k+1)(N-k+1)+(2M-k)(k-1)-1} \mathrm{d}u\mathrm{d}b.$$

or

$$\int \{u_1^4 u_2^4 \cdots u_s^4 u_{s+1}^2 b_{21}^4 (1 + \sum_{1 \le i < j \le M, i \le s, (i,j) \ne (1,2)} b_{ji}^2)$$
$$+ u_1^4 u_2^4 \cdots u_s^4 u_{s+1}^4 b_{21}^4 (\sum_{s+1 < j \le M} b_{j,s+1}^2 + \sum_{s+2 \le i < j \le M} (\sum_{k=s+2}^{N} b_{ik} b_{jk})^2)\}^z$$
$$u_{s+1}^{(M-s)(N-s)+(2M-1-s)s/2-1} b_{21}^{(M-s)(N-s)+(2M-1-s)s-1}$$
$$\prod_{k=1}^{s} u_k^{(M-k+1)(N-k+1)+(2M-k)(k-1)-1} \mathrm{d}u\mathrm{d}b,$$

which have the poles

$$\frac{(M-k+1)(N-k+1)+(2M-k)(k-1)}{4}, k = 1, \ldots, s+1,$$

and

$$\frac{(M-s)(N-s)+(2M-1-s)s/2}{2}.$$

Finally, we have

$$\int \{u_1^4 u_2^4 \cdots u_N^4 \sum_{1 \le i < j \le M, i \le N} b_{ji}^2\}^z \prod_{k=1}^{N} u_k^{(M-k+1)(N-k+1)+(2M-k)(k-1)-1} \mathrm{d}u\mathrm{d}b,$$

and obtain the poles

$$\frac{(M-k+1)(N-k+1)+(2M-k)(k-1)}{4}, k = 1, \ldots, N,$$

and

$$\frac{(2M-1-N)N}{4}.$$

Therefore, since we assume that $M > N$, we have the maximum pole $-\lambda = -\frac{MN}{4}$ and its order $\theta = \begin{cases} 1, & \text{if } M > N+1, \\ M, & \text{if } M = N+1. \end{cases}$ Q.E.D.

Proof of Theorem 4

Assume that $a^* = 0$

By the proof of Theorem 3, the maximum pole of $\int \{\sum_{1 \le i < j \le M} (B^{l_{ij}})^2\}^z db$ is that of $\int \{\sum_{1 \le i < j \le M} (\sum_{k=1}^{N} b_{ik} b_{jk})^2\}^z db$ even for $M \le N$. If $M \le N$ then the maximum pole of $\int \{\sum_{1 \le i < j \le M} (\sum_{k=1}^{N} b_{ik} b_{jk})^2\}^z db$ is $-M(M-1)/4$. Therefore the maximum pole $-\lambda$ of $\int \{\sum_{I \ne 0 \in I} (B^I)^2\}^z db$ satisfies $\lambda \ge M(M-1)/4$, since $\sum_{1 \le i < j \le M} (B^{l_{ij}})^2 \le \sum_{I \ne 0 \in I} (B^I)^2$.

Next let us prove that $\lambda \le \frac{2N+(M-1)(M-2)}{4}$. Consider Eq. (6) with $\ell = M$, $\ell' = M-1$ and $s = M-1$.

Let $\tilde{b}_{ji} = u_M \tilde{b}'_{ji}$ for $i < j < M$. Then we have the pole

$$\frac{N+(M-2)(M-1)/2}{2}.$$

For $a^* \ne 0$, Lemma 7 yields the statement.

Abstract

We introduce novel results for approximate inference on planar graphical models using the loop calculus framework. The loop calculus (Chertkov and Chernyak, 2006a) allows to express the exact partition function of a graphical model as a finite sum of terms that can be evaluated once the belief propagation (BP) solution is known. In general, full summation over all correction terms is intractable. We develop an algorithm for the approach presented in Chertkov et al. (2008) which represents an efficient truncation scheme on planar graphs and a new representation of the series in terms of Pfaffians of matrices. We analyze the performance of the algorithm for models with binary variables and pairwise interactions on grids and other planar graphs. We study in detail both the loop series and the equivalent Pfaffian series and show that the first term of the Pfaffian series for the general, intractable planar model, can provide very accurate approximations. The algorithm outperforms previous truncation schemes of the loop series and is competitive with other state of the art methods for approximate inference.

Keywords: belief propagation, loop calculus, approximate inference, partition function, planar graphs, Ising model

1. Introduction

Graphical models are popular tools widely used in many areas which require modeling of uncertainty. They provide an effective approach through a compact representation of the joint probability distribution. The two most common types of graphical models are Bayesian networks (BN) and Markov random fields (MRFs).

The partition function of a graphical model, which plays the role of normalization constant in a MRF or probability of evidence (likelihood) in a BN is a fundamental quantity which arises in many contexts such as hypothesis testing or parameter estimation. Exact computation of this quantity is only feasible when the graph is not too complex, or equivalently, when its tree-width is small. Currently many methods are devoted to approximate this quantity.

The belief propagation (BP) algorithm (Pearl, 1988) is at the core of many of these approximate inference methods. Initially thought as an exact algorithm for tree graphs, it is widely used as an

approximation method for loopy graphs (Murphy et al., 1999; Frey and MacKay, 1998). The exact partition function is explicitly related to the BP approximation through the loop calculus framework introduced by Chertkov and Chernyak (2006a). Loop calculus allows to express the exact partition function as a finite sum of terms (loop series) that can be evaluated once the BP solution is known. Each term maps uniquely to a subgraph, also denoted as a generalized loop, where the connectivity of any node within the subgraph is *at least* degree two. Summation of the entire loop series is a hard combinatorial task since the number of generalized loops is typically exponential in the size of the graph (see also Watanabe and Fukumizu, 2009). However, different approximations can be obtained by considering different subsets of generalized loops in the graph.

It has been shown empirically (Gómez et al., 2007; Chertkov and Chernyak, 2006b) that truncating this series may provide efficient corrections to the initial BP approximation. More precisely, whenever BP performs satisfactorily, which occurs in the case of sufficiently weak interactions between variables (or short-range influence of loops), accounting for only a small number of terms is sufficient to recover the exact result. On the other hand, for those cases where BP requires many iterations to converge, many terms of the series are required to improve substantially the approximation. Nevertheless, a formal characterization of the classes of problems which are tractable via loop calculus still remains an open question.

A step toward this goal with a focus on the class of planar graphs has been done in Chertkov et al. (2008). A graph is said to be planar if it can be embedded into a plane without crossing edges. Chertkov et al. (2008) showed that under this condition summation of certain (large) subset of terms can be performed in polynomial time via mapping to the problem of counting perfect matchings. A perfect matching is a subset of edges where every vertex has exactly one attached edge in the subset. Furthermore, the full loop series can be expressed as a sum over certain Pfaffians (or determinants), where each Pfaffian may account for a large number of loops and is solvable in polynomial time as well.

The approach of Chertkov et al. (2008) builds upon classical results from Fisher (1961), Kasteleyn (1961) and Temperley and Fisher (1961) who addressed the question of counting the number of perfect matchings on a planar grid, also known as the dimer covering problem in statistical physics. These classical results are consistent with the following related statement: the partition function of a *planar graphical model defined in terms of binary variables* can be solved in polynomial time by computing an appropriate Pfaffian under the key restriction that pairwise interactions only depend on agreement or disagreement between the signs of their variables, and not on their individual values. Such a model is known in statistical physics as planar Ising model without external field and in the machine learning community as planar, binary MRF with pure interaction potentials. Notice that exact inference for a general binary graphical model on a planar graph, namely Ising model *with* external field, is intractable, in particular #P (Barahona, 1982). A gentle overview of counting perfect matchings in planar graphs can be found in Jerrum (2003).

Recently, other inference methods models based on the Fisher-Temperley-Kasteleyn (FTK) method have been introduced in the machine learning community. Globerson and Jaakkola (2007) obtained upper bounds on the partition function for non-planar graphs with binary variables by decomposition of the partition function into a weighted sum over partition functions of spanning tractable (zero field) planar models. The resulting problem is a convex optimization problem and, since exact inference can be done in each planar *sub*-model via the FTK method, the bound can be calculated in polynomial time.

Another example is the work of Schraudolph and Kamenetsky (2008) which provides a framework for exact inference on a restricted class of planar graphs using directly the FTK approach. Since a planar Ising model can be transformed to a model *without* external field at the cost of introducing additional edges, one can allow local fields for a subset $\mathcal{B}$ of variables. If the graphical model is $\mathcal{B}-$outerplanar, which means that there exists a planar embedding in which the subset $\mathcal{B}$ of the nodes lie on the same face, the FTK technique can still be applied.

Contrary to these two approaches, which rely on exact inference on a tractable planar model, the loop calculus directly leads to a framework for approximate inference on general planar graphs. Truncating the loop series according to Chertkov et al. (2008) already gives the exact result in the zero external field case. In the general planar case, however, this truncation may result into an accurate approximation that can be incrementally corrected by considering subsequent terms in the series.

In the next Section we review the main theoretical results of the loop calculus approach for planar graphs and introduce the proposed algorithm for approximating the partition function and single-variable marginals. In Section 3 we provide experimental results for regular grids and other types of planar graphs. We focus on a planar-intractable binary model with symmetric pairwise interactions but nonzero single variable potentials.[1] We end this manuscript with conclusions and discussion of future work in Section 4.

2. Belief Propagation and Loop Series for Planar Graphs

We consider the Forney graph representation, also called general vertex model (Jr., 2001; Loeliger, 2004), of a probability distribution $p(\boldsymbol{\sigma})$ defined over a vector $\boldsymbol{\sigma}$ of binary variables (vectors are denoted using bold symbols). Forney graphs are associated with general graphical models which subsume other factor graphs, for instance those correspondent to BNs and MRFs. In Appendix A we explain how our approach is related to the more common bipartite factor graph model.

A binary Forney graph $\mathcal{G} := (\mathcal{V}, \mathcal{E})$ consists of a set of nodes $\mathcal{V}$ where each node $a \in \mathcal{V}$ represents an interaction and each edge $(a,b) \in \mathcal{E}$ represents a binary variable ab which take values $\sigma_{ab} := \{\pm 1\}$. We denote $\bar{a}$ the set of neighbors of node a. Interactions $f_a(\boldsymbol{\sigma}_a)$ are arbitrary functions defined over typically small subsets of variables where $\boldsymbol{\sigma}_a$ is the vector of variables associated with node a, that is, $\boldsymbol{\sigma}_a := (\sigma_{ab_1}, \sigma_{ab_2}, \dots)$ where $b_i \in \bar{a}$.

The joint probability distribution of such a model factorizes as:

$$p(\boldsymbol{\sigma}) = Z^{-1} \prod_{a \in \mathcal{V}} f_a(\boldsymbol{\sigma}_a), \qquad Z = \sum_{\boldsymbol{\sigma}} \prod_{a \in \mathcal{V}} f_a(\boldsymbol{\sigma}_a), \tag{1}$$

where Z is the normalization factor, also called the partition function.

From a variational perspective, a fixed point of the BP algorithm represents a stationary point of the Bethe "free energy" approximation under proper constraints (Yedidia et al., 2000). In the Forney style notation:

$$\begin{aligned} Z^{BP} &= \exp\left(-F^{BP}\right), \\ F^{BP} &= \sum_{a} \sum_{\boldsymbol{\sigma}_a} \tau_a(\boldsymbol{\sigma}_a) \ln\left(\frac{\tau_a(\boldsymbol{\sigma}_a)}{f_a(\boldsymbol{\sigma}_a)}\right) - \sum_{b \in \bar{a}} \sum_{\sigma_{ab}} \tau_{ab}(\sigma_{ab}) \ln \tau_{ab}(\sigma_{ab}), \end{aligned} \tag{2}$$

1. The source code used in this paper is freely available at `http://www.mbfys.ru.nl/staff/v.gomez/`.

where $\tau_a(\boldsymbol{\sigma}_a)$ and $\tau_{ab}(\sigma_{ab})$ are the beliefs (pseudo-marginals) associated with each node $a \in \mathcal{V}$ and edge $(a,b) \in \mathcal{E}$. For graphs without loops, Equation (2) coincides with the Gibbs "free energy" and therefore Z^{BP} coincides with the exact partition function Z. If the graph contains loops, Z^{BP} is just an approximation critically dependent on how strong the influence of the loops is.

We introduce now some convenient definitions related to the loop calculus framework.

Definition 1 *A **generalized loop** in a graph $\mathcal{G} := \langle \mathcal{V}, \mathcal{E} \rangle$ is any subgraph $C := \langle V', E' \rangle$, $V' \subseteq \mathcal{V}, E' \subseteq (V' \times V') \cap \mathcal{E}$ such that each node in V' has degree two or larger.*

For simplicity, we will use the term "loop", instead of "generalized loop", in the rest of this manuscript. Loop calculus allows to represent Z explicitly in terms of the BP approximation via the loop series expansion:

$$Z = Z^{BP} \cdot z, \qquad z = \left(1 + \sum_{C \in \mathcal{C}} r_C\right), \qquad r_C = \prod_{a \in C} \mu_{a;\bar{a}_C}, \tag{3}$$

where $\mathcal{C}$ is the set of all the loops within the graph and $\bar{a}_C$ the set of neighbors of node a within the loop C. Each term r_C is a product of terms $\mu_{a;\bar{a}_C}$ associated with every node a of the loop C:

$$\mu_{a;\bar{a}_C} = \frac{\mathbb{E}_{\tau_a}\left[\prod_{b \in \bar{a}_C} (\sigma_{ab} - m_{ab})\right]}{\sqrt{\prod_{b \in \bar{a}_C} \mathrm{Var}_{\tau_{ab}}(\sigma_{ab})}}, \qquad m_{ab} = \mathbb{E}_{\tau_{ab}}\left[\sigma_{ab}\right], \tag{4}$$

where we have used $\mathbb{E}_{\tau}[\cdot]$ to denote expectation with respect to the pseudo-marginal distribution τ. Equation (4) states that all terms of the expansion can be written as correlation functions between associated variables defined on the BP pseudo-marginals. In the case of $\{\pm 1\}$ alphabet we have:

$$\mu_{a;\bar{a}_C} = \frac{\sum_{\boldsymbol{\sigma}_a} \left(\tau_a(\boldsymbol{\sigma}_a) \prod_{b \in \bar{a}_C} (\sigma_{ab} - m_{ab})\right)}{\prod_{b \in \bar{a}_C} \sqrt{1 - m_{ab}^2}}, \qquad m_{ab} = \tau_{ab}(+1) - \tau_{ab}(-1). \tag{5}$$

In this work we consider planar graphs where nodes have degree at most three, that is $|\bar{a}_C| \leq 3$. We denote by *triplet* a node with degree exactly three in the graph. In Appendix A.2 we show how a graphical model stated in a bipartite factor graph representation can be converted to a Forney graph which satisfies this constraint at the cost of introducing auxiliary nodes.

Definition 2 *A **2-regular loop** is a loop in which all nodes have degree* exactly *two*.

Definition 3 *The **2-regular partition function** $Z_\emptyset$ is the truncated form of* (3) *which sums all* 2*-regular loops only:*[2]

$$\begin{aligned} Z_\emptyset &= Z^{BP} \cdot z_\emptyset, \\ z_\emptyset &= 1 + \sum_{\substack{C \in \mathcal{C}, \\ |\bar{a}_C| = 2, \forall a \in C}} r_C. \end{aligned} \tag{6}$$

As an example, Figure 1a shows a small Forney graph and Figure 1c shows seven loops found in the corresponding 2-regular partition function.

2. Notice that this is the *single-connected partition function* in Chertkov et al. (2008). We use the term 2-regular partition function instead because loops with more than one connected component are also included in this part of the series.

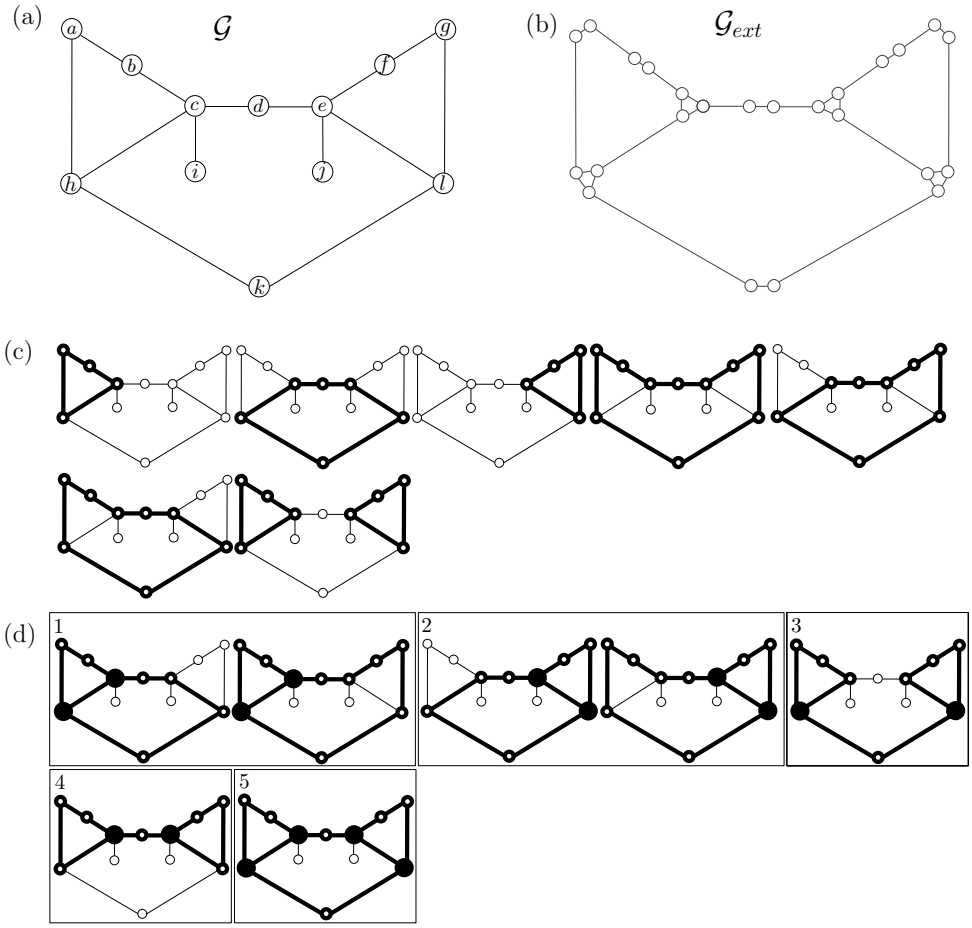

Figure 1: Example. **(a)** A Forney graph. **(b)** Corresponding extended graph. **(c)** Loops (in bold) included in the 2-regular partition function. **(d)** Loops (in bold) not included in the 2-regular partition function. Marked nodes denote triplets. Grouped in gray squares, the loops considered in different subsets Ψ of triplets: (d.1) $\Psi = \{c,h\}$, (d.2) $\Psi = \{e,l\}$, (d.3) $\Psi = \{h,l\}$, (d.4) $\Psi = \{c,e\}$ and (d.5) $\Psi = \{c,e,h,l\}$ (see Section 2.3).

Definition 4 *Consider the set P of all permutations α of the set $\mathcal{S} = \{1,\ldots,2n\}$ in pairs: $\alpha = (i_1,j_1),\ldots,(i_n,j_n))$, $i_k < j_k, \forall k = 1,\ldots,n$. The Pfaffian of a skew-symmetric matrix $A = (A_{ij})_{1\le i<j\le 2n}$ with ($A_{ij} = -A_{ji}$) is:*

$$\text{Pfaffian}(A) = \sum_{\alpha\in P} \text{sign}(\alpha) \prod_{(i,j)\in\alpha} A_{ij},$$

where the sign of a permutation α is -1 if the number of transpositions to get α from $\mathcal{S}$ is odd and $+1$ otherwise. The following identity allows to obtain the Pfaffian *up to a sign* by computing the determinant:

$$\text{Pfaffian}^2(A) = \text{Det}(A).$$

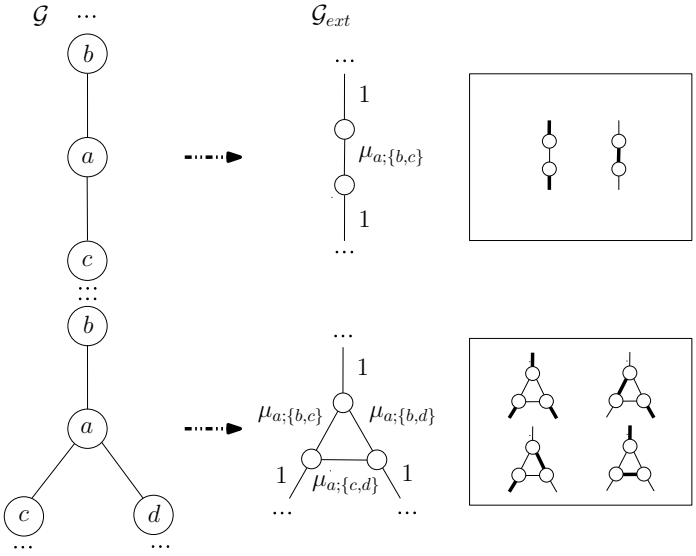

Figure 2: Fisher's rules. **(Top)** A node a of degree two in $\mathcal{G}$ is split in two nodes in $\mathcal{G}_{ext}$. **(Bottom)** A node a of degree three in $\mathcal{G}$ is split in three nodes in $\mathcal{G}_{ext}$. The squares on the right indicate all possible matchings in $\mathcal{G}_{ext}$ related to node a. Note that the rules preserve planarity.

2.1 Computing the 2-regular Partition Function Using Perfect Matchings

In Chertkov et al. (2008) it has been shown that computation of $Z_\emptyset$ in a Forney graph $\mathcal{G}$ can be mapped to the computation of the sum of all weighted perfect matchings within another extended weighted graph $\mathcal{G}_{ext} := (\mathcal{V}_{\mathcal{G}_{ext}}, \mathcal{E}_{\mathcal{G}_{ext}})$. A perfect matching is defined as a subset of edges such that each node neighbors exactly one edge from the subset and its weight is the product of weights of edges in it. The key idea of this mapping is that 2-regular loops in $\mathcal{G}$ are in one-to-one correspondence to perfect matchings in $\mathcal{G}_{ext}$ (see Figures 1b and c for an illustration). If $\mathcal{G}_{ext}$ is planar, the sum of its weighted perfect matchings can be calculated in polynomial time via the FTK approach, evaluating the Pfaffian of an associated matrix. Here we reproduce these results with little variations and emphasis on the algorithmic aspects.

Given a Forney graph $\mathcal{G}$ and the BP approximation, we obtain the 2-core of $\mathcal{G}$ by removing nodes of degree 1 recursively. The 2-core excludes all nodes that do not appear in any loop. After this step, $\mathcal{G}$ is either the null graph (and then BP is exact) or it is only composed of vertices of degree two or three.

To construct $\mathcal{G}_{ext}$ we split each node in $\mathcal{G}$ according to the rules introduced by Fisher (1966) and illustrated in Figure 2. The procedure results in an extended graph of $|\mathcal{V}_{\mathcal{G}_{ext}}| \leq 3|\mathcal{V}|$ nodes and $|\mathcal{E}_{\mathcal{G}_{ext}}| \leq 3|\mathcal{E}|$ edges. To see that each 2-regular loop in $\mathcal{G}$ is associated with a perfect matching in $\mathcal{G}_{ext}$ consider, for instance, the vertex of degree three in the bottom of Figure 2. Given a 2-regular loop C, vertex a can appear in four different configurations: either node a does not appear in C, or C contains one of the following three paths: -b-a-c-, -b-a-d- or -c-a-d-. These four cases correspond to node terms in a loop with values 1, $\mu_{a;\{b,c\}}$, $\mu_{a;\{b,d\}}$ and $\mu_{a;\{c,d\}}$ respectively, and coincide with

the matchings in $\mathcal{G}_{ext}$ shown within the box on the bottom-right. An simpler argument applies to the vertex of degree two of the top portion of Figure 2.

Therefore, if we associate to each internal edge (new edge in $\mathcal{G}_{ext}$ not in $\mathcal{G}$) of each split node a the corresponding weight $\mu_{a;\bar{a}_C}$ of Equation (4) and to the external edges (existing edges already in $\mathcal{G}$) weight 1, the sum over all weighted perfect matchings defined on $\mathcal{G}_{ext}$ is precisely $z_\emptyset$:

$$z_\emptyset = \sum \text{perfect matchings in } \mathcal{G}_{ext}.$$

The 2-regular partition function $Z_\emptyset$ is obtained using Equation (6).

Kasteleyn (1963) provided a method to compute this sum in polynomial time for planar graphs. First, edges are properly oriented in such a way that for every face (except possibly the external face) the number of clockwise oriented edges is odd. We use the linear time algorithm in Karpinski and Rytter (1998) described here as Algorithm 1 to produce such an orientation. It receives an undirected graph $\mathcal{G}_{ext}$ and constructs a copy $\mathcal{G}'_{ext} := (\mathcal{V}_{\mathcal{G}'_{ext}}, \mathcal{E}_{\mathcal{G}'_{ext}})$ with properly oriented edges $\mathcal{E}_{\mathcal{G}'_{ext}}$. It is convenient that $\mathcal{G}_{ext}$ is bi-connected, that is, has no articulation points. If needed, we add edges with zero weight which do not alter Z.

Algorithm 1 Pfaffian orientation

Arguments: undirected bi-connected extended graph $\mathcal{G}_{ext}$.

1: Construct a planar embedding $\bar{\mathcal{G}}_{ext}$ of $\mathcal{G}_{ext}$.
2: Construct a spanning tree T of $\bar{\mathcal{G}}_{ext}$.
3: Construct a graph H having vertices corresponding to the faces of $\bar{\mathcal{G}}_{ext}$:
   Connect two vertices in H if the respective face boundaries share an edge not in T.
   H is a tree. Root H to the external face.
4: $\mathcal{G}'_{ext} := T$.
5: Orient all edges in $\mathcal{G}'_{ext}$ arbitrarily.
6: **for all** face (vertex in H) traversed in post-order **do**
7: Add to $\mathcal{G}'_{ext}$ the unique edge not in $\mathcal{G}'_{ext}$.
8: Orient it such that the number of clock-wise oriented edges is odd.
9: **end for**
10: **RETURN** directed bi-connected extended graph $\mathcal{G}'_{ext}$.

Second, denote μ_{ij} the weight of the edge between nodes i and j in $\mathcal{G}'_{ext}$ and define the following skew-symmetric matrix:

$$\hat{A}_{ij} = \begin{cases} +\mu_{ij} & \text{if } (i,j) \in \mathcal{E}_{\mathcal{G}'_{ext}} \\ -\mu_{ij} & \text{if } (j,i) \in \mathcal{E}_{\mathcal{G}'_{ext}} \\ 0 & \text{otherwise} \end{cases}.$$

The Pfaffian of $\hat{A}_{ij}$ is the weighted sum of all perfect matchings. Calculation of $z_\emptyset$ can be performed in time $O(N^3_{\mathcal{G}_{ext}})$:

$$z_\emptyset = \sqrt{\text{Det}(\hat{A})}.$$

For the tractable case, namely, Ising model without external field or pairwise MRF with pure interaction potentials, the 2-regular partition function coincides with the exact partition function $Z =$

$Z_\emptyset = Z^{BP} \cdot z_\emptyset$ since other terms in the loop series vanish. In this case, it can be shown that all terms $\mu_{a;\{b,c,d\}}$ associated with triplets a (vertices with degree three in $\mathcal{G}$) are zero using the following argument: first, note that a BP fixed point is attained when all variables have zero magnetizations, that is, uniform beliefs $\tau_{ab}(\sigma_{ab}) = 1/2$, which reduces Equation (5) to:

$$\mu_{a;\{b,c,d\}} = \sum_{\boldsymbol{\sigma}_a} \tau_a(\boldsymbol{\sigma}_a)\, \sigma_{ab}\sigma_{ac}\sigma_{ad}. \tag{7}$$

Second, since by construction pseudo-marginals on the triplets $\tau_a(\boldsymbol{\sigma}_a)$ only depend on agreement or disagreement between the variables:

$$\tau_a(\boldsymbol{\sigma}_a) = \begin{cases} \tau_a(=), & \text{for } \sigma_{ab} = \sigma_{ac} = \sigma_{ad}, \\ \tau_a(\neq), & \text{otherwise,} \end{cases}$$

it suffices to see that for each term $\tau_a(\boldsymbol{\sigma}_a)\sigma_{ab}\sigma_{ac}\sigma_{ad}$ in the sum, the "symmetric" term where σ_{ab}, σ_{ac} and σ_{ad} are replaced by their opposite values, has same absolute value but different sign, therefore the sum (7) is zero.

2.2 Computing Estimates of Marginal Distributions

Given the estimate $Z_\emptyset$, estimates for the marginals $P_{ab}(\sigma_{ab})$ can be obtained:

$$P_{ab}(\sigma_{ab}) = \left.\frac{\partial \log Z_\emptyset(\theta_{ab})}{\partial \theta_{ab}(\sigma_{ab})}\right|_{\theta_{ab}\to 0}, \qquad \text{where} \qquad Z_\emptyset(\theta_{ab}) := \sum_{\boldsymbol{\sigma}} \exp(\theta_{ab}\sigma_{ab}) \prod_{a\in\mathcal{V}} f_a(\boldsymbol{\sigma}_a)$$

is the partition sum of the network perturbed with respect to an additional local field potential θ_{ab} of variable σ_{ab}.

Alternatively, one can compute different partition functions for different settings of the variables $Z_\emptyset^{\sigma_{ab}=+1}$ and $Z_\emptyset^{\sigma_{ab}=-1}$, and derive the marginals from respective ratios:

$$P_{ab}(\sigma_{ab} = +1) = \frac{Z_\emptyset^{\sigma_{ab}=+1}}{Z_\emptyset^{\sigma_{ab}=+1} + Z_\emptyset^{\sigma_{ab}=-1}},$$

where $Z_\emptyset^{\sigma_{ab}=+1}$ indicates the 2-regular partition function calculated from the same model conditioning on variable σ_{ab}, that is, with variable σ_{ab} fixed (clamped) to $+1$. Therefore, approximation errors in the computation of any marginal can be related to approximation errors in the computation of $Z_\emptyset$. In the following we will mainly focus on evaluating $Z_\emptyset$, although marginal probabilities will be discussed as well.

2.3 Computing the Full Loop Series Using Perfect Matchings

Chertkov et al. (2008) established that $z_\emptyset$ is just the first term of a finite sum involving Pfaffians. We briefly reproduce their results here and provide an algorithm for computing the full loop series as a Pfaffian series.

Consider $\mathcal{T}$ defined as the set of all possible triplets in the original graph $\mathcal{G}$. For each possible subset $\Psi \in \mathcal{T}$, including an *even* number of triplets, there exists a unique correspondence between loops in $\mathcal{G}$ including the triplets in Ψ and perfect matchings in another extended graph $\mathcal{G}_{ext_\Psi}$ constructed after removal of the triplets Ψ in $\mathcal{G}$. Using this representation the full loop series can be

represented as a Pfaffian series, where each term Z_Ψ is tractable and is a product of the respective Pfaffian and the $\mu_{a;\bar{a}}$ terms associated with each triplet of Ψ:[3]

$$z = \sum_{\Psi} Z_\Psi \qquad Z_\Psi = z_\Psi \prod_{a \in \Psi} \mu_{a;\bar{a}} \qquad (8)$$
$$z_\Psi = \text{sign}\left(\text{Pfaffian}\left(\hat{B}_\Psi\right)\right) \cdot \text{Pfaffian}\left(\hat{A}_\Psi\right).$$

where $\hat{B}_\Psi$ corresponds to the original Kasteleyn matrix with weights $+1$ instead of $+\mu_{ij}$ and -1 instead of $-\mu_{ij}$ and we make explicit use of the Pfaffians to correct for the sign. The correction sign(Pfaffian($\hat{B}_\Psi$)) is necessary because loop terms can be negative and even evaluating Pfaffian($\hat{A}_\Psi$) with the correct sign would only give the contribution up to a sign. In the previous Subsection, we assumed $z_\emptyset$ positive.

The 2-regular partition function thus corresponds to $\Psi = \emptyset$. We refer to the remaining terms of the series ($\Psi \neq \emptyset$) as higher order terms. Notice that matrices $\hat{A}_\Psi$ and $\hat{B}_\Psi$ depend on the removed triplets and therefore each z_Ψ requires different matrices and different edge orientations. In addition, after removal of vertices in $\mathcal{G}$, the resulting extended graph may be disconnected. As before, in these cases we add dummy edges with zero weight so that $\mathcal{G}_{ext}$ remains bi-connected.

Figure 1d shows loops corresponding to the higher order Pfaffian terms on our illustrative example. The first and second subsets of triplets (d.1 and d.2) include summation over two loops whereas the remaining Pfaffian terms include uniquely one loop.

Exhaustive enumeration of all subsets of triplets leads to a $2^{|\mathcal{T}|}$ time algorithm, which is prohibitive. However, many triplet combinations may lead to forbidden configurations. Experimentally, we found that a principled way to look for higher order Pfaffian terms with large contribution is to search first for pairs of triplets, then groups of four, and so on. For large graphs, this also becomes intractable. However, the key advantage of the Pfaffian representation is that $Z_\emptyset$ is always the term that accounts for the largest number of loop terms in the series. In this work we do not derive any heuristic for searching higher order Pfaffian terms with larger contributions. Instead, in Section 3.1 we study the full Pfaffian series and subsequently we restrict our attention to analyze the accuracy of $Z_\emptyset$.

Algorithm 2 describes the procedure for computing all terms using Equation (8). The main loop of the algorithm can be interrupted at any time, thus leading to a sequence of algorithms producing corrections incrementally.

3. Experiments

In this Section we study numerically the proposed algorithm. To facilitate the evaluation and the comparison with other algorithms we focus on the pairwise binary Ising model, a particular case of the model (1) where factors only depend on the disagreement between variables and take the form: $\log f_a(\sigma_{ab}, \sigma_{ac}) = \phi_a \sigma_{ab} \sigma_{ac}$. We consider also nonzero local potentials in all variables parameterized by: $\log f_a(\sigma_{ab}) = \theta_{ab} \sigma_{ab}$ so that the model becomes planar-intractable.

We create different inference problems by choosing different interactions ϕ_a and local field parameters θ_{ab}. To generate them we draw independent samples from a normal distribution $\phi_a \sim \mathcal{N}(0, \beta/2)$ and $\theta_{ab} \sim \mathcal{N}(0, \beta\Theta)$, where Θ and β determine how difficult the inference problem is. Generally, for $\Theta = 0$ the planar problem is tractable (zero field). For $\Theta > 0$, small values of β result

3. We omit the loop index in the triplet term $\mu_{a;\bar{a}}$ because nodes have at most degree three and therefore the set $\bar{a}$ always coincide in all loops which contain that triplet.

Algorithm 2 Pfaffian series

Arguments: Forney graph $\mathcal{G}$

1: $z := 0$.
2: **for all** $\{\Psi \in \mathcal{T}, |\Psi| \text{even}\}$ **do**
3: Build extended graph $\mathcal{G}_{ext_\Psi}$ applying rules of Figure 2.
4: Set Pfaffian orientation in $\mathcal{G}_{ext_\Psi}$ according to Algorithm 1.
5: Build matrices $\hat{A}$ and $\hat{B}$.
6: Compute Pfaffian with sign correction z_Ψ according to Equation (8).
7: $z := z + z_\Psi \prod_{a \in \Psi} \mu_{a;\bar{a}}$.
8: **end for**
9: **RETURN** $Z^{BP} \cdot z$.

in weakly coupled variables (easy problems) and large values of β in strongly coupled variables (hard problems). Larger values of Θ result in easier inference problems.

In the next Subsection we analyze the full Pfaffian series using a small example and compare it with the original representation based on the loop series. Next, we compare our algorithm with the following ones:[4]

Truncated Loop-Series for BP (TLSBP) (Gómez et al., 2007), which accounts for a certain number of loops by performing depth-first-search on the factor graph and then merging the found loops iteratively. We adapted TSLBP as an any-time algorithm (**anyTLSBP**) in a way that the length of the loop is used as the only parameter instead of the two parameters S and M (see Gómez et al., 2007, for details). This is equivalent to setting $M = 0$ and discarding S. In this way, anyTLSBP does not compute all possible loops of a certain length (in particular, complex loops[5] are not included), but search can be performed faster.

Cluster Variation Method (**CVM-Loopk**) A double-loop implementation of CVM (Heskes et al., 2003). This algorithm is a special case of generalized belief propagation (Yedidia et al., 2005) with convergence guarantees. We use as outer clusters all (maximal) factors together with loops of four (k=4) or six (k=6) variables in the factor graph.

Tree-Structured Expectation Propagation (**TreeEP**) (Minka and Qi, 2004). This method performs exact inference on a base tree of the graphical model and approximates the other interactions. The method yields good results if the graphical model is very sparse.

When possible, we also compare with the following two variational methods which provide upper bounds on the partition function:

Tree Reweighting (**TRW**) (Wainwright et al., 2005) which decomposes the parameterization of a probabilistic graphical model as a mixture of spanning trees of the model, and then uses the convexity of the partition function to get an upper bound.

Planar graph decomposition (**PDC**) (Globerson and Jaakkola, 2007) which decomposes the parameterization of a probabilistic graphical model as a mixture of tractable planar graphs (with zero local field).

4. We use the libDAI library (Mooij, 2008) for algorithms **CVM-Loopk**, **TreeEP** and **TRW**.
5. A complex loop is defined as a loop which can not be expressed as the union of two or more circuits or simple loops.

To evaluate the accuracy of the approximations we consider errors in Z and, when possible, computational cost as well. As shown in Gómez et al. (2007), errors in Z, obtained from a truncated form of the loop series, are very similar to errors in single variable marginal probabilities, which can be obtained by conditioning over the variables under interest. We only consider tractable instances for which Z can be computed via the junction tree algorithm (Lauritzen and Spiegelhalter, 1988) using 8GB of memory.

The error measure for a given approximation Z' of Z is:

$$\text{error } Z' = \frac{|\log Z - \log Z'|}{\log Z},$$

and given $P'_{ab}(\sigma_{ab})$ estimates for the exact marginals $P_{ab}(\sigma_{ab})$, the error is:

$$\text{error marginals} = \text{mean}_{\substack{(a,b)\in\mathcal{E} \\ \sigma_{ab}=\pm 1}} |P'_{ab}(\sigma_{ab}) - P_{ab}(\sigma_{ab})|.$$

As in Gómez et al. (2007), we use four different message updates for BP: fixed and random sequential updates, parallel (or synchronous) updates, and residual belief propagation (RBP), a method proposed by Elidan et al. (2006) which selects the next message to be updated which has maximum *residual*, a quantity defined as an upper bound on the distance of the current messages from the fixed point. We report non-convergence when none of the previous methods converged. We report convergence at iteration t when the maximum absolute value of the updates of all the messages from iteration $t-1$ to t is smaller than a threshold $\vartheta = 10^{-14}$.

3.1 Full Pfaffian Series

In the previous Section we have described two equivalent representations for Z in terms of the loop series and the Pfaffian series. Here we analyze numerically how these two representations differ using an example, shown in Figure 3 as a bipartite factor graph, for which all terms of both series can be computed. We analyze a single instance, parameterized using $\Theta = 0.1$ and different pairwise interactions $\beta \in \{0.1, 0.5, 1.5\}$.

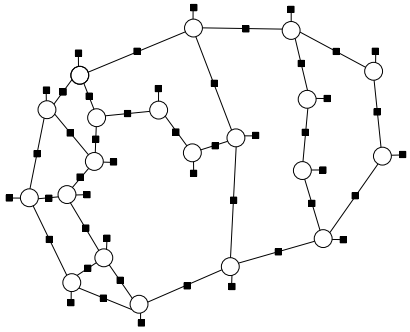

Figure 3: Planar bipartite factor graph used to compare the full Pfaffian series with the loop series. Circles and black squares denote variables and factors respectively.

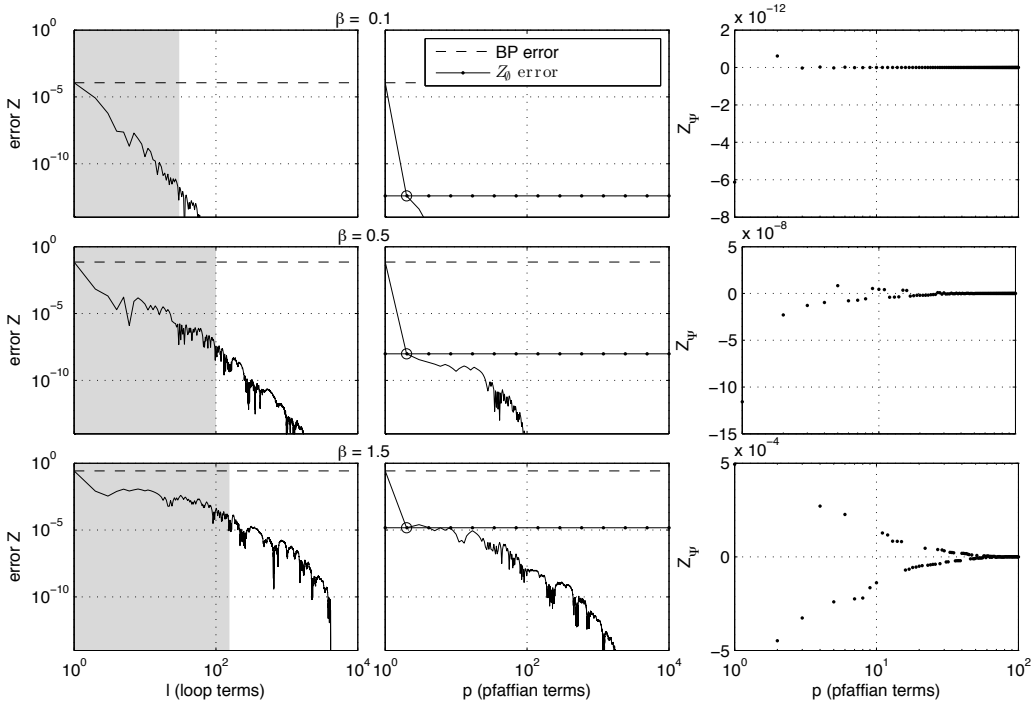

Figure 4: Comparison between the full loop series and the full Pfaffian series. Each row corresponds to a different value of the interaction strength β. **Left column** shows the error, considering loop terms $Z^{TLSBP}(l)$ in log-log scale. Shaded regions include all loop terms (not necessarily 2-regular loops) required to achieve the same (or better) accuracy than the accuracy of the 2-regular partition function $Z_\emptyset$. **Middle column** shows the error considering Pfaffian terms $Z^{Pf}(p)$ also in log-log scale. The first Pfaffian term corresponds to $Z_\emptyset$, marked by a circle. **Right column** shows the values of the first 100 Pfaffian terms sorted in descending order in $|Z_\Psi|$ and excluding $z_\emptyset$.

We use TLSBP to retrieve all loops, 8123 for this example, and Algorithm 2 to compute all Pfaffian terms. To compare the two approximations we sort all contributions, either loops or Pfaffians, by their absolute values in descending order, and then analyze how the errors are corrected as more terms are included in the approximation. We define partition functions for the truncated series in the following way:

$$Z^{TLSBP}(l) = Z^{BP}\left(1 + \sum_{i=1\ldots l} r_{C_i}\right), \qquad Z^{Pf}(p) = Z^{BP}\left(\sum_{i=1\ldots p} Z_{\Psi_i}\right).$$

Then $Z^{TLSBP}(l)$ accounts for the l most contributing loops and $Z^{Pf}(p)$ accounts for the p most contributing Pfaffian terms. In all cases, the Pfaffian term with largest absolute value Z_{Ψ_1} corresponds to $z_\emptyset$.

Figure 4 shows the error Z^{TLSBP} (first column) and Z^{Pf} (second column) for both representations. For weak interactions ($\beta = 0.1$) BP converges fast and provides an accurate approximation

with an error of order 10^{-4}. Summation of less than 50 loop terms (top-left panel) is enough to obtain machine precision accuracy. Notice that the error is almost reduced totally with $Z_\emptyset$ (top-middle panel). In this scenario, higher order terms of the Pfaffian series are negligible (top-right panel).

As we increase β, the quality of the BP approximation decreases. The number of loop corrections required to correct the BP error then increases. In this example, for intermediate interactions ($\beta = 0.5$) the first Pfaffian term $z_\emptyset$ improves considerably, more than five orders of magnitude, on the BP error, whereas approximately 100 loop terms are required to achieve a similar correction (gray region of middle-left panel).

For strong interactions ($\beta = 1.5$) BP converges after many iterations and gives a poor approximation. In this scenario also a larger proportion of loop terms (bottom-left panel) is necessary to correct the BP result up to machine precision. Looking at the bottom-left panel we find that approximately 200 loop terms are required to achieve the same correction as the one obtained by $Z_\emptyset$, which is quite accurate (bottom-middle panel).

As the right panels show, higher order Pfaffian contributions change progressively from a flat sequence of small terms to an alternating sequence of positive and negative terms which grow in absolute value as β increases. These oscillations are also present in the loop series expansion.

In general, we conclude that the $Z_\emptyset$ correction to the BP approximation can give a significant improvement even in hard problems for which BP converges after many iterations. Notice again that calculating $Z_\emptyset$, the most contributing term in the Pfaffian series, does not require explicit search for loop nor Pfaffian terms.

3.2 Grids

After analyzing the full Pfaffian series on a small random example we now restrict our attention to the first Pfaffian correction using grids (nearest neighbor connectivity). First, we compare this approximation, for both $Z_\emptyset$ and single-variable marginals, with other inference methods for different types of interactions (attractive or mixed) and then study the scalability of the method with the size of the graphs.

3.2.1 ATTRACTIVE INTERACTIONS

We first focus on binary models with "ferromagnetic" tendency, which favors alignment of neighboring variables, $\phi_a > 0$. If local fields are also positive $\theta_{ab} > 0$, Sudderth et al. (2007) showed that, under some additional condition, the BP approximation gives a *lower-bound* for the exact partition function and all loops (and therefore Pfaffian terms too) have the same sign.[6] Although this is not formally proved for general models with attractive interactions regardless of the sign of the local fields, numerical results suggest that this property holds as well for this more general type of models.

We generate grids with positive interactions and local fields, that is $|\phi_a| \sim \mathcal{N}(0, \beta/2)$ and $|\theta_{ab}| \sim \mathcal{N}(0, \beta\Theta)$, and study performance of the algorithms for various values of β, as well as for strong $\Theta = 1$ and weak $\Theta = 0.1$ local fields.

Figure 5 shows the average error over 50 instances reported by different methods. For this setup, BP converged in all instances using random sequential updates of the messages. The error curves of all methods show an initial growth and a subsequent decrease, a fact explained by the phase

6. The condition is that all single variable beliefs at the BP fixed point must satisfy $m_{ab} = \tau_{ab}(+1) - \tau_{ab}(-1) > 0, \forall (a,b) \in \mathcal{E}$.

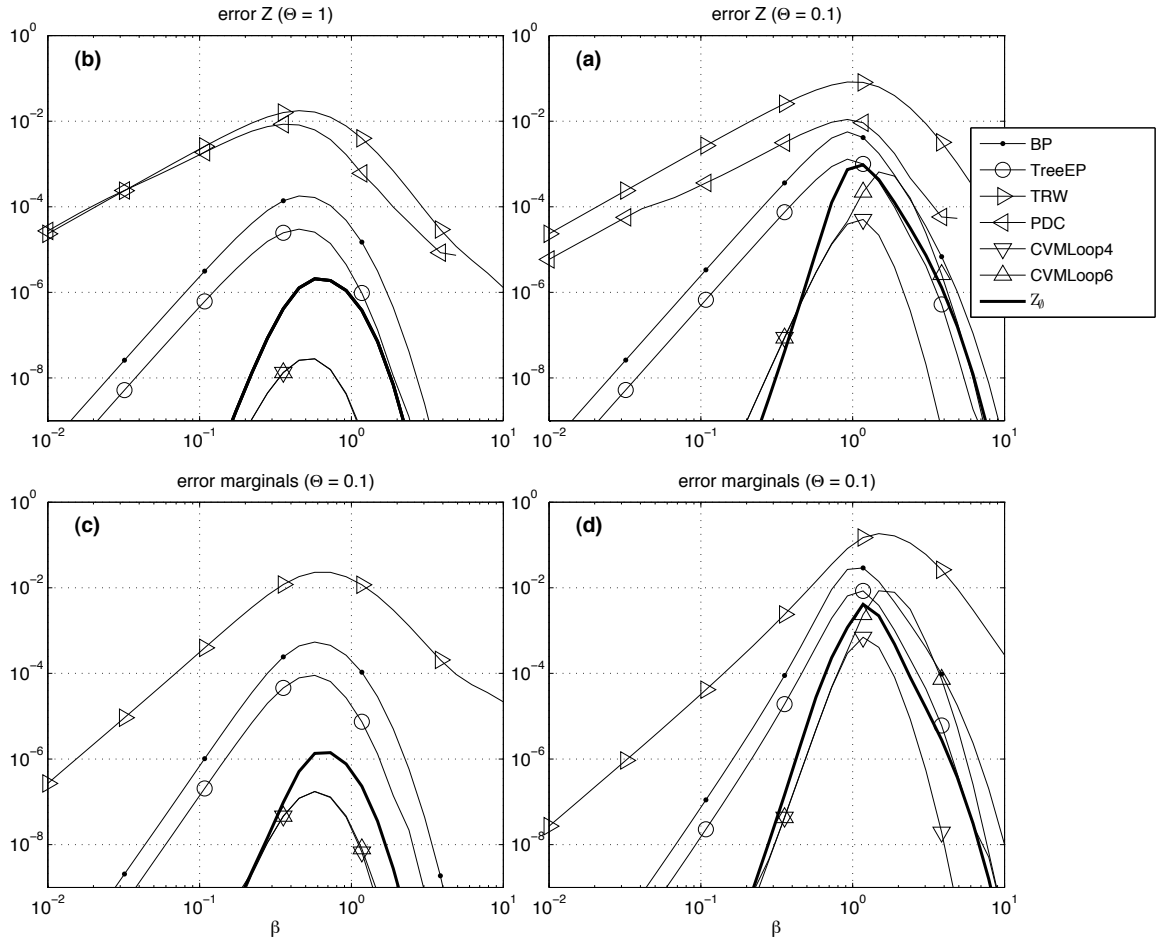

Figure 5: 7x7 grid *attractive* interactions and positive local fields. BP converged always. Errors are averages over 50 random instances for fixed β and Θ. Error in partition function Z for **(a)** strong local fields $\Theta = 1$ and **(b)** weak local fields $\Theta = 0.1$. Error in marginals for **(c)** strong local fields $\Theta = 1$ and **(d)** weak local fields $\Theta = 0.1$.

transition for $\Theta = 0$ and $\beta \approx 1$ (Mooij and Kappen, 2005). Figures suggest that errors are larger as Θ approaches zero. Notice that $Z_\emptyset = Z$ for $\Theta = 0$.

We observe that for all the instances $Z_\emptyset$ is *always an improvement* over the BP approximation. Corrections are most significant for weak interactions $\beta < 1$ and strong local fields. For strong interactions $\beta > 1$ and weak local fields, the improvement is less significant.

It appears that the $Z_\emptyset$ approximation performs better than TreeEP in all cases except for very strong couplings, where the two algorithms show very similar results. For weak local fields $Z_\emptyset$ performs similar to CVM-Loop4 which is known to be a very accurate approximation for this type of model, see Yedidia et al. (2000) for instance. Selecting larger outer-clusters such as loops of

length 6 does not necessarily leads to improvements although it leads to a dramatic increase in the computational cost.

The methods which provide upper bounds on Z (PDC and TRW) report the largest average error. PDC performs slightly better than TRW, as was shown in Globerson and Jaakkola (2007) for the case of mixed interactions. We note that the worse performance of PDC for strong couplings might be attributed to implementation artifacts, since for $\beta > 4$ the algorithm suffers from numerical precision errors. In general, both empirical upper bounds are significantly less tight than the lower bounds provided by BP and $Z_\emptyset$.

Finally, bottom plots show that errors in marginals behave very similar to errors in Z.

3.2.2 MIXED INTERACTIONS

We now analyze a more general Ising model where interactions and local fields can have mixed signs. In that case, Z^{BP} and $Z_\emptyset$ are no longer lower bounds on Z and loop terms can be positive or negative. Figure 6 shows results for this setup.

For strong local fields (subplots a,c,e), we observe that $Z_\emptyset$ improvements over BP results become less significant as β increases. It is important to note that $Z_\emptyset$ always improves the BP result, even when the couplings are very strong ($\beta = 10$) and BP fails to converge for a small percentage of instances. $Z_\emptyset$ performs very similar to CVM-Loop4 and substantially better than TreeEP for small and intermediate β. As in the case of attractive interactions, the best results are attained using CVM-loop4. CVM-loop6 gives worse estimates for $\beta > 1$.

For the case of weak local fields (subplots b,d,f), $Z_\emptyset$ is the best approximation in the weak coupling regime. BP fails to converge near the transition to the spin-glass phase. For $\beta = 10$, BP converges only in less than 25% of the instances. In the most difficult domain, $\beta > 22$, all methods under consideration give similar results (all comparable to BP). Moreover, it may happen that $Z_\emptyset$ degrades the Z^{BP} approximation because loops of alternating signs have major influence in the series. This result was also reported in Gómez et al. (2007) when loop terms, instead of Pfaffian terms, where considered.

Finally, as in the case of attractive interactions, errors in marginals behave similar to errors in Z.

3.2.3 SCALING WITH GRAPH SIZE

We now study how the accuracy of the $Z_\emptyset$ approximation changes as we increase the size of the grid. We generate random grids with mixed couplings for $\sqrt{N} = \{4, ..., 18\}$ and focus on a regime of very weak local fields $\Theta = 0.01$ and strong couplings $\beta = 1$, a difficult configuration according to the previous results. We compare $Z_\emptyset$ also with anyTLSBP, a variant of our previous algorithm for truncating the loop series. We run anyTLSBP by selecting loops shorter than a given length, and the length is increased progressively. To provide a fair comparison between both methods, we run anyTLSBP for the same amount of CPU time as the one required to obtain $Z_\emptyset$.

Figure 7a shows a comparison of the errors reported by the different algorithms. Since variability in the errors is larger than before, we take the median for comparison. In order of increasing accuracy we get BP, TreeEP, anyTLSBP, CVM-Loop6, CVM-Loop4 and $Z_\emptyset$. We note again that using larger clusters in CVM does not necessarily result in better performance.

Overall, we can see that results are roughly independent of the network size N in almost all methods that we compare. The error of anyTLSBP starts being the smallest but soon increases because the proportion of loops captured decreases very fast. For $N > 64$, anyTLSBP performs

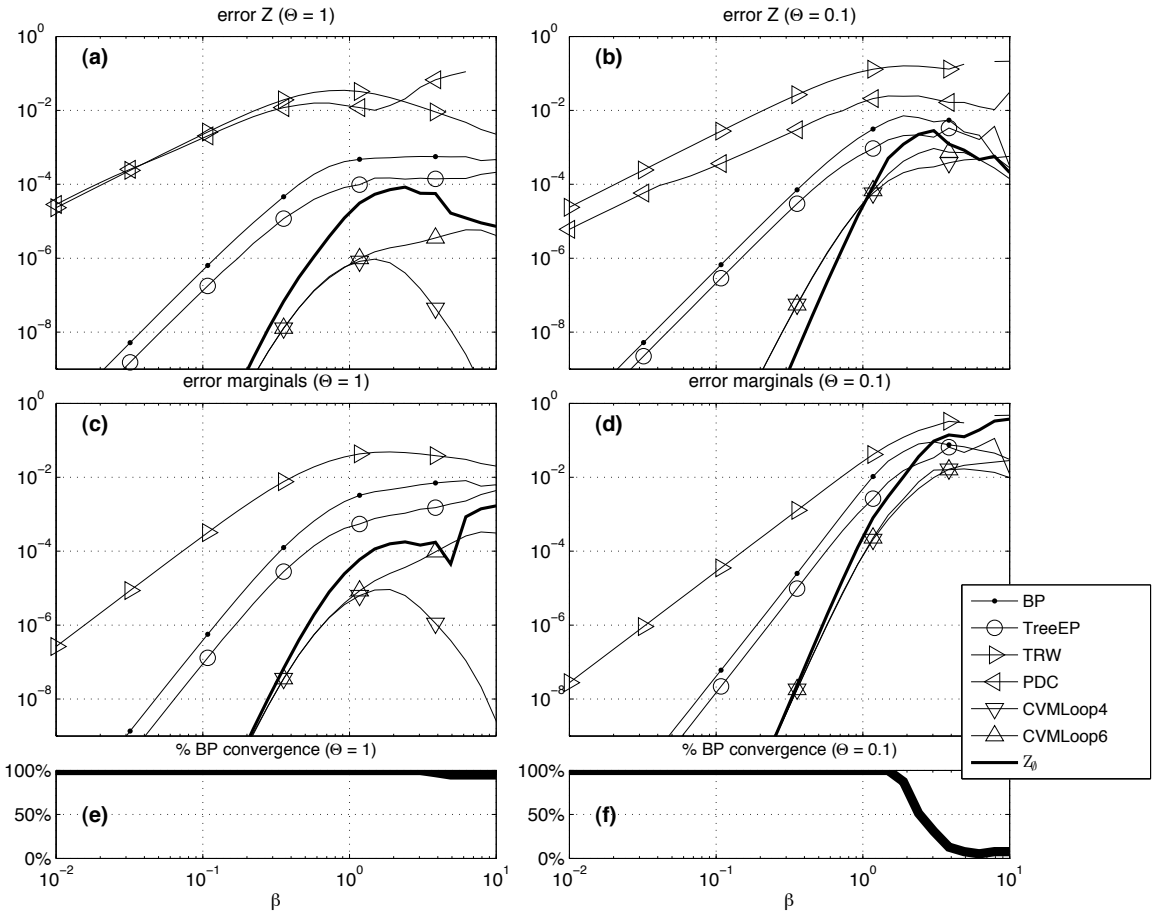

Figure 6: 7x7 grid *mixed* interactions and positive local fields. Errors are averages over 50 random instances for fixed β and Θ. Error in partition function Z for **(a)** strong local fields $\Theta = 1$ and **(b)** weak local fields $\Theta = 0.1$. Error in marginals for **(c)** strong local fields $\Theta = 1$ and **(d)** weak local fields $\Theta = 0.1$. Bottom panels show percentage of cases when BP converges using at least one of the methods described above for **(e)** strong local fields and **(f)** weak local fields.

worse than CVM. The $Z_\emptyset$ correction, on the other hand, stays flat and we can conclude that it scales reasonably well. Interestingly, although $Z_\emptyset$ and anyTLSBP use different ways to truncate the loop series, both methods show similar scaling behaviour for large graphs.

Figure 7b shows the CPU time for all the tested approaches averaged over all the cases. The CPU time of the junction tree method quickly increases with the tree-width of the graphs. For large enough N, exact solution via the junction tree method is no longer feasible because of the memory requirements. In contrast, for all the approximate inference methods, memory demands do not represent a limitation.

In order of increasing cost we have BP, $Z_\emptyset$ with anyTLSBP, TreeEP, CVM-Loop4 and CVM-Loop6. The $Z_\emptyset$ therefore is a very efficient correction to Z^{BP}.

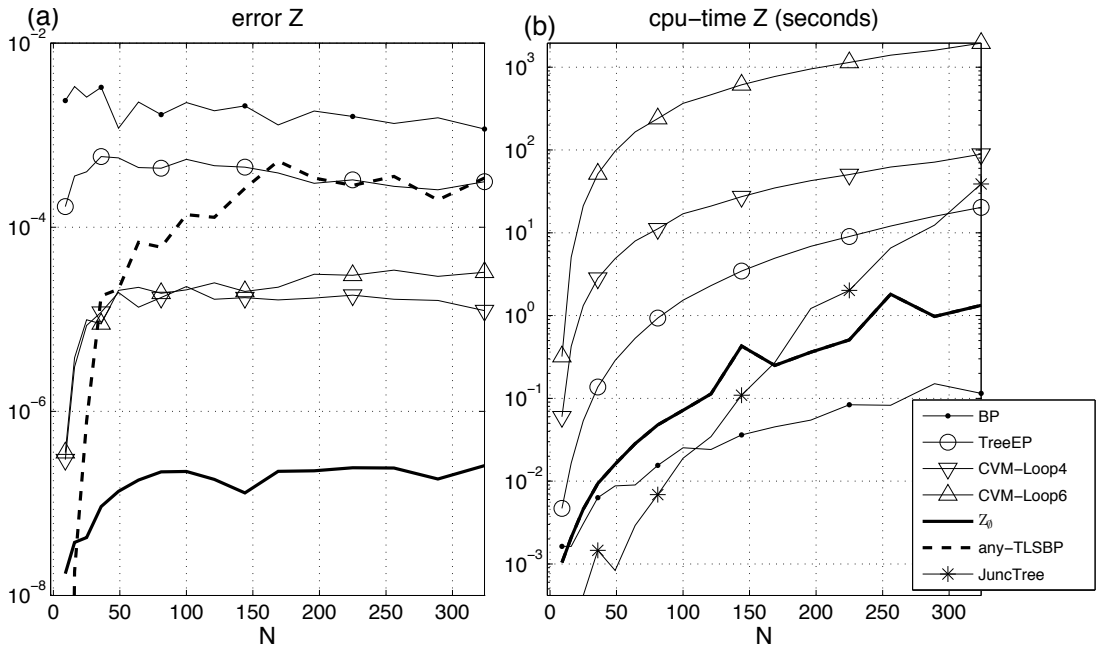

Figure 7: Results on regular grids: scaling with grid size for strong interactions $\beta = 1$ and very weak local fields $\Theta = 0.01$. Error medians over 50 random instances. BP converged always. **(a)** Partition function Z error. **(b)** CPU time to compute Z.

3.3 Radial Grid Graphs

In the previous Subsection we analyzed the quality of the $Z_\emptyset$ correction for graphs with a regular grid structure. Here, we carry over the analysis of the $Z_\emptyset$ correction using planar graphs which consist of concentric polygons with a variable number of sides. Figure 8 illustrates these spider-web graphs. We generate them as factor graphs with pairwise interactions which we subsequently convert to an equivalent Forney graph using the procedure described in Appendix A.2. Again, local field potentials are parameterized using $\Theta = 0.01$ and interactions using $\beta = 1$. We analyze the error in Z as a function of the degree d of the central node.

Figure 9a shows the median of errors in Z for 50 random instances. First, we see that the variability of all the methods, in particular anyTLSBP, is larger than in the regular grid scenario. CVM-Loop6 does not converge for instances with $d > 4$ before 10^4 seconds and it is thus not included in the analysis. We can say that all approaches scale reasonably well, and as d grows, the errors become independent of d.

The $Z_\emptyset$ approximation is the best method compared to the other tested approaches. The improvements of $Z_\emptyset$ over CVM-Loop4 (the second best method) can be more than two orders of magnitude and more than three orders of magnitude compared to BP.

Computational costs are shown in 9b. Again, for larger graphs, exact solution via the junction tree is not feasible due to the large tree-width and $Z_\emptyset$ represent the most efficient correction which improves BP of all approximate methods we compared.

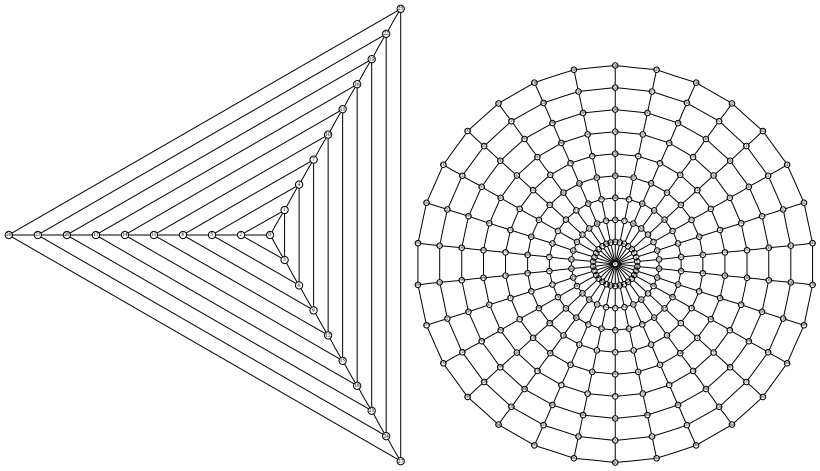

Figure 8: Two examples of planar graphs used for comparison between methods. We fix the number of concentric polygons to 9 and change the degree d of the central node within the range $[3,...,25]$. **(left)** Graph for $d = 3$. **(right)** Graph for $d = 25$. Here nodes represent variables and edges pairwise interactions. We also add external fields which depend on the state of each node (not drawn).

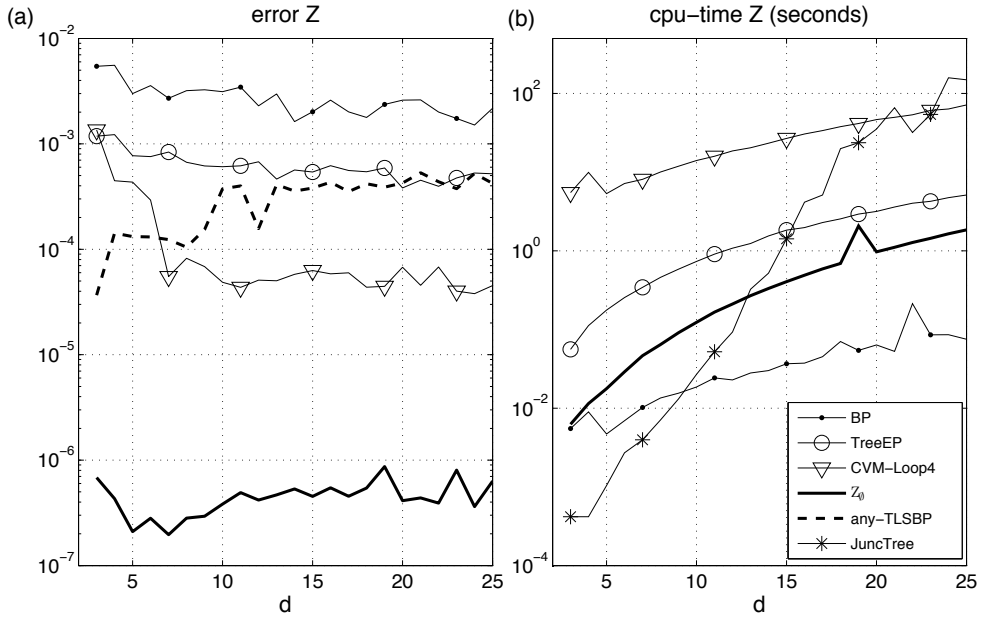

Figure 9: Results on spider-web graphs: scaling with the degree d of the central node for $\beta = 1$ and $\Theta = 0.01$. BP converged always. **(a)** Median of the error in the partition function Z over 50 random instances. **(b)** CPU time required to compute Z.

4. Discussion

We have presented an approximate algorithm based on the exact loop calculus framework for inference on planar graphical models defined in terms of binary variables. The proposed approach improves the estimate for the partition function provided by BP without an explicit search for loops.

The algorithm is illustrated on the example of ordered and disordered Ising model on a planar graph. Performance of the method is analyzed in terms of its dependence on the system size. The complexity of the partition function computation is exponential in the general case, unless the local fields are zero, when it becomes polynomial. We tested our algorithm on regular grids and planar graphs with different structures. Our experiments on regular grids show that significant improvements over BP are always obtained if single variable potentials (local magnetic fields) are sufficiently large. The quality of this correction degrades with decrease in the amplitude of external field, to become exact at zero external fields. This suggests that the difficulty of the inference task changes from very easy, with no local fields, to very hard, with small local fields, and then decays again as external fields become larger.

The $Z_\emptyset$ correction turns out to be competitive with other state of the art methods for approximate inference of the partition function. First of all, we showed that $Z_\emptyset$ is much more accurate than upper bounds based methods such as TRW or PDC, illustrating that such methods come at the cost of accuracy. We have also shown that for the case of grids with attractive symmetric interactions and positive local fields, the lower bound provided by $Z_\emptyset$ is the most accurate.

We also found that $Z_\emptyset$ performs much better than treeEP for weak and intermediate interactions and similar for strong interactions. Comparing with CVM, we have found that $Z_\emptyset$ presented better results for very small local fields. Using larger outer clusters in CVM does not necessarily lead to better approximations.

Finally, we have presented a comparison of $Z_\emptyset$ with TLSBP, which is another algorithm based on the loop series expansion for BP that uses the loop length as truncation parameter. On one hand, the calculation of $Z_\emptyset$ involves a *re-summation* of many loop terms which in the case of TLSBP are summed individually. This consideration favors the $Z_\emptyset$ approach. On the other hand, $Z_\emptyset$ is restricted to the class of 2-regular loops whereas TLSBP also accounts for terms corresponding to more complex loop structures in which nodes can have degree larger than two. Overall, for planar graphs, we have shown evidence that the $Z_\emptyset$ approach is better than TLSBP when the size of the graphs is not very small. We emphasize, however, that TLSBP can be applied to non-planar binary graphical models too.

Although planarity is a severe restriction, we emphasize that planar graphs appear in many contexts such as computer vision and image processing, magnetic and optical recording, or network routing and logistics. We have focused on inference problems defined on planar graphs with symmetric pairwise interactions and, to make the problems difficult, we have introduced local field potentials. Notice however, that the algorithm can also be used to solve models with more complex interactions, that is, more than pairwise typical from the Ising model (see Chertkov et al., 2008, for a discussion of possible generalizations). This makes our approach more applicable than other approaches, namely, (Globerson and Jaakkola, 2007; Schraudolph and Kamenetsky, 2008), designed specifically for the pairwise interaction case.

Summarizing, among the compared methods and models, the introduced approach based on $Z_\emptyset$ represents the best estimate to the partition function as long as the given graph does not deviate too much from perfect planarity, that is, we are in the small local field regime. It also represents

an efficient correction to the BP estimate of the partition function, being much more efficient than CVM, the second best method we have analyzed. Finally, we have shown that estimates of single-variable marginals calculated using $Z_\emptyset$ are comparable to state of the art inference methods.

Appendix A. Bipartite Factor Graph Representation

The Forney graph representation is convenient because each loop decomposes naturally in terms associated with nodes which have the same analytical form of Equation (4). However, probabilistic models are more frequently represented as bipartite factor graphs. In this Appendix we first show how the presented approach differs when it is directly applied to a bipartite factor graph and second, how to convert a bipartite factor graph to a Forney graph.

We consider binary variables i which take values $x_i \in \{\pm 1\}$ and factor functions $\psi_a(\mathbf{x}_a)$ defined over subsets a of variables which take values $\mathbf{x}_a := \{x_i | i \in a\}$. On a bipartite factor graph $\mathcal{G}_{fg} := (\mathcal{V}_{fg}, \mathcal{E}_{fg})$, the set $\mathcal{V}_{fg}$ consists of variable nodes $i \in I$ and factor nodes $a \in \mathcal{A}$, with an edge between i and a iff $i \in a$, that is i appears in the factor function ψ_a.

The joint probability distribution of vector $\mathbf{x} := \{x_i | i \in \mathcal{V}\}$ is specified as:

$$p(\mathbf{x}) = \frac{1}{Z(\psi)} \prod_{a \in \mathcal{A}} \psi_a(\mathbf{x}_a), \qquad Z(\psi) = \sum_{\mathbf{x}} \prod_{a \in \mathcal{A}} \psi_a(\mathbf{x}_a),$$

where we have stressed the dependency of Z on the potential functions ψ.

A.1 Loop Calculus for Standard Factor-Graph Model

Following Sudderth et al. (2007), one can use the reparameterized model in terms of the factor pseudo-marginals $\tau_a(\mathbf{x}_a)$ and the variable pseudo-marginals $\tau_i(x_i)$ associated with the minimum of the Bethe free energy:

$$p(\mathbf{x}) = \frac{1}{Z(\tau)} \prod_{i \in I} \tau_i(x_i) \prod_{a \in \mathcal{A}} \frac{\tau_a(\mathbf{x}_a)}{\prod_{j \in a} \tau_j(x_j)},$$

and express the relation between the exact $Z(\psi)$ and the Bethe partition functions $Z^{BP}(\psi;\tau)$ as $Z(\psi)/Z(\tau) = Z^{BP}(\psi;\tau)$. The loop series correction becomes:

$$Z(\tau) = 1 + \sum_{C \in \mathcal{C}} s_C, \qquad s_C = \prod_{a \in C} \mu_a(C) \prod_{i \in C} \mu_i(C),$$

where each term s_C is associated with a loop and can be specified as a product between terms $\mu_a(C)$ and $\mu_i(C)$ corresponding to factor nodes a and variable nodes i in C respectively:

$$\mu_a(C) = \frac{\mathbb{E}_{\tau_a}\left[\prod_{i\in a, i\in C}(x_i - m_i)\right]}{\prod_{i\in a, i\in C}\mathrm{Var}_{\tau_i}(x_i)} \qquad \mu_i(C) = \mathbb{E}_{\tau_i}\left[(x_i - m_i)^{d_i(C)}\right],$$

where $d_i(C)$ is the degree of variable node i in the loop C and m_i is again $\mathbb{E}_{\tau_i}[x_i]$. For the $x_i = \{\pm 1\}$ alphabet, we have $m_i = \tau_i(+1) - \tau_i(-1)$ and the formulas become:

$$\begin{aligned}
\mu_a(C) &= \frac{\sum_{\mathbf{x}_a}\tau_a(\mathbf{x}_a)\prod_{i\in a, i\in C}(x_i - m_i)}{\prod_{i\in a, i\in C}\tau_i(+1)(1-m_i)^2 + \tau_i(-1)(-1-m_i)^2} \\
&= \frac{\sum_{\mathbf{x}_a}\tau_a(\mathbf{x}_a)\prod_{i\in a, i\in C}(x_i - m_i)}{\prod_{i\in a, i\in C}\frac{1+m_i}{2}(1-m_i)^2 + \frac{1-m_i}{2}(1+m_i)^2} \\
&= \frac{\sum_{\mathbf{x}_a}\tau_a(\mathbf{x}_a)\prod_{i\in a, i\in C}(x_i - m_i)}{\prod_{i\in a, i\in C}(1-m_i^2)}, \qquad (9) \\
\mu_i(C) &= \tau_i(+1)(1-m_i)^{d_i(C)} + \tau_i(-1)(-1-m_i)^{d_i(C)} \\
&= \frac{1+m_i}{2}(1-m_i)(1-m_i)^{d_i(C)-1} + \frac{1-m_i}{2}(1+m_i)(-1)^{d_i(C)}(1+m_i)^{d_i(C)-1} \\
&= \frac{1-m_i^2}{2}\Big((1-m_i)^{d_i(C)-1} + (-1)^{d_i(C)}(1+m_i)^{d_i(C)-1}\Big). \qquad (10)
\end{aligned}$$

One can recover the original formulation of Chertkov and Chernyak (2006a, Pag.5) reallocating the denominator of (9) to (10) and simplifying.

Now consider Figure 2 where the construction of the extended graph $\mathcal{G}_{ext}$ is described. Clearly, the one-to-one correspondence from 2-regular loops in $\mathcal{G}$ to perfect matchings in $\mathcal{G}_{ext}$ is independent of whether $\mathcal{G}$ is expressed as a bipartite factor graph or a Forney graph. For a bipartite factor graph, the terms of Equation (5) are replaced with terms given by Equation (10) if the expanded node is a variable or by Equation (9) if the expanded node is a factor. As previously stated, the Forney style allows to express in the same form the weights of the extended graph $\mathcal{G}_{ext}$.

A.2 Converting a Bipartite Factor Graph to a Forney-Style Factor Graph.

We show here how to convert a bipartite factor graph defined in terms of binary variables to a more general Forney graph representation, for which the presented algorithm can be directly applied to.

We label variable and factor nodes using numbers and capital letters respectively. Thus $i \in I, i := \{1,2,\dots\}$ represents a variable and $a = \{A,B,\dots\}, a \in \mathcal{A}$ a factor. Given $\mathcal{G}_{fg} := (\mathcal{V}_{fg}, \mathcal{E}_{fg})$, a direct way to obtain an equivalent Forney graph $\mathcal{G} := (\mathcal{V}, \mathcal{E})$ is: first, to create a node $\delta_i \in \mathcal{V}$ for each variable node $i \in \mathcal{V}_{fg}$, and second, to associate a new binary variable $\delta_i a$ with values $\sigma_{\delta_i a} = \{\pm 1\}$ to edges $(\delta_i, a) \in \mathcal{E}$. Nodes $\delta_i \in \mathcal{V}$ are *equivalent factor nodes* denoting the characteristic function: $f_{\delta_i}(\boldsymbol{\sigma}_{\delta_i}) = 1$ if $\sigma_{\delta_i a} = \sigma_{\delta_i b}, \forall a,b \in \bar{\delta}_i$ and zero otherwise. Finally, factor nodes $c \in \mathcal{V}_{fg}$ with associated functions $\psi_c(\mathbf{x}_c)$ correspond to the same factor nodes c in $\mathcal{V}$ with same associated functions $f_c(\boldsymbol{\sigma}_c)$ and defined in terms of the new variables $\delta_i c, \forall i \in \bar{c}$. Figure 10 shows an example of this transformation. Notice that, although we impose a direction in the edge labels, they remain undirected: $(\delta_i, a) = (a, \delta_i), \forall \delta_i, a \in \mathcal{V}$. For variables $i \in \mathcal{V}_{fg}$ which only appear in two factors, such as variable 3 in Figure 10a, the corresponding node δ_3 is redundant and can be removed. The joint

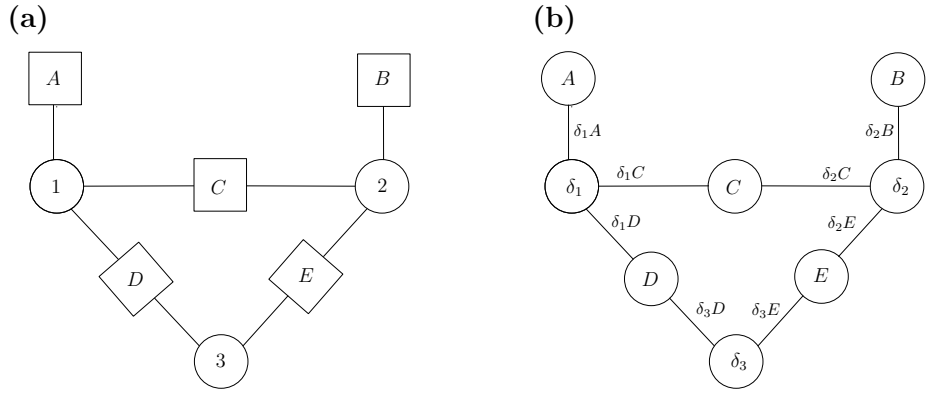

Figure 10: **(a)** Bipartite factor graph $\mathcal{G}_{fg}$ where squares represent factors and circles represent variables. **(b)** Equivalent Forney-style factor graph $\mathcal{G}$ where factors reside in the nodes and variables in the edges.

distribution of $\mathcal{G}_{fg}$ is related to the joint distribution of $\mathcal{G}$ by:

$$\begin{aligned}
&\frac{1}{Z}\psi_A(x_1)\psi_B(x_2)\psi_C(x_1,x_2)\psi_D(x_1,x_3)\psi_E(x_2,x_3)\\
\equiv&\frac{1}{Z}f_A(\sigma_{\delta_1 A})f_B(\sigma_{\delta_2 B})f_C(\sigma_{\delta_1 C},\sigma_{\delta_2 C})f_D(\sigma_{\delta_1 D},\sigma_{\delta_3 D})f_E(\sigma_{\delta_2 E},\sigma_{\delta_3 E})\\
&f_{\delta_1}(\sigma_{\delta_1 A},\sigma_{\delta_1 C},\sigma_{\delta_1 D})f_{\delta_2}(\sigma_{\delta_2 B},\sigma_{\delta_2 C},\sigma_{\delta_2 E})f_{\delta_3}(\sigma_{\delta_3 D},\sigma_{\delta_3 E}).
\end{aligned}$$

Once $\mathcal{G}$ has been generated following the previous procedure it may be the case that the nodes $\delta_i \in \mathcal{V}$ have degree three or larger. This happens if a variable i appears in more than three factors on $\mathcal{G}_{fg}$. It is easy to convert $\mathcal{G}$ to a graph were all δ_i nodes have maximum degree three by introducing new auxiliary variables $\delta_{i_1}, \delta_{i_2}, \ldots$ and new equivalent nodes. For instance, if variable $i \in \mathcal{V}_{fg}$ appears in four factors A, B, C, D:

$$f_{\delta_i}(\sigma_{\delta_i A},\sigma_{\delta_i B},\sigma_{\delta_i C},\sigma_{\delta_i D}) \equiv f_{\delta_{i_1}}(\sigma_{\delta_i A},\sigma_{\delta_i B},\sigma_{\delta_{i_1}})f_{\delta_{i_2}}(\sigma_{\delta_{i_1}},\sigma_{\delta_i C},\sigma_{\delta_i D}).$$

Notice that although the models are equivalent, the number of loops in $\mathcal{G}$ may be larger than in $\mathcal{G}_{fg}$. In the case that a factor in $\mathcal{G}_{fg}$ involves more than three variables, as sketched in Chertkov et al. (2008), one could split the node of degree N into auxiliary nodes of degree $N-1$ and compute $Z_\emptyset$ on the transformed model. Alternatively, one can reduce the number of variables that enter a factor conditioning over the variables.

Abstract

For many supervised learning tasks it may be infeasible (or very expensive) to obtain objective and reliable labels. Instead, we can collect subjective (possibly noisy) labels from multiple experts or annotators. In practice, there is a substantial amount of disagreement among the annotators, and hence it is of great practical interest to address conventional supervised learning problems in this scenario. In this paper we describe a probabilistic approach for supervised learning when we have multiple annotators providing (possibly noisy) labels but no absolute gold standard. The proposed algorithm evaluates the different experts and also gives an estimate of the actual hidden labels. Experimental results indicate that the proposed method is superior to the commonly used majority voting baseline.

Keywords: multiple annotators, multiple experts, multiple teachers, crowdsourcing

1. Supervised Learning From Multiple Annotators/Experts

A typical supervised learning scenario consists of a training set $\mathcal{D} = \{(\boldsymbol{x}_i, y_i)\}_{i=1}^{N}$ containing N instances, where $\boldsymbol{x}_i \in \mathcal{X}$ is an instance (typically a d-dimensional feature vector) and $y_i \in \mathcal{Y}$ is the corresponding known label. The task is to learn a function $f : \mathcal{X} \rightarrow \mathcal{Y}$ which generalizes well on unseen data. Specifically for binary classification the supervision is from the set $\mathcal{Y} = \{0,1\}$, for multi-class classification $\mathcal{Y} = \{1,\ldots,K\}$, for ordinal regression $\mathcal{Y} = \{1,\ldots,K\}$ (with an ordering $1 < \ldots < K$), and $\mathcal{Y} = \mathbb{R}$ for regression.

However, for many real life tasks, it may not be possible, or may be too expensive (or tedious) to acquire the actual label y_i for training—which we refer to as the *gold standard* or the *objective ground truth*. Instead, we may have multiple (possibly noisy) labels $y_i^1, \ldots, y_i^R$ provided by R different experts or annotators. In practice, there is a substantial amount of disagreement among the experts, and hence it is of great practical interest to address conventional supervised learning algorithms in this scenario.

Our motivation for this work comes from the area of computer-aided diagnosis[1] (CAD), where the task is to build a classifier to predict whether a suspicious region on a medical image (like a X-ray, CT scan, or MRI) is malignant (cancerous) or benign. In order to train such a classifier, a set of images is collected from hospitals. The actual gold standard (whether it is cancer or not) can only be obtained from a biopsy of the tissue. Since it is an expensive, invasive, and potentially dangerous process, often CAD systems are built from labels assigned by *multiple radiologists* who identify the locations of malignant lesions. Each radiologist visually examines the medical images and provides a *subjective* (possibly noisy) version of the gold standard.[2] The radiologist also annotates various descriptors of the potentially malignant lesion, like the size (a regression problem), shape (a multi-class classification problem), and also degree of malignancy (an ordinal regression problem). The radiologists come from a diverse pool including luminaries, experts, residents, and novices. Very often there is lot of disagreement among the annotations.

For a lot of tasks the labels provided by the annotators are inherently *subjective* and there will be substantial variation among different annotators. The domain of text classification offers such a scenario. In this context the task is to predict the category for a token of text. The labels for training are assigned by human annotators who read the text and attribute their subjective category. With the advent of crowdsourcing (Howe, 2008) services like Amazon's Mechanical Turk,[3] Games with a Purpose,[4] and reCAPTCHA[5] it is quite inexpensive to acquire labels from a large number of annotators (possibly thousands) in a short time (Sheng et al., 2008; Snow et al., 2008; Sorokin and Forsyth, 2008). Websites such as Galaxy Zoo[6] allow the public to label astronomical images over the internet. In situations like these, the performance of different annotators can vary widely (some may even be malicious), and without the actual gold standard, it may not be possible to evaluate the annotators.

In this work, we provide principled probabilistic solutions to the following questions:

1. How to adapt conventional supervised learning algorithms when we have multiple annotators providing subjective labels but no objective gold standard?

2. How to evaluate systems when we do not have absolute gold-standard?

3. A closely related problem—particularly relevant when there are a large number of annotators—is to estimate how reliable/trustworthy is each annotator.

1. See Fung et al. (2009) for an overview of the data mining issues in this area.
2. Sometimes even a biopsy cannot confirm whether it is cancer or not and hence all we can hope to get is subjective ground truth.

1.1 The Problem With Majority Voting

When we have multiple labels a commonly used strategy is to use the labels on which the majority of them agree (or average for regression problem) as an estimate of the actual gold standard. For binary classification problems this amounts to using the majority label,[7] that is,

$$\hat{y}_i = \begin{cases} 1 & \text{if } (1/R)\sum_{j=1}^{R} y_i^j > 0.5 \\ 0 & \text{if } (1/R)\sum_{j=1}^{R} y_i^j < 0.5 \end{cases},$$

as an *estimate of the hidden true label* and use this estimate to learn and evaluate classifiers/annotators. Another strategy is that of considering every pair (instance, label) provided by each expert as a separate example. Note that this amounts to using a soft probabilistic estimate of the actual ground truth to learn the classifier, that is,

$$\Pr[y_i = 1 | y_i^1, \ldots, y_i^R] = (1/R)\sum_{j=1}^{R} y_i^j.$$

Majority voting assumes all experts are equally good. However, for example, if there is only one true expert and the majority are novices, and if novices give the same incorrect label to a specific instance, then the majority voting method would favor the novices since they are in a majority. One could address this problem by introducing a weight capturing how good each expert is. But how would one measure the performance of an expert when there is no gold standard available?

1.2 Proposed Approach and Organization

To address the apparent chicken-and-egg problem, we present a maximum-likelihood estimator that *jointly* learns the classifier/regressor, the annotator accuracy, and the actual true label. For ease of exposition we start with binary classification problem in § 2. The performance of each annotator is measured in terms of the sensitivity and specificity with respect to the unknown gold standard (§ 2.1). The proposed algorithm automatically discovers the best experts and assigns a higher weight to them. In order to incorporate prior knowledge about each annotator, we impose a beta prior on the sensitivity and specificity and derive the maximum-a-posteriori estimate (§ 2.6). The final estimation is performed by an Expectation Maximization (EM) algorithm that iteratively establishes a particular gold standard, measures the performance of the experts given that gold standard, and refines the gold standard based on the performance measures. While the proposed approach is described using logistic regression as the base classifier (§ 2.2), it is quite general, and can be used with any black-box classifier (§ 2.7), and can also handle missing labels (that is, each expert is not required to label all the instances). Furthermore, we extend the proposed algorithm to handle categorical (§ 3), ordinal (§ 4), and regression problems (§ 5). In § 6 section we extensively validate our approach using both simulated data and real data from different domains.

1.3 Related Work and Novel Contributions

We first summarize the novel contributions of this work in context of other related work in this emerging new area. There has been a long line of work in the biostatistics and epidemiology literature on latent variable models where the task is to get an estimate of the observer error rates based

7. When there is no clear majority among the multiple experts (that is, $\hat{y}_i = 0.5$) in CAD domain the final decision is often made by an adjudicator or a super-expert. When there is no adjudicator a fair coin toss is used.

on the results from multiple diagnostic tests without a gold standard (see Dawid and Skene, 1979, Hui and Walter, 1980, Hui and Zhou, 1998, Albert and Dodd, 2004 and references therein). In the machine learning community Smyth et al. (1995) first addressed the same problem in the context of labeling volcanoes in satellite images of Venus. We differ from this previous body of work in the following aspects:

1. Unlike Dawid and Skene (1979) and Smyth et al. (1995) which just focused on estimating the ground truth from multiple noisy labels, we specifically address the issue of *learning a classifier*. Estimating the ground truth and the annotator/classifer performance is a byproduct of our proposed algorithm.

2. In order to learn a classifier Smyth (1995) proposed to first estimate the ground truth (without using the features) and then use the probabilistic ground truth to learn a classifier. In contrast, our proposed algorithm *learns the classifier and the ground truth jointly*. Our experiments (§ 6.1.1) show that the classifier learnt and ground truth obtained by the proposed algorithm is superior to that obtained by other procedures which first estimates the ground truth and then learns the classifier.

3. Our solution is more general and can be easily extended to categorical(§ 3), ordinal(§ 4), and continuous data(§ 5). It can also be used in conjunction with any supervised learning algorithm. A preliminary version of this paper (Raykar et al., 2009) mainly discussed the binary classification problem.

4. Our proposed algorithm is also Bayesian—we impose a prior on the experts. The priors can potential capture the skill of different annotators. In this paper we refrain from doing a full Bayesian inference and use the mode of the posterior as a point estimate. A recent complete Bayesian generalization of these kind of models has been developed by Carpenter (2008).

5. The EM approach used in this paper is similar to that proposed by Jin and Ghahramani (2003). However their motivation is somewhat different. In their setting, each training example is annotated with a set of possible labels, only one of which is correct.

There has been recent interest in the natural language processing (Sheng et al., 2008; Snow et al., 2008) and computer vision (Sorokin and Forsyth, 2008) communities where they use Amazon's Mechanical Turk to collect annotations from many people. They show that it can be potentially as good as that provided by an expert. Sheng et al. (2008) analyzed when it is worthwhile to acquire new labels for some of the training examples. There is also some theoretical work (see Lugosi, 1992 and Dekel and Shamir, 2009a) dealing with multiple experts. Recently Dekel and Shamir (2009b) presented an algorithm which does not resort to repeated labeling, that is, each example does not have to be labeled by multiple teachers. Donmez et al. (2009) address the issue of active learning in this scenario—How to jointly learn the accuracy of labeling sources and obtain the most informative labels for the active learning task? There has also been some work in the medical imaging community (Warfield et al., 2004; Cholleti et al., 2008).

2. Binary Classification

We first describe our proposed noise model for the annotators. The performance of each annotator is measured in terms of the sensitivity and specificity with respect to the unknown gold standard.

2.1 A Two-coin Model for Annotators

Let $y^j \in \{0,1\}$ be the label assigned to the instance $\boldsymbol{x}$ by the j^{th} annotator/expert. Let y be the actual (unobserved) label for this instance. Each annotator provides a version of this hidden true label based on two biased coins. If the true label is one, she flips a coin with bias α^j (*sensitivity*). If the true label is zero, she flips a coin with bias β^j (*specificity*). In each case, if she gets heads she keeps the original label, otherwise she flips the label.

If the true label is one, the sensitivity (true positive rate) for the j^{th} annotator is defined as the probability that she labels it as one.

$$\alpha^j := \Pr[y^j = 1 | y = 1]. \tag{1}$$

On the other hand, if the true label is zero, the specificity (1−false positive rate) is defined as the probability that she labels it as zero.

$$\beta^j := \Pr[y^j = 0 | y = 0]. \tag{2}$$

The assumption introduced is that α^j and β^j do not depend on the instance $\boldsymbol{x}$. For example, in the CAD domain, this means that the radiologist's performance is consistent across different sub-groups of data.[8]

2.2 Classification Model

While the proposed method can be used for any classifier, for ease of exposition, we consider the family of linear discriminating functions: $\mathcal{F} = \{f_{\boldsymbol{w}}\}$, where for any $\boldsymbol{x}, \boldsymbol{w} \in \mathbb{R}^d$, $f_{\boldsymbol{w}}(\boldsymbol{x}) = \boldsymbol{w}^\top \boldsymbol{x}$. The final classifier can be written in the following form: $\hat{y} = 1$ if $\boldsymbol{w}^\top \boldsymbol{x} \geq \gamma$ and 0 otherwise. The threshold γ determines the operating point of the classifier. The Receiver Operating Characteristic (ROC) curve is obtained as γ is swept from $-\infty$ to ∞. The probability for the positive class is modeled as a *logistic sigmoid* acting on $f_{\boldsymbol{w}}$, that is,

$$\Pr[y = 1 | \boldsymbol{x}, \boldsymbol{w}] = \sigma(\boldsymbol{w}^\top \boldsymbol{x}),$$

where the logistic sigmoid function is defined as $\sigma(z) = 1/(1+e^{-z})$. This classification model is known as *logistic regression*.

2.3 Estimation/Learning Problem

Given the training data $\mathcal{D}$ consisting of N instances with annotations from R annotators, that is, $\mathcal{D} = \{\boldsymbol{x}_i, y_i^1, \ldots, y_i^R\}_{i=1}^N$, the task is to estimate the weight vector $\boldsymbol{w}$ and also the sensitivity $\boldsymbol{\alpha} = [\alpha^1, \ldots, \alpha^R]$ and the specificity $\boldsymbol{\beta} = [\beta^1, \ldots, \beta^R]$ of the R annotators. It is also of interest to get an estimate of the unknown gold standard $y_1, \ldots, y_N$.

2.4 Maximum Likelihood Estimator

Assuming the training instances are independently sampled, the likelihood function of the parameters $\theta = \{\boldsymbol{w}, \boldsymbol{\alpha}, \boldsymbol{\beta}\}$ given the observations $\mathcal{D}$ can be factored as

$$\Pr[\mathcal{D}|\theta] = \prod_{i=1}^{N} \Pr[y_i^1, \ldots, y_i^R | \boldsymbol{x}_i, \theta].$$

8. While this is a reasonable assumption, it is not entirely true. It is known that some radiologists are good at detecting certain kinds of malignant lesions based on their training and experience.

Conditioning on the true label y_i, and also using the assumption y_i^j is conditionally independent (of everything else) given α^j, β^j and y_i, the likelihood can be decomposed as

$$\begin{aligned}\Pr[\mathcal{D}|\theta] &= \prod_{i=1}^{N}\big\{\Pr[y_i^1,\ldots,y_i^R|y_i=1,\boldsymbol{\alpha}]\Pr[y_i=1|\boldsymbol{x_i},\boldsymbol{w}] \\ &+ \Pr[y_i^1,\ldots,y_i^R|y_i=0,\boldsymbol{\beta}]\Pr[y_i=0|\boldsymbol{x_i},\boldsymbol{w}]\big\}.\end{aligned}$$

Given the true label y_i, we assume that $y_i^1,\ldots,y_i^R$ are independent, that is, the annotators make their decisions independently.[9] Hence,

$$\Pr[y_i^1,\ldots,y_i^R|y_i=1,\boldsymbol{\alpha}] = \prod_{j=1}^{R}\Pr[y_i^j|y_i=1,\alpha^j] = \prod_{j=1}^{R}[\alpha^j]^{y_i^j}[1-\alpha^j]^{1-y_i^j}.$$

Similarly, we have

$$\Pr[y_i^1,\ldots,y_i^R|y_i=0,\boldsymbol{\beta}] = \prod_{j=1}^{R}[\beta^j]^{1-y_i^j}[1-\beta^j]^{y_i^j}.$$

Hence the likelihood can be written as

$$\Pr[\mathcal{D}|\theta] = \prod_{i=1}^{N}\big[a_i p_i + b_i(1-p_i)\big],$$

where we have defined

$$\begin{aligned}p_i &:= \sigma(\boldsymbol{w}^\top \boldsymbol{x}_i). \\ a_i &:= \prod_{j=1}^{R}[\alpha^j]^{y_i^j}[1-\alpha^j]^{1-y_i^j}. \\ b_i &:= \prod_{j=1}^{R}[\beta^j]^{1-y_i^j}[1-\beta^j]^{y_i^j}.\end{aligned}$$

The maximum-likelihood estimator is found by maximizing the log-likelihood, that is,

$$\hat{\theta}_{\mathrm{ML}} = \{\hat{\boldsymbol{\alpha}},\hat{\boldsymbol{\beta}},\hat{\boldsymbol{w}}\} = \arg\max_{\theta}\{\ln\Pr[\mathcal{D}|\theta]\}.$$

2.5 The EM Algorithm

This maximization problem can be simplified a lot if we use the Expectation-Maximization (EM) algorithm (Dempster et al., 1977). The EM algorithm is an efficient iterative procedure to compute the maximum-likelihood solution in presence of missing/hidden data. We will use the unknown hidden true label y_i as the missing data. If we know the missing data $\boldsymbol{y} = [y_1,\ldots,y_N]$ then the complete likelihood can be written as

$$\ln\Pr[\mathcal{D},\boldsymbol{y}|\theta] = \sum_{i=1}^{N} y_i \ln p_i a_i + (1-y_i)\ln(1-p_i)b_i.$$

9. This assumption is not true in general and there is some correlations among the labels assigned by multiple annotators. For example in the CAD domain if the cancer is in advanced stage (which is very easy to detect) almost all the radiologists assign the same label.

Each iteration of the EM algorithm consists of two steps: an Expectation(E)-step and a Maximization(M)-step. The M-step involves maximization of a lower bound on the log-likelihood that is refined in each iteration by the E-step.

1. **E-step.** Given the observation $\mathcal{D}$ and the current estimate of the model parameters θ, the conditional expectation (which is a lower bound on the true likelihood) is computed as

$$\mathbb{E}\{\ln \Pr[\mathcal{D}, \boldsymbol{y}|\theta]\} = \sum_{i=1}^{N} \mu_i \ln p_i a_i + (1-\mu_i)\ln(1-p_i)b_i, \tag{3}$$

   where the expectation is with respect to $\Pr[\boldsymbol{y}|\mathcal{D},\theta]$, and $\mu_i = \Pr[y_i = 1|y_i^1,\ldots,y_i^R,\boldsymbol{x}_i,\theta]$. Using Bayes' theorem we can compute

$$\begin{aligned} \mu_i &\propto \Pr[y_i^1,\ldots,y_i^R|y_i=1,\theta]\cdot\Pr[y_i=1|\boldsymbol{x_i},\theta] \\ &= \frac{a_i p_i}{a_i p_i + b_i(1-p_i)}. \end{aligned}$$

2. **M-step.** Based on the current estimate μ_i and the observations $\mathcal{D}$, the model parameters θ are then estimated by maximizing the conditional expectation. By equating the gradient of (3) to zero we obtain the following estimates for the sensitivity and specificity:

$$\alpha^j = \frac{\sum_{i=1}^N \mu_i y_i^j}{\sum_{i=1}^N \mu_i}, \qquad \beta^j = \frac{\sum_{i=1}^N (1-\mu_i)(1-y_i^j)}{\sum_{i=1}^N (1-\mu_i)}.$$

   Due to the non-linearity of the sigmoid, we do not have a closed form solution for $\boldsymbol{w}$ and we have to use gradient ascent based optimization methods. We use the Newton-Raphson update given by $\boldsymbol{w}^{t+1} = \boldsymbol{w}^t - \eta \boldsymbol{H}^{-1}\mathbf{g}$, where $\boldsymbol{g}$ is the gradient vector, $\boldsymbol{H}$ is the Hessian matrix, and η is the step length. The gradient vector is given by

$$\boldsymbol{g}(w) = \sum_{i=1}^{N} \left[\mu_i - \sigma(\boldsymbol{w}^\top \boldsymbol{x}_i)\right] \boldsymbol{x}_i.$$

   The Hessian matrix is given by

$$\boldsymbol{H}(w) = -\sum_{i=1}^{N} \left[\sigma(\boldsymbol{w}^\top \boldsymbol{x}_i)\right]\left[1-\sigma(\boldsymbol{w}^\top \boldsymbol{x}_i)\right] \boldsymbol{x}_i \boldsymbol{x}_i^\top.$$

   Essentially, we are estimating *a logistic regression model with probabilistic labels* μ_i.

These two steps (the E- and the M-step) can be iterated till convergence. The log-likelihood increases monotonically after every iteration, which in practice implies convergence to a local maximum. The EM algorithm is only guaranteed to converge to a local maximum. In practice multiple restarts with different initializations can potentially mitigate the local maximum problem. In this paper we use majority voting $\mu_i = 1/R\sum_{j=1}^R y_i^j$ as the initialization for μ_i to start the EM-algorithm.

2.6 A Bayesian Approach

In some applications we may want to trust a particular expert more than the others. One way to achieve this is by imposing priors on the sensitivity and specificity of the experts. Since α_j and β_j represent the probability of a binary event, a natural choice of prior is the beta prior. The beta prior is also conjugate to the binomial distribution. For any $a > 0$, $b > 0$, and $\delta \in [0,1]$ the beta distribution is given by

$$\text{Beta}(\delta|a,b) = \frac{\delta^{a-1}(1-\delta)^{b-1}}{\text{B}(a,b)},$$

where $\text{B}(a,b) = \int_0^1 \delta^{a-1}(1-\delta)^{b-1} d\delta$ is the beta function.We assume a beta prior[10] for both the sensitivity and the specificity as

$$\begin{aligned} \Pr[\alpha_j|a_1^j,a_2^j] &= \text{Beta}(\alpha_j|a_1^j,a_2^j). \\ \Pr[\beta_j|b_1^j,b_2^j] &= \text{Beta}(\beta_j|b_1^j,b_2^j). \end{aligned}$$

For sake of completeness we also assume a zero mean Gaussian prior on the weights $\boldsymbol{w}$ with inverse covariance matrix $\boldsymbol{\Gamma}$, that is, $\Pr[\boldsymbol{w}] = \mathcal{N}(\boldsymbol{w}|0,\boldsymbol{\Gamma}^{-1})$. Assuming that $\{\alpha_j\}$, $\{\beta_j\}$, and $\boldsymbol{w}$ have independent priors, the maximum-a-posteriori (MAP) estimator is found by maximizing the log-posterior, that is,

$$\hat{\theta}_{\text{MAP}} = \arg\max_{\theta} \{\ln \Pr[\mathcal{D}|\theta] + \ln \Pr[\theta]\}.$$

An EM algorithm can be derived in a similar fashion for MAP estimation by relying on the interpretation of Neal and Hinton (1998). The final algorithm is summarized below:

1. Initialize $\mu_i = (1/R)\sum_{j=1}^R y_i^j$ based on majority voting.

2. Given μ_i, estimate the sensitivity and specificity of each annotator/expert as follows.

$$\begin{aligned} \alpha^j &= \frac{a_1^j - 1 + \sum_{i=1}^N \mu_i y_i^j}{a_1^j + a_2^j - 2 + \sum_{i=1}^N \mu_i}. \\ \beta^j &= \frac{b_1^j - 1 + \sum_{i=1}^N (1-\mu_i)(1-y_i^j)}{b_1^j + b_2^j - 2 + \sum_{i=1}^N (1-\mu_i)}. \end{aligned} \tag{4}$$

   The Newton-Raphson update for optimizing $\boldsymbol{w}$ is given by $\boldsymbol{w}^{t+1} = \boldsymbol{w}^t - \eta \boldsymbol{H}^{-1}\mathbf{g}$, with step length η, gradient vector

$$\boldsymbol{g}(w) = \sum_{i=1}^N \Big[\mu_i - \sigma(\boldsymbol{w}^\top \boldsymbol{x}_i)\Big] \boldsymbol{x}_i - \boldsymbol{\Gamma}\boldsymbol{w},$$

   and Hessian matrix

$$\boldsymbol{H}(w) = -\sum_{i=1}^N \sigma(\boldsymbol{w}^\top \boldsymbol{x}_i)\Big[1 - \sigma(\boldsymbol{w}^\top \boldsymbol{x}_i)\Big] \boldsymbol{x}_i \boldsymbol{x}_i^\top - \boldsymbol{\Gamma}.$$

10. It may be convenient to specify a prior in terms of the mean μ and variance σ^2. The mean and the variance for a beta prior are given by $\mu = a/(a+b)$ and $\sigma^2 = ab/((a+b)^2(a+b+1))$. Solving for a and b we get $a = (-\mu^3 + \mu^2 - \mu\sigma^2)/\sigma^2$ and $b = a(1-\mu)/\mu$.

3. Given the sensitivity and specificity of each annotator and the model parameters, update μ_i as

$$\mu_i = \frac{a_i p_i}{a_i p_i + b_i(1-p_i)}, \tag{5}$$

where

$$\begin{aligned} p_i &= \sigma(\boldsymbol{w}^\top \boldsymbol{x}_i). \\ a_i &= \prod_{j=1}^{R} [\alpha^j]^{y_i^j} [1-\alpha^j]^{1-y_i^j}. \\ b_i &= \prod_{j=1}^{R} [\beta^j]^{1-y_i^j} [1-\beta^j]^{y_i^j}. \end{aligned} \tag{6}$$

Iterate (2) and (3) till convergence.

2.7 Discussions

1. **Estimate of the gold standard** The value of the posterior probability μ_i is a soft probabilistic estimate of the actual ground truth y_i, that is, $\mu_i = \Pr[y_i = 1 | y_i^1, \ldots, y_i^R, \boldsymbol{x}_i, \theta]$. The actual hidden label y_i can be estimated by applying a threshold on μ_i, that is, $y_i = 1$ if $\mu_i \geq \gamma$ and zero otherwise. We can use $\gamma = 0.5$ as the threshold. By varying γ we can change the misclassification costs and obtain a ground truth with large sensitivity or large specificity. Because of this in our experimental validation we can actually draw an ROC curve for the estimated ground truth.

2. **Log-odds of $\boldsymbol{\mu}$** A particularly revealing insight can be obtained in terms of the log-odds or the *logit* of the posterior probability μ_i. From (5) the logit of μ_i can be written as

$$\begin{aligned} \text{logit}(\mu_i) = \ln \frac{\mu_i}{1-\mu_i} &= \ln \frac{\Pr[y_i = 1 | y_i^1, \ldots, y_i^R, \boldsymbol{x}_i, \theta]}{\Pr[y_i = 0 | y_i^1, \ldots, y_i^R, \boldsymbol{x}_i, \theta]} \\ &= \boldsymbol{w}^\top \boldsymbol{x}_i + c + \sum_{j=1}^{R} y_i^j [\text{logit}(\alpha^j) + \text{logit}(\beta^j)]. \end{aligned}$$

where $c = \sum_{j=1}^{R} \log \frac{1-\alpha^j}{\beta^j}$ is a constant term which does not depend on i. This indicates that the estimated ground truth (in the logit form of the posterior probability) is a *weighted linear combination* of the labels from all the experts. The weight of each expert is the sum of the logit of the sensitivity and specificity.

3. **Using any other classifier** For ease of exposition we used logistic regression. However, the proposed algorithm can be used with any generalized linear model or in fact with any classifier that can be trained with soft probabilistic labels. In each step of the EM-algorithm, the classifier is trained with instances sampled from μ_i. This modification is easy for most probabilistic classifiers. For general black-box classifiers where we cannot tweak the training algorithm an alternate approach is to replicate the training examples according to the soft label. For example a probabilistic label $\mu_i = 0.8$ can be effectively simulated by adding 8 training examples with deterministic label 1 and 2 examples with label 0.

4. **Obtaining ground truth with no features** In some scenarios we may not have features $\boldsymbol{x}_i$ and we wish to obtain an estimate of the actual ground truth based only on the labels from multiple annotators. Here instead of learning a classifier we estimate p which is the prevalence of the positive class, that is, $p = \Pr[y_i = 1]$. We further assume a beta prior for the prevalence, that is, $\text{Beta}(p|p_1, p_2)$. The algorithm simplifies as follows.

   (a) Initialize $\mu_i = (1/R)\sum_{j=1}^{R} y_i^j$ based on majority voting.

   (b) Given μ_i, estimate the sensitivity and specificity of each annotator using (4). The prevalence of the positive class is estimated as follows.

$$p = \frac{p_1 - 1 + \sum_{i=1}^{N} \mu_i}{p_1 + p_2 - 2 + N}.$$

   (c) Given the sensitivity and specificity of each annotator and prevalence, refine μ_i as follows.

$$\mu_i = \frac{a_i p}{a_i p + b_i (1-p)}.$$

   Iterate (2) and (3) till convergence. This algorithm is similar to the one proposed by Dawid and Skene (1979) and Smyth et al. (1995).

5. **Handling missing labels** The proposed approach can easily handle missing labels, that is, when the labels from some experts are missing for some instances. Let R_i be the number of radiologists labeling the i^{th} instance, and let N_j be the number of instances labeled by the j^{th} radiologist. Then in the EM algorithm, we just need to replace N by N_j for estimating the sensitivity and specificity in (4), and replace R by R_i for updating μ_i in (6).

6. **Evaluating a classifier** We can use the probability scores μ_i directly to evaluate classifiers. If z_i are the labels obtained from any other classifier, then sensitivity and specificity can be estimated as

$$\alpha = \frac{\sum_{i=1}^{N} \mu_i z_i}{\sum_{i=1}^{N} \mu_i}, \quad \beta = \frac{\sum_{i=1}^{N} (1-\mu_i)(1-z_i)}{\sum_{i=1}^{N} (1-\mu_i)}.$$

7. **Posterior approximation** At the end of each EM iteration a crude approximation to the posterior is obtained as

$$\begin{aligned} \alpha_j &\sim \text{Beta}\left(\alpha_j | a_1^j + \sum_{i=1}^{N} \mu_i y_i^j, a_2^j + \sum_{i=1}^{N} \mu_i (1 - y_i^j)\right), \\ \beta_j &\sim \text{Beta}\left(\beta_j | b_1^j + \sum_{i=1}^{N} (1-\mu_i)(1-y_i^j), b_2^j + \sum_{i=1}^{N} (1-\mu_i) y_i^j\right). \end{aligned}$$

3. Multi-class Classification

In this section we describe how the proposed approach for binary classification can be extended to categorical data. Suppose there are $K \geq 2$ categories. An example for categorical data from the CAD domain is in LungCAD, where the radiologist needs to label whether a nodule (known to be precursors of cancer) is a solid, a part-solid, or a ground glass opacity—which are three

different kinds on nodules. We can extend the previous model and introduce a vector of multinomial parameters $\boldsymbol{\alpha}_c^j = (\alpha_{c1}^j, \ldots, \alpha_{cK}^j)$ for each annotator, where

$$\alpha_{ck}^j := \Pr[y^j = k | y = c]$$

and $\sum_{k=1}^K \alpha_{ck}^j = 1$. Here α_{ck}^j denotes the probability that the annotator j assigns class k to an instance given the true class is c. When $K = 2$, α_{11}^j and α_{00}^j are sensitivity and specificity, respectively. A similar EM algorithm can be derived. In the E-step, we estimate

$$\Pr[y_i = c | \mathcal{Y}, \boldsymbol{\alpha}] \propto \Pr[y_i = c | \boldsymbol{x}_i] \prod_{j=1}^R \prod_{k=1}^K (\alpha_{ck}^j)^{\delta(y_i^j, k)},$$

where $\delta(u, v) = 1$ if $u = v$ and 0 otherwise and in the M-step we learn a multi-class classifier and update the multinomial parameter as

$$\alpha_{ck}^j = \frac{\sum_{i=1}^N \Pr[y_i = c | \mathcal{Y}, \boldsymbol{\alpha}] \delta(y_i^j, k)}{\sum_{i=1}^N \Pr[y_i = c | \mathcal{Y}, \boldsymbol{\alpha}]}.$$

One can also assign a Dirichlet prior for the multinomial parameters, and this results in a smoothing term in the above updates in the MAP estimate.

4. Ordinal Regression

We now consider the situation where the outputs are categorical and have an ordering among the labels. In the CAD domain the radiologist often gives a score (for example, 1 to 5 from lowest to highest) to indicate how likely she thinks it is malignant. This is different from a multi-class setting in which we do not have any preference among the multiple class labels.

Let $y_i^j \in \{1, \ldots, K\}$ be the label assigned to the i^{th} instance by the j^{th} expert. Note that there is an ordering in the labels $1 < \ldots < K$. A simple approach is to convert the ordinal data into a series of binary data (Frank and Hall, 2001). Specifically the K class ordinal labels are transformed into $K - 1$ binary class labels as follows:

$$y_i^{jc} = \begin{cases} 1 & \text{if } y_i^j > c \\ 0 & \text{otherwise} \end{cases} \qquad c = 1, \ldots, K-1.$$

Applying the same procedure used for binary labels we can estimate $\Pr[y_i > c]$ for $c = 1, \ldots, K-1$. The probability of the actual class values can then be obtained as

$$\Pr[y_i = c] = \Pr[y_i > c - 1 \text{ and } y_i \leq c] = \Pr[y_i > c - 1] - \Pr[y_i > c].$$

The class with the maximum probability is assigned to the instance.

5. Regression

In this section we develop a similar algorithm to learn a regression function using annotations from multiple experts. In the CAD domain as a part of the annotation process a common task for a radiologist is to measure the diameter of a suspicious lesion.

5.1 Model for Annotators

Let $y_i^j \in \mathbb{R}$ be the continuous target value assigned to the i^{th} instance by the j^{th} annotator. Our model is that the annotator provides a noisy version of the actual true value y_i. For the j^{th} annotator we will assume a Gaussian noise model with mean y_i (the true unknown value) and inverse-variance (precision) τ^j, that is,

$$\Pr[y_i^j|y_i,\tau^j] = \mathcal{N}(y_i^j|y_i,1/\tau^j), \tag{7}$$

where the Gaussian distribution is defined as $\mathcal{N}(z|m,\sigma^2) = (2\pi\sigma^2)^{-1/2}\exp(-(z-m)^2/2\sigma^2)$. The unknown inverse-variance τ^j measures the accuracy of each annotator—the larger the value of τ^j the more accurate the annotator. We have assumed that τ^j does not depend on the instance $\boldsymbol{x}_i$. For example, in the CAD domain, this means that the radiologist's accuracy does not depend on the nodule she is measuring. While this a practical assumption, it is not entirely true. It is known that some nodules are harder to measure than others.

5.2 Linear Regression Model for Features

As before we consider the family of linear regression functions: $\mathcal{F} = \{f_{\boldsymbol{w}}\}$, where for any $\boldsymbol{x}, \boldsymbol{w} \in \mathbb{R}^d$, $f_{\boldsymbol{w}}(\boldsymbol{x}) = \boldsymbol{w}^\top \boldsymbol{x}$. We assume that the actual target response y_i is given by the deterministic regression function $f_{\boldsymbol{w}}$ with additive Gaussian noise, that is,

$$y_i = \boldsymbol{w}^\top \boldsymbol{x}_i + \varepsilon,$$

where ε is a zero-mean Gaussian random variable with inverse-variance (precision) γ. Hence

$$\Pr[y_i|\boldsymbol{x}_i,\boldsymbol{w},\gamma] = \mathcal{N}(y_i|\boldsymbol{w}^\top \boldsymbol{x}_i, 1/\gamma). \tag{8}$$

5.3 Combined Model

Combining both the annotator (7) and the regressor (8) model we have

$$\Pr[y_i^j|\boldsymbol{x}_i,\boldsymbol{w},\tau^j,\gamma] = \int \Pr[y_i^j|y_i,\tau^j]\Pr[y_i|\boldsymbol{x}_i,\boldsymbol{w},\gamma]dy_i = \mathcal{N}(y_i^j|\boldsymbol{w}^\top \boldsymbol{x}_i, 1/\gamma + 1/\tau^j).$$

Since the two precision terms (γ and τ_j) are grouped together they are not uniquely identifiable. Hence we will define a new precision term λ^j as

$$\frac{1}{\lambda^j} = \frac{1}{\gamma} + \frac{1}{\tau^j}.$$

So we have the following model

$$\Pr[y_i^j|\boldsymbol{x}_i,\boldsymbol{w},\lambda^j] = \mathcal{N}(y_i^j|\boldsymbol{w}^\top \boldsymbol{x}_i, 1/\lambda^j). \tag{9}$$

5.4 Estimation/Learning Problem

Given the training data $\mathcal{D}$ consisting of N instances with annotations from R experts, that is, $\mathcal{D} = \{\boldsymbol{x}_i, y_i^1, \ldots, y_i^R\}_{i=1}^N$, the task is to estimate the weight vector $\boldsymbol{w}$ and the precision $\boldsymbol{\lambda} = [\lambda^1, \ldots, \lambda^R]$ of all the annotators.

5.5 Maximum-likelihood Estimator

Assuming the instances are independent the likelihood of the parameters $\theta = \{\boldsymbol{w}, \boldsymbol{\lambda}\}$ given the observations $\mathcal{D}$ can be factored as

$$\Pr[\mathcal{D}|\theta] = \prod_{i=1}^{N} \Pr[y_i^1, \ldots, y_i^R | \boldsymbol{x}_i, \theta].$$

Conditional on the instance $\boldsymbol{x}_i$ we assume that $y_i^1, \ldots, y_i^R$ are independent, that is, the annotators provide their responses independently. Hence from (9) the likelihood can be written as

$$\Pr[\mathcal{D}|\theta] = \prod_{i=1}^{N} \prod_{j=1}^{R} \mathcal{N}(y_i^j | \boldsymbol{w}^\top \boldsymbol{x}_i, 1/\lambda^j).$$

The maximum-likelihood estimator is found by maximizing the log-likelihood

$$\widehat{\theta}_{\text{ML}} = \{\widehat{\boldsymbol{\lambda}}, \widehat{\boldsymbol{w}}\} = \arg\max_{\theta} \{\ln \Pr[\mathcal{D}|\theta]\}.$$

By equating the gradient of the log-likelihood to zero we obtain the following update equations for the precision and the weight vector.

$$\frac{1}{\widehat{\lambda}^j} = \frac{1}{N} \sum_{i=1}^{N} \left(y_i^j - \widehat{\boldsymbol{w}}^\top \boldsymbol{x_i} \right)^2. \tag{10}$$

$$\widehat{\boldsymbol{w}} = \left(\sum_{i=1}^{N} \boldsymbol{x}_i \boldsymbol{x}_i^\top \right)^{-1} \sum_{i=1}^{N} \boldsymbol{x}_i \left(\frac{\sum_{j=1}^{R} \widehat{\lambda}^j y_i^j}{\sum_{j=1}^{R} \widehat{\lambda}^j} \right). \tag{11}$$

As the parameters $\widehat{\boldsymbol{w}}$ and $\widehat{\boldsymbol{\lambda}}$ are coupled together we iterate these two steps till convergence.

5.6 Discussions

1. **Is this standard least-squares?** Define the design matrix $\boldsymbol{X} = [\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N]^\top$ and the response vector for each annotator as $\boldsymbol{y}^j = [y_1^j, \ldots, y_N^j]^\top$. Using matrix notation Equation 11 can be written as

$$\widehat{\boldsymbol{w}} = (\boldsymbol{X}^\top \boldsymbol{X})^{-1} \boldsymbol{X}^\top \widehat{\boldsymbol{y}} \quad \text{where} \quad \widehat{\boldsymbol{y}} = \frac{\sum_{j=1}^{R} \widehat{\lambda}^j \boldsymbol{y}^j}{\sum_{j=1}^{R} \widehat{\lambda}^j}. \tag{12}$$

   Equation 12 is essentially the solution to a standard linear regression model, except that we are training a linear regression model with $\widehat{\boldsymbol{y}}$ as the ground truth, which is a precision weighted mean of the response vectors from all the annotators. The variance of each annotator is estimated using (10). The final algorithm iteratively establishes a particular gold standard ($\widehat{\boldsymbol{y}}$), measures the performance of the annotators and learns a regressor given that gold standard, and refines the gold standard based on the performance measures.

2. **Are we better than the best annotator?** If we assume $\widehat{\boldsymbol{\lambda}}$ is fixed (i.e., we ignore the variability and assume that it is well estimated) then $\hat{\boldsymbol{w}}$ is an unbiased estimator of $\boldsymbol{w}$ and the covariance matrix is given by

$$\text{Cov}(\hat{\boldsymbol{w}}) = \text{Cov}(\widehat{\boldsymbol{y}}) \left(\boldsymbol{X}^\top \boldsymbol{X} \right)^{-1} = \frac{1}{\sum_{j=1}^{R} \widehat{\lambda}_j} \left(\boldsymbol{X}^\top \boldsymbol{X} \right)^{-1}.$$

Since $\sum_{j=1}^{R} \widehat{\lambda}_j > \max_j(\widehat{\lambda}_j)$ the proposed method has a lower variance than the regressor learnt with the best annotator (i.e., the one with the minimum variance).

3. **Are we better than the average?** For a fixed $\boldsymbol{X}$ the error in $\widehat{\boldsymbol{w}}$ depends only on the variance of $\widehat{y}^j$. If we know the true λ^j then $\widehat{y}_i$ is the best linear unbiased estimator for y_i which minimizes the variance. To see this consider any linear estimator of the form $\widehat{y}_i = \sum_j a^j (y_i^j - b^j)$. The variance is given by $\mathrm{Var}[\widehat{y}_i] = \sum_j (a^j)^2/\lambda_j$. Since $\mathrm{E}[\widehat{y}_i] = y_i \sum_j a^j$, for the bias of this estimator to be zero we require that $\sum_j a^j = 1$. Solving the constrained minimization problem we see that $a_j = \lambda^j / \sum_j \lambda_j$ minimizes the variance.

4. **Obtaining a consensus without features** When no features are available the same algorithm can be simplified to get a consensus estimate of the actual ground truth and also evaluate the annotators. Essentially we have to iterate the following two updates till convergence

$$\widehat{y}_i = \frac{\sum_{j=1}^{R} \widehat{\lambda}^j y_i^j}{\sum_{j=1}^{R} \widehat{\lambda}^j} \quad \frac{1}{\widehat{\lambda}^j} = \frac{1}{N} \sum_{i=1}^{N} \left(y_i^j - \widehat{y}_i \right)^2.$$

6. Experimental Validation

We now experimentally validate the proposed algorithms on both simulated and real data.

6.1 Classification Experiments

We use two CAD and one text data set in our experiments. The CAD data sets include a digital mammography data set and a breast MRI data set, both of which are biopsy proven, that is, the gold standard is available. For the digital mammography data set we simulate the radiologists in order to validate our methods. The breast MRI data has annotations from four radiologists. We also report results on a Recognizing Textual Entailment data collected by Snow et al. (2008) using the Amazon's Mechanical Turk which has annotations from 164 annotators.

6.1.1 DIGITAL MAMMOGRAPHY WITH SIMULATED RADIOLOGISTS

Mammograms are used as a screening tool to detect early breast cancer. CAD systems search for abnormal areas (*lesions*) in a digitized mammographic image. These lesions generally indicate the presence of malignant cancer. The CAD system then highlights these areas on the images, alerting the radiologist to the need for a further diagnostic mammogram or a biopsy. In classification terms, given a set of descriptive morphological features for a region on a image, the task is to predict whether it is potentially malignant (1) or not (0). In order to train such a classifier, a set of mammograms is collected from hospitals. The ground truth (whether it is cancer or not) is obtained from biopsy. Since biopsy is an expensive, tedious, and an invasive process, very often CAD systems are built from labels collected from *multiple expert radiologists* who visually examine the mammograms and mark the lesion locations—this constitutes our ground truth (multiple labels) for learning.

In this experiment we use a proprietary biopsy-proven data set (Krishnapuram et al., 2008) containing 497 positive and 1618 negative examples. Each instance is described by a set of 27 morphological features. In order to validate our proposed algorithm, we simulate multiple radiologists according to the two-coin model described in § 2.1. Based on the labels from multiple radiologists,

we can simultaneously (1) learn a logistic-regression classifier, (2) estimate the sensitivity and specificity of each radiologist, and (3) estimate the golden ground truth. We compare the results with the classifier trained using the biopsy proved ground truth as well as the majority-voting baseline. For the first set of experiments we use 5 radiologists with sensitivity $\boldsymbol{\alpha} = [0.90\ 0.80\ 0.57\ 0.60\ 0.55]$ and specificity $\boldsymbol{\beta} = [0.95\ 0.85\ 0.62\ 0.65\ 0.58]$. This corresponds to a scenario where the first two radiologists are experts and the last three are novices. Figure 1 summarizes the results. We compare on three different aspects: (1) How good is the learnt classifier? (2) How well can we estimate the sensitivity and specificity of each radiologist? (3) How good is the estimated ground truth? The following observations can be made.

1. **Classifier performance** Figure 1(a) plots the ROC curve of the learnt classifier on the training set. The dotted (black) line is the ROC curve for the classifier learnt using the actual ground truth. The solid (red) line is the ROC curve for the proposed algorithm and the dashed (blue) line is for the classifier learnt using the majority-voting scheme. The classifier learnt using the proposed method is as good as the one learnt using the golden ground truth. The area under the ROC curve (AUC) for the proposed algorithm is around 3.5% greater than that learnt using the majority-voting scheme.

2. **Radiologist performance** The actual sensitivity and specificity of each radiologist is marked as a black $\times$ in Figure 1(b). The end of the solid red line shows the estimates of the sensitivity and specificity from the proposed method. We used a uniform prior on all the parameters. The ellipse plots the contour of one standard deviation as obtained from the beta posterior estimates. The end of the dashed blue line shows the estimate obtained from the majority-voting algorithm. We see that the proposed method is much closer to the actual values of sensitivity and specificity.

3. **Actual ground truth** Since the estimates of the actual ground truth are probabilistic scores, we can also plot the ROC curves of the estimated ground truth. From Figure 1(b) we can see that the ROC curve for the proposed method dominates the majority voting ROC curve. Furthermore, the area under the ROC curve (AUC) is around 3% higher. The estimate obtained by majority voting is closer to the novices since they form a majority (3/5). It does not have an idea of who is an expert and who is a novice. The proposed algorithm appropriately weights each radiologist based on their estimated sensitivity and specificity. The improvement obtained is quite large in Figure 2 which corresponds a situation where we have only one expert and 7 novices.

4. **Joint Estimation** To learn a classifier, Smyth et al. (1995) proposed to first estimate the golden ground truth and then use the probabilistic ground truth to learn a classifier. In contrast, our proposed algorithm learns the classifier and the ground truth *jointly* as a part of the EM algorithm. Figure 3 shows that the classifier and the ground truth learnt obtained by the proposed algorithm is superior than that obtained by other procedures which first estimates the ground truth and then learns the classifier.

6.1.2 BREAST MRI

In this example, each radiologist reviews the breast MRI data and assesses the malignancy of each lesion on a BIRADS scale of 1 to 5. The BIRADS scale is defined as follows: 1 Negative, 2 Benign,

Majority Voting	True 1	True 2	True 3	True 4	True 5
Estimated 1	x	0.0217	0	x	0.0000
Estimated 2	x	**0.5869**	0	x	0.1785
Estimated 3	x	0.2391	0	x	0.1071
Estimated 4	x	0.1521	1	x	0.2500
Estimated 5	x	0.0000	0	x	**0.4642**
EM algorithm	**True 1**	**True 2**	**True 3**	**True 4**	**True 5**
Estimated 1	x	0.0000	0	x	0.0000
Estimated 2	x	**0.6957**	0	x	0.1428
Estimated 3	x	0.1304	0	x	0.0000
Estimated 4	x	0.1739	1	x	0.3214
Estimated 5	x	0.0000	0	x	**0.5357**

Table 1: The confusion matrix for the estimate obtained using majority voting and the proposed EM algorithm. The x indicates that there was no such category in the true labels (the gold standard). The gold-standard is obtained by the biopsy which can confirm whether it is benign (BIRADS=2) or malignant (BIRADS=5).

3 Probably Benign, 4 Suspicious abnormality, and 5 Highly suggestive of malignancy. Our data set comprises of 75 lesions with annotations from four radiologists, and the true labels from biopsy. Based on eight morphological features, we have to predict whether a lesion is malignant or not.

For the first experiment we reduce the BIRADS scale to a binary one: any lesion with a BIRADS > 3 is considered malignant and benign otherwise. The set included 28 malignant and 47 benign lesions. Figure 4 summarizes the results. We show the leave-one-out cross validated ROC for the classifier. The cross-validated AUC of the proposed method is approximately 6% better than the majority voting baseline.

We also consider the BIRADS labels as a set of ordinal measurements since there is an ordering among the BIRADS label. The confusion matrix in Table 1 shows that the EM algorithm is significantly superior than the majority voting in estimating the true BIRADS.

6.1.3 RECOGNIZING TEXTUAL ENTAILMENT

Finally we report results on Recognizing Textual Entailment data collected by Snow et al. (2008) using the Amazon's Mechanical Turk. In this task, the annotator is presented with two sentences and given a choice of whether the second sentence can be inferred from the first. The data has 800 tasks and 164 distinct readers, with 10 annotations per task along with the golden ground truth. The majority of the entries (94 %) in the 800x164 matrix are missing. There is one annotator who has labeled all the tasks. We use this data set to obtain an estimate of the actual ground truth. Figure 5 plots the accuracy of the estimated ground truth as a function of the number of annotators. The proposed EM algorithm achieves a higher accuracy than majority voting. In other words to achieve a desired accuracy the proposed algorithm needs fewer annotators than the majority voting scheme.

(b)

Figure 1: Results for the digital mammography data set with annotations from 5 simulated radiologists. (a) The ROC curve of the learnt classifier using the golden ground truth (dotted black line), the majority voting scheme (dashed blue line), and the proposed EM algorithm (solid red line). (b) The ROC curve for the estimated ground truth. The actual sensitivity and specificity of each of the radiologists is marked as a $\times$. The end of the dashed blue line shows the estimates of the sensitivity and specificity obtained from the majority voting algorithm. The end of the solid red line shows the estimates from the proposed method. The ellipse plots the contour of one standard deviation.

Figure 3: ROC curves comparing the proposed algorithm (solid red line) with the *Decoupled Estimation* procedure (dotted blue line), which refers to the algorithm where the ground truth is first estimated using just the labels from the five radiologists and then a logistic regression classifier is trained using the soft probabilistic labels. In contrast the proposed EM algorithm estimates the ground truth and learns the classifier simultaneously during the EM algorithm.

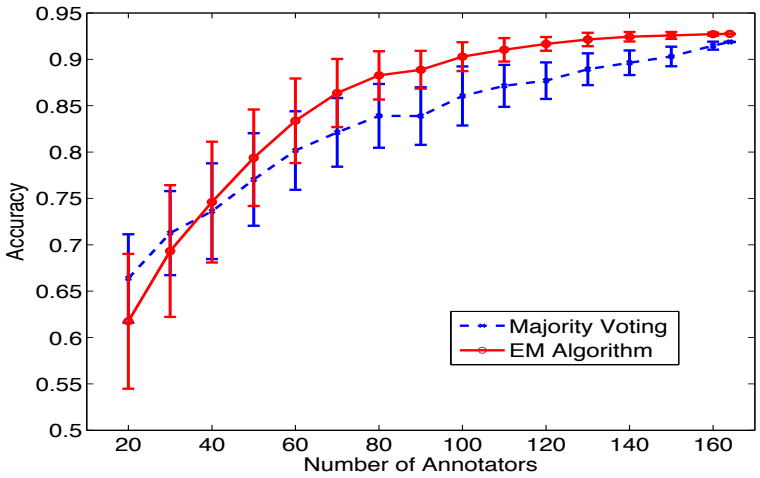

Figure 5: The mean and the one standard deviation error bars for the accuracy of the estimated ground truth for the Recognizing Textual Entailment task as a function of the number of annotators. The plot was generated by randomly sampling the annotators 100 times.

6.2 Regression Experiments

We first illustrate the algorithm on a toy dataset and then present a case study for automated polyp measurements.

6.2.1 ILLUSTRATION

Figure 6 illustrates the the proposed algorithm for regression on a one-dimensional toy data set with three annotators. The actual regression model (shown as a blue dotted line) is given by $y = 5x - 2$. We simulate 20 samples from three annotators with precisions 0.01, 0.1, and 1.0. The data are shown by the annotators's number. While we can fit a regression model using each annotators's response, we see that only the model for annotator three (with highest precision) is close to the true regression model. The green dashed line shows the model learnt using the average response from all the three annotators. The red line shows the model learnt by the proposed algorithm.

6.2.2 AUTOMATED POLYP MEASUREMENTS

Colorectal polyps are small colonic findings that may develop into cancer at a later stage. The diameter of the polyp is one of the key factors which decides the malignancy of a suspicious polyp. Hence accurate size estimation is crucial to decide the action to be taken on a polyp. We have developed various algorithms to segment a polyp. Multiple segmentation algorithms give rise to a set of features which are correlated with the diameter of the polyp. We want to learn a regression function which can predict the diameter of a polyp as a function of these features. In order to learn a regression function we collect our ground truth by asking many radiologists to manually measure the the diameter of the polyps from the three-dimensional images. In practice there is a lot of disagreement among the radiologists as to the actual size of the polyp.

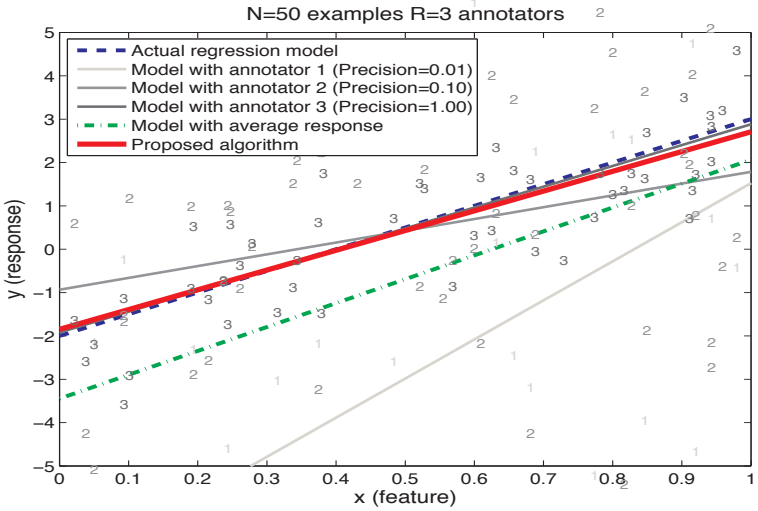

Figure 6: Illustration of the proposed algorithm on a one-dimensional toy data set. The actual regression model (shown as a blue dotted line) is given by $y = 5x - 2$. We simulate 50 samples from three annotators with precisions 0.01, 0.1, and 1.0. The data are shown by the annotators's number. While we can fit a regression model using each annotators's response, we see that only the model for annotator three (with highest precision) is close to the true regression model. The green dashed line shows the model learnt using the average response from all the three annotators. The red line shows the model learnt by the proposed algorithm.

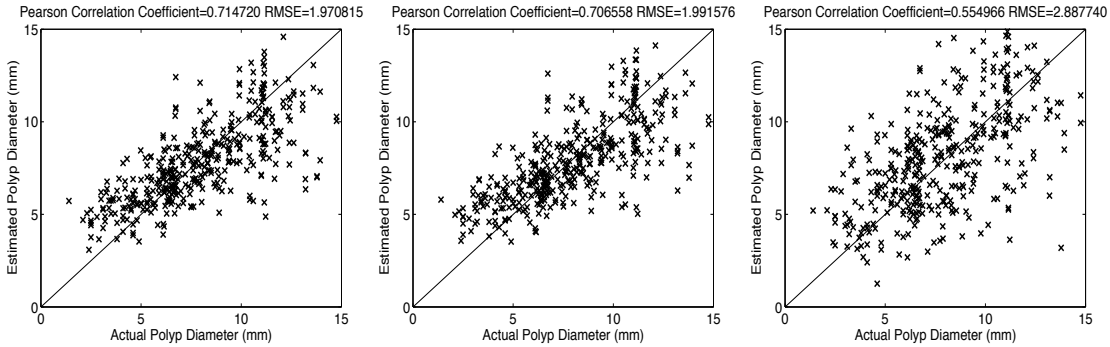

(a) Gold standard model (b) Proposed model (c) Average model

Figure 7: Scatter plot of the actual polyp diameter vs the diameter predicted by the models learnt using (a) the actual gold standard, (b) the proposed algorithm with annotations from five radiologists, and (c) the average of the radiologist's annotations. (See § 6.2.2 for a description of the experimental setup.)

We use a proprietary data set containing 393 examples (which point to 285 distinct polyps—the segmentation algorithms generally return multiple marks on the same polyp.) along with the measured diameter (ranging from 2mm to 15mm) as our training set. Each example is described by a set of 60 morphological features which are correlated to the diameter of the polyp. In order to validate the feasibility of our proposed algorithm, we simulate five radiologists according to the noisy model described in § 5.1 with $\tau = [0.001\ 0.01\ 0.1\ 1\ 10]$. This corresponds to a situation where the first three radiologists are extremely noisy and the last two are quite accurate. Based on the measurements from multiple radiologists, we can simultaneously (1) learn a linear regressor and (2) estimate the precision of each radiologist. We compare the results with the classifier trained using the actual golden ground truth as well as the regressor learnt using the average of the radiologists measurements. The results are validated on an independent test set containing 397 examples (which point to 298 distinct polyps).

Figure 7 shows the scatter plot of the actual polyp diameter vs the diameter predicted by the three different models. We compare the performance based on the root mean squared error (RMSE) and also the Pearson's correlation coefficient. The regressor learnt using the proposed iterative algorithm (Figure 7(b)) is almost as good as the one learnt using the golden ground truth (Figure 7(a)). The correlation coefficient for the proposed algorithm is significantly larger than that learnt using the average of the radiologists response. The estimate obtained by averaging is closer to the novices since they form a majority (3/5). The proposed algorithm appropriately weights each radiologist based on their estimated precisions.

7. Conclusions and Future Work

In this paper we proposed a probabilistic framework for supervised learning with multiple annotators providing labels but no absolute gold standard. The proposed algorithm iteratively establishes a particular gold standard, measures the performance of the annotators given that gold standard, and then refines the gold standard based on the performance measures. We specifically discussed binary/categorical/ordinal classification and regression problems.

We made two key assumptions: (1) the performance of each annotator does not depend on the feature vector for a given instance and (2) conditional on the truth the experts are independent, that is, they make their errors independently. As we pointed out earlier these assumptions are not true in practice. The annotator performance depends on the instance he is labeling and there is some degree of correlation among the annotators. We briefly discuss some strategies to relax these two assumptions.

7.1 Instance Difficulty

One drawback of the current model is that it doesn't estimate difficulty of items. It is often observed that for the easy instances all the annotators agree on the labels—thus violating our conditional independence assumption. The difficulty of annotating an item can be captured by another latent variable γ_i for each instance—which modulates the annotators performance. Models for this have been developed in the area of item-response theory (Baker and Kim, 2004) and also in epidemiology (Uebersax and Grove, 1993)—see also Whitehill et al. (2009) for a recent paper in the machine learning community. While these models do not take into account the available features our pro-

posed model for sensitivity and specificity can be extended as follows (in place of (1) and (2)):

$$\alpha^j(\gamma_i) := \Pr[y_i^j = 1 | y_i = 1, \gamma_i] = \sigma(a_{j1} + b_{j1}\gamma_i).$$

$$\beta^j(\gamma_i) := \Pr[y_i^j = 0 | y_i = 0, \gamma_i] = \sigma(a_{j0} + b_{j0}\gamma_i).$$

Here the parameters a_{j1} and a_{j0} are related to the sensitivity and specificity of the j^{th} annotator, while the latent term γ_i captures the difficulty of the instance. The key assumption here is that the annotators are independent conditional on both y_i and γ_i. Various assumptions can be made on two parameters b_{j1} and b_{j0} to simplify these models further—for example we could set $b_{j1} = b_1$ and $b_{j0} = b_0$ for all the annotators.

7.2 Annotators Actually Look at the Data

In our model we made the assumption that the sensitivity α^j and the specificity β^j of the j^{th} annotator does not depend on the feature vector $\boldsymbol{x}_i$. For example, in the CAD domain, this meant that the radiologist's performance is consistent across different sub-groups of data—which is not entirely true. It is known that some radiologists are good at detecting certain kinds of malignant lesions based on their training and experience. We can extend the previous model such that the sensitivity and the specificity depends on the feature vector $\boldsymbol{x}_i$ explicitly as follows

$$\alpha^j(\gamma_i, \boldsymbol{x}_i) := \Pr[y_i^j = 1 | y_i = 1, \gamma_i, \boldsymbol{x}_i] = \sigma(a_{j1} + b_{j1}\gamma_i + \boldsymbol{w}_\alpha^{j\top} \boldsymbol{x}_i).$$

$$\alpha^j(\gamma_i, \boldsymbol{x}_i) := \Pr[y_i^j = 0 | y_i = 0, \gamma_i, \boldsymbol{x}_i] = \sigma(a_{j0} + b_{j0}\gamma_i + \boldsymbol{w}_\beta^{j\top} \boldsymbol{x}_i).$$

However this change increases the number of parameters to be learned.

Abstract

Estimating the error rates of classifiers or regression models is a fundamental task in machine learning which has thus far been studied exclusively using supervised learning techniques. We propose a novel unsupervised framework for estimating these error rates using only unlabeled data and mild assumptions. We prove consistency results for the framework and demonstrate its practical applicability on both synthetic and real world data.

Keywords: classification and regression, maximum likelihood, latent variable models

1. Introduction

A common task in machine learning is predicting a response variable $y \in \mathcal{Y}$ based on an explanatory variable $x \in \mathcal{X}$. Assuming a joint distribution $p(x,y)$ and a loss function $L(y,\hat{y})$, a predictor $f : \mathcal{X} \to \mathcal{Y}$ is characterized by an expected loss or risk function

$$R(f) = \mathsf{E}_{p(x,y)}\{L(y, f(x))\}.$$

For example, in classification we may have $\mathcal{X} = \mathbb{R}^d$, $\mathcal{Y} = \{1,\ldots,l\}$, and $L(y,\hat{y}) = I(y \neq \hat{y})$ where $I(A) = 1$ if A is true and 0 otherwise. The resulting risk is known as the 0-1 risk or simply the classification error rate

$$R(f) = P(f \text{ predicts the wrong class}).$$

In regression we may have $\mathcal{X} = \mathcal{Y} = \mathbb{R}$, and $L(y,\hat{y}) = (y-\hat{y})^2$. The resulting risk is the mean squared error

$$R(f) = \mathsf{E}_{p(x,y)}(y - f(x))^2.$$

We consider the case where we are provided with k predictors $f_i : \mathcal{X} \to \mathcal{Y}$, $i = 1,\ldots,k$ ($k \geq 1$) whose risks are unknown. The main task we are faced with is estimating the risks $R(f_1),\ldots,R(f_k)$ without using any labeled data whatsoever. The estimation of $R(f_i)$ is rather based on an estimator $\hat{R}(f_i)$ that uses unlabeled data $x^{(1)},\ldots,x^{(n)} \overset{\text{iid}}{\sim} p(x)$.

A secondary task that we consider is obtaining effective schemes for combining k predictors $f_1,\ldots,f_k$ in a completely unsupervised manner. We refer to these two tasks of risk estimation and predictor combination as unsupervised-supervised learning since they refer to unsupervised analysis of supervised prediction models.

It may seem surprising that unsupervised risk estimation is possible at all. After all in the absence of labels there is no ground truth that guides us in estimating the risks. However, as we show in this paper, if the marginal $p(y)$ is known it is possible in some cases to obtain a consistent estimator for the risks using only unlabeled data, that is,

$$\lim_{n\to\infty} \hat{R}(f_i;x^{(1)},\ldots,x^{(n)}) = R(f_i) \quad \text{with probability 1}, \quad i=1,\ldots,k.$$

In addition to demonstrating consistency, we explore the asymptotic variance of the risk estimators and how it is impacted by changes in n (amount of unlabeled data), k (number of predictors), and $R(f_1),\ldots,R(f_k)$ (risks). We also demonstrate that the proposed estimation technique works well in practice on both synthetic and real world data.

The assumption that $p(y)$ is known seems restrictive, but there are plenty of cases where it holds. Examples include medical diagnosis ($p(y)$ is the well known marginal disease frequency), handwriting recognition/OCR ($p(y)$ is the easily computable marginal frequencies of different English letters), regression model for life expectancy ($p(y)$ is the well known marginal life expectancy tables). In these and other examples $p(y)$ is obtained from extremely accurate histograms.

There are several reasons that motivate our approach of using exclusively unlabeled data to estimate the risks. Labeled data may be unavailable due to privacy considerations where the predictors are constructed by organizations using training sets with private labels. For example, in medical diagnosis prediction, the predictors $f_1,\ldots,f_k$ may be obtained by k different hospitals, each using a private internal labeled set. Following the training stage, each hospital releases its predictor to the public who then proceed to estimate $R(f_1),\ldots,R(f_k)$ using a separate unlabeled data set.

Another motivation for using unlabeled data is domain adaptation where predictors that are trained on one domain, are used to predict data from a new domain from which we have only unlabeled data. For example, predictors are often trained on labeled examples drawn from the past but are used at test time to predict data drawn from a new distribution associated with the present. Here the labeled data used to train the predictors will not provide an accurate estimate due to differences in the test and train distributions.

Another motivation is companies releasing predictors to clients as black boxes (without their training data) in order to protect their intellectual property. This is the situation in business analytics and consulting. In any case, it is remarkable that without labels we can still accurately estimate supervised risks.

The collaborative nature of this diagnosis is especially useful for multiple predictors as the predictor ensemble $\{f_1,\ldots,f_k\}$ diagnoses itself. However, our framework is not restricted to a large k and works even for a single predictor with $k=1$. It may further be extended to the case of active learning where classifiers are queried for specific data and the case of semi-supervised learning where a small amount of labeled data is augmented by massive unlabeled data.

We proceed in the next section to describe the general framework and some important special cases. In Section 3 we discuss extensions to the general framework and in Section 4-5 we discuss the theory underlying our estimation process. In Section 6 we discuss practical optimization algorithms. Section 7 contains an experimental study. We conclude with a discussion in Section 8.

2. Unsupervised Risk Estimation Framework

We adopt the framework presented in Section 1 with the added requirement that the predictors $f_1,\ldots,f_k$ are stochastic, that is, their prediction $\hat{y} = f_i(x)$ (conditioned on x) is a random variable. Such stochasticity occurs if the predictors are conditional models predicting values according to their estimated probability, that is, f_i models a conditional distribution q_i and predicts y' with probability $q_i(y'|x)$.

As mentioned previously our goal is to estimate the risk associated with classification or regression models $f_1,\ldots,f_k$ based on unlabeled data $x^{(1)},\ldots,x^{(n)} \overset{\text{iid}}{\sim} p(x)$. The testing marginal and conditional distributions $p(x), p(y|x)$ may differ from the distributions used at training time for the different predictors. In fact, each predictor may have been trained on a completely different training distribution, or may have been designed by hand with no training data whatsoever. We consider the predictors as black boxes and do not assume any knowledge of their modeling assumptions or training processes.

At the center of our framework is the idea to define a parameter vector $\theta \in \Theta$ which characterizes the risks $R(f_1),\ldots,R(f_k)$, that is, $R(f_j) = g_j(\theta)$ for some function $g_j : \Theta \to \mathbb{R}$, $j = 1,\ldots,k$. The parameter vector θ is estimated from data by connecting it to the probabilities

$$p_j(y'|y) \overset{\text{def}}{=} p(f_j \text{ predicts } y' | \text{ true label is } y).$$

More specifically, we use a plug-in estimate $\hat{R}(f_j) = g_j(\hat{\theta})$ where $\hat{\theta}$ maximizes the likelihood of the predictor outputs $\hat{y}_j^{(i)} = f_j(x^{(i)})$ with respect to the model $p_\theta(\hat{y}) = \int p_\theta(\hat{y}|y)p(y)\,dy$. The precise equations are:

$$\hat{R}(f_j;\hat{y}^{(1)},\ldots,\hat{y}^{(n)}) = g_j(\hat{\theta}^{\text{mle}}(\hat{y}^{(1)},\ldots,\hat{y}^{(n)})) \quad \text{where} \tag{1}$$

$$\hat{y}^{(i)} \overset{\text{def}}{=} (\hat{y}_1^{(i)},\ldots,\hat{y}_k^{(i)})$$

$$\hat{y}_j^{(i)} \overset{\text{def}}{=} f_j(x^{(i)}),$$

$$\hat{\theta}^{\text{mle}}(\hat{y}^{(1)},\ldots,\hat{y}^{(n)}) = \arg\max \ell(\theta;\hat{y}^{(1)},\ldots,\hat{y}^{(n)}), \tag{2}$$

$$\ell(\theta;\hat{y}^{(1)},\ldots,\hat{y}^{(n)}) = \sum_{i=1}^{n} \log p_\theta(\hat{y}_1^{(i)},\ldots,\hat{y}_k^{(i)}) \tag{3}$$

$$= \sum_{i=1}^{n} \log \int_{\mathcal{Y}} p_\theta(\hat{y}_1^{(i)},\ldots,\hat{y}_k^{(i)}|y^{(i)})p(y^{(i)})\,d\mu(y^{(i)}).$$

The integral in (3) is over the unobserved label $y^{(i)}$ associated with $x^{(i)}$. It should be a continuous integral $\int_{y^{(i)}=-\infty}^{\infty}$ for regression and a finite summation $\sum_{y^{(i)}=1}^{l}$ for classification. For notational simplicity we maintain the integral sign for both cases with the understanding that it is over a continuous or discrete measure μ, depending on the topology of $\mathcal{Y}$. Note that (3) and its maximizer are computable without any labeled data. All that is required are the classifiers (as black boxes), unlabeled data $x^{(1)},\ldots,x^{(n)}$, and the marginal label distribution $p(y)$.

Besides being a diagnostic tool for the predictor accuracy, $\hat{\theta}^{\text{mle}}$ can be used to effectively aggregate $f_1,\ldots,f_j$ to predict the label of a new example x^{new}

$$\begin{aligned}\hat{y}^{\text{new}} &= \arg\max_{y\in\mathcal{Y}} p_{\hat{\theta}^{\text{mle}}}(y \mid f_1(x^{\text{new}}),\ldots,f_k(x^{\text{new}})) \\ &= \arg\max_{y\in\mathcal{Y}} p(y)\prod_{j=1}^{k} p_{\hat{\theta}_j^{\text{mle}}}(f_j(x^{\text{new}}) \mid y). \end{aligned} \tag{4}$$

As a result, our framework may be used to combine existing classifiers or regression models in a completely unsupervised manner.

There are three important research questions concerning the above framework. First, what are the statistical properties of $\hat{\theta}^{\text{mle}}$ and $\hat{R}$ (consistency, asymptotic variance). Second, how can we efficiently solve the maximization problem (2). And third, how does the framework work in practice. We address these three questions in Sections 4-5, 6, 7 respectively, We devote the rest of the current section to examine some important special cases of (2)-(3) and consider some generalizations in the next section.

2.1 Non-Collaborative Estimation of the Risks

In the non-collaborative case we estimate the risk of each one of the predictors $f_1,\ldots,f_k$ separately. This reduces the problem to that of estimating the risk of a single predictor, which is repeated k times for each one of the predictors. We thus assume in this subsection the framework (1)-(3) with $k=1$ with no loss of generality. For simplicity we denote the single predictor by f rather than f_1 and denote $g=g_1$ and $\hat{y}^{(i)}=\hat{y}_1^{(i)}$. The corresponding simplified expressions are

$$\begin{aligned}&\hat{R}(f;\hat{y}^{(1)},\ldots,\hat{y}^{(n)}) = g(\hat{\theta}^{\text{mle}}(\hat{y}^{(1)},\ldots,\hat{y}^{(n)})), \\ &\hat{\theta}^{\text{mle}}(\hat{y}^{(1)},\ldots,\hat{y}^{(n)}) = \arg\max_{\theta} \sum_{i=1}^{n} \log \int_{\mathcal{Y}} p_\theta(\hat{y}^{(i)}|y^{(i)})p(y^{(i)})\,d\mu(y^{(i)}) \end{aligned} \tag{5}$$

where $\hat{y}^{(i)}=f(x^{(i)})$.

We consider below several important special cases.

2.1.1 CLASSIFICATION

Assuming l labels $\mathcal{Y}=\{1,\ldots,l\}$, the classifier f defines a multivariate Bernoulli distribution $p_\theta(\hat{y}|y)$ mapping the true label y to $\hat{y}$

$$p_\theta(\hat{y}|y) = \theta_{\hat{y},y}. \tag{6}$$

where θ is the stochastic confusion matrix or noise model corresponding to the classifier f. In this case, the relationship between the risk $R(f)$ and the parameter θ is

$$R(f) = 1 - \sum_{y\in\mathcal{Y}} \theta_{yy}\,p(y). \tag{7}$$

Equations (6)-(7) may be simplified by assuming a symmetric error distribution (Cover and Thomas, 2005)

$$p_\theta(\hat{y}|y) = \theta^{I(\hat{y}=y)} \left(\frac{1-\theta}{l-1}\right)^{I(\hat{y}\neq y)}, \tag{8}$$
$$R(f) = 1-\theta$$

where I is the indicator function and $\theta \in [0,1]$ is a scalar corresponding to the classifier accuracy. Estimating θ by maximizing (5), with (6) or (8) substituting p_θ completes the risk estimation task.

In the simple binary case $l = 2, \mathcal{Y} = \{1,2\}$ with the symmetric noise model (8) the loglikelihood

$$\ell(\theta) = \sum_{i=1}^{n} \log \sum_{y^{(i)}=1}^{2} \theta^{I(\hat{y}^{(i)}=y^{(i)})}(1-\theta)^{I(\hat{y}^{(i)}\neq y^{(i)})} p(y^{(i)})$$

may be shown to have the following closed form maximizer

$$\hat{\theta}^{\text{mle}} = \frac{p(y=1) - m/n}{2p(y=1)-1}. \tag{9}$$

where $m \stackrel{\text{def}}{=} |\{i \in \{1,\ldots,n\} : \hat{y}^{(i)} = 2\}|$. The estimator (9) works well in practice and is shown to be a consistent estimator in the next section (i.e., it converges to the true parameter value). In cases where the symmetric noise model (8) does not hold, using (9) to estimate the classification risk may be misleading. For example, in some cases (9) may be negative. In these cases, using the more general model (6) instead of (8) should provide more accurate results. We discuss this further from theoretical and experimental perspectives in Sections 4-5, and 7 respectively.

2.1.2 REGRESSION

Assuming a regression equation

$$y = ax + \varepsilon, \qquad \varepsilon \sim N(0, \tau^2)$$

and an estimated regression model or predictor $\hat{y} = a'x$ we have

$$\hat{y} = a'x = a'a^{-1}(y-\varepsilon) = \theta y - \theta\varepsilon$$

where $\theta = a'a^{-1}$. Thus, in the regression case the distribution $p_\theta(\hat{y}|y)$ and the relationship between the risk and the parameter $R(f) = g(\theta)$ are

$$p_\theta(\hat{y}|y) = (2\pi\theta^2\tau^2)^{-1/2} \exp\left(-\frac{(\hat{y}-\theta y)^2}{2\theta^2\tau^2}\right), \tag{10}$$
$$R(f|y) = \mathsf{bias}^2(f) + \mathsf{Var}(f) = (1-\theta)^2 y^2 + \theta^2\tau^2,$$
$$R(f) = \theta^2\tau^2 + (1-\theta)^2 \mathsf{E}_{p(y)}(y^2).$$

Note that we consider regression as a stochastic estimator in that it predicts $y = a'x + \varepsilon$ or $y|x \sim N(a'x, \tau^2)$.

Assuming $p(y) = N(\mu_y, \sigma_y^2)$ (as is often done in regression analysis) we have

$$p_\theta(\hat{y}^{(i)}) = \int_{\mathbb{R}} p_\theta(\hat{y}^{(i)}|y)p(y)dy = (2\pi\theta^2\tau^2 2\pi\sigma_y^2)^{-1/2} \int_{\mathbb{R}} \exp\left(-\frac{(\hat{y}-\theta y)^2}{2\theta^2\tau^2} - \frac{(y-\mu_y)^2}{2\sigma_y^2}\right) dy \quad (11)$$

$$= \frac{1}{\theta\sqrt{2\pi(\tau^2+\sigma_y^2)}} \exp\left(\frac{(\hat{y}^{(i)})^2}{2\theta^2\tau^2}\left(\frac{\sigma_y^2}{\sigma_y^2+\tau^2}-1\right) + \frac{\mu_y^2}{2\sigma_y^2}\left(\frac{\tau^2}{\sigma_y^2+\tau^2}-1\right) + \frac{\hat{y}^{(i)}\mu_y}{\theta\left(\tau^2+\sigma_y^2\right)}\right)$$

where we used the following lemma in the last equation.

Lemma 1 (e.g., Papoulis, 1984)

$$\int_{-\infty}^{\infty} A e^{-Bx^2+Cx+D}\, dx = A\sqrt{\frac{\pi}{B}} \exp\left(C^2/4B + D\right)$$

where A, B, C, D are constants that do not depend on x.

In this case the loglikelihood simplifies to

$$\ell(\theta) = -n\log\left(\theta\sqrt{2\pi(\tau^2+\sigma_y^2)}\right) - \left(\frac{\sum_{i=1}^n (\hat{y}^{(i)})^2}{2(\tau^2+\sigma_y^2)}\right)\frac{1}{\theta^2} + \left(\frac{\mu_y\sum_{i=1}^n \hat{y}^{(i)}}{\tau^2+\sigma_y^2}\right)\frac{1}{\theta} - n\frac{\mu_y^2}{2(\sigma_y^2+\tau^2)}$$

which can be shown to have the following closed form maximizer

$$\hat{\theta}^{\text{mle}} = -\frac{\mu_y\sum_{i=1}^n \hat{y}^{(i)}}{2n(\tau^2+\sigma_y^2)} \pm \sqrt{\frac{\left(\mu_y\sum_{i=1}^n \hat{y}^{(i)}\right)^2}{4n^2(\tau^2+\sigma_y^2)^2} + \frac{\sum_{i=1}^n (\hat{y}^{(i)})^2}{n(\tau^2+\sigma_y^2)}}$$

where the two roots correspond to the two cases where $\theta = a'/a > 0$ and $\theta = a'/a < 0$.

The univariate regression case described above may be extended to multiple explanatory variables, that is, $y = Ax + \varepsilon$ where y, x, ε are vectors and A is a matrix. This is an interesting extension which falls beyond the scope of the current paper.

2.1.3 NOISY GAUSSIAN CHANNEL

In this case our predictor f corresponds to a noisy channel mapping a real valued signal y to its noisy version $\hat{y}$. The aim is to estimate the mean squared error or noise level $R(f) = \mathsf{E}\,\|y-\hat{y}\|^2$. In this case the distribution $p_\theta(\hat{y}|y)$ and the relationship between the risk and the parameter $R(f) = g(\theta)$ are

$$p_\theta(\hat{y}|y) = (2\pi\theta^2)^{-1/2}\exp\left(-\frac{(\hat{y}-y)^2}{2\theta^2}\right),$$
$$R(f|y) = \theta^2,$$
$$R(f) = \theta^2 \mathsf{E}_{p(y)}(y).$$

The loglikelihood and other details in this case are straightforward variations on the linear regression case described above. We therefore concentrate in this paper on the classification and linear regression cases.

As mentioned above, in both classification and regression, estimating the risks for $k \geq 2$ predictors rather than a single one may proceed by repeating the optimization process described above for each predictor separately. That is $\hat{R}(f_j) = g_j(\hat{\theta}_j^{\text{mle}})$ where $\hat{\theta}_1^{\text{mle}}, \ldots, \hat{\theta}_k^{\text{mle}}$ are estimated by maximizing k different loglikelihood functions. In some cases the convergence rate to the true risks can be accelerated by jointly estimating the risks $R(f_1), \ldots, R(f_k)$ in a collaborative fashion. Such collaborative estimation is possible under some assumptions on the statistical dependency between the noise processes defining the k predictors. We describe below such an assumption followed by a description of more general cases.

2.2 Collaborative Estimation of the Risks: Conditionally Independent Predictors

We have previously seen how to estimate the risks of k predictors by separately applying (1) to each predictor. If the predictors are known to be conditionally independent given the true label, that is, $p_\theta(\hat{y}_1, \ldots, \hat{y}_k|y) = \prod_j p_{\theta_j}(\hat{y}_j|y)$ the loglikelihood (3) simplifies to

$$\ell(\theta) = \sum_{i=1}^{n} \log \int_{\mathcal{Y}} \prod_{j=1}^{k} p_{\theta_j}(\hat{y}_j^{(i)}|y^{(i)}) p(y^{(i)}) \, d\mu(y^{(i)}), \quad \text{where} \quad \hat{y}_j^{(i)} = f_j(x^{(i)}) \tag{12}$$

and p_{θ_j} above is (6) or (8) for classification and (10) for regression. Maximizing the loglikelihood (12) jointly over $\theta_1, \ldots, \theta_k$ results in estimators $\hat{R}(f_1), \ldots, \hat{R}(f_k)$ that converge to the true value faster than the non-collaborative MLE (5) (more on this in Section 7). Equation (12) does not have a closed form maximizer requiring the use of iterative computational techniques.

The conditional independence of the predictors is a much weaker condition than the independence of the predictors which is very unlikely to hold. In our case, each predictor f_j has its own stochastic noise operator $T_j(r,s) = p(\hat{y} = r|y = s)$ (regression) or matrix $[T_j]_{rs} = p_j(\hat{y} = r|y = s)$ (classification) where $T_1, \ldots, T_k$ may be arbitrarily specified. In particular, some predictors may be similar, for example, $T_i \approx T_j$, and some may be different, for example, $T_i \not\approx T_j$. The conditional independence assumption that we make in this subsection is that conditioned on the latent label y the predictions of the predictors proceed stochastically according to $T_1, \ldots, T_k$ in an independent manner.

Figure 1 displays the loglikelihood functions $\ell(\theta)$ for three different data set sizes $n = 100, 250, 500$. As the size n of the unlabeled data grows the curves become steeper and $\hat{\theta}_n^{\text{mle}}$ approach θ^{true}. Figure 2 displays a similar figure for $k = 1$ in the case of regression.

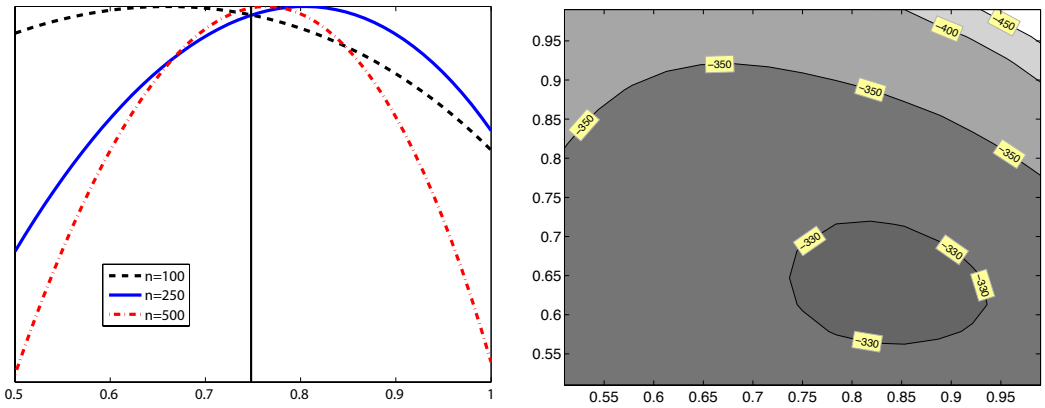

Figure 1: A plot of the loglikelihood functions $\ell(\theta)$ in the case of classification for $k = 1$ (left, $\theta^{\text{true}} = 0.75$) and $k = 2$ (right, $\theta^{\text{true}} = (0.8, 0.6)^\top$). The loglikelihood was constructed based on random samples of unlabeled data with sizes $n = 100, 250, 500$ (left) and $n = 250$ (right) and $p(y = 1) = 0.75$. In the left panel the y values of the curves were scaled so their maxima would be aligned. For $k = 1$ the estimators $\hat{\theta}^{\text{mle}}$ (and their errors $|\hat{\theta}^{\text{mle}} - 0.75|$) for $n = 100, 250, 500$ are 0.6633 (0.0867), 0.8061 (0.0561), 0.765 (0.0153). As additional unlabeled examples are added the loglikelihood curves become steeper and their maximizers become more accurate and closer to θ^{true}.

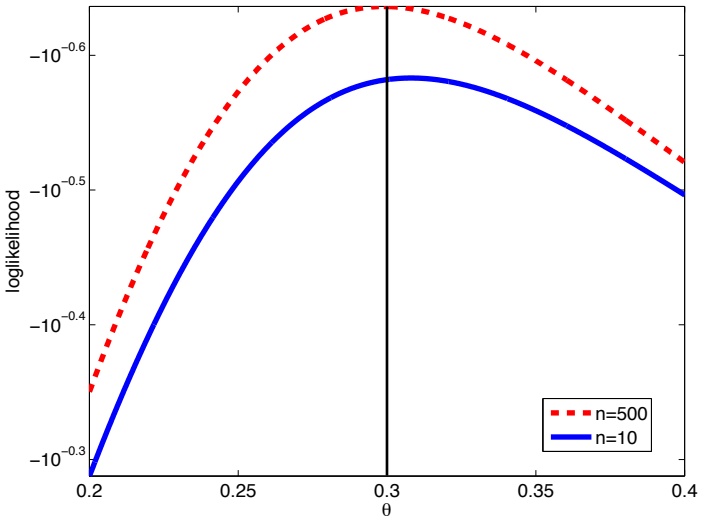

Figure 2: A plot of the loglikelihood function $\ell(\theta)$ in the case of regression for $k = 1$ with $\theta^{\text{true}} = 0.3, \tau = 1, \mu_y = 0$ and $\sigma_y = 0.2$. As additional unlabeled examples are added the loglikelihood curve become steeper and their maximizers get closer to the true parameter θ^{true} resulting in a more accurate risk estimate.

In the case of regression (12) involves an integral over a product of $k+1$ Gaussians, assuming that $y \sim N(\mu_y, \sigma_y^2)$. In this case the integral in (12) simplifies to

$$\begin{aligned}
p_\theta(\hat{y}_1^{(i)}, \ldots, \hat{y}_k^{(i)}) &= \int_{-\infty}^{\infty} \left(\prod_{j=1}^{k} \frac{1}{\theta_j \tau \sqrt{2\pi}} e^{-\left(\hat{y}_j^{(i)} - \theta_j y^{(i)}\right)^2 \Big/ 2\theta_j^2 \tau^2} \right) \frac{1}{\sigma_y \sqrt{2\pi}} e^{-\left(y^{(i)} - \mu_y\right)^2 \Big/ 2\sigma_y^2} dy^{(i)} \\
&= \frac{1}{\tau^k (\sqrt{2\pi})^{k+1} \sigma_y \prod_{j=1}^{k} \theta_j} \int_{-\infty}^{\infty} \exp\left[-\frac{1}{2} \left(\left(\frac{y^{(i)} - \mu_y}{\sigma_y} \right)^2 + \sum_{j=1}^{k} \left(\frac{y^{(i)}}{\tau} - \frac{\hat{y}_j^{(i)}}{\tau \theta_j} \right)^2 \right) \right] dy^{(i)} \\
&= \frac{\int_{-\infty}^{\infty} \exp\left(-\frac{1}{2} \left(\frac{1}{\sigma_y^2} + \frac{k}{\tau^2} \right) (y^{(i)})^2 + \left(\frac{\mu_y}{\sigma_y^2} + \sum_{j=1}^{k} \frac{\hat{y}_j^{(i)}}{\tau^2 \theta_j} \right) y^{(i)} - \frac{1}{2} \left(\frac{\mu_y^2}{\sigma_y^2} + \sum_{j=1}^{k} \frac{(\hat{y}_j^{(i)})^2}{\tau^2 \theta_j^2} \right) \right)}{\tau^k (\sqrt{2\pi})^{k+1} \sigma_y \prod_{j=1}^{k} \theta_j} \\
&= \frac{\sqrt{\pi} \left[\frac{1}{2} \left(\frac{1}{\sigma_y^2} + \frac{k}{\tau^2} \right) \right]^{-1/2}}{\tau^k (\sqrt{2\pi})^{k+1} \sigma_y \prod_{j=1}^{k} \theta_j} \exp\left(\frac{\left(\frac{\mu_y}{\sigma_y^2} + \sum_{j=1}^{k} \frac{\hat{y}_j^{(i)}}{\tau^2 \theta_j} \right)^2}{2 \left(\frac{1}{\sigma_y^2} + \frac{k}{\tau^2} \right)} - \sum_{j=1}^{k} \frac{(\hat{y}_j^{(i)})^2}{2\tau^2 \theta_j^2} - \frac{\mu_y^2}{2\sigma_y^2} \right)
\end{aligned} \tag{13}$$

where the last equation was obtained using Lemma 1 concerning Gaussian integrals. Note that this equation does not have a closed form maximizer requiring the use of iterative computational techniques.

2.3 Collaborative Estimation of the Risks: Conditionally Correlated Predictors

In some cases the conditional independence assumption made in the previous subsection does not hold and the factorization (12) is violated. In this section, we discuss how to relax this assumption in the classification case. A similar approach may also be used for regression. We omit the details here due to notational clarity.

There are several ways to relax the conditional independence assumption. Most popular, perhaps, is the mechanism of hierarchical loglinear models for categorical data (Bishop et al., 1975). For example, generalizing our conditional independence assumption to second-order interaction log-linear models we have

$$\log p(\hat{y}_1, \ldots, \hat{y}_k | y) = \alpha_y + \sum_{i=1}^{l} \beta_{i,\hat{y}_i,y} + \sum_{i<j} \gamma_{i,j,\hat{y}_i,\hat{y}_j,y} \tag{14}$$

where the following ANOVA-type parameter constraints are needed (Bishop et al., 1975)

$$\begin{aligned}
0 &= \sum_{\hat{y}_i} \beta_{i,\hat{y}_i,y} \quad \forall i, y, \\
0 &= \sum_{\hat{y}_i} \gamma_{i,j,\hat{y}_i,\hat{y}_j,y} = \sum_{\hat{y}_j} \gamma_{i,j,\hat{y}_i,\hat{y}_j,y} \quad \forall i, j, y.
\end{aligned} \tag{15}$$

The β parameters in (14) correspond to the order-1 interaction between the variables $\hat{y}_1, \ldots, \hat{y}_k$, conditioned on y. They correspond to the θ_i in the independent formulation (6)-(8). The γ parameters capture two-way interactions which do not appear in the conditionally independent case. Indeed, setting $\gamma_{i,j,\hat{y}_i,\hat{y}_j,y} = 0$ retrieves the independent models (6)-(8).

In the case of classification, the number of degrees of freedom or free unconstrained parameters in (14) depends on whether the number of classes is 2 or more and what additional assumptions exist on β and γ. For example, assuming that the probability of f_i, f_j making an error depends on the true class y but not on the predicted classes $\hat{y}_i, \hat{y}_j$ results in a $k+k^2$ parameters. Relaxing that assumption but assuming binary classification results in $2k+4k^2$ parameters. The estimation and aggregation techniques described in Section 2.1 work as before with a slight modification of replacing (6)-(8) with variations based on (14) and enforcing the constraints (15).

Equation (14) captures two-way interactions but cannot model higher order interactions. However, three-way and higher order interaction models are straightforward generalizations of (14) culminating in the full loglinear model which does not make any assumption on the statistical dependency of the noise operators $T_1, \ldots, T_k$. However, as we weaken the assumptions underlying the loglinear models and add higher order interactions the number of parameters increases adding to the difficulty in estimating the risks $R(f_1), \ldots, R(f_k)$.

In our experiments on real world data (see Section 7), it is often the case that maximizing the loglikelihood under the conditionally independent assumption (12) provides adequate accuracy and there is no need for the more general (14)-(15). Nevertheless, we include here the case of loglinear models as it may be necessary in some situations.

3. Extensions: Missing Values, Active Learning, and Semi-Supervised Learning

In this section, we discuss extensions to the current framework. Specifically, we consider extending the framework to the cases of missing values, active and semi-supervised learning.

Occasionally, some predictors are unable to provide their output over specific data points. That is assuming a data set $x^{(1)}, \ldots, x^{(n)}$ each predictor may provide output on an arbitrary subset of the data points $\{f_j(x^{(i)}) : i \in S_j\}$, where $S_j \subset \{1, \ldots, n\}$, $j = 1, \ldots, k$.

Commonly referred to as a missing value situation, this scenario may apply in cases where different parts of the unlabeled data are available to the different predictors at test time due to privacy, computational complexity, or communication cost. Another example where this scenario applies is active learning where operating f_j involves a certain cost $c_j \geq 0$ and it is not advantageous to operate all predictors with the same frequency for the purpose of estimating the risks $R(f_1), \ldots, R(f_k)$. Such is the case when f_j corresponds to judgments obtained from human experts or expensive machinery that is busy serving multiple clients. Active learning fits into this situation with S_j denoting the set of selected data points for each predictor.

We proceed in this case by defining indicators β_{ji} denoting whether predictor j is available to emit $f_j(x^{(i)})$. The risk estimation proceeds as before with the observed likelihood modified to account for the missing values.

In the case of collaborative estimation with conditional independence, the estimator and loglikelihood become

$$\begin{aligned}
\hat{\theta}_n^{\text{mle}} &= \arg\max_{\theta} \ell(\theta), \\
\ell(\theta) &= \sum_{i=1}^{n} \log \sum_{r:\beta_{ri}=0} \int_{\mathcal{Y}} p_\theta(\hat{y}_1^{(i)}, \ldots, \hat{y}_k^{(i)})\, d\mu(\hat{y}_r^{(i)}) \qquad (16) \\
&= \sum_{i=1}^{n} \log \sum_{r:\beta_{ri}=0} \iint_{\mathcal{Y}^2} p_\theta(\hat{y}_1^{(i)}, \ldots, \hat{y}_k^{(i)} | y^{(i)}) p(y^{(i)})\, d\mu(\hat{y}_r^{(i)}) d\mu(y^{(i)})
\end{aligned}$$

where p_θ may be further simplified using the non-collaborative approach, or using the collaborative approach with conditional independence or loglinear model assumptions.

In the case of semi-supervised learning a small set of labeled data is augmented by a large set of unlabeled data. In this case our framework remains as before with the likelihood summing over the observed labeled and unlabeled data. For example, in the case of collaborative estimation with conditional independence we have

$$\ell(\theta) = \sum_{i=1}^{n} \log \int_{\mathcal{Y}} \prod_{j=1}^{k} p_{\theta_j}(\hat{y}_j^{(i)}|y^{(i)}) p(y^{(i)})\, d\mu(y^{(i)}) + \sum_{i=n+1}^{m} \log \prod_{j=1}^{k} p_{\theta_j}(\hat{y}_j^{(i)}|y^{(i)}) p(y^{(i)}).$$

The different variations concerning missing values, active learning, semi-supervised learning, and non-collaborative or collaborative estimation with conditionally independent or correlated noise processes can all be combined in different ways to provide the appropriate likelihood function. This provides substantial modeling flexibility.

4. Consistency of $\hat{\theta}_n^{\text{mle}}$ and $\hat{R}(f_j)$

In this and the next section we consider the statistical behavior of the estimator $\hat{\theta}_n^{\text{mle}}$ defined in (2) and the risk estimator $\hat{R}(f_j) = g_j(\hat{\theta}^{\text{mle}})$ defined in (1). The analysis is conducted under the assumption that the vectors of observed predictors outputs $\hat{y}^{(i)} = (\hat{y}_1^{(i)}, \ldots, \hat{y}_k^{(i)})$ are iid samples from the distribution

$$p_\theta(\hat{y}) = p_\theta(\hat{y}_1, \ldots, \hat{y}_k) = \int_{\mathcal{Y}} p_\theta(\hat{y}_1, \ldots, \hat{y}_k|y) p(y)\, d\mu(y).$$

We start by investigating whether estimator $\hat{\theta}^{\text{mle}}$ in (2) converges to the true parameter value. More formally, strong consistency of the estimator $\hat{\theta}_n^{\text{mle}} = \hat{\theta}(\hat{y}^{(1)}, \ldots, \hat{y}^{(n)})$, $\hat{y}^{(1)}, \ldots, \hat{y}^{(n)} \overset{\text{iid}}{\sim} p_{\theta_0}$ is defined as strong convergence of the estimator to θ_0 as $n \to \infty$ (Ferguson, 1996)

$$\lim_{n\to\infty} \hat{\theta}_n^{\text{mle}}(\hat{y}^{(1)}, \ldots, \hat{y}^{(n)}) = \theta_0 \text{ with probability 1.}$$

In other words as the number of samples n grows, the estimator will surely converge to the true parameter θ_0 governing the data generation process.

Assuming that the risks $R(f_j) = g_j(\theta)$ are defined using continuous functions g_j, strong consistency of $\hat{\theta}^{\text{mle}}$ implies strong convergence of $\hat{R}(f_j)$ to $R(f_j)$. This is due to the fact that continuity preserves limits. Indeed, as the g_j functions are continuous in both the classification and regression cases, strong consistency of the risk estimators $\hat{R}(f_j)$ reduces to strong consistency of the estimators $\hat{\theta}^{\text{mle}}$.

It is well known that the maximum likelihood estimator is often strongly consistent. Consider, for example, the following theorem.

Proposition 2 (e.g., Ferguson, 1996) *Let* $\hat{y}^{(1)}, \ldots, \hat{y}^{(n)} \overset{\text{iid}}{\sim} p_{\theta_0}$, $\theta_0 \in \Theta$. *If the following conditions hold*

1. Θ *is compact* *(compactness)*
2. $p_\theta(\hat{y})$ *is upper semi-continuous in* θ *for all* $\hat{y}$ *(continuity)*
3. *There exists a function* $K(\hat{y})$ *such that* $E_{p_{\theta_0}}|K(\hat{y})| < \infty$ *and* $\log p_\theta(\hat{y}) - \log p_{\theta_0}(\hat{y}) \le K(\hat{y}) \quad \forall \hat{y} \quad \forall \theta$ *(boundedness)*
4. *For all* θ *and sufficiently small* $\rho > 0$, $\sup_{|\theta'-\theta|<\rho} p_{\theta'}(\hat{y})$ *is measurable in* $\hat{y}$ *(measurability)*
5. $p_\theta \equiv p_{\theta_0} \Rightarrow \theta = \theta_0$ *(identifiability)*

then the maximum likelihood estimator is strongly consistent, that is, $\hat{\theta}^{mle} \to \theta_0$ *as* $n \to \infty$ *with probability 1.*

Note that $p_\theta(\hat{y})$ in the proposition above corresponds to $\int_{\mathcal{Y}} p_\theta(\hat{y}|y)p(y)\,d\mu(y)$ in our framework. That is the MLE operates on the observed data or predictor output $\hat{y}^{(1)},\ldots,\hat{y}^{(n)}$ that is sampled iid from the distribution $p_{\theta_0}(\hat{y}) = \int_{\mathcal{Y}} p_{\theta_0}(\hat{y}|y)p(y)\,d\mu(y)$.

Of the five conditions above, the last condition of identifiability is the only one that is truly problematic. The first condition of compactness is trivially satisfied in the case of classification. In the case of regression it is satisfied assuming that the regression parameter and model parameter are finite and $a \neq 0$ as the estimator $\hat{\theta}^{\text{mle}}$ will eventually lie in a compact set. The second condition of continuity is trivially satisfied in both classification and regression as the function $\int_{\mathcal{Y}} p_\theta(\hat{y}|y)p(y)\,d\mu(y)$ is continuous in θ once $\hat{y}$ is fixed. The third condition is trivially satisfied for classification (finite valued y). In the case of regression due to conditions 1,2 (compactness and semi-continuity) we can replace the quantifier $\forall\theta$ with a particular value $\theta' \in \Theta$ representing worst case situation in the bound of the logarithm difference. Then, the bound K may be realized by the difference of log terms (with respect to that worst case θ') whose expectation converges to the KL divergence which in turn is never ∞ for Gaussian distributions or its derivatives. The fourth condition of measurability follows as p_θ is specified in terms of compositions, summations, multiplications, and point-wise limits of well-known measurable functions.

The fifth condition of identifiability states that if $p_\theta(\hat{y})$ and $p_{\theta_0}(\hat{y})$ are identical as functions, that is, they are identical for every value of $\hat{y}$, then necessarily $\theta = \theta_0$. This condition does not hold in general and needs to be verified in each one of the special cases.

We start with establishing consistency in the case of classification where we rely on a symmetric noise model (8). The non-symmetric case (6) is more complicated and is treated afterwards. We conclude the consistency discussion with an examination of the regression case.

4.1 Consistency of Classification Risk Estimation

Proposition 3 *Let* $f_1,\ldots,f_k$ *be classifiers* $f_i : \mathcal{X} \to \mathcal{Y}$, $|\mathcal{Y}| = l$, *with conditionally independent noise processes described by* (8). *If the classifiers are weak learners, that is,* $1/l < 1 - err(f_i) < 1$ *and* $p(y)$ *is not uniform the unsupervised collaborative diagnosis model is identifiable.*

Corollary 4 *Let* $f_1,\ldots,f_k$ *be classifiers* $f_i : \mathcal{X} \to \mathcal{Y}$ *with* $|\mathcal{Y}| = l$ *and noise processes described by* (8). *If the classifiers are weak learners, that is,* $1/l < 1 - err(f_i) < 1$, *and* $p(y)$ *is not uniform the unsupervised non-collaborative diagnosis model is identifiable.*

Proof Proving identifiability in the non-collaborative case proceeds by invoking Proposition 3 (whose proof is given below) with $k = 1$ separately for each classifier. The conditional independence assumption in Proposition 3 becomes redundant in this case of a single classifier, resulting in identifiability of $p_{\theta_j}(\hat{y}_j)$ for each $j = 1,\ldots,k$ ■

Corollary 5 *Under the assumptions of Proposition 3 or Corollary 4 the unsupervised maximum likelihood estimator is consistent, that is,*

$$P\left(\lim_{n\to\infty} \hat{\theta}_n^{mle}(\hat{y}^{(1)},\ldots,y^{(n)}) = (\theta_1^{true},\ldots,\theta_k^{true})\right) = 1.$$

Consequentially, assuming that $R(f_j) = g_j(\theta), j = 1,\ldots,k$ with continuous g_j we also have

$$P\left(\lim_{n\to\infty} \hat{R}(f_j; y^{(1)},\ldots,y^{(n)}) = R(f_j), \quad \forall j = 1,\ldots,k\right) = 1.$$

Proof Proposition 3 or Corollary 4 establishes identifiability, which in conjunction with Proposition 2 proves the corollary. ■

Proof (**for Proposition 3**) We prove identifiability by induction on k. In the base case of $k = 1$, we have a set of l equations, corresponding to $i = 1,2\ldots l$,

$$\begin{aligned} p_\theta(\hat{y}_1 = i) &= p(y=i)\theta_1 + \left(\sum_{j\neq i} p(y=j)\right)\frac{(1-\theta_1)}{(l-1)} \\ &= p(y=i)\theta_1 + (1-p(y=i))\frac{(1-\theta_1)}{(l-1)} \\ &= \frac{\theta_1(lp(y=i)-1)+1-p(y=i)}{(l-1)} \end{aligned}$$

from which we can see that if $\eta \neq \theta$ and $p(y=i) \neq 1/l$ then $p_\theta(\hat{y}_1) \neq p_\eta(\hat{y}_1)$. This proves identifiability for the base case of $k = 1$.

Next, we assume identifiability holds for k and prove that it holds for $k+1$. We do so by deriving a contradiction from the assumption that identifiability holds for k but not for $k+1$. We denote the parameters corresponding to the k labelers by the vectors $\theta, \eta \in [0,1]^k$ and the parameters corresponding the additional $k+1$ labeler by θ_{k+1}, η_{k+1}.

In the case of k classifiers we have

$$p_\theta(\hat{y}_1,\ldots,\hat{y}_k) = \sum_{i=1}^{l} p_\theta(\hat{y}_1,\ldots,\hat{y}_k|y=i)p(y=i) = \sum_{i=1}^{l} G(\mathcal{A}_i,\theta)$$

where

$$\begin{aligned} G(\mathcal{A}_i,\theta) &\stackrel{\text{def}}{=} p(y=i)\prod_{j\in\mathcal{A}_i}\theta_j \cdot \prod_{j\notin\mathcal{A}_i}\frac{(1-\theta_j)}{(l-1)}, \\ \mathcal{A}_i &\stackrel{\text{def}}{=} \{j \in \{1,2...,k\} : \hat{y}_j = i\}. \end{aligned}$$

Note that the $\mathcal{A}_1,\ldots,\mathcal{A}_l$ form a partition of $\{1,\ldots,k\}$, that is, they are disjoint and their union is $\{1,\ldots,k\}$.

In order to have unidentifiability for the $k+1$ classifiers we need $(\theta,\theta_{k+1}) \neq (\eta,\eta_{k+1})$ and the following l equations (corresponding to $\hat{y}_{k+1} = 1,2,\ldots,l$) to hold for any $\hat{y}_1,\ldots,\hat{y}_k$ which corre-

sponds to any partition $\mathcal{A}_1,\ldots,\mathcal{A}_l$

$$\theta_{k+1}G(\mathcal{A}_1,\theta)+\frac{(1-\theta_{k+1})}{(l-1)}\sum_{i\neq 1}G(\mathcal{A}_i,\theta)=\eta_{k+1}G(\mathcal{A}_1,\eta)+\frac{(1-\eta_{k+1})}{(l-1)}\sum_{i\neq 1}G(\mathcal{A}_i,\eta),$$
$$\theta_{k+1}G(\mathcal{A}_2,\theta)+\frac{(1-\theta_{k+1})}{(l-1)}\sum_{i\neq 2}G(\mathcal{A}_i,\theta)=\eta_{k+1}G(\mathcal{A}_2,\eta)+\frac{(1-\eta_{k+1})}{(l-1)}\sum_{i\neq 2}G(\mathcal{A}_i,\eta),$$
$$\vdots$$
$$\theta_{k+1}G(\mathcal{A}_l,\theta)+\frac{(1-\theta_{k+1})}{(l-1)}\sum_{i\neq l}G(\mathcal{A}_i,\theta)=\eta_{k+1}G(\mathcal{A}_l,\eta)+\frac{(1-\eta_{k+1})}{(l-1)}\sum_{i\neq l}G(\mathcal{A}_i,\eta).$$

We consider two cases in which $(\theta,\theta_{k+1})\neq(\eta,\eta_{k+1})$: (a) $\theta\neq\eta$, and (b) $\theta=\eta,\theta_{k+1}\neq\eta_{k+1}$. In the case of (a) we add the l equations above which marginalizes $\hat{y}_{k+1}$ out of $p_\theta(\hat{y}_1,\ldots,\hat{y}_k,\hat{y}_{k+1})$ and $p_\eta(\hat{y}_1,\ldots,\hat{y}_k,\hat{y}_{k+1})$ to provide

$$\sum_{i=1}^{l}G(\mathcal{A}_i,\theta)=\sum_{i=1}^{l}G(\mathcal{A}_i,\eta)$$

which together with $\theta\neq\eta$ contradicts the identifiability for the case of k classifiers.

In case (b) we have from the l equations above

$$\theta_{k+1}G(\mathcal{A}_t,\theta)+\frac{1-\theta_{k+1}}{l-1}\left(\sum_{i=1}^{l}G(\mathcal{A}_i,\theta)-G(\mathcal{A}_t,\theta)\right)$$
$$=\eta_{k+1}G(\mathcal{A}_t,\eta)+\frac{1-\eta_{k+1}}{l-1}\left(\sum_{i=1}^{l}G(\mathcal{A}_i,\eta)-G(\mathcal{A}_t,\eta)\right)$$

for any $t\in\{1,\ldots,l\}$ which simplifies to

$$0=(\theta_{k+1}-\eta_{k+1})\left(lG(\mathcal{A}_t,\theta)-\sum_{i=1}^{l}G(\mathcal{A}_i,\theta)\right)\quad t=1,\ldots,k.$$

As we assume at this point that $\theta_{k+1}\neq\eta_{k+1}$ the above equality entails

$$lG(\mathcal{A}_t,\theta)=\sum_{i=1}^{l}G(\mathcal{A}_i,\theta). \tag{17}$$

We show that (17) cannot hold by examining separately the cases $p(y=t)>1/l$ and $p(y=t)<1/l$. Recall that there exists a t for which $p(y=t)\neq 1/l$ since the proposition requires that $p(y)$ is not uniform.

If $p(y=t)>1/l$ we choose $\mathcal{A}_t=\{1,\ldots,k\}$ and obtain

$$lp(y=t)\prod_{j=1}^{k}\theta_j=\sum_{i\neq t}p(y=i)\prod_{j=1}^{k}\frac{1-\theta_j}{l-1}+p(y=t)\prod_{j=1}^{k}\theta_j$$
$$(l-1)p(y=t)\prod_{j=1}^{k}\theta_j=(1-p(y=t))\prod_{j=1}^{k}\frac{1-\theta_j}{l-1}$$
$$p(y=t)\prod_{j=1}^{k}\theta_j=\frac{(1-p(y=t))}{(l-1)}\prod_{j=1}^{k}\frac{1-\theta_j}{l-1}$$

which cannot hold as the term on the left hand side is necessarily larger than the term on the right hand side (if $p(y=t) > 1/l$ and $\theta_j > 1/l$). In the case $p(y=t) < 1/l$ we choose $\mathcal{A}_s = \{1,\ldots,k\}$, $s \neq t$ to obtain

$$lp(y=t)\prod_{j=1}^{k}\frac{1-\theta_j}{l-1} = \sum_{i\neq s} p(y=i)\prod_{j=1}^{k}\frac{1-\theta_j}{l-1} + p(y=s)\prod_{j=1}^{k}\theta_j$$

$$(lp(y=t) - p(y\neq s))\prod_{j=1}^{k}\frac{1-\theta_j}{l-1} = p(y=s)\prod_{j=1}^{k}\theta_j$$

which cannot hold as the term on the left hand side is necessarily smaller than the term on the right hand side (if $p(y=t) < 1/l$ and $\theta_j > 1/l$).

Since we derived a contradiction to the fact that we have k-identifiability but not $k+1$ identifiability, the induction step is proven which establishes identifiability for any $k \geq 1$. ■

The conditions asserted above that $p(y) \neq 1/l$ and $1/l < 1 - \mathrm{err}(f_i) < 1$ are intuitive. If they are violated a certain symmetry may emerge which renders the model non-identifiable and the MLE estimator not consistent.

In the case of the non-collaborative estimation for binary classification with the non-symmetric noise model, the matrix θ in (6) is a 2×2 matrix with two degrees of freedom as each row sums to one. In particular we have $\theta_{11} = p_\theta(\hat{y}=1|y=1)$, $\theta_{12} = p_\theta(\hat{y}=1|y=2)$, $\theta_{21} = p_\theta(\hat{y}=2|y=1)$, $\theta_{22} = p_\theta(\hat{y}=2|y=2)$ with the overall risk $R(f) = 1-\theta_{11}p(y=1)-\theta_{22}p(y=2)$. Unfortunately, the matrix θ is not identifiable in this case and neither is the scalar parameter $\theta_{11}p(y=1)+\theta_{22}p(y=2)$ that can be used to characterize the risk.

We can, however, obtain a consistent estimator for θ (and therefore for $R(f)$) by first showing that the parameter $\theta_{11}p(y=1)-\theta_{22}p(y=2)$ is identifiable and then taking the intersection of two such estimators.

Lemma 6 *In the case of the non-collaborative estimation for binary classification with the non-symmetric noise model and $p(y) \neq 0$, the parameter $\theta_{11}p(y=1)-\theta_{22}p(y=2)$ is identifiable.*

Proof For two different parameterizations θ, η we have

$$p_\theta(\hat{y}=1) = p(y=1)\theta_{11} + (1-p(y=1))(1-\theta_{22}), \tag{18}$$

$$p_\theta(\hat{y}=2) = p(y=1)(1-\theta_{11}) + (1-p(y=1))\theta_{22} \tag{19}$$

and

$$p_\eta(\hat{y}=1) = p(y=1)\eta_{11} + (1-p(y=1))(1-\eta_{22}), \tag{20}$$

$$p_\eta(\hat{y}=2) = p(y=1)(1-\eta_{11}) + (1-p(y=1))\eta_{22}. \tag{21}$$

Equating the two Equations (18) and (20) we have

$$p(y=1)(\theta_{11}+\theta_{22}) + 1 - p(y=1) - \theta_{22} = p(y=1)(\eta_{11}+\eta_{22}) + 1 - p(y=1) - \eta_{22}$$

$$p(y=1)\theta_{11} - (1-p(y=1))\theta_{22} = p(y=1)\eta_{11} - (1-p(y=1))\eta_{22}$$

$$p(y=1)\theta_{11} - p(y=2)\theta_{22} = p(y=1)\eta_{11} - p(y=2)\eta_{22}$$

Similarly, equating Equation (19) and Equation (21) also results in $p(y=1)\theta_{11} - p(y=2)\theta_{22} = p(y=1)\eta_{11} - p(y=2)\eta_{22}$. As a result, we have

$$p_\theta \equiv p_\eta \quad \Rightarrow \quad p(y=1)\theta_{11} - p(y=2)\theta_{22} = p(y=1)\eta_{11} - p(y=2)\eta_{22}.$$

■

The above lemma indicates that we can use the maximum likelihood method to obtain a consistent estimator for the parameter $\theta_{11}p(y=1) - \theta_{22}p(y=2)$. Unfortunately the parameter $\theta_{11}p(y=1) - \theta_{22}p(y=2)$ does not have a clear probabilistic interpretation and does not directly characterize the risk. As the following proposition shows we can obtain a consistent estimator for the risk $R(f)$ if we have two populations of unlabeled data drawn from distributions with two distinct marginals $p_1(y)$ and $p_2(y)$.

Proposition 7 *Consider the case of the non-collaborative estimation of binary classification risk with the non-symmetric noise model. If we have access to two unlabeled data sets drawn independently from two distributions with different marginals, that is,*

$$x^{(1)}, \ldots, x^{(n)} \overset{\text{iid}}{\sim} p_1(x) = \sum_y p(x|y)p_1(y),$$
$$x'^{(1)}, \ldots, x'^{(m)} \overset{\text{iid}}{\sim} p_2(x) = \sum_y p(x|y)p_2(y)$$

we can obtain a consistent estimator for the classification risk $R(f)$.

Proof Operating the classifier f on both sets of unlabeled data we get two sets of observed classifier outputs $\hat{y}^{(1)}, \ldots, \hat{y}^{(n)}$, $\hat{y}'^{(1)}, \ldots, \hat{y}'^{(m)}$ where $\hat{y}^{(i)} \overset{\text{iid}}{\sim} \sum_y p_\theta(\hat{y}|y)p_1(y)$ and $\hat{y}'^{(i)} \overset{\text{iid}}{\sim} \sum_y p_\theta(\hat{y}|y)p_2(y)$. In particular, note that the marginal distributions $p_1(y)$ and $p_2(y)$ are different but the parameter matrix θ is the same in both cases as we operate the same classifier on samples from the same class conditional distribution $p(x|y)$.

Based on Lemma 6 we construct a consistent estimator for $p_1(y=1)\theta_{11} - p_1(y=2)\theta_{22}$ by maximizing the likelihood of $\hat{y}^{(1)}, \ldots, \hat{y}^{(n)}$. Similarly, we construct a consistent estimator for $p_2(y=1)\theta_{11} - p_2(y=2)\theta_{22}$ by maximizing the likelihood of $\hat{y}'^{(1)}, \ldots, \hat{y}'^{(m)}$. Note that $p_1(y=1)\theta_{11} - p_1(y=2)\theta_{22}$ and $p_2(y=1)\theta_{11} - p_2(y=2)\theta_{22}$ describe two lines in the 2-D space $(\theta_{11}, \theta_{22})$. Since the true value of θ_{11}, θ_{22} represent a point in that 2-D space belonging to both lines, it is necessarily the intersection of both lines (the lines cannot be parallel since their linear coefficients are distributions which are assumed to be different).

As n and m increase to infinity, the two estimators converge to the true parameter values. As a result, the intersection of the two lines described by the two estimators converges to the true values of $(\theta_{11}, \theta_{22})$ thus allowing reconstruction of the matrix θ and the risk $R(f)$. ■

Clearly, the conditions for consistency in the asymmetric case are more restricted than in the symmetric case. However, situations such as in Proposition 7 are not necessarily unrealistic. In many cases it is possible to identify two unlabeled sets with different distributions. For example, if y denotes a medical condition, it may be possible to obtain two unlabeled sets from two different

hospitals or two different regions with different marginal distribution corresponding to the frequency of the medical condition.

As indicated in the previous section, the risk estimation framework may be extended beyond non-collaborative estimation and collaborative conditionally independent estimation. In these extensions, the conditions for identifiability need to be determined separately, in a similar way to Corollary 4. A systematic way to do so may be obtained by noting that the identifiability equations

$$0 = p_\theta(\hat{y}_1,\ldots,\hat{y}_k) - p_\eta(\hat{y}_1,\ldots,\hat{y}_k) \quad \forall \hat{y}_1,\ldots,\hat{y}_k$$

is a system of polynomial equations in (θ,η). As a result, demonstrating lack of identifiability becomes equivalent to obtaining a solution to a system of polynomial equations. Using Hilbert's Nullstellensatz theorem we have that a solution to a polynomial system exists if the polynomial system defines a proper ideal of the ring of polynomials (Cox et al., 2006). As k increases the chance of identifiability failing decays dramatically as we have a system of l^k polynomials with $2k$ variables. Such an over-determined system with substantially more equations than variables is very unlikely to have a solution.

These observations serve as both an interesting theoretical connection to algebraic geometry as well as a practical tool due to the substantial research in computational algebraic geometry. See Sturmfels (2002) for a survey of computational algorithms and software associated with systems of polynomial equations.

4.2 Consistency of Regression Risk Estimation

In this section, we prove the consistency of the maximum likelihood estimator $\hat{\theta}^{\text{mle}}$ in the regression case. As in the classification case our proof centers on establishing identifiability.

Proposition 8 *Let $f_1,\ldots,f_k$ be regression models $f_i(x) = a_i'x$ with $y \sim N(\mu_y,\sigma_y^2)$, $y = ax+\varepsilon$. Assuming that $a \neq 0$ the unsupervised collaborative estimation model assuming conditionally independent noise processes* (12) *is identifiable.*

Corollary 9 *Let $f_1,\ldots,f_k$ be regression models $f_i(x) = a_i'x$ with $y \sim N(\mu_y,\sigma_y^2)$, $y = ax+\varepsilon$. Assuming that $a \neq 0$ the unsupervised non-collaborative estimation model* (12) *is identifiable.*

Proof Proving identifiability in the non-collaborative case proceeds by invoking Proposition 8 (whose proof is given below) with $k = 1$ separately for each regression model. The conditional independence assumption in Proposition 8 becomes redundant in this case of a single predictor, resulting in identifiability of $p_{\theta_j}(\hat{y}_j)$ for each $j = 1,\ldots,k$. ■

Corollary 10 *Under the assumptions of Proposition 8 or Corollary 9 the unsupervised maximum likelihood estimator is consistent, that is,*

$$P\left(\lim_{n\to\infty} \hat{\theta}_n^{mle}(\hat{y}^{(1)},\ldots,y^{(n)}) = (\theta_1^{true},\ldots,\theta_k^{true})\right) = 1.$$

Consequentially, assuming that $R(f_j) = g_j(\theta)$, $j = 1,\ldots,k$ with continuous g_j we also have

$$P\left(\lim_{n\to\infty} \hat{R}(f_j;y^{(1)},\ldots,y^{(n)}) = R(f_j), \quad \forall j = 1,\ldots,k\right) = 1.$$

Proof Proposition 8 or Corollary 9 establish identifiability, which in conjunction with Proposition 2 completes the proof. ■

Proof (of Proposition 8).

We will proceed, as in the case of classification, with induction on the number of predictors k. In the base case of $k=1$ we have derived $p_{\theta_1}(\hat{y}_1)$ in Equation (11). Substituting in it $\hat{y}_1 = 0$ we get

$$P_{\theta_1}(\hat{y}_1 = 0) = \frac{1}{\theta_1\sqrt{2\pi(\tau^2+\sigma_y^2)}} \exp\left(\frac{\mu_y^2}{2\sigma_y^2}\left(\frac{\tau^2}{\sigma_y^2+\tau^2}-1\right)\right),$$

$$P_{\eta_1}(\hat{y}_1 = 0) = \frac{1}{\eta_1\sqrt{2\pi(\tau^2+\sigma_y^2)}} \exp\left(\frac{\mu_y^2}{2\sigma_y^2}\left(\frac{\tau^2}{\sigma_y^2+\tau^2}-1\right)\right).$$

The above expression leads to $\theta_1 \neq \eta_1 \Rightarrow p_{\theta_1}(\hat{y}_1 = 0) \neq p_{\eta_1}(\hat{y}_1 = 0)$ which implies identifiability.

In the induction step we assume identifiability holds for k and we prove that it holds also for $k+1$ by deriving a contradiction to the assumption that it does not hold. We assume that identifiability fails in the case of $k+1$ due to differing parameter values, that is,

$$p_{(\theta,\theta_{k+1})}(\hat{y}_1,\ldots,\hat{y}_k,\hat{y}_{k+1}) = p_{(\eta,\eta_{k+1})}(\hat{y}_1,\ldots,\hat{y}_k,\hat{y}_{k+1}) \;\forall \hat{y}_j \in \mathbb{R}\; j = 1,\ldots,k+1 \tag{22}$$

with $(\theta,\theta_{k+1}) \neq (\eta,\eta_{k+1})$ where $\theta,\eta \in \mathbb{R}^k$. There are two cases which we consider separately: (a) $\theta \neq \eta$ and (b) $\theta = \eta$.

In case (a) we marginalize both sides of (22) with respect to $\hat{y}_{k+1}$ which leads to a contradiction to our assumption that identifiability holds for k

$$\int_{-\infty}^{\infty} p_{(\theta,\theta_{k+1})}(\hat{y}_1,\ldots,\hat{y}_k,\hat{y}_{k+1})d\hat{y}_{k+1} = \int_{-\infty}^{\infty} p_{(\eta,\eta_{k+1})}(\hat{y}_1,\ldots,\hat{y}_k,\hat{y}_{k+1})d\hat{y}_{k+1}$$
$$p_\theta(\hat{y}_1,\ldots,\hat{y}_k) = p_\eta(\hat{y}_1,\ldots,\hat{y}_k).$$

In case (b) $\theta = \eta$ and $\theta_{k+1} \neq \eta_{k+1}$. Substituting $\hat{y}_1 = \cdots = \hat{y}_{k+1} = 0$ in (22) (see (13) for a derivation) we have

$$P_{(\theta,\theta_{k+1})}(\hat{y}_1 = 0,\ldots,\hat{y}_{k+1} = 0) = P_{(\eta,\eta_{k+1})}(\hat{y}_1 = 0,\ldots,\hat{y}_{k+1} = 0)$$

or

$$\frac{\sqrt{\pi}\left[\frac{1}{2}\left(\frac{1}{\sigma_y^2}+\frac{k+1}{\tau^2}\right)\right]^{-1/2}}{\tau^{k+1}(\sqrt{2\pi})^{k+2}\sigma_y\theta_{k+1}\prod_{j=1}^k\theta_j} \exp\left(\frac{\left(\frac{\mu_y}{\sigma_y^2}\right)^2}{2\left(\frac{1}{\sigma_y^2}+\frac{k+1}{\tau^2}\right)} - \frac{\mu_y^2}{2\sigma_y^2}\right)$$
$$= \frac{\sqrt{\pi}\left[\frac{1}{2}\left(\frac{1}{\sigma_y^2}+\frac{k+1}{\tau^2}\right)\right]^{-1/2}}{\tau^{k+1}(\sqrt{2\pi})^{k+2}\sigma_y\eta_{k+1}\prod_{j=1}^k\eta_j} \exp\left(\frac{\left(\frac{\mu_y}{\sigma_y^2}\right)^2}{2\left(\frac{1}{\sigma_y^2}+\frac{k+1}{\tau^2}\right)} - \frac{\mu_y^2}{2\sigma_y^2}\right)$$

which cannot hold if $\theta = \eta$ but $\theta_{k+1} \neq \eta_{k+1}$. ■

5. Asymptotic Variance of $\hat{\theta}_n^{\text{mle}}$ and $\hat{R}$

A standard result from statistics is that the MLE has an asymptotically normal distribution with mean vector θ^{true} and variance matrix $(nJ(\theta^{\text{true}}))^{-1}$, where $J(\theta)$ is the $r \times r$ Fisher information matrix

$$J(\theta) = \mathsf{E}_{p_\theta}\{\nabla \log p_\theta(\hat{y})(\nabla \log p_\theta(\hat{y}))^\top\}$$

with $\nabla \log p_\theta(\hat{y})$ represents the $r \times 1$ gradient vector of $\log p_\theta(\hat{y})$ with respect to θ. Stated more formally, we have the following convergence in distribution as $n \to \infty$ (Ferguson, 1996)

$$\sqrt{n}\,(\hat{\theta}_n^{\text{mle}} - \theta_0) \rightsquigarrow N(0, J^{-1}(\theta^{\text{true}})). \tag{23}$$

It is instructive to consider the dependency of the Fisher information matrix, which corresponds to the asymptotic estimation accuracy, on $n, k, p(y), \theta^{\text{true}}$.

In the case of classification considering (8) with $k = 1$ and $\mathcal{Y} = \{1, 2\}$ it can be shown that

$$J(\theta) = \frac{\alpha(2\alpha-1)^2}{(\theta(2\alpha-1)-\alpha+1)^2} - \frac{(2\alpha-1)^2(\alpha-1)}{(\alpha-\theta(2\alpha-1))^2} \tag{24}$$

where $\alpha = P(y = 1)$. As Figure 3 (right) demonstrates, the asymptotic accuracy of the MLE (as indicated by J) tends to increase with the degree of non-uniformity of $p(y)$. Recall that since identifiability fails for a uniform $p(y)$ the risk estimate under a uniform $p(y)$ is not consistent. The above derivation (24) is a quantification of that fact reflecting the added difficulty in estimating the risk as we move closer to a uniform label distribution $\alpha \to 1/2$. The dependency of the asymptotic accuracy on θ^{true} is more complex, tending to favor θ^{true} values close to 1 or 0.5. Figure 3 (left) displays the empirical accuracy of the estimator as a function of $p(y)$ and θ^{true} and shows remarkable similarity to the contours of the Fisher information (see Section 7 for more details on the experiments). In particular, whenever the estimation error is high the asymptotic variance of the estimator is high (or equivalently, the Fisher information is low). For instance, the top contours in the left panel have smaller estimation error on the top right than in the top left. Similarly, the top contours in the right panel have smaller asymptotic variance on the top right than on the top left. We thus conclude that the Fisher information provides practical, as well as theoretical insight into the estimation accuracy.

Similar calculations of $J(\theta^{\text{true}})$ for collaborative classification case or for the regression case result in more complicated but straightforward derivations. It is important to realize that consistency is ensured for any identifiable $\theta^{\text{true}}, p(y)$. The value $(J(\theta^{\text{true}}))^{-1}$ is the constant dominating that consistency convergence.

A similar distributional analysis can be derived for the risk estimator. Applying Cramer's theorem (Ferguson, 1996) to $\hat{R}(f_j) = g_j(\hat{\theta}^{\text{mle}})$, $j = 1, \ldots, k$ and (23) we have

$$\sqrt{n}(\hat{R}(f) - R(f)) \rightsquigarrow N\left(0, \nabla g(\theta^{\text{true}}) J(\theta^{\text{true}}) \nabla g(\theta^{\text{true}})^\top\right)$$

where $R(f), \hat{R}(f)$ are the vectors of true risk and risk estimates for the different predictors $f_1, \ldots, f_k$ and $\nabla g(\theta^{\text{true}})$ is the Jacobian matrix of the mapping $g = (g_1, \ldots, g_k)$ evaluated at θ^{true}.

For example, in the case of classification with $k = 1$ we have $R(f_j) = 1 - \theta_j$ and the Jacobian matrix is -1, leading to an identical asymptotic distribution to that of the MLE (23)-(24)

$$\sqrt{n}(\hat{R}(f) - R(f)) \rightsquigarrow N\left(0, \left(\frac{\alpha(2\alpha-1)^2}{(\theta(2\alpha-1)-\alpha+1)^2} - \frac{(2\alpha-1)^2(\alpha-1)}{(\alpha-\theta(2\alpha-1))^2}\right)^{-1}\right).$$

6. Optimization Algorithms

Recall that we obtained closed forms for the likelihood maximizers in the cases of non-collaborative estimation for binary classifiers and non-collaborative estimation for one dimensional regression models. The lack of closed form maximizers in the other cases necessitates iterative optimization techniques.

One class of technique for optimizing nonlinear loglikelihoods is the class of gradient based methods such as gradient descent, conjugate gradients, and quasi Newton methods. These techniques proceed iteratively following a search direction; they often have good performance and are easy to derive. The main difficulty with their implementation is the derivation of the loglikelihood and its derivatives. For example, in the case of collaborative estimation of classification ($l \geq 2$) with symmetric noise model and missing values the loglikelihood gradient is

$$\frac{\partial \ell}{\partial \theta_j} = \sum_{i=1}^{n} \frac{\sum_{y^{(i)}} p(y^{(i)}) \sum_{r:\beta_{ri}=0} \sum_{\hat{y}_r^{(i)}} \prod_{p \neq j} h_{pi} (I(\hat{y}_j^{(i)} = y^{(i)}) - \theta_j)((l-1)\theta_j)^{I(\hat{y}_j^{(i)}=y^{(i)})-1}(1-\theta_j)^{-I(\hat{y}_j^{(i)}=y^{(i)})}}{\sum_{y^{(i)}} p(y^{(i)}) \sum_{r:\beta_{ri}=0} \sum_{\hat{y}_r^{(i)}} \prod_{p=1}^{k} h_{pi}},$$

$$h_{pi} = \theta_p^{I(\hat{y}_p^{(i)}=y^{(i)})} \left(\frac{1-\theta_p}{l-1}\right)^{I(\hat{y}_p^{(i)} \neq y^{(i)})}$$

Similar derivations may be obtained in the other cases in a straightforward manner.

An alternative iterative optimization technique for finding the MLE is expectation maximization (EM). The derivation of the EM update equations is again relatively straightforward. For example in the above case of collaborative estimation of classification ($l \geq 2$) with symmetric noise model and missing values the EM update equations are

$$\begin{aligned}
\theta^{(t+1)} &= \arg\max_{\theta} \sum_{i=1}^{n} \sum_{y^{(i)}} \sum_{r:\beta_{ri}=0} \sum_{\hat{y}_r^{(i)}} q^{(t)}(\hat{y}_r^{(i)}, y^{(i)}) \sum_{j=1}^{k} \log p_j(\hat{y}_j^{(i)} | y^{(i)}) \\
&= \frac{1}{n} \sum_{i=1}^{n} \sum_{y^{(i)}} \sum_{r:\beta_{ri}=0} \sum_{\hat{y}_r^{(i)}} q^{(t)}(\hat{y}_r^{(i)}, y^{(i)}) I(\hat{y}_j^{(i)} = y^{(i)}), \\
q^{(t)}(\hat{y}_r^{(i)}, y^{(i)}) &= \frac{p(y^{(i)}) \prod_{j=1}^{k} p_j(\hat{y}_j^{(i)} | y^{(i)}, \theta^{(t)})}{\sum_{y^{(i)}} \sum_{r:\beta_{ri}=0} \sum_{\hat{y}_r^{(i)}} p(y^{(i)}) \prod_{j=1}^{k} p_j(\hat{y}_j^{(i)} | y^{(i)}, \theta^{(t)})}.
\end{aligned}$$

where $q^{(t)}$ is the conditional distribution defining the EM bound over the loglikelihood function.

If all the classifiers are always observed, that is, $\beta_{ri} = 1 \ \forall r, i$ Equation (16) reverts to (12), and the loglikelihood and its gradient may be efficiently computed in $O(nlk^2)$. In the case of missing classifier outputs a naive computation of the gradient or EM step is exponential in the number of missing values $R = \max_i \sum_r \beta_{ri}$. This, however, can be improved by careful dynamic programming. For example, the nested summations over the unobserved values in the gradient may be computed using a variation of the elimination algorithm in $O(nlk^2R)$ time.

7. Empirical Evaluation

We start with some experiments demonstrating our framework using synthetic data. These experiments are meant to examine the behavior of the estimators in a controlled setting. We then describe

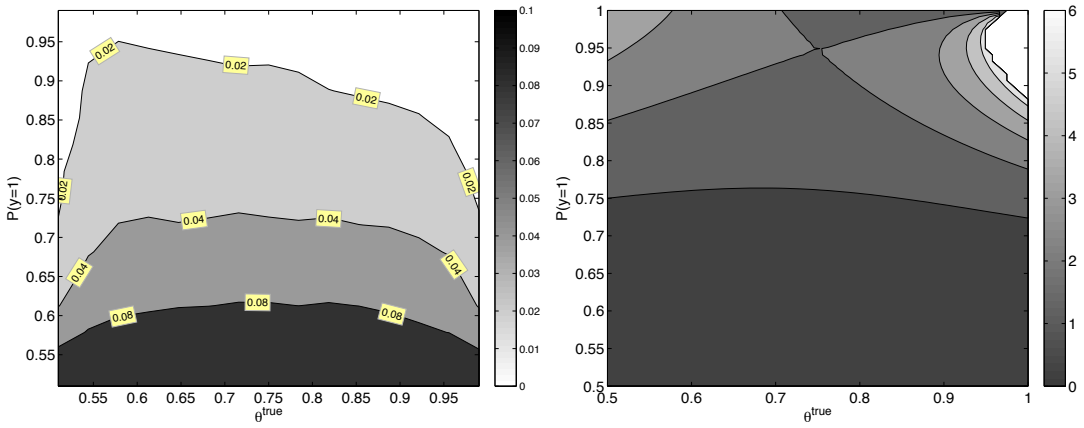

Figure 3: Left: Average value of $|\hat{\theta}_n^{\text{mle}} - \theta^{\text{true}}|$ as a function of θ^{true} and $p(y=1)$ for $k=1$ classifier and $n=500$ (computed over a uniform spaced grid of 15×15 points). The plot illustrates the increased accuracy obtained by a less uniform $P(y)$. Right: Fisher information $J(\theta)$ for $k=1$ as a function of θ^{true} and $P(y)$. The asymptotic variance of the estimator is $J^{-1}(\theta)$ which closely matches the experimental result in the left panel.

some experiments using several real world data sets. In these experiments we examine the behavior of the estimators in an uncontrolled setting where some of the underlying assumptions may be violated. In most of the experiments we consider the mean absolute error (mae) or the ℓ_1 error as a metric that measures the estimation quality

$$\text{mae}(\hat{\theta}^{\text{mle}}, \theta^{\text{true}}) = \frac{1}{k} \sum_{i=1}^{k} \left| \theta_i^{\text{true}} - \hat{\theta}_i^{\text{mle}} \right|.$$

In the non-collaborative case (which is equivalent to the collaborative case with $k=1$) this translates into the absolute deviation of the estimated parameter from the true parameter.

In Figure 3 (left) we display $\text{mae}(\hat{\theta}^{\text{mle}}, \theta^{\text{true}})$ for classification with $k=1$ as a function of θ^{true} and $p(y)$ for $n=500$ simulated data points. The estimation error, while overall relatively small, decays as $p(y)$ diverges from the uniform distribution. The dependency on θ^{true} indicates that the error is worst for θ^{true} around 0.75 and it decays as $|\theta^{\text{true}} - 0.75|$ increases with a larger decay attributed to higher θ^{true}. These observations are remarkably consistent with the developed theory as Figure 3 (right) shows by demonstrating the value of the inverse asymptotic variance $J(\theta)$ which agrees nicely with the empirical measurement in the left panel.

Figure 4 (left) contains a scatter plot contrasting values of θ^{true} and $\hat{\theta}^{\text{mle}}$ for $k=1$ classifier and $p(y=1)=0.8$. The estimator was constructed based on 500 simulated data points. We observe a symmetric Gaussian-like distribution of estimated values $\hat{\theta}^{\text{mle}}$, conditioned on specific values of θ^{true}. This is in agreement with the theory predicting an asymptotic Gaussian distribution for the mle, centered around the true value θ^{true}. A similar observation is made in Figure 5 (left) which contains a similar scatter plot in the regression case ($k=1$, $\sigma_y=1$, $n=1000$). In both figures, the striped effect is due to selection of θ^{true} over a discrete grid with a small perturbation for increased visibility. Similar plots of larger and smaller n values (not shown) verify that the variation of $\hat{\theta}^{\text{mle}}$

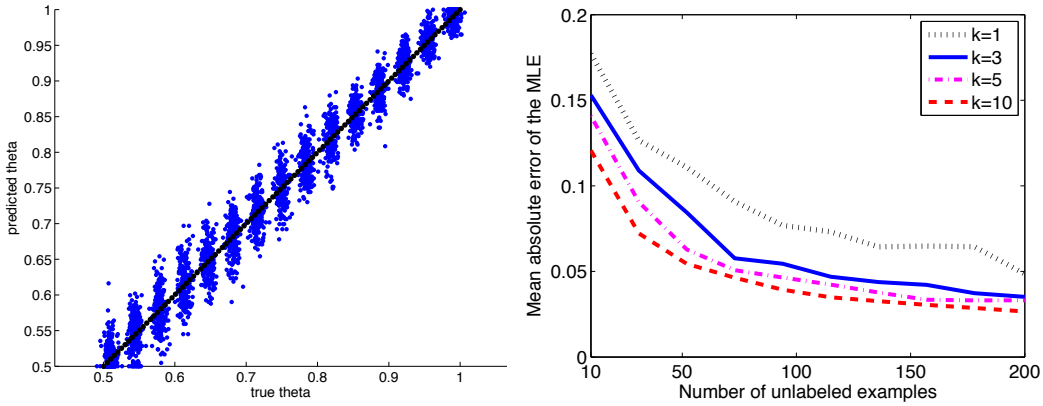

Figure 4: Left: Scatter plot contrasting the true and predicted values of θ in the case of a single classifier $k = 1$, $p(y = 1) = 0.8$, and $n = 500$ unlabeled examples. The displayed points were perturbed for improved visualization and the striped effect is due to empirical evaluation over a discrete grid of θ^{true} values. Right: $\text{mae}(\hat{\theta}^{\text{mle}}, \theta^{\text{true}})$ as a function of the number of unlabeled examples for different number of classifiers ($\theta_i^{\text{true}} = p(y = 1) = 0.75$) in the collaborative case. The estimation error decreases as more classifiers are used due to the collaborative nature of the estimation process.

around θ^{true} decreases as n increases. This agrees with the theory that indicates a $O(n^{-1})$ rate of decay for the variance of the asymptotic distribution.

Figures 4 and 5 (right) show the $\text{mae}(\hat{\theta}^{\text{mle}}, \theta^{\text{true}})$ for various k values in classification and regression, respectively. In classification, $\hat{\theta}^{\text{mle}}$ was obtained by sampling data from $p(y = 1) = 0.75 = \theta_i^{\text{true}}, \forall i$. In regression, the data was sampled from the regression equation with $\theta_i^{\text{true}} = 1$ and $p(y) = N(0,1)$. In both cases, the mae error decays with n as expected from the consistency proof and with k as a result of the collaborative estimation effect.

To further illustrate the effect of the collaboration on the estimation accuracy, we estimated the error rates individually (non-collaboratively) for 10 predictors and compared their mae to that of the collaborative estimation case in Figure 6. This shows that each of the classifiers have a similar mae curve when non-collaborative estimation is used. However, all of these curves are higher than the collaborative mae curve (solid black line in Figure 6) demonstrating the improvement of the collaborative process.

We compare in Figure 7 the proposed unsupervised estimation framework with supervised estimation that takes advantage of labeled information to determine the classifier accuracy. We conducted this study using equal number of examples for both supervised and unsupervised cases. Clearly, this is an unfair comparison if we assume that labeled data is unavailable or is difficult to obtain. The unsupervised estimation does not perform as well as the supervised version especially in general. Nevertheless, the unsupervised estimation accuracy improves significantly with increasing number of classifiers and finally reaches the performance level of the supervised case due to collaborative estimation.

In Figure 8 we report the effect of misspecification of the marginal $p(y)$ on the estimation accuracy. More specifically, we generated synthetic data using a true marginal distribution but

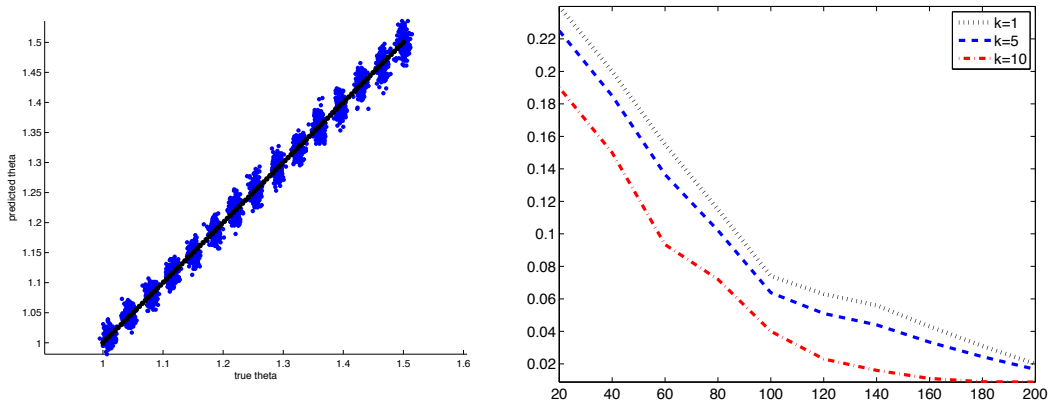

Figure 5: Left: Scatter plot contrasting the true and predicted values of θ in the case of a single regression model $k = 1$, $\sigma_y = 1$, and $n = 1000$ unlabeled examples. The displayed points were perturbed for improved visualization and the striped effect is due to empirical evaluation over a discrete grid of θ^{true} values. Right: $\text{mae}(\hat{\theta}^{\text{mle}}, \theta^{\text{true}})$ as a function of the number of unlabeled examples for different number of regression models ($\theta_i^{\text{true}} = \sigma_y = 1$) in the collaborative case. The estimation error decreases as more regression models are used due to the collaborative nature of the estimation process.

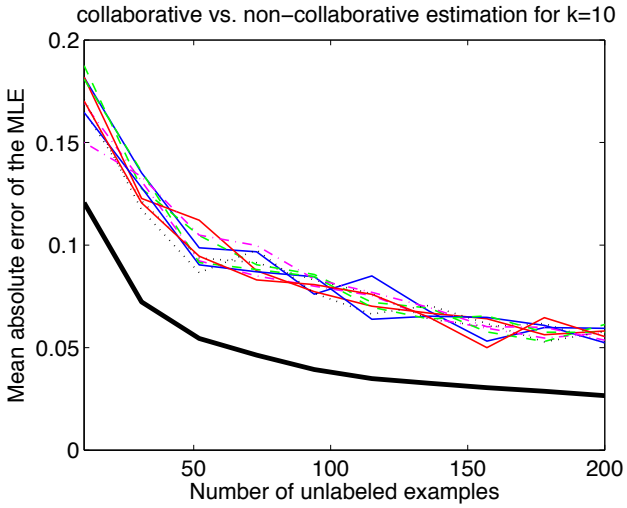

Figure 6: Comparison of collaborative and non-collaborative estimation for $k = 10$ classifiers. $\text{mae}(\hat{\theta}^{\text{mle}}, \theta^{\text{true}})$ as a function of n is reported for $\theta_i^{\text{true}} = 0.75\ \forall k_i$ and $P(y = 1) = 0.75$. The colored lines represent the estimation error for each individual classifier and the solid black line represents the collaborative estimation for all classifiers. The estimation converges to the truth faster in the collaborative case than in the non-collaborative case.

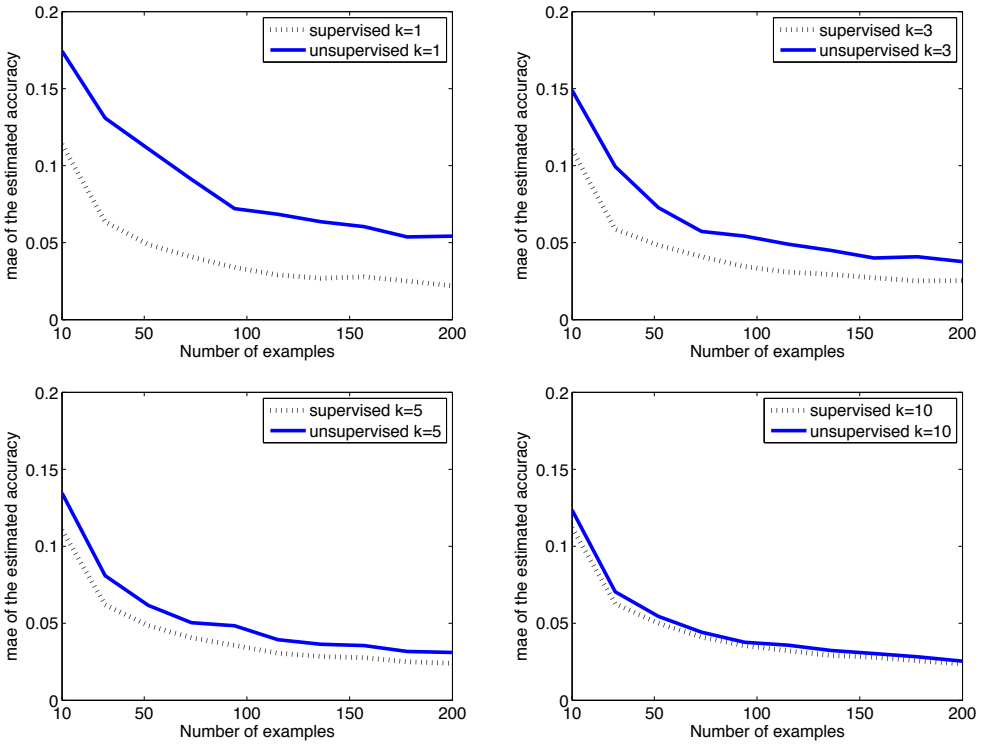

Figure 7: Comparison of supervised and unsupervised estimation for different values of classifiers with $k = 1,3,5,10$. Supervised estimation uses the true labels to determine the accuracy of the classifiers whereas in the unsupervised case the estimation proceeds according to the collaborative estimation framework. Despite the fact that the supervised case uses labels the unsupervised framework reaches similar levels by increasing the number of classifiers.

estimated the classifier accuracy on this data assuming a misspecified marginal. Generally, the estimation framework is robust to small perturbations while over-specifying tends to hurt less than under-specifying (misspecification closer to uniform distribution).

Figure 9 shows the mean prediction accuracy for the unsupervised predictor combination scheme in (4) for synthetic data. The left panel displays classification accuracy and the right panel displays the regression accuracy as measured by $1 - \frac{1}{m}\sum_{i=1}^{m}(\hat{y}_i^{\text{new}} - y_i^{\text{new}})^2$. The graphs show that in both cases the accuracy increases with k and n in accordance with the theory and the risk estimation experiments. The parameter θ_i^{true} was chosen uniformly in the range $(0.5,1)$, and $P(y=1) = 0.75$ for classification and $\theta_i^{\text{true}} = 0.3$, $p(y) = N(0,1)$ in the case of regression.

We also experimented with the natural language understanding data set introduced in Snow et al. (2008). This data was created using the Amazon Mechanical Turk (AMT) for data annotation. AMT is an online tool that uses paid employees to complete small labeling and annotation tasks. We selected two binary tasks from this data: the textual entailment recognition (RTE) and temporal event recognition (TEMP) tasks. In the former task, the annotator is presented with two sentences for each question. He needs to decide whether the second sentence can be inferred from the first.

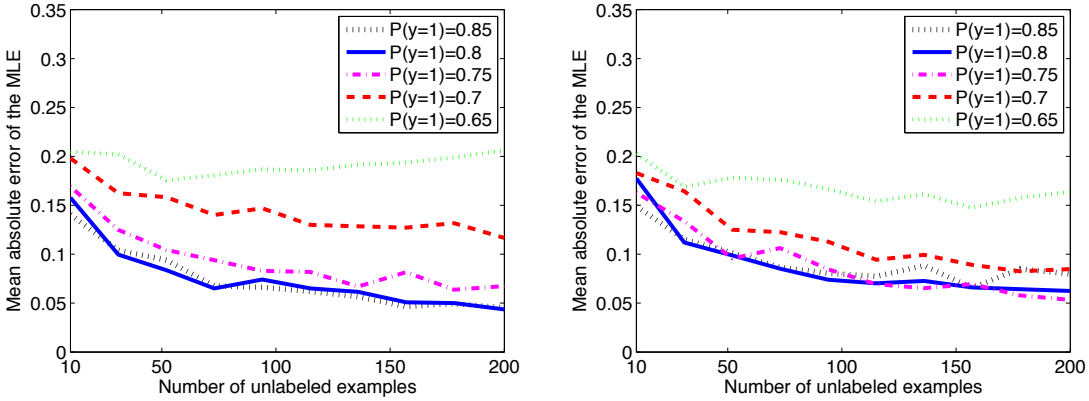

Figure 8: The figure compares the estimator accuracy assuming that the marginal $p(y)$ is misspecified. The plots draw $\mathrm{mae}(\hat{\theta}^{\mathrm{mle}}, \theta^{\mathrm{true}})$ as a function of n for $k = 1$ and $\theta^{\mathrm{true}} = 0.75$ when $P^{\mathrm{true}}(y = 1) = 0.8$ (left) and $P^{\mathrm{true}}(y = 1) = 0.75$ (right). Small perturbations in $P^{\mathrm{true}}(y)$ do not affect the results significantly; interestingly over-specifying $P^{\mathrm{true}}(y = 1)$ leads to more accurate estimates than under-specifying (misspecification closer to uniform distribution)

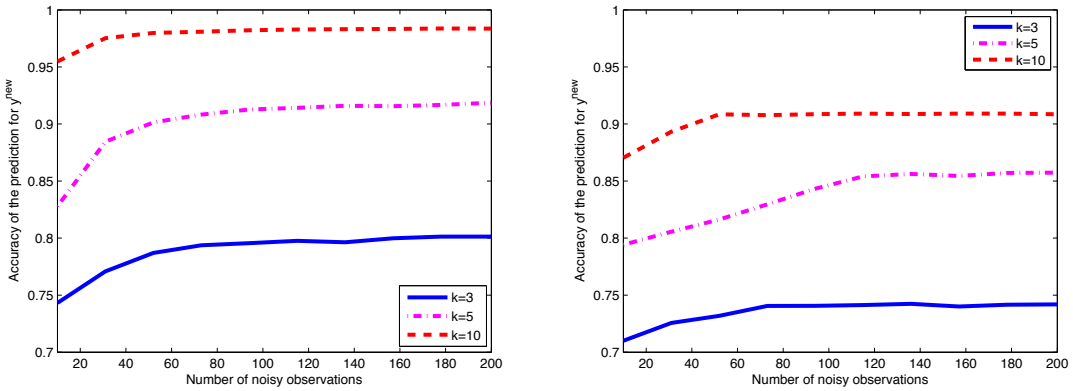

Figure 9: Mean prediction accuracy for the unsupervised predictor combination scheme in (4) for synthetic data. The left panel displays classification accuracy and the right panel displays the regression accuracy as measured by $1 - \frac{1}{m}\sum_{i=1}^{m}(\hat{y}_i^{\mathrm{new}} - y_i^{\mathrm{new}})^2$. The graphs show that in both cases the accuracy increases with k and n in accordance with the theory and the risk estimation experiments.

The original data set contains 800 sentence pairs with a total of 165 annotators. The latter task involves recognizing the temporal relation in verb-event pairs. The annotator is forced to decide whether the event described by the first verb occurs before or after the second. The original data set contains 462 pairs and 76 annotators. In both data sets, most of the annotators have completed only a handful of tasks. Therefore, we selected a subset of these annotators for each task such that each annotator has completed at least 100 problems and has differing accuracies. The data sets contain ground truth labels which are used solely to calculate the annotator accuracy and not used

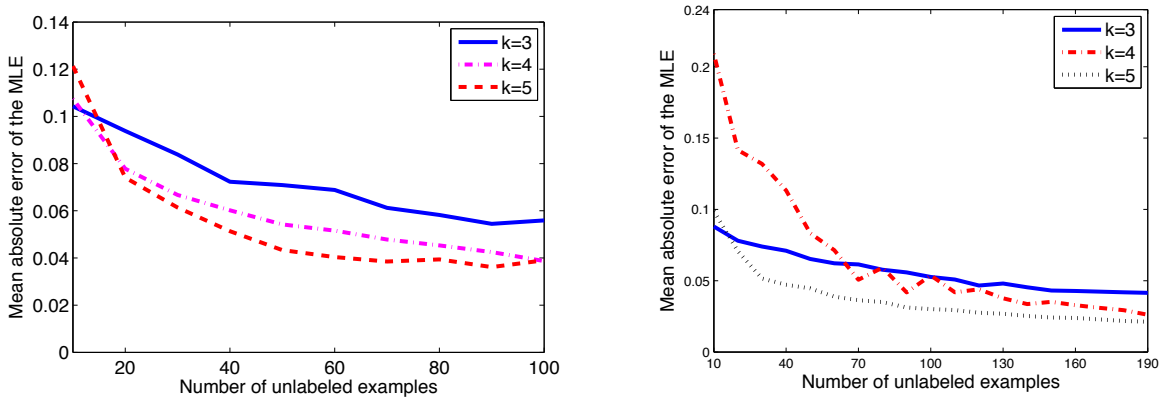

Figure 10: $\text{mae}(\hat{\theta}^{\text{mle}}, \theta^{\text{true}})$ as a function of n for different number of annotators k on RTE (left) and TEMP (right) data sets. Left: $n = 100$, $P(y = 1) = 0.5$ and $\theta^{\text{true}} = \{0.85, 0.92, 0.58, 0.5, 0.51\}$. Right: $n = 190$, $P(y = 1) = 0.56$ and $\theta^{\text{true}} = \{0.93, 0.92, 0.54, 0.44, 0.92\}$. The classifiers were added in the order specified.

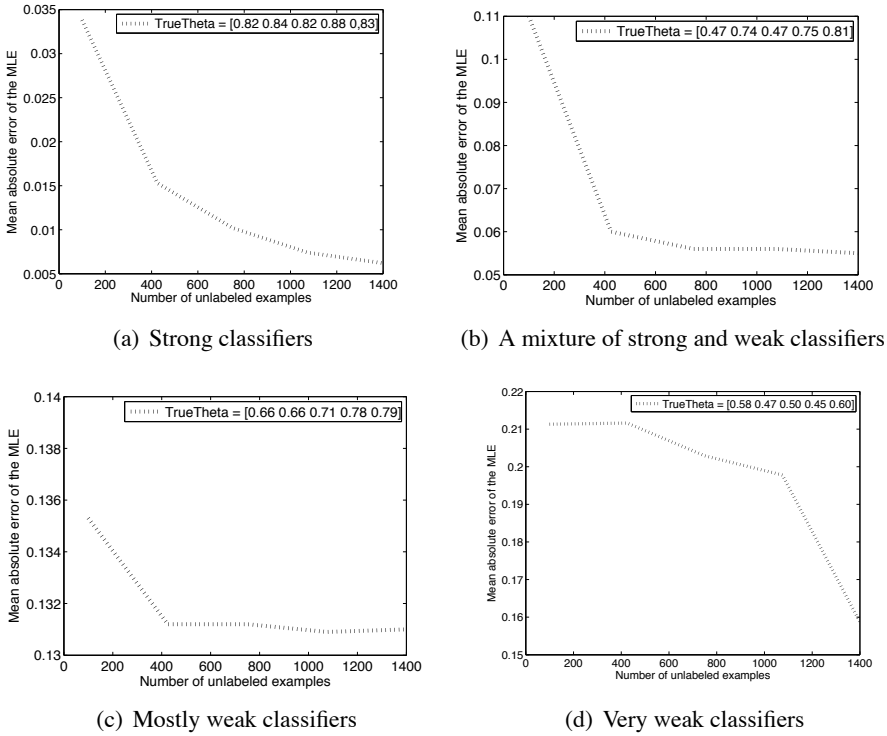
at all during the estimation process. For efficiency, we selected only the instances for which all annotators provide an answer. This resulted in $n = 100, 190$ for RTE and TEMP, respectively.

In Figure 10 we display $\text{mae}(\theta^{\text{true}}, \hat{\theta}^{\text{mle}})$ for these data sets as function of n for different values of k. These plots generated from real-world data show similar trend to the synthetic experiments. The estimation errors decay to 0 as n increases and generally tend to decrease as k increases. This correspondence is remarkable since two of the labelers have worse than random accuracy and since it is not clear whether the conditional independence assumption actually holds in reality for these data sets. Nevertheless, the collaborative estimation error behaves in accordance with the synthetic data experiments and the theory. This shows that the estimation framework is robust to the breakdown of the assumption that the classifier accuracy must be higher than random choice. Also, whether the conditional independence assumption holds or not is not crucial in this case.

We further experimented with classifiers trained on different representations of the same data set and estimated their error rates. We adopted the Ringnorm data set generated by Breiman (1996). Ringnorm is a 2-class artificial data set with 20 dimensions where each class is drawn from a multivariate normal distribution. One class has zero mean and a covariance $\Sigma = 4I$ where I is the identity matrix. The other class has unit covariance and a mean $\mu = (\frac{2}{\sqrt{20}}, \frac{2}{\sqrt{20}}, \ldots, \frac{2}{\sqrt{20}})$. The total size is 7400. We created 5 different representations of the data by projecting it onto mutually exclusive sets of principal components obtained by Principal Component Analysis (PCA). We trained an SVM classifier (with 2-degree polynomial kernel) (Vapnik, 2000; Joachims, 1999) on samples from each representation while holding out 1400 examples as the test set resulting in a total of 5 classifiers. We tested each of the 5 classifiers on the test set and used their outputs to estimate the corresponding parameters. The true labels of the test set examples were used as ground truth to calculate the mae of the mle estimators.

The mae curves for this data set appear in Figure 11 as a function of the number n of unlabeled examples. When all classifiers are highly accurate (upper left panel), the collaborative unsupervised estimator is reliable, see Figure 11(a). With a mixture of weak and strong classifiers (upper right panel), the collaborative unsupervised estimator is also reliable. This is despite the fact that some of



(a) Strong classifiers

(b) A mixture of strong and weak classifiers

(c) Mostly weak classifiers

(d) Very weak classifiers

Figure 11: $\text{mae}(\theta^{\text{true}}, \hat{\theta}^{\text{mle}})$ as a function of the test set size on the Ringnorm data set. $p(y=1) = 0.47$, and θ^{true} is indicated in the legend in each plot. The four panels represent mostly strong classifiers (upper left), a mixture of strong and weak classifiers (upper right), mostly weak classifiers (bottom left), and mostly very weak classifiers (bottom right). The figure shows that the framework is robust to occasional deviations from the assumption regarding better than random guess classification accuracy (upper right panel). However, as most of the classifiers become weak or very weak, the collaborative unsupervised estimation framework results in worse estimation error.

the weak classifiers in Figure 11(b) have worse than random accuracy which violates the assumptions in the consistency proposition. This shows again that the estimation framework is robust to occasional deviations from the requirement concerning better than random classification accuracies. On the other hand, as most of the classifiers become worse (bottom row), the accuracy of the unsupervised estimator decreases, in accordance with the theory developed in Sections 5 (recall the Fisher information contour plot).

Our experiments thus far assumed the symmetric noise model (8). Despite it not being always applicable for real world data and classifiers, it did result in good estimation accuracy in some of the cases described thus far. However, in some cases this assumption is grossly violated and the more general noise model is needed (6). For this reason, we conducted two experiments using real world data assuming the more general (6).

The first experiment concerned domain adaptation (Blitzer et al., 2007) for Amazon's product reviews in four different product domains: books, DVDs, electronics and kitchen appliances. Each

	book	dvd	kitchen	electronics	20newsgroup
training error	0.22	0.23	0.26	0.30	0.028
non-collaborative	**0.04**	**0.04**	**0.08**	**0.06**	**0.006**
collaborative	0.10	0.10	0.09	0.08	n/a

Figure 12: $\text{mae}(\hat{\theta}^{\text{mle}}, \theta^{\text{true}})$ for the domain adaptation ($n = 1000$, $p(y = 1) = 0.75$) and 20 newsgroup ($n = 15{,}000$, $p(y = 1) = 0.05$ for each one-vs-all data). The unsupervised non-collaborative estimator outperforms the collaborative estimator due to violation of the conditional independence assumption. Both unsupervised estimators perform substantially better than the baseline training error rate estimator. In both cases the results were averaged over 50 random train test splits.

domain consists of positive ($y = 1$) and negative ($y = 2$) reviews with $p(y = 1) = 0.75$. The task was to estimate the error rates of classifiers (linear SVM, Vapnik, 2000; Joachims, 1999) that are trained on 300 examples from one domain but tested on other domains. The mae values for the classification risks are displayed in Figure 12 with the columns indicating the test domain. In this case, the unsupervised non-collaborative estimator outperforms the collaborative estimator due to violation of the conditional independence assumption. Both unsupervised estimators perform substantially better than the baseline estimator that uses the training error on one domain to predict testing error on another domain.

In the second experiment using (6) we estimated the risk (non-collaboratively) of 20 one vs. all classifiers (trained to predict one class) on the 20 newsgroup data (Lang, 1995). The train set size was 1000 and the unlabeled data size was 15000. In this case the unsupervised non-collaborative estimator returned extremely accurate risk estimators. As a comparison, the risk estimates obtained from the training error are four times larger than the unsupervised MLE estimator (See Figure 12).

8. Discussion

We have demonstrated a collaborative framework for the estimation of classification and regression error rates for $k \geq 1$ predictors. In contrast to previous supervised risk estimation methods such as cross validation (Duda et al., 2001), bootstrap (Efron and Tibshirani, 1997), and others (Hand, 1986), our approach is fully unsupervised and thus able to use vast collections of unlabeled data. Other related work includes Smyth et al. (1995) and Sheng et al. (2008) which consider repeated labeling where each instance is labeled by multiple experts and the final label is decided based on a majority voting scheme. However, Smyth et al. and Sheng et al. fail to address estimating the risks of the predictors which is the main focus of our work.

We prove statistical consistency in the unsupervised case and derive the asymptotic variance. Our experiments on synthetic data demonstrate the effectiveness of the framework and verify the theoretical results. Experiments on real world data show robustness to underlying assumptions. The framework may be applied to estimate additional quantities in an unsupervised manner, including noise level in noisy communication channels (Cover and Thomas, 2005) and error rates in structured prediction problems.

Abstract

Appropriate selection of the kernel function, which implicitly defines the feature space of an algorithm, has a crucial role in the success of kernel methods. In this paper, we consider the problem of optimizing a kernel function over the class of translation invariant kernels for the task of binary classification. The learning capacity of this class is invariant with respect to rotation and scaling of the features and it encompasses the set of radial kernels. We show that how translation invariant kernel functions can be embedded in a nested set of sub-classes and consider the kernel learning problem over one of these sub-classes. This allows the choice of an appropriate sub-class based on the problem at hand. We use the criterion proposed by Lanckriet et al. (2004) to obtain a functional formulation for the problem. It will be proven that the optimal kernel is a finite mixture of cosine functions. The kernel learning problem is then formulated as a semi-infinite programming (SIP) problem which is solved by a sequence of quadratically constrained quadratic programming (QCQP) sub-problems. Using the fact that the cosine kernel is of rank two, we propose a formulation of a QCQP sub-problem which does not require the kernel matrices to be loaded into memory, making the method applicable to large-scale problems. We also address the issue of including other classes of kernels, such as individual kernels and isotropic Gaussian kernels, in the learning process. Another interesting feature of the proposed method is that the optimal classifier has an expansion in terms of the number of cosine kernels, instead of support vectors, leading to a remarkable speedup at run-time. As a by-product, we also generalize the kernel trick to complex-valued kernel functions. Our experiments on artificial and real-world benchmark data sets, including the USPS and the MNIST digit recognition data sets, show the usefulness of the proposed method.

Keywords: kernel learning, translation invariant kernels, capacity control, support vector machines, classification, semi-infinite programming

1. Introduction

Kernel-based methods, such as support vector machines (SVM) and kernel principal component analysis (KPCA), increase the flexibility of machine learning algorithms by implicitly mapping the input data into a feature space and performing the algorithm in that space. This flexibility is achieved by a so called kernel function which substitutes the dot-product operation in an ordinary algorithm. The kernel function, by implicitly defining the feature space, plays a crucial role in the

success of kernel methods. In fact, as shown by Xiong et al. (2005), if the kernel function is not chosen appropriately, it may even worsen the performance of an algorithm. This significant impact on the performance of the kernel-based algorithms and the fact that the appropriate feature space is problem-dependent, have driven researchers to devise various algorithms to learn the kernel function from the problem data.

The earliest method for learning a kernel function is cross-validation which is very slow and is only applicable to kernels with a small number of parameters. Cristianini et al. (1998) proposed an algorithm for adapting kernel functions with only one unconstrained parameter. Instead of optimizing the parameters of a kernel, Amari and Wu (1999) suggested conformal transformation of the kernel function and proposed an algorithm for learning the parameters of the new kernel. Chapelle et al. (2002) devised a gradient-based algorithm for local optimization of a kernel with multiple unconstrained parameters. Glasmachers and Igel (2005) proposed a gradient-based method for learning the covariance matrix of Gaussian kernels (Note that since the covariance matrix of a Gaussian kernel is constrained to be positive semi-definite, the method of Chapelle et al. (2002) cannot be used for learning this matrix). Ong et al. (2005) introduced the notion of hyperkernels and used it for kernel learning. They formulated the kernel learning problem as a functional with three terms: an empirical quality functional, a regularization term that penalizes the functions in a reproducing kernel Hilbert space (RKHS), and another regularization term that penalizes the kernels in a hyper reproducing kernel Hilbert space.

A milestone in the kernel learning literature is the introduction of the multiple kernel learning (MKL) framework by Lanckriet et al. (2004). They considered the problem of finding the optimal convex combination of multiple kernels and formulated it as a quadratically constrained quadratic programming (QCQP) problem. They also introduced a generalized performance measure which encompasses the hard-margin, 1-norm soft-margin, and 2-norm soft-margin performance measures as special cases. Although these performance measures have extensively been used for learning the optimal separating hyperplane in SVMs, their use as performance measures for kernel selection was unprecedented. Since the formulation of the resulting QCQP requires storing several kernel matrices in memory, their method was only applicable to problems with a small number of training samples. Bach et al. (2004) introduced an SMO-based algorithm to widen the range of solvable MKL problems by using the Moreau-Yosida regularization technique. Sonnenburg et al. (2005, 2006) reformulated the MKL problem as a semi-infinite linear program (SILP) which was then reduced to training a sequence of classical SVMs with a single kernel for which several sophisticated large-scale algorithms exist. Rakotomamonjy et al. (2008) argued that the main difficulty with the SILP formulation of Sonnenburg et al. (2006) is that its objective function is non-smooth and introduced an equivalent convex formulation with a smooth objective function. Using convexity of the problem and the smoothness of the objective function, they proposed a reduced gradient algorithm for MKL which is also applicable to large-scale problems. The weakness of the reduced gradient algorithm is that, in contrast to to the SILP algorithm, it does not use the information collected in the previous points in the calculation of the next point. Combining the strengths of the SILP method of Sonnenburg et al. (2006) with those of the reduced gradient method of Rakotomamonjy et al. (2008), Xu et al. (2008) proposed an extended level method which is remarkably faster than both methods.

In their seminal work, Micchelli and Pontil (2005) generalized the class of admissible kernels to convex combination of an infinite number of kernels indexed by a compact set and applied their method to the problem of learning radial kernels (Argyriou et al., 2005, 2006). They used a classical

result proved by Schoenberg (1938) which states that every continuous radial kernel belongs to the convex hull of radial Gaussian kernels. They also proposed an efficient DC programming algorithm for numerically learning radial kernels in Argyriou et al. (2006). Gehler and Nowozin (2008) reformulated the optimization problem of Argyriou et al. (2006) as a semi-infinite programming problem and proposed the IKL (infinite kernel learning) framework for solving it numerically.

In this work, we consider the class of translation invariant kernel functions which encompasses the class of radial kernels as well as the class of anisotropic Gaussian kernel functions. This class contains exactly those kernels which can be defined solely based on the difference of kernel arguments; that is, the kernel functions with the property:

$$k(x,z) = \tilde{k}(x-z).$$

The general form of continuous translation invariant kernels on $\mathbb{R}^n$ was discovered by Bochner (1933). He proved that every function of the form[1]

$$k(x,z) = \tilde{k}(x-z) = \int_{\mathbb{R}^n} e^{j\gamma^T(x-z)}\, dV(\gamma) \tag{1}$$

is positive semi-definite, where V(.) is a monotonically increasing bounded function and the integration is in the Lebesgue-Stieltjes sense. He also proved that, conversely, every continuous translation invariant positive semi-definite kernel function can be represented in the above form. In statistics, the translation invariance property is referred to as the stationarity of the kernel function. Genton (2001) and Schölkopf and Smola (2002) give a list of the properties of this class along with important examples of stationary kernel functions, including the Gaussian, exponential, rational quadratic, and B_n spline kernels.

The rest of the paper proceeds as follows: Table 1 lists the choice of notations for familiar concepts in the field. Notations specific to this paper will be introduced in the course of discussions. Although the kernel learning formulation of Micchelli and Pontil (2005) contains a regularization term for controlling the complexity of the RKHS associated with the kernel function, there is no mechanism for controlling the capacity of the class of admissible kernels. In our formulation, we have provisioned a mechanism for controlling the complexity of the class of admissible kernels which is described in Section 2. The idea is to multiply a vanishing function inside the integral of Equation (1). In addition to controlling the capacity of the learning machine, this choice substitutes the compactness assumption of the integration region made by Micchelli and Pontil (2005). In Section 3, we propose a learning criterion which is essentially a reformulation of the generalized performance measure of Lanckriet et al. (2004). The proposed criterion ensures the compactness of the parameter space of SVM, and gives a probabilistic meaning to the regularization parameter of the 2-norm soft-margin SVM. The problem of finding an optimal kernel which minimizes this criterion over the class of translation invariant kernels leads to (4) which is our main variational problem.

In Section 4, we prove some important theorems which pave the way for an algorithmic solution to this problem. First, in Section 4.1 we prove the existence of an optimal solution for problem (4).

1. In this paper we will represent translation invariant kernels both as $k : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{C}$ with two arguments and as $\tilde{k} : \mathbb{R}^d \to \mathbb{C}$ with only one argument.

In Section 4.2, we prove that the min and max operations in (4) can be interchanged, provided that the integration region is replaced by a compact set. In addition, it will be shown that the optimal kernel is a finite mixture of the basic kernels of the form $k_\gamma(x,z) = \exp(j\gamma^T(x-z))$. In Section 4.3, it will be proved that the integration region can indeed be replaced by a compact set. To solve problem (4) numerically, we introduce a semi-infinite programming (SIP) formulation in Section 4.4. In Section 4.5, using a topological argument, the issue of including other classes of kernels in the learning process will be addressed. It is well known that the regularization parameter of the 2-norm SVM, usually denoted by τ, can be regarded as the weight of a Kronecker delta kernel function, which is incidently a translation invariant kernel, as well. In Section 4.4 we introduce the semi-infinite programming problem (19) which is our main numerical optimization problem and corresponds to the simultaneous learning of the optimal translation invariant kernel as well as the parameter τ. As another application of the discussion of Section 4.5, in Section 4.7 we will introduce a method for learning the best combination of stabilized translation invariant kernels and isotropic Gaussian kernels.

In Section 5, we address the problem of numerically solving (19) on a computer. The proposed optimization algorithm is a variant of the class of local-reduction-based algorithms for solving SIP problems. An important feature of the proposed optimization algorithm is that it does not require loading the kernel matrices into memory and so it is applicable to large-scale problems. As stated above, it will be shown in Section 4.2 that the optimal kernel is complex-valued. Since algorithms are usually designed for real Euclidean spaces, this complicates the application of the kernel trick to the optimal kernel (consider for example an algorithm that checks the sign of a dot product). In Section 6, we show that the feature space induced by the real part of a complex-valued kernel is essentially equivalent to the original complex-valued kernel and deduce that the optimal real-valued kernel is a mixture of cosines. Yet another astounding feature of the proposed method is concerned with the evaluation time of the classifier which is even faster than a classical SVM with a single Gaussian kernel. Usually, multiple kernel learning methods yield a model whose evaluation time is in the order of the number of kernels times the number of support vectors. In Section 7, we show that the evaluation time of the optimal translation invariant kernel is proportional to the number of cosine kernels, regardless of the number of support vectors. In Section 8, using a learning theory discussion, we show the necessity of controlling the complexity of the class of translation invariant kernels.

In Section 9, we will assess the practical usefulness of the proposed method on several data sets. In Section 9.1, we first perform some experiments on 13 artificial and real-world data sets collected from the UCI, DELVE, and STATLOG benchmark repositories by Rätsch et al. (2001).In Section 9.2, we perform experiments on the USPS handwritten digit recognition data set, comparing the proposed method with the MKL of Chapelle et al. (2002). In Section 9.3, we compare the proposed method with the DC method of Argyriou et al. (2006) on the MNIST handwritten digit recognition data set. In Section 9.4, we experimentally assess the role of the capacity control mechanism of Section 2. Finally, we conclude the paper in Section 10.

2. A Hierarchy of Classes for Translation Invariant Kernels

It is well-known in learning theory that to have a small generalization error, there should be a problem-dependent compromise between the complexity of the learning machine and the empirical error on the training data (Vapnik, 1998; Cucker and Zhou, 2007). In the previous section we saw

Symbol	Meaning	Symbol	Meaning
n	input space dimension	l	number of training data
l_1	number of training data with label +1	l_2	number of training data with label -1
X	input space	F	Feature space
Φ	feature map: $\Phi : X \to F$	nsv	number of support vectors
α	lagrange multipliers in SVM	C	regularization parameter in SVM
k	the kernel function	Δ	maximal margin
C^+	the set of data with label +1	C^-	the set of data with label -1
m	number of kernels in MKL framework	μ	weight of kernels in MKL
R	radius of the smallest ball surrounding the data in the feature space	$\Re(z)$	real part of the complex number z
		j	unit imaginary number: $\sqrt{-1}$
$\bar{z}$	the complex conjugate of z	S^c	the complement of set S

Table 1: Notations

that Equation (1) captures the general form of the large class of translation invariant kernels. To obtain the best tradeoff between approximation and estimation errors, we introduce a hierarchy of classes of translation invariant kernels. The appropriate class for a specific problem is then chosen by cross-validation. It must be mentioned that the idea of controlling the complexity of the class of admissible kernels has been previously used by Ong et al. (2005) for learning the kernels with hyperkernels. Although this type of complexity control is not provisioned by Micchelli and Pontil (2005), we, based on our experiments, believe that it is an important ingredient of the framework. To restrict the class of translation invariant kernels, we propose to limit the high frequency components of the kernel function. This is similar to the use of stabilizer functions in regularization theory (see Girosi et al., 1993). But, instead of adding a stabilizer function to the objective functional, which requires the determination of both the stabilizer and the regularization parameter, we explicitly define a nested class of translation invariant kernels $\mathcal{K}_\beta$ as:

$$\mathcal{K}_\beta := \left\{ k(x,z) = \int_{\mathbb{R}^n} e^{j\gamma^T(x-z)} G_\beta(\|\gamma\|)\, dp(\gamma) \quad : \text{ p is a probablity measure on } \mathbb{R}^n \right\}$$

where β is defined on an ordered set, and $G_\beta : \mathbb{R}_+ \to [0,1]$ is a decreasing continuous function with $G_\beta(0) = 1$ and $G_\beta(\infty) = 0$. In addition, to ensure that these classes of kernels are nested, we require that $G_{\beta_1}(r) \geq G_{\beta_2}(r)$ for every $r > 0$ and $\beta_1 \leq \beta_2$. Important candidates for $G_\beta(\|\gamma\|)$ are $\exp(-\beta\|\gamma\|^2)$ and $\|\gamma\|^{-\beta}$ for $\beta > 0$. Note that we have left the choice of the norm to the application. Two important candidates are L_1 and L_2 norms. In Section 5, we will also assume that the function $G_\beta(\|\gamma\|)$ is differentiable with respect to γ.

3. Kernel Selection Criterion

In the process of learning the kernel function, one needs a criterion for choosing a kernel (or equivalently, feature space) from the class of admissible kernels. In the classification task, the ideal criterion is the misclassification error. But since the probability density of data is unknown, this criterion cannot be computed. This problem has been circumvented by proposing upper bounds on the misclassification error which hold with high probability (see for example Vapnik, 1999 and Chapter 4 of Cristianini and Shawe-Taylor, 2000). In Chapelle et al. (2002), several criteria have

been studied and the authors suggested minimizing the radius-margin bound $(R/\Delta)^2$ as the preferred criterion.

Consider the training set of a classification task consisting of the input-output pairs $\{(x_1,y_1),...,(x_l,y_l)\}$, with $y_i \in \{-1,1\}$. For a fixed kernel, support vector machines compute the maximal hard/soft margin separating hyperplane. By generalizing hard margin, 1-norm soft margin, and 2-norm soft-margin objective functions, Lanckriet et al. (2004) obtained the following generalized criterion for $1/\Delta^2$ (which must be minimized):

$$\omega'_{C',\tau'}(k) := \max_{\substack{\alpha:\ 0\le\alpha\le C',\\ \alpha^T y=0}} \left\{ 2\alpha^T e - \sum_{u=1}^{l}\sum_{v=1}^{l} \alpha_u\alpha_v y_u y_v k(x_u,x_v) - \tau'\alpha^T\alpha \right\} \tag{2}$$

where e is the $n\times 1$ vector of ones and the prime sign is used to distinguish the parameters from those used in this paper. If (C',τ') is equal to $(\infty,0)$,$(C',0)$, and $(\infty,1/C')$, one obtains hard margin, 1-norm soft margin, and 2-norm soft-margin performance measures, respectively. Our first change to this criterion is adding the constraint $\alpha^T e = 2$. It has been shown (Crisp and Burges, 1999; Mavroforakis and Theodorodis, 2006) that by adjusting the parameters C and the offset b appropriately, this new constraint does not change the separating hyperplane. However, the new constraint plus $\alpha^T y = 0$ gives $\sum_{i\in C^-}\alpha_i = \sum_{i\in C^+}\alpha_i = 1$, which makes the exposition of our method simpler. Furthermore, we divide (2) by $1+\tau'$ and define $\tau := \frac{\tau'}{1+\tau'}$. So, in this paper we use the criterion:

$$\omega_{C,\tau}(k) := \min_{\alpha\in\mathcal{A}} \left\{ (1-\tau)\sum_{u=1}^{l}\sum_{v=1}^{l} \alpha_u\alpha_v y_u y_v k(x_u,x_v) + \tau\alpha^T\alpha \right\} \tag{3}$$

where $\mathcal{A} := \left\{\alpha\in\mathbb{R}^l :\ 0\le\alpha\le C,\ \alpha^T y = 0,\ \alpha^T e = 2\right\}$. Note that in the new criterion $\max\{\frac{1}{l_1},\frac{1}{l_2}\} \le C \le 2$ and $0\le\tau\le 1$. This criterion works well for a fixed kernel by maximizing the margin Δ. But in general, to minimize the radius-margin bound $(R/\Delta)^2$, one must impose some constraint on the radius R, as well. For translation invariant kernels we have $R^2 = \|\Phi(x)\|^2 = k(x,x) = \tilde{k}(0)$. Hence, bounding the radius R is equivalent to bounding $\tilde{k}(0)$. One can easily verify that bounding $trace\{K\}$, where K is the kernel matrix in the transductive framework (see Lanckriet et al., 2004, Equation 17), also leads to a bound on $\tilde{k}(0)$. Since by exploding R and $trace\{K\}$, the margin Δ also explodes by the same amount, whilst the radius-margin bound remains constant, we from now on assume that $\tilde{k}(0) = 1$ and obtain the following optimization problem:[2]

$$\begin{aligned} \sup_k \min_{\alpha\in\mathcal{A}} & \left\{ (1-\tau)\sum_{u=1}^{l}\sum_{v=1}^{l} \alpha_u\alpha_v y_u y_v k(x_u,x_v) + \tau\alpha^T\alpha \right\} \\ \text{s.t.}\quad & k(x,z) = \int_{\mathbb{R}^n} e^{j\gamma^T(x-z)} G_\beta(\|\gamma\|)\, dV(\gamma) \\ & \int_{\mathbb{R}^n} dV(\gamma) = 1, \\ & \text{V is monotonically increasing} \end{aligned}$$

2. Note that since k is a complex-valued positive semi-definite kernel, the objective function is real-valued and non-negative.

or equivalently

$$\sup_{p\in\mathcal{P}(\mathbb{R}^n)} \min_{\alpha\in\mathcal{A}} \int_{\mathbb{R}^n} \alpha^T H(\gamma)\alpha \, dp(\gamma) \tag{4}$$

where $\mathcal{P}(\Gamma)$ denotes the set of all probability measures on Γ and $H(\gamma)$ is defined below. Let $G(\gamma)$ be the $l\times l$ matrix whose (u,v)th entry is $y_u y_v \exp(j\gamma^T(x_u - x_v))G_\beta(\|\gamma\|)$. Define $H(\gamma) := (1-\tau)G(\gamma) + \tau I_l$ where I_l is the $l\times l$ identity matrix. The following equation shows an $O(l)$ computational method for computing $\alpha^T G(\gamma)\alpha$:

$$\alpha^T G(\gamma)\alpha = \left\| \sum_{u=1}^{l} \alpha_u y_u \exp(j\gamma^T x_u) \right\|_2^2 G_\beta(\|\gamma\|). \tag{5}$$

4. Variational Optimization

In this section, we first prove the existence of a solution to problem (4). Next we prove that (4) can be written as a min-max problem with integration replaced by summation. This allows us to introduce a SIP formulation of the problem. We then introduce another SIP problem for learning the optimal kernel and parameter τ.

4.1 Replacing Sup with Max

We will prove that the sup operation in (4) can be substituted by the max operation. Note that all the variability in the choice of a probability measure p from $\mathcal{P}(\mathbb{R}^n)$ collapses to the choice of an $l\times l$ matrix $\int_{\mathbb{R}^n} H(\gamma)\, dp(\gamma)$ from $S(\mathbb{C}^l)$, where $S(\mathbb{C}^l)$ is the space of all $l\times l$ Hermitian complex-valued matrices. So, it is sufficient to prove that the set of all these matrices is compact, which ensures that any sequence of these matrices has a convergent subsequence, and subsequently, the supremum value is achieved. Furthermore, by compacting the parameter space $\mathcal{A}$ in (3) there is no need to assume that the kernel matrices are strictly positive definite, as was done in Lemma 2 of Micchelli and Pontil (2005).

Let $C_0(\mathbb{R}^n)$ denote the function space of all continuous complex-valued functions defined on $\mathbb{R}^n$ which vanish at infinity, that is, $\lim_{\|\gamma\|\to\infty} g(\gamma) = 0$ for any $g \in C_0(\mathbb{R}^n)$. By Theorem 3.17 of Rudin (1987), the function space $C_0(\mathbb{R}^n)$ with the norm

$$\|g\| := \max_{\gamma\in\mathbb{R}^n} |g(\gamma)|$$

is a Banach space. Note that the use of max operation is justified by the continuity and vanishing properties of $g \in C_0(\mathbb{R}^n)$. Considering the above discussions, we need to prove the following theorem.

Theorem 1 *For any fixed sample data $Z = \{(x_1,y_1),...,(x_l,y_l)\}$, the set*

$$\mathcal{K}_Z := \left\{ \int_{\mathbb{R}^n} H(\gamma)\, dp(\gamma) \;\; : p \in \mathcal{P}(\mathbb{R}^n) \right\}$$

is a compact subset of $S(\mathbb{C}^l)$.[3]

Proof Consider any sequence (p_n) in $\mathcal{P}(\mathbb{R}^n)$. Define positive linear functionals $T_n : C_0(\mathbb{R}^n) \to \mathbb{C}$ by $T_n g := \int_{\mathbb{R}^n} g(\gamma)\, dp_n(\gamma)$. So, $T_n \in C_0'(\mathbb{R}^n)$, the dual space of $C_0(\mathbb{R}^n)$. Since for each n, $\|T_n\| = 1$, by Banach-Alaoglu theorem (see for example Theorem 3.15 of Rudin, 1991 or page 237 of Royden, 1988), there exists some $T \in C_0'(\mathbb{R}^n)$ with $\|T\| \leq 1$ and a subsequence (T_m) such that $T_m \to T$ in weak* topology. This means that for every $g \in C_0(\mathbb{R}^n)$, we have $T_m g \to Tg$. Since, each element of the matrix $H(\gamma)$ belongs to $C_0(\mathbb{R}^n)$, it follows that $\int_{\mathbb{R}^n} H(\gamma)\, dP_m(\gamma) \to TH$. One can easily prove by contradiction that $\|T\| = 1$ and T is in fact a positive linear functional. By the Riesz representation theorem (see Theorem 6.19 of Rudin, 1987), the functional T can be represented uniquely by a complex Borel measure μ ,with $\int_{\mathbb{R}^n} d|\mu| = \|T\| = 1$, in the sense that

$$Tg = \int_{\mathbb{R}^n} g\, d\mu \quad \text{for every } g \in C_0(\mathbb{R}^n).$$

The positivity of T implies that μ is a positive real measure. So, $\int_{\mathbb{R}^n} d\mu = 1$ and consequently μ is also a probability measure on $\mathbb{R}^n$. Thus,

$$\int_{\mathbb{R}^n} H(\gamma)\, dp_m(\gamma) \longrightarrow \int_{\mathbb{R}^n} H(\gamma)\, d\mu(\gamma)$$

which indicates that the set $\mathcal{K}_Z$ is compact. ■

4.2 Interchanging the min and max Operations

We first prove a theorem about interchanging the min and max operations which is an abstracted and generalized version of Theorem 20 in Micchelli and Pontil (2005).

Theorem 2 *Assume that* Γ *is a compact Hausdorff space and the function* $g : \Gamma \times \mathbb{R}^l \to \mathbb{R}$ *is continuous in the first parameter and convex and differentiable in the second parameter. Let* $\mathcal{E}$ *and* I *be finite index sets ,* a_i*, where* $i \in \mathcal{E} \cup I$*, be* $l \times 1$ *vectors, and* b_i*, where* $i \in \mathcal{E} \cup I$*, be real-valued scalars. Considering problem (6), assume that the Slater's condition (see Boyd and Vandenberghe, 2004) holds, that is, there exists some* α *such that* $a_i^T \alpha = b_i$ *for all* $i \in \mathcal{E}$ *and* $a_i^T \alpha < b_i$ *for all* $i \in I$*. Then there exist a discrete probability measure* $\tilde{p} \in \mathcal{P}(\Gamma)$ *with at most* $l+1$ *atoms and some feasible point* $\tilde{\alpha}$ *which solve the max-min problem*

$$\max_{p \in \mathcal{P}(\Gamma)} \min_{\substack{\alpha : a_i^T \alpha = b_i \text{ for } i \in \mathcal{E}, \\ a_i^T \alpha \geq b_i \text{ for } i \in I}} \int_\Gamma g(\gamma, \alpha)\, dp(\gamma) \tag{6}$$

and the min-max problem

$$\min_{\substack{\alpha : a_i^T \alpha = b_i \text{ for } i \in \mathcal{E}, \\ a_i^T \alpha \geq b_i \text{ for } i \in I}} \max_{p \in \mathcal{P}(\Gamma)} \int_\Gamma g(\gamma, \alpha)\, dp(\gamma) \tag{7}$$

simultaneously. In addition, each atom of $\tilde{p}$ *is a global maximum of* $g(\gamma, \tilde{\alpha})$ *as a function of* γ.

3. Note that the topology of $S(\mathbb{C}^l)$ is the same as that of $\mathbb{R}^{l^2}$.An $l \times l$ hermitian matrix contains l real-valued diagonal elements and $\frac{l^2-l}{2}$ independent complex-valued off-diagonal element.

Proof Assume that $\hat{\alpha}$ and $\hat{p}$ solve the problem (7). Define the function

$$\phi : \mathbb{R}^l \to \mathbb{R}$$
$$\phi(\alpha) := \max_{\gamma \in \Gamma} \{g(\gamma, \alpha)\}$$

and the set

$$\Gamma^* := \{\gamma : \gamma \in \Gamma, g(\gamma, \hat{\alpha}) = \phi(\hat{\alpha})\}.$$

By Lemma 24 of Micchelli and Pontil (2005), the directional derivative of ϕ along the direction $d \in \mathbb{R}^l$, denoted by $\phi'_+(\alpha; d)$, is given by:

$$\phi'_+(\alpha; d) = \max_{\gamma \in \Gamma^*} \left\{ d^T \nabla_\alpha g(\gamma, \alpha) \right\}.$$

Since $\hat{\alpha}$ minimizes (7), we have

$$\phi'_+(\hat{\alpha}; d) = \max_{\gamma \in \Gamma^*} \left\{ d^T \nabla_\alpha g(\gamma, \alpha) \mid_{\alpha = \hat{\alpha}} \right\} \geq 0 \tag{8}$$

for any direction d such that $a_i^T d = 0$ for $i \in \mathcal{E}$ and $a_i^T d \geq 0$ for $i \in I^*$, where $I^* := \{i \in I : a_i^T \alpha = b_i\}$.

Let $\mathcal{M}$ be the convex hull of the set of vectors $\mathcal{N} := \{\nabla_\alpha g(\gamma, \alpha) \mid_{\alpha = \hat{\alpha}} : \gamma \in \Gamma^*\} \subseteq \mathbb{R}^l$. Since $\mathcal{M} \subseteq \mathbb{R}^l$, by the Caratheodory theorem (see for example Section 17 of Rockafellar, 1970) every vector in $\mathcal{M}$ can be expressed as a convex combination of at most $l+1$ elements of $\mathcal{N}$. We claim that the set

$$O := \left\{ \sum_{i \in \mathcal{E} \cup I^*} \lambda_i a_i : \ \lambda_i \geq 0 \text{ for all } i \in I^* \right\}$$

intersects $\mathcal{M}$. Assume, on the contrary, that $\mathcal{M}$ and O are distinct. Since $\mathcal{M}$ is convex and compact and O is convex and closed, by the strict separating hyperplane theorem (see corollary 11.4.2 of Rockafellar, 1970), there exists a separating hyperplane $w^T \alpha + b = 0$, $w \in \mathbb{R}^l$, $b \in \mathbb{R}$, such that

$$\sum_{i \in \mathcal{E} \cup I^*} \lambda_i w^T a_i + b > 0, \qquad \forall \lambda : \ \lambda_i \geq 0 \text{ for } i \in I^*$$

and

$$w^T \nabla_\alpha g(\gamma, \alpha) \mid_{\alpha = \hat{\alpha}} + b < 0, \qquad \forall \gamma \in \Gamma^*. \tag{9}$$

The first condition, for $\lambda = 0$ implies that $b > 0$ and since λ_i can take any real value for $i \in \mathcal{E}$ and any nonnegative value for $i \in I^*$, we have

$$w^T a_i = 0, \quad \forall i \in \mathcal{E},$$
$$w^T a_i \geq 0, \quad \forall i \in I^*.$$

By combining these results with (9), we get

$$\max_{\gamma \in \Gamma^*} w^T \nabla_\alpha g(\gamma, \hat{\alpha})\,|_{\alpha=\hat{\alpha}} < 0.$$

This means that w is a feasible descent direction at $\hat{\alpha}$ which contradicts (8). So, the sets O and $\mathcal{M}$ intersect. This means that there exist real numbers $\hat{\lambda}_i,\ i \in \mathcal{E}$, nonnegative numbers $\hat{\lambda}_i,\ i \in I^*$, and a discrete probability measure $\hat{p}$ with at most $l+1$ atoms such that

$$\sum_{i \in \mathcal{E} \cup I^*} \hat{\lambda}_i a_i = \int_\Gamma \nabla_\alpha g(\gamma, \hat{\alpha})\, d\hat{p}. \tag{10}$$

Now, we turn our attention to the solution of problem (6) for $p = \hat{p}$. This is a convex optimization problem. Since by assumption the Slater's condition holds, the KKT conditions provide a necessary and sufficient condition for optimality (see Boyd and Vandenberghe, 2004, page 244) and therefore a solution $\check{\alpha}$ to problem (6) is found by solving the following KKT conditions:

$$\begin{aligned}
\sum_{i \in \mathcal{E} \cup I} \check{\lambda}_i a_i &= \int_\Gamma \nabla_\alpha g(\gamma, \check{\alpha}) d\hat{p} \\
a_i^T(\check{\alpha}) &= 0, \quad i \in \mathcal{E} \\
a_i^T(\check{\alpha}) &\geq 0, \quad i \in I \\
\check{\lambda}_i &\geq 0, \quad i \in I \\
\check{\lambda}_i \left(a_i^T \check{\alpha} - b_i\right) &= 0, \quad i \in I.
\end{aligned}$$

By defining $\hat{\lambda}_i = 0$ for $i \in I \setminus I^*$, using (10), and recalling the definition of I^*, it can be seen that $\hat{\alpha}, \hat{\lambda}$ are the unique solution to the above KKT conditions. Thus, $\tilde{\alpha} = \hat{\alpha}$ and $\tilde{p} = \hat{p}$ solve problems (6) and (7) simultaneously and the theorem follows. ■

Corollary 3 *Assume that Γ is any compact subset of $\mathbb{R}^n$ and the parameter C is chosen*[4] *such that $C > \max\{\frac{1}{l_1}, \frac{1}{l_2}\}$. Then, there exist $\tilde{\alpha} \in \mathbb{R}^n$ and $\tilde{p} \in \mathcal{P}(\Gamma)$ that solve problems (11) and (12) simultaneously. Furthermore, $\tilde{p}$ is a discrete probability measure with at most $l+1$ atoms and each atom of $\tilde{p}$ is a global maximum of $\tilde{\alpha}^T H(\gamma)\tilde{\alpha}$.*

$$\max_{p \in \mathcal{P}(\Gamma)} \min_{\alpha \in \mathcal{A}} \int_\Gamma \alpha^T H(\gamma) \alpha\, dp(\gamma), \tag{11}$$

$$\min_{\alpha \in \mathcal{A}} \max_{p \in \mathcal{P}(\Gamma)} \int_\Gamma \alpha^T H(\gamma) \alpha\, dp(\gamma). \tag{12}$$

4. For a similar constraint in the context of ν-SVMs see Section 4 of Crisp and Burges (1999).

Proof It is sufficient to show that the Slater's condition holds, that is, there exists $\alpha \in \mathbb{R}^l$ such that $\alpha^T e = 2$, $\alpha^T y = 0$, $\alpha > 0$, and $\alpha < C$. One can easily verify that the choice $\alpha_i = \frac{1}{l_1}$ for $i \in C^+$ and $\alpha_i = \frac{1}{l_2}$ for $i \in C^-$ satisfies these conditions. ■

In the rest of the paper, we assume that $C > \max\{\frac{1}{l_1}, \frac{1}{l_2}\}$.

4.3 Confining Integration to a Compact Region

To write (4) as a min-max optimization problem, we first proved in Section 4.1 that the sup operation can be replaced by the max operation. In the previous section we proved Corollary 3 which asserts that if the integration region of (4) could have been replaced by a compact set, then the max and min operations could also be interchanged. In this section, we show that the integration region of (4) can safely be confined to a compact subset of $\mathbb{R}^n$. Let us first prove two useful lemmas.

Lemma 4 *For arbitrary domains X and Y and every function $f : X \times Y \to \mathbb{R}$, the following inequality holds:*

$$\sup_{x\in X} \inf_{y\in Y} f(x,y) \leq \inf_{y\in Y} \sup_{x\in X} f(x,y).$$

Proof Assume on the contrary that

$$\sup_{x\in X} \inf_{y\in Y} f(x,y) > \inf_{y\in Y} \sup_{x\in X} f(x,y).$$

Then, there exist $\tilde{x} \in X$ and $\tilde{y} \in Y$ such that

$$\inf_{y\in Y} f(\tilde{x},y) > \sup_{x\in X} f(x,\tilde{y})$$

which contradicts with the existence of $f(\tilde{x},\tilde{y})$. ■

Lemma 5 *If $\tau < 1$, then there exists some compact subset Γ_β of $\mathbb{R}^n$, independent of α, where all γ's that maximize $\alpha^T H(\gamma)\alpha$ lie in it.*[5]

Proof For each $\alpha \in \mathbb{R}^l$ we have

$$\max_{\gamma\in\mathbb{R}^n} \alpha^T H(\gamma)\alpha = (1-\tau) \max_{\gamma\in\mathbb{R}^n} \left\{ \left\| \sum_{u=1}^{l} \alpha_u y_u \exp(j\gamma^T x_u) \right\|_2^2 G_\beta(\|\gamma\|) \right\} + \tau\alpha^T\alpha. \tag{13}$$

Let $t(\alpha)$ denote the maximum value of the term in the braces in the above equation. Since G_β is continuous and $G_\beta(0) = 1$, there is an open ball around zero in $\mathbb{R}^n$ such that $G_\beta(\|\gamma\|) > 0$. This fact plus the condition $\alpha^T e = 2$, ensure that the coefficient of at least one of the exponential terms in (13) is nonzero. Hence, the term in the braces in (13), as a function of γ, is never identically zero and thus $t(\alpha) > 0$. For all values of γ with $G_\beta(\|\gamma\|) < \frac{t}{4}$ we have

5. Note that by (3), the choice $\tau = 1$ is unrealistic.

$$\alpha^T H(\gamma)\alpha - \tau\alpha^T\alpha = \left\| \sum_{u=1}^{l} \alpha_u y_u \exp(j\gamma^T x_u) \right\|^2 G_\beta(\|\gamma\|) \leq 4G_\beta(\|\gamma\|) < t(\alpha)$$

and the lemma's assertion follows from $lim_{r\to\infty} G(r) = 0$. ■

Theorem 6 *There exists an optimal solution $(\tilde{\alpha}, \tilde{p})$ to problem (4) which is also a solution to it when the integration domain is confined to the compact set Γ_β.*

Proof Let $(\tilde{\alpha}, \tilde{p})$ be a solution to problems (6) and (7) with Γ replaced by Γ_β. By Lemma 4 and Corollary 3, we have the following sequence of inequalities:

$$\begin{aligned}
\max_{p\in\mathcal{P}(\Gamma_\beta)} \min_{\alpha\in\mathcal{A}} \int_{\Gamma_\beta} \alpha^T H(\gamma)\alpha\, dp(\gamma) \leq \\
\max_{p\in\mathcal{P}(\mathbb{R}^n)} \min_{\alpha\in\mathcal{A}} \int_{\mathbb{R}^n} \alpha^T H(\gamma)\alpha\, dp(\gamma) \leq \\
\min_{\alpha\in\mathcal{A}} \max_{p\in\mathcal{P}(\mathbb{R}^n)} \int_{\mathbb{R}^n} \alpha^T H(\gamma)\alpha\, dp(\gamma) \leq \\
\min_{\alpha\in\mathcal{A}} \max_{p\in\mathcal{P}(\mathbb{R}^n)} \int_{\mathbb{R}^n} \max_{\gamma\in\mathbb{R}^n} \alpha^T H(\gamma)\alpha\, dp(\gamma) = \\
\min_{\alpha\in\mathcal{A}} \max_{\gamma\in\mathbb{R}^n} \alpha^T H(\gamma)\alpha = \\
\min_{\alpha\in\mathcal{A}} \max_{p\in\mathcal{P}(\Gamma_\beta)} \int_{\Gamma_\beta} \alpha^T H(\gamma)\alpha\, dp(\gamma).
\end{aligned}$$

However, the first and the last terms are equal by Corollary 3.

4.4 Semi-infinite Programming Formulation

We have not yet addressed the problem of how (12) is to be really solved on a machine. In this section, we reformulate (12) as a semi-infinite programming problem for which many algorithms have been proposed (see Hettich and Kortanek, 1993; Reemtsen and Görner, 1998, for two reviews on the subject).

Theorem 7 *Let $\tilde{\alpha}$ and $\tilde{t}$ be a solution to the semi-infinite programming problem (14) and define the set $\Gamma_\beta^H(\alpha) := \left\{\gamma \in \Gamma_\beta : \alpha^T H(\gamma)\alpha = max_{\gamma\in\Gamma_\beta}\alpha^T H(\gamma)\alpha\right\}$. Let (Q) be the QCQP problem that is obtained by replacing Γ_β by $\Gamma_\beta^H(\tilde{\alpha}) \equiv \{\gamma_1, ..., \gamma_m\}$ in (14) and let $\tilde{\mu}_1, ..., \tilde{\mu}_m$ be a set of Lagrange multipliers associated with the constraints $t \geq \alpha^T H(\gamma_i)\alpha$, $1 \leq i \leq m$ which optimize the dual problem of (Q). If $\tilde{p}$ is the discrete probability measure defined by $\tilde{p}(\gamma_i) := \tilde{\mu}_i$ $i = 1, ..., m$, then $\tilde{\alpha}$ and $\tilde{p}$ solve the problem (4). In addition, there exists a solution pair $(\tilde{\alpha}^*, \tilde{p}^*)$ such that $\tilde{p}^*$ contains at most $l+1$ nonzero atoms.*

$$\begin{array}{ll} \min_{\alpha,t} & t \\ s.t. & t \geq \alpha^T H(\gamma)\alpha \;\; \textit{for all} \;\; \gamma \in \Gamma_\beta \\ & 0 \leq \alpha \leq C \\ & \alpha^T y = 0 \\ & \alpha^T e = 2. \end{array} \tag{14}$$

Proof Since for all $\gamma \notin \Gamma_\beta^H(\tilde{\alpha})$ the strict inequality $\tilde{t} > \tilde{\alpha}^T H(\gamma)\tilde{\alpha}$ holds, $\tilde{\alpha}$ and $\tilde{t}$ also solve the following QCQP problem:

$$\begin{array}{ll} \min_{\alpha,t} & t \\ s.t. & t \geq \alpha^T H(\gamma_i)\alpha \;\; i = 1,...,m \\ & 0 \leq \alpha \leq C \\ & \alpha^T y = 0 \\ & \alpha^T e = 2. \end{array}$$

In addition, from $\tilde{t} = \tilde{\alpha}^T H(\gamma_1)\tilde{\alpha} = ... = \tilde{\alpha}^T H(\gamma_m)\tilde{\alpha}$, it follows that $\tilde{\alpha}$ and $\tilde{t}$ also solve the following problem:

$$\min_{\alpha \in \mathcal{A}} \max_{\mu \geq 0,\, \sum_{i=1}^m \mu_i = 1} \alpha^T \left[\sum_{i=1}^m \mu_i H(\gamma_i) \right] \alpha \tag{15}$$

By Theorem 17 of Lanckriet et al. (2004), if $\tilde{\mu}$ is chosen as specified by the statement of this theorem, then $\tilde{\alpha}$ and $\tilde{\mu}$ simultaneously solve the min-max problem (15) and the following max-min problem:

$$\max_{\mu \geq 0,\, \sum_{i=1}^m \mu_i = 1} \min_{\alpha \in \mathcal{A}} \alpha^T \left[\sum_{i=1}^m \mu_i H(\gamma_i) \right] \alpha$$

which can also be written as

$$\max_{p \in \mathcal{P}(\Gamma_\beta^H(\tilde{\alpha}))} \min_{\alpha \in \mathcal{A}} \int \alpha^T H(\gamma)\alpha \, dP(\gamma)$$

The first assertion of the theorem follows from the following inequalities:

$$\begin{aligned} \tilde{t} = \max_{p \in \mathcal{P}(\Gamma_\beta^H(\tilde{\alpha}))} \min_{\alpha \in \mathcal{A}} \int \alpha^T H(\gamma)\alpha \, dP(\gamma) \leq \\ \max_{p \in \mathcal{P}(\Gamma_\beta)} \min_{\alpha \in \mathcal{A}} \int \alpha^T H(\gamma)\alpha \, dP(\gamma) \leq \\ \min_{\alpha \in \mathcal{A}} \max_{p \in \mathcal{P}(\Gamma_\beta)} \int \alpha^T H(\gamma)\alpha \, dP(\gamma) = \tilde{t} \end{aligned}$$

where the last equality follows from a simple reformulation of problem (14). The last part of the theorem follows from Corollary 3 and reversing the above proof. ■

4.5 Including Other Kernels in the Learning Process

Although the focus of this paper is on the task of learning translation invariant kernels, it is easy to furnish the set of admissible kernels with other kernel functions. For example, one may want to find the best convex combination of stabilized translation invariant kernels along with isotropic/non-isotropic Gaussian kernels, and polynomial kernels with degrees one to five.[6] In general, assume that we have M classes of kernels

$$K_i := \left\{k_\gamma(x,z) : \ \gamma \in \Gamma_i\right\} \qquad i = 1,...,M$$

where $\Gamma_1,...,\Gamma_M$ are distinct compact Hausdorff spaces. For $i \in 1,...,M$ let $G_i(\gamma)$ be the $l \times l$ matrix whose (u,v)'s entry is $y_u y_v k_\gamma(x_u,x_v)$ and define $H_i(\gamma) := (1-\tau)G_i(\gamma) + \tau I_l$. The problem of learning the best convex combination of kernels from these classes for classification with support vector machines can be stated as

$$\sup_{p\in\mathcal{P}(\Gamma_0)} \min_{\alpha\in\mathcal{A}} \int_{\Gamma_0} \alpha^T H_0(\gamma)\alpha \, dp(\gamma) \tag{16}$$

where $\Gamma_0 := \Gamma_1 \cup ... \cup \Gamma_M$ and

$$H_0(\gamma) := \begin{cases} H_1(\gamma) & if \gamma \in \Gamma_1 \\ H_2(\gamma) & if \gamma \in \Gamma_2 \\ \qquad \vdots & \\ H_M(\gamma) & if \gamma \in \Gamma_M \end{cases}.$$

The results of the previous sections will hold for this combined class of kernels if we prove that Γ_0 is a compact Hausdoff space and that $h_0(\gamma,\alpha) := \alpha^T H_0(\gamma)\alpha$ is continuous with respect to γ. Let $\mathcal{T}_i$ denote the topology on Γ_i for $i \in 1,...,M$. Define the set $\mathcal{T}_0$ of subsets of Γ_0 as:

$$\mathcal{T}_0 := \{O_1 \cup O_2 ... \cup O_M : O_1 \in \mathcal{T}_1, O_2 \in \mathcal{T}_2, ..., O_M \in \mathcal{T}_M\}.$$

Proposition 8 *$\mathcal{T}_0$ is a topology.*

Proof Clearly $\Gamma_0 \in \mathcal{T}_0$. Next we must show that $\mathcal{T}_0$ is closed under arbitrary union. Let $O = \bigcup_{i\in\mathfrak{I}} O_i$ where $O_i \in \mathcal{T}_0$ and $\mathfrak{I}$ is an arbitrary index set. We have

$$O = \bigcup_{j\in\{1,...,M\}} \left(\bigcup_{i\in\mathfrak{I}} O_i \cap \Gamma_j \right)$$

6. Although the class of translation invariant kernels includes the set of isotropic/non-isotropic Gaussian kernels, it is not the case for the stabilized class $\mathcal{K}_\beta$.

which shows that $O \in \mathcal{T}_0$. Finally, we should show that finite intersection of closed sets is a closed set. Assume that $C = \bigcap_{i=1}^{r} C_i$, where $r \in \mathbb{N}$ and $C_i^c \in \mathcal{T}_0$. We have

$$C^c = \bigcup_{i\in\{1,...,r\}} C_i^c = \bigcup_{i\in\{1,...,r\}} \bigcup_{j\in\{1,...,M\}} (C_i^c \cap \Gamma_j).$$

Since C_i^c and Γ_j are both open in $\mathcal{T}_j$, the set $C_i^c \cap \Gamma_j$ is open in $\mathcal{T}_j$. By the properties of topologies $\mathcal{T}_1, ..., \mathcal{T}_M$ and the definition of topology $\mathcal{T}_0$ it follows that $C^c \in \mathcal{T}_0$ which shows that C is closed in $\mathcal{T}_0$. ■

Proposition 9 *Assume that the functions $h_i(\gamma, \alpha) : \Gamma_i \times \mathbb{R}^l \to \mathbb{R}$ defined as $h_i(\gamma, \alpha) = \alpha^T H_i(\gamma)\alpha$, where $i = 1, ..., M$, are continuous in the first parameter. Then, the function $h_0(\gamma, \alpha) : \Gamma_0 \times \mathbb{R}^l \to \mathbb{R}$ defined as $h_0(\gamma, \alpha) = \alpha^T H(\gamma)\alpha$,where the topology of Γ_0 is $\mathcal{T}_0$, is also continuous in the first parameter.*

Proof Fix α to any value and define $\bar{h}_i(\gamma) := h_i(\gamma, \alpha)$ for $i = 0, ..., M$. Let O be an open subset of $\mathbb{R}$. We must show that $\bar{h}_0^{-1}(O)$ is open in topology $\mathcal{T}_0$. We have

$$\bar{h}_0^{-1}(O) = \bigcup_{i=1,...,M} \left(\bar{h}_0^{-1}(O) \cap \Gamma_i\right) = \bigcup_{i=1,..,M} \bar{h}_i^{-1}(O).$$

Since the set $\bar{h}_i^{-1}(O)$ is open in $\mathcal{T}_i$ for each $i \in \{1, ..., M\}$, it follows from the definition of $\mathcal{T}_0$ that the union of these sets is also open in $\mathcal{T}_0$. So, $\bar{h}_0^{-1}(O)$ is open in $\mathcal{T}_0$ and the result follows. ■

Proposition 10 *The set Γ_0 with topology $\mathcal{T}_0$ is compact in itself.*

Proof Let $O = \{O_i : i \in I_0\}$ be an open covering of Γ_0, where I_0 is some index set. Let j be any number in the set $\{1, ..., M\}$. Since $\Gamma_j \subseteq \Gamma_0$, the set O is also an open covering for Γ_j. By compactness of Γ_j, there exists a finite index set $I_j \subseteq I_0$ such that the set $\left\{O_i : i \in I_j\right\}$ is an open subcovering of Γ_j. Thus, the set $\{O_i : i \in I_1 \cup ... \cup I_M\}$ is a finite open subcovering of $\mathcal{T}_0$ which proves that Γ_0 is compact. ■

Proposition 11 *Assume that topologies $\mathcal{T}_1, ..., \mathcal{T}_M$ are Hausdorff. Then, so is the topology $\mathcal{T}_0$.*

Proof We must prove that for any two points $\gamma_1, \gamma_2 \in \Gamma_0$ there are disjoint open sets O_1 and O_2 such that $\gamma_1 \in O_1$ and $\gamma_2 \in O_2$. If γ_1 and γ_2 belong to the same set Γ_j for some $j \in 1, ..., M$, then the assertion follows from the Hausdorffness property of $\mathcal{T}_j$. Without loss of generality, assume that $\gamma_1 \in \Gamma_1$ and $\gamma_2 \in \Gamma_2$. The choice $O_1 = \Gamma_1$ and $O_2 = \Gamma_2$ completes the proof. ■

Theorem 12 *Assume that $\Gamma_1, ..., \Gamma_M$ are compact Hausdorff spaces and the matrices H_j are as defined previously in this section. Furthermore, assume that for $j = 1, ..., M$ the functions $h_j(\gamma, \alpha) : \Gamma_j \to \mathbb{R}^l$ defined by $h_j(\gamma, \alpha) := \alpha^T H_j(\gamma)\alpha$ are continuous in the first parameter. Let $\tilde{\alpha}$ and $\tilde{t}$ be a solution to the semi-infinite programming problem $P(\Gamma_1, ..., \Gamma_M)$, which is defined as*

$$
\begin{array}{rll}
 & \min_{\alpha,t} & t \\
 & s.t. & t \geq \alpha^T H_1(\gamma)\alpha \ \ \textit{for all} \ \ \gamma \in \Gamma_1 \\
 & & \vdots \\
P(\Gamma_1,...,\Gamma_M) := & & t \geq \alpha^T H_M(\gamma)\alpha \ \ \textit{for all} \ \ \gamma \in \Gamma_M \\
 & & 0 \leq \alpha \leq C \\
 & & \alpha^T y = 0 \\
 & & \alpha^T e = 2.
\end{array} \tag{17}
$$

Define the set $\Gamma_j^H(\alpha) := \left\{\gamma \in \Gamma_j : \alpha^T H_j(\gamma)\alpha = max_{\gamma\in\Gamma_j}\alpha^T H_j(\gamma)\alpha\right\}$. *Let (Q) be the QCQP problem that is obtained by replacing every* Γ_j *with* $j = 1,...,M$ *by* $\Gamma_j^H(\tilde{\alpha}) \equiv \left\{\gamma_1^j,...,\gamma_{m_j}^j\right\}$ *in (17). For any* $j \in \{1,...,M\}$ *let* $\tilde{\mu}_1^j,...,\tilde{\mu}_{m_j}^j$ *be a set of Lagrange multipliers associated with the constraints* $t \geq \alpha^T H_j(\gamma_i^j)\alpha,\ \ 1 \leq i \leq m_j$ *which optimize the dual problem of (Q). If* $\tilde{p}$ *is the discrete probability measure defined by* $\tilde{p}(\gamma_i^j) := \tilde{\mu}_i^j \ \ i = 1,...,m_j \ \ j = 1,...,M$, *then the pair* $(\tilde{\alpha},\tilde{p})$ *solves the problem (16). In addition, there exists a solution pair* $(\tilde{\alpha}^*,\tilde{p}^*)$ *such that* $\tilde{p}^*$ *contains at most* $l+1$ *nonzero atoms*.

Proof The result is immediately obtained by replacing the set Γ_β by Γ_0 in Theorem 7. ■

4.6 Automatic Adjustment of the Parameter τ

In this section, we consider the following problem:

$$
\max_{0\leq\tau\leq 1, p\in\mathcal{P}(\mathbb{R}^n)} \min_{\alpha\in\mathcal{A}} \int_{\mathbb{R}^n} \alpha^T H(\gamma)\alpha \, dP(\gamma). \tag{18}
$$

It is well known that the parameter τ can be envisioned as the weight of the kernel $\delta(x,z)$, where δ is the Kronecker delta function. So, the problem of learning the parameter τ is equivalent to choosing the best convex combination of the set of translation invariant kernels augmented with the delta kernel $\delta(x,z)$. By using Theorem 12 we get the following corollary.

Corollary 13 *Let* $\tilde{\alpha}$ *and* $\tilde{t}$ *be a solution to the semi-infinite programming problem* $P_\tau(\Gamma_\beta)$, *where for each compact set* Γ *the problem* $P_\tau(\Gamma)$ *is defined by (19). Define the set*

$$
\Gamma_\beta^G(\alpha) := \left\{\gamma \in \Gamma_\beta : \alpha^T G(\gamma)\alpha = max_{\gamma\in\Gamma_\beta}\alpha^T G(\gamma)\alpha\right\}.
$$

Let (Q) be the QCQP problem that is obtained by replacing Γ *by* $\Gamma_\beta^G(\tilde{\alpha}) \equiv \{\gamma_1,...,\gamma_m\}$ *in (19) and let* $\tilde{\mu}_1,...,\tilde{\mu}_m$ *be a set of Lagrange multipliers associated with the constraints* $t \geq \alpha^T G(\gamma_i)\alpha,\ \ 1 \leq i \leq m$ *which optimize the dual problem of (Q). In addition, let* $\tilde{\mu}_0$ *be a Lagrange multiplier associated with the constraint* $t \geq \alpha^T\alpha$ *in the dual problem of (Q). If* $\tilde{p}$ *is the discrete probability measure defined by* $\tilde{p}(\gamma_i) := \tilde{\mu}_i \ \ i = 1,...,m$ *and* $\tilde{\tau} := \tilde{\mu}_0$, *then* $\tilde{\alpha}$, $\tilde{\tau}$, *and* $\tilde{p}$ *solve the problem (18). In addition, there exist some solution* $\tilde{\alpha}^*$, $\tilde{\tau}^*$, *and* $\tilde{p}^*$ *such that* $\tilde{p}^*$ *contains at most* $l+1$ *nonzero atoms*.

$$P_\tau(\Gamma) := \begin{array}{ll} \min_{\alpha,t} & t \\ s.t. & t \geq \alpha^T G(\gamma)\alpha \;\; \textit{for all} \;\; \gamma \in \Gamma \\ & t \geq \alpha^T \alpha \\ & 0 \leq \alpha \leq C \\ & \alpha^T y = 0 \\ & \alpha^T e = 2. \end{array} \tag{19}$$

Proof Let $\omega_0 \notin \Gamma_\beta$ and assign the kernel $\delta(x,z)$ to this point. The corollary is proved by applying theorem 12 to the sets Γ_β and $\{\omega_0\}$. ■

4.7 Furnishing the Class of Admissible Kernels with Isotropic Gaussian Kernels

Although the class of translation invariant kernels encompasses the class of Gaussian kernels with arbitrary covariance matrices, the stabilized class of translation invariant kernels $\mathcal{K}_\beta$ does not. So, it may be advantageous to combine the class $\mathcal{K}_\beta$ with the class of Gaussian kernels. In this section, we consider learning the best convex combination of kernels of the classes $\mathcal{K}_\beta$ and the stabilized class of isotropic Gaussian kernels

$$\mathcal{K}_\eta := \left\{ k(x,z) = \int_{\mathbb{R}} e^{-\omega\|x_u - x_v\|^2} e^{-\eta\|\omega\|^2} \, dp(\omega) \quad : \text{ p is a probablity measure on } \mathbb{R} \right\}$$

where $\eta > 0$. We also learn the parameter τ automatically. The proof that there exists some compact set $\Omega_\eta \subseteq R$ where we can confine the integration to it parallels the discussion of Section 4.3 and is omitted. By using Theorem 12, it follows that the expansion of the optimal kernel along with the weight of each kernel can be obtained by solving the SIP problem $P_\tau(\Gamma_\beta, \Omega_\eta)$, where $P_\tau(\Gamma, \Omega)$ is defined as:

$$P_\tau(\Gamma,\Omega) := \begin{array}{ll} \min_{\alpha,t} & t \\ s.t. & t \geq \alpha^T G(\gamma)\alpha \;\; \text{for all} \;\; \gamma \in \Gamma \\ & t \geq \sum_{u=1}^{l}\sum_{v=1}^{l} \alpha_u \alpha_v y_u y_v e^{-\omega\|x-z\|^2} e^{-\eta\|\omega\|^2} \;\; \text{for all} \;\; \omega \in \Omega \\ & t \geq \alpha^T \alpha \\ & 0 \leq \alpha \leq C \\ & \alpha^T y = 0 \\ & \alpha^T e = 2. \end{array}$$

5. Optimization Algorithm

We now turn to the problem of numerically solving the nonlinear convex semi-infinite programming problem $P_\tau(\Gamma_\beta)$.[7] The term semi-infinite stems from the fact that whilst the number of variables is

7. Modifying the proposed algorithm to solve problem $P_\tau(\Gamma, \Omega)$ is straightforward.

finite, there is an infinite number of constraints which are indexed by the compact set Γ_β. Hopefully, for each finite set $\Gamma \subseteq \Gamma_\beta$, the problem $P_\tau(\Gamma)$ is QCQP and therefore convex. Hence, in principle, one can construct a sequence of QCQP problems with an increasing number of constraints such that their solutions converge to the solution of problem $P_\tau(\Gamma_\beta)$. This is the principle used by discretization and exchange algorithms (see Hettich and Kortanek, 1993; Reemtsen and Görner, 1998). On the other hand, by Corollary 13, only a finite number of constraints will be active in a solution. Furthermore, it is easy to show that this property is not limited to a solution point, and the active constraints at a solution also identify the active constraints in a neighborhood of it. This is the principle behind the methods based on local reduction (see Reemtsen and Görner, 1998; Hettich and Kortanek, 1993). Reemtsen and Görner (1998) proposed that to further speed up the methods based on local reduction, the set of active constraints be locally adapted. Combining these ideas with numerous experiments, we arrived at Algorithm 1. This algorithm is very similar to Algorithm 7 in Reemtsen and Görner (1998) which is based on local reduction.

5.1 Choosing the Initial Value of α

We choose the initial value of α such that maximizing the criterion (3) with respect to the kernel function k and the parameter τ correspond to maximizing the distance of the means of the two classes in a feature space. Let us first write the distance between means of two classes in the feature space of some kernel k'

$$\|m_1 - m_2\|^2 = \left\| \frac{1}{l_1} \sum_{u \in C^+} \Phi(x_u) - \frac{1}{l_2} \sum_{v \in C^-} \Phi(x_v) \right\|^2$$

$$= \frac{1}{l_1^2} \sum_{u \in C^+} \sum_{v \in C^-} k'(x_u, x_v) + 2\frac{1}{l_1 l_2} \sum_{u \in C^+} \sum_{v \in C^-} k'(x_u, x_v) + \frac{1}{l_2^2} \sum_{u \in C^-} \sum_{v \in C^-} k'(x_u, x_v).$$

By choosing $\alpha_i = 1/l_1$ for $i \in C^+$ and $\alpha_i = 1/l_2$ for $i \in C^-$, we have

$$\|m_1 - m_2\|^2 = \sum_{u=1}^{l} \sum_{v=1}^{l} \alpha_u \alpha_v y_u y_v k'(x_u, x_v).$$

Comparing the above equation with (3), we see that maximizing the criterion (3) with respect to the kernel function k and the parameter τ is equivalent to maximizing the distance between means of the samples of the two classes in the feature space of kernel $k'(x,z) = k(x,z) + \tau\delta(x,z)$. Note that this choice for α also satisfies the required conditions $\alpha^T e = 2$, $\alpha^T y = 0$, and $\max\{\frac{1}{l_1}, \frac{1}{l_2}\} \leq \alpha \leq C$; and thus $\alpha \in \mathcal{A}$.

5.2 Global Search for Local Maxima of $\alpha^T G(\gamma)\alpha$

The algorithm presented in this section attempts to gather a subset of unsatisfied constraints to be considered in the next iteration of Algorithm 1. Although at the solution point $\tilde{\alpha}$ the set of active constraints globally maximize $\tilde{\alpha}^T G(\gamma)\tilde{\alpha}$, for other choices of α it is possible that the constraints be violated by the local maxima of the function $\alpha^T G(\gamma)\alpha$. So, in Algorithm 2, we try to find the

values of γ which locally maximize the function $\alpha^T G(\gamma)\alpha$ for given α. Here we also assume that the function $G_\beta(\|\gamma\|)$ is differentiable with respect to γ. The choice of limited-memory BFGS algorithm (Nocedal, 1980; Liu and Nocedal, 1989; Nocedal and Wright, 2006) for this optimization is very important. For large-scale problems with large n, the memory needed to store the Hessian matrix and the associated computations become prohibitive. Although a gradient-ascent algorithm does not compute the Hessian matrix, its convergence rate is very slow. The limited-memory BFGS algorithm provides an excellent practical compromise between the computations at each step and the number of iterations till convergence, without storing the full Hessian matrix in memory.

Algorithm 1 General Optimization Algorithm

Require: T_1

1. $\Gamma^{(0)} \leftarrow \{\}$, $t^{(0)} \leftarrow \frac{1}{l_1} + \frac{1}{l_2}$
   {A lower bound for parameter t is the minimum value of $\alpha^T\alpha$ for $\alpha \in \mathcal{A}$}
2. Initialize $\alpha^{(0)}$ as described in Section 5.1
3. **for** $i = 1, 2, \ldots$ **do**
4. set R such that for all γ with $\|\gamma\| > R$, the relation $\alpha^T G(\gamma)\alpha < t^{(i-1)}$ holds for all α
5. $\Gamma_g^{(i)} \leftarrow GlobalSearchForLocals(\alpha^{(i-1)}, R)$
   {denote the maximum value obtained by the global search by $s^{(i)}$}
6. $\Gamma_s^{(i)} \leftarrow \Gamma^{(i-1)} \bigcup \Gamma_g^{(i)}$
7. Solve problem $P_\tau(\Gamma_s^{(i)})$ to obtain the optimal parameters $t_s^{(i)}, \alpha_s^{(i)}$ and $\mu_s^{(i)}$
   {see Section 5.3}
8. Locally adapt $\Gamma_s^{(i)}$ and $\mu_s^{(i)}$ to obtain the optimal parameters $t_l^{(i)}, \alpha_l^{(i)}, \Gamma_l^{(i)}$ and $\mu_l^{(i)}$
   {see Section 5.4}
9. $t^{(i)} \leftarrow t_l^{(i)}$, $\alpha^{(i)} \leftarrow \alpha_l^{(i)}$
10. Construct $\mu^{(i)}$ and $\Gamma^{(i)}$ by eliminating zero indices of $\mu_l^{(i)}$ along with the corresponding vectors in $\Gamma_l^{(i)}$
11. **if** $t^{(i)} - t^{(i-1)} < \varepsilon t^{(i-1)}$ or $i = T_1$ **then**
12. terminate algorithm with the kernel $k(x,z) := \sum_{j=1}^m \mu_j^{(i)} \cos\left((x-z)^T \gamma_j^{(i)}\right)$
    {we assume that $\Gamma^{(i)} = \left\{\gamma_1^{(i)}, \ldots, \gamma_m^{(i)}\right\}$ and that $\mu_j^{(i)}$ is the Lagrange multiplier associated with the constraint $\alpha^T G(\gamma_j^{(i)})\alpha \le t$ in problem $P_\tau(\Gamma^{(i)})$}

14. **end for**

5.3 Solving the Problem $P_\tau(\Gamma)$ for Finite Set Γ

Let $\Gamma = \{\gamma_1, \ldots, \gamma_m\}$ be a finite subset of Γ_β. Since Γ is finite, the problem $P_\tau(\Gamma)$ can be written as the following QCQP problem:

Algorithm 2 GlobalSearchForLocals

Require: α, R, T_2, and T_3

1. $\Gamma = \{\}, i = 0$
2. **for** $j = 1, 2, \ldots$ **do**
3. generate a random point $x \in \mathbb{R}^n$
4. generate a random number $r \in [0, R]$
5. $\gamma_0 \leftarrow r \frac{x}{\|x\|}$
6. starting from γ_0 and using the limited-memory BFGS algorithm find a local maximum $\gamma^{(i)}$ for function $\alpha^T G(\gamma)\alpha$
7. **if** $\gamma^{(i)} \in \Gamma$ **then**
8. $i \leftarrow i + 1$ {count the number of repeating local maxima}
9. **end if**
10. $\Gamma \leftarrow \Gamma \cup \gamma^{(i)}$
11. **if** $(i - |\Gamma|) \geq T_2$ or $j = T_3$ **then**
12. **return** Γ
13. **end if**
14. **end for**

$$\begin{array}{ll} \min_{\alpha,t} & t \\ s.t. & t \geq \alpha^T G(\gamma_i)\alpha \quad \text{for all} \quad i = 1, \ldots, m \\ & t \geq \alpha^T \alpha \\ & 0 \leq \alpha \leq C \\ & \alpha^T y = 0 \\ & \alpha^T e = 2. \end{array} \tag{20}$$

This problem has been studied in Section 4.6 of Lanckriet et al. (2004) and it has been suggested to store the $l \times l$ kernel matrices $G(\gamma_1), \ldots, G(\gamma_m)$ in memory and solve the problem with general purpose software packages. But, the memory requirement of this approach limits its applicability to small-sized problems. However, the facts that

$$\alpha^T \Im\{G(\gamma)\}\alpha = 0$$

and

$$\begin{aligned} \Re\{G(\gamma)\} &= v_c(\gamma)^T v_c(\gamma) + v_s(\gamma)^T v_s(\gamma), \\ v_c(\gamma) &:= \left[y_1 cos(\gamma^T x_1),\ y_2 cos(\gamma^T x_2),\ \ldots\ , y_l cos(\gamma^T x_l)\right], \\ v_s(\gamma) &:= \left[y_1 sin(\gamma^T x_1),\ y_2 sin(\gamma^T x_2),\ \ldots\ , y_l sin(\gamma^T x_l)\right] \end{aligned}$$

where $\Re\{z\}$ and $\Im\{z\}$ are the real and imaginary parts of z, respectively, show that the kernel matrices $G(\gamma_1),...,G(\gamma_m)$ appearing in problem (20) are effectively[8] of rank two. This allows us to reformulate (20) as a new QCQP problem as follows:

$$\begin{array}{ll} \min_{\alpha,t,c,s} & t \\ s.t. & t \geq c_i^2 + s_i^2 \quad i = 1,...,m \\ & c_i = \sum_{u=1}^{l} \alpha_i y_i \cos(\gamma_i^T x_u) \quad i = 1,...,m \\ & s_i = \sum_{u=1}^{l} \alpha_i y_i \sin(\gamma_i^T x_u) \quad i = 1,...,m \\ & t \geq \alpha^T \alpha \\ & 0 \leq \alpha \leq C \\ & \alpha^T y = 0 \\ & \alpha^T e = 2. \end{array} \tag{21}$$

Now, there is no need to load the kernel matrices into memory and so general-purpose QCQP solvers such as Mosek (Andersen and Andersen, 2000) can be used to solve (21) even when the training set size is huge.

5.4 Local Adaptation

As stated in the previous section, for any finite set $\Gamma = \{\gamma_1,...,\gamma_m\} \subseteq \Gamma_\beta$, the problem $P_\tau(\Gamma)$ is convex and so every local solution is also globally optimal. But, if we consider the values $\gamma_1,...,\gamma_m$ as points in the space $\mathbb{R}^n$, we get the following non-convex optimization problem:

$$\max_{\substack{\mu \geq 0, \mu^T e = 1, \\ \gamma_1,...,\gamma_m \in \mathbb{R}^n}} \min_{\alpha \in \mathcal{A}} \sum_{i=1}^{m} \mu_i \alpha^T G(\gamma_i) \alpha + \mu_0 \alpha^T \alpha. \tag{22}$$

Now, we can use the the solution of the problem $P_\tau(\Gamma)$ obtained in the previous section as the starting point for problem (22) and locally improve it by an ascent method. By unrolling (22), we obtain the following optimization problem:

$$\max_{\substack{\mu \in \mathbb{R}^{m+1}, \\ \gamma_1,...,\gamma_m \in \mathbb{R}^n}} \hat{f}(\mu, \gamma_1,...,\gamma_m) \quad s.t.\ \mu \geq 0, \mu^T e = 1 \tag{23}$$

where

8. In this paper, we say that a matrix G is effectively of rank r if there exists some matrix H of rank r such that for all vectors $\alpha \in \mathcal{A}$ we have $\alpha^T G \alpha = \alpha^T H \alpha$.

$\hat{J}(\mu,\gamma_1,...,\gamma_m) :=$

$$\min_{\alpha\in\mathcal{A}} \left\{ \sum_{u=1}^{l}\sum_{v=1}^{l} \alpha_u\alpha_v y_u y_v \sum_{i=1}^{m} \mu_i G_\beta\left(\|\gamma_i\|\right)\cos(\gamma_i^T(x_u-x_v)) + \mu_0 \sum_{u=1}^{l}\alpha_u^2 \right\}. \tag{24}$$

Problem (23), corresponds to adapting the kernel parameters $\gamma_1,...,\gamma_m$ and $\mu_0,...,\mu_m$ of the kernel function $k(x,z) = \sum_{i=1}^{m}\mu_i\cos(\gamma_i^T(x-z)) + \mu_0\delta(x-z)$ for the task of SVM classification, where δ denotes the Kronecker delta function. This problem has been previously studied by Chapelle et al. (2002) for general kernel functions with unconstrained parameters and they proved that the function $\hat{J}(.)$ is differentiable provided that problem (24) has a unique solution.[9] They also proposed a simple gradient-based iterative algorithm for adapting the kernel parameters. Recently, Rakotomamonjy et al. (2008) performed a more detailed analysis of this problem in MKL and proposed a reduced gradient algorithm with line search. They reasoned that since the computation of the function $\hat{J}$ is costly,[10] the overhead of a line search preserves the effort.

To avoid the difficulties of the constrained optimization, we replace the constrained vector μ by the unconstrained vector ρ, connected by the relation $\mu_i = \frac{\rho_i^2}{\rho^T\rho}$, $i = 0,...m$, and rewrite (23) as the following problem:

$$\max_{\substack{\rho\in\mathbb{R}^{m+1},\\ \gamma_1,...,\gamma_m\in\mathbb{R}^n}} \quad J(\rho,\gamma_1,...,\gamma_m) \tag{25}$$

where

$J(\rho,\gamma_1,...,\gamma_m) :=$

$$\min_{\alpha\in\mathcal{A}} \frac{1}{\rho^T\rho} \left\{ \sum_{u=1}^{l}\sum_{v=1}^{l} \alpha_u\alpha_v y_u y_v \sum_{i=1}^{m} \rho_i^2 G_\beta\left(\|\gamma_i\|\right)\cos(\gamma_i^T(x_u-x_v)) + \rho_0^2 \sum_{u=1}^{l}\alpha_u^2 \right\}. \tag{26}$$

We use the limited-memory BFGS algorithm to numerically solve (25). Our experiments on MKL tasks show that the method proposed in this section is several times fatser than the reduced gradient algorithm of Rakotomamonjy et al. (2008).[11] It has been also stated by Rakotomamonjy et al. (2008) that their method could be improved if the Hessian matrix could be computed efficiently. This is not the case for the problem (25) with $m\times(n+1)$ variables; where, even for moderate size problems, the storage of the Hessian matrix requires lots of memory.

5.5 Solving the Intermediate SVM Problem and Its Gradient

To compute the function $J(.)$ defined by Equation (26), we have to solve the following constrained quadratic programming problem:

9. Truely speaking, the proof should be credited to Danskin (1966).
10. Although the definition of the function J in Rakotomamonjy et al. (2008) differs from (24), computation of both functions corresponds to training a single-kernel SVM.
11. We leave this comparison along with some theoretical results to another paper.

$$\begin{aligned} \min_{\alpha} \quad & \alpha^T \left(\sum_{i=1}^{m} \frac{\rho_i^2}{\rho^T \rho} G(\gamma_i) \right) \alpha + \frac{\rho_0^2}{\rho^T \rho} \alpha^T \alpha \\ s.t. \quad & 0 \leq \alpha \leq C \\ & \alpha^T y = 0 \\ & \alpha^T e = 2. \end{aligned} \tag{27}$$

Although the traditional algorithms for solving quadratic programming problems, such as active set methods, are fast, they need to store the kernel matrix in memory which prevents their application in large-scale problems. So, various algorithms for large-scale training of SVMs, such as SMO (Platt, 1999) or SVM^{Light} (Joachims, 1999), have been proposed. Again, since the effective rank of the kernels $G(\gamma_1), ..., G(\gamma_m)$ is two, we can re-state the problem (27) in a memory efficient manner as:

$$\begin{aligned} \min_{\alpha,c,s} \quad & \frac{\rho_0^2}{\rho^T \rho} \alpha^T \alpha + \sum_{i=1}^{m} \frac{\rho_i^2}{\rho^T \rho} \left(c_i^2 + s_i^2 \right) \\ s.t. \quad & c_i = \sum_{u=1}^{l} \alpha_u y_u \cos(\gamma_i^T x_u) \quad i = 1, ..., m \\ & s_i = \sum_{u=1}^{l} \alpha_u y_u \sin(\gamma_i^T x_u) \quad i = 1, ..., m \\ & 0 \leq \alpha \leq C \\ & \alpha^T y = 0 \\ & \alpha^T e = 2. \end{aligned}$$

In our experiments we have used the optimization software Mosek (Andersen and Andersen, 2000) to solve this problem. After computing the value of the function $J(.)$ and obtaining a solution $\tilde{\alpha}$ to (26), we compute the gradient using the following formulas:

$$\nabla_{\gamma_j} J = \frac{\rho_j^2}{\rho^T \rho} \nabla_{\gamma} \left\{ \tilde{\alpha}^T G(\gamma) \tilde{\alpha} \right\} |_{\gamma = \gamma_j} \quad j = 1, ..., m, \tag{28}$$

$$\nabla_{\rho_j} J = 2 \frac{\rho_j}{\rho^T \rho} \left\{ \tilde{\alpha}^T G(\gamma_j) \tilde{\alpha} - \sum_{i=1}^{m} \frac{\rho_i^2}{(\rho^T \rho)} \tilde{\alpha}^T G(\gamma_i) \tilde{\alpha} - \frac{\rho_0^2}{(\rho^T \rho)} \tilde{\alpha}^T \tilde{\alpha} \right\} \quad j = 1, ..., m. \tag{29}$$

Note that, in general, the computational complexity of computing formulas (28) and (29) is $O(m \times n \times nsv^2)$ as was pointed out by Rakotomamonjy et al. (2008).[12] The following formulas show an $O(m \times (nsv + n))$ method for computing the gradient of function $J(.)$.

$$\begin{aligned} \nabla_{\gamma_j} J &= \frac{\rho_j^2}{\rho^T \rho} \left(c_j^2 + s_j^2 \right) \nabla_{\gamma} G_{\beta}(\|\gamma\|)|_{\gamma = \gamma_j} + 2 \frac{\rho_j^2}{\rho^T \rho} \left(s'_j s_j + c'_j c_j \right) G_{\beta}(\|\gamma_j\|) \quad j = 1, ..., m, \\ \nabla_{\rho_j} J &= 2 \frac{\rho_j}{\rho^T \rho} \left\{ (c_j^2 + s_j^2) G_{\beta}(\|\gamma_j\|) - \sum_{i=1}^{m} \frac{\rho_i^2}{\rho^T \rho} (c_j^2 + s_j^2) G_{\beta}(\|\gamma_j\|) - \frac{\rho_0^2}{\rho^T \rho} \tilde{\alpha}^T \tilde{\alpha} \right\} \quad j = 1, ..., m \end{aligned}$$

where

12. Note that in Rakotomamonjy et al. (2008) the function $J(.)$ has only m variables, while here the number of variables is $m \times (n+1)$.

$$c_j = \sum_{u=1}^{nsv} \tilde{\alpha}_u y_u \cos(\gamma_j^T x_u) \quad j = 1, ..., m,$$
$$s_j = \sum_{u=1}^{nsv} \tilde{\alpha}_u y_u \sin(\gamma_j^T x_u) \quad j = 1, ..., m,$$
$$c'_j = -\sum_{u=1}^{nsv} \tilde{\alpha}_u y_u x_u \sin(\gamma_j^T x_u) \quad j = 1, ..., m,$$
$$s'_j = \sum_{u=1}^{nsv} \tilde{\alpha}_u y_u x_u \cos(\gamma_j^T x_u) \quad j = 1, ..., m.$$

5.6 Convergence Analysis

In this section, we study the convergence properties of Algorithm 1. We hope the contents of this section help the reader to get a better feeling of this algorithm. For any finite or infinite set Γ, we denote the solution of problem $P_\tau(\Gamma)$ by $S(\Gamma)$. Let us first prove a useful lemma.

Lemma 14 *If the loop inside Algorithm 1 is executed for the i'th iteration, then $S(\Gamma_l^{(i)}) = S(\Gamma^{(i)})$. In other words, removing the constraints where their associated Lagrange multipliers are zero, does not change $S(\Gamma_l^{(i)})$.*

Proof Assume that $\Gamma_l^{(i)} = \{\gamma_1, ..., \gamma_m\}$. Without loss of generality, we assume that $\Gamma^{(i)} = \{\gamma_1, ..., \gamma_{m'}\}$, where $m' < m$. Denote the Lagrangian of $P_\tau(\Gamma_l^{(i)})$ by $\mathcal{L}(\alpha, t, \mu, \lambda)$, where $\mu_1, ..., \mu_m$ are the Lagrange multipliers associated with the constraints $\alpha^T G(\gamma_1)\alpha \leq t$, ..., $\alpha^T G(\gamma_m)\alpha \leq t$, respectively, and $\lambda \in \Lambda$ denotes the Lagrange multipliers associated with all other constraints. Since $P_\tau(\Gamma_l^{(i)})$ is convex, by the strong duality we have

$$S(\Gamma_l^{(i)}) = \max_{\mu \geq 0, \lambda \in \Lambda} \min_{\alpha, t} \mathcal{L}(\alpha, t, \lambda, \mu) = \mathcal{L}(\alpha^*, t^*, \lambda^*, \mu^*)$$

where it is assumed that α^*, t^*, λ^*, and μ^* are a solution to problem $S(\Gamma_l^{(i)})$. Since $\mu^*_{m'+1}, ..., \mu^*_m$ are zero, we also have

$$S(\Gamma_l^{(i)}) = \max_{\mu_1 \geq 0, ..., \mu_{m'} \geq 0, \lambda \in \Lambda} \min_{\alpha, t} \mathcal{L}(\alpha, t, \lambda, \mu).$$

Since the strong duality also holds for $P_\tau(\Gamma^{(i)})$, the last expression is equal to $S(\Gamma^{(i)})$ and the lemma follows. ■

Now, we prove that for any $\varepsilon > 0$ the Algorithm 1 converges, even without limiting the maximum number of iterations.

Proposition 15 *The sequence of numbers $t^{(0)}, t^{(1)}, ...$ generated by Algorithm 1 is increasing and bounded.*

Proof By steps 6 and 8 of Algorithm 1, it follows that $S(\Gamma^{(i-1)}) \leq S(\Gamma_s^{(i)})$ and $S(\Gamma_s^{(i)}) \leq S(\Gamma_l^{(i)})$. By Lemma 14, $S(\Gamma_l^{(i)}) = S(\Gamma^{(i)})$. So, $t^{(i-1)} = S(\Gamma^{(i-1)}) \leq S(\Gamma^{(i)}) = t^{(i)}$. By Equation (5) and the fact that $\alpha^T e = 2$, it follows that $\alpha^T \alpha \leq 4$ and $\alpha^T G(\gamma)\alpha \leq 4$ for all choices of α and γ; and thus, the sequence is bounded. ■

Define $g(\alpha,\gamma) := \alpha^T G(\gamma)\alpha$. The following theorem is essentially Theorem 7.2 of Hettich and Kortanek (1993), where its proof is reconstructed here for the sake of completeness.

Theorem 16 *Assume that in every run of step 5 of Algorithm 1 at least one global maximizer of the function $g(\alpha^{(i-1)},\gamma)$ is found and that the steps 10-13 of the algorithm are omitted (Note that the key point is the omission of step 10). Let $\bar{\alpha}$ be any accumulation point of the sequence $\alpha^{(0)},\alpha^{(1)},...$ and assume that $t^{(i)} \nearrow \bar{t}$. Then the pair $(\bar{\alpha},\bar{t})$ is a solution of $P_\tau(\Gamma_\beta)$.*

Proof First note that since $\alpha^{(i)} \in \mathcal{A}$ and $\mathcal{A}$ is compact, a point of accumulation for the sequence $\alpha^{(0)},\alpha^{(1)},...$ always exists. Recall the definition of Ω_β from Section 4.6 and define the function $g(\alpha)$ as:

$$g(\alpha) := \max_{\gamma \in \Omega_\beta} \alpha^T G(\gamma)\alpha$$

For simplicity, assume that $\alpha^{(i)} \to \bar{\alpha}$. Let (α^*,t^*) denote a solution of problem $P_\tau(\Gamma_\beta)$. Clearly $\bar{t} \leq t^*$. If $\bar{t} = t^*$ then the theorem is proved. Assume on the contrary that $\bar{t} < t^*$. Then, there exists $\bar{\gamma} \in \Omega_\beta$ such that $\bar{t} < g(\bar{\alpha},\bar{\gamma}) = g(\bar{\alpha})$. But, since $\bar{\alpha}^T\bar{\alpha} \leq \bar{t}$, it follows that $\bar{\gamma} \in \Gamma_\beta$. For $i = 0,1,...$ choose $\gamma^{(i)} \in \Omega_\beta$ such that $g(\alpha^{(i)},\gamma^{(i)}) = g(\alpha^{(i)})$. We have

$$g(\bar{\alpha}) - \bar{t} = \left[g(\alpha^{(i)}) - \bar{t}\right] + \left[g(\bar{\alpha}) - g(\alpha^{(i)})\right] = \left[g(\alpha^{(i)},\gamma^{(i)}) - \bar{t}\right] + \left[g(\bar{\alpha}) - g(\alpha^{(i)})\right] \tag{30}$$

On the other hand, by omission of step 10 from Algorithm 1, all constraints of the previous iterations will continue to appear in the next iterations. Since $g(\alpha,\gamma)$ is continuous, $\bar{\alpha}$ is a feasible point for all problems $P_\tau(\Gamma^{(i)})$, where $i = 0,1,...,\infty$. Therefore,

$$g(\bar{\alpha},\gamma^{(i)}) \geq \sup_{j=1,...,\infty} t^{(j)} = \bar{t} \quad \text{for all } i = 0,1,... \tag{31}$$

Using (31) in (30) we obtain

$$\begin{aligned} g(\bar{\alpha}) - \bar{t} &= \left[g(\alpha^{(i)},\gamma^{(i)}) - \bar{t}\right] + \left[g(\bar{\alpha}) - g(\alpha^{(i)})\right] \\ &\leq \left[g(\alpha^{(i)},\gamma^{(i)}) - g(\bar{\alpha},\gamma^{(i)})\right] + \left[g(\bar{\alpha}) - g(\alpha^{(i)})\right]. \end{aligned} \tag{32}$$

By continuity of $g(.,.)$, the right hand side of (32) tends to zero, which contradicts the assumption $\bar{t} < g(\bar{\alpha})$. ■

6. Generalizing the Kernel Trick to Complex-valued Kernels

Consider a machine learning algorithm designed for a real-valued Euclidean space. The kernel trick for real-valued kernels states that if all geometric concepts of an algorithm are defined solely based on the dot-product operation, then by replacing all of these dot-products by a kernel function k, we arrive at a version of the very algorithm running in a feature space associated with kernel k. For complex-valued kernels, the dot-product of any two vectors may be complex-valued which makes the application of these kernels to machine learning algorithms more tricky. We now introduce a generalization of the kernel trick for complex-valued kernels. Assume that $k(x,z)$ is a complex-valued kernel. Then there exists at least one complex feature space, say F, and a mapping $\Phi : X \to F$ such that $k(x,z) = \langle \Phi(x), \Phi(z) \rangle_F$. Each axis in the complex feature space F can be substituted by two real-valued axes, one representing the real part and the other the imaginary part. Let us call this real-valued space G. To use the kernel trick, we replace the complex feature space F with the equivalent real feature space G. Now, we show that the dot product between elements of G can be computed by the real-valued kernel function $\Re\{k(x,z)\}$,[13] where $\Re\{z\}$ is the real part of z.

Theorem 17 *Let F be a complex Hilbert space of dimension N (possibly infinite) and G the corresponding $2N$-dimensional Hilbert space obtained by representing real and imaginary parts of F in separate real axes. Then $\langle x', z' \rangle_G = \Re\{\langle x, z \rangle_F\}$, where x' is the $2N$-dimensional vector obtained by concatenating real and imaginary parts of x.*

Proof For finite N we have

$$\begin{aligned}\Re\{\langle x,z\rangle_F\} &= \Re \sum_{i=1}^{N} x_i \bar{z}_i = \Re \sum_{i=1}^{N} (x_i^{re} + j x_i^{im})(z_i^{re} - j z_i^{im}) \\ &= \sum_{i=1}^{N} (x_i^{re} z_i^{re} + x_i^{im} z_i^{im}) = \sum_{i=1}^{2N} x'_i z'_i = \langle x', z' \rangle_G\end{aligned}$$

If F is infinite dimensional, then it has an orthonormal basis (see Kreyszig, 1989 p.168) and x and z can have at most countably many nonzero elements (see Kreyszig, 1989 p.165) which we indicate by index set $\mathfrak{I}$. So,

$$\begin{aligned}\Re\{\langle x,z\rangle_F\} &= \Re \sum_{i\in\mathfrak{I}} x_i \bar{z}_i = \Re \sum_{i\in\mathfrak{I}} (x_i^{re} + j x_i^{im})(z_i^{re} - j z_i^{im}) \\ &= \sum_{i\in\mathfrak{I}} (x_i^{re} z_i^{re} + x_i^{im} z_i^{im}) = \sum_{i\in\mathfrak{I}} x'_i z'_i = \langle x', z' \rangle_G.\end{aligned}$$

■

After fully developing the paper based on the complex-valued form of translation invariant kernels, one of the reviewers introduced us to the real-valued form of these kernels as was discovered by Bochner (1955). He proved that every continuous real-valued translation invariant positive definite kernel in $\mathbb{R}^n$ has the general form

13. The fact that real part of a complex kernel is a real kernel is not new (see Schölkopf and Smola, 2002 page 31). But, as far as we know, the relation between the corresponding Hilbert spaces, as stated in the theorem, is new.

$$k(x,z) = \tilde{k}(x-z) = \int_{\mathbb{R}^n} cos\gamma^T (x-z)\, dV(\gamma).$$

It is interesting that after applying the appropriate kernel trick to both real-valued and complex-valued forms of translation invariant kernels, the optimal kernel is found to be a mixture of cosines.

7. The Method at Runtime

One frequently denounced feature of SVMs is that the resulting classifier has an expansion based on support vectors. Although support vectors are considered to be sparse in the training set, the resulting classifier is usually slower than other competing methods such as neural networks (Schölkopf et al., 1998). In general, the computation of a support vector classifier requires $O(n \times nsv)$ steps. The problem becomes more severe when the kernel function becomes a combination of several kernels, where the computational complexity of evaluating the classifier grows up to $O(m \times n \times nsv)$. For some kernels, such as the Gaussian kernel with isotropic covariance matrix, the computation time can be reduced to $O((m+n) \times nsv)$. Our method has the eminent property that the resulting classifier is not expanded based on support vectors at all. Considering the SVM classifier $f(x) = \sum_{u=1}^{nsv} \alpha_u y_u k(x, x_u) + b$, we have

$$f(x) = \sum_{u=1}^{nsv} \alpha_u y_u k(x,x_u) + b = \sum_{u=1}^{nsv} \alpha_u y_u \left(\sum_{i=1}^{m} \mu_i \cos(\gamma_i^T (x - x_u)) G_\beta(\|\gamma_i\|) \right) + b$$

$$= \sum_{i=1}^{m} \mu_i G_\beta(\|\gamma_i\|) \sum_{u=1}^{nsv} \alpha_u y_u \left(\cos(\gamma_i^T x)\cos(\gamma_i^T x_u) + \sin(\gamma_i^T x)\sin(\gamma_i^T x_u) \right) + b$$

$$= \sum_{i=1}^{m} \mu_i G_\beta(\|\gamma_i\|) \left[\left(\sum_{u=1}^{nsv} \alpha_u y_u \cos(\gamma_i^T x_u) \right) \cos(\gamma_i^T x) + \left(\sum_{u=1}^{nsv} \alpha_u y_u \sin(\gamma_i^T x_u) \right) \sin(\gamma_i^T x) \right] + b.$$

But $\sum_{u=1}^{nsv} \alpha_u y_u \cos(\gamma_i^T x_u)$ and $\sum_{u=1}^{nsv} \alpha_u y_u \sin(\gamma_i^T x_u)$ are constant values. So, the computational complexity of evaluating the classifier of the proposed method is $O(m \times n)$. Note that the classifier has an expansion based on the number of kernels, instead of support vectors. In addition, by Theorem 2, the number of kernels is limited to $l+1$. Furthermore, since the deletion of non-support vector samples from the training set has no effect on the optimal classifier, it follows that $m \leq nsv + 1$. Although, theoretically, the number of kernels can reach the number of support vectors, our experiments show that the number of kernels is usually a fraction of the number of support vectors.

8. A Learning Theory Perspective

A common feature between the class of radial kernels, considered by Micchelli and Pontil (2005), and the class of translation invariant kernels, considered here, is that the kernels of both classes

have the property that $k(x,x) = 1$ for every $x \in \mathbb{R}^n$.[14] Micchelli et al. (2005b) used this feature along with a result from Yiming and Zhou (2007) to obtain a probably approximately correct (PAC) upper bound on the generalization error of their kernel learning framework over the class of radial kernel functions. They concluded that the regularization parameter of a single-kernel learning machine is sufficient for controlling the complexity of the class of radial kernels, rejecting the use of an auxiliary method for controlling the complexity of the class of radial kernels.

But, the situation for translation invariant kernels is completely different. It is well-known that the VC-dimension of the class of cosine functions with arbitrary frequencies is infinite (see Vapnik, 1998, page 160). In addition, the finiteness of the VC-dimension is a necessary and sufficient condition for distribution independent learning of binary classification tasks (see Vapnik, 1998, Theorem 4.5). So, controlling the complexity of the class of translation invariant kernels is a necessary ingredient of our framework. This discussion will be experimentally verified in Section 9, where we will show the vital role of the complexity control mechanism of Section 2.

9. Experimental Results

In this section we report the results of our experiments on several artificial and real-world benchmark data sets. In addition, we will experimentally investigate the role of the complexity control mechanism of Section 2. In all the experiments we have set $C = \infty$, $T_1 = 1000$, $T_2 = 4$, $T_3 = 500$, $G_\beta(\|\gamma\|_2) = \exp(-\beta\|\gamma\|_2^2))$ and the parameter τ is automatically learnt according to Algorithm 1. The implementation of this paper is packaged in the SIKL (Stabilized infinite kernel learning) toolbox and is available at *http://www.mloss.org*. We obtained the implementation of the limited memory BFGS algorithm from the website *http://www.chokkan.org/software/liblbfgs* which is a C++ translation of the original implementation made available by Nocedal in Fortran 77. For limited-memory BFGS algorithm, the 17 most recent curvature information are used and the maximum number of line-search tries is set to 20. We also changed the stopping condition of the algorithm from $\frac{\|\nabla x\|}{\|x\|} < \varepsilon$ to $\|\nabla x\| < \varepsilon$ to avoid the degradation of the accuracy of the global search algorithm for points far from the origin. The QCQP sub-problem of Algorithm 1 and the QP problem of Section 5.5 are solved by the optimization software Mosek (Andersen and Andersen, 2000). All the experiments have been performed on a 2.8GHz Pentium D computer with 2GB memory and running the Linux operating system.

9.1 Experiments on Small-size Benchmark Data Sets

In this section, we report our experiments on the benchmark data sets prepared by Rätsch et al. (2001). This benchmark consists of 13 data sets and there exist 100 splits of each data set into training and test sets. The classification error for each data set is obtained by averaging the classification error over these splits. For this experiment we set $\varepsilon = 0.001$. The comparison is among the following methods:

- **Single Gaussian (SG)** Rätsch et al. (2001) performed experiments with a single isotropic Gaussian kernel. The variance parameter σ of the isotropic Gaussian kernel and the parameter C of the 1-norm soft-margin SVM are optimized by performing 5-fold cross-validation on the first five instances of the training set.

14. In fact, the classes of radial/translation invariant kernel functions contain kernels with arbitrary positive values for $k(x,x)$. But, the constraint $k(x,x) = 1$ is imposed for reasons stated in Section 3.

- **Gaussian Mixture (GM)** A generalization of the method of Gehler and Nowozin (2008) is implemented and used for learning the optimal kernel over the class $\mathcal{K}_\eta$. The number of Gaussian kernels $\bar{m}$, their parameters, and the parameter τ are learnt automatically. The parameter η is set to 0.001 and the parameter C is learnt by performing 5-fold cross validation on the first five instances of the training set.

- **Cosine Mixture (CM)** Here, the method of Section 4.6 is used. The number of cosine kernels m, their parameters, and the parameter τ are learnt automatically. The parameter C is fixed to ∞ and the parameter β is optimized by performing 5-fold cross validation on the first five instances of the training set.

- **Cosine and Gaussian Mixture (CGM)** Here, the method of Section 4.7 is used. The number of cosine kernels m, the number of Gaussian kernels $\bar{m}$, the parameters of cosine and Gaussian kernels, and the parameter τ are learnt automatically. The parameter C is set to ∞ and the parameter η is set to 0.03. The parameter β is optimized by performing 5-fold cross validation on the first five instances of the training set.

To compare the training and evaluation times of these methods, we repeated the experiments of Rätsch et al. (2001) on our machine. For training a single-kernel SVM we used the implementation of SMO algorithm (Platt, 1999) contained in the Statistical Pattern Recognition Toolbox.[15] To keep the results reported by Rätsch et al. (2001) as reference, we neglect the accuracies obtained by the SG method.

Table 2 summarizes the test error rates and training times of the methods on each data set. It can be seen that the GM method has the worst performance and does not provide any improvement over other methods. The only benefit of the GM over SG is that while the latter requires specifying the kernel function by hand, GM learns the kernel function automatically. The SG and CM are the only methods of this experiment that do not store the kernel matrices in memory; and thus are applicable to large-scale problems. In addition, they have also the best training times. To our surprise, although the CM method solves a musch more difficult problem than SG, it has also improved the training time in some data sets. Considering the test error rates, the CGM method has the best overall performance. But, the SG method on the *F.Solar* data set, and CM method on the *Thyroid* data set provide significantly better results. For the *Ringnorm* data set, the CM method has obtained a high error rate of 8.5%. Interestingly, the number of training and testing samples of the *Ringnorm* data set are exactly equal to the *Twonorm* data set, for which the CM method has even improved the accuracy. The essential difference between the *Twonorm* and the *Ringnorm* data sets, where in both data sets each class has a multivariate normal distribution, is that in the *Twonorm* data set the classes have separate means, whilst in the *Ringnorm* data set the classes have separate covariance matrices. So, it seems that the Gaussian kernel is inherently much more suitable for solving the *Ringnorm* data set than the cosine kernel. In fact, this is exactly why combining several kernels is important. By combining the cosine and Gaussian kernels, the CGM method provides the best performance.

Table 3 compares the methods in terms of the evaluation time. For each method, the factors that influence the evaluation time are also reported. As can be seen, except for the *Ringnorm* data set, the CM is significantly faster at run-time than all other methods, including a classical SVM with Gaussian kernel. The best speedup is for the *Twonorm* data set for which, in addition to a lower test

9.2 Experiments on the USPS Data Set

In this section, we show the applicability of the proposed method[16] to a real-world digit recognition problem. We consider the problem of classifying digits 0-4 against 5-9 on the USPS handwritten digit recognition data set as considered by Chapelle et al. (2002) for evaluating their kernel learning method. This data set consists of 7291 training examples and 2007 test examples of digit images of size 16×16. With polynomial kernel and 256 scaling factors, Chapelle et al. (2002) were able to get a test error rate of 9.0%. We trained the proposed method with the parameters $\varepsilon = 0.001$, and $\beta = 3.0$. After two hours of training, the algorithm produced a model with 244 cosine kernels and 790 support vectors. It took 1.3 of a second to test the model on the 2007 test samples and we obtained a test error rate of 3.4% which is significantly better than the 9.0% result reported by Chapelle et al. (2002). Figure 1 shows the evolution of the values m, nsv, $t^{(i)}$, $s^{(i)}$, training error, and test error during training of the USPS data set, where $s^{(i)}$ and $t^{(i)}$ are defined in Algorithm 1.

9.3 Experiments on the MNIST Data Set

While many algorithms for kernel learning consider the combination of a finite number of kernels, learning translation invariant kernels corresponds to combining an infinite number of kernels. In

16. From this section onward, the proposed method refers to the cosine mixture method.

this section, we compare the proposed algorithm with the DC method proposed by Argyriou et al. (2006) which is based on the theory developed by Micchelli and Pontil (2005). They considered the problem of finding an optimal kernel over the whole class of radial kernels which is equivalent to the problem of learning the best convex combination of Gaussian kernels with isotropic covariance matrices.

Argyriou et al. (2006) performed a series of experiments on the MNIST data set by using the first 500 training examples for training and the first 1000 test examples for evaluation. The MNIST data set contains 28×28 images of handwritten digits which are divided into 60,000 training and 10,000 test examples. In addition, the results reported by the DC method have been obtained by splitting each image into four sub-images which is a use of extra information. In the first experiment, we use the first $3,000$ training examples[17] for training both systems and evaluate them on the whole test set. As Argyriou et al. (2006), we consider the tasks of classifying digits 3 vs. 8, 4 vs. 7, and odds vs. evens. We downloaded the implementation of the DC method from *http://www.cs.ucl.ac.uk/staff/a.argyriou/code/dc* and chose the range $[75, 25000]$ for the parameter σ of the Gaussian kernel which is the largest range considered by Argyriou et al. (2006). The parameter μ of the DC method and the parameter β of the CM method were optimized by hand. The parameter ε was set to the value 0.001. The first three rows of Table 4 show the results of this experiment. It can be seen that the main benefit of the DC method is its short training time, while the CM method has superiority in terms of the evaluation time.

Another remarkable feature of the CM method is its applicability to large-scale problems. To illustrate this fact, we increased the size of the training set of the previous experiments from $3,000$ to $10,000$. We also increased the parameter ε from 0.001 to 0.01 to decrease the training time. The DC method could not handle this size of training samples and ran out of memory. The last three rows and columns of Table 4 show the results of the experiments with the CM method. Figure 2 depicts the evolution of the values m, nsv, $t^{(i)}$, $s^{(i)}$, training error, and test error during training of CM algorithm on the ods vs even task with $10,000$ training samples. Note that the model produced by the CM method on the larger training set is more accurate and faster-to-evaluate than the best model that the DC algorithm could produce. We think that the capabilities of the CM method and DC method are complementary. The DC method works with full-rank matrices, is not large-scale, converges fast, and its model takes more time to compute. On the other hand, the CM method works with low-rank matrices, is large-scale, converges slowly, and its model can be evaluated very fast. One open problem is that whether these methods can be combined in a way that the benefits of both methods are achieved.

9.4 Assessing the Effect of the Proposed Complexity Control Mechanism

In Section 8 we provided theoretical support for the necessity of controlling the complexity of the class of translation invariant kernels. Here we support this claim by experimenting on the *Heart* data set chosen from the benchmark produced by Rätsch et al. (2001). This data set contains 170 train patterns and 100 test patterns of dimension 13. The experiments of the previous section show that the proposed method was completely successful in obtaining a low test error rate on this data set. In addition, the mean error rate of the proposed method on the train set is 14.0% which is close to the mean error rate of 15.5% obtained on the test set. The left plot of Figure 3 illustrates the trajectories of the train and test errors of the proposed method during training on the *Heart* data set.

17. This is approximately the largest possible train-set size where the DC method did not ran out of memory.

Data Set		DC method			Cosine mixture		
Task	**#tr**	**error** (%)	**train** (*min*)	**test** (*sec*)	**error** (%)	**train** (*min*)	**test** (*sec*)
odd vs even	3000	3.1	11	60.1	3.2	37	10.1
3 vs 8	3000	0.7	9	24.8	0.8	192	2.6
4 vs 7	3000	0.4	16	26.1	0.5	122	2.5
odd vs even	10000	-	-	-	2.0	63	9.1
3 vs 8	10000	-	-	-	0.4	1133	5.3
4 vs 7	10000	-	-	-	0.2	649	3.1

Table 4: Test errors of the proposed method (CM) and the DC method on different tasks on the MNIST data set. The dash sign indicates running out of memory.

In another experiment we disabled our complexity control mechanism by setting $\beta = 10^{-6}$ and instead tried to control the capacity of the learning machine by adjusting the parameter C.[18] We optimized the parameter C using the 5-fold cross-validation method described in the previous section. After testing on all the 100 splits of the *Heart* data set we obtained a mean test error rate of 20.8% and a mean train error rate of 17.4%. The right plot of Figure 3 illustrates the trajectories of the train and test error rates of this experiment on the *Heart* data set. This experiment confirms the usefulness of controlling the complexity of the class of translation invariant kernels, as was claimed in Section 8.

10. Conclusions

In this paper we addressed the problem of learning a translation invariant kernel function for the task of binary classification with SVM. We proposed a mechanism for controlling the complexity of the class of translation invariant kernels which was found to be very useful in practice. The criterion proposed by Lanckriet et al. (2004) was modified to ensure the compactness of the parameter space of SVM and to give a probabilistic meaning to the regularization parameter of the 2-norm SVM. We then introduced a semi-infinite programming formulation of the problem. The proposed method can automatically learn the regularization parameter of the 2-norm SVM, as well. We have also shown that how other classes of kernels can be included in the learning process. To numerically solve the SIP problem on a computer, we introduced a large-scale algorithm which is applicable to problems with both huge number of training samples and large number of features. Since the optimal translation invariant kernel is complex-valued, we then introduced a method for applying the kernel trick to complex-valued kernels. It revealed that the optimal translation invariant kernel is a mixture of cosine kernels. An interesting feature of the proposed method is that there is a very fast way for evaluating the classifier at run-time. While an ordinary MKL algorithm with m kernels requires $O(m \times nsv \times n)$ steps for computing the classifier, the optimal classifier of the proposed method can be computed in $O(m \times n)$ steps.

In continuation of this work, we plan to extend it in several directions. First, we intend to generalize the proposed kernel learning method from binary classification to other learning problems, including regression, multiclass classification, clustering, and kernel PCA. Second, we will try to propose a novel large-scale algorithm that combines the benefits of the full-rank Gaussian and the

18. Setting $\beta = 0$ (exactly) allowed the global search algorithm to find points at infinity which caused problems.

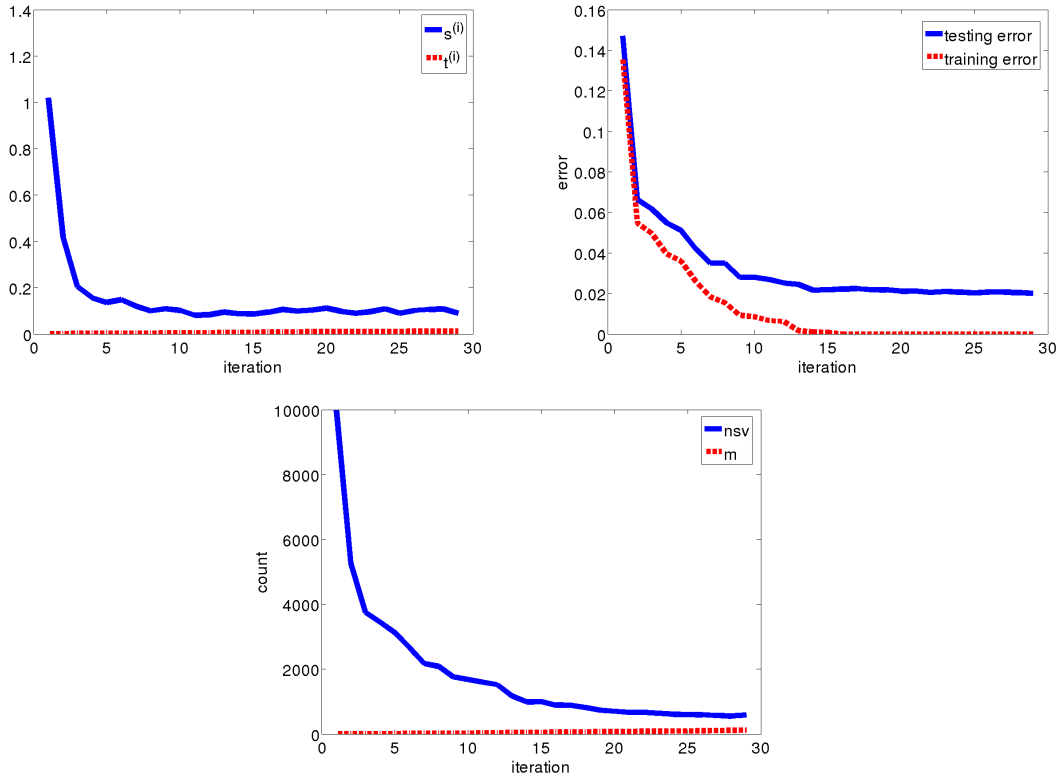

Figure 2: Evolution of the values $m, nsv, t^{(i)}, s^{(i)}$, training error, and testing error during training of the proposed method with the first 10,000 samples of the MNIST data set for the task of classifying odds vs. evens.

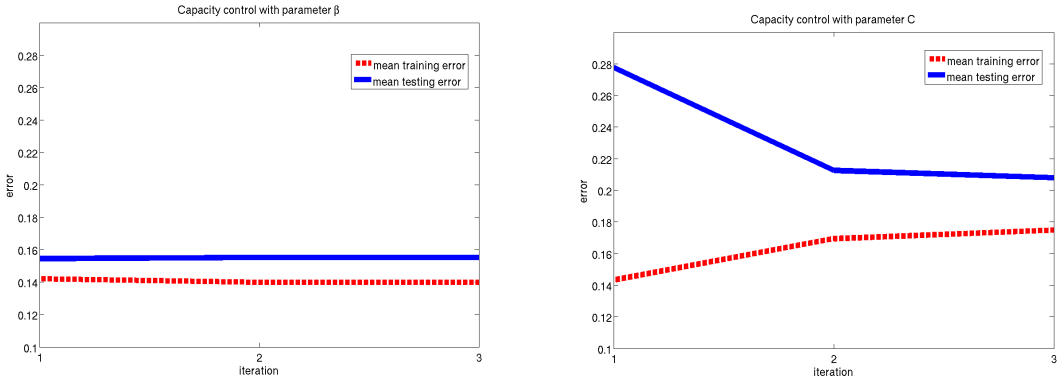

Figure 3: Comparison between the parameters β and C for controlling the capacity of the class of translation invariant kernels on the *Heart* data set.

low-rank cosine kernels. Third, we intend to investigate the applicability of the idea of Xu et al. (2008) about adding a regularization term that smoothes the fluctuating behaviour of SILP algorithms, to the proposed SIP algorithm. We hope that this study would greatly decrease the training time of the proposed method. Another direction is to support the complexity control mechanism of Section 2 by introducing upper bounds for the generalization error of the proposed method. Our long time plan is to investigate the use of other low-rank kernels and make it a competing popular technology.

Acknowledgments

The first author would like to thank professor Abdolhamid Riazi for allowing him to participate in his functional analysis class and helping him to get acquainted with the concepts of this graduate course. We also want to thank Stephen Boyd, Andreas Argoriou, and Peter Gehler for providing us with their valuable materials.

Abstract

Three simple and explicit procedures for testing the independence of two multi-dimensional random variables are described. Two of the associated test statistics (L_1, log-likelihood) are defined when the empirical distribution of the variables is restricted to finite partitions. A third test statistic is defined as a kernel-based independence measure. Two kinds of tests are provided. Distribution-free strong consistent tests are derived on the basis of large deviation bounds on the test statistics: these tests make almost surely no Type I or Type II error after a random sample size. Asymptotically α-level tests are obtained from the limiting distribution of the test statistics. For the latter tests, the Type I error converges to a fixed non-zero value α, and the Type II error drops to zero, for increasing sample size. All tests reject the null hypothesis of independence if the test statistics become large. The performance of the tests is evaluated experimentally on benchmark data.

Keywords: hypothesis test, independence, L1, log-likelihood, kernel methods, distribution-free consistent test

1. Introduction

Consider a sample of $\mathbb{R}^d \times \mathbb{R}^{d'}$-valued random vectors $(X_1,Y_1),\ldots,(X_n,Y_n)$ with independent and identically distributed (i.i.d.) pairs defined on the same probability space. The distribution of (X,Y) is denoted by ν, while μ_1 and μ_2 stand for the distributions of X and Y, respectively. We are interested in testing the null hypothesis that X and Y are independent,

$$\mathcal{H}_0 : \nu = \mu_1 \times \mu_2, \tag{1}$$

while making minimal assumptions regarding the distribution.

We consider two main approaches to independence testing. The first is to partition the underlying space, and to evaluate the test statistic on the resulting discrete empirical measures. Consistency of the test must then be verified as the partition is refined for increasing sample size. Previous multivariate hypothesis tests in this framework, using the L_1 divergence measure, include homogeneity tests (to determine whether two random variables have the same distribution), by Biau and Györfi

*. Also at Carnegie Mellon University, Pittsburgh, PA, USA.

(2005); and goodness-of-fit tests (for whether a random variable has a particular distribution), by Györfi and van der Meulen (1990); Beirlant et al. (1994). The log-likelihood has also been employed on discretised spaces as a statistic for goodness-of-fit testing, by Györfi and Vajda (2002). We provide generalizations of both the L_1 and log-likelihood based tests to the problem of testing independence, representing to our knowledge the first application of these techniques to independence testing.

We obtain two kinds of tests for each statistic: first, we derive *strong consistent* tests—meaning that both on $\mathcal{H}_0$ and on its complement the tests make a.s. no error after a random sample size[1]—based on large deviation bounds. While such tests are not common in the classical statistics literature, they are well suited to data analysis from streams, where we receive a sequence of observations rather than a sample of fixed size, and must return the best possible decision at each time using only current and past observations. Our strong consistent tests are *distribution-free*, meaning they require no conditions on the distribution being tested; and *universal*, meaning the test threshold holds independent of the distribution. Second, we obtain tests based on the asymptotic distribution of the L_1 and log-likelihood statistics, which assume only that ν is nonatomic. Subject to this assumption, the tests are *consistent*: for a given asymptotic error rate on $\mathcal{H}_0$, the probability of error on $\mathcal{H}_1$ drops to zero as the sample size increases. Moreover, the thresholds for the asymptotic tests are distribution-independent. We also present conjectures regarding the form taken by strong consistent and asymptotic tests based on the Pearson χ^2 statistic, using the goodness-of-fit results of Györfi and Vajda (2002) (further related test statistics include the power divergence family of Read and Cressie, 1988, although we do not study them here). We emphasize that our tests are explicit, easy to carry out, and require very few assumptions on the partition sequences.

Our second approach to independence testing is kernel-based. In this case, our test statistic has a number of different interpretations: as an L_2 distance between Parzen window estimates (Rosenblatt, 1975), as a smoothed difference between empirical characteristic functions (Feuerverger, 1993; Kankainen, 1995; Ushakov, 1999), or as the Hilbert-Schmidt norm of a cross-covariance operator mapping between functions of the random variables (Gretton et al., 2005a, 2008). Each test differs from the others regarding the conditions on the kernels: the Parzen window statistic requires the kernel bandwidth to decrease with increasing sample size, and has a different limiting distribution to the remaining two statistics; while the Hilbert-Schmidt approach uses a fixed bandwidth, and can be thought of as a generalization of the characteristic function-based test. We provide two new results: a strong consistent test of independence based on a tighter large deviation bound than that of Gretton et al. (2005a), and an empirical comparison of the limiting distributions of the kernel-based statistic for fixed and decreasing kernel bandwidth, as used in asymptotic tests.

Additional independence testing approaches also exist in the statistics literature. For $d = d' = 1$, an early nonparametric test for independence, due to Hoeffding (1948); Blum et al. (1961), is based

1. In other words, denoting by $\mathbf{P}_0$ (*resp*. $\mathbf{P}_1$) the probability under the null hypothesis (*resp*. under the alternative), we have

$$\mathbf{P}_0\{\text{rejecting } \mathcal{H}_0 \text{ for only finitely many } n\} = 1 \tag{2}$$

and

$$\mathbf{P}_1\{\text{accepting } \mathcal{H}_0 \text{ for only finitely many } n\} = 1. \tag{3}$$

This concept relates to the definition of discernability introduced by Dembo and Peres (1994): two ensembles $\mathcal{H}_0$ and $\mathcal{H}_1$ of probability measures on $\mathbb{R}^k$ are said to be discernible if there exists a sequence $f_n : (\mathbb{R}^k)^n \to \{0,1\}$ of Borel measurable functions achieving (2) and (3). Thus our test implies discernability of the set $\mathcal{H}_0$ in (1) and the set $\mathcal{H}_1$ of dependent random variables.

on the notion of differences between the joint distribution function and the product of the marginals. The associated independence test is consistent under appropriate assumptions. Two difficulties arise when using this statistic in a test, however. First, quantiles of the null distribution are difficult to estimate. Second, and more importantly, the quality of the empirical distribution function estimates becomes poor as the dimensionality of the spaces $\mathbb{R}^d$ and $\mathbb{R}^{d'}$ increases, which limits the utility of the statistic in a multivariate setting. Further approaches to independence testing can be employed when particular assumptions are made on the form of the distributions, for instance that they should exhibit symmetry. We do not address these approaches in the present study.

The current work is built on an earlier presentation by Gretton and Györfi (2008). Compared with this earlier work, the present study contains more detailed proofs of the main theorems, proofs of secondary theorems omitted by Gretton and Györfi (2008) due to space constraints, additional experiments on higher dimensional benchmark data, and an experimental comparison with the bootstrap approach for the L_1 and log-likelihood based tests (a similar comparison for the kernel-based test was made by Gretton et al., 2008).

The paper is organized as follows. Section 2 describes the large deviation and limit distribution properties of the L_1-test statistic. The large deviation result is used to formulate a distribution-free strong consistent test of independence, which rejects the null hypothesis if the test statistic becomes large. The limit distribution is used in an asymptotically α-level test, which is consistent when the distribution is nonatomic. Both a distribution-free strong consistent test and an asymptotically α-level test are presented for the log-likelihood statistic in Section 3. Section 4 contains a review of kernel-based independence statistics, and describes the associated hypothesis tests for both the fixed-bandwidth and variable-bandwidth cases. Finally, a numerical comparison between the tests is given in Section 5.

2. L_1-based Statistic

Denote by ν_n, $\mu_{n,1}$ and $\mu_{n,2}$ the empirical measures associated with the samples $(X_1,Y_1),\dots,(X_n,Y_n)$, $X_1,\dots,X_n$, and $Y_1,\dots,Y_n$, respectively, so that

$$\begin{aligned}\nu_n(A\times B) &= n^{-1}\#\{i : (X_i,Y_i)\in A\times B, i=1,\dots,n\},\\ \mu_{n,1}(A) &= n^{-1}\#\{i : X_i\in A, i=1,\dots,n\}, \quad \text{and}\\ \mu_{n,2}(B) &= n^{-1}\#\{i : Y_i\in B, i=1,\dots,n\},\end{aligned}$$

for any Borel subsets A and B. Given the finite partitions $\mathcal{P}_n = \{A_{n,1},\dots,A_{n,m_n}\}$ of $\mathbb{R}^d$ and $Q_n = \{B_{n,1},\dots,B_{n,m_n'}\}$ of $\mathbb{R}^{d'}$, we define the L_1 test statistic comparing ν_n and $\mu_{n,1}\times\mu_{n,2}$ as

$$L_n(\nu_n,\mu_{n,1}\times\mu_{n,2}) = \sum_{A\in\mathcal{P}_n}\sum_{B\in Q_n}|\nu_n(A\times B)-\mu_{n,1}(A)\cdot\mu_{n,2}(B)|.$$

In the following two sections, we derive the large deviation and limit distribution properties of this L_1 statistic, and the associated independence tests.
