Editor: Stefan Wrobel

Abstract

We present a general method for explaining individual predictions of classification models. The method is based on fundamental concepts from coalitional game theory and predictions are explained with contributions of individual feature values. We overcome the method's initial exponential time complexity with a sampling-based approximation. In the experimental part of the paper we use the developed method on models generated by several well-known machine learning algorithms on both synthetic and real-world data sets. The results demonstrate that the method is efficient and that the explanations are intuitive and useful.

Keywords: data postprocessing, classification, explanation, visualization

1. Introduction

Acquisition of knowledge from data is the quintessential task of machine learning. The data are often noisy, inconsistent, and incomplete, so various preprocessing methods are used before the appropriate machine learning algorithm is applied. The knowledge we extract this way might not be suitable for immediate use and one or more *data postprocessing* methods could be applied as well. Data postprocessing includes the integration, filtering, evaluation, and *explanation* of acquired knowledge. The latter is the topic of this paper.

To introduce the reader with some of the concepts used in this paper, we start with a simple illustrative example of an explanation for a model's prediction (see Fig. 1). We use Naive Bayes because its prediction can, due to the assumption of conditional independence, easily be transformed into *contributions of individual feature values* - a vector of numbers, one for each feature value, which indicates how much each feature value contributed to the Naive Bayes model's prediction. This can be done by simply applying the logarithm to the model's equation (see, for example, Kononenko and Kukar, 2007; Becker et al., 1997).

In our example, the contributions of the three feature values can be interpreted as follows. The prior probability of a Titanic passenger's survival is 32% and the model predicts a 67% chance of survival. The fact that this passenger was female is the sole and largest contributor to the increased chance of survival. Being a passenger from the third class and an adult both speak against survival, the latter only slightly. The actual class label for this instance is "yes", so the classification is correct. This is a trivial example, but providing the end-user with such an explanation on top of a prediction, makes the prediction easier to understand and to trust. The latter is crucial in situations

where important and sensitive decisions are made. One such example is medicine, where medical practitioners are known to be reluctant to use machine learning models, despite their often superior performance (Kononenko, 2001). The inherent ability of explaining its decisions is one of the main reasons for the frequent use of the Naive Bayes classifier in medical diagnosis and prognosis (Kononenko, 2001). The approach used to explain the decision in Fig. 1 is specific to Naive Bayes, but *can we design an explanation method which works for any type of classifier?* In this paper we address this question and propose a method for explaining the predictions of classification models, which can be applied to any classifier in a *uniform way*.

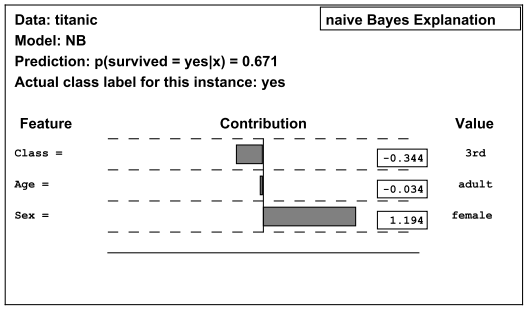

Figure 1: An instance from the well-known Titanic data set with the Naive Bayes model's prediction and an explanation in the form of contributions of individual feature values. A copy of the Titanic data set can be found at http://www.ailab.si/orange/datasets.psp.

1.1 Related Work

Before addressing *general* explanation methods, we list a few *model-specific* methods to emphasize two things. First, most models have model-specific explanation methods. And second, providing an explanation in the form of contributions of feature values is a common approach. Note that many more model-specific explanation methods exist and this is far from being a complete reference. Similar to Naive Bayes, other machine learning models also have an inherent explanation. For example, a decision tree's prediction is made by following a decision rule from the root to the leaf, which contains the instance. Decision rules and Bayesian networks are also examples of transparent classifiers. Nomograms are a way of visualizing contributions of feature values and were applied to Naive Bayes (Možina et al., 2004) and, in a limited way (linear kernel functions), to SVM (Jakulin et al., 2005). Other related work focusses on explaining the SVM model, most recently in the form of visualization (Poulet, 2004; Hamel, 2006) and rule-extraction (Martens et al., 2007). The ExplainD framework (Szafron et al., 2006) provides explanations for additive classifiers in the form of contributions. Breiman provided additional tools for showing how individual features contribute to the predictions of his Random Forests (Breiman, 2001). The explanation and interpretation of artificial neural networks, which are arguably one of the least transparent models, has also received a lot of attention, especially in the form of rule extraction (Towell and Shavlik, 1993; Andrews et al., 1995; Nayak, 2009).

So, *why do we even need a general explanation method?* It is not difficult to think of a reasonable scenario where a general explanation method would be useful. For example, imagine a user using a classifier and a corresponding explanation method. At some point the model might be replaced with a better performing model of a different type, which usually means that the ex-

planation method also has to be modified or replaced. The user then has to invest time and effort into adapting to the new explanation method. This can be avoided by using a general explanation method. Overall, a good general explanation method reduces the dependence between the user-end and the underlying machine learning methods, which makes work with machine learning models more user-friendly. This is especially desirable in commercial applications and applications of machine learning in fields outside of machine learning, such as medicine, marketing, etc. An effective and efficient general explanation method would also be a useful tool for comparing how a model predicts different instances and how different models predict the same instance.

As far as the authors are aware, there exist two other general explanation methods for explaining a model's prediction: the work by Robnik-Šikonja and Kononenko (2008) and the work by Lemaire et al. (2008). While there are several differences between the two methods, both explain a prediction with contributions of feature values and both use the same basic approach. A feature value's contribution is defined as the difference between the model's initial prediction and its average prediction across perturbations of the corresponding feature. In other words, we look at how the prediction would change if we "ignore" the feature value. This myopic approach can lead to serious errors if the feature values are conditionally dependent, which is especially evident when a disjunctive concept (or any other form of redundancy) is present. We can use a simple example to illustrate how these methods work. Imagine we ask someone who is knowledgeable in boolean logic *What will the result of (*1 *OR* 1*) be?*. It will be one, of course. Now we mask the first value and ask again *What will the result of (something OR* 1*) be?*. It will still be one. So, it does not matter if the person knows or does not know the first value - the result does not change. Hence, we conclude that the first value is irrelevant for that persons decision regarding whether the result will be 1 or 0. Symmetrically, we can conclude that the second value is also irrelevant for the persons decision making process. Therefore, both values are irrelevant. This is, of course, an incorrect explanation of how these two values contribute to the persons decision.

Further details and examples of where existing methods would fail can be found in our previous work (Štrumbelj et al., 2009), where we suggest observing the changes across all possible subsets of features values. While this effectively deals with the shortcomings of previous methods, it suffers from an exponential time complexity.

To summarize, we have existing general explanation methods, which sacrifice a part of their effectiveness for efficiency, and we know that generating effective contributions requires observing the power set of all features, which is far from efficient. The contribution of this paper and its improvement over our previous work is twofold. First, we provide a rigorous theoretical analysis of our explanation method and link it with known concepts from game theory, thus formalizing some of its desirable properties. And second, we propose an efficient sampling-based approximation method, which overcomes the exponential time complexity and does not require retraining the classifier.

The remainder of this paper is organized as follows. Section 2 introduces some basic concepts from classification and coalitional game theory. In Section 3 we provide the theoretical foundations, the approximation method, and a simple illustrative example. Section 4 covers the experimental part of our work. With Section 5 we conclude the paper and provide ideas for future work.

2. Preliminaries

First, we introduce some basic concepts from classification and coalitional game theory, which are used in the formal description of our explanation method.

2.1 Classification

In machine learning classification is a form of supervised learning where the objective is to predict the *class label* for unlabelled input instances, each described by feature values from a *feature space*. Predictions are based on background knowledge and knowledge extracted (that is, learned) from a sample of labelled instances (usually in the form of a training set).

Definition 1 *The feature space $\mathcal{A}$ is the cartesian product of n features (represented with the set $N = \{1,2,...,n\}$): $\mathcal{A} = A_1 \times A_2 \times ... \times A_n$, where each feature A_i is a finite set of feature values.*

Remark 1 *With this definition of a feature space we limit ourselves to finite (that is, discrete) features. However, we later show that this restriction does not apply to the approximation method, which can handle both discrete and continuous features.*

To formally describe situations where feature values are ignored, we define a subspace $\mathcal{A}_S = A'_1 \times A'_2 \times ... \times A'_n$, where $A'_i = A_i$ if $i \in S$ and $A'_i = \{\varepsilon\}$ otherwise. Therefore, given a set $S \subset N$, $\mathcal{A}_S$ is a feature subspace, where features not in S are "ignored" ($\mathcal{A}_N = \mathcal{A}$). Instances from a subspace have one or more components unknown as indicated by ε. Now we define a classifier.

Definition 2 *A classifier, f, is a mapping from a feature space to a normalized $|C|$-dimensional space $f : \mathcal{A} \to [0,1]^{|C|}$, where C is a finite set of labels.*

Remark 2 *We use a more general definition of a classifier to include classifiers which assign a rank or score to each class label. However, in practice, we mostly deal with two special cases: classifiers in the traditional sense (for each vector, one of the components is 1 and the rest are 0) and probabilistic classifiers (for each vector, the vector components always add up to 1 and are therefore a probability distribution over the class label state space).*

2.2 Coalitional Game Theory

The following concepts from coalitional game theory are used in the formalization of our method, starting with the definition of a coalitional game.

Definition 3 *A coalitional form game is a tuple $\langle N, v \rangle$, where $N = \{1,2,...,n\}$ is a finite set of n players, and $v : 2^N \to \Re$ is a characteristic function such that $v(\varnothing) = 0$.*

Subsets of N are *coalitions* and N is referred to as the *grand coalition* of all players. Function v describes the *worth* of each coalition. We usually assume that the grand coalition forms and the goal is to split its worth $v(N)$ among the players in a "fair" way. Therefore, the *value* (that is, solution) is an operator ϕ which assigns to $\langle N, v \rangle$ a vector of payoffs $\phi(v) = (\phi_1, ..., \phi_n) \in \Re^n$. For each game with at least one player there are infinitely many solutions, some of which are more "fair" than others. The following four statements are attempts at axiomatizing the notion of "fairness" of a solution ϕ and are key for the axiomatic characterization of the Shapley value.

Axiom 1 $\sum_{i \in N} \phi_i(v) = v(N)$. *(efficiency axiom)*

Axiom 2 *If for two players i and j $v(S \cup \{i\}) = v(S \cup \{j\})$ holds for every S, where $S \subset N$ and $i, j \notin S$, then $\phi_i(v) = \phi_j(v)$). (symmetry axiom)*

Axiom 3 *If $v(S\cup\{i\}) = v(S)$ holds for every S, where $S \subset N$ and $i \notin S$, then $\phi_i(v) = 0$. (dummy axiom)*

Axiom 4 *For any pair of games $v, w : \phi(v+w) = \phi(v) + \phi(w)$, where $(v+w)(S) = v(S) + w(S)$ for all S. (additivity axiom)*

Theorem 1 *For the game $\langle N, v\rangle$ there exists a unique solution ϕ, which satisfies axioms 1 to 4 and it is the Shapley value:*

$$Sh_i(v) = \sum_{S\subseteq N\setminus\{i\}, s=|S|} \frac{(n-s-1)!s!}{n!}(v(S\cup\{i\}) - v(S)), \quad i = 1,...,n.$$

Proof For a detailed proof of this theorem refer to Shapley's paper (1953). ■

The Shapley value has a wide range of applicability as illustrated in a recent survey paper by Moretti and Patrone (2008), which is dedicated entirely to this unique solution concept and its applications. From the few applications of the Shapley value in machine learning, we would like to bring to the readers attention the work of Keinan et al. (2004), who apply the Shapley value to function localization in biological and artificial networks. Their MSA framework is later used and adapted into a method for feature selection (Cohen et al., 2007).

3. Explaining Individual Predictions

In this section we provide the theoretical background. We start with a description of the intuition behind the method and then link it with coalitional game theory.

3.1 Definition of the Explanation Method

Let $N = \{1,2,...,n\}$ be a set representing n features, f a classifier, and $x = (x_1, x_2, ..., x_n) \in \mathcal{A}$ an instance from the feature space. First, we choose a class label. We usually chose the predicted class label, but we may choose any other class label that is of interest to us and explain the prediction from that perspective (for example, in the introductory example in Fig. 1 we could have chosen "survival = no" instead). Let c be the chosen class label and let $f_c(x)$ be the prediction component which corresponds to c. Our goal is to explain how the given feature values contribute to the *prediction difference* between the classifiers prediction for this instance and the expected prediction if no feature values are given (that is, if all feature values are "ignored"). The prediction difference can be generalized to an arbitrary subset of features $S \subseteq N$.

Definition 4 *The prediction difference $\Delta(S)$ when only values of features represented in S are known, is defined as follows:*

$$\Delta(S) = \frac{1}{|\mathcal{A}_{N\setminus S}|}\sum_{y\in\mathcal{A}_{N\setminus S}} f_c(\tau(x,y,S)) - \frac{1}{|\mathcal{A}_N|}\sum_{y\in\mathcal{A}_N} f_c(y), \tag{1}$$

$$\tau(x,y,S) = (z_1, z_2, ..., z_n), \quad z_i = \begin{cases} x_i & ; \quad i \in S \\ y_i & ; \quad i \notin S. \end{cases}$$

Remark 3 *In our previous work (Štrumbelj et al., 2009) we used a different definition:* $\Delta(S) = f_c^*(S) - f_c^*(\varnothing)$*, where* $f^*(W)$ *is obtained by retraining the classifier only on features in* W *and re-classifying the instance (similar to the wrappers approach in feature selection Kohavi and John 1997). With this retraining approach we avoid the combinatorial explosion of going through all possible perturbations of "ignored" feature's values, but introduce other issues. However, the exponential complexity of going through all subsets of* N *still remains.*

The expression $\Delta(S)$ is the difference between the expected prediction when we know only those values of x, whose features are in S, and the expected prediction when no feature values are known. Note that we assume uniform distribution of feature values. Therefore, we make no assumption about the prior relevance of individual feature values. In other words, we are equally interested in each feature value's contribution. The main shortcoming of existing general explanation methods is that they do not take into account all the potential dependencies and interactions between feature values. To avoid this issue, we implicitly define interactions by defining that each prediction difference $\Delta(S)$ is composed of 2^N contributions of interactions (that is, each subset of feature values might contribute something):

$$\Delta(S) = \sum_{W \subseteq S} I(W), \quad S \subseteq N. \tag{2}$$

Assuming $I(\varnothing) = 0$ (that is, an interaction of nothing always contributes 0) yields a recursive definition. Therefore, function I, which describes the interactions, always exists and is uniquely defined for a given N and function Δ:

$$I(S) = \Delta(S) - \sum_{W \subset S} I(W), \quad S \subseteq N. \tag{3}$$

Now we distribute the interaction contributions among the n feature values. For each interaction the involved feature values can be treated as equally responsible for the interaction as the interaction would otherwise not exist. Therefore, we define a feature value's contribution φ_i by assigning it an equal share of each interaction it is involved in

$$\varphi_i(\Delta) = \sum_{W \subseteq N \setminus \{i\}} \frac{I(W \cup \{i\})}{|W \cup \{i\}|}, \quad i = 1,2,...,n. \tag{4}$$

It is not surprising that we manage in some way to uniquely quantify all the possible interactions, because we explore the entire power set of the involved feature values. So, two questions arise: *Can we make this approach computationally feasible?* and *What are the advantages of this approach over other possible divisions of contributions?*. We now address both of these issues, starting with the latter.

Theorem 2 $\langle N = \{1,2,...,n\}, \Delta \rangle$ *is a coalitional form game and* $\varphi(\Delta) = (\varphi_1, \varphi_2, ..., \varphi_n)$ *corresponds to the game's Shapley value* $Sh(\Delta)$.

Proof Following the definition of Δ we get that $\Delta(\varnothing) = 0$, so the explanation of the classifier's prediction can be treated as a coalitional form game $\langle N, \Delta \rangle$. Now we provide an elementary proof that the contributions of individual feature values correspond to the Shapley value for the game

$\langle N, \Delta \rangle$. The recursive definition of I given in Eq. (3) can be transformed into its non-recursive form:

$$I(S) = \sum_{W \subseteq S} ((-1)^{|S|-|W|} \Delta(W)). \tag{5}$$

Eq. (5) can be proven by induction. We combine Eq. (4) and Eq. (5) into the following non-recursive formulation of the contribution of a feature value:

$$\varphi_i(\Delta) = \sum_{W \subseteq N \setminus \{i\}} \frac{\sum_{Q \subseteq (W \cup \{i\})} ((-1)^{|W \cup \{i\}|-|Q|} \Delta(Q))}{|W \cup \{i\}|}. \tag{6}$$

Let us examine the number of times $\Delta(S \cup \{i\})$, $S \subseteq N, i \notin S$, appears on the right-hand side of Eq. (6). Let $M_{\Delta(S \cup \{i\})}$ be the number of all such appearances and $k = n - |S| - 1$. The term $\Delta(S \cup \{i\})$ appears when $S \subseteq W$ and only once for each such W. For W, where $S \subseteq W$ and $|W| = |S| + a$, $\Delta(S \cup \{i\})$ appears with an alternating sign, depending on the parity of a, and there are exactly $\binom{k}{a}$ such W in the sum in Eq. (6), because we can use any combination of a additional elements from the remaining k elements that are not already in the set S. If we write all such terms up to $W = N$ and take into account that each interaction $I(W)$ is divided by $|W|$, we get the following series:

The treatment is similar for $\Delta(S)$, $i \notin S$ where we get $M_{\Delta(S)} = -V(n,k)$. The series $V(n,k)$ can be expressed with the beta function:

$$(1-x)^k = \binom{k}{0} - \binom{k}{1} x + \binom{k}{2} x^2 - \ldots \pm \binom{k}{k} x^k$$

$$\int_0^1 x^{n-k-1} (1-x)^k \, dx = \int_0^1 (\binom{k}{0} x^{n-k-1} - \binom{k}{1} x^{n-k} + \ldots \pm \binom{k}{n-1} x^{n-1}) \, dx$$

$$B(n-k, k+1) = \frac{\binom{k}{0}}{n-k} - \frac{\binom{k}{1}}{n-k+1} + \ldots \pm \frac{\binom{k}{k}}{n} = V(n,k).$$

Using $B(p,q) = \frac{\Gamma(p)\Gamma(q)}{\Gamma(p+q)}$, we get $V(n,k) = \frac{(n-k-1)!k!}{n!}$. Therefore:

$$\varphi_i(\Delta) = \sum_{S \subseteq N \setminus \{i\}} V(n, n-s-1) \cdot \Delta(S \cup \{i\}) - \sum_{S \subseteq N \setminus \{i\}} V(n, n-s-1) \cdot \Delta(S) =$$

$$= \sum_{S \subseteq N \setminus \{i\}} \frac{(n-s-1)!s!}{n!} \cdot (\Delta(S \cup \{i\}) - \Delta(S)).$$

■

So, the explanation method can be interpreted as follows. The instance's feature values form a coalition which causes a change in the classifier's prediction. We divide this change amongst the feature values in a way that is fair to their contributions across all possible sub-coalitions. Now that we have established that the contributions correspond to the Shapley value, we take another look at its axiomatization. Axioms 1 to 3 and their interpretation in the context of our explanation method are of particular interest. The 1st axiom corresponds to our decomposition in Eq. (2) - the

sum of all n contributions in an instance's explanation is equal to the difference in prediction $\Delta(N)$. Therefore, the contributions are implicitly normalized, which makes them easier to compare across different instances and different models. According to the 2nd axiom, if two features values have an identical influence on the prediction they are assigned contributions of equal size. The 3rd axiom says that if a feature has no influence on the prediction it is assigned a contribution of 0. When viewed together, these properties ensure that any effect the features might have on the classifiers output will be reflected in the generated contributions, which effectively deals with the issues of previous general explanation methods.

3.1.1 AN ILLUSTRATIVE EXAMPLE

In the introduction we used a simple boolean logic example to illustrate the shortcomings of existing general explanation methods. We concluded that in the expression (1 OR 1) both values are irrelevant and contribute nothing to the result being 1. This error results from not observing all the possible subsets of features. With the same example we illustrate how our explanation method works. We write $N = \{1,2\}$, $\mathcal{A} = \{0,1\} \times \{0,1\}$, and $x = (1,1)$. In other words, we are explaining the classifier's prediction for the expression $(1 \text{ OR } 1)$. Following the steps described in Section 3, we use Eq. (1) to calculate the $\Delta-$terms. Intuitively, $\Delta(S)$ is the difference between the classifiers expected prediction if only values of features in S are known and the expected prediction if no values are known. If the value of at least one of the two features is known, we can predict, with certainty, that the result is 1. If both values are unknown (that is, masked) one can predict that the probability of the result being 1 is $\frac{3}{4}$. Therefore, $\Delta(1) = \Delta(2) = \Delta(1,2) = 1 - \frac{3}{4} = \frac{1}{4}$ and $\Delta(\varnothing) = \frac{3}{4} - \frac{3}{4} = 0$. Now we can calculate the interactions. $I(1) = \Delta(1) = \frac{1}{4}$ and $I(2) = \Delta(2) = \frac{1}{4}$. When observed together, the two features contribute less than their individual contributions would suggest, which results in a negative interaction: $I(1,2) = \Delta(1,2) - (I(1) + I(2)) = -\frac{1}{4}$. Finally, we divide the interactions to get the final contributions: $\varphi_1 = I(1) + \frac{I(1,2)}{2} = \frac{1}{8}$ and $\varphi_2 = I(2) + \frac{I(1,2)}{2} = \frac{1}{8}$. The generated contributions reveal that both features contribute the same amount towards the prediction being 1 and the contributions sum up to the initial difference between the prediction for this instance and the prior belief.

3.2 An Approximation

We have shown that the generated contributions, φ_i, are effective in relating how individual feature values influence the classifier's prediction. Now we provide an efficient approximation. The approximation method is based on a well known alternative formulation of the Shapley value. Let $\pi(N)$ be the set of all ordered permutations of N. Let $Pre^i(O)$ be the set of players which are predecessors of player i in the order $O \in \pi(N)$. A feature value's contribution can now be expressed as:

$$\varphi_i(\Delta) = \frac{1}{n!} \sum_{O \in \pi(N)} \left(\Delta(Pre^i(O) \cup \{i\}) - \Delta(Pre^i(O)) \right), \quad i = 1, ..., n. \tag{7}$$

Eq. (7) is the a well-known alternative formulation of the Shapley value. An algorithm for the computation of the Shapley value, which is based on Eq. (7), was presented by Castro et al. (2008). However, in our case, the exponential time complexity is still hidden in our definition of Δ (see Eq. (1)). If we use the alternative definition used in our previous work (see Remark 3), we can compute function $\Delta(S)$, for a given S, in polynomial time (assuming that the learning algorithm has

a polynomial time complexity). However, this requires retraining the classifier for each $S \subseteq N$, so the method would no longer be independent of the learning algorithm and we would also require the training set that the original classifier was trained on. To avoid this and still achieve an efficient explanation method, we extend the sampling algorithm in the following way. We use a different, but equivalent formulation of Eq. (1). While the sum in this equation redundantly counts each $f(\tau(x,y,S))$ term $|\mathcal{A}_S|$ times (instead of just once) it is equivalent to Eq. (1) and simplifies the sampling procedure:

$$\Delta(S) = \frac{1}{|\mathcal{A}|} \sum_{y \in \mathcal{A}} \left(f(\tau(x,y,S)) - f(y) \right). \tag{8}$$

We replace occurrences of Δ in Eq. (7) with Eq. (8):

$$\varphi_i(\Delta) = \frac{1}{n! \cdot |\mathcal{A}|} \sum_{O \in \pi(N)} \sum_{y \in \mathcal{A}} \left(f(\tau(x,y,Pre^i(O) \cup \{i\})) - f(\tau(x,y,Pre^i(O))) \right).$$

We use the following sampling procedure. Our sampling population is $\pi(N) \times \mathcal{A}$ and each order/instance pair defines one sample $X_{O,y \in \mathcal{A}} = f(\tau(x,y,Pre^i(O) \cup \{i\})) - f(\tau(x,y,Pre^i(O)))$. If some features are continuous, we have an infinite population, but the properties of the sampling procedure do not change. If we draw a sample completely at random then all samples have an equal probability of being drawn ($\frac{1}{n! \cdot |\mathcal{A}|}$) and $E[X_{O,y \in \mathcal{A}}] = \varphi_i$. Now consider the case where m such samples are drawn (with replacement) and observe the random variable $\hat{\varphi}_i = \frac{1}{m} \sum_{j=1}^{m} X_j$, where X_j is the $j-$th sample. According to the central limit theorem, $\hat{\varphi}_i$ is approximately normally distributed with mean φ_i and variance $\frac{\sigma_i^2}{m}$, where σ_i^2 is the population variance for the $i-$th feature. Therefore, $\hat{\varphi}_i$ is an unbiased and consistent estimator of φ_i. The computation is summarized in Algorithm 1.

Algorithm 1 Approximating the contribution of the i-th feature's value, φ_i, for instance $x \in \mathcal{A}$.

determine m, the desired number of samples
$\varphi_i \leftarrow 0$
for $j = 1$ to m **do**
  choose a random permutation of features $O \in \pi(N)$
  choose a random instance $y \in \mathcal{A}$
  $v_1 \leftarrow f(\tau(x,y,Pre^i(O) \cup \{i\}))$
  $v_2 \leftarrow f(\tau(x,y,Pre^i(O)))$
  $\varphi_i \leftarrow \varphi_i + (v_1 - v_2)$
end for
$\varphi_i \leftarrow \frac{\varphi_i}{m}$

$\{v_1$ and v_2 are the classifier's predictions for two instances, which are constructed by taking instance y and then changing the value of each feature which appears before the i-th feature in order O (for v_1 this includes the $i-$th feature) to that feature's value in x. Therefore, these two instances only differ in the value of the $i-$th feature.$\}$

3.2.1 ERROR/SPEED TRADEOFF

We have established an unbiased estimator of the contribution. Now we investigate the relationship between the number of samples we draw and the approximation error. For each φ_i, the number of samples we need to draw to achieve the desired error, depends only on the population variance σ_i^2. In practice, σ_i^2 is usually unknown, but has an upper bound, which is reached if the population is uniformly distributed among its two extreme values. According to Eq. (1), the maximum and minimum value of a single sample are 1 and -1, respectively, so $\sigma_i^2 \leq 1$. Let the tuple $\langle 1-\alpha, e\rangle$ be a description of the desired error restriction and $P(|\varphi_i - \hat{\varphi}_i| < e) = 1-\alpha$ the condition, which has to be fulfilled to satisfy the restriction. For any given $\langle 1-\alpha, e\rangle$, there is a constant number of samples we need to satisfy the restriction: $m_i(\langle 1-\alpha, e\rangle) = \frac{Z_{1-\alpha}^2 \cdot \sigma^2}{e^2}$, where $Z_{1-\alpha}^2$ is the Z-score, which corresponds to the $1-\alpha$ confidence interval. For example, we want 99% of the approximated contributions to be less than 0.01 away from their actual values and we assume worst-case variance $\sigma_i^2 = 1$, for each $i \in N$. Therefore, we have to draw approximately 65000 samples per feature, regardless of how large the feature space is. The variances are much lower in practice, as we show in the next section.

For each feature value, the number of samples $m_i(\langle 1-\alpha, e\rangle)$ is a linear function of the sample variance σ_i^2. The key to minimizing the number of samples is to estimate the sample variance σ_i^2 and draw the appropriate number of samples. This estimation can be done during the sampling process, by providing confidence intervals for the required number of samples, based on our estimation of variance on the samples we already took. While this will improve running times, it will not have any effect on the time complexity of the method, so we delegate this to further work. The optimal (minimal) number of samples we need for the entire explanation is: $m_{min}(\langle 1-\alpha, e\rangle) = n \cdot \frac{Z_{1-\alpha}^2 \cdot \overline{\sigma^2}}{e^2}$, where $\overline{\sigma^2} = \frac{1}{n}\sum_{i=1}^{n} \sigma_i^2$. Therefore, the number $n \cdot \overline{\sigma^2}$, where $\overline{\sigma^2}$ is estimated across several instances, gives a complete description of how complex a model's prediction is to explain (that is, proportional to how many samples we need).

A note on the method's time complexity. When explaining an instance, the sampling process has to be repeated for each of the n feature values. Therefore, for a given error and confidence level, the time complexity of the explanation is $O(n \cdot T(\mathcal{A}))$, where function $T(\mathcal{A})$ describes the instance classification time of the model on $\mathcal{A}$. For most machine learning models $T(\mathcal{A}) \leq n$.

4. Empirical Results

The evaluation of the approximation method is straightforward as we focus only on approximation errors and running times. We use a variety of different classifiers both to illustrate that it is indeed a general explanation method and to investigate how the method behaves with different types of classification models. The following models are used: a decision tree (DT), a Naive Bayes (NB), a SVM with polynomial kernel (SVM), a multi-layer perceptron artificial neural network (ANN), Breiman's random forests algorithm (RF), logistic regression (logREG), and ADABoost boosting with either Naive Bayes (bstNB) or a decision tree (bstDT) as the weak learner. All experiments were done on an off-the-shelf laptop computer (2GHz dual core CPU, 2GB RAM), the explanation method is a straightforward Java implementation of the equations presented in this paper, and the classifiers were imported from the Weka machine learning software (`http://www.cs.waikato.ac.nz/~ml/weka/index.html`).

Table 1: List of data sets used in our experiments. The variance of the most complex feature value and the variance of most complex model to explain are included.

The list of data sets used in our experiments can be found in Table 1. The first 8 data sets are synthetic data sets, designed specifically for testing explanation methods (see Robnik-Šikonja and Kononenko, 2008; Štrumbelj et al., 2009). The synthetic data sets contain the following concepts: conditionally independent features (CondInd), the xor problem (Xor, Cross, Chess), irrelevant features only (Random), disjunction (Disjunct, Sphere), and spatially clustered class values (Group). The Oncology data set is a real-world oncology data set provided by the Institute of Oncology, Ljubljana. To conserve space, we do not provide all the details about this data set, but we do use an instance from it as an illustrative example. Those interested in a more detailed description of this data set and how our previous explanation method is successfully applied in practice can refer to our previous work (Štrumbelj et al., 2009). The remaining 14 data sets are from the UCI machine learning repository (Asuncion and Newman, 2009).

The goal of our first experiment is to illustrate how approximated contributions converge to the actual values. The fact that they do is already evident from the theoretical analysis. However, the reader might find useful this additional information about the behavior of the approximation error. The following procedure is used. For each data set we use half of the instances for training and half for testing the explanation method. For each data set/classifier pair, we train the classifier on the training set and use both the explanation method and its approximation on each test instance. For the approximation method the latter part is repeated several times, each time with a different setting of how many samples are drawn per feature. Only synthetic data sets were used in this procedure, because the smaller number of features allows us to compute the actual contributions.

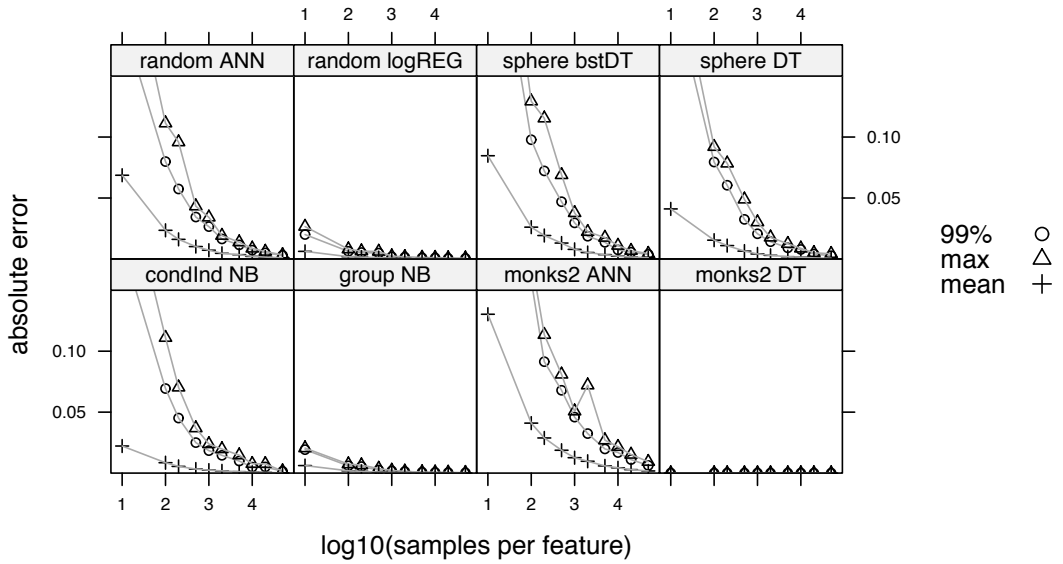

Figure 2: Mean, 99th-percentile, and maximum errors for several data set/classifier pairs and across different settings of how many samples are drawn per feature. Note that the error is the absolute difference between the approximated and actual contribution of a feature's value. The maximum error is the largest such observed difference across all instances.

Some of the results of this experiment are shown in Fig. 2. We can see that it only takes about a thousand of samples per feature to achieve a reasonably low approximation error. When over 10000 samples are drawn, all the contributions across all features and all test instances are very close to the actual contributions. From the discussion of the approximation error, we can see that the number of samples depends on the variance in the model's output, which in turn directly depends on how much the model has learned. Therefore, it takes only a few samples for a good approximation when explaining a model which has acquired little or no knowledge. This might be either due to the model not being able to learn the concepts behind the data set or because there are no concepts to learn. A few such examples are the Naive Bayes model on the Group data set (model's accuracy: 0.32, relative freq. of majority class: 0.33), the Decision Tree on Monks2 (acc. 0.65 , rel. freq. 0.67), and Logistic Regression on the Random data set (acc. 0.5 , rel. freq. 0.5). On the other hand, if a model successfully learns from the data set, it requires more samples to explain. For example, Naive Bayes on CondInd (acc. 0.92 , rel. freq. 0.50) and a Decision Tree on Sphere (acc. 0.80 , rel. freq. 0.50). In some cases a model acquires incorrect knowledge or over-fits the data set. One such example is the ANN model, which was allowed to over-fit the Random data set (acc. 0.5 , rel. freq. 0.5). In this case the method explains what the model has learned, regardless of whether the knowledge is correct or not. And although the explanations would not tell us much about the concepts behind the data set (we conclude from the model's performance, that it's knowledge is useless), they would reveal what the model has learned, which is the purpose of an explanation method.

In our second experiment we measure sample variances and classification running times. These will provide insight into how much time is needed for a good approximation. We use the same procedure as before, on all data sets, using only the approximation method. We draw 50000 samples per feature. Therefore, the total number of samples for each data set/classifier pair is: 50000n times

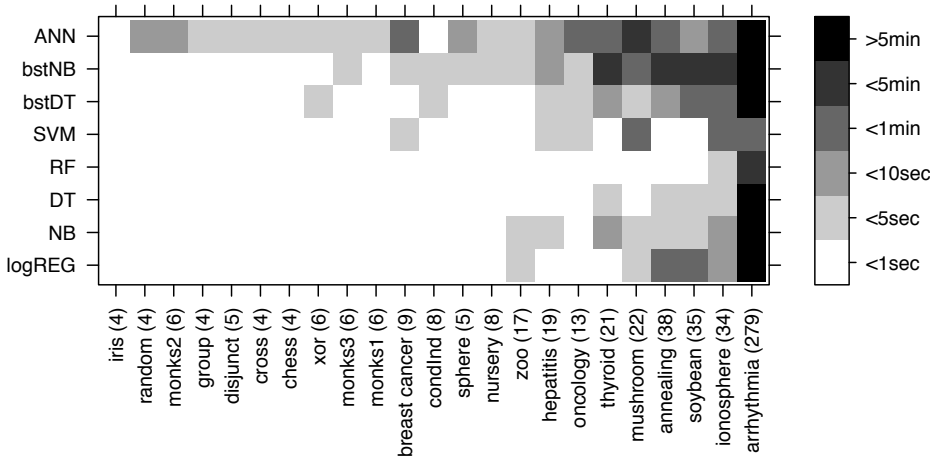

Figure 3: Visualization of explanation running times across all data set/classifier pairs.

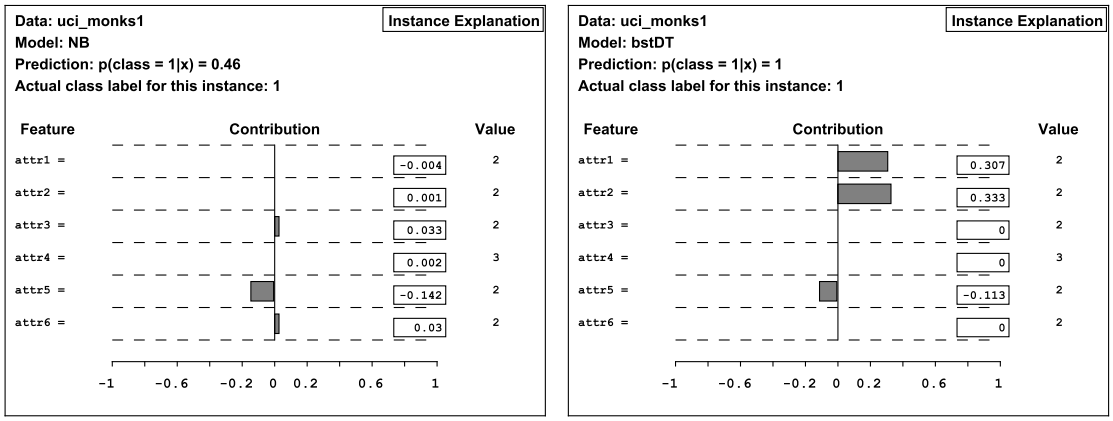
the number of test instances, which is sufficient for a good estimate of classification times and variances. The maximum σ_i^2 in Table 1 reveal that the crisp features of synthetic data sets have higher variance and are more difficult to explain than features from real-world data sets. Explaining the prediction of the ANN model for an instance Monks2 is the most complex explanation (that is, requires the most samples - see Fig. 2), which is understandable given the complexity of the Monks2 concept (class label = 1 iff exactly two feature values are 1). Note that most maximum values are achieved when explaining ANN.

From the data gathered in our second experiment, we generate Fig. 3, which shows the time needed to provide an explanation with the desired error $\langle 99\%, 0.01 \rangle$. For smaller data sets (smaller in the number of features) the explanation is generated almost instantly. For larger data sets, generating an explanation takes less than a minute, with the exception of bstNB on a few data sets and the ANN model on the Mushroom data set. These two models require more time for a single classification.

The Arrhythmia data set, with its 279 features, is an example of a data set, where the explanation can not be generated in some sensible time. For example, it takes more than an hour to generate an explanation for a prediction of the bstNB model. The explanation method is therefore less appropriate for explaining models which are built on several hundred features or more. Arguably, providing a comprehensible explanation involving a hundred or more features is a problem in its own right and even inherently transparend models become less comprehensible with such a large number of features. However, the focus of this paper is on providing an effective and general explanation method, which is computationally feasible on the majority of data sets we encounter. Also note that large data sets are often reduced to a smaller number of features in the preprocessing step of data acquisition before a learning algorithm is applied. Therefore, when considering the number of features the explanation method can still handle, we need not count irrelevant features, which are not included in the final model.

4.1 Example Explanation

Unlike running times and approximation errors, the usefulness and intuitiveness of the generated explanations is a more subjective matter. In this section we try to illustrate the usefulness of the



(a) *NB model* (b) *bstDT model*

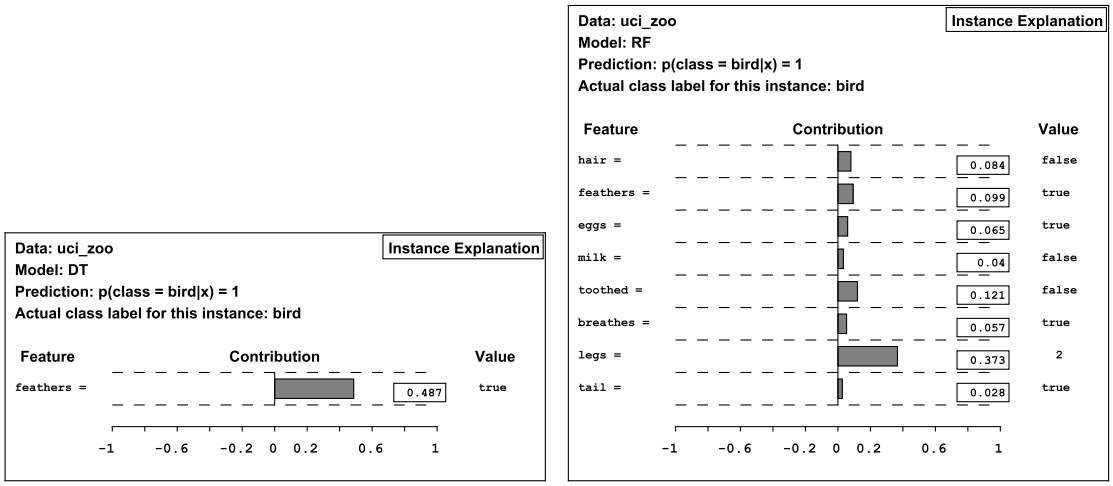
Figure 4: The boosting model correctly learns the concepts of the Monks1 data set, while Naive Bayes does not and misclassifies this instance.

method's explanations with several examples. When interpreting the explanations, we take into account both the magnitude and the sign of the contribution. If a feature-value has a larger contribution than another it has a larger influence on the model's prediction. If a feature-value's contribution has a positive sign, it contributes towards increasing the model's output (probability, score, rank, ...). A negative sign, on the other hand, means that the feature-value contributes towards decreasing the model's output. An additional advantage of the generated contributions is that they sum up to the difference between the model's output prediction and the model's expected output, given no information about the values of the features. Therefore, we can discern how much the model's output moves when given the feature values for the instance, which features are responsible for this change, and the magnitude of an individual feature-value's influence. These examples show how the explanations can be interpreted. They were generated for various classification models and data sets, to show the advantage of having a general explanation method.

The first pair of examples (see Fig. 4) are explanations for an instance from the first of the well-known Monks data sets. For this data set the class label is 1 iff attr1 and attr2 are equal or attr5 equals 1. The other 3 features are irrelevant. The NB model, due to its assumption of conditional independence, does not learn the importance of equality between the first two features and misclassifies the instance. However, both NB and bstDT learn the importance of the fifth feature and explanations reveal that value 2 for the fifth feature speaks against class 1.

The second pair of examples (see Fig. 5) is from the Zoo data set. Both models predict that the instance represents a bird. Why? The explanations reveal that DT predicts this animal is a bird, because it has feathers. The more complex RF model predicts its a bird, because it has two legs, but also because the animal is toothless, with feathers, without hair, etc... These first two pairs of examples illustrate how the explanations reflect what the model has learnt and how we can compare explanations from different classifiers.

In our experiments we are not interested in the prediction quality of the classifiers and do not put much effort into optimizing their performance. Some examples of underfitting and overfitting are actually desirable as they allow us to inspect if the explanation method reveals what the classifier has (or has not) learned. For example, Fig. 6(a) shows the explanation of the logREG model's prediction for an instance from the Xor data set. Logistic regression is unable to learn the exclusive-



(a) *DT model* (b) *RF model*

Figure 5: Explanations for an instance from the Zoo data set. The DT model uses a single feature, while several feature values influence the RT model. Feature values with contributions ≤ 0.01 have been removed for clarity.

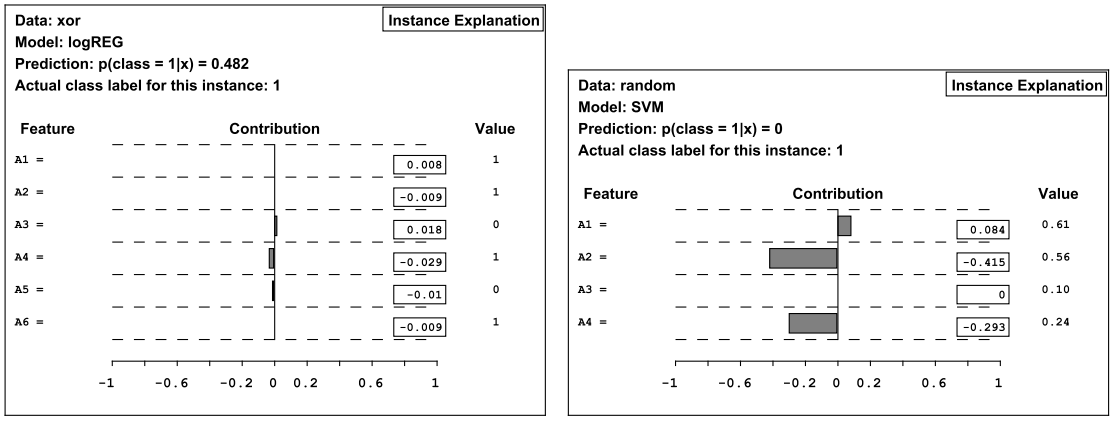
or concept of this data set (for this data set the class label is the odd parity bit for the first three feature values) and the explanation is appropriate. On the other hand, SVM manages to overfit the Random data set and finds concepts where there are none (see Fig. 6(b)).

Fig. 7(a) is an explanation for ANN's prediction for the introductory instance from the Titanic data set (see Fig. 1). Our explanation for the NB model's prediction (Fig. 7(b)) is very similar to the inherent explanation (taking into account that a logarithm is applied in the inherent explanation). The ANN model, on the other hand, predicts a lower chance of survival, because being a passenger from the 3rd class has a much higher negative contribution for ANN.

Our final example illustrates how the method can be used in real-world situations. Fig. 8 is an explanation for RT's prediction regarding whether breast cancer will (class = 1) or will not (class = 2) recur for this patient. According to RF it is more likely that cancer will not recur and the explanation indicates that this is mostly due to a low number of positive lymph nodes (nLymph). The lack of lymphovascular invasion (LVI) or tissue invasion (invasive) also contributes positively. A high ratio of removed lymph nodes was positive (posRatio) has the only significant negative contribution. Oncologists found this type of explanation very useful.

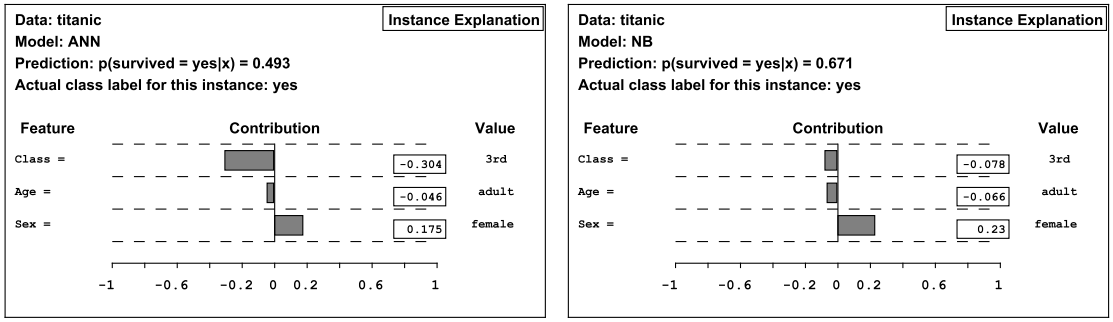
5. Conclusion

In the introductive section, we asked if an efficient and effective general explanation method for classifiers' predictions can be made. In conclusion, we can answer yes. Using only the input and output of a classifier we decompose the changes in its prediction into contributions of individual feature values. These contributions correspond to known concepts from coalitional game theory. Unlike with existing methods, the resulting theoretical properties of the proposed method guarantee that no matter which concepts the classifier learns, the generated contributions will reveal the influence of feature values. Therefore, the method can effectively be used on any classifier. As we show



(a) *logREG model* (b) *SVM model*

Figure 6: The left hand side explanation indicates that the feature values have no significant influence on the logREG model on the Xor data set. The right hand side explanation shows how SVM overfits the Random data set.



(a) *ANN model* (b) *NB model*

Figure 7: Two explanations for the Titanic instance from the introduction. The left hand side explanation is for the ANN model. The right hand side explanation is for the NB model.

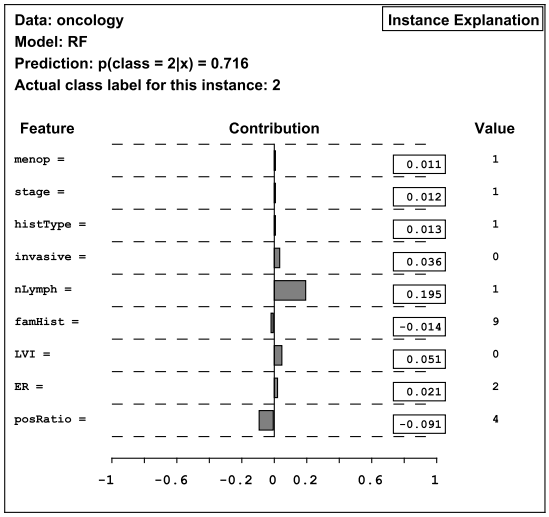


Figure 8: An explanation or the RF model's prediction for a patient from the Oncology data set.

on several examples, the method can be used to visually inspect models' predictions and compare the predictions of different models.

The proposed approximation method successfully deals with the initial exponential time complexity, makes the method efficient, and feasible for practical use. As part of further work we intend to research whether we can efficiently not only compute the contributions, which already reflect the interactions, but also highlight (at least) the most important individual interactions as well. A minor issue left to further work is extending the approximation with an algorithm for optimizing the number of samples we take. It would also be interesting to explore the possibility of applying the same principles to the explanation of regression models.

Abstract

Sparse coding—that is, modelling data vectors as sparse linear combinations of basis elements—is widely used in machine learning, neuroscience, signal processing, and statistics. This paper focuses on the large-scale matrix factorization problem that consists of *learning* the basis set in order to adapt it to specific data. Variations of this problem include dictionary learning in signal processing, non-negative matrix factorization and sparse principal component analysis. In this paper, we propose to address these tasks with a new online optimization algorithm, based on stochastic approximations, which scales up gracefully to large data sets with millions of training samples, and extends naturally to various matrix factorization formulations, making it suitable for a wide range of learning problems. A proof of convergence is presented, along with experiments with natural images and genomic data demonstrating that it leads to state-of-the-art performance in terms of speed and optimization for both small and large data sets.

Keywords: basis pursuit, dictionary learning, matrix factorization, online learning, sparse coding, sparse principal component analysis, stochastic approximations, stochastic optimization, non-negative matrix factorization

1. Introduction

The linear decomposition of a signal using a few atoms of a *learned* dictionary instead of a predefined one—based on wavelets (Mallat, 1999) for example—has recently led to state-of-the-art results in numerous low-level signal processing tasks such as image denoising (Elad and Aharon, 2006; Mairal et al., 2008b), texture synthesis (Peyré, 2009) and audio processing (Grosse et al., 2007; Févotte et al., 2009; Zibulevsky and Pearlmutter, 2001), as well as higher-level tasks such as image classification (Raina et al., 2007; Mairal et al., 2008a, 2009b; Bradley and Bagnell, 2009; Yang et al., 2009), showing that sparse learned models are well adapted to natural signals. Unlike decompositions based on principal component analysis and its variants, these models do not im-

pose that the basis vectors be orthogonal, allowing more flexibility to adapt the representation to the data.[1] In machine learning and statistics, slightly different matrix factorization problems are formulated in order to obtain a few *interpretable* basis elements from a set of data vectors. This includes non-negative matrix factorization and its variants (Lee and Seung, 2001; Hoyer, 2002, 2004; Lin, 2007), and sparse principal component analysis (Zou et al., 2006; d'Aspremont et al., 2007, 2008; Witten et al., 2009; Zass and Shashua, 2007). As shown in this paper, these problems have strong similarities; even though we first focus on the problem of dictionary learning, the algorithm we propose is able to address all of them. While learning the dictionary has proven to be critical to achieve (or improve upon) state-of-the-art results in signal and image processing, effectively solving the corresponding optimization problem is a significant computational challenge, particularly in the context of large-scale data sets that may include millions of training samples. Addressing this challenge and designing a generic algorithm which is capable of efficiently handling various matrix factorization problems, is the topic of this paper.

Concretely, consider a signal $\mathbf{x}$ in $\mathbb{R}^m$. We say that it admits a sparse approximation over a *dictionary* $\mathbf{D}$ in $\mathbb{R}^{m\times k}$, with k columns referred to as *atoms*, when one can find a linear combination of a "few" atoms from $\mathbf{D}$ that is "close" to the signal $\mathbf{x}$. Experiments have shown that modelling a signal with such a sparse decomposition (*sparse coding*) is very effective in many signal processing applications (Chen et al., 1999). For natural images, predefined dictionaries based on various types of wavelets (Mallat, 1999) have also been used for this task. However, learning the dictionary instead of using off-the-shelf bases has been shown to dramatically improve signal reconstruction (Elad and Aharon, 2006). Although some of the learned dictionary elements may sometimes "look like" wavelets (or Gabor filters), they are tuned to the input images or signals, leading to much better results in practice.

Most recent algorithms for dictionary learning (Olshausen and Field, 1997; Engan et al., 1999; Lewicki and Sejnowski, 2000; Aharon et al., 2006; Lee et al., 2007) are iterative *batch* procedures, accessing the whole training set at each iteration in order to minimize a cost function under some constraints, and cannot efficiently deal with very large training sets (Bottou and Bousquet, 2008), or dynamic training data changing over time, such as video sequences. To address these issues, we propose an *online* approach that processes the signals, one at a time, or in mini-batches. This is particularly important in the context of image and video processing (Protter and Elad, 2009; Mairal et al., 2008c), where it is common to learn dictionaries adapted to small patches, with training data that may include several millions of these patches (roughly one per pixel and per frame). In this setting, online techniques based on stochastic approximations are an attractive alternative to batch methods (see, e.g., Bottou, 1998; Kushner and Yin, 2003; Shalev-Shwartz et al., 2009). For example, first-order stochastic gradient descent with projections on the constraint set (Kushner and Yin, 2003) is sometimes used for dictionary learning (see Aharon and Elad, 2008; Kavukcuoglu et al., 2008 for instance). We show in this paper that it is possible to go further and exploit the specific structure of sparse coding in the design of an optimization procedure tuned to this problem, with low memory consumption and lower computational cost than classical batch algorithms. As demonstrated by our experiments, it scales up gracefully to large data sets with millions of training samples, is easy to use, and is faster than competitive methods.

The paper is structured as follows: Section 2 presents the dictionary learning problem. The proposed method is introduced in Section 3, with a proof of convergence in Section 4. Section 5

1. Note that the terminology "basis" is slightly abusive here since the elements of the dictionary are not necessarily linearly independent and the set can be overcomplete—that is, have more elements than the signal dimension.

extends our algorithm to various matrix factorization problems that generalize dictionary learning, and Section 6 is devoted to experimental results, demonstrating that our algorithm is suited to a wide class of learning problems.

1.1 Contributions

This paper makes four main contributions:

- We cast in Section 2 the dictionary learning problem as the optimization of a smooth non-convex objective function over a convex set, minimizing the (desired) *expected* cost when the training set size goes to infinity, and propose in Section 3 an iterative online algorithm that solves this problem by efficiently minimizing at each step a quadratic surrogate function of the empirical cost over the set of constraints. This method is shown in Section 4 to converge almost surely to a stationary point of the objective function.

- As shown experimentally in Section 6, our algorithm is significantly faster than previous approaches to dictionary learning on both small and large data sets of natural images. To demonstrate that it is adapted to difficult, large-scale image-processing tasks, we learn a dictionary on a 12-Megapixel photograph and use it for inpainting—that is, filling some holes in the image.

- We show in Sections 5 and 6 that our approach is suitable to large-scale matrix factorization problems such as non-negative matrix factorization and sparse principal component analysis, while being still effective on small data sets.

- To extend our algorithm to several matrix factorization problems, we propose in Appendix B efficient procedures for projecting onto two convex sets, which can be useful for other applications that are beyond the scope of this paper.

1.2 Notation

We define for $p \geq 1$ the ℓ_p norm of a vector $\mathbf{x}$ in $\mathbb{R}^m$ as $||\mathbf{x}||_p \triangleq (\sum_{i=1}^m |\mathbf{x}[i]|^p)^{1/p}$, where $\mathbf{x}[i]$ denotes the i-th coordinate of $\mathbf{x}$ and $||\mathbf{x}||_\infty \triangleq \max_{i=1,\ldots,m} |\mathbf{x}[i]| = \lim_{p\to\infty} ||\mathbf{x}||_p$. We also define the ℓ_0 pseudo-norm as the sparsity measure which counts the number of nonzero elements in a vector:[2] $||\mathbf{x}||_0 \triangleq \#\{i \text{ s.t. } \mathbf{x}[i] \neq 0\} = \lim_{p\to 0^+} (\sum_{i=1}^m |\mathbf{x}[i]|^p)$. We denote the Frobenius norm of a matrix $\mathbf{X}$ in $\mathbb{R}^{m\times n}$ by $||\mathbf{X}||_F \triangleq (\sum_{i=1}^m \sum_{j=1}^n \mathbf{X}[i,j]^2)^{1/2}$. For a sequence of vectors (or matrices) $\mathbf{x}_t$ and scalars u_t, we write $\mathbf{x}_t = O(u_t)$ when there exists a constant $K > 0$ so that for all t, $||\mathbf{x}_t||_2 \leq K u_t$. Note that for finite-dimensional vector spaces, the choice of norm is essentially irrelevant (all norms are equivalent). Given two matrices $\mathbf{A}$ in $\mathbb{R}^{m_1\times n_1}$ and $\mathbf{B}$ in $\mathbb{R}^{m_2\times n_2}$, $\mathbf{A}\otimes\mathbf{B}$ denotes the Kronecker product between $\mathbf{A}$ and $\mathbf{B}$, defined as the matrix in $\mathbb{R}^{m_1 m_2\times n_1 n_2}$, defined by blocks of sizes $m_2 \times n_2$ equal to $\mathbf{A}[i,j]\mathbf{B}$. For more details and properties of the Kronecker product, see Golub and Van Loan (1996), and Magnus and Neudecker (1999).

2. Note that it would be more proper to write $||\mathbf{x}||_0^0$ instead of $||\mathbf{x}||_0$ to be consistent with the traditional notation $||\mathbf{x}||_p$. However, for the sake of simplicity, we will keep this notation unchanged.

2. Problem Statement

Classical dictionary learning techniques for sparse representation (Olshausen and Field, 1997; Engan et al., 1999; Lewicki and Sejnowski, 2000; Aharon et al., 2006; Lee et al., 2007) consider a finite training set of signals $\mathbf{X} = [\mathbf{x}_1, \ldots, \mathbf{x}_n]$ in $\mathbb{R}^{m \times n}$ and optimize the empirical cost function

$$f_n(\mathbf{D}) \triangleq \frac{1}{n} \sum_{i=1}^{n} \ell(\mathbf{x}_i, \mathbf{D}), \tag{1}$$

where $\mathbf{D}$ in $\mathbb{R}^{m \times k}$ is the dictionary, each column representing a basis vector, and ℓ is a loss function such that $\ell(\mathbf{x}, \mathbf{D})$ should be small if $\mathbf{D}$ is "good" at representing the signal $\mathbf{x}$ in a sparse fashion. The number of samples n is usually large, whereas the signal dimension m is relatively small, for example, $m = 100$ for 10×10 image patches, and $n \geq 100{,}000$ for typical image processing applications. In general, we also have $k \ll n$ (e.g., $k = 200$ for $n = 100{,}000$), but each signal only uses a few elements of $\mathbf{D}$ in its representation, say 10 for instance. Note that, in this setting, overcomplete dictionaries with $k > m$ are allowed. As others (see for example Lee et al., 2007), we define $\ell(\mathbf{x}, \mathbf{D})$ as the optimal value of the ℓ_1 *sparse coding* problem:

$$\ell(\mathbf{x}, \mathbf{D}) \triangleq \min_{\alpha \in \mathbb{R}^k} \frac{1}{2} ||\mathbf{x} - \mathbf{D}\alpha||_2^2 + \lambda ||\alpha||_1, \tag{2}$$

where λ is a regularization parameter. This problem is also known as *basis pursuit* (Chen et al., 1999), or the *Lasso* (Tibshirani, 1996).[3] It is well known that ℓ_1 regularization yields a sparse solution for α, but there is no direct analytic link between the value of λ and the corresponding effective sparsity $||\alpha||_0$. To prevent $\mathbf{D}$ from having arbitrarily large values (which would lead to arbitrarily small values of α), it is common to constrain its columns $\mathbf{d}_1, \ldots, \mathbf{d}_k$ to have an ℓ_2-norm less than or equal to one. We will call $\mathcal{C}$ the convex set of matrices verifying this constraint:

$$\mathcal{C} \triangleq \{\mathbf{D} \in \mathbb{R}^{m \times k} \ \text{ s.t. } \ \forall j = 1, \ldots, k, \ \ \mathbf{d}_j^T \mathbf{d}_j \leq 1\}.$$

Note that the problem of minimizing the empirical cost $f_n(\mathbf{D})$ is not convex with respect to $\mathbf{D}$. It can be rewritten as a joint optimization problem with respect to the dictionary $\mathbf{D}$ and the coefficients $\alpha = [\alpha_1, \ldots, \alpha_n]$ in $\mathbb{R}^{k \times n}$ of the sparse decompositions, which is not jointly convex, but convex with respect to each of the two variables $\mathbf{D}$ and α when the other one is fixed:

$$\min_{\mathbf{D} \in \mathcal{C}, \alpha \in \mathbb{R}^{k \times n}} \sum_{i=1}^{n} \left(\frac{1}{2} ||\mathbf{x}_i - \mathbf{D}\alpha_i||_2^2 + \lambda ||\alpha_i||_1 \right). \tag{4}$$

This can be rewritten as a *matrix factorization* problem with a sparsity penalty:

$$\min_{\mathbf{D} \in \mathcal{C}, \alpha \in \mathbb{R}^{k \times n}} \frac{1}{2} ||\mathbf{X} - \mathbf{D}\alpha||_F^2 + \lambda ||\alpha||_{1,1},$$

3. To be more precise, the original formulation of the Lasso is a constrained version of Eq. (2), with a constraint on the ℓ_1-norm of α:

$$\min_{\alpha \in \mathbb{R}^k} \frac{1}{2} ||\mathbf{x} - \mathbf{D}\alpha||_2^2 \ \text{ s.t. } \ ||\alpha||_1 \leq T. \tag{3}$$

Both formulations are equivalent in the sense that for every $\lambda > 0$ (respectively every $T > 0$), there exists a scalar T (respectively λ) so that Equations (2) and (3) admit the same solutions.

where, as before, $\mathbf{X} = [\mathbf{x}_1, \ldots, \mathbf{x}_n]$ is the matrix of data vectors, and $||\alpha||_{1,1}$ denotes the ℓ_1 norm of the matrix α—that is, the sum of the magnitude of its coefficients. A natural approach to solving this problem is to alternate between the two variables, minimizing over one while keeping the other one fixed, as proposed by Lee et al. (2007) (see also Engan et al. 1999 and Aharon et al. 2006, who use ℓ_0 rather than ℓ_1 penalties, or Zou et al. 2006 for the problem of sparse principal component analysis).[4] Since the computation of the coefficients vectors α_i dominates the cost of each iteration in this block-coordinate descent approach, a second-order optimization technique can be used to accurately estimate $\mathbf{D}$ at each step when α is fixed.

As pointed out by Bottou and Bousquet (2008), however, one is usually not interested in the minimization of the *empirical cost* $f_n(\mathbf{D})$ with high precision, but instead in the minimization of the *expected cost*

$$f(\mathbf{D}) \triangleq \mathbb{E}_{\mathbf{x}}[\ell(\mathbf{x}, \mathbf{D})] = \lim_{n \to \infty} f_n(\mathbf{D}) \text{ a.s.},$$

where the expectation (which is supposed finite) is taken relative to the (unknown) probability distribution $p(\mathbf{x})$ of the data.[5] In particular, given a finite training set, one should not spend too much effort on accurately minimizing the empirical cost, since it is only an approximation of the expected cost. An "inaccurate" solution may indeed have the same or better expected cost than a "well-optimized" one. Bottou and Bousquet (2008) further show that stochastic gradient algorithms, whose rate of convergence is very poor in conventional optimization terms, may in fact in certain settings be shown both theoretically and empirically to be faster in reaching a solution with low expected cost than second-order batch methods. With large training sets, the risk of overfitting is lower, but classical optimization techniques may become impractical in terms of speed or memory requirements.

In the case of dictionary learning, the classical projected first-order projected stochastic gradient descent algorithm (as used by Aharon and Elad 2008; Kavukcuoglu et al. 2008 for instance) consists of a sequence of updates of $\mathbf{D}$:

$$\mathbf{D}_t = \Pi_{\mathcal{C}}\Big[\mathbf{D}_{t-1} - \delta_t \nabla_{\mathbf{D}} \ell(\mathbf{x}_t, \mathbf{D}_{t-1})\Big],$$

where $\mathbf{D}_t$ is the estimate of the optimal dictionary at iteration t, δ_t is the gradient step, $\Pi_{\mathcal{C}}$ is the orthogonal projector onto $\mathcal{C}$, and the vectors $\mathbf{x}_t$ are i.i.d. samples of the (unknown) distribution $p(\mathbf{x})$. Even though it is often difficult to obtain such i.i.d. samples, the vectors $\mathbf{x}_t$ are in practice obtained by cycling on a randomly permuted training set. As shown in Section 6, we have observed that this method can be competitive in terms of speed compared to batch methods when the training set is large and when δ_t is carefully chosen. In particular, good results are obtained using a learning rate of the form $\delta_t \triangleq a/(t+b)$, where a and b have to be well chosen in a data set-dependent way. Note that first-order stochastic gradient descent has also been used for other matrix factorization problems (see Koren et al., 2009 and references therein).

The optimization method we present in the next section falls into the class of online algorithms based on stochastic approximations, processing one sample at a time (or a mini-batch), but further exploits the specific structure of the problem to efficiently solve it by sequentially minimizing a quadratic local surrogate of the expected cost. As shown in Section 3.5, it uses second-order information of the cost function, allowing the optimization without any explicit learning rate tuning.

4. In our setting, as in Lee et al. (2007), we have preferred to use the convex ℓ_1 norm, that has empirically proven to be better behaved in general than the ℓ_0 pseudo-norm for dictionary learning.

5. We use "a.s." to denote almost sure convergence.

3. Online Dictionary Learning

We present in this section the basic components of our online algorithm for dictionary learning (Sections 3.1–3.3), as well as a few minor variants which speed up our implementation in practice (Section 3.4) and an interpretation in terms of a Kalman algorithm (Section 3.5).

3.1 Algorithm Outline

Our procedure is summarized in Algorithm 1. Assuming that the training set is composed of i.i.d. samples of a distribution $p(\mathbf{x})$, its inner loop draws one element $\mathbf{x}_t$ at a time, as in stochastic gradient descent, and alternates classical sparse coding steps for computing the decomposition α_t of $\mathbf{x}_t$ over the dictionary $\mathbf{D}_{t-1}$ obtained at the previous iteration, with dictionary update steps where the new dictionary $\mathbf{D}_t$ is computed by minimizing over $\mathcal{C}$ the function

$$\hat{f}_t(\mathbf{D}) \triangleq \frac{1}{t}\sum_{i=1}^{t}\Big(\frac{1}{2}||\mathbf{x}_i - \mathbf{D}\alpha_i||_2^2 + \lambda||\alpha_i||_1\Big), \tag{5}$$

and the vectors α_i for $i < t$ have been computed during the previous steps of the algorithm. The motivation behind this approach is twofold:

- The function $\hat{f}_t$, which is quadratic in $\mathbf{D}$, aggregates the past information with a few sufficient statistics obtained during the previous steps of the algorithm, namely the vectors α_i, and it is easy to show that it upperbounds the empirical cost $f_t(\mathbf{D}_t)$ from Eq. (1). One key aspect of our convergence analysis will be to show that $\hat{f}_t(\mathbf{D}_t)$ and $f_t(\mathbf{D}_t)$ converge almost surely to the same limit, and thus that $\hat{f}_t$ acts as a *surrogate* for f_t.
- Since $\hat{f}_t$ is close to $\hat{f}_{t-1}$ for large values of t, so are $\mathbf{D}_t$ and $\mathbf{D}_{t-1}$, under suitable assumptions, which makes it efficient to use $\mathbf{D}_{t-1}$ as warm restart for computing $\mathbf{D}_t$.

3.2 Sparse Coding

The sparse coding problem of Eq. (2) with fixed dictionary is an ℓ_1-regularized linear least-squares problem. A number of recent methods for solving this type of problems are based on coordinate descent with soft thresholding (Fu, 1998; Friedman et al., 2007; Wu and Lange, 2008). When the columns of the dictionary have low correlation, we have observed that these simple methods are very efficient. However, the columns of learned dictionaries are in general highly correlated, and we have empirically observed that these algorithms become much slower in this setting. This has led us to use instead the LARS-Lasso algorithm, a homotopy method (Osborne et al., 2000; Efron et al., 2004) that provides the whole regularization path—that is, the solutions for all possible values of λ. With an efficient Cholesky-based implementation (see Efron et al., 2004; Zou and Hastie, 2005) for brief descriptions of such implementations), it has proven experimentally at least as fast as approaches based on soft thresholding, while providing the solution with a higher accuracy and being more robust as well since it does not require an arbitrary stopping criterion.

3.3 Dictionary Update

Our algorithm for updating the dictionary uses block-coordinate descent with warm restarts (see Bertsekas, 1999). One of its main advantages is that it is parameter free and does not require any

Algorithm 1 Online dictionary learning.

Require: $\mathbf{x} \in \mathbb{R}^m \sim p(\mathbf{x})$ (random variable and an algorithm to draw i.i.d samples of p), $\lambda \in \mathbb{R}$ (regularization parameter), $\mathbf{D}_0 \in \mathbb{R}^{m \times k}$ (initial dictionary), T (number of iterations).

1: $\mathbf{A}_0 \in \mathbb{R}^{k \times k} \leftarrow 0, \mathbf{B}_0 \in \mathbb{R}^{m \times k} \leftarrow 0$ (reset the "past" information).
2: **for** $t = 1$ to T **do**
3: Draw $\mathbf{x}_t$ from $p(\mathbf{x})$.
4: Sparse coding: compute using LARS

$$\alpha_t \triangleq \arg\min_{\alpha \in \mathbb{R}^k} \frac{1}{2}||\mathbf{x}_t - \mathbf{D}_{t-1}\alpha||_2^2 + \lambda||\alpha||_1.$$

5: $\mathbf{A}_t \leftarrow \mathbf{A}_{t-1} + \alpha_t \alpha_t^T$.
6: $\mathbf{B}_t \leftarrow \mathbf{B}_{t-1} + \mathbf{x}_t \alpha_t^T$.
7: Compute $\mathbf{D}_t$ using Algorithm 2, with $\mathbf{D}_{t-1}$ as warm restart, so that

$$\begin{aligned} \mathbf{D}_t &\triangleq \arg\min_{\mathbf{D} \in \mathcal{C}} \frac{1}{t} \sum_{i=1}^{t} \left(\frac{1}{2}||\mathbf{x}_i - \mathbf{D}\alpha_i||_2^2 + \lambda||\alpha_i||_1 \right), \\ &= \arg\min_{\mathbf{D} \in \mathcal{C}} \frac{1}{t} \left(\frac{1}{2} \mathrm{Tr}(\mathbf{D}^T \mathbf{D} \mathbf{A}_t) - \mathrm{Tr}(\mathbf{D}^T \mathbf{B}_t) \right). \end{aligned} \tag{6}$$

8: **end for**
9: **Return** $\mathbf{D}_T$ (learned dictionary).

Algorithm 2 Dictionary Update.

Require: $\mathbf{D} = [\mathbf{d}_1, \ldots, \mathbf{d}_k] \in \mathbb{R}^{m \times k}$ (input dictionary),
$\mathbf{A} = [\mathbf{a}_1, \ldots, \mathbf{a}_k] \in \mathbb{R}^{k \times k}$
$\mathbf{B} = [\mathbf{b}_1, \ldots, \mathbf{b}_k] \in \mathbb{R}^{m \times k}$

1: **repeat**
2: **for** $j = 1$ to k **do**
3: Update the j-th column to optimize for (6):

$$\begin{aligned} \mathbf{u}_j &\leftarrow \frac{1}{\mathbf{A}[j,j]}(\mathbf{b}_j - \mathbf{D}\mathbf{a}_j) + \mathbf{d}_j, \\ \mathbf{d}_j &\leftarrow \frac{1}{\max(||\mathbf{u}_j||_2, 1)} \mathbf{u}_j. \end{aligned} \tag{7}$$

4: **end for**
5: **until convergence**
6: **Return D (updated dictionary).**

learning rate tuning. Moreover, the procedure does not require to store all the vectors $\mathbf{x}_i$ and α_i, but only the matrices $\mathbf{A}_t = \sum_{i=1}^t \alpha_i \alpha_i^T$ in $\mathbb{R}^{k \times k}$ and $\mathbf{B}_t = \sum_{i=1}^t \mathbf{x}_i \alpha_i^T$ in $\mathbb{R}^{m \times k}$. Concretely, Algorithm 2 sequentially updates each column of $\mathbf{D}$. A simple calculation shows that solving (6) with respect to the j-th column $\mathbf{d}_j$, while keeping the other ones fixed under the constraint $\mathbf{d}_j^T \mathbf{d}_j \leq 1$, amounts to an orthogonal projection of the vector $\mathbf{u}_j$ defined in Eq. (7), onto the constraint set, namely

the ℓ_2-ball here, which is solved by Eq. (7). Since the convex optimization problem (6) admits separable constraints in the updated blocks (columns), convergence to a global optimum is guaranteed (Bertsekas, 1999). In practice, the vectors α_i are sparse and the coefficients of the matrix $\mathbf{A}_t$ are often concentrated on the diagonal, which makes the block-coordinate descent more efficient.[6] After a few iterations of our algorithm, using the value of $\mathbf{D}_{t-1}$ as a warm restart for computing $\mathbf{D}_t$ becomes effective, and a single iteration of Algorithm 2 has empirically found to be sufficient to achieve convergence of the dictionary update step. Other approaches have been proposed to update $\mathbf{D}$: For instance, Lee et al. (2007) suggest using a Newton method on the dual of Eq. (6), but this requires inverting a $k \times k$ matrix at each Newton iteration, which is impractical for an online algorithm.

3.4 Optimizing the Algorithm

We have presented so far the basic building blocks of our algorithm. This section discusses a few simple improvements that significantly enhance its performance.

3.4.1 HANDLING FIXED-SIZE DATA SETS

In practice, although it may be very large, the size of the training set often has a predefined finite size (of course this may not be the case when the data must be treated on the fly like a video stream for example). In this situation, the same data points may be examined several times, and it is very common in online algorithms to simulate an i.i.d. sampling of $p(\mathbf{x})$ by cycling over a randomly permuted training set (see Bottou and Bousquet, 2008 and references therein). This method works experimentally well in our setting but, when the training set is small enough, it is possible to further speed up convergence: In Algorithm 1, the matrices $\mathbf{A}_t$ and $\mathbf{B}_t$ carry all the information from the past coefficients $\alpha_1, \ldots, \alpha_t$. Suppose that at time t_0, a signal $\mathbf{x}$ is drawn and the vector α_{t_0} is computed. If the same signal $\mathbf{x}$ is drawn again at time $t > t_0$, then it is natural to replace the "old" information α_{t_0} by the new vector α_t in the matrices $\mathbf{A}_t$ and $\mathbf{B}_t$—that is, $\mathbf{A}_t \leftarrow \mathbf{A}_{t-1} + \alpha_t \alpha_t^T - \alpha_{t_0} \alpha_{t_0}^T$ and $\mathbf{B}_t \leftarrow \mathbf{B}_{t-1} + \mathbf{x}_t \alpha_t^T - \mathbf{x}_t \alpha_{t_0}^T$. In this setting, which requires storing all the past coefficients α_{t_0}, this method amounts to a block-coordinate descent for the problem of minimizing Eq. (4). When dealing with large but finite sized training sets, storing all coefficients α_i is impractical, but it is still possible to partially exploit the same idea, by removing the information from $\mathbf{A}_t$ and $\mathbf{B}_t$ that is older than two *epochs* (cycles through the data), through the use of two auxiliary matrices $\mathbf{A}'_t$ and $\mathbf{B}'_t$ of size $k \times k$ and $m \times k$ respectively. These two matrices should be built with the same rules as $\mathbf{A}_t$ and $\mathbf{B}_t$, except that at the end of an epoch, $\mathbf{A}_t$ and $\mathbf{B}_t$ are respectively replaced by $\mathbf{A}'_t$ and $\mathbf{B}'_t$, while $\mathbf{A}'_t$ and $\mathbf{B}'_t$ are set to 0. Thanks to this strategy, $\mathbf{A}_t$ and $\mathbf{B}_t$ do not carry any coefficients α_i older than two epochs.

3.4.2 SCALING THE "PAST" DATA

At each iteration, the "new" information α_t that is added to the matrices $\mathbf{A}_t$ and $\mathbf{B}_t$ has the same weight as the "old" one. A simple and natural modification to the algorithm is to rescale the "old" information so that newer coefficients α_t have more weight, which is classical in online learning. For instance, Neal and Hinton (1998) present an online algorithm for EM, where sufficient statistics are aggregated over time, and an exponential decay is used to forget out-of-date statistics. In this

6. We have observed that this is true when the columns of $\mathbf{D}$ are not too correlated. When a group of columns in $\mathbf{D}$ are highly correlated, the coefficients of the matrix $\mathbf{A}_t$ concentrate instead on the corresponding principal submatrices of $\mathbf{A}_t$.

paper, we propose to replace lines 5 and 6 of Algorithm 1 by

$$\mathbf{A}_t \leftarrow \beta_t \mathbf{A}_{t-1} + \alpha_t \alpha_t^T,$$
$$\mathbf{B}_t \leftarrow \beta_t \mathbf{B}_{t-1} + \mathbf{x}_t \alpha_t^T,$$

where $\beta_t \triangleq \left(1 - \frac{1}{t}\right)^\rho$, and ρ is a new parameter. In practice, one can apply this strategy after a few iterations, once $\mathbf{A}_t$ is well-conditioned. Tuning ρ improves the convergence rate, when the training sets are large, even though, as shown in Section 6, it is not critical. To understand better the effect of this modification, note that Eq. (6) becomes

$$\begin{aligned}\mathbf{D}_t &\triangleq \arg\min_{\mathbf{D}\in C} \frac{1}{\sum_{j=1}^t (j/t)^\rho} \sum_{i=1}^t \left(\frac{i}{t}\right)^\rho \left(\frac{1}{2}||\mathbf{x}_i - \mathbf{D}\alpha_i||_2^2 + \lambda||\alpha_i||_1\right),\\ &= \arg\min_{\mathbf{D}\in C} \frac{1}{\sum_{j=1}^t (j/t)^\rho} \left(\frac{1}{2}\operatorname{Tr}(\mathbf{D}^T\mathbf{D}\mathbf{A}_t) - \operatorname{Tr}(\mathbf{D}^T\mathbf{B}_t)\right).\end{aligned}$$

When $\rho = 0$, we obtain the original version of the algorithm. Of course, different strategies and heuristics could also be investigated. In practice, this parameter ρ is useful for large data sets only ($n \geq 100\,000$). For smaller data sets, we have not observed a better performance when using this extension.

3.4.3 MINI-BATCH EXTENSION

In practice, we can also improve the convergence speed of our algorithm by drawing $\eta > 1$ signals at each iteration instead of a single one, which is a classical heuristic in stochastic gradient descent algorithms. In our case, this is further motivated by the fact that the complexity of computing η vectors α_i is not linear in η. A Cholesky-based implementation of LARS-Lasso for decomposing a single signal has a complexity of $O(kms + ks^2)$, where s is the number of nonzero coefficients. When decomposing η signals, it is possible to pre-compute the Gram matrix $\mathbf{D}_t^T\mathbf{D}_t$ and the total complexity becomes $O(k^2m + \eta(km + ks^2))$, which is much cheaper than η times the previous complexity when η is large enough and s is small. Let us denote by $\mathbf{x}_{t,1}, \ldots, \mathbf{x}_{t,\eta}$ the signals drawn at iteration t. We can now replace lines 5 and 6 of Algorithm 1 by

$$\mathbf{A}_t \leftarrow \mathbf{A}_{t-1} + \frac{1}{\eta}\sum_{i=1}^{\eta} \alpha_{t,i}\alpha_{t,i}^T,$$
$$\mathbf{B}_t \leftarrow \mathbf{B}_{t-1} + \frac{1}{\eta}\sum_{i=1}^{\eta} \mathbf{x}_{t,i}\alpha_{t,i}^T.$$

3.4.4 SLOWING DOWN THE FIRST ITERATIONS

As in the case of stochastic gradient descent, the first iterations of our algorithm may update the parameters with large steps, immediately leading to large deviations from the initial dictionary. To prevent this phenomenon, classical implementations of stochastic gradient descent use gradient steps of the form $a/(t+b)$, where b "reduces" the step size. An initialization of the form $\mathbf{A}_0 = t_0\mathbf{I}$ and $\mathbf{B}_0 = t_0\mathbf{D}_0$ with $t_0 \geq 0$ also slows down the first steps of our algorithm by forcing the solution of the dictionary update to stay close to $\mathbf{D}_0$. As shown in Section 6, we have observed that our method does not require this extension to achieve good results in general.

3.4.5 PURGING THE DICTIONARY FROM UNUSED ATOMS

Every dictionary learning technique sometimes encounters situations where some of the dictionary atoms are never (or very seldom) used, which typically happens with a very bad initialization. A common practice is to replace these during the optimization by randomly chosen elements of the training set, which solves in practice the problem in most cases. For more difficult and highly regularized cases, it is also possible to choose a continuation strategy consisting of starting from an easier, less regularized problem, and gradually increasing λ. This continuation method has not been used in this paper.

3.5 Link with Second-order Stochastic Gradient Descent

For unconstrained learning problems with twice differentiable expected cost, the second-order stochastic gradient descent algorithm (see Bottou and Bousquet, 2008 and references therein) improves upon its first-order version, by replacing the learning rate by the inverse of the Hessian. When this matrix can be computed or approximated efficiently, this method usually yields a faster convergence speed and removes the problem of tuning the learning rate. However, it cannot be applied easily to constrained optimization problems and requires at every iteration an inverse of the Hessian. For these two reasons, it cannot be used for the dictionary learning problem, but nevertheless it shares some similarities with our algorithm, which we illustrate with the example of a different problem.

Suppose that two major modifications are brought to our original formulation: (i) the vectors α_t are independent of the dictionary $\mathbf{D}$—that is, they are drawn at the same time as $\mathbf{x}_t$; (ii) the optimization is unconstrained—that is, $\mathcal{C} = \mathbb{R}^{m\times k}$. This setting leads to the least-square estimation problem

$$\min_{\mathbf{D}\in\mathbb{R}^{m\times k}} \mathbb{E}_{(\mathbf{x},\alpha)}\left[||\mathbf{x}-\mathbf{D}\alpha||_2^2\right], \tag{8}$$

which is of course different from the original dictionary learning formulation. Nonetheless, it is possible to address Eq. (8) with our method and show that it amounts to using the recursive formula

$$\mathbf{D}_t \leftarrow \mathbf{D}_{t-1} + (\mathbf{x}_t - \mathbf{D}_{t-1}\alpha_t)\alpha_t^T\Big(\sum_{i=1}^{t}\alpha_i\alpha_i^T\Big)^{-1},$$

which is equivalent to a second-order stochastic gradient descent algorithm: The gradient obtained at $(\mathbf{x}_t,\alpha_t)$ is the term $-(\mathbf{x}_t-\mathbf{D}_{t-1}\alpha_t)\alpha_t^T$, and the sequence $(1/t)\sum_{i=1}^{t}\alpha_i\alpha_i^T$ converges to the Hessian of the objective function. Such sequence of updates admit a fast implementation called Kalman algorithm (see Kushner and Yin, 2003 and references therein).

4. Convergence Analysis

The main tools used in our proofs are the convergence of empirical processes (Van der Vaart, 1998) and, following Bottou (1998), the convergence of quasi-martingales (Fisk, 1965). Our analysis is limited to the basic version of the algorithm, although it can in principle be carried over to the optimized versions discussed in Section 3.4. Before proving our main result, let us first discuss the (reasonable) assumptions under which our analysis holds.

4.1 Assumptions

(A) The data admits a distribution with compact support K. Assuming a compact support for the data is natural in audio, image, and video processing applications, where it is imposed by the data acquisition process.

(B) The quadratic surrogate functions $\hat{f}_t$ are strictly convex with lower-bounded Hessians. We assume that the smallest eigenvalue of the positive semi-definite matrix $\frac{1}{t}\mathbf{A}_t$ defined in Algorithm 1 is greater than or equal to some constant κ_1. As a consequence, $\mathbf{A}_t$ is invertible and $\hat{f}_t$ is strictly convex with Hessian $\mathbf{I} \otimes \frac{2}{t}\mathbf{A}_t$. This hypothesis is in practice verified experimentally after a few iterations of the algorithm when the initial dictionary is reasonable, consisting for example of a few elements from the training set, or any common dictionary, such as DCT (bases of cosines products) or wavelets (Mallat, 1999). Note that it is easy to enforce this assumption by adding a term $\frac{\kappa_1}{2}||\mathbf{D}||_F^2$ to the objective function, which is equivalent to replacing the positive semi-definite matrix $\frac{1}{t}\mathbf{A}_t$ by $\frac{1}{t}\mathbf{A}_t + \kappa_1\mathbf{I}$. We have omitted for simplicity this penalization in our analysis.

(C) A particular sufficient condition for the uniqueness of the sparse coding solution is satisfied. Before presenting this assumption, let us briefly recall classical optimality conditions for the ℓ_1 decomposition problem in Eq. (2) (Fuchs, 2005). For $\mathbf{x}$ in K and $\mathbf{D}$ in $\mathcal{C}$, α in $\mathbb{R}^k$ is a solution of Eq. (2) if and only if

$$\begin{aligned} &\mathbf{d}_j^T(\mathbf{x} - \mathbf{D}\alpha) = \lambda \operatorname{sign}(\alpha[j]) \text{ if } \alpha[j] \neq 0, \\ &|\mathbf{d}_j^T(\mathbf{x} - \mathbf{D}\alpha)| \leq \lambda \text{ otherwise.} \end{aligned} \tag{9}$$

Let $\alpha^\star$ be such a solution. Denoting by Λ the set of indices j such that $|\mathbf{d}_j^T(\mathbf{x} - \mathbf{D}\alpha^\star)| = \lambda$, and $\mathbf{D}_\Lambda$ the matrix composed of the columns from $\mathbf{D}$ restricted to the set Λ, it is easy to see from Eq. (9) that the solution $\alpha^\star$ is necessary unique if $(\mathbf{D}_\Lambda^T\mathbf{D}_\Lambda)$ is invertible and that

$$\alpha_\Lambda^\star = (\mathbf{D}_\Lambda^T\mathbf{D}_\Lambda)^{-1}(\mathbf{D}_\Lambda^T\mathbf{x} - \lambda\varepsilon_\Lambda), \tag{10}$$

where $\alpha_\Lambda^\star$ is the vector containing the values of $\alpha^\star$ corresponding to the set Λ and $\varepsilon_\Lambda[j]$ is equal to the sign of $\alpha_\Lambda^\star[j]$ for all j. With this preliminary uniqueness condition in hand, we can now formulate our assumption: *We assume that there exists* $\kappa_2 > 0$ *such that, for all* $\mathbf{x}$ *in* K *and all dictionaries* $\mathbf{D}$ *in the subset of* $\mathcal{C}$ *considered by our algorithm, the smallest eigenvalue of* $\mathbf{D}_\Lambda^T\mathbf{D}_\Lambda$ *is greater than or equal to* κ_2. This guarantees the invertibility of $(\mathbf{D}_\Lambda^T\mathbf{D}_\Lambda)$ and therefore the uniqueness of the solution of Eq. (2). It is of course easy to build a dictionary $\mathbf{D}$ for which this assumption fails. However, having $\mathbf{D}_\Lambda^T\mathbf{D}_\Lambda$ invertible is a common assumption in linear regression and in methods such as the LARS algorithm aimed at solving Eq. (2) (Efron et al., 2004). It is also possible to enforce this condition using an elastic net penalization (Zou and Hastie, 2005), replacing $||\alpha||_1$ by $||\alpha||_1 + \frac{\kappa_2}{2}||\alpha||_2^2$ and thus improving the numerical stability of homotopy algorithms, which is the choice made by Zou et al. (2006). Again, we have omitted this penalization in our analysis.

4.2 Main Results

Given assumptions **(A)**–**(C)**, let us now show that our algorithm converges to a stationary point of the objective function. Since this paper is dealing with non-convex optimization, neither our algorithm nor any one in the literature is guaranteed to find the global optimum of the optimization problem. However, such stationary points have often been found to be empirically good enough

for practical applications, for example, for image restoration (Elad and Aharon, 2006; Mairal et al., 2008b).

Our first result (Proposition 2 below) states that given **(A)–(C)**, $f(\mathbf{D}_t)$ converges almost surely and $f(\mathbf{D}_t) - \hat{f}_t(\mathbf{D}_t)$ converges almost surely to 0, meaning that $\hat{f}_t$ acts as a converging surrogate of f. First, we prove a lemma to show that $\mathbf{D}_t - \mathbf{D}_{t-1} = O(1/t)$. It does not ensure the convergence of $\mathbf{D}_t$, but guarantees the convergence of the positive sum $\sum_{t=1}^{\infty} ||\mathbf{D}_t - \mathbf{D}_{t-1}||_F^2$, a classical condition in gradient descent convergence proofs (Bertsekas, 1999).

Lemma 1 [Asymptotic variations of $\mathbf{D}_t$].
Assume **(A)–(C)**. *Then,*

$$\mathbf{D}_{t+1} - \mathbf{D}_t = O\Big(\frac{1}{t}\Big) \ \ a.s.$$

Proof This proof is inspired by Prop 4.32 of Bonnans and Shapiro (2000) on the Lipschitz regularity of solutions of optimization problems. Using assumption **(B)**, for all t, the surrogate $\hat{f}_t$ is strictly convex with a Hessian lower-bounded by κ_1. Then, a short calculation shows that it verifies the *second-order growth condition*

$$\hat{f}_t(\mathbf{D}_{t+1}) - \hat{f}_t(\mathbf{D}_t) \geq \kappa_1 ||\mathbf{D}_{t+1} - \mathbf{D}_t||_F^2. \tag{11}$$

Moreover,

$$\begin{aligned}\hat{f}_t(\mathbf{D}_{t+1}) - \hat{f}_t(\mathbf{D}_t) &= \hat{f}_t(\mathbf{D}_{t+1}) - \hat{f}_{t+1}(\mathbf{D}_{t+1}) + \hat{f}_{t+1}(\mathbf{D}_{t+1}) - \hat{f}_{t+1}(\mathbf{D}_t) + \hat{f}_{t+1}(\mathbf{D}_t) - \hat{f}_t(\mathbf{D}_t) \\ &\leq \hat{f}_t(\mathbf{D}_{t+1}) - \hat{f}_{t+1}(\mathbf{D}_{t+1}) + \hat{f}_{t+1}(\mathbf{D}_t) - \hat{f}_t(\mathbf{D}_t),\end{aligned}$$

where we have used that $\hat{f}_{t+1}(\mathbf{D}_{t+1}) - \hat{f}_{t+1}(\mathbf{D}_t) \leq 0$ because $\mathbf{D}_{t+1}$ minimizes $\hat{f}_{t+1}$ on $\mathcal{C}$. Since $\hat{f}_t(\mathbf{D}) = \frac{1}{t}(\frac{1}{2}\mathrm{Tr}(\mathbf{D}^T\mathbf{D}\mathbf{A}_t) - \mathrm{Tr}(\mathbf{D}^T\mathbf{B}_t))$, and $||\mathbf{D}||_F \leq \sqrt{k}$, it is possible to show that $\hat{f}_t - \hat{f}_{t+1}$ is Lipschitz with constant $c_t = (1/t)(||\mathbf{B}_{t+1} - \mathbf{B}_t||_F + \sqrt{k}||\mathbf{A}_{t+1} - \mathbf{A}_t||_F)$, which gives

$$\hat{f}_t(\mathbf{D}_{t+1}) - \hat{f}_t(\mathbf{D}_t) \leq c_t ||\mathbf{D}_{t+1} - \mathbf{D}_t||_F. \tag{12}$$

From Eq. (11) and (12), we obtain

$$||\mathbf{D}_{t+1} - \mathbf{D}_t||_F \leq \frac{c_t}{\kappa_1}.$$

Assumptions **(A)**, **(C)** and Eq. (10) ensure that the vectors α_i and $\mathbf{x}_i$ are bounded with probability one and therefore $c_t = O(1/t)$ a.s. ■

We can now state and prove our first proposition, which shows that we are indeed minimizing a smooth function.

Proposition 2 [Regularity of f].
Assume **(A)** *to* **(C)**. *For* $\mathbf{x}$ *in the support K of the probability distribution p, and* $\mathbf{D}$ *in the feasible set $\mathcal{C}$, let us define*

$$\alpha^\star(\mathbf{x}, \mathbf{D}) = \arg\min_{\alpha \in \mathbb{R}^k} \frac{1}{2}||\mathbf{x} - \mathbf{D}\alpha||_2^2 + \lambda||\alpha||_1. \tag{13}$$

Then,

1. the function ℓ defined in Eq. (2) is continuously differentiable and

$$\nabla_{\mathbf{D}}\ell(\mathbf{x},\mathbf{D}) = -(\mathbf{x}-\mathbf{D}\alpha^\star(\mathbf{x},\mathbf{D}))\alpha^\star(\mathbf{x},\mathbf{D})^T.$$

2. f is continuously differentiable and $\nabla f(\mathbf{D}) = \mathbb{E}_{\mathbf{x}}\left[\nabla_{\mathbf{D}}\ell(\mathbf{x},\mathbf{D})\right]$;

3. $\nabla f(\mathbf{D})$ is Lipschitz on $\mathcal{C}$.

Proof Assumption **(A)** ensures that the vectors $\alpha^\star$ are bounded for $\mathbf{x}$ in K and $\mathbf{D}$ in $\mathcal{C}$. Therefore, one can restrict the optimization problem (13) to a compact subset of $\mathbb{R}^k$. Under assumption **(C)**, the solution of Eq. (13) is unique and $\alpha^\star$ is well-defined. Theorem 5 in Appendix A from Bonnans and Shapiro (1998) can be applied and gives us directly the first statement. Since K is compact, and ℓ is continuously differentiable, the second statement follows immediately.

To prove the third claim, we will show that for all $\mathbf{x}$ in K, $\alpha^\star(\mathbf{x},.)$ is Lipschitz with a constant independent of $\mathbf{x}$,[7] which is a sufficient condition for ∇f to be Lipschitz. First, the function optimized in Eq. (13) is continuous in $\alpha, \mathbf{D}, \mathbf{x}$ and has a unique minimum, implying that $\alpha^\star$ is continuous in $\mathbf{x}$ and $\mathbf{D}$.

Consider a matrix $\mathbf{D}$ in $\mathcal{C}$ and $\mathbf{x}$ in K and denote by $\alpha^\star$ the vector $\alpha^\star(\mathbf{x},\mathbf{D})$, and again by Λ the set of indices j such that $|\mathbf{d}_j^T(\mathbf{x}-\mathbf{D}\alpha^\star)| = \lambda$. Since $\mathbf{d}_j^T(\mathbf{x}-\mathbf{D}\alpha^\star)$ is continuous in $\mathbf{D}$ and $\mathbf{x}$, there exists an open neighborhood V around $(\mathbf{x},\mathbf{D})$ such that for all $(\mathbf{x}',\mathbf{D}')$ in V, and $j \notin \Lambda$, $|\mathbf{d}_j^{T'}(\mathbf{x}'-\mathbf{D}'\alpha^{\star\prime})| < \lambda$ and $\alpha^{\star\prime}[j] = 0$, where $\alpha^{\star\prime} = \alpha^\star(\mathbf{x}',\mathbf{D}')$.

Denoting by $\mathbf{U}_\Lambda$ the matrix composed of the columns of a matrix $\mathbf{U}$ corresponding to the index set Λ and similarly by $\mathbf{u}_\Lambda$ the vector composed of the values of a vector $\mathbf{u}$ corresponding to Λ, we consider the function $\tilde{\ell}$

$$\tilde{\ell}(\mathbf{x},\mathbf{D}_\Lambda,\alpha_\Lambda) \triangleq \frac{1}{2}||\mathbf{x}-\mathbf{D}_\Lambda\alpha_\Lambda||_2^2 + \lambda||\alpha_\Lambda||_1,$$

Assumption **(C)** tells us that $\tilde{\ell}(\mathbf{x},\mathbf{D}_\Lambda,.)$ is strictly convex with a Hessian lower-bounded by κ_2. Let us consider $(\mathbf{x}',\mathbf{D}')$ in V. A simple calculation shows that

$$\tilde{\ell}(\mathbf{x},\mathbf{D}_\Lambda,\alpha_\Lambda^{\star\prime}) - \tilde{\ell}(\mathbf{x},\mathbf{D}_\Lambda,\alpha_\Lambda^\star) \geq \kappa_2||\alpha_\Lambda^{\star\prime} - \alpha_\Lambda^\star||_2^2.$$

Moreover, it is easy to show that $\tilde{\ell}(\mathbf{x},\mathbf{D}_\Lambda,.) - \tilde{\ell}(\mathbf{x}',\mathbf{D}'_\Lambda,.)$ is Lipschitz with constant $e_1||\mathbf{D}_\Lambda - \mathbf{D}'_\Lambda||_F + e_2||\mathbf{x}-\mathbf{x}'||_2$, where e_1, e_2 are constants independent of $\mathbf{D},\mathbf{D}',\mathbf{x},\mathbf{x}'$ and then, one can show that

$$||\alpha^{\star\prime} - \alpha^\star||_2 = ||\alpha_\Lambda^{\star\prime} - \alpha_\Lambda^\star||_2 \leq \frac{1}{\kappa_2}\left(e_1||\mathbf{D}-\mathbf{D}'||_F + e_2||\mathbf{x}-\mathbf{x}'||_2\right).$$

Therefore, $\alpha^\star$ is locally Lipschitz. Since $K \times \mathcal{C}$ is compact, $\alpha^\star$ is uniformly Lipschitz on $K \times \mathcal{C}$, which concludes the proof. ■

Now that we have shown that f is a smooth function, we can state our first result showing that the sequence of functions $\hat{f}_t$ acts asymptotically as a surrogate of f and that $f(\mathbf{D}_t)$ converges almost surely in the following proposition.

7. From now on, for a vector $\mathbf{x}$ in $\mathbb{R}^m$, $\alpha^\star(\mathbf{x},.)$ denotes the function that associates to a matrix $\mathbf{D}$ verifying Assumption **(C)**, the optimal solution $\alpha^\star(\mathbf{x},\mathbf{D})$. For simplicity, we will use these slightly abusive notation in the rest of the paper.

Proposition 3 [Convergence of $f(\mathbf{D}_t)$ and of the surrogate function]. *Let $\hat{f}_t$ denote the surrogate function defined in Eq. (5). Assume* **(A)** *to* **(C)**. *Then,*

1. *$\hat{f}_t(\mathbf{D}_t)$ converges almost surely;*
2. *$f(\mathbf{D}_t) - \hat{f}_t(\mathbf{D}_t)$ converges almost surely to 0;*
3. *$f(\mathbf{D}_t)$ converges almost surely.*

Proof Part of this proof is inspired by Bottou (1998). We prove the convergence of the sequence $\hat{f}_t(\mathbf{D}_t)$ by showing that the stochastic positive process

$$u_t \triangleq \hat{f}_t(\mathbf{D}_t) \geq 0,$$

is a quasi-martingale and use Theorem 6 from Fisk (1965) (see Appendix A), which states that if the sum of the "positive" variations of u_t are bounded, u_t is a quasi-martingale, which converges with probability one (see Theorem 6 for details). Computing the variations of u_t, we obtain

$$\begin{aligned} u_{t+1} - u_t &= \hat{f}_{t+1}(\mathbf{D}_{t+1}) - \hat{f}_t(\mathbf{D}_t) \\ &= \hat{f}_{t+1}(\mathbf{D}_{t+1}) - \hat{f}_{t+1}(\mathbf{D}_t) + \hat{f}_{t+1}(\mathbf{D}_t) - \hat{f}_t(\mathbf{D}_t) \\ &= \hat{f}_{t+1}(\mathbf{D}_{t+1}) - \hat{f}_{t+1}(\mathbf{D}_t) + \frac{\ell(\mathbf{x}_{t+1}, \mathbf{D}_t) - f_t(\mathbf{D}_t)}{t+1} + \frac{f_t(\mathbf{D}_t) - \hat{f}_t(\mathbf{D}_t)}{t+1}, \end{aligned} \tag{14}$$

using the fact that $\hat{f}_{t+1}(\mathbf{D}_t) = \frac{1}{t+1}\ell(\mathbf{x}_{t+1}, \mathbf{D}_t) + \frac{t}{t+1}\hat{f}_t(\mathbf{D}_t)$. Since $\mathbf{D}_{t+1}$ minimizes $\hat{f}_{t+1}$ on $\mathcal{C}$ and $\mathbf{D}_t$ is in $\mathcal{C}$, $\hat{f}_{t+1}(\mathbf{D}_{t+1}) - \hat{f}_{t+1}(\mathbf{D}_t) \leq 0$. Since the surrogate $\hat{f}_t$ upperbounds the empirical cost f_t, we also have $f_t(\mathbf{D}_t) - \hat{f}_t(\mathbf{D}_t) \leq 0$. To use Theorem 6, we consider the filtration of the past information $\mathcal{F}_t$ and take the expectation of Eq. (14) conditioned on $\mathcal{F}_t$, obtaining the following bound

$$\begin{aligned} \mathbb{E}[u_{t+1} - u_t | \mathcal{F}_t] &\leq \frac{\mathbb{E}[\ell(\mathbf{x}_{t+1}, \mathbf{D}_t) | \mathcal{F}_t] - f_t(\mathbf{D}_t)}{t+1} \\ &\leq \frac{f(\mathbf{D}_t) - f_t(\mathbf{D}_t)}{t+1} \\ &\leq \frac{||f - f_t||_\infty}{t+1}, \end{aligned}$$

For a specific matrix $\mathbf{D}$, the central-limit theorem states that $\mathbb{E}[\sqrt{t}(f(\mathbf{D}_t) - f_t(\mathbf{D}_t))]$ is bounded. However, we need here a stronger result on empirical processes to show that $\mathbb{E}[\sqrt{t}||f - f_t||_\infty]$ is bounded. To do so, we use the Lemma 7 in Appendix A, which is a corollary of Donsker theorem (see Van der Vaart, 1998, chap. 19.2). It is easy to show that in our case, all the hypotheses are verified, namely, $\ell(\mathbf{x}, .)$ is uniformly Lipschitz and bounded since it is continuously differentiable on a compact set, the set $\mathcal{C} \subset \mathbb{R}^{m \times k}$ is bounded, and $\mathbb{E}_{\mathbf{x}}[\ell(\mathbf{x}, \mathbf{D})^2]$ exists and is uniformly bounded. Therefore, Lemma 7 applies and there exists a constant $\kappa > 0$ such that

$$\mathbb{E}[\mathbb{E}[u_{t+1} - u_t | \mathcal{F}_t]^+] \leq \frac{\kappa}{t^{\frac{3}{2}}}.$$

Therefore, defining δ_t as in Theorem 6, we have

$$\sum_{t=1}^{\infty} \mathbb{E}[\delta_t (u_{t+1} - u_t)] = \sum_{t=1}^{\infty} \mathbb{E}[\mathbb{E}[u_{t+1} - u_t | \mathcal{F}_t]^+] < +\infty.$$

Thus, we can apply Theorem 6, which proves that u_t converges almost surely and that

$$\sum_{t=1}^{\infty} |\mathbb{E}[u_{t+1} - u_t | \mathcal{F}_t]| < +\infty \text{ a.s.}$$

Using Eq. (14) we can show that it implies the almost sure convergence of the positive sum

$$\sum_{t=1}^{\infty} \frac{\hat{f}_t(\mathbf{D}_t) - f_t(\mathbf{D}_t)}{t+1}.$$

Using Lemma 1 and the fact that the functions f_t and $\hat{f}_t$ are bounded and Lipschitz, with a constant independent of t, it is easy to show that the hypotheses of Lemma 8 in Appendix A are satisfied. Therefore

$$f_t(\mathbf{D}_t) - \hat{f}_t(\mathbf{D}_t) \underset{t \to +\infty}{\longrightarrow} 0 \text{ a.s.}$$

Since $\hat{f}_t(\mathbf{D}_t)$ converges almost surely, this shows that $f_t(\mathbf{D}_t)$ converges in probability to the same limit. Note that we have in addition $||f_t - f||_\infty \to_{t \to +\infty} 0$ a.s. (see Van der Vaart, 1998, Theorem 19.4 (Glivenko-Cantelli)). Therefore,

$$f(\mathbf{D}_t) - \hat{f}_t(\mathbf{D}_t) \underset{t \to +\infty}{\longrightarrow} 0 \text{ a.s.}$$

and $f(\mathbf{D}_t)$ converges almost surely, which proves the second and third points. ■

With Proposition 3 in hand, we can now prove our final and strongest result, namely that first-order necessary optimality conditions are verified asymptotically with probability one.

Proposition 4 [Convergence to a stationary point]. *Under assumptions* **(A)** *to* **(C)**, *the distance between* $\mathbf{D}_t$ *and the set of stationary points of the dictionary learning problem converges almost surely to* 0 *when* t *tends to infinity.*

Proof Since the sequences of matrices $\mathbf{A}_t, \mathbf{B}_t$ are in a compact set, it is possible to extract converging subsequences. Let us assume for a moment that these sequences converge respectively to two matrices $\mathbf{A}_\infty$ and $\mathbf{B}_\infty$. In that case, $\mathbf{D}_t$ converges to a matrix $\mathbf{D}_\infty$ in $\mathcal{C}$. Let $\mathbf{U}$ be a matrix in $\mathbb{R}^{m \times k}$. Since $\hat{f}_t$ upperbounds f_t on $\mathbb{R}^{m \times k}$, for all t,

$$\hat{f}_t(\mathbf{D}_t + \mathbf{U}) \geq f_t(\mathbf{D}_t + \mathbf{U}).$$

Taking the limit when t tends to infinity,

$$\hat{f}_\infty(\mathbf{D}_\infty + \mathbf{U}) \geq f(\mathbf{D}_\infty + \mathbf{U}).$$

Let $h_t > 0$ be a sequence that converges to 0. Using a first order Taylor expansion, and using the fact that ∇f is Lipschitz and $\hat{f}_\infty(\mathbf{D}_\infty) = f(\mathbf{D}_\infty)$ a.s., we have

$$f(\mathbf{D}_\infty) + \text{Tr}(h_t \mathbf{U}^T \nabla \hat{f}_\infty(\mathbf{D}_\infty)) + o(h_t \mathbf{U}) \geq f(\mathbf{D}_\infty) + \text{Tr}(h_t \mathbf{U}^T \nabla f(\mathbf{D}_\infty)) + o(h_t \mathbf{U}),$$

and it follows that

$$\text{Tr}\Big(\frac{1}{||\mathbf{U}||_F} \mathbf{U}^T \nabla \hat{f}_\infty(\mathbf{D}_\infty)\Big) \geq \text{Tr}\Big(\frac{1}{||\mathbf{U}_t||_F} \mathbf{U}^T \nabla f(\mathbf{D}_\infty)\Big),$$

Since this inequality is true for all $\mathbf{U}, \nabla \hat{f}_\infty(\mathbf{D}_\infty) = \nabla f(\mathbf{D}_\infty)$. A first-order necessary optimality condition for $\mathbf{D}_\infty$ being an optimum of $\hat{f}_\infty$ is that $-\nabla \hat{f}_\infty$ is in the *normal cone* of the set $\mathcal{C}$ at $\mathbf{D}_\infty$ (Borwein and Lewis, 2006). Therefore, this first-order necessary conditions is verified for f at $\mathbf{D}_\infty$ as well. Since $\mathbf{A}_t, \mathbf{B}_t$ are asymptotically close to their accumulation points, $-\nabla f(\mathbf{D}_t)$ is asymptotically close the normal cone at $\mathbf{D}_t$ and these first-order optimality conditions are verified asymptotically with probability one. ■

5. Extensions to Matrix Factorization

In this section, we present variations of the basic online algorithm to address different optimization problems. We first present different possible regularization terms for α and $\mathbf{D}$, which can be used with our algorithm, and then detail some specific cases such as non-negative matrix factorization, sparse principal component analysis, constrained sparse coding, and simultaneous sparse coding.

5.1 Using Different Regularizers for α

In various applications, different priors for the coefficients α may lead to different regularizers $\psi(\alpha)$. As long as the assumptions of Section 4.1 are verified, our algorithm can be used with:

- Positivity constraints on α that are added to the ℓ_1-regularization. The homotopy method presented in Efron et al. (2004) is able to handle such constraints.
- The Tikhonov regularization, $\psi(\alpha) = \frac{\lambda_1}{2}||\alpha||_2^2$, which does not lead to sparse solutions.
- The elastic net (Zou and Hastie, 2005), $\psi(\alpha) = \lambda_1||\alpha||_1 + \frac{\lambda_2}{2}||\alpha||_2^2$, leading to a formulation relatively close to Zou et al. (2006).
- The group Lasso (Yuan and Lin, 2006; Turlach et al., 2005; Bach, 2008), $\psi(\alpha) = \sum_{i=1}^{s} ||\alpha_i||_2$, where α_i is a vector corresponding to a group of variables.

Non-convex regularizers such as the ℓ_0 pseudo-norm, ℓ_p pseudo-norm with $p < 1$ can be used as well. However, as with any classical dictionary learning techniques exploiting non-convex regularizers (e.g., Olshausen and Field, 1997; Engan et al., 1999; Aharon et al., 2006), there is no theoretical convergence results in these cases. Note also that convex smooth approximation of sparse regularizers (Bradley and Bagnell, 2009), or structured sparsity-inducing regularizers (Jenatton et al., 2009a; Jacob et al., 2009) could be used as well even though we have not tested them.

5.2 Using Different Constraint Sets for D

In the previous subsection, we have claimed that our algorithm could be used with different regularization terms on α. For the dictionary learning problem, we have considered an ℓ_2-regularization on $\mathbf{D}$ by forcing its columns to have less than unit ℓ_2-norm. We have shown that with this constraint set, the dictionary update step can be solved efficiently using a block-coordinate descent approach. Updating the j-th column of $\mathbf{D}$, when keeping the other ones fixed is solved by orthogonally projecting the vector $\mathbf{u}_j = \mathbf{d}_j + (1/\mathbf{A}[j,j])(\mathbf{b}_j - \mathbf{D}\mathbf{a}_j)$ on the constraint set $\mathcal{C}$, which in the classical dictionary learning case amounts to a projection of $\mathbf{u}_j$ on the ℓ_2-ball.

It is easy to show that this procedure can be extended to different convex constraint sets $\mathcal{C}'$ as long as the constraints are a union of independent constraints on each column of $\mathbf{D}$ and the orthogonal projections of the vectors $\mathbf{u}_j$ onto the set $\mathcal{C}'$ can be done efficiently. Examples of different sets $\mathcal{C}'$ that we propose as an alternative to $\mathcal{C}$ are

- The "non-negative" constraints:

$$\mathcal{C}' = \{\mathbf{D} \in \mathbb{R}^{m\times k} \text{ s.t. } \forall j = 1,\ldots,k, \ ||\mathbf{d}_j||_2 \leq 1 \text{ and } \mathbf{d}_j \geq 0\}.$$

- The "elastic-net" constraints:

$$\mathcal{C}' \triangleq \{\mathbf{D} \in \mathbb{R}^{m\times k} \text{ s.t. } \forall j = 1,\ldots,k, \ ||\mathbf{d}_j||_2^2 + \gamma||\mathbf{d}_j||_1 \leq 1\}.$$

  These constraints induce sparsity in the dictionary $\mathbf{D}$ (in addition to the sparsity-inducing regularizer on the vectors α_i). By analogy with the regularization proposed by Zou and Hastie (2005), we call these constraints "elastic-net constraints." Here, γ is a new parameter, controlling the sparsity of the dictionary $\mathbf{D}$. Adding a non-negativity constraint is also possible in this case. Note that the presence of the ℓ_2 regularization is important here. It has been shown by Bach et al. (2008) that using the ℓ_1-norm only in such problems lead to trivial solutions when k is large enough. The combination of ℓ_1 and ℓ_2 constraints has also been proposed recently for the problem of matrix factorization by Witten et al. (2009), but in a slightly different setting.

- The "fused lasso" (Tibshirani et al., 2005) constraints. When one is looking for a dictionary whose columns are sparse and piecewise-constant, a fused lasso regularization can be used. For a vector $\mathbf{u}$ in $\mathbb{R}^m$, we consider the ℓ_1-norm of the consecutive differences of $\mathbf{u}$ denoted by

$$\text{FL}(\mathbf{u}) \triangleq \sum_{i=2}^{m} |\mathbf{u}[i] - \mathbf{u}[i-1]|,$$

  and define the "fused lasso" constraint set

$$\mathcal{C}' \triangleq \{\mathbf{D} \in \mathbb{R}^{m\times k} \text{ s.t. } \forall j = 1,\ldots,k, \ ||\mathbf{d}_j||_2^2 + \gamma_1||\mathbf{d}_j||_1 + \gamma_2 \text{FL}(\mathbf{d}_j) \leq 1\}.$$

  This kind of regularization has proven to be useful for exploiting genomic data such as CGH arrays (Tibshirani and Wang, 2008).

In all these settings, replacing the projections of the vectors $\mathbf{u}_j$ onto the ℓ_2-ball by the projections onto the new constraints, our algorithm is still guaranteed to converge and find a stationary point of the optimization problem. The orthogonal projection onto the "non negative" ball is simple (additional thresholding) but the projection onto the two other sets is slightly more involved. In Appendix B, we propose two algorithms for efficiently solving these problems. The first one is presented in Section B.1 and computes the projection of a vector onto the elastic-net constraint in linear time, by extending the efficient projection onto the ℓ_1-ball from Maculan and de Paula (1989) and Duchi et al. (2008). The second one is a homotopy method, which solves the projection on the fused lasso constraint set in $O(ks)$, where s is the number of piecewise-constant parts in the solution. This method also solves efficiently the fused lasso signal approximation problem presented in Friedman et al. (2007):

$$\min_{\mathbf{u}\in\mathbb{R}^n} \frac{1}{2}||\mathbf{b} - \mathbf{u}||_2^2 + \gamma_1||\mathbf{u}||_1 + \gamma_2 \text{FL}(\mathbf{u}) + \gamma_3||\mathbf{u}||_2^2.$$

Being able to solve this problem efficiently has also numerous applications, which are beyond the scope of this paper. For instance, it allows us to use the fast algorithm of Nesterov (2007) for solving the more general fused lasso problem (Tibshirani et al., 2005). Note that the proposed method could be used as well with more complex constraints for the columns of $\mathbf{D}$, which we have not tested in this paper, addressing for instance the problem of structured sparse PCA (Jenatton et al., 2009b).

Now that we have presented a few possible regularizers for α and $\mathbf{D}$, that can be used within our algorithm, we focus on a few classical problems which can be formulated as dictionary learning problems with specific combinations of such regularizers.

5.3 Non Negative Matrix Factorization

Given a matrix $\mathbf{X} = [\mathbf{x}_1, \ldots, \mathbf{x}_n]$ in $\mathbb{R}^{m \times n}$, Lee and Seung (2001) have proposed the non negative matrix factorization problem (NMF), which consists of minimizing the following cost

$$\min_{\mathbf{D} \in \mathcal{C}, \alpha \in \mathbb{R}^{k \times n}} \sum_{i=1}^{n} \frac{1}{2} ||\mathbf{x}_i - \mathbf{D}\alpha_i||_2^2 \text{ s.t. } \mathbf{D} \geq 0, \ \forall \, i, \ \ \alpha_i \geq 0.$$

With this formulation, the matrix $\mathbf{D}$ and the vectors α_i are forced to have non negative components, which leads to sparse solutions. When applied to images, such as faces, Lee and Seung (2001) have shown that the learned features are more localized than the ones learned with a classical singular value decomposition. As for dictionary learning, classical approaches for addressing this problem are batch algorithms, such as the multiplicative update rules of Lee and Seung (2001), or the projected gradient descent algorithm of Lin (2007).

Following this line of research, Hoyer (2002, 2004) has proposed non negative sparse coding (NNSC), which extends non-negative matrix factorization by adding a sparsity-inducing penalty to the objective function to further control the sparsity of the vectors α_i:

$$\min_{\mathbf{D} \in \mathcal{C}, \alpha \in \mathbb{R}^{k \times n}} \sum_{i=1}^{n} \left(\frac{1}{2} ||\mathbf{x}_i - \mathbf{D}\alpha_i||_2^2 + \lambda \sum_{j=1}^{k} \alpha_i[j] \right) \text{ s.t. } \mathbf{D} \geq 0, \ \forall \, i, \ \ \alpha_i \geq 0.$$

When $\lambda = 0$, this formulation is equivalent to NMF. The only difference with the dictionary learning problem is that non-negativity constraints are imposed on $\mathbf{D}$ and the vectors α_i. A simple modification of our algorithm, presented above, allows us to handle these constraints, while guaranteeing to find a stationary point of the optimization problem. Moreover, our approach can work in the setting when n is large.

5.4 Sparse Principal Component Analysis

Principal component analysis (PCA) is a classical tool for data analysis, which can be interpreted as a method for finding orthogonal directions maximizing the variance of the data, or as a low-rank matrix approximation method. Jolliffe et al. (2003), Zou et al. (2006), d'Aspremont et al. (2007), d'Aspremont et al. (2008), Witten et al. (2009) and Zass and Shashua (2007) have proposed different formulations for sparse principal component analysis (SPCA), which extends PCA by estimating sparse vectors maximizing the variance of the data, some of these formulations enforcing orthogonality between the sparse components, whereas some do not. In this paper, we formulate SPCA as a sparse matrix factorization which is equivalent to the dictionary learning problem with

eventually sparsity constraints on the dictionary—that is, we use the ℓ_1-regularization term for α and the "elastic-net" constraint for $\mathbf{D}$ (as used in a penalty term by Zou et al. 2006):

$$\min_{\alpha\in\mathbb{R}^{k\times n}} \sum_{i=1}^{n} \left(\frac{1}{2}||\mathbf{x}_i - \mathbf{D}\alpha_i||_2^2 + \lambda||\alpha_i||_1\right) \text{ s.t. } \forall j = 1,\ldots,k, \ ||\mathbf{d}_j||_2^2 + \gamma||\mathbf{d}_j||_1 \leq 1.$$

As detailed above, our dictionary update procedure amounts to successive orthogonal projection of the vectors $\mathbf{u}_j$ on the constraint set. More precisely, the update of $\mathbf{d}_j$ becomes

$$\begin{aligned}
\mathbf{u}_j &\leftarrow \frac{1}{\mathbf{A}[j,j]}(\mathbf{b}_j - \mathbf{D}\mathbf{a}_j) + \mathbf{d}_j,\\
\mathbf{d}_j &\leftarrow \arg\min_{\mathbf{d}\in\mathbb{R}^m} ||\mathbf{u}_j - \mathbf{d}||_2^2 \text{ s.t. } ||\mathbf{d}||_2^2 + \gamma||\mathbf{d}||_1 \leq 1,
\end{aligned}$$

which can be solved in linear time using Algorithm 3 presented in Appendix B. In addition to that, our SPCA method can be used with fused Lasso constraints as well.

5.5 Constrained Sparse Coding

Constrained sparse coding problems are often encountered in the literature, and lead to different loss functions such as

$$\ell'(\mathbf{x},\mathbf{D}) = \min_{\alpha\in\mathbb{R}^k} ||\mathbf{x} - \mathbf{D}\alpha||_2^2 \text{ s.t. } ||\alpha||_1 \leq T, \tag{15}$$

or

$$\ell''(\mathbf{x},\mathbf{D}) = \min_{\alpha\in\mathbb{R}^k} ||\alpha||_1 \text{ s.t. } ||\mathbf{x} - \mathbf{D}\alpha||_2^2 \leq \varepsilon, \tag{16}$$

where T and ε are pre-defined thresholds. Even though these loss functions lead to equivalent optimization problems in the sense that for given $\mathbf{x},\mathbf{D}$ and λ, there exist ε and T such that $\ell(\mathbf{x},\mathbf{D})$, $\ell'(\mathbf{x},\mathbf{D})$ and $\ell''(\mathbf{x},\mathbf{D})$ admit the same solution $\alpha^\star$, the problems of learning $\mathbf{D}$ using ℓ, ℓ' of ℓ'' are not equivalent. For instance, using ℓ'' has proven experimentally to be particularly well adapted to image denoising (Elad and Aharon, 2006; Mairal et al., 2008b).

For all T, the same analysis as for ℓ can be carried for ℓ', and the simple modification which consists of computing α_t using Eq. (15) in the sparse coding step leads to the minimization of the expected cost $\min_{\mathbf{D}\in\mathcal{C}} \mathbb{E}_{\mathbf{x}}[\ell'(\mathbf{x},\mathbf{D})]$.

Handling the case ℓ'' is a bit different. We propose to use the same strategy as for ℓ'—that is, using our algorithm but computing α_t solving Eq. (16). Even though our analysis does not apply since we do not have a quadratic surrogate of the expected cost, experimental evidence shows that this approach is efficient in practice.

5.6 Simultaneous Sparse Coding

In some situations, the signals $\mathbf{x}_i$ are not i.i.d samples of an unknown probability distribution, but are structured in groups (which are however independent from each other), and one may want to address the problem of simultaneous sparse coding, which appears also in the literature under various names such as group sparsity or grouped variable selection (Cotter et al., 2005; Turlach et al., 2005; Yuan and Lin, 2006; Obozinski et al., 2009, 2008; Zhang et al., 2008; Tropp et al., 2006; Tropp, 2006). Let $\mathbf{X} = [\mathbf{x}_1,\ldots,\mathbf{x}_q] \in \mathbb{R}^{m\times q}$ be a set of signals. Suppose one wants to obtain sparse decompositions of the signals on the dictionary $\mathbf{D}$ that share the same active set (non-zero coefficients).

Let $\alpha = [\alpha_1, \ldots, \alpha_q]$ in $\mathbb{R}^{k \times q}$ be the matrix composed of the coefficients. One way of imposing this *joint sparsity* is to penalize the number of non-zero rows of α. A classical convex relaxation of this joint sparsity measure is to consider the $\ell_{1,2}$-norm on the matrix α

$$||\alpha||_{1,2} \triangleq \sum_{j=1}^{k} ||\alpha^j||_2,$$

where α^j is the j-th row of α. In that setting, the $\ell_{1,2}$-norm of α is the ℓ_1-norm of the ℓ_2-norm of the rows of α.

The problem of jointly decomposing the signals $\mathbf{x}_i$ can be written as a $\ell_{1,2}$-sparse decomposition problem, which is a subcase of the group Lasso (Turlach et al., 2005; Yuan and Lin, 2006; Bach, 2008), by defining the cost function

$$\ell'''(\mathbf{X}, \mathbf{D}) = \min_{\alpha \in \mathbb{R}^{k \times q}} \frac{1}{2} ||\mathbf{X} - \mathbf{D}\alpha||_F^2 + \lambda ||\alpha||_{1,2},$$

which can be computed using a block-coordinate descent approach (Friedman et al., 2007) or an active set method (Roth and Fischer, 2008).

Suppose now that we are able to draw groups of signals $\mathbf{X}_i, i = 1, \ldots, n$ which have bounded size and are independent from each other and identically distributed, one can learn an adapted dictionary by solving the optimization problem

$$\min_{\mathbf{D} \in \mathcal{C}} \lim_{n \to \infty} \frac{1}{n} \sum_{i=1}^{n} \ell'''(\mathbf{X}_i, \mathbf{D}).$$

Being able to solve this optimization problem is important for many applications. For instance, in Mairal et al. (2009c), state-of-the-art results in image denoising and demosaicking are achieved with this formulation. The extension of our algorithm to this case is relatively easy, computing at each sparse coding step a matrix of coefficients α, and keeping the updates of $\mathbf{A}_t$ and $\mathbf{B}_t$ unchanged.

All of the variants of this section have been implemented. Next section evaluates some of them experimentally. An efficient C++ implementation with a Matlab interface of these variants is available on the Willow project-team web page `http://www.di.ens.fr/willow/SPAMS/`.

6. Experimental Validation

In this section, we present experiments on natural images and genomic data to demonstrate the efficiency of our method for dictionary learning, non-negative matrix factorization, and sparse principal component analysis.

6.1 Performance Evaluation for Dictionary Learning

For our experiments, we have randomly selected 1.25×10^6 patches from images in the Pascal VOC'06 image database (Everingham et al., 2006), which is composed of varied natural images; 10^6 of these are kept for training, and the rest for testing. We used these patches to create three data sets A, B, and C with increasing patch and dictionary sizes representing various settings which are typical in image processing applications: We have centered and normalized the patches to have unit ℓ_2-norm and used the regularization parameter $\lambda = 1.2/\sqrt{m}$ in all of our experiments. The $1/\sqrt{m}$

Data set	Signal size m	Nb k of atoms	Type
A	$8 \times 8 = 64$	256	b&w
B	$12 \times 12 \times 3 = 432$	512	color
C	$16 \times 16 = 256$	1024	b&w

term is a classical normalization factor (Bickel et al., 2009), and the constant 1.2 has shown to yield about 10 nonzero coefficients for data set A and 40 for data sets B and C in these experiments. We have implemented the proposed algorithm in C++ with a Matlab interface. All the results presented in this section use the refinements from Section 3.4 since this has lead empirically to speed improvements. Although our implementation is multithreaded, our experiments have been run for simplicity on a single-CPU, single-core 2.66Ghz machine.

The first parameter to tune is η, the number of signals drawn at each iteration. Trying different powers of 2 for this variable has shown that $\eta = 512$ was a good choice (lowest objective function values on the training set—empirically, this setting also yields the lowest values on the test set). Even though this parameter is fairly easy to tune since values of $64, 128, 256$ and 1024 have given very similar performances, the difference with the choice $\eta = 1$ is significant.

Our implementation can be used in both the online setting it is intended for, and in a regular batch mode where it uses the entire data set at each iteration. We have also implemented a first-order stochastic gradient descent algorithm that shares most of its code with our algorithm, except for the dictionary update step. This setting allows us to draw meaningful comparisons between our algorithm and its batch and stochastic gradient alternatives, which would have been difficult otherwise. For example, comparing our algorithm to the Matlab implementation of the batch approach from Lee et al. (2007) developed by its authors would have been unfair since our C++ program has a built-in speed advantage.[8] To measure and compare the performances of the three tested methods, we have plotted the value of the objective function on *the test set*, acting as a surrogate of the expected cost, as a function of the corresponding training time.

6.1.1 ONLINE VS. BATCH

The left column of Figure 1 compares the online and batch settings of our implementation. The full training set consists of 10^6 samples. The online version of our algorithm draws samples from the entire set, and we have run its batch version on the full data set as well as subsets of size 10^4 and 10^5 (see Figure 1). The online setting systematically outperforms its batch counterpart for every training set size and desired precision. We use a logarithmic scale for the computation time, which shows that in many situations, the difference in performance can be dramatic. Similar experiments have given similar results on smaller data sets. Our algorithm uses all the speed-ups from Section 3.4. The parameter ρ was chosen by trying the values $0, 5, 10, 15, 20, 25$, and t_0 by trying different powers of 10. We have selected $(t_0 = 0.001, \rho = 15)$, which has given the best performance in terms of objective function evaluated on the training set for the three data sets. We have plotted three curves for our method: OL1 corresponds to the optimal setting $(t_0 = 0.001, \rho = 15)$. Even though tuning two parameters might seem cumbersome, we have plotted two other curves showing that, on the contrary, our method is very easy to use. The curve OL2, corresponding to the setting

8. Both LARS and the feature-sign algorithm (Lee et al., 2007) require a large number of low-level operations which are not well optimized in Matlab. We have indeed observed that our C++ implementation of LARS is up to 50 times faster than the Matlab implementation of the feature-sign algorithm of Lee et al. (2007) for our experiments.

$(t_0 = 0.001, \rho = 10)$, is very difficult to distinguish from the first curve and we have observed a similar behavior with the setting $(t_0 = 0.001, \rho = 20)$. showing that our method is *robust to the choice of the parameter* ρ. We have also observed that the parameter ρ is useful for large data sets only. When using smaller ones ($n \leq 100,000$), it did not bring any benefit.

Moreover, the curve OL3 is obtained without using a tuned parameter t_0—that is, $\rho = 15$ and $t_0 = 0$, and shows that its influence is very limited since very good results are obtained without using it. On the other hand, we have observed that using a parameter t_0 too big, could slightly slow down our algorithm during the first epoch (cycle on the training set).

6.1.2 COMPARISON WITH STOCHASTIC GRADIENT DESCENT

Our experiments have shown that obtaining good performance with stochastic gradient descent requires using both the mini-batch heuristic *and* carefully choosing a learning rate of the form $a/(\eta t + b)$. To give the fairest comparison possible, we have thus optimized these parameters. As for our algorithm, sampling η values among powers of 2 (as before) has shown that $\eta = 512$ was a good value and gives a significant better performance than $\eta = 1$.

In an earlier version of this work (Mairal et al., 2009a), we have proposed a strategy for our method which does not require any parameter tuning except the mini-batch η and compared it with the stochastic gradient descent algorithm (SGD) with a learning rate of the form $a/(\eta t)$. While our method has improved in performance using the new parameter ρ, SGD has also proven to provide much better results when using a learning rate of the form $a/(\eta t + b)$ instead of $a/(\eta t)$, at the cost of an extra parameter b to tune. Using the learning rate $a/(\eta t)$ with a high value for a results indeed in too large initial steps of the algorithm increasing dramatically the value of the objective function, and a small value of a leads to bad asymptotic results, while a learning rate of the form $a/(\eta t + b)$ is a good compromise.

We have tried different powers of 10 for a and b. First selected the couple $(a = 100,000, b = 100,000)$ and then refined it, trying the values $100,000 \times 2^i$ for $i = -3, \ldots, 3$. Finally, we have selected $(a = 200,000, b = 400,000)$. As shown on the right column of Figure 1, this setting represented by the curve SG1 leads to similar results as our method. The curve SG2 corresponds to the parameters $(a = 400,000, b = 400,000)$ and shows that increasing slightly the parameter a makes the curves worse than the others during the first iterations (see for instance the curve between 1 and 10^2 seconds for data set A), but still lead to good asymptotic results. The curve SG3 corresponds to a situation where a and b are slightly too small $(a = 50,000, b = 100,000)$. It is as good as SG1 for data sets A and B, but asymptotically slightly below the others for data set C. All the curves are obtained as the average of three experiments with different initializations. Interestingly, even though the problem is not convex, the different initializations have led to very similar values of the objective function and the variance of the experiments was always insignificant after 10 seconds of computations.

6.2 Non Negative Matrix Factorization and Non Negative Sparse Coding

In this section, we compare our method with the classical algorithm of Lee and Seung (2001) for NMF and the non-negative sparse coding algorithm of Hoyer (2002) for NNSC. The experiments have been carried out on three data sets with different sizes:

- Data set D is composed of $n = 2,429$ face images of size $m = 19 \times 19$ pixels from the the MIT-CBCL Face Database #1 (Sung, 1996).

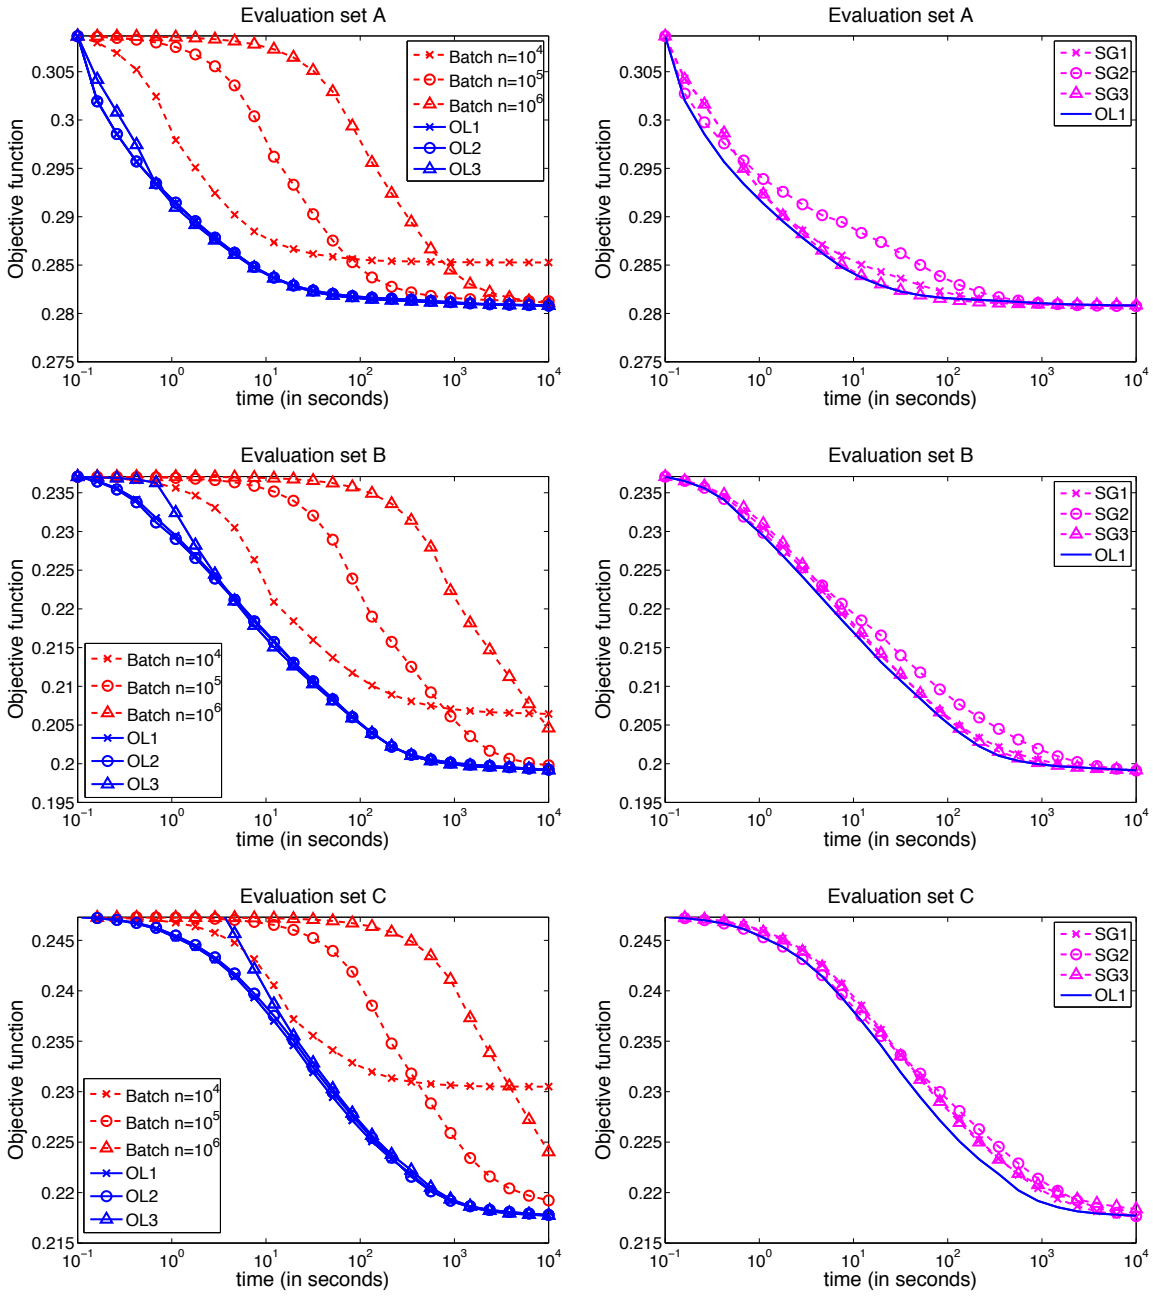

Figure 1: Left: Comparison between our method and the batch approach for dictionary learning. Right: Comparison between our method and stochastic gradient descent. The results are reported for three data sets as a function of computation time on a logarithmic scale. Note that the times of computation that are less than $0.1s$ are not reported. See text for details.

- Data set E is composed of $n = 2,414$ face images of size $m = 192 \times 168$ pixels from the Extended Yale B Database (Georghiades et al., 2001; Lee et al., 2005).
- Data set F is composed of $n = 100,000$ natural image patches of size $m = 16 \times 16$ pixels from the Pascal VOC'06 image database (Everingham et al., 2006).

We have used the Matlab implementations of NMF and NNSC of P. Hoyer, which are freely available at `http://www.cs.helsinki.fi/u/phoyer/software.html`. Even though our C++ implementation has a built-in advantage in terms of speed over these Matlab implementations, most of the computational time of NMF and NNSC is spent on large matrix multiplications, which are typically well optimized in Matlab. All the experiments have been run for simplicity on a single-CPU, single-core 2.4GHz machine, without using the parameters ρ and t_0 presented in Section 3.4—that is, $\rho = 0$ and $t_0 = 0$. As in Section 6.1, a minibatch of size $\eta = 512$ is chosen. Following the original experiment of Lee and Seung (2001) on data set D, we have chosen to learn $k = 49$ basis vectors for the face images data sets D and E, and we have chosen $k = 64$ for data set F. Each input vector is normalized to have unit ℓ_2-norm.

The experiments we present in this section compare the value of the objective function on the data sets obtained with the different algorithms as a function of the computation time. Since our algorithm learns the matrix $\mathbf{D}$ but does not provide the matrix α, the computation times reported for our approach include two steps: First, we run our algorithm to obtain $\mathbf{D}$. Second, we run one sparse coding step over all the input vectors to obtain α. Figure 2 presents the results for NMF and NNSC. The gradient step for the algorithm of Hoyer (2002) was optimized for the best performance and λ was set to $\frac{1}{\sqrt{m}}$. Both $\mathbf{D}$ and α were initialized randomly. The values reported are those obtained for more than 0.1s of computation. Since the random initialization provides an objective value which is by far greater than the value obtained at convergence, the curves are all truncated to present significant objective values. All the results are obtained using the average of 3 experiments with different initializations. As shown on Figure 2, our algorithm provides a significant improvement in terms of speed compared to the other tested methods, even though the results for NMF and NNSC could be improved a bit using a C++ implementation.

6.3 Sparse Principal Component Analysis

We present here the application of our method addressing SPCA with various types of data: faces, natural image patches, and genomic data.

6.3.1 FACES AND NATURAL PATCHES

In this section, we compare qualitatively the results obtained by PCA, NMF, our dictionary learning and our sparse principal component analysis algorithm on the data sets used in Section 6.2. For dictionary learning, PCA and SPCA, the input vectors are first centered and normalized to have a unit norm. Visual results are presented on figures 3, 4 and 5, respectively for the data sets D, E and F. The parameter λ for dictionary learning and SPCA was set so that the decomposition of each input signal has approximately 10 nonzero coefficients. The results for SPCA are presented for various values of the parameter γ, yielding different levels of sparsity. The scalar τ indicates the percentage of nonzero values of the dictionary.

Each image is composed of k small images each representing one learned feature vector. Negative values are blue, positive values are red and the zero values are represented in white. Confirming

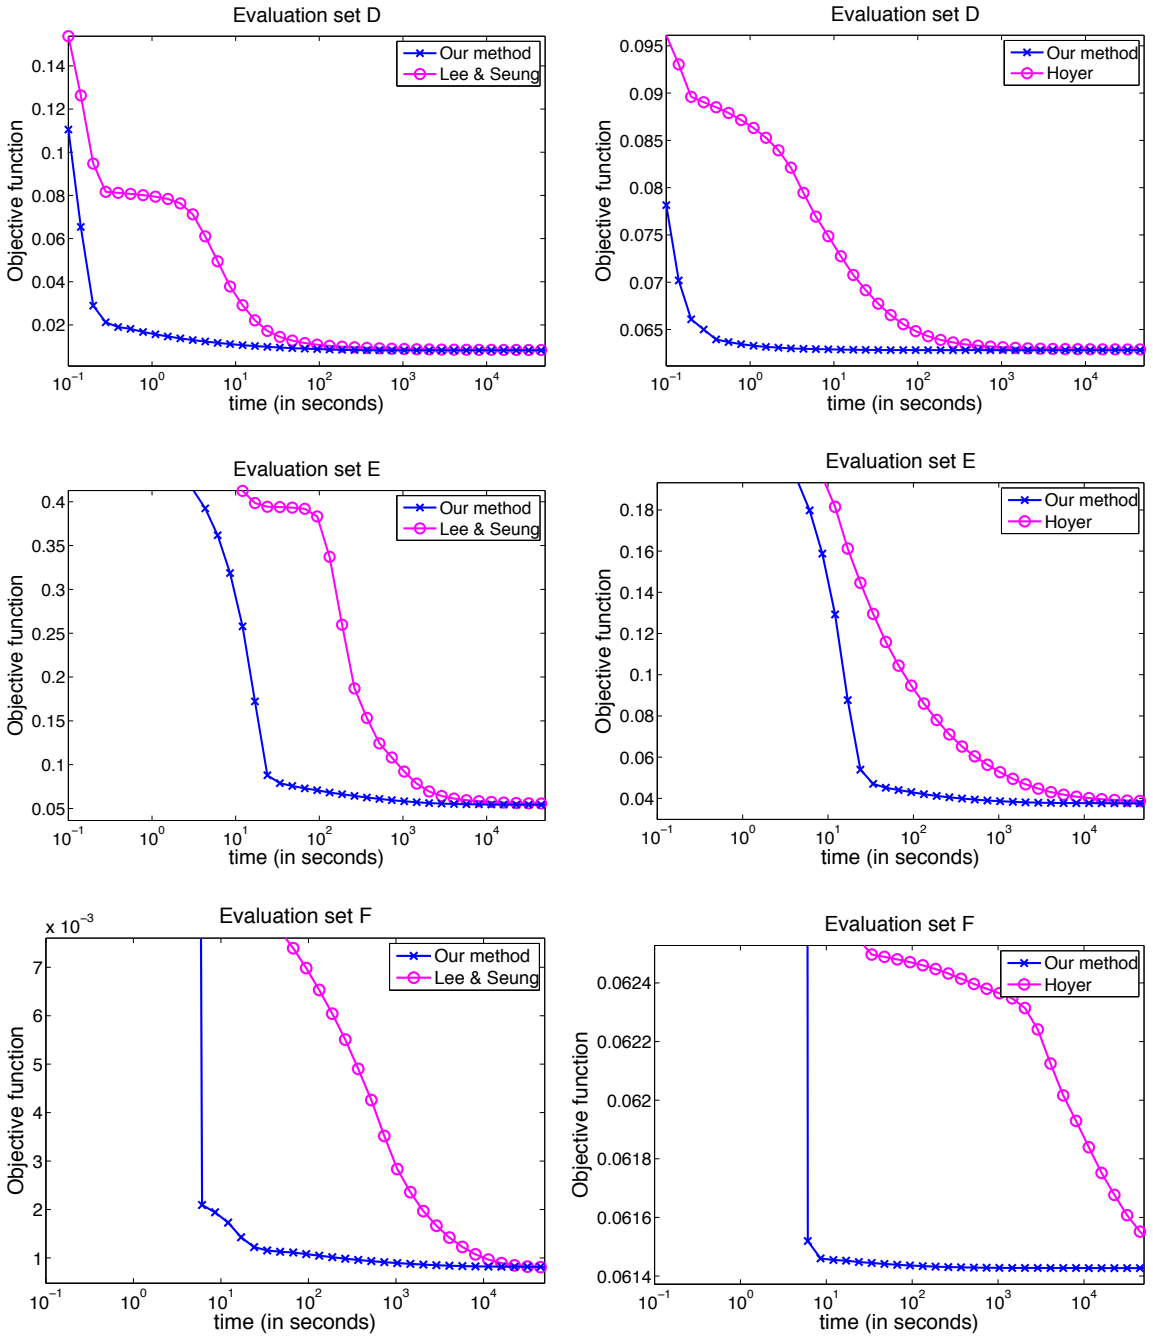

Figure 2: Left: Comparison between our method and the approach of Lee and Seung (2001) for NMF. Right: Comparison between our method and the approach of Hoyer (2002) for NNSC. The value of the objective function is reported for three data sets as a function of computation time on a logarithmic scale.

earlier observations from Lee and Seung (2001), PCA systematically produces features spread out over the images, whereas NMF produces more localized features on the face databases D and E. However, neither PCA, nor NMF are able to learn localized features on the set of natural patches F. On the other hand, the dictionary learning technique is able to learn localized features on data set F, and SPCA is the only tested method that allows controlling the level of sparsity among the learned matrices.

6.3.2 GENOMIC DATA

This experiment follows Witten et al. (2009) and demonstrates that our matrix decomposition technique can be used for analyzing genomic data. Gene expression measurements and DNA copy number changes (comparative genomic hybridization CGH) are two popular types of data in genomic research, which can be used to characterize a set of abnormal tissue samples for instance. When these two types of data are available, a recent line of research tries to analyze the correlation between them—that is, to determine sets of expression genes which are correlated with sets of chromosomal gains or losses (see Witten et al., 2009 and references therein). Let us suppose that for n tissue samples, we have a matrix $\mathbf{X}$ in $\mathbb{R}^{n\times p}$ of gene expression measurements and a matrix $\mathbf{Y}$ in $\mathbb{R}^{n\times q}$ of CGH measurements. In order to analyze the correlation between these two sets of data, recent works have suggested the use of canonical correlation analysis (Hotelling, 1936), which solves[9]

$$\min_{\mathbf{u}\in\mathbb{R}^p,\mathbf{v}\in\mathbb{R}^q} \text{cov}(\mathbf{Xu},\mathbf{Yv}) \;\text{ s.t. }\; ||\mathbf{Xu}||_2 \leq 1 \;\text{ and }\; ||\mathbf{Yv}||_2 \leq 1.$$

When $\mathbf{X}$ and $\mathbf{Y}$ are centered and normalized, it has been further shown that with this type of data, good results can be obtained by treating the covariance matrices $\mathbf{X}^T\mathbf{X}$ and $\mathbf{Y}^T\mathbf{Y}$ as diagonal, leading to a rank-one matrix decomposition problem

$$\min_{\mathbf{u}\in\mathbb{R}^p,\mathbf{v}\in\mathbb{R}^q} ||\mathbf{X}^T\mathbf{Y}-\mathbf{uv}^T||_F^2 \;\text{ s.t. }\; ||\mathbf{u}||_2 \leq 1, \;\text{ and }\; ||\mathbf{v}||_2 \leq 1.$$

Furthermore, as shown by Witten et al. (2009), this method can benefit from sparse regularizers such as the ℓ_1 norm for the gene expression measurements and a fused lasso for the CGH arrays, which are classical choices used for these data. The formulation we have chosen is slightly different from the one used by Witten et al. (2009) and can be addressed using our algorithm:

$$\min_{\mathbf{u}\in\mathbb{R}^p,\mathbf{v}\in\mathbb{R}^q} ||\mathbf{Y}^T\mathbf{X}-\mathbf{vu}^T||_F^2+\lambda||\mathbf{u}||_2 \;\text{ s.t. }\; ||\mathbf{v}||_2^2+\gamma_1||\mathbf{v}||_1+\gamma_2\,\text{FL}(\mathbf{v}) \leq 1. \tag{17}$$

In order to assess the effectivity of our method, we have conducted the same experiment as Witten et al. (2009) using the breast cancer data set described by Chin et al. (2006), consisting of $q = 2,148$ gene expression measurements and $p = 16,962$ CGH measurements for $n = 89$ tissue samples. The matrix decomposition problem of Eq. (17) was addressed once for each of the 23 chromosomes, using each time the CGH data available for the corresponding chromosome, and the gene expression of all genes. Following the original choice of Witten et al. (2009), we have selected a regularization parameter λ resulting in about 25 non-zero coefficients in $\mathbf{u}$, and selected $\gamma_1 = \gamma_2 = 1$, which results in sparse and piecewise-constant vectors $\mathbf{v}$. The original matrices $(\mathbf{X},\mathbf{Y})$ are divided into a training set $(\mathbf{X}_{tr},\mathbf{Y}_{tr})$ formed with $3/4$ of the n samples, keeping the rest $(\mathbf{X}_{te},\mathbf{Y}_{te})$ for testing. This

9. Note that when more than one couple of factors are needed, two sequences $\mathbf{u}_1,\mathbf{u}_2,\ldots$ and $\mathbf{v}_1,\mathbf{v}_2,\ldots$ of factors can be obtained recursively subject to orthogonality constraints of the sequences $\mathbf{Xu}_1,\mathbf{Xu}_2,\ldots$ and $\mathbf{Yv}_1,\mathbf{Yv}_2,\ldots$.

experiment is repeated for 10 random splits, for each chromosome a couple of factors $(\mathbf{u}, \mathbf{v})$ are computed, and the correlations $\text{corr}(\mathbf{X}_{tr}\mathbf{u}, \mathbf{Y}_{tr}\mathbf{v})$ and $\text{corr}(\mathbf{X}_{te}\mathbf{u}, \mathbf{Y}_{te}\mathbf{v})$ are reported on Figure 6. The average standard deviation of the experiments results was 0.0339 for the training set and 0.1391 for the test set.

Comparing with the original curves reported by Witten et al. (2009) for their penalized matrix decomposition (PMD) algorithm, our method exhibits in general a performance similar as PMD.[10] Nevertheless, the purpose of this section is more to demonstrate that our method can be used with genomic data than comparing it carefully with PMD. To draw substantial conclusions about the performance of both methods, more experiments would of course be needed.

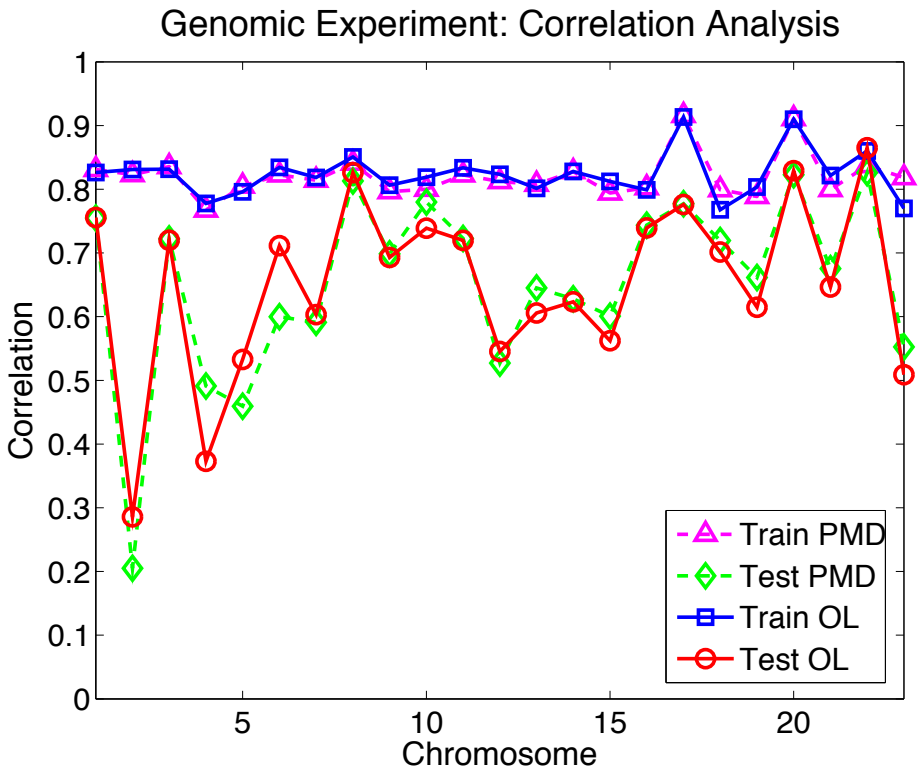

Figure 6: SPCA was applied to the covariance matrix obtained from the breast cancer data (Chin et al., 2006). A fused lasso regularization is used for the CGH data. $3/4$ of the n samples are used as a training set, keeping the rest for testing. Average correlations from 10 random splits are reported for each of the 23 chromosomes, for PMD (Witten et al., 2009) and our method denoted by OL.

10. The curves for PMD were generated with the R software package available at `http://cran.r-project.org/web/packages/PMA/index.html` and a script provided by Witten et al. (2009).

Figure 7: Inpainting example on a 12-Megapixel image. Top: Damaged and restored images. Bottom: Zooming on the damaged and restored images. Note that the pictures presented here have been scaled down for display. (Best seen in color).

6.4 Application to Large-Scale Image Processing

We demonstrate in this section that our algorithm can be used for a difficult large-scale image processing task, namely, removing the text (*inpainting*) from the damaged 12-Megapixel image of Figure 7. Using a multi-threaded version of our implementation, we have learned a dictionary with 256 elements from the roughly 7×10^6 undamaged 12×12 color patches in the image with two epochs in about 8 minutes on a 2.4GHz machine with eight cores. Once the dictionary has been learned, the text is removed using the sparse coding technique for inpainting of Mairal et al. (2008b). Our intent here is of course *not* to evaluate our learning procedure in inpainting tasks, which would require a thorough comparison with state-the-art techniques on standard data sets. Instead, we just wish to demonstrate that it can indeed be applied to a realistic, non-trivial image processing task on a large image. Indeed, to the best of our knowledge, this is the first time that dictionary learning is used for image restoration on such large-scale data. For comparison, the dictionaries used for inpainting in Mairal et al. (2008b) are learned (in batch mode) on 200,000 patches only.

7. Conclusion

We have introduced in this paper a new stochastic online algorithm for learning dictionaries adapted to sparse coding tasks, and proven its convergence. Experiments demonstrate that it is significantly faster than batch alternatives such as Engan et al. (1999), Aharon et al. (2006) and Lee et al. (2007) on large data sets that may contain millions of training examples, yet it does not require a careful learning rate tuning like regular stochastic gradient descent methods. Moreover, we have extended it to other matrix factorization problems such as non negative matrix factorization, and we have proposed a formulation for sparse principal component analysis which can be solved efficiently using our method. Our approach has already shown to be useful for image restoration tasks such as denoising (Mairal et al., 2009c); more experiments are of course needed to better assess its promise in bioinformatics and signal processing. Beyond this, we plan to use the proposed learning framework for sparse coding in computationally demanding video restoration tasks (Protter and Elad, 2009), with dynamic data sets whose size is not fixed, and extending this framework to different loss functions (Mairal et al., 2009b) to address discriminative tasks such as image classification, which are more sensitive to overfitting than reconstructive ones.

This paper was supported in part by ANR under grant MGA ANR-07-BLAN-0311. The work of Guillermo Sapiro is partially supported by ONR, NGA, NSF, ARO, and DARPA. The authors would like to like to thank Sylvain Arlot, Léon Bottou, Jean-Philippe Vert, and the members of the Willow project-team for helpful discussions, and Daniela Witten for providing us with her code to generate the curves of Figure 6.

Appendix A. Theorems and Useful Lemmas

We provide in this section a few theorems and lemmas from the optimization and probability literature, which are used in this paper.

Theorem 5 [Corollary of Theorem 4.1 from Bonnans and Shapiro (1998), due to Danskin (1967)].
Let $f : \mathbb{R}^p \times \mathbb{R}^q \to \mathbb{R}$. Suppose that for all $\mathbf{x} \in \mathbb{R}^p$ the function $f(\mathbf{x},.)$ is differentiable, and that f and $\nabla_{\mathbf{u}} f(\mathbf{x},\mathbf{u})$ the derivative of $f(\mathbf{x},.)$ are continuous on $\mathbb{R}^p \times \mathbb{R}^q$. Let $v(\mathbf{u})$ be the optimal value function $v(\mathbf{u}) = \min_{\mathbf{x} \in C} f(\mathbf{x},\mathbf{u})$, where C is a compact subset of $\mathbb{R}^p$. Then $v(\mathbf{u})$ is directionally differentiable. Furthermore, if for $\mathbf{u}_0 \in \mathbb{R}^q$, $f(.,\mathbf{u}_0)$ has a unique minimizer $\mathbf{x}_0$ then $v(\mathbf{u})$ is differentiable in $\mathbf{u}_0$ and $\nabla_{\mathbf{u}} v(\mathbf{u}_0) = \nabla_{\mathbf{u}} f(\mathbf{x}_0,\mathbf{u}_0)$.

Theorem 6 [Sufficient condition of convergence for a stochastic process, see Bottou (1998) and references therein (Métivier, 1983; Fisk, 1965)].
Let $(\Omega,\mathcal{F},P)$ be a measurable probability space, u_t, for $t \geq 0$, be the realization of a stochastic process and $\mathcal{F}_t$ be the filtration determined by the past information at time t. Let

$$\delta_t = \begin{cases} 1 & \text{if } \mathbb{E}[u_{t+1} - u_t | \mathcal{F}_t] > 0, \\ 0 & \text{otherwise.} \end{cases}$$

If for all t, $u_t \geq 0$ and $\sum_{t=1}^{\infty} \mathbb{E}[\delta_t(u_{t+1} - u_t)] < \infty$, then u_t is a quasi-martingale and converges almost surely. Moreover,

$$\sum_{t=1}^{\infty} |\mathbb{E}[u_{t+1} - u_t | \mathcal{F}_t]| < +\infty \ \ a.s.$$

Lemma 7 [A corollary of Donsker theorem see Van der Vaart, 1998, chap. 19.2, lemma 19.36 and example 19.7].
Let $F = \{f_\theta : \chi \to \mathbb{R}, \theta \in \Theta\}$ be a set of measurable functions indexed by a bounded subset Θ of $\mathbb{R}^d$. Suppose that there exists a constant K such that

$$|f_{\theta_1}(x) - f_{\theta_2}(x)| \leq K||\theta_1 - \theta_2||_2,$$

for every θ_1 and θ_2 in Θ and x in χ. Then, F is P-Donsker (see Van der Vaart, 1998, chap. 19.2). For any f in F, Let us define $\mathbb{P}_n f$, $\mathbb{P}f$ and $\mathbb{G}_n f$ as

$$\mathbb{P}_n f = \frac{1}{n}\sum_{i=1}^{n} f(X_i), \quad \mathbb{P}f = \mathbb{E}_X[f(X)], \quad \mathbb{G}_n f = \sqrt{n}(\mathbb{P}_n f - \mathbb{P}f).$$

Let us also suppose that for all f, $\mathbb{P}f^2 < \delta^2$ and $||f||_\infty < M$ and that the random elements $X_1, X_2, \ldots$ are Borel-measurable. Then, we have

$$\mathbb{E}_P||\mathbb{G}_n||_F = O(1),$$

where $||\mathbb{G}_n||_F = \sup_{f \in F} |\mathbb{G}_n f|$. For a more general variant of this lemma and additional explanations and examples, see Van der Vaart (1998).

Lemma 8 [A simple lemma on positive converging sums].
Let a_n, b_n be two real sequences such that for all n, $a_n \geq 0, b_n \geq 0$, $\sum_{n=1}^{\infty} a_n = \infty$, $\sum_{n=1}^{\infty} a_n b_n < \infty$, $\exists K > 0 \ \ s.t. \ |b_{n+1} - b_n| < K a_n$. Then, $\lim_{n \to +\infty} b_n = 0$.

Proof The proof is similar to Bertsekas (1999, prop 1.2.4). ■

Appendix B. Efficient Projections Algorithms

In this section, we address the problem of efficiently projecting a vector onto two sets of constraints, which allows us to extend our algorithm to various other formulations.

B.1 A Linear-time Projection on the Elastic-Net Constraint

Let $\mathbf{b}$ be a vector of $\mathbb{R}^m$. We consider the problem of projecting this vector onto the elastic-net constraint set:

$$\min_{\mathbf{u} \in \mathbb{R}^m} \frac{1}{2}||\mathbf{b} - \mathbf{u}||_2^2 \ \text{ s.t. } \ ||\mathbf{u}||_1 + \frac{\gamma}{2}||\mathbf{u}||_2^2 \leq \tau. \tag{18}$$

To solve efficiently the case $\gamma > 0$, we propose Algorithm 3, which extends Maculan and de Paula (1989) and Duchi et al. (2008), and the following lemma which shows that it solves our problem.

Lemma 9 [Projection onto the elastic-net constraint set].
For $\mathbf{b}$ in $\mathbb{R}^m$, $\gamma \geq 0$ and $\tau > 0$, Algorithm 3 solves Eq. (18).

Proof First, if $\mathbf{b}$ is a feasible point of (18), then $\mathbf{b}$ is a solution. We suppose therefore that it is not the case—that is,$||\mathbf{b}||_1 + \frac{\gamma}{2}||\mathbf{b}||_2^2 > \tau$. Let us define the Lagrangian of (18)

$$\mathcal{L}(\mathbf{u},\lambda) = \frac{1}{2}||\mathbf{b}-\mathbf{u}||_2^2 + \lambda\big(||\mathbf{u}||_1 + \frac{\gamma}{2}||\mathbf{u}||_2^2 - \tau\big).$$

For a fixed λ, minimizing the Lagrangian with respect to $\mathbf{u}$ admits a closed-form solution $\mathbf{u}^\star(\lambda)$, and a simple calculation shows that, for all j,

$$\mathbf{u}^\star(\lambda)[j] = \frac{\text{sign}(\mathbf{b}[j])(|\mathbf{b}[j]| - \lambda)^+}{1+\lambda\gamma}.$$

Eq. (18) is a convex optimization problem. Since Slater's conditions are verified and strong duality holds, it is equivalent to the dual problem

$$\max_{\lambda \geq 0} \mathcal{L}(\mathbf{u}^\star(\lambda),\lambda).$$

Since $\lambda = 0$ is not a solution, denoting by $\lambda^\star$ the solution, the complementary slackness condition implies that

$$||\mathbf{u}^\star(\lambda^\star)||_1 + \frac{\gamma}{2}||\mathbf{u}^\star(\lambda^\star)||_2^2 = \tau. \tag{19}$$

Using the closed form of $\mathbf{u}^\star(\lambda)$ is possible to show that the function $\lambda \rightarrow ||\mathbf{u}^\star(\lambda)||_1 + \frac{\gamma}{2}||\mathbf{u}^\star(\lambda)||_2^2$, is strictly decreasing with λ and thus Eq. (19) is a necessary and sufficient condition of optimality for λ. After a short calculation, one can show that this optimality condition is equivalent to

$$\frac{1}{(1+\lambda\gamma)^2}\sum_{j \in S(\lambda)}\Big(|\mathbf{b}[j]| + \frac{\gamma}{2}|\mathbf{b}[j]|^2 - \lambda\big(1+\frac{\gamma\lambda}{2}\big)\Big) = \tau,$$

where $S(\lambda) = \{j \text{ s.t. } |\mathbf{b}[j]| \geq \lambda\}$. Suppose that $S(\lambda^\star)$ is known, then $\lambda^\star$ can be computed in closed-form. To find $S(\lambda^\star)$, it is then sufficient to find the index k such that $S(\lambda^\star) = S(|\mathbf{b}[k]|)$, which is the solution of

$$\max_{k \in \{1,\ldots,m\}} |\mathbf{b}[k]| \text{ s.t. } \frac{1}{(1+|\mathbf{b}[k]|\gamma)^2}\sum_{j \in S(|\mathbf{b}[k]|)}\Big(|\mathbf{b}[j]| + \frac{\gamma}{2}|\mathbf{b}[j]|^2 - |\mathbf{b}[k]|\big(1+\frac{\gamma|\mathbf{b}[k]|}{2}\big)\Big) < \tau.$$

Lines 4 to 14 of Algorithm 3 are a modification of Duchi et al. (2008) to address this problem. A similar proof as Duchi et al. (2008) shows the convergence to the solution of this optimization problem in $O(m)$ in the average case, and lines 15 to 18 of Algorithm 3) compute $\lambda^\star$ after that $S(\lambda^\star)$ has been identified. Note that setting γ to 0 leads exactly to the algorithm of Duchi et al. (2008). ■

As for the dictionary learning problem, a simple modification to Algorithm 3 allows us to handle the non-negative case, replacing the scalars $|\mathbf{b}[j]|$ by $\max(\mathbf{b}[j],0)$ in the algorithm.

B.2 A Homotopy Method for Solving the Fused Lasso Signal Approximation

Let $\mathbf{b}$ be a vector of $\mathbb{R}^m$. We define, following Friedman et al. (2007), the fused lasso signal approximation problem $\mathcal{P}(\gamma_1,\gamma_2,\gamma_3)$:

$$\min_{\mathbf{u} \in \mathbb{R}^m} \frac{1}{2}||\mathbf{b}-\mathbf{u}||_2^2 + \gamma_1||\mathbf{u}||_1 + \gamma_2 \text{FL}(\mathbf{u}) + \frac{\gamma_3}{2}||\mathbf{u}||_2^2, \tag{20}$$

Algorithm 3 Efficient projection on the elastic-net constraint.

Require: $\tau \in \mathbb{R}$; $\gamma \in \mathbb{R}$; $\mathbf{b} \in \mathbb{R}^m$;

if $||\mathbf{b}||_1 + \frac{\gamma}{2}||\mathbf{b}||_2^2 \leq \tau$ **then**
  Return $\mathbf{u} \leftarrow \mathbf{b}$.
else
  $U \leftarrow \{1,\ldots,m\}$; $s \leftarrow 0$; $\rho \leftarrow 0$.
  while $U \neq \emptyset$ **do**
    Pick $k \in U$ at random.
    Partition U:

$$G = \{j \in U \text{ s.t. } |\mathbf{b}[j]| \geq |\mathbf{b}[k]|\},$$
$$L = \{j \in U \text{ s.t. } |\mathbf{b}[j]| < |\mathbf{b}[k]|\}.$$

    $\Delta\rho \leftarrow |G|$; $\Delta s \leftarrow \sum_{j \in G} |\mathbf{b}[j]| + \frac{\gamma}{2}|\mathbf{b}[j]|^2$.
    if $s + \Delta s - (\rho + \Delta\rho)(1 + \frac{\gamma}{2}|\mathbf{b}[k]|)|\mathbf{b}[k]| < \tau(1 + \gamma|\mathbf{b}[k]|)^2$ **then**
      $s \leftarrow s + \Delta s$; $\rho \leftarrow \Delta\rho$; $U \leftarrow L$.
    else
      $U \leftarrow G \setminus \{k\}$.
    end if
  end while
  $a \leftarrow \gamma^2\tau + \frac{\gamma}{2}\rho$,
  $b \leftarrow 2\gamma\tau + \rho$,
  $c \leftarrow \tau - s$,
  $\lambda \leftarrow \frac{-b+\sqrt{b^2-4ac}}{2a}$

$$\forall j = 1,\ldots,n, \mathbf{u}[j] \leftarrow \frac{\text{sign}(\mathbf{b}[j])(|\mathbf{b}[j]| - \lambda)^+}{1 + \lambda\gamma}$$

  Return $\mathbf{u}$.
end if

the only difference with Friedman et al. (2007) being the addition of the last quadratic term. The method we propose to this problem is a homotopy, which solves $\mathcal{P}(\tau\gamma_1, \tau\gamma_2, \tau\gamma_3)$ for all possible values of τ. In particular, for all ε, it provides the solution of the constrained problem

$$\min_{\mathbf{u} \in \mathbb{R}^m} \frac{1}{2}||\mathbf{b} - \mathbf{u}||_2^2 \text{ s.t. } \gamma_1||\mathbf{u}||_1 + \gamma_2 \text{FL}(\mathbf{u}) + \frac{\gamma_3}{2}||\mathbf{u}||_2^2 \leq \varepsilon. \tag{21}$$

The algorithm relies on the following lemma

Lemma 10 *Let* $\mathbf{u}^\star(\gamma_1,\gamma_2,\gamma_3)$ *be the solution of Eq. (20), for specific values of* $\gamma_1,\gamma_2,\gamma_3$. *Then*

- $\mathbf{u}^\star(\gamma_1,\gamma_2,\gamma_3) = \frac{1}{1+\gamma_3}\mathbf{u}^\star(\gamma_1,\gamma_2,0)$.
- *For all* i, $\mathbf{u}^\star(\gamma_1,\gamma_2,0)[i] = \text{sign}(\mathbf{u}^\star(0,\gamma_2,0)[i])\max(|\mathbf{u}^\star(0,\gamma_2,0)[i]| - \lambda_1, 0)$ *—that is,* $\mathbf{u}^\star(\gamma_1,\gamma_2,0)$ *can be obtained by soft thresholding of* $\mathbf{u}^\star(0,\gamma_2,0)$.

The first point can be shown by short calculation. The second one is proven in Friedman et al. (2007) by considering subgradient optimality conditions. This lemma shows that if one knows the solution of $\mathcal{P}(0,\gamma_2,0)$, then $\mathcal{P}(\gamma_1,\gamma_2,\gamma_3)$ can be obtained in linear time.

It is therefore natural to consider the simplified problem

$$\min_{\mathbf{u}\in\mathbb{R}^m} \frac{1}{2}||\mathbf{b}-\mathbf{u}||_2^2+\gamma_2 \mathrm{FL}(\mathbf{u}). \tag{22}$$

With the change of variable $\mathbf{v}[1]=\mathbf{u}[1]$ and $\mathbf{v}[i]=\mathbf{u}[i]-\mathbf{u}[i-1]$ for $i>1$, this problem can be recast as a weighted Lasso

$$\min_{\mathbf{v}\in\mathbb{R}^m} \frac{1}{2}||\mathbf{b}-\mathbf{D}\mathbf{v}||_2^2+\sum_{i=1}^{m} w_i|\mathbf{v}[i]|, \tag{23}$$

where $w_1=0$ and $w_i=\gamma_2$ for $i>1$, and $\mathbf{D}[i,j]=1$ if $i\geq j$ and 0 otherwise. We propose to use LARS (Efron et al., 2004) and exploit the specific structure of the matrix $\mathbf{D}$ to make this approach efficient, by noticing that:

- For a vector $\mathbf{w}$ in $\mathbb{R}^m$, computing $\mathbf{e}=\mathbf{D}\mathbf{w}$ requires $O(m)$ operations instead of $O(m^2)$, by using the recursive formula $\mathbf{e}[1]=\mathbf{w}[1]$, $\mathbf{e}[i+1]=\mathbf{w}[i]+\mathbf{e}[i]$.
- For a vector $\mathbf{w}$ in $\mathbb{R}^n$, computing $\mathbf{e}=\mathbf{D}^T\mathbf{w}$ requires $O(m)$ operations instead of $O(m^2)$, by using the recursive formula $\mathbf{e}[n]=\mathbf{w}[n]$, $\mathbf{e}[i-1]=\mathbf{w}[i-1]+\mathbf{e}[i]$.
- Let $\Gamma=\{a_1,\ldots,a_p\}$ be an active set and suppose $a_1<\ldots<a_p$. Then $(\mathbf{D}_\Gamma^T\mathbf{D}_\Gamma)^{-1}$ admits the closed form value

$$(\mathbf{D}_\Gamma^T\mathbf{D}_\Gamma)^{-1}=\begin{pmatrix} c_1 & -c_1 & 0 & \ldots & 0 & 0\\ -c_1 & c_1+c_2 & -c_2 & \ldots & 0 & 0\\ 0 & -c_2 & c_2+c_3 & \ldots & 0 & 0\\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots\\ 0 & 0 & 0 & \ldots & c_{p-2}+c_{p-1} & -c_{p-1}\\ 0 & 0 & 0 & \ldots & -c_{p-1} & c_{p-1}+c_p \end{pmatrix},$$

  where $c_p=\frac{1}{n+1-a_p}$ and $c_i=\frac{1}{a_{i+1}-a_i}$ for $i<p$.

This allows the implementation of this homotopy method without using matrix inversion or Cholesky factorization, solving Eq. (23) in $O(ms)$ operations, where s is the number of non-zero values of the optimal solution $\mathbf{v}$.[11]

Adapting this method for solving Eq. (21) requires following the regularization path of the problems $\mathcal{P}(0,\tau\gamma_2,0)$ for all values of τ, which provides as well the regularization path of the problem $\mathcal{P}(\tau\lambda_1,\tau\lambda_2,\tau\lambda_3)$ and stops whenever the constraint becomes unsatisfied. This procedure still requires $O(ms)$ operations.

Note that in the case $\gamma_1=0$ and $\gamma_3=0$, when only the fused-lasso term is present in Eq (20), the same approach has been proposed in a previous work by Harchaoui and Lévy-Leduc (2008), and Harchaoui (2008) to solve Eq. (22), with the same tricks for improving the efficiency of the procedure.

11. To be more precise, s is the number of kinks of the regularization path. In practice, s is roughly the same as the number of non-zero values of the optimal solution $\mathbf{v}$.

Abstract

The principle of parsimony also known as "Ockham's razor" has inspired many theories of model selection. Yet such theories, all making arguments in favor of parsimony, are based on very different premises and have developed distinct methodologies to derive algorithms. We have organized challenges and edited a special issue of JMLR and several conference proceedings around the theme of model selection. In this editorial, we revisit the problem of avoiding overfitting in light of the latest results. We note the remarkable convergence of theories as different as Bayesian theory, Minimum Description Length, bias/variance tradeoff, Structural Risk Minimization, and regularization, in some approaches. We also present new and interesting examples of the complementarity of theories leading to hybrid algorithms, neither frequentist, nor Bayesian, or perhaps both frequentist and Bayesian!

Keywords: model selection, ensemble methods, multilevel inference, multilevel optimization, performance prediction, bias-variance tradeoff, Bayesian priors, structural risk minimization, guaranteed risk minimization, over-fitting, regularization, minimum description length

1. Introduction

The problem of learning is often decomposed into the tasks of fitting parameters to some training data, and then selecting the best model using heuristic or principled methods, collectively referred to as *model selection* methods. Model selection methods range from simple yet powerful cross-validation based methods to the optimization of cost functions penalized for model complexity, derived from performance bounds or Bayesian priors.

This paper is not intended as a general review of the state-of-the-art in model selection nor a tutorial; instead it is a synthesis of the collection of papers that we have assembled. It also provides a unifying perspective on Bayesian and frequentist methodologies used in various model selection methods. We highlight a new trend in research on model selection that blends these approaches.

The reader is expected to have some basic knowledge of familiar learning machines (linear models, neural networks, tree classifiers and kernel methods) and elementary notions of learning theory (bias/variance tradeoff, model capacity or complexity, performance bounds). Novice readers are directed to the companion paper (Guyon, 2009), which reviews basic learning machines, common model selection techniques, and provides elements of learning theory.

When we started organizing workshops and competitions around the problem of model selection (of which this collection of papers is the product), both theoreticians and practitioners welcomed us with some scepticism; model selection being often viewed as somewhat "old hat". Some think that the problem is solved, others that it is not a problem at all! For Bayesian theoreticians, the problem of model selection is circumvented by averaging all models over the posterior distribution. For risk minimization theoreticians (called "frequentists" by the Bayesians) the problem is solved by minimizing performance bounds. For practitioners, the problem is solved using cross-validation. However, looking more closely, most theoretically grounded methods of solving or circumventing model selection have at least one hyper-parameter left somewhere, which ends up being optimized by cross-validation. Cross-validation seems to be the universally accepted ultimate remedy. But it has its dark sides: (a) there is no consensus on how to choose the fraction of examples reserved training and for validation; (b) the overall learning problem may be prone to over-fitting the cross-validation error (Cawley and Talbot, 2009). Therefore, from our point of view, the problem of optimally dividing the learning problem into multiple levels of inference and optimally allocating training data to these various levels remains unsolved, motivating our efforts. From the novel contributions we have gathered, we are pleased to see that researchers are going beyond the usual Bayesian/frequentist divide to provide new creative solutions to those problems: we see the emergence of multi-level optimization methods, which are both Bayesian and frequentist. How can that be? Read on!

After explaining in Section 2 our notational conventions, we briefly review a range of different Bayesian and frequentist approaches to model selection in Section 3, which we then unify in Section 4 under the framework of multi-level optimization. Section 5 then presents the advances made by the authors of papers that we have edited. In Section 6, we open a discussion on advanced topics and open problems. To facilitate reading, a glossary is appended; throughout the paper, words found in the glossary are indicated in boldface.

2. Notations and Conventions

In its broadest sense, *model selection* designates an ensemble of techniques used to select a model, that best explains some data or phenomena, or best predicts future data, observations or the consequences of actions. This broad definition encompasses both scientific and statistical modeling. In this paper, we address only the problem of statistical modeling and are mostly concerned with **supervised learning** from independently and identically distributed (*i.i.d.*) data. Extensions to **unsupervised learning** and non *i.i.d.* cases will be discussed in Section 6.

The goal of supervised learning is to predict a target variable $y \in \mathcal{Y}$, which may be continuous (regression) or categorical or binary (classification). The predictions are made using observations

$\mathbf{x}$ from a domain $\mathcal{X}$, often a vectorial space of dimension n, the number of features. The data pairs $\{\mathbf{x}, y\}$ are independently and identically distributed according to an unknown (but fixed) distribution $P(\mathbf{x}, y)$. A number m of pairs drawn from that distribution are given, forming the training data $D = \{(\mathbf{x}_k, y_k), k = 1, ...m\}$. We will denote by $X = [x_{ki}]$, $k = 1, ...m, i = 1, ...n$, the matrix of dimensions (m, n) whose rows are the training patterns and whose columns are the features. Finally, we denote by $\mathbf{y}$ the column vector of dimensions $(m, 1)$ containing the target values y_k.

There are several formulations of the supervised learning problem:

- **Function approximation** (induction) methods seek a function f (called *model* or *learning machine*) belonging to a model class $\mathcal{F}$, which minimizes a specified risk functional (or maximizes a certain utility). The goal is to minimize an *expected risk* $R[f] = \int \mathcal{L}(f(\mathbf{x}), y)\, dP(\mathbf{x}, y)$, also called *generalization error*, where $\mathcal{L}(f(\mathbf{x}), y)$ is a loss function (often a negative log likelihood) measuring the discrepancy between $f(\mathbf{x})$ and y. Since $P(\mathbf{x}, y)$ is unknown, only estimates of $R[f]$ can be computed, which we call *evaluation functions* or *estimators*. Function approximation methods differ in the choice of evaluation function and optimization algorithm and include **risk minimization**, **PAC leaning**, **maximum likelihood optimization**, and **MAP learning**.

- **Bayesian and ensemble methods** make predictions according to model averages that are convex combinations of models $f \in \mathcal{F}$, that is, which belong to the convex closure of the model class $\mathcal{F}^*$. Such methods differ in the type of model averaging performed. **Bayesian learning** methods approximate $E_f(y|\mathbf{x}) = \int_{f \in \mathcal{F}} f(\mathbf{x})\, dP(f)$, an expectation taken over a class of models $\mathcal{F}$, using an unknown probability distribution $P(f)$ over the models. Starting from a "prior", our knowledge of this distribution is refined into a "posterior" when we see some data. **Bagging** ensemble methods approximate $E_D(f(\mathbf{x}, D))$, where $f(\mathbf{x}, D)$ is a function from the model class $\mathcal{F}$, trained with m examples and $E_D(\cdot)$ is the mathematical expectation over all training sets of size m. The key point in these methods is to generate a diverse set of functions, each providing a different perspective over the problem at hand, the ensemble thus forming a concensus view.

- **Transduction** methods make direct predictions of y given $\mathbf{x}$ and X, bypassing the modeling step. We do not address such methods in this paper.

The desired properties of the chosen predictor include: good generalization performance, fast training/prediction, and ease of interpretation of the predictions. Even though all of these aspects are important in practice, we will essentially focus on the first aspect: obtaining the best possible generalization performance. Some of the other aspects of model selection will be discussed in Section 6.

The parametrization of f differentiates the problem of *model selection* from the general machine learning problem. Instead of parameterizing f with one set of parameters, the model selection framework distinguishes between *parameters* and *hyper-parameters*. We adopt the simplified notation $f(\mathbf{x}; \boldsymbol{\alpha}, \boldsymbol{\theta})$ for a model of parameters $\boldsymbol{\alpha}$ and hyper-parameters $\boldsymbol{\theta}$. It should be understood that different models may be parameterized differently. Hence by $f(\mathbf{x}; \boldsymbol{\alpha}\boldsymbol{\theta})$ we really mean $f(\mathbf{x}; \boldsymbol{\alpha}(\boldsymbol{\theta}), \boldsymbol{\theta})$ or $f_{\boldsymbol{\theta}}(\mathbf{x}; \boldsymbol{\alpha})$. For instance, for a linear model $f(\mathbf{x}, \mathbf{w}) = \mathbf{w}^T\mathbf{x}$, $\boldsymbol{\alpha} = \mathbf{w}$; for a kernel method $f(\mathbf{x}, \boldsymbol{\alpha}) = \sum_k \alpha_k K(\mathbf{x}, \mathbf{x}_k)$, $\boldsymbol{\alpha} = [\alpha_k]$. The hyper-parameters may include indicators of presence or absence of features, choice of preprocessing methods,, choice of algorithm or model sub-class (e.g., linear models, neural networks, kernel methods, etc.), algorithm or model sub-class

parameters (e.g., number of layers and units per layer in a neural network, maximum degree of a polynomial, bandwidth of a kernel), choice of post-processing, etc. We also refer to the parameters of the prior $P(f)$ in **Bayesian/MAP learning** and the parameters of the **regularizer** $\Omega[f]$ in **risk minimization** as hyper-parameters even if the resulting predictor is not an explicit function of those parameters, because they are used in the process of learning. In what follows, we relate the problem of model selection to that of *hyper-parameter selection*, taken in is broadest sense and encompassing all the cases mentioned above.

We refer to the adjustment of the model parameters $\boldsymbol{\alpha}$ as the *first level of inference*. When data are split in several subsets for the purpose of training and evaluating models, we call m_{tr} the number of *training examples* used to adjust $\boldsymbol{\alpha}$. If the hyper-parameters $\boldsymbol{\theta}$ are adjusted from a subset of data of size m_{va}, we call the examples used to adjust them at this *second level of inference* the *"validation sample"*. Finally we call m_{te} the number of test examples used to evaluate the final model. The corresponding empirical estimates of the *expected risk* $R[f]$, denoted $R_{tr}[f]$, $R_{va}[f]$, and $R_{te}[f]$, will be called respectively *training error*, *validation error*, and *test error*.

3. The Many Faces of Model Selection

In this section, we track *model selection* from various angles to finally reduce it to the unified view of *multilevel inference*.

3.1 Is Model Selection "Really" a Problem?

It is legitimate to first question whether the distinction between parameters and hyper-parameters is relevant. Splitting the learning problem into two levels of inference may be convenient for conducting experiments. For example, combinations of preprocessing, feature selection, and post-processing are easily performed by fixing $\boldsymbol{\theta}$ and training $\boldsymbol{\alpha}$ with off-the-shelf programs. But, the distinction between parameters and hyper-parameters is more fundamental. For instance, in the model class of kernel methods $f(\mathbf{x}) = \sum_k \boldsymbol{\alpha}_k K(\mathbf{x}, \mathbf{x}_k; \boldsymbol{\theta})$, why couldn't we treat both $\boldsymbol{\alpha}$ and $\boldsymbol{\theta}$ as regular parameters?

One common argument is that, for fixed values of $\boldsymbol{\theta}$, the problem of learning $\boldsymbol{\alpha}$ can be formulated as a convex optimization problem, with a single unique solution, for which powerful mathematical programming packages are available, while the overall optimization of $\boldsymbol{\alpha}$ and $\boldsymbol{\theta}$ in non-convex. Another compelling argument is that, splitting the learning problem into several levels might also benefit to the performance of the learning machine by "alleviating" (but not eliminating) the problem of **over-fitting**. Consider for example the Gaussian redial basis function kernel $K(\mathbf{x}, \mathbf{x}_k; \theta) = \exp(-\|\mathbf{x} - \mathbf{x}_k\|^2/\theta^2)$. The function $f(\mathbf{x}) = \sum_{k=1}^{m} \alpha_k K(\mathbf{x}, \mathbf{x}_k; \theta)$ is a universal approximator if θ is let to vary and if the sum runs over the training examples. If both $\boldsymbol{\alpha}$ and θ are optimized simultaneously, solutions with a small value of θ^2 might be picked, having zero training error but possibly very poor generalization performance. The model class $\mathcal{F}$ to which f belongs has infinite capacity $C(\mathcal{F})$. In contrast, for a fixed value of the hyper-parameter θ^o, the model $f(\mathbf{x}) = \sum_{k=1}^{m} \boldsymbol{\alpha}_k K(\mathbf{x}, \mathbf{x}_k; \theta^o)$ is linear in its parameters $\boldsymbol{\alpha}_k$ and has a finite capacity, bounded by m. In addition, the capacity of $f(\mathbf{x}) = \sum_{k=1}^{m} \boldsymbol{\alpha}_k^o K(\mathbf{x}, \mathbf{x}_k^o; \theta)$ of parameter θ for fixed values $\boldsymbol{\alpha}_k^o$ and x_k^o is very low (to see that, note that very few examples can be learned without error by just varying the kernel width, given fixed vectors x_k^o and fixed parameters $\boldsymbol{\alpha}_k^o$). Hence, *using multiple levels of inference may reduce over-fitting, while still searching for solutions in a model class of universal approximators*.

This last idea has been taken one step further in the method of *structural risk minimization* (Vapnik, 1979), by introducing new hyper-parameters in learning problems, which initially did not have any. Consider for instance the class of linear models $f(\mathbf{x}) = \sum_{i=1}^{n} w_i x_i$. It is possible to introduce hyper-parameters by imposing a structure in parameter space. A classical example is the structure $\|\mathbf{w}\|^2 \leq A$, where $\|\mathbf{w}\|$ denotes the Euclidean norm and A is a positive hyper-parameter. For increasing values of A the space of parameters is organized in nested subsets. Vapnik (1998) proves for Support Vector Machines (SVM) and Bartlett (1997) for neural networks that tighter performance bounds are obtained by increasing A. The newly introduced parameter allows us to monitor the **bias/variance tradeoff**. Using a Lagrange multiplier, the problem may be replaced by that of minimizing a regularized risk functional $R_{reg} = R_{tr} + \gamma\|\mathbf{w}\|^2$, $\gamma > 0$, where the training loss function is the so-called "hinge loss" (see *e.g.,* Hastie et al., 2000). The same regularizer $\|\mathbf{w}\|^2$ is used in ridge regression (Hoerl, 1962), "weight decay" neural networks (Werbos, 1988), regularized radial-basis function networks (Poggio and Girosi, 1990), Gaussian processes (MacKay, 1992), together with the square loss function. Instead of the Euclidean norm or 2-norm, the 1-norm regularizer $\|\mathbf{w}\|_1 = \sum_i |w_i|$ is used in LASSO (Tibshirani, 1994) and 1-norm versions of SVMs (see *e.g.,* Zhu et al., 2003), logistic regression (Friedman et al., 2009), and Boosting (Rosset et al., 2004). Weston et al. (2003) have proposed a 0-norm regularizer $\|\mathbf{w}\|_0 = \sum_i \mathbf{1}(w_i)$, where $\mathbf{1}(x) = 1$, if $x \neq 0$ and 0 otherwise.

Interestingly, each method stems from a different theoretical justification (some are Bayesian, some are frequentist and some a a little bit of both like PAC-Bayesian bounds, see, for example, Seeger, 2003, for a review), showing a beautiful example of theory convergence (Guyon, 2009). Either way, for a fixed value of the hyper-parameter A or γ the complexity of the learning problem is lower than that of the original problem. We can optimize A or γ at a second level of inference, for instance by cross-validation.

3.2 Bayesian Model Selection

In the Bayesian framework, there is no model selection *per se*, since learning does not involve searching for an optimum function, but averaging over a posterior distribution. For example, if the model class $\mathcal{F}$ consists of models $f(\mathbf{x};\boldsymbol{\alpha},\boldsymbol{\theta})$, the Bayesian assumption is that the parameters $\boldsymbol{\alpha}$ and hyper-parameters $\boldsymbol{\theta}$ of the model used to generate the data are drawn from a prior $P(\boldsymbol{\alpha},\boldsymbol{\theta})$. After observing some data D the predictions should be made according to:

$$E_{\boldsymbol{\alpha},\boldsymbol{\theta}}(y|\mathbf{x},D) = \int\int f(\mathbf{x};\boldsymbol{\alpha},\boldsymbol{\theta})\, P(\boldsymbol{\alpha},\boldsymbol{\theta}|D)\, d\boldsymbol{\alpha}\, d\boldsymbol{\theta}\ .$$

Hence there is no selection of a single model, but a summation over models in the model class $\mathcal{F}$, weighed by $P(\boldsymbol{\alpha},\boldsymbol{\theta}|D)$. The problem is to integrate over $P(\boldsymbol{\alpha},\boldsymbol{\theta}|D)$.[1] A two-level decomposition can be made by factorizing $P(\boldsymbol{\alpha},\boldsymbol{\theta}|D)$ as $P(\boldsymbol{\alpha},\boldsymbol{\theta}|D) = P(\boldsymbol{\alpha}|\boldsymbol{\theta},D)P(\boldsymbol{\theta}|D)$:

$$E_{\boldsymbol{\alpha},\boldsymbol{\theta}}(y|\mathbf{x},D) = \int \left(\int f(\mathbf{x};\boldsymbol{\alpha},\boldsymbol{\theta}) P(\boldsymbol{\alpha}|\boldsymbol{\theta},D)\, d\boldsymbol{\alpha} \right) P(\boldsymbol{\theta}|D)\, d\boldsymbol{\theta}\ . \tag{1}$$

Bayesian model selection decomposes the prior $P(\boldsymbol{\alpha},\boldsymbol{\theta})$ into parameter prior $P(\boldsymbol{\alpha}|\boldsymbol{\theta})$ and a "hyper-prior" $P(\boldsymbol{\theta})$. In **MAP learning**, the type-II likelihood (also called the "evidence") $P(D|\boldsymbol{\theta}) =$

1. The calculation of the integral in closed form may be impossible to carry out; in this case, variational approximations are made or numerical simulations are performed, sampling from $P(\boldsymbol{\alpha},\boldsymbol{\theta}|D)$, and replacing the integral by the summation over a finite number of models.

$\sum_{\boldsymbol{\alpha}} P(D|\boldsymbol{\alpha},\boldsymbol{\theta})P(\boldsymbol{\alpha}|\boldsymbol{\theta})$ is maximized with respect to the hyper-parameters $\boldsymbol{\theta}$ (therefore assuming a flat prior for $\boldsymbol{\theta}$), while the "regular" parameters $\boldsymbol{\alpha}$ are obtained by maximizing the posterior $\boldsymbol{\alpha}^* = \text{argmax}_{\boldsymbol{\alpha}} P(\boldsymbol{\alpha}|\boldsymbol{\theta},D) = \text{argmax}_{\boldsymbol{\alpha}} P(D|\boldsymbol{\alpha},\boldsymbol{\theta})P(\boldsymbol{\alpha}|\boldsymbol{\theta})$.[2]

3.3 Frequentist Model Selection

While Bayesians view probabilities as being realized in the idea of "prior" and "posterior" knowledge of distributions, frequentists define probability in terms of *frequencies of occurrence of events*. In this section, the "frequentist" approach is equated with risk minimization.

There are obvious ties between the problem of *model selection* and that of *performance prediction*. *Performance prediction* is the problem of estimating the *expected risk* or *generalization error* $R[f]$. *Model selection* is the problem of adjusting the capacity or complexity of the models to the available amount of training data to avoid either **under-fitting** or **over-fitting**. Solving the *performance prediction* problem would also solve the *model selection* problem, but model selection is an easier problem. If we find an ordering index $r[f]$ such that for all pairs of functions $r[f_1] < r[f_2] \Rightarrow R[f_1] < R[f_2]$, then the index allows us to correctly carry out *model selection*. Theoretical performance bounds providing a *guaranteed risk* have been proposed as ranking indices (Vapnik, 1998). Arguably, the tightness of the bound is of secondary importance in obtaining a good ranking index. Bounds of the form $r[f] = R_{tr}[f] + \varepsilon(C/m_{tr})$, where C characterizes the capacity or complexity of the model class, penalizes complex models, but the penalty vanishes as $m_{tr} \to \infty$. Some learning algorithms, for example, SVMs (Boser et al., 1992) or boosting (Freund and Schapire, 1996), optimize a *guaranteed risk* rather than the *empirical risk* $R_{tr}[f]$, and therefore provide some guarantee of good *generalization*. Algorithms derived in this way have an embedded model selection mechanism. Other closely related penalty-based methods include Bayesian **MAP learning** and **regularization**.

Many models (and particularly *compound models* including feature selection, preprocessing, learning machine, and post-processing) are not associated with known performance bounds. Common practice among frequentists is to split available training data into m_{tr} training examples to adjust parameters and m_{va} validation examples to adjust hyper-parameters. In an effort to reduce variance, the validation error $R_{va}[f]$ may be averaged over many data splits, leading to a cross-validation (CV) estimator $R_{CV}[f]$. The most widely used CV method is *K-fold cross-validation*. It consists in partitioning training data into $K \simeq (m_{tr} + m_{va})/m_{va}$ disjoint subsets of roughly equal sizes (up to rounding errors), each corresponding to one validation set (the complement being used as training set). In stratified cross-validation, the class proportions of the full data sets are respected in all subsets. The variance of the results may be reduced by performing Q times K-fold cross-validation and averaging the results of the Q runs. Another popular method consists in holding out a single example at a time for validation purposes. The resulting cross-validation error is referred to as "leave-one-out" error $R_{LOO}[f]$. Some preliminary study design is necessary to determine the sufficient amount of test data to obtain a good estimate of the generalization error (Langford, 2005), the sufficient amount of training data to attain desired generalization performances, and an adequate split of the training data between training and validation set. See Guyon (2009) for a discussion of these issues.

2. In some Bayesian formulations of multi-layer Perceptrons, the evidence framework maximizes over $\boldsymbol{\theta}$ but marginalises over the weights, rather than maximizing, so in this case the MAP can apply to the parameters or the hyper-parameters or both.

4. Multi-level Inference: A Unifying View of Model Selection

What is common among the various views of model selection is the idea of multiple levels of inference, each level corresponding to one set of parameters or hyper-parameters. Consider a two-level case for a model class $f(\mathbf{x};\boldsymbol{\alpha},\boldsymbol{\theta})$ parameterized by one set of parameters $\boldsymbol{\alpha}$ and one set of hyper-parameters $\boldsymbol{\theta}$. From the frequentist (risk minimization) point of view, instead of jointly optimizing a risk functional with respect to all parameters $\boldsymbol{\alpha}$ and $\boldsymbol{\theta}$, one creates a hierarchy of optimization problems:[3]

$$f^{**} = \text{argmin}_{\boldsymbol{\theta}} R_2[f^*, D] \ , \ \text{ such that } \ f^* = \text{argmin}_{\boldsymbol{\alpha}} R_1[f, D] \tag{2}$$

where R_1 and R_2 are first and second level risk functionals.

From the Bayesian point of view, the goal is to estimate the integral of Equation 1. There are striking similarities between the two approaches. To make the similarity more obvious, we can rewrite Equation 1 to make it look more like Equation 2, using the notation f^{**} for $E_{\boldsymbol{\alpha},\boldsymbol{\theta}}(y|\mathbf{x},D)$:

$$f^{**} = \int f^* \ e^{-R_2} \ d\boldsymbol{\theta} \ , \ \text{ such that } \ f^* = \int f \ e^{-R_1} \ d\boldsymbol{\alpha} \tag{3}$$

where $R_1 = -\ln P(\boldsymbol{\alpha}|\boldsymbol{\theta},D)$ and $R_2 = -\ln P(\boldsymbol{\theta}|D)$. Note that in Bayesian multi-level inference f^* and f^{**} do not belong to $\mathcal{F}$ but to $\mathcal{F}^*$, the closure of $\mathcal{F}$ under convex combinations.

More generally, we define a *multi-level inference problem* as a learning problem organized into a hierarchy of learning problems. Formally, consider a machine learning toolkit which includes a choice of learning machines $\mathcal{A}[\mathcal{B},R]$, where $\mathcal{B}$ is a model space of functions $f(\mathbf{x};\boldsymbol{\theta})$, of parameters $\boldsymbol{\theta}$ and R is an evaluation function (e.g., a risk functional or a negative log posterior). We think of $\mathcal{A}[\mathcal{B},R]$ not as a procedure, but as an "object", in the sense of object oriented programming, equipped with a method "train", which processes data according to a training algorithm:[4]

$$f^{**} = \text{train}(\mathcal{A}[\mathcal{B},R_2],D); \tag{4}$$

This framework embodies the second level of inference of both Equations 2 and 3. The solution f^{**} belongs to $\mathcal{B}^*$, the convex closure of $\mathcal{B}$. To implement the first level of inference, we will consider that $\mathcal{B}$ is itself a learning machine and not just a model space. Its model space $\mathcal{F}$ includes functions $f(\mathbf{x};\boldsymbol{\theta},\boldsymbol{\alpha})$ of variable parameters $\boldsymbol{\alpha}$ ($\boldsymbol{\theta}$ is fixed), which are adjusted by the "train" method of $\mathcal{B}$:

$$f^* = \text{train}(\mathcal{B}[\mathcal{F},R_1],D); \tag{5}$$

The solution f^* belongs to $\mathcal{F}^*$, the convex closure of $\mathcal{F}$. The method "train" of $\mathcal{A}$ should call the method "train" of $\mathcal{B}$ as a subroutine, because of the nested nature of the learning problems of Equations 2 and 3. Notice that it is possible that different subsets of the data D are used at the different levels of inference.

We easily see two obvious extensions:

(i) *Multi-level inference:* Equation 4 and 5 are formally equivalent, so this formalism can be extended to more than two levels of inference.

3. It would be more correct if the argmin was assigned to parameters not functions, since the search domain is over parameters, and write $\boldsymbol{\theta}^{**} = \arg\min_{\boldsymbol{\theta}} R_2[f^*,D]$, such that $\boldsymbol{\alpha}^* = \arg\min_{\boldsymbol{\alpha}} R_1[f,D], f^* = f(\mathbf{x},\boldsymbol{\alpha}^*)$, but we adopt a shorthand to emphasize the similarities between the frequentist and Bayesian approaches.

4. We adopt a Matlab-style notation: the first argument is the object of which the function is a method; the function "train" is overloaded, there is one for each algorithm. The notations are inspired and adapted from the conventions of the Spider package and the CLOP packages (Saffari and Guyon, 2006).

(ii) *Ensemble methods:* The method "train" returns either a single model or a linear combination of models, so the formalism can include all ensemble methods.

We propose in the next section a new classification of *multi-level inference* methods, orthogonal to the classical Bayesian versus frequentist divide, referring to the way in which data are processed rather than the means by which they are processed.

5. Advances in Multi-level Inference

We dedicate this section to reviewing the methods proposed in the collection of papers that we have edited. We categorize multi-level inference modules, each implementing one level of inference, into *filter*, *wrapper*, and *embedded methods*, borrowing from the conventional classification of feature selection methods (Kohavi and John, 1997; Blum and Langley, 1997; Guyon et al., 2006a). *Filters* are methods for narrowing down the model space, without training the learning machine. Such methods include preprocessing, feature construction, kernel design, architecture design, choice of prior or regularizers, choice of a noise model, and filter methods for feature selection. They constitute the highest level of inference[5]. *Wrapper methods* consider the learning machine as a black-box capable of learning from examples and making predictions once trained. They operate with a search algorithm in hyper-parameter space (for example grid search or stochastic search) and an evaluation function assessing the trained learning machine performances (for example the cross-validation error or the Bayesian evidence). They are the *middle-ware* of multi-level inference. *Embedded* methods are similar to wrappers, but they exploit the knowledge of the learning machine algorithm to make the search more efficient and eventually jointly optimize parameters and hyper-parameters, using multi-level optimization algorithms. They are usually used at the lowest level of inference.

5.1 Filters

Filter methods include a broad class of techniques aiming to reduce the model space $\mathcal{F}$ prior to training the learning machine. Such techniques may use "prior knowledge" or "domain knowledge", data from prior studies or from R&R (repeatability and reproducibility) studies, and even the training data themselves. But they do not produce the final model used to make predictions. Several examples of filter methods are found in the collection of papers we have edited:

Preprocessing and feature construction. An important part of machine learning is to find a good data representation, but choosing an appropriate data representation is very domain dependent. In benchmark experiments, it has often been found that generating a large number of low-level features yields better result than hand-crafting a few features incorporating a lot of expert knowledge (Guyon et al., 2007). The feature set can then be pruned by feature selection. In the challenges we have organized (Clopinet, 2004-2009) the data were generally already preprocessed to facilitate the work of the participants. However, additional normalizations, space dimensionality reduction and discretization were often performed by the participants. Of all space dimensionality reduction methods *Principal Component Analysis* (PCA) remains the most widely used. Several top-ranking participants to challenges we organized used PCA, including Neal and Zhang (2006), winners of the NIPS 2003 feature selection challenge, and Lutz (2006), winner of the WCCI 2006 performance prediction

5. Preprocessing is often thought of as a "low-level" operation. However, with respect to model selection, the selection of preprocessing happens generally in the "outer loop" of selection, hence it is at the highest level.

challenge. *Clustering* is also a popular preprocessing method of dimensionality reduction, championed by Saeed (2009) who used a Bernoulli mixture model as an input to an artificial neural network. In his paper on data grid models Boullé (2009) proposes a new method of *data discretization*. It can be used directly as part of a learning machine based on data grids (stepwise constant predictors) or as a preprocessing to other learning machines, such as the Naïve Bayes classifier. Of particular interest in this paper is the use of *data dependent priors*.

Designing kernels and model architectures. Special purpose neural network architectures implementing the idea of "weight sharing" such as Time Delay Neural Networks (Waibel, 1988) or two-dimensional convolutional networks (LeCun et al., 1989) have proved to be very effective in speech and image processing. More recently a wide variety of special purpose kernels have been proposed to incorporate domain knowledge in kernel learning algorithms. Examples include kernels invariant under various transforms (Simard et al., 1993; Pozdnoukhov and Bengio, 2006), string matching kernels (Watkins, 2000), and other sequence and tree kernels (Vishwanathan and Smola, 2003). Along these lines, in our collection of papers, Chloé Agathe Azencott and Pierre Baldi have proposed two-dimensional kernels for high-thoughput screening (Azencott and Baldi, 2009). Design effort has also be put into general purpose kernels. For instance, in the paper of Adankon and Cheriet (2009) , the SVM regularization hyper-parameter C (box-constraint) is incorporated in the kernel function. This facilitates the task of multi-level inference algorithms.

Defining regularizers or priors. Designing priors $P(f)$ or **regularizers** $\Omega[f]$ or structuring parameter space into parameters and several levels of hyper-parameters can also be thought of as a filter method. Most priors commonly used do not embed domain knowledge, they just enforce Ockham's razor by favoring simple (smooth) functions or eliminating irrelevant features. Priors are also often chosen out of convenience to facilitate the closed-form calculation of Bayesian integrals (for instance the use of so-called "conjugate priors", see *e.g.,* Neal and Zhang, 2006). The 2-norm regularizer $\Omega[f] = \|f\|^2_{\mathcal{H}}$ for kernel ridge regression, Support Vector Machines (SVM) and Least-Square Support Vector Machines (LSSVM) have been applied with success by many top-ranking participants of the challenges we organized. Gavin Cawley was co-winner of the WCCI 2006 performance prediction challenge using LSSVMs (Cawley, 2006). Another very successful regularizer is the **Automatic Relevance Determination** (ARD) prior. This regularizer was used in the winning entry of Radford Neal in the NIPS 2003 feature selection challenge (Neal and Zhang, 2006). Gavin Cawley also made top ranking reference entries in the IJCNN 2007 ALvsPK challenge (Cawley and Talbot, 2007b) using a similar ARD prior. For linear models, the 1-norm regularizer $\|\mathbf{w}\|$ is also popular (see *e.g.,* Pranckeviciene and Somorjai, 2009), but this has not been quite as successful in challenges as the 2-norm regularizer or the ARD prior.

Noise modeling. While the prior (or the regularizer) embeds our prior or domain knowledge of the model class, the likelihood (or the loss function) embeds our prior knowledge of the noise model on the predicted variable y. In regression, the square loss corresponds to Gaussian noise model, but other choices are possible. For instance, recently, Gavin Cawley and Nicola Talbot implemented Poisson regression for kernel machines (Cawley et al., 2007). For classification, the many loss functions proposed do not necessarily correspond to a noise model, they are often just bounding the 0/1 loss and are used for computational convenience. In the

Bayesian framework, an sigmoidal function is often used (like the logistic or probit functions) to map the output of a discriminant function $f(\mathbf{x}_k)$ to probabilities p_k. Assuming target values $y_k \in \{0,1\}$, the likelihood $\Pi_k p_k^{y_k}(1-p_k)^{1-y_k}$ corresponds to the cross-entropy cost function $\sum_k y_k \ln p_k + (1-y_k)\ln(1-p_k)$. A clever piece-wise S-shaped function, flat on the asymptotes, was used in Chu et al. (2006) to implement sparsity for a Bayesian SVM algorithm. Noise modeling is not limited to noise models for the target y, it also concerns modeling noise on the input variables $\mathbf{x}$. Many authors have incorporated noise models on $\mathbf{x}$ as part of the kernel design, for example, by enforcing invariance (Simard et al., 1993; Pozdnoukhov and Bengio, 2006). A simple but effective means of using a noise model is to generate additional training data by distorting given training examples. Additional "unsupervised" data is often useful to fit a noise model on the input variables $\mathbf{x}$. Repeatability and reproducibility (*R&R*) studies may also provide data to fit a noise model.

Feature selection filters. Feature selection, as a filter method, allows us to reduce the dimensionality of the feature space, to ease the computations performed by learning machines. This is often a necessary step for computationally expensive algorithms such as neural networks. Radford Neal for instance, used filters based on univariate statistical tests to prune the feature space before applying his Bayesian neural network algorithm (Neal and Zhang, 2006). Univariate filters were also widely used in the KDD cup 2009, which involved classification tasks on a very large database, to cut down computations (Guyon et al., 2009b). Feature selection filters are not limited to univariate filters. Markov blanket methods, for instance, provide powerful feature selection filters (Aliferis et al., 2003). A review of filters for feature selection can be found in Guyon et al. (2006a, Chapter 3).

5.2 Wrappers

Wrapper methods consider learning machines as *black boxes* capable of internally adjusting their parameters $\boldsymbol{\alpha}$ given some data D and some hyper-parameter values $\boldsymbol{\theta}$. No knowledge either of the architecture, of the learning machines, or of their learning algorithm should be required to use a wrapper. Wrappers are applicable to selecting a classifier from amongst a finite set of learning machines ($\boldsymbol{\theta}$ is then a discrete index), or an infinite set (for continuous values of $\boldsymbol{\theta}$). Wrappers can also be used to build ensembles of learning machines, including Bayesian ensembles. Wrappers use a *search algorithm* or a *sampling algorithm* to explore hyper-parameter space and an *evaluation function* (a risk functional $R_D[f(\boldsymbol{\theta})]$, a posterior probability $P(f(\boldsymbol{\theta})|D)$, or any model selection index $r[f(\boldsymbol{\theta})]$) to assess the performance of the sample of trained learning machines , and, either select one single best machine or create an ensemble of machine voting to make predictions.

Search and sampling algorithms. Because the learning machines in the wrapper setting are "black boxes", we cannot sample directly from the posterior distribution $P(f(\boldsymbol{\theta})|D)$ (or according to $\exp -R_D[f(\boldsymbol{\theta})]$ or $\exp -r[f(\boldsymbol{\theta})]$). We can only compute the evaluation function for given values of $\boldsymbol{\theta}$ for which we run the learning algorithm of $f(\boldsymbol{\theta})$, which internally adjusts its parameters $\boldsymbol{\alpha}$. A **search strategy** defines which hyper-parameter values will be considered and in which order (in case a halting criterion ends the search prematurely). Gavin Cawley, in his challenge winning entries, used the Nelder-Mead simplex algorithm (Cawley and Talbot, 2007a). **Monte-Carlo Markov Chain MCMC methods** are used in Bayesian modeling to sample the posterior probability and have given good results in challenges (Neal

and Zhang, 2006). The resulting ensemble is a simple average of the sampled functions $F(\mathbf{x}) = (1/s)\sum_{i=1}^{s} f(\mathbf{x}|\boldsymbol{\theta}_k)$. Wrappers for *feature selection* use all sort of techniques, but sequential *forward selection* or *backward elimination* methods are most popular (Guyon et al., 2006a, Chapter 4). Other stochastic search methods include biologically inspired methods such as *genetic algorithms* and *particle swarm optimization*. Good results have been obtained with this last method in challenges (H. J. Escalante, 2009), showing that extensive search does not necessarily yield over-fit solutions, if some regularization mechanism is used. The authors of that paper rely for that purpose on weight decay and early stopping. Frequentist ensemble methods, including Random Forests (Breiman, 2001) and Logitboost (Friedman et al., 2000) also gave good results in challenges (Lutz, 2006; Tuv et al., 2009; Dahinden, 2009).

Evaluation functions. For Bayesian approaches, the standard evaluation function is the "evidence", that is the marginal likelihood (also called type-II likelihood) (Neal and Zhang, 2006), or, in other words, the likelihood at the second level of inference. For frequentist approaches, the most frequently used evaluation function is the cross-validation estimator. Specifically, K-fold cross-validation is most often used (H. J. Escalante, 2009; Dahinden, 2009; Lutz, 2006; Reunanen, 2007). The values $K = 10$ or $K = 5$ are typically used by practitioners regardless of the difficulty of the problem (error rate, number of examples, number of variables). Computational considerations motivate this choice, but the authors report a relative insensitivity of the result in that range of values of K. The leave-one-out (LOO) estimator is also used, but due to its high variance, it should rather be avoided, except for computational reasons (see in Section 5.3 cases in which the LOO error is inexpensive to compute). These estimators may be poor predictors of the actual learning machine performances, but they are decent model selection indices, provided that the same data splits are used to compute the evaluation function for all models. For **bagging** methods (like Random Forests, Breiman, 2001), the bootstrap estimator is a natural choice: the "out-of-bag" samples, which are those samples not used for training, are used to predict performance. Using empirical estimators at the second level on inference poses the problem of possibly over-fitting them. Some authors advocate using evaluation functions based on prediction risk bounds: Koo and Kil (2008) and Claeskens et al. (2008) derive in this way information criteria for regression models (respectively called "modulus of continuity information criterion" or MCIC and "kernel regression information criterion" or KRIC) and Claeskens et al. (2008) and Pranckeviciene and Somorjai (2009) propose information criteria for classification problems (respectively called "support vector machine information criterion" SVMIC and "transvariation intensity"). The effectiveness of these new criteria is compared empirically in the papers to the classical "Akaike information criterion" or AIC (Akaike, 1973) and the "Bayesian information criterion" or BIC (Schwarz, 1978).

5.3 Embedded Methods

Embedded methods are similar to wrappers. They need an evaluation function and a search strategy to explore hyper-parameter space. But, unlike wrapper methods, they exploit specific features of the learning machine architecture and/or learning algorithm to perform multi-level inference. It is easy to appreciate that knowledge of the nature and structure of a learning machine can allow us to search hyper-parameter space in a more efficient way. For instance, the function $f(\mathbf{x};\boldsymbol{\alpha},\boldsymbol{\theta})$ may be differentiable with respect to hyper-parameters $\boldsymbol{\theta}$ and it may be possible to use *gradient descent* to

optimize an evaluation function $r[f]$. Embedded methods have been attracting substantial attention within the machine learning community in the past few years because of the mathematical elegance of some of the new proposed methods.

Bayesian embedded methods. In the Bayesian framework, the embedded search, sampling or summation over parameters and hyper-parameters is handled in an elegant and consistent way by defining priors both for parameters and hyper-parameters, and computing the posterior, perhaps in two steps, as indicated in Equation 3. Of course, it is more easily said than done and the art is to find methods to carry out this integration, particularly when it is analytically intractable. Variational methods are often used to tackle that problem. Variational methods convert a complex problem into a simpler problem, but the simplification introduces additional "variational" parameters, which must then be optimized, hence introducing another level of inference. Typically, the posterior is bounded from above by a family of functions parameterized by given variational parameters. Optimizing the variational parameters yields the best approximation of the posterior (see *e.g.,* Seeger, 2008). Bayesian pragmatists optimize the evidence (also called type-II likelihood or marginal likelihood) at the second level of inference, but non-purists sometimes have a last recourse to cross-validation. The contributions of Boullé (2007, 2009) stand out in that respect because they propose model selection methods for classification and regression, which have no last recourse to cross-validation, yet performed well in recent benchmarks (Guyon et al., 2008a, 2009b). Such methods have been recently extended to the less studied problem of rank regression (Hue and Boullé, 2007). The methods used are Bayesian in spirit, but make use of original data-dependent priors.

Regularized functionals. In the frequentist framework, the choice of a prior is replaced by the choice of a regularized functional. Those are two-part evaluation functions including the empirical risk (or the negative log-likelihood) and a regularizer (or a prior). For kernel methods, a 2-norm regularizer is often used, yielding the classical penalized functional $R_{reg}[f] = R_{emp}[f] + \gamma \|f\|^2_{\mathcal{F}}$. Pranckeviciene and Somorjai (2009) explore the possibilities offered by a 1-norm regularizer. Such approaches provide an embedded method of feature selection, since the constraints thus imposed on the weight vector drive some weights to exactly zero. We emphasized in the introduction that, in some cases, decomposing the inference problem into multiple levels allows us to conveniently regain the convexity of the optimization problem involved in learning. Ye et al. (2008) propose a multiple kernel learning (MKL) method, in which the optimal kernel matrix is obtained as a linear combination of pre-specified kernel matrices, which can be brought back to a convex program. Few approaches are fully embedded and a wrapper is often used at the last level of inference. For instance, in kernel methods, the kernel parameters may be optimized by gradient descent on the regularized functional, but then the regularization parameter is selected by cross-validation. One approach is to use a bound on the generalization error at the second level of inference. For instance, Guermeur (2007) proposes such a bound for the multi-class SVM, which can be used to choose the values of the "soft margin parameter" C and the kernel parameters. Cross-validation may be preferred by practitioners because it has performed consistently well in benchmarks (Guyon et al., 2006b). This motivated Kunapuli et al. (2009) to integrate the search for optimal parameters and hyper-parameters into a multi-level optimization program, using a regularized functional at the lower level, and cross-validation at the upper level. Another way of integrating a second level of inference performed by cross-validation and the optimization of

a regularized functional at the first level of inference is to use a closed-form expression of the leave-one-out error (or a bound) and optimize it by gradient descent or another classical optimization algorithm. Such *virtual leave-one-out* estimators, requiring training a single classifier on all the data (see *e.g.*, Cawley and Talbot, 2007a; Debruyne et al., 2–8, in the collection of papers we have assembled).

6. Advanced Topics and Open Problems

We have left aside many important aspects of model selection, which, space permitting, would deserve a longer treatment. We briefly discuss them in this section.

6.1 Ensemble Methods

In Section 4, we have made an argument in favor of unifying *model selection* and *ensemble methods*, stemming either from a Bayesian or frequentist perspective, in the common framework of *multi-level optimization*. In Sections 5.1, 5.2, and 5.3, we have given examples of model selection and ensemble methods following *filter*, *wrapper* or *embedded* strategies. While this categorization has the advantage of erasing the dogmatic origins of algorithms, it blurs some of the important differences between model selection and ensemble methods. Ensemble methods can be thought of as a way of circumventing model selection by voting among models rather than choosing a single model. Recent challenges results have proved their effectiveness (Guyon et al., 2009b). Arguably, model selection algorithms will remain important in applications where model simplicity and data understanding prevail, but ever increasing computer power has brought ensemble methods to the forefront of multi-level inference techniques. For that reason, we would like to single out those papers of our collection that have proposed or applied ensemble methods:

Lutz (2006) used boosted shallow decision trees for his winning entries in two consecutive challenges. Boosted decision trees have often ended up among the top ranking methods in other challenges (Guyon et al., 2006a, 2009b). The particular implementation of Lutz of the Logitboost algorithm (Friedman et al., 2000) use a "shrinkage" regularization hyper-parameter, which seems to be key to attain good performance, and is adjusted by cross-validation as well as the total number of *base learners*. Dahinden (2009) successfully applied the Random Forest (RF) algorithm (Breiman, 2001) in the performance prediction challenge (Guyon et al., 2006b). She demonstrated that with minor adaptations (adjustment of the bias value for improved handling of unbalanced classes), the RF algorithm can be applied without requiring user intervention. RF continues to be a popular and successful method in challenges (Guyon et al., 2009b). The top ranking models use very large ensembles of hundreds of trees. One of the unique features of RF algorithms is that they subsample both the training examples and the features to build base learners. Using random subsets of features seems to be a winning strategy, which was applied by others to ensembles of trees using both boosting and bagging (Tuv et al., 2009) and to other base learners (Nikulin, 2009). Boullé (2007) also adopts the idea of creating ensembles using base learners constructed with different subsets of features. Their base learner is the naïve Bayes classifier and, instead of using random subsets, they select subsets with a forward-backward method, using a maximum A Posteriori (MAP) evaluation function (hence not requiring cross-validation). The base learners are then combined with an weighting scheme based on an information theoretic criterion, instead on weighting the models with the posterior probability as in Bayesian model averaging. This basically boils down to using the logarithm of the posterior probabilities instead of the posterior probabilities themselves

for weighting the models. The weights have an interpretation in terms of model compressibility. The authors show that this strategy outperforms Bayesian model averaging on several benchmark data sets. This can be understood by the observation that when the posterior distribution is sharply peaked around the posterior mode, averaging is almost the same as selecting the MAP model. Robustness is introduced by performing a more balanced weighting of the base learners. In contrast with the methods we just mentioned, which choose identical base learners (trees of naïve Bayes), other successful challenge participants have built heterogeneous ensembles of learning machines (including, for example, linear models, kernel methods, trees, naïve Bayes, and neural networks), using cross-validation to evaluate their candidates for inclusion in the ensemble (Wichard, 2007; IBM team, 2009). While Wichard (2007) evaluates classifiers independently, IBM team (2009) uses a forward selection method, adding a new candidate in the ensemble based on the new performance of the ensemble.

6.2 PAC Bayes Approaches

Unifying Bayesian and frequentist model selection procedures under the umbrella of *multi-level inference* may shed new light on correspondences between methods and have a practical impact on the design of toolboxes incorporating model selection algorithms. But there are yet more synergies to be exploited between the Bayesian and the frequentist framework. In this section, we would like to capture the spirit of the PAC Bayes approach and outline possible fruitful directions of research.

The PAC learning framework (Probably Approximately Correct), introduced by Valiant (1984) and later recognized to closely resemble the approach of the Russian school popularized in the US by Vapnik (1979), has become the beacon of frequentist learning theoretic approaches. It quantifies the generalization performance (the *Correct* aspect) of a learning machine via performance bounds (the *Approximate* aspect) holding in probability (the *Probable* aspect):

$$Prob\Big[(R[f] - R_{emp}[f]) \leq \varepsilon(\delta)\Big] \geq (1-\delta) \ ,$$

In this equation, the confidence interval $\varepsilon(\delta)$ (*Approximate* aspect) bounds, with probability $(1-\delta)$ (*Probable* aspect),the difference between the *expected risk* or generalization error $R[f]$ and the *empirical risk*[6] $R_{emp}[f]$ (*Correct* aspect). Recently, many bounds have been proposed to quantify the generalization performance of algorithms (see *e.g.,* Langford, 2005, for a review). The idea of deriving new algorithms, which optimize a bound $\varepsilon(\delta)$ (*guaranteed risk* optimization) has been popularized by the success of SVMs (Boser et al., 1992) and boosting (Freund and Schapire, 1996).

The PAC framework is rooted in the frequentist philosophy of defining probability in terms of *frequencies of occurrence of events* and bounding differences between mathematical expectations and frequencies of events, which vanish with increasingly large sample sizes (law of large numbers). Yet, since the pioneering work of Haussler et al. (1994), many authors have proposed so-called PAC-Bayes bounds. Such bounds assess the performance of existing Bayesian algorithms (see *e.g.,* Seeger, 2003), or are used to derive new Bayesian algorithms optimizing a guaranteed risk functional (see Germain et al. 2009 and references therein).

This is an important paradigm shift, which bridges the gap between the frequentist *structural risk minimization* approach to model selection (Vapnik, 1998) and the *Bayesian prior* approach.

6. at the first level of inference, this would be the training error $R_{tr}[f]$; at the second level of inference this may be the validation error $R_{va}[f]$

It erases the need for assuming that *the model used to fit the data comes from a concept space of functions that generated the data*. Instead, priors may be used to provide a "structure" on a chosen model space (called *hypothesis space* to distinguish it from the *concept space*), which does not necessarily coincide with the *concept space*, of which we often know nothing. Reciprocally, we can interpret structures imposed on a hypothesis space as our prior belief that certain models are going to perform better than others (see, for instance, the examples at the end of Section 3.1).

This opens the door to also regularizing the second level of inference by using performance bounds on the cross-validation error, as was done for instance in Cawley and Talbot (2007a) and Guyon (2009).

6.3 Open Problems

- **Domain knowledge:** From the earliest embodiments of Okcham's razor using the number of free parameters to modern techniques of regularization and bi-level optimization, model selection has come a long way. The problem of finding the right structure remains, the rights prior or the right regularizer. Hence know-how and domain knowledge are still required. But in a recent challenge we organized called "agnostic learning *vs*. prior knowledge" (Guyon et al., 2008b) it appeared that the relatively small incremental improvements gained with prior knowledge came at the expense of important human effort. In many domains, collecting more data is less costly than hiring a domain expert. Hence there is pressure towards improving machine learning toolboxes and, in particular equipping them with model selection tools. For the competitions we organized (Clopinet, 2004-2009), we made a toolbox available with state-of-the-art models (Saffari and Guyon, 2006), which we progressively augmented with the best performing methods. The Particle Swarm Optimization (PSO) model selection method can find the best models in the toolbox and reproduce the results of the challenges (H. J. Escalante, 2009). Much remains to be done to incorporate filter and wrapper model selection algorithms in machine learning toolboxes.

- **Unsupervised learning:** Multi-level optimization and model selection are also central problems for **unsupervised learning**. When no target variable is available as "teaching signal" one can still define regularized risk functionals and multi-level optimization problems (Smola et al., 2001). Hyper-parameters (e.g., "number of clusters") can be adjusted by optimizing a second level objective such as model stability (Ben-Hur et al., 2002), which is an erzatz of cross-validation. The primary difficulty with model selection for unsupervised learning is to validate the selected model. To this day, there is no consensus on how to benchmark methods, hence it is very difficult to quantify progress in this field. This is why we have so far shied away from evaluating unsupervised learning algorithms, but this remains on our agenda.

- **Semi-supervised learning:** Very little has been done for model selection in **semi-supervised learning** problems, in which only some training instances come with target values. Semi-supervised tasks can be challenging for traditional model selection methods, such as cross-validation, because the number of labeled data is often very small. Schuurmans and Southey (2001) used the unlabeled data to test the consistency of a model, by defining a metric over the hypothesis space. Similarly, Madani et al. (2005) introduced the co-validation method, which uses the disagreement of various models on the predictions over the unlabeled data as a model selection tool. In some cases there is no performance gain by using the unlabeled

data for training (Singh et al., 2008). Deciding whether all or part of the unlabeled data should be used for training (*data selection*) may also be considered a model selection problem.

- **Non *i.i.d.* data:** The problem of non *i.i.d.* data raises a number of other questions because if there are significant differences between the distribution of the training and the test data, the cross-validation estimator may be worthless. For instance, in causal discovery problems, training data come from a "natural" distribution while test data come from a different "manipulated" distribution (resulting from some manipulations of the system by an external agent, like clamping a given variable to given values). Several causal graphs may be consistent with the "natural distribution" (not just with the training data, with the true unknown distribution), but yield very different predictions of manipulated data. Rather selecting a single model, it make more sense to select a model class. We have started a program of data exchange and benchmarks to evaluate solutions to such problems (Guyon et al., 2008a, 2009a).

- **Computational considerations:** The selection of the model best suited to a given application is a multi-dimensional problem in which prediction performance is only one of the dimensions. Speed of model building and processing efficiency of deployed models are also important considerations. Model selection algorithms (or ensemble methods) which often require many models to be trained (e.g., wrapper methods with extensive search strategies and using cross-validation to validate models) may be unable to build solutions in a timely manner. At the expense of some acceptable loss in prediction performance, methods using *greedy search strategies* (like forward selection methods) and *single-pass evaluation functions* (requiring the training of only a single model to evaluate a given hyper-parameter choice), may considerably cut the training time. Greedy search methods include forward selection and backward elimination methods. Single-pass evaluation functions include penalized training error functionals (regularized functionals, MAP estimates) and virtual-leave-one-out estimators. The latter allows users to compute the leave-one-out-error at almost no additional computational expense than training a single predictor on all the training data (see *e.g.,* Guyon et al., 2006a, Chapter 2, for a review). Other tricks-of-the-trade include following *regularization paths* to sample the hyper-parameter space more effectively (Rosset and Zhu, 2006; Hastie et al., 2004). For some models, the evaluation function is piecewise linear between a few discontinuous changes occurring for a few finite hyper-parameter values. The whole path can be reconstructed from only the values of the evaluation function at those given points. Finally, Reunanen (2007) proposed clever ways of organizing nested cross-validation evaluations in multiple level of inference model selection using cross-indexing. The author also explored the idea of spending more time to refine the evaluation of the most promising models. Further work needs to be put into model selection methods, which simultaneously address multiple objectives, including optimizing prediction performance and computational cost.

7. Conclusion

In the past twenty years, much effort has been expended towards finding the best regularized functionals. The many embodiments of Ockham's razor in machine learning have converged towards similar regularizers. Yet, the problem of model selection remains because we need to optimize the regularization parameter(s) and often we need to select among various preprocessings, learning machines, and post-processings. In the proceedings of three of the challenges we organized around the

problem of model selection, we have collected a large number of papers, which testify to the vivid activity of the field. Several researchers do not hesitate to propose heretic approaches transcending the usual "frequentist" or Bayesian dogma. We have seen the idea of using the Bayesian machinery to design regularizers with "data-dependent priors" emerge (Boullé, 2007, 2009), much like a few years ago data-dependent performance bounds (Bartlett, 1997; Vapnik, 1998) and PAC-Bayes bounds (Haussler et al., 1994; Seeger, 2003) revolutionized the "frequentist" camp, up to then very fond of uniform convergence bounds and the VC-dimension (Vapnik and Chervonenkis, 1971). We have also seen the introduction of regularization of cross-validation estimators using Bayesian priors (Cawley and Talbot, 2007a). Ensemble methods may be thought of as a way of circumventing model selection. Rather, we think of model selection and ensemble methods as two options to perform multi-level inference, which can be formalized in a unified way.

Within this general framework, we have categorized approaches into *filter*, *wrapper* and *embedded* methods. These methods complement each other and we hope that in a not too distant future, they will be integrated into a consistent methodology: Filters first can prune model space; Wrappers can perform an outer level model selection to select pre/post processings and feature subsets; Embedded methods can perform an inner level hyper-parameter selection integrated within a bi-level optimization program. We conclude that we are moving towards a unified framework for model selection and there is a beneficial synergy between methods, both from a theoretical and from a practical perspective.

Appendix A. Glossary

Automatic Relevance Determination (ARD) prior. The ARD prior was invented for neural networks (MacKay, 1992): all network input variables and all neuron outputs (internal features) are weighed by a scaling factor κ_i, before being independently weighted by the network connections. A hyper-prior must be chosen to favor small values of the κ_i, which makes the influence of irrelevant variables or features naturally fade away. For kernel methods, ARD falls under the same framework as the $\|f\|^2_{\mathcal{H}}$ regularizer, for a special class of kernels using variable (feature) scaling factors. For instance, the ARD prior is implemented by defining the Gaussian kernel (for positive hyper-parameters κ_i):

$$K(\mathbf{x}_h, \mathbf{x}_k) = \exp\left\{ -\sum_{j=1}^{n} \kappa_i (x_{h,j} - x_{k,j})^2 \right\}$$

instead of the regular Gaussian kernel $K(\mathbf{x}_h, \mathbf{x}_k) = \exp\left\{-\kappa \|\mathbf{x}_h - \mathbf{x}_k\|^2\right\}$.

Base learner. In an ensemble method, the individual learning machines that are part of the ensemble.

Bagging. Bagging stands for bootstrap aggregating. Bagging is a parallel ensemble method (all **base learners** are built independently from training data subsets). Several data subsets of size m are drawn independently with replacement from the training set of m examples. On average each subset thus built contains approximately 2/3 of the training examples. The ensemble predictions are made by averaging the predictions of the baser learners. The ensemble approximates $E_D(f(\mathbf{x},D))$, where $f(\mathbf{x},D)$ is a function from the model class F, trained with m examples and $E_D(.)$ is the mathematical expectation over all training sets of size m. The rationale comes from the **bias/variance decomposition** of the **generalization error**. The "out-of-bag" samples (samples not used for learning for each data subset drawn for training) may be used to create a bootstrap prediction of performance.

Bayesian learning. Under the Bayesian framework, it is assumed that the data were generated from a double random process: (1) a model is first drawn according to a **prior** distribution in a **concept space**; (2) data are produced using the model. In the particular case of supervised learning, as for **maximum likelihood learning**, a three-part data generative model is assumed: $P(\mathbf{x})$, $f \in \mathcal{F}$, and a zero-mean noise model. But, it is also assumed that the function f was drawn according to a prior distribution $P(f)$. This allows us to compute the probability of an output y given an input $\mathbf{x}$, $P(y|\mathbf{x}) = \int_{f\in\mathcal{F}} P(y|\mathbf{x},f)dP(f)$, or its mathematical expectation $E(y|\mathbf{x}) = \int_{f\in\mathcal{F}} f(\mathbf{x})dP(f)$, averaging out the noise. After training data D are observed, the prior $P(f)$ is replaced by the **posterior** $P(f|D)$. The mathematical expectation of y given $\mathbf{x}$ is estimated as: $E(y|\mathbf{x},D) = \int_{f\in\mathcal{F}} f(\mathbf{x})dP(f|D)$. Hence, learning consists of calculating the posterior distribution $P(f|D)$ and integrating over it. The predictions are made according to $E(y|\mathbf{x},D)$, a function not necessarily belonging to $\mathcal{F}$. In the case of classification, $E(y|\mathbf{x},D)$ does not take values in $\mathcal{Y}$ (although thresholding the output just takes care of the problem). If we want a model in $\mathcal{F}$, we can use the Gibbs algorithm, which picks one sample in $\mathcal{F}$ according to the posterior distribution $P(f|D)$, or use the **MAP learning** approach. In Bayesian learning, analytically integrating over the posterior distribution is often impossible and the integral may be approximated by finite sum of models, weighted by positive coefficients (see **variational methods**) or by sampling models from the posterior distribution (see **Weighted majority algorithm** and **Monte-Carlo Markov Chain** or MCMC). The resulting estimators of $\hat{E}(y|\mathbf{x},D)$ are convex combinations of functions in $\mathcal{F}$ and, in that sense, Bayesian learning is similar to **ensemble methods**.

Bias/variance decomposition. In the case of a least-square loss, the bias/variance decomposition is given by $E_D[(f(\mathbf{x};D)-E[y|\mathbf{x}])^2] = (E_D[f(\mathbf{x};D)]-E(y|\mathbf{x}))^2+E_D[(f(\mathbf{x};D)-E_D[f(\mathbf{x};D)])^2]$. The second term (the "variance" of the estimator $f(\mathbf{x},D)$) vanishes if $f(\mathbf{x};D)$ equals $E_D[f(\mathbf{x};D)$. The motivates the idea of using an approximation of $E_D[f(\mathbf{x};D)$ as a predictor. In **bagging** the approximation is obtained by averaging over functions trained from m examples drawn at random with replacement from the training set D (bootstrap method). The method works best if $\mathcal{F}$ is not biased (i.e., contains $E(y|\mathbf{x})$). Most models with low bias have a high variance and vice versa, hence the well-known bias/variance tradeoff.

Concept space. A space of data generative models from which the data are drawn. Not to be confused with **model space** or **hypothesis space**.

Empirical risk. An estimator of the **expected risk** that is the average of the loss over a finite number of examples drawn according to $P(\mathbf{x},y)$: $R_{emp} = (1/m)\sum_{k=1}^{m} \mathcal{L}(f(\mathbf{x}_k),y_k)$.

Ensemble methods. Methods of building predictors using multiple **base learners**, which vote to make predictions. Predictions of y are made using a convex combination of functions $f_j \in \mathcal{F}$: $F(\mathbf{x}) = \sum_j p_j f_j(\mathbf{x})$, where p_j are positive coefficients. The two most prominent ensemble methods are bagging (Breiman, 1996) and boosting (Freund and Schapire, 1996). Bagging is a parallel ensemble method (all trees are built independently from training data subsets), while boosting is a serial ensemble method (trees complementing each other are progressively added to decrease the residual error). Random Forests (RF) (Breiman, 2001) are a variant of bagging methods in which both features and examples are subsampled. Boosting methods come in various flavors including Adaboost, Gentleboost, and Logitboost. The original algorithm builds successive models (called "weak learners") by resampling data in a way that emphasizes examples that have proved hardest to learn. Newer versions use a weighting scheme instead of resampling (Friedman, 2000).

Expected risk. The mathematical expectation of a risk functional over the unknown probability distribution $P(\mathbf{x},y)$: $R[f] = \int \mathcal{L}(f(\mathbf{x}),y)\, dP(\mathbf{x},y)$. Also called **generalization error**.

Generalization error. See **expected risk**.

Greedy search strategy. A search strategy, which does not revisit partial decisions already made, is called "greedy". Examples include forward selection and backward elimination in feature selection.

Guaranteed risk. A bound on the **expected risk**. See **PAC learning** and **Structural Risk Minimization** (SRM).

Hypothesis space. A space of models, which are fit to data, not necessarily identical to the **concept space** (which is often unknown).

Loss function. A function $\mathcal{L}(f(\mathbf{x}),y)$, which measures the discrepancy between target values y and model predictions $f(\mathbf{x})$. Examples include the square loss $(y - f(\mathbf{x}))^2$ for regression of the 0/1 loss $\mathbf{1}[f(\mathbf{x}) \neq y]$ for classification).

MAP learning. Maximum a posteriori (MAP) learning shares the same framework as Bayesian learning, but it is further assumed that the posterior $P(f|D)$ is concentrated and that $E(y|\mathbf{x},D)$ can be approximated by $f^*(\mathbf{x})$, with $f^* = \operatorname{argmax}_f P(f|D) = \operatorname{argmax}_f P(D|f)P(f) = \operatorname{argmin}_f -\ln P(D|f) - \ln P(f)$. If we assume a uniform prior, we are brought back to maximum likelihood learning. If both $P(D|f)$ and $P(f)$ are exponentially distributed ($P(y|\mathbf{x},f) = exp - \mathcal{L}(f(\mathbf{x}),y)$ and $P(f) = exp - \Omega[f]$), then MAP learning is equivalent to the minimization of a regularized risk functional.

Maximum likelihood learning. It is assumed that the data were generated by an input distribution $P(\mathbf{x})$, a function f from a **model space** $\mathcal{F}$ coinciding with the **concept space**, and a zero-mean **noise model**. For regression, for instance, if Gaussian noise $\varepsilon \sim \mathcal{N}(0,\sigma^2)$ is assumed, y is distributed according to $P(y|\mathbf{x},f) = \mathcal{N}(f(\mathbf{x}),\sigma^2)$. In the simplest case, $P(\mathbf{x})$ and the noise model are not subject to training (the values of $\mathbf{x}$ are fixed and the noise model is known). Learning then consists in searching for the function f^*, which maximizes the likelihood $P(D|f)$, or equivalently (since $P(\mathbf{x})$ is not subject to training) $f^* = \operatorname{argmax}_f P(\mathbf{y}|X,f) = \operatorname{argmin}_f - \ln P(\mathbf{y}|X,f)$. With the *i.i.d.* assumption, $f^* = \operatorname{argmax}_f \Pi_{k=1}^m P(y_k|\mathbf{x}_k,f) = \operatorname{argmin}_f \sum_{k=1}^m -$

$\ln P(y_k|\mathbf{x}_k, f)$. For distributions belonging to the exponential family $P(y|\mathbf{x}, f) = \exp\{-\mathcal{L}(f(\mathbf{x}), y)\}$, the maximum likelihood method is equivalent to the method of minimizing the **empirical risk**. In the case of Gaussian noise, this corresponds to the method of least squares.

Model space. A space of predictive models, which are fit to data. Synonym of **hypothesis space**. For Bayesian models, also generally coincides with the **concept space**, but not for frequentists.

Monte-Carlo Markov Chain (MCMC) method. To approximate Bayesian integrals one can sample from the posterior distribution $P(f|D)$ following a Monte-Carlo Markov chain (MCMC), then make predictions according to $\hat{E}(y|\mathbf{x}, D) = \sum_j f_j(\mathbf{x})$. In a MCMC, at each step new candidate models $f_j \in \mathcal{F}$ are considered, in a local neighborhood of the model selected at the previous step. The new model is accepted if it provides a better fit to the data according to the posterior distribution or, if not, a random decision is made to accept it, following the Gibbs distribution (better models having a greater chance of acceptance).

Over-fitting avoidance. Model selection is traditionally associated with the so-called problem of **over-fitting** avoidance. Over-fitting means fitting the training examples well (i.e., obtaining large model likelihood or low empirical risk values, computed from training data), but generalizing poorly on new test examples. Over-fitting is usually blamed on too large a large number of free parameters to be estimated, relative to the available number of training examples. The most basic model selection strategy is therefore to restrict the number of free parameters according to "strict necessity". This heuristic strategy is usually traced back in history to the principle known as Ockham's razor "Plurilitas non est ponenda sin necessitate" (William of Ockham, 14^{th} century). In other words, of two theories providing similarly good predictions, the simplest one should be preferred, that is, shave off unnecessary parameters. Most modern model selection strategies claim some affiliation with Ockham's razor, but the number of free parameters is replaced by a measure of **capacity** or **complexity** of the model class, $C[\mathcal{F}]$. Intuitively, model classes with large $C[\mathcal{F}]$ may include the correct model, but it is hard to find. In this case, even models with a low training error may have a large generalization error (high "variance"; over-fitting problem). Conversely, model classes with small $C[\mathcal{F}]$ may yield "biased" models, that is, with both high training and generalization error (under-fitting). See **bias/variance decomposition.**.

PAC learning. The "probably approximately correct" (PAC) learning procedures, seek a function minimizing a **guaranteed risk** $R_{gua}[f] = R_{emp}[f] + \varepsilon(C, \delta)$ such that with (high) probability $(1-\delta)$, $R[f] \leq R_{gua}[f]$. C is a measure of capacity or complexity.

Regularizers and regularization. The regularization method consists of replacing the minimization of the **empirical risk** $R_{emp}[f]$ by that of $R_{reg}[f] = R_{emp} + \Omega[f]$. A regularizer $\Omega[f]$ is a functional penalizing "complex" functions. If both $R_{tr}[f]$ and $\Omega[f]$ are convex, there is a unique minimum of $R_{reg}[f]$ with respect to f. In **MAP learning**, $-\ln P(f)$ can be thought of as a **regularizer**. One particularly successful regularizer is the 2-norm regularizer $\|f\|^2_{\mathcal{H}}$ for model functions $f(\mathbf{x}) = \sum_{k=1}^{m} \alpha_k K(\mathbf{x}, \mathbf{x}_k)$ belonging to a Reproducing Kernel Hilbert Space $\mathcal{H}$ (kernel methods). In the particular case of the linear model $f(\mathbf{x}) = \mathbf{w} \cdot \mathbf{x}$,

we have $\|f\|^2_{\mathcal{H}} = \|\mathbf{w}\|^2$, a commonly used regularized found in many algorithms including ridge regression (Hoerl, 1962) and SVMs (Boser et al., 1992). In the general case, $\|f\|^2_{\mathcal{H}} = \mathbf{f}K^{-1}\mathbf{f} = \boldsymbol{\alpha}^T K\boldsymbol{\alpha}$, where $\mathbf{f} = [f(\mathbf{x}_k)]_{k=1}^m$ is the vector of predictions of the training examples, $\boldsymbol{\alpha} = [\alpha_k]_{k=1}^m$ and $K = [K(\mathbf{x}_h, \mathbf{x}_k]$, $h = 1, ...m$ $k = 1, ...m$. Due to the duality between RKHS and stochastic processes (Wahba, 1990), the functions in the RKHS can also be explained as a family of random variables in a Gaussian process, assuming a prior $P(f)$ proportional to $\exp(-\gamma\|f\|_{\mathcal{H}}) = \exp(-\gamma\mathbf{f}K^{-1}\mathbf{f})$ and the kernel matrix K is interpreted as a covariance matrix $K(\mathbf{x}_h, \mathbf{x}_k)$ =cov$[f(x_k), f(x_k)]$.

Risk minimization. Given a **model space** or **hypothesis space** $\mathcal{F}$ of functions $y = f(\mathbf{x})$, and a **loss function** $\mathcal{L}(f(\mathbf{x}), y)$, we want to find the function $f^* \in \mathcal{F}$ that minimizes the **expected risk** $R[f] = \int \mathcal{L}(f(\mathbf{x}), y)\, dP(\mathbf{x}, y)$. Since $P(\mathbf{x}, y)$ is unknown, only estimations of $R[f]$ can be computed. The simplest estimator is the average of the loss over a finite number of examples drawn according to $P(\mathbf{x}, y)$ called the **empirical risk**: $R_{emp} = (1/m)\sum_{k=1}^m \mathcal{L}(f(\mathbf{x}_k), y_k)$. The minimization of the empirical risk is the basis of many machine learning approaches to selecting f^*, but minimizing regularized risk functionals is often preferred. See **regularization**. Also, related are the **PAC learning** procedures and the method of **Structural Risk Minimization** (SRM).

Search strategy. There are *optimal search strategies*, which guarantee that the optimum of the evaluation function will be found, including the *exhaustive search* method, for discrete hyper-parameter spaces. The popular *grid search* method for continuous hyper-parameter spaces performs an exhaustive search, up to a certain precision. A related *stochastic search* method is *uniform sampling*. Uniformly sampling parameter space may be computationally expensive and inefficient. If we use a non-uniform distribution $G(\boldsymbol{\theta})$ to sample hyper-parameter space, which resembles $P(f(\boldsymbol{\theta})|D)$, the search can be made more efficient. This idea is exploited in *rejection sampling* and *importance sampling*: according to these methods a Bayesian ensemble $F(\mathbf{x}) = \sum_k w_k f(\mathbf{x}; \boldsymbol{\theta}_k)$ would use weight w_k proportional to $P(f(\boldsymbol{\theta})|D)/G(\boldsymbol{\theta})$. Because of the computational burden of (near) optimum strategies, other strategies are often employed, usually yielding only a *local optimum*. These include *sequential search strategies* such as *coordinate ascent* or descent (making small steps along coordinate axes) or *pattern search* (Momma and Bennett, 2002) (making local steps according to a certain pattern), which, by accepting only moves that improve the evaluation function, find the local optimum nearest to the starting point. Some stochastic search methods accept moves not necessarily improving the value of the evaluation function, like simulated annealing or **Markov chain Monte Carlo (MCMC) methods**. Both methods accept all moves improving the evaluation function and some moves that do not, for example, with probability $\exp -\Delta r/T$, where T is a positive parameter (T=1 for MCMC and progressively diminishes for simulated annealing). Such stochastic methods search hyper-parameter space more intensively and do not become stuck in the nearest local optimum of the evaluation function.

Semi-supervised learning. In semi-supervised learning, in addition to the labeled data, the learning machine is given a (possibly large) set of unlabeled data. Such unlabeled data may be used for training or model selection.

Structural Risk Minimization. The method of Structural Risk Minimization (SRM) provides aeans of building regularized risk functionals (see **Regularization**), using the idea of **guaranteed**

risk minimization, but not requiring the calculation of the model class capacity or complexity, which is often unknown or hard to compute. In the risk minimization framework, it is not assumed that the model space includes a function or "concept", which generated the data (see **concept space** and **hypothesis space**).

Supervised learning. Learning with teaching signal or target y.

Under-fitting. While **over-fitting** is the problem of learning the training data too well the expense of a large **generalization error**, under-fitting is the problem of having a too weak model not even capable of learning the training data and also generalizing poorly.

Unsupervised learning. Learning in the absence of teaching signal or target y.

Weighted majority algorithm. To approximate Bayesian integrals one can draw samples f_j uniformly from the model space of functions $\mathcal{F}$ and make predictions according to $\hat{E}(y|\mathbf{x},D) = \sum_j P(f_j|D) f_j(\mathbf{x})$.

Abstract

We consider a sequential version of the classical bin packing problem in which items are received one by one. Before the size of the next item is revealed, the decision maker needs to decide whether the next item is packed in the currently open bin or the bin is closed and a new bin is opened. If the new item does not fit, it is lost. If a bin is closed, the remaining free space in the bin accounts for a loss. The goal of the decision maker is to minimize the loss accumulated over n periods. We present an algorithm that has a cumulative loss not much larger than any strategy in a finite class of reference strategies for any sequence of items. Special attention is payed to reference strategies that use a fixed threshold at each step to decide whether a new bin is opened. Some positive and negative results are presented for this case.

Keywords: bin packing, on-line learning, prediction with expert advice

1. Introduction

In the classical *off-line* bin packing problem, an algorithm receives *items* (also called *pieces*) of size $x_1, x_2, \ldots, x_n \in (0,1]$. We have an infinite number of bins, each with capacity 1, and every item is to be assigned to a bin. Further, the sum of the sizes of the items (also denoted by x_t) assigned to any bin cannot exceed its capacity. A bin is empty if no item is assigned to it, otherwise, it is used. The goal of the algorithm is to minimize the number of used bins. This is one of the classical NP-hard problems and heuristic and approximation algorithms have been investigated thoroughly, see, for example, Coffman et al. (1997).

Another well-studied version of the problem is the so-called *on-line* bin packing problem. Here items arrive one by one and each item x_t must be assigned to a bin (with free space at least x_t)

immediately, without any knowledge of the next pieces. In this setting the goal is the same as in the off-line problem, that is, the number of used bins is to be minimized, see, for example, Seiden (2002).

In both the off-line and on-line problems the algorithm has access to the bins in arbitrary order. In this paper we abandon this assumption and introduce a more restricted version that we call *sequential bin packing*. In this setting items arrive one by one (just like in the on-line problem) but in each round the algorithm has only two possible choices: assign the given item to the (only) open bin or to the "next" empty bin (in this case this will be the new open bin), and items cannot be assigned anymore to closed bins. An algorithm thus determines a sequence of binary decisions $i_1, \ldots, i_n$ where $i_t = 0$ means that the next item is assigned to the open bin and $i_t = 1$ means that a new bin is opened and the next item is assigned to that bin. Of course, if $i_t = 0$, then it may happen that the item x_t does not fit in the open bin. In that case the item is "lost." If the decision is $i_t = 1$ then the remaining empty space in the last closed bin is counted as a loss. The measure of performance we use is the total sum of all lost items and wasted empty space.

Just as in the original bin packing problem, we may distinguish off-line and on-line versions of the sequential bin packing problem. In the *off-line sequential* bin packing problem the entire sequence $x_1, \ldots, x_n$ is known to the algorithm at the outset. Note that unlike in the classical bin packing problem, the order of the items is relevant. This problem turns out to be computationally significantly easier than its non-sequential counterpart. In Section 3 we present a simple algorithm with running time of $O(n^2)$ that minimizes the total loss in the off-line sequential bin packing problem.

Much more interesting is the on-line variant of the sequential bin packing problem. Here the items x_t are revealed one by one, *after* the corresponding decision i_t has been made. In other words, each decision has to be made without any knowledge on the size of the item. Formulated this way, the problem is reminiscent of an on-line *prediction problem*, see Cesa-Bianchi and Lugosi (2006). However, unlike in standard formulations of on-line prediction, here the loss the predictor suffers depends not only on the outcome x_t and decision i_t but also on the "state" defined by the fullness of the open bin.

Our goal is to extend the usual bin packing problems to situations in which one can handle only one bin at a time, and items must be processed immediately so they cannot wait for bin changes. To motivate the on-line sequential model, one may imagine a simple revenue management problem in which a decision maker has a unit storage capacity at his disposal. A certain product arrives in packages of different size and after each arrival, it has to be decided whether the stored packages are shipped or not. (Storage of the product is costly.) If the stored goods are shipped, the entire storage capacity becomes available again. If they are not shipped one waits for the arrival of the next package. However, if the next package is too large to fit in the remaining open space, it is lost (it will be stored in another warehouse).

In another example of application, a sensor collects measurements that can be compressed to variable size (these are the items). The sensor communicates its measurements by sending frames of some fixed size (bins). Since it has limited memory, it cannot store more data than one frame. To save energy, the sensor must maximize its throughput (the proportion of useful data in each frame) and at the same time minimize data loss (this trade-off is reflected in the definition of the loss function).

Just like in on-line prediction, we compare the performance of an algorithm with the best in a pool of reference algorithms (experts). Given a set of N reference strategies, we construct a

randomized algorithm for the sequential on-line bin packing problem that achieves a cumulative loss (measured as the sum of the total wasted capacity and lost items) that is less than the total loss of the best strategy in the class (determined in hindsight) plus a quantity of the order of $n^{2/3}\ln^{1/3} N$.

Arguably the most natural comparison class contains all algorithms that use a fixed threshold to decide whether a new bin is opened. In other words, reference predictors are parameterized by a real number $p \in (0,1]$. An expert with parameter p simply decides to open a new bin whenever the remaining free space in the open bin is less than p. We call such an expert a *constant-threshold* strategy. First we point out that obtaining uniform regret bounds for this class is difficult. We present some impossibility results in relation to this problem. We also offer some data-dependent bounds for an algorithm designed to compete with the best of all constant-threshold strategies, and show that if item sizes are jittered with a certain noise then a uniform regret bound of the order of $n^{2/3}\ln^{1/3} n$ may be achieved .

The principal difficulty of the problem lies in the fact that each action of the decision maker takes the problem in a new "state" (determined by the remaining empty space in the open bin) which has an effect on future losses. Moreover, the state of the algorithm is typically different from the state of the experts which makes comparison difficult. In related work, Merhav et al. (2002) considered a similar setup in which the loss function has a "memory," that is, the loss of a predictor depends on the loss of past actions. Furthermore, Even-Dar et al. (2005) and Yu et al. (2009) considered the MDP case where the adversarial reward function changes according to some fixed stochastic dynamics. However, there are several main additional difficulties in the present case. First, unlike in Merhav et al. (2002), but similarly to Even-Dar et al. (2005) and Yu et al. (2009), the loss function has an unbounded memory as the state may depend on an arbitrarily long sequence of past predictions. Second, the state space is infinite (the $[0,1)$ interval) and the class of experts we compare to is also infinite, in contrast to both of the above papers. However, the special properties of the bin packing problem make it possible to design a prediction strategy with small regret.

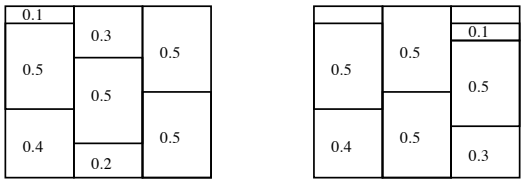
Note that the MDP setting of Even-Dar et al. (2005) and Yu et al. (2009) would be a too pessimistic approach to our problem, as in our case there is a strong connection between the rewards in different states, thus the absolute adversarial reward function results in an overestimated worst case. Also, in the present case, state transitions are deterministically given by the outcome, the previous state, and the action of the decision maker, while in the setup of Even-Dar et al. (2005) and Yu et al. (2009) transitions are stochastic and depend only on the state and the decision of the algorithm, but not on the reward (or on the underlying individual sequence generating the reward).

We also mention here the similar *on-line bin packing with rejection* problem where the algorithm has an opportunity to reject some items and the loss function is the sum of the number of the used bins and the "costs" of the rejected items, see He and Dósa (2005).[1] However, instead of the number of used bins, we use the sum of idle capacities (missed or free spaces) in the used bins to measure the loss.

The following example may help explain the difference between various versions of the problem.

Example 1 *Let the sequence of the items be* $\langle 0.4, 0.5, 0.2, 0.5, 0.5, 0.3, 0.5, 0.1\rangle$. *Then the cumulative loss of the optimal off-line bin packing is* 0 *and it is* 0.4 *in the case of sequential off-line bin packing (see Figure 1). In the sequential case the third item (0.2) has been rejected.*

1. In sequential bin packing we assume that the cost of the items coincides with their size. In this case the optimal solution of bin-packing with rejection is trivially to reject all items.



a) off-line b) sequential off-line

Figure 1: The difference between the optimal solutions for the off-line and sequential off-line problems.

The rest of the paper is organized as follows. In Section 2 the problem is defined formally. In Section 3 the complexity of the off-line sequential bin packing problem is analyzed. The main results of the paper are presented in Sections 4 and 5.

2. Setup

We use a terminology borrowed from the theory of on-line prediction with expert advice. Thus, we call the sequential decisions of the on-line algorithm *predictions* and we use *forecaster* as a synonym for algorithm.

We denote by $I_t \in \{0,1\}$ the action of the forecaster at time t (i.e., when $t-1$ items have been received). Action 0 means that the next item will be assigned to the open bin and action 1 represents the fact that a new bin is opened and the next item is assigned to the next empty bin. Note that we assume that we start with an open empty bin, thus for any reasonable algorithm, $I_1 = 0$, and we will restrict our attention to such algorithms. The sequence of decisions up to time t is denoted by $\mathbf{I}_t \in \{0,1\}^t$.

Denote by $\widehat{s}_t \in [0,1)$ the free space in the open (last) bin at time $t \geq 1$, that is, after having placed the items $x_1, x_2, \ldots, x_t$ according to the sequence $\mathbf{I}_t$ of actions. This is the *state* of the forecaster. More precisely, the state of the forecaster is defined, recursively, as follows: As at the beginning we have an empty bin, $\widehat{s}_0 = 1$. For $t = 1, 2, \ldots, n$,

- $\widehat{s}_t = 1 - x_t$, when the algorithm assigns the item to the next empty bin (i.e., $I_t = 1$);
- $\widehat{s}_t = \widehat{s}_{t-1}$, when the assigned item does not fit in the open bin (i.e., $I_t = 0$ and $\widehat{s}_{t-1} < x_t$);
- $\widehat{s}_t = \widehat{s}_{t-1} - x_t$, when the assigned item fits in the open bin (i.e., $I_t = 0$ and $\widehat{s}_{t-1} \geq x_t$).

This may be written in a more compact form:

$$\begin{aligned} \widehat{s}_t &= \widehat{s}_t(I_t, x_t, \widehat{s}_{t-1}) \\ &= I_t(1-x_t) + (1-I_t)(\widehat{s}_{t-1} - \mathbb{I}_{\{\widehat{s}_{t-1} \geq x_t\}} x_t) \end{aligned}$$

where $\mathbb{I}_{\{\cdot\}}$ denotes the indicator function of the event in brackets, that is, it equals 1 if the event is true and 0 otherwise. The loss suffered by the forecaster at round t is

$$\ell(I_t, x_t \mid \widehat{s}_{t-1}),$$

where the loss function ℓ is defined by

$$\ell(0,x \mid s) = \begin{cases} 0, & \text{if } s \geq x; \\ x, & \text{otherwise} \end{cases} \tag{1}$$

and

$$\ell(1,x \mid s) = s\,. \tag{2}$$

The goal of the forecaster is to minimize its cumulative loss defined by

$$\widehat{L}_t = L_{\mathbf{I}_t,t} = \sum_{s=1}^{t} \ell(I_s, x_s \mid \widehat{s}_{s-1})\,.$$

In the off-line version of the problem, the entire sequence $x_1,\ldots,x_n$ is given and the solution is the optimal sequence $\mathbf{I}_n^*$ of actions

$$\mathbf{I}_n^* = \operatorname*{argmin}_{\mathbf{I}_n \in \{0,1\}^n} L_{\mathbf{I}_n,n}\,.$$

In the on-line version of the problem the forecaster does not know the size of the next items, and the sequence of items can be completely arbitrary. We allow the forecaster to randomize its decisions, that is, at each time instance t, I_t is allowed to depend on a random variable U_t where $U_1,\ldots,U_n$ are i.i.d. uniformly distributed random variables in $[0,1]$.

Since we allow the forecaster to randomize, it is important to clarify that the entire sequence of items are determined *before* the forecaster starts making decisions, that is, $x_1,\ldots,x_n \in (0,1]$ are fixed and cannot depend on the randomizing variables. (This is the so-called *oblivious adversary* model known in the theory of sequential prediction, see, for example, Cesa-Bianchi and Lugosi 2006.)

The performance of a sequential on-line algorithm is measured by its cumulative loss. It is natural to compare it to the cumulative loss of the off-line solution $\mathbf{I}_n^*$. However, it is easy to see that in general it is impossible to achieve an on-line performance that is comparable to the optimal solution. (This is in contrast with the non-sequential counterpart of the bin packing problem in which there exist on-line algorithms for which the number of used bins is within a constant factor of that of the optimal solution, see Seiden 2002.)

So in order to measure the performance of a sequential on-line algorithm in a meaningful way, we adopt an approach extensively used in on-line prediction (the so-called "experts" framework). We define a set of reference forecasters, the so-called *experts*. The performance of the algorithm is evaluated relative to this set of experts, and the goal is to perform asymptotically as well as the best expert from the reference class.

Formally, let $f_{E,t} \in \{0,1\}$ be the decision of an expert E at round t, where $E \in \mathcal{E}$ and $\mathcal{E}$ is the set of the experts. This set may be finite or infinite, we consider both cases below. Similarly, we denote the state of expert E with $s_{E,t}$ after the t-th item has been revealed. Then the loss of expert E at round t is

$$\ell(f_{E,t}, x_t \mid s_{E,t-1})$$

and the cumulative loss of expert E is

$$L_{E,n} = \sum_{t=1}^{n} \ell(f_{E,t}, x_t \mid s_{E,t-1}).$$

SEQUENTIAL ON-LINE BIN PACKING PROBLEM WITH EXPERT ADVICE

Parameters: set $\mathcal{E}$ of experts, state space $\mathcal{S} = [0,1)$, action space $\mathcal{A} = \{0,1\}$, non-negative loss function $\ell : (\mathcal{A} \times (0,1] | \mathcal{S}) \to [0,1)$, number n of items.
Initialization: $\widehat{s}_0 = 1$ and $s_{E,0} = 1$ for all $E \in \mathcal{E}$.
For each round $t = 1, \ldots, n$,

(a) each expert forms its action $f_{E,t} \in \mathcal{A}$;

(b) the forecaster observes the actions of the experts and forms its own decision $I_t \in \mathcal{A}$;

(c) the next item $x_t \in (0,1]$ is revealed;

(d) the algorithm incurs loss $\ell(I_t, x_t \mid \widehat{s}_{t-1})$ and each expert $E \in \mathcal{E}$ incurs loss $\ell(f_{E,t}, x_t \mid s_{E,t-1})$. The states of the experts and the algorithm are updated.

Figure 2: Sequential on-line bin packing problem with expert advice.

The goal of the algorithm is to perform almost as well as the best expert from the reference class $\mathcal{E}$ (determined in hindsight). Ideally, the normalized difference of the cumulative losses (the so-called *regret*) should vanish as n grows, that is, one wishes to achieve

$$\limsup_{n\to\infty} \frac{1}{n}(\widehat{L}_n - \inf_{E\in\mathcal{E}} L_{E,n}) \le 0$$

with probability one, regardless of the sequence of items. This property is called *Hannan consistency*, see Hannan (1957). The model of sequential on-line bin packing with expert advice is given in Figure 2.

In Sections 4 and 5 we design sequential on-line bin packing algorithms. In Section 4 we assume that the class $\mathcal{E}$ of experts is finite. For this case we establish a uniform regret bound, regardless of the class and the sequence of items. In Section 5 we consider the (infinite) class of experts defined by constant-threshold strategies. This case turns out to be considerably more difficult. We show that algorithms, similar (in some sense) to the one developed for the finite expert classes, cannot work in general in this situation. We provide a data-dependent regret bound for a generalization of the finite-expert algorithm of Section 4, which, in accordance with the previous result, does not guarantee consistency in general. However, we show that if the item sizes are jittered with certain noise, the regret of the algorithm vanishes uniformly regardless of the original sequence of items.

But before turning to the on-line problem, we show how the off-line problem can be solved by a simple quadratic-time algorithm.

3. Sequential Off-line Bin Packing

As it is well known, most variants of the bin packing problem are NP-hard, including bin packing with rejection, see He and Dósa (2005), and maximum resource bin packing, see Boyar et al. (2006).

In this section we show that the sequential bin packing problem is significantly easier. Indeed, we offer an algorithm to find the optimal sequential strategy with time complexity $O(n^2)$ where n is the number of the items.

The key property is that after the t-th item has been received, the 2^t possible sequences of decisions cannot lead to more than t different states.

Lemma 1 *For any fixed sequence of items $x_1, x_2, \ldots, x_n$ and for every $1 \leq t \leq n$,*

$$|\mathcal{S}_t| \leq t,$$

where

$$\mathcal{S}_t = \{s : s = s_{\mathbf{I}_t,t}, \mathbf{I}_t \in \{0,1\}^t\}$$

and $s_{\mathbf{I}_t,t}$ is the state reached after receiving items $x_1, \ldots, x_t$ with the decision sequence $\mathbf{I}_t$.

Proof The proof goes by induction. Note that since $I_1 = 0$, we always have $s_{\mathbf{I}_1,1} = 1 - x_1$, and therefore $|\mathcal{S}_1| = 1$. Now assume that $|\mathcal{S}_{t-1}| \leq t-1$. At time t, the state of every sequence of decisions with $I_t = 0$ belongs to the set $\mathcal{S}'_t = \{s' : s' = s - \mathbb{I}_{\{s \geq x_t\}} x_t, s \in \mathcal{S}_{t-1}\}$ and the state of those with $I_t = 1$ becomes $1 - x_t$. Therefore,

$$|\mathcal{S}_t| \leq |\mathcal{S}'_t| + 1 \leq |\mathcal{S}_{t-1}| + 1 \leq t$$

as desired. ■

To describe a computationally efficient algorithm to compute $\mathbf{I}^*_n$, we set up a graph with the set of possible states as a vertex set (there are $O(n^2)$ of them by Lemma 1) and we show that the shortest path on this graph yields the optimal solution of the sequential off-line bin packing problem.

To formalize the problem, consider a finite directed acyclic graph with a set of vertices $V = \{v_1, \ldots, v_{|V|}\}$ and a set of edges $E = \{e_1, \ldots, e_{|E|}\}$. Each vertex $v_k = v(s_k, t_k)$ of the graph is defined by a time index t_k and a state $s_k \in \mathcal{S}_{t_k}$ and corresponds to state s_k reachable after t_k steps. To show the latter dependence, we will write $v_k \in \mathcal{S}_{t_k}$. Two vertices (v_i, v_j) are connected by an edge if and only if $v_i \in \mathcal{S}_{t-1}$, $v_j \in \mathcal{S}_t$ and state v_j is reachable from state v_i. That is, by choosing either action 0 or action 1 in state v_i, the new state becomes v_j after item x_t has been placed. Each edge has a label and a weight: the label corresponds to the action (zero or one) and the weight equals the loss, depending on the initial state, the action, and the size of the item. Figure 3 shows the proposed graph. Moreover a sink vertex $v_{|V|}$ is introduced that is connected with all vertices in $\mathcal{S}_n$. These edges have weight equal to the loss of the final states. These losses only depend on the initial state of the edges. More precisely, for $(v_i, v_{|V|})$ the loss is $1 - s_i$, where $v_i \in \mathcal{S}_n$.

Notice that there is a one to one correspondence between paths from v_1 to $v_{|V|}$ and possible sequences of actions of length n. Furthermore, the total weight of each path (calculated as the sum of the weights on the edges of the path) is equal to the loss of the corresponding sequence of actions. Thus, if we find a path with minimal total weight from v_1 to $v_{|V|}$, we also find the optimal sequence of actions for the off-line bin packing problem. It is well known that this can be done in $O(|V| + |E|)$ time.[2]

Now by Lemma 1, $|V| \leq n(n+1)/2 + 1$, where the additional vertex accounts for the sink. Moreover it is easy to see that $|E| \leq n(n-1) + n = n^2$. Hence the total time complexity of finding the off-line solution is $O(n^2)$.

2. Here we assume the simplified computational model that referring to each vertex (and edge) requires a constant number of operations. In a more refined computational model this may be scaled with an extra $\log |V|$ factor.

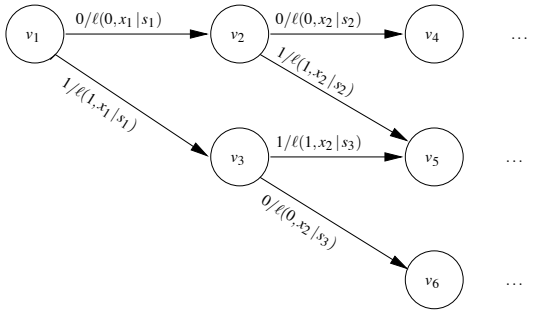


Figure 3: The graph corresponding to the off-line sequential bin packing problem.

4. Sequential On-line Bin Packing

In this section we study the sequential on-line bin packing problem with expert advice, as described in Section 2. We deal with two special cases. First we consider finite classes of experts (i.e., reference algorithms) without any assumption on the form or structure of the experts. We construct a randomized algorithm that, with large probability, achieves a cumulative loss not larger than that of the best expert plus $O(n^{2/3}\ln^{1/3}N)$ where $N=|\mathcal{E}|$ is the number of experts.

The following simple lemma is a key ingredient of the results of this section. It shows that in sequential on-line bin packing the cumulative loss is not sensitive to the initial states in the sense that the cumulative loss depends on the initial state in a minor way.

Lemma 2 *Let $i_1,\ldots,i_m\in\{0,1\}$ be a fixed sequence of decisions and let $x_1,\ldots,x_m\in(0,1]$ be a sequence of items. Let $s_0,s_0'\in[0,1)$ be two different initial states. Finally, let $s_0,\ldots,s_m$ and $s_0',\ldots,s_m'$ denote the sequences of states generated by $i_1,\ldots,i_m$ and $x_1,\ldots,x_m$ starting from initial states s_0 and s_0', respectively. Then*

$$\left|\sum_{t=1}^{m}\ell(i_t,x_t\mid s_{t-1}')-\sum_{t=1}^{m}\ell(i_t,x_t\mid s_{t-1})\right|\le s_0'+s_0\le 2\,.$$

Proof Let m' denote the smallest index for which $i_{m'}=1$. Note that $s_{t-1}=s_{t-1}'$ for all $t>m'$. Therefore, we have

$$\begin{aligned}
&\sum_{t=1}^{m}\ell(i_t,x_t\mid s_{t-1}')-\sum_{t=1}^{m}\ell(i_t,x_t\mid s_{t-1})\\
&\quad=\sum_{t=1}^{m'}\ell(i_t,x_t\mid s_{t-1}')-\sum_{t=1}^{m'}\ell(i_t,x_t\mid s_{t-1})\\
&\quad=\sum_{t=1}^{m'-1}\ell(0,x_t\mid s_{t-1}')-\sum_{t=1}^{m'-1}\ell(0,x_t\mid s_{t-1})+\ell(1,x_{m'}\mid s_{m'-1}')-\ell(1,x_{m'}\mid s_{m'-1})\,.
\end{aligned}$$

Now using the definition of the loss (see Equations 1 and 2), we write

$$\begin{aligned}
&\sum_{t=1}^{m} \ell(i_t, x_t \mid s'_{t-1}) - \sum_{t=1}^{m} \ell(i_t, x_t \mid s_{t-1}) \\
&= \sum_{t=1}^{m'-1} x_t (\mathbb{I}_{\{s'_{t-1} < x_t\}} - \mathbb{I}_{\{s_{t-1} < x_t\}}) + s'_{m'-1} - s_{m'-1} \\
&\le \sum_{t=1}^{m'-1} x_t (1 - \mathbb{I}_{\{s_{t-1} < x_t\}}) + s'_{m'-1} - s_{m'-1} \\
&\le \sum_{t=1}^{m'-1} x_t (1 - \mathbb{I}_{\{s_{t-1} < x_t\}}) + s'_0 \\
&\le s_0 + s'_0
\end{aligned}$$

where the next-to-last inequality holds because $s'_{m'-1} \le s'_0$ and $s_{m'-1} \ge 0$, and the last inequality follows from the fact that

$$\begin{aligned}
0 \le s_{m'-1} &= s_{m'-2} - \mathbb{I}_{\{s_{m'-2} \ge x_{m'-1}\}} x_{m'-1} \\
&= s_{m'-3} - \mathbb{I}_{\{s_{m'-3} \ge x_{m'-2}\}} x_{m'-2} - \mathbb{I}_{\{s_{m'-2} \ge x_{m'-1}\}} x_{m'-1} \\
&= s_0 - \sum_{t=1}^{m'-1} \mathbb{I}_{\{s_{t-1} \ge x_t\}} x_t \ .
\end{aligned}$$

Similarly,

$$\sum_{t=1}^{m} \ell(i_t, x_t \mid s_{t-1}) - \sum_{t=1}^{m} \ell(i_t, x_t \mid s'_{t-1}) \le s'_0 + s_0$$

and the statement follows. ■

The following example shows that the upper bound of the lemma is tight.

Example 2 *Let $x_1 = s_0$, $s'_0 < s_0$, and $m' = 2$. Then*

$$\begin{aligned}
&\sum_{t=1}^{m} \ell(i_t, x_t \mid s'_{t-1}) - \sum_{t=1}^{m} \ell(i_t, x_t \mid s_{t-1}) \\
&= \ell(0, x_1 \mid s'_0) + \ell(1, x_2 \mid s'_1) - \big(\ell(0, x_1 \mid s_0) + \ell(1, x_2 \mid s_1)\big) \\
&= \ell(0, s_0 \mid s'_0) + \ell(1, x_2 \mid s'_0) - \big(\ell(0, s_0 \mid s_0) + \ell(1, x_2 \mid 0)\big) \\
&= s_0 + s'_0 - (0 + 0) \ .
\end{aligned}$$

Now we consider the on-line sequential bin packing problem when the goal of the algorithm is to keep its cumulative loss close to the best in a finite set of experts. In other words, we assume that the class of experts is finite, say $|\mathcal{E}| = N$, but we do not assume any additional structure of the experts. The ideas presented here will be used in Section 5 when we consider the infinite class of constant-threshold experts.

The proposed algorithm partitions the time period $t = 1, \ldots, n$ into segments of length m where $m < n$ is a positive integer whose value will be specified later. This way we obtain $n' = \lfloor n/m \rfloor$

segments of length m, and, if m does not divide n, an extra segment of length less than m. At the beginning of each segment, the algorithm selects an expert randomly, according to an exponentially weighted average distribution. During the entire segment, the algorithm follows the advice of the selected expert. By changing actions so rarely, the algorithm achieves a certain synchronization with the chosen expert, since the effect of the difference in the initial states is minor, according to Lemma 2. (A similar idea was used in Merhav et al. (2002) in a different context.) The algorithm is described in Figure 4. Recall that each expert $E \in \mathcal{E}$ recommends an action $f_{E,t} \in \{0,1\}$ at every time instance $t = 1,\dots,n$. Since we have N experts, we may identify $\mathcal{E}$ with the set $\{1,\dots,N\}$. Thus, experts will be indexed by the positive integers $i \in \{1,\dots,N\}$. At the beginning of each segment, the algorithm chooses expert i randomly, with probability $p_{i,t}$, where the distribution $\mathbf{p}_t = (p_{1,t},\dots,p_{N,t})$ is specified in the algorithm. The random selection is made independently for each segment.

The following theorem establishes a performance bound of the algorithm. Recall that $\widehat{L}_n$ denotes the cumulative loss of the algorithm while $L_{i,n}$ is that of expert i.

Theorem 3 *Let n, $N \geq 1$, $\eta > 0$, $1 \leq m \leq n$, and $\delta \in (0,1)$. For any sequence $x_1,\dots,x_n \in (0,1]$ of items, the cumulative loss $\widehat{L}_n$ of the randomized strategy defined in Figure 4 satisfies for all $i = 1,\dots,N$, with probability at least $1-\delta$,*

$$\widehat{L}_n \leq L_{i,n} + \frac{m}{\eta}\ln\frac{1}{w_{i,0}} + \frac{m\eta}{8} + \sqrt{\frac{nm}{2}\ln\frac{1}{\delta}} + \frac{2n}{m} + 2m.$$

In particular, choosing $w_{i,0} = 1/N$ for all $i = 1,\dots,N$, $m = (16n/\ln(N/\delta))^{1/3}$ and $\eta = \sqrt{8m\ln N/n}$, one has

$$\widehat{L}_n - \min_{i=1,\dots,N} L_{i,n} \leq \frac{3}{\sqrt[3]{2}} n^{2/3}\ln^{1/3}\frac{N}{\delta} + 4\left(\frac{2n}{\ln(N/\delta)}\right)^{1/3}.$$

Proof We introduce an auxiliary quantity, the so-called *hypothetical loss*, defined as the loss the algorithm would suffer if it had been in the same state as the selected expert. This hypothetical loss does not depend on previous decisions of the algorithm. More precisely, the true loss of the algorithm at time instance t is $\ell(I_t, x_t \mid \widehat{s}_t)$ and its hypothetic loss is $\ell(I_t, x_t \mid s_{J_t,t})$. Introducing the notation

$$\ell_{i,t} = \ell(f_{i,t}, x_t \mid s_{i,t}),$$

the hypothetical loss of the algorithm is just

$$\ell(I_t, x_t \mid s_{J_t,t}) = \ell(f_{J_t,t}, x_t \mid s_{J_t,t}) = \ell_{J_t,t}.$$

Now it follows by a well-known result of randomized on-line prediction (see, e.g., Lemma 5.1 and Corollary 4.2 in Cesa-Bianchi and Lugosi, 2006) that the hypothetical loss of the sequential on-line bin packing algorithm satisfies simultaneously for all $i = 1,\dots,N$, with probability at least $1-\delta$,

$$\sum_{t=1}^{n}\ell_{J_t,t} \leq \sum_{t=1}^{n}\ell_{i,t} + m\left(\frac{1}{\eta}\ln\frac{1}{w_{i,0}} + \frac{n'\eta}{8} + \sqrt{\frac{n'}{2}\ln\frac{1}{\delta}}\right) + m, \tag{3}$$

where $n' = \lfloor \frac{n}{m} \rfloor$ and the last m term comes from bounding the difference on the last, not necessarily complete segment. Now we may decompose the regret relative to expert i as follows:

$$\widehat{L}_n - L_{i,n} = \left(\widehat{L}_n - \sum_{t=1}^{n}\ell_{J_t,t}\right) + \left(\sum_{t=1}^{n}\ell_{J_t,t} - L_{i,n}\right).$$

SEQUENTIAL ON-LINE BIN PACKING ALGORITHM

Parameters: Real number $\eta > 0$ and $m \in \mathbb{N}^+$.
Initialization: $\widehat{s}_0 = 1$, $s_{i,0} = 1$ and $w_{i,0} > 0$ are set arbitrarily for $i = 1,\ldots,N$ such that $w_{1,0} + w_{2,0} + \cdots + w_{N,0} = 1$.
For each round $t = 1,\ldots,n$,

(a) If $((t-1) \bmod m) = 0$ then

- calculate the updated probability distribution

$$p_{i,t} = \frac{w_{i,t-1}}{\sum_{j=1}^{N} w_{j,t-1}}$$

for $i = 1,\ldots,N$;

- randomly select an expert $J_t \in \{1,\ldots,N\}$ according to the probability distribution $\mathbf{p}_t = (p_{1,t},\ldots,p_{N,t})$;

otherwise, let $J_t = J_{t-1}$.

(b) Follow the chosen expert: $I_t = f_{J_t,t}$.

(c) The size of next item $x_t \in (0,1]$ is revealed.

(d) The algorithm incurs loss

$$\ell(I_t, x_t \mid \widehat{s}_{t-1})$$

and each expert i incurs loss $\ell(f_{i,t}, x_t \mid s_{i,t-1})$. The states of the experts and the algorithm are changed.

(e) Update the weights

$$w_{i,t} = w_{i,t-1} e^{-\eta \ell(f_{i,t}, x_t \mid s_{i,t-1})}$$

for all $i \in \{1,\ldots,N\}$.

Figure 4: Sequential on-line bin packing algorithm.

The second term on the right-hand side is bounded using (3). To bound the first term, observe that by Lemma 2,

$$\begin{aligned}
\widehat{L}_n - \sum_{t=1}^{n} \ell_{J_t,t} &= \sum_{t=1}^{n} \ell(I_t, x_t \mid \widehat{s}_{t-1}) - \sum_{t=1}^{n} \ell(I_t, x_t \mid s_{J_{t-1},t-1}) \\
&\le m + \sum_{s=0}^{n'-1} \sum_{t=1}^{m} \left(\ell(I_{sm+t}, x_{sm+t} \mid \widehat{s}_{sm+t-1}) - \ell(I_{sm+t}, x_{sm+t} \mid s_{J_{sm+t-1},sm+t-1}) \right) \\
&\le m + 2n'
\end{aligned}$$

where in the first inequality we bounded the difference on the last segment separately. ■

5. Constant-threshold Experts

In this section we address the sequential on-line bin packing problem when the goal is to perform almost as well as the best in the class of all constant-threshold strategies. Recall that a constant-threshold strategy is parameterized by a number $p \in (0,1]$ and it opens a new bin if and only if the remaining empty space in the bin is less than p. More precisely, if the state of the algorithm defined by expert with parameter p is $s_{p,t-1}$, then at time t the expert's advice is $\mathbb{I}_{\{s_{p,t-1}<p\}}$. To simplify notation, we will refer to each expert with its parameter, and, similarly to the previous section, $f_{p,t}$ and $s_{p,t}$ will denote the decision of expert p at time t, and its state after the decision, respectively.

The difficulty in this setup is that there are uncountably many constant-threshold experts. The simplest possibility is to discretize the class. For example, by considering the set of constant-threshold experts with values of p in the set $\{1/N, 2/N, \ldots, 1\}$ and using the randomized algorithm described in the previous section, we immediately obtain that the cumulative regret of the algorithm, when compared to the best constant-threshold expert with p in this set is bounded by $O(n^{2/3}\ln^{1/3} N)$ with high probability. It is natural to suspect that if N is large, the loss of the best discretized constant-threshold expert is not much larger than that corresponding to the best (unrestricted) value of $p \in (0,1]$. However, this is not true in general. The next lemma shows that any such discretization is doomed to failure, at least in the worst-case sense. We denote by $L_{p,n}$ the cumulative loss of the constant-threshold expert indexed by $p \in (0,1]$.

Lemma 4 *For all n such that $n/4$ is a positive integer and $1/2 < a < b \le 1$ there exists a sequence $x_1, \ldots, x_n$ of items such that*

$$\sup_{p \in (a,b]} L_{p,n} < \inf_{p \notin (a,b]} L_{p,n} - \frac{n}{4} + 3$$

for any values of the initial states $s_{p,0} \in [p,1], p \in (0,1]$.[3]

Proof Given $1/2 \le a < b \le 1$, we construct a sequence with the announced property. The first fourth of the sequence is defined by $x_1 = 1-a$ and $x_2 = \cdots = x_{n/4} = 1$. If an expert asks for a new bin after the first item then it suffers no loss for $t = 2, \ldots, n/4$, thus the cumulative loss up to time $n/4$ is bounded as $L_{p,n/4} \le 1$. Note that any expert with parameter $p > a$ is such, as the first item always fits the actual bin, as by the conditions of the lemma $1-a \le a < p \le s_{p,0}$, but then the empty space becomes $s_{0,p} - (1-a) \le a < p$, and so expert p opens a new bin. In case of an expert with parameter $q \le a$, it depends on the initial state if the expert opens a new bin. If the actual bin is left open after the first item then the expert suffers loss $L_{q,n/4} = n/4 - 1$. In particular, if $s_{q,0} = 1$ then after the first item expert q moves to state $s_{q,1} = a$ and leaves the bin open. Thus, after time $n/4$ an expert either suffers loss at least $n/4-1$ (then the parameter of the expert is at most a), or it suffers loss at most 1, but then it is in the state $s_{p,n/4} = 1$. Now for the second forth of the sequence repeat the first one, that is, let $x_{n/4+1} = 1-a, x_{n/4+2} = \cdots = x_{n/2} = 1$. By the above argument we can see that if an expert with parameter $q \le a$ does not suffer large loss up to time $n/4$ then it starts with an empty bin and suffers a large loss in the second fourth of the segment. Thus, $L_{q,n/2} \ge n/4 - 1$ for any $q \le a$. On the other hand, for any expert $p > a$ we have $L_{p,n/2} < 2$ and $s_{p,n/2} = 1$.

3. Note that for any expert $p \in (0,1]$, $s_{p,t} \in [p,1]$ for all $t \ge 1$ regardless of the initial state, and so it is natural to restrict the initial state to $[p,1]$, as well.

After this point of time, let $x_{n/2+1} = 1-b$, $x_{n/2+2} = b$ and repeat this pair of items $n/4$ times. After receiving $x_{n/2+1} = 1-b$, every expert with parameter $p \in (a,b]$ keeps the bin open and therefore does not suffer any loss after receiving the next item. On the other hand, experts with parameter $r > b$ close the bin, suffer loss b, and after $x_{n/2+2} = b$ is received, once again they close the bin and suffer loss $1-b$ (here we used the fact that $r > 1-b$ since we assumed $b > 1/2$. Thus, between periods $n/2+1$ and n, all experts with $p \in (a,b]$ suffer zero loss while experts with parameter $r > b$ suffer loss $n/4$.

Summarizing, for the sequence

$$1-a, \underbrace{1,1,\ldots,1}_{n/4-1 \text{ periods}}, 1-a, \underbrace{1,1,\ldots,1}_{n/4-1 \text{ periods}}, \underbrace{1-b,b,1-b,b\ldots,1-b,b}_{n/2 \text{ periods}},$$

we have

$$L_{p,n} \begin{cases} < 2 & \text{if } p \in (a,b] \\ \geq n/4-1 & \text{if } p \leq a \\ \geq n/4 & \text{if } p > b. \end{cases}$$

■

Lemma 4 implies that one cannot expect a small regret with respect to all possible constant-threshold experts. This is true for any algorithm that, as the one proposed in the previous section, divides time into segments and on each segment chooses a constant-threshold expert and acts as the chosen expert during the following segment. Recall that this segmentation was necessary to make sure that the state of the algorithm gets synchronized with the chosen one. The statement is formalized below.

Theorem 5 *Consider any sequential on-line bin packing algorithm that divides time into segments of lengths $m_1, m_2, \ldots, m_k \geq 3$ (where $\sum_{i=1}^k m_i = n$) such that, at the beginning of each segment m_i, the algorithm chooses (in a possibly randomized way) a parameter $p_i \in (0,1]$ and follows this expert during the segment, that is, $I_t = \mathbb{I}_{\{\widehat{s}_{t-1} < p_i\}}$ for all $t = \sum_{j=1}^{i-1} m_j + 1, \ldots, \sum_{j=1}^{i} m_j$. Then there exists a sequence of items $x_1, \ldots, x_n$ such that the loss of the algorithm satisfies, with probability at least $1/2$,*

$$\widehat{L}_n \geq \inf_{p \in (0,1]} L_{p,n} + \frac{n}{4} - 6k\,.$$

Proof We construct the sequence of items using the sequence shown in the proof of Lemma 4 as a building block. At time 1, divide the interval $(0,1]$ into $2k$ subintervals of equal length and choose one of these intervals uniformly at random. Denote the end points of this interval by $(A_1, B_1]$. Then during the first segment we define the items by

$$1-A_1, \underbrace{1,1,\ldots,1}_{\lfloor m_1/4 \rfloor - 1 \text{ periods}}, 1-A_1, \underbrace{1,1,\ldots,1}_{\lfloor m_1/4 \rfloor - 1 \text{ periods}}, \underbrace{1-B_1,B_1,1-B_1,B_1\ldots,1-B_1,B_1}_{\lfloor m_1/2 \rfloor \text{ periods}}\,.$$

If m_1 is not divisible by 4, we may define the remaining (at most three) items arbitrarily. Then, according to Lemma 4, if the algorithm does not choose an expert to follow from the interval $(A_1, B_1]$ then its loss is larger by at least $\frac{m_1}{4} - 6$ than that of any expert in $(A_1, B_1]$. (The extra 3 come from

the possibility that m_1 is not divisible by 4.) However, no matter how the algorithm chooses the expert to follow, the probability that it finds the correct subinterval is $1/(2k)$.

To continue the construction, we now divide the interval $(A_1, B_1]$ into $2k$ intervals of equal length and choose one at random, say $(A_2, B_2]$. We define the next items similarly to the first segment, but now we make sure that the optimal constant-threshold expert falls in the interval $(A_2, B_2]$, that is, the items of the second segment are defined by

$$1-A_2, \underbrace{1,1,\ldots,1}_{\lfloor m_2/4\rfloor-1 \text{ periods}}, 1-A_2, \underbrace{1,1,\ldots,1}_{\lfloor m_2/4\rfloor-1 \text{ periods}}, \underbrace{1-B_2, B_2, 1-B_2, B_2 \ldots, 1-B_2, B_2}_{\lfloor m_2/2\rfloor \text{ periods}}.$$

As before, if m_2 is not divisible by 4, we may define the remaining (at most three) items arbitrarily. Once again, the excess loss of the algorithm, when compared to the best constant-threshold expert, is at least $\frac{m_2}{4} - 6$ with probability $1/(2k)$.

We may continue the same randomized construction of the item sizes in the same manner, always dividing the previously chosen interval into $2k$ equal pieces, choosing one at random, and constructing the item sequence so that experts in the chosen interval are significantly better than any other expert.

By the union bound, the probability that the forecaster never chooses the correct interval is at least $1/2$, so with probability at least $1/2$,

$$\widehat{L}_n - \inf_{p\in(0,1]} L_{p,n} \geq \sum_{i=1}^{k} \left(\frac{m_i}{4} - 6\right) = \frac{n}{4} - 6k$$

as desired. ■

The theorem above shows that if one uses a segmentation for synchronization purposes, one cannot expect nontrivial regret bounds that hold uniformly over all possible sequences of items and for all constant-threshold experts, unless the number of segments is proportional to n. It seems unlikely that without such synchronization one may achieve $o(n)$ regret. Unfortunately, we do not have a formal proof for arbitrary algorithms (that do not divide time into segments).

However, one may still obtain meaningful regret bounds that depend on the data. We derive such a bound next. We also show that under some natural restrictions on the item sizes, this result allows us to derive regret bounds that hold uniformly over all constant-threshold experts.

In order to understand the structure of the problem of constant-threshold experts, it is important to observe that on any sequence of n items, experts can exhibit only a finite number of different behaviors. In a sense, the "effective" number of experts is not too large and this fact may be exploited by an algorithm.

For $t = 1,\ldots,n$ we call two experts *t-indistinguishable* (with respect to the sequence of items $x_1,\ldots,x_{t-1}$) if their decision sequences are identical up to time t (note that any two experts are 1-indistinguishable, as all experts p start with a decision $f_{p,1} = 0$). This property defines a natural partitioning of the class of experts into maximal t-indistinguishable sets, where any two experts that belong to the same set are t-indistinguishable, and experts from different sets are not t-indistinguishable. Obviously, there are no more than 2^t maximal t-indistinguishable sets. This bound, although finite, is still too large to be useful. However, it turns out that the number of maximal t-indistinguishable sets only grows at most quadratically with t.

The first step in proving this fact is the next lemma that shows that the maximal t-indistinguishable expert sets are intervals.

Lemma 6 *Let $1 \geq p > r > 0$ be such that expert p and expert r are t-indistinguishable. Then for any $p > q > r$ expert q is t-indistinguishable from both experts p and r. Thus, the maximal t-indistinguishable expert sets form subintervals of $(0,1]$.*

Proof By the assumption of the lemma the decision sequences of experts p and r coincide, that is,

$$f_{p,u} = f_{r,u} \qquad \text{and} \qquad s_{p,u} = s_{r,u}$$

for all $u = 1,2,\ldots,t$. Let $t_1,t_2,\ldots$ denote the time instances when expert p (or expert r) assigns the next item to the next empty bin (i.e., $f_{p,u} = 1$ for $u = t_1,t_2,\ldots$). If expert q also decides 1 at time t_k for some k, then it will decide 0 for $t = t_k+1,\ldots,t_{k+1}-1$ since so does expert p and $p > q$, and will decide 1 at time t_{k+1} as $q > r$. Thus the decision sequence of expert q coincides with that of expert p and r for time instances $t_k+1,\ldots,t_{k+1}$ in this case. Since all experts start with the empty bin at time 0, the statement of the lemma follows by induction. ■

Based on the lemma we can identify the t-indistinguishable sets by their end points. Let $Q_t = \{q_{1,t},\ldots,q_{N_t,t}\}$ denote the set of the end points after receiving $t-1$ items, where $N_t = |Q_t|$ is the number of maximal t-indistinguishable sets, and $q_{0,t} = 0 < q_{1,t} < q_{2,t} < \cdots < q_{N_t,t} = 1$. Then the t-indistinguishable sets are $(q_{k-1,t},q_{k,t}]$ for $k = 1,\ldots,N_t$. The next result shows that the number of maximal t-indistinguishable sets cannot grow too fast.

Lemma 7 *The number of the maximal t-indistinguishable sets is at most quadratic in the number of the items t. More precisely, $N_t \leq 1+t(t-1)/2$ for any $1 \leq t \leq n$.*

Proof The proof is by induction. First, $N_1 = 1$ (and $Q_1 = \{1\}$) since the first decision of each expert is 1. Now assume that $N_t \leq 1+t(t-1)/2$ for some $1 \leq t \leq n-1$. When the next item x_t arrives, an expert p with state s decides 1 in the next step if and only if $0 \leq s - x_t < p$. Therefore, as each expert belonging to the same indistinguishable set has the same state, the k-th maximal $(t-1)$-indistinguishable interval with state s is split into two subintervals if and only if $q_{k-1,t-1} < s - x_t \leq q_{k,t-1}$ (experts in this interval with parameters larger than $s-x_t$ will form one subset, and the ones with parameter at most $s-x_t$ will form the other one). As the number of possible states after t decisions (the number of different possible values of $s-x_t$) is at most t by Lemma 1, it follows that at most t intervals can be split, and so $N_{t+1} \leq N_t + t \leq 1+t(t+1)/2$, where the second inequality holds by the induction hypothesis. ■

Lemma 7 shows that the "effective" number of constant-threshold experts is not too large. This fact makes it possible to apply our earlier algorithm for the case of finite expert classes with reasonable computational complexity. However, note that the number of "distinguishable" experts, that is, the number of the maximal indistinguishable sets, constantly grows with time, and each indistinguishable set contains a continuum number of experts. Therefore we need to redefine the algorithm carefully. This may be done by a two-level random choice of the experts: first we choose an indistinguishable expert set, then we pick one expert from this set randomly. The resulting algorithm is given in Figure 5.

SEQUENTIAL ON-LINE BIN PACKING ALGORITHM WITH CONSTANT-THRESHOLD EXPERTS

Parameters: $\eta > 0$ and $m \in \mathbb{N}^+$.
Initialization: $w_{0,1} = 1, N_1 = 1, Q_1 = \{1\}, s_{1,0} = 1$ and $\widehat{s}_0 = 1$.
For each round $t = 1, \ldots, n$,

(a) If $((t-1) \bmod m) = 0$ then

- for $i = 1, \ldots, N_t$, compute the probabilities

$$p_{i,t} = \frac{w_{i,t-1}}{\sum_{j=1}^{N_t} w_{j,t-1}};$$

- randomly select an interval $J_t \in \{1, \ldots, N_t\}$ according to the probability distribution $\mathbf{p}_t = (p_{1,t}, \ldots, p_{N_t,t})$;
- choose an expert p_t uniformly from the interval $(q_{J_t-1,t}, q_{J_t,t}]$;

otherwise, let $p_t = p_{t-1}$.

(b) Follow the decision of expert p_t: $I_t = f_{p_t,t}$.

(c) $x_t \in (0,1]$, the size of the next item is revealed.

(d) The algorithm incurs loss $\ell(I_t, x_t \mid \widehat{s}_{t-1})$ and each expert $p \in (0,1]$ incurs loss $\ell(f_{p,t}, x_t \mid s_{p,t-1})$, where $p \in [0,1)$.

(e) Compute the state $\widehat{s}_t$ of the algorithm by (1), and calculate the auxiliary weights and states of the expert sets for all $i = 1, \ldots, N_t$ by

$$\begin{aligned} \tilde{w}_{i,t} &= w_{i,t-1} e^{-\eta \ell(f_{i,t}, x_t \mid s_{i,t-1})} \\ \tilde{s}_{i,t} &= f_{i,t}(1-x_t) + (1-f_{i,t})(s_{i,t} - \mathbb{I}_{\{s_{i,t} \geq x_t\}} x_t). \end{aligned}$$

(f) Update the end points of the intervals:

$$Q_{t+1} = Q_t \cup \bigcup_{i=1}^{N_t} \{\tilde{s}_{i,t} : q_{i-1,t} < \tilde{s}_{i,t} \leq q_{i,t}\}$$

and $N_{t+1} = |Q_{t+1}|$.

(g) Assign the new states and weights to the $(t+1)$-indistinguishable sets

$$s_{i,t+1} = \tilde{s}_{j,t} \quad \text{and} \quad w_{i,t+1} = \tilde{w}_{j,t} \frac{q_{i,t+1} - q_{i-1,t+1}}{q_{j,t} - q_{j-1,t}}$$

for all $i = 1, \ldots, N_{t+1}$ and $j = 1, \ldots, N_t$ such that $q_{j-1,t} < q_{i,t+1} \leq q_{j,t}$.

Figure 5: Sequential on-line bin packing algorithm with constant-threshold experts.

Up to step (e) the algorithm is essentially the same as in the case of finitely many experts. The two-level random choice of the expert is performed in step (a). In step (f) we update the t-indistinguishable sets, and usually introduce new indistinguishable expert sets. Because of these new expert sets, the update of the weights $w_{i,t}$ and the states $s_{i,t}$ are performed in two steps, (e) and (g), where the actual update is made in step (e), and reordering of these quantities according to the new indistinguishable sets is performed in step (g) together with the introduction of the weights and states for the newly formed expert sets. (Note that in step (g) the factor $(q_{i,t+1} - q_{i-1,t+1})/(q_{j,t} - q_{j-1,t})$ is the proportion of the lengths of the indistinguishable intervals expert $q_{i,t+1}$ belongs to at times $t+1$ and t.)

The performance and complexity of the algorithm is given in the next theorem.

Theorem 8 *Let $n \geq 1$, $\eta > 0$, $1 \leq m \leq n$, and $\delta \in (0,1)$. For any sequence $x_1, \ldots, x_n \in (0,1]$ of items, the cumulative loss $\widehat{L}_n$ of the randomized strategy defined above satisfies for all $p \in (0,1]$, with probability at least $1-\delta$,*

$$\widehat{L}_n \leq L_{p,n} + \frac{m}{\eta} \ln \frac{1}{l_{p,n}} + \frac{n\eta}{8} + \sqrt{\frac{nm}{2} \ln \frac{1}{\delta}} + \frac{2n}{m} + 2m$$

where $l_{p,n}$ is the length of the maximal n-indistinguishable interval that contains p. Moreover, the algorithm can be implemented with time complexity $O(n^3)$ and space complexity $O(n^2)$.

Remark 9 *(i) By choosing $m \sim n^{1/3}$ and $\eta \sim n^{-1/3}$, the regret bound is of the order of $n^{2/3} \ln(1/l_{p,n})$. Note that the constant $\ln(1/l_{p,n})$ reflects the difficulty of the problem (similarly to, for example, the notion of margin in classification, $l_{p,n}$ measures the freedom in choosing an optimal decision boundary, that is, an optimal threshold). If the indistinguishable interval containing the optimal experts is small, then the problem is hard (and the corresponding penalty term in the bound is large). On the other hand, as $N_n \leq 1 + n(n-1)/2$, if the classes of indistinguishable experts are more or less of uniform size, then the corresponding term in the bound is of the order of $\ln n$. We show below that this is always the case if there is a certain randomness in the item sizes.*

(ii) The way of splitting the weight between new maximal indistinguishable classes in step (g) could be modified in many different ways. For example, instead of assigning weights proportionally to the length of the new intervals, one could simply give half of the weight to both new classes. In this case, instead of the term $\ln(1/l_{p^*,n})$ for the optimal expert p^*, we would get in the bound the number of splits performed until reaching the optimal maximal n-indistinguishable class. The hardness of the problem comes from the fact that the partitioning of the experts into maximal indistinguishable classes is not known in advance. If we knew it, we could just simply apply the algorithm of Theorem 3 to the resulting N_n experts (as in Theorem 4.1 of Cesa-Bianchi and Lugosi, 2006) to obtain a uniformly good bound over all constant-threshold experts.

Proof It is easy to see that the two-level choice of the expert p_t ensures that the algorithm is the same as for the finite expert class with the experts defined by Q_n with initial weights $w_{i,0} = l_{q_{i,n},n} = q_{i,n} - q_{i-1,n}$ for the n-indistinguishable expert class containing $q_{i,n}$. Thus, Theorem 3 can be used to bound the regret, where the number of experts is N_t.

For the second part note that the algorithm has to store the states, the intervals, the weights and the probabilities, each on the order of $O(n^2)$ based on Lemma 7. Concerning time complexity, the algorithm has to update the weights and states in each round (requiring $O(n^2)$ computations per

round), and has to compute the probabilities once in every m step, which requires $O(n^3/m)$ computations. Thus the time complexity of the algorithm is $O(n^3)$. ■

Next we use Theorem 8 to show that, for many natural sequences of items, the algorithm above guarantees a small regret uniformly for all constant-threshold experts. In particular, we show that if item sizes are jittered by random noise, then the algorithm shown above has a small regret with respect to all constant-threshold experts (it is well-known that, for general systems, introducing such random perturbations often reduces the sensitivity, and hence results in a more uniform performance, for different values of the input). To this end, we simply need to show that n-indistinguishable intervals cannot be too short. We consider a simple model when the item sizes are noisy versions of an arbitrary fixed sequence. For simplicity we assume that the noise is uniformly distributed but the result remains true under more general circumstances. For illustration purposes the simplified model is sufficient.

Theorem 10 *Let $y_1,\dots,y_n \in (0,1]$ be arbitrary and define the item sizes by*

$$x_t = \begin{cases} y_t+\sigma_t & \text{if } y_t+\sigma_t \in (0,1] \\ 1 & \text{if } y_t+\sigma_t > 1 \\ 0 & \text{if } y_t+\sigma_t \le 0 \end{cases}$$

where $\sigma_1,\dots,\sigma_n$ are independent random variables, uniformly distributed on the interval $[-\varepsilon,\varepsilon]$ for some $\varepsilon > 0$. If the algorithm of Figure 5 is used with parameters $m = (16n/\ln(n^5/\varepsilon\delta))^{1/3}$ and $\eta = \sqrt{8m\ln(n^5/\varepsilon)/n}$, then with probability at least $1-\delta-1/(4n)$, one has

$$\widehat{L}_n - \min_{p\in(0,1]} L_{p,n} \le \frac{3}{\sqrt[3]{2}} n^{2/3} \ln^{1/3}\frac{n^5}{\varepsilon\delta} + 4\left(\frac{2n}{\ln(n^5/\varepsilon\delta)}\right)^{1/3}. \tag{4}$$

Proof The result follows directly from Theorem 8 if we show that the length of the shortest maximal n-indistinguishable interval is at most ε/n^5 with probability at least $1-1/(4n)$ (with respect to the distribution of the random noise). A very crude bounding suffices to show this. Simply recall from the proof of Lemma 7 that, at time t, a maximal t-indistinguishable interval (p,q) is split if and only if $x_t \in (s+p, s+q)$ where s denotes the state of a corresponding constant-threshold expert. Note that $(s+p,s+q) \subseteq (0,1)$, since $x_t = 0$ or $x_t = 1$ cannot split any maximal t-indistinguishable interval, but any such interval can be split by an appropriately chosen x_t. At time t there are at most $t^2/2$ different maximal t-indistinguishable intervals and at most t different states, so by the union bound, the probability that there exists a maximal t-indistinguishable interval of length at most ε/n^5 that is split at time t is bounded by $t^3/2$ times the probability that $x_t \in (s+p,s+q)$ for a fixed interval with $q-p \le \varepsilon/n^5$. Because of the assumption on how x_t is generated, the latter probability is bounded by $(q-p)/(2\varepsilon) \le 1/(2n^5)$ (the truncation of x_t at 0 and 1 has no effect, because $(s+p,s+q) \subseteq (0,1)$). Hence, the probability that there exists a maximal t-indistinguishable interval of length at most ε/n^5 that is split at time t is no more than $t^3/2 \cdot 1/(2n^5) \le 1/(4n^2)$. Thus, using the union bound again, the probability that during the n rounds of the game there exists any maximal t-indistinguishable interval of length at most ε/n^5 that is split is at most $1/(4n)$, and therefore, with probability at least $1-1/(4n)$, all maximal n-indistinguishable intervals have length at least ε/n^5, as desired. ■

Remark 11 *(i) The theorem above shows that, for example, if* $\varepsilon = \Omega(n^{-a})$ *for some* $a > 0$ *(i.e., if the noise level is not too small), then the regret with respect to the best constant-threshold expert is* $O(n^{2/3}\ln^{1/3} n)$.

(ii) A similar model can be obtained, if, instead of having perturbed item sizes, the experts observe the free space in their bins with some noise. Thus, instead of $s_{p,t-1}$*, expert* p *observes* $s_{p,t-1} + \sigma_{p,t}$ *truncated to the interval* $[0,1]$*, and makes decision* $f_{p,t}$ *based on this value. As in the case of Theorem 10, we assume that the noise is independent over time, that is, the random ensembles* $\{\sigma_{p,t}\}_{p\in(0,1]}$ *are independent for all* t*. If each component is identical, that is,* $\sigma_{p,t} = \sigma_t$ *for all* $p \in (0,1]$*, then essentially the same argument applies as in the previous theorem, and so* (4) *holds if the sequence* $\sigma_1, \ldots, \sigma_n$ *satisfies the assumptions of Theorem 10. On the other hand, if the components of the vectors are also independent, then the problem becomes more difficult, as the* t*-indistinguishable classes may not be disjoint intervals anymore. An intermediate assumption on the noise that still guarantees that* (4) *holds for this scenario is that* $\sigma_{p,t} = \sigma_{q,t}$ *if* p *and* q *are* t*-indistinguishable. Then the same argument as in Theorem 10 works with the only difference (omitting the effects of truncation to* $[0,1]$*) that here we have to estimate the probability that* $x_t \in (s+p+\sigma_{t,q}, s+q+\sigma_{t,q})$ *for a fixed* x_t *instead of estimating the probability that* $x_t \in (s+p, s+q)$ *with a randomized* x_t*. However, it is easy to see that the same bound holds in both cases.*

Finally, we present a simple example that reveals that the loss of the best expert can be arbitrarily far from that of the optimal sequential off-line packing.

Example 3 *Let the sequence of items be*

$$\langle \underbrace{\varepsilon, 1{-}\varepsilon, \varepsilon, 1{-}\varepsilon, \ldots, \varepsilon, 1{-}\varepsilon}_{2k}, \varepsilon, \underbrace{1, 1, \ldots, 1}_{k} \rangle,$$

where the number of items is $n = 3k+1$ *and* $0 < \varepsilon < 1/2$*. An optimal sequential off-line packing is achieved if we drop any of the* ε *terms; then the total loss is* ε*. In contrast to this, the loss of any constant-threshold expert is* $1-\varepsilon+k$ *independently of the choice of the parameter* p*. Namely, if* $p \le 1-\varepsilon$ *then the loss is* 0 *for the first* $2k$ *items, but after the algorithm is stuck and suffers* $k+1-\varepsilon$ *loss. If* $p > 1-\varepsilon$*, then the loss is* k *for the first* $2k$ *items and after that* $1-\varepsilon$ *for the rest of the sequence.*

6. Conclusions

In this paper we provide an extension of the classical bin packing problems to an on-line sequential scenario. In this setting items are received one by one, and before the size of the next item is revealed, the decision maker needs to decide whether the next item is packed in the currently open bin or the bin is closed and a new bin is opened. If the new item does not fit, it is lost. If a bin is closed, the remaining free space in the bin accounts for a loss. The goal of the decision maker is to minimize the loss accumulated over n periods.

We give an algorithm that has a cumulative loss not much larger than any finite set of reference algorithms. We also study in detail the case when the class of reference strategies contains all constant-threshold experts. We prove some negative results, showing that it is hard to compete with the overall best constant-threshold expert if no assumption is imposed on the item sizes. We also derive data-dependent regret bounds and show that under some mild assumptions on the data the

cumulative loss can be made not much larger than that of any strategy that uses a fixed threshold at each step to decide whether a new bin is opened. An interesting aspect of the problem is that the loss function has an (unbounded) memory. The presented solutions rely on the fact that one can "synchronize" the loss function in the sense that no matter in what state an algorithm is started, its loss may change only by a small additive constant. The result for constant-threshold experts is obtained by a covering of the uncountable set of constant-threshold experts such that the cardinality of the chosen finite set of experts grows only quadratically with the sequence length. The approach in the paper can easily be extended to any control problem where the loss function has such a synchronizable property.

Acknowledgments

The authors would like to thank Robert Kleinberg for pointing out a crucial mistake in the earlier version (György et al., 2008) of this paper. In that paper we erroneously claimed that it was possible to construct a sequential on-line bin packing algorithm that has a small regret with respect to all constant-threshold experts for all possible item sequences.

Abstract

In this paper, we investigate the problem of binary classification with a reject option in which one can withhold the decision of classifying an observation at a cost lower than that of misclassification. Since the natural loss function is non-convex so that empirical risk minimization easily becomes infeasible, the paper proposes minimizing convex risks based on surrogate convex loss functions. A necessary and sufficient condition for infinite sample consistency (both risks share the same minimizer) is provided. Moreover, we show that the excess risk can be bounded through the excess surrogate risk under appropriate conditions. These bounds can be tightened by a generalized margin condition. The impact of the results is illustrated on several commonly used surrogate loss functions.

Keywords: classification, convex surrogate loss, empirical risk minimization, generalized margin condition, reject option

1. Introduction

In binary classification, one observes independent realizations $(X_1,Y_1),\ldots,(X_n,Y_n)$ of the random pair (X,Y) where $X \in \mathcal{X}$ and $Y \in \mathcal{Y} = \{-1,1\}$. The goal is to learn from these training data a classification rule $g : \mathcal{X} \mapsto \mathcal{Y}$ that classifies an observation X into the two classes. It is recognized that in many applications the consequences of misclassification can be substantial. In such situations, a less specific response that reserves the right of not making a decision, sometimes referred to as a reject option (see, e.g., Herbei and Wegkamp, 2006), may even be more preferable than risking misclassification. This, for example, is typical in medical studies where screening of a certain disease can be done based on relatively inexpensive clinical measures. If the classification based on these measurements are satisfactory, nothing further needs to be done. But in the event that there are ambiguities, it would be more desirable to take a rejection option and seek more expensive studies to identify a subject's disease status. Similar approaches are often adopted in DNA sequencing or genotyping applications, where the rejection option is commonly referred to as a "no-call". Similar problems have attracted much attention in various application fields and also received increasing

amount of interest more recently in machine learning literature. See Ripley (1996) and Bartlett and Wegkamp (2008) and references therein.

To accommodate the reject option, we now seek a classification rule $g : \mathcal{X} \to \tilde{\mathcal{Y}}$ where $\tilde{\mathcal{Y}} = \{-1, 1, 0\}$ is an augmented response space and $g(X) = 0$ indicates that no definitive classification will be made for X or a reject option is taken. To measure the performance of a classification rule, we employ the following loss function that generalizes the usual 0-1 loss to account for reject option:

$$\ell[g(X), Y] = \begin{cases} 1 & \text{if } g(X) \neq Y \text{ and } g(X) \neq 0 \\ d & \text{if } g(X) = 0 \\ 0 & \text{if } g(X) = Y \end{cases} .$$

In other words, an ambiguous response ($g(X) = 0$) incurs a loss of d whereas misclassification incurs a loss of 1. Note that d is necessarily smaller than $1/2$. Otherwise, rather than taking a rejection option with a loss d, we can always flip a fair coin to randomly assign ± 1 as the value of $g(X)$, which incurs an average loss of $1/2 \leq d$. For this reason, we shall assume that $d < 1/2$ in what follows.

For any classification rule $g : \mathcal{X} \to \tilde{\mathcal{Y}}$, the risk function is then given by $R(g) = \mathbb{E}(\ell[g(X), Y])$ where the expectation is taken over the joint distribution of X and Y. It is not hard to show that the optimal classification rule $g^* := \arg\min R(g)$ is given by (see, e.g., Bartlett and Wegkamp, 2008)

$$g^*(X) = \begin{cases} 1 & \text{if } \eta(X) > 1 - d \\ 0 & \text{if } d \leq \eta(X) \leq 1 - d \\ -1 & \text{if } \eta(X) < d \end{cases}$$

where $\eta(X) = \mathbb{P}(Y = 1|X)$. The corresponding risk is

$$R^* := \inf R(g) = R(g^*) = \mathbb{E}\left(\min\{\eta(X), 1 - \eta(X), d\}\right).$$

Thus, the performance of any classification rule $g : \mathcal{X} \to \tilde{\mathcal{Y}}$ can be measured by the excess risk $\Delta R(g) := R(g) - R^*$.

Appealing to the general empirical risk minimization strategy, one could attempt to derive a classification rule from the training data by minimizing the empirical risk

$$R_n(g) = \frac{1}{n} \sum_{i=1}^{n} \ell[g(X_i), Y_i].$$

Similar to the usual 0-1 loss, however, ℓ is not convex in g; and direct minimization of R_n is typically an NP-hard problem. A common remedy is to consider a surrogate convex loss function. To this end, let $\phi : \mathbb{R} \mapsto \mathbb{R}$ be a convex function. Denote by

$$Q(f) = \mathbb{E}[\phi(Y f(X))]$$

the corresponding risk for a discriminant function $f : \mathcal{X} \mapsto \mathbb{R}$. Let $\hat{f}_n$ be the minimizer of

$$Q_n(f) = \frac{1}{n} \sum_{i=1}^{n} \phi(Y_i f(X_i))$$

over a certain functional space $\mathcal{F}$ consisting of functions that map from $\mathcal{X}$ to $\mathbb{R}$. $\hat{f}_n$ can be conveniently converted to a classification rule $C(\hat{f}_n;\delta)$ as follows:

$$C(f(X);\delta) = \begin{cases} 1 & \text{if } f(X) > \delta \\ 0 & \text{if } |f(X)| \le \delta \\ -1 & \text{if } f(X) < -\delta \end{cases}$$

where $\delta > 0$ is a parameter that as we shall see plays a critical role in determining the performance of $C(\hat{f}_n,\delta)$.

In this paper, we investigate the statistical properties of this general convex risk minimization technique. To what extent $C(\hat{f}_n,\delta)$ mimics the optimal classification rule g^* plays a critical role in the success of this technique. Let f_ϕ^* be the minimizer of $Q(f)$. We shall assume throughout the paper that f_ϕ^* is uniquely defined. Typically f_ϕ^* reflects the limiting behavior of $\hat{f}_n$ when $\mathcal{F}$ is rich enough and there are infinitely many training data. Therefore the first question is whether or not f_ϕ^* can be used to recover the optimal rule g^*. A surrogate loss function ϕ that satisfies this property is often called infinite sample consistent (see, e.g., Zhang, 2004) or classification calibrated (see, e.g., Bartlett, Jordan and McAuliffe, 2006). A second question further concerns the relationship between the excess risk $\Delta R[C(f,\delta)]$ and the excess ϕ risk $\Delta Q(f) = Q(f) - \inf Q(f)$: Can we find an increasing function $\rho : \mathbb{R} \mapsto \mathbb{R}$ such that for all f,

$$\Delta R[C(f,\delta)] \le \rho\left(\Delta Q(f)\right) ? \tag{1}$$

Clearly the infinite sample consistency of ϕ implies that $\rho(0) = 0$. Such a bound on the excess risk provides useful tools in bounding the excess risk of $\hat{f}_n$. In particular, (1) indicates that

$$\Delta R[C(\hat{f}_n,\delta)] \le \rho\left(\Delta Q(\hat{f}_n)\right) = \rho\left[\Delta Q(\bar{f}) + \left(Q(\hat{f}_n) - Q(\bar{f})\right)\right],$$

where $\bar{f} = \arg\min_{f\in\mathcal{F}} Q(f)$. The first term $\Delta Q(\bar{f})$ on the right-hand side exhibits the approximation error of functional class $\mathcal{F}$ whereas the second term $Q(\hat{f}_n) - Q(\bar{f})$ is the estimation error.

In the case when there is no reject option, these problems have been well investigated in recent years (Lin, 2002; Zhang, 2004; Bartlett, Jordan and McAuliffe, 2006). In this paper, we establish similar results when there is a reject option. The most significant difference between the two situations, with or without the reject option, is the role of δ. As we shall see, for some loss functions such as least squares, exponential or logistic, a good choice of δ yields classifiers that are infinite sample consistent. For other loss functions, however, such as the hinge loss, no matter how δ is chosen, the classification rule $C(f,\delta)$ cannot be infinite sample consistent.

The remainder of the paper is organized as follows. We first examine in Section 2 the infinite sample consistency for classification with reject option. After establishing a general result, we consider its implication on several commonly used loss functions. In Section 3, we establish bounds on the excess risk in the form of (1), followed by applications to the popular loss functions. We also show that under an additional assumption on the behavior of $\eta(X)$ near d and $1-d$ as in Herbei and Wegkamp (2006), generalizing the condition in the case of $d = 1/2$ of Mammen and Tsybakov (1999) and Tsybakov (2004), the bound (1) can be tightened considerably. Section 4 discusses rates of convergence of the empirical risk minimizer $\widehat{f}_n$ that minimizes the empirical risk $Q_n(f)$ over a bounded class $\mathcal{F}$. Section 5 considers extension to asymmetric loss where one type of misclassification may be more costly than the other. All proofs are relegated to Section 6.

2. Infinite Sample Consistency

We first give a general result on the infinite sample consistency of the classification rule $C(f_\phi^*, \delta)$.

Theorem 1 *Assume that ϕ is convex. Then the classification rule $C(f_\phi^*, \delta)$ for some $\delta > 0$ is infinite sample consistent, that is, $C(f_\phi^*, \delta) = g^*$ if and only if $\phi'(\delta)$ and $\phi'(-\delta)$ both exist, $\phi'(\delta) < 0$, and*

$$\frac{\phi'(\delta)}{\phi'(\delta) + \phi'(-\delta)} = d. \tag{2}$$

When there is no reject option, it is known that the necessary and sufficient condition for the infinite sample consistency is that ϕ is differentiable at 0 and $\phi'(0) < 0$ (see, e.g., Bartlett, Jordan and McAuliffe, 2006). As indicated by Theorem 1, the differentiability of ϕ at $\pm\delta$ plays a more prominent role in the general case when there is a reject option.

From Theorem 1 it is also evident that the infinite sample consistency depends on both ϕ and the choice of thresholding parameter δ. Observe that for any $\delta_1 < \delta_2$,

$$\phi'(-\delta_2) \le \phi'(-\delta_1) \le \phi'(\delta_1) \le \phi'(\delta_2),$$

which implies that the left-hand side of (2) is a decreasing function of δ. If ϕ is strictly convex, then it is strictly decreasing; and therefore there is at most one value of δ that satisfies (2). In other words, for strictly convex ϕ, there is at most one thresholding parameter δ such that $C(f_\phi^*, \delta) = g^*$. On the other hand, if ϕ is twice differentiable such that $\phi'(0) < 0$ and $\phi'(z) \ge 0$ as $z \to +\infty$, then for any $d < 1/2$, there always exists a $\delta > 0$ such that (2) holds. This is because the left-hand side of (2) is a decreasing function of δ, which approaches its supremum $1/2$ when $\delta \downarrow 0$ and 0 when δ increases. Moreover, the twice differentiability of ϕ ensures that the left-hand side of (2) is also a continuous function of δ. The following is therefore a direct consequence of Theorem 1:

Corollary 2 *If ϕ is strictly convex, then either there is a unique $\delta > 0$ such that $C(f_\phi^*, \delta)$ is infinite sample consistent; or $C(f_\phi^*, \delta)$ is not infinite sample consistent for any $\delta > 0$. In addition to convexity, if ϕ is twice differentiable such that $\phi'(0) < 0$ and $\phi'(z) \ge 0$ as $z \to +\infty$, then there always exists a $\delta > 0$ such that $C(f_\phi^*, \delta)$ is infinite sample consistent.*

Theorem 1 provides a general guideline on how to choose δ for common choices of convex losses. Below we look at several concrete examples.

2.1 Least Squares Loss

We first examine the least squares loss $\phi(z) = (1-z)^2$. Observe that

$$\frac{\phi'(\delta)}{\phi'(-\delta) + \phi'(\delta)} = \frac{1-\delta}{2}.$$

All conditions of Theorem 1 are met if and only if $\delta = 1 - 2d$.

Corollary 3 *For the least squares loss,*

$$C(f_\phi^*, 1-2d) = g^*.$$

2.2 Exponential Loss

Exponential loss, $\phi(z) = \exp(-z)$, is connected with boosting (Friedman, Hastie and Tibshirani, 2000). Because

$$\frac{\phi'(\delta)}{\phi'(-\delta)+\phi'(\delta)} = \frac{1}{1+\exp(2\delta)},$$

Therefore all conditions of Theorem 1 are met if and only if

$$\delta = \frac{1}{2}\log\left(\frac{1}{d}-1\right).$$

Corollary 4 *For the exponential loss,*

$$C\left(f_\phi^*, \frac{1}{2}\log\left(\frac{1}{d}-1\right)\right) = g^*.$$

2.3 Logistic Loss

Logisitic regression employs loss $\phi(z) = \ln(1+\exp(-z))$. Similar to before,

$$\frac{\phi'(\delta)}{\phi'(-\delta)+\phi'(\delta)} = \frac{1}{1+\exp(\delta)},$$

which suggests that all conditions of Theorem 1 are met if

$$\delta = \log\left(\frac{1}{d}-1\right).$$

Corollary 5 *For the logistic loss,*

$$C\left(f_\phi^*, \log\left(\frac{1}{d}-1\right)\right) = g^*.$$

2.4 Squared Hinge Loss

Squared hinge loss, $\phi(z) = (1-z)_+^2$, is another popular choice for which

$$\frac{\phi'(\delta)}{\phi'(-\delta)+\phi'(\delta)} = \frac{1-\delta}{2}.$$

Similar to the least squares loss, we have the following corollary.

Corollary 6 *For the squared hinge loss,*

$$C\left(f_\phi^*, 1-2d\right) = g^*.$$

2.5 Distance Weighted Discrimination

Marron, Todd and Ahn (2007) recently introduced the so-called distance weighted discrimination method where the following loss function (see, e.g., Bartlett, Jordan and McAuliffe, 2006) is used

$$\phi(z) = \begin{cases} \frac{1}{z} & \text{if } z \geq \gamma \\ \frac{1}{\gamma}\left(2 - \frac{z}{\gamma}\right) & \text{if } z < \gamma \end{cases}, \tag{3}$$

where $\gamma > 0$ is a constant. It is not hard to see that ϕ is convex. Moreover,

$$\phi'(z) = \begin{cases} -1/z^2 & \text{if } z \geq \gamma \\ -1/\gamma^2 & \text{if } z < \gamma \end{cases}.$$

Thus,

$$\frac{\phi'(\delta)}{\phi'(-\delta) + \phi'(\delta)} = \begin{cases} 1/2 & \text{if } \delta < \gamma \\ \frac{1/\delta^2}{1/\delta^2 + 1/\gamma^2} & \text{if } \delta > \gamma \end{cases}.$$

In other words, we have the following result for the distance weighted discrimination loss.

Corollary 7 *For the loss (3),*

$$C\left(f_\phi^*, [(1-d)/d]^{1/2}\gamma\right) = g^*.$$

2.6 Hinge Loss

The popular support vector machine employs the hinge loss, $\phi(z) = (1-z)_+$. The hinge loss is differentiable everywhere except 1. Therefore

$$\frac{\phi'(\delta)}{\phi'(-\delta) + \phi'(\delta)} = \begin{cases} \frac{1}{2} & \text{if } 0 < \delta < 1 \\ 0 & \text{if } \delta > 1 \end{cases}.$$

Because $0 < d < 1/2$, there does not exist a δ such that all conditions of Theorem 1 are met. As a matter of fact, for any $\delta > 0$, $C(f_\phi^*, \delta) \neq g^*$. Motivated by this observation, Bartlett and Wegkamp (2008) introduce the following modification to the hinge loss:

$$\phi(z) = \begin{cases} 1 - az & \text{if } z \leq 0 \\ 1 - z & \text{if } 0 < z \leq 1 \\ 0 & \text{if } z > 1 \end{cases}, \tag{4}$$

where $a > 1$. Note that with this modification,

$$\frac{\phi'(\delta)}{\phi'(-\delta) + \phi'(\delta)} = \begin{cases} 1/(a+1) & \text{if } 0 < \delta < 1 \\ 0 & \text{if } \delta > 1 \end{cases}.$$

Therefore, we have the following corollary.

Corollary 8 *For the modified hinge loss (4) and any $\delta < 1$, if $a = (1-d)/d$, then*

$$C\left(f_\phi^*, \delta\right) = g^*.$$

It is interesting to note that for the examples we considered previously, a specific choice of δ is needed to ensure the infinite sample consistent. Whereas for the modified hinge loss, a range of choice of δ can serve the same purpose. However, as we shall see in the next section, different choices of δ for the modified hinge loss may result in slightly different bound on the excess risk with $\delta = 1/2$ appearing to be more preferable in that it yields the smallest upper bound of the excess risk.

3. Excess Risk

We now turn to the excess risk $\Delta R[C(f,\delta)]$ and show how it can be bounded through the excess ϕ risk

$$\Delta Q(f) := Q(f) - Q(f_\phi^*).$$

Recall that the infinite sample consistency established in the previous section means that $\Delta Q(f) = 0$ implies throughout this section that $\Delta R(C(f,\delta)) = 0$. For brevity, we shall assume implicitly that δ is chosen in accordance with Theorem 1 to ensure infinite sample consistency. Write

$$Q_{\eta(X)}(z) = \eta(X)\phi(z) + (1-\eta(X))\phi(-z).$$

By definition,

$$Q_{\eta(X)}(f_\phi^*(X)) = \inf_z Q_{\eta(X)}(z).$$

Denote

$$\Delta Q_\eta(f) = Q_\eta(f) - Q_\eta(f_\phi^*)$$

where we suppress the dependence of η, f and f_ϕ^* on X for brevity.

Theorem 9 *Assume that ϕ is convex, $\phi'(\delta)$ and $\phi'(-\delta)$ both exist, $\phi'(\delta) < 0$, and (2) holds. In addition, suppose that there exist constants $C > 0$ and $s \geq 1$ such that*

$$\begin{aligned} |\eta - d|^s &\leq C^s \Delta Q_\eta(-\delta); \\ |(1-\eta) - d|^s &\leq C^s \Delta Q_\eta(\delta). \end{aligned}$$

Then

$$\Delta R[C(f,\delta)] \leq 2C\left[\Delta Q(f)\right]^{1/s}. \tag{5}$$

It is immediate from Theorem 9 that $\Delta Q(\hat{f}_n) \to_p 0$ implies $\Delta R(\hat{f}_n) \to_p 0$. In other words, consistency in terms of ϕ risk implies the consistency in terms of loss ℓ. It is worth noting that the constant in the upper bound can be tightened under stronger conditions.

Theorem 10 *In addition to the assumptions of Theorem 9, assume that*

$$\begin{aligned} (2\eta - 1)_+^s &\leq C^s \Delta Q_\eta(-\delta); \\ (1 - 2\eta)_+^s &\leq C^s \Delta Q_\eta(\delta). \end{aligned}$$

Then

$$\Delta R[C(f,\delta)] \leq C\left[\Delta Q(f)\right]^{1/s}.$$

We can improve the bounds even further by the following margin condition. Assume that for some $\alpha \geq 0$ and $A \geq 1$

$$\mathbb{P}\{|\eta(X) - z| \leq t\} \leq A t^\alpha \tag{6}$$

for all $0 \leq t < d$ at $z = d$ and $z = 1 - d$. This assumption was introduced in Herbei and Wegkamp (2006) and generalizes the margin condition of Mammen and Tsybakov (1999) and Tsybakov (2004). It is always met for $\alpha = 0$ and $A = 1$. The other extreme is for $\alpha \to +\infty$ - the case where $\eta(X)$ stays away from d and $1 - d$ with probability one.

Theorem 11 *In addition to the assumptions of Theorem 9, assume that (6) holds for some $\alpha \geq 0$ and $A \geq 1$. Then, for some K depending on A and α,*

$$\Delta R\left[C(f,\delta)\right] \leq K\left[\Delta Q(f)\right]^{1/(s+\beta-\beta s)}, \tag{7}$$

where $\beta = \alpha/(1+\alpha)$.

In case $\alpha = 0$, the exponent $1/(s+\beta-\beta s)$ is $1/s$ on the right hand side in (7) above, and the situation is as in Theorem 9. For $\alpha \to +\infty$, the bound (7) improves upon the one in Theorem 9 as the exponent $1/(s+\beta-\beta s)$ converges to 1.

We now examine the consequences of Theorems 9, 10 and 11 on several common loss functions.

3.1 Least Squares

Note that for the least squares loss

$$\Delta Q_\eta(f) = (2\eta - 1 - f)^2.$$

Simple algebraic manipulations show that

$$\begin{aligned} \Delta Q_\eta(-\delta) &= 4|\eta - d|^2; \\ \Delta Q_\eta(\delta) &= 4|(1-\eta) - d|^2. \end{aligned}$$

Therefore, by Theorems 9 and 11,

Corollary 12 *For the least squares loss,*

$$\Delta R[C(f,1-2d)] \leq \left[\Delta Q(f)\right]^{1/2}.$$

Furthermore, if the margin condition (6) holds, then

$$\Delta R[C(f,1-2d)] \leq K\left[\Delta Q(f)\right]^{\frac{1+\alpha}{2+\alpha}}$$

for some constant $K > 0$.

3.2 Exponential Loss

An application of Taylor expansion yields (see, e.g., Zhang, 2004)

$$\Delta Q_\eta(f) \geq 2\left(\eta - \frac{1}{1+\exp(-2f)}\right)^2.$$

Therefore,

$$\begin{aligned} \Delta Q_\eta(-\delta) &\geq 2|\eta - d|^2; \\ \Delta Q_\eta(\delta) &\geq 2|(1-\eta) - d|^2. \end{aligned}$$

Therefore, by Theorems 9 and 11,

Corollary 13 *For the exponential loss,*

$$\Delta R\left[C\left(f,\frac{1}{2}\log\left(\frac{1}{d}-1\right)\right)\right] \leq \sqrt{2}\left[\Delta Q(f)\right]^{1/2}.$$

Furthermore, if the margin condition (6) holds, then

$$\Delta R\left[C\left(f,\frac{1}{2}\log\left(\frac{1}{d}-1\right)\right)\right] \leq K\left[\Delta Q(f)\right]^{\frac{1+\alpha}{2+\alpha}}$$

for some constant $K > 0$.

3.3 Logistic Loss

Similar to exponential loss, an application of Taylor expansion yields

$$\Delta Q_\eta(f) \geq 2\left(\eta - \frac{1}{1+\exp(-f)}\right)^2.$$

Therefore,

$$\begin{aligned}\Delta Q_\eta(-\delta) &\geq 2|\eta - d|^2;\\ \Delta Q_\eta(\delta) &\geq 2|(1-\eta) - d|^2.\end{aligned}$$

Therefore, by Theorems 9 and 11,

Corollary 14 *For the logistic loss,*

$$\Delta R\left[C\left(f,\log\left(\frac{1}{d}-1\right)\right)\right] \leq \sqrt{2}\left[\Delta Q(f)\right]^{1/2}.$$

Furthermore, if the margin condition (6) holds, then

$$\Delta R\left[C\left(f,\log\left(\frac{1}{d}-1\right)\right)\right] \leq K\left[\Delta Q(f)\right]^{\frac{1+\alpha}{2+\alpha}}$$

for some constant $K > 0$.

3.4 Squared Hinge Loss

Simple algebraic derivation shows

$$\Delta Q_\eta(f) = (2\eta - 1 - f)^2 - \eta(f-1)_+^2 - (1-\eta)(f+1)_-^2.$$

Therefore,

$$\begin{aligned}\Delta Q_\eta(-\delta) &= 4|\eta - d|^2;\\ \Delta Q_\eta(\delta) &= 4|(1-\eta) - d|^2.\end{aligned}$$

By Theorems 9 and 11,

Corollary 15 *For the squared hinge loss,*

$$\Delta R\left[C(f,1-2d)\right] \leq \left[\Delta Q(f)\right]^{1/2}.$$

Furthermore, if the margin condition (6) holds, then

$$\Delta R[C(f,1-2d)] \leq K\left[\Delta Q(f)\right]^{\frac{1+\alpha}{2+\alpha}}$$

for some constant $K > 0$.

3.5 Distance Weighted Discrimination

Observe that

$$Q_\eta(z) = \begin{cases} \frac{\eta}{z} + \frac{(1-\eta)z}{\gamma^2} + \frac{2(1-\eta)}{\gamma} & \text{if } z \geq \gamma \\ \frac{2}{\gamma} + \frac{z}{\gamma^2}(1-2\eta) & \text{if } |z| < \gamma \\ \frac{2\eta}{\gamma} - \frac{\eta z}{\gamma^2} - \frac{1-\eta}{z} & \text{if } z \leq -\gamma \end{cases}.$$

Hence

$$\inf Q_\eta(z) = \frac{2}{\gamma}\left(\sqrt{\eta(1-\eta)} + \min\{\eta, 1-\eta\}\right)$$

and

$$f_\phi^* = \begin{cases} (\eta/(1-\eta))^{1/2}\gamma & \text{if } \eta > 1/2 \\ \text{any value in } [-\gamma,\gamma] & \text{if } \eta = 1/2 \\ ((1-\eta)/\eta)^{1/2}\gamma & \text{if } \eta < 1/2 \end{cases}.$$

Recall that $\delta = ((1-d)/d)^{1/2}\gamma$. Then

$$\begin{aligned} \Delta Q_\eta(\delta) &\geq \left(\frac{\eta}{\delta} + \frac{(1-\eta)\delta}{\gamma^2} - 2\sqrt{\eta(1-\eta)}/\gamma\right) \\ &= \left(\left(\frac{\eta}{\delta}\right)^{1/2} - \left(\frac{(1-\eta)\delta}{\gamma^2}\right)^{1/2}\right)^2 \\ &= \frac{\eta\delta}{\gamma^2}\left(\left(\frac{d}{1-d}\right)^{1/2} - \left(\frac{1-\eta}{\eta}\right)^{1/2}\right)^2 \\ &= \frac{\eta\delta}{\gamma^2}\left(\left(\frac{d}{1-d}\right)^{1/2} + \left(\frac{1-\eta}{\eta}\right)^{1/2}\right)^{-2}\left(\frac{d}{1-d} - \frac{1-\eta}{\eta}\right)^2 \\ &= \frac{\delta}{\gamma^2(1-d)^2}\left[\left(\frac{d}{1-d}\right)^{1/2}\eta^{1/2} + (1-\eta)^{1/2}\right]^{-2}(1-\eta-d)^2. \end{aligned}$$

Observe that

$$\left(\frac{d}{1-d}\right)^{1/2}\eta^{1/2} + (1-\eta)^{1/2} \leq (1-d)^{-1/2}.$$

Thus,

$$(1-\eta-d)^2 \leq \gamma(1-d)^{1/2}d^{1/2}\Delta Q_\eta(\delta).$$

Similarly,

$$(\eta-d)^2 \leq \gamma(1-d)^{1/2}d^{1/2}\Delta Q_\eta(-\delta).$$

From Theorems 9 and 11, we conclude that

Corollary 16 *For the distance weighted discrimination loss,*

$$\Delta R\left[C(f,((1-d)/d)^{1/2}\gamma)\right] \leq \gamma^{1/2}(1-d)^{1/4}d^{1/4}[\Delta Q(f)]^{1/2}.$$

Furthermore, if the margin condition (6) holds, then

$$\Delta R\left[C(f,((1-d)/d)^{1/2}\gamma)\right] \leq K\,[\Delta Q(f)]^{\frac{1+\alpha}{2+\alpha}}$$

for some constant $K > 0$.

3.6 Hinge Loss with Rejection Option

As shown by Bartlett and Wegkamp (2008), for the modified hinge loss (4),

$$\arg\min_z Q_\eta(z) = \begin{cases} -1 & \text{if } \eta \le d \\ 0 & \text{if } d < \eta < 1-d \\ 1 & \text{if } \eta > 1-d \end{cases} .$$

Simple algebraic manipulations lead to

$$\Delta Q_\eta(-\delta) = \begin{cases} (1-\delta)(d-\eta)/d & \text{if } \eta \le d \\ (\eta-d)\delta/d & \text{if } d < \eta < 1-d \\ 1-(1-\eta)/d+(\eta-d)\delta/d & \text{if } \eta > 1-d \end{cases} ,$$

and

$$\Delta Q_\eta(\delta) = \begin{cases} 1-\eta/d+(1-\eta-d)\delta/d & \text{if } \eta \le d \\ (1-\eta-d)\delta/d & \text{if } d < \eta < 1-d \\ (\delta-1)(1-\eta-d)/d & \text{if } \eta > 1-d \end{cases} .$$

Therefore,

$$\begin{aligned} \frac{\min\{\delta,1-\delta\}}{d}|\eta-d| &\le \Delta Q_\eta(-\delta); \\ \frac{\min\{\delta,1-\delta\}}{d}|(1-\eta)-d| &\le \Delta Q_\eta(\delta). \end{aligned}$$

Furthermore,

$$\begin{aligned} \frac{\min\{\delta,1-\delta\}}{d}(2\eta-1)_+ &\le \Delta Q_\eta(-\delta); \\ \frac{\min\{\delta,1-\delta\}}{d}(1-2\eta)_+ &\le \Delta Q_\eta(\delta). \end{aligned}$$

From Theorems 10 and 11, we conclude that

Corollary 17 *For the modified hinge loss and any* $\delta < 1$,

$$\Delta R[C(f,\delta)] \le \frac{d}{\min\{\delta,1-\delta\}}\Delta Q(f). \tag{8}$$

Furthermore, if the margin condition (6) holds, then

$$\Delta R[C(f,\delta)] \le K\Delta Q(f) \tag{9}$$

for some constant $K > 0$.

Notice that the corollary also suggests that $\delta = 1/2$ yields the best constant $2d$ in the upper bound. A similar result has also been recently established by Bartlett and Wegkamp (2008). It is also interesting to see that (8) cannot be further improved by the generalized margin condition (6) as the bounds (8) and (9) only differ by a constant.

4. Rates of Convergence for Empirical Risk Minimizers

In this section we briefly review the possible rates of convergence for minimizers of the empirical risk $Q_n(f) = (1/n)\sum_{i=1}^n \phi(Y_i f(X_i))$ over a convex class of discriminant functions $\mathcal{F}$; and show the implications of the excess risk bounds obtained in the previous section. The analysis of the generalized hinge loss is complicated and is treated in detail in Wegkamp (2007) and Bartlett and Wegkamp (2008). The other loss functions ϕ considered in this paper have in common that the modulus of convexity of Q,

$$\delta(\varepsilon) = \inf\left\{ \frac{Q(f)+Q(g)}{2} - Q\left(\frac{f+g}{2}\right) : \ \mathbb{E}[(f-g)^2(X)] \geq \varepsilon^2 \right\}$$

satisfies $\delta(\varepsilon) \geq c\varepsilon^2$ for some $c > 0$ and that, for some $L < \infty$,

$$|\phi(x) - \phi(x')| \leq L|x - x'| \text{ for all } x, x' \in \mathbb{R}.$$

We have the following result that imposes a restriction on the $1/n$-covering number $N_n = N(1/n, L_\infty, \mathcal{F})$, the cardinality of the set of closed balls with radius $1/n$ in L_∞ needed to cover $\mathcal{F}$.

Theorem 18 *Assume that $|f| \leq B$ for all $f \in \mathcal{F}$ and let $0 < \gamma < 1$. With probability at least $1-\gamma$,*

$$Q(\hat{f}_n) \quad \leq \quad \inf_{f\in\mathcal{F}} Q(f) + \frac{3L}{n} + 8\left(\frac{L^2}{2c} + \frac{B}{6}\right)\frac{\log(N_n/\gamma)}{n}$$

Together with the excess risk bounds from Theorems 9 and 11, we have

Corollary 19 *Under the assumptions of Theorems 9 and 18, we have, with probability at least $1-\gamma$,*

$$\Delta R(C(\hat{f}_n, \delta)) \quad \leq \quad 2C\left\{ \inf_{f\in\mathcal{F}} \Delta Q(f) + \frac{3L}{n} + 8\left(\frac{L^2}{2c} + \frac{LB}{3}\right)\frac{\log(N_n/\gamma)}{n} \right\}^{1/s}.$$

Furthermore, if the generalized margin condition (6) holds, then with probability at least $1-\gamma$,

$$\Delta R(C(\hat{f}_n, \delta)) \quad \leq \quad K\left\{ \inf_{f\in\mathcal{F}} \Delta Q(f) + \frac{3L}{n} + 8\left(\frac{L^2}{2c} + \frac{LB}{3}\right)\frac{\log(N_n/\gamma)}{n} \right\}^{1/(s+\beta-\beta s)}$$

for some constant $K > 0$.

In the special case where $\mathcal{F}$ consists of linear combinations

$$\mathsf{f}_\lambda(x) = \sum_{j=1}^M \lambda_j f_j(x)$$

of simple discriminant functions (decision stumps) $f_1, \ldots, f_M$ with $\sum_{j=1}^M |\lambda_j| \leq B$ and $|f_j| \leq 1$, we obtain the rate $(M \log n/n)^{1/(s+\beta-\beta s)}$. We can view B as a tuning parameter here, and if the functions f_j are near orthogonal in the sense that

$$\max_{1\leq i\neq j\leq M} \frac{\mathbb{E}[f_i(X)f_j(X)]}{\sqrt{\mathbb{E}[f_i^2(X)]\mathbb{E}[f_j^2(X)]}} \leq \frac{c}{|\lambda_0|_0}$$

for some small $c > 0$, a small modification of Theorem 1 in Wegkamp (2007) shows that we also adapt to the unknown sparsity of the minimizer λ_0 of $Q(\mathsf{f}_\lambda)$ over λ in that the rate becomes $(|\lambda_0|_0 \log n/n)^{1/(s+\beta-\beta s)}$ for suitably chosen $B = B(n)$.

5. Asymmetric Loss

We have focused thus far on the case where misclassifying from one class to the other, either $g(X) = 1$ while $Y = -1$ or $g(X) = -1$ while $Y = 1$, is assigned the same loss. In many applications, however, one type of misclassification may incur a heavier loss than the other. Such situations naturally arise in risk management or medical diagonsis. To this end, the following loss function can be adopted in place of ℓ:

$$\ell_\theta[g(X),Y] = \begin{cases} 1 & \text{if } g(X) = -1 \text{ and } Y = 1 \\ \theta & \text{if } g(X) = 1 \text{ and } Y = -1 \\ d & \text{if } g(X) = 0 \\ 0 & \text{if } g(X) = Y \end{cases}.$$

We shall assume that $\theta < 1$ without loss of generality. It can be shown that the rejection option is only available if $d < \theta/(1+\theta)$ (see, e.g., Herbei and Wegkamp, 2006), which we shall assume throughout the section. When this holds, the corresponding Bayes rule is given by (see, e.g., Herbei and Wegkamp, 2006)

$$g^*_\theta(X) = \begin{cases} 1 & \text{if } \eta(X) > 1 - d/\theta \\ 0 & \text{if } d \le \eta(X) \le 1 - d/\theta \\ -1 & \text{if } \eta(X) < d \end{cases}.$$

Instead of $C(\hat{f}_n, \delta)$, an asymmetrically truncated classification rule, $\hat{f}_n, C(\hat{f}_n; \delta_1, \delta_2)$, can be used for our purpose here where

$$C(f(X); \delta_1, \delta_2) = \begin{cases} 1 & \text{if } f(X) > \delta_1 \\ 0 & \text{if } -\delta_2 \le f(X) \le \delta_1 \\ -1 & \text{if } f(X) < -\delta_2 \end{cases}.$$

The behavior of the asymmetically truncated classification rule $C(\hat{f}_n; \delta_1, \delta_2)$ can be studied in a similar fashion as before. In particular, we have the following results in parallel to Theorems 1 and 9.

Theorem 20 *Assume that ϕ is convex. Then $C(f^*_\phi, \delta_1, \delta_2)$ for some $\delta_1, \delta_2 > 0$ is infinite sample consistent, that is, $C(f^*_\phi, \delta_1, \delta_2) = g^*_\theta$ if and only if $\phi'(\pm\delta_1)$ and $\phi'(\pm\delta_2)$ exist; $\phi'(\delta_1), \phi'(\delta_2) < 0$; and*

$$\begin{aligned} \frac{\phi'(\delta_1)}{\phi'(-\delta_1) + \phi'(\delta_1)} &= \frac{d}{\theta}; \\ \frac{\phi'(\delta_2)}{\phi'(-\delta_2) + \phi'(\delta_2)} &= d. \end{aligned}$$

Furthermore, if $C(f^*_\phi, \delta_1, \delta_2)$ is infinite sample consistent and

$$\begin{aligned} |\theta(1-\eta) - d|^s &\le C^s \Delta Q_\eta(\delta_1); \\ |\eta - d|^s &\le C^s \Delta Q_\eta(-\delta_2), \end{aligned}$$

then

$$\Delta R_\theta[C(f, \delta_1, \delta_2)] \le 2C[\Delta Q(f)]^{1/s},$$

where $\Delta R_\theta(g) = R_\theta(g) - R_\theta(g^*_\theta)$ and $R_\theta(g) = \mathbb{E}[\ell_\theta(g(X), Y)]$.

Theorem 20 can be proved in the same fashion as Theorems 1 and 9 and is therefore omitted for brevity.

6. Proofs

Proof of Theorem 1. We first show the "if" part. Recall that

$$\begin{aligned} Q(f) &= \mathbb{E}[\phi(Yf(X))] \\ &= \mathbb{E}\left(\mathbb{E}\left[\phi(Yf(X))|X\right]\right) \\ &= \mathbb{E}\left[\eta(X)\phi(f(X)) + (1-\eta(X))\,\phi(-f(X))\right]. \end{aligned}$$

With slight abuse of notation, write

$$Q_{\eta(X)}(f(X)) = \eta(X)\phi(f(X)) + (1-\eta(X))\,\phi(-f(X)).$$

Then $f_\phi^*(X)$ minimizes $Q_{\eta(X)}(\cdot)$.

We now proceed by separately considering three different scenarios: (a) $\eta(X) < d$; (b) $\eta(X) > 1-d$; and (c) $d < \eta(X) < 1-d$. For brevity, we shall abbreviate the dependence of η and f_ϕ^* on X in the reminder of the proof when no confusion occurs.

First consider the case when $\eta < d$. Recall that $\phi'(-\delta) < \phi'(\delta) < 0$, and

$$\frac{\phi'(\delta)}{\phi'(-\delta)+\phi'(\delta)} = d.$$

Therefore,

$$\eta\phi'(-\delta) - (1-\eta)\phi'(\delta) > 0.$$

By the convexity of ϕ, for any $z > 0$,

$$\begin{aligned} \phi(z-\delta) - \phi(-\delta) &\geq \phi'(-\delta)z; \\ \phi(-z+\delta) - \phi(\delta) &\geq -\phi'(\delta)z. \end{aligned}$$

Hence

$$Q_\eta(z-\delta) - Q_\eta(-\delta) \geq \left[\eta\phi'(-\delta) - (1-\eta)\phi'(\delta)\right] z > 0,$$

which implies that $f_\phi^* \leq -\delta$.

It now suffices to show that $f_\phi^* \neq -\delta$. By the definition of $\phi'(-\delta)$ and $\phi'(\delta)$, for any $\varepsilon > 0$, there exists a $\zeta > 0$ such that for any $0 < z < \zeta$,

$$\begin{aligned} \frac{\phi(-z-\delta) - \phi(-\delta)}{-z} &\geq \phi'(-\delta) - \varepsilon; \\ \frac{\phi(z+\delta) - \phi(\delta)}{z} &\leq \phi'(\delta) + \varepsilon. \end{aligned}$$

Therefore for any $0 < z < \zeta$,

$$\begin{aligned} Q_\eta(-z-\delta) - Q_\eta(-\delta) &= \eta\left[\phi(-z-\delta) - \phi(-\delta)\right] + (1-\eta)\left[\phi(z+\delta) - \phi(\delta)\right] \\ &\leq -\eta\left[\phi'(-\delta) - \varepsilon\right] z + (1-\eta)\left[\phi'(\delta) + \varepsilon\right] z \\ &= \left(\left[(1-\eta)\phi'(\delta) - \eta\phi'(-\delta)\right] + \varepsilon\right) z. \end{aligned}$$

Recall that $(1-\eta)\phi'(\delta) - \eta\phi'(-\delta) < 0$. By setting ε small enough, we can ensure that $(1-\eta)\phi'(\delta) - \eta\phi'(-\delta) + \varepsilon$ remains negative. Hence

$$Q_\eta(-z-\delta) < Q_\eta(-\delta),$$

which implies that $f_\phi^* \neq -\delta$.

Now consider the case when $\eta > 1-d$. Observe that $Q_\eta(z) = Q_{1-\eta}(-z)$. From the previous discussion,

$$f_\phi^* = \arg\min_z Q_\eta(z) = -\arg\min_z Q_{1-\eta}(-z) > \delta.$$

At last, consider the case when $d < \eta < 1-d$. Observe that in this case,

$$\eta\phi'(\delta) - (1-\eta)\phi'(-\delta) > 0;$$
$$\eta\phi'(-\delta) - (1-\eta)\phi'(\delta) < 0.$$

Hence for any $z > 0$,

$$Q_\eta(z+\delta) - Q_\eta(\delta) \geq \left[\eta\phi'(\delta) - (1-\eta)\phi'(-\delta)\right] z > 0,$$

which implies that $f_\phi^* \leq \delta$. Similarly,

$$Q_\eta(-z-\delta) - Q_\eta(-\delta) \geq \left[-\eta\phi'(-\delta) + (1-\eta)\phi'(\delta)\right] z > 0,$$

which implies that $f_\phi^* \geq -\delta$. In summary, $f_\phi^* \in [-\delta, \delta]$.

We now consider the "only if" part. Let $[a_-, b_-]$ and $[a_+, b_+]$ be the subdifferential of ϕ at $-\delta$ and δ respectively. We need to show that $a_- = b_-$, $a_+ = b_+$ and $a_+/(a_+ + a_-) = d$. We begin by showing that $b_+ \leq 0$. Assume the contrary. The infinite sample consistency implies that for any $\eta > 1-d$, $f_\phi^* > \delta$. Because $b_+ > 0$, we have $\phi(f_\phi^*) > \phi(\delta)$. Together with the fact that $Q_\eta(f_\phi^*) < Q_\eta(\delta)$, this implies that $\phi(-f_\phi^*) < \phi(-\delta)$. Subsequently, we have $a_- > 0$. The convexity of ϕ also suggests that $a_- \leq a_+ \leq b_- \leq b_+$. Because

$$\begin{aligned} \phi(f_\phi^*) - \phi(\delta) &\geq b_+(f_\phi^* - \delta); \\ \phi(-\delta) - \phi(-f_\phi^*) &\leq a_-(f_\phi^* - \delta), \end{aligned}$$

we have

$$Q_\eta(f_\phi^*) - Q_\eta(\delta) \geq (\eta b_+ - (1-\eta)a_-)(f_\phi^* - \delta) > 0.$$

This contradiction suggests that $b_+ \leq 0$.

Given that $a_- \leq a_+ \leq b_- \leq b_+ \leq 0$, we have $|a_-| \geq |a_+| \geq |b_-| \geq |b_+|$, which implies that

$$\frac{b_+}{a_- + b_+} \leq \frac{a_+}{b_- + a_+}.$$

It suffices to show that

$$\frac{b_+}{a_- + b_+} \geq d \qquad \text{and} \qquad \frac{a_+}{b_- + a_+} \leq d.$$

Assume the contrary. First consider the case when $b_+/(a_- + b_+) < d$. Let η be such that $b_+/(a_- + b_+) < \eta < d$. By definition, for any $f < -\delta$,

$$\begin{aligned} \phi(f) - \phi(-\delta) &\geq a_-(f + \delta); \\ \phi(-f) - \phi(\delta) &\geq b_+(-f - \delta). \end{aligned}$$

Hence

$$Q_\eta(f) - Q_\eta(-\delta) \geq [\eta a_- - (1-\eta)b_+](f + \delta) > 0,$$

which implies that $\arg\min Q_\eta(z) \geq -\delta$. This contradicts with the infinite sample consistency. Therefore, $b_+/(a_-+b_+) \geq d$. Next we deal with the case of $a_+/(b_-+a_+) > d$. Let η be such that $a_+/(b_-+a_+) > \eta > d$. Following a similar argument as before, one can show that $Q_{1-\eta}(f) - Q_{1-\eta}(\delta) > 0$ for any $f > \delta$, which implies that $\arg\min Q_\eta(z) \leq \delta$. This again contradicts infinite sample consistency because $1-\eta < 1-d$. Therefore, $a_+/(b_-+a_+) \leq d$.

The proof is now concluded. ∎

Proof of Theorem 9. Recall that

$$Q_\eta(f) = \eta\phi(f) + (1-\eta)\phi(-f).$$

Similarly, write

$$R_\eta[C(f,\delta)] = \eta\ell(C(f,\delta),1) + (1-\eta)\ell(C(f,\delta),-1).$$

Also write $\Delta Q_\eta(f) = Q_\eta(f) - \inf Q_\eta(f)$ and $\Delta R_\eta(f) = R_\eta(f) - \inf R_\eta(f)$. It suffices to show that

$$\Delta R_\eta[C(f,\delta)] \leq 2C\left[\Delta Q_\eta(f)\right]^{1/s}. \tag{10}$$

The theorem can be deduced from (10) by Jensen's inequality:

$$\begin{aligned}
\Delta R[C(f,\delta)] &= \mathbb{E}\left[\Delta R_{\eta(X)}[C(f(X),\delta)]\right] \\
&\leq 2C\mathbb{E}\left[\Delta Q_{\eta(X)}(f(X))\right]^{1/s} \\
&\leq 2C\left(\mathbb{E}\left[\Delta Q_{\eta(X)}(f(X))\right]\right)^{1/s} \\
&= 2C\left[\Delta Q(f)\right]^{1/s}.
\end{aligned}$$

To show (10), we consider separately the different combinations of values of η and f. For brevity, we shall abbreviate their dependence on X in what follows.

Case 1. $\eta < d$ and $f < -\delta$. As shown before, in this case $f^*_\phi(X) < -\delta$. Thus,

$$\Delta R_\eta[C(f,\delta)] = 0 \leq C\left[\Delta Q_\eta(f)\right]^{1/s}.$$

Case 2. $\eta < d$ and $|f| < \delta$. Observe that

$$Q_\eta(f) - Q_\eta(-\delta) \geq \left[\eta\phi'(-\delta) - (1-\eta)\phi'(\delta)\right](f+\delta) = \frac{-\phi'(\delta)}{d}(d-\eta)(f+\delta) \geq 0.$$

Together with the fact that $C^s\Delta Q_\eta(-\delta) \geq |\eta-d|^s$, we have

$$\Delta Q_\eta(f) \geq \Delta Q_\eta(-\delta) \geq C^{-s}|\eta-d|^s.$$

Note that

$$\Delta R_\eta[C(f,\delta)] = d-\eta.$$

We have

$$\Delta R_\eta[C(f,\delta)] \leq C\left[\Delta Q_\eta(f)\right]^{1/s}.$$

Case 3. $\eta < d$ and $f > \delta$. Observe that

$$Q_\eta(f) - Q_\eta(\delta) \geq \left[\eta\phi'(\delta) - (1-\eta)\phi'(-\delta)\right](f-\delta) = \frac{-\phi'(\delta)}{d}(1-\eta-d)(f-\delta) \geq 0.$$

Together with the facts that $d < 1/2$ and $C^s \Delta Q_\eta(\delta) \geq |1-\eta-d|^s$, we have

$$\Delta Q_\eta(f) \geq \Delta Q_\eta(\delta) \geq C^{-s}|1-\eta-d|^s \geq (2C)^{-s}|1-2\eta|^s.$$

Note that

$$\Delta R_\eta[C(f,\delta)] = 1-2\eta.$$

Therefore,

$$\Delta R_\eta[C(f,\delta)] \leq 2C\left[\Delta Q_\eta(f)\right]^{1/s}.$$

Case 4. $d < \eta < 1-d$ and $f < -\delta$. Following a similar argument as before,

$$Q_\eta(f) - Q_\eta(-\delta) \geq \frac{-\phi'(\delta)}{d}(d-\eta)(f+\delta) \geq 0.$$

Therefore,

$$\Delta Q_\eta(f) \geq \Delta Q_\eta(-\delta) \geq C^{-s}|\eta-d|^s,$$

which, together with the fact that $\Delta R_\eta[C(f,\delta)] = \eta - d$, implies that

$$\Delta R_\eta[C(f,\delta)] \leq C\left[\Delta Q_\eta(f)\right]^{1/s}.$$

Case 5. $d < \eta < 1-d$ and $|f| < \delta$. In this case,

$$\Delta R_\eta[C(f,\delta)] = 0 \leq C\left[\Delta Q_\eta(f)\right]^{1/s}.$$

Case 6. $d < \eta < 1-d$ and $f > \delta$. Observe that

$$Q_\eta(f) - Q_\eta(\delta) \geq \frac{-\phi'(\delta)}{d}(1-\eta-d)(f-\delta) \geq 0.$$

Hence

$$\Delta Q_\eta(f) \geq \Delta Q_\eta(\delta) \geq C^{-s}|1-\eta-d|^s,$$

which, together with the fact that $\Delta R_\eta[C(f,\delta)] = 1-\eta-d$, implies that

$$\Delta R_\eta[C(f,\delta)] \leq C\left[\Delta Q_\eta(f)\right]^{1/s}.$$

Case 7. $\eta > 1-d$. Observe that $R_\eta[C(f,\delta)] = R_{1-\eta}[C(-f,\delta)]$, and $Q_\eta(f) = Q_{1-\eta}(-f)$. Because $1-\eta < d$, from Cases 1, 2 and 3, we have

$$\begin{aligned}
\Delta R_\eta[C(f,\delta)] &= \Delta R_{1-\eta}[C(-f,\delta)] \\
&\leq 2C\left[\Delta Q_{1-\eta}(-f)\right]^{1/s} \\
&= 2C\left[\Delta Q_\eta(f)\right]^{1/s}.
\end{aligned}$$

The proof is therefore completed. ∎

Proof of Theorem 10. The proof follows from the same argument as that of Theorem 9. The only difference takes place in Case 3 where under the current assumptions

$$\Delta R_\eta(f) = 1 - 2\eta \le C\left[\Delta Q_\eta(\delta)\right]^{1/s}. \blacksquare$$

Proof of Theorem 11. The last part of the proof is based on the proof of Theorem 3 in Bartlett, Jordan and McAuliffe (2006). Let $g = C(f,\delta)$ be the classification rule with reject option based on $f : \mathcal{X} \to \mathbb{R}$ and set $g^* = C(f^*_\phi,\delta)$. We have shown above that under the assumptions of Theorem 9,

$$\begin{aligned}
|d-\eta|1\{g \neq g^*\}\left(1\{g=-1\}+1\{g^*=-1\}\right) &\le C\left[\Delta Q_\eta(f)\right]^{1/s} \\
|1-d-\eta|1\{g \neq g^*\}\left(1\{g=1\}+1\{g^*=1\}\right) &\le C\left[\Delta Q_\eta(f)\right]^{1/s}.
\end{aligned}$$

Moreover, Lemma 1 in Herbei and Wegkamp (2006) states that

$$\begin{aligned}
\Delta R(g) &= \mathbb{E}\left[|d-\eta(X)|1\{g(X) \neq g^*(X)\}\left(1\{g(X)=-1\}+1\{g^*(X)=-1\}\right)\right] \\
&\quad +\mathbb{E}\left[|1-d-\eta(X)|1\{g(X) \neq g^*(X)\}\left(1\{g(X)=1\}+1\{g^*(X)=1\}\right)\right].
\end{aligned} \tag{11}$$

Hence, for any $\varepsilon > 0$,

$$\begin{aligned}
&\Delta R(g) \\
&= \mathbb{E}\left[|d-\eta(X)|1\{d-\eta(X)| \le \varepsilon\}1\{g(X) \neq g^*(X)\}\left(1\{g(X)=-1\}+1\{g^*(X)=-1\}\right)\right] \\
&+\mathbb{E}\left[|d-\eta(X)|1\{d-\eta(X)| > \varepsilon\}1\{g(X) \neq g^*(X)\}\left(1\{g(X)=-1\}+1\{g^*(X)=-1\}\right)\right] \\
&+\mathbb{E}\left[|1-d-\eta(X)|1\{|1-d-\eta(X)| \le \varepsilon\}1\{g(X) \neq g^*(X)\}\left(1\{g(X)=1\}+1\{g^*(X)=1\}\right)\right] \\
&+\mathbb{E}\left[|1-d-\eta(X)|1\{|1-d-\eta(X)| > \varepsilon\}1\{g(X) \neq g^*(X)\}\left(1\{g(X)=1\}+1\{g^*(X)=1\}\right)\right] \\
&\le 2\varepsilon\mathbb{P}\{g^*(X) \neq g(X)\} + 2\varepsilon^{1-s}\Delta Q(f)
\end{aligned}$$

where we used (11) and the inequality $|x|1\{|x| \ge \varepsilon\} \le |x|^r\varepsilon^{1-r}$ for $r \ge 1$. Using the bound

$$\mathbb{P}\{g(X) \neq g^*(X)\} \le \left[2(8A)^{1/\alpha}\Delta R(g)\right]^\beta$$

from the proof of Lemma 4 of Herbei and Wegkamp (2006), and choosing

$$\varepsilon = c\left[\Delta R(g)\right]^{1-\beta}$$

with $c = [2(8A)^{1/\alpha}]^\beta/4$ readily gives the desired claim with $K = 4Cc^{1-s}$. $\blacksquare$

Proof of Theorem 18. Recall that $\bar{f} \in \mathcal{F}$ minimizes $Q(f)$ over $f \in \mathcal{F}$. Let $h(yf(x)) = \phi(yf(x)) - \phi(y\bar{f}(x))$. Since

$$\begin{aligned}
\frac{Q(f)+Q(\bar{f})}{2} &\ge Q\left(\frac{f+\bar{f}}{2}\right) + c\mathbb{E}\left[(f-\bar{f})^2(X)\right] \\
&\ge Q(\bar{f}) + c\mathbb{E}\left[(f-\bar{f})^2(X)\right],
\end{aligned}$$

we have

$$\begin{aligned}
\mathbb{E}\left[h^2(Yf(X))\right] &\le L^2\mathbb{E}\left[(f-\bar{f})^2(X)\right] \\
&\le \frac{L^2}{2c}\{Q(f)-Q(\bar{f})\} \\
&= \frac{L^2}{2c}\mathbb{E}\left[h(Yf(X))\right],
\end{aligned}$$

see, for example, Bartlett, Jordan and McAuliffe (2006). Since $\widehat{f}_n$ minimizes $Q_n(f)$, we have

$$\begin{aligned} Q(\widehat{f}_n) - Q(\bar{f}) &= Ph(y\widehat{f}_n(x)) \\ &= 2\mathbb{P}_n h(Y\widehat{f}_n(X)) + (P - 2\mathbb{P}_n)h(Y\widehat{f}_n(X)) \\ &\leq 2\mathbb{P}_n h(Y\bar{f}(X)) + (P - 2\mathbb{P}_n)h(Y\widehat{f}_n(X)) \\ &\leq \sup_{f\in\mathcal{F}}(P - 2\mathbb{P}_n)h(Yf(X)) \end{aligned}$$

where $\mathbb{P}h(Yf(X)) = \mathbb{E}[h(Yf(X))]$ and $\mathbb{P}_n h(Yf(X)) = (1/n)\sum_{i=1}^n h(Y_i f(X_i))$ for any $f \in \mathcal{F}$. Next we observe that

$$\sup_{f\in\mathcal{F}}(\mathbb{P} - 2\mathbb{P}_n)h(Yf(X)) \leq \frac{3L}{n} + \max_{f\in\mathcal{F}_n}(\mathbb{P} - 2\mathbb{P}_n)h(Yf(X))$$

where $\mathcal{F}_n$ is the minimal $1/n$-net of $\mathcal{F}$. By Bernstein's inequality, we get

$$\begin{aligned} \mathbb{P}\left\{\sup_{f\in\mathcal{F}_n}(\mathbb{P} - 2\mathbb{P}_n)h(Yf(X)) \geq t\right\} &\leq N_n \exp\left[-\frac{n\{t + \mathbb{P}h(Yf(X))\}^2/8}{\mathbb{P}h^2(Yf(X)) + (2LB)\{t + \mathbb{P}h(Yf(X))\}/6}\right] \\ &\leq N_n \exp\left[-\frac{nt}{8}\left(\frac{L^2}{2c} + \frac{LB}{3}\right)^{-1}\right] \end{aligned}$$

and the conclusion follows easily. ∎

Abstract

There are many different methods used by classification tree algorithms when missing data occur in the predictors, but few studies have been done comparing their appropriateness and performance. This paper provides both analytic and Monte Carlo evidence regarding the effectiveness of six popular missing data methods for classification trees applied to binary response data. We show that in the context of classification trees, the relationship between the missingness and the dependent variable, as well as the existence or non-existence of missing values in the testing data, are the most helpful criteria to distinguish different missing data methods. In particular, separate class is clearly the best method to use when the testing set has missing values and the missingness is related to the response variable. A real data set related to modeling bankruptcy of a firm is then analyzed. The paper concludes with discussion of adaptation of these results to logistic regression, and other potential generalizations.

Keywords: classification tree, missing data, separate class, RPART, C4.5, CART

1. Classification Trees and the Problem of Missing Data

Classification trees are a supervised learning method appropriate for data where the response variable is categorical. The simple methodology behind classification trees is to recursively split data based upon the predictors that best distinguish the response variable classes. There are, of course, many subtleties, such as the choice of criterion function used to pick the best split variable, stopping rules, pruning rules, and so on. In this study, we mostly rely on the built-in features of the tree algorithms C4.5 and RPART to implement tree methods. Details about classification trees can be found in various references, for example, Breiman, Friedman, Olshen, and Stone (1998) and Quinlan (1993). Classification trees are computationally efficient, can handle mixed variables (continuous and discrete) easily and the rules generated by them are relatively easy to interpret and understand. Classification trees are highly flexible, and naturally uncover interaction effects among the independent variables. Classification trees are also popular because they can easily be incorporated into learning ensembles or larger learning systems as base learners.

Like most statistics or machine learning methods, "base form" classification trees are designed assuming that data are complete. That is, all of the values in the data matrix, with the rows being the observations (instances) and the columns being the variables (attributes), are observed. However, missing data (meaning that some of the values in the data matrix are not observed) is a very common problem, and for this reason classification trees have to, and do, have ways of dealing with missing data in the predictors. (In supervised learning, an observation with missing response value has no information about the underlying relationship, and must be omitted. There is, however, research in the field of semi-supervised learning methods that tries to handle the situation where the response value is missing, for example, Wang and Shen 2007.)

Although there are many different ways of dealing with missing data in classification trees, there are relatively few studies in the literature about the appropriateness and performance of these missing data methods. Moreover, most of these studies limited their coverage to the simplest missing data scenario, namely, missing completely at random (MCAR), while our study shows that the missing data generating process is one of the two crucial criteria in determining the best missing data method. The other crucial criterion is whether or not the testing set is complete. The following two subsections describe in more detail these two criteria.

1.1 Different Types of Missing Data Generating Process

Data originate according to the data generating process (DGP) under which the data matrix is "generated" according to the probabilistic relationships between the variables. We can think of the missingness itself as a random variable, realized as the matrix of the missingness indicator I_m. I_m is generated according to the missingness generating process (MGP), which governs the relationship between I_m and the variables in the data matrix. I_m has the same dimension as the original data matrix, with each entry equal to 0 if the corresponding original data value is observed and 1 if the corresponding original data value is not observed (missing). Note that an I_m value not only can be related to its corresponding original data value, but can also be related to other variables of the same observation.

Depending on the relationship between I_m and the original data, Rubin (1976) and Little and Rubin (2002) categorize the missingness into three different types. If I_m is dependent upon the missing values (the unobserved original data values), then the missingness pattern is called "not missing at random" (NMAR). Otherwise, the missingness pattern is called "missing at random" (MAR). As a special case of MAR, when the missingness is also not dependent on the observed values (that is, is independent of all data values), the missingness pattern is called "missing completely at random" (MCAR). The definition of MCAR is rather restrictive, which makes MCAR unlikely in reality. For example, in the bankruptcy data discussed later in the paper, there is evidence that after the Enron scandal in 2001, when both government and the public became more wary about financial reporting misconduct, missingness of values in financial statement data was related to the well-being of the company, and thus other values in the data. This makes intuitive sense because when scrutinized, a company is more likely to have trouble reporting their financial data if there were problems. Thus, focusing on the MCAR case is a major limitation that will be avoided in this paper. In fact, this paper shows that the categorization of MCAR, MAR and NMAR itself is not appropriate for the missing data problem in classification trees, as well as in another supervised learning context (at least with respect to prediction), although it has been shown to be helpful with likelihood-based or Bayesian analysis.

	Missingness is related to				
	Missing values	Observed Predictors	Response Variable	LR	Three-Letter
1	No	No	No	MCAR	$---$
2	No	Yes	No	MAR	$-X-$

4	Yes	Yes	No	NMAR	$MX-$
5	No	No	Yes	MAR	$--Y$
6	No	Yes	Yes	MAR	$-XY$
7	Yes	No	Yes	NMAR	$M-Y$
8	Yes	Yes	Yes	NMAR	MXY

Table 1: Eight missingness patterns investigated in this study and their correspondence to the categorization MCAR, MAR and NMAR defined by Rubin (1976) and Little and Rubin (2002) (the LR column). The column Three-Letter shows the notation that is used in this paper.

In this paper, we investigate eight different missingness patterns, depending on the relationship between the missingness and three types of variables, the observed predictors, the unobserved predictors (the missing values) and the response variable. The relationship is conditional upon other factors, for example, missingness is not dependent upon the missing values means that the missingness is conditionally independent of the missing values given the observed predictors and/or the response variable. Table 1 shows their correspondence with the MCAR/MAR/NMAR categorization as well as the three-letter notation we use in this paper. The three letters indicate if the missingness is conditionally dependent on the missing values (M), on other predictors (X) and on the response variable (Y), respectively. As will be shown, the dependence of the missingness on the response variable (the letter Y) is the one that affects the choice of best missingness data method. Later in the paper, some derived notations are also used. For example, $*X*$ means the union of $-X-$, $-XY$, $MX-$ and MXY, that is, the missingness is dependent upon the observed predictors, and it may or may not be related to the missing values and/or the response variable.

1.2 Scenarios Where the Testing Data May or May Not Be Complete

There are essentially two stages of applying classification trees, the training phase where the historical data (training set) are used to construct the tree, and the testing phase where the tree is put into use and applied to testing data. Similar to most other studies, this study deals with the scenario where missing data occur in the training set, but the testing set may or may not have missing values. One basic assumption is, of course, that the DGP (as well as MGP if the testing set also contains missing values) is the same for both the training set and the testing set.

While it would probably typically be the case that the testing data would also have missing values (generated by the same process that generated them in the training set), it should be noted that in certain circumstances a testing set without missing values could be expected. For example, consider a problem involving prediction of bankruptcy from various financial ratios. If the training set comes from a publicly available database, there could be missing values corresponding to information that was not supplied by various companies. If the goal is to use these publicly available data to try

to predict bankruptcy from ratios from one's own company, it would be expected that all of the necessary information for prediction would be available, and thus the test set would be complete.

This study shows that when the missingness is dependent upon the response variable and the test set has missing values, separate class is the best missing data method to use. In other situations, the choice is not as clear, but some insights on effective choices are provided. The rest of paper provides detailed theoretical and empirical analysis and is organized as follows. Section 2 gives a brief introduction to the previous research on this topic. This is followed by discussion of the design of this study and findings in Section 3. The generality of the results are then tested on real data sets in Section 4. A brief extension of the results to logistic regression is presented in Section 5. We conclude with discussion of these results and future work in Section 6.

2. Previous Research

There have been several studies of missing data and classification trees in the literature. Liu, White, Thompson, and Bramer (1997) gave a general description of the problem, but did not discuss solutions. Saar-Tsechansky and Provost (2007) discussed various missing data methods in classification trees and proposed a cost-sensitive approach to the missing data problem for the scenario when missing data occur only at the testing phase, which is different from the problem studied here (where missing values occur in the training phase).

Kim and Yates (2003) conducted a simulation study of seven popular missing value methods but did not find any dominant method. Feelders (1999) compared the performance of surrogate split and imputation and found the imputation methods to work better. (These methods, and the methods described below, are described more fully in the next section.) Batista and Monard (2003) compared four different missing data methods, and found that 10 nearest neighbor imputation outperformed other methods in most cases. In the context of cost sensitive classification trees, Zhang, Qin, Ling, and Sheng (2005) studied four different missing data methods based on their performances on five data sets with artificially generated random missing values. They concluded that the internal node method (the decision rules for the observations with the next split variable missing will be made at the (internal) node) is better than the other three methods examined. Fujikawa and Ho (2002) compared several imputation methods based on preliminary clustering algorithms to probabilistic split on simulations based on several real data sets and found comparable performance. A weakness of all of the above studies is that they focused only on the restrictive MCAR situation.

Other studies examined both MAR and NMAR missingness. Kalousis and Hilario (2000) used simulations from real data sets to examine the properties of seven algorithms: two rule inducers, a nearest neighbor method, two decision tree inducers, a naive Bayes inducer, and linear discriminant analysis. They found that the naive Bayes method was by far most resilient to missing data, in the sense that its properties changed the least when the missing rate was increased (note that this resilience is related to, but not the same as, its overall predictive performance). They also found that the deleterious effects of missing data are more serious if a given amount of missing values are spread over several variables, rather than concentrated in a few.

Twala (2009) used computer simulations based on real data sets to compare the properties of different missing value methods, including using complete cases, single imputation of missing values, likelihood-based multiple imputation (where missing values are imputed several times, and the results of fitting trees to the different generated data sets are combined), probabilistic split, and surrogate split. He studied MAR, MCAR, and NMAR missingness generating processes, although

dependence of missingness on the response variable was not examined. Multiple imputation was found to be most effective, with probabilistic split also performing reasonably well, although little difference was found between methods when the proportion of missing values was low. As would be expected, MCAR missingness caused the least problems for methods, while NMAR missingness caused the most, and as was also found by Kalousis and Hilario (2000), missingness spread over several predictors is more serious than if it is concentrated in only one. Twala, Jones, and Hand (2008) proposed a method closely related to creating a separate class for missing values, and found that its performance was competitive with that of likelihood-based multiple imputation.

The study described in the next section extends these previous studies in several ways. First, theoretical analyses are provided for simple situations that help explain observed empirical performance. We then extend these analyses to more complex situations and data sets (including large ones) using Monte Carlo simulations based on generated and real data sets. The importance of whether missing is dependent on the response variable, which has been ignored in previous studies on classification trees yet turns out to be of crucial importance, is a fundamental aspect of these results. The generality of the conclusions is finally tested using real data sets and application to logistic regression.

3. The Effectiveness of Missing Data Methods

The recursive nature of classification trees makes them almost impossible to analyze analytically in the general case beyond 2×2 tables (where there is only one binary predictor and a binary response variable). On the other hand, trees built on 2×2 tables, which can be thought of as "stumps" with a binary split, can be considered as degenerate classification trees, with a classification tree being built (recursively) as a hierarchy of these degenerate trees. Therefore, analyzing 2×2 tables can result in important insights for more general cases. We then build on the 2×2 analyses using Monte Carlo simulation, where factors that might have impact on performance are incrementally added, in order to see the effect of each factor. The factors include variation in both the data generating process (DGP) and the missing data generating process (MGP), the number and type of predictors in the data, the number of predictors that contain missing values, and the number of observations with missing data.

This study examines six different missing data methods: probabilistic split, complete case method, grand mode/mean imputation, separate class, surrogate split, and complete variable method. Probabilistic split is the default method of C4.5 (Quinlan, 1993). In the training phase, observations with values observed on the split variable are split first. The ones with missing values are then put into each of the child nodes with a weight given as the proportion of non-missing instances in the child. In the testing phase, an observation with a missing value on a split variable will be associated with all of the children using probabilities, which are the weights recorded in the training phase. The complete case method deletes all observations that contain missing values in any of the predictors in the training phase. If the testing set also contains missing values, the complete case method is not applicable and thus some other method has to be used. In the simulations, we use C4.5 to realize the complete case method. In the training phase, we manually delete all of the observations with missing values and then run C4.5 on the pre-processed remaining complete data. In the testing phase, the default missing data method, probabilistic split, is used. Grand mode imputation imputes the missing value with the grand mode of that variable if it is categorical. Grand mean is used if the variable is continuous. The separate class method treats the missing values as a new class

(category) of the predictor. This is trivial to apply when the original variable is categorical, where we can create a new category called "missing". To apply the separate class method to a numerical variable, we give all of the missing values a single extremely large value that is obviously outside of the original data range. This creates the needed separation between the nonmissing values and the missing values, implying that any split that involves the variable with missing values will put all of the missing observations into the same branch of the tree. Surrogate split is the default method of CART (realized using RPART in this study; Breiman et al. 1998 and Therneau and Atkinson 1997). It finds and uses a surrogate variable (or several surrogates in order) within a node if the variable for the next split contains missing values. In the testing phase, if a split variable contains missing values, the surrogate variables in the training phase are used instead. The complete variable method simply deletes all variables that contain missing values.

Before we start presenting results, we define a performance measure that is appropriate for measuring the impact of missing data. Accuracy, calculated as the percentage of correctly classified observations, is often used to measure the performance of classification trees. Since it can be affected by both the data structure (some data are intrinsically easier to classify than others) and by the missing data, this is not necessarily a good summary of the impact of missing data. In this study, we define a measure called *relative accuracy* (*RelAcc*), calculated as

$$RelAcc = \frac{\text{Accuracy with missing data}}{\text{Accuracy with original full data}}.$$

This can be thought of as a standardized accuracy, as *RelAcc* measures the accuracy achievable with missing values relative to that achievable with the original full data.

3.1 Analytical Results

In the following consistency theorems, the data are assumed to reflect the DGP exactly, and therefore the training set and the testing set are exactly the same. Several of the theorems are for 2×2 tables, and in those cases stopping and pruning rules are not relevant, since the only question is whether or not the one possible split is made. The proofs are thus dependent on the underlying parameters of the DGP and MGP, rather than on data randomly generated from them. It is important to recognize that these results are only designed to be illustrative of the results found in the much more realistic simulation analyses to follow. Proofs of all of the results are given in the appendix.

Before presenting the theorems, we define some terms to avoid possible confusion. First, a partition of the data refers to the grouping of the observations defined by the classification tree's splitting rules. Note that it is possible for two different trees on the same data set to define the same partition. For example, suppose that there are only two binary explanatory variables, X_1 and X_2, and one tree splits on X_1 then X_2 while another tree splits on X_2 then X_1. In this case, these two trees have different structures, but they can lead to the same partition of the data. Secondly, the set of rules defined by a classification tree consists of the rules defined by the tree leaves on each of the groups (the partition) of the data.

3.1.1 WHEN THE TEST SET IS FULLY OBSERVED WITH NO MISSING VALUES

We start with Theorems 1 to 3 that apply to the complete case method. Theorems 4 and 5 apply to probabilistic split and mode imputation, respectively. Proofs of the theorems can be found in the appendix.

Theorem 1 *Complete Case Method: If the MGP is conditionally independent of Y given X, then the tree built on the data containing missing values using the complete case method gives the same set of rules as the tree built on the original full data set.*

Theorem 2 *Complete Case Method: If the partition of the data defined by the tree built on the incomplete data is not changed from the one defined by the tree built on the original full data, the loss in accuracy when the testing set is complete is bounded above by P_M, where P_M is the missing rate, defined as the percentage of observations that contain missing values.*

Theorem 3 *Complete Case Method: If the partition of the data defined by the tree built on the incomplete data is not changed from the one defined by the tree built on the original full data, the relative accuracy when the testing set is complete is bounded below by*

$$RelAcc_{min} = \frac{1-P_M}{1+P_M},$$

where P_M is the missing rate. Notice that the tree structure itself could change as long as it gives the same final partition of the data.

There are similar results in regression analyses as in Theorem 1. In regression analyses, when the missingness is independent of the response variable, by using only the complete observations, the parameter estimators are all unbiased (Allison, 2001). This implies that in theory, when the missingness is independent of the response variable, using complete cases only is not a bad approach on average. However, in practice, as will be seen later, deleting observations with missing values can cause severe loss in information, and thus has generally poor performance.

Theorem 4 *Probabilistic Split: In a 2×2 data table, if the MGP is independent of either Y or X, given the other variable, then the following results hold for probabilistic split.*

1. *If X is not informative in terms of classification, that is, the majority classes of Y for different X values are the same, then probabilistic split will give the same rule as the one that would be obtained from the original full data;*

2. *If probabilistic split shows that X is informative in terms of classification, that is, the majority classes of Y for different X values are different, then it finds the same rule as the one that would be obtained from the original full data;*

3. *The absolute accuracy when the testing set is complete is bounded below by 0.5. Since the original full data accuracy is at most 1, the relative accuracy is also bounded below by 0.5.*

Theorem 5 *Mode Imputation: If the MGP is independent of Y, given X, then the same results hold for mode imputation as for probabilistic split under the conditions of Theorem 4.*

Theorems 1, 2 and 3 (for the complete case method) are true for general data sets. Theorems 4 and 5 are for 2×2 tables only but they imply that probabilistic split and mode imputation have advantages over the complete case method, which can have very poor performance (as will be shown in Figure 1).

Moreover, with 2×2 tables, the complete variable method will always have a higher than 0.5 accuracy since by ignoring the only predictor, we will always classify all of the data to the overall majority class and achieve at least 0.5 accuracy, and thus at least 0.5 relative accuracy. Together with Theorems 4 and 5, as well as the evidence to be shown in Figure 1, this is an indication that classification trees tend not to be hurt much by missing values, since trees built on 2×2 tables can be considered as degenerate classification trees and more complex trees are composites of these degenerate trees. The performance of a classification tree is the average (weighted by the number of observations at each leaf) over the degenerate trees at the leaf level, and, as will be seen later in the simulations, can often be quite good.

Surrogate split is not applicable to 2×2 tables because there are no other predictors. For 2×2 table problems with a complete testing set, separate class is essentially the same as the complete case method, because as long as the data are split according to the predictor (and it is very likely that this will be so), the separate class method builds separate rules for the observations with missing values; when the testing set is complete, the rules that are used in the testing phase are exactly the ones built on the complete observations. When there is more than one predictor, however, the creation of the "separate class" will save the observations with missing values from being deleted and affect the tree building process. It will very likely lead to a change in the tree structure. This, as will be seen, tends to have a favorable impact on the performance accuracy.

Figure 1 illustrates the lower bound calculated in Theorem 3. The illustration is achieved by Monte Carlo simulation of 2×2 tables. A 2×2 table with missing values has only eight cells, that is, eight different value combinations of the binary variables X, Y and M, where M is the missingness indicator such that $M = 0$ if X is observed and $M = 1$ if X is missing. There is one constraint, that the sum of the eight cell probabilities must equal one. Therefore, this table is determined by seven parameters. In the simulation, for each 2×2 table, the following seven parameters (probabilities) are randomly and independently generated from a uniform distribution between $(0,1)$: (1)$P(X = 1)$, (2)$P(Y = 1|X = 0)$, (3)$P(Y = 1|X = 1)$, (4)$P(M = 1|X = 0,Y = 0)$, (5)$P(M = 1|X = 0,Y = 1)$, (6)$P(M = 1|X = 1,Y = 0)$ and (7)$P(M = 1|X = 1,Y = 1)$. Here we assume the data tables reflect the true underlying DGP and MGP without random variation, and thus the expected performance of the classification trees can be derived using the parameters. In this simulation, sets of the seven parameters are generated (but no data sets are generated using these parameters) repeatedly, and the relative accuracy of each missing data method on each parameter set is determined. One million sets of parameters are generated for each missingness pattern.

In Figure 1, the plot on the left is a scatter plot of relative accuracy versus missing rate for each Monte Carlo replication for the complete case method when the MGP depends on the response variable. The lower bound is clearly shown. We can see that when the missing rate is high, the lower bound can reduce to almost zero (implying that not only relative accuracy, but accuracy itself, can approach zero). This perhaps somewhat counterintuitive result can occur in the following way. Imagine the extreme case where almost all cases are positive and (virtually) all of the positive cases have missing predictor value at the training phase; in this situation the resultant rule will be to classify everything as negative. When this rule is applied to a complete testing set with almost all positive cases, the accuracy will be almost zero. The graph on the right is the quantile version of the scatter plot on the left. The lines shown in the quantile plot are the theoretical lower bound, the 10th, 20th, 30th, 40th and 50th percentile lines from the lowest to the highest. Higher percentile lines are the same as the 50th percentile (median) line, which is already the horizontal line at $RelAcc = 1$. The percentile lines are constructed by connecting the corresponding percentiles in a moving window

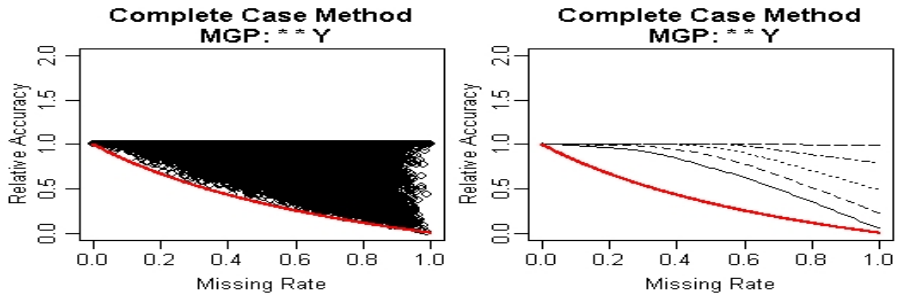

Figure 1: Scatter plot and the corresponding quantile plot of the complete testing set *RelAcc* vs. missing rate of the complete case method when the MGP is dependent on the response variable. Recall that "$* * Y$" means the MGP is conditionally dependent on the response variable but no restriction on the relationship between the MGP and other variables, missing or observed, is assumed. Each point in the scatter plot represents the result on one of the simulated data tables.

of data from the left to the right. Due to space limitations, we do not show quantile plots of other missing data methods and/or under different scenarios, but in all of the other plots, the quantile lines are all higher (that is, the quantile plot in Figure 1 shows the worst case scenario). The plots show that the missing data problem, when the missing rate is not too high, may not be as serious as we might have thought. For example, when 40% of the observations contain missing data, 80% of the time the expected relative accuracy is higher than 90%, and 90% of the time the expected relative accuracy is higher than 80%.

3.1.2 WHEN THE TEST SET HAS MISSING VALUES

Theorem 6 *Separate Class: In 2×2 data tables, if missing values occur in both the training set and the testing set, then the separate class method achieves the best possible performance.*

In the Monte Carlo simulation of the 2×2 tables, the head-to-head comparison between the separate class method and other missing data methods confirmed the uniform dominance of the separate class when the test set also contains missing values, regardless whether the MGP is dependent on the response variable or not. However, as shown in Figure 2, when the MGP is independent of the response variable, separate class never performances better than the performance on the original full data, indicated by relative accuracies less than one. This means that separate class is not gaining from the missingness. On the other hand, when the MGP is dependent on the response variable, a fairly large percentage of the time the relative accuracy of the separate class method is larger than one (the quantiles shown are from the 10th to the 90th percentile with increment 10 percent). This means that trees based on the separate class method can improve on predictive performance compared to the situation where there are no missing data. Our simulations show that other methods can also gain from the missingness when the MGP is dependent on the response variable, but not as frequently as the separate class method and the gains are in general not as large. We follow up on this behavior in more detail in the next section, but the simple explanation is that since missingness depends on the response variable, the tree algorithm can use the presence of missing data in an observation to improve prediction of the response for that observation. Duda, Hart, and Stork (2001) and Hand (1997) briefly mentioned this possibility in the classification context, but did not give any

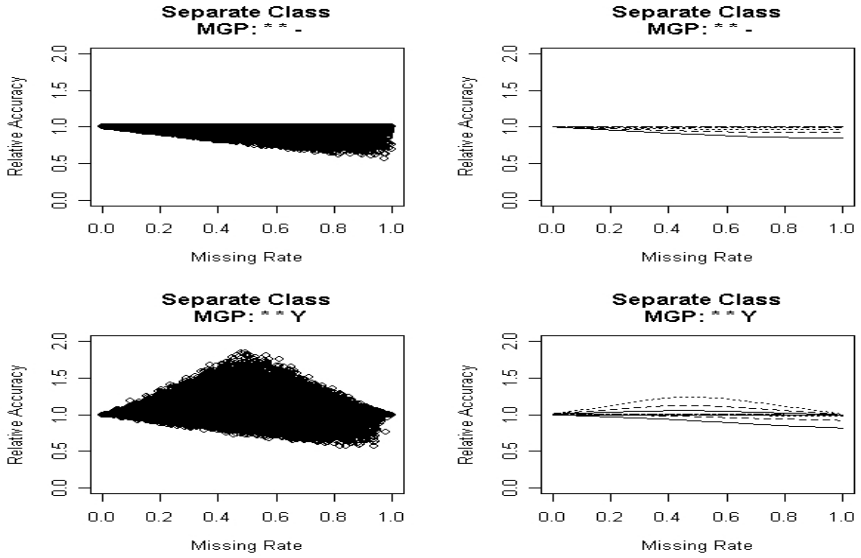

Figure 2: Scatter plot of the separate class method with incomplete testing set. Each point in the scatter plot represents the result on one of the simulated data tables.

supporting evidence. Theorem 6 makes a fairly strong statement in the simple situation, and it will be seen to be strongly indicative of the results in more general cases.

3.2 Monte Carlo Simulations of General Data Sets

In this section extensions of the simulations in the last section are summarized.

3.2.1 AN OVERVIEW OF THE SIMULATION

The following simulations are carried out.

1. 2×2 tables, missing values occur in the only predictor.
2. Up to seven binary predictors, missing values occur in only one predictor.
3. Eight binary predictors, missing values occur in two of them.
4. Twelve binary predictors, missing values occur in six of them.
5. Eight continuous predictors, missing values occur in two of them.
6. Twelve continuous predictors, missing values occur in six of them.

Two different scenarios of each of the last four simulations listed above were performed. In the first scenario, the six complete predictors are all independent of the missing ones, while in the second scenario three of the six complete predictors are related to the missing ones. Therefore, ten simulations were done in total.

In each of the simulations, 5000 sets of DGPs are simulated in order to cover a wide range of different-structured data sets so that a generalizable inference from the simulation is possible. For

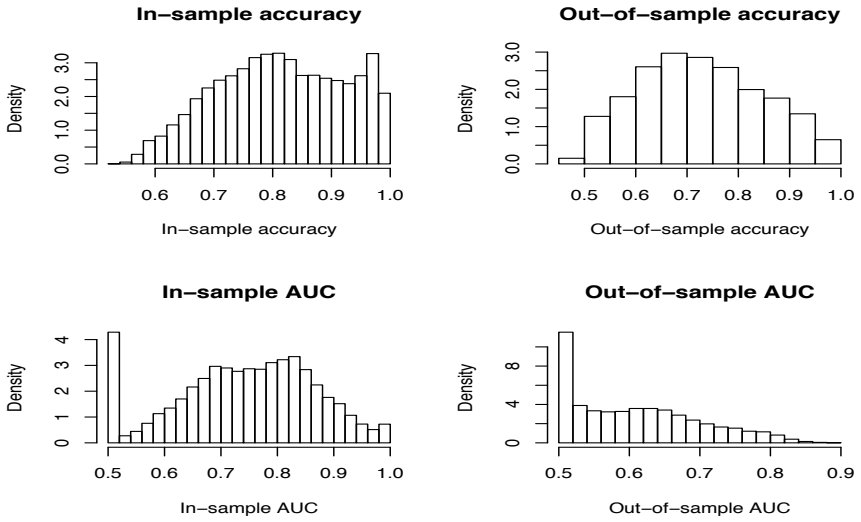

Figure 3: A summary of the tree performance on the simulated original full data.

each DGP, eight different MGPs are simulated to cover different types of missingness patterns. For each data set, the variables are generated sequentially in the order of the predictors, the response and the missingness. The probabilities associated with the binary response variable and the binary missingness variable are generated using conditional logit functions. The predictors may or may not be correlated with each other. Details about the simulations implementation can be found in Ding and Simonoff (2008). For each set of DGP/MGP, several different sample sizes are simulated to see any possible learning curve effect, since it was shown by Perlich, Provost, and Simonoff (2003) that sample size is an important factor in the effectiveness of classification trees. Figure 3 shows the distribution of the tree performance on the simulated original full data, as measured by accuracy and area under the ROC curve (AUC). As we can see, there is broad coverage of the entire range of strength of the underlying relationship. Also, as expected, the out-of-sample performance (on the test set) is generally worse than the in-sample performance (on the training set). When the in-sample AUC is close to 0.5, a tree is likely to not split and as a result, any missing data method will not actually be applied, resulting in equivalent performance over all of them. To make the comparisons more meaningful, we exclude the cases where the in-sample AUC is below 0.7. Lower thresholds for exclusion (0.55 and 0.6) yield very similar results.

Of the six missing data methods covered by this study, five of them, namely, complete case method, probabilistic split, separate class, imputation and complete variable method, are realized using C4.5. These methods are always comparable. However, surrogate split is carried out using RPART, which makes it less comparable to the other methods because of differences between RPART and C4.5 other than the missing data methods. To remedy this problem, we tuned the RPART parameters (primarily the parameter "cp") so that it gives balanced results compared to C4.5 when applied to the original full data (i.e., each has a similar probability of outperforming the other), and special attention is given when comparing RPART with other methods. The out-of-sample performances of each pair of missing data methods were compared based on both t-tests and nonparametric tests; each difference discussed in the following sections was strongly statistically significant.

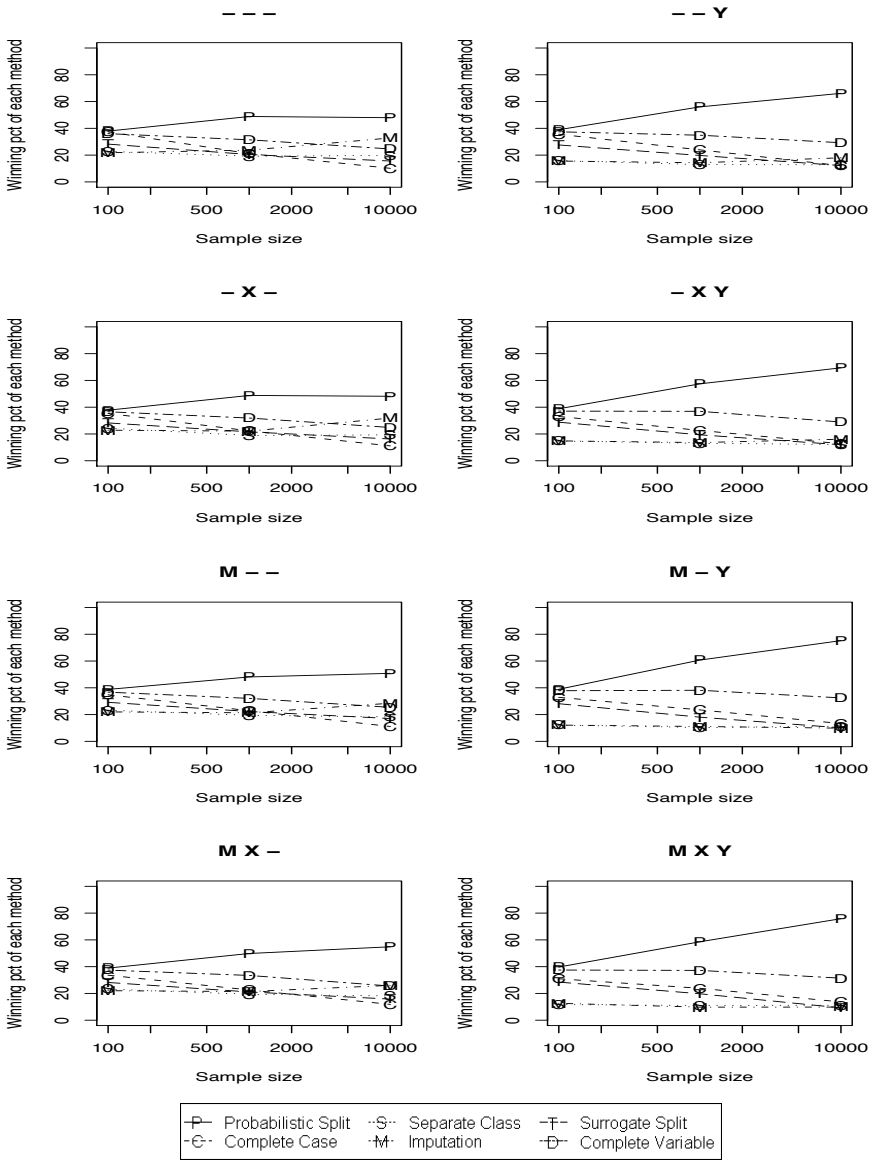

Figure 4: A summary of the order of six missing data methods when tested on a new complete testing set. The Y axis is the percentage of times each method is the best (including being tied with other methods; therefore the percentages do not sum up to one).

3.2.2 THE TWO FACTORS THAT DETERMINE THE PERFORMANCE OF DIFFERENT MISSING DATA METHODS

The simulations make clear that the dependence relationship between the missingness and the response variable is the most informative factor in differentiating different missing data methods, and thus is most helpful in determining the appropriateness of the methods. This can be clearly seen in Figures 4 and 5 (these figures refer to the case with twelve continuous predictors, six of which are subject to missing values, but results for other situations were broadly similar). The left column in

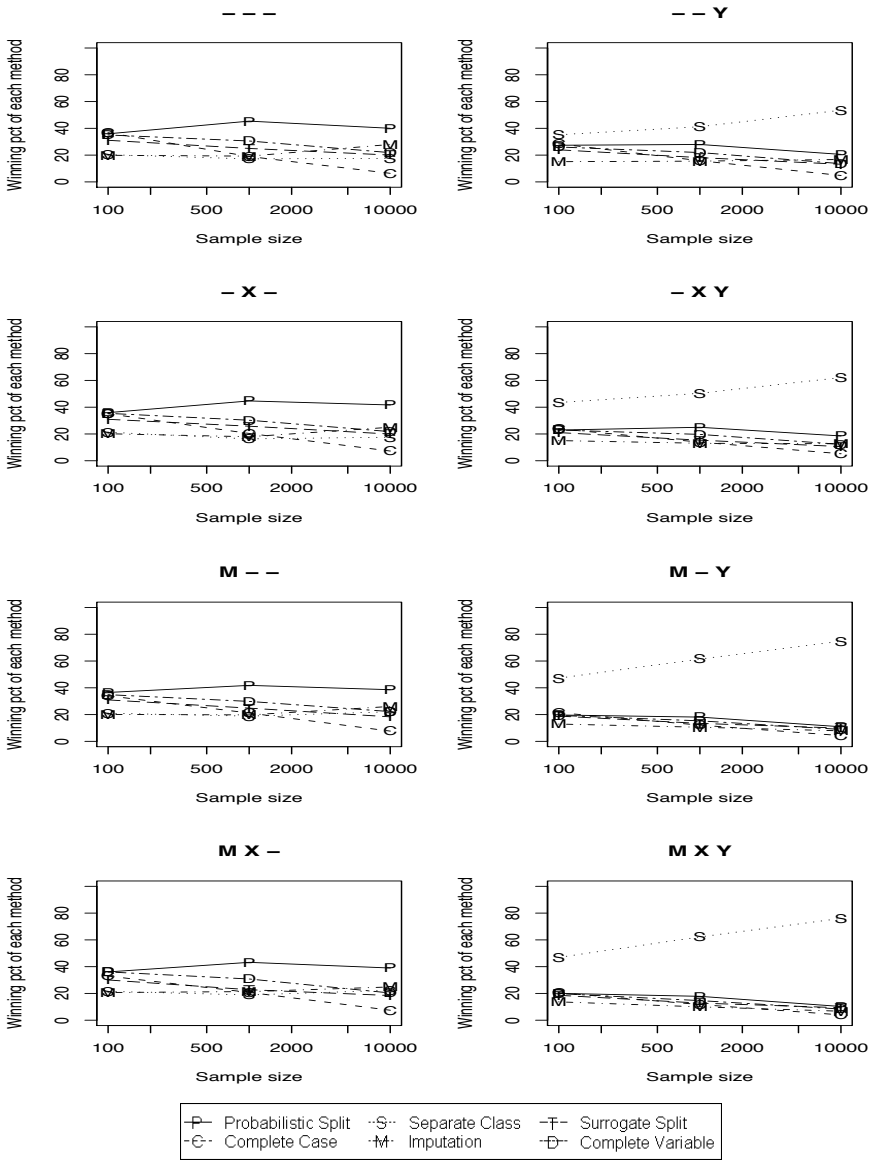

Figure 5: A summary of the order of six missing data methods when tested on a new incomplete testing set. The Y axis is the percentage of times each method is the best (including being tied with other methods).

the pictures shows the results when the missingness is independent of the response variable and the right column shows the results when the missingness is dependent on the response variable. We can see that there are clear differences between the two columns, but within each column there is essentially no difference. This also says the categorization of MCAR/MAR/NMAR (which is based upon the dependence relationship between the missingness and missing values, and does not distinguish the dependence of the missingness on other Xs and on Y) is not helpful in this context.

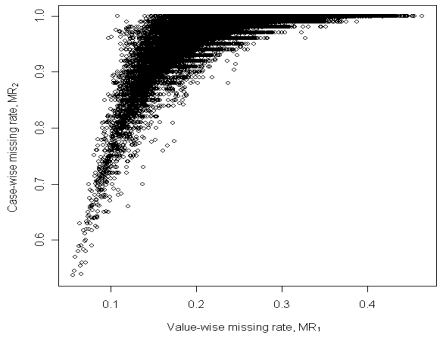

Figure 6: Plot of the case-wise missing rate MR_2 versus the value-wise missing rate MR_1 in the simulations using the 36 real data sets.

Comparison of the right columns of Figures 4 and 5 shows that whether or not there are missing values in the testing set is the second important criterion in differentiating between the methods. The separate class method is strongly dominant when the testing set contains missing values and the missingness is related to the response variable. The reason for this is that when missing data exist in both the training phase and the testing phase, they become part of the data and the MGP becomes an essential part of the DGP. This, of course, requires the assumption that the MGP (as well as the DGP) is the same in both the training phase and the testing phase. Under this scenario, if the missingness is related to the response variable, then there is information about the response variable in the missingness, which should be helpful when making predictions. Separate class, by taking the missingness directly as an "observed" variable, uses the information in the missingness about the response variable most effectively and thus is the best method to use. As a matter of fact, as can be seen in the bottom rows of Figures 7 and 8 (which give average relative accuracies separated by missing rate), the average relative accuracy of separate class under this situation is larger than one, indicating, on average, a better performance than with the original full data.

On the other hand, when the missing data only occur in the training phase and the testing set does not have missing values, or when the missingness is not related to and carries no information about the response variable, the existence of missing values is a nuisance. Its only effect is to obscure the underlying DGP and thus would most likely reduce a tree's performance. In this case, simulations show probabilistic split to be the dominantly best method. However, we don't see this dominance later in results based on real data sets. More discussion of this point will follow in Section 4.

3.2.3 MISSING RATE EFFECT

There are two ways of defining the missing rate: the percentage of predictor values that are missing from the data set (the value-wise missing rate, termed here MR_1), and the percentage of observations that contain missing values (the case-wise missing rate, termed here MR_2). If there is only one predictor, as is the case with 2×2 tables, then the two definitions are the same. We have seen earlier in the theoretical analyses that the missing rate has a clear impact on the performance of the missing data methods. In the simulations, there is also evidence of a relationship between relative performance and missing rate, whichever definition is used to define the missing rate.

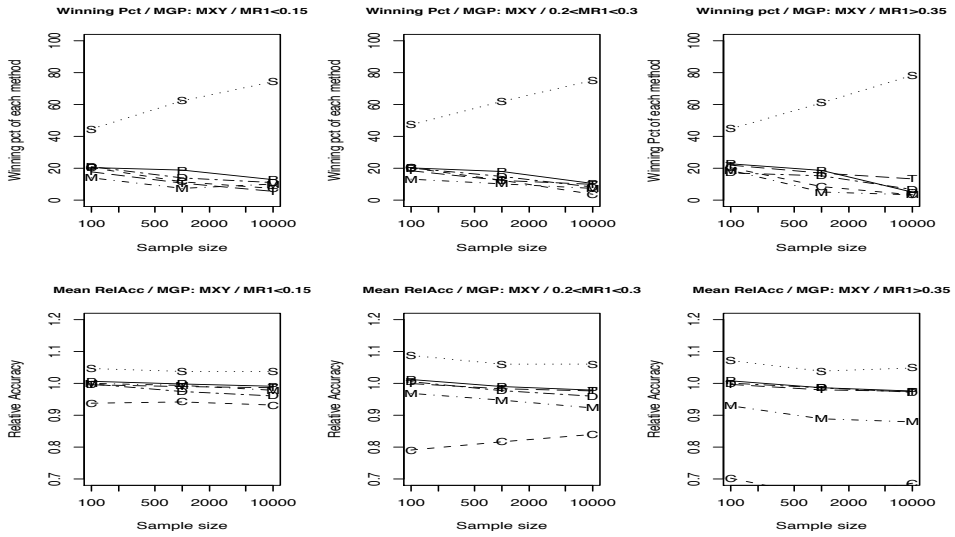

Figure 7: A comparison of the low, median and high missing rate situations. The top row shows the comparison in terms of winning percentage and the bottom row shows the comparison of the absolute performance of each missing data method.

Figure 6 shows the relationship between MR_1 and MR_2 in the simulations with 12 continuous predictors and 6 of them with missing values. Notice that in this setting, MR_1 is naturally between 0 and 0.5 (since half of the predictors can have missing values). MR_2 values are considerably larger than MR_1 values, as would be expected.

The simulations clearly show that the relative performance of different missing data methods is very consistent regardless of the missing rate (see the top row of Figure 7). However, the bottom row of Figure 7 shows that the absolute performance of the complete case method and the mean imputation method deteriorate as the missing rate gets higher. It also shows that separate class method performs best when the missing rate is neither too high or too low, although this effect is relatively small. Interestingly, the relative accuracy of the other missing data methods is very close to one regardless of the missing rate, indicating that they can almost achieve the same accuracy as if the data are complete without missing values.

A final effect connected to missing rate relates to results in earlier papers (Kalousis and Hilario, 2000; Twala, 2009) that suggested that missingness over several predictors is more problematic than missingness concentrated in a few predictors. This pattern was not evident here (e.g., in comparing the results for 8 predictors with 2 having missing values to those for 12 predictors with 6 having missing values), but it should be noted that the comparisons here are based on relative performance between methods, not absolute performance. That is, even if absolute performance deteriorates in the presence of missingness over multiple predictors, this is less important to the data analyst than is relative performance between methods (since a method must be chosen), and with respect to the latter criterion the observed patterns are reasonably stable.

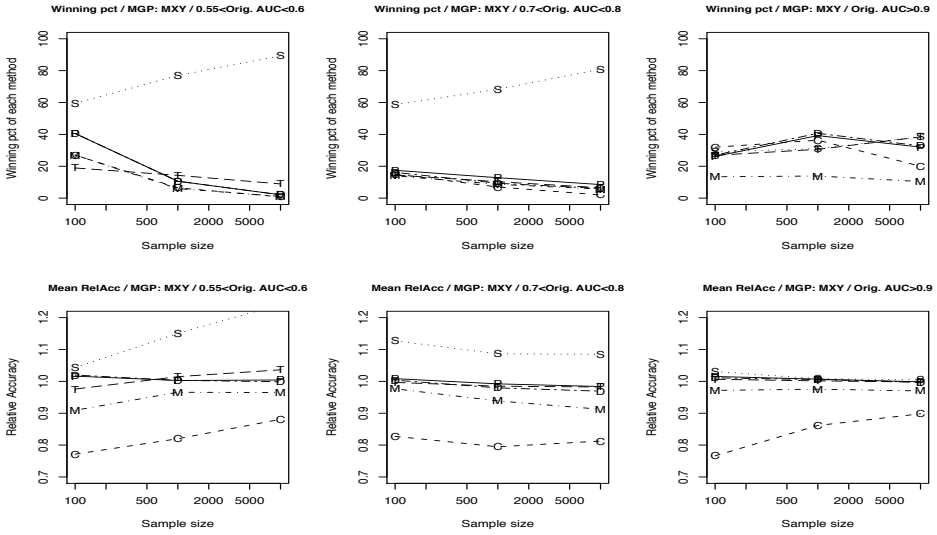

Figure 8: A comparison of the low, median and high original full data AUC situations. The top row shows the comparison in terms of winning percentage and the bottom row shows the comparison of the absolute performance of each missing data method.

3.2.4 THE IMPACT OF THE ORIGINAL FULL DATA AUC

Figure 8 shows that the original full data AUC primarily has an impact on the performance of separate class method. When the original full data AUC is higher, the loss in information due to missing values is less likely to be compensated by the information in the missingness, and thus separate class method deteriorates in performance (see the bottom row of Figure 8). When the original AUC is very high, although separate class still does a little better on average, it loses the dominance over the other methods.

Another observation is that the missing data methods other than separate class have fairly stable relative accuracy, with complete case and mean imputation consistently being the poorest performers (see the graphs in the bottom rows of both Figure 7 and Figure 8). This is true regardless of the AUC or the missing rate, even when the missingness does not depend on the response variable and there are no missing data in the testing set where, in theory, the complete case method can eventually recover the DGP.

4. Performance On Real Data Sets

In this section, we show that most of the previously described results hold when using real data sets. Moreover, we propose a method of determining the best missing data method to use when analyzing a real data set. Unlike in the previous sections, in these simulations based on real data, default settings of C4.5 are used and RPART is tuned (primarily using its parameter "cp") to get similar performance on the original full data as C4.5. Therefore, in particular, the effect of pruning is present. In Section 4.1, we show the results on 36 data sets that were originally complete. In Section 4.2, we propose a way to determine the best missing data method to use when facing real

Missingness is related to

data sets that contain missing values (since in that case the true missingness generating process is not known by the data analyst).

4.1 Results on Real Data Sets with Simulated Missing Values

The same 36 data sets as in Perlich, Provost, and Simonoff (2003) are used here (except for Covertype and Patent, which are too big for RPART to handle; in those cases a random subset of 100,000 observations for each of them was used as the "true" underlying data set). They are either complete or were made complete by Perlich et al. (2003). Missing values with different missingness patterns were generated for the purpose of this study. According to the earlier results, the only important factor in the missingness generating process is the relationship between the missingness and the response variable. Therefore, two missingness patterns are included. In one of them, missingness is independent of all of the variables (including the response variable). In the other one, missingness is related to the response variable, but independent of all of the predictors. These two missingness patterns can be categorized as missing completely at random (MCAR) and missing at random (MAR), respectively. To account for this categorization of MGPs, the third type of missingness, not missing at random (NMAR), is also included. In the NMAR case, missingness is made dependent upon the missing values but not on the response variable (see Table 2). To maximize the possible effect of missing values, the first split variable of the original full data is chosen as the variable that contains missing values. It can be either numeric or categorical (binary or multi-categorical). Ten new data sets with missing values are generated for each combination of data set, training set size, and missingness pattern combination, with the missing rate chosen randomly for each. The performance of the missing data methods is measured out-of-sample, on a hold out test sample.

The same six missing data methods, namely, the complete case method, the complete variable method, probabilistic split, grand mode/mean imputation, surrogate split and the separate class method are applied. All of them are realized using C4.5 except for surrogate split, which is realized using RPART. C4.5 is run with its default settings. To make surrogate split comparable to the other missing data methods, the RPART parameters are tuned for each data set and each sample size so that RPART and C4.5 have comparable in sample performance on the original full data (by comparable performance we mean the average in sample original full data accuracies are similar to each other).

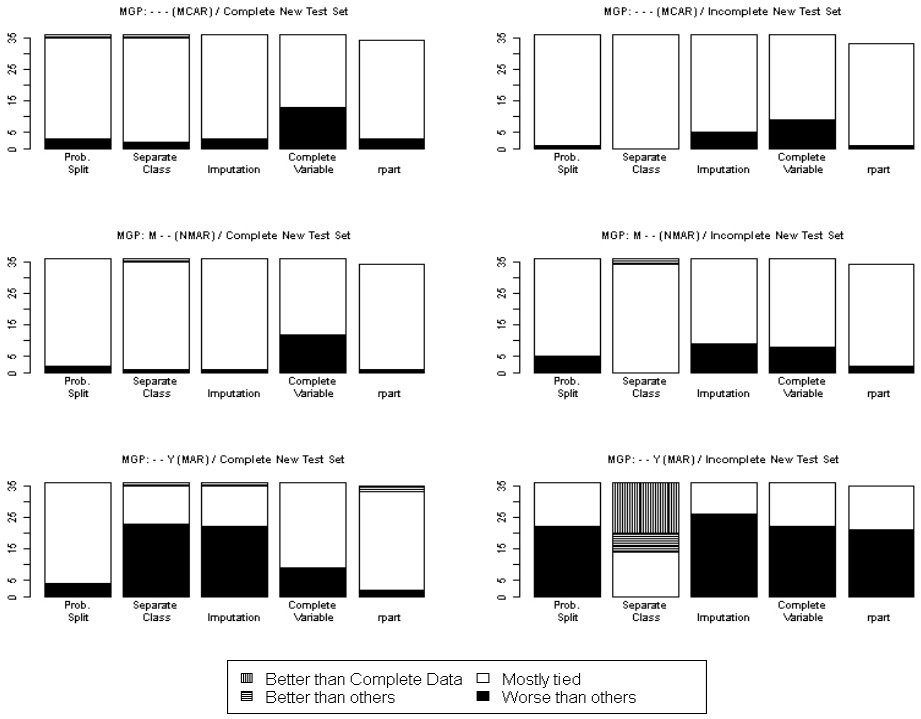

Figure 9: A tally of the relative out-of-sample performance measured in accuracy of all of the missing data methods on the 36 data sets.

4.1.1 THE TWO FACTORS AND THE BEST MISSING DATA METHOD

Consistent with the earlier results, the two factors that differentiate the performance of different missing data methods are whether the testing set is complete and whether the missingness is dependent upon the response variable. Figure 9 summarizes the relative out-of-sample performance in terms of accuracy of all of the missing data methods under different situations. In the graph, each bar represents one missing data method. Since the complete case method is consistently the worst method, it is omitted in the comparisons. Within each bar, the blank block shows the frequency that the missing data method has comparable performance with others. The shadowed block on the bottom shows the frequency that the missing data method has worse performance than others. The line-shadowed blocks on the top show the frequency that the missing data method has better performance than others, with the vertically line-shadowed block further indicating that the missing data method has better performance than with the original full data.

As was seen in the previous section, when missingness is related to the response variable and the test set contains missing values (the graph at the bottom right corner of Figure 9), the separate class method is dominant and in almost half of the cases, its performance is even better than the full data performance. Interestingly, the middle plot on the right shows that the separate class method still has an edge over the others (sometimes even over the original full data) when the test set contains missing values and the missingness is dependent upon the predictor but conditionally independent of the response variable. This is probably due to the indirect relationship between the missingness

and the response variable because both the missingness and the response variable are related to the predictor.

However, the dominance of probabilistic split is not observed in these real data sets. One possible reason could be the effect of pruning, which is used in these real data sets. The other two methods realized using C4.5 (imputation and separate class) both work with "filled-in" data sets, while probabilistic split takes the missing values as-is. Given this, we speculate that the branches with missing values are more likely to be pruned under probabilistic split, which causes it to lose predictive power. Another possible reason could be the competition from surrogate split, which is realized using RPART. Although we tried to tune RPART for each data set and each sample size, RPART and C4.5 are still two different algorithms. Different features of RPART and C4.5, other than the missing data methods, may cause RPART to outperform C4.5. Complete variable method performs a bit worse than the others, presumably because in these simulations the initial split variable on the full data was used as the variable with missing values.

In addition to accuracy, AUC was also tested as an alternative performance measure. We also examined the use of bagging (bootstrap aggregating) to reduce the variability of classification trees (discussion of bagging can be found in many sources, for example, Hastie et al. 2001). The learning curve effect (that is, the relationship between effectiveness and sample size) is also examined. We see patterns consistent with those in the simulated data sets. That is, the relative performance of the missing data methods is fairly consistent across different sample sizes.

4.1.2 THE EFFECT OF MISSING RATE

Figure 10 shows the distribution of the generated missing rates in these simulations. Recall that missing values occur in one variable, so this missing rate is the percentage of observations that have missing values, that is, MR_2 as defined earlier. Figure 11 shows a comparison between the case when the missing rate is low ($MR_2 < 0.2$) and the case when the missing rate is high ($MR_2 > 0.8$). For brevity, only the result when the MGP is dependent on the response variable is shown; differences between the low and high missing rate situations for other MGP's are similar. Since the missing rate is chosen at random, some of the original data sets do not have any generated data sets with simulated missing values with low missing rate, while for others we do not have any with high missing rate, which accounts for the "no data" category in the figures. Also, when the missing rate is high, the complete case method is obviously much worse than other missing data methods, and is therefore omitted from the comparison in that situation.

By comparing the graphs in Figures 11 with the corresponding ones in Figure 9, we can see some of the effects of missing rate. First, when the missing rate is lower than 0.2, the complete case method has comparable performance to other methods other than the complete variable method. This is unsurprising, as in this situation the complete case method does not lose much information from omitted observations. Secondly, the complete variable method has the worst performance when the missing rate is low, presumably (as noted earlier) because the complete variable method omits the most important explanatory variable in these simulations.

Moreover, in both the low and high missing rate cases, when the missingness depends on the response and the testing set is incomplete, the dominance of the separate class is not as strong as it is in Figure 9. This indicates that separate class works best when the missing rate is moderate. If the missing rate is too low, there might not be enough observations in the category of "missing" for the separate class method to be as effective. On the other hand, if the missing rate is very high, the

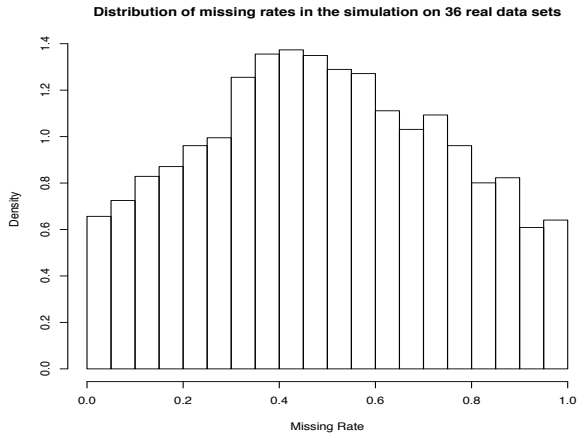

Figure 10: The distribution of missing rate in the simulation on 36 real data sets.

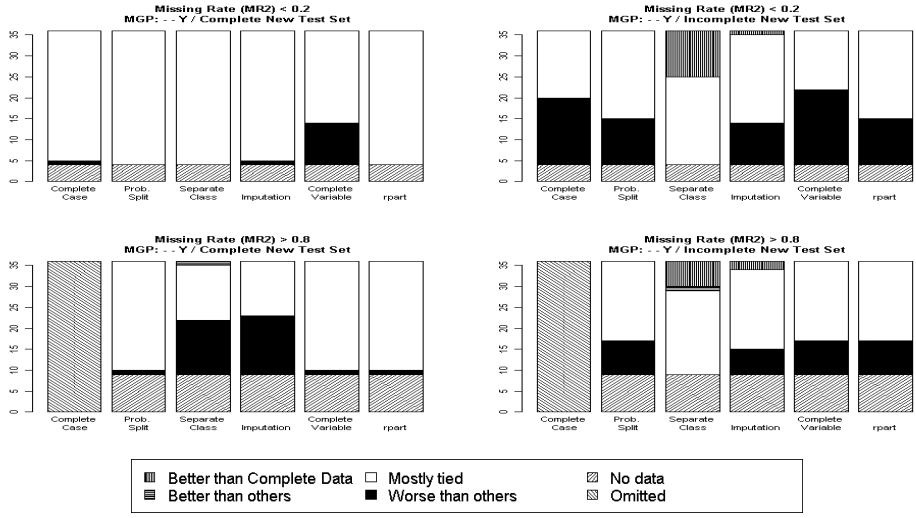

Figure 11: A comparison of the relative out-of-sample performance with low and high missing rates. Shown here, as an example, is the relative performance when the missingness is dependent upon the response variable. The left column is for the cases where the test set is fully observed and the right column for the cases where the test set has missing values. Top row shows the cases with low missing rate ($MR_2 < 0.2$) and bottom row shows the cases with high missing rate ($MR_2 > 0.8$)

.

information gained by separate class may not be enough to compensate for the lost information in the missing values, making all of the methods more comparable. This observation is consistent with Figure 2, where it is very clear that separate class gains the most when the missing rate is around 50%, as well as Figure 7, where the bottom row shows that separate class has better performance when the missing rate is neither too high or too low.

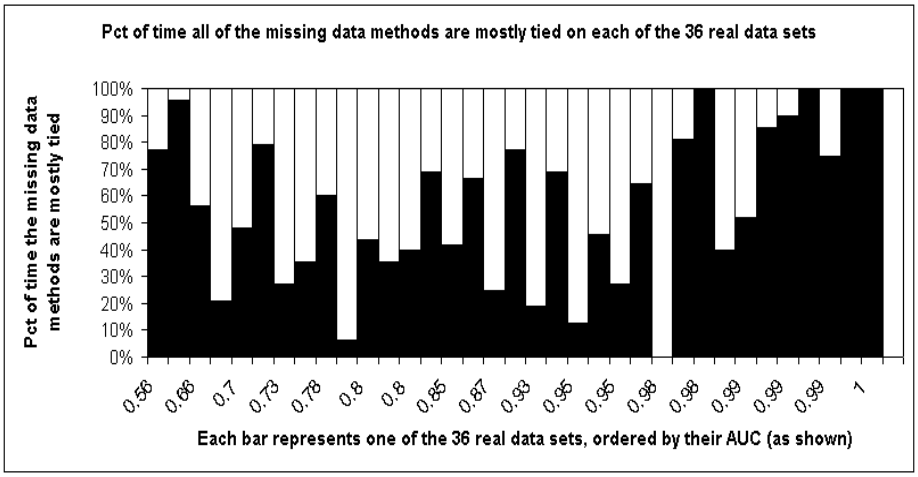

Figure 12: A tally of the missing data methods performance differentiation by data separability (measured by AUC).

4.1.3 IMPACT OF THE DATA SEPARABILITY, MEASURED BY ORIGINAL FULL DATA AUC

The experiment with these 36 data sets also shows that data separability (measured by AUC) is informative about the performance differentiation between different missing data methods (see Figure 12). In the graph, each vertical bar represents one of the 36 data sets, which are ordered from left to right according to their maximum full data AUC (as calculated by Perlich et al. 2003) from smallest to the greatest. The X-axis label shows the AUCs of the data sets. The height of each black bar shows the percentage of time when all of the missing data methods have mostly tied performance on the data set. The percentage is calculated as follows. There are three simulated missingness patterns (MCAR, NMAR and missingness depending on Y), four different testing sets (complete training set, complete new test set, incomplete training set and incomplete new test set) and four performance measures (accuracy, AUC and their bagged versions). This yields 48 measurement blocks for each data set. The performances of all of the missing data methods are compared within each block. If within a block, all of the missing data methods have very similar performance, the block is marked as mostly tied. Otherwise, the block is marked as having at least one method performing differently. The percentage is the proportion of the 48 blocks that are marked as mostly tied.

Figure 12 shows that when data separability is very high, as indicated by an AUC very close to 1 (the right end of the graph), the performances of different missing data methods are more likely to be tied. This is presumably due to the fact that strong signals in the data are less likely to be affected by missing data. The last data set (Nurse) is an exception because there is only one useful predictor. Since we picked the most significant predictor to create missing values in, when the complete variable method is used, the only useful predictor was always deleted and thus the complete variable method always had worse performance than others. As a result, on this data set, none of the measurement blocks is marked as mostly tied. This is consistent with the observations made in Figure 8.

4.2 A Real Data Set With Missing Values

We now present a real data example with naturally occurred missing values. In this example, we try to model a company's bankruptcy status given its key financial statement items. The data are annual financial statement data and the predictions are sequential. That is, we build the tree on one year's data and then test its performance on the following year's data. For example, we build a tree on 1987's data and test its performance on 1988's data, then build a tree on 1988's data and test it on 1989 data, and so on.

The data are retrieved from Compustat North America (a database of U.S. and Canadian fundamental and market information on more than 24,000 active and inactive publicly held companies). Following Altman and Sabato (2005), twelve variables from the data base are used as potential predictors: Current Assets, Current Liabilities, Assets, Sales, Operating Income Before Depreciation, Retained Earnings, Net Income, Operating Income After Depreciation, Working Capital, Liabilities, Stockholder's Equity and year. The response variable, bankruptcy status, is determined using two footnote variables, the footnote for Sales and the footnote for Assets. Companies with remarks corresponding to "Reflects the adoption of fresh-start accounting upon emerging from Chapter 11 bankruptcy" or "Company in bankruptcy or liquidation" are marked as bankruptcy. The data include all active companies, and span 19 years from 1987 to 2005. There are 177560 observations in the original retrieved data, but 76504 of the observations have no data except for the company identifications, and are removed from the data set, resulting in 99056 observations. There are 19238 (19.4%) observations containing missing values and there are 56820 (4.8%) missing data values.

According to the results in Sections 3 and 4.1, there are two criteria that differentiate the performance of different missing data methods, that is, whether or not there are missing values in the testing set and whether or not the missingness depends on the response variable. In the bankruptcy data, there are missing values in every year's data, and thus missing values in each testing data set. To assess the dependence of the missingness on the response variable, the following test is carried out. First, we define twelve new binary missingness indicators corresponding to the original twelve predictors. Each indicator takes on value 1 if the original value for the associated variable is missing and 0 if the original value is observed for that observation. We then build a tree for each year's data using the indicators as the predictors and the original response variable, the bankruptcy status, as the response variable. From 1987 to 2000, the tree makes no split, indicating the tree algorithm is not able to establish a relationship between the missingness and the response variable. From 2001 to 2005, the classification tree consistently splits on the missingness indicators of Sales and Retained Earnings. This indicates that the missingness of these predictors has information about the response variable in these years, and the MGP across the years is fairly consistent in missingness in sales and retained earnings being related to bankruptcy status. However, the AUC values calculated from the trees built with the missingness indicators are not very high, all being between 0.5 and 0.6. Therefore, the relationship is not a very strong one.

Given these observations and the fact that the sample sizes are fairly large, we would make the following propositions based on our earlier conclusions. First, from 1988 to 2001 (since the tree tested on 2001 data is built on 2000 data), different missing data methods should have similar performance, with no clear winners. However, from year 2002 to year 2005, the separate class method should have better performance than the others (but perhaps not much better since the relationship between missingness and the response is not very strong). The actual relative performance of different missing data methods is shown in Figure 13. Since surrogate split is realized using

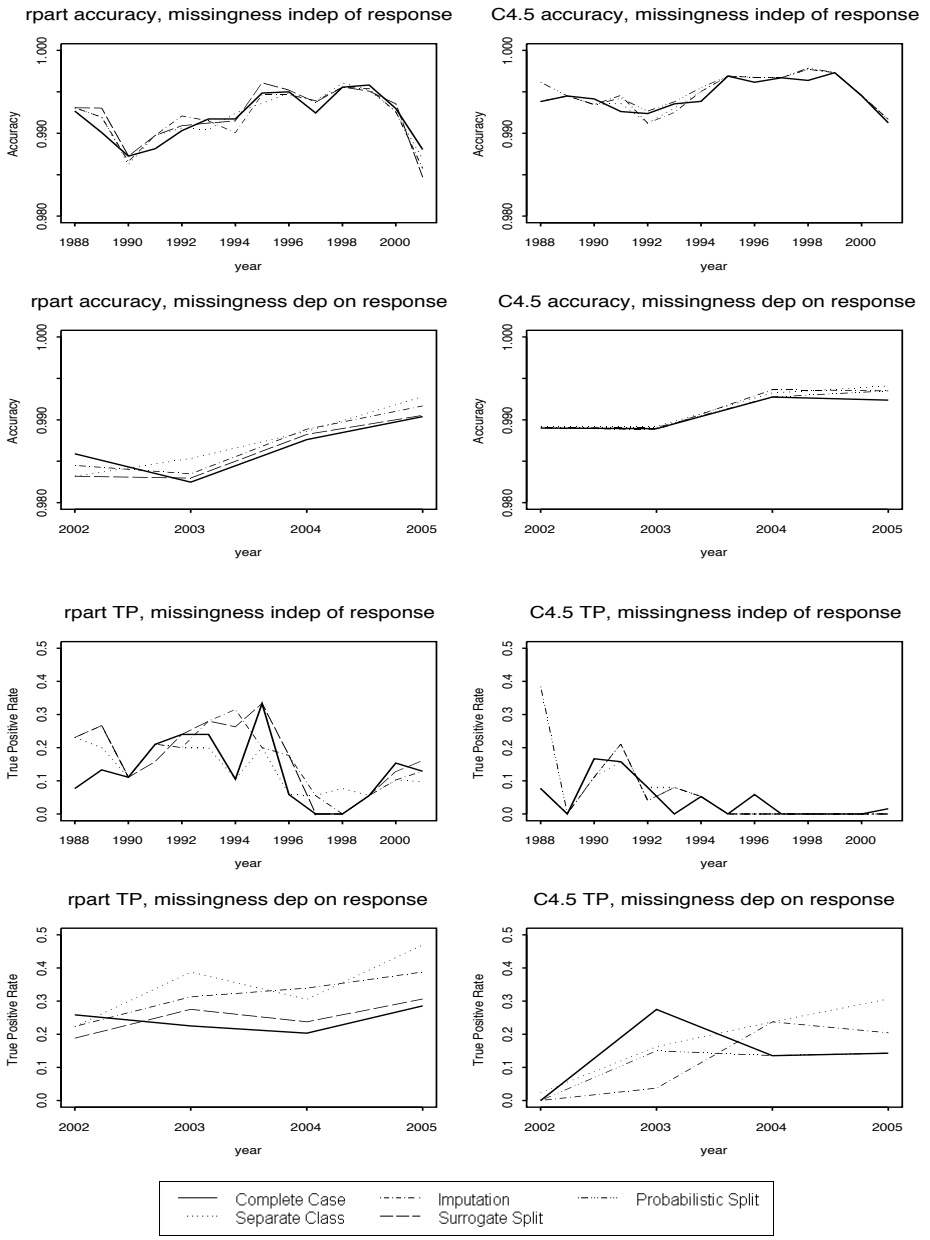

Figure 13: The relative performance of all of the missing data methods on the bankruptcy data. The left column gives methods using RPART (and includes all of the methods except for probabilistic split) and the right column gives methods using C4.5 (and includes all of the methods except for surrogate split). The top rows are performance in terms of accuracy while the bottom rows are in terms of true positive rate.

RPART while probabilistic split is realized using C4.5, we run all of the other methods using both RPART and C4.5 so that we can compare both surrogate split and probabilistic split with all of the other methods. In Figure 13, the plots on the left are the results from RPART, which include all of

the missing data methods except for probabilistic split. The plots on the right are the results from C4.5, which include all of the missing data methods except for surrogate split. The performances of methods common to both plots are slightly different because of differences between C4.5 and RPART in splitting and pruning rules. Both the accuracy and the true positive rates are shown. Since the number of actual bankruptcy cases in the data is small, the accuracy is always very high. The true positive rate is defined as

$$TP = \frac{\text{Number of correctly predicted bankruptcy cases}}{\text{Actual number of bankruptcy cases}}.$$

The graphs in the first and the second rows are for accuracies, with the first row for the first time period from 1988 to 2001 and the second row for the second time period from 2002 to 2005. The graphs in the third and the fourth rows are for true positive rates, with the third row for the first time period from 1988 to 2001 and the fourth row for the second time period from 2002 to 2005. It is apparent that in the first time period, there are no clear winners. However, in the second time period, separate class is a little better than the others, in line with expectations.

5. Extension To Logistic Regression

One obvious observation from this study is that when missing values occur in both the model building and model application stages, it should be considered as part of the data generating process rather than a separate mechanism. That is, taking the missingness into consideration can improve predictive performance, sometimes significantly. This should also apply to other supervised learning methodologies, non-parametric or parametric, when predictive performance is concerned. We present here the results from a real data analysis study involving logistic regression, similar to the one presented in Section 4.1. Missing values are generated the same way as in Section 4.1 and then logistic regression models (without variable selection) with different ways of handling missing data are applied to those data sets. Finally a tally is made on the relative performances of different missing data methods. Results measured in accuracy, bagged accuracy, AUC and bagged AUC are almost identical to each other; results in terms of accuracy are shown in Figure 14.

Included in the study are five ways of handling missing data: using only complete cases (complete case method), including a missingness dummy variable in the explanatory variable (dummy method, sometimes called the missing-indicator method),[1] building separate models for data with values missing and data without missing values (by-group method),[2] imputing missing values with grand mean/mode (imputation method), and only using predictors without missing values (complete variable method). Note that the methods using a dummy variable and building separate models for

1. If explanatory variable X_1 has missing values, then we create a missingness dummy variable M_1 that has value 1 if X_1 is observed and 0 otherwise. Then M_1 and $X_1 * M_1$ are both used as explanatory variables. The result of this set-up is that the effect of X_1 is fit on the observations with X_1 observed but a single mean value is fit to the observations with X_1 missing. All of the observations, with or without X_1 values, have the same coefficients for all of the other explanatory variables. Jones (1996) showed that this method can result in biased coefficient estimates in regression modeling, but did not address the question of predictive accuracy that is the focus here.
2. The biggest difference between the by-group method and the dummy method is whether the explanatory variables, other than the one containing missing values, have different coefficients or not. The by-group method fits two separate models to observations with and without missing values. Therefore, even if an explanatory variable is fully observed, its coefficient would most likely be different for fully observed observations and for observations with missing values. The dummy method, on the other hand, fits a single model to the entire data set so that variables that are fully observed will have the same coefficients whether an observation has missing values or not.

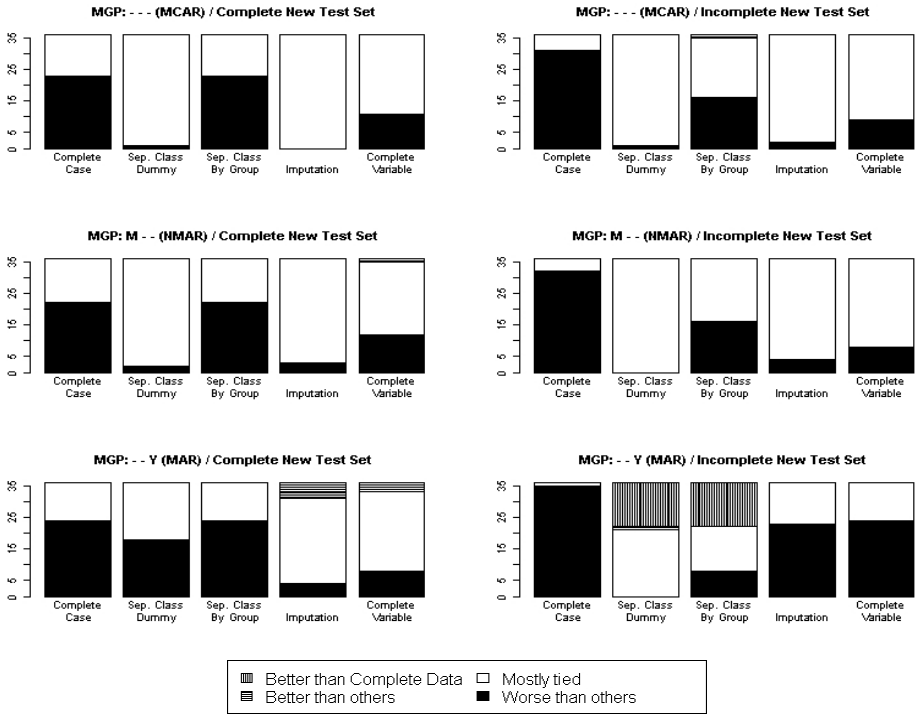

Figure 14: A tally of the relative out-of-sample performance with logistic regression measured in accuracy of all of the missing data methods on the 36 data sets.

observations with and without missing values each are analogous to the separate class method for trees. The most obvious observation is that when missingness is related to the response variable and missingness occurs in the test set, the dummy method and the by-group method dominate the other methods; in fact, more than a third of the time, they perform better than logistic regression on the original full data. Comparing Figure 14 with Figure 9, we see a clear similarity, in that the methods using a separate class model missingness directly, and thus use the information contained in the missingness about the response variable most efficiently. This suggests that the result that predictive performance of supervised learning methods is driven by the dependence (or lack of dependence) on the response variable is not limited to trees, but is rather a general phenomenon.

6. Conclusion And Future Study

The main conclusions from this study are as follows:

1. The two most important criteria that differentiate the performance of different missing data methods are whether or not the testing set is complete and whether or not the missingness depends on the response variable. There is strong evidence, both analytically and empirically, that separate class is the best missing data method to use when the testing data also contains missing values and the missingness is dependent upon the response variable.

   In practice, one way to detect the dependence of missingness on the response variable is to try building a model, with a classification tree being a natural choice, of the response variable on

the missingness indicators (which equals to 1 if the corresponding original value is missing and 0 otherwise). If such a model supports a relationship, then it is an indication that the missingness is related to the response variable.

2. The performance of classification trees is on average not too negatively affected by missing values, except for the complete case method and the mean imputation method, which are sensitive to different missing rates. Separate class tend to perform better when the missing rate is neither too high nor too low, trading off between information loss due to missing values and information gain from the informative MGP.

3. The original full data AUC has an impact on the performance of separate class method. The higher the original AUC, the more severe the information loss due to missing value, and thus relatively the worse the performance of the separate class method.

The consistency of these results across the theoretical analyses, simulations from the artificial data, and simulations based on real data provides strong support for their general validity.

The findings here also have implications beyond analysis of the data at hand. For example, since missingness that is dependent on the response variable can actually improve predictive performance, it is clear that expending time, effort, and money to recover the missing values is potentially a poor way to allocate resources. Another interesting implication of these results is related to data disclosure limitation. It is clear that any masking of values must be done in a way that is independent of the response variables of interest (or any predictors highly related to such variables), since otherwise data disclosure using regression-type methods (Palley and Simonoff, 1987) could actually increase.

Classification trees are designed for the situation where the response variable is categorical, not just binary; it would be interesting to see how these results carry over to that situation. Tree-based methodologies for the situation with a numerical response have also been developed (i.e., regression trees), and the problems of missing data occur in that context also. Investigating such trees would be a natural extension of this paper. In this paper, we focused on base form classification trees using C4.5 and RPART, although bagging was included in the study. It would be worthwhile to see how the performance of different missing data methods is affected by different tree features such as stopping and pruning or when techniques such as cross-validation, tree ensembles, etc. are used.

Moreover, as was shown in Section 5, the relationship between the missingness and the response variable can be helpful in prediction when missingness occurs in both the training data and the testing data in situations other than classification trees. This is very likely true for other supervised learning methods, and thus testing more learning methods would also be a natural extension to this study.

Table 3: *RelAcc* of tree built on data with missing values and tested on the original full data set when there is no variation from true DGP

Appendix A. Proofs of the Theorems

The relative accuracy (*RelAcc*) when there are missing values in the training set but not in the testing set can be summarized into Table 3, where T is the threshold value (an observation will be classified as class 0 if the predicted probability for it to be 0 is greater than T). The value of T reflects the misclassification cost. It is taken as 0.5 reflecting an equal misclassification cost. In Table 3, the columns show different rules given by the classification trees when there are missing values, and the rows show actual DGP's. The entries are the *RelAcc* values under different scenarios. For example, all of the entries on the diagonal are one's because the rules given by the classification trees when there are missing values are the same as the true DGP's and thus the accuracy achieved by the trees are the same with or without the missing values and thus $RelAcc = 1$. Cell $(1,2)$, for example, shows that if the true DGP is $P(Y=0|X=0) > T$ and $P(Y=0|X=1) > T$ but the classification tree gives rule $P(Y=0|X=0) > T$ and $P(Y=0|X=1) \leq T$ when there are missing values, that is, $P(Y=0|X=0,\text{with missing value}) > T$ and $P(Y=0|X=1\text{with missing value}) \leq T$, then the relative accuracy is determined to be

$$\frac{P(X=0,Y=0)+P(X=1,Y=1)}{P(Y=0)}.$$

Proof of Theorem 1 : The expected performance of the complete case method when the missingness does not depend on the response variable and the testing set is complete.

Proof

First, we define A as the case-wise missingness indicator which equals 1 if the observation contains missing values in one or more of the predictors or 0 if the observation does not

contain missing values in any of the predictors. Y is the response variable and $\underline{X}$ is the vector of the predictors.

If only the complete cases are used, if $P(Y|A=0,\underline{X}) = P(Y|\underline{X})$, then only the diagonal in Table 3 can be achieved, and thus there is no loss in accuracy.

This condition will be satisfied if and only if the MGP is conditionally independent of Y given $\underline{X}$, that is, $P(A=0|\underline{X},Y) = P(A=0|\underline{X})$.

1. "$P(Y|A=0,\underline{X}) = P(Y|\underline{X}) \Rightarrow P(A=0|\underline{X},Y) = P(A=0|\underline{X})$"

   $$\begin{aligned} \text{P(A=0}|\underline{\text{X}},\text{Y)} &= \frac{P(A=0,\underline{X},Y)}{P(\underline{X},Y)} \\ &= \frac{P(Y|A=0,\underline{X})P(A=0,\underline{X})}{P(\underline{X},Y)} \\ &= \frac{P(Y|\underline{X})P(A=0,\underline{X})}{P(Y|\underline{X})P(\underline{X})} \\ &= P(A=0|\underline{X}) \end{aligned}$$

2. "$P(Y|A=0,\underline{X}) = P(Y|\underline{X}) \Leftarrow P(A=0|\underline{X},Y) = P(A=0|\underline{X})$"

   $$\begin{aligned} \text{P(Y}|\text{A=0,}\underline{\text{X}}\text{)} &= \frac{P(A=0,\underline{X},Y)}{P(A=0,\underline{X})} \\ &= \frac{P(A=0|\underline{X},Y)P(\underline{X},Y)}{P(A=0,\underline{X})} \\ &= \frac{P(A=0|\underline{X})P(\underline{X},Y)}{P(A=0|\underline{X})P(\underline{X})} \\ &= \frac{P(\underline{X},Y)}{P(\underline{X})} \\ &= P(Y|\underline{X}) \end{aligned}$$

■

Proof of Theorems 2 and 3 : The expected performance of the complete case method when the missingness depends on the response variable and the testing set is complete.

We first observe the following lemmas.

Lemma 7 *For the partition defined by the tree built on the original full data (and not changed by missing values), let the k^{th} section contain P^k proportion of data and within the partition, the majority class have proportion P^k_{mj}. Note that $\sum_{k=1}^{K} P^k = 1$, while the full data set accuracy, that is, the accuracy achievable with the full data set, is $\sum_k P^k P^k_{mj}$.)*

The rule for the k^{th} section will be classifying it as the majority class of the section. The impact of missing data on its rule is to either leave it unchanged or make it classify the data as the minority class instead of the majority class.

The smallest missing rate needed in k^{th} section to change the rule is $P(A=1|k) = 2P^k_{mj} - 1$, where A is defined as in Theorem 1, that is, it is the case-wise indicator, which takes value 1 if the observation contains missing value or 0 otherwise. If the rule is changed the loss in accuracy within that section is $2P^k_{mj} - 1$.

Proof

We assume the partition of the data is not changed by the missing values. The structure of the trees need not to be the same because different trees may lead to the same partition of data.

For any k, to make the rule of the k^{th} section change, we need to observe more minority class cases than the majority ones within that section. To achieve this in the most efficient way, we only make the majority ones missing. Originally, there are P_{mj}^k majorities and $1-P_{mj}^k$ minorities. Only when there are $P_{mj}^k-(1-P_{mj}^k)=2P_{mj}^k-1$ majorities missing will it become less than the minorities, so this is the smallest missing rate we need to make the rule change.

After the rule is changed, only $1-P_{mj}^k$ of the data, that is, the minorities, will be correctly classified. Therefore, the loss in accuracy is $P_{mj}^k-(1-P_{mj}^k)=2P_{mj}^k-1$.

■

Lemma 8 *For a given data set and the partition defined by the tree built on the full data set (which is not changed by the missing values), the largest loss in accuracy is* $\sum_k 2P_{mj}^k-1$. *The smallest missing rate needed to achieve this is also* $\sum_k 2P_{mj}^k-1$.

Proof

The largest loss is achieved if and only if the rules are changed in every section of data in the partition. The result then follows from Lemma 7.

■

Lemma 9 *For a certain missing rate, say* P_m, *the largest effect it can have on the classification accuracy of any data that won't be split is* P_m *itself.*

In this case, the data set has its majority proportion $P_{mj}=\frac{1}{2}(1+P_m)$.

Proof

Similar to the proof of Lemma 7, for missing values to have an impact on the classification rule, it has to switch the order status of the majority and minority. To achieve this, it has to be that $P_{mj}-(1-P_{mj})\leq P_m$. We know that once the rule is changed, the loss in accuracy is $P_{mj}-(1-P_{mj})$. Therefore, the largest loss is P_m when the equality holds. In this case, we have $P_{mj}=\frac{1}{2}(1+P_m)$.

■

We now prove Theorem 2.

Proof

For any data set, once it is partitioned and the partition is not changed by missing values, the rules in different sections of data are independent of each other, so we can look at them separately.

Suppose the data are partitioned into K segments, in which some contain missing data and the others do not. Let K_0 be the set of sections whose rules are changed by missing data and K_1 be the set of all other sections. Also let the k^{th} segment ($k = 1 \ldots K$) contain proportion P^k of the data. We have $\sum_{k=1}^{K} P^k = 1$.

Assume that the k^{th} segment ($k \in K_0$) contains proportion P_m^k of missing data. Then we have

$$\sum_{k \in K_0} P_m^k P^k \leq P_m.$$

For the k^{th} segment ($k \in K_0$), by Lemma 9, the largest possible loss in accuracy is P_m^k and it occurs if and only if $P_{mj}^k = \frac{1}{2}(1 + P_m^k)$. Therefore, the possible loss for the entire data set is

$$\sum_{k \in K_0} P_m^k P^k \leq P_m,$$

the largest loss being achieved when the equality holds. In that case, the rules in all of the categories that contain missing values are changed and the maximum loss is P_m.

■

We now prove Theorem 3.

Proof

Assuming the partitions of data are not changed by the missing values, we have

$$\begin{aligned} RelAcc &= \frac{\sum_{k=1}^{K} P_{mj}^k P^k - \sum_{k \in K_0} (\text{loss in accuracy in } k^{th} \text{ segment})}{\sum_{k=1}^{K} P_{mj}^k P^k} \\ &= 1 - \frac{\sum_{k \in K_0} (\text{loss in accuracy in } k^{th} \text{ segment})}{\sum_{k=1}^{K} P_{mj}^k P^k} \\ &= 1 - \frac{\sum_{k \in K_0} (\text{loss in accuracy in } k^{th} \text{ segment})}{\sum_{k \in K_0} P_{mj}^k P^k + \sum_{k \in K_1} P_{mj}^k P^k} \end{aligned}$$

This is an increasing function of $\sum_{k \in K_1} P_{mj}^k P^k$ in the denominator, which is independent of other factors; setting it to zero minimize the *relative accuracy*, so

$$RelAcc \leq 1 - \frac{\sum_{k \in K_0} (\text{loss in accuracy in } k^{th} \text{ segment})}{\sum_{k \in K_0} P_{mj}^k P^k}$$

Denote the numerator $\sum_{k \in K_0} (\text{loss in accuracy in } k^{th} \text{ segment})$ as a. Now, from the proof of Theorem 2, the numerator $a \leq P_m$ and the denominator $\sum_{k \in K_0} P_{mj}^k P^k = \frac{1}{2}(1 + a)$. So,

$$RelAcc \leq 1 - \frac{a}{\frac{1}{2}(1 + a)}$$

This is a decreasing function of a and subject to $a \leq P_m$. Therefore, the minimum *RelAcc* is achieved when $a = P_m$. This gives

$$\begin{aligned} RelAcc &\leq 1 - \frac{P_m}{\frac{1}{2}(1+P_m)} \\ &= \frac{1-P_m}{1+P_m} \end{aligned}$$

■

Proof of Theorem 4 : Some properties of probabilistic split when the missingness does not depend on both the predictor and the response variable.

Proof

1. Part 1
   - If the MGP is independent of Y given X, that is, $P(M|X,Y) = P(M|X)$ then $P(Y|M,X) = P(Y|X)$ by the proof of Theorem 1.
     The rules given by probabilistic split when there are missing values are as follows:

$$\begin{aligned} & P(Y=0|X=0, Prob\_split) \\ = \; & P(Y=0|M=0,X=0)P(M=0) + P(Y=0|M=1)P(M=1) \\ = \; & P(Y=0|X=0)P(M=0) + P(Y=0|M=1)P(M=1) \\ = \; & P(Y=0|X=0)P(M=0) \\ & +[P(Y=0,X=0|M=1) + P(Y=0,X=1|M=1)]P(M=1) \\ = \; & P(Y=0|X=0)P(M=0) \\ & +[P(Y=0|M=1,X=0)P(X=0|M=1) \\ & +P(Y=0|M=1,X=1)P(X=1|M=1)]P(M=1) \\ = \; & P(Y=0|X=0)P(M=0) + [P(Y=0|X=0)P(X=0|M=1) \\ & +P(Y=0|X=1)P(X=1|M=1)]P(M=1) \\ = \; & P(Y=0|X=0)P(M=0) + P(Y=0|X=0)P(M=1,X=0) \\ & +P(Y=0|X=1)P(M=1,X=1) \\ = \; & P(Y=0|X=0)[P(M=0) + P(M=1,X=0)] \\ & +P(Y=0|X=1)P(M=1,X=1) \end{aligned}$$

     and following the similar route, we can get

$$\begin{aligned} & P(Y=0|X=1, Prob\_split) \\ = \; & P(Y=0|X=1)[P(M=0) + P(M=1,X=1)] \\ & +P(Y=0|X=0)P(M=1,X=0). \end{aligned}$$

     Note that

$$P(M=0) + P(M=1,X=1) + P(M=1,X=0) = 1.$$

Therefore, both $P(Y=0|X=0,Prob\_split)$ and$P(Y=0|X=1,Prob_split)$ are weighted averages of $P(Y=0|X=0)$ and $P(Y=0|X=1)$.
It follows that if both $P(Y=0|X=0)$ and $P(Y=0|X=1)$ are greater (less) than 0.5, then both $P(Y=0|X=0,Prob\_split)$ and $P(Y=0|X=1,Prob\_split)$ are also greater (less) than 0.5.

- If the MGP is independent of X given Y, without loss of generality, we prove the case when $P(Y=0|X=0) > T = 0.5$ and $P(Y=0|X=1) > T = 0.5$.

$$
\begin{aligned}
& P(Y=0|X=0,Prob\_split) \\
= \; & \frac{P(M=0,X=0,Y=0)}{P(M=0,X=0)}P(M=0)+P(Y=0|M=1)P(M=1) \\
= \; & \frac{P(M=0|X=0,Y=0)P(X=0,Y=0)P(M=0)}{P(M=0,X=0)} \\
& +P(M=1,Y=0) \\
= \; & \frac{P(M=0|Y=0)P(X=0,Y=0)P(M=0)}{P(M=0,X=0)} \\
& +P(M=1,X=0,Y=0)+P(M=1,X=1,Y=0) \\
= \; & \frac{P(M=0|Y=0)P(Y=0|X=0)P(M=0)}{P(M=0,X=0)} \\
& +P(M=1,X=0|Y=0)P(Y=0) \\
& +P(M=1,X=1|Y=0)P(Y=0) \\
= \; & \frac{P(M=0|Y=0)P(Y=0|X=0)P(M=0)}{P(M=0,X=0)} \\
& +P(M=1|Y=0)P(X=0|Y=0)P(Y=0) \\
& +P(M=1|Y=0)P(X=1|Y=0)P(Y=0) \\
= \; & \frac{P(M=0|Y=0)P(Y=0|X=0)P(M=0)}{P(M=0,X=0)} \\
& +P(M=1|Y=0)P(Y=0|X=0)P(X=0) \\
& +P(M=1|Y=0)P(Y=0|X=1)P(X=1) \\
> \; & T[\frac{P(M=0|Y=0)P(M=0)}{P(M=0,X=0)} \\
& +P(M=1|Y=0)P(X=0)+P(M=1|Y=0)P(X=1)] \\
= \; & T[\frac{P(M=0|Y=0)P(M=0)}{P(M=0,X=0)}+P(M=1|Y=0)] \\
> \; & T\,(P(M=0|Y=0)+P(M=1|Y=0)) \\
= \; & T
\end{aligned}
$$

A similar argument gives $P(Y=0|X=1,Prob\_split) > T$.

2. Part 2

- If the MGP is independent of Y given X, then from the proof of part 1,

$$P(Y=0|X=0,Prob\_split)$$

$$\begin{aligned} &= P(Y=0|X=0)(P(M=0)+P(M=1,X=0)) \\ &\quad +P(Y=0|X=1)P(M=1,X=1) \end{aligned}$$

and

$$\begin{aligned} &P(Y=0|X=1,Prob\_split) \\ &= P(Y=0|X=1)(P(M=0)+P(M=1,X=1)) \\ &\quad +P(Y=0|X=0)P(M=1,X=0). \end{aligned}$$

Taking the difference, we get

$$\begin{aligned} &P(Y=0|X=0,Prob\_split)-P(Y=0|X=1,Prob\_split) \\ &= P(Y=0|X=0)(P(M=0)+P(M=1,X=0)) \\ &\quad +P(Y=0|X=1)P(M=1,X=1) \\ &\quad -[P(Y=0|X=1)(P(M=0)+P(M=1,X=1)) \\ &\quad +P(Y=0|X=0)P(M=1,X=0)] \\ &= P(Y=0|X=0)P(M=0)-P(Y=0|X=1)P(M=0) \\ &= (P(Y=0|X=0)-P(Y=0|X=1))P(M=0). \end{aligned}$$

Without loss of generality, assume $P(Y=0|X=0,Prob\_split) > T$ and $P(Y=0|X=1,Prob\_split) < T$. It then follows that $P(Y=0|X=0) > P(Y=0|X=1)$. There are three possibilities:

(a) $P(Y=0|X=0) > T > P(Y=0|X=1)$

(b) $T > P(Y=0|X=0) > P(Y=0|X=1)$

(c) $P(Y=0|X=0) > P(Y=0|X=1) > T$

Conditions (b) and (c) are not possible because in these two cases, X is actually not informative and by Part 1, probabilistic split will show they are not informative. Therefore, it holds that $P(Y=0|X=0) > T > P(Y=0|X=1)$.

- If the MGP is independent of X given Y, that is, $P(M|X,Y) = P(M|Y)$, we have

$$\begin{aligned} &P(Y=0|X=0,Prob\_split) \\ &= \frac{P(M=0,X=0,Y=0)}{P(M=0,X=0)}P(M=0)+P(Y=0|M=1)P(M=1) \\ &= \frac{P(M=0|X=0,Y=0)P(X=0,Y=0)P(M=0)}{P(M=0|X=0,Y=0)P(X=0,Y=0)+P(M=0|X=0,Y=1)P(X=0,Y=1)} \\ &\quad +P(Y=0|M=1)P(M=1) \\ &= \frac{P(M=0|Y=0)P(X=0,Y=0)P(M=0)}{P(M=0|Y=0)P(X=0,Y=0)+P(M=0|Y=1)P(X=0,Y=1)} \\ &\quad +P(Y=0|M=1)P(M=1) \\ &= \frac{P(M=0|Y=0)P(Y=0|X=0)P(M=0)}{P(M=0|Y=0)P(Y=0|X=0)+P(M=0|Y=1)P(Y=1|X=0)} \\ &\quad +P(Y=0|M=1)P(M=1), \end{aligned}$$

and following the same route, we have

$$\begin{aligned} &P(Y=0|X=1,Prob\_split) \\ &= \frac{P(M=0|Y=0)P(Y=0|X=1)P(M=0)}{P(M=0|Y=0)P(Y=0|X=1)+P(M=0|Y=1)P(Y=1|X=1)} \\ &\quad +P(Y=0|M=1)P(M=1). \end{aligned}$$

Therefore,

$$\begin{aligned}
& P(Y=0|X=0,Prob_split) - P(Y=0|X=1,Prob_split) \\
= & \frac{P(M=0|Y=0)P(Y=0|X=0)P(M=0)}{P(M=0|Y=0)P(Y=0|X=0)+P(M=0|Y=1)P(Y=1|X=0)} \\
& - \frac{P(M=0|Y=0)P(Y=0|X=1)P(M=0)}{P(M=0|Y=0)P(Y=0|X=1)+P(M=0|Y=1)P(Y=1|X=1)} \\
= & [P(Y=0|X=0)P(M=0|Y=0)P(Y=0|X=1) \\
& +P(Y=0|X=0)P(M=0|Y=1)P(Y=1|X=1) \\
& -P(Y=0|X=1)P(M=0|Y=0)P(Y=0|X=0) \\
& -P(Y=0|X=1)P(M=0|Y=1)P(Y=1|X=0)]\frac{P(M=0|Y=0)P(M=0)}{D_1D_2} \\
= & [P(Y=0|X=0)-P(Y=0|X=1)]\frac{P(M=0|Y=1)P(M=0|Y=0)P(M=0)}{D_1D_2} \\
= & [P(Y=0|X=0)-P(Y=0|X=1)]K
\end{aligned}$$

where

$$D_1 = P(M=0|Y=0)P(Y=0|X=0)+P(M=0|Y=1)P(Y=1|X=0),$$
$$D_2 = P(M=0|Y=0)P(Y=0|X=1)+P(M=0|Y=1)P(Y=1|X=1)$$

and

$$K = \frac{P(M=0|Y=1)P(M=0|Y=0)P(M=0)}{D_1D_2}.$$

Since K is always positive as long as there are different Y values observed, we can see that the probabilistic split preserves the order of the conditional probability of Y given X.

Now, without loss of generality, assume $P(Y=0|X=0,Prob\_split) > T$ and $P(Y=0|X=1,Prob\_split) < T$. It follows that $P(Y=0|X=0) > P(Y=0|X=1)$ because probabilistic split preserves the correct order. There are three possibilities:

(a) $P(Y=0|X=0) > T > P(Y=0|X=1)$

(b) $T > P(Y=0|X=0) > P(Y=0|X=1)$

(c) $P(Y=0|X=0) > P(Y=0|X=1) > T$

Conditions (b) and (c) are not possible because in these two cases, X is actually not informative and by the earlier result in Part 1, probabilistic split will show they are not informative. Therefore, it holds that $P(Y=0|X=0) > T > P(Y=0|X=1)$.

3. Part 3

The results of Part 1 and Part 2 lead to the simplification of Table 3 into Table 4.

Without loss of generality, we provide the proof only for the case when $P(Y=0|X=0) > T$ and $P(Y=0|X=1) \leq T$ but $P(Y=0|X=0,prob\_split) > T$ and $P(Y=0|X=1,prob\_split) > T$, where *RelAcc* is

$$RelAcc = \frac{P(Y=0)}{P(X=0,Y=0)+P(X=1,Y=1)}.$$

It suffices to show that $P(Y=0) > 0.5$

- If M is independent of Y given X,

$$\begin{aligned}
& P(Y=0) \\
= & P(X=0,Y=0)+P(X=1,Y=0)
\end{aligned}$$

Simplified possibilities	$>T$ $>T$	$>T$ $\leq T$	$\leq T$ $>T$	$\leq T$ $\leq T$
Full data				
$>T$ $>T$	1	—	—	—
$>T$ $\leq T$	$\frac{P(Y=0)}{P(X=0,Y=0)+P(X=1,Y=1)}$	1	—	$\frac{P(Y=1)}{P(X=0,Y=0)+P(X=1,Y=1)}$
$\leq T$ $>T$	$\frac{P(Y=0)}{P(X=0,Y=1)+P(X=1,Y=0)}$	—	1	$\frac{P(Y=1)}{P(X=0,Y=1)+P(X=1,Y=0)}$
$\leq T$ $\leq T$	—	—	—	1

Table 4: *RelAcc* with a 2×2 table of probabilistic split when the missingness is independent of either X or Y or both

$$
\begin{aligned}
= \;& P(M=0,X=0,Y=0)+P(M=1,X=0,Y=0) \\
& +P(Y=0|X=1)P(X=1) \\
= \;& P(Y=0|M=0,X=0)P(M=0,X=0) \\
& +P(Y=0|M=1,X=0)P(M=1,X=0)+P(Y=0|X=1)P(X=1) \\
=^{1} \;& P(Y=0|X=0)P(M=0,X=0)+P(Y=0|X=0)P(M=1,X=0) \\
& +P(Y=0|X=1)P(X=1) \\
>^{2} \;& P(Y=0|X=0)P(M=1,X=0)+P(Y=0|X=1)P(M=0,X=0) \\
& +P(Y=0|X=1)P(X=1) \\
= \;& P(Y=0|X=1)(P(M=0)+P(M=1,X=1)) \\
& +P(Y=0|X=0)P(M=1,X=0) \\
= \;& P(Y=0|X=1,prob\_split) \\
> \;& 0.5
\end{aligned}
$$

where 1 follows because $P(Y|M,X)=P(Y|X)$ and 2 follows because $P(Y=0|X=0)>T\geq P(Y=0|X=1)$. Therefore,

$$\frac{P(Y=0)}{P(X=0,Y=0)+P(X=1,Y=1)}>P(Y=0)>0.5$$

- If M is independent of X given Y,

$$P(Y=0)=P(M=0,Y=0)+P(M=1,Y=0)$$

and by assumption,

$$
\begin{aligned}
& P(Y=0|X=1,prob\_split) \\
= \;& P(Y=0|M=0,X=1)P(M=0)+P(M=1,Y=0) \\
> \;& 0.5
\end{aligned}
$$

If $P(M=0,Y=0)>P(Y=0|M=0,X=1)P(M=0)$, then $P(Y=0)>P(Y=0|X=1,prob\_split)>0.5$, it suffices to show

$$P(M=0,Y=0)>P(Y=0|M=0,X=1)P(M=0).$$

By the earlier results in Part 2, probabilistic split preserves the order of conditional probabilities of Y given X when the missingness is conditionally independent of X given Y, that is, in this case, since

$$P(Y=0|X=0) > T \geq P(Y=0|X=1),$$

we have

$$\begin{aligned}
& P(Y=0|X=0,Prob_split) - P(Y=0|X=1,Prob_split) \\
= \; & P(Y=0|M=0,X=0)P(M=0) + P(Y=0|M=1)P(M=1) \\
& -(P(Y=0|M=0,X=1)P(M=0) + P(Y=0|M=1)P(M=1)) \\
= \; & (P(Y=0|M=0,X=0) - P(Y=0|M=0,X=1))P(M=0) \\
> \; & 0.
\end{aligned}$$

That is, $P(Y=0|M=0,X=0) > P(Y=0|M=0,X=1)$. We then have

$$\begin{aligned}
& P(Y=0|M=0,X=0) > P(Y=0|M=0,X=1) \\
\Rightarrow \; & P(Y=0|M=0,X=0)P(M=0,X=0) \\
& > P(Y=0|M=0,X=1)P(M=0,X=0) \\
\Rightarrow \; & P(M=0,X=0,Y=0) > P(Y=0|M=0,X=1)P(M=0,X=0) \\
\Rightarrow \; & P(M=0,X=0,Y=0) + P(M=0,X=1,Y=0) \\
& > P(Y=0|M=0,X=1)P(M=0,X=0) + P(M=0,X=1,Y=0) \\
\Rightarrow \; & P(M=0,Y=0) \\
& > P(Y=0|M=0,X=1)P(M=0,X=0) + P(Y=0|M=0,X=1)P(M=0,X=1) \\
\Rightarrow \; & P(M=0,Y=0) > P(Y=0|M=0,X=1)(P(M=0,X=0) + P(M=0,X=1) \\
\Rightarrow \; & P(M=0,Y=0) > P(Y=0|M=0,X=1)P(M=0)
\end{aligned}$$

■

Proof of Theorem 5 : Some properties of the mode imputation when the missingness does not depend on the response variable.

Proof

Without loss of generality, we assume that $P(X=0|M=0) > P(X=1|M=0)$, that is, there are more X=0 cases observed than X=1 ones. As a result, all of the missing X values will be labeled as X=0, the observed mode. Then the decision rules when the mode imputation is used can be written as

$$\begin{aligned}
& P(Y=0|X=0,Imp) \\
= \; & \frac{P(M=0,X=0,Y=0) + P(M=1,Y=0)}{P(M=0,X=0) + P(M=1)} \\
= \; & \frac{P(M=0,X=0,Y=0) + P(M=1,X=0,Y=0) + P(M=1,X=1,Y=0)}{P(M=0,X=0) + P(M=1)} \\
= \; & \frac{P(X=0,Y=0) + P(M=1,X=1,Y=0)}{P(X=0) + P(M=1,X=1)} \\
= \; & \frac{P(X=0,Y=0) + P(Y=0|M=1,X=1)P(M=1,X=1)}{P(X=0) + P(M=1,X=1)}
\end{aligned}$$

$$
\begin{aligned}
= & \frac{P(Y=0|X=0)P(X=0)+P(Y=0|X=1)P(M=1,X=1)}{P(X=0)+P(M=1,X=1)} \\
& P(Y=0|X=1,Imp) \\
= & P(Y=0|M=0,X=1) \\
= & P(Y=0|X=1)
\end{aligned}
$$

1. Note that $P(Y=0|X=0,Imp)$ is a weighted average of $P(Y=0|X=0)$ and $P(Y=0|X=1)$. Therefore, if they are both larger (or smaller) than 0.5, $P(Y=0|X=0,Imp)$ will also be, and thus it gives the same rule as $P(Y=0|X=0)$. Moreover, $P(Y=0|X=1,Imp)=P(Y=0|X=1)$, so it also gives the correct rule.
2. Suppose

$$
\begin{aligned}
P(Y=0|X=0,Imp) &> 0.5 \\
P(Y=0|X=1,Imp) &< 0.5,
\end{aligned}
$$

   then $P(Y=0|X=1)=P(Y=0|X=1,Imp)<0.5$, which is always correct. Moreover, note that $P(Y=0|X=0,Imp)$ is a weighted average of $P(Y=0|X=0)$ and $P(Y=0|X=1)$. Since $P(Y=0|X=0,Imp)>0.5$ and $P(Y=0|X=1)<0.5$, we must have $P(Y=0|X=0)>0.5$. Therefore, $P(Y=0|X=0,Imp)$ gives the correct rule.
3. Again the possibilities simplify to Table 4. Without loss of generality, we prove the situation when both $P(Y=0|X=0,Imp)$ and $P(Y=0|X=1,Imp)$ are greater than 0.5, that is

$$
\begin{aligned}
& P(Y=0|X=0,Imp) \\
= & \frac{P(Y=0|X=0)P(X=0)+P(Y=0|X=1)P(M=1,X=1)}{P(X=0)+P(M=1,X=1)} \\
> & 0.5 \\
& P(Y=0|X=1,Imp) \\
= & P(Y=0|X=1) \\
> & 0.5
\end{aligned}
$$

   Under the assumption that $P(X=0|M=0)>P(X=1|M=0)$, the missing values have an effect only if $P(Y=0|X=0)<0.5$ and $P(Y=0|X=1)>0.5$. In this case, the relative accuracy is $\frac{P(Y=0)}{P(X=0,Y=1)+P(X=1,Y=0)}$. This is the cell of the 3^{rd} row and the 1^{st} column in Table 4.
   But,

$$
\begin{aligned}
& \frac{P(Y=0)}{P(X=0,Y=1)+P(X=1,Y=0)} \\
> & P(Y=0) \\
= & P(X=0,Y=0)+P(X=1,Y=0) \\
>^{1} & 0.5(P(X=0)+P(M=1,X=1))-P(Y=0|X=1)P(M=1,X=1) \\
& +P(X=1,Y=0) \\
= & 0.5(P(X=0)+P(M=1,X=1))+P(Y=0|X=1)(P(X=1)-P(M=1,X=1)) \\
= & 0.5(1-P(M=0,X=1))+P(Y=0|X=1)P(M=0,X=1) \\
= & 0.5-0.5P(M=0,X=1))+P(Y=0|X=1)P(M=0,X=1) \\
>^{2} & 0.5-0.5P(M=0,X=1))+0.5P(M=0,X=1) \\
> & 0.5,
\end{aligned}
$$

where 1 follows because

$$\begin{aligned} & P(Y=0|X=0,Imp) \\ = & \frac{P(Y=0|X=0)P(X=0)+P(Y=0|X=1)P(M=1,X=1)}{P(X=0)+P(M=1,X=1)} \\ > & 0.5. \end{aligned}$$

By rearranging terms,

$$\begin{aligned} & P(Y=0|X=0)P(X=0) \\ = & P(X=0,Y=0) \\ > & 0.5(P(X=0)+P(M=1,X=1))-P(Y=0|X=1)P(M=1,X=1), \end{aligned}$$

where 2 follows because P(Y=0|X=1)=P(Y=0|X=1,Imp)>0.5.

■

Proof of Theorem 6 : The dominance of the separate class method when there are missing values in both the training set and the testing set and the missingness depends on the response variable.

Proof

When there are missing data in X in both the training set and the testing set, the finest partition of the data will be $X=0$, $X=1$ and X is missing. The best rule we can derive is to classify the majority class in each of these three partitions. This is achieved by using the separate class method.

Abstract

We present an algorithmic framework for learning local causal structure around target variables of interest in the form of direct causes/effects and Markov blankets applicable to very large data sets with relatively small samples. The selected feature sets can be used for causal discovery and classification. The framework (*Generalized Local Learning*, or GLL) can be instantiated in numerous ways, giving rise to both existing state-of-the-art as well as novel algorithms. The resulting algorithms are sound under well-defined sufficient conditions. In a first set of experiments we evaluate several algorithms derived from this framework in terms of predictivity and feature set parsimony and compare to other local causal discovery methods and to state-of-the-art non-causal feature selection methods using real data. A second set of experimental evaluations compares the algorithms in terms of ability to induce local causal neighborhoods using simulated and resimulated data and examines the relation of predictivity with causal induction performance.

Our experiments demonstrate, consistently with causal feature selection theory, that local causal feature selection methods (under broad assumptions encompassing appropriate family of distribu-

tions, types of classifiers, and loss functions) exhibit strong feature set parsimony, high predictivity and local causal interpretability. Although non-causal feature selection methods are often used in practice to shed light on causal relationships, we find that they cannot be interpreted causally even when they achieve excellent predictivity. Therefore we conclude that only local causal techniques should be used when insight into causal structure is sought.

In a companion paper we examine in depth the behavior of GLL algorithms, provide extensions, and show how local techniques can be used for scalable and accurate global causal graph learning.

Keywords: local causal discovery, Markov blanket induction, feature selection, classification, causal structure learning, learning of Bayesian networks

1. Introduction

This paper addresses the problem of how to learn local causal structure around a target variable of interest using observational data. We focus on two specific types of local discovery: (a) identification of variables that are direct causes or direct effects of the target, and (b) discovery of Markov blankets. A Markov Blanket of a variable T is a minimal variable subset conditioned on which all other variables are probabilistically independent of T.

Discovery of local causal relationships is significant because it plays a central role in causal discovery and classification, because of its scalability benefits, and because by naturally bridging causation with predictivity, it provides significant benefits in feature selection for classification. More specifically, solving the local causal induction problem helps understanding how natural and artificial systems work; it helps identify what interventions to pursue in order for these systems to exhibit desired behaviors; under certain assumptions, it provides minimal feature sets required for classification of a chosen response variable with maximum predictivity; and finally local causal discovery can form the basis of efficient algorithms for learning the global causal structure of all variables in the data.

The paper is organized as follows: Section 2 provides necessary background material. The section summarizes related prior work in feature selection and causal discovery; reviews recent results that connect causality with predictivity; explains the central role of local causal discovery for achieving scalable global causal induction; reviews prior methods for local causal and Markov blanket discovery and published applications; finally it introduces the open problems that are the focus of the present report. Section 3 provides formal concepts and definitions used in the paper. Section 4 provides a general algorithmic framework, *Generalized Local Learning (GLL)*, which can be instantiated in many different ways yielding sound algorithms for local causal discovery and feature selection. Section 5 evaluates a multitude of algorithmic instantiations and parameterizations from GLL and compares them to state-of-the-art local causal discovery and feature selection methods in terms of classification performance, feature set parsimony, and execution time in many real data sets. Section 6 evaluates and compares new and state-of-the-art algorithms in terms of ability to induce correct local neighborhoods using simulated data from known networks and resimulated data from real-life data sets. Section 7 discusses the experimental findings and their significance.

The experiments presented here support the conclusion that local structural learning in the form of Markov blanket and local neighborhood induction is a theoretically well-motivated and empirically robust learning framework that can serve as a powerful tool for data analysis geared toward classification and causal discovery. At the same time several existing open problems offer possibilities for non-trivial theoretical and practical discoveries making it an exciting field of research. A companion paper (part II of the present work) studies the GLL algorithm properties

empirically and theoretically, introduces algorithmic extensions, and connects local to global causal graph learning (Aliferis et al., 2010). An online supplement to the present work is available at `http://www.nyuinformatics.org/downloads/supplements/JMLR2009/index.html`. In addition to supplementary tables and figures, the supplement provides all software and data needed to reproduce the analyses of the present paper.

2. Background

In the present section we provide a brief review of feature selection and causal discovery research, summarize theoretical results motivating this work, present methods to speed-up scalability of discovery, give desiderata for local algorithms, review prior methods for Markov blanket and local neighborhood induction, and finally discuss open problems and focus of this paper.

2.1 Brief Review of Feature Selection and Causal Discovery Research

Variable selection for predictive modeling (also called feature selection) has received considerable attention during the last three decades both in statistics and in machine learning (Guyon and Elisseeff, 2003; Kohavi and John, 1997). Intuitively, variable selection for prediction aims to select only a subset of variables for constructing a diagnostic or predictive model for a given classification or regression task. The reasons to perform variable selection include (a) improving the model predictivity and addressing the curse-of-dimensionality, (b) reducing the cost of observing, storing, and using the predictive variables, and finally, (c) gaining an understanding of the underlying process that generates the data. The problem of variable selection is more pressing than ever, due to the recent emergence of extremely large data sets, sometimes involving tens to hundreds of thousands of variables and exhibiting a very small sample-to-variable ratio. Such data sets are common in gene expression array studies, proteomics, computational biology, text categorization, information retrieval, image classification, business data analytics, consumer profile analysis, temporal modeling, and other domains and data-mining applications.

There are many different ways to define the variable selection problem depending on the needs of the analysis. Often however, the feature selection problem for classification/prediction is defined as identifying the minimum-size subset of variables that exhibit the maximal predictive performance (Guyon and Elisseeff, 2003). Variable selection methods can be broadly categorized into *wrappers* (i.e., heuristic search in the space of all possible variable subsets using a classifier of choice to assess each subset's predictive information), or *filters* (i.e., not using the classifier per se to select features, but instead applying statistical criteria to first select features and then build the classifier with the best features). In addition, there exist learners that perform *embedded variable selection*, that is, that attempt to simultaneously maximize classification performance while minimizing the number of variables used. For example, shrinkage regression methods introduce a bias into the parameter estimation regression procedure that imposes a penalty on the size of the parameters. The parameters that are close to zero are essentially filtered-out from the predictive model.

A variety of embedded variable selection methods have been recently introduced. These methods are linked to a statement of the classification or regression problem as an optimization problem with specified loss and penalty functions. These techniques usually fall into a few broad classes: One class of methods uses the $\mathcal{L}^2$-norm penalty (also known as ridge penalty), for example, the recursive feature elimination (RFE) method is based on the $\mathcal{L}^2$-norm formulation of SVM classification problem (Rakotomamonjy, 2003; Guyon et al., 2002). Other methods are based on the $\mathcal{L}^1$-norm

penalty (also known as lasso penalty), for example, feature selection via solution of the $\mathcal{L}^1$-norm formulation of SVM classification problem (Zhu et al., 2004; Fung and Mangasarian, 2004) and penalized least squares with lasso penalty on the regression coefficients (Tibshirani, 1996). A third set of methods is based on convex combinations of the $\mathcal{L}^1$- and $\mathcal{L}^2$-norm penalties, for example, feature selection using the doubly SVM formulation (Wang et al., 2006) and penalized least squares with elastic net penalty (Zou and Hastie, 2005). A fourth set uses the $\mathcal{L}^0$-norm penalty, for example, feature selection via approximate solution of the $\mathcal{L}^0$-norm formulation of SVM classification problem (Weston et al., 2003). Finally other methods use other penalties, for example, smoothly clipped absolute deviation penalty (Fan and Li, 2001).

Despite the recent emphasis on mathematically sophisticated methods such as the ones mentioned, the majority of feature selection methods in the literature and in practice are heuristic in nature in the sense that in most cases it is unknown what consists an optimal feature selection solution *independently of the class of models fitted*, and under which conditions an algorithm will output such an optimal solution.

Typical variable selection approaches also include forward, backward, forward-backward, local and stochastic search wrappers (Guyon and Elisseeff, 2003; Kohavi and John, 1997; Caruana and Freitag, 1994). The most common family of filter algorithms ranks the variables according to a score and then selects for inclusion the top k variables (Guyon and Elisseeff, 2003). The score of each variable is often the univariate (pairwise) association with the outcome variable T for different measures of associations such as the signal-to-noise ratio, the G^2 statistic and others. Information-theoretic (estimated mutual information) scores and multivariate scores, such as the weights received by a Support Vector Machine, have also been suggested (Guyon and Elisseeff, 2003; Guyon et al., 2002). Excellent recent reviews of feature selection can be found in Guyon et al. (2006a), Guyon and Elisseeff (2003) and Liu and Motoda (1998).

An emerging successful but also principled filtering approach in variable selection, and the one largely followed in this paper, is based on identifying the Markov blanket of the response ("target") variable T. The Markov blanket of T (denoted as $MB(T)$) is defined as a minimal set conditioned on which all other *measured* variables become independent of T (more details in Section 3).

While classification is often useful for *recognizing or predicting the behavior* of a system, in many problem-solving activities one needs to *change the behavior* of the system (i.e., to "manipulate it"). In such cases, knowledge of the causal relations among the various parts of the system is necessary. Indeed, in order to design new drugs and therapies, institutional policies, or economic strategies, one needs to know how the diseased organism, the institution, or the economy work. Often, heuristic methods based on multivariate or univariate associations and prediction accuracy are used to induce causation, for example, consider as causally "related" the features that have a strong association with T. Such heuristics may lead to several pitfalls and erroneous inductions, as we will show in the present paper. For principled causal discovery with known theoretical properties a causal theory is needed and classification is not, in general, sufficient (Spirtes et al., 2000; Pearl, 2000; Glymour and Cooper, 1999). Consider the classical epidemiologic example of the tar-stained finger of the heavy smoker: it does predict important outcomes (e.g., increased likelihood for heart attack and lung cancer). However, eliminating the yellow stain by washing the finger does not alter these outcomes. While experiments can help discover causal structure, quite often experimentation is impossible, impractical, or unethical. For example, it is unethical to force people to smoke and it is currently impossible to manipulate most genes in humans in order to discover which genes cause disease and how they interact in doing so. Moreover, the discoveries anticipated due to the explosive

growth of biomedical and other data cannot be made in any reasonable amount of time using solely the classical experimental approach where a single gene, protein, treatment, or intervention is attempted each time, since the space of needed experiments is immense. It is clear that computational methods are needed to catalyze the discovery process.

Fortunately, relatively recently (1980's), it was shown that it is possible to soundly infer causal relations from *observational* data in many practical cases (Spirtes et al., 2000; Pearl, 2000; Glymour and Cooper, 1999; Pearl, 1988). Since then, algorithms that infer such causal relations have been developed that can greatly reduce the number of experiments required to discover the causal structure. Several empirical studies have verified their applicability (Tsamardinos et al., 2003b; Spirtes et al., 2000; Glymour and Cooper, 1999; Aliferis and Cooper, 1994).

One of the most common methods to model and induce causal relations is by learning causal Bayesian networks (Neapolitan, 2004; Spirtes et al., 2000; Pearl, 2000). A special, important and quite broad class of such networks is the family of *faithful networks* intuitively defined as those whose probabilistic properties, and specifically the dependencies and independencies, are a direct function of their structure (Spirtes et al., 2000). Cooper and Herskovits were the first to devise a score measuring the fit of a network structure to the data based on Bayesian statistics, and used it to learn the highest score network structure (Cooper and Herskovits, 1992). Heckerman and his colleagues studied theoretically the properties of the various scoring metrics as they pertain to causal discovery (Glymour and Cooper, 1999; Heckerman, 1995; Heckerman et al., 1995). Heckerman also recently showed that Bayesian-scoring methods also assume (implicitly) faithfulness, see Chapter 4 of Glymour and Cooper (1999). Another prototypical method for learning causal relationships by inducing causal Bayesian networks is the constraint-based approach as exemplified in the PC algorithm by Spirtes et al. (2000). The PC induces causal relations by assuming faithfulness and by performing tests of independence. A network with a structure consistent with the results of the tests of independence is returned. Several other methods for learning networks have been devised subsequently (Chickering, 2003; Moore and Wong, 2003; Cheng et al., 2002a; Friedman et al., 1999b).

There may be many different networks that fit the data equally well, even in the sample limit, and that exhibit the same dependencies and independencies and are thus statistically equivalent. These networks belong to the same Markov equivalence class of causal graphs and contain the same causal edges but may disagree on the direction of some of them, that is, whether A causes B or vice-versa (Chickering, 2002; Spirtes et al., 2000). An *essential graph* is a graph where the directed edges represent the causal relations on which all equivalent networks agree upon their directionality and all the remaining edges are undirected. Causal discovery by employing causal Bayesian networks is based on the following principles. The PC (Spirtes et al., 2000), Greedy Equivalence Search (Chickering, 2003) and other prototypical or state-of-the-art Bayesian network-learning algorithms provide theoretical guarantees, that under certain conditions such as faithfulness they will converge to a network that is statistically indistinguishable from the true, causal, data-generating network, if there is such. Thus, if the conditions hold the existence of all and the direction of some of the causal relations can be induced by these methods and graphically identified in the essential graph of the learnt network.

A typical condition of the aforementioned methods is causal sufficiency (Spirtes et al., 2000). This condition requires that for every pair of measured variables all their common direct causes are also measured. In other words, there are no hidden, unmeasured confounders for any pair of variables. Algorithms, such as the FCI, that in some cases can discover causal relationships in the

presence of hidden confounding variables and selection bias, have also been designed (see Spirtes et al. 2000 and Chapter 6 of Glymour and Cooper 1999).

As it was mentioned above, using observational data alone (even a sample of an infinite size), one can infer only a Markov equivalence class of causal graphs, which may be inadequate for causal discovery. For example, it is not possible to distinguish with observational data any of these two graphs that belong to the same Markov equivalence class: $X \rightarrow Y$ and $X \leftarrow Y$. However, experimental data can distinguish between these graphs. For example, if we manipulate X and see no change in the distribution of Y, we can conclude that the data-generative graph is not $X \rightarrow Y$. This principle is exploited by active learning algorithms. Generally speaking, causal discovery with active learning can be described as follows: learn an approximation of a causal network structure from available data (which is initially only observational data), select and perform an experiment that maximizes some utility function, augment data and possibly current best causal network with the result of experiment, and repeat the above steps until some termination criterion is met.

Cooper and Yoo (1999) proposed a Bayesian scoring metric that can incorporate both observational and experimental data. Using a similar metric (Tong and Koller, 2001) designed an algorithm to select experiments that reduce the entropy of probability of alternative edge orientations. A similar but more general algorithm has been proposed in Murphy (2001) where the expected information gain of a new experiment is calculated and the experiment with the largest information gain is selected. Both above methods were designed for discrete data distributions. Pournara and Wernisch (2004) proposed another active learning algorithm that uses a loss function defined in terms of the size of transition sequence equivalence class of networks (Tian and Pearl, 2001) and can handle continuous data. Meganck et al. (2006) have introduced an active learning algorithm that is based on a general decision theoretic framework that allows to assign costs to each experiment and each measurement. It is also worthwhile to mention the GEEVE system of Yoo and Cooper (2004) that recommends which experiments to perform to discover gene-regulation pathway. This instance of causal active learning allows to incorporate preferences of the experimenter. Recent work has also provided theoretical bounds and related algorithms to minimize the number of experiments needed to infer causal structure (Eberhardt et al., 2006, 2005).

2.2 Synopsis of Theoretical Results Motivating Present Research

A key question that has been investigated in the feature selection literature is which family of methods is more advantageous: filters or wrappers. A second one is what are the "relevant" features? The latter question presumably is important because "relevant" features should be important for discovery and so several definitions appeared defining relevancy (Guyon and Elisseeff, 2003; Kohavi and John, 1997). Finally, how can we design optimal and efficient feature selection algorithms? Fundamental theoretical results connecting Markov blanket induction for feature selection and local causal discovery to standard notions of relevance were given in Tsamardinos and Aliferis (2003). The latter paper provides a technical account and together with Spirtes et al. (2000), Pearl (2000), Kohavi and John (1997) and Pearl (1988) they constitute the core theoretical framework underpinning the present work. Here we provide a very concise description of the results in Tsamardinos and Aliferis (2003) since they partially answer these questions and pave the way to principled feature selection:

1. Relevance cannot be defined independently of the learner and the model-performance metric (e.g., the loss function used) in a way that the relevant features are the solution to the feature

selection problem. The quest for a universally applicable notion of relevancy for prediction is futile.

2. Wrappers are subject to the No-Free Lunch Theorem for optimization: averaged out on all possible problems any wrapper algorithm will do as well as a random search in the space of feature subsets. Therefore, there cannot be a wrapper that is a priori more efficient than any other (i.e., without taking into account the learner and model-performance metric). The quest for a universally efficient wrapper is futile as well.

3. Any filter algorithm can be viewed as the implementation of a definition of relevancy. Because of #1, there is no filter algorithm that is universally optimal, independently of the learner and model-performance metric.

4. Because of #2, wrappers cannot guarantee universal efficiency and because of #3, filters cannot guarantee universal optimality and in that respect, neither approach is superior to the other.

5. Under the conditions that (i) the learner that constructs the classification model can actually learn the distribution $P(T|MB(T))$ and (ii) that the loss function is such that perfect estimation of the probability distribution of T is required with the smallest number of variables, the Markov blanket of T is the optimal solution to the feature selection problem.

6. Sound Markov blanket induction algorithms exist for faithful distributions.

7. In faithful distributions and under the conditions of #5, the strongly/weakly/irrelevant taxonomy of variables (Kohavi and John, 1997) can be mapped naturally to causal graph properties. Informally stated, strongly relevant features were defined by Kohavi and John (1997) to be features that contain information about the target not found in other variables; weakly relevant features are informative but redundant; irrelevant features are not informative (for formal definitions see Section 3). Under the causal interpretation of this taxonomy of relevancy, strongly relevant features are the members of the Markov blanket of the target variable, weakly relevant features are all variables with an undirected path to T which are not themselves members of $MB(T)$, and irrelevant features are variables with no undirected path to the target.

8. Since in faithful distributions the $MB(T)$ contains the direct causes and direct effects of T, and since state-of-the-art $MB(T)$ algorithms output the spouses separately from the direct causes and direct effects, inducing the $MB(T)$ not only solves the feature selection problem but also a form of local causal discovery problem.

Figure 1 provides a summary of the connection between causal structure and predictivity.

We will refer to algorithms that perform feature selection by formal causal induction as *causal feature selection* and algorithms that do not as *non-causal*. As highly complementary to the above results we would add the arguments in favor of causal feature selection presented in Guyon et al. (2007) and recent theoretical (Hardin et al., 2004) and empirical (Statnikov et al., 2006) results that show that under the same sufficient conditions that make Markov blanket the optimal solution to the feature selection and local causal discovery problem, state-of-the-art methods such as ranking features by SVM weights (RFE being a prototypical algorithm Guyon et al. 2002) do not return the

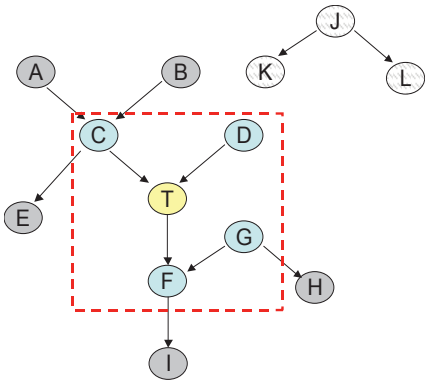

Figure 1: Relationship between causal structure and predictivity in faithful distributions. Cyan variables are members of Markov blanket of T. They are depicted inside the red dotted square (i.e., variables that have undirected path to target T and that are predictive of T given the remaining variables which makes them strongly relevant). Markov blanket variables include direct causes of T (C,D), direct effects (F), and "spouses" of T (i.e., direct causes of the direct effects of T) (G). Grey variables are non-members of Markov blanket of T that have undirected path to T. They are not predictive of T given the remaining variables but they are predictive given a subset of the remaining variables (which makes them weakly relevant). Light-gray variables are variables that do not have an undirected path to T. They are not predictive of T given any subset of the remaining variables, thus they are irrelevant.

correct causal neighborhood and are not minimal, that is, do not solve the feature selection problem) even in the large sample limit.

The above theoretical results also suggest that one should not attempt to define and identify the relevant features for prediction, when discovery is the goal of the analysis. Instead, we argue that a set of features with well-defined *causal* semantics should be identified instead: for example, the $MB(T)$, the set of direct causes and direct effects of T, the set of all (direct and indirect) causes of T, and so on.

We will investigate limitations of prominent non-causal feature selection algorithms in the companion paper (Aliferis et al., 2010).

2.3 Methods to Speed-up Discovery: Local Discovery as a Critical Tool for Scalability

As appealing as causal discovery may be for understanding a domain, predicting effects of intervention, and pursuing principled feature selection for classification, a major problem up until recent years has been scalability. The PC algorithm is worst-case exponential (Spirtes et al., 2000) and in practical settings it cannot typically handle more than a hundred variables. The FCI algorithm is similarly worst-case intractable (Spirtes et al., 2000) and does not handle more than a couple of dozen of variables practically. Learning Bayesian networks with Bayesian scoring techniques is NP-Hard (Chickering et al., 1994). Heuristic hill-climbing techniques such as the Sparse Candidate Algorithm (Friedman et al., 1999b) do not provide guaranteed correct solutions, neither they are very efficient (they can cope with a few hundred variables at the most in practical applications).

With the advent of massive data sets in biology, medicine, information retrieval, the WWW, finance, economics, and so on, scalability has become a critical requirement for practical algorithms. In early 2000's predictions about the feasibility of causal discovery in high-dimensional data were bleak (Silverstein et al., 2000). A variety of methods to scale up causal discovery have been devised to address the problem:

1. Learn the full graph but focus on special types of distributions;

2. Exploit domain knowledge to speed-up learning;

3. Abandon the effort to learn the full causal graph and instead develop methods that find a portion of the true arcs (not specific to some target variable);

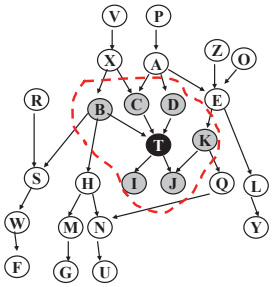
4. Abandon the effort to learn the full causal graph and instead develop methods that learn the local neighborhood of a specific target variable directly;

5. Abandon the effort to learn the fully oriented causal graph and instead develop methods that learn the unoriented graph;

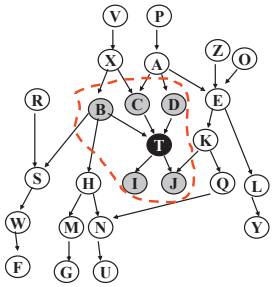
6. Induce constrains of the possible relationships among variables and then learn the full causal graph.

Techniques #1 and #2 were introduced in Chow and Liu (1968) for learning tree-like graphs and Naïve-Bayes graphs (Duda and Hart, 1973), while modern versions are exemplified in (i) TAN/BAN classifiers that relax the Naïve-Bayes structure (Cheng and Greiner, 2001, 1999; Friedman et al., 1997), (ii) efficient complete model averaging of Naïve-Bayes classifiers (Dash and Cooper, 2002), and (iii) algorithm TPDA which restricts the class of distributions so that learning becomes from worst-case intractable to solvable in 4^{th} degree polynomial time to the number of variables (and quadratic if prior knowledge about the ordering of variables is known) (Cheng et al., 2002a). Technique #3 was introduced by Cooper (1997) and replaced learning the complete graph by learning only a small portion of the edges (not pre-specified by the user but determined by the discovery method). Techniques $\#4-6$ pertain to local learning: Technique #4 seeks to learn the complete causal neighbourhood around a target variable provided by the user (Aliferis et al., 2003a; Tsamardinos et al., 2003b). We emphasize that local learning (technique #4) is not the same as technique #3 (incomplete learning) although inventors of incomplete methods often call them 'local'. Technique #5 abandons directionality and learns only a fully connected but undirected graph by using local learning methods (Tsamardinos et al., 2006; Brown et al., 2005). Often post-processing with additional algorithms can provide directionality. The latter can also be obtained by domain-specific criteria or experimentation. Finally, technique #6 uses local learning to restrict the search space for full-graph induction algorithms (Tsamardinos et al., 2006; Aliferis and Tsamardinos, 2002b).

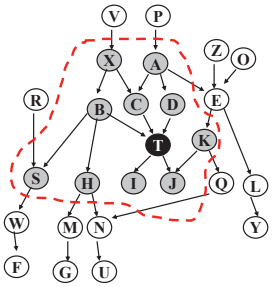
In the present paper we explore methods to learn local causal neighborhoods and test them in high-dimensional data sets. In the companion paper (Aliferis et al., 2010) we provide a framework for building global graphs using the local methods. Incomplete learning (technique #3) is not pursued because it is redundant in light of the other (complete) local and global learning approaches. Figure 2 provides a visual reference guide to the kinds of causal discovery problems the methods in the present work are able to address by starting from local causal discovery.



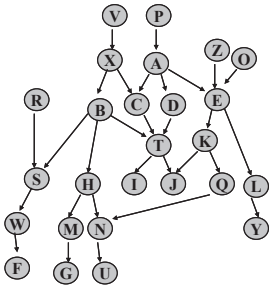
Problem #1: Consider a target variable T and discover Markov Blanket of T.



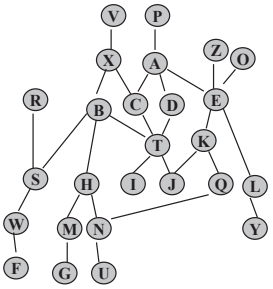
Problem #2: Consider a target variable T and discover Parents and Children of T.



Problem #3: Consider a target variable T and discover regions (e.g., of depth 2 edges) around T.



Problem #4: Discover directed graph.



Problem #5: Discover undirected graph.

Figure 2: Five types of causal discovery from local (types 1, 2), to global (4, 5) and intermediate (3). Specialized algorithms that solve type 2 (local causes and effects) can become building blocks for relatively efficiently solving all other types of causal discovery as well (see text for details).

2.4 Desiderata for Local Algorithms, Brief Review of Prior Methods for Markov Blanket and Local Neighborhood Induction

An ideal local learning algorithm should have three characteristics: (a) well-defined properties, especially broadly applicable conditions that guarantee correctness, (b) good performance in practical distributions and corresponding data sets, including ones with small sample and many features, and finally (c) scalability in terms of running time. We briefly review progress made in the field toward these goals.

Firm theoretical foundations of Bayesian networks were laid down by Pearl and his co-authors (Pearl, 1988). Furthermore, all local learning methods exploit either the constraint-based framework for causal discovery developed by Spirtes, Glymour, Schienes, Pearl, and Verma and their co-authors (Spirtes et al., 2000; Pearl, 2000; Pearl and Verma, 1991) or the Bayesian search-and-score Bayesian network learning framework introduced by Cooper and Herskovits (1992). The relevant key contributions were covered in Section 2.1 and will not be repeated here.

While the above foundations were introduced and developed in the span of at least the last 30 years, local learning is no more than 10 years old. Specialized Markov blanket learning methods were first introduced in 1996 (Koller and Sahami, 1996), incomplete causal methods in 1997 (Cooper, 1997), and local causal discovery methods (for targeted complete induction of direct causes and effects) were first introduced in 2002 and 2003 (Tsamardinos et al., 2003b; Aliferis and Tsamardinos, 2002a). In 1996, Koller et al. introduced a heuristic algorithm for inducing the

Markov blanket from data and tested the algorithm in simulated, real text, and other types of data from the UCI repository (Koller and Sahami, 1996). In 1997 Cooper and colleagues introduced and applied the heuristic method K2MB for finding the Markov blanket of a target variable in the task of predicting pneumonia mortality (Cooper, 1997). In 1997 Cooper introduced an incomplete method for causal discovery (Cooper et al., 1997). The algorithm was able to circumvent lack of scalability of global methods by returning a subset of arcs from the full network. To avoid notational confusion we point out that the algorithm was termed LCD (local causal discovery) despite being an *incomplete rather than local* algorithm as local algorithms are defined in the present paper (i.e., focused on some user-specified target variable or localized region of the network). A revision of the algorithm termed LCD2 was presented in Mani and Cooper (1999).

In 1999 Margaritis and Thrun introduced the GS algorithm with the intent to induce the Markov blanket for the purpose of speeding up global network learning (i.e., not for feature selection) (Margaritis and Thrun, 1999). GS was the first published sound Markov blanket induction algorithm. The weak heuristic used by GS combined with the need to condition on at least as many variables simultaneously as the Markov blanket size makes it impractical for many typical data sets since the required sample grows exponentially to the size of the Markov blanket. This in turn forces the algorithm to stop its execution prematurely (before it identifies the complete Markov blanket) because it cannot grow the conditioning set while performing reliable tests of independence. Evaluations of GS by its inventors were performed in data sets with a few dozen variables leaving the potential of scalability largely unexplored.

In 2001 Cheng et al. applied the TPDA algorithm (a global BN learner) (Cheng et al., 2002a) to learn the Markov blanket of the target variable in the Thrombin data set in order to solve a prediction problem of drug effectiveness on the basis of molecular characteristics (Cheng et al., 2002b). Because TPDA could not be run with more than a few hundred variables efficiently, they pre-selected 200 variables (out of 139,351 total) using univariate filtering. Although this procedure in general will not find the true Markov blanket (because otherwise-unconnected with the target spouses can be missed, many true parents and children may not be in the first 200 variables, and many non-Markov blanket members cannot be eliminated), the resulting classifier performed very well winning the 2001 KDD Cup competition.

Friedman et al. proposed a simple Bootstrap procedure for determining membership in the Markov blanket for small sample situations (Friedman et al., 1999a). The Markov blanket in this method is to be extracted from the full Bayesian network learned by the SCA (Sparse Candidate Algorithm) learner (Friedman et al., 1999b).

In 2002 and 2003 Tsamardinos, Aliferis, et al. presented a modified version of GS, termed IAMB and several variants of the latter that through use of a better inclusion heuristic than GS and optional post-processing of the tentative and final output of the local algorithm with global learners would achieve true scalability to data sets with many thousands of variables and applicability in modest (but not very small) samples (Tsamardinos et al., 2003a; Aliferis et al., 2002). IAMB and several variants were tested both in the high-dimensional Thrombin data set (Aliferis et al., 2002) and in data sets simulated from both existing and random Bayesian networks (Tsamardinos et al., 2003a). The former study found that IAMB scales to high-dimensional data sets. The latter study compared IAMB and its variants to GS, Koller-Sahami, and PC and concluded that IAMB variants on average perform best in the data sets tested.

In 2003 Tsamardinos and Aliferis presented a full theoretical analysis explaining relevance as defined by Kohavi and John (1997) in terms of Markov blanket and causal connectivity (Tsamardi-

nos and Aliferis, 2003). They also provided theoretical results about the strengths and weaknesses of filter versus wrapper algorithms, the impossibility of a universal definition of relevance, and the optimality of Markov blanket as a solution to the feature selection problem in formal terms. These results were summarized in Section 2.2.

The extension of Sparse Candidate Algorithm to create a local-to-global learning strategy was first introduced in Aliferis and Tsamardinos (2002b) and led to the MMHC algorithm introduced and evaluated in Tsamardinos et al. (2006). MMHC was shown in Tsamardinos et al. (2006) to achieve best-of-class performance in quality and scalability compared to most state-of-the-art global network learning algorithms.

In 2002 Aliferis et al. also introduced parallel and distributed versions of the IAMB family of algorithms (Aliferis et al., 2002). These serve as the precursor of the parallel and distributed local neighborhood learning method presented in the companion paper (Aliferis et al., 2010). The precursor of the GLL framework was also introduced by Aliferis and Tsamardinos in 2002 for the explicit purpose of reducing the sample size requirements of IAMB-style algorithms (Aliferis and Tsamardinos, 2002a).

In 2003 Aliferis et al. introduced algorithm HITON[1] Aliferis et al., and Tsamardinos et al. introduced algorithms MMPC and MMMB (Aliferis et al., 2003a; Tsamardinos et al., 2003b). These are the first concrete algorithms that would find sets of direct causes or direct effects and Markov blankets in a scalable and efficient manner. HITON was tested in 5 biomedical data sets spanning clinical, text, genomic, structural and proteomic data and compared against several feature selection methods with excellent results in parsimony and classification accuracy (Aliferis et al., 2003a). MMPC was tested in data simulated from human-derived Bayesian networks with excellent results in quality and scalability. MMMB was tested in the same data sets and compared to prior algorithms such as Koller-Sahami algorithm and IAMB variants with superior results in the quality of Markov blankets. These benchmarking and comparative evaluation experiments provided evidence that the local learning approach held not only theoretical but also practical potential.

HITON-PC, HITON-MB, MMPC, and MMMB algorithms lacked so-called "symmetry correction" (Tsamardinos et al., 2006), however HITON used a wrapping post-processing that at least in principle removed this type of false positives. The symmetry correction was introduced in 2005 and 2006 by Tsamardinos et al. in the context of the introduction of MMHC (Tsamardinos et al., 2006, 2005). Peña et al. also published work pointing to the need for a symmetry correction in MMPC (Peña et al., 2005b).

HITON was applied in 2005 to understand physician decisions and guideline compliance in the diagnosis of melanomas (Sboner and Aliferis, 2005). HITON has been applied for the discovery of biomarkers in human cancer data using microarrays and mass spectrometry and is also implemented in the GEMS and FAST-AIMS systems for the automated analysis of microarray and mass spectrometry data respectively (Statnikov et al., 2005b; Fananapazir et al., 2005). In a recent extensive comparison of biomarker selection algorithms (Aliferis et al., 2006a,b) it was found that HITON outperforms 16 state-of-the-art representatives from all major biomarker algorithmic families in terms of combined classification performance and feature set parsimony. This evaluation used 9 human cancer data sets (gene expression microarray and mass spectrometry) in 10 diagnostic and outcome (i.e., survival) prediction classification tasks. In addition to the above real data, resimulation was also used to create two gold standard network structures, one re-engineered from

1. From the Greek word "Χιτών" meaning "cloak", and pronounced <hee tó n>.

human lung cancer data and one from yeast data. Several applications of HITON in text categorization have been published where the algorithm was used to understand complex "black box" SVM models and convert complex models to Boolean queries usable by Boolean interfaces of Medline (Aphinyanaphongs and Aliferis, 2004), to examine the consistency of editorial policies in published journals (Aphinyanaphongs et al., 2006), and to predict drug-drug interactions (Duda et al., 2005). HITON was also compared with excellent results to manual and machine feature selection in the domain of early graft failure in patients with liver transplantations (Hoot et al., 2005).

In 2003 Frey et al. explored the idea of using decision tree induction to indirectly approximate the Markov blanket (Frey et al., 2003). They produced promising results, however a main problem with the method was that it requires a threshold parameter that cannot be optimized easily. Furthermore, as we show in the companion paper (Aliferis et al., 2010) decision tree induction is subject to synthesis and does not select only the Markov blanket members.

In 2004 Mani et al. introduced BLCD-MB, which resembles IAMB but using a Bayesian scoring metric rather than conditional independence testing (Mani and Cooper, 2004). The algorithm was applied with promising results in infant mortality data (Mani and Cooper, 2004).

A method for learning regions around target variables by recursive application of MMPC or other local learning methods was introduced in Tsamardinos et al. (2003c). Peña et al. applied interleaved MMPC for learning regions in the domain of bioinformatics (Peña et al., 2005a).

In 2006 Gevaert et al. applied K2MB for the purpose of learning classifiers that could be used for prognosis of breast cancer from microarray and clinical data (Gevaert et al., 2006) . Univariate filtering was used to select 232 genes before applying K2MB.

Other recent efforts in learning Markov blankets include the following algorithms: PCX, which post-processes the output of PC (Bai et al., 2004); KIAMB, which addresses some violations of faithfulness using a stochastic extension to IAMB (Peña et al., 2007); FAST-IAMB, which speeds up IAMB (Yaramakala and Margaritis, 2005); and MBFS, which is a PC-style algorithm that returns a graph over Markov blanket members (Ramsey, 2006).

2.5 Open Problems and Focus of Paper

The focus of the present paper is to describe state-of-the-art algorithms for inducing direct causes and effects of a response variable or its Markov blanket using a novel cohesive framework that can help in the analysis, understanding, improvement, application (including configuration / parameterization) and dissemination of the algorithms. We furthermore study comparative performance in terms of predictivity and parsimony of state-of-the-art local causal algorithms; we compare them to non-causal algorithms in real and simulated data sets using the same criteria; and show how novel algorithms can be obtained. A second major hypothesis (and set of experiments in the present paper) is that non-causal feature selection methods may yield predictively optimal feature sets while from a causal perspective their output is unreliable. Testing this hypothesis has tremendous implications in many areas (e.g., analysis of biomedical molecular data) where highly predictive variables (biomarkers) of phenotype (e.g., disease or clinical outcome) are often interpreted as being causally implicated for the phenotype and great resources are invested in pursuing these markers for new drug development and other research.

In the second part of our work (Aliferis et al., 2010) we address gaps in the theoretical understanding of local causal discovery algorithms and provide empirical and theoretical analyses of their

behavior as well as several extensions including algorithms for learning the full causal graph using a divide-and-conquer local learning approach.

3. Notation and Definitions

In the present paper we use Bayesian networks as the language in which to represent data generating processes and causal relationships. We thus first formally define causal Bayesian networks. Recall that in a directed acyclic graph (DAG), a node A is the parent of B (B is the child of A) if there is a direct edge from A to B, A is the ancestor of B (B is the descendant of A) if there is a direct path from A to B. "Nodes", "features", and "variables" will be used interchangeably.

3.1 Notation

We will denote variables with uppercase letters X, Y, Z, values with lowercase letters, x, y, z, and sets of variables or values with boldface uppercase or lowercase respectively. A "target" (i.e., response) variable is denoted as T unless stated otherwise.

Definition 1 ***Conditional Independence***. *Two variables X and Y are conditionally independent given $\boldsymbol{Z}$, denoted as $I(X,Y|\boldsymbol{Z})$, iff $P(X=x,Y=y|\boldsymbol{Z}=\boldsymbol{z}) = P(X=x|\boldsymbol{Z}=\boldsymbol{z})P(Y=y|\boldsymbol{Z}=\boldsymbol{z})$, for all values $x, y, \boldsymbol{z}$ of $X, Y, \boldsymbol{Z}$ respectively, such that $P(\boldsymbol{Z}=\boldsymbol{z}) > 0$.*

Definition 2 ***Bayesian network*** $\langle \boldsymbol{V}, G, J \rangle$. *Let $\boldsymbol{V}$ be a set of variables and J be a joint probability distribution over all possible instantiations of $\boldsymbol{V}$. Let G be a directed acyclic graph (DAG) such that all nodes of G correspond one-to-one to members of $\boldsymbol{V}$. We require that for every node $A \in \boldsymbol{V}$, A is probabilistically independent of all non-descendants of A, given the parents of A (i.e.,* Markov Condition *holds). Then we call the triplet $\langle \boldsymbol{V}, G, J \rangle$ a Bayesian network (abbreviated as "BN"), or equivalently a belief network or probabilistic network (Neapolitan, 1990).*

Definition 3 ***Operational criterion for causation***. *Assume that a variable A can be forced by a hypothetical experimenter to take values a_i. If the experimenter assigns values to A according to a uniformly random distribution over values of A, and then observes $P(B|A=a_i) \neq P(B|A=a_j)$ for some i and j, (and within a time window dt), then variable A is a cause of variable B (within dt).*

We note that randomization of values of A serves to eliminate any combined causative influences on both A and B. We also note that universally acceptable definitions of causation have eluded scientists and philosophers for centuries. Indeed the provided criterion is not a proper definition, because it examines one cause at a time (thus multiple causation can be missed), it assumes that a hypothetical experiment is feasible even when in practice this is not attainable, and the notion of "forcing" variables to take values presupposes a special kind of causative primitive that is formally undefined. Despite these limitations, the above criterion closely matches the notion of a Randomized Controlled Experiment which is a de facto standard for causation in many fields of science, and following common practice in the field (Glymour and Cooper, 1999) will serve operationally the purposes of the present paper.

Definition 4 ***Direct and indirect causation***. *Assume that a variable A is a cause of variable B according to the operational criterion for causation in definition 3. A is an indirect cause for B with respect to a set of variables $\boldsymbol{V}$, iff A is not a cause of B for some instantiation of values of $\boldsymbol{V} \setminus \{A, B\}$, otherwise A is a direct cause of B.*

Definition 5 ***Causal probabilistic network (a.k.a. causal Bayesian network)***. *A causal probabilistic network (abbreviated as "CPN") $\langle \boldsymbol{V}, G, J \rangle$ is the Bayesian network $\langle \boldsymbol{V}, G, J \rangle$ with the additional semantics that if there is an edge $A \rightarrow B$ in G then A directly causes B (for all $A, B \in \boldsymbol{V}$) (Spirtes et al., 2000).*

Definition 6 ***Faithfulness***. *A directed acyclic graph G is faithful to a joint probability distribution J over variable set $\boldsymbol{V}$ iff every independence present in J is entailed by G and the Markov Condition. A distribution J is faithful iff there exists a directed acyclic graph G such that G is faithful to J (Spirtes et al., 2000; Glymour and Cooper, 1999).*

It follows from the Markov Condition that in a CPN $C = \langle \boldsymbol{V}, G, J \rangle$ every conditional independence entailed by the graph G is also present in the probability distribution J encoded by C. *Thus, together faithfulness and the causal Markov Condition establish a close relationship between a causal graph G and some empirical or theoretical probability distribution J. Hence we can associate statistical properties of the sample data with causal properties of the graph of the CPN.* The d-separation criterion determines all independencies entailed by the Markov Condition and a graph G.

Definition 7 ***d-separation, d-connection***. *A* collider *on a path p is a node with two incoming edges that belong to p. A path between X and Y given a conditioning set $\boldsymbol{Z}$ is open, if (i) every collider of p is in $\boldsymbol{Z}$ or has a descendant in $\boldsymbol{Z}$, and (ii) no other nodes on p are in $\boldsymbol{Z}$. If a path is not open, then it is* blocked. *Two variables X and Y are d-separated given a conditioning set $\boldsymbol{Z}$ in a BN or CPN C iff every path between X, Y is blocked (Pearl, 1988).*

Property 1 *Two variables X and Y are d-separated given a conditioning set $\boldsymbol{Z}$ in a faithful BN or CPN iff $I(X, Y | \boldsymbol{Z})$ (Spirtes et al., 2000). It follows, that if they are d-connected, they are conditionally dependent.*

Thus, in a faithful CPN, d-separation captures *all* conditional dependence and independence relations that are encoded in the graph.

Definition 8 ***Markov blanket of T, denoted as $MB(T)$***. *A set $MB(T)$ is a minimal set of features with the following property: for every variable subset $\boldsymbol{S}$ with no variables in $MB(T)$, $I(\boldsymbol{S}, T | MB(T))$. In Pearl's terminology this is called the Markov Boundary (Pearl, 1988).*

Property 2 *The $MB(T)$ of any variable T in a faithful BN or a CPN is unique (Tsamardinos et al., 2003b) (also directly derived from Pearl and Verma 1991 and Pearl and Verma 1990).*

Property 3 *The $MB(T)$ in a faithful CPN is the set of parents, children, and parents of children (i.e., "spouses") of T (Pearl, 2000, 1988).*

Definition 9 ***Causal sufficiency***. *For every pair of measured variables, all their common causes are also measured.*

Definition 10 ***Feature selection problem***. *Given a sample S of instantiations of variable set $\boldsymbol{V}$ drawn from distribution D, a classifier induction algorithm C and a loss function L, find: smallest subset of variables $\boldsymbol{F} \subseteq \boldsymbol{V}$ such that $\boldsymbol{F}$ minimizes expected loss $L(M, D)$ in distribution D where M is the classifier model (induced by C from sample S projected on $\boldsymbol{F}$).*

In the above definition, we mean "exact" minimization of $L(M,D)$. In other words, out of all possible subsets of variable set $\boldsymbol{V}$, we are interested in subsets $\boldsymbol{F} \subseteq \boldsymbol{V}$ that satisfy the following two criteria: (i) $\boldsymbol{F}$ minimizes $L(M,D)$ and (ii) there is no subset $\boldsymbol{F}^* \subseteq \boldsymbol{V}$ such that $|\boldsymbol{F}^*| < |\boldsymbol{F}|$ and $\boldsymbol{F}^*$ also minimizes $L(M,D)$.

Definition 11 ***Wrapper feature selection algorithm***. *An algorithm that tries to solve the Feature Selection problem by searching in the space of feature subsets and evaluating each one with a user-specified classifier and loss function estimator.*

Definition 12 ***Filter feature selection algorithm***. *An algorithm designed to solve the Feature Selection problem by looking at properties of the data and not by applying a classifier to estimate expected loss for different feature subsets.*

Definition 13 ***Causal feature selection algorithm***. *An algorithm designed to solve the Feature Selection problem by (directly or indirectly) inducing causal structure and by exploiting formal connections between causation and predictivity.*

Definition 14 ***Non-causal feature selection algorithm***. *An algorithm that tries to solve the Feature Selection problem without reference to the causal structure that underlies the data.*

Definition 15 ***Irrelevant, strongly relevant, weakly relevant, relevant feature (with respect to target variable*** T***)***. *A variable set $\boldsymbol{I}$ that conditioned on every subset of the remaining variables does not carry predictive information about T is irrelevant to T. Variables that are not irrelevant are called relevant. Relevant variables are strongly relevant if they are predictive for T given the remaining variables, while a variable is weakly relevant if it is non-predictive for T given the remaining variables (i.e., it is not strongly relevant) but it is predictive given some subset of the remaining variables.*

4. A General Framework for Local Learning

In this section we present a formal general framework for learning local causal structure. Such a framework enables a systematic exploration of a family of related but not identical algorithms which can be seen as instantiations of the same broad algorithmic principles encapsulated in the framework. Also, the framework allows us to think about formal conditions for correctness not only at the algorithm level but also at the level of algorithm family. We are thus able to identify two distinct sets of assumptions for correctness: the more general set of assumptions (*admissibility rules*) applies to the generative algorithms and provides a set of flexible rules for constructing numerous algorithmic instantiations each one of which is guaranteed to be correct provided that in addition a more specific and fixed set of assumptions hold (i.e., specific sufficient conditions for correctness of the algorithms that are instantiations of the generative framework).

We consider the following two problems of local learning:

Problem 1 *Given a set of variables $\boldsymbol{V}$ following distribution P, a sample D drawn from P, and a target variable of interest $T \in \boldsymbol{V}$: determine the direct causes and direct effects of T.*

Problem 2 *Given a set of variables $\boldsymbol{V}$ following distribution P, a sample D drawn from P, and a target variable of interest $T \in \boldsymbol{V}$: determine the direct causes, direct effects, and the direct causes of the direct effects of T.*

From the work of Spirtes et al. (2000) and Pearl (2000, 1988) we know that when the data are observational, causal sufficiency holds for the variables $\boldsymbol{V}$, and the distribution P is faithful to a causal Bayesian network, then the direct causes, direct effects, and direct causes of the direct effects of T, correspond to the parents, children, and spouses of T respectively in that network.

Thus, in the context of the above assumptions, Problem 1 seeks to identify the parents and children set of T in a Bayesian network G faithful to P; we will denote this subset as $PC_G(T)$. There may be several networks that faithfully capture distribution P, however, as we have shown in Tsamardinos et al. (2003b) (also directly derived from Pearl and Verma 1991, 1990) $PC_G(T) = PC_{G'}(T)$, for any two networks G and G' faithful to the same distribution. So, the set of parents and children of T is unique among all Bayesian networks faithful to the same distribution and so we will drop the superscript and denote it simply as $PC(T)$. Notice that, a node may be a parent of T in one network and a child of T in another, for example, the graphs $X \leftarrow T$ and $X \rightarrow T$ may both be faithful to the same distribution. However, the set of parents and children of T, that is, $\{X\}$, remains the same in both networks. Finally, by Theorem 4 in Tsamardinos et al. (2003b) we know that the Markov blanket $MB(T)$ is unique in all networks faithful to the same distribution. Therefore, under the assumptions of the existence of a causal Bayesian network that faithfully captures P and causal sufficiency of $\boldsymbol{V}$, the problems above can be recast as follows:

Problem 3 *Given a set of variables $\boldsymbol{V}$ following distribution P, a sample D drawn from P, and a target variable of interest $T \in \boldsymbol{V}$: determine the $PC(T)$.*

Problem 4 *Given a set of variables $\boldsymbol{V}$ following distribution P, a sample D drawn from P, and a target variable of interest $T \in \boldsymbol{V}$: determine the $MB(T)$.*

Problem 1 is geared toward local causal discovery, while Problem 2 is oriented toward causal feature selection for classification. The solutions to these problems can form the basis for solving several other related local discovery problems, such as learning the unoriented set of causal relations (skeleton of a Bayesian network), a region of interest of a given depth of d edges around T, or further analyze the data to discover the orientation of the causal relations.

The *Generalized Local Learning* (GLL) framework consists of two main types of algorithms: GLL-PC (GLL Parent and Children) for Problem 1 and GLL-MB for Problem 2.

4.1 Discovery of the $PC(T)$ Set

Identification of the $PC(T)$ set is based on the following theorem in Spirtes et al. (2000):

Theorem 1 *In a faithful BN $\langle \boldsymbol{V}, G, P \rangle$ there is an edge between the pair of nodes $X \in \boldsymbol{V}$ and $Y \in \boldsymbol{V}$ iff $\neg I(X, Y | \boldsymbol{Z})$, for all $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \{X, Y\}$.*

Any variable X that does have an edge with T belongs to the $PC(T)$. Thus, the theorem gives rise to an immediate algorithm for identifying $PC(T)$: for any variable $X \in \boldsymbol{V} \setminus \{T\}$, and all $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \{X, T\}$, test whether $\mathrm{I}(X, T | \boldsymbol{Z})$. If such a $\boldsymbol{Z}$ exists for which $\mathrm{I}(X, T | \boldsymbol{Z})$, then $X \notin PC(T)$, otherwise $X \in PC(T)$. This algorithm is equivalent to a "localized version" of SGS (Spirtes et al., 2000). The problem of course is that the algorithm is very inefficient because it tests all subsets of the variables and thus does not scale beyond problems of trivial size. The order of complexity is $\mathrm{O}(|\boldsymbol{V}| 2^{|\boldsymbol{V}|-2})$. The general framework presented below attempts to characterize not only the above algorithm but also efficient implementations of the theorem that maintain soundness.

There are several observations that lead to more efficient but still sound algorithms. First notice that, once a subset $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \{X,T\}$ has been found s.t. $\mathrm{I}(X,T|\boldsymbol{Z})$ there is no need to perform any other test of the form $\mathrm{I}(X,T|\boldsymbol{Z}')$: we know that $X \notin PC(T)$. Thus, the sooner we identify good candidate subsets $\boldsymbol{Z}$ that can render the variables conditionally independent from T, the fewer tests will be necessary.

Second, to determine whether $X \in PC(T)$ there is no need to test whether $\neg\mathrm{I}(X,T|\boldsymbol{Z})$ for all subsets $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \{X,T\}$ but only for all subsets $\boldsymbol{Z}' \subseteq Parents_G(T) \setminus \{X\}$ and all $\boldsymbol{Z}' \subseteq Parents_G(X) \setminus \{T\}$ where G is any network faithful to the distribution. To see this, let us first assume that there is no edge between X and T. Notice that either X is a non-descendant of T or T is a non-descendant of X since the network is acyclic and they cannot be both descendants of each other. If X is a non-descendant of T in G, then by the Markov Condition we know that there is a subset $\boldsymbol{Z}$ of $Parents_G(T) = Parents_G(T) \setminus \{X\}$ (the equality because we assume no edge between T and X) such that $\mathrm{I}(X,T|\boldsymbol{Z})$. Similarly, if T is a non-descendant of X in G then there is $\boldsymbol{Z} \subseteq Parents_G(X) \setminus \{T\}$ such that $\mathrm{I}(X,T|\boldsymbol{Z})$. Conversely, if there is an edge $X \rightarrow T$ or $T \rightarrow X$, then the dependence $\neg\mathrm{I}(X,T|\boldsymbol{Z})$ holds for all $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \{X,T\}$ (by the theorem), thus also holds for all $\boldsymbol{Z} \subseteq Parents_G(T) \setminus \{X\}$ or $\boldsymbol{Z} \subseteq Parents_G(X) \setminus \{T\}$. We just proved that:

Proposition 1 *In a faithful BN $\langle \boldsymbol{V}, G, P \rangle$ there is an edge between the pair of nodes $X \in \boldsymbol{V}$ and $T \in \boldsymbol{V}$ iff $\neg I(X,T|\boldsymbol{Z})$, for all $\boldsymbol{Z} \subseteq Parents_G(X) \setminus \{T\}$ and $\boldsymbol{Z} \subseteq Parents_G(T) \setminus \{X\}$.*

Since the networks in most practical problems are relatively sparse, if we knew the sets $Parents_G(T)$ and $Parents_G(X)$ then the number of subsets that would need to be checked for conditional independence for each $X \in PC(T)$ is significantly smaller: $|2^{|\boldsymbol{V}\setminus\{T,X\}|}| \gg |2^{|Parents_G(X)|}| + |2^{|Parents_G(T)|}|$. Of course, we do not know the sets $Parents_G(T)$ and $Parents_G(X)$ but one could work with any superset of them as shown by the following proposition:

Proposition 2 *In a faithful BN $\langle \boldsymbol{V}, G, P \rangle$ there is an edge between the pair of nodes $X \in \boldsymbol{V}$ and $T \in \boldsymbol{V}$ iff $\neg I(X,T|\boldsymbol{Z})$, for all $\boldsymbol{Z} \subseteq \boldsymbol{S}$ and $\boldsymbol{Z} \subseteq \boldsymbol{S}'$, where $Parents_G(X) \setminus \{T\} \subseteq \boldsymbol{S} \subseteq \boldsymbol{V} \setminus \{X,T\}$ and $Parents_G(X) \setminus \{T\} \subseteq \boldsymbol{S}' \subseteq \boldsymbol{V} \setminus \{X,T\}$.*

Proof If there is an edge between the pair of nodes X and T then $\neg\mathrm{I}(X,T|\boldsymbol{Z})$, for all subsets $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \{X,T\}$ (by Theorem 1) and so $\neg\mathrm{I}(X,T|\boldsymbol{Z})$ for all $\boldsymbol{Z} \subseteq \boldsymbol{S}$ and $\boldsymbol{Z} \subseteq \boldsymbol{S}'$ too. Conversely, if there is no edge between the pair of nodes X and T, then $\mathrm{I}(X,T|\boldsymbol{Z})$, for some $\boldsymbol{Z} \subseteq Parents_G(X) = Parents_G(X) \setminus \{T\} \subseteq \boldsymbol{S}$ or $\boldsymbol{Z} \subseteq Parents_G(T) = Parents_G(T) \setminus \{X\} \subseteq \boldsymbol{S}'$ (by Proposition 1). ■

Now, the sets $Parents_G(X)$ and $Parents_G(T)$ depend on the specific network G that we are trying to learn. As we mentioned however, there may be several such statistically equivalent networks among which we cannot differentiate from the data, forming an equivalence class. Thus, it is preferable to work with supersets of $Parents_G(T)$ and $Parents_G(X)$ that do not depend on a specific network member of the class: these supersets are the sets $PC(T)$ and $PC(X)$.

Let us suppose that we have available a superset of $PC(T)$ called $TPC(T)$ (tentative PC). For any node $X \in TPC(T)$ if $\mathrm{I}(X,T|\boldsymbol{Z})$ for some $\boldsymbol{Z} \subseteq TPC(T) \setminus \{X,T\}$, then by Proposition 2, we know that X has no edge with T, that is, $X \notin PC(T)$. So, X should also be removed from $TPC(T)$ to obtain a better approximation of $PC(T)$. If however, $\neg\mathrm{I}(X,T|\boldsymbol{Z})$ for all $\boldsymbol{Z} \subseteq TPC(T) \setminus \{X,T\}$, then it is still possible that $X \notin PC(T)$ because there may be a set $\boldsymbol{Z} \subseteq PC(X)$ where $\boldsymbol{Z} \nsubseteq PC(T)$ for which $\mathrm{I}(X,T|\boldsymbol{Z})$.

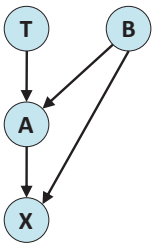


Figure 3: $PC(T) = \{A\}, PC(X) = \{A,B\}, X \notin PC(T)$. Notice that, there is no subset of $PC(T)$ that makes T conditionally independent of $X : \neg I(X,T|\emptyset), \neg I(X,T|A)$. However, there is a subset of $PC(X)$ for which X and T become conditionally independent: $I(X,T|\{A,B\})$. The Extended $PC(T)$ (see Definition 16 in this section) is $EPC(T) = \{A,X\}$.

Is there actually a case, where X cannot be made independent of T by conditioning on some subset of $PC(T)$? We know that all non-descendants of T can be made independent of T conditioned on a subset of its parents, thus, if there is such an X it has to be a descendant of T. Figure 3 shows such a case. These situations are rare in practice as indicated by our empirical results in Sections 5 and 6, which implies that by conditioning on all subsets of $TPC(T)$ one will approximate $PC(T)$ quite closely.

Definition 16 *We call the Extended $PC(T)$, denoted as $EPC(T)$, the set $PC(T)$ union the set of variables X for which $\neg I(X,T|\boldsymbol{Z})$, for all $\boldsymbol{Z} \subseteq PC(T) \setminus \{X\}$.*

The previous results allow us to start building algorithms that operate locally around T in order to find $PC(T)$ efficiently and soundly. Consider first the sketch of the algorithm below:

Algorithm 1

Find a superset $TPC(T)$ of $PC(T)$
for** each variable $X \in TPC(T)$ **do
  if** $\exists \boldsymbol{Z} \subseteq TPC(T) \setminus \{X\}$, s.t. $I(X,T|\boldsymbol{Z})$ **then
    remove X from $TPC(T)$
  end if
end for
Return $TPC(T)$

This algorithm will output $TPC(T) \subseteq EPC(T)$. To ensure we end up with the exact $PC(T)$ we can use the following pruning algorithm:

Algorithm 2

***for all** $X \in TPC(T)$ **do** {returned from Algorithm 1}*
  if** $T \notin TPC(X)$ **then
    remove X from $TPC(T)$ {$TPC(X)$ is obtained by running Algorithm 1}
  end if
end for

GLL-PC: High-level pseudocode and main components of Generalized Local Learning - Parents and Children. Returns PC(*T*)

1. $\boldsymbol{U} \leftarrow$ GLL-PC-nonsym(T) // first approximate *PC(T)* without symmetry check
2. For all $X \in \boldsymbol{U}$
3. If $T \notin$ GLL-PC-nonsym(X) then $\boldsymbol{U} \leftarrow \boldsymbol{U} \setminus \{X\}$ // check for symmetry
4. Return $\boldsymbol{U}$ // true set of parents and children

GLL-PC-nonsym(*T*) // returns a set which is a subset of $EPC(T)$ and a superset of $PC(T)$

1. Initialization
   a. Initialize a set of candidates for the true $PC(T)$ set: *TPC(T)* $\leftarrow S$, s.t. $S \subseteq \boldsymbol{V} \setminus \{T\}$
   b. Initialize a priority queue of variables to be examined for inclusion in *TPC(T)*: OPEN $\leftarrow \boldsymbol{V} \setminus \{T \cup TPC(T)\}$
2. Apply inclusion heuristic function
   a. Prioritize variables in OPEN for inclusion in *TPC(T)*;
   b. Throw away non-eligible variables from OPEN;
   c. Insert in *TPC(T)* the highest-priority variable(s) in OPEN and remove them from OPEN
3. Apply elimination strategy to remove variables from *TPC(T)*
4. Apply interleaving strategy by repeating steps #2 and #3 until a termination criterion is met
5. Return *TPC(T)*

Figure 4: High-level outline and main components (underlined) of GLL-PC algorithm.

In essence, the second algorithm checks for every $X \in TPC(T)$ whether the *symmetrical relation* holds: $T \in TPC(X)$. If the symmetry is broken, we know that $X \notin PC(T)$ since the parents-and-children relation is symmetrical.

What is the complexity of the above algorithms? In Algorithm 1 if step 1 is performed by an Oracle with constant cost, and with $TPC(T)$ equal to $PC(T)$, then the first algorithm requires an order of $O(|\boldsymbol{V}|2^{|PC(T)|})$ tests. The second algorithm will require an order of $O(|\boldsymbol{V}|2^{|PC(X)|})$ tests for each X in $TPC(T)$. Two observations to notice are: (i) the complexity order of the first algorithm depends linearly on the size of the problem $|\boldsymbol{V}|$, exponentially on $|PC(T)|$, which is a structural property of the problem, and how close $TPC(T)$ is to $PC(T)$ and (ii) the second algorithm requires multiple times the time of the first algorithm for minimal returns in quality of learning, that is, just to take care of the scenario in Figure 3 and remove the variables $EPC(T) \setminus PC(T)$ (i.e., X in Figure 3).

Since an Oracle is not available the complexity of both algorithms strongly depends on how close approximation of the $PC(T)$ is and how efficiently this approximation is found. The simplest strategy for example is to set $TPC(T) = \boldsymbol{V}$, essentially getting the local version of the algorithm SGS described above. In general any heuristic method that returns a superset of $PC(T)$ is admissible, that is, it could lead to sound algorithms.

Also notice that in the first algorithm the identification of the members of the $TPC(T)$ (step 1) and the removal of variables from it (step 3) can be interleaved. $TPC(T)$ can grow gradually by one, many variables, or all members of it at a time before it satisfies the requirement that is a superset of $PC(T)$. The requirement for the algorithm to be sound is that, in the end, all tests $I(X, T|\boldsymbol{Z})$ for all subsets $\boldsymbol{Z}$ of $PC(T) \setminus \{X\}$ have been performed.

Given the above, the components of Generalized Local Learning GLL-PC, that is, an algorithm for $PC(T)$ identification based on the above principles are the following: an *inclusion heuristic function* to prioritize variables for consideration as members of $TPC(T)$ and include them in $TPC(T)$ according to established priority. The second component of the framework is an *elimination strategy*, which eliminates variables from the $TPC(T)$ set. An *interleaving strategy* is the third component and it iterates between inclusion and elimination until a stopping criterion is satisfied. Finally

the fourth component is the check that the *symmetry requirement* mentioned above is satisfied. See Figure 4 for details. The main algorithm calls an internally defined subroutine that induces parents and children of T without symmetry correction (i.e., returns a set which is a subset of $EPC(T)$ and a superset of $PC(T)$). Note that in all references to $TPC(T)$ hereafter, due to generality of the stated algorithms and the process of convergence of $TPC(T)$ to $PC(T)$, $TPC(T)$ stands for just an approximation to $PC(T)$.

Also notice that the term "priority queue" in the schema of Figure 4 indicates an abstract data structure that satisfies the requirement that its elements are ranked by some priority function so that the highest-priority element is extracted first. $TPC(T)$ in step 1a of the GLL-PC-nonsym subroutine will typically be instantiated with the empty set when no prior knowledge about membership in $PC(T)$ exists. When the user does have prior knowledge indicating that X is a member of $PC(T)$, $TPC(T)$ can be instantiated to contain X. This prior knowledge may come from domain knowledge, experiments, or may be the result of running GLL-PC on variable X and finding that T is in $PC(X)$ when conducting local-to-global learning (Aliferis et al., 2009; Tsamardinos et al., 2006).

Steps #2, 3, 4 in GLL-PC-nonsym can be instantiated in various ways. Obeying a set of specific rules generates what we call "admissible" instantiations. These admissibility rules are given in Figure 5.

Theorem 2 *When the following sufficient conditions hold:*

a. There is a causal Bayesian network faithful to the data distribution P;

b. The determination of variable independence from the sample data D is correct;

c. Causal sufficiency in $\mathbf{V}$

any algorithmic instantiation of GLL-PC in compliance with the admissibility rules $\#1 - \#3$ *above will return the direct causes and direct effects of* T.

The proof is provided in the Appendix.

We note that the algorithm schema does not address various optimizations and does not address the issue of statistical decisions in finite sample. These will be discussed later. We also note that initialization of $TPC(T)$ in step 1a of the GLL-PC-nonsym function is arbitrary because correctness (unlike efficiency) of the algorithm is not affected by the initial contents of $TPC(T)$.

We next instantiate the GLL-PC schema to derive two pre-existing algorithms, interleaved HITON-PC with symmetry correction and MMPC with symmetry correction (Tsamardinos et al., 2006; Aliferis et al., 2003a; Tsamardinos et al., 2003b). Figure 6 depicts the instantiations needed to obtain interleaved HITON-PC.

The interleaved HITON-PC with symmetry correction algorithm starts with an empty set of candidates, then ranks variables for priority for inclusion in the candidate set by univariate association. It discards variables with zero univariate association. It then accepts each variable into $TPC(T)$. If any variable inside the candidate set becomes independent of the response variable T given some subset of the candidate set, then the algorithm removes that variable from the candidate set and never considers it again. In other words, the algorithm attempts to eliminate weakly relevant features from the $TPC(T)$ every time the $TPC(T)$ receives a new member. Iterations of insertion and elimination stop when there are no more variables to examine for inclusion. Once iterating has stopped, the candidate set is filtered using symmetry criterion. Finally, the candidate set is output. Because the

GLL-PC: Admissibility rules

1. The inclusion heuristic function should respect the following requirement:

   // *Admissibility rule #1*
   All variables $X \in PC(T)$ are eligible for inclusion in the candidate set $TPC(T)$ and each one is assigned a non-zero value by the ranking function. Variables with zero values are discarded and never considered again.

   Note that variables may be re-ranked after each update of the candidate set, or the original ranking may be used throughout the algorithm's operation.

2. The elimination strategy should satisfy the following requirement:

   // *Admissibility rule #2*
   All and only variables that become independent of the target variable T given any subset of the candidate set $TPC(T)$ are discarded and never considered again (whether they are inside or outside $TPC(T)$).

3. The interleaving strategy iterates inclusion and elimination any number of times provided that iterating stops when the following criterion is satisfied:

   //Admissibility rule #3
   At termination no variable outside the set $TPC(T)$ is eligible for inclusion and no variable in the candidate set can be removed at termination.

Figure 5: GLL-PC admissibility rules.

Interleaved HITON-PC with symmetry correction
Derived from GLL-PC with following instantiation specifics:

Initialization
$TPC(T) \leftarrow \varnothing$

Inclusion heuristic function

a. Sort in descending order the variables X in OPEN according to their pairwise association with T, i.e., $Assoc(X, T|\varnothing)$.
b. Remove from OPEN variables with zero association with T, *i.e.,* when $I(X, T|\varnothing)$
c. Insert at end of $TPC(T)$ the first variable in OPEN and remove it from OPEN

Elimination strategy

For each $X \in TPC(T)$
If $\exists \mathbf{Z} \subseteq TPC(T)\backslash\{X\}$, s.t. $I(X, T|\mathbf{Z})$ remove X from $TPC(T)$

Interleaving strategy

Repeat
steps #2 and #3 of GLL-PC-nonsym
Until OPEN=$\varnothing$

Figure 6: Interleaved HITON-PC with symmetry correction as an instance of GLL-PC.

admissibility criteria are obeyed, the algorithm is guaranteed to be correct when the assumptions of Theorem 2 hold.

Below we prove that that admissibility rules are obeyed in interleaved HITON-PC with symmetry under the assumptions of Theorem 2:

1. Rule #1 (inclusion) is obeyed because all $PC(T)$ members have non-zero univariate association with T in faithful distributions.

2. Rule #2 (elimination) is directly implemented so it holds.

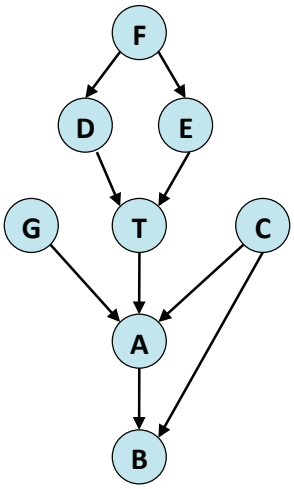

Figure 7: Bayesian network used to trace the algorithms.

Table 1: Trace of GLL-PC-nonsym(T) during execution of interleaved HITON-PC algorithm.

3. Rule #3 (termination) is obeyed because termination requires empty OPEN and thus eligible variables (i.e., members of $PC(T)$) outside $TPC(T)$ could only be previously discarded from OPEN or $TPC(T)$. Neither case can happen because of admissibility rules #1, #2 respectively. Similarly all variables in $TPC(T)$ that can be removed are removed because of admissibility rule #2.

A trace of the algorithm is provided below for data coming out of the example BN of the Figure 7. We assume that the network is faithful and so the conditional dependencies and indepen-

dencies can be read off the graph directly using the d-separation criterion. Consider that we want to find parents and children of the target variable T using interleaved HITON-PC with symmetry. Table 1 gives a complete trace of step 1 of the instantiated GLL-PC algorithm, that is, execution of GLL-PC-nonsym subroutine for variable T. The Roman numbers in the table refer to iterations of steps 2 and 3 in GLL-PC-nonsym.

Thus we have $TPC(T) = \{D,E,A,B\}$ by the end of GLL-PC-nonsym subroutine, so $\boldsymbol{U} = \{D,E,A,B\}$ in step 1 of GLL-PC. Next, in steps 2 and 3 we first run GLL-PC-nonsym for all $X \in \boldsymbol{U}$:

- GLL-PC-nonsym$(D) \rightarrow \{T,F\}$
- GLL-PC-nonsym$(E) \rightarrow \{T,F\}$
- GLL-PC-nonsym$(A) \rightarrow \{T,G,C,B\}$
- GLL-PC-nonsym$(B) \rightarrow \{A,C\}$

and then check symmetry requirement. Since $T \notin$ GLL-PC-nonsym(B), the variable B is removed from $\boldsymbol{U}$. Finally, the GLL-PC algorithm returns $\boldsymbol{U} = \{D,E,A\}$ in step 4.

Figure 8 shows how algorithm MMPC is obtained from GLL-PC. MMPC is also guaranteed to be sound when the conditions of Theorem 2 hold. Interleaving consists of iterations of just the inclusion heuristic function until OPEN is empty. The heuristic inserts into $TPC(T)$ the next variable F that maximizes the minimum association of variables in OPEN with T given all subsets of $TPC(T)$. In the algorithm, this minimum association of X with T conditioned over all subsets of $\boldsymbol{Z}$ is denoted by $\text{Min}_{\boldsymbol{Z}}\text{Assoc}(X,T|\boldsymbol{Z})$. The intuition is that we accept next the variable that despite our best efforts to be made conditionally independent of T (i.e., conditioned on all subsets of our current estimate $TPC(T)$) is still highly associated with T. The two main differences of the MMPC algorithm from interleaved HITON-PC are the more complicated inclusion heuristic function and the absence of interleaving of the inclusion-exclusion phases before all variables have been processed by the inclusion heuristic function. A set of optimizations and caching operations render the algorithm efficient; for complete details see Tsamardinos et al. (2006, 2003b).

Below we prove that admissibility rules are obeyed in MMPC with symmetry under the assumptions of Theorem 2:

1. Rule #1 (inclusion) is obeyed because all $PC(T)$ members have non-zero conditional association with T in faithful distributions.
2. Rule #2 (elimination) is directly implemented so it holds.
3. Rule #3 (termination) is obeyed because termination requires empty OPEN and thus eligible variables (i.e., members of $PC(T)$) outside $TPC(T)$ could only be previously discarded from OPEN or $TPC(T)$. Neither case can happen because of admissibility rules #1, #2 respectively. Similarly all variables in $TPC(T)$ that can be removed are removed because of admissibility rule #2.

We now introduce a new algorithm, semi-interleaved HITON-PC with symmetry correction, see Figure 9. Semi-interleaved HITON-PC operates like interleaved HITON-PC with one major difference: it does not perform a full variable elimination in $TPC(T)$ with each $TPC(T)$ expansion.

MMPC with symmetry correction

Derived from GLL-PC with following instantiation specifics:

Initialization

TPC(T) ← ∅

Inclusion heuristic function

a. Sort in descending order the variables X in OPEN according to $\text{Min}_{\boldsymbol{Z}}\text{Assoc}(X, T|\boldsymbol{Z})$ for $\boldsymbol{Z} \subseteq TPC(T)\backslash\{X\}$
b. Remove from OPEN variables X with zero association with T, given some $\boldsymbol{Z} \subseteq TPC(T)\backslash\{X\}$
c. Insert at end of *TPC(T)* the first variable in OPEN and remove it from OPEN

Elimination strategy

If OPEN=∅
  For each $X \in TPC(T)$
    If $\exists\, \boldsymbol{Z} \subseteq TPC(T)\backslash\{X\}$, s.t. $I(X, T|\boldsymbol{Z})$ remove X from *TPC(T)*

Interleaving strategy

Repeat
  steps #2 and #3 of GLL-PC-nonsym
Until OPEN=∅

Figure 8: MMPC with symmetry correction as an instance of GLL-PC.

Semi-Interleaved HITON-PC with symmetry correction

Derived from GLL-PC with following instantiation specifics:

Initialization

TPC(T) ← ∅

Inclusion heuristic function

a. Sort in descending order the variables X in OPEN according to their pairwise association with T, i.e., $Assoc(X, T|\emptyset)$.
b. Remove from OPEN variables with zero association with T, *i.e.,* when $I(X, T|\emptyset)$
c. Insert at end of *TPC(T)* the first variable in OPEN and remove it from OPEN

Elimination strategy

If OPEN=∅
  For each $X \in TPC(T)$
    If $\exists\, \boldsymbol{Z} \subseteq TPC(T)\backslash\{X\}$, s.t. $I(X, T|\boldsymbol{Z})$ remove X from *TPC(T)*
Else
  X ← last variable added to *TPC(T)* // in step 2 of GLL-PC-nonsym
  If $\exists\, \boldsymbol{Z} \subseteq TPC(T)\backslash\{X\}$, s.t. $I(X, T|\boldsymbol{Z})$ remove X from *TPC(T)*

Interleaving strategy

Repeat
  steps #2 and #3 of GLL-PC-nonsym
Until OPEN=∅

Figure 9: Semi-interleaved HITON-PC with symmetry correction as an instance of GLL-PC.

On the contrary, once a new variable is selected for inclusion, it attempts to eliminate it and if successful it discards it without further attempted eliminations. If it is not eliminated, it is added to the end of the $TPC(T)$ and new candidates for inclusion are sought. Because the admissibility criteria are obeyed the algorithm is guaranteed to be correct under the assumptions of Theorem 2.

Below we prove that admissibility rules are obeyed in semi-interleaved HITON-PC with symmetry under the assumptions of Theorem 2:

1. Rule #1 (inclusion) is obeyed because all $PC(T)$ members have non-zero univariate association with T in faithful distributions.

Step of GLL-PC-nonsym	*Comments*	OPEN	*TPC(T)*
1	Initialize *TPC(T)* and OPEN	*{A, B, C, D, E, F, G}*	∅
2a (I)	Prioritize variables in OPEN for inclusion in *TPC(T)*	*{F, D, E, A, B, G, C}*	∅
2b (I)	Throw away non-eligible members of OPEN (*G* and *C*)	*{F, D, E, A, B}*	∅
2c (I)	Insert in *TPC(T)* the highest-priority variable in OPEN (*F*) and remove it from OPEN	*{D, E, A, B}*	*{F}*
3 (I)	Apply elimination strategy to *TPC(T)*: no effect	*{D, E, A, B}*	*{F}*
2 (II)	Insert the highest-priority variable (*D*) in *TPC(T)* and remove it from OPEN	*{E, A, B}*	*{F, D}*
3 (II)	Apply elimination strategy to *TPC(T)*: no effect	*{E, A, B}*	*{F, D}*
2 (III)	Insert the highest-priority variable (*E*) in *TPC(T)* and remove it from OPEN	*{A, B}*	*{F, D, E}*
3 (III)	Apply elimination strategy to *TPC(T)*: No effect	*{A, B}*	*{F, D, E}*
2 (IV)	Insert the highest-priority variable (*A*) in *TPC(T)* and remove it from OPEN	*{B}*	*{F, D, E, A}*
3 (IV)	Apply elimination strategy to *TPC(T)*: no effect	*{B}*	*{F, D, E, A}*
2 (V)	Insert the highest-priority variable (*B*) in *TPC(T)* and remove it from OPEN	∅	*{F, D, E, A, B}*
3 (V)	Apply elimination strategy to *TPC(T)*: remove *F* since I(*T, F*|*{D,E}*)	∅	*{D, E, A, B}*
4	Stop interleaving since OPEN = ∅	∅	*{D, E, A, B}*

Table 2: Trace of GLL-PC-nonsym(T) during execution of semi-interleaved HITON-PC algorithm.

2. Rule #2 (elimination) is directly implemented so it holds.

3. Rule #3 (termination) is obeyed because termination requires empty OPEN and thus eligible variables (i.e., members of $PC(T)$) outside $TPC(T)$ could only be previously discarded from OPEN or $TPC(T)$. Neither case can happen because of admissibility rules #1, #2 respectively. Similarly all variables in $TPC(T)$ that can be removed are removed because of admissibility rule #2.

A trace of the algorithm is provided below for data coming out of the example faithful BN of the Figure 7. Consider that we want to find parents and children of the target variable T using semi-interleaved HITON-PC with symmetry. Table 2 gives a complete trace of step 1 of the instantiated GLL-PC algorithm, that is, execution of GLL-PC-nonsym subroutine for variable T. The Roman numbers in the table refer to iterations of steps 2 and 3 in GLL-PC-nonsym.

Thus we have $TPC(T) = \{D, E, A, B\}$ by the end of GLL-PC-nonsym subroutine, so $\boldsymbol{U} = \{D, E, A, B\}$ in step 1 of GLL-PC. Next, in steps 2 and 3 we first run GLL-PC-nonsym for all $X \in \boldsymbol{U}$:

- GLL-PC-nonsym$(D) \rightarrow \{T, F\}$
- GLL-PC-nonsym$(E) \rightarrow \{T, F\}$
- GLL-PC-nonsym$(A) \rightarrow \{T, G, C, B\}$
- GLL-PC-nonsym$(B) \rightarrow \{A, C\}$

and then check symmetry requirement. Since $T \in$ GLL-PC-nonsym(B), the variable B is removed from $\boldsymbol{U}$. Finally, the GLL-PC algorithm returns $\boldsymbol{U} = \{D, E, A\}$ in step 4.

4.2 Discovery of the $MB(T)$ Set

As mentioned in Section 3 the $MB(T)$ contains all information sufficient for the determination of the conditional distribution of T : $P(T|MB(T)) = P(T|\boldsymbol{V} \setminus \{T\})$ and further, it coincides with the parents, children and spouses of T in any network faithful to the distribution (if any) under causal sufficiency. The previous subsection described a general family of algorithms to obtain the $PC(T)$ set, and so in order to find the $MB(T)$ one needs in addition to $PC(T)$, to also identify the spouses of T.

First notice that, approximating $MB(T)$ with $PC(T)$ and missing the spouse nodes may in theory discard very informative nodes. For example, suppose that X and T are two uniformly randomly chosen numbers in $[0,1]$ and that $Y = \min(1, X+T)$. Then, the only faithful network representing the joint distribution is $X \rightarrow Y \leftarrow T$, where X is the spouse of T. In predicting T, the spouse node X may reduce the uncertainty completely: conditioned on Y, T may become completely determined (when both X and T are less than 0.5). Thus, it theoretically makes sense to develop algorithms that identify the spouses in addition to the $PC(T)$, even though later in Section 5 we empirically determine that within the scope of distributions and problems tried, the $PC(T)$ resulted in feature subsets almost as predictive as the full $MB(T)$. In the companion paper (Aliferis et al., 2010) we also provide possible reasons explaining the good performance of $PC(T)$ versus $MB(T)$ for classification in practical tasks.

The theorem on which the algorithms in this family are based to discover the $MB(T)$ is the following:

Theorem 3 *In a faithful BN $\langle \boldsymbol{V}, G, P \rangle$, if for a triple of nodes X, T, Y in G, $X \in PC(Y)$, $Y \in PC(T)$, and $X \notin PC(T)$, then $X \rightarrow Y \leftarrow T$ is a subgraph of G iff $\neg I(X, T | \boldsymbol{Z} \cup \{Y\})$, for all $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \{X, T\}$ (Spirtes et al., 2000).*

We distinguish two cases: (i) X is a spouse of T but it is also a parent or child, for example, $X \rightarrow T \rightarrow Y$ and also $X \rightarrow Y$. In this case, we cannot use the theorem above to identify Y as a collider and X as a spouse. But at the same time we do not have to: $X \in PC(T)$ and so it will be identified by GLL-PC. (ii) $X \in MB(T) \setminus PC(T)$ in which case we can use the theorem to locally discover the subgraph $X \rightarrow Y \leftarrow T$ and determine that X should be included in $MB(T)$.

We now introduce the GLL-MB in Figure 10. The admissibility requirement is simply to use an admissible GLL-PC instantiation.

For the identification of $PC(T)$ any method of GLL-PC can be used. Also, in step 5a we know such a $\boldsymbol{Z}$ exist since $X \notin PC(T)$ (by Theorem 1); this $\boldsymbol{Z}$ has been previously determined and is cached during the call to GLL-PC.

Theorem 4 *When the following sufficient conditions hold*

a. There is a causal Bayesian network faithful to the data distribution P;

b. The determination of variable independence from the sample data D is correct;

GLL-MB: Generalized Local Learning - Markov Blanket

1. *PC(T)* ← GLL-PC*(T)* // obtain *PC*(*T*) by running *GLL-PC* for variable *T*
2. For every variable $Y \in PC(T)$
   $PC(Y)$ ← GLL-PC(Y) // obtain $PC(Y)$ for every member Y of $PC(T)$
3. *TMB(T)* ← *PC(T)* // initialize *TMB(T)* with *PC*(*T*) members
4. $\boldsymbol{S} \leftarrow \{\cup_{Y \in PC(T)} PC(Y)\} \setminus \{PC(T) \cup \{T\}\}$ // these are the potential spouses
5. For every variable $X \in \boldsymbol{S}$
   a. Retrieve a subset $\boldsymbol{Z}$ s.t. I(X, T | $\boldsymbol{Z}$) // subset was identified and stored in steps 1 and 2
   b. For every variable $Y \in PC(T)$ *s.t.* $X \in PC(Y)$ // Y is a potential common child of T and X
   c. If $\neg$I(X, T| $\boldsymbol{Z} \cup \{Y\}$) // X is a spouse
   d. Insert X into *TMB(T)*
6. Optionally: Eliminate from *TMB(T)* predictively redundant members using a backward wrapper approach.
7. Return *TMB*(*T*)

Figure 10: GLL-MB: Generalized Local Learning - Markov Blanket algorithm.

c. Causal sufficiency in $\boldsymbol{V}$

any algorithmic instantiation of GLL-MB in compliance with the admissibility rule will return $MB(T)$ *(with no need for step 6).*

The proof is provided in the Appendix.

A new Markov blanket algorithm, semi-interleaved HITON-MB, can be obtained by instantiating GLL-MB (Figure 10) with the semi-interleaved HITON-PC algorithm with symmetry correction for GLL-PC.

Semi-interleaved HITON-MB is guaranteed to be correct under the assumptions of Theorem 4, hence the only proof of correctness needed is the proof of correctness for semi-interleaved HITON-PC with symmetry (which was provided earlier).

A trace of the semi-interleaved HITON-MB algorithm for data coming out of the example faithful BN of the Figure 7 follows below. Please refer to Figure 10 for step numbers. Consider that we want to find Markov blanket of T. In step 1, we find $PC(T) = \{D, E, A\}$. Then in step 2 we find $PC(X)$ for all $X \in PC(T)$:

- $PC(D) = \{T, F\}$,
- $PC(E) = \{T, F\}$,
- $PC(A) = \{T, G, C, B\}$,

In step 3 we initialize $TMB(T) \leftarrow \{D, E, A\}$. The set $\boldsymbol{S}$ in step 4 contains the following variables: $\{F, G, C, B\}$. In step 5 we loop over all members of $\boldsymbol{S}$ to find spouses of T. Let us consider each variable separately:

- Loop for $X = F$: In step 5a we retrieve a subset $\boldsymbol{Z} = \{D, E\}$ that renders $X = F$ independent of T. In step 5b we loop over all potential common children of F and T, that is, $Y = D$ and $Y = E$. When we consider $Y = D$, we find that $X = F$ is independent of T given $\boldsymbol{Z} \cup \{Y\} = \{D, E\}$ and thus do not include F in $TMB(T)$ in step 5d. When we consider $Y = E$, we also do not include F in $TMB(T)$ in step 5d.

- Loop for $X = G$: In step 5a we retrieve a subset $\boldsymbol{Z} = \emptyset$ that renders $X = G$ independent of T. In step 5b we loop over all potential common children of G and T, that is, variable $Y = A$. We find that $X = G$ is dependent on T given $\boldsymbol{Z} \cup \{Y\} = \{A\}$ and thus include G in $TMB(T)$ in step 5d.

- Loop for $X = C$: In step 5a we retrieve a subset $\boldsymbol{Z} = \emptyset$ that renders $X = C$ independent of T. In step 5b we loop over all potential common children of C and T, that is, variable $Y = A$. We find that $X = C$ is dependent on T given $\boldsymbol{Z} \cup \{Y\} = \{A\}$ and thus include C in $TMB(T)$ in step 5d.

- Loop for $X = B$: In step 5a we retrieve a subset $\boldsymbol{Z} = \{A, C\}$ that renders $X = B$ independent of T. In step 5b we loop over all potential common children of B and T, that is, variable $Y = A$. We find that $X = B$ is independent of T given $\boldsymbol{Z} \cup \{Y\} = \{A, C\}$ and thus do not include G in $TMB(T)$ in step 5d.

By the end of step 5, we have $TMB(T) = \{D, E, A, G, C\}$. Notice that it is the true $MB(T)$. In step 6 we perform wrapping to remove members of $TMB(T)$ that are redundant for classification. Let us assume that we used a backward wrapping procedure that led to removal of variable G, for example because omitting this variable does not increase classification loss. Thus, we have $TMB(T) = \{D, E, A, C\}$ in step 7 when the algorithm terminates.

The above algorithm specifications and proofs demonstrate that it is relatively straightforward to derive correct algorithms and prove their correctness using the GLL framework. It is also straightforward to derive relaxed versions (for example non-symmetry corrected versions of interleaved and semi-interleaved HITON and MMPC) which trade-off correctness for improved tractability.

4.3 Computational Complexity

The complexity of all algorithms presented depends on the time for the tests of independence and measures of associations. For the G^2 test of independence for discrete variables, for example, we use in reported experiments an implementation linear to the sample size and exponential to the number of variables in the conditional set. However, because the latter number is small in practice, tests are relatively efficient. Faster implementations exist that only take time $n \log(n)$ to the number n of training instances, independent of the size of the conditioning set. Also, advanced data structures (Moore and Wong, 2003) can be employed to improve the time complexity (see Tsamardinos et al. 2006 for details on the implementation of the tests). In reported experiments we also implement the measure of association $\text{Assoc}(X, T|\boldsymbol{Z})$ to be the negative *p-value* returned by the test $I(X, T|\boldsymbol{Z})$ and so it takes exactly the same time to compute as a test of independence. In the following discussion, we consider the complexity of the algorithms in terms of the number of tests and measures of association they perform.

The number of tests of the GLL-PC algorithm in Figure 4 depends on several factors. These are the inclusion heuristic efficiency in approximating the $PC(T)$, the time required by the inclusion heuristic, and the size of the $PC(T)$ which is a structural property of the problem to solve. Interleaved-HITON-PC (algorithm in Figure 6) for example, will sort the variables using $|\boldsymbol{V}|$ measures of associations. Subsequently, it will perform a test $I(X, T|\boldsymbol{Z})$ for all subsets of the largest $TPC(T)$ in any iteration of interleaving of the inclusion-exclusion steps. With appropriate caching a test will never have to be repeated. Thus, assuming the largest size of the $TPC(T)$ is in the order of the $PC(T)$, the complexity of the GLL-PC-nonsym subroutine is $O(|\boldsymbol{V}|2^{|PC(T)|})$. In step 3, it will

execute the GLL-PC-nonsym subroutine again for all $X \in TPC(T)$. Assuming each neighborhood of X is about the same as the $PC(T)$, when checking the symmetry condition, the algorithm will perform another $O(|\boldsymbol{V}||PC(T)|2^{|PC(T)|})$tests.

To identify $MB(T)$ by the GLL-MB algorithm in Figure 10 we first need to initialize subset $\boldsymbol{S}$. Assuming all neighborhoods are about the same size (i.e., equal to $|PC(T)|$), the total complexity to find the set $\boldsymbol{S}$ is $O(|\boldsymbol{V}||PC(T)|^2 2^{|PC(T)|})$ since we call GLL-PC for each member of the $PC(T)$. In fact, several optimizations can reduce this order to $O(|\boldsymbol{V}||PC(T)|2^{|PC(T)|})$ but we will not elaborate further in this paper. In step 5, in the worst case we perform a single test for each node in $\boldsymbol{S}$ and each node in $PC(T)$ for a total of at most $O(|PC(T)|^2)$ tests (the subset $\boldsymbol{Z}$ in step 5a is cached and retrieved). So the order of the algorithm is $O(|\boldsymbol{V}||PC(T)|^2 2^{|PC(T)|})$ tests given the structural assumptions above.

All other algorithmic instantiations of the template in this section have similar complexity.

At this point it is worth noting a number of polynomial approximation algorithms in the literature that increase efficiency without sacrificing quality to a large degree. The identification of a subset $\boldsymbol{Z}$ in step 3 of the GLL-PC-nonsym subroutine as described in algorithm instantiations of GLL-PC is a step exponential to the size of the $TPC(T)$; however, one could attempt to discover it in a greedy fashion, for example by starting with the empty set and adding to $\boldsymbol{Z}$ the variable decreasing the association with T the most. These ideas started with the TPDA algorithm (Cheng et al., 2002a) and were further explored in Brown et al. (2005). Similar improvements can be applicable to inclusion strategy.

For the above analysis we assumed that all tests $I(X,T|\boldsymbol{Z})$ can or should be performed and return the correct results. However, in the next sub-section we discuss how the statistical decisions of independence or dependence are made; these decisions severely affect the complexity of the algorithms as well.

4.4 Dealing with Statistical Decisions

The quality of the algorithms in practice highly depends on their ability to statistically determine whether $I(X,T|\boldsymbol{Z})$ or $\neg I(X,T|\boldsymbol{Z})$ (equivalently whether $\text{Assoc}(X,T|\boldsymbol{Z})$ is zero or non-zero) for a pair of variables X and T and a set of variables Z. The test $I(X,T|\boldsymbol{Z})$ is implemented as a statistical hypothesis test with null hypothesis H_0: X and T are independent given $\boldsymbol{Z}$. A *p-value* corresponding to this test statistic's distribution expresses the probability of seeing the same or more extreme (i.e., indicative of dependence) test statistic values when sampling from distributions where H_0 is true. If the *p-value* is lower than a given threshold (i.e., significance level "alpha") α, then we consider the independence hypothesis to be improbable and reject it. Thus, for a sufficiently low *p-value* we accept *dependence*. If however, the *p-value* is not low enough to provide confidence in rejecting H_0 then there are two possibilities:

a) H_0 actually holds, that is, the variables are indeed conditionally independent.

b) H_0 does not hold, the variables are conditionally dependent but we cannot confidently reject H_0.

The reasons for b) are that either the dependence is weak relatively to the available sample to be detected (in order words, we have low probability to reject the null hypothesis H_0 when it does not hold, that is, low statistical power), or we are using the wrong statistical test for this type of dependency. In essence, we would like to distinguish between the following cases:

a) $I(X,T|\boldsymbol{Z})$ holds with high-probability

b) $\neg I(X,T|\boldsymbol{Z})$ holds with high-probability

c) Undetermined case given the available sample

To deal with case c) in our implementations we take the following approach, introduced by Spirtes et al. (2000): we consider that we are facing case c) if there is no sufficient power according to a *reliability criterion*. In our implementations this criterion depends on parameter *h-ps*. The criterion dictates that if and only if we have at least *h-ps* sample instances per number of cells (i.e., number of parameters to be estimated) in the contingency tables for the discrete statistical tests then the test is reliable.

Once a test is deemed unreliable an algorithm needs to decide how to handle the corresponding statistical decision. For example, the PC algorithm for global causal discovery (Spirtes et al., 2000) considers that given no other evidence, all variables are dependent with each other. That is, a pair of variables is always connected by an edge in the graph unless a subset $\boldsymbol{Z}$ is discovered that renders them conditionally independent.

The implementations of GLL instantiations in the present paper do not perform an unreliable test either. However, ignoring unreliable tests with 0-order conditioning test (i.e., univariate tests) is equivalent to assuming $I(X,T|\boldsymbol{Z})$ whereas ignoring unreliable tests with higher-order conditioning test (i.e., conditioning sets with 1 or more conditioning variables) is equivalent to assuming $\neg I(X,T|\boldsymbol{Z})$ as far as this unreliable test is concerned (because the final judgment on independence, is deferred to reliable, typically lower-order tests). Thus, given no evidence of dependence, we assume the unreliable tests to return $I(X,T|\boldsymbol{Z})$. The different treatment of the PC implementation leads to problems as discussed in Tsamardinos et al. (2006) pointing to the importance of this implementation aspect of the algorithms.

Another practical implementation issue arises when prior knowledge, experiments, or domain substantive knowledge ensures that a variable X is in $PC(T)$ or that X is not in $PC(T)$. In such cases the algorithm can be modified to "lock" X inside or outside $TPC(T)$ respectively in order to avoid the possibility that errors in statistical decisions will counter previously validated knowledge and possibly propagate more statistical decision errors.

In addition to *h-ps*, a second restriction on the conditioning set size is provided by parameter *max-k*. This parameter places an absolute limit on the number of elements in a conditioning set size, *without reference to available sample size*. As such *max-k* participates in the reliability judgment but also restricts the computational complexity of the algorithms by trading off computational complexity for fit to data.

Specifically first consider that more variables than the actual $PC(T)$ could be output by the algorithm. A variable X that becomes independent of T only when we condition on $\boldsymbol{Z}$, with $|\boldsymbol{Z}| >$ *max-k* could enter the $TPC(T)$ and will not be removed afterwards. For example, if *max-k* $= 1$, then variable F in Figure 7 cannot be d-separated from T given any $\boldsymbol{Z}$ with $|\boldsymbol{Z}| \leq 1$. Thus, the reliability criterion may increase the number of tests performed, since these depend on the size of the $TPC(T)$. On the other hand, the criterion forces certain tests not to be performed, specifically those whose conditioning set $\boldsymbol{Z}$ size is larger than *max-k*. Thus, since only $\binom{TPC(T)}{max\text{-}k}$ subsets are tested out of all possible $2^{|TPC(T)|}$ ones, the complexity of the algorithm GLL-PC-nonsym now becomes $O(|\boldsymbol{V}||TPC(T)|^{max\text{-}k})$, that is, polynomial of order *max-k*.

The parameters *h-ps* and *max-k* are user-specified or, alternatively, optimized automatically by cross-validation, or optimized for a whole domain. The role and importance of these two parameters, especially with respect to quality of statistical decisions, is explored in detail in the companion paper (Aliferis et al., 2010). Finally, because the quality of statistical decisions is not addressed in the proofs of correctness provided earlier, it was implicitly assumed that whenever sufficient sample size is provided to the algorithms statistical decisions are reliable.

A recent treatment that specifically addresses the role of statistical decisions in finite sample is presented in Tsamardinos and Brown (2008a). In this work, a bound of the p-value of the existence of an edge is provided; the bound can be used to control the False Discovery Rate of the identification of the $PC(T)$ or all the edges in a network.

5. Comparative Evaluation of Local Causal and Non-Causal Feature Selection Algorithms in Terms of Feature Selection Parsimony and Classification Accuracy

In the present section we examine the ability of GLL algorithms to discover compact sets of features with as high classification performance as possible for each data set and compare them with other local causal structure discovery methods as well as non-causal feature selection methods.

In order to avoid bias in error estimation we apply nested N-fold cross-validation. The inner loop is used to try different parameters for the feature selection and classifier methods while the outer loop tests the best configuration on an independent test set. Details are given in Statnikov et al. (2005b), Dudoit and van der Laan (2003) and Scheffer (1999).

All experiments discussed in this section and elsewhere in this paper were conducted on ACCRE (Advanced Computing Center for Research and Education) High Performance Computing system at Vanderbilt University. The ACCRE system consists of 924 x86 processors (the majority of which 2 GHz) and 668 PowerPC processors (2.2 GHz) running 32 and 64-bit Linux OS. The overall computational capacity of the cluster is approximately 6 TFLOPS. For preliminary and exploratory experiments we used a smaller cluster of eight 3.2 GHz x86 processors.

The evaluated algorithms are listed in the Appendix Tables 5-7. They were chosen on the basis of prior independently published results showing their state-of-the-art performance and applicability to the range of domains represented in the evaluation data sets. We compare several versions of GLL, including parents and children (PC) and Markov blanket (MB) inducers. Whenever we refer to HITON-PC algorithm in this paper, we mean semi-interleaved HITON-PC without symmetry correction, unless mentioned otherwise. Also, other GLL algorithms evaluated do not have symmetry correction unless mentioned otherwise. Finally, unless otherwise noted, GLL-MB does not implement a wrapping step.

Tables 8-9 in the Appendix present the evaluation data sets. The data sets were chosen on the basis of being representative of a wide range of problem domains (biology, medicine, economics, ecology, digit recognition, text categorization, and computational biology) in which feature selection is essential. These data sets are challenging since they have a large number of features with small-to-large sample sizes. Several data sets used in prior feature selection and classification challenges were included. All data sets have a single binary target variable.

To perform imputation in data sets with missing values, we applied a non-parametric nearest neighbor method (Batista and Monard, 2003). Specifically, this method imputes each missing value of a variable with the present value of the same variable in the most similar instance according to Euclidian distance metric. Discretization in non-sparse continuous data sets was performed by a

univariate method (Liu et al., 2002) implemented in *Causal Explorer* (Aliferis et al., 2003b). For a given continuous variable, the method considers many binary and ternary discretization thresholds (by means of a sliding window) and chooses the one that maximizes statistical association with the target variable. In sparse continuous data sets, discretization was performed by assigning value 1 to all non-zero values. All variables in each data set were also normalized to be in [0, 1] range to facilitate classification by SVM and KNN. All computations of statistics for the preprocessing steps were performed based on training data only to ensure unbiased classification error estimation. Statistical comparison between algorithms was done using two-sided permutation test (with 10,000 permutations) at 5% alpha level (Good, 2000). The null hypothesis of this test is that algorithms perform the same.

Both polynomial SVMs and KNN were used for building classifiers from each selected feature set. In complementary experiments, the *native* classifier for each one of several feature selection methods (LARS-EN, L0, and RFVS) was used and its performance was compared against classifiers induced by SVMs and KNN. For SVMs, the misclassification cost C and kernel degree d were optimized over values [1, 10, 100] and [1, 2, 3, 4], respectively. For KNN, the number of nearest neighbors k was optimized over values [1,...,min(1000, number of instances in the training set)]. All optimization was conducted in nested cross-validation using training data only, while the testing data was used only once to obtain an error estimate for the final classifier. We used the libSVM implementation of SVM classifiers (Fan et al., 2005) and our own implementation of KNN.

We note that use of SVMs and KNN does not imply that GLL methods are designed to be filters for these two algorithms only, or that the algorithm comparison results narrowly apply to these two classifiers. Rather as explained in Section 2.2, GLL algorithms provide performance guarantees as long as the classifier used has universal approximator properties. SVMs and KNN are two exemplars of practical and scalable such methods in wide use. We also emphasize that selecting features with a wrapper or embedded feature selection method that *is not* SVM or KNN specific is not affected by the inductive bias mismatch because such mismatch is affecting performance only when the classifier used is "handicapped" relative to the native classifier (Tsamardinos and Aliferis, 2003; Kohavi and John, 1997). We provide experimental data substantiating this point in the Appendix Table 10 (and Table S1 in the online supplement) where we compare classification performance of RFVS, LARS-EN, and L0 with features selected by each corresponding method to the classification performance of SVMs and KNN using the same features. It is shown that SVM predictivity matches, whereas KNN predictivity compares favorably, with the classifiers that are native to each feature selector. On the other hand, the choice of SVMs and KNN provides several advantages to the research design of the evaluation: (a) the same classifiers can be used with all data sets removing a possible confounder in the evaluation; (b) they can be used without feature selection (i.e., full variable set) to give a reference point of predictivity under no feature selection (that in practice is as good as empirically optimal predictivity especially when using SVMs); (c) they can be used when sample size is smaller than number of variables; (d) prior evidence suggests that they are suitable classifiers for the domains; (e) they can be executed in tractable time using nested cross-validation as required by our protocol.

In all cases when an algorithm had not terminated within 2 days of single-CPU time per run on a single training set (including optimization of the feature selector parameters) and in order to make the experimental comparison feasible with all methods and data sets in the study, we deemed it to be impractical and terminated it. While the practicality of spending more than two days of single-CPU time on a single training set can be debated, we believe that use of slower algorithms in

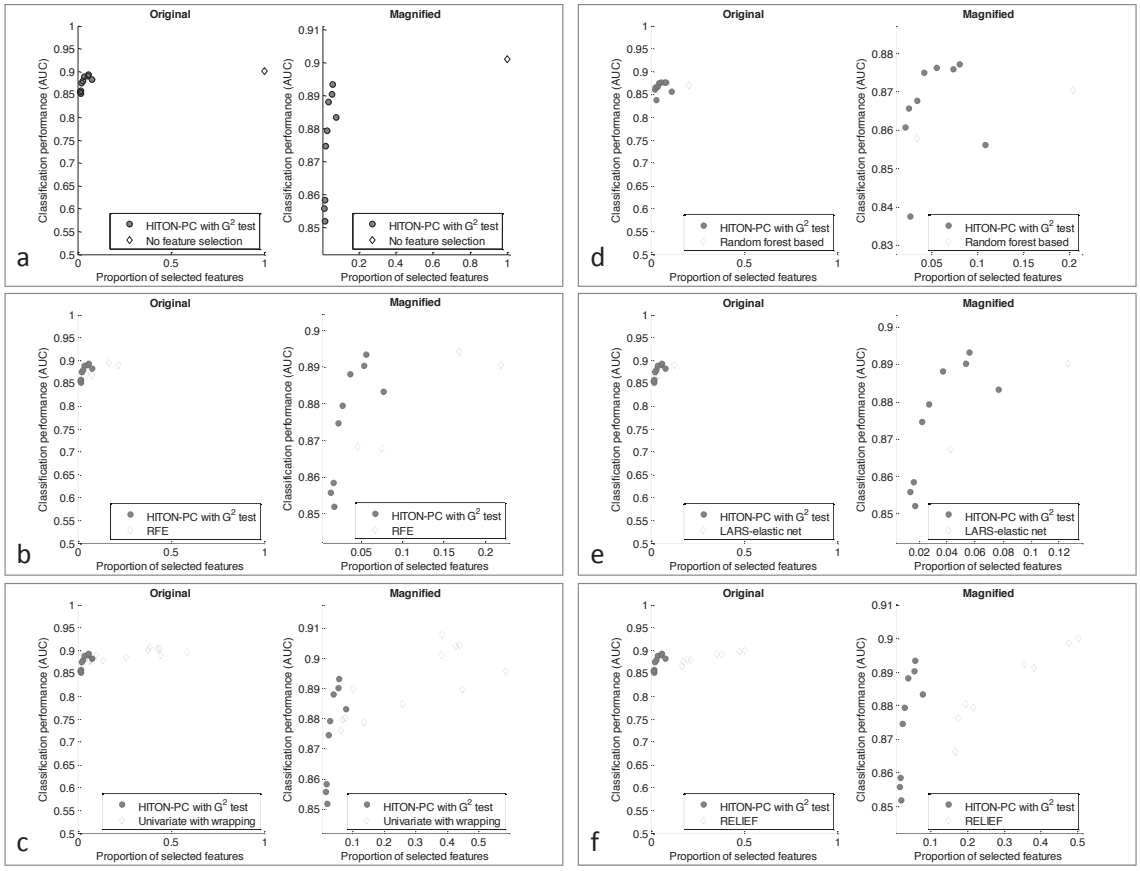

Figure 11: Causal Feature Selection Returns More Compact Feature Sets Than Non-Causal Feature Selection—Comparison of each algorithmic family with semi-interleaved HITON-PC with G^2 test. HITON-PC is executed with 9 different configurations: $\{max\text{-}k = 1, \alpha = 0.05\}$, $\{max\text{-}k = 2, \alpha = 0.05\}$, $\{max\text{-}k = 3, \alpha = 0.05\}$, $\{max\text{-}k = 4, \alpha = 0.05\}$, $\{max\text{-}k = 1, \alpha = 0.01\}$, $\{max\text{-}k = 2, \alpha = 0.01\}$, $\{max\text{-}k = 3, \alpha = 0.01\}$, $\{max\text{-}k = 4, \alpha = 0.01\}$, and a configuration that selects one of the above parameterizations by nested cross-validation. Results shown are averaged across all real data sets where both HITON-PC with G^2 test and an algorithmic family under consideration are applicable and terminate within 2 days of single-CPU time per run on a single training set. Multiple points for each algorithm correspond to different parameterizations/configurations. See Appendix Tables 5- 7 for detailed list of algorithms. The left graph has x-axis (proportion of selected features) ranging from 0 to 1 and y-axis (classification performance AUC) ranging from 0.5 to 1. The right graph has the same data, but the axes are magnified to see the details better. This figure is continued in Figures 12 and 13.

practice is problematic due to the following reasons: (i) in the context of N-fold cross-validation the total running time is at least N times longer (i.e., >20 days single-CPU time); (ii) the analyst does not know whether the algorithm will terminate within a reasonable amount of time, and (iii) when quantification of uncertainty about various parameters (e.g., estimating variance in error estimates via bootstrapping) is needed the analysis becomes prohibitive regardless of analyst flexibility and

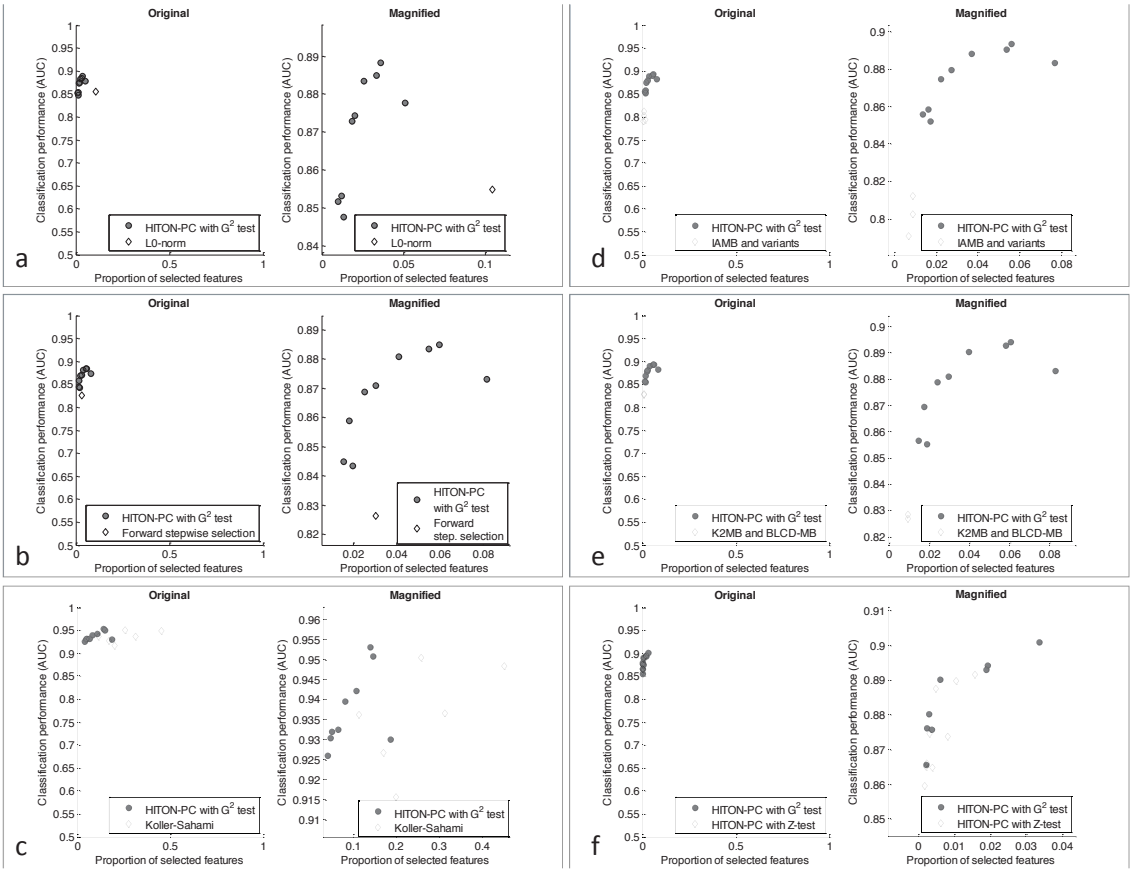

Figure 12: Continued from Figure 11.

computational resources. When comparing a pair of algorithms we consider only the data sets where both algorithms terminate within the allotted time.

We evaluate the algorithms using the following metrics:

1. Number of features selected;
2. Proportion of features selected relative to the original number of features (i.e., prior to feature selection);
3. Classification performance measured as area under ROC curve (AUC) (Fawcett, 2003);
4. Feature selection time in minutes.[2]

Figure 11 compares each evaluated algorithm to semi-interleaved HITON-PC with G^2 test as a reference performance for GLL, in the two-dimensional space defined by proportion of selected features and classification performance by SVM (results for KNN are similar and are available in

2. In all cases we used the implementations provided by the authors of methods, or state-of-the-art implementations, and thus reported time should be considered representative of what practitioners can expect in real-life with equipment and data similar to the ones used in the present study. However, we note that running times should be interpreted as indicative only since numerous implementation details and possible optimizations as well as computer platform discrepancies can affect results.

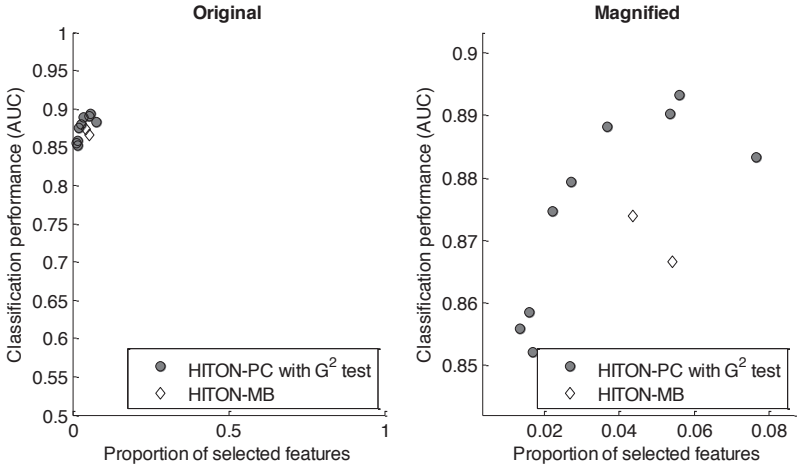

Figure 13: Continued from Figure 12.

Table S5 in the online supplement). As can be seen in the figure (and also in Figure S1 of the online supplement), GLL algorithms typically return much more compact sets than other methods. More compact results are provided by versions that induce the PC set rather than the MB for obvious reasons. Out of GLL methods, the most compact sets are returned when the Z-test is applicable (continuous data) compared to G^2 test (discrete or discretized data). As seen in Tables S2-S3 in the online supplement, depending on the parameterization of GLL, compactness varies. However, regardless of configuration, both GLL and other local causal methods (i.e., IAMB, BLCD-MB, FAST-IAMB, K2MB) with the exception of Koller-Sahami are typically more compact than non-causal feature selection methods (i.e., univariate methods with backward wrapping, RFE, RELIEF, Random Forest-based Variable Selection, L0, and LARS-EN). Forward stepwise selection and some configurations of LARS-EN, Random Forest-based Variable Selection, and RFE are often very parsimonious, however their parsimony varies greatly across data sets. Notice that whenever an algorithm variant employed statistical comparison among feature sets (in particular non-causal ones), it improved compactness (Figure S1 and Tables S2-S3 in the online supplement). Table 3 gives statistical comparisons of compactness between one reference GLL algorithm (semi-interleaved HITON-PC with G^2 test and cross-validation-based optimization of the algorithm parameters) and 43 non-GLL algorithms and variants (including no feature selection). In 21 cases the GLL reference method gives statistically significantly more compact sets compared to all other methods, in 16 cases parsimony is not statistically distinguishable, and in 6 cases HITON-PC gives less compact feature sets. These 6 cases correspond strictly to non-GLL causal feature selection algorithms and at the expense of severe predictive suboptimality (0.06 to 0.10 AUC) relative to the reference GLL method (see Tables S4-S5 in the online supplement).

5.1 Compactness Versus Classification Performance

Compactness is only one of the two requirements for solving the feature selection problem. A maximally compact algorithm that does not achieve optimal predictivity does not solve the feature selection problem. Figure 11 examines the trade-off of compactness and SVM predictivity (results for KNN are similar and available in Table S5 in the online supplement). The best possible point for each graph is at the upper left corner. For ease of visualization the results are plotted for each

Table 3: Statistical comparison via permutation test (Good, 2000) of 43 non-GLL algorithms (including no feature selection) to the reference GLL algorithm (semi-interleaved HITON-PC with G^2 test and cross-validation-based optimization of the algorithm parameters by SVM classifier) in terms of SVM predictivity and parsimony. Each non-GLL algorithm compared to HITON-PC in each row is denoted by "Other". Bolded p-values are statistically significant at 5% alpha.

algorithmic family separately. To avoid overfitting and to examine robustness of various methods to parameterization we did not select the best performing configuration, but plotted all of them. Notice that some algorithms did not run on all 13 real data sets (i.e., algorithms with Fisher's Z-test are applicable only to continuous data, while some algorithms did not terminate within 2 days of single-CPU time per run on a single training set). For such cases, we plotted results only for data sets where the algorithms were applicable and the results for HITON-PC correspond to the same data sets. As can be seen, GLL algorithms that induce PC sets dominate both other causal and non-causal feature

selection algorithms. This is also substantiated in Table 3 (and Table S7 in the online supplement that provides results for KNN classifier) that gives statistical comparisons of predictivity between the reference GLL algorithm and all 43 non-GLL algorithms and variants (including no feature selection). In 9 cases the GLL reference method gives statistically significantly more predictive sets compared to all other methods, in 33 cases predictivity is not statistically distinguishable, and in 1 case GLL gives less predictive feature sets (however the magnitude of the GLL suboptimal predictivity is only 0.018 AUC on average, whereas the difference in compactness is more than 33% features selected on average).

The overall performance patterns of combined predictivity and parsimony are highly consistent with Markov blanket induction theory (Section 2.2) which predicts maximum compactness and optimal classification performance when using the MB. Different instantiations of the GLL method give different trade-offs between predictivity and parsimony (details and statistical comparisons to the reference method are provided in online supplement Tables S2-S6 and S8).

In the companion paper (Aliferis et al., 2010), we examine in detail conditions under which PC induction can give optimal classification performance (the empirical illustration is provided in Figure 13). The comparison of HITON-PC with G^2 test and HITON-PC with Z-test reveals that both statistics perform similarly, while the latter (where it is applicable) does not require discretization of continuous data that can simplify data analysis significantly (see Figure 12 and statistical comparisons in Table S9 in the online supplement). In Table S10 of the online supplement we provide statistical comparisons of non-GLL causal feature selection methods in terms of predictivity and parsimony. K2MB, BLCD-MB, IAMB, and FAST-IAMB rather unexpectedly perform statistically indistinguishably in terms of predictivity and parsimony. Since BLCD-MB differs from K2MB by an additional backward elimination step, this implies that this step rarely results in elimination of features in the real data sets tested.

5.2 Analysis of Running Times

Table S6 in the online supplement gives detailed running times for all feature selection experiments. Major observations include that: (i) univariate methods, RELIEF, RFE, LARS-EN are in general the fastest ones, (ii) Koller-Sahami is probably the slowest method since it does not terminate on several data sets within the allotted time limit, (iii) FAST-IAMB is two orders of magnitude faster than IAMB on the average, and (iv) GLL algorithms are practical for very high-dimensional data (e.g., in the Thrombin data set with $>$ 100,000 features GLL-PC requires 10 to 52 minutes single-CPU time depending on fixed-parameter configuration, and less than 3 hours when GLL-PC is automatically optimized by cross-validation).

In conclusion, the GLL reference algorithm dominates most feature selection methods in predictivity and compactness. Some non-GLL causal methods are more parsimonious than the reference GLL method at the expense of severe classification suboptimality. One univariate method exhibits slightly higher predictivity but with severe disadvantage in parsimony. No feature selection method achieves equal or better compactness with equal or better classification performance than GLL.

6. Comparative Evaluation of Markov Blanket Induction, Local Causal Neighborhood and Other Non-Causal Algorithms for Local Structure Discovery

In the present section we study the ability of GLL algorithms to discover local causal structure (in the form of parent and children sets and Markov blankets) and compare them with other local

structure discovery methods as well as non-causal feature selection. While many researchers apply feature selection techniques strictly to improve the cost and effectiveness of classification, in many fields researchers routinely apply feature selection in order to gain insights *about the causal structure of the domain*. A frequently encountered example is in bioinformatics where a plethora of feature selection methods are applied in high-throughput genomic and proteomic data to discover biomarkers suitable for new drug development, personalizing medical treatments, and orienting subsequent experimentation (Zhou et al., 2002; Li et al., 2001; Holmes et al., 2000; Eisen et al., 1998). It is thus necessary to test the appropriateness of various feature selection techniques for causal discovery, not just classification.

In order to compare the performance of the tested techniques for causal discovery, we simulate data from known Bayesian networks and also use resimulation, whereby real data is used to elicit a causal network and then data is simulated from the obtained network (see Table 11 in the Appendix). For each network, we randomly select 10 different targets and generate 5 samples (except for sample size 5,000 where one sample is generated) to reduce variability due to sampling.[3] An independent sample of 5,000 instances is used for evaluation of classification performance.

In order to avoid overfitting of the results to the method used to induce the causal network, an algorithm with different inductive bias is used than the algorithms tested. In our case we use SCA (Friedman et al., 1999b). We note that SCA has greatly different inductive bias from the GLL variants and thus the comparison (provided that the causal generative model is a Bayesian network) is not unduly biased toward them, while still allowing induction of a credible causal graphical model. Specifically, the inductive biases of the two methods can be described as follows: SCA performs global, heuristically constrained, Bayesian search-and-score, greedy TABU iterative search for a Bayesian network that has maximum-a-posteriori probability given the data under uninformative prior on all possible network structures. GLL algorithms induce a local causal neighborhood, under the distributional assumption of faithfulness and causal sufficiency, employing statistical tests of conditional independence, and preferring to assume a variable is in the local neighborhood whenever a conditional test is not applicable due to small sample (provided that a univariate association exists, otherwise independence is the default) in order to minimize false negative risk of losing a true member and overall risk of false positives and false negatives if true network is not dense. More about the inductive bias of GLL can be found in Aliferis et al. (2010).

We obtained two resimulated networks as follows: (a) *Lung_Cancer* network: We randomly selected 799 genes and a phenotype target (cancer versus normal tissue indicator) from human gene expression data of Bhattacharjee et al. (2001). Then we discretized continuous gene expression data and applied SCA to elicit network structure. (b) *Gene* network: It was obtained from a subset of variables of yeast gene expression data of Spellman et al. (1998) that contained 800 randomly selected genes and a target variable denoting cell cycle state. Continuous gene expression data was also discretized and SCA was applied to learn network. This research design follows Friedman et al. (2000).

Furthermore, we note that additional factors not captured in the simulation or resimulation process make real-life discovery potentially harder than in our experiments. Such factors include for example, deviations of faithfulness, existence of temporal and cellular aggregation effects, unmea-

3. For networks *Lung_Cancer* and *Gene*, we also add an eleventh target that corresponds to the natural response variable: lung cancer diagnosis and cell cycle state, respectively. For network *Munin* we use only 6 targets because of extreme probability distributions of the majority of variables that do not allow variability in the finite sample of size 500 and even 5000. Because of the same reason, we did not experiment with sample size 200 in the *Munin* network.

sured variables, and various measurement, normalization, and noise artifacts. However evaluations with simulated and resimulated data yield comparative performances that are still highly informative since if a method cannot induce the correct structure from relatively easier settings, it is unlikely that in harder real-life situations it will perform any better. In other words successful causal structure discovery performance in simulated and resimulated networks represents at a minimum "gate-keeper" level performance that will filter the more promising from the less promising methods (Spirtes et al., 2000). Finally, as Spirtes et al. (2000) note the behavior of constraint-based algorithms is particularly complex and theoretical analyses are very difficult to perform. The same is true for several other modern feature selection methods. Hence, simulation experiments are necessary in order to gain a deeper understanding of the strengths and limitations of many state-of-the-art algorithms. The evaluated algorithms are provided in Appendix Table 12.

We evaluate the algorithms using the following metrics:

1. *Graph distance*. This metric calculates the average shortest unoriented graph distance of each variable returned by an algorithm to the local neighborhood of target, normalized by the average such distance of all variables in the graph. The rationale is to normalize the score to allow for comparisons across data sets and to correct the score for randomly choosing variables. The score is a non-negative number and has the following interpretation: value 0 means that current feature set is a subset of the true local neighborhood of the target, values less than 1 are better than random selection in the specific network, values equal to 1 are as good as random selection in the specific network and values higher than 1 are worse than random selection. The metric is computed using Dijkstra's shortest path algorithm.

2. *Euclidean distance from the perfect sensitivity and specificity (in the ROC space)* for discovery of local neighborhood of the target variable. This is computed as in Tsamardinos et al. (2003b) and provides a loss function-neutral combination of sensitivity and specificity.

3. *Proportion of false positives and proportion of false negatives*.

4. *Classification performance using polynomial SVM and KNN classifiers* with parameters optimized by nested cross-validation (misclassification cost C and kernel degree d for SVMs and number of nearest neighbors k for KNN) on an independently sampled test data set with large sample (n=5000). The performance is measured by AUC (Fawcett, 2003) on binary tasks and proportion of correct classifications on multiclass tasks.

5. *Feature selection time in minutes*. All caveats regarding interpretation of running times stated in Section 5 apply here as well.

We note that the causal discovery evaluations emphasize *local* discovery of direct causes and direct effects and this choice is supported by several reasons. First, in many domains searching for direct causes and effects is natural (e.g., biological pathway discovery). Second, for non-causal feature selection methods, a natural causal interpretation of their output is being among the direct causes and direct effects (or the Markov blanket) of the target. Consider for example clustering or differential gene expression in bioinformatics where if *Gene1* clusters with *Gene2*, or if *Gene3* is more strongly differentially expressed with respect to some phenotype than *Gene4* then *Gene1* and *Gene2* are interpreted to be members of the same pathway (i.e., in close proximity in the gene regulatory/causal network), and *Gene 3* is interpreted to be more likely to determine the phenotype

than *Gene4*. Similar interpretations abound for other non-causal feature selection methods. We notice that if a method is locally causally inconsistent then it is very unlikely that it will be globally causally consistent either. The logic of this argument is that algorithms either return global or local causal knowledge. If an algorithm outputs a global causal graph and this is incorrect, then this implies that locally it will be wrong for at least some variables. Conversely, if the global graph is correct then locally it is correct as well. If algorithm B outputs a correct local causal set (e.g., direct causes and direct effects) then we can "piece together" these sets and obtain a correct global graph. Finally, if an algorithm outputs an incorrect non-empty local causal set, this implies that B returns non-causes as direct causes or remote causes as direct causes (and the same for effects). Thus, it is not possible to construct the full causal graph strictly from knowledge provided by the algorithm. As a result, local causal consistency is necessary for global consistency as well.

A second reason for focusing on local causal discovery is that it is much harder in practice than indirect causal discovery in highly interconnected causal networks. In our bioinformatics example, because cancer affects many pathways, it is trivial to find genes affected by cancer, since a large proportion (e.g., half) of the measured genes are expected to be affected. However, it is vastly harder to find the chain of events that leads from occurrence of cancer to *Gene1* becoming under- or over-expressed. In such settings, discovery of remote causation is not particularly hard, neither it is particularly interesting. Conversely, when one has a locally correct causal discovery algorithm as elucidated in Section 2, global causal learners can be relatively easily constructed.

Finally, in our evaluations we do not examine quality of causal orientation of the algorithms output for several reasons: First, while GLL algorithms' output can be oriented by constraint-based or other post-processing, non-causal feature selection methods do not readily admit orientation. Second, orientation is not needed when target T is a terminal variable as is often the case in the real data. Third, oriented local causal discovery is harder than unoriented one (Ramsey et al., 2006), and it makes sense to examine the ability of the feature selection algorithms for causal discovery in tasks of incremental difficulty, especially since as we will see most of the non-causal algorithms do not perform well even when seeking unoriented causality. Fourth, orientation information can be obtained subsequently by experiments or knowledge-based post-processing and in many practical settings it is not the primary obstacle to causal discovery.

6.1 Superiority of Causal Over Non-Causal Feature Selection Methods for Causal Discovery

Causal methods achieve, consistently under a variety of conditions and across all metrics employed, superior causal discovery performance than non-causal feature selection methods in our experiments. Figures 14(a) and 15 compare semi-interleaved HITON-PC to HITON-MB, RFE, UAF, L0, and LARS-EN in terms of graph distance and for different sample sizes. Other GLL instantiations such as Interleaved-HITON-PC, MMPC, and Interleaved-MMPC perform similarly to HITON-PC (data in Table S12 in the online supplement). We apply HITON-PC as is and also with a variable pre-filtering step such that only variables that pass a test of univariate association with the target at 5% False Discovery Rate (FDR) threshold are input into the algorithm (Benjamini and Yekutieli, 2001; Benjamini and Hochberg, 1995). Motivation and analysis of incorporating FDR in GLL is provided in Aliferis et al. (2010).

As can be seen, in all samples HITON-PC variants return features closely localized near the target while HITON-MB requires relatively larger sample size to localize well. The distance is smaller as sample size grows. Methods such as univariate filtering localize features well in some

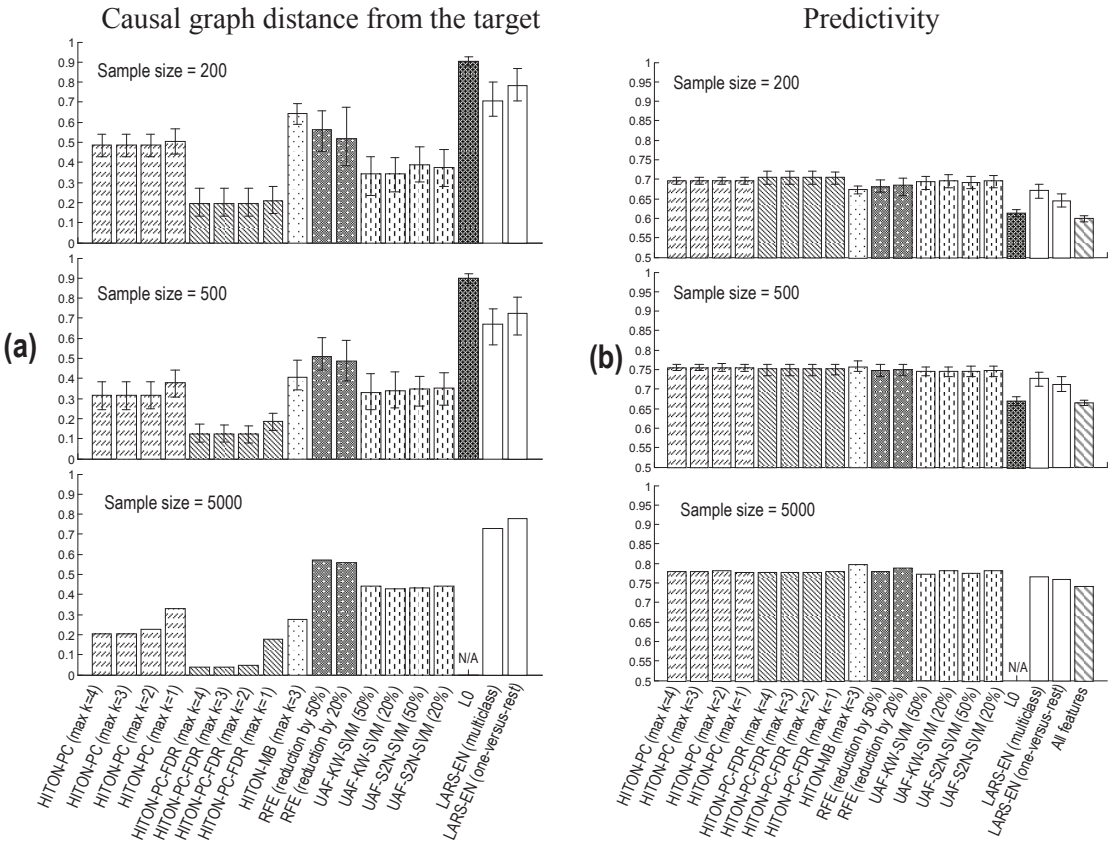

Figure 14: Performance of feature selection algorithms in 9 simulated and resimulated data sets: (a) *graph distance*, (b) *classification performance of polynomial SVM classifiers*. The smaller is causal graph distance and the larger is classification performance, the better is the algorithm. The results are given for training sample sizes = 200, 500, and 5000. The bars denote maximum and minimum performance over multiple training samples of each size (data is available only for sample sizes 200 and 500). The metrics reported in the figure are averaged over all data sets, selected targets, and multiple samples of each size. L0 did not terminate within 2 days (per target) for sample size 5000. Please see text for more details.

data sets and badly in others. As sample size grows, localization of univariate filtering deteriorates. Methods L0, and LARS-EN exhibit a *reverse-localization* bias (i.e., preferentially select features *away* from the target). Performance of RFE varies greatly across data sets in its ability to localize features and this is independent of sample size. A "bull's eye" plot for *Insurance10* data set is provided in Figure 16. A localization example for *Insurance10* data set is shown in Figure 17. The presented visualization examples are representative of the relative performance of causal versus non-causal algorithms. Table 4 provides p-values (via a permutation test at 5% alpha) for the differences of localization among algorithms.

Tables S13-S16 and Figure S2(a)-(d) in the online supplement compare the same algorithms in terms of (a) Euclidian distance from the point of perfect sensitivity and specificity, (b) proportion of false negatives, (c) proportion of false positives, and (d) running time in minutes. Consistent with the results presented in the main text, local causal discovery algorithms strongly outperform

Figure 15: Causal graph distance results for training sample sizes = 200, 500 and 5000. The results reported in the figure are averaged over all selected targets. Lighter cells correspond to smaller (better) values of graph distance; darker cells correspond to larger (worse) values of graph distance. L0 did not terminate within 2 days (per target) for sample size 5000.

non-causal feature selection methods in ability to find the direct causes and effects of the target variable.

6.2 Classification Performance is Misleading for Causal Discovery

Despite causally wrong outputs (i.e., failing to return the Markov blanket or parents and children set), several non-causal feature selection methods achieve comparable classification performance with causal algorithms in the simulated data. Figure 14(b) (and Tables S17-S18 and Figure S2(e)

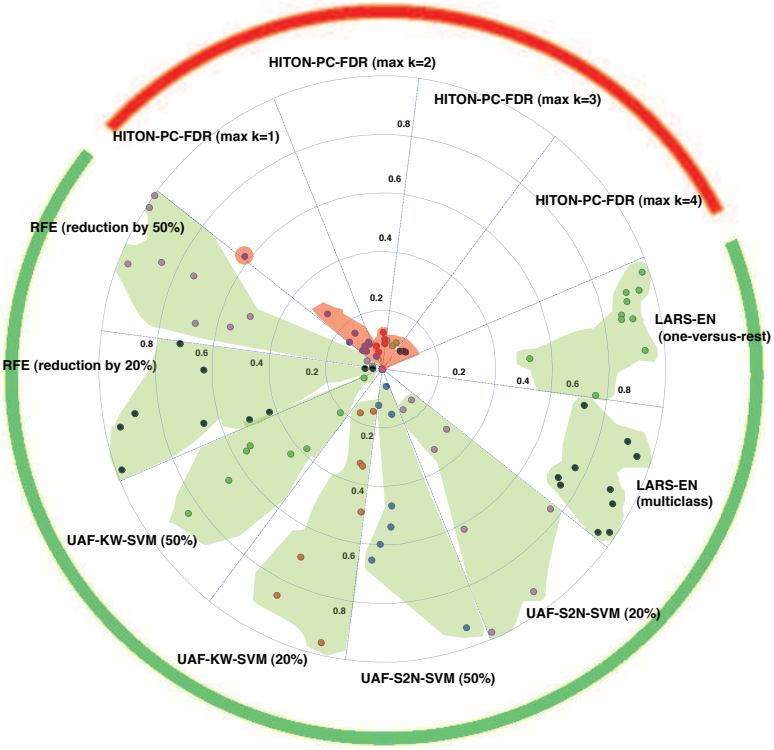

Figure 16: Visualization of graph distances for *Insurance10* network and sample size 5000 by "bull's eye" plot. For each method, results for 10 randomly selected targets are shown. The closer are points to the origin, the better is ability for local causal discovery. Results for GLL method HITON-PC-FDR are highlighted with red; results for baseline methods are highlighted with green.

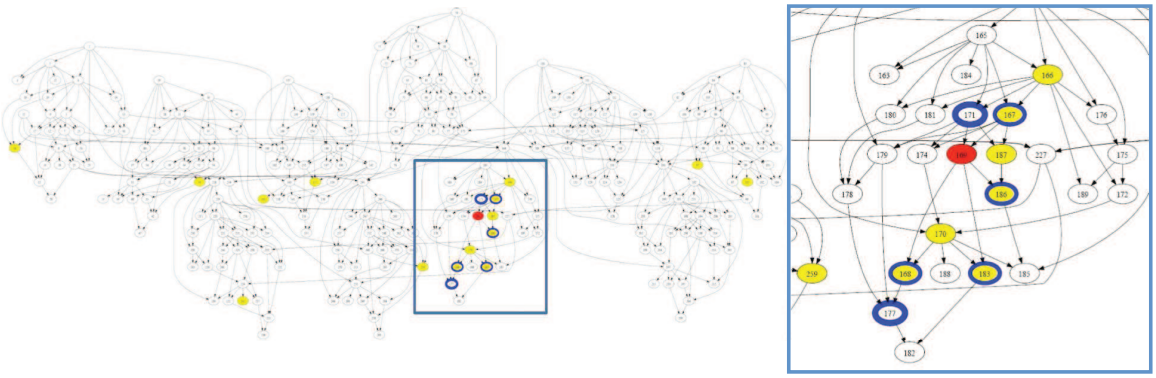

Figure 17: An example of poor localization by a baseline method and good localization by a GLL method. *Left*: Graph of the adjacency matrix of *Insurance10* network. Target variable is shown with red. HITON-PC discovers all 5 members of the parents and children set and a false positive variable #177 that is located close to the true neighborhood (discovered variables are shown with blue bolded circles). RFE discovers 4 out of 5 members of the PC set and introduces many false positives scattered throughout the network (discovered variables are shown with yellow circles). *Right*: A magnified area of the *Insurance10* network close to the target variable.

in the online supplement) shows the average AUC and proportion of correct classifications. This phenomenon is related to information redundancy of features in relation to the target in non-sparse causal processes. In addition, it is facilitated by the relative insensitivity of state-of-the-art classifiers to irrelevant and redundant features. *Good classification performance is thus greatly misleading as a criterion for quality of causal hypotheses* generated by non-causal feature selection algorithms.

In conclusion, the results in the present section strongly undermine the hope that non-causal feature selection methods can be used as good heuristics for causal discovery. The idea that non-causal feature selection can be used for causal discovery should be viewed with caution (Guyon et al., 2007). Whole research programs are, in many domains, built on experiments motivated by causal hypotheses that were generated by non-causal feature selection results (Zhou et al., 2002; Li et al., 2001; Holmes et al., 2000; Eisen et al., 1998) and this seems an unfortunate and inadvisable practice, in light of existence of principled causal algorithms. On the other hand, generalized local learning algorithms in simulated and resimulated experiments show great potential for local causal discovery.

7. Discussion

In the present section we discuss main findings of this research, state limitations and outline open problems, and give an overview of problems addressed in the companion paper.

7.1 Main Findings

Our experimental evaluation shows that GLL algorithms typically attain the theoretically expected benefits of strong feature set parsimony without loss of performance relative to the best classification attained by any method used in the experiments. The wide range of data sets and algorithms used shows that the sufficient conditions stated in the proofs for correctness for GLL are likely to hold and/or that violations may be small or well tolerated.

The second major result from our experiments is that we showed that use of non-causal feature selection methods for learning causality although very widespread, is generally inadvisable. We used resimulated and simulated data and showed that causally-motivated feature selection methods connect local causal discovery with feature selection for classification consistent with recent theoretical work. Feature selection algorithms that are not causal have a tendency to return highly predictive feature sets that are scattered all over the network, or that are in the periphery of the network, and cannot be otherwise interpreted in a way that makes useful and consistent causal sense. We strongly caution practitioners to use principled causal discovery algorithms whenever available and to not substitute causal discovery methods with predictive/non-causal feature selection ones for reasons of convenience or due to non familiarity with such methods. Practical software widely exists that can be used to apply state-of-the-art causal methods including the methods studied in the present paper that is available for download from the online supplement.

Finally, the theoretical framework that is based in large part on faithfulness and other assumptions summarized in Sections 2 and 3 is a valuable frame of reference both conceptually and algorithmically. However, we do not consider it to be an absolute and immutable measure by which to judge all new and existing algorithms. Our data shows that algorithms that are not deemed correct under the more general assumptions of the framework (e.g., algorithms that do not employ symmetry correction, or algorithms that use $PC(T)$ instead of $MB(T)$ for feature selection for classification) offer in many real data sets same predictive quality and better computational tractability than the sound algorithms. This is a reflection of several factors. One of them is the existence of distributions that are special classes of faithful ones and are easier to analyze (e.g., where symmetry correction is not required, or in other words where $EPC(T) = PC(T)$). A second factor is mitigating circumstances for violations of assumptions (Aliferis et al., 2010). A third factor is that practical implementations of sound algorithms are statistically imperfect (in other words, a theoretical assumption that conveniently leads to a proof of correctness, for example that a conditional test of independence is correct, does not entail immediate or flawless practical feasibility since all such tests admit errors in practice). An alternative set of assumptions for correctness may require vaguely 'sufficient sample size' disregarding the practical difficulty of determining whether in any given analysis this requirement is met. As a result, practical implementations may claim soundness without being demonstrably sound in applied settings. We address the small-sample behavior of GLL algorithms with empirical analysis in the companion paper (Aliferis et al., 2010).

7.2 Limitations and Open Problems

A possible critique of the present work is that Markov blanket features may not work well with a plethora of classifiers, distributions and loss functions. Indeed, a feature selector that is uniformly optimal is not attainable as shown by the results in Tsamardinos and Aliferis (2003), and several (possibly infinite) conceivable classifiers will fail to capture the information in the selected features. Our focus was to examine if the GLL framework has merit in the sense of whether GLL instantia-

tions when applied and compared to reasonable state-of-the-art baseline feature selectors in many complex data sets from typical analysis domains and with practical classifiers, loss function and sample sizes, yield good performance consistent with the theoretical claims of GLL.

Another possibility we would like to address is that best predictivity achieved in our experiments for each data set may not be optimal since some classifier other than SVMs and KNN may yield better predictivity. We believe that this possibility is remote for the following reason: Evidence from earlier published work where we have applied instances of GLL with classifiers such as ANNs, Decision Trees, Simple Bayes, as well as SVMs and KNN supports that the choice of classifier matters very little in practice and similar predictivity/parsimony patterns as the ones reported here were found (Aliferis et al., 2003a). On the other hand, the use of SVMs and KNN as classifiers uniformly across our experiments confers many benefits explained in Section 5. To further support the use of these classifiers we provide additional experimental results in Appendix Table 10 where we use features extracted from embedded or wrapper-based feature selectors (L0, RFVS, LARS-EN) and compare SVMs and KNN to classifiers native to the above embedded and wrapper-based methods. We found that SVMs and KNN achieve predictivity comparable to the classifiers from the aforementioned feature selectors.

Additional strong evidence in favor of our conclusions that GLL algorithms yield highly predictive and parsimonious feature sets is given by the simulated and resimulated data experiments where both the data-generative model and optimal feature sets are known. In those experiments the true Markov blanket is directly given by the model and does constitute the gold standard for the smallest and optimally informative feature set for common loss functions in the sense that *it contains all information available for predicting the target*. The experiments showed that the GLL algorithms identify this Markov blanket very well and better than the baseline comparison algorithms.

Although the GLL framework and the studied instantiations and implementations are theoretically well motivated and empirically robust in many practical data analysis domains, as demonstrated in our experiments, as with all machine learning methods they should be expected to not perform well in quality or efficiency in certain distributions. Such distributions may include cases where the Markov blanket is very large and thus the combinatorics of the elimination phase makes it too slow. Another case can be when extreme non-linearities render the $PC(T)$ members "invisible" to the algorithm (because univariate association with the target is zero). Another possibility for hurting efficiency arises when excessive synthesis of information exists such that the true members of $PC(T)$ are not considered before other weakly relevant variables enter the $TPC(T)$. Also when certain types of deterministic relationships exist or more broadly target information equivalence (i.e., special types of violations of faithfulness), many Markov blankets may exist and the algorithms will return a predictively optimal feature set but both causal localization and optimal parsimony may be lost (Statnikov, 2008). The practical importance of these possibilities needs to be assessed domain-by-domain.

Some of the adverse situations described in the limitations sub-section can be addressed by relaxing the algorithm operation (e.g., for very large Markov blankets the analyst can set *max-k* to a very small number and achieve faster execution but incur some false positives). In some domains, violation of assumptions are mitigated by other factors (e.g., Aliferis et al. 2010 describes how connectivity can make extremely epistatic parents visible to the algorithms). These and other situations constitute open research areas and very recent research efforts attempt to address these issues. For example, Statnikov (2008) provides algorithms that address multiplicity of Markov blankets and Tsamardinos and Brown (2008b) introduce a method for kernel mapping of extremely

non-linear functions to a faithful feature space that can be used to do feature selection via GLL in the transformed feature space.

Although the emphasis of the present work was in classification, Markov blanket theory applies equally well to regression and thus the GLL framework can be used for regression problems as well. An empirical analysis of performance of regression-oriented GLL instantiations and comparisons to state-of-the-art methods were not pursued here however.

7.3 Further Problems Addressed in the Companion Paper

While the theory motivating local learning and especially Markov blanket induction for feature selection has wide implications, it is far from complete. To begin with, all theoretical arguments to-date apply to the large sample case. While the theory implies that the large-sample Markov blanket and the corresponding classifiers fitted from large sample, are predictively optimal, it is not known to what extend learning from small samples affects the optimality of Markov blanket based feature selection. More specifically, it is not clear how often in small samples and real-life distributions the true Markov blanket (i.e., obtained from the data-generative process) gives an optimal classifier when the latter is fitted from small samples with state-of-the-art classifiers. Similarly, we do not know whether the estimated Markov blanket gives an optimal classifier when the latter is fitted from small samples or even when it is fitted from the large sample. Related to the above for practical applications, we do not know how fast is convergence of the estimated Markov blanket/classifier to true Markov blanket/optimal classification as a function of sample size, for the available state-of-the-art Markov blanket inducing algorithms. In the second part of our work (Aliferis et al., 2010) we examine these issues. We also provide explanations why counter-intuitively relaxed versions of some algorithms that trade-off computational efficiency for theoretical soundness tend to outperform sound versions in some domains. Moreover, we systematically study the factors that influence the quality and number of statistical decisions, explain the inductive bias of the algorithms, show how non-causal feature selection methods can be understood in light of Markov blanket induction theory, and address divide-and-conquer local to global causal graph learning strategies.

Appendix A.

This Appendix provides proofs of theorems and additional tables referenced in the paper.

A.1 Proof of Theorem 2

Consider the algorithm in Figure 4. First notice, that as we mentioned above, when conditions (a) and (c) hold the direct causes and direct effects of T will coincide with the parents and children of T in the causal Bayesian network G that faithfully captures the distribution (Spirtes et al., 2000). As we have shown in Section 4 and in Tsamardinos et al. (2003b), the $PC_G(T) = PC(T)$ is unique in all networks faithfully capturing the distribution.

First we show that the algorithm will terminate, that is that the termination criterion of admissibility rule #3 will be met. The criterion requires that no variable eligible for inclusion will fail to enter $TPC(T)$ and that no variable that can be eliminated from $TPC(T)$ is left inside. Indeed because (a) due to admissibility rule #1 all eligible variables in OPEN are identified, (b) $\boldsymbol{V}$ is finite and OPEN instantiated to $\boldsymbol{V} \setminus \{T\}$, and (c) termination will not happen before all eligible members of OPEN are moved from OPEN to $TPC(T)$, the first part of the termination criterion will be satisfied.

The second part of the termination criterion will also be satisfied because of admissibility rule #2 which examines for removal all variables and discards the ones that can be removed.

Lemma 1 *The output of GLL-PC-nonsym $TPC(T)$ is such that: $PC(T) \subseteq TPC(T) \subseteq EPC(T)$.*

Proof Let us assume that $X \in PC(T)$ and show that $X \in TPC(T)$ by the end of GLL-PC-nonsym. By admissibility rule #3, X will never fail to enter $TPC(T)$ by the end of GLL-PC-nonsym. By Theorem 1, for all $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \{X\}$, $\neg I(X,T|\boldsymbol{Z})$ and so the elimination strategy because of admissibility rule #2 will never remove X from $TPC(T)$ by the end of GLL-PC-nonsym.

Now, let us assume that $X \in TPC(T)$ by the end of GLL-PC-nonsym and show that $X \in EPC(T)$. Let us assume the opposite, that is, that $X \notin EPC(T)$ and so by definition $I(X,T|\boldsymbol{Z})$, for some $\boldsymbol{Z} \subseteq PC(T) \setminus \{X\}$. By the same argument as in the previous paragraph, we know that at some point before termination of the algorithm, in step 4, $TPC(T)$ will contain the $PC(T)$. Since $X \notin EPC(T)$, the elimination strategy will find that $I(X,T|\boldsymbol{Z})$, for some $\boldsymbol{Z} \subseteq PC(T) \setminus \{X\}$ and remove X from $TPC(T)$ contrary to what we assumed. Thus, $X \in EPC(T)$ by the end of GLL-PC-nonsym. ■

Lemma 2 *If $X \in EPC(T) \setminus PC(T)$, then $T \notin EPC(X) \setminus PC(X)$*

Proof Let us assume that $X \in EPC(T) \setminus PC(T)$. For every network G faithful to the distribution P $Parents_G(T) \subseteq PC_G(T) = PC(T)$. X has to be a descendant of T in every network G faithful to the distribution because if it is not a descendant, then there is a subset $\boldsymbol{Z}$ of T's parents s.t., $I(X,T|\boldsymbol{Z})$ (by the Markov Condition). Since $X \in EPC(T) \setminus PC(T)$, we know that by definition $\neg I(X,T|\boldsymbol{Z})$, for all $\boldsymbol{Z} \subseteq PC(T) \setminus \{X\}$. By the same argument, if also $T \in EPC(X) \setminus PC(X)$, T would have to be a descendant of X in the every network G which is impossible since the networks are acyclic. So, $T \notin EPC(X) \setminus PC(X)$. ■

Let us assume that $X \in PC(T)$. By Lemma 1, $X \in TPC(T)$ by the end of GLL-PC-nonsym. Since also $T \in PC(X)$, substituting X for T, we also have that by the end of GLL-PC-nonsym, $T \in TPC(X)$. So, X will not be removed from $\boldsymbol{U}$ by the symmetry requirement of GLL-PC either, and will be in the final output of the algorithm.

Conversely, let us assume that $X \notin PC(T)$ and show $X \notin \boldsymbol{U}$ at termination of algorithm GLL-PC. If X never enters $TPC(T)$ by the inclusion heuristic, the proof is done. Similarly, if X enters but is later removed from $TPC(T)$ by the exclusion strategy, the proof is done too. So, let us assume that X enters $TPC(T)$ at some point and by the end of GLL-PC-nonsym(T) is not removed by the exclusion strategy. By Lemma 1, we get that by the end of GLL-PC-nonsym, $X \in EPC(T)$ and since we assumed $X \notin PC(T)$, we get that $X \in EPC(T) \setminus PC(T)$. By Lemma 2, we get that $T \notin EPC(X) \setminus PC(X)$. Since also $T \notin PC(X)$, we get that $T \notin EPC(X)$. Step 3 of GLL-PC will thus eliminate X from $\boldsymbol{U}$.

A.2 Proof of Theorem 4

Since we assume faithful Bayesian networks, d-separation in the graph of such a network is equivalent to independence and can be used interchangeably (Spirtes et al., 2000).

(2006a)
Random Forest Variable Selection (RFVS)	• best performing feature subset is returned • statistically same as best performing feature subset is returned	(Diaz-Uriarte and Alvarez de Andres, 2006; Breiman, 2001)

Table 5: Algorithms used in evaluation on real data sets. When statistical comparison was performed inside a wrapper, we used a non-parametric method by DeLong et al. (1988). The only exception is Random Forest-based Variable Selection (RFVS), where we used a method recommended by its authors (Diaz-Uriarte and Alvarez de Andres, 2006). For GLL algorithms (i.e., variants of HITON-PC, HITON-MB, MMPC, MMMB) we experimented with both G^2 and Fisher's Z-test whenever the latter was applicable. This table is continued in Tables 6 and 7.

If $X \in MB(T)$, we show $X \in TMB(T)$ in the end. If $X \in MB(T)$ and $X \in PC(T)$, it will be included in the $TMB(T)$ in step 3, will not be removed afterwards and will be included in the final output.

If $X \in MB(T) \setminus PC(T)$ then X will be included in $\boldsymbol{S}$ since if X is a spouse of T, there exists Y (by definition of spouse) s.t., $X \in PC(Y), Y \in PC(T)$ and $X \notin PC(T)$. For that Y, by Theorem 3 we know that $\neg I(X,T|\boldsymbol{Z} \cup \{Y\})$, for all $\boldsymbol{Z} \subseteq \boldsymbol{V} \setminus \{X,T\}$ and so the test in step 5c will succeed and X will be included in $TMB(T)$ in the end.

Table 6: Continued from Table 5.

Conversely, if $X \notin MB(T)$ we show that $X \notin TMB(T)$ by the end of the algorithm. Let $\boldsymbol{Z}$ be the subset in step 5a, s.t., $I(X, T|\boldsymbol{Z})$ (i.e., $\boldsymbol{Z}$ d-separates X and T). Then, $\boldsymbol{Z}$ blocks all paths from X to T. For the test in step 5c to succeed a node Y must exist that opens a new path, previously closed by $\boldsymbol{Z}$, from X to T. Since by conditioning on an additional node a path opens, Y has to be a collider (by the d-separation definition) or a descendant of a collider on a path from X to T. In addition, this path must have length two edges since all nodes in $\boldsymbol{S}$ are the parents and children of the $PC(T)$ but without belonging in $PC(T)$. Thus, for the test in step 5c to succeed there has to be a path of length two from X to T with a collider in-between, that is, X has to be a spouse of T. Since $X \notin MB(T)$ the test will fail for all Y and $X \notin TMB(T)$ by the end of the algorithm.

Infant Mortality	Clinical	86	5,337	Died within the first year	Discrete	1-fold cross-val.	Already discrete	Imputed by nearest neighbor method	(Mani and Cooper, 1999)
Ohsumed	Text	14,373	5,000	Relevant to neonatal diseases	Continuous	1-fold cross-val.	Word absent / present		(Joachims, 2002)
ACPJ Etiology	Text	28,228	15,779	Relevant to etiology	Continuous	1-fold cross-val.	Word absent / present		(Aphinyanaphongs et al., 2006)
Lymphoma	Gene expression	7,399	227	3-year survival: dead vs. alive	Continuous	10-fold cross-val.	Binary/ternary univariate; used window sizes 10,15, 20, 25, 30 for ternary		(Rosenwald et al., 2002)
Gisette	Digit recognition	5,000	7,000	Separate 4 from 9	Continuous	1-fold cross-val.	Pixel present / absent	Used original training & validation sets only	NIPS 2003 Feature Selection Challenge (Guyon et al., 2006a)
Dexter	Text	19,999	600	Relevant to corporate acquisitions	Continuous	10-fold cross-val.	Word absent / present	Used original training & validation sets only	NIPS 2003 Feature Selection Challenge (Guyon et al., 2006a)
Sylva	Ecology	216	14,394	Ponderosa pine vs. everything else	Continuous & discrete	1-fold cross-val.	Binary/ternary univariate; used window sizes 1000, 1500, 2000, 2500, 3000 for ternary	Used original training & validation sets only	WCCI 2006 Performance Prediction Challenge

Table 8: Real data sets used in evaluation of predictivity and compactness. This table is continued in Table 9.

Data set name	**Domain**	**Num. variables**	**Num. samples**	**Target**	**Data type**	**Cross-val. design**	**Discretization applied**	**Notes**	**Reference**
Ovarian Cancer	Proteomics	2,190	216	Cancer vs. normals	Continuous	10-fold cross-val.	Binary/ternary univariate; used window sizes 10, 15, 20, 25, 30 for ternary		(Conrads et al., 2004)
Thrombin	Drug discovery	139,351	2,543	Binding to thrombin	Discrete (binary)	1-fold cross-val.	Already discrete		KDD Cup 2001
Breast Cancer	Gene expression	17,816	286	Estrogen-receptor positive (ER+) vs. ER-	Continuous	10-fold cross-val.	Binary/ternary univariate, used window sizes 10, 15, 20, 25, 30 for ternary		(Wang et al., 2005)
Hiva	Drug discovery	1,617	4,229	Activity to AIDS HIV infection	Discrete (binary)	1-fold cross-val.	Already discrete	Used original training & validation sets only	WCCI 2006 Performance Prediction Challenge
Nova	Text	16,969	1,929	Separate politics from religion topics	Discrete (binary)	1-fold cross-val.	Already discrete	Used original training & validation sets only	WCCI 2006 Performance Prediction Challenge
Bankruptcy	Financial	147	7,063	Personal bankruptcy	Continuous & discrete	1-fold cross-val.	Binary/ternary univariate, used window sizes 1000, 1500, 2000, 2500, 3000 for ternary	Imputed by nearest neighbor method	(Foster and Stine, 2004)

Table 9: Continued from Table 8.

Abstract

In part I of this work we introduced and evaluated the *Generalized Local Learning* (GLL) framework for producing local causal and Markov blanket induction algorithms. In the present second part we analyze the behavior of GLL algorithms and provide extensions to the core methods. Specifically, we investigate the empirical convergence of GLL to the true local neighborhood as a function of sample size. Moreover, we study how predictivity improves with increasing sample size. Then we investigate how sensitive are the algorithms to multiple statistical testing, especially in the presence of many irrelevant features. Next we discuss the role of the algorithm parameters and also show that Markov blanket and causal graph concepts can be used to understand deviations from optimality of state-of-the-art non-causal algorithms. The present paper also introduces the following extensions to the core GLL framework: parallel and distributed versions of GLL algorithms, versions with false discovery rate control, strategies for constructing novel heuristics for specific domains, and divide-and-conquer *local-to-global learning* (LGL) strategies. We test the generality of the LGL approach by deriving a novel LGL-based algorithm that compares favorably

to the state-of-the-art global learning algorithms. In addition, we investigate the use of non-causal feature selection methods to facilitate global learning. Open problems and future research paths related to local and local-to-global causal learning are discussed.

Keywords: local causal discovery, Markov blanket induction, feature selection, classification, causal structure learning, learning of Bayesian networks

1. Introduction

The present paper constitutes the second part of the study of *Generalized Local Learning* (GLL) which provides a unified framework for discovering local causal structure around a target variable of interest using observational data under broad assumptions. GLL supports local discovery of variables that are direct causes or direct effects of the target and of the Markov blanket of the target. In the first part of the work (Aliferis et al., 2010) we introduced GLL and explained the importance of local causal discovery both for identification of highly predictive and parsimonious feature sets (feature selection problem), and for scaling up causal discovery. We then evaluated GLL instantiations against a plethora of state-of-the-art alternatives in many real, simulated and resimulated data sets. The main conclusions were that GLL algorithms achieved excellent predictivity, compactness and ability to learn local neighborhoods. Moreover, state-of-the-art non-causal feature selection methods often achieve excellent predictivity but are misleading in terms of causal discovery.

In the present paper we provide several extensions to GLL, study its properties, and extend to global graph learning using GLL as the core method. Because of the close relationship with Aliferis et al. (2010) we do not repeat here background material, technical definitions, or algorithm specifications. These are found in Aliferis et al. (2010), Sections 2-4.

The paper is organized as follows: Section 2 studies the empirical convergence of GLL instantiations to the true local neighborhood and to optimal predictivity as a function of sample size. Section 3 studies the effects of multiple statistical testing and the sensitivity of GLL algorithms to large numbers of irrelevant features. Section 4 provides a theoretical analysis of GLL algorithms with respect to determinants of statistical decisions, heuristic efficiency and construction of inclusion heuristic functions, reasons for good performance of direct causes and effects instead of induced Markov blanket, and reduced sensitivity to error estimation problems that affect wrappers and traditional filters. Section 5 covers two algorithmic extensions, parallel processing and False Discovery Rate pre-filtering. Section 6 investigates the use of local learners like GLL for global learning and provides a general local-to-global learning framework. In that section we also derive a new algorithm HHC and compare it to the previously described MMHC, and show the potential of local induction variable ordering for tractability and quality improvements. Section 7 uses causal feature selection theory to shed light on limitations of established and newer feature selection methods and the inappropriateness of causally interpreting their output. Section 8 concludes with a discussion of the findings of the present paper and several open problems. An appendix and an online supplement (`http://www.nyuinformatics.org/downloads/supplements/JMLR2009/index.html`) provide additional results, as well as code and data sets that can be used to replicate the experiments.

2. Empirical Convergence and Comparison of Theoretical to Estimated Markov Blanket

As explained in Aliferis et al. (2010), arguments about the suitability of Markov blanket induction for feature selection for classification are based on large sample results, with convergence of small sample performance to the theoretical optimum being unknown. In the present section we use simulated data sets from published Bayesian networks to produce an empirical evaluation of classification performance convergence with respect to training sample size of two types of classifiers: one that uses the estimated Markov blanket ($MB(T)$) or parents and children set ($PC(T)$) and one that uses the true $MB(T)$ or $PC(T)$ set (obtained from the known generative network). We use polynomial SVMs and KNN to fit each classifier type from three training sample sizes: 200, 500 and 5,000 samples. We note that GLL algorithms provide predictive and optimality guarantees for universal approximator classifiers and SVMs and KNN are used here as exemplars of this class of algorithms. In Aliferis et al. (2010) we also discuss more generally suitable classifiers, distributions and loss functions for GLL instantiations. An independent sample of 5,000 instances is used as evaluation test for classification performance (measured by AUC for binary and proportion of correct classifications for multiclass classification tasks). We use data sets sampled from 9 different Bayesian networks (See Table 15 in the Appendix). For each Bayesian network, we randomly select 10 different targets and generate 5 samples (except for sample size 5,000 where one sample is generated) to reduce variability due to sampling.[1] An independent sample of 5,000 instances is used as evaluation test for classification performance. Several local causal induction algorithms are used (including algorithms that induce direct causes/direct effects, and Markov blankets), and are compared to several non-causal algorithms to obtain reference points for baseline performance: RFE, UAF (univariate association filtering), L0, and LARS-EN (see Table 16 in the Appendix for the list of all algorithms). Classifier parameters (misclassification cost C and degree d for polynomial SVMs and number of neighbors K for KNN) are optimized by nested cross-validation following the same methodology as in Aliferis et al. (2010).

Results are presented in Figure 1 (and more details are given in Tables S19 and S20 of the online supplement). The main conclusions follow. Note that similar patterns are present when KNN is used instead of SVMs (with the only difference that convergence is slightly slower for KNN than for SVMs). For brevity we discuss here the SVM results only.

(a) Classification performance of the true parents and children and Markov blanket feature sets are not statistically significantly different at the 0.05 alpha level in sample 200 (p-value = 0.1440) and are statistically significantly different for larger samples (p-values = 0.0098 and $<$0.0001 for sample sizes 500 and 5,000, respectively). The difference in SVM classification performance between using the $PC(T)$ and $MB(T)$ sets however does not exceed 0.02 AUC in favor of the $MB(T)$ set. This means that even when the true $PC(T)$ and $MB(T)$ sets are known in the tested data, fitting classifiers from small data using the $PC(T)$ set is as good as using the $MB(T)$ set. In large sample, $MB(T)$ features have a small predictive advantage over $PC(T)$ features.

1. For networks *Lung_Cancer* and *Gene*, we also add an eleventh target that corresponds to the natural response variable: lung cancer diagnosis and cell cycle state, respectively. For network *Munin* we use only 6 targets because of extreme probability distributions of the majority of variables that do not allow variability in the finite sample of size 500 and even 5000. Because of the same reason, we did not experiment with sample size 200 in the *Munin* network.

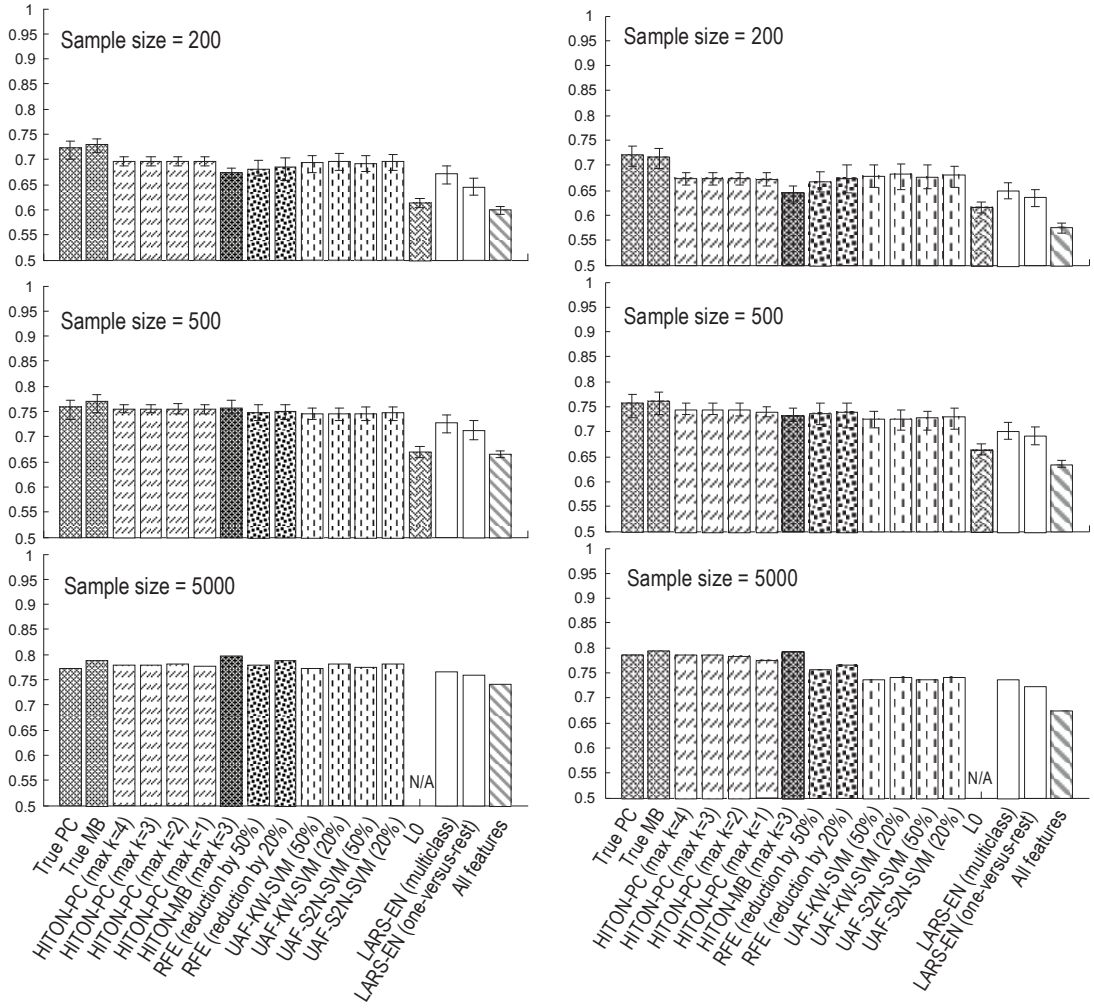

Figure 1: Classification performance of polynomial SVM (left) and KNN (right) classifiers in 9 simulated and resimulated data sets. Results are given for training sample sizes = 200, 500, and 5000. "True-PC" and "True-MB" correspond to the true $PC(T)$ and $MB(T)$ feature sets obtained from the known generative network. The bars denote maximum and minimum performance over multiple training samples of each size (data is available only for sample sizes 200 and 500). The performances reported in the figure are averaged over all data sets, selected targets, and multiple samples of each size. L0 did not terminate within the allotted time limit for sample size 5000.

(b) In small samples, feature selection increases classification performance for all tested classifier types (i.e., both when we know the $PC(T)$ or $MB(T)$ sets and when we estimate them from data) over using all features. This advantage becomes smaller but does not vanish in large sample. The difference in SVM classification performance between an average feature selection method and using all features is statistically significant at the 0.05 alpha level (p-values = $<0.0001, 0.0028, <0.0001$ for sample sizes 200, 500, and 5,000, respectively).

(c) The true $PC(T)$ or true $MB(T)$ features set when fitted from sample size of 200 has a small (0.02-0.03 AUC/proportion of correct classifications for SVM) advantage over the estimated $PC(T)$ or $MB(T)$ features fitted from small sample. This difference is statistically significant at the 0.05 alpha level with p-values 0.0144 and $<$0.0001 for the $PC(T)$ and $MB(T)$ classifiers, respectively. Very quickly (as sample size becomes 500), this advantage becomes insignificant (0.01 point of AUC/proportion of correct classifications for SVM) with corresponding p-values 0.4708 and 0.0506 for the $PC(T)$ and $MB(T)$ classifiers, respectively. This implies that predictivity of estimated $MB(T)$ and $PC(T)$ sets converge to the optimal one very quickly with respect to sample size.

(d) Classifiers for estimated $MB(T)$/$PC(T)$ sets fitted from small sample and classifiers for the true $MB(T)$/$PC(T)$ sets fitted from small sample have indistinguishable performance in sample size 500 (as shown in (c) above); then performance increases in sample size 5,000 for both types of classifiers (p-values ranging from $<$0.0001 to 0.0174 with AUC increases between 0.01 and 0.04). We thus conclude that fitting the right classifier parameters to the identified features is less sample efficient than identifying the right feature set.

(e) Some of the non-causal feature selection methods (e.g., L0, LARS-EN) tend to compare less favorably in small sample to their large sample performance compared to GLL algorithms.

3. Multiple Statistical Tests and Insensitivity to Irrelevant Variables

In this section we focus our attention to a subtle but an important problem facing many feature and causal discovery algorithms operating in very high dimensional spaces, namely the problem of multiple statistical comparisons, which is exacerbated when many irrelevant features are present. We will show that GLL algorithms have inherent control to false positives due to multiple comparisons while the same is not true for other non-causal feature selection methods tested.

Briefly stated, when conducting n statistical tests with an error type I level α (i.e., statistical significance level, that is probability that a truly null hypothesis is rejected, thus falsely concluding that a statistical difference or association or dependence exists when in reality it does not) it is expected that $\alpha \cdot n$ false positives will occur on average. Consider a common analysis situation in bioinformatics research where a researcher conducts one test per variable (i.e., single nucleotide polymorphism (SNP)) in an assay with 10,000 SNP probes in total. 10,000 such tests need be conducted to see whether univariately each SNP probe is differentially present in two or more phenotype categories. If the researcher uses α equal to 5%, then under the null hypothesis (i.e., all 10,000 SNPs are not truly differentially expressed) the analysis will yield 500 false positive SNP probes. Standard statistical practice involves addressing the problem via one of two basic approaches. The first approach, the classic Bonferroni correction (Casella and Berger, 2002), adjusts the α by replacing it by α/n so that in our example the 5% false positive rate is preserved for each feature selected by the multiple tests. This approach preserves the desired α, but reduces the power to detect statistically significant features (namely the features that are truly differentially expressed and detectable at α but non-detectable at α/n), hence creates false negatives that were not present before the correction. The second approach, False Discovery Rate (FDR) control (Benjamini and Yekutieli, 2001; Benjamini and Hochberg, 1995), trades off false positives and false negatives by ensuring not that each feature passing the chosen p-value threshold preserves the original α, but that from the all features found to be significant (i.e., for which the null hypothesis is rejected) a desired proportion will be false

Low classification performance — *High classification performance*

Table 1: Classification performance (AUC) of polynomial SVM estimated on 5,000 sample independent testing set for features selected by HITON-PC with parameter *max-k*={0,1,2,3,4} on different training sample sizes {100,200,500,1000,2000,5000}. The color of each table cell denotes strength of predictivity with yellow (light) corresponding to low classification performance and red (dark) to high classification performance.

positives on average. In our example, FDR methods may, for example, allow the researcher to ensure that on average no more than 10 out of 100 SNPs selected are false positives. This is highly useful in exploratory analysis of high-dimensional data where subsequent experimentation can sort out false positives easily but where false negatives have high cost.

Constraint-based causal methods employ, in large data sets and depending on connectivity and inclusion heuristic efficiency, many thousands of statistical tests of independence and are thus expected a priori to be particularly sensitive to the multiple testing problem. We note that, rather not obviously at first, testing under the null hypothesis does not only occur when irrelevant features exist but also whenever we test weakly relevant features conditioned on a set of variables that blocks all paths connecting it with the target. Other feature selection methods do not explicitly conduct statistical tests of independence but may also be sensitive to many irrelevant features as we will show. In the present section we first systematically explore empirically and then examine theoretically the degree of sensitivity of GLL algorithms to irrelevant features, how they address the multiple testing problem, and how other feature selection and causal discovery algorithms compare along these dimensions.

In the first set of experiments we run only semi-interleaved HITON-PC without symmetry correction on two networks and variants. The networks, described in Aliferis et al. (2010), are the *Lung_Cancer* resimulated network and the *Alarm10* network. The former is chosen for its higher

Small number of false negatives — *Large number of false negatives*

Table 2: Number of false negatives in the parents and children set for features selected by HITON-PC with parameter *max-k*=$\{0,1,2,3,4\}$ on different training sample sizes $\{100,200,500,1000,2000,5000\}$. For Version 4 of the network the parents and children set is empty since there are no relevant variables. The color of each table cell denotes number of false negatives with yellow (light) corresponding to smaller values and red (dark) to larger ones.

connectivity whereas the latter is designed to have lower connectivity. In the *Lung_Cancer* network we focused our attention on the natural target variable; this target has 26 members of the parents and children set and 18 spouses, 14 irrelevant variables, and 741 weakly relevant ones. We created four versions of this network: *Version 1* contains the original network (total number of variables 800). In *Version 2* we augment the original network with 7990 irrelevant variables (total number of variables 8790). *Version 3* is the same as Version 2, except for 10% of values of the target are randomly flipped to weaken the signal (total number of variables 8790). Finally, *Version 4* is same as Version 2, except that there are only irrelevant variables and the target (total number of variables is $8790-741-18-26=8005$). The tiled *Alarm10* has also four corresponding versions but its target was chosen randomly and it has only 6 members of the parents and children set and no spouses. In both networks (and their variants) we create irrelevant variables by randomly permuting values of weakly and strongly variables so that the distribution of each variable values is realistic. With these 8 data set versions we can systematically examine the effects of presence of irrelevant variables, strength of predictive signal of features for the target, network connectivity and of the values of the GLL *max-k* parameter (Aliferis et al., 2010).

We run HITON-PC and build SVM classifiers for all networks and variants, varying sample size and the *max-k* parameter, and measure AUC, false negatives, false positives that are weakly relevant,

Small number of false positives — *Large number of false positives*

Table 3: Number of false positives (within weakly relevant variables) in the parents and children set for features selected by HITON-PC with parameter *max-k*=$\{0,1,2,3,4\}$ on different training sample sizes $\{100,200,500,1000,2000,5000\}$. For Version 4 of the network there are no weakly relevant variables. The color of each table cell denotes number of false positives with yellow (light) corresponding to smaller values and red (dark) to larger ones.

false positives that are irrelevant and total false positives. To ensure that our results are not affected by variability in small samples, we generate 10 random samples of each size and average results.

Tables 1– 5 provide evidence for the following conclusions:

(a) Classification performance is mildly or not affected by false positives and false negatives (Table 1). When many false negatives are present, predictivity is compensated by the few remaining strong relevant features plus strongly predictive weakly relevant ones. This implies that classification performance cannot be used to inform us about the presence of false positives/negatives.

(b) As expected, false negatives are reduced as sample size grows (because power increases), however they also increase as *max-k* grows, because the number of tests increases as *max-k* grows and thus overall power decreases (Table 2).

(c) When no irrelevant features are present, as sample size grows the number of false positives that are weakly relevant increases if *max-k* is not sufficient to block paths from/to each weakly relevant to/from the target. As *max-k* increases the false positives decrease to the point that they vanish (Table 3). Overall, both false negatives and false positives vanish given enough

Small number of false positives — *Large number of false positives*

Table 4: Number of false positives in the parents and children set for features selected by HITON-PC with parameter *max-k*=$\{0,1,2,3,4\}$ on different training sample sizes $\{100,200,500,1000,2000,5000\}$. The color of each table cell denotes number of false positives with yellow (light) corresponding to smaller values and red (dark) to larger ones.

sample size and sufficient (but not excessive) *max-k*, (i.e., sample size $\geq$ 2,000, *max-k*=2) (Tables 2 and 4).

(d) When irrelevant features are present, as sample size grows the number of false positives that are weakly relevant increases if *max-k* is not sufficient to block paths from/to each weakly relevant to/from the target. As *max-k* increases, the false positives decrease to the point that they vanish (Table 3). False positives due to irrelevant features (Table 5) quickly vanish as *max-k* becomes 2 or higher and this holds as long as sample size is larger than 200. False negatives are not affected by presence of irrelevant features (Table 2). Thus, overall, with enough sample size and right value of *max-k*, both false negatives and false positives vanish (Tables 2 and 4).

(e) When the predictive signal is weaker, both false negatives are increased and false positives within weakly relevant variables are decreased for a given sample size (because power is smaller) (Tables 2 and 3). However false positive irrelevant variables (Table 5) are increased. This is due to the fact that fewer features enter the $TPC(T)$ set thus leading to fewer tests that can be performed hence smaller capacity to remove irrelevant false positives. As previously with enough sample and right *max-k*, false positives and negatives are fully eliminated (Tables 2 and 4).

(f) When the data consists only of irrelevant features, false positives (irrelevant) are reduced as *max-k* increases for all sample sizes (Table 5). There is a very small persistent residual number of false positives regardless of how small the sample is or how big the *max-k*. These phenom-

Small number of false positives — *Large number of false positives*

Table 5: Number of false positives (within irrelevant variables) in the parents and children set for features selected by HITON-PC with parameter *max-k*=$\{0,1,2,3,4\}$ on different training sample sizes $\{100,200,500,1000,2000,5000\}$. The color of each table cell denotes number of false positives with yellow (light) corresponding to smaller values and red (dark) to larger ones.

ena happen because the algorithm needs a sufficient number of elements in the $TPC(T)$ set (i.e., tentative parents and children of T) in order to execute conditional independence tests and remove the false positive irrelevant features.

(g) The above trends are remarkably consistent in both networks suggesting that different redundancy and connectivity do not affect the above algorithm behavior.

In the second set of experiments we compare empirically in the above two networks (four variants for each as previously) and 6 sample sizes the following algorithms: semi-interleaved HITON-PC, MMPC, a version of HITON-PC where we pre-filter features by Benjamini FDR control (at FDR rate threshold of 5%) (Benjamini and Yekutieli, 2001), the true $PC(T)$ set extracted from the data generating network (denoted as "True-PC" in Table 6), UAF (univariate association filtering) with Bonferroni correction, UAF with Benjamini FDR control, uncorrected UAF, "wrapped" UAF, RFE, and LARS-EN. Tables 6–9 provide support for the following conclusions:

(h) Due to strength of signal and redundancy of predictors, AUC reaches the theoretical maximum (provided by the generative network) very quickly and for all methods (Table 6).

(i) When no irrelevant features are present and in the stronger signal setting, simple and FDR-corrected UAF (but not wrapped UAF) has the least false negatives in very small samples (Table 7). As sample size grows all methods reduce their false negatives (Table 7). GLL methods pick up the strongly relevant features without false positives and reach near perfect

Low classification performance — *High classification performance*

Table 6: Classification performance (AUC) of polynomial SVM estimated on 5,000 sample independent testing set for selected features. HITON-PC, HITON-PC-FDR, and MMPC are applied with *max-k*=2. The color of each table cell denotes strength of predictivity with yellow (light) corresponding to low classification performance and red (dark) to high classification performance.

Small number of false negatives — *Large number of false negatives*

Table 7: Number of false negatives in the parents and children set for selected features. HITON-PC, HITON-PC- FDR, and MMPC are applied with *max-k*=2. For Version 4 of the network the parents and children set is empty since there are no relevant variables. The color of each table cell denotes number of false negatives with yellow (light) corresponding to smaller values and red (dark) to larger ones.

separation (i.e., 1-2 false negatives and zero false positives) at sample size 1,000 and higher (Table 8). No other method simultaneously minimizes false positives and false negatives as GLL.

(j) In the setting of strong signal with irrelevant features, simple UAF has the least false negatives in very small samples (Table 7) and the largest number of false positives (Table 8).

(k) When the predictive signal is weaker, false negatives are increased and weakly relevant false positives are decreased for a given sample size compared to the stronger signal case (Tables 7 and 8). Simple UAF is again most sensitive in terms of detecting strongly relevant features in smaller samples until sample size 1,000-2,000 where UAF-Bonferroni and UAF-FDR and GLL match the false negative rates (Table 7). As previously, GLL (with HITON-PC and

Small number of false positives *Large number of false positives*

Table 8: Number of false positives (within weakly relevant variables) in the parents and children set for selected features. HITON-PC, HITON-PC-FDR, and MMPC are applied with *max-k*=2. For Version 4 of the network there are no weakly relevant variables. The color of each table cell denotes number of false positives with yellow (light) corresponding to smaller values and red (dark) to larger ones.

MMPC performing similarly) achieves excellent false positive rates better than those by FDR not only for weakly relevant but also for irrelevant features.

(l) HITON-PC augmented with FDR pre-filtering behaves almost identically as regular HITON-PC except for the case with only irrelevant features in the data where HITON-PC without FDR admits a few false positives (Table 9).

(m) State-of-the-art feature selection methods are prone to select very large numbers of irrelevant features (Table 9).

In conclusion, HITON-PC and by extension GLL algorithms (since the same fundamental mechanisms for variable inclusion and elimination are shared because of the GLL-PC template and admissibility requirements), have a very strong built-in capacity to control for false positives due to multiple comparisons. False positives due to multiple comparisons quickly vanish for *max-k* 1 or

Small number of false positives — *Large number of false positives*

Table 9: Number of false positives(within irrelevant variables) in the parents and children set for selected features. HITON-PC, HITON-PC-FDR, and MMPC are applied with *max-k*=2. The color of each table cell denotes number of false positives with yellow (light) corresponding to smaller values and red (dark) to larger ones.

higher *regardless of sample size*. Given enough sample size (∼1,000 or more in the data tested), and by choosing 5% as the nominal α for all conditioning independence tests executed, the algorithm fully eliminates irrelevant features from its output without incurring a penalty in false negatives, even when irrelevant features are the majority among observed features. Parameter *max-k* controls the false positives due to both weakly relevant and irrelevant features. The false positive rate in this worst-case situation is in the presented experiments $\sim 5/8{,}000 = 0.000625$ which is much better than what the conservative Bonferroni-adjusted α guarantees, and *without* incurring false negatives (as both Bonferroni and FDR methods do). Both established feature selectors such as variants of UAF and newer ones are very sensitive to irrelevant features and produce large numbers of false positives. Given the attractive characteristics of FDR-augmented HITON-PC, we evaluate it with real data sets in Section 5.

4. Theoretical Analysis of GLL

In the present section we provide a theoretical analysis of the Generalized Local Learning algorithms.

4.1 Determinants of Quality of Statistical Decisions and Computational Tractability. Parameters *max-k* and *h-ps*

On a rather superficial level when conditioning sets are large enough, statistical tests become less reliable. For example, as explained in Aliferis et al. (2010), cells in contingency tables used to calculate p-values of discrete tests of independence (such as the widely-used G^2 or X^2 test) become scarcely populated and this leads to unreliable test results. This motivates the heuristic practice of considering as unreliable and not executing a test in which the sample size is less than: ("number of cells to be fitted" $\cdot$ *h-ps*), with parameter *h-ps* set to 10 by default in the PC algorithm (Spirtes et al., 2000) and 5 in GLL instantiations. Recall from Aliferis et al. (2010) that *h-ps* stands for "heuristic power size" and denotes the smallest sample size per cell in the contingency table of a reliable conditional test of independence. Moreover, when the conditioning set size is large enough to block all paths between a weekly relevant variable and the target, there is no need to exceed this conditioning set size because the resulting tests are redundant and the operation of the algorithm becomes unnecessarily slow. Thus it seems reasonable that we would wish to restrict the conditioning set size to not exceed this sufficient blocking size. This is accomplished by setting the value of parameter *max-k*. We will see however that *max-k* has a much more elaborate function than simply "trimming away" excessive computations.

In reality things are significantly more complicated because, as first pointed out by Spirtes et al. (2000), statistical reliability of a single test is a misleading concept in the context of complex constraint-based algorithms such as GLL. Standard statistical considerations of the type of testing a hypothesis once do not carry over well to the constraint-based algorithm setting. Similarly, running time is also a complex function of direct or indirect restrictions placed on number of tests and the number of variables with which to build such tests (i.e., the size of $TPC(T)$).

We first explain what happens when running semi-interleaved HITON-PC in faithful distributions (same arguments can be generalized to other GLL-PC and GLL-MB versions). Consider first that in the case of a strongly relevant feature S, when conducting just one test $\mathrm{I}(S, T|\emptyset)$ for the purposes of inclusion of S in $TPC(T)$, regardless of how small power is, we should always execute this test because the worst that can happen is that we fail to include S in $TPC(T)$, whereas if we do not

execute the test and assume independence by default, we will surely miss it. In the context of *many tests* however, the notion of single-test reliability for S no longer applies. For example, when we consider a test that has the potential to reject S from $TPC(T)$ (where it was placed previously by a *different* test), by allowing the conditioning test size to grow large, the power is reduced (assuming monotonic association of S through the potentially multiple paths connecting S with T). Hence, we need to preserve the combined power (i.e., combination of individual powers of all tests applied to S) in order to not eliminate S from $TPC(T)$. Although these tests are highly correlated and combined power is larger than the product of powers of the same set of tests performed on independent samples, still the more tests are executed the smaller the combined power and the larger the possibility of falsely eliminating S becomes. The parameter *h-ps* partially controls power because the larger it is, the smaller number of tests (that would eliminate S) are executed. However *h-ps* should not be too large either because a strongly relevant S will not be included in $TPC(T)$ in the first place. Parameter *max-k* also controls in part the number of tests allowed. *Max-k* does not fully determine the number of tests because it specifies the dimensionality of allowed tests, not their total number. As *max-k* grows, more tests for eliminating S from $TPC(T)$ are executed, thus the combined power drops. In summary, for a given distribution the number of tests performed is affected by *h-ps*, *max-k* and the size of $TPC(T)$.

So far the discussion has centered on one type of conditional independence test, that is, tests where the candidate member of $PC(T)$, X, is a strongly relevant feature (type 1). This is the first of four types of conditional tests. The other three are: conditional independence tests where the candidate member of $PC(T)$, X, is a weakly relevant feature and some paths with T are not blocked by the conditioning set (type 2a), conditional independence tests where the candidate member of $PC(T)$, X, is a weakly relevant feature and all paths with T are blocked by the conditioning set (type 2b), and finally conditional independence tests where the candidate member of $PC(T)$, X, is an irrelevant feature (type 3).

The quality of conditional tests of the first type is determined by the *power* of the association of X with T given the conditioning set. Since not one but potentially many such tests are conducted, the combined power of all such tests determines whether X will be selected and stay in the $TPC(T)$ set. For example, variable X (a true member of $PC(T)$) will be considered for inclusion in $TPC(T)$ by HITON-PC with probability = power of detecting $\neg \mathrm{I}(X,T)$ given the available sample size and test employed. However for X to stay in $TPC(T)$ until the algorithm terminates, and assuming B, C have entered $TPC(T)$, none of the tests $\mathrm{I}(X,T|B)$, $\mathrm{I}(X,T|C)$, $\mathrm{I}(X,T|\{B,C\})$ must conclude independence. The power or each one of these tests can be lower or higher than the power of $\mathrm{I}(X,T)$ and the combined power can quickly diminish, however several mitigating factors prevent this from happening. First, when using linear tests under common distributional assumptions such as multivariate normality, the necessary sample size to achieve desired level of power grows linearly to number of variables in the conditional set. Second, as explained earlier, conditional independence tests of the same variable and T in the same sample are highly correlated. Third, controlling the number of members of $TPC(T)$ by a good heuristic inclusion function reduces the total number of tests; such control occurs indirectly by putting first the true members of $PC(T)$ or members that block many variables. Fourth, the order of executing the tests and constructing conditioning sets is important for reducing the number of tests performed on strongly relevant variables. This is exemplified in semi-interleaved HITON-PC where new entrants in $TPC(T)$ are tested before current $TPC(T)$ members thus if the heuristic inclusion function is a good one, strongly relevant members are tested a smaller number of times at the elimination phase.

Returning our attention to the quality of statistical decisions for weakly relevant variables, we observe that when a conditioning set *does not* block all paths to/from T either for inclusion or for elimination purposes (type 2a), we are sampling under the alternative hypothesis (i.e., there exists association) and the determining factor for failing to reject the weakly relevant feature is the combined power which is determined by the same factors as elaborated for strongly relevant variables previously. The combined probability for rejection may be small for similar reasons as type 1 conditional independence tests (albeit higher than for strongly relevant features due to the fact that under a good inclusion heuristic weakly relevant features enter $TPC(T)$ later than strongly relevant ones and thus more tests are applied on each weakly relevant than on each strongly relevant feature on average).

However, when the conditioning set blocks all paths from/to T (type 2b), *then we sample under the null hypothesis* and the determining factor shifts from the combined power to the *combined* α (i.e., statistical significance). Given that the α for each conditional test is typically low (i.e., 5% or smaller) and that as the number of tests under the null increases, the combined α drops up to exponentially fast, and eliminating weakly relevant features occurs with high probability as the number of applied tests increases. In HITON-PC, the smaller is *h-ps*, the easier it is to include a weakly relevant feature (based on univariate association heuristic), whereas *max-k* does not affect this function. In terms of rejecting a weakly relevant feature in $TPC(T)$, the larger *max-k* and the smaller *h-ps* become, the easier it is to eliminate a weakly relevant feature.

The quality of statistical decisions for type 3 of conditional independence tests, that is for irrelevant variables, is determined by the combined α since we *always* test under the null hypothesis. Because the combined α drops fast as the number of tests applied to each irrelevant variable (and these tests are abundant when even a handful of variables have been admitted in $TPC(T)$), the combined probability for admitting and not rejecting irrelevant variables is exceedingly small. However when no strongly (and thus no weakly) relevant feature exists, conditioning sets inside the $TPC(T)$ set become smaller as irrelevant variables are eliminated from it with the end result of leaving a small number of "residual" irrelevant features in the final output as evidenced in the simulation experiments of Section 3. By pre-filtering variables with an FDR filter (Benjamini and Yekutieli, 2001; Benjamini and Hochberg, 1995), we not only gain the security that if the data consists exclusively of irrelevant variables fewer or no false positives will be returned, but also we can use *max-k* to control sensitivity and specificity trading weakly relevant false positives for strongly relevant true positives and vice versa (i.e., without worrying about adversely trading off irrelevant features).

Finally, the total number of tests is determined by both parameters *h-ps* and *max-k*, in a non-monotonic manner. That is, whenever *h-ps* is extremely large it effectively disallows most tests and the algorithm quickly terminates returning the empty set regardless of *max-k*. For medium/small values of *h-ps*, more tests are executed, more variables enter $TPC(T)$, and many tests are executed before $TPC(T)$ is finalized. *Max-k* modifies this number by potentially restricting the number of tests. When *h-ps* is very small, tests are allowed with very large conditioning tests and as long as *max-k* does not disallow them, the total number of tests grow very large.

	Number of conditional independence tests			*Cost of conditional independence tests*			*Number of false positives (fp) and false negatives (fn)**

* Results are same for HITON-PC and MMPC for number of false positives and false negatives

Figure 2: Efficiency of HITON-PC versus MMPC.

4.2 Efficiency and Heuristic Robustness of HITON-PC Versus MMPC

Figure 2 presents the number and cost[2] (proportional to time) of conditional independence tests performed by semi-interleaved HITON-PC versus MMPC in the 2,000-sample data set from the *Alarm10* and *Lung_Cancer* networks. As can be seen, HITON-PC performs fewer tests on average while achieving the same performance as MMPC. We notice that the max-min association heuristic closely reflects the logic behind the combined probability for error for the weakly relevant features. MMPC when testing under the alternative hypothesis (i.e., strongly relevant features, or unblocked weakly relevant ones) requires measuring all relevant associations, whereas HITON requires just the univariate ones *for inclusion purposes*. However semi-interleaved HITON tries to eliminate the newly included variable immediately upon inclusion and thus effectively conducts a similar number of tests as MMPC. Both algorithms when testing under the null hypothesis (irrelevant or fully-blocked weakly relevant features) on average execute the same number of tests. The max-min association inclusion heuristic is a priori more prone to basing its decisions for inclusion in $TPC(T)$ on less statistically reliable criteria. This is because the more associations are considered and the larger the conditioning sets are, the higher variance in the minimum association estimates is expected, making the maximum of such associations over all variables considered more prone to sampling error (i.e., it is likely to be overfitted to the sample). Because of better robustness of the univariate association relative to the weakest association over many conditional associations true members of $PC(T)$ may enter the $TPC(T)$ set earlier. However both HITON-PC and MMPC exhibit similar performance in real and simulated data sets, demonstrating that the theoretical problem with max-min association is in practice very rare.

4.3 Synthesis and Problems for Inclusion Heuristics; Constructing New Inclusion Heuristics

A problem when inducing local neighborhoods and particularly Markov blankets is that of *information synthesis*. The problem consists of a variable X that is not in $PC(T)$ having higher association (univariate or conditional on some subsets) with T than members of $PC(T)$ (for a concrete example see Figure 13). We will call such variables, *synthesis variables*. Synthesis variables were identified

2. The cost of a conditional independence test is calculated as the number of variables participating in it (excluding target variable). For example, univariate tests have cost = 1, tests with conditioning on two variables have cost = 3.

as major problems for algorithms such as IAMB (Tsamardinos and Aliferis, 2003; Tsamardinos et al., 2003a) or GS (Margaritis and Thrun, 1999) that induce Markov blankets and do so by conditioning in their inclusion phase on all variables in the tentative $MB(T)$. Because of the requirement to condition on all variables in the tentative $MB(T)$, the sample requirements grow exponentially fast to the size of the tentative $MB(T)$ and thus it is absolutely imperative to keep out of it synthesis variables since they unnecessarily increase the sample requirements to the point that the algorithm may need to stop executing conditional independence tests (and either halt or output the tentative $MB(T)$ as best but flawed estimate of the true $MB(T)$).

With regards to GLL algorithms, most efficient operation is achieved when the variables that alone or in combination have the property that block the largest fraction of weakly relevant variables, enter first in $TPC(T)$ (even if they are not strongly relevant themselves). Synthesis variables may or may not have this property, so synthesis may or may not be a problem for a specific GLL algorithm based on characteristics of the specific data in hand.

Construction of new inclusion heuristics may be required in difficult cases where the univariate and max-min heuristics do not work well leading to very slow processing time and very large $TPC(T)$ sets, in order to make operation of local learning tractable. In practice, both the univariate and max-min association heuristics work very well with real and simulated data sets, so we do not pursue here implementation and testing new heuristics in artificial problems, although we recognize the possibility of such need in future problematic data distributions. We outline here, in broad strokes, general strategies for creating new inclusion heuristics for such cases:

1. *Random heuristic search informed by standard heuristic values*. This strategy is based on using one of the usual heuristics to rank candidate variables and making selection decisions based on random selection of a candidate variable with probability proportional to the original heuristic value. This enables using the older heuristic as a starting point but allowing occasionally deviations from it to explore the possibility that lower-ranked candidates may have better potential as blocking variables. A simulated-annealing determination of probability of selection (or other efficient stochastic search algorithms) can be pursued as well.

2. *Constructing new heuristic functions by observing blocking capability* (in terms of candidate variables blocked by conditioning sets in which V is a member) or *probability of a variable V to remain in $TPC(T)$*. The empirical observations can be collected from a variety of tractable sources: either from a single incomplete run of the algorithm (i.e., without waiting to terminate), or in other data sets characteristic of the domain, or in multiple runs on smaller (randomly chosen) subsets of the original feature set. The new heuristic function F can be constructed as the conditional probability:

$$F(V_i) = P(V_i \in TPC(T) | h(V_i))$$

where $h(V_i)$ is the original heuristic value of variable V_i, or the proportion of candidates blocked by a conditioning set containing V_i:

$$F(V_i) = \sum_{k=1}^{M} N_k(V_i)/M$$

where $N_k(V_i)$ is the number of candidate variables blocked by a conditioning set that contains variable V_i in trial k.

3. *Exploiting known domain structure*. When properties of the causal structure of the data generating structure and/or distributional characteristics are known, one can use this information alone or in conjunction with the previous two strategies to derive more efficient heuristics.

We note that developing an inclusion heuristic that leads to efficient execution of GLL is not always feasible since the very problem of finding the features with direct edges with the target is intractable in the worst case (e.g., consider a graph that is fully connected). In some cases, as we will show in Section 6, *it is possible to transform an intractable local learning problem into a tractable one by employing a global learning strategy (i.e., exploiting asymmetries in connectivity)*.

4.4 Inductive Bias of GLL

Informally the inductive bias of GLL is that it seeks a balance of false negatives for strongly relevant variables with false positives for weakly relevant and irrelevant variables. The main regulating parameters (for standard inclusion heuristics, elimination and interleaving strategies) are *h-ps* and *max-k*. In practice, the algorithms tested in our work to date reveal higher sensitivity to *max-k* and thus at first approximation we treat optimization of this parameter as having higher priority. Smaller *max-k* empirically decreases false negatives and increases false positives overall. Larger *max-k* increases the false negatives and decreases the false positives. GLL in moderate to large samples achieves small numbers of false negatives and small numbers of false positives. In very small samples GLL prefers false positive errors than false negative ones when *max-k* is small. This occurs because given *some* evidence in favor of $PC(T)$ membership (provided by lower-dimensional and thus more sample efficient) tests of a variable X but *no reliable proof* to the contrary (provided by omitted higher-dimensional and thus unreliable tests), the algorithm outputs X as member of $PC(T)$. A similar behavior exists for the $MB(T)$ versions (with respect to $MB(T)$ membership). Notice that as *max-k* grows many more tests can be executed provided that a liberal *h-ps* is chosen, and these tests can be used to eliminate both weakly relevant as well as strongly relevant features in $TPC(T)$. The choice of a more liberal *h-ps* default value in GLL (compared to the more stringent value in the published implementation of PC algorithm) allows a more effective control of the tradeoff between false positives and false negatives in small samples by changing values of *max-k*.

By contrast, the SGS and PC algorithms (Spirtes et al., 2000) given *no evidence* in favor of membership of X in $PC(T)$ and *no reliable proof* to the contrary, assumes that X has a common edge with T. IAMB (Tsamardinos and Aliferis, 2003; Tsamardinos et al., 2003a) to the contrary, given *some* reliable evidence in favor of a variable X belonging to $MB(T)$ but *no reliable proof* to the contrary, outputs X as member of $MB(T)$ if X is in the tentative Markov blanket $TMB(T)$ and is agnostic with respect to membership in $MB(T)$ if X is outside $TMB(T)$. Bayesian scoring methods in small samples are dominated by their priors and typically they prefer sparse networks which lead to fewer false positives and more false negatives.

4.5 Reasons for Good Performance of Non-Symmetry Corrected Algorithms

The empirical evaluations in part I of this work (Aliferis et al., 2010) have shown that the addition of symmetry correction adds little to quality, while it detracts from computational efficiency. Evidently very often $EPC(T) \approx PC(T)$ in real-life distributions and targets of interest. In addition, due to imperfect power to detect and return strongly relevant features, applying symmetry correction leads to reduced power and increased false negatives.

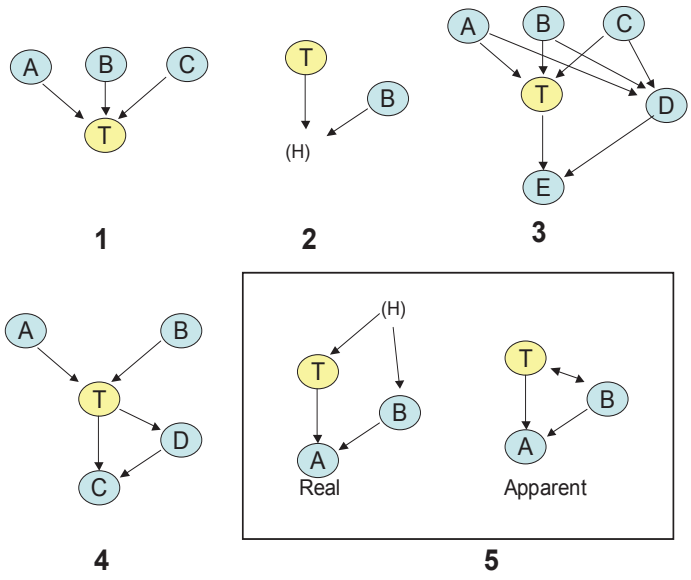

Figure 3: Scenarios explaining good empirical performance of $PC(T)$ set for classification.

4.6 Reasons for Good Performance of the $PC(T)$ Set Instead of the $MB(T)$ Set for Classification

According to the theoretical results summarized in Aliferis et al. (2010), under broad assumptions spouses are needed for optimal classification performance. Given that in the majority of data sets tested in Aliferis et al. (2010) as well as the experiments in Section 2 of the present paper, when the set of parents and children is used instead of $MB(T)$ it produces equal or almost equal performance, more compact feature sets and faster feature selection times than inducting the full $MB(T)$ (i.e., both $PC(T)$ and $MB(T)$ estimated under the same assumptions of the theory that predicts that $MB(T)$ is needed for optimal feature selection). In this sub-section we provide likely explanations for the empirically excellent performance of substituting the set $PC(T)$ in place of $MB(T)$ for classification (apart from the obvious possibility that spouses may be much fewer and with smaller predictive value than parents and children). Figure 3 describes visually five plausible scenarios explaining the phenomenon.

The first scenario corresponds to the situation whereby the target variable T does not have children (and thus no spouses) by virtue of domain constraints. Such situations happen when the target variable is a variable preceded in time by all other variables (e.g., patient outcome on the basis of earlier observations); or when naturally the target variable cannot have children (e.g., the target being meaning category of a text document as a function of patterns of presence/absence of words in the text). The second scenario describes the situation where a child is not observed (hidden) in the data set and thus the spouse B cannot be made informative for the target and thus it can neither be detected nor can it enhance a classifier built from the data. The third scenario describes the situation where a spouse has connecting paths to the target but these cannot be blocked simultaneously because of small sample size and/or choice of *max-k*. Hence GLL-PC could admit the spouse D as a member of $PC(T)$. The fourth scenario simply shows a case where a spouse is also a child (or parent) and thus will be a member of $PC(T)$ as well as $MB(T)$. Finally the fifth

scenario shows that an unmeasured variable may make a spouse appear as having a direct edge to or from the target (and thus are detectable by GLL-PC).

We note that in practical data analysis and evaluations when both $PC(T)$ and $MB(T)$ are induced and are found to have similar classification performance, typically $MB(T)$ is much larger than $PC(T)$. However this may be a reflection of the inductive bias of GLL which prefers to admit potential false positives if they cannot be shown for sample size reasons to be independent of the target.

Finally note that explanations #1, 2, 3, and 4 are special cases of the assumptions of the Markov blanket induction theory and thus they do not refute these assumptions (whereas #5 violates causal sufficiency). In the discussion section we consider additional situations with violations of GLL assumptions.

4.7 Error Estimation Problems in Wrapping and Standard Filters Due to Small Sample Size. GLL Filtering is Less Sensitive to Error Estimation Difficulties and Robust to Small Samples

Wrapping has been praised as a feature selection methodology for its ability to tailor the feature selection to the inductive bias of the classifier(s) of choice as well as to the loss function of interest (Kohavi and John, 1997). Occasionally, this property will work against the analysis (see Section 7 for example for how it can jeopardize causal discovery). On the other hand, wrapping has been criticized for its very large computational cost as well as on the grounds that it is subject to No Free Lunch Theorem limitations (i.e., a priori all wrappers are equally good, making it hard to find the right wrapper for the distribution, loss function and classifier(s) of interest) (Tsamardinos and Aliferis, 2003). In the present section we explain what we believe is perhaps the most serious practical shortcoming of wrapping feature selection methods, namely that *they rely on error estimation procedures that are often unreliable because of small sample sizes*. The difficulties that will be presented here help explain the sometimes poor performance of some of the feature selection algorithms in the evaluation part (Aliferis et al., 2010). In contrast, we will show that GLL filtering is resistant to these problems.

Recall that the critical point when applying error estimators is to have a sufficiently small variance and to be unbiased or to correct for any bias, as for example is the case of the (biased) Bootstrap estimator. Consider an idealized example where a greedy (steepest-descent) backward selection wrapper algorithm is applied on faithful data that contains 5 irrelevant features $I_1, \ldots, I_5$ and one strongly relevant feature S.

Assume that in reality the optimal feature set consisting of only the strongly relevant feature S gives a predictor model with true error measured by AUC is 0.75 in the large sample (i.e., in the distribution where the data is sampled from). For all practical unbiased error estimators, because of variability in the estimates of error due to small sample sizes, and because of potential sensitivity of the classifier employed to irrelevant features, some subsets that contain S will have error estimates in small sample situations that are larger and some smaller than the true AUC of 0.75. The backward wrapping starts by eliminating one variable at a time producing feature sets and corresponding predictor models and by eliminating the feature that decreases error the most relative to the starting model that contains all features. As a result, a feature set can be chosen, not because the error is truly decreased if we remove any more features, but because the error estimates vary and the backward wrapper (naively) does not take this into account. If the wrapper is configured

Action	Decision	Notes
Rank variables according to univariate association with target T	S (association = 0.8) I_1 (association = 0.3) I_2 (association = 0.1) I_3 (association = 0.1) I_4 (association = 0.05) I_5 (association = 0.0)	Some associations of irrelevant variables are non-zero due to sampling variation
Test S for inclusion: $\neg I(S, T)$	Admit S in $TPC(T)$	Assuming S is a strong predictor of the target, the power of the univariate test will be sufficient to reject independence
Test I_1 for inclusion: $I(I_1, T)$	Eliminate I_1	Test will be correct with probability 1-α (typically 0.95)
Test I_2 for inclusion: $I(I_2, T)$	Eliminate I_2	Test will be correct with probability 1-α (typically 0.95)
Test I_3 for inclusion: $\neg I(I_3, T)$	Consider I_3	Assume we were unlucky and had a false positive
Test I_3 for inclusion: $I(I_3, T \mid S)$	Eliminate I_3	Test will be correct with probability 1-α (typically 0.95). Very unlikely (probability = 0.0025) that I_3 will pass through second test
Test I_4 for inclusion: $I(I_4, T)$	Eliminate I_4	Test will be correct with probability 1-α (typically 0.95)
Test I_5 for inclusion: $I(I_5, T)$	Eliminate I_5	Test will be correct with probability 1-α (typically 0.95)
Test S for final elimination: no test to be made	Accept S	
Return $\{S\}$ as final output		

Table 10: Trace of semi-interleaved HITON-PC without symmetry correction (i.e., GLL-PC-nonsym subroutine) showing insensitivity to error estimation difficulties that affect wrappers.

to employ statistical significance tests each time it compares estimates of error between pairs of feature sets and corresponding classifiers, because statistical tests of error estimate differences are often underpowered (which is another manifestation of the large variance in error estimates) such tests will often fail to reveal true differences. Thus the wrapper can falsely conclude that two models have same error when in reality they do not. This will entail choosing wrongly the smallest of the two and eliminating valuable features. Also due to multiple comparisons, such an algorithm will falsely conclude for a proportion of feature sets that a difference in predictor model performance is statistically significant thus continuing removal of relevant features when they should not be removed.

We emphasize that this problem is not present in wrapper methods only. In traditional feature ranking methods, the above problem is also present but often ignored in the sense that many studies on feature ranking algorithms produce a performance-to-feature-number plot, with performance estimated on a single data set. However the practical data analysis problem of how to select a specific number of features that achieves at most some desired error is left unspecified and in fact subject to the same error estimation difficulty that applies to wrapping. Moreover, in recent algorithms such as RFE, the problem is acknowledged implicitly in the applied examples provided by the authors of the method, since feature sets are reduced by for example 50% in each iteration of the

algorithm creating a new subset of features examined by cross-validation by the algorithm (Guyon et al., 2002). This is done to reduce overfitting of selected feature set to the data because of the large variability of error estimates. As evidenced by the evaluations presented in Aliferis et al. (2010), it is possible to improve on traditional wrapping, ranking and RFE selection by applying statistical tests of difference of error estimates, or by increasing/decreasing the granularity of feature selection (i.e., proportion of features removed at each iteration). Still the produced feature sets are not optimal in parsimony. The numbers of strongly relevant, weakly relevant and irrelevant features is not critical to the existence of the problem, neither is the type of wrapper (forward, backward, forward-backward, GA, etc.) as long as some basic requirements are met: error estimation is not perfect but subject to sampling variability due to small sample, and enough features exist in data for enough error estimate comparisons to be spurious.

Contrary to the above, GLL filtering relies little on error estimation[3] and uses robust mechanisms to control false negatives and false positives separately for strongly relevant, weakly relevant and irrelevant features respectively. In Table 10 we give a concrete demonstration of how semi-interleaved HITON-PC (without symmetry correction for simplicity) is less prone to errors in the same example. The critical observation is for an irrelevant feature to enter $TPC(T)$ and stay in it, it has to survive multiple (i.e., $2^{|TPC(T)|}$) tests of conditional independence and each such test has probability $1-\alpha$ to leave the irrelevant feature in $TPC(T)$. The total probability of failing to reject the irrelevant variable thus grows up to exponentially small to the number of tests performed and is independent of the sample size. In our simplified example with just one strongly irrelevant feature inside $TPC(T)$, each irrelevant feature has probability of entering and staying in $TPC(T)$ of at most $\alpha^2 = 0.0025$. This is true regardless of whether sample size is 10,000 samples or just 10 samples.

5. Algorithmic Extensions to GLL

In the present section we introduce algorithmic extensions to the Generalized Local Learning algorithms: parallel and distributed local learning and FDR pre-filtering.

5.1 Parallel and Distributed Local Learning

Following ideas for parallelizing the IAMB algorithm for $MB(T)$ estimation (Aliferis et al., 2002), we introduce a coarse-grain parallelization of GLL-PC that addresses two problems: (a) the data does not fit into fast memory (RAM), and (b) even if the data fits, we wish to speedup execution time by parallel processing. We allow for the possibility that the user may have access to just one node or, alternatively, may have access to several nodes arranged in a parallel cluster. The algorithm presented can return $PC(T)$ and can run with any instantiation of GLL-PC. The algorithm is designed to be correct provided that no symmetry correction is required (i.e., in distributions where $EPC(T) \equiv PC(T)$). Correct parallel/distributed versions in distributions where symmetry correction is needed can also be obtained as can algorithms that parallelize $MB(T)$ induction. In the present paper we only discuss parallel GLL-PC without symmetry correction because of its concep-

3. Notice that some reliance on error estimation exists in domains where a suitable *max-k* and α are not known and need be optimized by cross-validation. The corresponding number of parameterizations is very small however (typically at the order of 10 combined parameter configurations) and thus error estimation is less likely to lead the algorithm astray. The same is true for the optional wrapping step in GLL-MB which selects features from a highly reduced set compared to the original feature set (notice that this wrapping step is seldom needed in practice and is reserved for higher sample settings).

Chunked Parallel GLL-PC Algorithm (not symmetry corrected)

Input: Dataset D, target variable T, desired number of data chunks ch.

1. Split the data D into ch arrays C_i of equal size, such that each array contains a non-overlapping subset of the variables plus T.
2. For all i, compute $ChunkPC_i(T) \leftarrow$ GLL-PC-nonsym(T, C_i)
3. $\boldsymbol{L} \leftarrow$ GLL-PC-nonsym(T, $\cup_i ChunkPC_i(T)$)
4. Return $\boldsymbol{L}$ and exit

Figure 4: Chunked Parallel GLL-PC algorithm (not symmetry corrected).

tual and implementation simplicity and speed, because it can be used for both causal discovery and prediction, and because as demonstrated empirically (Aliferis et al., 2010), many real distributions behave consistently with being "symmetrical" (i.e., $EPC(T) \equiv PC(T)$).

Chunked Parallel GLL-PC algorithm (not symmetry corrected): This algorithm assumes that one has access to several nodes and that the data can fit to the available memory once distributed, while it may or may not fit to a single node. Initially the algorithm divides the input data D into ch chunks C_i such that every C_i includes all cases, but only a subset $\boldsymbol{V}_i$ of the variable set $\boldsymbol{V}$ plus T. For simplicity we assume that each chunk has an equal number of features (that can be determined, for example, by the maximum size that can be processed in fast memory or the number of available computer nodes in a parallel implementation). Variations where unequal variable allocations are employed can be easily obtained in similar fashion. Then GLL-PC-nonsym is run on each chunk (as indicated by the extra input argument C_i) returning $ChunkPC_i(T)$ (i.e., parents and children of T in chunk C_i). Next, GLL-PC-nonsym is run on one node with the union $\cup_i ChunkPC_i(T)$, it obtains a local neighborhood $\boldsymbol{L}$, and terminates by outputting $\boldsymbol{L}$. Figure 4 gives the parallel GLL-PC high-level pseudo-code. Step #2 is the parallel step.

We note that a potential problem with chunked GLL-PC is that the tentative neighborhood in some chunk(s) may grow very large (up to the size of the chunk in the worst case) while the true neighborhood across all variables may be very small. This creates the possibility of overflow both in the sense of data not fitting in a single node and in the sense of not having enough sample size to perform reliable statistical inferences.

Theorem 1 *Chunked parallel GLL-PC without symmetry correction is sound given the sufficient conditions for soundness of GLL-PC and the requirement that in the generating distribution P, $PC(T)$ is the same as the Extended $PC(T)$ (see definition of $EPC(T)$ in Aliferis et al. 2010).*

Proof In each chunk, GLL-PC-nonsym will identify all true members of $PC(T)$ that are in the chunk (because these can never be rendered independent of T, according to Theorem 1 in Aliferis et al. 2010) and some false positives which cannot be eliminated without conditioning on $PC(T)$ members that belong to another chunk. Thus in step #3, GLL-PC-nonsym is executed on a superset of $PC(T)$. By definition, all non-members of $PC(T)$ can be rendered independent of T conditioned on some subset of $PC(T)$ as long as $PC(T) \equiv EPC(T)$. Since $PC(T) \equiv EPC(T)$, the identified $PC(T)$ will be correct. ■

The complexity of Chunked Parallel GLL-PC without symmetry correction is in the worst case exponentially slower than running GLL-PC on all data. This is because the complexity of GLL-PC

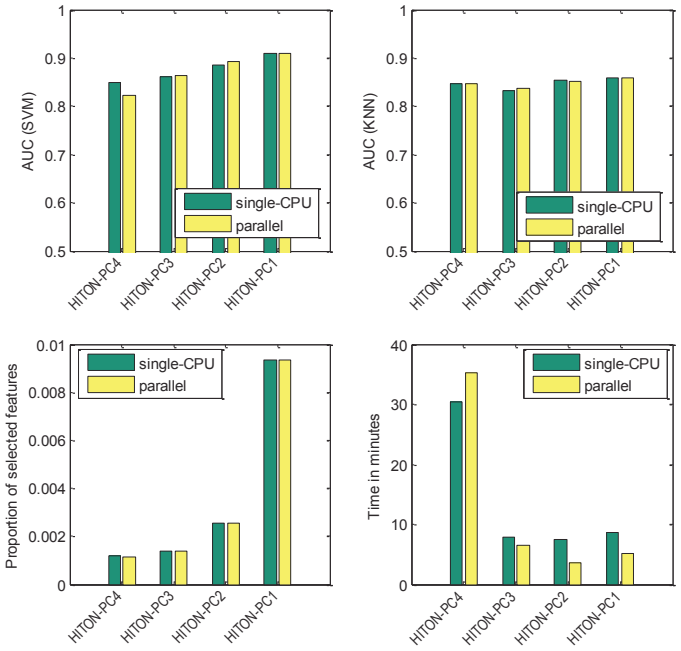

Figure 5: Results of application of single-CPU and parallel versions of semi-interleaved HITON-PC on the four largest real data sets (*Ohsumed, ACPJ_Etiology, Thrombin*, and *Nova*). Average results over 4 data sets are shown. The following versions of HITON-PC are used: HITON-PC4 (*max-k*=4, α=0.05), HITON-PC3 (*max-k*=3, α=0.05), HITON-PC2 (*max-k*=2, α=0.05), HITON-PC1 (*max-k*=1, α=0.05).

is worst-case exponential to the size of $TPC(T)$ and while $TPC(T)$ in all data can be very small, in some chunks $TPC(T)$ can be as large as the chunk itself. When however local neighborhoods in each chunk are smaller than the global $TPC(T)$ and since GLL-PC is worst-case exponential, the algorithm can also be exponentially faster than running GLL-PC on all data. This is in sharp contrast with parallel IAMB where both the speedup is linear to the number of chunks in the best case (upper bound on the speed-up factor is *ch*) and worst-case running time is a small constant multiple of running the algorithm on all data (Aliferis et al., 2002).

Chunked Distributed GLL: When we run the algorithm with data already distributed, the data splitting and transfer step #1 (as well as associated transfer cost) is omitted. Typically we will need to link the distributed data using a suitable common key. For example consider a large organization wishing to analyze data in order to find determinants of production costs overall many and geographically dispersed branches, each with its own local data set and different recorded features. An appropriate key might be time label of observations. Another example is hospital patient data distributed among numerous local databases in different units and labs of the hospital, where patient id is a suitable key.

Chunked GLL with single CPU: This variant assumes access to one CPU only and addresses the problem of data not fitting in the fast memory. By processing parts of the data sequentially and obtaining a small superset of $PC(T)$ each time, a much larger data set than what fits in fast memory can be analyzed.

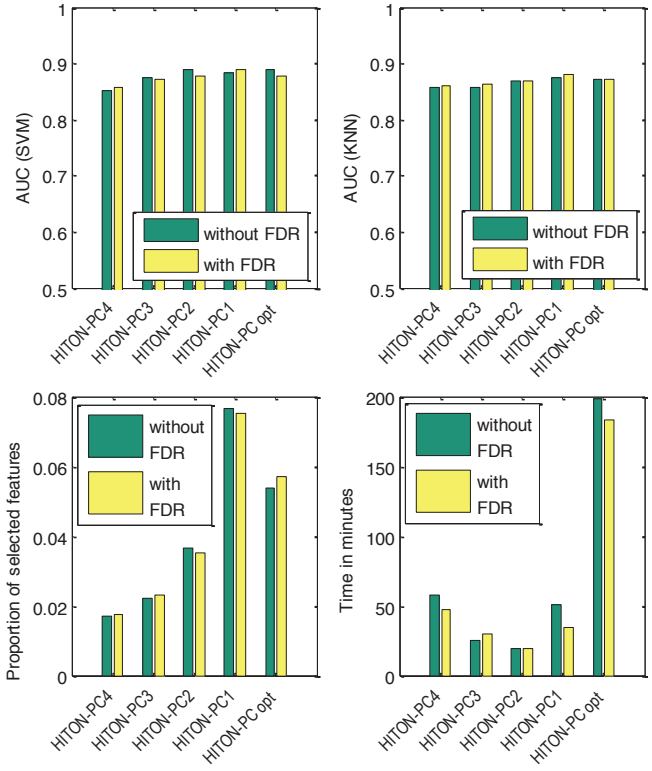

Figure 6: Results of application of semi-interleaved HITON-PC with and without FDR correction on 13 real data sets. Average results over the data sets are shown. The following versions of HITON-PC are used: HITON-PC4 (*max-k*=4, α=0.05), HITON-PC3 (*max-k*=3, α=0.05), HITON-PC2 (*max-k*=2, α=0.05), HITON-PC1 (*max-k*=1, α=0.05), HITON-PC opt (*max-k* and α are optimized over values $\{1,2,3,4\}$ and $\{0.05,0.01\}$, respectively, by cross-validation to maximize SVM classification performance).

We now apply a parallel version of semi-interleaved HITON-PC on the four largest real data sets (*Ohsumed*, *ACPJ_Etiology*, *Thrombin*, and *Nova*) of the empirical evaluation in Aliferis et al. (2010). We use 10 CPU's on the ACCRE cluster described in Aliferis et al. (2010). As can be seen in Figure 5 the parallel version achieves the same parsimony and classification performance as the single-CPU application with speedup for three out of four versions of HITON-PC (see Figure 5). P-values from the permutation test of the null hypothesis that single-CPU and parallel GLL-PC algorithms achieve the same performance are 0.7468 (for SVM classification), 0.4950 (for KNN classification), 0.2408 (for proportion of selected features), and 0.6374 (for running time in minutes). We note that running times for HITON-PC algorithm in this subsection are less than in the remainder of the paper because these experiments were executed on the most recent version of the ACCRE cluster.

5.2 FDR pre-Filtering

As explained in Section 3, in simulated and resimulated data sets with weak-signal/small sample and in all-irrelevant features situations, removing features using false discovery rate control can

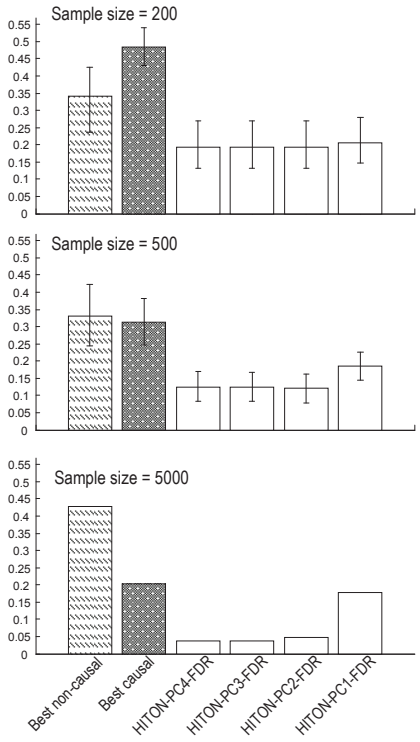

Figure 7: Graph distances averaged over all 9 simulated and resimulated data sets, all selected targets in each data set, and multiple samples of a given size. The following versions of semi-interleaved HITON-PC with FDR correction are used: HITON-PC4-FDR (*max-k*=4, α=0.05), HITON-PC3-FDR (*max-k*=3, α=0.05), HITON-PC2-FDR (*max-k*=2, α=0.05), and HITON-PC1-FDR (*max-k*=1, α=0.05). "Best causal" is the best causal feature selection algorithm among techniques that do not incorporate FDR. "Best non-causal" is the best non-causal feature selection algorithm. See Aliferis et al. (2010) for a detailed list of algorithms.

improve the number of false positives in HITON-PC and MMPC. We applied HITON-PC with FDR pre-filtering in all real data sets of Aliferis et al. (2010). As can be seen in Figure 6, this enhancement does not entail improvements in parsimony, classification performance or running time in the data sets tested. P-values from the permutation test of the null hypothesis that GLL-PC algorithms with and without FDR correction achieve the same performance are 0.5254 (for SVM classification), 0.3698 (for KNN classification), 0.9426 (for proportion of selected features), and 0.3776 (for running time in minutes). Since however the algorithm exhibits small sensitivity to false positives due to multiple comparisons when many irrelevant features are expected and few relevant features are present, we recommend pre-filtering with FDR. Alternatively, if one gets a few variables combined with error estimates consistent with uninformative classifier, then re-running standard GLL with FDR pre-processing can be tried.

When evaluating local causal discovery performance in the simulated data of Aliferis et al. (2010), semi-interleaved HITON-PC with FDR pre-processing achieves dramatically better performance than other algorithms including other HITON and MMPC variants with respect to graph

LGL: Local-to-Global Learning

1. Find *PC(X)* for every variable *X* in the data using an admissible instantiation of GLL-PC and prioritizing which variables to induce *PC(X)* for, according to a prioritization strategy.
2. Piece together the undirected skeleton from the local GLL-PC results.
3. Use any desired arc orientation scheme to orient edges.

Figure 8: Local-to-Global Learning (LGL) algorithmic schema.

MMHC Global Learning Algorithm

1. Find *PC(X)* for every variable *X* in data using MMPC (without symmetry correction) and lexicographic prioritization.
2. Piece together the undirected skeleton using an "OR rule" (an edge exists between *A* and *B* iff *A* is in *PC*(*B*) or *B* is in *PC*(*A*)).
3. Use greedy steepest-ascent TABU search and BDeu score to orient edges.

Figure 9: MMHC global learning algorithm as an instance of LGL.

HHC Global Learning Algorithm

1. Find *PC*(*X*) for every variable *X* in data using semi-interleaved HITON-PC (without symmetry correction) and lexicographic prioritization.
2. Piece together the undirected skeleton using an "OR rule" (an edge exists between *A* and *B* iff *A* is in *PC*(*B*) or *B* is in *PC*(*A*)).
3. Use greedy steepest-ascent TABU search and BDeu score to orient edges.

Figure 10: HHC global learning algorithm as an instance of LGL.

distance score, which indicates average causal proximity to the target of the returned variables. Specifically, in large sample (N=5,000) HITON-PC with FDR correction achieves up to 5-fold reduction in the graph distance score relative to the best non-FDR filtered causal algorithm and up to 9-fold reduction compared to the best non-causal algorithm. In small sample (N=200) the reduction in both cases is 2-fold. P-values from the permutation test of the null hypothesis that the best non-causal algorithm performs the same as the average HITON-PC with FDR correction are <0.0001 for sample sizes 200, 500, and 5,000. P-values for comparison with the best causal algorithm are <0.0001, 0.0030, and <0.0001 for sample sizes 200, 500, and 5000, respectively. See Figure 7. This improvement incurs only a very small decrease in sensitivity as evidenced by small concurrent increases in false negatives.

6. Spanning Local to Global Learning

In the present section we investigate the use of local learning methods (such as GLL) for global learning in a divide-and-conquer fashion. We remind that a major motivation for pursuing local causal learning methods is scaling up causal discovery and causal feature selection as explained in Aliferis et al. (2010). Although similar concepts can be used for region learning, we will not address this type of discovery problem here. The main points of the present section are that (a) the local-to-global framework can be instantiated in several ways with excellent empirical results; (b) an important previously unnoticed factor is the variable order in which to execute local learning, and (c) trying to use non-causal feature selection in order to facilitate global learning (instead of causal local learning) is not as a promising strategy as previously thought.

6.1 General Concepts

A precursor to the main idea behind the local-to-global learning approach can be found in SCA (Friedman et al., 1999), where a heuristic approximation of the local causes of every variable constraints the space of search of the standard greedy search-and-score Bayesian algorithm for global learning increasing thus computational efficiency. Given powerful methods for finding local neighborhoods, provided by the GLL framework, one can circumvent the need for uniform connectivity (as well as user knowledge of that connectivity) and avoid the application of inefficient heuristics employed in SCA thus improving on quality and speed of execution. Figure 8 provides the general algorithmic schema term LGL (for local-to-global learning). Steps #1-3 can be instantiated in numerous ways. If an admissible GLL-PC (as defined in Section 4 of Aliferis et al. 2010) is used in step #1, and step #2 is consistent with the results of GLL-PC for all variables, and a sound orientation scheme in step #3, then the total algorithm is trivially sound under the assumptions of correctness of GLL-PC. These are the admissibility requirements for the LGL template. It follows that:

Proposition 1 *Under the following sufficient conditions we obtain correctly oriented causal graph with any* admissible *instantiation of LGL:*

a. There is a causal Bayesian network faithful to the data distribution P;

b. The determination of variable independence from the sample data D is correct;

c. Causal sufficiency in $\boldsymbol{V}$.

The recently-introduced algorithm MMHC is an instance of the LGL framework (Tsamardinos et al., 2006). Figure 9 shows how MMHC instantiates LGL. MMHC is not sound with respect to orientation because greedy steepest-ascent search is not a sound search strategy for search-and-score global learning. Despite being theoretically not sound the algorithm works very well in practice and in an extensive empirical evaluation it was shown to outperform in speed and quality several state-of-the-art algorithms (Greedy Search, GES, OR, PC, TPDA, and SCA) (Tsamardinos et al., 2006).

6.2 A New Instantiation of LGL: HHC

To demonstrate the generality and robustness of the LGL framework we provide here as an instantiation of LGL, a new global learning algorithm termed HHC (see Figure 10), and compare it empirically to the state-of-the-art MMHC algorithm. We also show that the two algorithms are not identical in edge quality or computational efficiency, with the new algorithm being at least as good on average as MMHC.

Table 11 presents results for missing/extra edges in undirected skeleton, number of statistical tests for construction of skeleton, structural Hamming distance (SHD), Bayesian score, and execution time on 9 of the largest data sets used for the evaluation of MMHC. Since the data sets were simulated from known networks, the algorithm output can be compared to the true structure. As can be seen, in all 9 data sets, HHC performs equally well with MMHC in terms of SHD and Bayesian score. In 8 out of 9 data sets it performs from 10% to 50% fewer tests, and in one data set (*Link*) it performs $>$10 times the tests performed by MMHC resulting in running 35% slower in terms of execution time. Because MMHC was found to be superior to a number of other algorithms for the

Table 11: Comparison of HHC and MMHC global learning algorithms. Both algorithms were executed on a random sample of size 1000, using default parameters of MMHC as implemented in *Causal Explorer* (i.e., G^2 test for conditional independence, $\alpha = 0.05$, *max-k* = 10, Dirichlet weight = 10, BDeu priors).

data sets tested, HHC's better performance over MMHC in 8 out of 9 data sets (in terms of number of statistical tests for skeleton construction) and similar performance in 9 out of 9 data sets (in terms

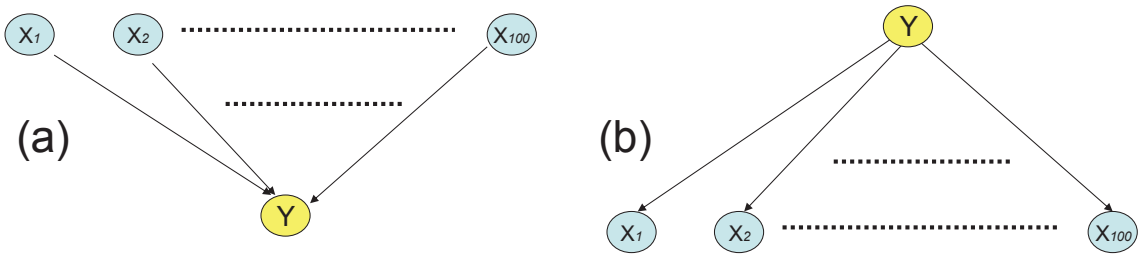

Figure 11: Two examples where the variable ordering for local learning can make execution of the LGL algorithm from quadratic to exponential-time.

of quality metrics) translates also to excellent performance of HHC relative to Greedy Search, GES, OR, PC, TPDA, and SCA (Tsamardinos et al., 2006).

6.3 Importance of Variable Prioritization for Quality and Efficiency

An important parameter of local-to-global learning previously unnoticed in algorithms such as SCA and MMHC is the ordering of variables when executing the local causal discovery variable-by-variable (i.e., not in parallel). We will assume that results are shared among local learning runs of GLL-PC, that is when we start learning $PC(X)$ by GLL-PC rather than starting with an empty $TPC(X)$ set, we start with all variables Y: $X \in PC(Y)$. This constitutes a sound instantiation of the GLL-PC algorithm template as explained in Aliferis et al. (2010). Figure 11 gives two extreme examples where the right order can "make-or-break" an LGL algorithm.

In Figure 11(a) it is straightforward (and left to the reader to verify) that an order of local learning $< X_1, X_2, \ldots, X_{100}, Y >$ without symmetry correction (the latter being a reasonable choice as we have seen) requires a quadratic number of conditional independence tests (CITs) for the unoriented graph to be correctly learned. However, the order of local learning $< Y, X_1, X_2, \ldots, X_{100} >$ requires up to an exponential number of CITs as *max-k* and sample are allowed to grow without bounds. Even with modest *max-k* values, the number of CITs is higher-order polynomial and thus intractable. Even when Y is not in the beginning but as long as a non-trivial number of X's are after it in the ordering, the algorithm will be intractable or at least very slow. The latter setting occurs in the majority of runs of the algorithm with random orderings.

In Table 12 we provide data from a simulation experiment showing the above in concrete terms and exploring the effects of limited sample and connectivity at the same time. As can be seen, under fixed sample, running HHC with order from larger to smaller connectivity, as long as the sample is enough for the number of parents to be learned (i.e., number of parents is ≤ 20), increases run time by more than 100-fold. However because sample is fixed, as the number of parents grows the number of conditional independence tests equalizes between the two strategies because CITs that have too large conditioning sets for the fixed sample size are not executed. Although the number of CITs is self-limiting under these conditions, quality (in terms of number of missing edges, that is, number of undiscovered parents of T) drops very fast as the number of parents increases. The random ordering strategy trades off quality for execution time with the wrong (larger-to-smaller connectivity) ordering, however in all instances the right ordering offers better quality and 2 to 100-fold faster execution that random ordering.

Number of parents of Y	order from low-to-high connectivity			random order (average results over 10 orders)			order from high-to-low connectivity		
	extra edges	missing edges	CITs	extra edges	missing edges	CITs	extra edges	missing edges	CITs

Table 12: Results of simulation experiment with HHC algorithm. The graphical structure is depicted on Figure 11(a). HHC was run on a random sample of size 1,000 with G^2 test for conditional independence, α=0.05, *max-k* = 5, Dirichlet weight = 10, BDeu priors.

A more dramatic difference exists for the structure in Figure 11(b) where Y is a parent of all X's. Here the number of tests required to find the parent (Y) of each X_i is quadratic to the number of variables with the right ordering (low-to-high connectivity) whereas an exponential number is needed with the wrong ordering (large-to-small connectivity). Because the sample requirements are constant to the number of children of Y, quality is affected very little and there is no self-restricting effect of the number of CITs, opposite to what holds for causal structure in Figure 11(a). Hence the number of CITs grows exponentially larger for the large-to-small connectivity ordering versus the opposite ordering and a similar trend is also present for the average random ordering in full concordance with our theoretical expectations. See Table 13 for results of related simulation experiments.

These results show that in some cases, *it is possible to transform an intractable local learning problem into a tractable one by employing a global learning strategy (i.e., by exploiting asymmetries in connectivity)*. Thus the variable order in local-to-global learning may have promise for substantial speedup and improved quality in real-life data sets (assuming the order of connectivity is known or can be estimated). However the optimal order is a priori unknown for some domain. Can we use local variable connectivity as a proxy to optimal order in real data? The next experiment assumes the existence of an oracle that gives the true local connectivity for each variable. The experiment examines empirically the effect of three orders (low-to-high connectivity, lexicographical (random) order, and high-to-low connectivity order) on the quality of learning and number of CITs in the MMHC evaluation data sets. It also compares the sensitivity of HHC to order.

As can be seen in Figure 12, the order does have an effect on computational efficiency however not nearly as dramatic in the majority of these more realistic data sets compared to the simpler structures of Figure 11. An exception is the *Link* data set in which low-to-high connectivity allows HHC to run 17 times faster than lexicographical (random) order and 27 times faster than high-to-low connectivity order. For the majority of cases, running these algorithms with lexicographical (i.e.,

Number of children of Y	order from low-to-high connectivity			random order (average results over 10 orders)			order from high-to-low connectivity

random) order is very robust and does not affect quality adversely but affects run time and number of CITs to a small degree (details in Table S21 in the online supplement).

Thus, while connectivity affects which variable order is optimal in LGL algorithms, ranking by local connectivity does not exactly correspond to the optimal order. Figure S3 in the online supplement shows the number of CITs plotted against true local connectivity in each one of the 9 data sets used in this section. Related to the above, Figure S4 in the supplement also shows the distribution of true local connectivity in each data set. Consistent trends indicating the shape of the distributions by which the degree of local connectivity may determine an advantage of orderings low-to-high to high-to-low connectivity are not apparent in these data sets.

We hypothesize that more robust criteria for the effect of variable ordering in LGL algorithms can be devised. For example, the number or total cost of CITs required to locally learn the neighborhood of each variable. Such criteria are also more likely to be available or to be approximated well during practical execution of an algorithm than true connectivity. A variant of HHC, algorithm HHC-OO (standing for HHC with optimal order) (Aliferis and Statnikov, 2008) orders variables dynamically according to heuristic approximations to the total number of CITs for each variable. We also conjecture that the strategy for piecing together the local learning results strongly interacts with the local variable ordering to determine the tradeoff between the quality and efficiency of LGL algorithms. Evaluation of these hypotheses is outside the scope of the present paper.

6.4 Using non-Causal Feature Selection for Global Learning

In recent years several researchers have proposed that because modern feature selection methods can deal with large dimensionality/small sample data sets, they could also be used to speed up or approximate large scale causal discovery (e.g., Kohane et al. 2003 use univariate feature selection to build so-called "relevance networks"), or hybrid methods can be employed that use feature selection

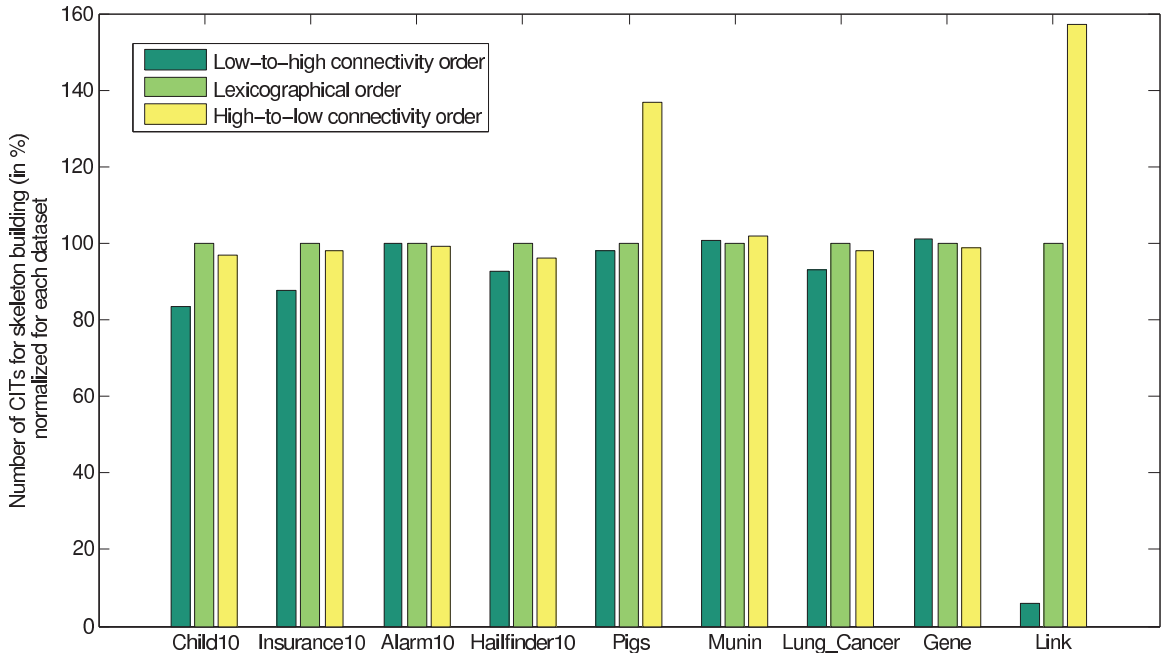

Figure 12: Number of CITs required for skeleton construction during execution of HHC expressed as % points and normalized within each data set to lexicographical order. Data for three orderings of variables is shown on the figure: low-to-high connectivity, lexicographical, and high-to-low connectivity orders. HHC was executed with same parameters as in Table 11. More detailed results are provided in Table 11 and Table S21 in the online supplement.

as a pre-processing to build a skeleton and then an orientation algorithm like Greedy Search in the spirit of MMHC and LGL (Schmidt et al., 2007). The results of Aliferis et al. (2010) contradict this postulate because they show that non-causal feature selection does not give locally correct results. However it is still conceivable that orientation-and-repair post-processing algorithms (e.g., with Bayesian search-and-score) can still provide a high quality final causal graph. We test this hypothesis by examining several such hybrid methods using respectively RFE, LARS-EN and UAF post-processed by Greedy TABU Bayesian search-and-score. We use simulated data sets from 5 out of 9 Bayesian networks employed earlier in the present section. This is because the other 4 networks cannot be used for reliable training and testing of the underlying classifier since they have several variables with very unbalanced distributions. As shown in Table 14, the hypothesis is not corroborated by the experimental results. In particular, Greedy Search with feature selection-based skeleton, exhibits substantial drops in quality of the returned networks (measured by structural hamming distance Tsamardinos et al., 2006) and typically more than one order of magnitude longer running times compared to HHC with lexicographical (random) variable ordering. On the basis of these findings, which are consistent with the results in Aliferis et al. (2010), we do not find encouraging evidence that non-causal feature selection can be used as an adjunct to global causal discovery. Strong evidence exists however in favor of using principled local causal methods instead, within the frameworks of LGL.

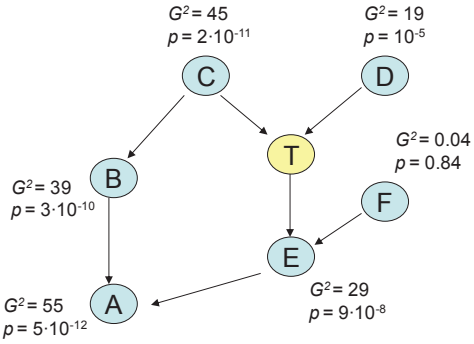
7. Using Causal Graphs and Markov Blanket Theory as a Conceptual Analysis Framework for Feature Selection Methods

In the present section we show that by adopting a causal structural perspective founded on the theoretical results outlined in Aliferis et al. (2010), several strengths and weaknesses and general performance characteristics of non-causal feature selection algorithms become apparent and our empirical findings in Aliferis et al. (2010) can be better understood. We review several established and state-of-the-art methods both from a feature selection perspective (e.g., does the algorithm exhibit false positives and false negatives relative to minimal feature set that yields optimal predictivity?) and from a causal discovery perspective (is the output of the algorithm causally sound?). With respect to the latter for reasons elucidated in Aliferis et al. (2010), we focus on localization of causal inferences (i.e., whether the feature selection output is locally causally correct), and when this is not obtained, we examine whether some other useful causal inference can be made.



Select first *k* features:

Selected		FN	FP	Predictivity
A	(k=1)	C,D,E,F	A	Suboptimal
A,C	(k=2)	D,E,F	A	Suboptimal
A,B,C	(k=3)	D,E,F	A,B	Suboptimal
A,B,C,E	(k=4)	D,F	A,B	Suboptimal
A,B,C,D,E	(k=5)	F	A,B	Suboptimal

Figure 13: Limitations of univariate feature selection explained using a causal graph perspective. Strength of univariate association with the target variable T is measured in a fixed sample of size 10,000 by the negative p-value of a G^2-test and depicted next to each variable.

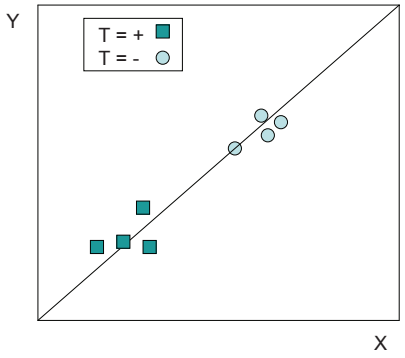


Figure 14: Example showing that Principal Component Analysis yields redundant features.

7.1 Univariate Association Filtering

Figure 13 shows the causal structure of a data-generating process. The causal structure is parameterized as shown in Appendix Figure 19. This structure and parameterization entails that $association(B,T) < association(C,T)$. Because of *synthesis of information along two paths* however, $association(A,T) > association(C,T)$ and $association(A,T) > association(E,T)$. The example illustrates that from the feature selection perspective the optimal predictor set (i.e., the Markov blanket) for predicting or classifying the target T is $\{C,D,E,F\}$. However, because univariate associations of non-$MB(T)$ members can be higher than those of members, false positives are incurred when selecting features using univariate association-based filters. Furthermore, spouses without connecting path to the target will have zero univariate association and thus will not be selected at all by univariate filtering. The embedded table shows the false positives and false negatives (relative to the gold standard set $MB(T)$) at each possible threshold for variable inclusion. In all cases predictivity is suboptimal.

From the causal discovery perspective, the example makes evident that non-causally relevant features such as A and B can be selected with higher ranking than causally relevant ones such as D and E. Association synthesis thus forbids an interpretation of the higher-ranked causal variables as more direct causes (or effects) than lower-ranked features even when all of them are causal. Worse yet, even without synthesis, an arbitrarily large number of non-causal features can be selected before

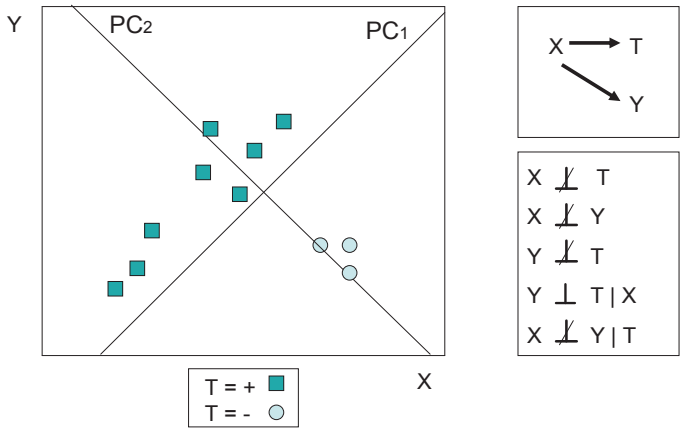

Figure 15: Example showing that Principal Component Analysis yields locally causally inconsistent results.

truly causal ones are selected. To see why this is the case consider that between C and B there may be arbitrarily many variables arranged in a chain so that their association with T is larger than that of both true cause D and true effect E.

7.2 Principal Component Analysis

As can be seen in Figure 14, the principal component defined by the diagonal ($Y - X = 0$) perfectly separates the two target classes and will be chosen by a PCA procedure since it explains maximum proportion of variance in the data. While projecting the original data on this single dimension reduces dimensionality of the classification problem, from the perspective of finding the original features that are important and non-redundant the method leads to false positives (since the coefficients of both Y and X are equal in the depicted Principal Component, indicating that both features are deemed equally necessary).

The example in Figure 15 shows that PCA is not sound for causal discovery. As shown in the figure, X is a direct cause of T and Y is not causal for T but confounded by X. Application of causal learning via the usual assumptions and procedures reveals that X is a direct cause or effect of T and that Y is not directly causally linked with T (the requisite conditional independence tests are depicted). However, an optimal procedure for Principal Component classification will select the second principal component PC_2 which achieves perfect classification. However both X and Y have equal coefficients in each principal component. Hence PCA may select both redundant features and non-causal features.

7.3 Feature Selection Using SVM Weights

A fundamental weakness of the maximum-gap inductive bias, as employed in SVMs, is its local causal inconsistency. Consider a scenario (Figure 16) similar to the previous sub-section where we wish to discover the direct causes of a response variable T, from observations about variables X, Y, T. Assume for simplicity that T is a terminal variable and thus X and Y precede it in time. For example, T can be a clinical phenotype and X, Y can be gene expression values. The causal process that generates the data is seen in the upper right corner of Figure 16. As can be seen in the

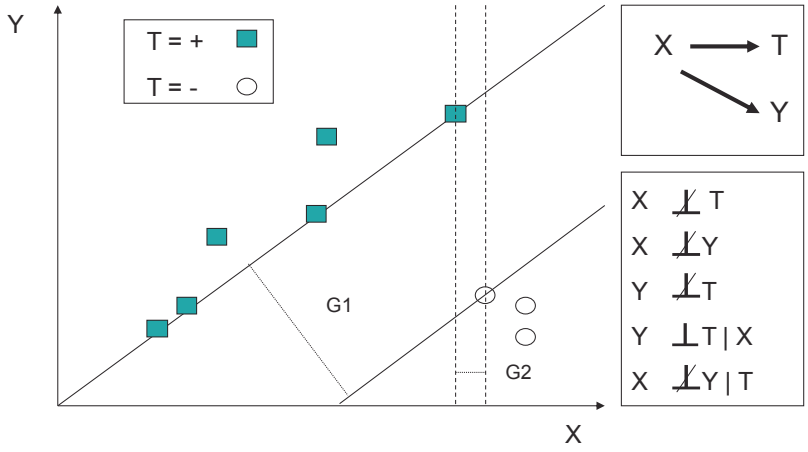

Figure 16: Example showing that SVM weight-based feature selection yields locally causally inconsistent results and redundant features.

left part of the figure, the SVM classifier can perfectly predict T using X and Y as predictors. In doing so it prefers the classifier with gap G1 to the classifier with smaller gap G2. The preferred classifier assigns non-zero (and in fact equal) weights to both X, Y thereby admitting Y in the local causal neighborhood if selected variables are interpreted causally. However, X *renders* Y *independent from* T *and not vice versa*. More generally, in distributions where the Causal Markov Condition holds, SVMs will occasionally fail to detect that Y is not a local cause of T. Sound causal discovery algorithms do not face this problem, however. In addition, the preference for maximum gap classifier biases in favor of assigning non-zero weights to redundant features (Y in the example).

On the positive side, theoretical results show that SVMs in the large sample will assign zero weights to irrelevant variables (Hardin et al., 2004). Despite this theoretical good property, in the experiments of Aliferis et al. (2010) it was found that in realistic finite sample weights of irrelevant variables are non-zero. In the work of Statnikov et al. (2006) it was found that weights of irrelevant features occasionally exceed those of weakly relevant features and furthermore that SVM weights are also susceptible to assigning larger weights to synthesis features rather than direct causes and effects.

7.4 Wrapping

One of the widely-cited advantages of wrapping as a feature selection method is that it allows to tailor the selection of features to the inductive bias of the classifier (Kohavi and John, 1997). We show here how this property when combined with rich connectivity may yield causally misleading results. Consider the generative process of Figure 17. The target T is a quadratic function of its true causes A, B. Variables X, Y are effects of A, B respectively with similar non-linear functional relationships. A causal discovery procedure such as HITON-PC given enough sample and a suitable statistical test of independence will discover $\{A, B\}$ as the correct set of direct causes and direct effects. Consider however a practitioner who attacks the problem of learning a good classifier for T and reducing the necessary feature set using wrapping instead. If, as would normally be the case, the analyst starts with a simpler model class before proceeding to consider more complex

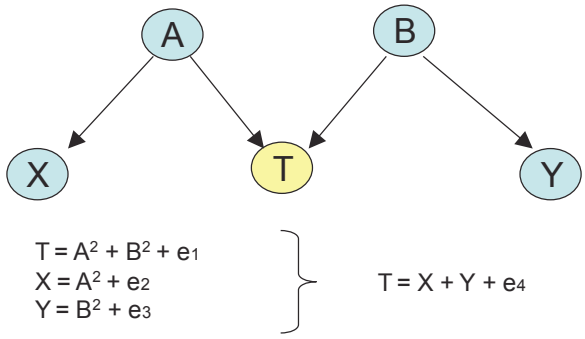

Figure 17: Example showing that wrapping, by tailoring feature selection to the classifier inductive bias may produce causally misleading results.

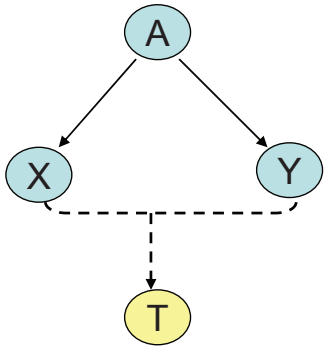

P(T | X, Y)	(X=0, Y=0)	(X=0, Y=1)	(X=1, Y=0)	(X=1, Y=1)
T=0	1	0	0	1
T=1	0	1	1	0

P(X | A)	A=0	A=1
X=0	0.40	0.75
X=1	0.60	0.25

P(A)	
A=0	0.71
A=1	0.29

P(Y | A)	A=0	A=1
Y=0	0.80	0.10
Y=1	0.20	0.90

Figure 18: Example showing that connectivity may mitigate violations of faithfulness. Dashed line indicates a highly non-linear function (XOR). The left part shows the causal structure, while the right part shows its parameterization.

ones, assuming that noise components e2, and e3 are small enough then the linear classifier would perform very well with $\{X, Y\}$ as predictors and a wrapper tailored to the linear inductive bias would eliminate A and B.

In small networks with a few variables and limited connectivity the above possibility is small, however in large networks with thousands of variables and rich connectivity as well as with massive information redundancy (e.g., biological networks) such "variable replacement" is entirely feasible and thus tailoring feature selection to a classifier's inductive bias (as wrapping does) can be an obstacle to sound causal discovery.

7.5 Connectivity and Priors Compensating for Violations of Faithfulness - Learning XOR Parents Using Univariate Association in GLL and Other Algorithms

A violation of faithfulness where constraint-based algorithms are expected to fail is when the target is an extremely non-linear function of its parents. A prototypical example is when T is the parity (XOR) of its parents A and B. Conventional wisdom, based on the truth table of the XOR function, dictates that first-order effects are zero and, as a result, the parents cannot be detected by the inclusion heuristic of the algorithm (i.e., HITON-PC or MMPC). As shown in Figure 18 however,

connectivity among variables can mitigate this difficulty. In the figure, variables X and Y can have non-zero univariate association with T, even though in textbook descriptions of parity where parents are unconnected and with 50% prior probability each for being 0 or 1, univariate association vanishes. An example parameterization that allows for this effect is given in the figure as well. This counter-intuitive phenomenon occurs because when X and Y are common effects of A, knowing the value of X is informative about A and thus about Y. Therefore the joint values of $\{X,Y\}$ are constrained and this creates univariate association of X and Y with T. Similarly, conditional association of X with T given Y is non zero. The phenomenon is not restricted to parity (or other extremely non-linear) functions in which the parity parents are connected in the network. Figure 20 in the Appendix shows an example where skewed priors on the unconnected parity parents X, Y lead to non-zero univariate association of X and Y with the target T.

The phenomenon described in this sub-section does not only apply to GLL algorithms but extends to other feature selectors as well. For example, the success of univariate filtering as feature selector, which has been documented in many domains (Guyon et al., 2006), can in part be explained via connectivity effects that allow univariate association to detect complex non-linear relationships of selected features with the target variable.

The discussion in this section is complemented by analysis of embedded feature selection in decision tree induction and of RELIEF in the online supplement Figures S5 and S6 (omitted here due to space limitations). It is shown that these algorithms can admit false positives and false negatives both predictively and causally with respect to the target variable neighborhood.

8. Discussion and Open Problems

In this section we present a thorough discussion of results, outline open problems and future directions, and provide a conclusion.

8.1 Discussion of Results

The algorithms presented, and their applied evaluation and theoretical analysis clarify many of the initially open questions discussed in Aliferis et al. (2010) and point to several new research directions. We showed that in empirical tests with 9 simulated data sets, GLL convergence to optimal performance is very fast with respect to sample size both in the sense of producing feature sets that have equal predictivity as the true $MB(T)$ and $PC(T)$ sets, and in the sense of achieving near optimal predictivity even at moderate samples sizes. These results corroborate the empirically good performance of GLL instantiations in real data sets (Aliferis et al., 2010).

An unexpected and important finding was that *GLL algorithms exhibit strong intrinsic control of false positives due not only to weakly relevant but also due to irrelevant features*. This control is empirically better in the tested data sets than what formal state-of-the-art FDR control provides except in the rare case when the data consists exclusively of irrelevant features. In Statnikov et al. (2010) we show that GLL can discover differentially expressed genes when the sample size is so small that FDR does not yield any gene. The same cannot be said for other feature selection methods that were found to be particularly prone to false positives due to both irrelevant and weakly relevant features. On the other hand, it needs to be noted that classical FDR methods do not control at all weakly relevant false positives (as GLL does). A simple pre-filtering of GLL algorithms with an FDR control method eliminates false positives in all cases tested and yields the best algorithm for

local causal learning among tested algorithms. We expect that other algorithms for example PC and MMHC will benefit from such an FDR prefiltering as well.

Within the GLL framework both the *max-k* and *h-ps* parameters control the false positives and false negatives tradeoff, through control of combined power and combined significance levels. We examined via targeted experiments and theoretical discussion the complex determination of quality of statistical decisions in GLL algorithms (aspects of which are shared by previous global constraint-based algorithms). Having two parameters to control quality of statistical decisions confers advantages since they can regulate different aspects of such decisions, and trade-off statistical quality with computational complexity.

Our efforts to explain the good predictive performance of the estimated $PC(T)$ set compared to the estimated $MB(T)$ set focused on producing explanations consistent with sufficient assumptions for Markov blanket optimality so that the good performance of the $PC(T)$ set would not be wrongly construed as entailing rejection of the theoretical assumptions, or as inability to infer the correct $MB(T)$ when the assumptions hold in the data. This is because both the results of our simulated experiments in Aliferis et al. (2010) as well as previously published experiments (Tsamardinos et al., 2003b) show that GLL algorithms estimate very well the $MB(T)$ and $PC(T)$ sets.

We also used a causal graph point of view and Markov blanket concepts to understand a variety of non-causal feature selection algorithms. This approach *provides a cohesive and fresh perspective into the behavior of several algorithms for feature selection*. We made this point by showing that the theory readily reveals why prominent feature selection methods exhibit many false positives and why they cannot be used for sound causal discovery. This complements the findings of Aliferis et al. (2010) that demonstrate empirical feature selection and causal discovery suboptimality for many state-of-the-art non-causal feature selection methods.

We discussed in detail a fundamental statistical weakness of wrapping, namely that it is prone to errors due to imperfect error estimation. This is especially the case when sample size is small whereby practical unbiased error estimators have large variance. The same problem applies implicitly to widely-used feature selection approaches such as ranking by univariate association and selecting the first k features. We showed why GLL algorithms are less sensitive to this shortcoming. In general our results show that GLL instantiations are robust enough to apply across a wide variety of domains.

Established feature selection criteria in statistics such as the AIC (Akaike Information Criterion) bare some resemblance to Markov blanket feature selection in the sense that AIC does not require classification error estimation. Specifically, AIC balances the number of features (parameters) with the likelihood of the data given a model: $\text{AIC} = 2k - 2log(L)$, where k is the number of parameters and L is the likelihood function. Model selection is driven by optimizing AIC. A critical difference however is that Markov blanket induction does not require a generative model of the data to be calculated (but relies on conditional independence tests). Given that inducing a generative model is in general harder than finding features that cannot be rendered independent of the target, and given that many recent powerful classifiers do not build generative models (e.g., SVMs) it follows that the Markov blanket induction approach has a corresponding advantage over AIC. Markov blanket induction is less model-dependent than AIC for the same reason. Note that similarly the GLL algorithms by not attempting to induce edge directionality (a task harder than edge detection, Ramsey et al., 2006) except when absolutely necessary they avoid incurring errors in edge detection produced by false conclusions about directionality (since one type of discovery affects the other). As

a result, Markov blanket induction via the GLL framework has advantages over eliciting Markov blankets by using methods that require global or local orientation.

The extensive evaluation of GLL algorithms in Aliferis et al. (2010) shows that the sufficient conditions stated in the proofs for correctness are likely to hold often, or that violations may be small. In some cases we showed that the algorithms may not fail when the assumptions are violated. Due to the critical role of non-faithfulness as a major source of possible failure we discuss it here in more detail. Faithfulness is violated in a variety of situations (Spirtes et al., 2000), notably in practice when (a) extremely non-linear or deterministic functions exist, when (b) causality cannot be localized, and when (c) variables share the same information for a response (target variable). Practical examples, respectively, are extreme epistasis in genetics, non-local causation in quantum mechanics, and gene-phenotype information redundancy in gene expression microarrays. For many additional reasons see Spirtes et al. (2000) and Meek (1995).

However, we showed that even in prototypical non-faithful functions such as XOR, the existence of unbalanced priors or the existence of connectivity among XOR parent variables of the target can make such parent variables visible again to the GLL algorithms as well as other feature selectors (e.g., univariate association filtering). We believe that this finding may have broad implications of which we mention a few. First, it explains in part the success of univariate feature selection methods in many domains since univariate filtering can pick up features that are involved in extremely non-linear functions. Second, other algorithms that are typically thought to not be able to learn such functions, such as Genetic Algorithms (Sharpe, 2000) in many situations may be able to do just that. In addition, to the extent that biological systems have evolved by evolutionary processes similar to genetic algorithms, truly extreme epistatic functions may not be as rare as previously thought. Recent proposals that suggest that such functions (i.e., biological systems) can be learned (i.e., evolved) by GAs (i.e., by evolution) through multiple objective optimization may be too pessimistic (Lenski et al., 2003). Third, previous postulates that randomized experiments (e.g., in biology, medicine and psychology) because they examine one causal factor at a time are thus unable to detect parity-like functions, may also be pessimistic (Aliferis and Cooper, 1998).

Returning to non-local causality, we point out that cognitively it is advantageous to modularize causal knowledge in order to reduce the connectivity of causal graphs and thus to control learning complexity (as well as to increase ability to store and process such knowledge with limited cognitive resources). We may thus be facing in both natural as well as artificial systems a selection bias (relative to all possible theoretical distributions) where causal systems and models of those are highly modular because it is easier to create and handle such systems and their models. Indeed in most known macroscopic causal processes (e.g., biological pathways, medicine, engineering, economics, social networks) causal systems are highly modular and thus local.

For all of the above reasons faithfulness is a very reasonable a priori, and powerful in practice, distributional assumption. At the same time at least some violations can be tolerated well by causal algorithms that are designed to use it and existing research addresses violations systematically, for example extensions of standard causal discovery algorithms capable of addressing target information equivalency (Statnikov, 2008).

The exploration of parallel and distributed techniques in the present paper showed that *GLL is amenable to parallelized and distributed local causal discovery and feature selection*. We established empirically the potential of parallelization for speeding up processing time without loss of quality. The presented parallel algorithm can also be used for distributed feature selection and causal discovery in a principled manner. Many more algorithms (namely that induce Markov blankets and

admit symmetry correction when needed) can be constructed following the approach introduced in parallel and distributed IAMB for Markov blanket induction (Aliferis et al., 2002). In contrast to parallel IAMB however, parallel GLL-PC can be exponentially faster (or slower) than induction in the full data. This is a very interesting future research direction.

In exploring the transition from local-to-global strategies we showed that the local-to-global learning framework LGL can be instantiated in several ways. We examined one new instantiation of local-to-global learning, algorithm HHC. Although in most real data tested a random variable order is as good as perfectly-informed ordering by local connectivity, we showed in the present paper something previously unnoticed, namely that in some cases the right order of local neighborhood learning can entail exponential time vs. low-order polynomial time execution of local-to-global algorithms. This finding has a subtle implication: if the right ordering can be found for local learning, the resulting global learning of all variables can be faster than the local learning targeted at just one variable. Thus, just as local learning can speed up global learning the reverse may also be true.

On the other hand, our results showed that the idea that non-causal feature selection methods could help in addressing scalability of formal causal algorithms may be misplaced in light of the failure of non-causal feature selection methods to induce causality and given that highly scalable and sound methods such as GLL algorithms do exist. Several tested algorithms where non-causal feature selection is used to elicit a skeleton which is then oriented and refined by formal causal global methods are very slow and typically produce lower-quality graphs than LGL instantiations relying on sound local causal methods.

8.2 Open Problems and Future Directions

The results presented in Aliferis et al. (2010) and in the present paper merely scratch the surface of causal feature selection algorithms, local causal learning, and local-to-global learning. We briefly discuss here a few salient opportunities for moving this exciting area forward.

An assumption that is probably too strong for soundness of $MB(T)$ induction is that of causal sufficiency. For example, we conjecture without formal proof, that the algorithms should attain soundness even if the causal sufficiency is localized among the target and the members of its Markov blanket. Even when this local causal sufficiency is violated, predictive optimality among measured variables may not be compromised in many practical situations (although the usual causal interpretation of the found features is affected). Characterizing localized versions of faithfulness and causal sufficiency is an area that is likely to give a better understanding of existing algorithms and possibly lead to improvements. Examining and dealing with the effects of temporal aggregation, sampling (e.g., cellular) aggregation, feedback loops, and limited local causality on feasibility of local causal discovery will be helpful in determining the space of practical usefulness of the GLL framework.

A previously underemphasized important parameter for false negatives control is the order of conditional independence tests used for elimination (i.e., part of the elimination strategy in the GLL-PC schema). In general, the earlier time that strongly relevant variables are being examined for elimination, the better the chances for avoiding a false negative conditional independence test result since the combined power is larger. This is accomplished implicitly in HITON-PC and MMHC by using heuristics that include strongly relevant features first in $TPC(T)$ and then in both semi-interleaved HITON-PC and MMHC, where new candidates are considered for elimination *first* and where conditioning sets are constructed with stronger candidates for $PC(T)$ *first*. Systematic study

of such prioritization schemes may yield performance benefits over existing GLL instantiations. Other areas that may yield improved performance is selective or full model averaging to address instability of $MB(T)$ estimation in small samples and optimizing alpha thresholds and FDR thresholds either for a domain or a data set, possibly separately for each variable.

In general, the treatment of determination of unreliable tests by means of the heuristic rule and parameter *h-ps* in GLL instantiations can be improved by incorporating formal power-size analysis whenever possible. More broadly, removing the requirement for a uniform sample size requirement across independence tests of same order (but different response function) is likely to yield improved algorithms. Other statistical issues such as improved statistical handling of structural zeros for discrete statistics, improved statistical tests that combine discrete and continuous data, handling "forced" covariates (i.e., variables that need to remain in $TPC(T)$ or $TMB(T)$ so that a particular effect is controlled for) are also worth exploring. Related to proper statistical testing is the issue of optimal discretization, not for classification as has been explored before in the literature, but for causal discovery (for a study toward that direction see Fu 2005). Other statistical extensions are to adapt the GLL method for survival analysis, or other time-to-event analyses without discretizing outcomes and with ability to handle observation censoring.

Exploitation of prior knowledge and development of methods to exploit prior causal knowledge (e.g., variable ordering, forced edges, forbidden edges, known size of local neighborhoods, known directionalities/structure and degree of connectivity, etc.) may yield greatly improved methods. Comparisons of knowledge-enhanced to pure data-driven instantiations will then be very informative.

An obvious possibility not examined in the present work is using GLL methods for regression. Another natural line of future research is to study situations where a loss function does not require exact knowledge of the conditional probability $P(T|MB(T))$ in which a promising strategy is to use a wrapping post-processing step to remove unnecessary features thus tailoring the final feature set to a loss function less stringent than the ones that typically guarantee soundness for GLL-MB algorithms.

Different distributional assumptions, for example monotone DAG faithfulness to make GLL and LGL algorithms faster (for a first attempt see Brown et al. 2005) may provide algorithms that tradeoff well quality for speed in specific domains.

Although we did not address the issue in this work, post-processing the results of GLL and LGL output using algorithms that detect hidden variables and orient edges is an obvious direction for research.

The study of convergence behavior of GLL and of false discovery rate control were either empirical or qualitative in the present paper. Derivation of mathematical analyses of convergence to the optimal $MB(T)$ and optimal classifier (as function of sample size), of effects of synthesis, of how common synthesis is, of combined power and alpha for specific distributions will be very interesting, especially as other components of the framework (for example handling of unreliable tests) are also formalized.

Developing methods that handle efficiently very large neighborhoods with hundreds of features and small sample size, as well as developing methods for special-purpose causal structures (e.g., genome-wide association studies) is also an area where significant improvements can be made.

The skeleton phase of LGL is a form of dynamic programming and this explains its efficiency and soundness and probably leaves reduced opportunity for dramatic efficiency improvements. One possible avenue would be the exploration of different strategies for linking together the local skele-

P(T | C, D)	(D=0, C=0)	(D=0, C=1)	(D=1, C=0)	(D=1, C=1)

ton results (step #2 in LGL schema). Both MMHC and HHC use an "OR" strategy but many alternative approaches can be devised. Furthermore, the edge orientation step may be greatly improved over the use of greedy search-and-score. Numerous other obvious instantiations of LGL (for instance combining GLL-PC versions with global algorithms such as GES, and TPDA) can also be implemented with substantial potential for good empirical performance. Moreover, methods to automatically identify optimal variable prioritization for local learning can yield improvements in certain distributions and we outlined related research directions in Section 6.3.

Finally, extending the framework to address broader definitions of feature selection is particularly important. Examples include finding: all sets that give desired trade-off between feature number and predictivity; all sets with smallest cost that give highest predictivity (i.e., when different observation costs apply for each variable); and all sets that optimize arbitrary multi-attribute utility/loss functions.

8.3 Conclusions

The empirical and theoretical results presented in the present paper and its companion paper (Aliferis et al., 2010) support the notion that local causal learning in the form of Markov blanket and local neighborhood induction is a theoretically well-motivated and empirically robust learning methodology as embodied in the Generalized Local Learning framework. Generalized Local Learning yields algorithms with excellent performance in data analysis geared toward classification and causal discovery. Local-to-global learning strategies have the potential to enhance large-scale causal discovery. Several existing open problems offer possibilities for non-trivial theoretical and practical discoveries, making this an exciting field of research.

Editor: David Maxwell Chickering

Abstract

We study the problem of learning an optimal Bayesian network in a constrained search space; skeletons are compelled to be subgraphs of a given undirected graph called the super-structure. The previously derived constrained optimal search (COS) remains limited even for sparse super-structures. To extend its feasibility, we propose to divide the super-structure into several clusters and perform an optimal search on each of them. Further, to ensure acyclicity, we introduce the concept of ancestral constraints (ACs) and derive an optimal algorithm satisfying a given set of ACs. Finally, we theoretically derive the necessary and sufficient sets of ACs to be considered for finding an optimal constrained graph. Empirical evaluations demonstrate that our algorithm can learn optimal Bayesian networks for some graphs containing several hundreds of vertices, and even for super-structures having a high average degree (up to four), which is a drastic improvement in feasibility over the previous optimal algorithm. Learnt networks are shown to largely outperform state-of-the-art heuristic algorithms both in terms of score and structural hamming distance.

Keywords: Bayesian networks, structure learning, constrained optimal search

1. Introduction

Although structure learning is a fundamental task for building Bayesian networks (BNs), when minimizing a score function, the computational complexity often prevents us from finding optimal BN structures (Perrier et al., 2008). With currently available exact algorithms (Koivisto et al., 2004; Ott et al., 2004; Silander et al., 2006; Singh et al., 2005) and a decomposable score like BDeu, the computational complexity remains exponential, and therefore, such algorithms are intractable for BNs with more than around 30 vertices given our actual computational capacity. For larger systems, heuristic searches like greedy hill-climbing search (HC) or customized versions of this search are employed in practice (Tsamardinos et al., 2006).

Recently, Tsamardinos et al. (2006) proposed an algorithm called max-min hill-climbing (MMHC) that combines an independence test (IT) approach with a score-based search strategy: first, an undirected graph is built based on an IT approach, and then, a constrained greedy hill-climbing search returns a local optimum of the score function. Thus, MMHC can be considered as a constrained search, a concept introduced by Friedman et al. (1999) together with the sparse can-

didate (SC) algorithm. Such algorithms have been empirically shown to outperform unconstrained greedy hill-climbing (Friedman et al., 1999; Tsamardinos et al., 2006). Based on the success of constrained approaches, Perrier et al. (2008) proposed an algorithm that can learn an optimal BN when an undirected graph is given as a structural constraint. Perrier et al. (2008) defined this undirected graph as a super-structure; the skeleton of every graph considered is compelled to be a subgraph of the super-structure. This algorithm can learn optimal BNs containing up to 50 vertices when the average degree of the super-structure is around two, that is, a sparse structural constraint is assumed. However, its feasibility remains limited.

Independently, Friedman et al. (1999) suggested that when the structural constraint is a directed graph (in the case of SC), an optimal search can be carried out on the cluster tree extracted from the constraint. This cluster-based approach could potentially increase the feasibility of optimal searches; nevertheless, the algorithm proposed in Friedman et al. (1999) requires to be given a directed graph-based constraint and to extract a cluster tree. For the latter, a large cluster might be generated, preventing an optimal search from being carried out.

Another potential approach is to search the best BN by checking the network obtained by withdrawing edges in cycles one-by-one, beginning from an initial network which is build by connecting children and their optimal parents with directed edges without checking acyclicity as in B&B algorithm (de Campos et al., 2009). However, children in the best BN are often selected as the best parents without considering acyclicity if the size of a given data set is sufficient. Thus, for the estimation of the best BN of more than hundred vertices and sufficient data samples, the initial network may contain hundreds of small cycles, and it is impossible to check these cycles in the search process.

In this study, we take up the concept of a super-structure constraint and propose a cluster-based search algorithm that can learn an optimal BN given the constraint. Therefore, unlike in Friedman et al. (1999), our algorithm uses an undirected graph as the structural constraint. In addition, we use a different cluster decomposition that enables us to consider more complex cases. As Tsamardinos et al. (2006) and Perrier et al. (2008) showed, good approximations of the true super-structure can be obtained by an IT approach like the max-min parent-children (MMPC) method (Tsamardinos et al., 2006).

If the super-structure is divided into clusters of moderate size (around 30 vertices), a constrained optimal search can be applied on each cluster. Then, to find a globally optimal graph, one could consider all patterns of directions for the edges between clusters and apply a constrained optimal search on each cluster for every pattern of directions independently and return the best result found. We theorize this idea by introducing ancestral constraints; further, we derive the necessary and sufficient ancestral constrains that we must consider to find an optimal network and introduce a pruning technique to skip superfluous cases. Finally, we develop a super-structure constrained optimal algorithm that extends the size of networks that we can consider by more than one order.

The performance of our algorithm is evaluated on the Alarm, Insurance, and Child networks (Beinlich et al., 1989; Binder et al., 1997; Cowell et al., 1999) extended by the tiling method (Tsamardinos et al., 2006) to obtain networks having several hundreds of vertices. Experiments show that our algorithm clearly outperforms MMHC and HC with the TABU search extension.

2. Related Works

Given data D for a set of random variables V, learning an optimal BN using a decomposable score like BDeu involves finding a directed acyclic graph (DAG) N^* such that

$$N^* = \arg\min_N \sum_{v \in V} s(v, Pa_N(v); D), \tag{1}$$

where $Pa_N(v) \subseteq V$ is a set of parents for a vertex v in network N and $s(v, Pa_N(v); D)$ is the value of the score function for v in N. Hereafter, we omit the subscript N for Pa and D for s. In this section, we introduce some structure learning algorithms to show the motivation of our research.

2.1 Optimal search

Although finding a global optimum, that is, a solution of (1), is NP-hard, several optimal algorithms have been developed (Koivisto et al., 2004; Ott et al., 2004; Silander et al., 2006; Singh et al., 2005). The time complexity has been successfully reduced to $O(n2^n)$, where n is the number of vertices in BN (i.e., $|V| = n$).

2.2 Hill-climbing

For learning a larger system, heuristic algorithms must be used. Greedy hill-climbing (HC) is one of the most commonly used algorithms in practice. HC only finds local optima, and upgraded versions of this base algorithm have been extensively studied, leading to some improvement in the score and structure of the results (e.g., by using a TABU list).

2.3 Sparse Candidate

To improve HC, Friedman et al. (1999) limited the maximum number of parents and restricted the set of candidate parents for each vertex. They established SC algorithm and introduced the concept of constraining the search space of score-based approaches.

2.4 Max-min Hill-climbing

MMHC is a hybrid method combining an IT approach and a score-based search strategy. Tsamardinos et al. (2006) showed that on average, MMHC outperforms other heuristic approaches including SC and HC.

2.5 Constrained Optimal Search

In SC and MMHC, the learnt structures are local optima. Perrier et al. (2008) extended the optimal algorithm of Ott et al. (2004) and established a constrained optimal search (COS) that learns an optimal BN structure whose skeleton is a subgraph of a given undirected graph $G = (V, E)$ called the super-structure, that is, COS aims to find N^*_G, the solution of (1), while constraining $Pa_N(v)$ to be included in $\mathcal{N}(v)$, where $\mathcal{N}(v)$ is the neighborhood of v in G. Although using a super-structure increases the feasibility of optimal searches, COS is still limited when the super-structure is dense (high average degree).

2.6 Optimal Search with Cluster Tree

Friedman et al. (1999) suggested the possibility of optimally searching acyclic subgraphs of a digraph constructed by connecting each vertex and its pre-selected candidate parents with directed edges without checking acyclicity. Here, unlike MMHC and COS, the structural constraint is represented by a directed graph. An algorithm would proceed by converting the digraph into a cluster tree, where clusters are densely connected subgraphs. Then, it would perform an optimal search on each cluster for every ordering of the vertices contained in the separators of clusters. However, due to the difficulty of building a minimal cluster tree, large clusters can make the search impractical.

2.7 B&B Algorithm

Recently, de Campos et al. (2009) proposed an optimal branch-and-bound algorithm. This algorithm constructs an initial directed graph by linking every vertex to its optimal parents although this might create directed cycles. Then, it tries to search every possible case in which the direction of one edge comprising each directed cycle is constrained for keeping acyclicity, and finds optimal parents under the constraints iteratively until DAGs are obtained. After the completion of the full search, the optimal solution is finally given by the best DAG found. In addition, for score functions decomposable into penalization and fitting components, optimal parents under the constraints are further effectively computed using a branch-and-bound technique that was originally proposed by Suzuki et al. (1996). This method is interesting in that it is original and allows the development of an anytime search that returns the best current solution found and an upper bound to the global optimum. When the sample size is small, few directed cycles occur in the initial directed graph and updated graphs because information criteria tend to select a smaller parent set for each vertex in small sample data (Dojer, 2006). However, for a large sample size, due to the occurrence of a large number of directed cycles, the complexity of this method can be practically worse than classic optimal searches.

Thereafter, we will consider the same problem as in the COS approach, that is, to find N_G^*, an optimal BN constrained by the super-structure $G = (V,E)$, an undirected graph. In our case, we propose a cluster-based search to reduce the complexity drastically; here, clusters are of a different nature from the ones in Friedman et al. (1999), as shown in the next section.

3. Edge Constrained Optimal Search

In this section, we describe procedures of the proposed algorithm in a bottom-up manner. Under the assumption that the skeleton is separated to small subgraphs, we first describe the definition of ancestral constraints for each subgraph and consider an algorithm to learn an optimal BN on a subgraph under some ancestral constrains. We then explain the procedures in order to efficiently build up an optimal BN on the skeleton by using information of optimal BN on each subgraph under the conditions of ancestral constraints to be considered.

3.1 Ancestrally Constrained Optimal Search for A Cluster

Hereafter, we assume that we are given a set of edges $E^- \subset E$ such that the undirected graph $G^- = (V, E \setminus E^-)$ is not connected.

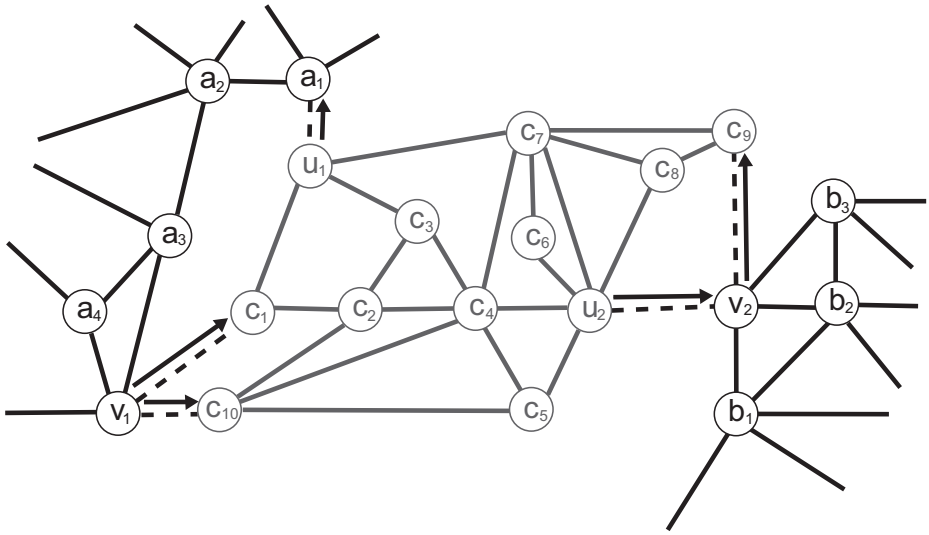

Figure 1: An example of a super-structure to illustrate the definitions we have introduced. The edges of E^- are dashed and they define a cluster C (gray). δ indicated by arrows is one of the 32 TDMs possible over E^C that defines $V^{in}_{C,\delta} = \{v_1, v_2\}$ and $V^{out}_{C,\delta} = \{u_1, u_2\}$.

Definition 1 (cluster and cluster edges) *Let $C = (V_C, E_C)$ be a maximal connected component of G^-. We refer to C as a* cluster *and call $E^C \subset E^-$ containing all and only the edges incident to a vertex in V_C the* set of cluster edges *for C.*

Definition 2 (tentative direction map) *Given a set of edges E^C, we define a* tentative direction map (TDM) δ *on E^C as a set of pairs $\{(e,d), e \in E^C$ and $d \in \{\leftarrow, \rightarrow\}\}$ such that for $\forall e \in E^C$, there uniquely exists d such that $(e,d) \in \delta$. In other words, δ associates a unique direction with each edge in E^C.*

In the following sections, we show that by successively considering every possible δ on E^- and learning the optimal BN on each cluster independently we can reconstruct N^*_G. However, to avoid creating cycles over several clusters, our method has to consider all the possible ancestral constraints for a cluster, a notion that we introduce hereafter.

Definition 3 (in-vertex and out-vertex) *Considering a cluster C and a TDM δ on E^C, we define $V^{in}_{C,\delta}$ and $V^{out}_{C,\delta}$ as $V^{in}_{C,\delta} = \{v \in V \setminus V_C \mid \exists v_a \in V_C, (\{v, v_a\}, \rightarrow) \in \delta\}$ and $V^{out}_{C,\delta} = \{v \in V_C \mid \exists v_a \in V \setminus V_C, (\{v, v_a\}, \rightarrow) \in \delta\}$, respectively. We drop the subscripts C and δ when there is no ambiguity. We call $v \in V^{in}_{C,\delta}$ an* in-vertex *and $v \in V^{out}_{C,\delta}$, an* out-vertex.

Figure 1 illustrates the previously introduced definitions. In this section, we assume C and δ to remain constant.

Definition 4 (ancestral constraints) *An* ancestral constraint (AC) *is a pair (v,u) with $v \in V^{in}_{C,\delta}$ and $u \in V^{out}_{C,\delta}$ that is used to disable v as an ancestor of u. Let $\mathcal{A}$ be a set of ancestral constraints* (ACS),

and $\mathcal{A}(v)$ be the set of all out-vertices u_i such that $(v,u_i) \in \mathcal{A}$. We say that $\mathcal{A}$ is a nested ancestral constraint set (NACS) *if and only if for any v_a and v_b in $V^{in}_{C,\delta}$, $\mathcal{A}(v_a) \subseteq \mathcal{A}(v_b)$ or $\mathcal{A}(v_a) \supseteq \mathcal{A}(v_b)$ holds. Finally, given two ACSs $\mathcal{A}$ and $\mathcal{B}$, if $\forall v \in V^{in}_{C,\delta}$, we have that $\mathcal{A}(v) \subseteq \mathcal{B}(v)$, and we say that $\mathcal{B}$ is* stronger than or equal to *$\mathcal{A}$ and denote this relation as $\mathcal{A} \leq \mathcal{B}$.*

Finally, we recall the definition of a topological ordering and some notions related to it.

Definition 5 (π-linearity and $\mathcal{A}$-linearity) *Given an ordering π (i.e., a bijection of $[|1,n|]$ in V), we say that it is a topological ordering of a BN N if for every v, $Pa(v)$ is included in $P_\pi(v) = \{u \in V \mid \pi^{-1}(u) < \pi^{-1}(v)\}$, the set of the predecessors of v; in such a case, N is said to be* π-linear. *Given an ACS $\mathcal{A}$ and a BN N, we say that N is* $\mathcal{A}$-linear *if and only if it respects all ACs in $\mathcal{A}$. In addition, in the case of a NACS, there exists a topological ordering π of N such that $\forall v \in V^{in}_{C,\delta}$ and $\forall u \in \mathcal{A}(v)$, $\pi^{-1}(u) < \pi^{-1}(v)$ holds.*

For notational brevity, if $\pi^{-1}(u) < \pi^{-1}(v)$ holds for two vertices v and u, we hereafter write $u \prec_\pi v$. Using the previous definitions, we can now prove the validity of our approach.

Theorem 1 *There exists δ^* on E^- and NACSs $\mathcal{A}^*_i$ for every cluster C_i of G^- coherent with a global optimal BN N^*_G. In other words, we can obtain N^*_G by considering the separately obtained optimal BN for every cluster, NACS, and TDM possible.*

Proof We consider an optimal DAG N^*_G and one of its topological orderings π^*. There exists a unique TDM δ^* coherent with π^*. From δ^*, we define for every cluster C_i the ACS $\mathcal{A}^*_i$ such that $\forall v \in V^{in}_{C_i,\delta^*}, \mathcal{A}^*_i(v) = P_{\pi^*}(v) \cap V^{out}_{C_i,\delta^*}$. $\mathcal{A}^*_i$ are definitely NACSs since for every v_a and $v_b \in V^{in}_{C_i,\delta^*}$ if $v_a \prec_{\pi^*} v_b$, then by definition, $\mathcal{A}^*_i(v_a) \subseteq \mathcal{A}^*_i(v_b)$. Further, the subgraphs N^*_i of N^*_G on the sets $V_i = V_{C_i} \cup V^{in}_{C_i,\delta^*}$ are $\mathcal{A}^*_i$-linear (because the definition of $\mathcal{A}^*_i$ is based on π^*). Furthermore, each N^*_i is an optimal graph on $V_{C_i} \cup V^{in}_{C_i,\delta^*}$ given the constraints of δ^* and $\mathcal{A}^*_i$ (otherwise, we could build a DAG having a lower score than N^*_G). Therefore, if we independently compute an optimal BN for every cluster, for every TDM and every NACS, and return the best combination, we can build a globally optimal BN on V. ■

From Theorem 1, the ACS to be considered is limited to only NACS, and N^*_G can be obtained by searching the best combination of an optimal BN separately obtained on every cluster and for every NACS and every TDM. Figure 2 shows the flowchart of the search strategy of our approach. First, an optimal BN and its score on every cluster for every NACS and every TDM are computed. Then, by using this information, an optimal BN and its score on a cluster obtained by merging two clusters are computed for every NACS and every TDM. After the repeated computation of optimal BNs and scores on merged clusters, an optimal BN and its score on a single cluster covering the super-structure are finally obtained. The details and validity of the algorithms shown in the flowchart are discussed in later sections.

The fundamental step involves learning an optimal BN on a cluster C for a given δ and $\mathcal{A}$; we call this algorithm ancestrally constrained optimal search (ACOS). To describe it, we need to recall some functions defined in optimal search algorithm by Ott et al. (2004); however, we prefer to use the notations introduced by Perrier et al. (2008) for the sake of simplicity.

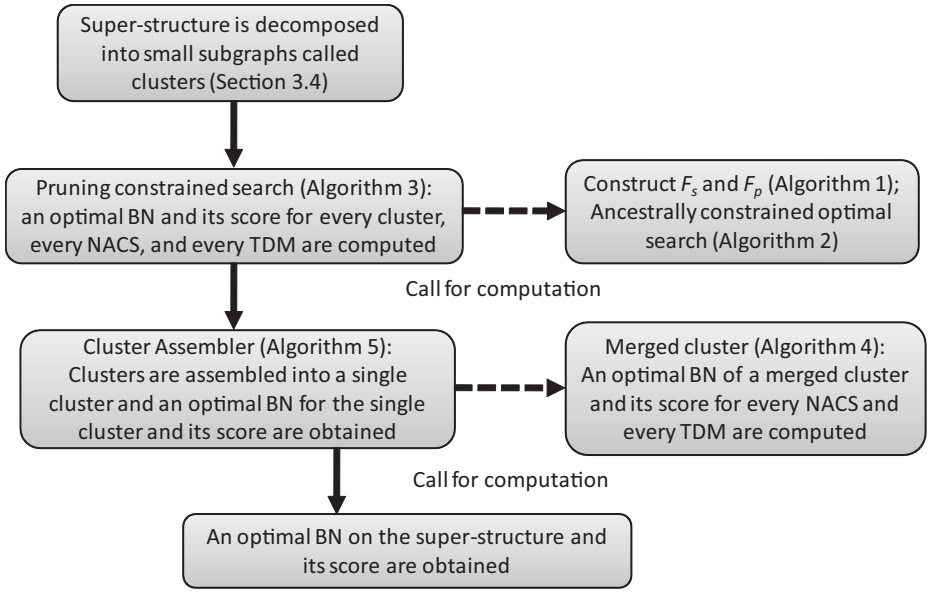

Figure 2: Flowchart of algorithms for the computation of an optimal BN on a super-structure. The details of these algorithms are discussed in later sections.

Definition 6 (Perrier et al. 2008) *For every $v \in V$ and every $X \subseteq \mathcal{N}(v)$, we define $F_p(v,X)$ as being the best parent set for v included in X and $F_s(v,X)$ as the associated score:*

$$\begin{aligned} F_s(v,X) &= \min_{Pa \subseteq X} s(v,Pa), \\ F_p(v,X) &= \arg\min_{Pa \subseteq X} s(v,Pa). \end{aligned}$$

Further, considering a cluster C, δ, and $\mathcal{A}$, for every $X \subseteq V_C$, we define $\hat{s}^{\mathcal{A}}(X)$ to be the best score possible for a DAG over $X \cup V^{in}_{C,\delta}$ that satisfies $\mathcal{A}$ (the scores of the vertices in V^{in} are not considered), and $\ell^{\mathcal{A}}(X)$ to be the last element of a topological ordering (restricted to X) of an optimal DAG over $X \cup V^{in}_{C,\delta}$ that satisfies $\mathcal{A}$ (given the constraints). Later, the subscript $\mathcal{A}$ is omitted.

We first introduce an algorithm described in Perrier et al. (2008) that calculates F_s and F_p using dynamic programming and then explain how we adapt the calculation of $\hat{s}$ and ℓ to satisfy the TDM and the NACS.

Algorithm 1: Calculate F_s and F_p (Perrier et al., 2008)
Input: Score function s and super-structure G
Output: Functions F_p and F_s

1. Set $F_s(v,\emptyset) = s(v,\emptyset)$ and $F_p = \emptyset$ for all $v \in V$.

2. For all $v \in V$ and all $X(\neq \emptyset) \subseteq \mathcal{N}(v) \setminus \{v\}$, compute

$$\begin{aligned} u^* &= \arg\min_{u \in X} F_s(v, X \setminus \{u\}), \\ F_s(v,X) &= \min\{s(v,X), F(v, X \setminus \{u^*\})\}, \\ F_p(v,X) &= \begin{cases} X & \text{if } s(v,X) \leq F_s(v, X \setminus \{u^*\}) \\ F_p(v, X \setminus u^*) & \text{otherwise} \end{cases}. \end{aligned}$$

Note that the in-vertices are considered differently in our algorithm; they either have no parents or fixed parents, and can only be parents of few vertices in V_C depending on $\mathcal{A}$. Thus, although the DAGs considered in the following algorithm are optimal on $X \cup V_{C,\delta}^{in}$, the score of $v \in V_{C,\delta}^{in}$ (that is fixed depending on δ) is not counted in $\hat{s}(X)$ since it is the same for every DAG irrespective of whether it is optimal or not.

From Theorem 1, the only orderings π such that $u \prec_\pi v$ for every $v \in V_{C,\delta}^{in}$ and $u \in \mathcal{A}(v)$ are to be considered. Therefore, for $w \in V_C$ and $v \in V_{C,\delta}^{in}$, v can be a parent of w if and only if $v \prec_\pi w$, implying $u \prec_\pi w$ for every $u \in \mathcal{A}(v)$. Therefore, we do not need to consider $v \in V_{C,\delta}^{in}$ in our ordering since we can infer whether v can be a parent of w by checking if it is ordered after all nodes in $\mathcal{A}(v)$. We define for every $X \subseteq V_C$ the associate set $PC(X) = X \cup \{v \in V_{C,\delta}^{in} \mid \mathcal{A}(v) \subseteq X\}$; in other words, for a given topological ordering π over X, the possible parents in $X \cup V_{C,\delta}^{in}$ of $w \in X$ are in $PC(P_\pi(w)) \cap \mathcal{N}(w)$. Using this result, we can present ACOS:

Algorithm 2: AncestrallyConstrainedOptimalSearch
Input: Cluster C, TDM δ, NACS $\mathcal{A}$, super-structure G, and functions F_p and F_s (previously computed)
Output: Optimal BN under $\mathcal{A}$, δ, G, and its score, $\hat{s}(V_C)$

1. Set $\hat{s}(\emptyset) = \infty$ and $\ell(\emptyset) = \emptyset$.
2. For all X $(\neq \emptyset) \subseteq V_C$, do:
   (a) Compute $\ell(X) = \arg\min_{v \in X}\{F_s(v, PC(X \setminus \{v\}) \cap \mathcal{N}(v)) + \hat{s}(X \setminus \{v\})\}$.
   (b) Define $\hat{s}(X)$ as the minimal score obtained during the previous step.
3. Construct N^*, an optimal $\mathcal{A}$-linear BN over V_C, using F_p and ℓ, and return N^* and its score $\hat{s}(V_C)$.

In Algorithm 2, the computation of F_s and F_p is carried out during preprocessing because it does not depend on δ and $\mathcal{A}$. Step 3 can be completed in linear time in n and is presented in Perrier et al. (2008). To prove the correctness of ACOS, we explain the computation of ℓ in step (a).

Theorem 2 *Given C, δ, and $\mathcal{A}$, ACOS constructs an optimal constrained BN over $V_C \cup V_{C,\delta}^{in}$.*

Proof First, we recursively show on the size of X that the computation of ℓ and $\hat{s}$ in Algorithm 2 respects their definition. Since the initialization in step 1 is correct, let us consider $X \neq \emptyset$ such that for $\forall Y \subset X$, $\hat{s}(Y)$ and $\ell(Y)$ are well defined. For any $v \in X$, we would like to find the score of the best DAG having v as a sink (i.e., v is the last element of a topological ordering over X). In that configuration, all nodes in $X \setminus \{v\}$ are predecessors of v, and therefore, they are potential

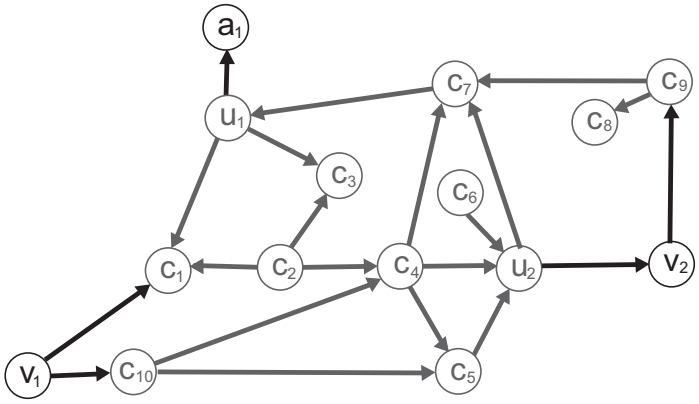

Figure 3: If this graph is the best $\mathcal{A}$-linear DAG with $\mathcal{A} = \{(v_1, u_1)\}$, since both v_1 and v_2 are not ancestors of u_1 and u_2, its strongest NACS is $\mathcal{B}$ with $\mathcal{B}(v_1) = \mathcal{B}(v_2) = \{u_1, u_2\}$. Therefore, this graph is optimal for all seven NACSs included between $\mathcal{A}$ and $\mathcal{B}$.

parents. Moreover, as stated previously, $w \in V_{C,\delta}^{in}$ such that $\mathcal{A}(w) \subseteq X \setminus \{v\}$ can also be a parent of v while satisfying ACs. Consequently, after adding the structural constraint G, the best score for v is $F_s(v, PC(X \setminus \{v\}) \cap \mathcal{N}(v))$. Finally, since v cannot be a parent of any nodes in $X \setminus \{v\}$, the best score over this set is $\hat{s}(X \setminus \{v\})$. Thus, step (a) of Algorithm 2 finds the best sink for X and correctly defines $\ell(X)$ and $\hat{s}(X)$. Finally, as explained in Perrier et al. (2008), we can rebuild an optimal ordering π^* over V_C by using ℓ and obtain an optimal DAG by assigning $\forall v \in V_C$, $Pa(v) = F_p(v, PC(P_{\pi^*}(v)) \cap \mathcal{N}(v))$. ■

3.2 Pruning

Following Theorem 1, we know that ACOS has to be computed only for all NACSs. Although the number of NACSs can be shown to be less than $O(|E^C|!)$ (because all NACSs can be generated through orderings of $V_{C,\delta}^{in} \cup V_{C,\delta}^{out}$), it is experimentally worse than exponential in the number of cluster edges. Fortunately, different NACSs frequently lead to the same optimal networks, and many NACS do not need to be considered. For the cluster C and TDM δ shown in Figure 1, Figure 3 shows an optimal BN N under NACS $\mathcal{A} = \{(v_1, u_1)\}$. Since both v_1 and v_2 are not ancestors of u_1 and u_2, its strongest NACS is $\mathcal{B} = \{(v_1, u_1), (v_1, u_2), (v_2, u_2), (v_2, u_2)\}$. Therefore, N is an optimal BN of seven NACSs between $\mathcal{A}$ and $\mathcal{B}$: $\{(v_1, u_1)\}$, $\{(v_1, u_1), (v_2, u_1)\}$, $\{(v_1, u_1), (v_1, u_2)\}$, $\{(v_1, u_1), (v_1, u_2), (v_2, u_1)\}$, $\{(v_1, u_1), (v_1, u_2), (v_2, u_2)\}$, $\{(v_1, u_1), (v_2, u_1), (v_2, u_2)\}$, $\{(v_1, u_1), (v_1, u_2), (v_2, u_2), (v_2, u_2)\}$. The next lemma formally describes this observation.

Lemma 1 *Let $\mathcal{A}$ be a NACS and $\mathcal{B}$, an ACS such that $\mathcal{B} \geq \mathcal{A}$ and that an optimal $\mathcal{A}$-linear DAG N^* is also $\mathcal{B}$-linear. Then, $\forall \mathcal{A}'$ such that $\mathcal{A} \leq \mathcal{A}' \leq \mathcal{B}$, N^* is also an optimal $\mathcal{A}'$-linear DAG.*

Proof Since $\mathcal{A}'$ is more restrictive than $\mathcal{A}$, an optimal $\mathcal{A}'$-linear DAG N'^* verifies that $s(N'^*) \geq s(N^*)$. However, since N^* is $\mathcal{B}$-linear, it is also $\mathcal{A}'$-linear; therefore, it is optimal and $s(N'^*) = s(N^*)$. ■

By browsing the space of NACS in an order verifying that $\forall i$ and j if $\mathcal{A}_i \leq \mathcal{A}_j$ then $i \leq j$, and by using the previous lemma as a pruning criterion, we can considerably reduce the number of NACSs to which ACOS is applied. For a given C and δ, we consider a score-and-network (SN) map $S_{C,\delta}$ as a list containing pairs of optimal scores and networks generated by every NACS, not to be pruned. We denote the set of $S_{C,\delta}$ for all TDM as S_C.

Algorithm 3: PruningConstrainedSearch
Input: Cluster C and TDM δ
Output: SN maps $S_{C,\delta}$

1. Initialize an empty set of NACSs U and an empty SN map $S_{C,\delta}$.
2. For every NACS $\mathcal{A}_i$ (ordered such that $j \leq k$ if $\mathcal{A}_j \leq \mathcal{A}_k$), do:
   (a) If $\mathcal{A}_i \in U$, $i++$ and restart step (a).
   (b) Otherwise, learn N^*, an optimal $\mathcal{A}_i$-linear DAG of score s^*, using Algorithm 2.
   (c) Let $\mathcal{B}$ be the ACS containing all ACs satisfied in N^*.
   (d) $\forall \mathcal{A}'$ such that $\mathcal{A}_i \leq \mathcal{A}' \leq \mathcal{B}$, add $\mathcal{A}'$ in U.
   (e) Add the pair (N^*, s^*) to $S_{C,\delta}$.

For enumerating ordered NACSs, see Appendix A. The following theorem shows the correctness of PruningConstrainedSearch.

Theorem 3 *For every NACS $\mathcal{A}$, there is an optimal DAG in $S_{C,\delta}$.*

Proof This is trivial since from Lemma 1, we have already found an optimal DAG N^* for the NACS $\mathcal{A}'$ that are pruned (added to U in step (d)). ■

3.3 Assembling Clusters

Next, we describe how the results of two clusters C_1 and C_2 are combined. The algorithm given below builds a set of SN maps S_C for the merged cluster C out of S_{C_1} and S_{C_2} (with $V_C = V_{C_1} \cup V_{C_2}$).

Algorithm 4: MergeCluster
Input: Clusters C_1 and C_2 and sets of SN maps S_{C_1} and S_{C_2}
Output: Merged cluster C and set of SN maps S_C

1. Define $C = (V_{C_1} \cup V_{C_2}, E_{C_1} \cup E_{C_2} \cup (E^{C_1} \cap E^{C_2}))$
2. For every TDM δ of E^C, do:
   (a) For every pair of TDM δ_1 and δ_2 of E^{C_1} and E^{C_2} that satisfy the following conditions:
   Condition i $\forall (e,d) \in \delta$, then $(e,d) \in \delta_i$ ($i = 1$ or 2),
   Condition ii $\forall e \in E^{C_1} \cap E^{C_2}$, $(e,d) \in \delta_1$ if and only if $(e,d) \in \delta_2$,
      i. For every pair of optimal networks and scores (N_1^*, s_1^*) and (N_2^*, s_2^*) of S_{C_1,δ_1} and S_{C_2,δ_2}, respectively, do:

A. Define $N^* = N_1^* \cup N_2^*$ and $s^* = s_1^* + s_2^*$
B. If there exists a directed cycle in N^*, restart step i with the next pair.
C. Let $\mathcal{A}$ be the ACS containing all ACs satisfied in N^*.
D. If there exists an optimal $\mathcal{A}$-linear network in $S_{C,\delta}$ that has a score smaller than s^*, restart step i with the next pair.
E. Add the pair (N^*, s^*) to $S_{C,\delta}$.
F. Remove every pair (N', s') of $S_{C,\delta}$ such that N' is $\mathcal{A}$-linear and $s' > s^*$.

The next theorem shows that $S_{C,\delta}$ contains an optimal BN and its score for every NACS on C.

Theorem 4 *If for every pair of TDMs δ_1 and δ_2 and for every NACS, S_{C_1,δ_1} and S_{C_2,δ_2} contain pairs of an optimal BN and its score, then $S_{C,\delta}$ constructed by Algorithm 4 contains a pair of an optimal BN and its score for every NACS.*

Proof First, we show that for every NACS $\mathcal{A}$ over C, we can build an optimal $\mathcal{A}$-linear BN by merging two optimal networks on C_1 and C_2 for some NACSs $\mathcal{A}_1$ and $\mathcal{A}_2$. To do so, for a given TDM δ, let us consider a NACS $\mathcal{A}$ for C, an optimal $\mathcal{A}$-linear BN N^* of score s^* and one of its topological orderings π^* defined over V_C (that is also in agreement with δ and $\mathcal{A}$). i is used instead of 1 and 2. We define π_i^* the ordering of the vertices in V_{C_i} derived from π^*. Further, we call δ_i the TDM of E^{C_i} derived from π_i^*; we have that δ_1 and δ_2 verify trivially conditions (i) and (ii) stated in step (a) of Algorithm 4. Finally, we define $\mathcal{A}_i$ as a NACS for C_i such that for $\forall v \in V_{C_i,\delta_i}^{in}$, $\mathcal{A}_i(v) = P_{\pi_i}(v) \cap V_{C_i,\delta_i}^{out}$. Given an optimal $\mathcal{A}_i$-linear network of S_{C_i,δ_i} N_i^* and its score s_i^*, let us consider the graph $N' = N_1^* \cup N_2^*$. This graph is acyclic since it is π^*-linear by construction. Further, its score $s' = s_1^* + s_2^*$ is minimal for $\mathcal{A}$-linear; otherwise, one of the N_i^* graphs would not be optimal. Therefore, although N' might be different from N^*, they both have the same score. Therefore, since Algorithm 4 considers every coherent pair δ_1 and δ_2 (that verify conditions (i) and (ii)) and every pair of NACS, $S_{C,\delta}$ is correctly constructed. ■

Given the previous algorithm, we simply need to merge all the clusters to obtain an optimal DAG N_G^* and its score, as explained in the following algorithm.

Algorithm 5: ClusterAssembler
Input: Set of all clusters $\mathcal{C}$
Output: Optimal BN N_G^* and its score s^*

1. $\forall C \in \mathcal{C}$, compute S_C using Algorithm 3 for every δ.
2. While $|\mathcal{C}| > 1$, do:
   (a) Select a pair of clusters C_1 and C_2 such that $|(E^{C_1} \cup E^{C_2}) \setminus (E^{C_1} \cap E^{C_2})|$ is minimal.
   (b) Compute the cluster C and S_C by merging C_1 and C_2 using Algorithm 4.
   (c) Remove C_1 and C_2 from $\mathcal{C}$, and add C to $\mathcal{C}$.
3. Since G is the last element in $\mathcal{C}$, return N_G^* and s^*, the sole pair stored in $S_{G,\emptyset}$.

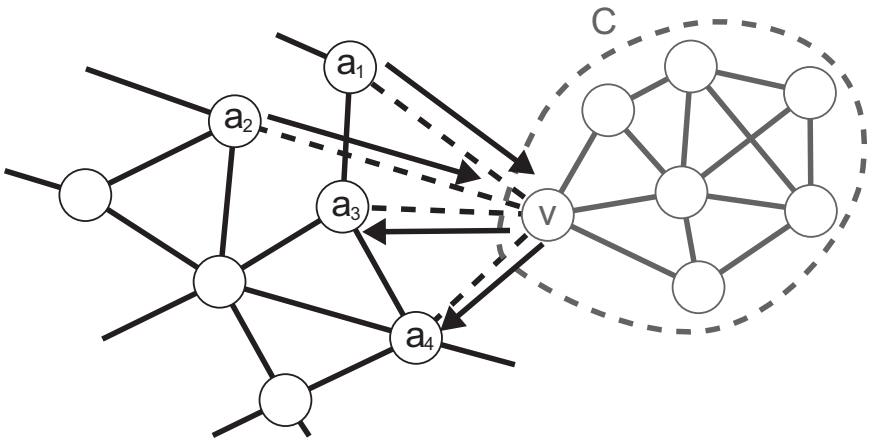

Figure 4: An example of super-structure shrinkage. A block $C = (V_C, E_C)$ (gray) can be separated from the rest of the super-structure by the removal of a cut-vertex $v \in V_C$. Arrows indicate the unique TDM δ_X for $X = \{a_1, a_2\}$.

The correctness of Algorithm 5 is directly derived from Theorem 4. In (a), although we do not prove that the complexity is minimal by merging the clusters that imply less cluster edges for the merged cluster at each step, we decided to use this heuristic. This is because the complexity depends on the number of cluster edges in Algorithm 4; therefore, it is faster to always manipulate a cluster with a small number of cluster edges.

3.4 Preprocessings

In this section, we describe a preprocessing that can drastically reduce the time complexity of our method and the heuristic we used to select the edges in E^-.

3.4.1 SUPER-STRUCTURE SHRINKAGE

First, we introduce the notions of a block and a block tree of an undirected graph. Their formal definitions are described in Diestel (2005). A block is a biconnected subgraph of the undirected graph, and vertices in the intersection of blocks are called cut-vertices, that is, the removal of cut-vertices separates blocks. A block tree is a tree comprised of blocks as vertices and cut-vertices as edges. We here show leaves of a block tree of the super-structure can be removed if their size is small. Let us consider the case shown in Figure 4 where a block $C = (V_C, E_C)$ of the super-structure G can be separated by withdrawing a cut-vertex $v \in V_C$ and that C is of a moderate size ($|V_C| < 30$). Then, all edges (v, w), where $w \notin V_C$, are considered as cluster edges; because only v is connected to cluster edges, no cycle can be created while merging an optimal DAG N_C^* over V_C with another cluster; otherwise, it would imply that there is a cycle in N_C^*. Therefore, there is no need of AC and we propose to process this case in a different manner. For every TDM δ, we learn an optimal DAG N_δ^* and its score s_δ^* over V_C. Then, we replace C by a single vertex $\hat{v}$ in G to obtain the condensed super-structure $\hat{G}$. For every candidate parent set X of $\hat{v}$ in $\hat{G}$ (i.e., $\forall X \subseteq \mathcal{N}(v) \setminus V_C$), there exists the unique TDM δ_X corresponding to C. For example, if a candidate parent set X is set to $\{a_1, a_2\}$ in

Figure 4, unique TDM δ_X for cluster edges (v,a_1), (v,a_2), (v,a_3), and (v,a_4) is indicated by arrows. Using this observation, we redefine F_s on $\hat{v}$ to be $\hat{F}_s(\hat{v},X) = s^*_{\delta_X}$ and F_p to be $\hat{F}_p(\hat{v},X) = N^*_{\delta_X}$; here, $\hat{F}_p$ is used not only to store the optimal parent set of v in $X \cup (V_C \cap \mathcal{N}(v))$ but also to save the optimal network over C. We can repeat this technique to shrink every small subgraph separated by the removal of a single vertex in G during preprocessing. This can lead to a drastic reduction of complexity in some real cases, as discussed later.

3.4.2 PARTITIONING THE SUPER-STRUCTURE INTO CLUSTERS

To apply our algorithm, we need to select a set of edges E^- that separates the super-structure into small strongly connected subgraphs (clusters) having balanced numbers of vertices while minimizing the number of cluster edges for each cluster. Such a problem is called graph partitioning. In our case, we employed an algorithm based on edge betweenness centrality that works efficiently for practical networks (Newman et al., 2004).

3.5 Resulting Algorithm

We summarize all results presented thus far in the following algorithm that learns a super-structure constrained optimal network and its score.

Algorithm 6: EdgeConstrainedOptimalSearch (ECOS)
Input: Super-structure $G = (V,E)$ and data D
Output: Optimal constrained BN N^*_G and its score s^*

1. $\forall v \in V$ and $\forall X \subseteq \mathcal{N}(v)$ compute $F_s(v,X)$ and $F_p(v,X)$.
2. Shrink every block possible in G to obtain a shrunk super-structure $\hat{G}$ and the functions $\hat{F}_s$ and $\hat{F}_p$.
3. Select E^- using the graph partitioning algorithm and obtain the set of all clusters $\mathcal{C}$.
4. $\forall C \in \mathcal{C}$ and $\forall \delta$; apply Algorithm 3 and obtain the set of SN maps S_C.
5. Merge all clusters using Algorithm 5 to obtain $\hat{N}^*_G$ and its score s^*.
6. Expand the subgraphs shrunk during step 2 to obtain N^*_G.

Note that after the expansion of shrunk subgraphs, s^* does not change as the scores for these subgraphs are packed in $\hat{F}_s$.

3.6 Complexity

In this last section, although it is hardly feasible to derive the complexity of Algorithm 6 in a general case because it strongly depends on the topology of the super-structure used, we propose an upper bound of the complexity depending on a few characteristics of G. Subsequently, we describe some practical generic structures to which ECOS can or cannot be profitably applied. We then present an empirical evaluation of the algorithm over randomly generated networks and real networks, with promising results being found for the latter.

Considering step 1 of ECOS, after defining the maximal degree of G as $m = \max_{v \in V} |\mathcal{N}(v)|$, we obtain that the number of scores calculated is upper bounded by $O(n2^m)$. This is actually the main

reason for using a structural constraint because the functions F_p and F_s can be computed in a linear time for bounded degree structures ($m < 30$). Actually, this is feasible even for large m if an additional constraint on the number of parents c is added, the complexity becoming $O(nm^c)$.

Next, if n_1 is the size of the largest cluster that has been shrunk (this is a tunable parameter), and considering that at maximum, the number of cluster edges of a shrunk block m' is $m-1$ and the number of TDM is $2^{m'}$, given the exponential complexity of calculating $\hat{s}$ and ℓ, we find that the complexity of step 2 is bounded by $O(b2^{m-1}2^{n_1})$, where b is the number of blocks shrunk. In other words, if n_1 is tuned suitably, step 2 has negligible complexity as compared to the subsequent steps. Similarly, step 3 is negligible since its complexity is only polynomial in n ($O(mn^3)$).

However, step 4 requires a more detailed analysis. Given E^-, we define $n_2 = \max_{C \in \mathcal{C}} |V_C|$, the size of the largest cluster, and $k = \max_{C \in \mathcal{C}} |E^C|$, the largest number of cluster edges. The complexity of ACOS is trivially bounded by $O(2^{n_2})$. Further, because the number of NACS is less than the number of permutations over $V^{in} \cup V^{out}$ for a given TDM, we have that for every cluster, ACOS is applied at maximum $k!2^k$ times. We derive an upper bound complexity for step 4 as $O(q2^{n_2}k!2^k)$, where q is the number of obtained clusters. Note, however, that the factorial term experimentally appears to be largely overestimated and that ACOS may actually be computed only $O(\beta^k)$ times for some $\beta > 2$.

Finally, at worst, step 5 involves trying every pair of entries in two SN map sets; with the maximum size of cluster edges of merged clusters K, the complexity might theoretically be as bad as $O(q(K!2^K)^2)$. However, in practice, because a major part of NACS was pruned in step 4, many pairs are pruned in step 5, and because all superfluous values of the SN maps are eliminated in Algorithm 4, its complexity is closer to $O(q\beta^k)$.

Following those rough upper bounds, we can derive some generic super-structures that are feasible for any number of vertices while not being naïve. For example, considering step 2, any super-structure whose block tree contains only small blocks (less than 30 vertices) is feasible. Otherwise, we can consider all the networks that can be generated by the following method:

- Generate an undirected graph G_0 of low maximal degree ($m < 10$).
- Replace every vertex v_i by a small graph C_i (up to 20 or slightly more) and randomly connect all edges connected to v_i in G_0 to vertices in C_i.

If ECOS can select all edges between clusters for such networks while defining E^-, the search should finish in reasonable time even for larger networks (up to several hundreds of vertices). Conversely, if a super-structure contains a large clique (containing more than 30 vertices), ECOS cannot finish as other optimal searches. To conclude, our algorithm may be a decisive breakthrough in some real cases where neither optimal searches nor COS can be applied because of a large number of vertices or a high average degree.

4. Experimental Evaluation

We conduct two types of numerical experiments for evaluating the performance of ECOS. In the former experiment, the practical time complexity of ECOS is estimated by the comparison with COS, using random networks of various sizes. In order to show the performance on practically structured networks, we then apply ECOS to the synthetically generated large scale network from Alarm, Insurance, and Child networks in the latter experiment. The performance of ECOS is compared with

$n \setminus \tilde{m}$	2	2.5	3	3.5
10	100	100	100	100
20	100	100	100	100
30	100	100	100	100
50	100	100	95	40
75	100	100	61	0
100	100	100	4	0

Table 1: Number of times the computation finished within one day for a random graph of n vertices and average degree $\tilde{m}$.

Algorithm	$\tilde{m}$	2	2.5	3	3.5
ECOS	$\delta_{\tilde{m}}$	1.06	1.08	1.15	1.25
	$n_{\max}(\tilde{m})$	355	273	151	93
COS	$\delta_{\tilde{m}}$	1.50	1.63	1.74	1.81
	$n_{\max}(\tilde{m})$	51	43	38	35

Table 2: Values of coefficients $\delta_{\tilde{m}}$ and $n_{\max}(\tilde{m})$ of ECOS and COS for average degree of super-structure $\tilde{m}$. $\delta_{\tilde{m}}$ is the estimated base of exponential time complexity and $n_{\max}(\tilde{m})$ is the feasible size of the super-structure for computation.

those of MMHC and greedy hill-climbing. All the computations in the following experiments were performed on machines having 3.0 GHz Intel Xeon processors with a Core microarchitecture (only one core was used for each experiment).

4.1 Benefit in Terms of Complexity

In the first series of experiments, we aimed to evaluate the average complexity of ECOS depending on n and $\tilde{m}$, the average degree of G. Since the feasibility of ECOS depends on the pruning of the search space, the theoretical derivation of the practical time complexity is difficult. Here, we hypothesize that the average complexity is in the form of $O(\delta_{\tilde{m}}^n)$, and then estimate $\delta_{\tilde{m}}$. Let $t_{\tilde{m},n}$ be the time required for a network of n vertices and average degree $\tilde{m}$. Under our assumption of time complexity, $t_{\tilde{m},n}$ is given by

$$t_{\tilde{m},n} = const \cdot \delta_{\tilde{m}}^n, \tag{2}$$

where *const* indicates the dependency of the implementation and machine specifications. From Equation (2), we have that $\delta_{\tilde{m}} = \exp(\frac{1}{n}(\log t_{\tilde{m},n} - \log const))$. Because $\frac{\log const}{n}$ can be ignored for large n, $\delta_{\tilde{m}}$ can be estimated by $\exp(\frac{\log t_{\tilde{m},m}}{n})$. For $\forall \tilde{m} \in \{2, 2.5, 3, 3.5\}$ and $\forall n \in \{10, 20, 30, 50, 75, 100\}$, we generate 100 random networks and we apply ECOS using 1,000 artificially generated samples in each case. We compute the average time $\tilde{t}_{\tilde{m},n}$ that is required and calculate $\delta_{\tilde{m},n} = \exp(\frac{\log(\tilde{t}_{\tilde{m},n})}{n})$. If our hypothesis is correct, $\delta_{\tilde{m},n}$ should converge to $\delta_{\tilde{m}}$ while n increases. However, to keep the computation manageable, we stop the calculation if it requires more

Table 3: Characteristics of the real networks considered in the computational experiment.

than one day. Hence, we probably underestimate $\delta_{\tilde{m}}$ slightly; nevertheless, here, we attempt to derive the exponential nature of the average complexity and not the real value of the constants. Further, the following results are sufficient to obtain a rough estimate. The number of times we finished the calculation for each pair of parameters is listed in Table 1. Due to the small ratio of finished experiments for $\tilde{m} = 3$ and 3.5, we selected the values $\delta_{3,75}$, $\delta_{3.5,50}$ for δ_3 and $\delta_{3.5}$, respectively. Further, for every average degree, we evaluated the maximal number of vertices $n_{\max}(\tilde{m})$ feasible from the value of $\delta_{\tilde{m}}$ calculated as proposed in Perrier et al. (2008).

Table 2 lists the values of $\delta_{\tilde{m}}$ and $n_{\max}(\tilde{m})$ for ECOS and COS. We should note that $n_{\max}(\tilde{m})$ of ECOS for $\tilde{m} = 3$ and 3.5 is overestimated since in this case, $\delta_{\tilde{m}}$ is underestimated because only the computations that finished were used to calculate it. In practice, $n_{\max}(\tilde{m})$ of ECOS for $\tilde{m} = 3$ and 3.5 are respectively around 75 and 50 from the results listed in Table 1; therefore, we can clearly see the practical advantage of ECOS over COS, and the improvement in terms of feasibility achieved by our method. In addition, we should emphasize that random networks penalize the results of ECOS because they do not have a logical partitioning. In real cases, we can hope that super-structures can be efficiently partitioned, enabling better performances for ECOS.

4.2 Case Study

We considered four networks whose characteristics are summarized in Table 3; those networks were generated from Alarm, Insurance, and Child networks by the tiling algorithm (Tsamardinos et al., 2006). We compare the performances of ECOS to those of the following state-of-the-art greedy algorithms: MMHC and greedy hill-climbing (HC), both using a TABU search extension; the TABU list size was set to 100 as in Tsamardinos et al. (2006). COS is not included in this evaluation because COS and ECOS are learning the same networks (or at least networks having the same score, that is, the best one possible given the structural constraint). Further, COS cannot be applied to such large networks when using such high values for α (cf. Perrier et al. 2008). The super-structures were generated in two different ways: the true skeleton was given or a skeleton was inferred by using MMPC (Tsamardinos et al., 2006) implemented in the Causal Explorer System

Table 4: Coverage and average degree of super-structures for each experimental condition (mean ± standard deviation).

(Aliferis et al., 2003) with a significance level $\alpha \in \{0.01, 0.02, 0.05\}$. Ten data sets of 500, 1,000, and 10,000 samples were synthetically generated from each BN considered. Here, we evaluate and discuss the cases of Alarm5, Alarm10, Insurance5, Insurance10, Child5, and Child10 with 1,000 and 10,000 samples. The results of all the cases including the remaining ones are summarized in the supplemental material. To help evaluate the quality of the super-structures learnt by MMPC, we

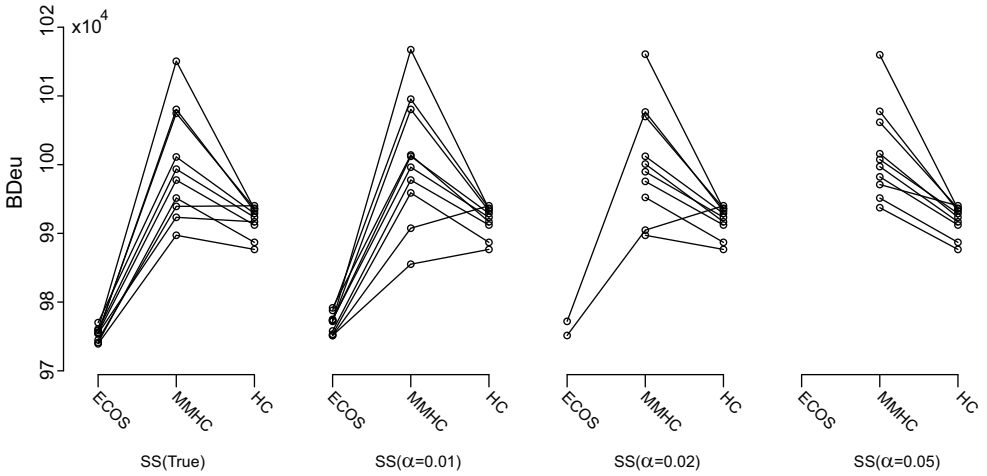

Figure 5: BDeu scores for ten data sets of Alarm10 with 10,000 samples.

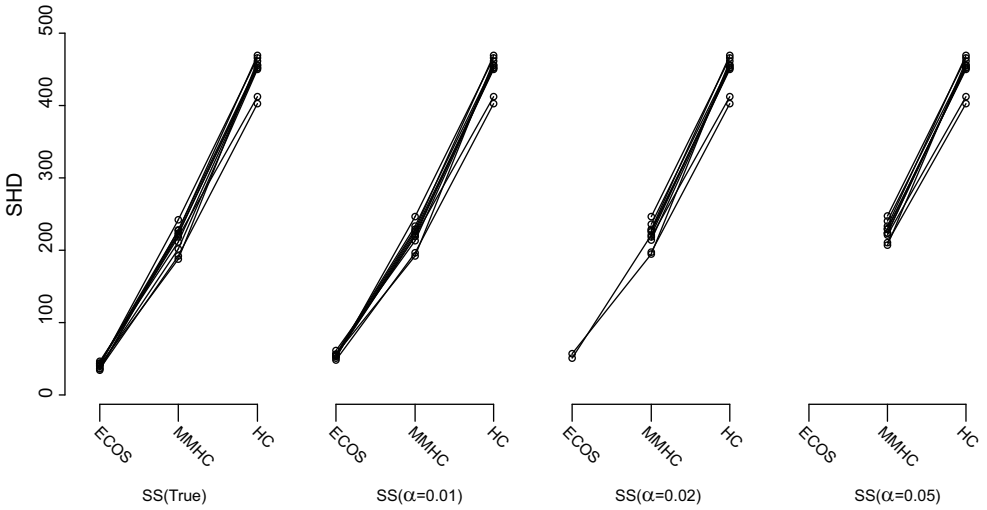

Figure 6: Values of SHD for ten data sets of Alarm10 with 10,000 samples.

summarized the ratio of true edges learnt (this ratio is called coverage) and the average degree of the super-structures in Table 4.

For every experimental condition, the algorithms are compared both in terms of score (we used the negative BDeu score, that is, smaller values are better) and structural hamming distance (SHD, Tsamardinos et al. 2006) that counts the number of differences in the completed partially DAG (CPDAG, Chikdering 2002) of the true network and the learnt one.

Figures 5 and 6 respectively show BDeu and SHD scores of ECOS, MMHC, and HC for ten data sets of Alarm10 with 10,000 samples given the true skeleton and super-structures inferred by MMPC with $\alpha = 0.01$, 0.02, and 0.05. In order to clarify the relation between the results of ECOS, MMHC, and HC for each data set, results from the same data set are linked up. In addition,

the scaling of the plots for the four conditions are the same, and therefore, the results of HC are the same for the four structural constraints considered. For the true skeleton and super-structures obtained with $\alpha = 0.01$, all ten computations of ECOS finished within two days and ECOS gives the best scores in all the data sets both in terms of BDeu and SHD. In terms of BDeu, HC usually performs better than MMHC, whereas it is the opposite in terms of SHD.

For $\alpha = 0.02$, only two computations of ECOS finished within two days; nonetheless, the computed scores are better than those of MMHC and HC both in terms of BDeu and SHD. For the super-structures of $\alpha = 0.05$, no computations of ECOS finished within two days. However, every time ECOS finished, it gave better results than both HC and MMHC. With regard to the structural constraint, the best results were obtained when the true skeleton was known. Further, for $\alpha = 0.01$, MMHC is better than HC for two data sets; but for $\alpha = 0.02$, it is better for one data set; and $\alpha = 0.05$, it is better for no data sets. Because the coverage of super-structures with $\alpha = 0.01$ for Alarm10 with 10,000 samples is already maximal, as shown in Table 4, super-structures for higher α contain more false-positive edges, which worsens the results of MMHC. We observe the same results in terms of SHD as well.

BDeu and SHD scores for all the experiments are summarized in Tables 5 and 6; for each experimental setup, the best result is in bold and the best result without the knowledge of the true skeleton is underlined. The numbers in parentheses for ECOS represent the number of times ECOS could finish within ten data sets in two days. The cases in which no computation finished are indicated by "none". Note that all computations of MMHC and HC finished in two days. BDeu and SHD scores of the finished computations are averaged and rounded off to the nearest integer.

While HC outperforms MMHC in BDeu, MMHC outperforms HC in SHD, which agrees with the results in Tsamardinos et al. (2006). A comparison of the results of MMHC and HC suggests that a structural constraint helps to find networks with smaller SHD. However, this should not mislead us into thinking that minimizing a score function is not a good method to learn a graph having a small SHD. In fact, ECOS returns considerably better results than both MMHC and HC in terms of SHD, strongly illustrating the validity of score-based approaches and also the use of a structural constraint.

One could argue that it is possible to increase the quality of the results returned by MMHC by using a larger α. However, as we can see in Table 6, although the score improves with higher α, it is not always the case with the SHD. This is expected because MMHC converges to HC with an increasing α; hence, it is essential in the greedy case to properly select α. On the other hand, ECOS converges to OS for increasing significance levels. Although in rare cases, SHD slightly worsens with an increasing α, we should generally use as large a significance level as possible when applying ECOS, while ensuring that the algorithm finishes.

The average running time for the experiments in seconds (rounded off to the nearest integer) are summarized in Table 7. All the algorithms except for MMPC are implemented in Java. For ECOS and MMHC, the running time of MMPC is also included. Among the experiments performed till the end, ECOS requires the maximum computational time (around 34 hours) in Insurance10 with 10,000 samples and the true skeleton. The maximum memory space (10 GB) was required by ECOS during Insurance10 with 1,000 samples and $\alpha = 0.01$. Fortunately, for all experimental setups, ECOS outperformed the other two methods both in BDeu and SHD. Although it stopped for some $\alpha > 0.01$, our algorithm is still better with $\alpha = 0.01$ than MMHC with $\alpha = 0.05$.

Model	Sample Size	α	Algorithm

5. Discussion and Conclusion

We presented a new BN learning algorithm that finds the optimal network given a structural constraint, the super-structure. Our algorithm decomposes the super-structure into several clusters and computes optimal networks on each cluster for every ancestral constraint in order to ensure acyclic networks. Experimental evaluations using extended Alarm, Insurance, and Child networks show that our algorithm outperforms state-of-the-art greedy algorithms such as MMHC and HC with a TABU search extension both in terms of the BDeu score and SHD.

It may be possible to develop methods to further increase the feasibility of ECOS; we suggest some ready-to-apply tunings that should make our algorithm faster. First, the algorithm is highly parallelizable since each call to ACOS can be made independently. Further, one could apply a similar shrinkage technique to the interior nodes of the block tree as well if they are of a small size. The algorithm may also benefit from using ECOS recursively instead of ACOS or applying a COS search on the unbreakable clusters rather than a full OS (as is the current case with ACOS). Finally, limiting the maximal size of parent sets by a constant c, as proposed in Section 3.6, improves the feasibility of ECOS because it may also reduce the number of TDMs to consider in some cases. In terms of quality of the learnt network, the best improvements may be realized by developing better algorithms to learn super-structures; in fact, improvements in speed may also be obtained.

If there exist many edges between strongly connected components in the skeleton, the clusters obtained have too many cluster edges; this is usually the main bottleneck of our algorithm that limits its the feasibility. We should emphasize the fact that IT approaches add false-positive edges to the skeleton according to the specified significance level when learning the super-structure. Therefore, although the true skeleton may be well structured (i.e., the true skeleton can be clustered with a small number of cluster edges), the false-positive edges tend to be cluster edges and limit the feasibility of ECOS. For example, the super-structure of Insurance10 obtained with $\alpha = 0.05$ has a smaller average degree than the true skeleton; however, our algorithm did not finish the computation in two days. In addition, since the current version of ECOS depends on a super-structure estimated by the conditional independence test (MMPC), a causal relationship violating faithfulness, for example, XOR parents, can be missed.

We now consider whether our method is practically different from the one suggested by Friedman et al. (1999) and whether it is more efficient. Although we can argue that our method has been implemented and tested practically, it is also obvious that both strategies are different since ECOS can be applied on a skeleton that is not only decomposable in cluster trees but also decomposable in cluster graphs. For example, we converted the true skeleton of Alarm5 into a cluster tree. The true skeleton was decomposed into nine clusters, the largest of them containing 34 vertices and 20 cluster edges. This is not computable for an optimal search, and therefore, the method proposed by Friedman et al. (1999) would not be able to consider this case; such a case motivated us to relax the tree structure condition between clusters. Following the experimental results, we conclude that our approach, that is, decomposing the search on every cluster, succeeded in scaling-up the constrained optimal search.

We would like to thank André Fujita and Masao Nagasaki for their helpful comments in the initial stage of this work. Computational resources were provided by the Human Genome Center, Institute of Medical Science, University of Tokyo.

Appendix A.

Given a cluster C and a TDM δ (i.e., the corresponding $V_{C,\delta}^{in}$ and $V_{C,\delta}^{out}$ sets), we define for every possible NACS $\mathcal{A}$.

Definition 7 (NACS template) *The NACS template of $\mathcal{A}$ is a finite list of pairs of positive integers $\{(I_1,O_1),\cdots,(I_l,O_l)\}$ such that $|V_{C,\delta}^{out}| \geq O_1 > \cdots > O_l \geq 0$ and there are exactly I_k in-vertices v_j^{in} such that $|\mathcal{A}(v_j^{in})| = O_k$.*

For example, let us consider the following NACS $\mathcal{A}$ with $V_{C,\delta}^{in} = \{v_1^{in},\ldots,v_6^{in}\}$ and $V_{C,\delta}^{out} = \{v^{out},\ldots,v_3^{out}\}$ defined by

$$\begin{aligned}
\mathcal{A}(v_1^{in}) &= \{v_1^{out},v_2^{out},v_3^{out}\},\\
\mathcal{A}(v_6^{in}) &= \{v_1^{out},v_3^{out},v_3^{out}\},\\
\mathcal{A}(v_2^{in}) &= \{v_1^{out},v_3^{out}\},\\
\mathcal{A}(v_4^{in}) &= \{v_3^{out}\},\\
\mathcal{A}(v_3^{in}) &= \{v_3^{out}\},\\
\mathcal{A}(v_5^{in}) &= \emptyset.
\end{aligned}$$

Here, we arranged the AC sets by size to illustrate the fact that due to the definition of NACS, two in-vertices having the same size of ancestral constraint actually have the same ancestral constraint. The NACS template of $\mathcal{A}$ is

$$\{(2,3),(1,2),(2,1),(1,0)\}.$$

Further, following the definition of the NACS template, we have trivially that $\sum_{i=1}^{l} I_i = |V_{C,\delta}^{in}|$. Because every NACS admits a unique NACS template, templates define a partition of the space of NACS. Given the template $\{(I_1,O_1),\cdots,(I_l,O_l)\}$, there exist

$$\begin{pmatrix} |V_{C,\delta}^{out}| \\ O_1 \end{pmatrix} \times \begin{pmatrix} O_1 \\ O_2 \end{pmatrix} \times \cdots \times \begin{pmatrix} O_{l-1} \\ O_l \end{pmatrix}$$

different ways to assign the out-vertices and

$$\begin{pmatrix} |V_{C,\delta}^{in}| \\ I_1 \end{pmatrix} \times \begin{pmatrix} |V_{C,\delta}^{in}| - I_1 \\ I_2 \end{pmatrix} \times \cdots \times \begin{pmatrix} |V_{C,\delta}^{in}| - \sum_{i=1}^{l-1} I_i \\ I_l \end{pmatrix}$$

different ways to assign in-vertices. The product of these two values gives the number of NACSs corresponding to this template. All these NACSs can be generated by a brute force method that considers every possibility. Next, we introduce an algorithm that generates an ordered list of all NACSs by considering each template successively, starting from $(|V_{C,\delta}^{in}|,0)$ and ending with $(|V_{C,\delta}^{in}|,|V_{C,\delta}^{out}|)$.

Algorithm 7: NACS Enumerator
Input: A set of in-vertices $V_{C,\delta}^{in}$ and a set of out-vertices $V_{C,\delta}^{out}$
Onput: List of NACSs, L

1. Initialize an empty list of NACSs L.
2. Initialize a NACS template NT to $(|V^{in}_{C,\delta}|, 0)$ and l to 1.
3. While true, do:
   (a) Put all the NACSs having NT as template at the end of L.
   (b) If $NT = \{(|V^{in}_{C,\delta}|, |V^{out}_{C,\delta}|)\}$, return L.
   (c) If $l > 1$ and $O_{l-1} = O_l + 1$, increment I_{l-1}, otherwise insert $(1, O_l + 1)$ in NT immediately before (I_l, O_l) and increment l.
   (d) Decrement I_l and set O_l to 0.
   (e) If $I_l = 0$, remove (I_l, O_l) from NT and decrement l.

First, we define an order relation for the templates; we say that $(I_i, O_i) > (I'_j, O'_j)$ if $O_i > O'_j$ or $O_i = O'_j$ and $I_i > I'_j$. Then, we say that a NACS template NT is greater than another NT' if $(I_1, O_1) > (I'_1, O'_1)$ or $(I_j, O_j) = (I'_j, O'_j)$ for every $j < k$ and $(I_k, O_k) > (I'_k, O'_k)$. We note that if $\mathcal{A}_1 > \mathcal{A}_2$, then the template of $\mathcal{A}_1$ is greater than that of $\mathcal{A}_2$. Therefore, to prove that Algorithm 7 is correct, we simply need to prove that it considers every template in increasing order, that is, that the loop of step 3 generates the successor of a given template NT. Given the constraint that the sum of all I_k is $|V^{in}_{C,\delta}|$, there exist three different cases. If NT is of a size $l = 1$, then $NT = \{(|V^{in}_{C,\delta}|, O_1)\}$ and the following template is $\{(1, O_1 + 1), (|V^{in}_{C,\delta}| - 1, 0)\}$, as done in steps (c) and (d). Otherwise, in a similar manner to the previous case, if $O_{l-1} \neq O_l + 1$, the next template will be $\{(I_1, O_1), \cdots, (I_{l-1}, O_{l-1}), (1, O_l + 1), (I_l - 1, 0)\}$, as in Algorithm 7. Finally, in general, $O_{l-1} = O_l + 1$ holds, and we simply need to increment I_{l-1}, decrement I_l, and reset O_l to 0. After decrementing I_l, it is possible that $I_l = 0$, in which case the last element should be removed. Since Algorithm 7 accesses the direct successor of NT at each step starting from the smaller template $(|V^{in}_{C,\delta}|, 0)$ until the largest one, we can assert its correctness.

Abstract

A wide variety of machine learning problems can be described as minimizing a regularized risk functional, with different algorithms using different notions of risk and different regularizers. Examples include linear Support Vector Machines (SVMs), Gaussian Processes, Logistic Regression, Conditional Random Fields (CRFs), and Lasso amongst others. This paper describes the theory and implementation of a scalable and modular convex solver which solves all these estimation problems. It can be parallelized on a cluster of workstations, allows for data-locality, and can deal with regularizers such as L_1 and L_2 penalties. In addition to the unified framework we present tight convergence bounds, which show that our algorithm converges in $O(1/\varepsilon)$ steps to ε precision for general convex problems and in $O(\log(1/\varepsilon))$ steps for continuously differentiable problems. We demonstrate the performance of our general purpose solver on a variety of publicly available data sets.

Keywords: optimization, subgradient methods, cutting plane method, bundle methods, regularized risk minimization, parallel optimization

1. Introduction

At the heart of many machine learning algorithms is the problem of minimizing a regularized risk functional. That is, one would like to solve

$$\min_w J(w) := \lambda\Omega(w) + R_{\text{emp}}(w), \tag{1}$$

$$\text{where } R_{\text{emp}}(w) := \frac{1}{m}\sum_{i=1}^{m} l(x_i, y_i, w) \tag{2}$$

is the empirical risk. Moreover, $x_i \in \mathcal{X} \subseteq \mathbb{R}^d$ are referred to as training instances and $y_i \in \mathcal{Y}$ are the corresponding labels. l is a (surrogate) convex loss function measuring the discrepancy between y and the predictions arising from using w. For instance, w might enter our model via $l(x,y,w) = (\langle w,x\rangle - y)^2$, where $\langle\cdot,\cdot\rangle$ denotes the standard Euclidean dot product. Finally, $\Omega(w)$ is a convex function serving the role of a regularizer with regularization constant $\lambda > 0$. Typically Ω is differentiable and cheap to compute. In contrast, the empirical risk term $R_{\text{emp}}(w)$ is often non-differentiable, and almost always computationally expensive to deal with.

For instance, if we consider the problem of predicting binary valued labels $y \in \{\pm 1\}$, we can set $\Omega(w) = \frac{1}{2}\|w\|_2^2$ (i.e., L_2 regularization), and the loss $l(x,y,w)$ to be the binary hinge loss, $\max(0, 1 - y\langle w,x\rangle)$, thus recovering linear Support Vector Machines (SVMs) (Joachims, 2006). Using the same regularizer but changing the loss function to $l(x,y,w) = \log(1+\exp(-y\langle w,x\rangle))$, yields logistic regression. Extensions of these loss functions allow us to handle structure in the output space (Bakir et al., 2007) (also see Appendix A for a comprehensive exposition of many common loss functions). On the other hand, changing the regularizer $\Omega(w)$ to the sparsity inducing $\|w\|_1$ (i.e., L_1 regularization) leads to Lasso-type estimation algorithms (Mangasarian, 1965; Tibshirani, 1996; Candes and Tao, 2005).

If the objective function J is differentiable, for instance in the case of logistic regression, we can use smooth optimization techniques such as the standard quasi-Newtons methods like BFGS or its limited memory variant LBFGS (Nocedal and Wright, 1999). These methods are effective and efficient even when m and d are large (Sha and Pereira, 2003; Minka, 2007). However, it is not straightforward to extend these algorithms to optimize a non-differentiable objective, for instance, when dealing with the binary hinge loss (see, e.g., Yu et al., 2008).

When J is non-differentiable, one can use nonsmooth convex optimization techniques such as the cutting plane method (Kelly, 1960) or its *stabilized* version the bundle method (Hiriart-Urruty and Lemaréchal, 1993). The bundle methods not only stabilize the optimization procedure but make the problem a well-posed one, that is, with unique solution. However, the amount of *external* stabilization that needs to be added is a parameter that requires careful tuning.

In this paper, we bypass this stabilization parameter tuning problem by taking a different route. The resultant algorithm – Bundle Method for Regularized Risk Minimization (BMRM) – has certain desirable properties: a) it has no parameters to tune, and b) it is applicable to a wide variety of regularized risk minimization problems. Furthermore, we show that BMRM has an $O(1/\varepsilon)$ rate of convergence for nonsmooth problems and $O(\log(1/\varepsilon))$ for smooth problems. This is significantly tighter than the $O(1/\varepsilon^2)$ rates provable for standard bundle methods (Lemaréchal et al., 1995). A related optimizer, SVM$^{\text{struct}}$ (Tsochantaridis et al., 2005), which is widely used in machine learning applications was also shown to converge at $O(1/\varepsilon^2)$ rates. Our analysis also applies to SVM$^{\text{struct}}$, which we show to be a special case of our solver, and hence tightens its convergence rate to $O(1/\varepsilon)$.

Very briefly, we highlight the two major advantages of our implementation. First, it is completely modular; new loss functions, regularizers, and solvers can be added with relative ease. Second, our architecture allows the empirical risk computation (2) to be easily parallelized. This makes our solver amenable to large data sets which cannot fit into the memory of a single computer. Our open source C/C++ implementation is freely available for download.[1]

The outline of our paper is as follows. In Section 2 we describe BMRM and contrast it with standard bundle methods. We also prove rates of convergence. In Section 3 we discuss implementation issues and present principled techniques to control memory usage, as well as to speed up computation via parallelization. Section 4 puts our work in perspective, and discusses related work. Section 5 is devoted to extensive experimental evaluation, which shows that our implementation is comparable to or better than specialized state-of-the-art solvers on a number of publicly available data sets. Finally, we conclude our work and discuss related issues in Section 6. In Appendix A we describe various *classes* of loss functions organized according to their common traits in computation. Long proofs are relegated to Appendix B. Before we proceed a brief note about our notation:

1.1 Notation

The indices of elements of a sequence or a set appear in subscript, for example, u_1, u_2. The i-th component of a vector u is denoted by $u^{(i)}$. $[k]$ is the shorthand for the set $\{1, 2, \ldots, k\}$. The L_p norm is defined as $\|u\|_p = (\sum_{i=1}^{d} |u^{(i)}|^p)^{1/p}$, for $p \geq 1$, and we use $\|\cdot\|$ to denote $\|\cdot\|_2$ whenever the context is clear. $\mathbf{1}_d$ and $\mathbf{0}_d$ denote the d-dimensional vectors of all ones and zeros respectively.

2. Bundle Methods

The precursor to the bundle methods is the cutting plane method (CPM) (Kelly, 1960). CPM uses subgradients, which are a generalization of gradients appropriate for convex functions, including those which are not necessarily smooth. Suppose w' is a point where a convex function J is finite. Then a subgradient is the normal vector of any tangential supporting hyperplane of J at w' (see Figure 1 for geometric intuition). Formally s' is called a subgradient of J at w' if, and only if,

$$J(w) \geq J(w') + \left\langle w - w', s' \right\rangle \quad \forall w. \tag{3}$$

The set of all subgradients at w' is called the subdifferential, and is denoted by $\partial_w J(w')$. If this set is not empty then J is said to be *subdifferentiable at* w'. On the other hand, if this set is a singleton then the function is said to be *differentiable* at w'. Convex functions are subdifferentiable everywhere in their domain (Hiriart-Urruty and Lemaréchal, 1993).

As implied by (3), J is bounded from below by its linearization (i.e., first order Taylor approximation) at w'. Given subgradients $s_1, s_2, \ldots, s_t$ evaluated at locations $w_0, w_1, \ldots, w_{t-1}$, we can state a tighter (piecewise linear) lower bound for J as follows

$$J(w) \geq J_t^{\mathrm{CP}}(w) := \max_{1 \leq i \leq t} \{J(w_{i-1}) + \langle w - w_{i-1}, s_i \rangle\}. \tag{4}$$

This lower bound forms the basis of the CPM, where at iteration t the set $\{w_i\}_{i=0}^{t-1}$ is augmented by

$$w_t := \operatorname*{argmin}_w J_t^{\mathrm{CP}}(w).$$

1. Software available at `http://users.rsise.anu.edu.au/~chteo/BMRM.html`.

This iteratively refines the piecewise linear lower bound J^{CP} and allows us to get close to the minimum of J (see Figure 2 for an illustration).

If w^* denotes the minimizer of J, then clearly each $J(w_i) \geq J(w^*)$ and hence $\min_{0 \leq i \leq t} J(w_i) \geq J(w^*)$. On the other hand, since $J \geq J_t^{\mathrm{CP}}$ it follows that $J(w^*) \geq J_t^{\mathrm{CP}}(w_t)$. In other words, $J(w^*)$ is sandwiched between $\min_{0 \leq i \leq t} J(w_i)$ and $J_t^{\mathrm{CP}}(w_t)$ (see Figure 3 for an illustration). The CPM monitors the monotonically decreasing quantity

$$\varepsilon_t := \min_{0 \leq i \leq t} J(w_i) - J_t^{\mathrm{CP}}(w_t),$$

and terminates whenever ε_t falls below a predefined threshold ε. This ensures that the solution $J(w_t)$ satisfies $J(w_t) \leq J(w^*) + \varepsilon$.

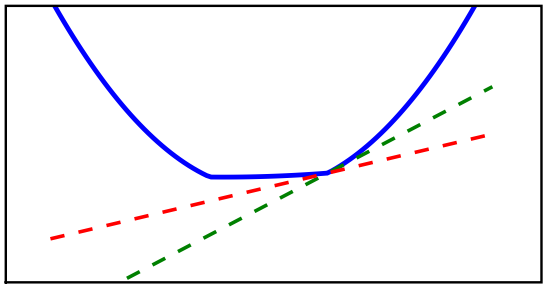

Figure 1: Geometric intuition of a subgradient. The nonsmooth convex function (solid blue) is only subdifferentiable at the "kink" points. We illustrate two of its subgradients (dashed green and red lines) at a "kink" point which are tangential to the function. The normal vectors to these lines are subgradients.

2.1 Standard Bundle Methods

Although CPM was shown to be convergent (Kelly, 1960), it is well known (see, e.g., Lemaréchal et al., 1995; Belloni, 2005) that CPM can be very slow when new iterates move too far away from the previous ones (i.e., causing unstable "zig-zag" behavior in the iterates).

Bundle methods stabilize CPM by augmenting the piecewise linear lower bound (e.g., $J_t^{\mathrm{CP}}(w)$ as in (4)) with a prox-function (i.e., proximity control function) which prevents overly large steps in the iterates (Kiwiel, 1990). Roughly speaking, there are 3 popular types of bundle methods, namely, *proximal* (Kiwiel, 1990), *trust region* (Schramm and Zowe, 1992), and *level set* (Lemaréchal et al., 1995).[2] All three versions use $\frac{1}{2}\|\cdot\|^2$ as their prox-function, but differ in the way they compute the

2. For brevity we will only describe "first-order" bundle methods, and omit discussion about "second-order" variants such as the bundle-Newton method of Lukšan and Vlček (1998).

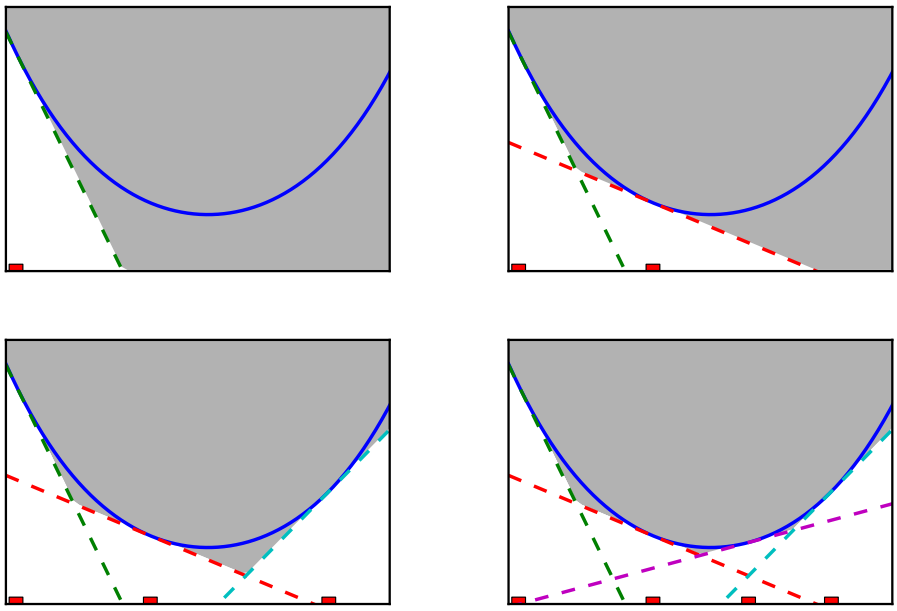

Figure 2: A convex function (blue solid curve) is bounded from below by its linearizations (dashed lines). The gray area indicates the piecewise linear lower bound obtained by using the linearizations. We depict a few iterations of the cutting plane method. At each iteration the piecewise linear lower bound is minimized and a new linearization is added at the minimizer (red rectangle). As can be seen, adding more linearizations improves the lower bound.

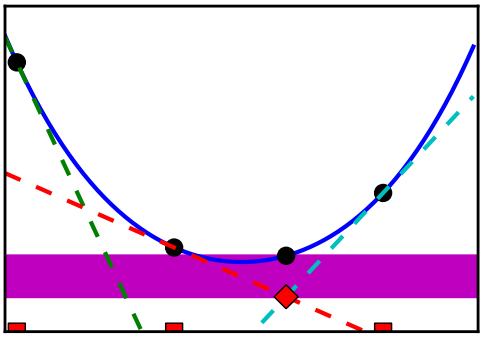

Figure 3: A convex function (blue solid curve) with three linearizations (dashed lines) evaluated at three different locations (red squares). The approximation gap ϵ_3 at the end of third iteration is indicated by the height of the magenta horizontal band, that is, difference between lowest value of $J(w)$ evaluated so far (lowest black circle) and the minimum of $J_3^{\mathrm{CP}}(w)$ (red diamond).

new iterate:

$$\text{proximal:} \quad w_t := \operatorname*{argmin}_w \{\tfrac{\zeta_t}{2}\|w-\hat{w}_{t-1}\|^2 + J_t^{\mathrm{CP}}(w)\}, \tag{5}$$

$$\text{trust region:} \quad w_t := \operatorname*{argmin}_w \{J_t^{\mathrm{CP}}(w) \mid \tfrac{1}{2}\|w-\hat{w}_{t-1}\|^2 \leq \kappa_t\}, \tag{6}$$

$$\text{level set:} \quad w_t := \operatorname*{argmin}_w \{\tfrac{1}{2}\|w-\hat{w}_{t-1}\|^2 \mid J_t^{\mathrm{CP}}(w) \leq \tau_t\},$$

where $\hat{w}_{t-1}$ is the current prox-center, and ζ_t, κ_t, and τ_t are positive trade-off parameters of the stabilization. Although (5) can be shown to be equivalent to (6) for appropriately chosen ζ_t and κ_t, tuning ζ_t is rather difficult while a trust region approach can be used for automatically tuning κ_t. Consequently the trust region algorithm BT of Schramm and Zowe (1992) is widely used in practice.

Since our methods (see Section 2.2) are closely related to the proximal bundle method, we will now describe them in detail. Similar to the CPM the proximal bundle method also builds a piecewise linear lower bound J_t^{CP} (see (4)). In contrast to the CPM, the piecewise linear lower bound augmented with a stabilization term $\frac{\zeta_t}{2}\|w-\hat{w}_{t-1}\|^2$, is minimized to produce the intermediate iterate $\bar{w}_t$. The approximation gap in this case includes the prox-function:

$$\varepsilon_t := J(\hat{w}_{t-1}) - \left[J_t^{\mathrm{CP}}(\bar{w}_t) + \frac{\zeta_t}{2}\|\bar{w}_t - \hat{w}_{t-1}\|^2\right].$$

If ε_t is less than the pre-defined threshold ε the algorithm exits. Otherwise, a line search is performed along the line joining $\hat{w}_{t-1}$ and $\bar{w}_t$ to produce the new iterate w_t. If w_t results in a sufficient decrease of the objective function then it is accepted as the new prox-center $\hat{w}_t$; this is called a serious step. Otherwise, the prox-center remains the same; this is called a null step. Detailed pseudocode can be found in Algorithm 1.

If the approximation gap ε_t is smaller than ε, then this ensures that the solution $J(\hat{w}_{t-1})$ satisfies $J(\hat{w}_{t-1}) \leq J(w) + \frac{\zeta_t}{2}\|w-\hat{w}_{t-1}\|^2 + \varepsilon$ for all w. In particular, if $J(w^*)$ denotes the optimum as before, then $J(\hat{w}_{t-1}) \leq J(w^*) + \frac{\zeta_t}{2}\|w^*-\hat{w}_{t-1}\|^2 + \varepsilon$. Contrast this with the approximation guarantee of the CPM, which does not involve the $\frac{\zeta_t}{2}\|w^*-\hat{w}_{t-1}\|^2$ term.

Although the positive coefficient ζ_t is assumed fixed throughout the algorithm, in practice it must be updated after every iteration to achieve faster convergence, and to guarantee a good quality solution (Kiwiel, 1990). Same is the case for κ_t and τ_t in trust region and level set bundle methods, respectively. Although the update is not difficult, the procedure relies on other parameters which require careful *tuning* (Kiwiel, 1990; Schramm and Zowe, 1992; Lemaréchal et al., 1995).

In the next section, we will describe our method (BMRM) which avoids this problem. There are two key differences between BMRM and the proximal bundle method: Firstly, BMRM maintains a piecewise linear lower bound of $R_{\mathrm{emp}}(w)$ instead of $J(w)$. Secondly, the the stabilizer (i.e., $\|w-\hat{w}_t\|^2$) in proximal bundle method is replaced by the regularizer $\Omega(w)$ hence there is no stabilization parameter to tune. As we will see, not only is the implementation straightforward, but the rates of convergence also improve from $O(1/\varepsilon^3)$ or $O(1/\varepsilon^2)$ to $O(1/\varepsilon)$.

Algorithm 1 Proximal Bundle Method

input & initialization: $\varepsilon \geq 0, \rho \in (0,1), w_0, t \leftarrow 0, \hat{w}_0 \leftarrow w_0$
loop
  $t \leftarrow t+1$
  Compute $J(w_{t-1})$ and $s_t \in \partial_w J(w_{t-1})$
  Update model $J_t^{\mathrm{CP}}(w) := \max_{1 \leq i \leq t} \{J(w_{i-1}) + \langle w - w_{i-1}, s_i \rangle\}$
  $\bar{w}_t \leftarrow \operatorname{argmin}_w J_t^{\mathrm{CP}}(w) + \frac{\zeta_t}{2} \|w - \hat{w}_{t-1}\|^2$
  $\varepsilon_t \leftarrow J(\hat{w}_{t-1}) - \left[J_t^{\mathrm{CP}}(\bar{w}_t) + \frac{\zeta_t}{2} \|\bar{w}_t - \hat{w}_{t-1}\|^2\right]$
  if $\varepsilon_t < \varepsilon$ **then return** $\bar{w}_t$
  Linesearch: $\eta_t \leftarrow \operatorname{argmin}_{\eta \in \mathbb{R}} J(\hat{w}_{t-1} + \eta(\bar{w}_t - \hat{w}_{t-1}))$ (if expensive, set $\eta_t = 1$)
  $w_t \leftarrow \hat{w}_{t-1} + \eta_t(\bar{w}_t - \hat{w}_{t-1})$
  if $J(\hat{w}_{t-1}) - J(w_t) \geq \rho\varepsilon_t$ **then**
    SERIOUS STEP: $\hat{w}_t \leftarrow w_t$
  else
    NULL STEP: $\hat{w}_t \leftarrow \hat{w}_{t-1}$
  end if
end loop

2.2 Bundle Methods for Regularized Risk Minimization (BMRM)

Define:

$$\begin{aligned}
\text{(subgradient of } R_{\mathrm{emp}}) \quad & a_t \in \partial_w R_{\mathrm{emp}}(w_{t-1}), \\
\text{(offset)} \quad & b_t := R_{\mathrm{emp}}(w_{t-1}) - \langle w_{t-1}, a_t \rangle, \\
\text{(piecewise linear lower bound of } R_{\mathrm{emp}}) \quad & R_t^{\mathrm{CP}}(w) := \max_{1 \leq i \leq t} \{\langle w, a_i \rangle + b_i\}, \\
\text{(piecewise convex lower bound of } J) \quad & J_t(w) := \lambda\Omega(w) + R_t^{\mathrm{CP}}(w), \\
\text{(iterate)} \quad & w_t := \min_w J_t(w), \\
\text{(approximation gap)} \quad & \varepsilon_t := \min_{0 \leq i \leq t} J(w_i) - J_t(w_t).
\end{aligned}$$

We now describe BMRM (Algorithm 2), and contrast it with the proximal bundle method. At iteration t the algorithm builds the lower bound R_t^{CP} to the empirical risk R_{emp}. The new iterate w_t is then produced by minimizing J_t which is R_t^{CP} augmented with the regularizer Ω; this is the key difference from the proximal bundle method which uses the $\frac{\zeta_t}{2} \|w - \hat{w}_{t-1}\|^2$ prox-function for stabilization. The algorithm repeats until the approximation gap ε_t is less than the pre-defined threshold ε. Unlike standard bundle methods there is no notion of a serious or null step in our algorithm. In fact, our algorithm does not even maintain a prox-center. It can be viewed as a special case of standard bundle methods where the prox-center is always the origin and never updated (hence every step is a null step). Furthermore, unlike the proximal bundle method, the approximation guarantees of our algorithm do not involve the $\frac{\zeta_t}{2} \|w^* - w_t\|^2$ term.

Algorithm 2 is simple and easy to implement as it does not involve a line search. In fact, whenever efficient (exact) line search is available, it can be used to achieve faster convergence as

Algorithm 2 BMRM

input & initialization: $\varepsilon \geq 0, w_0, t \leftarrow 0$
repeat
  $t \leftarrow t+1$
  Compute $a_t \in \partial_w R_{\text{emp}}(w_{t-1})$ and $b_t \leftarrow R_{\text{emp}}(w_{t-1}) - \langle w_{t-1}, a_t \rangle$
  Update model: $R_t^{\text{CP}}(w) := \max_{1 \leq i \leq t} \{\langle w, a_i \rangle + b_i\}$
  $w_t \leftarrow \operatorname{argmin}_w J_t(w) := \lambda\Omega(w) + R_t^{\text{CP}}(w)$
  $\varepsilon_t \leftarrow \min_{0 \leq i \leq t} J(w_i) - J_t(w_t)$
until $\varepsilon_t \leq \varepsilon$
return w_t

observed by Franc and Sonnenburg (2008) in the case of linear SVMs with binary hinge loss.[3] We now turn to a variant of BMRM which uses a line search (Algorithm 3); this is a generalization of the optimized cutting plane algorithm for support vector machines (OCAS) of Franc and Sonnenburg (2008). This variant first builds R_t^{CP} and minimizes J_t to obtain an intermediate iterate w_t. Then, it performs a line search along the line joining w_{t-1}^b and w_t to produce w_t^b which acts like the new prox-center. Note that $w_t - w_{t-1}^b$ is not necessarily a direction of descent; therefore the line search might return a zero step. Instead of using w_t^b as the new iterate the algorithm uses the pre-set parameter θ to generate w_t^c on the line segment joining w_t^b and w_t. Franc and Sonnenburg (2008) report that setting $\theta = 0.9$ works well in practice. It is easy to see that Algorithm 3 reduces to Algorithm 2 if we set $\eta_t = 1$ for all t, and use the same termination criterion. It is worthwhile noting that this variant is not applicable for structured learning problems such as Max-Margin Markov Networks (Taskar et al., 2004), because no efficient line search is known for such problems.

A specialized variant of BMRM which handles quadratic regularizers, that is, $\Omega(w) = \frac{1}{2}\|w\|^2$ was first introduced to the machine learning community by Tsochantaridis et al. (2005) as SVM$^{\text{struct}}$. In particular, SVM$^{\text{struct}}$ handles quadratic regularizers $\Omega(w) = \frac{1}{2}\|w\|^2$ and non-differentiable large margin loss functions such as (24). Its 1-slack formulation (Joachims et al., 2009) can be shown to be equivalent to BMRM for this specific type of regularizer and loss function. Somewhat confusingly, these algorithms are called the cutting plane method even though they are closer in spirit to bundle methods.

2.3 Dual Problems

In this section, we describe how the sub-problem

$$w_t = \operatorname*{argmin}_w J_t(w) := \lambda\Omega(w) + \max_{1 \leq i \leq t} \langle w, a_i \rangle + b_i \tag{7}$$

in Algorithms 2 and 3 is solved via a dual formulation. In fact, we will show that we need not know $\Omega(w)$ at all, instead it is sufficient to work with its Fenchel dual (Hiriart-Urruty and Lemaréchal, 1993):

Definition 1 (Fenchel Dual) *Denote by $\Omega : \mathcal{W} \to \mathbb{R}$ a convex function on a convex set $\mathcal{W}$. Then the dual Ω^* of Ω is defined as*

$$\Omega^*(\mu) := \sup_{w \in \mathcal{W}} \langle w, \mu \rangle - \Omega(w). \tag{8}$$

3. A different optimization method but with identical efficient line search procedure is described in Yu et al. (2008).

Algorithm 3 BMRM with Line Search

input & initialization: $\varepsilon \geq 0$, $\theta \in (0,1]$, $w_0^b, w_0^c \leftarrow w_0^b, t \leftarrow 0$
repeat
  $t \leftarrow t+1$
  Compute $a_t \in \partial_w R_{\text{emp}}(w_{t-1}^c)$, and $b_t \leftarrow R_{\text{emp}}(w_{t-1}^c) - \langle w_{t-1}^c, a_t \rangle$
  Update model: $R_t^{\text{CP}}(w) := \max_{1 \leq i \leq t} \{\langle w, a_i \rangle + b_i\}$
  $w_t \leftarrow \operatorname{argmin}_w J_t(w) := \lambda \Omega(w) + R_t^{\text{CP}}(w)$
  Linesearch: $\eta_t \leftarrow \operatorname{argmin}_{\eta \in \mathbb{R}} J(w_{t-1}^b + \eta(w_t - w_{t-1}^b))$
  $w_t^b \leftarrow w_{t-1}^b + \eta_t(w_t - w_{t-1}^b)$
  $w_t^c \leftarrow (1-\theta) w_t^b + \theta w_t$
  $\varepsilon_t \leftarrow J(w_t^b) - J_t(w_t)$
until $\varepsilon_t \leq \varepsilon$
return w_t^b

Several choices of regularizers are common. For $\mathcal{W} = \mathbb{R}^d$ the squared norm regularizer yields

$$\Omega(w) = \frac{1}{2}\|w\|_2^2 \qquad \text{and} \qquad \Omega^*(\mu) = \frac{1}{2}\|\mu\|_2^2.$$

More generally, for L_p norms one obtains (Boyd and Vandenberghe, 2004; Shalev-Shwartz and Singer, 2006):

$$\Omega(w) = \frac{1}{2}\|w\|_p^2 \qquad \text{and} \qquad \Omega^*(\mu) = \frac{1}{2}\|\mu\|_q^2 \text{ where } \frac{1}{p} + \frac{1}{q} = 1.$$

For any positive definite matrix B, we can construct a quadratic form regularizer which allows non-uniform penalization of the weight vector as:

$$\Omega(w) = \frac{1}{2} w^\top B w \qquad \text{and} \qquad \Omega^*(\mu) = \frac{1}{2} \mu^\top B^{-1} \mu.$$

For the *unnormalized* negative entropy, where $\mathcal{W} = \mathbb{R}_+^d$, we have

$$\Omega(w) = \sum_i w^{(i)} \log w^{(i)} \qquad \text{and} \qquad \Omega^*(\mu) = \sum_i \exp \mu^{(i)}.$$

For the *normalized* negative entropy, where $\mathcal{W} = \{w \mid w \geq 0 \text{ and } \|w\|_1 = 1\}$ is the probability simplex, we have

$$\Omega(w) = \sum_i w^{(i)} \log w^{(i)} \qquad \text{and} \qquad \Omega^*(\mu) = \log \sum_i \exp \mu^{(i)}.$$

If Ω is differentiable the w at which the supremum of (8) is attained can be written as $w = \partial_\mu \Omega^*(\mu)$ (Boyd and Vandenberghe, 2004). In the sequel we will always assume that Ω^* is twice differentiable. Note that all the regularizers we discussed above are twice differentiable. The following theorem states the dual problem of (7).

Theorem 2 *Denote by $A = [a_1, \ldots, a_t]$ the matrix whose columns are the (sub)gradients, and let $b = [b_1, \ldots, b_t]$. The dual problem of*

$$w_t = \operatorname*{argmin}_{w \in \mathbb{R}^d} \{J_t(w) := \max_{1 \le i \le t} \langle w, a_i \rangle + b_i + \lambda \Omega(w)\} \quad \text{is} \tag{9}$$

$$\alpha_t = \operatorname*{argmax}_{\alpha \in \mathbb{R}^t} \{J_t^*(\alpha) := -\lambda \Omega^*(-\lambda^{-1} A\alpha) + \alpha^\top b \mid \alpha \ge 0,\ \|\alpha\|_1 = 1\}. \tag{10}$$

Furthermore, w_t and α_t are related by the dual connection $w_t = \partial \Omega^*(-\lambda^{-1} A\alpha_t)$.

Proof We rewrite (9) as a constrained optimization problem: $\min_{w,\xi} \lambda\Omega(w) + \xi$ subject to $\xi \ge \langle w, a_i \rangle + b_i$ for $i = 1, \ldots, t$. By introducing non-negative Lagrange multipliers α and recalling that $\mathbf{1}_t$ denotes the t dimensional vector of all ones, the corresponding Lagrangian can be written as

$$L(w, \xi, \alpha) = \lambda\Omega(w) + \xi - \alpha^\top \left(\xi \mathbf{1}_t - A^\top w - b\right) \text{ with } \alpha \ge 0, \tag{11}$$

where $\alpha \ge 0$ denotes that each component of α is non-negative. Taking derivatives with respect to ξ yields $1 - \alpha^\top \mathbf{1}_t = 0$. Moreover, minimization of L with respect to w implies solving $\max_w \left\langle w, -\lambda^{-1} A\alpha \right\rangle - \Omega(w) = \Omega^*(-\lambda^{-1} A\alpha)$. Plugging both terms back into (11) we eliminate the primal variables ξ and w. ■

Since Ω^* is assumed to be twice differentiable and the constraints of (10) are simple, one can easily solve (10) with standard smooth optimization methods such as the *penalty/barrier* methods (Nocedal and Wright, 1999). Recall that for the square norm regularizer $\Omega(w) = \frac{1}{2}\|w\|_2^2$, commonly used in SVMs and Gaussian Processes, the Fenchel dual is given by $\Omega^*(\mu) = \frac{1}{2}\|\mu\|_2^2$. The following corollary is immediate:

Corollary 3 *For quadratic regularization, that is, $\Omega(w) = \frac{1}{2}\|w\|_2^2$, (10) becomes*

$$\alpha_t = \operatorname*{argmax}_{\alpha \in \mathbb{R}^t} \{-\tfrac{1}{2\lambda} \alpha^\top A^\top A\alpha + \alpha^\top b \mid \alpha \ge 0,\ \|\alpha\|_1 = 1\}.$$

This means that for quadratic regularization the dual optimization problem is a quadratic program (QP) where the number of constraints equals the number of (sub)gradients computed previously. Since t is typically in the order of 10s to 100s, the resulting QP is very cheap to solve. In fact, we do not even need to know the (sub)gradients explicitly. All that is required to define the QP are the inner products between (sub)gradients $\langle a_i, a_j \rangle$.

2.4 Convergence Analysis

While the variants of bundle methods we proposed are intuitively plausible, it remains to be shown that they have good rates of convergence. In fact, past results, such as those by Tsochantaridis et al. (2005) suggest a slow $O(1/\varepsilon^2)$ rate of convergence. In this section we tighten their results and show an $O(1/\varepsilon)$ rate of convergence for nonsmooth loss functions and $O(\log(1/\varepsilon))$ rates for smooth loss functions under mild assumptions. More concretely we prove the following two convergence results:

(a) Assume that $\max_{u \in \partial_w R_{\text{emp}}(w)} \|u\| \le G$. For regularizers $\Omega(w)$ for which $\left\|\partial_\mu^2 \Omega^*(\mu)\right\| \le H^*$ we prove $O(1/\varepsilon)$ rate of convergence, that is, we show that our algorithm converges to within ε of the optimal solution in $O(1/\varepsilon)$ iterations.

(b) Under the above conditions, if furthermore $\left\|\partial_w^2 J(w)\right\| \leq H$, that is, the Hessian of J is bounded, we can show $O(\log(1/\varepsilon))$ rate of convergence.

For our convergence proofs we use a duality argument similar to those put forward in Shalev-Shwartz and Singer (2006) and Tsochantaridis et al. (2005), both of which share key techniques with Zhang (2003). Recall that ε_t denotes our approximation gap, which in turn upper bounds how far away we are from the optimal solution. In other words, $\varepsilon_t \geq \min_{0\leq i\leq t} J(w_i) - J^*$, where J^* denotes the optimum value of the objective function J. The quantity $\varepsilon_t - \varepsilon_{t+1}$ can thus be viewed as the "progress" made towards J^* in iteration t. The crux of our proof argument lies in showing that for nonsmooth loss functions the recurrence $\varepsilon_t - \varepsilon_{t+1} \geq c \cdot \varepsilon_t^2$ holds for some appropriately chosen constant c. The rates follow by invoking a lemma from Abe et al. (2001). In the case of the smooth losses we show that $\varepsilon_t - \varepsilon_{t+1} \geq c' \cdot \varepsilon_t$ thus implying an $O(\log(1/\varepsilon))$ rate of convergence.

In order to show the required recurrence, we first observe that by strong duality the values of the primal and dual problems (9) and (10) are equal at optimality. Hence, any progress in J_{t+1} can be computed in the dual. Next, we observe that the solution of the dual problem (10) at iteration t, denoted by α_t, forms a feasible set of parameters for the dual problem (10) at iteration $t+1$ by means of the parameterization $(\alpha_t, 0)$, that is, by padding α_t with a 0. The value of the objective function in this case equals $J_t(w_t)$.

To obtain a lower bound on the improvement due to $J_{t+1}(w_{t+1})$ we perform a 1-d optimization along $((1-\eta)\alpha_t, \eta)$ in (10). The constraint $\eta \in (0,1)$ ensures dual feasibility. We will then bound this improvement in terms of ε_t. Note that, in general, solving the dual problem (10) results in a increase which is larger than that obtained via the line search. The 1-d minimization is used only for analytic tractability. We now state our key theorem and prove it in Appendix B.

Theorem 4 *Assume that* $\max_{u\in\partial_w R_{\mathrm{emp}}(w)} \|u\| \leq G$ *for all* $w \in \operatorname{dom} J$. *Also assume that* Ω^* *has bounded curvature, that is,* $\left\|\partial_\mu^2 \Omega^*(\mu)\right\| \leq H^*$ *for all* $\mu \in \{-\lambda^{-1}\sum_{i=1}^{t+1}\alpha_i a_i$ *where* $\alpha_i \geq 0,\ \forall i$ *and* $\sum_{i=1}^{t+1}\alpha_i = 1\}$. *In this case we have*

$$\varepsilon_t - \varepsilon_{t+1} \geq \tfrac{\varepsilon_t}{2}\min(1, \lambda\varepsilon_t/4G^2H^*). \tag{12}$$

Furthermore, if $\left\|\partial_w^2 J(w)\right\| \leq H$, *then we have*

$$\varepsilon_t - \varepsilon_{t+1} \geq \begin{cases} \varepsilon_t/2 & \text{if } \varepsilon_t > 4G^2H^*/\lambda \\ \lambda/8H^* & \text{if } 4G^2H^*/\lambda \geq \varepsilon_t \geq H/2 \\ \lambda\varepsilon_t/4HH^* & \text{otherwise.} \end{cases}$$

Note that the error keeps on halving initially and settles for a somewhat slower rate of convergence after that, whenever the Hessian of the overall risk is bounded from above. The reason for the difference in the convergence bound for differentiable and non-differentiable losses is that in the former case the gradient of the risk converges to 0 as we approach optimality, whereas in the former case, no such guarantees hold (e.g., when minimizing $|x|$ the (sub)gradient does not vanish at the optimum). The dual of many regularizers, for example, norm, squared L_p norm, and the entropic regularizer have bounded second derivative. See, for example, Shalev-Shwartz and Singer (2006) for a discussion and details. Thus our condition $\left\|\partial_\mu^2 \Omega^*(\mu)\right\| \leq H^*$ is not unreasonable. We are now in a position to state our convergence results. The proof is in Appendix B.

Theorem 5 *Assume that $J(w) \geq 0$ for all w. Under the assumptions of Theorem 4 we can give the following convergence guarantee for Algorithm 2. For any $\varepsilon < 4G^2H^*/\lambda$ the algorithm converges to the desired precision after*

$$n \leq \log_2 \frac{\lambda J(0)}{G^2 H^*} + \frac{8G^2 H^*}{\lambda \varepsilon} - 1$$

steps. Furthermore if the Hessian of $J(w)$ is bounded, convergence to any $\varepsilon \leq H/2$ takes at most the following number of steps:

$$n \leq \log_2 \frac{\lambda J(0)}{4G^2 H^*} + \frac{4H^*}{\lambda} \max\left[0, H - 8G^2 H^*/\lambda\right] + \frac{4HH^*}{\lambda} \log(H/2\varepsilon).$$

Several observations are in order: First, note that the number of iterations only depends *logarithmically* on how far the initial value $J(0)$ is away from the optimal solution. Compare this to the result of Tsochantaridis et al. (2005), where the number of iterations is linear in $J(0)$.

Second, we have an $O(1/\varepsilon)$ dependence in the number of iterations in the non-differentiable case, as opposed to the $O(1/\varepsilon^2)$ rates of Tsochantaridis et al. (2005). In addition to that, the convergence is $O(\log(1/\varepsilon))$ for continuously differentiable problems.

Note that whenever R_{emp} is the average over many piecewise linear functions, R_{emp} behaves essentially like a function with bounded Hessian as long as we are taking large enough steps not to "notice" the fact that the term is actually nonsmooth.

Remark 6 *For $\Omega(w) = \frac{1}{2}\|w\|^2$ the dual Hessian is exactly $H^* = 1$. Moreover we know that $H \geq \lambda$ since $\left\|\partial_w^2 J(w)\right\| = \lambda + \left\|\partial_w^2 R_{\text{emp}}(w)\right\|$.*

Effectively the rate of convergence of the algorithm is governed by upper bounds on the primal and dual curvature of the objective function. This acts like a condition number of the problem—for $\Omega(w) = \frac{1}{2} w^\top Q w$ the dual is $\Omega^*(z) = \frac{1}{2} z^\top Q^{-1} z$, hence the largest eigenvalues of Q and Q^{-1} would have a significant influence on the convergence.

In terms of λ the number of iterations needed for convergence is $O(\lambda^{-1})$. In practice the iteration count *does* increase with λ, albeit not as badly as predicted. This is likely due to the fact that the empirical risk R_{emp} is typically rather smooth and has a certain inherent curvature which acts as a natural regularizer in addition to the regularization afforded by $\lambda\Omega(w)$.

For completeness we also state the convergence guarantees for Algorithm 3 and provide a proof in Appendix B.3.

Theorem 7 *Under the assumptions of Theorem 4 Algorithm 3 converges to the desired precision ε after*

$$n \leq \frac{8G^2 H^*}{\lambda \varepsilon}$$

steps for any $\varepsilon < 4G^2H^*/\lambda$.

3. Implementation Issues

In this section, we discuss the memory and computational issues of the implementation of BMRM. In addition, we provide two variants of BMRM: one is memory efficient and the other one is parallelized.

3.1 Solving the BMRM Subproblem (7) with Limited Memory Space

In Section 2.3 we mentioned the dual of subproblem (7) (i.e., (10)) which is usually easier to solve when the dimensionality d of the problem is larger than the number of iterations t required by BMRM to reach desired precision ε. Although t is usually in the order of 10^2, a problem with d in the order of 10^6 or higher may use up all memory of a typical machine to store the bundle, that is, linearizations $\{(a_i, b_i)\}$, before the convergence is achieved.[4] Here we describe a principled technique which controls the memory usage while maintaining convergence guarantees.

Note that at iteration t, before the computation for new iterate w_t, Algorithm 2 maintains a bundle of t (sub)gradients $\{a_i\}_{i=1}^{t}$ of R_{emp} computed at the locations $\{w_i\}_{i=0}^{t-1}$. Furthermore, the Lagrange multipliers α_{t-1} obtained in iteration $t-1$ satisfy $\alpha_{t-1} \geq 0$ and $\sum_{i=1}^{t-1} \alpha_{t-1}^{(i)} = 1$ by the constraints of (10). We define the *aggregated* (sub)gradient $\hat{a}_I$, offset $\hat{b}_I$ and Lagrange multiplier $\hat{\alpha}_{t-1}^{(I)}$ as

$$\hat{a}_I := \frac{1}{\hat{\alpha}_{t-1}^{(I)}} \sum_{i \in I} \alpha_{t-1}^{(i)} a_i, \quad \hat{b}_I := \frac{1}{\hat{\alpha}_{t-1}^{(I)}} \sum_{i \in I} \alpha_{t-1}^{(i)} b_i, \quad \text{and} \quad \hat{\alpha}_{t-1}^{(I)} := \sum_{i \in I} \alpha_{t-1}^{(i)},$$

respectively, where $I \subseteq [t-1]$ is an index set (Kiwiel, 1983). Clearly, the optimality of (10) at the end of iteration $t-1$ is maintained when a subset $\left\{(a_i, b_i, \alpha_{t-1}^{(i)})\right\}_{i \in I}$ is replaced by the aggregate $(\hat{a}_I, \hat{b}_I, \hat{\alpha}_{t-1}^{(I)}))$ for any $I \subseteq [t-1]$.

To obtain a new iterate w_t via (10) with memory space for at most k linearizations, we can, for example, replace $\{(a_i, b_i)\}_{i \in I}$ with $(\hat{a}_I, \hat{b}_I)$ where $I = [t-k+1]$ and $2 \leq k \leq t$. Then, we solve a k-dimensional variant of (10) with $A := [\hat{a}_I, a_{t-k+2}, \ldots, a_t]$, $b := [\hat{b}_I, b_{t-k+2}, \ldots, b_t]$, and $\alpha \in \mathbb{R}^k$. The optimum of this variant will be lower than or equal to that of (10) as the latter has higher degree of freedom than the former. Nevertheless, solving this variant with $2 \leq k \leq t$ will still guarantee convergence (recall that our convergence proof only uses $k = 2$). In the sequel we name the aforementioned number k as the "bundle size" since it indicates the number of linearizations the algorithm keeps.

For concreteness, we provide here a memory efficient BMRM variant for the cases where $\Omega(w) = \frac{1}{2}\|w\|_2^2$ and $k = 2$. We first see that the dual of subproblem (7) now reads:

$$\begin{aligned} \eta &= \operatorname*{argmax}_{0 \leq \eta \leq 1} -\tfrac{1}{2\lambda} \left\| \hat{a}_{[t-1]} + \eta(a_t - \hat{a}_{[t-1]}) \right\|_2^2 + \hat{b}_{[t-1]} + \eta(b_t - \hat{b}_{[t-1]}) \\ &\equiv \operatorname*{argmax}_{0 \leq \eta \leq 1} -\tfrac{\eta}{\lambda} \hat{a}_{[t-1]}^\top (a_t - \hat{a}_{[t-1]}) - \tfrac{\eta^2}{2\lambda} \left\| a_t - \hat{a}_{[t-1]}^\top \right\|^2 + \eta(b_t - \hat{b}_{[t-1]}). \end{aligned} \tag{13}$$

Since (13) is quadratic in η, we can obtain the optimal η by setting the derivative of the objective in (13) to zero and clipping η in the range $[0, 1]$:

$$\eta = \min\left(\max\left(0, \frac{b_t - \hat{b}_{[t-1]} + w_{t-1}^\top a_t + \lambda \|w_{t-1}\|^2}{\frac{1}{\lambda}\|a_t + \lambda w_{t-1}\|^2}\right), 1\right) \tag{14}$$

4. In practice, we can remove those linearizations $\{(a_i, b_i)\}$ whose Lagrange multipliers α_i are 0 after solving (10). Although this heuristic works well and does not affect the convergence guarantee, there is no bound on the minimum number of linearizations with non-zero Lagrange multipliers needed to achieve convergence.

where $w_{t-1} = -\frac{1}{\lambda}\hat{a}_{[t-1]}$ by the dual connection. With the optimal η, we obtain the new primal iterate $w_t = (1-\eta)w_{t-1} - (\eta/\lambda)a_t$. Algorithm 4 lists the details. Note that this variant is simple to implement and does not require a QP solver.

Algorithm 4 BMRM with Aggregation of Previous Linearizations

input & initialization: $\varepsilon \geq 0, w_0, t \leftarrow 1$
Compute $a_1 \in \partial_w R_{\text{emp}}(w_0)$, and $b_1 \leftarrow R_{\text{emp}}(w_0) - \langle w_0, a_1 \rangle$
$w_1 \leftarrow -\frac{1}{\lambda}a_1$
$\hat{b}_{[1]} \leftarrow b_1$
repeat
  $t \leftarrow t+1$
  Compute $a_t \in \partial_w R_{\text{emp}}(w_{t-1})$ and $b_t \leftarrow R_{\text{emp}}(w_{t-1}) - \langle w_{t-1}, a_t \rangle$
  Compute η using Eq. (14)
  $w_t \leftarrow (1-\eta)w_{t-1} - (\eta/\lambda)a_t$
  $\hat{b}_{[t]} \leftarrow (1-\eta)\hat{b}_{[t-1]} + \eta b_t$
  $\varepsilon_t \leftarrow \min_{0 \leq i \leq t} \frac{\lambda}{2}\|w_i\|^2 + R_{\text{emp}}(w_i) - \frac{\lambda}{2}\|w_t\|^2 - \hat{b}_{[t]}$
until $\varepsilon_t \leq \varepsilon$

3.2 Parallelization

Algorithms 2, 3, and 4 the evaluation of $R_{\text{emp}}(w)$ (and $\partial_w R_{\text{emp}}(w)$) is cleanly separated from the computation of new iterate and the choice of regularizer. If R_{emp} is additively decomposable over the examples (x_i, y_i), that is, can be expressed as a sum of some independent loss terms $l(x_i, y_i, w)$, then we can parallelize these algorithms easily by splitting the data sets and the computation R_{emp} over multiple machines. This parallelization scheme not only reduces the computation time but also allows us to handle data set with size exceeding the memory available on a single machine.

Without loss of generality, we describe a parallelized version of Algorithm 2 here. Assume there are p slave machines and 1 master machine available. At the beginning, we partition a given data set $D = \{(x_i, y_i)\}_{i=1}^m$ into p disjoint sub-datasets $\{D_i\}_{i=1}^p$ and assign one sub-dataset to each slave machine. At iteration t, the master first broadcasts the current iterate w_{t-1} to all p slaves (e.g., using MPI function `MPI::Broadcast` Gropp et al. 1999). The slaves then compute the losses and (sub)gradients on their local sub-datasets in parallel. As soon as the losses and (sub)gradients computation finished, the master combines the results (e.g., using `MPI::AllReduce`). With the combined (sub)gradient and offset, the master computes the new iterate w_t as in Algorithms 2 and 3. This process repeats until convergence is achieved. Detailed pseudocode can be found in Algorithm 5.

4. Related Research

The *kernel trick* is widely used to transform many existing machine learning algorithms into ones operating on a Reproducing Kernel Hilbert Space (RKHS). One lifts w into an RKHS and replaces all inner product computations with a positive definite kernel function $k(x, x') \leftarrow \langle x, x' \rangle$. Examples of algorithms which employ the kernel trick (but essentially still solve (1)) include Support Vector regression (Vapnik et al., 1997), novelty detection (Schölkopf et al., 2001), Huber's robust regression, quantile regression (Takeuchi et al., 2006), ordinal regression (Herbrich et al., 2000), rank-

Algorithm 5 Parallel BMRM

input: $\varepsilon \geq 0$, w_0, data set D, number of slave machines p
initialization: $t \leftarrow 0$, assign sub-dataset D_i to slave i, $i = 1, \ldots, p$
repeat
  $t \leftarrow t + 1$
  Master: Broadcast w_{t-1} to all slaves
  Slaves: Computes $R^i_{\text{emp}}(w_{t-1}) := \sum_{(x,y)\in D_i} l(x, y, w_{t-1})$ and $a^i_t \in \partial_w R^i_{\text{emp}}(w_{t-1})$
  Master: Aggregate $a_t := \frac{1}{|D|}\sum_{i=1}^{p} a^i_t$ and $b_t := \frac{1}{|D|}\sum_{i=1}^{p} R^i_{\text{emp}}(w_{t-1}) - \langle w_{t-1}, a_t \rangle$
  Master: Update model $R^{\text{CP}}_t(w) := \max_{1\leq j\leq t}\{\langle w, a_j \rangle + b_j\}$
  Master: $w_t \leftarrow \operatorname{argmin}_w J_t(w) := \lambda\Omega(w) + R^{\text{CP}}_t(w)$
  Master: $\varepsilon_t \leftarrow \min_{0\leq i\leq t} J(w_i) - J_t(w_t)$
until $\varepsilon_t \leq \varepsilon$
return w_t

ing (Crammer and Singer, 2005), maximization of multivariate performance measures (Joachims, 2005), structured estimation (Taskar et al., 2004; Tsochantaridis et al., 2005), Gaussian Process regression (Williams, 1998), conditional random fields (Lafferty et al., 2001), graphical models (Cowell et al., 1999), exponential families (Barndorff-Nielsen, 1978), and generalized linear models (Fahrmeir and Tutz, 1994).

Traditionally, specialized solvers have been developed for solving the kernel version of (1) in the dual (see, e.g., Chang and Lin, 2001; Joachims, 1999). These algorithms construct the Lagrange dual, and solve for the Lagrange multipliers efficiently. Only recently, research focus has shifted back to solving (1) in the primal (see, e.g., Chapelle, 2007; Joachims, 2006; Sindhwani and Keerthi, 2006). This spurt in research interest is due to three main reasons: First, many interesting problems in diverse areas such as text classification, word-sense disambiguation, and drug design already employ rich high dimensional data which does not necessarily benefit from the kernel trick. All these domains are characterized by large data sets (with m in the order of a million) and very sparse features (e.g., the bag of words representation of a document). Second, efficient factorization methods (e.g., Fine and Scheinberg, 2001) can be used for a low rank representation of the kernel matrix thereby effectively rendering the problem linear. Third, approximation methods such as the *Random Feature Map* proposed by Rahimi and Recht (2008) can efficiently approximate a infinite dimensional nonlinear feature map associated to a kernel by a finite dimensional one. Therefore our focus on the primal optimization problem is not only pertinent but also timely.

The widely used SVM$^{\text{struct}}$ optimizer of Thorsten Joachims[5] is closely related to BMRM. While BMRM can handle many different regularizers and loss functions, SVM$^{\text{struct}}$ is mainly geared towards square norm regularizers and non-differentiable soft-margin type loss functions. On the other hand, SVM$^{\text{struct}}$ can handle kernels while BMRM mainly focuses on the primal problem.

Our convergence analysis is closely related to Shalev-Shwartz and Singer (2006) who prove mistake bounds for online algorithms by lower bounding the progress in the dual. Although not stated explicitly, essentially the same technique of lower bounding the dual improvement was used by Tsochantaridis et al. (2005) to show polynomial time convergence of the SVM$^{\text{struct}}$ algorithm. The main difference however is that Tsochantaridis et al. (2005) only work with a quadratic ob-

5. Software available at `http://svmlight.joachims.org/svm_struct.html`.

jective function while the framework proposed by Shalev-Shwartz and Singer (2006) can handle arbitrary convex functions. In both cases, a weaker analysis led to $O(1/\varepsilon^2)$ rates of convergence for nonsmooth loss functions. On the other hand, our results establish a $O(1/\varepsilon)$ rate for nonsmooth loss functions and $O(\log(1/\varepsilon))$ rates for smooth loss functions under mild technical assumptions.

Another related work is SVM$^{\text{perf}}$ (Joachims, 2006) which solves the SVM with linear kernel in linear time. SVM$^{\text{perf}}$ finds a solution with accuracy ε in $O(md/(\lambda\varepsilon^2))$ time, where the m training patterns $x_i \in \mathbb{R}^d$. This bound was improved by Shalev-Shwartz et al. (2007) to $\tilde{O}(1/\lambda\delta\varepsilon)$ for obtaining an accuracy of ε with confidence $1-\delta$. Their algorithm, Pegasos, essentially performs stochastic (sub)gradient descent but projects the solution back onto the L_2 ball of radius $1/\sqrt{\lambda}$. Note that Pegasos also can be used in an online setting. This, however, only applies whenever the empirical risk decomposes into individual loss terms (e.g., it is not applicable to multivariate performance scores Joachims 2005).

The third related strand of research considers gradient descent in the primal with a line search to choose the optimal step size (see, e.g., Boyd and Vandenberghe, 2004, Section 9.3.1). Under assumptions of smoothness and strong convexity – that is, the objective function can be upper and lower bounded by quadratic functions – it can be shown that gradient descent with line search will converge to an accuracy of ε in $O(\log(1/\varepsilon))$ steps. Our solver achieves the same rate guarantees for smooth functions, under essentially similar technical assumptions.

We would also like to point out connections to subgradient methods (Nedich and Bertsekas, 2000). These algorithms are designed for nonsmooth functions, and essentially choose an arbitrary element of the subgradient set to perform a gradient descent like update. Let $\max_{u \in \partial_w J(w)} \|u\| \leq G$, and $B(w^*, r)$ denote a ball of radius r centered around the minimizer of $J(w)$. By applying the analysis of Nedich and Bertsekas (2000) to the regularized risk minimization problem with $\Omega(w) := \frac{\lambda}{2}\|w\|^2$, Ratliff et al. (2007) show that subgradient descent with a fixed, but sufficiently small, stepsize will converge linearly to $B(w^*, G/\lambda)$.

Finally, several papers (Keerthi and DeCoste, 2005; Chapelle, 2007) advocate the use of Newton-like methods to solve Support Vector Machines in the "primal". However, they need to take precautions when dealing with the fact that the soft-margin type of loss functions such as the hinge loss is only piecewise differentiable. Instead, our method only requires *subdifferentials*, which always exist for convex functions, in order to make progress. The large number of and variety of implemented problems shows the flexibility of our approach.

5. Experiments

In this section, we examine the convergence behavior of BMRM and show that it is versatile enough to solve a variety of machine learning problems. All our experiments were carried out on a cluster of 24 machines each with a 2.4GHz AMD Dual Core processor and 4GB of RAM. Details of the loss functions, data sets, competing solvers and experimental objectives are described in the following subsections.

5.1 Convergence Behavior

We investigated the convergence rate of our method (Algorithm 2) empirically with respect to regularization constant λ, approximation gap ε, and bundle size k. In addition, we investigated the speedup gained by parallelizing the empirical risk computation. Finally, we examined empirically how generalization performance is related to approximation gap. For simplicity, we focused on the

training of a linear SVM with binary hinge loss:[6]

$$\min_w J(w) := \frac{\lambda}{2}\|w\|^2 + \frac{1}{m}\sum_{i=1}^{m}\max(0, 1 - y_i \langle w, x_i \rangle). \tag{15}$$

The experiments were conducted on 6 data sets commonly used in binary classification studies, namely, adult9, astro-ph, news20-b,[7] rcv1, real-sim, and worm. adult9, news20-b, rcv1, and real-sim are available on the LIBSVM tools website.[8] astro-ph (Joachims, 2006) and worm (Franc and Sonnenburg, 2008) are available upon request from Thorsten Joachims and Soeren Sonnenburg, respectively. Table 1 summarizes the properties of the data sets.

Data Set	#examples m	dimension d	density %
adult9	48,842	123	11.27
astro-ph	94,856	99,757	0.08
news20-b	19,954	1,355,191	0.03
rcv1	677,399	47,236	0.15
real-sim	72,201	20,958	0.25
worm	1,026,036	804	25.00

Table 1: Properties of the binary classification data sets used in our experiments.

5.1.1 REGULARIZATION CONSTANT λ AND APPROXIMATION GAP ε

As suggested by the convergence analysis, the linear SVM with the nonsmooth binary hinge loss should converge in $O(\frac{1}{\lambda\varepsilon})$ iterations, where λ and ε are two parameters which one normally tunes during the model selection phase. Therefore, we investigated the scaling behavior of our method w.r.t. these two parameters. We performed the experiments with unlimited bundle size and with a heuristic that removes subgradients which remained inactive (i.e., Lagrange multiplier = 0) for 10 or more consecutive iterations.[9]

Figure 4 shows the approximation gap ε_t as a function of number of iterations t. As predicted by our convergence analysis, BMRM converges faster for larger values of λ. Furthermore, the empirical convergence curves exhibit a $O(\log(1/\varepsilon))$ rate instead of the (pessimistic) theoretical rate of $O(\frac{1}{\varepsilon})$, especially for large values of λ. Interestingly, BMRM converges faster on high-dimensional text data sets (i.e., astro-ph, news20-b, rcv1, and real-sim) than on lower dimensional data sets (i.e., adult9 and worm).

5.1.2 BUNDLE SIZE

The dual of our method (10) is a concave problem which has dimensionality equal to the number of iterations executed. In the case of linear SVM, (10) is a QP. Hence, as described in Section 3.1, we can trade potentially greater bundle improvement for memory efficiency.

6. Similar behavior was observed with other loss functions.
7. The data set is originally named news20; we renamed it to avoid confusion with the multiclass version of the data set.
8. Software available at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/binary.html`.
9. Note that this heuristic does not have any implication in the convergence analysis.

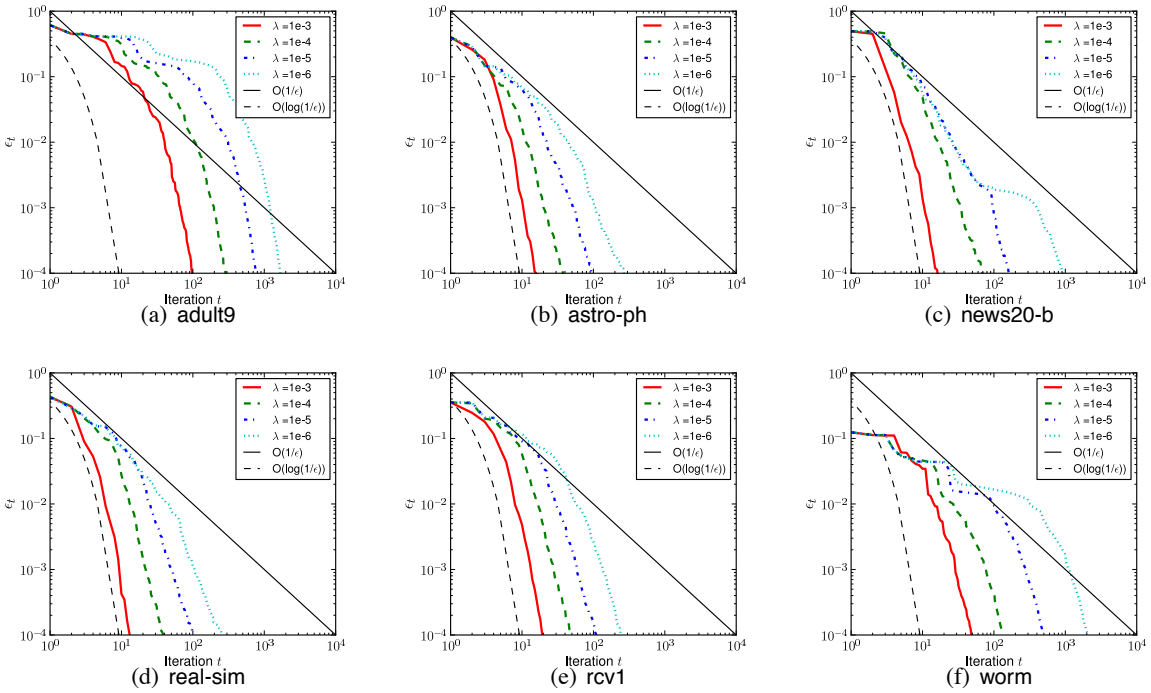

Figure 4: Approximation gap ε_t as a function of number of iterations t; for different regularization constants λ (and unlimited bundle size).

Figure 5 shows the approximation gap ε_t during the training of linear SVM as a function of the number of iterations t, for different bundle sizes $k \in \{2, 10, 50, \infty\}$. In the case of $k = \infty$, we employed the same heuristics which remove inactive linearizations as those mentioned in Section 5.1.1. As expected, the larger k is, the faster the algorithm converges. Although the case $k = 2$ is the slowest, its convergence rate is still faster than the theoretical bound $\frac{1}{\lambda\varepsilon}$.

5.1.3 PARALLELIZATION

When the empirical risk R_{emp} is additively decomposable, the loss and subgradient computation can be executed concurrently on multiple processors for different subsets of data points.[10]

We performed experiments for linear SVMs training with parallelized risk computation on the worm data set. Figure 6(a) shows the wallclock time for the overall training phase (e.g., data loading, risk computation, and solving the QP) and CPU time for just the risk computation as a function of number of processors p. Note that the gap between the two curves essentially tells the runtime upper bound of the sequential part of the algorithm. As expected, both overall and risk computation time decrease as the number of processors p increases. However, in Figure 6(b), we see two different speedups.[11] The speedup for the risk computation is roughly linear as there is no sequential part in

10. This requires only slight modification to the data loading process and the addition of some parallelization related code before and after the code segment for empirical risk computation.

11. Speedup $S_p = \frac{T_1}{T_p}$ where p is the number of processors and T_q is the runtime of the parallelized algorithm on q processors.

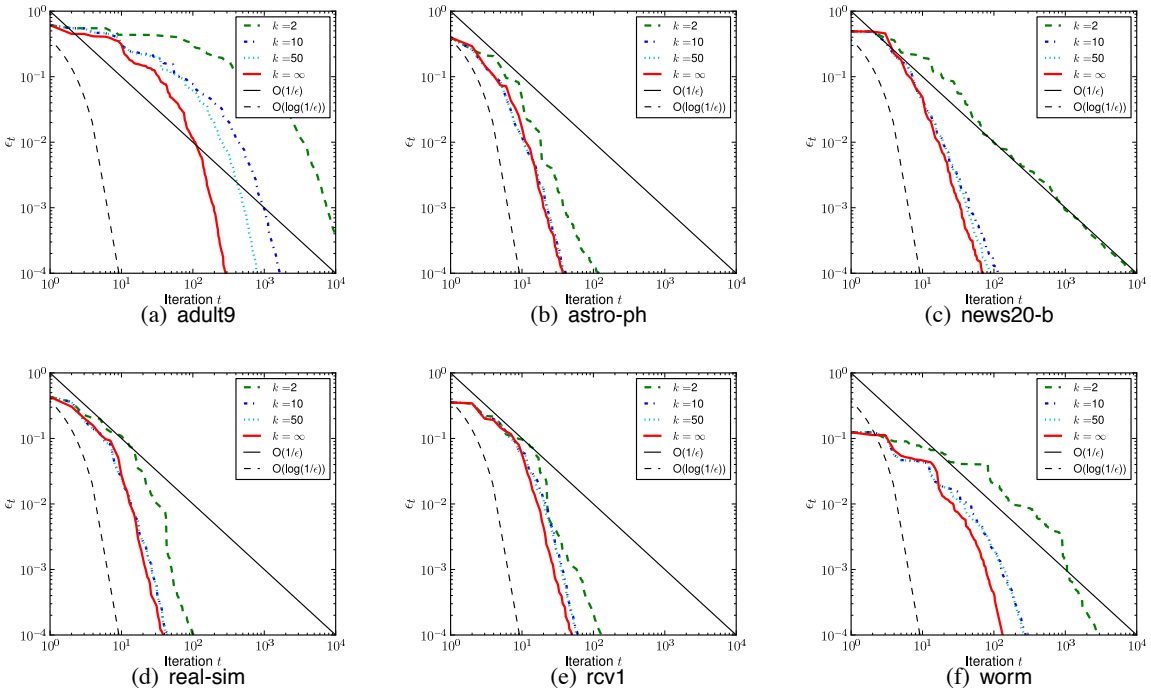

Figure 5: Approximation gap ε_t as a function of number of iterations t; for different bundle sizes k (and fixed regularization constant $\lambda = 10^{-4}$).

it; the speedup of overall computation is approaching a limit[12] as well-explained by Amdahl's law (Amdahl, 1967).

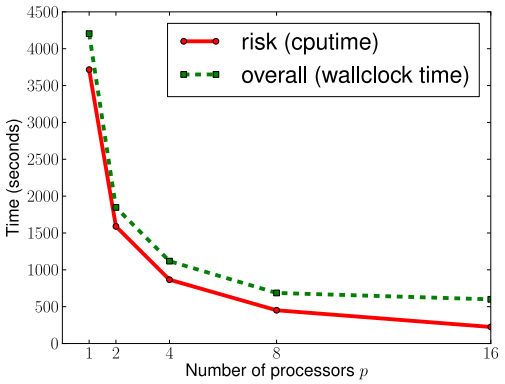
5.1.4 GENERALIZATION VERSUS APPROXIMATION GAP

Since the problems we are considering are convex, all properly convergent optimizers will converge to the same solution. Therefore, comparing generalization performance of the final solution is meaningless. But, in real life one is often interested in the speed with which the algorithm achieves good generalization performance. In this section we study this question. We focus on the generalization (in terms of accuracy) as a function of approximation gap during training. For this experiment, we randomly split each of the data sets into training (60%), validation (20%) and testing (20%) sets.

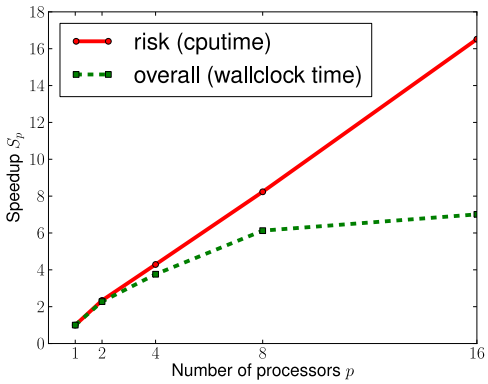
We first obtained the best $\lambda \in \{2^{-20}, \ldots, 2^{0}\}$ for each of the data sets using their corresponding validation sets. With these best λ's, we (re)trained linear SVMs and recorded the testing accuracy as well as the approximation gap at every iteration, with termination criterion $\varepsilon = 10^{-4}$. Figure 7 shows the difference between the testing accuracy evaluated at every iteration and that after training, as a function of approximation gap at each iteration.

From the figure, we see that the testing accuracies for adult9 and worm data sets are less stable in general and the approximation gap must be reduced to at least 10^{-3} to reach the 0.5% regime

12. The limit of speedup is the inverse of the sequential fraction of the algorithm such as the QP.



(a) Risk computation in CPU time (red solid line) and overall computation (i.e., data loading + risk computation + solving the QP) in wallclock time (green dashed line) as a function of number of processors.



(b) Speedup in risk computation (in CPU time) and overall computation (in wallclock time) as a function of number of processors.

Figure 6: CPU and wallclock time for training linear SVM using parallel BMRM on worm data set with varying number of processors $p \in \{1,2,4,8,16\}$. In these experiments, regularization constant $\lambda = 10^{-6}$, and termination criterion $\varepsilon = 10^{-4}$.

of the final testing accuracies; the testing accuracies for the rest of the data sets arrived at the same regime with approximation gap of 10^{-2} or lower.

In general, the generalization improved as the approximation gap decreased. The improvement in generalization became rather insignificant (say, the maximum of changes in testing accuracies is less than 0.1%) when the approximation gap was further reduced to below some effective threshold ε_{eff}; that said, it is not necessary to continue the optimization when $\varepsilon_t \leq \varepsilon_{\text{eff}}$.[13] Since ε_{eff} (or its scale) is not known *a priori* and the asymptotic analysis in Shalev-Schwartz and Srebro (2008) does not reveal the actual scale of ε_{eff} directly applicable in our case, we carried out another set of experiments to investigate if ε_{eff} could be estimated with as little effort as possible: For each data set, we randomly subsampled $10\%,\ldots,50\%$ of the training set as sub-datasets and performed the same experiment on all sub-datasets. We then determined the largest ε_{eff} such that the maximum changes in testing accuracies is less than 0.1%.

Table 5.1.4 shows the (base 10 logarithm of) ε_{eff} for all sub-datasets as well as the full data sets. It seems that the ε_{eff} estimated on a smaller sub-dataset is at most 1 order of magnitude larger than the actual ε_{eff} required on full data set. In addition, we show in the table that the necessary threshold $\varepsilon_{10\%}$ required by the sub-datasets and the full data sets to attain the final testing accuracies attained by the 10% sub-datasets. The observations obey the analysis in Shalev-Schwartz and Srebro (2008) that for a fixed testing accuracy, approximation gap (i.e., optimization error) can be relaxed when more data is given.

13. Heuristically, we could terminate the training phase following the *early stopping* strategy by monitoring the changes in accuracies on validation set evaluated in some most recent iterations.

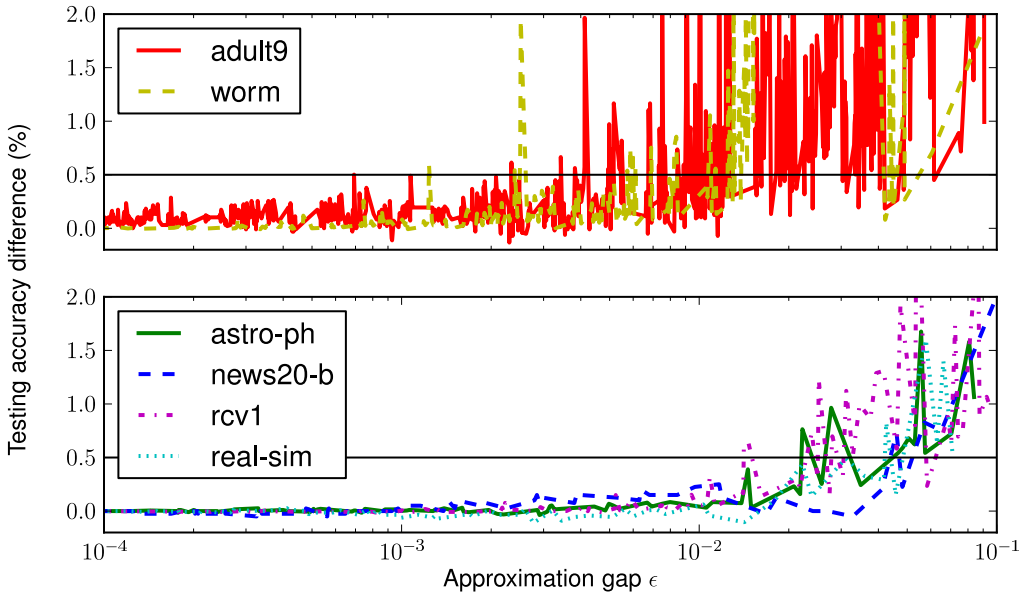


Figure 7: Difference between testing accuracies of intermediate and final models.

5.2 Comparison with Existing Bundle Methods

In this section we compare BMRM with a BT implementation obtained from Schramm and Zowe (1992).[14] We also compare the performance of BMRM (Algorithm 2) and LSBMRM (Algorithm 3). The multiclass line search used in LSBMRM can be found in Yu et al. (2008).

For binary classification, we solve the linear SVM (15) on the data sets: adult9, astro-ph, news20-b, rcv1, real-sim, and worm as mentioned in Section 5.1. For multiclass classification, we solve (Crammer and Singer, 2003):

$$\min_w J(w) := \frac{\lambda}{2}\|w\|^2 + \frac{1}{m}\sum_{i=1}^{m} \max_{y_i' \in [c]} \left\langle w, e_{y_i'} \otimes x_i - e_{y_i} \otimes x_i \right\rangle + \mathbf{I}(y_i \neq y_i'), \tag{16}$$

where c is the number of classes in the problem, e_i is the i-th standard basis for $\mathbb{R}^c$, $\otimes$ denotes Kronecker product; and $\mathbf{I}(\cdot)$ is an indicator function that has value 1 if its argument is evaluated true, and 0 otherwise. The data sets used in multiclass classification experiments were inex, letter, mnist, news20-m,[15] protein, and usps. inex is available for download on the website of Antoine Bordes[16] and the rest can be found on the LIBSVM tools website.[17] Table 3 summarizes the properties of these data sets.

In each of the experiments, we first obtain the optimal weight vector $\bar{w}$ by running BMRM until the termination criteria $J(w_t) - J_t(w_t) \leq 0.01 J(w_t)$ is satisfied. Then we run BT, LSBMRM, and

14. The original FORTRAN implementation was automatically converted into C for use in our library.
15. The data set is originally named news20; we renamed it to avoid confusion with the binary version of the data set.

BMRM until the following termination criteria is satisfied:

$$J(w_t) - J(\bar{w}) \leq 0.01 J(\bar{w}). \tag{17}$$

Figure 8 shows the number of iterations t required by the three methods on each data set to satisfy (17) as a function of regularization constant $\lambda \in \left\{10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}\right\}$. As expected, LSBMRM, which uses an exact line search, outperformed both BMRM and BT on all data sets. BMRM performed better than BT on all high dimensional data sets except news20-m but worse on the rest.

Although BT tunes the stabilization trade-off parameter κ_t automatically, it still does not guarantee superiority over BMRM which is considerably simpler. Nevertheless, external stabilization (in BT) clearly helps speed up the convergence in certain cases.

5.3 Versatility

In the following subsections, we will illustrate some of the applications of BMRM to various machine learning problems with smooth and non-differentiable loss functions, and with different regularizers. Our aim is to show that BMRM is versatile enough to be used in a variety of seemingly different problems. Readers not interested in this aspect of BMRM can safely skip this subsection.

5.3.1 BINARY CLASSIFICATION

In this section, we evaluate the performance of our method BMRM in the training of binary classifier using linear SVMs (15) and logistic loss:

$$\min_w J(w) := \frac{\lambda}{2}\|w\|^2 + \frac{1}{m}\sum_{i=1}^{m} \log(1+\exp(-y_i \langle w, x_i \rangle)),$$

on the binary classification data sets mentioned in Section 5.1 with split similar to that in Section 5.1.4. Since we will compare BMRM with other solvers which use different termination criteria, we consider the CPU time used in reducing the relative difference between the current smallest objective function value and the optimum:

$$\frac{\min_{i \le t} J(w_i) - J(w^*)}{J(w^*)},$$

where w_i is the weight vector at time/iteration i, and w^* is the minimizer obtained by running BMRM until the approximation gap $\varepsilon_t < 10^{-4}$. The best $\lambda \in \{2^{-20}, \ldots, 2^0\}$ for each of the data sets was determined by evaluating the performance on the corresponding validation set.[18]

In the case of linear SVMs, we compared BMRM to three publicly available state of the art *batch learning* solvers:

1. OCAS (Franc and Sonnenburg, 2008). Since this method is equivalent to LSBMRM with binary hinge loss, we refer to this software by LSBMRM for naming consistency.
2. LIBLINEAR (Fan et al., 2008) version 1.33 with option "-s 3".
3. SVM$^{\text{perf}}$ (Joachims, 2006) version 2.5 with option "-w 3" and with double precision floating point numbers.

LIBLINEAR solves the dual problem of linear SVM using a coordinate descent method (Hsieh et al., 2008). SVM$^{\text{perf}}$ was chosen for comparison as it is algorithmically identical to BMRM in this case. Both LIBLINEAR and SVM$^{\text{perf}}$ provide a "shrinking" technique to speed up the algorithms by ignoring some data points which are not likely to affect the objective. Since BMRM does not provide such shrinking technique, we excluded this option in both LIBLINEAR and SVM$^{\text{perf}}$ for a fair comparison.

Figure 9 shows the relative difference in objective value as a function of training time (CPU seconds) for three methods on various data sets. BMRM is faster than SVM$^{\text{perf}}$ on all data sets

18. The corresponding penalty parameter C for LIBLINEAR and OCAS is $1/(m\lambda)$, and for SVM$^{\text{perf}}$ is $1/(100\lambda)$.

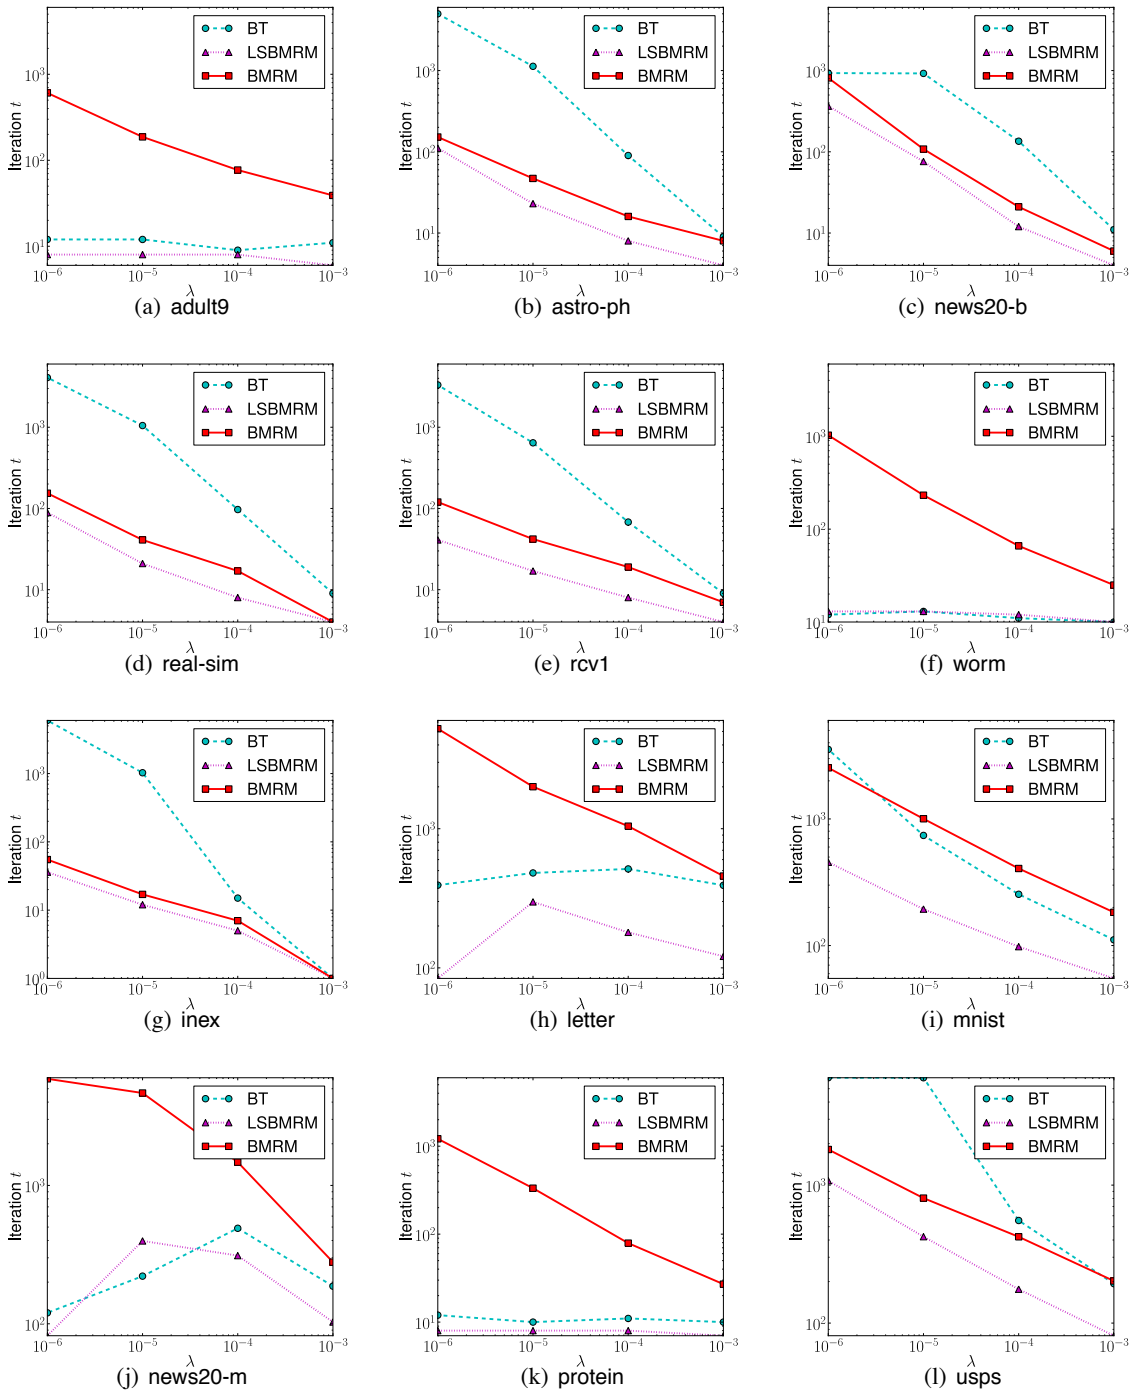

Figure 8: Smallest number of iterations required to satisfy the termination criterion (17) for each data set and various regularization constants. (BT did not satisfy (17) in the inex and usps experiments for $\lambda = 10^{-6}$ after 6000 iterations.)

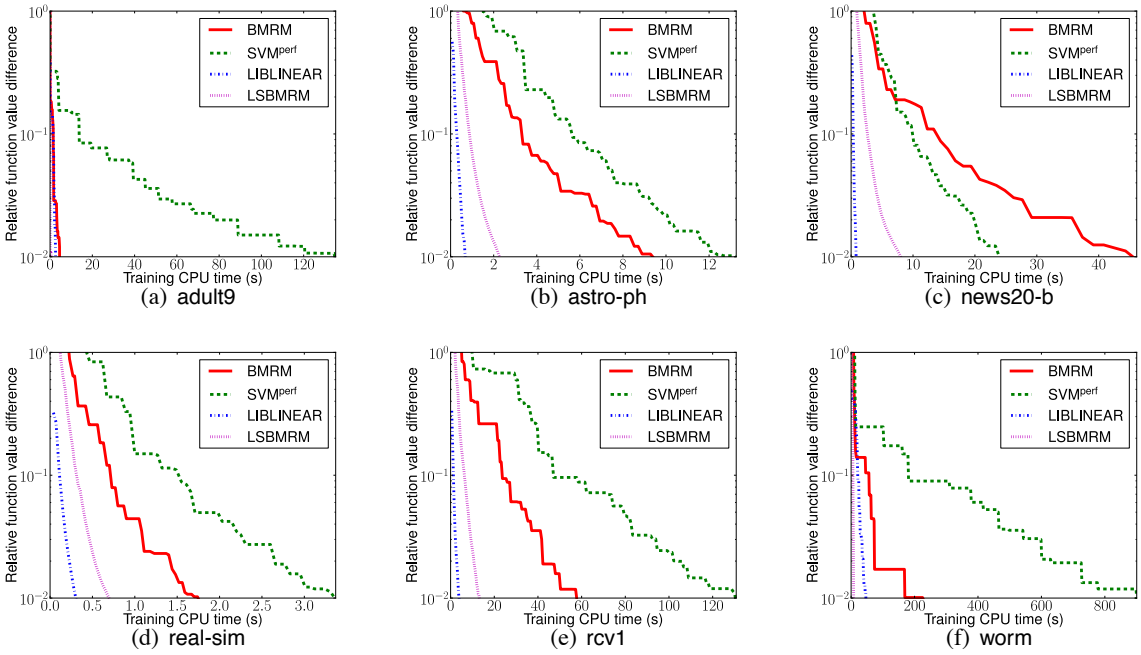

Figure 9: Linear SVMs. Relative primal objective value difference during training.

except news20-b. The performance difference observed here is largely due to the differences in the implementations (e.g., feature vector representation, QP solver, etc.). Nevertheless, both BMRM and SVM^{perf} are significantly outperformed by LSBMRM and LIBLINEAR on all data sets, and LIBLINEAR is almost always faster than LSBMRM. It is clear from the figure that LSBMRM and LIBLINEAR enjoy progression with "strictly" decreasing objective values; whereas the progress of both BMRM and SVM^{perf} are hindered by the "stalling" steps (i.e., the flat line segments in the plots). The fact that LSBMRM is different from BMRM and SVM^{perf} by one additional line search step implies that the "stalling" steps is the time that BMRM and SVM^{perf} improve the approximation at the regions which do not help reducing the primal objective function value.

In the case of logistic regression, we compare BMRM to the state of the art trust region Newton method for logistic regression (Lin et al., 2008) which is also available in the LIBLINEAR package (option "-s 0"). From Figure 10, we see that LIBLINEAR outperforms BMRM on all data sets and that BMRM suffers from the same "stalling" phenomenon as observed in the linear SVMs case.

5.3.2 LEARNING THE COST MATRIX FOR GRAPH MATCHING

In computer vision, there are problems which require matching the objects of interest in a pair of images. These problems are often modeled as attributed graph matching problems where the (extracted) landmark points x_i in the first image x must be matched to the corresponding points $x'_{i'}$ in the second image x'. Note that we represent the *point* x_i or $x'_{i'}$ as d-dimensional feature vectors. The attributed graph matching problem is then cast as a *Linear Assignment Problem* (LAP) which

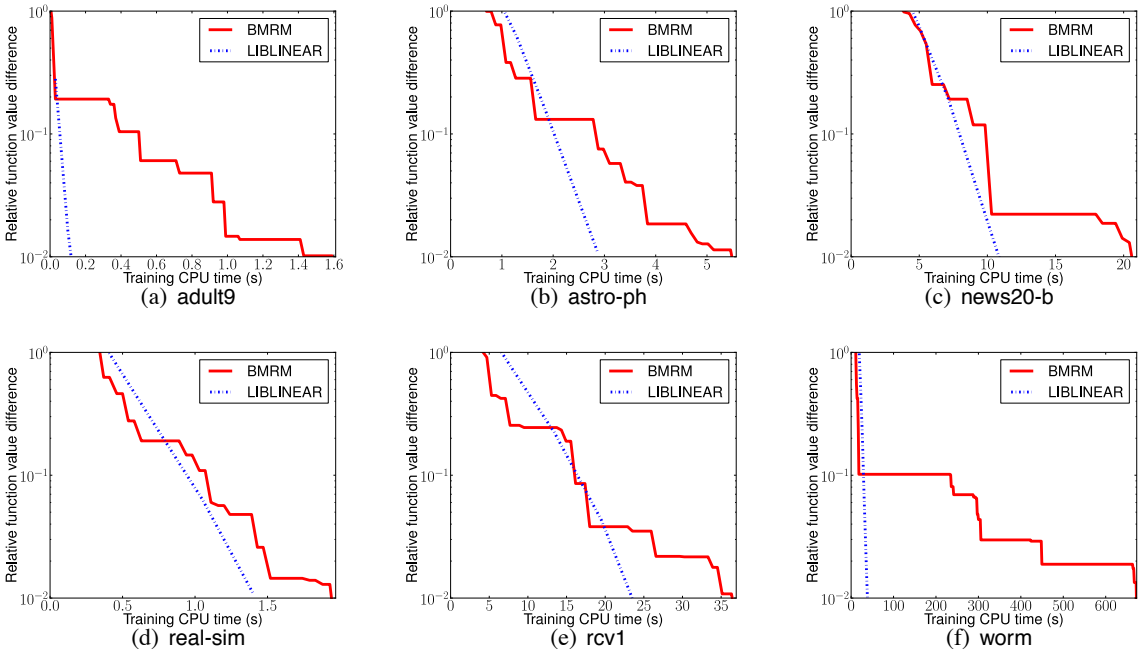

Figure 10: Logistic regression. Relative primal objective value difference during training.

can be solved in worst case $O(n^3)$ time where n is the number of landmark points (Kuhn, 1955).[19] Formally, the LAP reads

$$\max_{y \in \mathcal{Y}} \sum_{i=1}^{n} \sum_{i'=1}^{n} y_{ii'} C_{ii'},$$

where $\mathcal{Y}$ is the set of all $n \times n$ permutation matrices, and $C_{ii'}$ is the cost of matching point x_i to point $x'_{i'}$. In the standard setting of graph matching, one way to determine the cost matrix C is as

$$C_{ii'} := -\sum_{k=1}^{d} \left| x_i^{(k)} - x_{i'}^{\prime(k)} \right|^2.$$

Instead of finding more features to describe the points x_i and $x'_{i'}$ that might improve the matching results, Caetano et al. (2007) propose to learn a weighting to a given set of features that actually improved the matching results in many cases (Caetano et al., 2008).

In Caetano et al. (2007, 2008) the problem of learning the cost matrix for graph matching is formulated as a L_2 regularized risk minimization with loss function

$$l(x, x', y, w) = \max_{\bar{y} \in \mathcal{Y}} \left\langle w, \phi(x, x', \bar{y}) - \phi(x, x', y) \right\rangle + \Delta(\bar{y}, y), \tag{18}$$

where the feature map ϕ is defined as

$$\phi(x, x', y) = -\sum_{i=1}^{n} \sum_{i'=1}^{n} y_{ii'} (|x_i^{(1)} - x_{i'}^{\prime(1)}|^2, \ldots, |x_i^{(d)} - x_{i'}^{\prime(d)}|^2), \tag{19}$$

19. To achieve better matching results, one could further enforce edge-to-edge matching where edge refers to pair of landmark points. This additional matching requirement renders the problem as a *Quadratic Assignment Problem*.

and the label loss Δ is defined as the normalized Hamming loss

$$\Delta(\bar{y}, y) = 1 - \frac{1}{n}\sum_{i=1}^{n}\sum_{i'=1}^{n}\bar{y}_{ii'}y_{ii'}. \tag{20}$$

By (19) and (20), the argument of (18) becomes

$$\left\langle w, \phi(x,x',\bar{y}) - \phi(x,x',y)\right\rangle + \Delta(\bar{y},y) = \sum_{i=1}^{n}\sum_{i'=1}^{n}\bar{y}_{ii'}\tilde{C}_{ii'} + \text{constant},$$

where $\tilde{C}_{ii'} = -\sum_{k=1}^{d} w_k |x_i^{(k)} - x_{i'}^{\prime(k)}|^2 - y_{ii'}/n$. Therefore, (18) is exactly a LAP. We refer interested readers to Caetano et al. (2007, 2008) for more detailed exposition especially on the use of edge matching (in addition to point matching) which leads to much better performance.

We reproduced the experiment in Caetano et al. (2008) that used BMRM with L_2 regularization on the CMU house data set.[20] For this data set, there are 30 hand-labeled landmark points in each image and the features for those points are the 60-dimensional Shape Context features (Belongie et al., 2001; Caetano et al., 2008). The experiments evaluated the performance of the method for training/validation/testing pairs fixed at baselines (separation of frames) $0, 10, \ldots, 90$. Additionally, we ran the same set of experiments with L_1 regularization, that is, $\Omega(w) = \|w\|_1$.[21] The matching performance of the cost matrices augmented with learned weight vectors w's are compared with the original non-learning cost matrix, that is, with uniform weight vector $w = (1, \ldots, 1)$.

Figure 11 shows the results of the experiments. On the left, we see that the matching performance with learned cost matrices are getting more superior to that of non-learning as the baseline increases. The performance of L_1 and L_2 regularized learning are quite similar on average. On the right are the best learned weights for the features using L_1 regularization (top) and L_2 regularization (bottom) for baseline 50. The weights due to L_1 regularization is considerably sparser (i.e., 42 non-zeros) than that due to L_2 regularization (i.e., 52 non-zeros).

5.3.3 HUMAN ACTION SEGMENTATION AND RECOGNITION

In this section, we consider the problem of joint segmentation and recognition of human action from a video sequence using the discriminative Semi-Markov Models (SMM) proposed by Shi et al. (2008). Denote by $x = \{x_i\}_{i=1}^{n} \in \mathcal{X}$ a sequence of n video frames, and by $y = \{(s_i, c_i)\}_{i=1}^{\bar{n}} \in \mathcal{Y}$ the corresponding segment labeling where s_i is the starting location of the i-th segment which ends at $s_{i+1} - 1$, c_i is the frame label for all frames in the segment, and $\bar{n} \leq n$ the number of segments. For ease of presentation, we append a dummy video frame x_{n+1} to x and a dummy segment label $(s_{\bar{n}+1}, c_{\bar{n}+1})$ to y to mark x_{n+1} as the last segment.

In SMM, there exists a *segment* variable for each possible segment (i.e., multiple frames) of x that model the frame label and the boundaries (or length) of a segment jointly; these *segment* variables form a Markov Chain. On the contrary, the Hidden Markov Model (HMM) for the same video x has one *frame label* variable y_i for each video frame x_i. The fact that SMM models multiple frames as one variable allows one to exploit the *structure* and *information* in the problem more efficiently than in HMM. The *structure* exploitation is due to the fact that one human action usually

20. This data set consist of a sequence of 111 images of a toy house. Available at `http://vasc.ri.cmu.edu/idb/html/motion/house/index.html`.

21. Further description on L_1 regularized BMRM can be found in Appendix C.

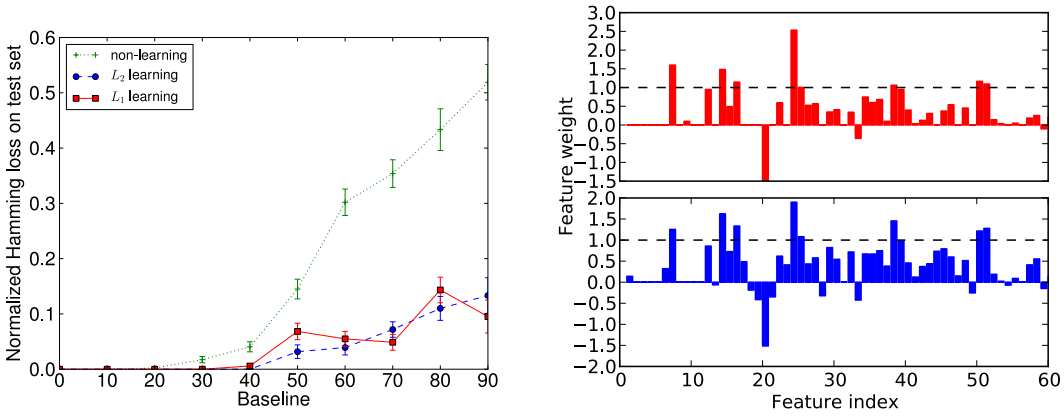

Figure 11: **Left:** Performance on the house data set as the baseline varies. For each baseline, the minimizer of validation loss is evaluated on all testing examples. The corresponding mean normalized Hamming losses (as points) and its standard errors (as error bars) are reported. **Right:** Feature weights for best models trained with L_1 regularization (top) and L_2 regularization (bottom) for baseline 50. Dashed lines indicate the feature weight value 1.

spans several consecutive frames, and the *information* exploitation is due to the possibility to extract features which only become apparent within a segment of several frames.

The discriminative SMM in Shi et al. (2008) is formulated as a regularized risk minimization problem where the loss function is

$$l(x,y,w) = \max_{\bar{y}\in\mathcal{Y}} \langle w, \phi(x,\bar{y}) - \phi(x,y)\rangle + \Delta(\bar{y},y). \tag{21}$$

The feature map ϕ is defined as

$$\phi(x,y) = \left(\sum_{i=1}^{\bar{n}} \phi_1(x,s_i,c_i), \sum_{i=1}^{\bar{n}} \phi_2(x,s_i,s_{i+1},c_i), \sum_{i=1}^{\bar{n}} \phi_3(x,s_i,s_{i+1},c_i,c_{i+1})\right),$$

where ϕ_1, ϕ_2, and ϕ_3 are some feature functions for the segment boundaries, segments, and adjacent segments, respectively. Let y_i be the frame label for x_i according to segment labeling y, the label loss function Δ is defined as

$$\Delta(\bar{y},y) = \sum_{i=1}^{n} \mathbf{I}(\bar{y}_i \neq y_i), \tag{22}$$

where $\mathbf{I}(\cdot)$ is an indicator function as defined in (16). We refer interested readers to Shi et al. (2008) for more details on the features and the dynamic programming to compute (21) and its subgradient.

We followed the experimental setup of Shi et al. (2008) by running BMRM for this problem with L_2 (i.e., $\Omega(w) = \frac{1}{2}\|w\|^2$) and L_1 (i.e., $\Omega(w) = \|w\|_1$) regularization, on the Walk-Bend-Draw (WBD) data sets (Shi et al., 2008) which consists of 18 video sequences with 3 human action classes (i.e.,

walking, *bending*, *drawing*). For this data set, the dimensionality of the image of the feature map ϕ is $d = 9917$.

Table 4 shows the 6 fold cross validation results for our methods (L_1 and L_2 SMM),[22] SVMs and SVM-HMM (Tsochantaridis et al., 2005). The latter two are adopted from Shi et al. (2008). SMM outperforms SVM-HMM and SVM as reported in Shi et al. (2008). Amongst L_1 and L_2 SMMs, the latter performs the best and converged to optimal. Although L_1 SMM failed to satisfy the termination criterion, the performance is comparable to that of L_2 SMM even with a 40 times sparser weight vector (see Figure 12 for the feature weights distributions of L_1 and L_2 SMMs).

Methods	CV mean (std. err.)	#iter.	CPU seconds	nnz(w)
L_2 SMM	0.954 (0.006)	231	1129	3690
L_1 SMM	0.930 (0.010)	500	2659	84
SVM-HMM	0.870 (0.020)	–	–	–
SVM	0.840 (0.030)	–	–	–

Table 4: Experimental results on WBD data set. The second column indicates the mean and standard error of the test accuracy (22). The third and fourth columns indicate the number of iterations and CPU seconds for the training of the final model with the best parameter, and the last column indicates the number of nonzero in the final weight vector w.

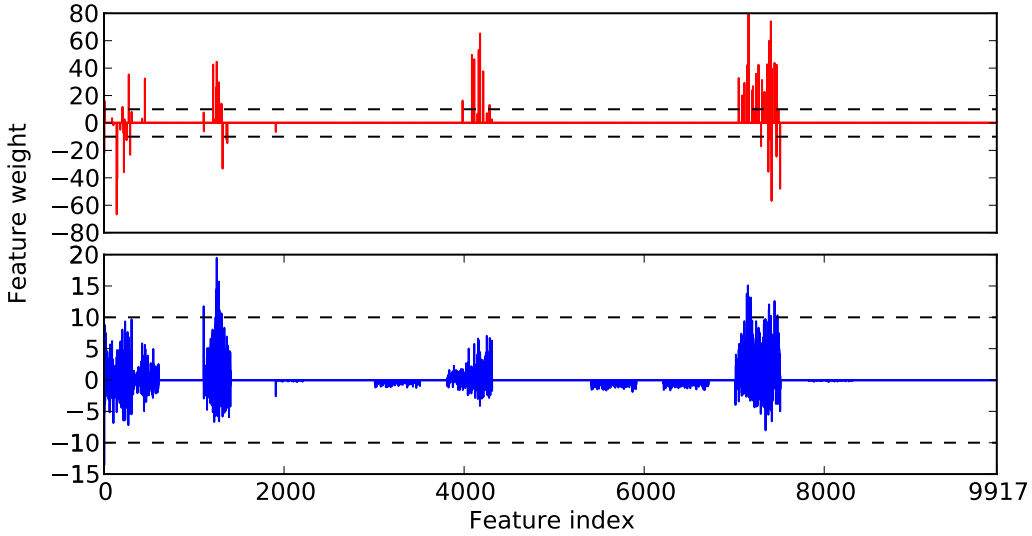

Figure 12: Feature weights for best models trained with L_1 regularization (top) and L_2 regularization (bottom). Dashed lines indicate the feature weight range $[\pm 10]$.

22. We set termination criterion $\varepsilon = 10^{-4}$ and limited the maximum number of iteration to 500.

6. Discussion and Conclusion

The experiments presented in the paper indicate that BMRM is suitable for a wide variety of machine learning problems. In fact, the *modularity* of BMRM not only brings the benefits of parallel and distributed computation but also makes BMRM a natural test bed for trying out new models/ideas on any particular problem with less effort, that is, the user is only required to implement the loss functions and/or regularizers corresponding to different models/ideas.

Nevertheless, we saw in the experiments that BMRM does not guarantee strict improvement in the primal when the dual is solved instead. This phenomenon could significantly hinder the performance of BMRM as seen in some of the experiments. Since efficient line search procedure may not exist for general structured prediction tasks, the *trust region* philosophy used in BT could be a potential strategy to alleviate this problem; we leave this to the future work. We also note that for computationally expensive nonsmooth loss functions, one way to make fuller use of each loss function evaluation is by updating the model R_t^{CP} with two or more linearizations at a non-diffferentiable location (Frangioni, 1997).

In conclusion, we have presented a variant of standard bundle methods, that is, BMRM, which is algorithmically simpler and, in some senses, more straightforward for regularized risk minimization problems than the standard bundle methods. We also showed a $O(1/\varepsilon)$ rate of convergence for nonsmooth objective functions and $O(\log(1/\varepsilon))$ rates for smooth objective functions.

NICTA is funded by the Australian Government's Backing Australia's Ability and the Center of Excellence programs. This work is also supported by the IST Program of the European Community, under the FP7 Network of Excellence, ICT-216886-NOE. We thank Jin Yu for many useful discussions and help with implementation issues. Julian McAuley and Qinfeng Shi provided their source code, facilitating some of the experimental comparisons reported in Sections 5.3.2 and 5.3.3. We thank Manfred Warmuth for pointing out Lemma 13. We also thank Sam Roweis, Yasemin Altun, and Nic Schraudolph for insightful discussions. A short, early version of this work appeared in Teo et al. (2007), while the convergence proofs first appeared in Smola et al. (2007).

Appendix A. Loss Functions

A multitude of loss functions are commonly used to derive seemingly different algorithms. This often blurs the similarities as well as subtle differences between them, often for historic reasons: Each new loss is typically accompanied by at least one publication dedicated to it. In many cases, the loss is not spelled out explicitly either but instead, it is only given by means of a constrained optimization problem. A case in point are the papers introducing (binary) hinge loss (Bennett and Mangasarian, 1992; Cortes and Vapnik, 1995) and structured loss (Taskar et al., 2004; Tsochantaridis et al., 2005). Likewise, a geometric description obscures the underlying loss function, as in novelty detection (Schölkopf et al., 2001).

In this section we give an expository yet unifying presentation of many of those loss functions. Many of them are well known, while others, such as multivariate ranking, hazard regression, or Poisson regression are not commonly used in machine learning. Tables 5 and 6 contain a choice subset of simple scalar and vectorial losses. Our aim is to put the multitude of loss functions in

Table 5: Scalar loss functions and their derivatives, depending on $f := \langle w,x \rangle$, and y.

	Loss $\bar{l}(f,y)$	Derivative $\bar{l}'(f,y)$
Hinge (Bennett and Mangasarian, 1992)	$\max(0, 1-yf)$	0 if $yf \geq 1$ and $-y$ otherwise
Squared Hinge (Keerthi and DeCoste, 2005)	$\frac{1}{2}\max(0, 1-yf)^2$	0 if $yf \geq 1$ and $f-y$ otherwise
Exponential (Cowell et al., 1999)	$\exp(-yf)$	$-y\exp(-yf)$
Logistic (Collins et al., 2000)	$\log(1+\exp(-yf))$	$-y/(1+\exp(-yf))$
Novelty (Schölkopf et al., 2001)	$\max(0, \rho - f)$	0 if $f \geq \rho$ and -1 otherwise
Least mean squares (Williams, 1998)	$\frac{1}{2}(f-y)^2$	$f-y$
Least absolute deviation	$\lvert f-y \rvert$	$\operatorname{sgn}(f-y)$
Quantile regression (Koenker, 2005)	$\max(\tau(f-y), (1-\tau)(y-f))$	τ if $f > y$ and $\tau - 1$ otherwise
ε-insensitive (Vapnik et al., 1997)	$\max(0, \lvert f-y \rvert - \varepsilon)$	0 if $\lvert f-y \rvert \leq \varepsilon$, else $\operatorname{sgn}(f-y)$
Huber's robust loss (Müller et al., 1997)	$\frac{1}{2}(f-y)^2$ if $\lvert f-y \rvert \leq 1$, else $\lvert f-y \rvert - \frac{1}{2}$	$f-y$ if $\lvert f-y \rvert \leq 1$, else $\operatorname{sgn}(f-y)$
Poisson regression (Cressie, 1993)	$\exp(f) - yf$	$\exp(f) - y$

Table 6: Vectorial loss functions and their derivatives, depending on the vector $f := Wx$ and on y.

	Loss	Derivative
Soft-Margin Multiclass (Taskar et al., 2004) (Crammer and Singer, 2003)	$\max_{y'}(f_{y'} - f_y + \Delta(y,y'))$	$e_{y^*} - e_y$ where y^* is the argmax of the loss
Scaled Soft-Margin Multiclass (Tsochantaridis et al., 2005)	$\max_{y'} \Gamma(y,y')(f_{y'} - f_y + \Delta(y,y'))$	$\Gamma(y,y')(e_{y^*} - e_y)$ where y^* is the argmax of the loss
Softmax Multiclass (Cowell et al., 1999)	$\log \sum_{y'} \exp(f_{y'}) - f_y$	$\left[\sum_{y'} e_{y'} \exp(f'_y)\right] / \sum_{y'} \exp(f'_y) - e_y$
Multivariate Regression	$\frac{1}{2}(f-y)^\top M(f-y)$ where $M \succeq 0$	$M(f-y)$

an unified framework, and to show how these losses and their (sub)gradients can be computed efficiently for use in our solver framework.

Note that not all losses, while convex, are continuously differentiable. In this situation we give *a* subgradient. While this may not be optimal, the convergence rates of our algorithm do not depend on which element of the subdifferential we provide: in all cases the first order Taylor approximation is a lower bound which is tight at the point of expansion.

In this setion, with little abuse of notation, v_i is understood as the i-th component of vector v when v is clearly not an element of a sequence or a set.

A.1 Scalar Loss Functions

It is well known (Wahba, 1997) that the convex optimization problem

$$\min_{\xi} \xi \text{ subject to } y\langle w,x\rangle \geq 1-\xi \text{ and } \xi \geq 0$$

takes on the value $\max(0,1-y\langle w,x\rangle)$. The latter is a convex function in w and x. Likewise, we may rewrite the ε-insensitive loss, Huber's robust loss, the quantile regression loss, and the novelty detection loss in terms of loss functions rather than a constrained optimization problem. In all cases, $\langle w,x\rangle$ will play a key role insofar as the loss is convex in terms of the *scalar* quantity $\langle w,x\rangle$. A large number of loss functions fall into this category, as described in Table 5. Note that not all functions of this type are continuously differentiable. In this case we adopt the convention that

$$\partial_x \max(f(x),g(x)) = \begin{cases} \partial_x f(x) & \text{if } f(x) \geq g(x) \\ \partial_x g(x) & \text{otherwise .} \end{cases}$$

Since we are only interested in obtaining an arbitrary element of the subdifferential this convention is consistent with our requirements.

Let us discuss the issue of efficient computation. For all scalar losses we may write $l(x,y,w) = \bar{l}(\langle w,x\rangle, y)$, as described in Table 5. In this case a simple application of the chain rule yields that $\partial_w l(x,y,w) = \bar{l}'(\langle w,x\rangle, y)\cdot x$. For instance, for squared loss we have

$$\bar{l}(\langle w,x\rangle, y) = \tfrac{1}{2}(\langle w,x\rangle - y)^2 \text{ and } \bar{l}'(\langle w,x\rangle, y) = \langle w,x\rangle - y.$$

Consequently, the derivative of the empirical risk term is given by

$$\partial_w R_{\text{emp}}(w) = \frac{1}{m}\sum_{i=1}^{m} \bar{l}'(\langle w,x_i\rangle, y_i)\cdot x_i.$$

This means that if we want to compute l and $\partial_w l$ on a large number of observations x_i, represented as matrix X, we can make use of fast linear algebra routines to pre-compute the vectors

$$f = Xw \text{ and } g^\top X \text{ where } g_i = \bar{l}'(f_i, y_i).$$

This is possible for any of the loss functions listed in Table 5, and many other similar losses. The advantage of this unified representation is that implementation of each individual loss can be done in very little time. The computational infrastructure for computing Xw and $g^\top X$ is shared. Evaluating $\bar{l}(f_i,y_i)$ and $\bar{l}'(f_i,y_i)$ for all i can be done in $O(m)$ time and it is not time-critical in comparison to the remaining operations. Algorithm 6 describes the details.

Algorithm 6 ScalarLoss(w, X, y)

1: **input:** Weight vector w, feature matrix X, and labels y
2: Compute $f = Xw$
3: Compute $r = \sum_i \bar{l}(f_i, y_i)$ and $g = \bar{l}'(f, y)$
4: $g \leftarrow g^\top X$
5: **return** Risk r and gradient g

An important but often neglected issue is worth mentioning. Computing f requires us to *right* multiply the matrix X with the vector w while computing g requires the *left* multiplication of X with the vector $g^\top$. If X is stored in a row major format then Xw can be computed rather efficiently while $g^\top X$ is expensive. This is particularly true if X cannot fit in main memory. Converse is the case when X is stored in column major format. Similar problems are encountered when X is a sparse matrix and stored in either compressed row format or in compressed column format.

A.2 Structured Loss

In recent years structured estimation has gained substantial popularity in machine learning (Tsochantaridis et al., 2005; Taskar et al., 2004; Bakir et al., 2007). At its core it relies on two types of convex loss functions: logistic loss:

$$l(x, y, w) = \log \sum_{y' \in \mathcal{Y}} \exp\left(\left\langle w, \phi(x, y')\right\rangle\right) - \left\langle w, \phi(x, y)\right\rangle, \tag{23}$$

and soft-margin loss:

$$l(x, y, w) = \max_{y' \in \mathcal{Y}} \Gamma(y, y') \left\langle w, \phi(x, y') - \phi(x, y)\right\rangle + \Delta(y, y'). \tag{24}$$

Here $\phi(x, y)$ is a *joint* feature map, $\Delta(y, y') \geq 0$ describes the cost of misclassifying y by y', and $\Gamma(y, y') \geq 0$ is a scaling term which indicates by how much the large margin property should be enforced. For instance, Taskar et al. (2004) choose $\Gamma(y, y') = 1$. On the other hand, Tsochantaridis et al. (2005) suggest $\Gamma(y, y') = \Delta(y, y')$, which reportedly yields better performance. Finally, McAllester (2007) recently suggested generic functions $\Gamma(y, y')$.

The logistic loss can also be interpreted as the negative log-likelihood of a conditional exponential family model:

$$p(y|x; w) := \exp(\langle w, \phi(x, y)\rangle - g(w|x)), \tag{25}$$

where the normalizing constant $g(w|x)$, often called the log-partition function, reads

$$g(w|x) := \log \sum_{y' \in \mathcal{Y}} \exp\left(\left\langle w, \phi(x, y')\right\rangle\right).$$

As a consequence of the Hammersley-Clifford theorem (Jordan, 2002) every exponential family distribution corresponds to a undirected graphical model. In our case this implies that the labels y factorize according to an undirected graphical model. A large number of problems have been addressed by this setting, amongst them named entity tagging (Lafferty et al., 2001), sequence alignment (Tsochantaridis et al., 2005), segmentation (Rätsch et al., 2007) and path planning (Ratliff

et al., 2006). It is clearly impossible to give examples of all settings in this section, nor would a brief summary do this field any justice. We therefore refer the reader to the edited volume by Bakir et al. (2007) and the references therein.

If the underlying graphical model is tractable then efficient inference algorithms based on dynamic programming can be used to compute (23) and (24). We discuss intractable graphical models in Section A.2.1, and now turn our attention to the derivatives of the above structured losses.

When it comes to computing derivatives of the logistic loss, (23), we have

$$\begin{aligned}\partial_w l(x,y,w) &= \frac{\sum_{y'} \phi(x,y') \exp\langle w, \phi(x,y')\rangle}{\sum_{y'} \exp\langle w, \phi(x,y')\rangle} - \phi(x,y) \\ &= \mathbf{E}_{y' \sim p(y'|x)}\left[\phi(x,y')\right] - \phi(x,y).\end{aligned}$$

where $p(y|x)$ is the exponential family model (25). In the case of (24) we denote by $\bar{y}(x)$ the argmax of the RHS, that is

$$\bar{y}(x) := \operatorname*{argmax}_{y'} \Gamma(y,y') \left\langle w, \phi(x,y') - \phi(x,y)\right\rangle + \Delta(y,y').$$

This allows us to compute the derivative of $l(x,y,w)$ as

$$\partial_w l(x,y,w) = \Gamma(y,\bar{y}(x))\left[\phi(x,\bar{y}(x)) - \phi(x,y)\right].$$

In the case where the loss is maximized for more than one distinct value $\bar{y}(x)$ we may average over the individual values, since any convex combination of such terms lies in the subdifferential.

Note that (24) majorizes $\Delta(y,y^*)$, where $y^* := \operatorname{argmax}_{y'} \langle w, \phi(x,y')\rangle$ (Tsochantaridis et al., 2005). This can be seen via the following series of inequalities:

$$\Delta(y,y^*) \leq \Gamma(y,y^*)\langle w, \phi(x,y^*) - \phi(x,y)\rangle + \Delta(y,y^*) \leq l(x,y,w).$$

The first inequality follows because $\Gamma(y,y^*) \geq 0$ and y^* maximizes $\langle w, \phi(x,y')\rangle$ thus implying that $\Gamma(y,y^*)\langle w, \phi(x,y^*) - \phi(x,y)\rangle \geq 0$. The second inequality follows by definition of the loss.

We conclude this section with a simple lemma which is at the heart of several derivations of Joachims (2005). While the proof in the original paper is far from trivial, it is straightforward in our setting:

Lemma 8 *Denote by $\delta(y,y')$ a loss and let $\phi(x_i,y_i)$ be a feature map for observations (x_i,y_i) with $1 \leq i \leq m$. Moreover, denote by X,Y the set of all m patterns and labels respectively. Finally let*

$$\Phi(X,Y) := \sum_{i=1}^m \phi(x_i,y_i) \text{ and } \Delta(Y,Y') := \sum_{i=1}^m \delta(y_i,y_i').$$

Then the following two losses are equivalent:

$$\sum_{i=1}^m \max_{y'} \left\langle w, \phi(x_i,y') - \phi(x_i,y_i)\right\rangle + \delta(y_i,y') \text{ and } \max_{Y'} \left\langle w, \Phi(X,Y') - \Phi(X,Y)\right\rangle + \Delta(Y,Y').$$

This is immediately obvious, since both feature map and loss decompose, which allows us to perform maximization over Y' by maximizing each of its m components. In doing so, we showed that aggregating all data and labels into a single feature map and loss yields results identical to minimizing the sum over all individual losses. This holds, in particular, for the sample error loss of Joachims (2005). Also note that this equivalence does *not* hold whenever $\Gamma(y,y')$ is not constant.

A.2.1 INTRACTABLE MODELS

We now discuss cases where computing $l(x,y,w)$ itself is too expensive. For instance, for intractable graphical models, the computation of $\sum_y \exp\langle w,\phi(x,y)\rangle$ cannot be computed efficiently. Wainwright and Jordan (2003) propose the use of a convex majorization of the log-partition function in those cases. In our setting this means that instead of dealing with

$$l(x,y,w) = g(w|x) - \langle w,\phi(x,y)\rangle \text{ where } g(w|x) := \log \sum_y \exp\langle w,\phi(x,y)\rangle$$

one uses a more easily computable convex upper bound on g via

$$\sup_{\mu\in \mathrm{MARG}(x)} \langle w,\mu\rangle + H_{\mathrm{Gauss}}(\mu|x). \tag{26}$$

Here $\mathrm{MARG}(x)$ is an outer bound on the conditional marginal polytope associated with the map $\phi(x,y)$. Moreover, $H_{\mathrm{Gauss}}(\mu|x)$ is an upper bound on the entropy by using a Gaussian with identical variance. More refined tree decompositions exist, too. The key benefit of our approach is that the solution μ of the optimization problem (26) can immediately be used as a gradient of the upper bound. This is computationally rather efficient.

Likewise, note that Taskar et al. (2004) use relaxations when solving structured estimation problems of the form

$$l(x,y,w) = \max_{y'} \Gamma(y,y')\left\langle w,\phi(x,y') - \phi(x,y)\right\rangle + \Delta(y,y'),$$

by enlarging the domain of maximization with respect to y'. For instance, instead of an integer programming problem we might relax the setting to a linear program which is much cheaper to solve. This, again, provides an upper bound on the original loss function.

In summary, we have demonstrated that convex relaxation strategies are well applicable for bundle methods. In fact, the results of the corresponding optimization procedures can be used directly for further optimization steps.

A.3 Scalar Multivariate Performance Scores

We now discuss a series of structured loss functions and how they can be implemented efficiently. For the sake of completeness, we give a concise representation of previous work on multivariate performance scores and ranking methods. All these loss functions rely on having access to $\langle w,x\rangle$, which can be computed efficiently by using the same operations as in Section A.1.

A.3.1 ROC SCORE

Denote by $f = Xw$ the vector of function values on the training set. It is well known that the area under the ROC curve is given by

$$\mathrm{AUC}(x,y,w) = \frac{1}{m_+ m_-} \sum_{y_i<y_j} \mathbf{I}(\langle w,x_i\rangle < \langle w,x_j\rangle),$$

where m_+ and m_- are the numbers of positive and negative observations respectively, and $\mathbf{I}(\cdot)$ is indicator function. Directly optimizing the cost $1-\mathrm{AUC}(x,y,w)$ is difficult as it is not continuous

Algorithm 7 ROCScore(X, y, w)

input: Feature matrix X, labels y, and weight vector w
initialization: $s_- = m_-$ and $s_+ = 0$ and $l = \mathbf{0}_m$ and $c = Xw - \frac{1}{2}y$
$\pi \leftarrow \{1, \ldots, m\}$ sorted in ascending order of c
for $i = 1$ **to** m **do**
  if $y_{\pi_i} = -1$ **then**
    $l_{\pi_i} \leftarrow s_+$ and $s_- \leftarrow s_- - 1$
  else
    $l_{\pi_i} \leftarrow -s_-$ and $s_+ \leftarrow s_+ + 1$
  end if
end for
Rescale $l \leftarrow l/(m_+ m_-)$ and compute $r = \langle l, c \rangle$ and $g = l^\top X$.
return Risk r and subgradient g

in w. By using $\max(0, 1 + \langle w, x_i - x_j \rangle)$ as the surrogate loss function for all pairs (i, j) for which $y_i < y_j$ we have the following convex multivariate empirical risk

$$R_{\text{emp}}(w) = \frac{1}{m_+ m_-} \sum_{y_i < y_j} \max(0, 1 + \langle w, x_i - x_j \rangle) = \frac{1}{m_+ m_-} \sum_{y_i < y_j} \max(0, 1 + f_i - f_j). \tag{27}$$

Obviously, we could compute $R_{\text{emp}}(w)$ and its derivative by an $O(m^2)$ operation. However Joachims (2005) shows that both can be computed in $O(m \log m)$ time using a sorting operation, which we now describe.

Denote by $c = f - \frac{1}{2}y$ an auxiliary variable and let i and j be indices such that $y_i = -1$ and $y_j = 1$. It follows that $c_i - c_j = 1 + f_i - f_j$. The efficient algorithm is due to the observation that there are at most m distinct terms c_k, $k = 1, \ldots, m$, each with different frequency l_k and sign, appear in (27). These frequencies l_k can be determined by first sorting c in ascending order then scanning through the labels according to the sorted order of c and keeping running statistics such as the number s_- of negative labels yet to encounter, and the number s_+ of positive labels encountered. When visiting y_k, we know c_k should appears s_+ (or s_-) times with positive (or negative) sign in (27) if $y_k = -1$ (or $y_k = 1$). Algorithm 7 spells out explicitly how to compute $R_{\text{emp}}(w)$ and its subgradient.

A.3.2 ORDINAL REGRESSION

Essentially the same preference relationships need to hold for ordinal regression. The only difference is that y_i need not take on binary values any more. Instead, we may have an arbitrary number of different values y_i (e.g., 1 corresponding to 'strong reject' up to 10 corresponding to 'strong accept', when it comes to ranking papers for a conference). That is, we now have $y_i \in \{1, \ldots, n\}$ rather than $y_i \in \{\pm 1\}$. Our goal is to find some w such that $\langle w, x_i - x_j \rangle < 0$ whenever $y_i < y_j$. Whenever this relationship is not satisfied, we incur a cost $C(y_i, y_j)$ for preferring x_i to x_j. For examples, $C(y_i, y_j)$ could be constant, that is, $C(y_i, y_j) = 1$ (Joachims, 2006) or linear, that is, $C(y_i, y_j) = y_j - y_i$.

Denote by m_i the number of x_j for which $y_j = i$. In this case, there are $\bar{M} = m^2 - \sum_{i=1}^n m_i^2$ pairs (y_i, y_j) for which $y_i \neq y_j$; this implies that there are $M = \bar{M}/2$ pairs (y_i, y_j) such that $y_i < y_j$.

Normalizing by the total number of comparisons we may write the overall cost of the estimator as

$$\frac{1}{M}\sum_{y_i<y_j} C(y_i,y_j)\mathbf{I}(\langle w,x_i\rangle > \langle w,x_j\rangle) \text{ where } M = \frac{1}{2}\left[m^2 - \sum_i^n m_i^2\right].$$

Using the same convex majorization as above when we were maximizing the ROC score, we obtain an empirical risk of the form

$$R_{\text{emp}}(w) = \frac{1}{M}\sum_{y_i<y_j} C(y_i,y_j)\max(0,1+\langle w,x_i-x_j\rangle).$$

Now the goal is to find an efficient algorithm for obtaining the number of times when the individual losses are nonzero such as to compute both the value and the gradient of $R_{\text{emp}}(w)$. The complication arises from the fact that observations x_i with label y_i may appear in either side of the inequality depending on whether $y_j < y_i$ or $y_j > y_i$. This problem can be solved as follows: sort $f = Xw$ in ascending order and traverse it while keeping track of how many items with a lower value y_j are no more than 1 apart in terms of their value of f_i. This way we may compute the count statistics efficiently. Algorithm 8 describes the details, generalizing the results of Joachims (2006). Again, its runtime is $O(m\log m)$, thus allowing for efficient computation.

A.3.3 PREFERENCE RELATIONS

In general, our loss may be described by means of a set of preference relations $j \succeq i$ for arbitrary pairs $(i,j) \in \{1,\dots m\}^2$ associated with a cost $C(i,j)$ which is incurred whenever i is ranked above j. This set of preferences may or may not form a partial or a total order on the domain of all observations. In these cases efficient computations along the lines of Algorithm 8 exist. In general, this is not the case and we need to rely on the fact that the set P containing all preferences is sufficiently small that it can be enumerated efficiently. The risk is then given by

$$\frac{1}{|P|}\sum_{(i,j)\in P} C(i,j)\mathbf{I}(\langle w,x_i\rangle > \langle w,x_j\rangle).$$

Again, the same majorization argument as before allows us to write a convex upper bound

$$R_{\text{emp}}(w) = \frac{1}{|P|}\sum_{(i,j)\in P} C(i,j)\max\left(0,1+\langle w,x_i\rangle - \langle w,x_j\rangle\right)$$

$$\text{where } \partial_w R_{\text{emp}}(w) = \frac{1}{|P|}\sum_{(i,j)\in P} C(i,j)\begin{cases}0 & \text{if } \langle w,x_j-x_i\rangle \geq 1\\ x_i - x_j & \text{otherwise.}\end{cases}$$

The implementation is straightforward, as given in Algorithm 9.

A.3.4 RANKING

In webpage and document ranking we are often in a situation similar to that described in Section A.3.2, however with the difference that we do not only care about objects x_i being ranked according to scores y_i but moreover that different degrees of importance are placed on different documents.

Algorithm 8 OrdinalRegression(X, y, w, C)

input: Feature matrix X, labels y, weight vector w, and score matrix C
initialization: $l = \mathbf{0}_n$ and $u_i = m_i \; \forall i \in [n]$ and $r = 0$ and $g = \mathbf{0}_m$
Compute $f = Xw$ and set $c = [f - \frac{1}{2}, f + \frac{1}{2}] \in \mathbb{R}^{2m}$ (concatenate the vectors)
Compute $M = (m^2 - \sum_{i=1}^{n} m_i^2)/2$
Rescale $C \leftarrow C/M$
$\pi \leftarrow \{1, \ldots, 2m\}$ sorted in ascending order of c

The information retrieval literature is full with a large number of different scoring functions. Examples are criteria such as *Normalized Discounted Cumulative Gain (NDCG)*, *Mean Reciprocal Rank (MRR)*, *Precision@n*, or *Expected Rank Utility (ERU)*. They are used to address the issue of evaluating rankers, search engines or recommender sytems (Voorhees, 2001; Jarvelin and Kekalainen, 2002; Breese et al., 1998; Basilico and Hofmann, 2004). For instance, in webpage

ranking only the first k retrieved documents that matter, since users are unlikely to look beyond the first k, say 10, retrieved webpages in an internet search. Le and Smola (2007) show that these scores can be optimized directly by minimizing the following loss:

$$l(X, y, w) = \max_\pi \sum_i c_i \left\langle w, x_{\pi(i)} - x_i \right\rangle + \langle a - a(\pi), b(y) \rangle . \tag{28}$$

Here c_i is a monotonically decreasing sequence, the documents are assumed to be arranged in order of decreasing relevance, π is a permutation, the vectors a and $b(y)$ depend on the choice of a particular ranking measure, and $a(\pi)$ denotes the permutation of a according to π. Pre-computing $f = Xw$ we may rewrite (28) as

$$l(f, y) = \max_\pi \left[c^\top f(\pi) - a(\pi)^\top b(y) \right] - c^\top f + a^\top b(y)$$

and consequently the derivative of $l(X, y, w)$ with respect to w is given by

$$\partial_w l(X, y, w) = (c(\bar{\pi}^{-1}) - c)^\top X \text{ where } \bar{\pi} = \operatorname*{argmax}_\pi c^\top f(\pi) - a(\pi)^\top b(y).$$

Here π^{-1} denotes the inverse permutation, such that $\pi \circ \pi^{-1} = 1$. Finding the permutation maximizing $c^\top f(\pi) - a(\pi)^\top b(y)$ is a linear assignment problem which can be easily solved by the Hungarian Marriage algorithm, that is, the Kuhn-Munkres algorithm.

The original papers by Kuhn (1955) and Munkres (1957) implied an algorithm with $O(m^3)$ cost in the number of terms. Later, Karp (1980) suggests an algorithm with expected quadratic time in the size of the assignment problem (ignoring log-factors). Finally, Orlin and Lee (1993) propose a linear time algorithm for large problems. Since in our case the number of pages is fairly small (in the order of 50 to 200 *per query*) the scaling behavior per query is not too important. We used an existing implementation due to Jonker and Volgenant (1987).

Note also that training sets consist of a *collection* of ranking problems, that is, we have several ranking problems of size 50 to 200. By means of parallelization we are able to distribute the work onto a cluster of workstations, which is able to overcome the issue of the rather costly computation per collection of queries. Algorithm 10 spells out the steps in detail.

A.3.5 CONTINGENCY TABLE SCORES

Joachims (2005) observed that F_β scores and related quantities dependent on a contingency table can also be computed efficiently by means of structured estimation. Such scores depend in general on

the number of true and false positives and negatives alike. Algorithm 11 shows how a corresponding empirical risk and subgradient can be computed efficiently. As with the previous losses, here again we use convex majorization to obtain a tractable optimization problem.

Given a set of labels y and an estimate y', the numbers of true positives (T_+), true negatives (T_-), false positives (F_+), and false negatives (F_-) are determined according to a contingency table as follows:

	$y > 0$	$y < 0$
$y' > 0$	T_+	F_+
$y' < 0$	F_-	T_-

In the sequel, we denote by $m_+ = T_+ + F_-$ and $m_- = T_- + F_+$ the numbers of positives and negative labels in y, respectively. We note that F_β score can be computed based on the contingency table (Joachims, 2005) as

$$F_\beta(T_+, T_-) = \frac{(1+\beta^2)T_+}{T_+ + m_- - T_- + \beta^2 m_+}.$$

If we want to use $\langle w, x_i \rangle$ to estimate the label of observation x_i, we may use the following structured loss to "directly" optimize w.r.t. F_β score (Joachims, 2005):

$$l(X, y, w) = \max_{y'} \left[(y' - y)^\top f + \Delta(T_+, T_-) \right],$$

where $f = Xw$, $\Delta(T_+, T_-) := 1 - F_\beta(T_+, T_-)$, and (T_+, T_-) is determined by using y and y'. Since Δ does not depend on the specific choice of (y, y') but rather just on which sets they disagree, l can be maximized as follows: Enumerating all possible $m_+ m_-$ contingency tables in a way such that given a configuration (T_+, T_-), T_+ (T_-) positive (negative) observations x_i with largest (lowest) value of $\langle w, x_i \rangle$ are labeled as positive (negative). This is effectively implemented as a nested loop hence run in $O(m^2)$ time. Algorithm 11 describes the procedure in details.

A.4 Vector Loss Functions

Next we discuss "vector" loss functions, that is, functions where w is best described as a matrix (denoted by W) and the loss depends on Wx. Here, we have feature vector $x \in \mathbb{R}^d$, label $y \in \mathbb{R}^k$, and weight matrix $W \in \mathbb{R}^{d \times k}$. We also denote feature matrix $X \in \mathbb{R}^{m \times d}$ as a matrix of m feature vectors x_i, and stack up the columns W_i of W as a vector w.

Some of the most relevant cases are multiclass classification using both the exponential families model and structured estimation, hierarchical models, that is, ontologies, and multivariate regression. Many of those cases are summarized in Table 6.

A.4.1 UNSTRUCTURED SETTING

The simplest loss is multivariate regression, where $l(x, y, W) = \frac{1}{2}(y - x^\top W)^\top M (y - x^\top W)$. In this case it is clear that by pre-computing XW subsequent calculations of the loss and its gradient are significantly accelerated.

A second class of important losses is given by plain multiclass classification problems, for example, recognizing digits of a postal code or categorizing high-level document categories. In this case, $\phi(x, y)$ is best represented by $e_y \otimes x$ (using a linear model). Clearly we may view $\langle w, \phi(x, y) \rangle$

Algorithm 11 $\mathrm{F}_\beta(X, y, w)$

input: Feature matrix X, labels y, and weight vector w
Compute $f = Xw$
$\pi^+ \leftarrow \{i : y_i = 1\}$ sorted in descending order of f
$\pi^- \leftarrow \{i : y_i = -1\}$ sorted in ascending order of f
Let $p_0 = 0$ and $p_i = 2\sum_{k=i}^{m_+} f_{\pi_k^+},\ i = 1, \ldots, m_+$
Let $n_0 = 0$ and $n_i = 2\sum_{k=i}^{m_-} f_{\pi_k^-},\ i = 1, \ldots, m_-$
$y' \leftarrow -y$ and $r \leftarrow -\infty$
for $i = 0$ **to** m_+ **do**
  for $j = 0$ **to** m_- **do**
    $r_{\text{tmp}} = \Delta(i, j) - p_i + n_j$
    if $r_{\text{tmp}} > r$ **then**
      $r \leftarrow r_{\text{tmp}}$
      $T_+ \leftarrow i$ and $T_- \leftarrow j$
    end if
  end for
end for
$y'_{\pi_i^+} \leftarrow 1,\ i = 1, \ldots, T_+$
$y'_{\pi_i^-} \leftarrow -1,\ i = 1, \ldots, T_-$
$g \leftarrow (y' - y)^\top X$
return Risk r and subgradient g

as an operation which chooses a column indexed by y from xW, since all labels y correspond to a different weight vector W_y. Formally we set $\langle w, \phi(x, y)\rangle = [xW]_y$. In this case, structured estimation losses can be rewritten as

$$l(x, y, W) = \max_{y'} \Gamma(y, y') \left\langle W_{y'} - W_y, x \right\rangle + \Delta(y, y') \tag{29}$$

$$\text{and } \partial_W l(x, y, W) = \Gamma(y, y^*)(e_{y^*} - e_y) \otimes x.$$

Here Γ and Δ are defined as in Section A.2 and y^* denotes the value of y' for which the RHS of (29) is maximized. This means that for unstructured multiclass settings we may simply compute xW. Since this needs to be performed for all observations x_i we may take advantage of fast linear algebra routines and compute $f = XW$ for efficiency. Likewise note that computing the gradient over m observations is now a matrix-matrix multiplication, too: denote by G the matrix of rows of gradients $\Gamma(y_i, y_i^*)(e_{y_i^*} - e_{y_i})$. Then $\partial_W R_{\text{emp}}(X, y, W) = G^\top X$. Note that G is very sparse with at most two nonzero entries per row, which makes the computation of $G^\top X$ essentially as expensive as two matrix vector multiplications. Whenever we have many classes, this may yield significant computational gains.

Log-likelihood scores of exponential families share similar expansions. We have

$$l(x, y, W) = \log \sum_{y'} \exp \left\langle w, \phi(x, y')\right\rangle - \langle w, \phi(x, y)\rangle = \log \sum_{y'} \exp \left\langle W_{y'}, x\right\rangle - \langle W_y, x\rangle$$

$$\partial_W l(x, y, W) = \frac{\sum_{y'} (e_{y'} \otimes x) \exp \left\langle W_{y'}, x\right\rangle}{\sum_{y'} \exp \left\langle W_{y'}, x\right\rangle} - e_y \otimes x.$$

The main difference to the soft-margin setting is that the gradients are *not* sparse in the number of classes. This means that the computation of gradients is slightly more costly.

A.4.2 ONTOLOGIES

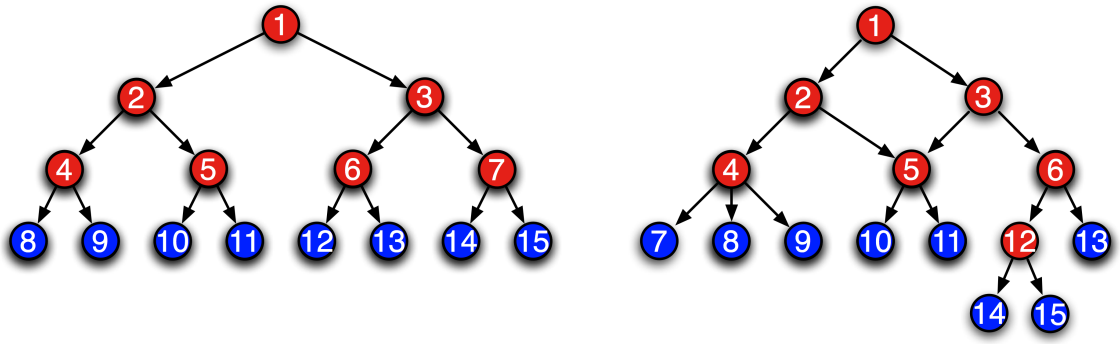

Figure 13: Two ontologies. **Left:** a binary hierarchy with internal nodes $\{1,\dots,7\}$ and labels $\{8,\dots 15\}$. **Right:** a generic directed acyclic graph with internal nodes $\{1,\dots,6,12\}$ and labels $\{7,\dots,11,13,\dots,15\}$. Note that node 5 has two parents, namely nodes 2 and 3. Moreover, the labels need not be found at the same level of the tree: nodes 14 and 15 are one level lower than the rest of the nodes.

Assume that the labels we want to estimate can be found to belong to a directed acyclic graph (DAG). For instance, this may be a gene-ontology graph (Ashburner et al., 2000) a patent hierarchy (Cai and Hofmann, 2004), or a genealogy. In these cases we have a hierarchy of categories to which an element x may belong. Figure 13 gives two examples of such directed acyclic graphs. The first example is a binary tree, while the second contains nodes with different numbers of children (e.g., node 4 and 12), nodes at different levels having children (e.g., nodes 5 and 12), and nodes which have more than one parent (e.g., node 5). It is a well known fundamental property of trees that they have at most as many internal nodes as they have leaf nodes.

It is now our goal to build a classifier which is able to categorize observations according to which leaf node they belong to (each leaf node is assigned a label y). Denote by $k+1$ the number of nodes in the DAG including the root node. In this case we may design a feature map $\phi(y) \in \mathbb{R}^k$ (Cai and Hofmann, 2004) by associating with every label y the vector describing the path from the root node to y, ignoring the root node itself. For instance, for the first DAG in Figure 13 we have

$$\phi(8) = (1,0,1,0,0,0,1,0,0,0,0,0,0,0) \text{ and } \phi(13) = (0,1,0,0,1,0,0,0,0,0,0,1,0,0)$$

Whenever several paths are admissible, as in the right DAG of Figure 13 we average over all possible paths. For example, we have

$$\phi(10) = (0.5,0.5,0,1,0,0,0,0,1,0,0,0,0,0) \text{ and } \phi(15) = (0,1,0,0,1,0,0,0,0,0,0,1,0,0,1).$$

Also note that the lengths of the paths need not be the same (e.g., to reach 15 it takes a longer path than to reach 13). Likewise, it is natural to assume that $\Delta(y,y')$, that is, the cost for mislabeling y

Algorithm 12 Ontology(X, y, W)

input: Feature matrix $X \in \mathbb{R}^{m \times d}$, labels y, and weight matrix $W \in \mathbb{R}^{d \times k}$
initialization: $G = \mathbf{0} \in \mathbb{R}^{m \times k}$ and $r = 0$
Compute $f = XW$ and let $f_i = x_i W$
for $i = 1$ **to** m **do**
  Let D_i be the DAG with edges annotated with the values of f_i
  Traverse D_i to find a path y^* that maximizes the value $z_{y^*} := \sum_{j=1}^{k} [\phi(y^*)]_j f_{ij} + \Delta(y_i, y^*)$
  $G_i = \phi(y^*) - \phi(y_i)$
  $r \leftarrow r + z_{y^*} - z_{y_i}$
end for
$g = G^\top X$
return Risk r and subgradient g

as y' will depend on the similarity of the path. In other words, it is likely that the cost for placing x into the wrong sub-sub-category is less than getting the main category of the object wrong.

To complete the setting, note that for $\phi(x, y) = \phi(y) \otimes x$ the cost of computing all labels is k inner products, since the value of $\langle w, \phi(x, y) \rangle$ for a particular y can be obtained by the sum of the contributions for the segments of the path. This means that the values for *all* terms can be computed by a simple breadth first traversal through the graph. As before, we may make use of vectorization in our approach, since we may compute $xW \in \mathbb{R}^k$ to obtain the contributions on all segments of the DAG before performing the graph traversal. Since we have m patterns x_i we may vectorize matters by pre-computing XW.

Also note that $\phi(y) - \phi(y')$ is nonzero only for those edges where the paths for y and y' differ. Hence we only change weights on those parts of the graph where the categorization differs. Algorithm 12 describes the subgradient and loss computation for the soft-margin type of loss function.

The same reasoning applies to estimation when using an exponential families model. The only difference is that we need to compute a *soft-max* over paths rather than exclusively choosing the best path over the ontology. Again, a breadth-first recursion suffices: each of the leaves y of the DAG is associated with a probability $p(y|x)$. To obtain $\mathbf{E}_{y \sim p(y|x)} [\phi(y)]$ all we need to do is perform a bottom-up traversal of the DAG summing over all probability weights on the path. Wherever a node has more than one parent, we distribute the probability weight equally over its parents.

Appendix B. Proofs

This section contains the proofs of Theorems 4, 5, and 7, along with the technical lemmas required for these.

B.1 Proof of Theorem 4

To show Theorem 4 we need several technical intermediate steps. Let $\gamma_t := J(w_t) - J_t(w_t)$ and recall that $\varepsilon_t := \min_{t' \leq t} J(w_{t'}) - J_t(w_t)$. The following lemma establishes some useful properties of γ_t and ε_t.

Lemma 9 *We have $J_{t'}(w_{t'}) \leq J_t(w_t) \leq J(w^*) \leq J(w_t) = J_{t+1}(w_t)$ for all $t' \leq t$. Furthermore, ε_t is monotonically decreasing with $\varepsilon_t - \varepsilon_{t+1} \geq J_{t+1}(w_{t+1}) - J_t(w_t) \geq 0$. Also, ε_t upper bounds the distance from optimality via $\gamma_t \geq \varepsilon_t \geq \min_{t' \leq t} J(w_{t'}) - J(w^*)$.*

Proof Since $J_{t'}(w) \leq J_t(w) \leq J(w)$ for all $t' \leq t$ this property also applies to their respective minima. Moreover, since w^* minimizes $J(w)$ we have $J(w^*) \leq J(w_t)$. Since Taylor expansions are exact at the point of expansion $J(w_t) = J_{t+1}(w_t)$. The first inequality follows from the definition of ε_t, and the fact that J_t is monotonically increasing. Finally, since $J_{t'+1}(w_{t'}) = J(w_{t'})$ it is easy to see that $\gamma_t \geq \varepsilon_t = \min_{t' \leq t} J(w_{t'}) - J_t(w_t) \geq \min_{t' \leq t} J(w_{t'}) - J(w^*)$. ■

Our second technical lemma allows us to bound the maximum value of a concave function provided that we know its first derivative and a bound on the second derivative.

Lemma 10 *Denote by $f : [0,1] \to \mathbb{R}$ a concave function with $f(0) = 0$, $f'(0) = l$, and $|f''(x)| \leq K \; \forall x \in [0,1]$. Then we have $\max_{x \in [0,1]} f(x) \geq \frac{l}{2} \min(\frac{l}{K}, 1)$.*

Proof We first observe that $g(x) := lx - \frac{K}{2}x^2 \leq f(x) \; \forall x$ implies $\max_{x \in [0,1]} f(x) \geq \max_{x \in [0,1]} g(x)$. g attains the unconstrained maximum $\frac{l^2}{2K}$ at $x = \frac{l}{K}$. Since g is monotonically increasing in $[0, \frac{l}{K}]$, if $l > K$ we pick $x = 1$ which yields constrained maximum $l - \frac{K}{2} > \frac{l}{2}$. Taking the minimum over both maxima proves the claim.

■

To apply the above result, we need to compute the gradient and Hessian of $J^*_{t+1}(\alpha)$ with respect to the search direction $((1-\eta)\alpha_t, \eta)$. The following lemma takes care of the gradient:

Lemma 11 *Denote by α_t the solution of (9) at time instance t. Moreover, denote by $\bar{A} = [A, a_{t+1}]$ and $\bar{b} = [b, b_{t+1}]$ the extended matrices and vectors needed to define the dual problem for step $t+1$, and let $\bar{\alpha} \in \mathbb{R}^{t+1}$. Then the following holds:*

$$\begin{aligned} \partial_{\bar{\alpha}} J^*_{t+1}([\alpha_t, 0]) &= \bar{A}^\top w_t + \bar{b} \text{ and} \\ [-\alpha_t, 1]^\top \left[\bar{A}^\top w_t + \bar{b}\right] &= J_{t+1}(w_t) - J_t(w_t) = \gamma_t. \end{aligned} \tag{30}$$

Proof By the dual connection $\partial \Omega^*(-\lambda^{-1} A \alpha_t) = w_t$. Hence we have that $\partial_{\bar{\alpha}} - \lambda \Omega^*(-\lambda^{-1} \bar{A} \bar{\alpha}) + \bar{\alpha}^\top \bar{b} = \bar{A}^\top w_t + \bar{b}$ for $\bar{\alpha} = [\alpha_t, 0]^\top$. This proves the first claim. To see the second part we eliminate ξ from of the Lagrangian (11) and write the partial Lagrangian

$$L(w, \alpha) = \lambda \Omega(w) + \alpha^\top \left(A^\top w + b\right) \text{ with } \alpha \geq 0.$$

The result follows by noting that at optimality $L(w_t, \alpha_t) = J_t(w_t)$ and $J_{t+1}(w_t) = \lambda \Omega(w_t) + \langle w_t, a_{t+1} \rangle + b_{t+1}$. Consequently we have

$$J_{t+1}(w_t) - J_t(w_t) = \lambda \Omega(w_t) + \langle w_t, a_{t+1} \rangle + b_{t+1} - \lambda \Omega(w_t) - \alpha_t (A^\top w_t + b_t).$$

Rearranging terms proves the claim. ■

To apply Lemma 10 we also need to bound the second derivative.

Lemma 12 *Under the assumptions of Lemma 11 we have*

$$\partial^2_{\bar{\alpha}} J^*_{t+1}(\bar{\alpha}) = -\lambda^{-1}\bar{A}^\top \partial^2\Omega^*(-\lambda^{-1}\bar{A}\bar{\alpha})\bar{A} \tag{31}$$

$$\text{moreover } \bar{A}[-\alpha_t, 1] = s_t \in \partial_w J(w_t). \tag{32}$$

Proof The first equality is immediate from the chain rule. Next note that $\partial_w\Omega(w_t) = -\lambda^{-1}A\alpha_t$ by dual connection. Since $a_{t+1} \in \partial_w R_{\text{emp}}(w_t)$ the claim follows from $J(w) = R_{\text{emp}}(w) + \lambda\Omega(w)$. ■

This result allows us to express the second derivative of the dual objective function (10) in terms of the gradient of the risk functional. The idea is that as we approach optimality, the second derivative will vanish. We will use this fact to argue that for continuously differentiable losses $R_{\text{emp}}(w)$ we enjoy linear convergence throughout.

Proof [Theorem 4] We overload the notation for J^*_{t+1} by defining the following one dimensional concave function

$$J^*_{t+1}(\eta) := J^*_{t+1}([(1-\eta)\alpha_t, \eta]) = -\lambda\Omega^*(-\lambda^{-1}\bar{A}[(1-\eta)\alpha_t^\top, \eta]) + [(1-\eta)\alpha_t^\top, \eta]\bar{b}.$$

Clearly, $J^*_{t+1}(0) = J_t(w_t)$. Furthermore, by (30), (31), and (32) it follows that

$$\begin{aligned}
\partial_\eta J^*_{t+1}(\eta)|_{\eta=0} &= [-\alpha_t, 1]^\top \partial_{\bar{\alpha}} J^*_{t+1}([\alpha_t, 0]) = \gamma_t \text{ and} \\
\partial^2_\eta J^*_{t+1}(\eta) &= -\lambda^{-1}[-\alpha_t, 1]^\top \bar{A}^\top \partial^2\Omega^*(-\lambda^{-1}\bar{A}[(1-\eta)\alpha_t, \eta])\bar{A}[-\alpha_t, 1]^\top \\
&= -\lambda^{-1} s_t^\top \partial^2\Omega^*(-\lambda^{-1}\bar{A}[(1-\eta)\alpha_t, \eta])s_t := r.
\end{aligned}$$

By our assumption on $\|\partial^2\Omega^*\| \le H^*$ we have

$$|r| \le H^*\|s_t\|^2/\lambda.$$

Next we need to bound the gradient of J. For this purpose note that $\partial_w\lambda\Omega(w_t) = -A^\top\alpha_t$ and moreover that $\|\alpha_t\|_1 = 1$. This implies that $\partial_w\lambda\Omega(w_t)$ lies in the convex hull of the past gradients, $a_{t'}$. By our assumption that $\max_{u\in\partial_w R_{\text{emp}}(w)}\|u\| \le G$ it follows that $\|\partial_w\lambda\Omega(w_t)\| \le G$. We conclude that

$$\|s_t\|^2 \le 4G^2 \text{ and } |r| \le 4G^2H^*/\lambda.$$

Invoking Lemma 10 on $J^*_{t+1}(\eta) - J_t(w_t)$ shows that

$$J^*_{t+1}(\eta) - J_t(w_t) \ge \tfrac{\gamma_t}{2}\min(1, \lambda\gamma_t/4G^2H^*).$$

We now upper bound the LHS of the above inequality as follows:

$$\varepsilon_t - \varepsilon_{t+1} \ge J_{t+1}(w_{t+1}) - J_t(w_t) \ge J^*_{t+1}(\eta) - J_t(w_t) \ge \tfrac{\gamma_t}{2}\min(1, \lambda\gamma_t/4G^2H^*). \tag{33}$$

The first inequality follows from Lemma 9 while the second follows by observing that $J_{t+1}(w_{t+1}) = J^*_{t+1}(\alpha_{t+1}) \ge J^*_{t+1}(\eta)$. The RHS of the third inequality on the other hand can be lower bounded by observing that $\gamma_t \ge \varepsilon_t$, which follows from Lemma 9. This in turn obtains (12).

For the second part note that (12) already yields the $\varepsilon_t/2$ decrease when $\varepsilon_t \ge 4G^2H^*/\lambda$. To show the other parts we need to show that the gradient of the regularized risk vanishes as we converge

to the optimal solution. Towards this end, we apply Lemma 10 in the *primal*.[23] This allows us to bound $\|\partial_w J(w_t)\|$ in terms of γ_t. Plugging in the first and second derivative of $J(w_t)$ we obtain

$$\gamma_t \geq \frac{1}{2}\|\partial_w J(w_t)\| \min(1, \|\partial_w J(w_t)\|/H).$$

If $\|\partial_w J(w_t)\| > H$, then $\gamma_t \geq \frac{1}{2}\|\partial_w J(w_t)\|$ which in turn yields $|r| \leq 4\gamma_t^2 H^*/\lambda$. Plugging this into Lemma 10 yields a lower bound on the improvement of $\lambda/8H^*$.

Finally, for $\|\partial_w J(w_t)\| \leq H$ we have $\gamma_t \geq \|\partial_w J(w_t)\|^2/2H$, which implies $|r| \leq 2HH^*\gamma_t/\lambda$. Plugging this into Lemma 10 yields an improvement of $\lambda\gamma_t/4HH^* \geq \lambda\varepsilon_t/4HH^*$.

Since both cases cover the remaining range of convergence, the minimum $\min(\lambda/8H^*, \lambda\varepsilon_t/4HH^*)$ provides a lower bound for the improvement. The crossover point between both terms occurs at $\varepsilon_t = H/2$. Rearranging the conditions leads to the (pessimistic) improvement guarantees of the second claim.

■

Note that a key step in the above analysis involved bounding $r := \partial_\eta^2 J^*_{t+1}(\eta)$. For a number of regularizers tighter bounds can be obtained. The following bounds are essentially due to Shalev-Shwartz and Singer (2006):

- For squared norm regularization, that is, $\Omega^*(\mu) = \frac{1}{2}\|\mu\|_2^2$ we have $r = \|\partial_w J(w_t)\|_2^2$.
- For L_p norm regularization, that is, $\Omega^*(\mu) = \frac{1}{2}\|\mu\|_q^2$ we have $r \leq (q-1)\|\partial_w J(w_t)\|_q^2$.
- For quadratic form regularization with PD matrix B, that is, $\Omega^*(\mu) = \frac{1}{2}\mu B^{-1}\mu$, we have $r = \partial_w J(w_t)^\top B^{-1}\partial_w J(w_t)$.
- For unnormalized entropic regularization we have $\partial_\mu^2\Omega^*(\mu) = \operatorname{diag}\left(e^{\mu^{(1)}}, \ldots, e^{\mu^{(d)}}\right)$. Hence we may bound $r \leq \|\partial_w J(w_t)\|_2^2 \exp(\|\mu\|_\infty)$. Clearly this bound may be very loose whenever μ has only very few large coefficients.
- For normalized entropy regularization, that is, $\Omega^*(\mu) = \log\sum_i \exp\mu^{(i)}$ we have $r \leq \|\partial_w J(w_t)\|_\infty^2$.

B.2 Proof of Theorem 5

We need the following technical lemma for the proof:

Lemma 13 *Let $\langle \rho_1, \rho_2, \ldots\rangle$ be a sequence of non-negative numbers satisfying the following recurrence, for $t \geq 1$: $\rho_t - \rho_{t+1} \geq c(\rho_t)^2$, where $c > 0$ is a constant. Then for all integers $t \geq 1$,*

$$\rho_t \leq \frac{1}{c(t-1+\frac{1}{\rho_1 c})}.$$

Furthermore $\rho_t \leq \rho$ whenever

$$t \geq \frac{1}{c\rho} - \frac{1}{\rho_1 c} + 1.$$

23. Define $\bar{J}(\eta) := J(w_t) - J(w_t + \eta p)$ where $p = -\frac{\partial_w J(w_t)}{\|\partial_w J(w_t)\|}$ is the unit-length gradient. We see that $\frac{d}{d\eta}\bar{J}(\eta)\Big|_{\eta=0} = [-\partial_w J(w_t + \eta p)^\top p]|_{\eta=0} = \|\partial_w J(w_t)\|$, and $\bar{J}(0) = 0$. Hence Lemma 10 is applicable in this case.

This is Sublemma 5.4 of Abe et al. (2001) which is easily proven by induction. Now we can prove the main result.

Proof [Theorem 5] For any $\varepsilon_t > 4G^2H^*/\lambda$ it follows from (12) that $\varepsilon_{t+1} \leq \varepsilon_t/2$. Moreover, $\varepsilon_0 \leq J(0)$, since we know that J is non-negative. Hence we need at most $\log_2[\lambda J(0)/4G^2H^*]$ to achieve this level of precision. Subsequently we have

$$\varepsilon_t - \varepsilon_{t+1} \geq \frac{\lambda}{8G^2H^*}\varepsilon_t^2.$$

Invoking Lemma 13 by setting $c = \frac{\lambda}{8G^2H^*}$ and $\rho_1 = 4G^2H^*/\lambda$ shows that $\varepsilon_t \leq \varepsilon$ after at most $\frac{8G^2H^*}{\lambda\varepsilon} - 1$ more steps. This proves the first claim.

To analyze convergence in the second case we need to study two additional phases: for $\varepsilon_t \in [H/2, 4G^2H^*/\lambda]$ we see constant progress. Hence it takes us $4\lambda^{-2}[8G^2(H^*)^2 - HH^*\lambda]$ steps to cover this interval. Finally in the third phase we have $\varepsilon_{t+1} \leq \varepsilon_t[1-\lambda/4HH^*]$. Starting from $\varepsilon_t = H/2$ we need $\log_2[2\varepsilon/H]/\log_2[1-\lambda/4HH^*]$ steps to converge. Expanding the logarithm in the denominator close to 1 proves the claim. ■

B.3 Proof of Theorem 7

We first note that the termination criterion of Algorithm 3 is slightly different from that of Algorithm 2. In order to apply the convergence results for Algorithm 2 to Algorithm 3 we redefine the following notations:

$$\begin{aligned} \varepsilon_t &:= J(w_t^b) - J_t(w_t) \\ a_{t+1} &\in \partial_w R_{\text{emp}}(w_t^c), \\ b_{t+1} &:= R_{\text{emp}}(w_t^c) - \langle w_t, a_{t+1} \rangle, \end{aligned} \tag{34}$$

where

$$\begin{aligned} \eta_t &:= \operatorname*{argmin}_{\eta} J(w_{t-1}^b + \eta(w_t - w_{t-1}^b)), \\ w_t^b &:= \hat{w}_{t-1} + \eta_t(\bar{w}_t - \hat{w}_{t-1}), \text{ and} \\ w_t^c &:= (1-\theta)w_t^b + \theta w_t. \end{aligned}$$

Then we state and prove the following lemma which is crucial to the application of Lemma 11 in the proof.

Lemma 14 $J_{t+1}(w_t) = \lambda\Omega(w_t) + \langle w_t, a_{t+1} \rangle + b_{t+1}$

Proof w_t^b is the optimal value of J on the line joining w_t and w_{t-1}^b while w_t^c is a convex combination of w_t and w_t^b. Moreover by definition of a_{t+1} and b_{t+1} we have $J(w_t^c) = J_{t+1}(w_t^c)$. Therefore,

$$J(w_t^c) = J_{t+1}(w_t^c) = \lambda\Omega(w_t^c) + \langle a_{t+1}, w_t^c \rangle + b_{t+1} \geq J(w_t^b). \tag{35}$$

But since Ω is convex

$$\Omega(\underbrace{(1-\theta)w_t^b + \theta w_t}_{w_t^c}) \leq (1-\theta)\Omega(w_t^b) + \theta\Omega(w_t),$$

which can be rearranged to

$$\theta(\Omega(w_t^b) - \Omega(w_t)) \leq \Omega(w_t^b) - \Omega(w_t^c).$$

Multiplying by λ and adding and subtracting $\theta R_{\text{emp}}(w_t^b)$ and $\theta R_t(w_t)$ respectively to the above equation

$$\underbrace{\lambda\theta\Omega(w_t^b) + \theta R_{\text{emp}}(w_t^b)}_{\theta J(w_t^b)} - \underbrace{\lambda\theta\Omega(w_t) - \theta R_t(w_t)}_{\theta J_t(w_t)} \leq \underbrace{\lambda\Omega(w_t^b) + R_{\text{emp}}(w_t^b)}_{J(w_t^b)} - \lambda\Omega(w_t^c) - (1-\theta)R_{\text{emp}}(w_t^b) - \theta R_t(w_t).$$

Plugging in (34) obtains

$$\theta\varepsilon_t \leq J(w_t^b) - \lambda\Omega(w_t^c) - (1-\theta)R_{\text{emp}}(w_t^b) - \theta R_t(w_t). \tag{36}$$

Putting (35) and (36) together

$$\langle a_{t+1}, w_t^c\rangle + b_{t+1} \geq J(w_t^b) - \lambda\Omega(w_t^c) \geq (1-\theta)R_{\text{emp}}(w_t^b) + \theta R_t(w_t) + \theta\varepsilon_t.$$

Since $w_t^c = (1-\theta)w_t^b + \theta w_t$ it follows that

$$(1-\theta)\left\langle a_{t+1}, w_t^b\right\rangle + \theta\langle a_{t+1}, w_t\rangle + b_{t+1} \geq (1-\theta)R_{\text{emp}}(w_t^b) + \theta R_t(w_t) + \theta\varepsilon_t.$$

Which can be rearranged to

$$(1-\theta)\left(\left\langle a_{t+1}, w_t^b\right\rangle - R_{\text{emp}}(w_t^b)\right) + \theta(\langle a_{t+1}, w_t\rangle - R_t(w_t)) + b_{t+1} \geq \theta\varepsilon_t.$$

Since $\left\langle w_t^b, a_{t+1}\right\rangle + b_{t+1}$ is the Taylor approximation of the convex function R_{emp} around w_t^c evaluated at w_t^b it follows that $R_{\text{emp}}(w_t^b) \geq \left\langle w_t^b, a_{t+1}\right\rangle + b_{t+1}$. Plugging this into the above equation yields

$$(1-\theta)(-b_{t+1}) + \theta(\langle w_t, a_{t+1}\rangle - R_t(w_t)) + b_{t+1} \geq \theta\varepsilon_t.$$

Dividing by $\theta > 0$ and rearranging yields

$$\langle w_t, a_{t+1}\rangle + b_{t+1} \geq R_t(w_t) + \varepsilon_t.$$

The conclusion of the lemma follows from observing that $R_{t+1}(w_t) = \max(\langle w_t, a_{t+1}\rangle + b_{t+1}, R_t(w_t)) = \langle w_t, a_{t+1}\rangle + b_{t+1}$ and $J_{t+1}(w_t) = \lambda\Omega(w_t) + R_{t+1}(w_t)$. ■

We also need the following two lemmas before we can proceed to the final proof.

Lemma 15 $\varepsilon_t - \varepsilon_{t+1} \geq J_{t+1}(w_{t+1}) - J_t(w_t)$

Proof

$$\begin{aligned}
\varepsilon_t - \varepsilon_{t+1} &= J(w_t^b) - J_t(w_t) - J(w_{t+1}^b) + J_{t+1}(w_{t+1}) \\
&= \underbrace{(J(w_t^b) - J(w_{t+1}^b))}_{\geq 0} + J_{t+1}(w_{t+1}) - J_t(w_t) \quad \text{(by the definition of } w_t^b\text{)} \\
&\geq J_{t+1}(w_{t+1}) - J_t(w_t).
\end{aligned}$$

■

Lemma 16 *Let* α_t, $\bar{A} := [a_1, \ldots, a_{t+1}]$, *and* $\bar{b} := [b_1, \ldots, b_{t+1}]$ *be as defined in Lemma 11. Then under the assumption of Theorem 4 that* $\max_{u \in \partial_w R_{\text{emp}}(w)} \|u\| \leq G$, *we have*

$$[-\alpha_t, 1]^\top \bar{A}^\top \bar{A} [-\alpha_t, 1] \leq 4G^2.$$

Proof By the dual connection, $\partial_w \lambda \Omega(w_t) = -A\alpha_t$. Also, $\alpha_t \geq 0$, and $\|\alpha_t\|_1 = 1$ as it is the optimal solution of (10) at iteration t. It follows that $\partial_w \lambda \Omega(w_t)$ lies in the convex hull of $a_{t'} \in \partial_w R_{\text{emp}}(w_{t'}^c)\ \forall t' \leq t$. Therefore $\|\partial_w \lambda \Omega(w_t)\| \leq G$. Consequently,

$$\begin{aligned}[-\alpha_t, 1]^\top \bar{A}^\top \bar{A} [-\alpha_t, 1] &= \|\partial_w \lambda \Omega(w_t) + a_{t+1}\|^2 \\ &= \|\partial_w \lambda \Omega(w_t)\|^2 + 2\partial_w \lambda \Omega(w_t)^\top a_{t+1} + \|a_{t+1}\|^2 \leq 4G^2,\end{aligned}$$

by Cauchy-Schwarz inequality. ■

Finally, we sketch the proof for Theorem 7.

Proof [Theorem 7] (Sketch) Theorem 4 holds for Algorithm 3 by applying Lemmas 14, 15, and 16 into the first part of the proof. Therefore, for $\varepsilon < 4G^2H^*/\lambda$, (33) reduces to $\varepsilon_t - \varepsilon_{t+1} \geq \lambda \varepsilon_t / 4G^2 H^*$. Applying Lemma 13 yields $\varepsilon_t \leq \frac{1}{c\left(t - 1 + \frac{1}{\varepsilon_1 c}\right)}$, with $c = \lambda / 8G^2 H^*$. Setting $\frac{1}{c\left(t-1+\frac{1}{\varepsilon_1 c}\right)} = \varepsilon$, assuming that $\varepsilon_1 > 0$, and solving for n yields $n \leq \frac{1}{c\varepsilon} = \frac{8G^2H^*}{\lambda\varepsilon}$. ■

Appendix C. L_1 Regularized BMRM

Following our convention, the L_1 norm regularized BMRM reads

$$\min_{\xi, w} \ \xi + \lambda \|w\|_1 \ \text{ subject to } w^\top a_i + b_i \leq \xi,\ i = 1, \ldots, t. \tag{37}$$

An equivalent formulation is

$$\min_{\xi, w} \ \xi \text{ subject to } w^\top a_i + b_i \leq \xi,\ i = 1, \ldots, t \text{ and } \|w\|_1 \leq \tau, \tag{38}$$

where one can show a monotone correspondence between τ and the λ in (37) by comparison of the KKT conditions for the two problems.

Note that our convergence proof does not apply in this case as the Fenchel dual of $\Omega(w) = \|w\|_1$ fails to satisfy the strong convexity assumption. Nevertheless, we see that (38) can be easily solved by CPM where the solution must lie in the L_1 ball of radius τ. Finally, we note that the L_1 regularized BMRM can be written in a rather standard linear programming (LP) formulation:

$$\begin{aligned}\min_{\xi, u, v} \ & \xi + \lambda \mathbf{1}_d^\top (u + v) \\ \text{s.t. } & a_i^\top u - a_i^\top v + b_i \leq \xi,\ i = 1, \ldots, t \\ & u, v \geq 0,\end{aligned}$$

with the variable of interest $w = u - v$.

Abstract

Actor-Critic based approaches were among the first to address reinforcement learning in a general setting. Recently, these algorithms have gained renewed interest due to their generality, good convergence properties, and possible biological relevance. In this paper, we introduce an online temporal difference based actor-critic algorithm which is proved to converge to a neighborhood of a local maximum of the average reward. Linear function approximation is used by the critic in order estimate the value function, and the temporal difference signal, which is passed from the critic to the actor. The main distinguishing feature of the present convergence proof is that both the actor and the critic operate on a similar time scale, while in most current convergence proofs they are required to have very different time scales in order to converge. Moreover, the same temporal difference signal is used to update the parameters of both the actor and the critic. A limitation of the proposed approach, compared to results available for two time scale convergence, is that convergence is guaranteed only to a neighborhood of an optimal value, rather to an optimal value itself. The single time scale and identical temporal difference signal used by the actor and the critic, may provide a step towards constructing more biologically realistic models of reinforcement learning in the brain.

Keywords: actor critic, single time scale convergence, temporal difference

1. Introduction

In Reinforcement Learning (RL) an agent attempts to improve its performance over time at a given task, based on continual interaction with the (usually unknown) environment (Bertsekas and Tsitsiklis, 1996; Sutton and Barto, 1998). Formally, it is the problem of mapping situations to actions in order to maximize a given average reward signal. The interaction between the agent and the environment is modeled mathematically as a Markov Decision Process (MDP). Approaches based on a direct interaction with the environment, are referred to as *simulation based algorithms*, and will form the major focus of this paper.

A well known subclass of RL approaches consists of the so called actor-critic (AC) algorithms (Sutton and Barto, 1998), where the agent is divided into two components, an actor and a critic. The critic functions as a value estimator, whereas the actor attempts to select actions based on the value estimated by the critic. These two components solve their own problems separately but interactively. Many methods for solving the critic's value estimation problem, for a *fixed* policy, have been proposed, but, arguably, the most widely used is *temporal difference* (TD) learning. TD learning was demonstrated to accelerate convergence by trading bias for variance effectively (Singh and Dayan, 1998), and is often used as a component of AC algorithms.

In general, policy selection may be randomized. When facing problems with a large number of states or actions (or even continuous state-action problems), effective policy selection may suffer from several problems, such as slow convergence rate or an inefficient representation of the policy. A possible approach to policy learning is the so-called *policy gradient method* (Baxter and Bartlett, 2001; Cao, 2007; Cao and Chen, 1997; Konda and Tsitsiklis, 2003; Marbach and Tsitsiklis, 1998). Instead of maintaining a separate estimate for the value for each state (or state-action pair), the agent maintains a parametrized policy function. The policy function is taken to be a differentiable function of a parameter vector and of the state. Given the performance measure, depending on the agent's policy parameters, these parameters are updated using a sampling-based estimate of the gradient of the average reward. While such approaches can be proved to converge under certain conditions (Baxter and Bartlett, 2001), they often lead to slow convergence, due to very high variance. A more general approach based on sensitivity analysis, which includes policy gradient methods as well as non-parametric average reward functions, has been discussed in depth in the recent manuscript by Cao (2007).

Several AC algorithms with associated convergence proofs have been proposed recently (a short review is given in Section 2.2). As far as we are aware, all the convergence results for these algorithms are based on two time scales, specifically, the actor is assumed to update its internal parameters on a much slower time scale than the one used by the critic. The intuitive reason for this time scale separation is clear, since the actor improves its policy based on the critic's estimates. It can be expected that rapid change of the policy parameters may not allow the critic to effectively evaluate the value function, which may lead to instability when used by the actor in order to re-update its parameters.

The objective of this paper is to propose an online AC algorithm and establish its convergence under conditions which do *not* require the separation into two time scales. In this context we note that recent work by Mokkadem and Pelletier (2006), based on earlier research by Polyak and colleagues, has demonstrated that combing the two-time scale approach with the averaging method of Polyak (1990), can lead to the single time scale convergence at the optimal rate. In these works the rate of convergence is defined in terms of convergence in distribution, while the present work focuses on convergence with probability 1. As far as we are aware, no rates of convergence are currently known for two time scale approaches in the latter, stronger, setting. In fact, our motivation for the current direction was based on the possible relevance of AC algorithms in a biological context (Daw et al., 2006), where it would be difficult to justify two very different time scales operating within the same anatomical structure.[1] We refer the reader to DiCastro et al. (2008) for some preliminary ideas and references related to these issues. Given the weaker conditions assumed on the time scales, our convergence result is, not surprisingly, somewhat weaker than that provided recently in Bhatnagar et al. (2008, 2009), as we are not ensured to converge to a local optimum, but only to a neighborhood of such an optimum. Nevertheless, it is shown that the neighborhood size can be algorithmically controlled. Further comparative discussion can be found in Section 2.

This paper is organized as follows. In Section 2 we briefly recapitulate current AC algorithms for which convergence proofs are available. In Section 3, we formally introduce the problem setup. We begin Section 4 by relating the TD signal to the gradient of the average reward, and then move on to motivate and derive the main AC algorithm, concluding the section with a convergence proof. A comparative discussion of the main features of our approach is presented in Section 5, followed

1. Note that the results in Mokkadem and Pelletier (2006), while providing optimal single time scale convergence, still rely on an underlying two time scale algorithm

by some simulation results in Section 6. Finally, in Section 7, we discuss the results and point out possible future work. In order to facilitate the readability of the paper, we have relegated all technical proofs to appendices.

2. Previous Work

In this section we briefly review some previous work in RL which bears direct relevance to our work. While many AC algorithms have been introduced over the years, we focus only on those for which a convergence proof is available, since the main focus of this work is on convergence issues, rather than on establishing the most practically effective algorithms. See, for example, Peters and Schaal (2008), for promising applications of AC algorithms in a robotic setting.

2.1 Direct Policy Gradient Algorithms

Direct policy gradient algorithms, employing agents which consist of an actor only, typically estimate a noisy gradient of the average reward, and are relatively close in their characteristics to AC algorithms. The main difference from the latter is that the agent does not maintain a separate value estimator for each state, but rather interacts with the environment directly, and in a sense maintains its value estimate implicitly through a mapping which signifies which path the agent should take in order to maximize its average reward per stage.

Marbach and Tsitsiklis (1998) suggested an algorithm for non-discounted environments. The gradient estimate is based on an estimate of the state values which the actor estimates while interacting with the environment. If the actor returns to a sequence of previously visited states, it re-estimates the states value, not taking into account its previous visits. This approach often results in large estimation variance.

Baxter and Bartlett (2001) proposed an online algorithm for partially observable MDPs. In this algorithm, the agent estimates the expected average reward for the non-discounted problems through an estimate of the value function of a related discounted problem. It was shown that when the discount factor approaches 1, the related discounted problem approximates the average reward per stage. Similar to the algorithms of Marbach and Tsitsiklis (1998), it suffers from relatively large estimation variance. Greensmith et al. (2004) have proposed a method for coping with the large variance by adding a baseline to the value function estimation.

2.2 Actor Critic Algorithms

As stated in Section 1, the convergence proofs of which we are aware for AC algorithms are based on two time scale stochastic approximation (Borkar, 1997), where the actor is assumed to operate on a time scale which is much slower than that used by the critic.

Konda and Borkar (1999) suggested a set of AC algorithms. In two of their algorithms (Algorithms 3 and 6), parametrized policy based actors were used while the critic was based on a lookup table. Those algorithms and their convergence proofs were specific to the Gibbs policy function in the actor.

As far as we are aware, Konda and Tsitsiklis (2003) provided the first convergence proof for an AC algorithm based on function approximation. The information passed from the critic to the actor is the critic's action-value function, and the critic's basis functions, which are explicitly used by the actor. They provided a convergence proof of their TD(λ) algorithm where λ approaches 1.

A drawback of the algorithm is that the actor and the critic must share the information regarding the actor's parameters. This detailed information sharing is a clear handicap in a biological context, which was one of the driving forces for the present work.

Finally, Bhatnagar et al. (2008, 2009) recently proposed an AC algorithm which closely resembles our proposed algorithm, and which was developed independently of ours. In this work the actor uses a parametrized policy function while the critic uses a function approximation for the state evaluation. The critic passes to the actor the TD(0) signal and based on it the actor estimates the average reward gradient. A detailed comparison will be provided in Section 5. As pointed out in Bhatnagar et al. (2008, 2009), their work is the first to provide a convergence proof for an AC algorithm incorporating bootstrapping (Sutton and Barto, 1998), where bootstrapping refers to a situation where estimates are updated based on other estimates, rather than on direct measurements (as in Monte Carlo approaches). This feature applies to our work as well. We also note that Bhatnagar et al. (2008, 2009) extend their approach to the so-called natural gradient estimator, which has been shown to lead to improved convergence in supervised learning as well as RL. The present study focuses on the standard gradient estimate, leaving the extension to natural gradients to future work.

3. The Problem Setup

In this section we describe the formal problem setup, and present a sequence of assumptions and lemmas which will be used in order to prove convergence of Algorithm 1 in Section 4. These assumptions and lemmas mainly concern the properties of the controlled Markov chain, which represents the environment, and the properties of the actor's parametrized policy function.

3.1 The Dynamics of the Environment and of the Actor

We consider an agent, composed of an actor and a critic, interacting with an environment. We model the environment as a *Markov Decision Process* (MDP) (Puterman, 1994) in discrete time with a finite state set $\mathcal{X}$ and an action set $\mathcal{U}$, which may be uncountable. We denote by $|\mathcal{X}|$ the size of the set $\mathcal{X}$. Each selected action $u \in U$ determines a stochastic matrix $P(u) = [P(y|x,u)]_{x,y\in\mathcal{X}}$ where $P(y|x,u)$ is the transition probability from a state $x \in \mathcal{X}$ to a state $y \in \mathcal{X}$ given the control u. For each state $x \in \mathcal{X}$ the agent receives a corresponding reward $r(x)$, which may be deterministic or random. In the present study we assume for simplicity that the reward is deterministic, a benign assumption which can be easily generalized.

Assumption 1 *The rewards, $\{r(x)\}_{x\in\mathcal{X}}$, are uniformly bounded by a finite constant B_r.*

The actor maintains a *parametrized policy function*. A parametrized policy function is a conditional probability function, denoted by $\mu(u|x,\theta)$, which maps an observation $x \in \mathcal{X}$ into a control $u \in \mathcal{U}$ given a parameter $\theta \in \mathbb{R}^K$. The agent's goal is to adjust the parameter θ in order to attain maximum average reward over time. For each θ, we have a Markov Chain (MC) induced by $P(y|x,u)$ and $\mu(u|x,\theta)$. The state transitions of the MC are obtained by first generating an action u according to $\mu(u|x,\theta)$, and then generating the next state according to $\{P(y|x,u)\}_{x,y\in\mathcal{X}}$. Thus, the MC has a transition matrix $P(\theta) = [P(y|x,\theta)]_{x,y\in\mathcal{X}}$ which is given by

$$P(y|x,\theta) = \int_{\mathcal{U}} P(y|x,u)d\mu(u|x,\theta). \tag{1}$$

We denote the space of these transition probabilities by $\mathcal{P} = \{P(\theta)|\theta \in \mathbb{R}^K\}$, and its closure by $\bar{\mathcal{P}}$. The following assumption is needed in the sequel in order to prove the main results (Brémaud, 1999).

Assumption 2 *Each MC, $P(\theta) \in \bar{\mathcal{P}}$, is aperiodic, recurrent, and irreducible.*

As a result of Assumption 2, we have the following lemma regarding the stationary distribution and a common recurrent state.

Lemma 1 *Under Assumption 2 we have:*

1. Each MC, $P(\theta) \in \bar{\mathcal{P}}$, has a unique stationary distribution, denoted by $\pi(\theta)$, satisfying $\pi(\theta)'P(\theta) = \pi(\theta)'$.
2. There exists a state, denoted by x^*, which is recurrent for all $P(\theta) \in \bar{\mathcal{P}}$.

Proof For the first part see Corollary 4.1 in Gallager (1995). The second part follows trivially from Assumption 2. ■

The next technical assumption states that the first and second derivatives of the parametrized policy function are bounded, and is needed to prove Lemma 3 below.

Assumption 3 *The conditional probability function $\mu(u|x,\theta)$ is twice differentiable. Moreover, there exist positive constants, B_{μ_1} and B_{μ_2}, such that for all $x \in \mathcal{X}$, $u \in \mathcal{U}$, $\theta \in \mathbb{R}^K$ and $k_1 \geq 1$, $k_2 \leq K$ we have*

$$\left|\frac{\partial \mu(u|x,\theta)}{\partial \theta_k}\right| \leq B_{\mu_1}, \quad \left|\frac{\partial^2 \mu(u|x,\theta)}{\partial \theta_{k_1} \partial \theta_{k_2}}\right| \leq B_{\mu_2}.$$

A notational comment concerning bounds *Throughout the paper we denote upper bounds on different variables by the letter B, with a subscript corresponding to the variable itself. An additional numerical subscript, 1 or 2, denotes a bound on the first or second derivative of the variable. For example, B_f, B_{f_1}, and B_{f_2} denote the bounds on the function f and its first and second derivatives respectively.*

3.2 Performance Measures

Next, we define a performance measure for an agent in an environment. The *average reward per stage* of an agent which traverses a MC starting from an initial state $x \in \mathcal{X}$ is defined by

$$J(x,\theta) \triangleq \lim_{T\to\infty} \mathrm{E}\left[\frac{1}{T}\sum_{n=0}^{T-1} r(x_n)\middle| x_0 = x, \theta\right],$$

where $\mathrm{E}[\cdot|\theta]$ denotes the expectation under the probability measure $P(\theta)$, and x_n is the state at time n. The agent's goal is to find $\theta \in \mathbb{R}^K$ which maximizes $J(x,\theta)$. The following lemma shows that under Assumption 2, the average reward per stage does not depend on the initial state; see Bertsekas (2006), vol. II, Section 4.1.

Lemma 2 *Under Assumption 2 and based on Lemma 1, the average reward per stage, $J(x,\theta)$, is independent of the starting state, is denoted by $\eta(\theta)$, and satisfies $\eta(\theta) = \pi(\theta)'r$.*

Based on Lemma 2, the agent's goal is to find a parameter vector θ, which maximizes the average reward per stage $\eta(\theta)$. In the sequel we show how this maximization can be performed by optimizing $\eta(\theta)$, using $\nabla_\theta \eta(\theta)$. A consequence of Assumption 3 and the definition of $\eta(\theta)$ is the following lemma.

Lemma 3

1. For each $x, y \in \mathcal{X}$, $1 \leq i, j \leq K$, and $\theta \in \mathbb{R}^K$, the functions $\partial P(y|x,\theta)/\partial\theta_i$ and $\partial^2 P(y|x,\theta)/\partial\theta_i\partial\theta_j$ are uniformly bounded by B_{P_1} and B_{P_2} respectively.

   (a) For each $x \in \mathcal{X}$, $1 \leq i, j \leq K$, and $\theta \in \mathbb{R}^K$, the functions $\partial\pi(x|\theta)/\partial\theta_i$ and $\partial^2\pi(x|\theta)/\partial\theta_i\partial\theta_j$ are uniformly bounded by , B_{π_1} and B_{π_2} respectively.

   (b) For all $1 \leq i, j \leq K$, and $\theta \in \mathbb{R}^K$, the functions $\eta(\theta)$, $\partial\eta(\theta)/\partial\theta_i$, $\partial^2\pi(x|\theta)/\partial\theta_i\partial\theta_j$ are uniformly bounded by , B_η, B_{η_1} and B_{η_2} respectively.

   (c) For all $x \in \mathcal{X}$ and $\theta \in \mathbb{R}^K$, there exists a constant $b_\pi > 0$ such that $\pi(x|\theta) \geq b_\pi$.

The proof is technical and is given in Appendix A.1. For later use, we define the random variable T, which denotes the first return time to the recurrent state x^*. Formally,

$$T \triangleq \min\{k > 0 | x_0 = x^*, x_k = x^*\}.$$

It is easy to show that under Assumption 2, the average reward per stage can be expressed by

$$\eta(\theta) = \lim_{T\to\infty} \mathrm{E}\left[\frac{1}{T}\sum_{n=0}^{T-1} r(x_n)\middle| x_0 = x^*, \theta\right].$$

Next, we define the *differential value function* of state $x \in \mathcal{X}$ which represents the average differential reward the agent receives upon starting from a state x and reaching the recurrent state x^* for the first time. Mathematically,

$$h(x,\theta) \triangleq \mathrm{E}\left[\sum_{n=0}^{T-1}(r(x_n) - \eta(\theta))\middle| x_0 = x, \theta\right].$$

Abusing notation slightly, we denote $h(\theta) \triangleq (h(x_1,\theta),\ldots,h(x_{|\mathcal{X}|},\theta)) \in \mathbb{R}^{|\mathcal{X}|}$. For each $\theta \in \mathbb{R}^K$ and $x \in \mathcal{X}$, $h(x,\theta)$, $r(x)$, and $\eta(\theta)$ satisfy Poisson's equation, as in Theorem 7.4.1 in Bertsekas (2006), that is,

$$h(x,\theta) = r(x) - \eta(\theta) + \sum_{y\in\mathcal{X}} P(y|x,\theta)h(y,\theta). \tag{2}$$

Based on the differential value we define the *temporal difference* (TD) between the states $x \in \mathcal{X}$ and $y \in \mathcal{X}$ (Bertsekas and Tsitsiklis, 1996; Sutton and Barto, 1998),

$$d(x,y,\theta) \triangleq r(x) - \eta(\theta) + h(y,\theta) - h(x,\theta). \tag{3}$$

According to common wisdom, the TD is interpreted as a prediction error. The next lemma states the boundedness of $h(x,\theta)$ and its derivatives. The proof is given in Appendix A.2.

Lemma 4

1. The differential value function, $h(x,\theta)$, is bounded and has bounded first and second derivative. Mathematically, for all $x \in \mathcal{X}$, $1 \leq i,j \leq K$, and for all $\theta \in \mathbb{R}^K$ we have

$$|h(x,\theta)| \leq B_h, \quad \left|\frac{\partial h(x,\theta)}{\partial \theta_i}\right| \leq B_{h_1}, \quad \left|\frac{\partial^2 h(x,\theta)}{\partial \theta_i \partial \theta_j}\right| \leq B_{h_2}.$$

   (a) There exists a constant B_D such that or all $\theta \in \mathbb{R}^K$ we have $|d(x,y,\theta)| \leq B_D$, where $B_D = 2(B_r + B_h)$.

3.3 The Critic's Dynamics

The critic maintains an estimate of the environmental state values. It does so by maintaining a parametrized function which approximates $h(x,\theta)$, and is denoted by $\tilde{h}(x,w)$. The function $\tilde{h}(x,w)$ is a function of the state $x \in \mathcal{X}$ and a parameter $w \in \mathbb{R}^L$. We note that $h(x,\theta)$ is a function of θ, and is induced by the actor policy $\mu(u|x,\theta)$, while $\tilde{h}(x,w)$ is a function of w. Thus, the critic's objective is to find the parameter w which yields the best approximation of $h(\theta) = (h(x_1,\theta),\ldots,h(x_{|\mathcal{X}|},\theta))$, in a sense to be defined later. We denote this optimal vector by $w^*(\theta)$. An illustration of the interplay between the actor, critic, and the environment is given in Figure 1.

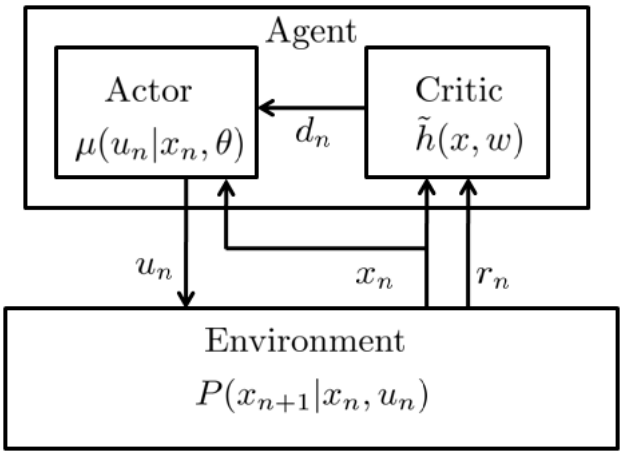

Figure 1: A schematic illustration of the dynamics between the actor, the critic, and the environment. The actor chooses an action, u_n, according to the parametrized policy $\mu(u|x,\theta)$. As a result, the environment proceeds to the next state according to the transition probability $P(x_{n+1}|x_n,u_n)$ and provides a reward. Using the TD signal, the critic improves its estimation for the environment state values while the actor improves its policy.

4. A Single Time Scale Actor Critic Algorithm with Linear Function Approximation

In this section, we present a version of an AC algorithm, along with its convergence proof. The core of the algorithm is based on (4) below, where the actor's estimate of $\nabla_\theta \eta(\theta)$ is based on the critic's estimate of the TD signal $d(x,y,\theta)$. The algorithm is composed of three iterates, one for the

actor and two for the critic. The actor maintains the iterate of the parameter vector θ corresponding to the policy $\mu(u|x,\theta)$, where its objective is to find the optimal value of θ, denoted by θ^*, which maximizes $\eta(\theta)$. The critic maintains the other two iterates. One iterate is used for estimating the average reward per stage, $\eta(\theta)$, where its estimate is denoted by $\tilde{\eta}$. The critic's second iterate maintains a parameter vector, denoted by $w \in \mathbb{R}^L$, which is used for the differential value estimate using a function approximator, denoted by $\tilde{h}(w)$. For each $\theta \in \mathbb{R}^K$, there exists a $w^*(\theta)$ which, under the policy induced by θ, is the optimal w for estimating $\tilde{\eta}(w)$. The critic's objective is to find the optimal $\tilde{\eta}$ and w.

4.1 Using the TD Signal to Estimate the Gradient of the Average Reward

We begin with a theorem which serves as the foundation for the policy gradient algorithm described in Section 4. The theorem relates the gradient of the average reward per stage, $\eta(\theta)$, to the TD signal. It was proved in Bhatnagar et al. (2008), and is similar in its structure to other theorems which connect $\eta(\theta)$ to the Q-value (Konda and Tsitsiklis, 2003), and to the differential value function (Cao, 2007; Marbach and Tsitsiklis, 1998).

We start with a definition of the *likelihood ratio derivative*

$$\psi(x,u,\theta) \triangleq \frac{\nabla_\theta \mu(u|x,\theta)}{\mu(u|x,\theta)},$$

where the gradient ∇_θ is w.r.t. θ, and $\psi(x,u,\theta) \in \mathbb{R}^K$. The following assumption states that $\psi(x,u,\theta)$ is bounded, and will be used to prove the convergence of algorithm 1.

Assumption 4 *For all $x \in \mathcal{X}$, $u \in \mathcal{U}$, and $\theta \in \mathbb{R}^K$, there exists a positive constant, B_ψ, such that*

$$\|\psi(x,u,\theta)\|_2 \leq B_\psi < \infty,$$

where $\|\cdot\|_2$ is the Euclidean L_2 norm.

Based on this, we present the following theorem which relates the gradient of $\eta(\theta)$ to the TD signal. For completeness, we supply a (straightforward) proof in Appendix B.

Theorem 5 *For any arbitrary function $f(x)$, the gradient w.r.t. θ of the average reward per stage can be expressed by*

$$\nabla_\theta \eta(\theta) = \sum_{x,y \in \mathcal{X}} P(x,u,y,\theta)\psi(x,u,\theta)d(x,y,\theta), \tag{4}$$

where $P(x,u,y,\theta)$ is the probability $\Pr(x_n = x, u_n = u, x_{n+1} = y)$ subject to the policy parameter θ.

4.2 The Updates Performed by the Critic and the Actor

We note that the following derivation regarding the critic is similar in some respects to the derivation in Section 6.3.3 in Bertsekas and Tsitsiklis (1996) and Tsitsiklis and Roy (1997). We define the following quadratic target function used to evaluate the critic's performance in assessing the differential value $h(\theta)$,

$$I(w,\theta) \triangleq \frac{1}{2}\sum_{x \in \mathcal{X}} \pi(x|\theta)\left(\tilde{h}(x,w) - h(x,\theta)\right)^2 . \tag{5}$$

The probabilities $\{\pi(x|\theta)\}_{x \in \mathcal{X}}$ are used in order to provide the proportional weight to the state estimates, according to the relative number of visits of the agent to the different states.

Limiting ourselves to the class of linear function approximations in the critic, we consider the following function for the differential value function

$$\tilde{h}(x,w) = \phi(x)'w, \tag{6}$$

where $\phi(x) \in \mathbb{R}^L$. We define $\Phi \in \mathbb{R}^{|\mathcal{X}|\times L}$ to be the matrix

$$\Phi \triangleq \begin{pmatrix} \phi_1(x_1) & \phi_2(x_1) & \dots & \phi_L(x_1) \\ \phi_1(x_2) & \phi_2(x_2) & \dots & \phi_L(x_2) \\ \vdots & \vdots & & \vdots \\ \phi_1(x_{|\mathcal{X}|}) & \phi_2(x_{|\mathcal{X}|}) & \dots & \phi_L(x_{|\mathcal{X}|}) \end{pmatrix},$$

where $\phi(\cdot)$ is a column vector. Therefore, we can express (6) in vector form as

$$\tilde{h}(w) = \Phi w,$$

where, abusing notation slightly, we set $\tilde{h}(w) = \left(\tilde{h}(x_1,w),\dots,\tilde{h}(x_{|\mathcal{X}|},w)\right)'$.

We wish to express (5), and the approximation process, in an appropriate Hilbert space. Define the matrix $\Pi(\theta)$ to be a diagonal matrix $\Pi(\theta) \triangleq \mathrm{diag}(\pi(\theta))$. Thus, (5) can be expressed as

$$I(w,\theta) = \frac{1}{2}\left\|\Pi(\theta)^{\frac{1}{2}}\left(h(\theta)-\Phi w\right)\right\|_2^2 \triangleq \frac{1}{2}\left\|h(\theta)-\Phi w\right\|_{\Pi(\theta)}^2. \tag{7}$$

In the sequel, we will need the following technical assumption.

Assumption 5

1. The columns of the matrix Φ are independent, that is, they form a basis of dimension L.

   (a) The norms of the column vectors of the matrix Φ are bounded above by 1, that is, $\|\phi_k\|_2 \leq 1$ for $1 \leq k \leq L$.

The parameter $w^*(\theta)$, which optimizes (7), can be directly computed, but involves inverting a matrix. Thus, in order to find the right estimate for $\tilde{h}(w)$, the following *gradient descent* (Bertsekas and Tsitsiklis, 1996) algorithm is suggested,

$$w_{n+1} = w_n - \gamma_n \nabla_w I(w_n,\theta), \tag{8}$$

where $\{\gamma_n\}_{n=1}^{\infty}$ is a positive series satisfying the following assumption, which will be used in proving the convergence of Algorithm 1.

Assumption 6 *The positive series* $\{\gamma_n\}_{n=1}^{\infty}$ *satisfies*

$$\sum_{n=1}^{\infty}\gamma_n = \infty, \quad \sum_{n=1}^{\infty}\gamma_n^2 < \infty.$$

Writing the term $\nabla_w I(w_n)$ explicitly yields

$$\nabla_w I(w_n) = \Phi' \Pi(\theta) \Phi w_n - \Phi' \Pi(\theta) h(\theta).$$

For each $\theta \in \mathbb{R}^K$, the value $w^*(\theta)$ is given by setting $\nabla_w I(w, \theta) = 0$, that is,

$$w^*(\theta) = \left(\Phi' \Pi(\theta) \Phi\right)^{-1} \Phi' \Pi(\theta) h(\theta).$$

Note that Bertsekas and Tsitsiklis (1996) prove that the matrix $\left(\Phi' \Pi(\theta) \Phi\right)^{-1} \Phi' \Pi(\theta)$ is a projection operator into the space spanned by Φw, with respect to the norm $\|\cdot\|_{\Pi(\theta)}$. Thus, the explicit gradient descent procedure (8) is

$$w_{n+1} = w_n - \gamma_n \Phi' \Pi(\theta) \left(\Phi w_n - h(\theta)\right). \tag{9}$$

Using the basis Φ, in order to approximates $h(\theta)$, yields an approximation error defined by

$$\varepsilon_{\text{app}}(\theta) \triangleq \inf_{w \in \mathbb{R}^L} \|h(\theta) - \Phi w\|_{\pi(\theta)} = \|h(\theta) - \Phi w^*(\theta)\|_{\pi(\theta)}.$$

We can bound this error by

$$\varepsilon_{\text{app}} \triangleq \sup_{\theta \in \mathbb{R}^K} \varepsilon_{\text{app}}(\theta). \tag{10}$$

The agent cannot access $h(x, \theta)$ directly. Instead, it can interact with the environment in order to estimate $h(x, \theta)$. We denote by $\hat{h}_n(x)$ the estimate of $h(x, \theta)$ at time step n, thus (9) becomes

$$w_{n+1} = w_n + \gamma_n \Phi' \Pi(\theta) \left(\hat{h}_n - \Phi w_n\right).$$

This procedure is termed *stochastic gradient descent* (Bertsekas and Tsitsiklis, 1996).

There exist several estimators for $\hat{h}_n$. One sound method, which performs well in practical problems (Tesauro, 1995), is the TD(λ) method; see Section 5.3.2 and 6.3.3 in Bertsekas and Tsitsiklis (1996), or Chapter 6 in Sutton and Barto (1998), where the parameter λ satisfies $0 \leq \lambda \leq 1$. This method devises an estimator which is based on previous estimates of $h(w)$, that is, w_n, and is based also on the environmental reward $r(x_n)$. This idea is a type of *a bootstrapping* algorithm, that is, using existing estimates and new information in order to build more accurate estimates; see Sutton and Barto (1998), Section 6.1.

The TD(λ) estimator for $\hat{h}_{n+1}$ is

$$\hat{h}_{n+1}(x_n) \quad = \quad (1-\lambda) \sum_{k=0}^{\infty} \lambda^k \hat{h}_{n+1}^{(k)}(x_n), \tag{11}$$

where the *k-steps predictor* is defined by

$$\hat{h}_{n+1}^{(k)}(x_n) = \left(\sum_{m=0}^{k} r(x_{n+m}) + \hat{h}_n(x_{n+k+1}) \right).$$

The idea of bootstrapping is apparent in (11): the predictor for the differential value of the state x_n at the $(n+1)$-Th time step, is based partially on the previous estimates through $\hat{h}_n(x_{n+k+1})$, and partially on new information, that is, the reward $r(x_{n+m})$. In addition, the parameter λ gives an

exponential weighting for the different k-step predictors. Thus, choosing the right λ can yield better estimators.

For the discounted setting, it was proved by Bertsekas and Tsitsiklis (1996) (p. 295) that an algorithm which implements the TD(λ) estimator (11) online and converges to the right value is the following one

$$\begin{aligned} w_{n+1} &= w_n + \gamma_n d_n e_n, \\ e_n &= \alpha\lambda e_{n-1} + \phi(x_n), \end{aligned} \tag{12}$$

where d_n is the temporal difference between the n-th and the $(n+1)$-th cycle, and e_n is the so-called *eligibility trace*; see Sections 5.3.3 and 6.3.3 in Bertsekas and Tsitsiklis (1996) or Chapter 7 in Sutton and Barto (1998), and the parameter α is the discount factor. The eligibility trace is an auxiliary variable, which is used in order to implement the idea of (11) as an online algorithm. As the name implies, the eligibility variable measures how eligible is the TD variable, d_n, in (12).

In our setting, the non-discounted case, the analogous equations for the critic, are

$$\begin{aligned} w_{n+1} &= w_n + \gamma_n \tilde{d}(x_n, x_{n+1}, w_n)\, e_n \\ \tilde{d}(x_n, x_{n+1}, w_n) &= r(x_n) - \tilde{\eta}_m + \tilde{h}(x_{n+1}, w_m) - \tilde{h}(x_n, w_m) \\ e_n &= \lambda e_{n-1} + \phi(x_n). \end{aligned}$$

The actor's iterate is motivated by Theorem 5. Similarly to the critic, the actor executes a stochastic gradient ascent step in order to find a local maximum of the average reward per stage $\eta(\theta)$. Therefore,

$$\theta_{n+1} = \theta_n + \gamma_n \psi(x_n, u_n, \theta_n) \tilde{d}_n(x_n, x_{n+1}, w_n),$$

where ψ is defined in Section 4.1. A summary of the algorithm is presented in Algorithm 1.

4.3 Convergence Proof for the AC Algorithm

In the remainder of this section, we state the main theorems related to the convergence of Algorithm 1. We present a sketch of the proof in this section, where the technical details are relegated to Appendices C and D. The proof is divided into two stages. In the first stage we relate the stochastic approximation to a set of ordinary differential equations (ODE). In the second stage, we find conditions under which the ODE system converges to a neighborhood of the optimal $\eta(\theta)$.

The ODE approach is a widely used method in the theory of stochastic approximation for investigating the asymptotic behavior of stochastic iterates, such as (13)-(15). The key idea of the technique is that the iterate can be decomposed into a mean function and a noise term, such as a martingale difference noise. As the iterates advance, the effect of the noise weakens due to repeated averaging. Moreover, since the step size of the iterate decreases (e.g., γ_n in (13)-(15)), one can show that asymptotically an interpolation of the iterates converges to a continuous solution of the ODE. Thus, the first part of the convergence proof is to find the ODE system which describes the asymptotic behavior of Algorithm 1. This ODE will be presented in Theorem 7. In the second part we use ideas from the theory of Lyapunov functions in order to characterize the relation between the constants, $|\mathcal{X}|$, Γ_η, Γ_w, etc., which ensure convergence to some neighborhood of the maximum point satisfying $\|\nabla_\theta \eta(\theta)\|_2 = 0$. Theorem 8 states conditions on this convergence.

Algorithm 1 TD AC Algorithm

Given:

- An MDP with a finite set $\mathcal{X}$ of states satisfying Assumption 2.
- An actor with a parametrized policy $\mu(u|x,\theta)$ satisfying Assumptions 3 and 4.
- A critic with a linear basis for $\tilde{h}(w)$, that is, $\{\phi\}_{i=1}^{L}$, satisfying Assumption 5.
- A set H, a constant B_w, and an operator Ψ_w according to Definition 6.
- Step parameters Γ_η and Γ_w.
- Choose a TD parameter $0 \leq \lambda < 1$.

For step $n = 0$:

- Initiate the critic and the actor variables: $\tilde{\eta}_0 = 0$,$w_0 = 0, e_0 = 0, \theta_0 = 0$.

For each step $n = 1, 2, \ldots$

Critic: Calculate the estimated TD and eligibility trace

$$\begin{aligned} \tilde{\eta}_{n+1} &= \tilde{\eta}_n + \gamma_n \Gamma_\eta \left(r(x_n) - \tilde{\eta}_n \right) \\ \tilde{h}(x, w_n) &= w_n' \phi(x), \\ \tilde{d}\left(x_n, x_{n+1}, w_n\right) &= r(x_n) - \tilde{\eta}_n + \tilde{h}(x_{n+1}, w_n) - \tilde{h}(x_n, w_n), \\ e_n &= \lambda e_{n-1} + \phi\left(x_n\right). \end{aligned} \tag{13}$$

Set,

$$w_{n+1} = w_n + \gamma_n \Gamma_w \tilde{d}\left(x_n, x_{n+1}, w_n\right) e_n \tag{14}$$

Actor:

$$\theta_{n+1} = \theta_n + \gamma_n \psi(x_n, u_n, \theta_n) \tilde{d}_n(x_n, x_{n+1}, w_n) \tag{15}$$

Project each component of w_{m+1} onto H (see Definition 6)

4.3.1 RELATE THE ALGORITHM TO AN ODE

In order to prove the convergence of this algorithm to the related ODE, we need to introduce the following assumption, which adds constraints to the iteration for w, and will be used in the sequel to prove Theorem 7. This assumption may seem restrictive at first but in practice it is not. The reason is that we usually assume the bounds of the constraints to be large enough so the iterates practically do not reach those bounds. For example, under Assumption 2 and additional mild assumptions, it is easy to show that $h(\theta)$ is uniformly bounded for all $\theta \in \mathbb{R}^K$. As a result, there exist a constant bounding $w^*(\theta)$ for all $\theta \in \mathbb{R}^K$. Choosing constraints larger than this constant will not influence the algorithm performance.

Definition 6 *Let us denote by* $\{w_i\}_{i=1}^{L}$ *the components of* w*, and choose a positive constant* B_w*. We define the set* $H \subset \mathbb{R}^K \times \mathbb{R}^L$ *to be*

$$H \triangleq \left\{(\theta, w) \,\middle|\, -\infty < \theta_i < \infty, \quad 1 \le i \le K, \quad -B_w \le w_j \le B_w, \quad 1 \le j \le L\right\},$$

and let Ψ_w *be an operator which projects* w *onto* H*, that is, for each Cramer's*$1 \le j \le L$, $\Psi_w w_j = \max(\min(w_j, B_w), -B_w)$.

The following theorem identifies the ODE system which corresponds to Algorithm 1. The detailed proof is given in Appendix C.

Theorem 7 *Define the following functions:*

$$\begin{aligned}
G(\theta) &= \Phi' \Pi(\theta) \sum_{m=0}^{\infty} \lambda^m P(\theta)^m, \\
D^{(x,u,y)}(\theta) &= \pi(x) P(u|x,\theta) P(y|x,u) \psi(x,u,\theta), \quad x,y \in \mathcal{X}, \quad u \in \mathcal{U}. \\
A(\theta) &= \Phi' \Pi(\theta) (M(\theta) - I) \Phi, \\
M(\theta) &= (1-\lambda) \sum_{m=0}^{\infty} \lambda^m P(\theta)^{m+1}, \\
b(\theta) &= \Phi' \Pi(\theta) \sum_{m=0}^{\infty} \lambda^m P(\theta)^m (r - \eta(\theta)).
\end{aligned} \tag{16}$$

Then,

1. Algorithm 1 converges to the invariant set of the following set of ODEs

$$\begin{cases}
\dot{\theta} = \nabla_\theta \eta(\theta) + \sum\limits_{x,y \in \mathcal{X} \times \mathcal{X}} D^{(x,u,y)}(\theta) \left(d(x,y,\theta) - \tilde{d}(x,y,w)\right), \\
\dot{w} = \Psi_w \left[\Gamma_w \left(A(\theta) w + b(\theta) + G(\theta)(\eta(\theta) - \tilde{\eta})\right)\right], \\
\dot{\tilde{\eta}} = \Gamma_\eta \left(\eta(\theta) - \tilde{\eta}\right),
\end{cases} \tag{17}$$

   with probability 1.

   (a) The functions in (16) are continuous with respect to θ.

4.3.2 INVESTIGATING THE ODE ASYMPTOTIC BEHAVIOR

Next, we quantify the asymptotic behavior of the system of ODEs in terms of the various algorithmic parameters. The proof of the theorem appears in Appendix D.

Theorem 8 *Consider the constants* Γ_η *and* Γ_w *as defined in Algorithm 1, and the function approximation bound* ε_{app} *as defined in* (10)*. Setting*

$$B_{\nabla\eta} \triangleq \frac{B_{\Delta td1}}{\Gamma_w} + \frac{B_{\Delta td2}}{\Gamma_\eta} + B_{\Delta td3} \varepsilon_{app},$$

where $B_{\Delta td1}, B_{\Delta td2}, B_{\Delta td3}$ *are a finite constants depending on the MDP and agent parameters. Then, the ODE system* (17) *satisfies*

$$\liminf_{t \to \infty} \|\nabla_\theta \eta(\theta_t)\| \le B_{\nabla\eta}.$$

Theorem 8 has a simple interpretation. Consider the trajectory $\eta(\theta_t)$ for large times, corresponding to the asymptotic behavior of η_n. The result implies that the trajectory visits a neighborhood of a local maximum infinitely often. Although it may leave the local vicinity of the maximum, it is guaranteed to return to it infinitely often. This occurs, since once it leaves the vicinity, the gradient of η points in a direction which has a positive projection on the gradient direction, thereby pushing the trajectory back to the vicinity of the maximum. It should be noted that in simulation (reported below) the trajectory usually remains within the vicinity of the local maximum, rarely leaving it. We also observe that by choosing appropriate values for Γ_η and Γ_w we can control the size of the ball to which the algorithm converges.

The key idea required to prove the Theorem is the following argument. If the trajectory does not satisfy $\|\nabla\eta(\theta)\|_2 \leq B_{\nabla\eta}$, we have $\dot{\eta}(\theta) > \varepsilon$ for some positive ε. As a result, we have a monotone function which increases to infinity, thereby contradicting the boundedness of $\eta(\theta)$. Thus, $\eta(\theta)$ must visit the set which satisfies $\|\nabla\eta(\theta)\|_2 \leq B_{\nabla\eta}$ infinitely often.

5. A Comparison to Other Convergence Results

In this section, we point out the main differences between Algorithm 1, the first algorithm proposed by Bhatnagar et al. (2009) and the algorithms proposed by Konda and Tsitsiklis (2003). The main dimensions along which we compare the algorithms are the time scale, the type of the TD signal, and whether the algorithm is on line or off line.

5.1 The Time Scale and Type of Convergence

As was mentioned previously, the algorithms of Bhatnagar et al. (2009) and Konda and Tsitsiklis (2003) need to operate in two time scales. More precisely, this refers to the following situation. Denote the time step of the critic's iteration by γ_n^c and the time step of the actor's iteration by γ_n^a, we have $\gamma_n^c = o(\gamma_n^a)$, that is,

$$\lim_{n\to\infty} \frac{\gamma_n^c}{\gamma_n^a} = 0.$$

The use of two time scales stems from the need of the critic to provide an accurate estimate of the state values, as in the work of Bhatnagar et al. (2009), or the state-action values, as in the work of Konda and Tsitsiklis (2003) before the actor uses them.

In the algorithm proposed here, a single time scale is used for the three iterates of Algorithm 1. We have $\gamma_n^a = \gamma_n$ for the actor iterate, $\gamma_n^{c,\eta} = \Gamma_\eta\gamma_n$ for the critic's η_n iterate, and $\gamma_n^{c,w} = \Gamma_w\gamma_n$ for the critic's w iterate. Thus,

$$\lim_{n\to\infty} \frac{\gamma_n^{c,\eta}}{\gamma_n^a} = \Gamma_\eta,$$
$$\lim_{n\to\infty} \frac{\gamma_n^{c,w}}{\gamma_n^a} = \Gamma_w.$$

with the ave

Due to the single time scale, Algorithm 1 has the potential to converge faster than algorithms based on two time scales, since both the actor and the critic may operate on the fast time scale. The drawback of Algorithm 1 is the fact that convergence to the optimal value cannot be guaranteed, as was proved by Bhatnagar et al. (2009) and by Konda and Tsitsiklis (2003). Instead, convergence to

a neighborhood in $\mathbb{R}^K$ around the optimal value is guaranteed. In order to make the neighborhood smaller, we need to choose Γ_η and Γ_w appropriately, as is stated in Theorem 8.

5.2 The TD Signal, the Information Passed Between the Actor and the Critic, and the Critic's Basis

The algorithm presented by Bhatnagar et al. (2009) is essentially a TD(0) algorithm, while the algorithm of Konda and Tsitsiklis (2003) is TD(1), Our algorithm is a TD(λ) for $0 \leq \lambda < 1$. A major difference between the approaches of Bhatnagar et al. (2009) and the present work, as compared to (Konda and Tsitsiklis, 2003), is the information passed from the critic to the actor. In the former cases, the information passed is the TD signal, while in the latter case the Q-value is passed. Additionally, in Bhatnagar et al. (2009) and in Algorithm 1 the critic's basis functions do not change through the simulation, while in Konda and Tsitsiklis (2003) the critic's basis functions are changed in each iteration according to the actor's parameter θ. Finally, we comment that Bhatnagar et al. (2009) introduced an additional algorithm, based on the so-called natural gradient, which led to improved convergence speed. In this work we limit ourselves to algorithms based on the regular gradient, and defer the incorporation of the natural gradient to future work. As stated in Section 1, our motivation in this work was the derivation of a single time scale online AC algorithm with guaranteed convergence, which may be applicable in a biological context. The more complex natural gradient approach seems more restrictive in this setting.

6. Simulations

We report empirical results applying Algorithm 1 to a set of abstract randomly constructed MDPs which are termed Average Reward Non-stationary Environment Test-bench or in short GARNET (Archibald et al., 1995). GARNET problems comprise a class of randomly constructed finite MDPs serving as a test-bench for control and RL algorithms optimizing the average reward per stage. A GARNET problem is characterized in our case by four parameters and is denoted by GARNET(X,U,B,σ). The parameter X is the number of states in the MDP, U is the number of actions, B is the branching factor of the MDP, that is, the number of non-zero entries in each line of the MDP's transition matrices, and σ is the variance of each transition reward.

We describe how a GARNET problem is generated. When constructing such a problem, we generate for each state a reward, distributed normally with zero mean and unit variance. For each state-action the reward is distributed normally with the state's reward as mean and variance σ^2. The transition matrix for each action is composed of B non-zero terms in each line which sum to one.

We note that a comparison was carried out by Bhatnagar et al. (2009) between their algorithm and the algorithm of Konda and Tsitsiklis (2003). We therefore compare our results directly to the more closely related former approach (see also Section 5.2).

We consider the same GARNET problems as those simulated by Bhatnagar et al. (2009). For completeness, we provide here the details of the simulation. For the critic's feature vector, we use a linear function approximation $\tilde{h}(x,w) = \phi(x)'w$, where $\phi(x) \in \{0,1\}^L$, and define l to be the number nonzero values in $\phi(x)$. The nonzero values are chosen uniformly at random, where any two states

have different feature vectors. The actor's feature vectors are of size $L \times |\mathcal{U}|$, and are constructed as

$$\xi(x,u) \triangleq (\overbrace{0,\ldots,0}^{L\times(u-1)}, \phi(x), \overbrace{0,\ldots,0}^{L\times(|\mathcal{U}|-u)}),$$
$$\mu(u|x,\theta) = \frac{e^{\theta'\xi(x,u)}}{\sum_{u'\in\mathcal{U}} e^{\theta'\xi(x,u')}}.$$

Bhatnagar et al. (2009) reported simulation results for two GARNET problems: GARNET$(30,4,2,0.1)$ and GARNET$(100,10,3,0.1)$. For the GARNET$(30,4,2,0.1)$ problem, Bhatnagar et al. (2009) used critic steps $\gamma_n^{c,w}$ and $\gamma_n^{c,\eta}$, and actor steps γ_n^a, where

$$\gamma_n^{c,w} = \frac{100}{1000+n^{2/3}}, \quad \gamma_n^{c,\eta} = 0.95\gamma_n^{c,w}, \quad \gamma_n^{a,\eta} = \frac{1000}{100000+n},$$

and for GARNET$(100,10,3,0.1)$ the steps were

$$\gamma_n^{c,w} = \frac{10^5}{10^6+n^{2/3}}, \quad \gamma_n^{c,\eta} = 0.95\gamma_n^{c,w}, \quad \gamma_n^{a,\eta} = \frac{10^6}{10^8+n}.$$

In our simulations we used a single time scale, γ_n, which was equal to $\gamma_n^{c,w}$ as used by Bhatnagar et al. (2009). The basis parameters for GARNET$(30,4,2,0.1)$ were $L=8$ and $l=3$, where for GARNET$(100,10,3,0.1)$ they were $L=20$ and $l=5$.

In Figures 2 we show results of applying Algorithm 1 (solid line) and algorithm 1 from Bhatnagar et al. (2009) (dashed line) on GARNET$(30,4,2,0.1)$ and GARNET$(100,10,3,0.1)$ problems. Each graph in Figure 2, represents an average of 100 independent simulations. Note that an agent with a uniform action selection policy will attain an average reward per stage of zero in these problems. Figure 3 presents similar results for GARNET$(30,15,15,0.1)$. We see from these results that in all simulations, during the initial phase, Algorithm 1 converges faster than algorithm 1 from Bhatnagar et al. (2009). The long term behavior is problem-dependent, as can be seen by comparing Figures 2 and 3; specifically, in Figure 2 the present algorithm converges to a higher value than Bhatnagar et al. (2009), while the situation is reversed in Figure 3. We refer the reader to Mokkadem and Pelletier (2006) for careful discussion of convergence rates for two time scales algorithms; a corresponding analysis of convergence rates for single time scale algorithms is currently an open problem.

The results displayed here suggest a possible avenue for combining both algorithms. More concretely, using the present approach may lead to faster initial convergence due to the single time scale setting, which allows both the actor and the critic to evolve rapidly, while switching smoothly to a two time scales approach as in Bhatnagar et al. (2009) will lead to asymptotic convergence to a point rather than to a region. This type of approach is reminiscent of the quasi-Newton algorithms in optimization, and is left for future work. As discussed in Section 5, we do not consider the natural gradient based algorithms from Bhatnagar et al. (2009) in this comparative study.

7. Discussion and Future Work

We have introduced an algorithm where the information passed from the critic to the actor is the temporal difference signal, while the critic applies a TD(λ) procedure. A policy gradient approach was used in order to update the actor's parameters, based on a critic using linear function approximation. The main contribution of this work is a convergence proof in a situation where both the actor

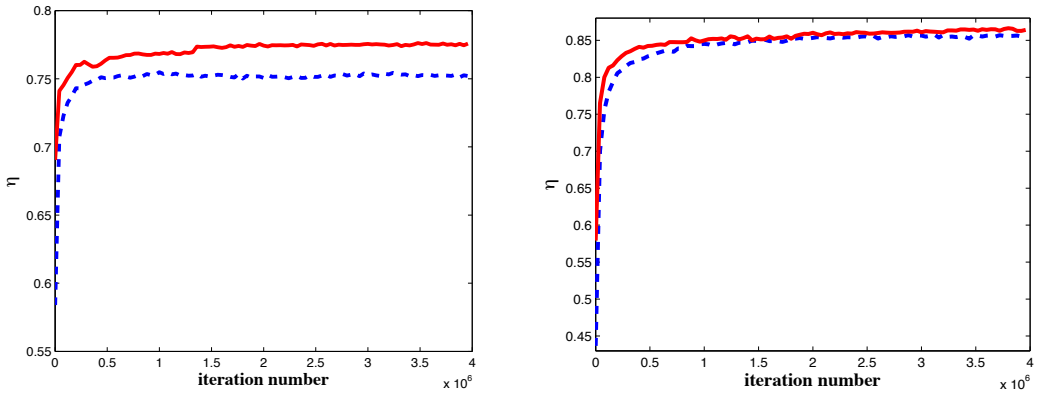

Figure 2: Simulation results applying Algorithm 1 (red solid line) and algorithm 1 from Bhatnagar et al. (2009) (blue dashed line) on a GARNET$(30,4,2,0.1)$ problem (a) and on GARNET$(100,10,3,0.1)$ problem (b). Standard errors of the mean (suppressed for visibility) are of the order of 0.04.

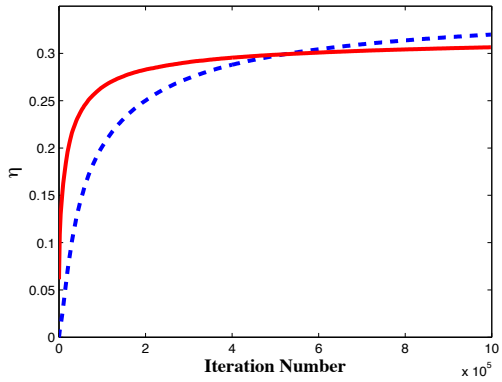

Figure 3: Simulation results applying Algorithm 1 (red solid line) and algorithm 1 from Bhatnagar et al. (2009) (blue dashed line) on a GARNET$(30,15,15,0.1)$ problem. Standard errors of the mean (suppressed for visibility) are of the order of 0.018.

and the critic operate on the same time scale. The drawback of the extra flexibility in time scales is that convergence is only guaranteed to a neighborhood of a local maximum value of the average reward per stage. However, this neighborhood depends on parameters which may be controlled to improve convergence.

This work sets the stage for much future work. First, as observed above, the size of the convergence neighborhood is inversely proportional to the step sizes Γ_w and Γ_η. In other words, in order to reduce this neighborhood we need to select larger values of Γ_w and Γ_η. This on the other hand increases the variance of the algorithm. Therefore, further investigation of methods which reduce

this variance are needed. However, the bounds used throughout are clearly rather loose, and cannot be effectively used in practical applications. Obviously, improving the bounds, and conducting careful numerical simulations in order to obtain a better practical understanding of the influence of the different algorithmic parameters, is called for. In addition, there is clearly room for combining the advantages of our approach with those of AC algorithms for which convergence to a single point is guaranteed, as discussed in Section 6,

From a biological point of view, our initial motivation to investigate TD based AC algorithms stemmed from questions related to the implementation of RL in the mammalian brain. Such a view is based on an interpretation of the transient activity of the neuromodulator dopamine as a TD signal (Schultz, 2002). Recent evidence suggested that the dorsal and ventral striatum may implement the actor and the critic, respectively Daw et al. (2006). We believe that theoretical models such as those of Bhatnagar et al. (2009) and Algorithm 1 may provide, even if partially, a firm foundation to theories at the neural level. Some initial attempts in a neural setting (using direct policy gradient rather than AC based approaches) have been made by Baras and Meir (2007) and Florian (2007). Such an approach may lead to functional insights as to how an AC paradigm may be implemented at the cellular level of the basal ganglia and cortex. An initial demonstration was given by DiCastro et al. (2008). From a theoretical perspective several issues remain open. First, strengthening Theorem 8 by replacing lim inf by lim would clearly be useful. Second, systematically combining the advantages of single time scale convergence (fast initial dynamics) and two time scale approaches (convergence to a point) would clearly be beneficial.

Acknowledgments

The authors are grateful to Mohammad Ghavamzadeh for sending them a copy of Bhatnagar et al. (2009) prior to publication, and to the anonymous reviewers for their helpful comments. The work of R. Meir was partially supported by an ISF Converging Technologies grant, and by ISF grant 665/08.

Appendix A. Proofs of Results from Section 3

We present proofs of the main results from section 3.

A.1 Proof of Lemma 3

1. Looking at (1) we see that $P(y|x,\theta)$ is a compound function of an integral and a twice differentiable function, $\mu(y|x,\theta)$, with bounded first and second derivatives according to Assumption 3. Therefore, $P(y|x,\theta)$ is a twice differentiable function with bounded first and second derivatives for all $\theta \in \mathbb{R}^K$.

2. According to Lemma 1, for each $\theta \in \mathbb{R}^K$ we have a unique solution to the following non-homogeneous linear equation system in $\{\pi(i|\theta)\}_{i=1}^{|\mathcal{X}|}$,

$$\begin{cases} \sum_{i=1}^{|\mathcal{X}|} \pi(i|\theta) P(j|i,\theta) = \pi(j|\theta), \quad j = 1,\ldots,|\mathcal{X}|-1, \\ \sum_{i=1}^{|\mathcal{X}|} \pi(i|\theta) = 1, \end{cases} \tag{18}$$

or in matrix form $M(\theta)\pi(\theta) = b$. By Assumption 2, the equation system (18) is invertible, therefore, $\det[M(\theta)] > 0$. This holds for all $P(\theta) \in \bar{P}$, thus, there exists a positive constant, b_M, which uniformly lower bounds $\det[M(\theta)]$ for all $\theta \in \mathbb{R}^K$.Thus, using Cramer's rule we have

$$\pi(i|\theta) = \frac{Q(i,\theta)}{\det[M(\theta)]},$$

where $Q(i,\theta)$ is a finite polynomial of $\{P(j|i,\theta)\}_{i,j\in\mathcal{X}}$ of at most degree $|\mathcal{X}|$ and with at most $|\mathcal{X}|!$ terms. Writing $\partial\pi(x|\theta)/\partial\theta_i$ explicitly gives

$$\begin{aligned} \left|\frac{\partial\pi(x|\theta)}{\partial\theta_i}\right| &= \left|\frac{\det[M(\theta)]\frac{\partial}{\partial\theta_i}Q(i,\theta) - Q(i,\theta)\frac{\partial}{\partial\theta_i}\det[M(\theta)]}{\det[M(\theta)]^2}\right| \\ &\leq \left|\frac{\frac{\partial}{\partial\theta_i}Q(i,\theta)}{\det[M(\theta)]}\right| + \left|\frac{Q(i,\theta)\frac{\partial}{\partial\theta_i}\det[M(\theta)]}{\det[M(\theta)]^2}\right| \\ &\leq \frac{|\mathcal{X}|\cdot|\mathcal{X}|!\cdot B_{P_1}}{b_M} + \frac{(|\mathcal{X}|\cdot|\mathcal{X}|!)\cdot B_{P_1}}{b_M^2}, \end{aligned}$$

which gives the desired bound. Following similar steps we can show the boundedness of the second derivatives.

3. The average reward per stage, $\eta(\theta)$ is a linear combination of $\{\pi(i|\theta)\}_{i=1}^{|\mathcal{X}|}$, with bounded coefficients by assumption 1. Therefore, using Section 2, $\eta(\theta)$ is twice differentiable with bounded first and second derivatives for all $\theta \in \mathbb{R}^K$.

4. Since $\pi(x|\theta)$ is the stationary distribution of a recurrent MC, according to Assumption 2 there is a positive probability to be in each state $x \in \mathcal{X}$. This applies to the closure of $\mathcal{P}$. Thus, there exist a positive constant b_π such that $\pi(x|\theta) \geq b_\pi$.

A.2 Proof of Lemma 4

1. We recall the Poisson Equation (2). We have the following system of linear equations in $\{h(x|\theta)\}_{x\in\mathcal{X}}$, namely,

$$\begin{cases} h(x|\theta) = r(x) - \eta(\theta) + \sum_{y\in\mathcal{X}} P(y|x,\theta)h(y|\theta), \quad \forall x \in \mathcal{X}, x \neq x^*, \\ h(x^*|\theta) = 0. \end{cases}$$

or in matrix form $N(\theta)h(\theta) = c$. Adding the equation $h(x^*|\theta) = 0$ yields a unique solution for the system; see Bertsekas (2006), Vol. 1, Prop. 7.4.1. Thus, using Cramer's rule we have

$h(x|\theta) = R(x,\theta)/\det[N(\theta)]$, where $R(x,\theta)$ and $\det[N(\theta)]$ are polynomial function of entries in $N(\theta)$, which are bounded and have bounded first and second derivatives according to Lemma 3. Continuing in the same steps of Lemma 3 proof, we conclude that $h(x|\theta)$ and its two first derivatives for all $x \in \mathcal{X}$ and for all $\theta \in \mathbb{R}^K$.

2. Trivially, by (3) and the previous section the result follows.

Appendix B. Proof of Theorem 5

We begin with a Lemma which was proved by Marbach and Tsitsiklis (1998). It relates the gradient of the average reward per stage to the differential value function.

Lemma 9 *The gradient of the average reward per stage can be expressed by*

$$\nabla_\theta \eta(\theta) = \sum_{x,y\in\mathcal{X},u\in\mathcal{U}} P(x,u,y,\theta)\psi(x,u,\theta)h(y,\theta).$$

For completeness, we present a proof,which will be used in the sequel.
Proof We begin with Poisson's Equation (2) in vector form

$$h(\theta) = \bar{r} - e\eta(\theta) + P(\theta)h(\theta),$$

where e is a column vector of 1's. Taking the derivative with respect to θ and rearranging yields

$$e\nabla_\theta \eta(\theta) = -\nabla_\theta h(\theta) + \nabla_\theta P(\theta)h(\theta) + P(\theta)\nabla_\theta h(\theta).$$

Multiplying the left hand side of the last equation by the stationary distribution $\pi(\theta)'$ yields

$$\begin{aligned}\nabla_\theta \eta(\theta) &= -\pi(\theta)'\nabla_\theta h(\theta) + \pi(\theta)'\nabla_\theta P(\theta)h(\theta) + \pi(\theta)'P(\theta)\nabla_\theta h(\theta)\\ &= -\pi(\theta)'\nabla_\theta h(\theta) + \pi(\theta)'\nabla_\theta P(\theta)h(\theta) + \pi(\theta)'\nabla_\theta h(\theta)\\ &= \pi(\theta)'\nabla_\theta P(\theta)h(\theta).\end{aligned}$$

Expressing the result explicitly we obtain

$$\begin{aligned}\nabla_\theta \eta(\theta) &= \sum_{x,y\in\mathcal{X}} P(x)\nabla_\theta P(y|x,\theta)h(y,\theta)\\ &= \sum_{x,y\in\mathcal{X}} P(x)\nabla_\theta \left(\sum_u (P(y|x,u)\mu(u|x,\theta))\right) h(y,\theta)\\ &= \sum_{x,y\in\mathcal{X}} P(x)\sum_u (P(y|x,u)\nabla_\theta \mu(u|x,\theta))\, h(y,\theta)\\ &= \sum_{x,y\in\mathcal{X},u\in\mathcal{U}} P(y|x,u)P(x)\nabla_\theta \mu(u|x,\theta)h(y,\theta)\\ &= \sum_{x,y\in\mathcal{X},u\in\mathcal{U}} P(y|x,u)\mu(u|x,\theta)P(x)\frac{\nabla_\theta \mu(u|x,\theta)}{\mu(u|x,\theta)}h(y,\theta)\\ &= \sum_{x,y\in\mathcal{X},u\in\mathcal{U}} P(x,u,y,\theta)\psi(x,u,\theta)h(y,\theta).\end{aligned} \tag{19}$$

■

Based on this, we can now prove Theorem 5. We start with the result in (19).

$$\begin{aligned}
\nabla_\theta \eta(\theta) &= \sum_{x,y\in\mathcal{X},u\in\mathcal{U}} P(x,u,y,\theta)\psi(x,u,\theta)h(y,\theta). \\
&= \sum_{x,y\in\mathcal{X},u\in\mathcal{U}} P(x,u,y,\theta)\psi(x,u,\theta)\left(h(y,\theta)-h(x,\theta)+\bar{r}(x)-\eta(\theta)+f(x)\right) \\
&\quad - \sum_{x,y\in\mathcal{X},u\in\mathcal{U}} P(x,u,y,\theta)\psi(x,u,\theta)\left(-h(x,\theta)+\bar{r}(x)-\eta(\theta)+f(x)\right) \\
&= \sum_{x,y\in\mathcal{X},u\in\mathcal{U}} P(x,u,y,\theta)\psi(x,u,\theta)\left(d(x,y,\theta)+f(x)\right) \\
&\quad - \sum_{x,y\in\mathcal{X},u\in\mathcal{U}} P(x,u,y,\theta)\psi(x,u,\theta)\left(-h(x,\theta)+\bar{r}(x)-\eta(\theta)+f(x)\right)
\end{aligned}$$

In order to complete the proof, we show that the second term equals 0. We define $F(x,\theta) \triangleq -h(x|\theta)+\bar{r}(x)-\eta(\theta)+f(x)$ and obtain

$$\begin{aligned}
\sum_{x,y\in\mathcal{X},u\in\mathcal{U}} P(x,u,y,\theta)\psi(x,u,\theta)F(x,\theta) &= \sum_{x\in\mathcal{X}} \pi(x,\theta)F(x,\theta) \sum_{u\in\mathcal{U},y\in\mathcal{X}} \nabla_\theta P(y|x,u,\theta) \\
&= 0.
\end{aligned}$$

Appendix C. Proof of Theorem 7

As mentioned earlier, we use Theorem 6.1.1 from Kushner and Yin (1997). We start by describing the setup of the theorem and the main result. Then, we show that the required assumptions hold in our case.

C.1 Setup, Assumptions and Theorem 6.1.1 of Kushner and Yin (1997)

In this section we describe briefly but accurately the conditions for Theorem 6.1.1 of Kushner and Yin (1997) and state the main result. We consider the following stochastic iteration

$$y_{n+1} = \Pi_H[y_n + \gamma_n Y_n],$$

where Y_n is a vector of "observations" at time n, and Π_H is a constraint operator as defined in Definition 6. Recall that $\{x_n\}$ is a Markov chain. Based on this, define $\mathcal{F}_n$ to be the σ-algebra

$$\begin{aligned}
\mathcal{F}_n &\triangleq \sigma\{y_0, Y_{i-1}, x_i \,|\, i \le n\} \\
&= \sigma\{y_0, Y_{i-1}, x_i, y_i \,|\, i \le n\},
\end{aligned}$$

and

$$\bar{\mathcal{F}}_n \triangleq \sigma\{y_0, Y_{i-1}, y_i \,|\, i \le n\}.$$

The difference between the σ-algebras is the sequence $\{x_n\}$. Define the conditioned average iterate

$$g_n(y_n, x_n) \triangleq \mathrm{E}[Y_n \,|\, \mathcal{F}_n],$$

and the corresponding *martingale difference noise*

$$\delta M_n \triangleq Y_n - \mathrm{E}[Y_n \,|\, \mathcal{F}_n].$$

Thus, we can write the iteration as

$$y_{n+1} = y_n + \gamma_n \left(g_n \left(y_n, x_n \right) + \delta M_n + Z_n \right),$$

where Z_n is a reflection term which forces the iterate to the nearest point in the set H whenever the iterates leaves it (Kushner and Yin, 1997). Next, set

$$\bar{g}\left(y \right) \triangleq \mathrm{E}\left[g_n \left(y, x_n \right) \middle| \bar{\mathcal{F}}_n \right].$$

Later, we will see that the sum of the sequence $\{\delta M_n\}$ converges to 0, and the r.h.s of the iteration behaves approximately as a the function $\bar{g}\left(y \right)$, which yields the corresponding ODE, that is,

$$\dot{y} = \bar{g}\left(y \right).$$

The following ODE method will show that the asymptotic behavior of the iteration is equal to the asymptotic behavior of the corresponding ODE.

Define the auxiliary variable

$$t_n \triangleq \sum_{k=0}^{n-1} \gamma_{k,}$$

and the monotone piecewise constant auxiliary function

$$m\left(t \right) = \left\{ n \left| t_n \leq t < t_{n+1} \right. \right\}.$$

The following assumption, taken from Section 6.1 of Kushner and Yin (1997), is required to establish the basic Theorem. An interpretation of the assumption follows its statement.

Assumption 7 *Assume that*

1. The coefficients $\{\gamma_n\}$ satisfy $\sum_{n=1}^{\infty} \gamma_n = \infty$ and $\lim_{n\to\infty} \gamma_n = 0$.

   (a) $\sup_n \mathrm{E}\left[\left\| Y_n \right\| \right] < \infty$.

   (b) $g_n \left(y_n, x \right)$ is continuous in y_n for each x and n.

   (c) For each $\mu > 0$ and for some $T > 0$ there is a continuous function $\bar{g}\left(\cdot \right)$ such that for each y

   $$\lim_{n\to\infty} \Pr\left(\sup_{j\geq n} \max_{0\leq t\leq T} \left\| \sum_{i=m(jT)}^{m(jT+t)-1} \gamma_i \left(g_n \left(y, x_i \right) - \bar{g}\left(y \right) \right) \right\| \geq \mu \right) = 0.$$

   (d) For each $\mu > 0$ and for some $T > 0$ we have

   $$\lim_{n\to\infty} \Pr\left(\sup_{j\geq n} \max_{0\leq t\leq T} \left\| \sum_{i=m(jT)}^{m(jT+t)-1} \gamma_i \delta M_i \right\| \geq \mu \right) = 0.$$

   (e) There are measurable and non-negative functions $\rho_3\left(y \right)$ and $\rho_{n4}\left(x \right)$such that

   $$\left\| g_n \left(y_n, x \right) \right\| \leq \rho_3 \left(y \right) \rho_{n4} \left(x \right)$$

   where $\rho_3\left(y \right)$ is bounded on each bounded y-set , and for each $\mu > 0$ we have

   $$\lim_{\tau\to 0} \lim_{n\to\infty} \Pr\left(\sup_{j\geq n} \sum_{i=m(j\tau)}^{m(j\tau+\tau)-1} \gamma_i \rho_{n4} \left(x_i \right) \geq \mu \right) = 0.$$

(f) There are measurable and non-negative functions $\rho_1(y)$ and $\rho_{n2}(x)$such that $\rho_1(y)$ is bounded on each bounded y-set and

$$\|g_n(y_1,x)-g_n(y_2,x)\| \leq \rho_1(y_1-y_2)\,\rho_{n2}(x),$$

where

$$\lim_{y\to 0}\rho_1(y)=0,$$

and

$$\Pr\left(\limsup_j \sum_{i=j}^{m(t_j+\tau)} \gamma_i \rho_{i2}(x_i) < \infty\right) = 1.$$

The conditions of Assumption 7 are quite general but can be interpreted as follows. Assumptions 7.1-3 are straightforward. Assumption 7.4 is reminiscent of ergodicity, which is used to replace the state-dependent function $g_n(\cdot,\cdot)$ with the state-independent of state function $\bar{g}(\cdot)$, whereas Assumption 7.5 states that the martingale difference noise converges to 0 in probability. Assumptions 7.6 and 7.7 ensure that the function $g_n(\cdot,\cdot)$ is not unbounded and satisfies a Lipschitz condition.

The following Theorem, adapted from Kushner and Yin (1997), provides the main convergence result required. The remainder of this appendix shows that the required conditions in Assumption 7 hold.

Theorem 10 *(Adapted from Theorem 6.1.1 in Kushner and Yin 1997) Assume that algorithm 1, and Assumption 7 hold. Then y_n converges to some invariant set of the projected ODE*

$$\dot{y} = \Pi_H[\bar{g}(y)].$$

Thus, the remainder of this section is devoted to showing that Assumptions 7.1-7.7 are satisfied.

For future purposes, we express Algorithm 1 using the augmented parameter vector y_n

$$y_n \triangleq \begin{pmatrix}\theta_n' & w_n' & \tilde{\eta}_n'\end{pmatrix}', \quad \theta_n \in \mathbb{R}^K, \quad w_n \in \mathbb{R}^L, \quad \tilde{\eta}_n \in \mathbb{R}.$$

The components of Y_n are determined according to (17). The corresponding sub-vectors of $\bar{g}(y_n)$ will be denoted by

$$\bar{g}(y_n) = \begin{bmatrix}\bar{g}(\theta_n)' & \bar{g}(w_n)' & \bar{g}(\tilde{\eta}_n)'\end{bmatrix}' \in \mathbb{R}^{K+L+1},$$

and similarly

$$g_n(y_n,x_n) = \begin{bmatrix}g_n(\theta_n,x_n)' & g_n(w_n,x_n)' & g_n(\tilde{\eta}_n,x_n)'\end{bmatrix}' \in \mathbb{R}^{K+L+1}.$$

We begin by examining the components of $g_n(y_n,x_n)$ and $\bar{g}(y_n)$. The iterate $g_n(\tilde{\eta}_n,x_n)$ is

$$\begin{aligned} g_n(\tilde{\eta}_n,x_n) &= \mathrm{E}[\Gamma_\eta(r(x_n)-\tilde{\eta}_n)|\mathcal{F}_n] \\ &= \Gamma_\eta(r(x_n)-\tilde{\eta}_n), \end{aligned} \tag{20}$$

and since there is no dependence on x_n we have also

$$\bar{g}(\tilde{\eta}_n) = \Gamma_\eta(\eta(\theta)-\tilde{\eta}_n).$$

The iterate $g_n(w_n,x_n)$ is

$$\begin{aligned} g_n(w_n,x_n) &= \mathrm{E}\left[\Gamma_w \tilde{d}(x_n,x_{n+1},w_n)\, e_n \middle| \mathcal{F}_n\right] \\ &= \mathrm{E}\left[\Gamma_w \sum_{k=0}^{\infty} \lambda^k \phi(x_{n-k}) \left(r(x_n) - \tilde{\eta}_n + \phi(x_{n+1})' w_n - \phi(x_n)' w_n\right) \middle| \mathcal{F}_n\right] \\ &= \Gamma_w \sum_{k=0}^{\infty} \lambda^k \phi(x_{n-k}) \left(r(x_n) - \tilde{\eta}_n + \sum_{y\in\mathcal{X}} P(y|x_n,\theta_n)\,\phi(y)' w_n - \phi(x_n)' w_n\right), \end{aligned} \tag{21}$$

and the iterate $\bar{g}(w_n)$ is

$$\begin{aligned} \bar{g}(w_n) &= \mathrm{E}\left[g_n(w_n,x_n) \middle| \bar{\mathcal{F}}_n\right] \\ &= \mathrm{E}\left[\Gamma_w \sum_{k=0}^{\infty} \lambda^k \phi(x_{n-k}) \left(r(x_n) - \tilde{\eta}_n + \sum_{y\in\mathcal{X}} P(y|x_n,\theta_n)\,\phi(y)' w_n - \phi(x_n)' w_n\right) \middle| \bar{\mathcal{F}}\right] \\ &= \Gamma_w \sum_{k=0}^{\infty} \lambda^k \sum_{x\in\mathcal{X}} \pi(x)\phi(x) \sum_{z\in\mathcal{X}} \left[P^k\right]_{xz} \\ &\qquad \times \left(r(z) - \tilde{\eta}_n + \sum_{y\in\mathcal{X}} P(y|z,\theta_n)\,\phi(z)' w_n - \phi(y)' w_n\right), \end{aligned}$$

which, following Bertsekas and Tsitsiklis (1996) Section 6.3, can be written in matrix form

$$\bar{g}(w_n) = \Phi'\Pi(\theta_n) \left((1-\lambda)\sum_{k=0}^{\infty} \lambda^k P^{k+1} - I\right) \Phi w_n + \Phi'\Pi(\theta_n) \sum_{k=0}^{\infty} \lambda^k P^k (r - \tilde{\eta}_n).$$

With some further algebra we can express this using (16),

$$\bar{g}(w_n) = A(\theta_n)\, w_n + b(\theta_n) + G(\theta_n)\left(\eta(\theta_n) - \tilde{\eta}_n\right).$$

Finally, the iterate $g_n(\theta_n,x_n)$ is

$$\begin{aligned} g_n(\theta_n,x_n) &= \mathrm{E}\left[\tilde{d}(x_n,x_{n+1},w_n)\,\psi(x_n,u_n,\theta_n) \middle| \mathcal{F}_n\right] \\ &= \mathrm{E}\left[d(x_n,x_{n+1},\theta_n)\,\psi(x_n,u_n,\theta_n) \middle| \mathcal{F}_n\right] \\ &\quad + \mathrm{E}\left[\left(\tilde{d}(x_n,x_{n+1},w_n) - d(x_n,x_{n+1},\theta_n)\right)\psi(x_n,u_n,\theta_n) \middle| \mathcal{F}_n\right] \\ &= \mathrm{E}\left[d(x_n,x_{n+1},\theta_n)\,\psi(x_n,u_n,\theta_n) \middle| \mathcal{F}_n\right] \\ &\quad + \sum_{z\in\mathcal{X}} P(z|x_n)\,\psi(x_n,u_n,\theta_n)\left(\tilde{d}(x_n,z,w_n) - d(x_n,z,\theta_n)\right), \end{aligned} \tag{22}$$

and

$$\begin{aligned} \bar{g}(\theta_n) &= \mathrm{E}\left[\tilde{d}(x_n,x_{n+1},w_n)\,\psi(x_n,u_n,\theta_n) \middle| \bar{\mathcal{F}}_n\right] \\ &= \mathrm{E}\left[d(x_n,x_{n+1},\theta_n)\,\psi(x_n,u_n,\theta_n) \middle| \bar{\mathcal{F}}_n\right] \\ &\quad + \mathrm{E}\left[\left(\tilde{d}(x_n,x_{n+1},w_n) - d(x_n,x_{n+1},\theta_n)\right)\psi(x_n,u_n,\theta_n) \middle| \bar{\mathcal{F}}_n\right] \\ &= \nabla\eta(\theta_n) + \sum_{x,y\in\mathcal{X}} \sum_{u\in\mathcal{U}} \pi(x)\,P(u|x,\theta_n)\,P(y|x,u)\,\psi(x,u,\theta_n) \\ &\qquad \times \left(\tilde{d}(x,y,w_n) - d(x,y,\theta_n)\right). \end{aligned}$$

Next, we show that the required assumptions hold.

C.2 Satisfying Assumption 7.2

We need to show that $\sup_n \mathrm{E}\left[\|Y_n\|_2\right] < \infty$. Since later we need to show that $\sup_n \mathrm{E}\left[\|Y_n\|_2^2\right] < \infty$, and the proof of the second moment is similar to the proof of the first moment, we consider both moments here.

Lemma 11 *The sequence $\tilde{\eta}_n$ is bounded w.p. 1, $\sup_n \mathrm{E}\left[\|Y_n(\tilde{\eta}_n)\|_2\right] < \infty$, and $\sup_n \mathrm{E}\left[\|Y_n(\tilde{\eta}_n)\|_2^2\right] < \infty$*

Proof We can choose M such that $\gamma_n \Gamma_\eta < 1$ for all $n > M$. Using Assumption 3 for the boundedness of the rewards, we have

$$\begin{aligned}
\tilde{\eta}_{n+1} &= (1-\gamma_n\Gamma_\eta)\tilde{\eta}_m + \gamma_n\Gamma_\eta r(x_n) \\
&\leq (1-\gamma_n\Gamma_\eta)\tilde{\eta}_n + \gamma_n\Gamma_\eta B_r \\
&\leq \begin{cases} \tilde{\eta}_n & \text{if } \tilde{\eta}_n > B_r, \\ B_r & \text{if } \tilde{\eta}_n \leq B_r, \end{cases} \\
&\leq \max\{\tilde{\eta}_n, B_r\},
\end{aligned}$$

which means that each iterate is bounded above by the previous iterate or by a constant. We denote this bound by $B_{\tilde{\eta}}$. Using similar arguments we can prove that $\tilde{\eta}_n$ is bounded below, and the first part of the lemma is proved. Since $\tilde{\eta}_{n+1}$ is bounded the second part follows trivially. ■

Lemma 12 *We have $\sup_n E\left[\|Y_n(w_n)\|_2^2\right] < \infty$ and $\sup_n E\left[\|Y_n(w_n)\|_2\right] < \infty$*

Proof For the first part we have

$$\begin{aligned}
\mathrm{E}\left[\|Y_n(w_n)\|_2^2\right] &= \mathrm{E}\left[\left\|\Gamma_w \tilde{d}(x_n, x_{n+1}, w_n)\, e_n\right\|_2^2\right] \\
&= \Gamma_w^2 \mathrm{E}\left[\left\|\sum_{k=0}^{\infty} \lambda^k \phi(x_{n-k})\left(r(x_n) - \tilde{\eta}_n + \phi(x_{n+1})' w_n - \phi(x_n)' w_n\right)\right\|_2^2\right] \\
&\overset{(a)}{\leq} \Gamma_w^2 \mathrm{E}\left[\sum_{k=0}^{\infty} \lambda^k \left\|\phi(x_{n-k})\left(r(x_n) - \tilde{\eta}_n + \phi(x_{n+1})' w_n - \phi(x_n)' w_n\right)\right\|_2\right]^2 \\
&\leq \Gamma_w^2 \mathrm{E}\left[\sup_k \left\|\phi(x_{n-k})\left(r(x_n) - \tilde{\eta}_n + \phi(x_{n+1})' w_n - \phi(x_n)' w_n\right)\right\|_2 \sum_{k=0}^{\infty} \lambda^k\right]^2 \\
&\overset{(b)}{\leq} \frac{4\Gamma_w^2}{(1-\lambda)^2} \|\phi(x_{n-k})\|_2^2 \\
&\qquad \times \left(|r(x_n)|^2 + |\tilde{\eta}_n|^2 + \|\phi(x_{n+1})\|_2^2 \|w_n\|_2^2 + \|\phi(x_n)\|_2^2 \|w_n\|_2^2\right) \\
&\leq \frac{4\Gamma_w^2}{(1-\lambda)^2} B_\phi^2 \left(B_r^2 + B_{\tilde{\eta}}^2 + 2B_\phi^2 B_w^2\right),
\end{aligned}$$

where we used the triangle inequality in (a) and the inequality $(a+b)^2 \leq 2a^2 + 2b^2$ in (b). The bound $\sup_n \mathrm{E}\left[\|Y_n(w_n)\|_2\right] < \infty$ follows directly from the Cauchy-Schwartz inequality. ■

Lemma 13 *We have* $\sup_n E\left[\|Y_n(\theta_n)\|_2^2\right] < \infty$ *and* $\sup_n E[\|Y_n(\theta_n)\|_2] < \infty$.*The proof proceeds as in Lemma 12*.

Based on Lemmas 11, 12, and 13 we can assert Assumption 7.2

C.3 Satisfying Assumption 7.3

Assumption 7.3 requires the continuity of $g_n(y_n, x_n)$ for each n and x_n. Again, we show that this assumption holds for the three parts of the vector y_n.

Lemma 14 *The function* $g_n(\tilde{\eta}_n, x_n)$ *is a continuous function of* $\tilde{\eta}_n$ *for each n and* x_n.

Proof Since $g_n(\tilde{\eta}_n, x_n) = \Gamma_\eta(r(x_n) - \tilde{\eta}_n)$ the claim follows. ■

Lemma 15 *The function* $g_n(w_n, x_n)$ *is a continuous function of* $\tilde{\eta}_n$, w_n, *and* θ_n *for each n and* x_n.

Proof The function is

$$g_n(w_n, x_n) = \Gamma_w \sum_k^\infty \lambda^k \phi(x_{n-k}) \left(r(x_n) - \tilde{\eta}_n + \sum_{y \in \mathcal{X}} P(y|x_n, \theta_n) \phi(y)' w_n - \phi(x_n)' w_n \right).$$

The probability transition $\sum_{y \in \mathcal{X}} P(y|x_n, \theta_n)$ is a function of $\mu(u_n|x_n, \theta_n)$. Thus it is continuous in θ_n by Assumption 3, and thus $g_n(w_n, x_n)$ is continuous in $\tilde{\eta}_n$ and θ_n and the lemma follows. ■

Lemma 16 *The function* $g_n(\theta_n, x_n)$ *is a continuous function of* $\tilde{\eta}_n$, w_n, *and* θ_n *for each n and* x_n.

Proof By definition, the function $g_n(\theta_n, x_n)$ is

$$\begin{aligned} g_n(\theta_n, x_n) &= E\left[\tilde{d}(x_n, x_{n+1}, w_n) \psi(x_n, u_n, \theta_n) \middle| \mathcal{F}_n\right] \\ &= \frac{\nabla_\theta \mu(u_n|x_n, \theta_n)}{\mu(u_n|x_n, \theta_n)} \left(r(x_n) - \tilde{\eta}_n + \sum_{y \in \mathcal{X}} P(y|x_n, \theta_n) \phi(y)' w_n - \phi(x_n)' w_n \right) \end{aligned}$$

Using similar arguments to Lemma 15 the claim holds. ■

C.4 Satisfying Assumption 7.4

In this section we prove the following convergence result: for each $\mu > 0$ and for some $T > 0$ there is a continuous function $\bar{g}(\cdot)$ such that for each y

$$\lim_{n \to \infty} \Pr\left(\sup_{j \geq n} \max_{0 \leq t \leq T} \left\| \sum_{i=m(jT)}^{m(jT+t)-1} \gamma_i (g_n(y, x_i) - \bar{g}(y)) \right\| \geq \mu \right). \tag{23}$$

We start by showing that there exist independent cycles of the algorithm since the underlying Markov chain is recurrent and aperiodic. Then, we show that the cycles behave as a martingale,

thus Doob's inequality can be used. Finally we show that the sum in (23) converges to 0 w.p. 1. We start investigating the regenerative nature of the process.

Based on Lemma 2, there exists a recurrent state common to all $MC(\theta)$, denoted by x^*. We define the series of *hitting times* of the recurrent state x^* by $t_0 = 0, t_1, t_2, ...$, where t_m it the m-th time the agent hits the state x^*. Mathematically, we can define this series recursively by

$$t_{m+1} = \inf\{n | x_n = x^*, n > t_m\}, \quad t_0 = 0,$$

and $T_m \triangleq t_{m+1} - t_m$. Define the m-th cycle of the algorithm to be the set of times

$$\mathcal{T}_m \triangleq \{n | t_{m-1} \leq n < t_m\},$$

and the corresponding trajectories

$$\mathcal{C}_m \triangleq \{x_n | n \in \mathcal{T}_m\}.$$

Define a function, $\rho(k)$, which returns the cycle to which the time k belongs to, that is,

$$\rho(k) \triangleq \{m | k \in \mathcal{T}_m\}.$$

We notice that based on Lemma 1, and using the *Regenerative Cycle Theorem* (Brémaud, 1999), the cycles $\mathcal{C}_m$ are independent of each other.

Next, we examine (23), and start by defining the following events:

$$\begin{aligned}
b_n^{(1)} &\triangleq \left\{ \omega \left| \sup_{j \geq n} \max_{0 \leq t \leq T} \left\| \sum_{i=m(jT)}^{m(jT+t)-1} \gamma_i \left(g_i(y, x_i) - \bar{g}(y) \right) \right\| \geq \mu \right. \right\}, \\
b_n^{(2)} &\triangleq \left\{ \omega \left| \sup_{j \geq n} \sup_{k \geq m(jT)} \left\| \sum_{i=m(jT)}^{k} \gamma_i \left(g_i(y, x_i) - \bar{g}(y) \right) \right\| \geq \mu \right. \right\}, \\
b_n^{(3)} &\triangleq \left\{ \omega \left| \sup_{j \geq n} \left\| \sum_{i=n}^{\infty} \gamma_i \left(g_i(y, x_i) - \bar{g}(y) \right) \right\| \geq \mu \right. \right\}.
\end{aligned}$$

It is easy to show that for each n we have $b_n^{(1)} \subset b_n^{(2)}$, thus,

$$\Pr\left(b_n^{(1)}\right) \leq \Pr\left(b_n^{(2)}\right). \tag{24}$$

It is easy to verify that the series $\left\{b_n^{(2)}\right\}$ is a subsequence of $\left\{b_n^{(3)}\right\}$. Thus, if we prove that $\lim_{n\to\infty} \Pr\left(b_n^{(3)}\right) = 0$, then $\lim_{n\to\infty} \Pr(b_n) = 0$, and using (24), Assumption 7.4 holds.

Next, we examine the sum defining the event $b_n^{(3)}$, by splitting it a sum over cycles and a sum within each cycle. We can write it as following

$$\sum_{i=n}^{\infty} \gamma_i \left(g_i(y, x_i) - \bar{g}(y) \right) = \sum_{m=\rho(n)}^{\infty} \sum_{i \in \mathcal{T}_m} \gamma_i \left(g_i(y, x_i) - \bar{g}(y) \right).$$

Denote $c_m \triangleq \sum_{j \in \mathcal{T}_m} \gamma_i \left(g_n(y, x_i) - \bar{g}(y) \right)$. Therefore, by the *Regenerative Cycle Theorem* (Brémaud, 1999), c_m are independent random variables. Also,

$$\mathrm{E}[c_m] = \mathrm{E}\left[\sum_{i \in \mathcal{T}_m} \gamma_i \left(g_i(y, x_i) - \bar{g}(y) \right) \right] = \mathrm{E}\left[\mathrm{E}\left[\sum_{j \in \mathcal{T}_m} \gamma_i \left(g_n(y, x_i) - \bar{g}(y) \right) \middle| \mathcal{T}_m \right] \right] = 0.$$

We argue that c_m is square integrable. To prove this we need to show that the second moments of T_m and $(g_n(y,x_i)-\bar{g}(y))$ are finite.

Lemma 17

1. The first two moments of the random times $\{T_m\}$ are bounded above by a constant B_T, for all $\theta \in \mathbb{R}^K$ and for all m, $1 \leq m < \infty$.
   (a) $\mathrm{E}\left[(g_n(y,x_i)-\bar{g}(y))^2\right] \leq B_g$
   (b) Define $\bar{\gamma}_m \triangleq \sup_{i \in \mathcal{T}_m} \gamma_i$, then $\sum_{m=0}^{\infty} \bar{\gamma}_m^2 < \infty$.
   (c) $\mathrm{E}\left[c_m^2\right] \leq (B_T B_g)^2$.

Proof ■

1. According to Assumption 2 and Lemma 1, each Markov chain in $\bar{\mathcal{P}}$ is recurrent. Thus, for each $\theta \in \mathbb{R}^K$ there exists a constant $\tilde{B}_T(\theta), 0 < \tilde{B}_T(\theta) < 1$, where for $k \leq |\mathcal{X}|$ we have

$$P(T_m = k|\theta_m) \leq \left(\tilde{B}_T(\theta_m)\right)^{\lfloor k/|\mathcal{X}| \rfloor}, \quad 1 \leq m < \infty, \quad 1 \leq k < \infty,$$

where $\lfloor a \rfloor$ is the largest integer which is not greater than a. Otherwise, if for $k > |\mathcal{X}|$ we have $\tilde{B}_T(\theta_m) = 1$ then the chain transitions equal 1 which contradicts the aperiodicity of the chains. Therefore,

$$\mathrm{E}[T_m|\theta_m] = \sum_{k=1}^{\infty} kP(T_m = k|\theta_m) \leq \sum_{k=1}^{\infty} k\left(\tilde{B}_T(\theta_m)\right)^{\lfloor k/|\mathcal{X}| \rfloor} = B_{T_1}(\theta_m) < \infty,$$

and

$$\mathrm{E}\left[T_m^2\middle|\theta_m\right] = \sum_{k=1}^{\infty} k^2 P(T_m = k|\theta_m) \leq \sum_{k=1}^{\infty} k^2\left(\tilde{B}_T(\theta_m)\right)^{\lfloor k/|\mathcal{X}| \rfloor} = B_{T_2}(\theta_m) < \infty.$$

Since the set $\bar{\mathcal{P}}$ is closed, by Assumption 2 the above holds for the closure of $\bar{\mathcal{P}}$ as well. Thus, there exists a constant B_T satisfying $B_T = \max\{\sup_\theta B_{T_1}(\theta), \sup_\theta B_{T_2}(\theta)\} < \infty$.

   (a) The proof proceeds along the same lines as the proofs of lemmas 11, 12, and 13.
   (b) The result follows trivially since the sequence $\{\bar{\gamma}_m\}$ is subsequence of the summable sequence$\{\gamma_m\}$.
   (c) By definition, for large enough m we have $\gamma_m \leq 1$. Therefore, we have

$$\begin{aligned}
\mathrm{E}\left[c_m^2\right] &= \mathrm{E}\left[\left(\sum_{j \in \mathcal{T}_m} \gamma_j (g_n(y,x_j)-\bar{g}(y))\right)^2\right] \\
&\leq \mathrm{E}\left[|\mathcal{T}_m|^2 \left(\sup_j \gamma_j\right)^2 \left(\sup_j (g_n(y,x_j)-\bar{g}(y))\right)^2\right] \\
&\leq B_T^2 B_g^2.
\end{aligned}$$

Next, we conclude by showing that Assumption 7.4 is satisfied. Define the process $d_n \triangleq \sum_{m=0}^{n} c_m$. This process is a martingale since the sequence $\{c_m\}$ is square integrable (by Lemma 17) and satisfies $\mathrm{E}[d_{m+1}|d_m] = d_m$. Using Doob's martingale inequality[2] we have

$$\begin{aligned}
&\Pr\left(\sup_{k\geq n}\sum_{m=\rho(n)}^{\rho(k)}\sum_{j\in\mathcal{T}_m}\gamma_i\left(g_n\left(y,x_i\right)-\bar{g}\left(y\right)\right)\geq\mu\right)\\
&\leq\lim_{n\to\infty}\frac{\mathrm{E}\left[\left(\sum_{m=\rho(n)}^{\infty}\sum_{j\in\mathcal{T}_m}\gamma_j\left(g_n\left(y,x_j\right)-\bar{g}\left(y\right)\right)\right)^2\right]}{\mu^2}\\
&=\lim_{n\to\infty}\frac{\sum_{m=\rho(n)}^{\infty}\mathrm{E}\left[\left(\sum_{j\in\mathcal{T}_m}\gamma_j\left(g_n\left(y,x_j\right)-\bar{g}\left(y\right)\right)\right)^2\right]}{\mu^2}\\
&\leq\lim_{n\to\infty}\sum_{m=\rho(n)}^{\infty}\bar{\gamma}_m^2 B_g B_T/\mu^2\\
&=0.
\end{aligned}$$

C.5 Satisfying Assumption 7.5

In this section we need to show that for each $\mu > 0$ and for some $T > 0$ we have

$$\lim_{n\to\infty}\Pr\left(\sup_{j\geq n}\max_{0\leq t\leq T}\left\|\sum_{i=m(jT)}^{m(jT+t)-1}\gamma_i\delta M_i\right\|\geq\mu\right)=0. \tag{25}$$

In order to follow the same lines as in Section C.4, we need to show that the second moment of the martingale difference noise, δM_i, is bounded with zero mean. By definition, $\delta M_n(\cdot)$ has zero mean.

Lemma 18 *The martingale difference noise, $\delta M_n(\cdot)$, is bounded in the second moment.*

Proof The claim is immediate from the fact that

$$\mathrm{E}\left[\left(\delta M_n\right)^2\right]=\mathrm{E}\left[\left\|Y_n-g_n\left(y_n,x_n\right)\right\|^2\right]\leq 2\mathrm{E}\left[\left\|Y_n\right\|^2+\left\|g_n\left(y_n,x_n\right)\right\|^2\right],$$

and from Lemma 11, Lemma 12, and Lemma 13. ■

Combining this fact with Lemma 18, and applying the regenerative decomposition of Section C.4, we conclude that statistically $\delta M_n(\cdot)$ behaves exactly as $(g_n(y,x_i)-\bar{g}(y))$ of Section C.4 and thus (25) holds.

C.6 Satisfying Assumption 7.6

In this section we need to prove that there are non-negative measurable functions $\rho_3(y)$ and $\rho_{n4}(x)$ such that

$$\left\|g_n\left(y_n,x\right)\right\|\leq\rho_3\left(y_n\right)\rho_{n4}\left(x\right),$$

2. If w_n is a martingale sequence then $\Pr\left(\sup_{m\geq 0}|w_n|\geq\mu\right)\leq\lim_{n\to\infty}\mathrm{E}\left[|w_n|^2\right]/\mu^2$.

where $\rho_3(y)$ is bounded on each bounded y-set, and for each $\mu > 0$ we have

$$\lim_{\tau\to 0}\lim_{n\to\infty}\Pr\left(\sup_{j\geq n}\sum_{i=m(j\tau)}^{m(j\tau+\tau)-1}\gamma_i\rho_{n4}(x_i)\geq\mu\right)=0.$$

The following lemma states a stronger condition for Assumption 7.6. In fact, we choose $\rho_3(y)$ to be a positive constant.

Lemma 19 *If* $\|g_n(y,x)\|$ is uniformly bounded for each y, x and n, then *Assumption 7.6 is satisfied*.

Proof Let us denote the upper bound by the random variable B, that is,

$$\|g_n(y,x)\|\leq B,\quad \text{w.p. 1.}$$

Thus

$$\begin{aligned}\lim_{\tau\to 0}\lim_{n\to\infty}\Pr\left(\sup_{j\geq n}\sum_{i=m(j\tau)}^{m(j\tau+\tau)-1}\gamma_i\rho_{n4}(x_i)\geq\mu\right) &\leq \lim_{\tau\to 0}\lim_{n\to\infty}\Pr\left(\sup_{j\geq n}\sum_{i=m(j\tau)}^{m(j\tau+\tau)-1}\gamma_i B\geq\mu\right)\\ &= \lim_{\tau\to 0}\lim_{n\to\infty}\Pr\left(\sup_{j\geq n}B\sum_{i=m(j\tau)}^{m(j\tau+\tau)-1}\gamma_i\geq\mu\right)\\ &\leq \lim_{\tau\to 0}\Pr(B\tau\geq\mu)\\ &= 0.\end{aligned}$$

■

Based on Lemma 19, we are left with proving that $g_n(y,x)$ is uniformly bounded. The following lemma states so.

Lemma 20 *The function* $g_n(y,x)$ is *uniformly bounded for all n*.

Proof We examine the components of $g_n(y_n,x_n)$. In (20) we showed that

$$g_n(\tilde{\eta}_n,x_n) = \Gamma_\eta\left(r(x_n)-\tilde{\eta}_n\right).$$

Since both $r(x_n)$ and $\tilde{\eta}_n$ are bounded by Assumption 1 and Lemma 11 respectively, we have a uniform bound on $g_n(\tilde{\eta}_n,x_n)$. Recalling (21) we have

$$\begin{aligned}g_n(w_n,x_n) &= \Gamma_w\sum_{k=0}^{\infty}\lambda^k\phi(x_{n-k})\left(r(x_n)-\tilde{\eta}_n+\sum_{y\in\mathcal{X}}P(y|x_n,\theta_n)\phi(y)'w_n-\phi(x_n)'w_n\right)\\ &\leq \Gamma_w\frac{1}{1-\lambda}B_\phi\left(B_r+B_{\tilde{\eta}}+2B_\phi B_w\right).\end{aligned}$$

Finally, recalling (22) we have

$$\begin{aligned}g_n(\theta_n,x_n) &= \mathrm{E}\left[\tilde{d}(x_n,x_{n+1},w_n)\psi(x_n,u_n,\theta_n)\middle|\mathcal{F}_n\right]\\ &\leq \left(B_r+B_{\tilde{\eta}}+2B_\phi B_w\right)B_\psi.\end{aligned}$$

■

C.7 Satisfying Assumption 7.7

In this section we show that there are non-negative measurable functions $\rho_1(y)$ and $\rho_{n2}(x)$ such that $\rho_1(y)$ is bounded on each bounded y-set and

$$\|g_n(y_1,x)-g_n(y_2,x)\| \leq \rho_1(y_1-y_2)\,\rho_{n2}(x) \tag{26}$$

where

$$\lim_{y\to 0}\rho_1(y)=0, \tag{27}$$

and for some $\tau>0$

$$\Pr\left(\limsup_j \sum_{i=j}^{m(t_j+\tau)} \gamma_i \rho_{i2}(x_i) < \infty\right)=1.$$

From Section C.6 we infer that we can choose $\rho_{n2}(x)$ to be a constant since $g_n(y,x)$ is uniformly bounded. Thus, we need to show the appropriate $\rho_1(\cdot)$ function. The following lemma shows it.

Lemma 21 *The following functions satisfy (26) and (27).*

1. The function $\rho_1(y)=\|\tilde{\eta}_2-\tilde{\eta}_1\|$ and $\rho_{n2}(x)=\Gamma_\eta$ for $g_n(\tilde{\eta},x)$.
   (a) The function $\rho_1(y)=\frac{1}{1-\lambda}B_\phi^2\left(\sum_{y\in\mathcal{X}}B_w\|P(y|x,\theta_1)-P(y|x,\theta_2)\|+\|w_1-w_2\|\right)$ and $\rho_{n2}(x)=\Gamma_w$ for $g_n(w,x)$.
   (b) The function $\rho_1(y)=\sum_{y\in\mathcal{X}}B_w\|P(y|x,\theta_1)-P(y|x,\theta_2)\|\cdot B_\psi$ and $\rho_{n2}(x)=1$ for $g_n(\theta,x)$.

Proof ■

1. Recalling (20) we have for $g_n(\tilde{\eta},x)$

$$\|g_n(\tilde{\eta}_1,x)-g_n(\tilde{\eta}_2,x)\| \quad\leq\quad \Gamma_\eta\|\tilde{\eta}_2-\tilde{\eta}_1\|,$$

   thus (26) and (27) are satisfied for 1.

2. Recalling (21) we have for $g_n(w,x)$

$$\begin{aligned}
&\|g_n(w_1,x)-g_n(w_2,x)\|\\
&\leq\left\|\Gamma_w\sum_k^\infty\lambda^k\phi(x_{n-k})\left(\left(\sum_{y\in\mathcal{X}}P(y|x,\theta_1)\,\phi(y)'w_1-\phi(x_n)'w_1\right)\right.\right.\\
&\quad\left.\left.-\left(\sum_{y\in\mathcal{X}}P(y|x,\theta_2)\,\phi(y)'w_2-\phi(x_n)'w_2\right)\right)\right\|\\
&\leq\frac{\Gamma_w B_\phi^2}{1-\lambda}\left(\sum_{y\in\mathcal{X}}\|P(y|x,\theta_1)\,w_1-P(y|x,\theta_2)\,w_2\|+\|w_1-w_2\|\right)\\
&\leq\frac{\Gamma_w B_\phi^2}{1-\lambda}\left(\sum_{y\in\mathcal{X}}B_w\|P(y|x,\theta_1)-P(y|x,\theta_2)\|+\|w_1-w_2\|\right)
\end{aligned}$$

(a) Trivially, with respect to w (26) and (27) are satisfied. Regarding θ, (26) and (27) are satisfied if we recall the definition of $P(y|x,\theta)$ from (1) and the continuity of $\mu(u|x,\theta)$ from Assumption 3.

(b) Recalling (22) we have for $g_n(\theta,x)$

$$\begin{aligned}\|g_n(\theta_1,x)-g_n(\theta_2,x)\| &= \left\|\mathrm{E}\left[\tilde{d}(x,y,w_1)\psi(x,u,\theta_1)\middle|\mathcal{F}_n\right]\right. \\ &\quad \left.-\mathrm{E}\left[\tilde{d}(x,y,w_2)\psi(x,u,\theta_2)\middle|\mathcal{F}_n\right]\right\| \\ &\leq \sum_{y\in\mathcal{X}} B_w \|P(y|x,\theta_1)-P(y|x,\theta_2)\| B_\psi.\end{aligned}$$

Using similar arguments to 2, (26) and (27) are satisfied for θ.

Appendix D. Proof of Theorem 8

In this section we find conditions under which Algorithm 1 converges to a neighborhood of a local maximum. More precisely, we show that $\liminf_{t\to\infty}\|\nabla\eta(\theta(t))\|_2 \leq \varepsilon_{\text{app}}+\varepsilon_{\text{dyn}}$, where the approximation error, ε_{app}, measures the error inherent in the critic's representation, and ε_{dyn} is an error related to the single time scale algorithm. We note that the approximation error depends on the basis functions chosen for the critic, and in general can be reduced only by choosing a better representation basis. The term ε_{dyn} is the dynamic error, and this error can be reduced by choosing the critic's parameters Γ_η and Γ_w appropriately.

We begin by establishing a variant of Lyapunov's theorem for asymptotic stability,[3] where instead of proving asymptotic convergence to a point, we prove convergence to a compact invariant set. Based on this result, we continue by establishing a bound on a time dependent ODE of the first order. This result is used to bound the critic's error in estimating the average reward per stage and the differential values. Finally, using these results, we establish Theorem 8.

We denote a closed ball of radius y in some normed vector space, $(\mathbb{R}^L,\|\cdot\|_2)$, by $\mathcal{B}_y$, and its surface by $\partial\mathcal{B}_y$. Also, we denote by $A\backslash B$ a set, which contains all the members of set A which are not members of B. Finally, we define the complement of $\mathcal{B}_y$ by $\mathcal{B}_y^c=\mathbb{R}^L\backslash\mathcal{B}_y$.

The following lemma is similar to Lyapunov's classic theorem for asymptotic stability; see Khalil (2002), Theorem 4.1. The main difference is that when the value of the Lyapunov function is unknown inside a ball, convergence can be established to the ball, rather than to a single point.

Lemma 22 *Consider a dynamical system, $\dot{x}=f(x)$ in a normed vector space, $(\mathbb{R}^L,\|\cdot\|)$, and a closed ball $\mathcal{B}_r\triangleq\left\{x\middle|x\in\mathbb{R}^L,\|x\|\leq r\right\}$. Suppose that there exists a continuously differentiable scalar function $V(x)$ such that $V(x)>0$ and $\dot{V}(x)<0$ for all $x\in\mathcal{B}_r^c$, and $V(x)=0$ for $x\in\partial\mathcal{B}_r$. Then,*

$$\limsup_{t\to\infty}\|x(t)\|\leq r.$$

Proof We prove two complementary cases. In the first case, we assume that $x(t)$ never enters $\mathcal{B}_r$. On the set $\mathcal{B}_r^c$, $V(x)$ is a strictly decreasing function in t, and it is bounded below, thus it converges. We denote this bound by C, and notice that $C\geq 0$ since for $x\in\mathcal{B}_r^c$, $V(x)>0$. We prove that $C=0$ by contradiction. Assume that $C>0$. Then, $x(t)$ converge to the invariant set

3. We say that the equilibrium point $x=0$ of the system $\dot{x}$=f(x) is *stable* if for each $\varepsilon>0$ there exists a $\delta>0$ such that $\|x(0)\|<\delta\Rightarrow\|x(t)\|<\varepsilon$ for all $t\geq 0$. We say that the point $x=0$ is *asymptotically stable* if it is stable and there exists a $\delta>0$ such that $\|x(0)\|<\delta$ implies $\lim_{t\to\infty}x(t)=0$ (Khalil, 2002).

$S_C \triangleq \{x|V(x) = C, x \in \mathcal{B}_r^c\}$. For each $x(t) \in \mathcal{S}_C$ we have $\dot{V}(x) < 0$. Thus, $V(x)$ continues to decrease which contradicts the boundedness from below. As a result, $V(x(t)) \to 0$.

In the second case, let us suppose that at some time, denoted by t_0, $x(t_0) \in \mathcal{B}_r$. We argue that the trajectory never leaves $\mathcal{B}_r$. Let us assume that at some time t_2, the trajectory $x(t)$ enters the set $\partial\mathcal{B}_{r+\varepsilon}$. Then on this set, we have $V(x(t_2)) > 0$. By the continuity of the trajectory $x(t)$, the trajectory must go through the set $\partial\mathcal{B}_r$. Denote the hitting time of this set by t_1. By definition we have $V(x(t_1)) = 0$. Without loss of generality, we assume that the trajectory in the times $t_1 < t \leq t_2$ is restricted to the set $\mathcal{B}_{r+\varepsilon}/\mathcal{B}_r$. Thus, since $\dot{V}(x(t)) \leq 0$ for $x \in \mathcal{B}_{r+\varepsilon}/\mathcal{B}_r$ we have

$$V(x(t_2)) = V(x(t_1)) + \int_{t_1}^{t_2} \dot{V}(x(t))dt < V(x(t_1)),$$

which contradicts the fact that $V(x(t_2)) \geq V(x(t_1))$. Since this argument holds for all $\varepsilon > 0$, the trajectory $x(t)$ never leaves $\mathcal{B}_r$. ■

The following lemma will be applied later to the linear equations (17), and more specifically, to the ODEs describing the dynamics of $\tilde{\eta}$ and w. It bounds the difference between an ODE's state variables and some time dependent functions.

Lemma 23 *Consider the following ODE in a normed space* $(\mathbb{R}^L, \|\cdot\|_2)$

$$\begin{cases} \frac{d}{dt}X(t) = \mathcal{M}(t)(X(t) - F_1(t)) + F_2(t), \\ X(0) = X_0, \end{cases} \tag{28}$$

where for sufficiently large t .

1. $\mathcal{M}(t) \in \mathbb{R}^{L\times L}$ *is a continuous matrix which satisfies* $\max_{\|x\|=1} x'\mathcal{M}(t)x \leq -\gamma < 0$ *for* $t \in \mathbb{R}$,
2. $F_1(t) \in \mathbb{R}^L$ *satisfies* $\|dF_1(t)/dt\|_2 \leq B_{F1}$,
3. $F_2(t) \in \mathbb{R}^L$ *satisfies* $\|F_2(t)\|_2 \leq B_{F2}$.

Then, the solution of the ODE satisfies $\limsup_{t\to 0} \|X(t) - F_1(t)\|_2 \leq (B_{F1} + B_{F2})/\gamma$.

Proof We express (28) as

$$\frac{d}{dt}(X(t) - F_1(t)) = \mathcal{M}(t)(X(t) - F_1(t)) - \frac{d}{dt}F_1(t) + F_2(t), \tag{29}$$

and define

$$Z(t) \triangleq (X(t) - F_1(t)), \quad G(t) \triangleq -\frac{d}{dt}F_1(t) + F_2(t).$$

Therefore, (29) can be written as

$$\dot{Z}(t) = \mathcal{M}(t)Z(t) + G(t),$$

where $\|G(t)\| \leq B_G \triangleq B_{F1} + B_{F2}$. In view of Lemma 22, we consider the function

$$V(Z) = \frac{1}{2}\left(\|Z(t)\|_2^2 - B_G^2/\gamma^2\right).$$

Let $\mathcal{B}_r$ be a ball with a radius $r = B_G/\gamma$. Thus we have $V(Z) > 0$ for $Z \in \mathcal{B}_r^c$ and $V(Z) = 0$ for $X \in \partial\mathcal{B}_r$. In order to satisfy the assumptions of Lemma 22 the condition that $\dot{V}(Z) < 0$ needs to be verified. For $\|Z(t)\|_2 > B_G/\gamma$ we have

$$\begin{aligned}
\dot{V}(Z) &= (\nabla_X V)' \dot{Z}(t) \\
&= Z(t)'\mathcal{M}(t)Z(t) + Z(t)'G(t) \\
&= \|Z(t)\|_2^2 \frac{Z(t)'}{\|Z(t)\|_2}\mathcal{M}(t)\frac{Z(t)}{\|Z(t)\|_2} + Z(t)'G(t) \\
&\leq \|Z(t)\|_2^2 \max_{\|Y(t)\|_2=1} Y(t)'\mathcal{M}(t)Y(t) + \|Z(t)\|_2 \|G(t)\|_2 \\
&= \|Z(t)\|_2 (-\gamma \|Z(t)\|_2 + B_G) \\
&< 0.
\end{aligned}$$

As a result, the assumptions of Lemma 22 are valid and the Lemma is proved. ■

The following lemma shows that the matrix $A(\theta)$, defined in (16), satisfies the conditions of Lemma 23. For the following lemmas, we define the weighted norm $\|w\|_{\Pi(\theta)}^2 \triangleq \|w'\Pi(\theta)w\|_2$.

Lemma 24 *The following inequalities hold:*

1. For any $w \in \mathbb{R}^L$and for all $\theta \in \mathbb{R}^K$, $\|P(\theta)w\|_{\Pi(\theta)} < \|w\|_{\Pi(\theta)}$..
2. The matrix $M(\theta)$ satisfies $\|M(\theta)w\|_{\Pi(\theta)} < \|w\|_{\Pi(\theta)}$ for all $\theta \in \mathbb{R}^K$ and $w \in \mathbb{R}^L$.
3. The matrix $\Pi(\theta)(M(\theta) - I)$ satisfies $x'\Pi(\theta)(M(\theta) - I)x < 0$ for all $x \in \mathbb{R}^L$ and for all $\theta \in \mathbb{R}^K$.
4. There exists a positive scalar γ such that $w'A(\theta)w < -\gamma$ for all $w'w = 1$.

Proof The following proof is similar in many aspects to the proof of Lemma 6.6 of Bertsekas and Tsitsiklis (1996). ■

1. By using Jensen's inequality for the function $f(\alpha) = \alpha^2$ we have

$$\left(\sum_{y\in\mathcal{X}} P(y|x,\theta)w(y)\right)^2 \leq \sum_{y\in\mathcal{X}} P(y|x,\theta)w(y)^2, \quad \forall x \in \mathcal{X}. \tag{30}$$

   If in Jensen's inequality we have a strictly convex fiction and non-degenerate probability measures then the inequality is strict. The function $f(\alpha)$ is strictly convex, and by Assumption 2 the matrix $P(\theta)$ is aperiodic, which implies that the matrix $P(\theta)$ is not a permutation matrix. As a result, there exists $x_0 \in \mathcal{X}$ such that the probability measure $P(y|x_0,\theta)$ is not degenerate, thus, the inequality in (30) is strict, that is,

$$\left(\sum_{y\in\mathcal{X}} P(y|x_0,\theta)w(y)\right)^2 < \sum_{y\in\mathcal{X}} P(y|x_0,\theta)w(y)^2. \tag{31}$$

Then, we have

$$\begin{aligned}
\|P(\theta)w\|_{\Pi(\theta)} &= w'P(\theta)'\Pi(\theta)P(\theta)w \\
&= \sum_{x\in\mathcal{X}}\pi(x|\theta)\left(\sum_{y\in\mathcal{X}}P(y|x,\theta)w(y)\right)^2 \\
&< \sum_{x\in\mathcal{X}}\pi(x|\theta)\sum_{y\in\mathcal{X}}P(y|x,\theta)w(y)^2 \\
&= \sum_{y\in\mathcal{X}}w(y)^2\sum_{x\in\mathcal{X}}\pi(x|\theta)P(y|x,\theta) \\
&= \sum_{y\in\mathcal{X}}w(y)^2\pi(y|\theta) \\
&= \|w\|_{\Pi(\theta)},
\end{aligned}$$

where in the inequality we have used (31).

2. Using the triangle inequality and 1 we have

$$\begin{aligned}
\|M(\theta)w\|_{\Pi(\theta)} &= \left\|(1-\lambda)\sum_{m=0}^{\infty}\lambda^m P(\theta)^{m+1}w\right\|_{\Pi(\theta)} \\
&\leq (1-\lambda)\sum_{m=0}^{\infty}\lambda^m\left\|P(\theta)^{m+1}w\right\|_{\Pi(\theta)} \\
&< (1-\lambda)\sum_{m=0}^{\infty}\lambda^m\|w\|_{\Pi(\theta)} \\
&= \|w\|_{\Pi(\theta)}.
\end{aligned}$$

3. By definition

$$\begin{aligned}
x'\Pi(\theta)M(\theta)x &= x'\Pi(\theta)^{1/2}\Pi(\theta)^{1/2}M(\theta)x \\
&\leq \left\|\Pi(\theta)^{1/2}x\right\|\cdot\left\|\Pi(\theta)^{1/2}M(\theta)x\right\| \\
&= \|x\|_{\Pi(\theta)}\|M(\theta)x\|_{\Pi(\theta)} \\
&< \|x\|_{\Pi(\theta)}\|x\|_{\Pi(\theta)}. \\
&= x'\Pi(\theta)x,
\end{aligned}$$

where in the first inequality we have used the Cauchy-Schwartz inequality, and in the second inequality we have used 1. Thus, $x'\Pi(\theta)(M(\theta)-I)x<0$ for all $x\in\mathbb{R}$, which implies that $\Pi(\theta)(M(\theta)-I)$ is a negative definite (ND) matrix.[4]

4. From 3, we know that for all $\theta\in\mathbb{R}^K$ and all $w\in\mathbb{R}^{|\mathcal{X}|}$ satisfying $w'w=1$, we have $w'\Pi(\theta)(M(\theta)-I)w<0$, and by Assumption (2), this is true also for the closure of $\left\{\Pi(\theta)(M(\theta)-I)|\theta\in\mathbb{R}^K\right\}$. Thus, there exists a positive scalar, γ', satisfying

$$w'\Pi(\theta)(M(\theta)-I)w\leq-\gamma'<0.$$

4. Usually, a ND matrix is defined for Hermitian matrices, that is, if B is an Hermitian matrix and it satisfies $x'Bx<0$ for all $x\in\mathbb{C}^K$ then B is a NSD matrix . We use here a different definition which states that a square matrix B is a ND matrix if it is real and it satisfies $x'Bx<0$ for all $x\in\mathbb{R}^k$ (Horn and Johnson, 1985).

By Assumption 5 the rank of the matrix Φ is full, thus there exists a scalar γ such that for all $w \in \mathbb{R}^L$, where $w'w = 1$, we have $w'A(\theta)w \leq -\gamma < 0$.

The following Lemma establishes the boundedness of $\dot{\theta}$.

Lemma 25 *There exists a constant* $B_{\theta 1} \triangleq B_{\eta 1} + B_\psi \left(B_D + B_r + B_{\tilde{\eta}} + 2B_\phi B_w\right)$ *such that* $\|\dot{\theta}\|_2 \leq B_{\theta 1}$.

Proof Recalling (17)

$$\begin{aligned}
\left\|\dot{\theta}\right\|_2 &= \left\|\nabla_\theta \eta(\theta) + \sum_{x,y\in\mathcal{X}\times\mathcal{X},u\in\mathcal{U}} D^{(x,u,y)}(\theta)\left(d(x,y,\theta) - \tilde{d}(x,y,w)\right)\right\|_2 \\
&\leq B_{\eta 1} + \sum_{x,y\in\mathcal{X}\times\mathcal{X},u\in\mathcal{U}} \left\|D^{(x,u,y)}(\theta)\right\|_2 \left\|d(x,y,\theta) - \tilde{d}(x,y,w)\right\|_2 \\
&\leq B_{\eta 1} + B_\psi \left(B_D + B_r + B_{\tilde{\eta}} + 2B_\phi B_w\right) \\
&\triangleq B_{\theta 1}.
\end{aligned}$$

■

Based on Lemma (25), the following Lemma shows the boundedness of $(\eta(\theta(t)) - \tilde{\eta})$.

Lemma 26 *We have*

$$\limsup_{t\to\infty} |\eta(\theta(t)) - \tilde{\eta}| \leq \frac{B_{\Delta\eta}}{\Gamma_\eta},$$

where $B_{\Delta\eta} \triangleq B_{\eta_1} B_{\theta 1}$.

Proof Using the Cauchy-Schwartz inequality we have

$$\begin{aligned}
|\dot{\eta}(\theta)| &= |\nabla\eta(\theta)'\dot{\theta}| \\
&\leq \|\nabla\eta(\theta)\|_2 \|\dot{\theta}\|_2 \\
&\leq B_{\eta_1} B_{\theta 1}.
\end{aligned} \tag{32}$$

Recalling the equation for $\tilde{\eta}$ in (17) we have

$$\dot{\tilde{\eta}} = \Gamma_\eta \left(\eta(\theta) - \tilde{\eta}\right).$$

We conclude by applying Lemma 23 and using (32) that

$$\limsup_{t\to\infty} |\eta(\theta(t)) - \tilde{\eta}| \leq \frac{B_{\eta_1} B_{\theta 1}}{\Gamma_\eta} = \frac{B_{\Delta\eta}}{\Gamma_\eta}. \tag{33}$$

■

In (33) we see that the bound on $|\eta(\theta) - \tilde{\eta}|$ is controlled by Γ_η, where larger values of Γ_η ensure smaller values of $|\eta(\theta) - \tilde{\eta}|$. Next, we bound $\|w^*(\theta) - w\|_2$. We recall the second equation of (17)

$$\begin{aligned}
\dot{w} &= \Psi_w \left[\Gamma_w \left(A(\theta)w + b(\theta) + G(\theta)(\eta(\theta) - \tilde{\eta})\right)\right], \\
A(\theta) &= \Phi'\Pi(\theta)(M - I)\Phi, \\
M(\theta) &= (1-\lambda)\sum_{m=0}^{\infty} \lambda^m P(\theta)^{m+1}, \\
b(\theta) &= \Phi'\Pi(\theta)\sum_{m=0}^{\infty} \lambda^m P(\theta)^m (r - \eta(\theta)), \\
G(\theta) &= \Phi'\Pi(\theta)\sum_{m=0}^{\infty} \lambda^m P(\theta)^m.
\end{aligned}$$

We can write the equation for $\dot{w}$ as

$$\dot{w} = \Psi_w \left[\Gamma_w \left(A(\theta) \left(w - w^*(\theta) \right) + G(\theta)(\eta(\theta) - \tilde{\eta}) \right) \right],$$

where $w^* = -A(\theta)^{-1} b(\theta)$. In order to use Lemma 23, we need to demonstrate the boundedness of $\left\| \frac{d}{dt} w^* \right\|$. The following lemma does so.

Lemma 27

1. There exists a positive constant, $B_b \triangleq \frac{1}{1-\lambda} |\mathcal{X}|^3 L B_\Phi B_r$, such that $\|b(\theta)\|_2 \leq B_b$.
   (a) There exists a positive constant, $B_G \triangleq \frac{1}{1-\lambda} |\mathcal{X}|^3 L B_\Phi$, such that $\|G(\theta)\|_2 \leq B_G$.
   (b) There exist positive constants, $\tilde{B} = B_{\pi 1} (B_r + B_\eta) B_{\theta 1} + B_{P1} (B_r + B_\eta) B_{\theta 1} + B_{\eta 1} B_{\theta 1}$ and $B_{b1} \triangleq \frac{1}{1-\lambda} |\mathcal{X}|^3 B_\Phi B_r \tilde{B}$, such that we have $\left\| \dot{b}(\theta) \right\|_2 \leq B_{b1}$.
   (c) There exist constants b_A and B_A such that
   $$0 < b_A \leq \|A(\theta)\|_2 \leq B_A.$$
   (d) There exist a constants B_{A1} such that
   $$\|A(\theta)\|_2 \leq B_{A1}.$$
   (e) We have
   $$\left\| \frac{d}{dt} \left(A(\theta)^{-1} \right) \right\|_2 \leq b_A^2 B_{A1}.$$
   (f) There exists a positive constant, B_{w1}, such that
   $$\left\| \frac{d}{dt} w^* \right\|_2 \leq B_{w1}.$$

Proof ■

1. We show that the entries of the vector $b(\theta)$ are uniformly bounded in θ, therefore, its norm is uniformly bounded in θ. Let us look at the i-th entry of the vector $b(\theta)$ (we denote by $[\cdot]_j$ the j-th row of a matrix or a vector)

$$\begin{aligned}
|[b(\theta)]_i| &= \left| \left[\Phi' \Pi(\theta) \sum_{m=0}^{\infty} \lambda^m P(\theta)^m (r - \eta(\theta)) \right]_i \right| \\
&\leq \sum_{m=0}^{\infty} \lambda^m \left| \left[\Phi' \Pi(\theta) P(\theta)^m (r - \eta(\theta)) \right]_i \right| \\
&= \sum_{m=0}^{\infty} \lambda^m \left| \sum_{l=1}^{|\mathcal{X}|} \sum_{j=1}^{|\mathcal{X}|} \sum_{k=1}^{|\mathcal{X}|} \left[\Phi' \right]_{ik} \Pi_{kj}(\theta) \left[P(\theta)^m \right]_{jl} (r_l - \eta(\theta)) \right| \\
&\leq \frac{1}{1-\lambda} |\mathcal{X}|^3 B_\Phi B_r,
\end{aligned}$$

thus $\|b(\theta)\|_2 \leq \frac{1}{1-\lambda} |\mathcal{X}|^3 L B_\Phi B_r$ is uniformly bounded in θ.

2. The proof is accomplished by similar argument to Section 1.

3. Similarly to Section 1, we show that the entries of the vector $\dot{b}(\theta)$ are uniformly bounded in θ, therefore, its norm is uniformly bounded in θ. First, we show that the following function of $\theta(t)$ is bounded.

$$\begin{aligned}
\left|\frac{d}{dt}\left(\Pi_{kj}(\theta)\left[P(\theta)^m\right]_{jl}(r_l-\eta(\theta))\right)\right| &= \left|\nabla_\theta\left(\Pi_{kj}(\theta)\left[P(\theta)^m\right]_{jl}(r_l-\eta(\theta))\right)\dot{\theta}\right| \\
&\leq \left|\left(\nabla_\theta\Pi_{kj}(\theta)\right)\left[P(\theta)^m\right]_{jl}(r_l-\eta(\theta))\dot{\theta}\right| \\
&\quad+\left|\Pi_{kj}(\theta)\left[\nabla_\theta P(\theta)^m\right]_{jl}(r_l-\eta(\theta))\dot{\theta}\right| \\
&\quad+\left|\Pi_{kj}(\theta)\left[P(\theta)^m\right]_{jl}\nabla_\theta(r_l-\eta(\theta))\dot{\theta}\right| \\
&\leq B_{\pi 1}(B_r+B_\eta)\cdot B_{\theta 1}+B_{P1}(B_r+B_\eta)B_{\theta 1} \\
&\quad+B_{\eta 1}B_{\theta 1} \\
&= \tilde{B},
\end{aligned}$$

where we used the triangle and Cauchy-Schwartz inequalities in the first and second inequalities respectively, and Lemmas 3 and 25 in the second inequality. Thus,

$$\begin{aligned}
\left|\left[\dot{b}(\theta)\right]_i\right| &= \left|\left[\Phi'\Pi(\theta)\sum_{m=0}^{\infty}\lambda^m P(\theta)^m(r-\eta(\theta))\right]_i\right| \\
&\leq \sum_{m=0}^{\infty}\lambda^m\left|\left[\Phi'\Pi(\theta)P(\theta)^m(r-\eta(\theta))\right]_i\right| \\
&= \sum_{m=0}^{\infty}\lambda^m\left|\sum_{l=1}^{|\mathcal{X}|}\sum_{j=1}^{|\mathcal{X}|}\sum_{k=1}^{|\mathcal{X}|}\left[\Phi'\right]_{ik}\frac{d}{dt}\left(\Pi_{kj}(\theta)\left[P(\theta)^m\right]_{jl}(r_l-\eta(\theta))\right)\right| \\
&\leq \frac{1}{1-\lambda}|\mathcal{X}|^3 B_\Phi B_r\tilde{B} \\
&= B_{b1}.
\end{aligned}$$

4. Since $A(\theta)$ satisfies $y'A(\theta)y<0$ for all nonzero y, it follows that all its eigenvalues are nonzero. Therefore, the eigenvalues of $A(\theta)'A(\theta)$ are all positive and real since $A(\theta)'A(\theta)$ is a symmetric matrix. Since by Assumption 2 this holds for all $\theta\in\mathbb{R}^K$, there is a global minimum, b_A, and a global maximum, B_A, such that

$$B_A^2\geq\lambda_{\max}\left(A(\theta)'A(\theta)\right)\geq\lambda_{\min}\left(A(\theta)'A(\theta)\right)\geq b_A^2,\quad\forall\theta\in\mathbb{R}^K,$$

where we denote by $\lambda_{\min}(\cdot)$ and $\lambda_{\max}(\cdot)$ the minimal and maximal eigenvalues of the matrix respectively. Using Horn and Johnson (1985) section 5.6.6, we have $\lambda_{max}\left(A(\theta)'A(\theta)\right)=\|A(\theta)\|_2$, thus, we get an upper bound on the matrix norm. Let us look at the norm of

$\left\|A(\theta)^{-1}\right\|_2$,

$$\begin{aligned}\left\|A(\theta)^{-1}\right\|_2^2 &= \lambda_{\max}\left(\left(A(\theta)^{-1}\right)' A(\theta)^{-1}\right)\\ &= \lambda_{\max}\left(\left(A(\theta)'\right)^{-1} A(\theta)^{-1}\right)\\ &= \lambda_{\max}\left(\left(A(\theta)A(\theta)'\right)^{-1}\right)\\ &= 1/\lambda_{\min}\left(A(\theta)A(\theta)'\right)\\ &= 1/\lambda_{\min}\left(\left(A(\theta)'A(\theta)\right)'\right)\\ &= 1/\lambda_{\min}\left(A(\theta)'A(\theta)\right),\end{aligned}$$

thus, we the lower bound on $\left\|A(\theta)^{-1}\right\|_2$ is $\sqrt{1/\lambda_{\min}\left(A(\theta)'A(\theta)\right)}$, that is, b_A.

5. Let us look at the ij entry of the matrix $\frac{d}{dt}A(\theta)$, where using similar arguments to Section 2 we get

$$\begin{aligned}\left[\left|\frac{d}{dt}A(\theta)\right|\right]_{ij} &= \left[\left|\frac{d}{dt}\left(\Phi'\Pi(\theta)\left((1-\lambda)\sum_{m=0}^{\infty}\lambda^m P(\theta)^{m+1}-I\right)\Phi\right)\right|\right]_{ij}\\ &\leq \left[\left|\Phi'\frac{d}{dt}(\Pi(\theta))\left((1-\lambda)\sum_{m=0}^{\infty}\lambda^m P(\theta)^{m+1}-I\right)\Phi\right|\right]_{ij}\\ &\quad+\left[\left|\Phi'\Pi(\theta)\frac{d}{dt}\left((1-\lambda)\sum_{m=0}^{\infty}\lambda^m P(\theta)^{m+1}-I\right)\Phi\right|\right]_{ij}\\ &\leq B_\Phi B_{\pi 1}\frac{1}{1-\lambda}B_\Phi + B_\Phi\frac{1}{(1-\lambda)^2}B_{P1}B_\Phi.\end{aligned}$$

Since the matrix entries are uniformly bounded in θ, so is the matrix $\frac{d}{dt}A(\theta)'\frac{d}{dt}A(\theta)$, and so is the largest eigenvalue of $\frac{d}{dt}A(\theta)'\frac{d}{dt}A(\theta)$ which implies the uniform boundedness of $\left\|\frac{d}{dt}A(\theta)\right\|_2$.

6. For a general invertible square matrix, $X(t)$, we have

$$0 = \frac{d}{dt}I = \frac{d}{dt}\left(X(t)^{-1}X(t)\right) = \frac{d}{dt}\left(X(t)^{-1}\right)X(t) + X(t)^{-1}\frac{d}{dt}(X(t)).$$

Rearranging it we get

$$\frac{d}{dt}\left(X(t)^{-1}\right) = -X(t)^{-1}\frac{d}{dt}(X(t))X(t)^{-1}.$$

Using this identity yields

$$\begin{aligned}\left\|\frac{d}{dt}\left(A(\theta)^{-1}\right)\right\|_2 &= \left\|-A(\theta)^{-1}\frac{d}{dt}(A(\theta))A(\theta)^{-1}\right\|_2\\ &\leq \left\|A(\theta)^{-1}\right\|_2\cdot\left\|\frac{d}{dt}(A(\theta))\right\|_2\cdot\left\|-A(\theta)^{-1}\right\|_2\\ &= b_A^2 B_{A1}.\end{aligned}$$

7. Examining the norm of $\frac{d}{dt}w^*$ yields

$$\begin{aligned}\left\|\frac{d}{dt}w^*\right\|_2 &= \left\|\frac{d}{dt}\left(A(\theta)^{-1}b(\theta)\right)\right\|_2 \\ &= \left\|\frac{d}{dt}A(\theta)^{-1}b(\theta)+A(\theta)^{-1}\frac{d}{dt}b(\theta)\right\|_2 \\ &\leq b_A^2 B_{A1}\frac{1}{1-\lambda}|\mathcal{X}|^3 B_\Phi B_r + b_A\tilde{B} \\ &= B_{w1}.\end{aligned}$$

We wish to use Lemma 23 for (17), thus, we show that the assumptions of Lemma 23 are valid.

Lemma 28

1. We have

$$\limsup_{t\to\infty}\|w^*(\theta(t))-w(t)\|_2 \leq \frac{1}{\Gamma_w}B_{\Delta w}, \tag{34}$$

where

$$B_{\Delta w} \triangleq \frac{B_{w1}+B_G\frac{B_{\Delta\eta}}{\Gamma_\eta}}{\gamma}.$$

(a) We have

$$\limsup_{t\to\infty}\|h(\theta(t))-\tilde{h}(w(t))\|_\infty \leq \frac{B_{\Delta h1}}{\Gamma_w}+\frac{\varepsilon_{\text{app}}}{\sqrt{b_\pi}},$$

where

$$B_{\Delta h} \triangleq |\mathcal{X}|L(B_{\Delta w})^2.$$

Proof ■

1. Without loss of generality, we can eliminate the projection operator since we can choose B_w to be large enough such that $w^*(\theta)$ will be inside the bounded space. We take $\mathcal{M}(t)=A(\theta)$, $F_1(t)=w^*(\theta(t))$, and $F_2(t)=G(\theta)(\eta(\theta)-\tilde{\eta})$. By previous lemmas we can see that the Assumption 23 holds. By Lemma 27 (6), $\|\dot{w}^*(\theta)\|_2$ is bounded by B_{w_1}, by Lemma 26 we have a bound on $|(\eta(\theta)-\tilde{\eta})|$, and by Lemma 24 we have a bound on $w'A(\theta)w$. Using these bounds and applying Lemma 23 provides the desired result.

(a) Suppressing the time dependence for simplicity and expressing $\|h(\theta)-\tilde{h}(w)\|_\infty$ using ε_{app} and the previous result yields

$$\begin{aligned}\|h(\theta)-\tilde{h}(w)\|_\infty &\leq \|h(\theta)-\tilde{h}(w)\|_2 \\ &= \|h(\theta)-\tilde{h}(w^*)+\tilde{h}(w^*)-\tilde{h}(w)\|_2 \\ &\leq \|h(\theta)-\tilde{h}(w^*)\|_2+\|\tilde{h}(w^*)-\tilde{h}(w)\|_2\end{aligned} \tag{35}$$

For the first term on the r.h.s. of the final equation in (35) we have

$$\begin{aligned}\|h(\theta)-\tilde{h}(w^*)\|_2 &= \left\| \left(\Pi(\theta)^{-\frac{1}{2}}\right)\left(\Pi(\theta)^{\frac{1}{2}}\right)\left(h(\theta)-\tilde{h}(w^*)\right)\right\|_2 \\ &\leq \left\|\Pi(\theta)^{-\frac{1}{2}}\right\|_2 \left\|h(\theta)-\tilde{h}(w^*)\right\|_{\Pi(\theta)} \\ &\leq \frac{\varepsilon_{\text{app}}}{(b_\pi)^{\frac{1}{2}}}\end{aligned}$$

where we use the sub-additivity of the matrix norms in the first inequality, and Lemma 3 and the (10) in the last inequality. For the second term on the r.h.s. of the final equation in (35) we have

$$\begin{aligned}\|\tilde{h}(w^*)-\tilde{h}(w)\|_2^2 &= \|\Phi(w^*(\theta)-w)\|_2^2 \\ &= \sum_{k=1}^{|\mathcal{X}|}\left(\sum_{l=1}^{L}\phi_l(k)\left(w_l^*(\theta)-w_l\right)\right)^2 \\ &\leq \sum_{k=1}^{|\mathcal{X}|}\left(\left(\sum_{l=1}^{L}\phi_l^2(k)\right)^{\frac{1}{2}}\left(\sum_{l=1}^{L}\left(w_l^*(\theta)-w_l\right)^2\right)^{\frac{1}{2}}\right)^2 \\ &\leq \sum_{k=1}^{|\mathcal{X}|}\left(\sum_{l=1}^{L}\phi_l^2(k)\right)\left(\sum_{l=1}^{L}\left(w_l^*(\theta)-w_l\right)^2\right) \\ &\leq |\mathcal{X}|L\|w^*(\theta)-w\|_2^2 \\ &= |\mathcal{X}|L\left(B_{\Delta w}\right)^2.\end{aligned} \tag{36}$$

Combining (34)-(36) yields the desired result.

Using Lemma 28 we can provide a bound on second term of (17).

Lemma 29 *We have*

$$\limsup_{t\to\infty}\left\|\sum_{x,y\in\mathcal{X}\times\mathcal{X},u\in\mathcal{U}} D^{(x,u,y)}(\theta)\left(d(x,y,\theta)-\tilde{d}(x,y,w)\right)\right\|_2 \leq \frac{B_{\Delta td1}}{\Gamma_w}+\frac{B_{\Delta td2}}{\Gamma_\eta}+B_{\Delta td3}\varepsilon_{app}$$

where

$$B_{\Delta td1}=\frac{1}{\Gamma_w}\cdot 2B_\Psi B_{\Delta h1},\quad B_{\Delta td2}=\frac{1}{\Gamma_\eta}\cdot B_{\Delta\eta}B_\Psi,\quad B_{\Delta td3}=\frac{2B_\Psi}{\sqrt{b_\pi}}.$$

Proof Simplifying the notation by suppressing the time dependence, we bound the TD signal in the limit, that is,

$$\begin{aligned}\limsup_{t\to\infty}|d(x,y,\theta)-\tilde{d}(x,y,w)| &= \limsup_{t\to\infty}|(r(x)-\eta(\theta)+h(y,\theta)-h(x,\theta)) \\ &\quad -\left(r(x)-\tilde{\eta}+\tilde{h}(y,w)-\tilde{h}(x,w)\right)| \\ &\leq \limsup_{t\to\infty}|\eta(\theta)-\tilde{\eta}|+\limsup_{t\to\infty}2\left\|h(\theta)-\tilde{h}(w)\right\|_\infty \\ &= \frac{B_{\Delta\eta}}{\Gamma_\eta}+2\left(\frac{B_{\Delta h1}}{\Gamma_w}+\frac{\varepsilon_{\text{app}}}{\sqrt{b_\pi}}\right).\end{aligned}$$

With some more algebra we have

$$\begin{aligned}
&\limsup_{t\to\infty}\left\|\sum_{x,y\in\mathcal{X}\times\mathcal{X},u\in\mathcal{U}} D^{(x,u,y)}(\theta)\left(d(x,y,\theta)-\tilde{d}(x,y,w)\right)\right\| \\
&\leq \limsup_{t\to\infty}\sum_{x,y\in\mathcal{X}\times\mathcal{X},u\in\mathcal{U}} \pi(x)P(u|x,\theta_n)P(y|x,u)\left\|\psi(x,u,\theta_n)\right\|\cdot\left|d(x,y,\theta)-\tilde{d}(x,y,w)\right| \\
&\leq B_\Psi\left(\frac{B_{\Delta\eta}}{\Gamma_\eta}+2\left(\frac{B_{\Delta h1}}{\Gamma_w}+\frac{\varepsilon_{\text{app}}}{\sqrt{b_\pi}}\right)\right) \\
&= \frac{B_{\Delta td1}}{\Gamma_w}+\frac{B_{\Delta td2}}{\Gamma_\eta}+B_{\Delta td3}\varepsilon_{\text{app}}.
\end{aligned}$$

■

We see that the term in this bound is adjustable by choosing appropriate Γ_η and Γ_w. The concluding lemma proves the conclusion of Theorem 8.

D.1 Proof of Theorem 8

We define

$$B_{\nabla\eta} \triangleq \frac{B_{\Delta td1}}{\Gamma_w}+\frac{B_{\Delta td2}}{\Gamma_\eta}+B_{\Delta td3}\varepsilon_{\text{app}}.$$

For an arbitrary $\delta>0$, define the set

$$\mathcal{B}_\delta \triangleq \{\theta:\ \|\nabla\eta(\theta)\|\leq B_{\nabla\eta}+\delta\}.$$

We claim that the trajectory $\eta(\theta)$ visits $\mathcal{B}_\delta$ infinitely often. Assume the contrary that

$$\liminf_{t\to\infty}\|\nabla\eta(\theta)\|_2 > B_{\nabla\eta}+\delta. \tag{37}$$

Thus, on the set $\mathcal{B}_\delta^c$ for t large enough we have

$$\begin{aligned}
\dot{\eta}(\theta) &= \nabla\eta(\theta)\cdot\dot{\theta} \\
&= \nabla\eta(\theta)\cdot\left(\nabla\eta(\theta)+\sum_{x,y\in\mathcal{X}\times\mathcal{X}} D^{(x,y)}(\theta)\left(d(x,y)-\tilde{d}(x,y)\right)\right) \\
&= \|\nabla\eta(\theta)\|_2^2+\nabla\eta(\theta)\cdot\left(\sum_{x,y\in\mathcal{X}\times\mathcal{X}} D^{(x,y)}(\theta)\left(d(x,y)-\tilde{d}(x,y)\right)\right) \\
&\geq \|\nabla\eta(\theta)\|_2^2-\|\nabla\eta(\theta)\|_2\left\|\sum_{x,y\in\mathcal{X}\times\mathcal{X}} D^{(x,y)}(\theta)\left(d(x,y)-\tilde{d}(x,y)\right)\right\|_2 \\
&= \|\nabla\eta(\theta)\|_2\left(\|\nabla\eta(\theta)\|_2-B_{\nabla\eta}\right) \\
&\geq \|\nabla\eta(\theta)\|_2\left(B_{\nabla\eta}+\delta-B_{\nabla\eta}\right) \\
&> (B_{\nabla\eta}+\delta)\delta.
\end{aligned}$$

By (37), there exists a time t_0 which for all $t>t_0$ we have $\eta(\theta)\in\mathcal{B}_\delta^c$. Therefore,

$$\eta(\infty)=\eta(t_0)+\int_{t_0}^{\infty}\dot{\eta}(\theta)dt > \eta(t_0)+\int_{t_0}^{\infty}(B_D+\delta)\delta dt=\infty,$$

which contradicts the boundedness of $\eta(\theta)$. Since the claim holds for all $\delta>0$, the result follows.

Abstract

We address instance-based learning from a perceptual organization standpoint and present methods for dimensionality estimation, manifold learning and function approximation. Under our approach, manifolds in high-dimensional spaces are inferred by estimating geometric relationships among the input instances. Unlike conventional manifold learning, we do not perform dimensionality reduction, but instead perform all operations in the original input space. For this purpose we employ a novel formulation of tensor voting, which allows an N-D implementation. Tensor voting is a perceptual organization framework that has mostly been applied to computer vision problems. Analyzing the estimated local structure at the inputs, we are able to obtain reliable dimensionality estimates at each instance, instead of a global estimate for the entire data set. Moreover, these local dimensionality and structure estimates enable us to measure geodesic distances and perform nonlinear interpolation for data sets with varying density, outliers, perturbation and intersections, that cannot be handled by state-of-the-art methods. Quantitative results on the estimation of local manifold structure using ground truth data are presented. In addition, we compare our approach with several leading methods for manifold learning at the task of measuring geodesic distances. Finally, we show competitive function approximation results on real data.

Keywords: dimensionality estimation, manifold learning, geodesic distance, function approximation, high-dimensional processing, tensor voting

1. Introduction

In this paper, we address a subfield of machine learning that operates in continuous domains and learns from observations that are represented as points in a Euclidean space. This type of learning is termed *instance-based* or *memory-based* learning (Mitchell, 1997). The goal of instance-based learning is to learn the underlying relationships between observations, which are points in an N-D continuous space, under the assumption that they lie in a limited part of the space, typically a manifold, the dimensionality of which is an indication of the degrees of freedom of the underlying system.

Instance-based learning has recently received renewed interest from the machine learning community, due to its many applications in the fields of pattern recognition, data mining, kinematics, function approximation and visualization, among others. This interest was sparked by a wave of new algorithms that advanced the state of the art and are capable of learning nonlinear manifolds in spaces of very high dimensionality. These include kernel PCA (Schölkopf et al., 1998), locally linear embedding (LLE) (Roweis and Saul, 2000), Isomap (Tenenbaum et al., 2000) and charting (Brand, 2003), which are reviewed in Section 2. They aim at reducing the dimensionality of the input space in a way that preserves certain geometric or statistical properties of the data. Isomap, for instance, attempts to preserve the geodesic distances between all points as the manifold is "unfolded" and mapped to a space of lower dimension.

Our research focuses on data presented as large sets of observations, possibly containing outliers, in high dimensions. We view the problem of learning an unknown function based on these observations as equivalent to learning a manifold, or manifolds, formed by a set of points. Having a good estimate of the manifold's structure, one is able to predict the positions of other points on it. The first task is to determine the intrinsic dimensionality of the data. This can provide insights on the complexity of the system that generates the data, the type of model needed to describe it, as well as the actual degrees of freedom of the system, which are not equal to the dimensionality of the input space, in general. We also estimate the orientation of a potential manifold that passes through each point. Dimensionality estimation and structure inference are accomplished simultaneously by encoding the observations as symmetric, second order, non-negative definite tensors and analyzing the outputs of tensor voting (Medioni et al., 2000). Since the process that estimates dimensionality and orientation is performed on the inputs, our approach falls under the "eager learning" category, according to Mitchell (1997). Unlike other eager approaches, however, ours is not global. This offers considerable advantages when the data become more complex, or when the number of instances is large.

We take a different path to manifold learning than Roweis and Saul (2000), Tenenbaum et al. (2000) and Brand (2003). Whereas these methods address the problem as one of dimensionality reduction, we propose an approach that does not embed the data in a lower dimensional space. Preliminary versions of this approach were published in Mordohai and Medioni (2005) and Mordohai (2005). A similar methodology was also presented by Dollár et al. (2007a). We compute local dimensionality estimates, but instead of performing dimensionality reduction, we perform all operations in the original input space, taking into account the estimated dimensionality of the data. We also estimate the orientation of the manifold locally and are able to approximate intrinsic or geodesic distances[1] and perform nonlinear interpolation. Since we perform all processing in the input space we are able to process data sets that are not manifolds globally, or ones with varying intrinsic dimensionality. The latter pose no additional difficulties, since we do not use a global estimate for the dimensionality of the data. Moreover, outliers, boundaries, intersections or disconnected components are handled naturally as in 2-D and 3-D (Medioni et al., 2000; Tang and Medioni, 1998). Quantitative results for the robustness to outliers that outnumber the inliers are presented in Sections 5 and 6. Once processing under our approach has been completed, dimensionality reduction

1. The requirements for a distance to be geodesic are stricter than those for being intrinsic. Intrinsic distances are computed on the manifold, while geodesics are based on the gradient of the distance function. For the manifolds we examine in this paper, these two almost always coincide. See Mémoli and Sapiro (2005) and references therein for more details.

can be performed using any of the approaches described in the next section to reduce the storage requirements, if appropriate and desirable.

Manifold learning serves as the basis for the last part of our work, which addresses function approximation. As suggested by Poggio and Girosi (1990), function approximation from samples and hypersurface inference are equivalent. The main assumption is that some form of smoothness exists in the data and unobserved outputs can be predicted from previously observed outputs for similar inputs. The distinction between low and high-dimensional spaces is necessary, since highly specialized methods for low-dimensional cases exist in the literature. Our approach is local, non-parametric and has a weak prior model of smoothness, which is implemented in the form of votes that communicate a point's preferred orientation to its neighbors. This generic prior and the absence of global computations allow us to address a large class of functions as well as data sets comprising very large numbers of observations. As most of the local methods reviewed in the next section, our algorithm is memory-based. This increases flexibility, since we can process data that do not conform to pre-specified models, but also increases storage requirements, since all samples are kept in memory.

All processing in our method is performed using tensor voting, which is a computational framework for perceptual organization based on the Gestalt principles of proximity and good continuation (Medioni et al., 2000). It has mainly been applied to organize generic points into coherent groups and for computer vision problems that were formulated as perceptual organization tasks. For instance, the problem of stereo vision can be formulated as the organization of potential pixel correspondences into salient surfaces, under the assumption that correct correspondences form coherent surfaces and wrong ones do not (Mordohai and Medioni, 2006). Salient structures are inferred based on the support potential correspondences receive from their neighbors in the form of votes, which are also second order tensors that are cast from each point to all other points within its neighborhood. Each vote conveys the orientation the receiver would have if the voter and receiver were in the same structure. In Section 3, we present a new implementation of tensor voting that is not limited to low-dimensional spaces as the original one of Medioni et al. (2000).

The paper is organized as follows: an overview of related work including the algorithms that are compared with ours is given in the next section; a new implementation of tensor voting applicable to N-D data is described in Section 3; results in dimensionality estimation are presented in Section 4, while results in local structure estimation are presented in Section 5; our algorithm for estimating geodesic distances and a quantitative comparison with state of the art methods are shown in Section 6; function approximation is described in Section 7; finally, Section 8 concludes the paper.

2. Related Work

In this section, we present related work in the domains of dimensionality estimation, manifold learning and multivariate function approximation.

2.1 Dimensionality Estimation

Bruske and Sommer (1998) present an approach for dimensionality estimation where an optimally topology preserving map (OTPM) is constructed for a subset of the data, which is produced after vector quantization. Principal Component Analysis (PCA) is then performed for each node of the OTPM under the assumption that the underlying structure of the data is locally linear. The average of the number of significant singular values at the nodes is the estimate of the intrinsic dimensionality.

Kégl (2003) estimates the capacity dimension of a manifold, which is equal to the topological dimension and does not depend on the distribution of the data, using an efficient approximation based on packing numbers. The algorithm takes into account dimensionality variations with scale and is based on a geometric property of the data, rather than successive projections to increasingly higher-dimensional subspaces until a certain percentage of the data is explained. Raginsky and Lazebnik (2006) present a family of dimensionality estimators based on the concept of quantization dimension. The family is parameterized by the distortion exponent and includes the method of Kégl (2003) when the distortion exponent tends to infinity. The authors show that small values of the distortion exponent yield estimators that are more robust to noise.

Costa and Hero (2004) estimate the intrinsic dimension of the manifold and the entropy of the samples using geodesic-minimal-spanning trees. The method, similarly to Isomap (Tenenbaum et al., 2000), considers global properties of the adjacency graph and thus produces a single global estimate.

Levina and Bickel (2005) compute maximum likelihood estimates of dimensionality by examining the number of neighbors included in spheres, the radii of which are selected in such a way that they contain enough points and that the density of the data contained in them can be assumed constant. These requirements cause an underestimation of the dimensionality when it is very high.

The difference between our approach and those of Bruske and Sommer (1998), Kégl (2003), Brand (2003), Weinberger and Saul (2004), Costa and Hero (2004) and Levina and Bickel (2005) is that it produces reliable dimensionality estimates at the point level. While this is not important for data sets with constant dimensionality, the ability to estimate local dimensionality reliably becomes a key factor when dealing with data generated by different unknown processes. Given reliable local estimates, the data set can be segmented in components with constant dimensionality.

2.2 Manifold Learning

Here, we briefly present recent approaches for learning low dimensional embeddings from points in high dimensional spaces. Most of them are inspired by linear techniques, such as Principal Component Analysis (PCA) (Jolliffe, 1986) and Multi-Dimensional Scaling (MDS) (Cox and Cox, 1994), based on the assumption that nonlinear manifolds can be approximated by locally linear parts.

Schölkopf et al. (1998) propose kernel PCA that extends linear PCA by implicitly mapping the inputs to a higher-dimensional space via kernels. Conceptually, applying PCA in the high-dimensional space allows the extraction of principal components that capture more information than their counterparts in the original space. The mapping to the high-dimensional space does not need to carried out explicitly, since dot product computations suffice. The choice of kernel is still an open problem. Weinberger et al. (2004) describe an approach to compute the kernel matrix by maximizing variance in feature space in the context of dimensionality reduction.

Locally Linear Embedding (LLE) was presented by Roweis and Saul (2000) and Saul and Roweis (2003). The underlying assumption is that if data lie on a locally linear, low-dimensional manifold, then each point can be reconstructed from its neighbors with appropriate weights. These weights should be the same in a low-dimensional space, the dimensionality of which is greater or equal to the intrinsic dimensionality of the manifold. The LLE algorithm computes the basis of such a low-dimensional space. The dimensionality of the embedding, however, has to be given as a parameter, since it cannot always be estimated from the data (Saul and Roweis, 2003). Moreover,

the output is an embedding of the given data, but not a mapping from the ambient to the embedding space. Global coordination of the local embeddings, and thus a mapping, can be computed according to Teh and Roweis (2003). LLE is not isometric and often fails by mapping distant points close to each other.

Tenenbaum et al. (2000) propose Isomap, which is an extension of MDS that uses geodesic instead of Euclidean distances and thus can be applied to nonlinear manifolds. The geodesic distances between points are approximated by graph distances. Then, MDS is applied on the geodesic distances to compute an embedding that preserves the property of points to be close or far away from each other. Isomap can handle points not in the original data set, and perform interpolation. C-Isomap, a variant of Isomap applicable to data with intrinsic curvature, but known distribution, and L-Isomap, a faster alternative that only uses a few landmark point for distance computations, have also been proposed by de Silva and Tenenbaum (2003). Isomap and its variants are limited to convex data sets.

The Laplacian Eigenmaps algorithm was developed by Belkin and Niyogi (2003). It computes the normalized graph Laplacian of the adjacency graph of the input data, which is an approximation of the Laplace-Beltrami operator on the manifold. It exploits locality preserving properties that were first observed in the field of clustering. The Laplacian Eigenmaps algorithm can be viewed as a generalization of LLE, since the two become identical when the weights of the graph are chosen according to the criteria of the latter. Much like LLE, the dimensionality of the manifold also has to be provided, the computed embeddings are not isometric and a mapping between the two spaces is not produced. The latter is addressed by He and Niyogi (2004) where a variation of the algorithm is proposed.

Donoho and Grimes (2003) propose Hessian LLE (HLLE), an approach similar to the above, which computes the Hessian instead of the Laplacian of the graph. The authors claim that the Hessian is better suited than the Laplacian in detecting linear patches on the manifold. The major contribution of this approach is that it proposes a global, isometric method, which, unlike Isomap, can be applied to non-convex data sets. The requirement to estimate second derivatives from possibly noisy, discrete data makes the algorithm more sensitive to noise than the others reviewed here.

Semidefinite Embedding (SDE) was proposed by Weinberger and Saul (2004, 2006) who address the problem of manifold learning by enforcing local isometry. The lengths of the sides of triangles formed by neighboring points are preserved during the embedding. These constraints can be expressed in terms of pairwise distances and the optimal embedding can be found by semidefinite programming. The method is among the most computationally demanding reviewed here, but can reliably estimate the underlying dimensionality of the inputs by locating the largest gap between the eigenvalues of the Gram matrix of the outputs. Similarly to our approach, dimensionality estimation does not require a threshold.

Other research related to ours includes the charting algorithm of Brand (2003). It computes a pseudo-invertible mapping of the data, as well as the intrinsic dimensionality of the manifold, which is estimated by examining the rate of growth of the number of points contained in hyper-spheres as a function of the radius. Linear patches, areas of curvature and noise can be distinguished using the proposed measure. At a subsequent stage a global coordinate system for the embedding is defined. This produces a mapping between the input space and the embedding space.

Wang et al. (2005) propose an adaptive version of the local tangent space alignment (LTSA) of Zhang and Zha (2004), a local dimensionality reduction method that is a variant of LLE. Wang et al. address a limitation of most of the approaches presented in this section, which is the use of

a fixed number of neighbors (k) for all points in the data. Inappropriate selection of k can cause problems at points near boundaries, or if the density of the data is not approximately constant. The authors propose a method to adapt the neighborhood size according to local criteria and demonstrate its effectiveness on data sets of varying distribution. Using an appropriate value for k at each point is important for graph-based methods, since the contributions of each neighbor are typically not weighted, making the algorithms very sensitive to the selection of k.

In a more recent paper, Sha and Saul (2005) propose Conformal Eigenmaps, an algorithm that operates on the output of LEE or Laplacian Eigenmaps to produce a conformal embedding, which preserves angles between edges in the original input space, without incurring a large increase in computational cost. A similar approach that "stiffens" the inferred manifolds employing a multi-resolution strategy was proposed by Brand (2005). Both these papers address the limitation of some of the early algorithms which preserve graph connectivity, but not local structure, during the embedding.

The most similar method to ours is that of Dollár et al. (2007a) and Dollár et al. (2007b) in which the data are not embedded in a lower dimensional space. Instead, the local structure of a manifold at a point is learned from neighboring observations and represented by a set of radial basis functions (RBFs) centered on K points discovered by K-means clustering. The manifold can then be traversed by "walking" on its tangent space between and beyond the observations. Representation by RBFs without dimensionality reduction allows the algorithm to be robust to outliers and be applicable to non-isometric manifolds. An evaluation of manifold learning using geodesic distance preservation as a metric, similar to the one of Section 6.1, is presented in Dollár et al. (2007b).

A different approach for intrinsic distance estimation that bypasses learning the structure of the manifold has been proposed by Mémoli and Sapiro (2005). It approximates intrinsic distances and geodesics by computing extrinsic Euclidean distances in a thin band that surrounds the points. The algorithm can handle manifolds in any dimension and of any co-dimension and is more robust to noise than graph-based methods, such as Isomap, since in the latter the outliers are included in the graph and perturb the approximation of geodesics.

Souvenir and Pless (2005) present an approach capable of learning multiple, potentially intersecting, manifolds of different dimensionality using an expectation maximization (EM) algorithm with a variant of MDS as the M step. Unlike our approach, however, the number and dimensionality of the manifolds have to be provided externally.

2.3 Function Approximation

Here we review previous research on function approximation focusing on methods that are applicable to large data sets in high-dimensional spaces. Neural networks are often employed as global methods for function approximation. Poggio and Girosi (1990) addressed function approximation in a regularization framework implemented as a three-layer neural network. They view the problem as hypersurface reconstruction, where the main assumption is that of smoothness. The emphasis is on the selection of the appropriate approximating functions and optimization algorithm. Other research based on neural networks includes the work of Sanger (1991) who proposed a tree-structured neural network, which does not suffer from the exponential growth with dimensionality of the number of models and parameters that plagued previous approaches. It does, however, require the selection of an appropriate set of basis functions to approximate a given function. Neural network based approaches with pre-specified types of models are also proposed by: Barron (1993) who derived

the bounds for approximation using a superposition of sigmoidal functions; Breiman (1993) who proposed a simpler and faster model based on hinging hyperplanes; and Saha et al. (1993) who used RBFs.

Xu et al. (1995) modified the training scheme for the mixture of experts architecture so that a single-loop EM algorithm is sufficient for optimization. Mitaim and Kosko (2001) approached the problem within the fuzzy systems framework. They investigated the selection of the shape of fuzzy sets for an adaptive fuzzy system and concluded that no shape emerges as the best choice. These approaches, as well as the ones based on neural networks, are global and model-based. They can achieve good performance, but they require all the inputs to be available at the same time for training and the selection of an appropriate model that matches the unknown function. If the latter is complex, the resulting model may have an impractically large number of parameters.

Support Vector Machines (SVMs), besides classification, have also been extensively applied for regression based on the work of Vapnik (1995). Collobert and Bengio (2001) address a limitation of the SVM algorithm for regression, which is its increased computational complexity as the number of samples grows, with a decomposition algorithm. It operates on a working set of the variables, while keeping fixed variables that are less likely to change.

All the above methods are deterministic and make hard decisions. On the other hand, Bayesian learning brings the advantages of probabilistic predictions and a significant decrease in the number of basis functions. Tresp (2000) introduced the Bayesian Committee Machine that is able to handle large data sets by splitting them in subsets and training an estimator for each. These estimators are combined with appropriate weights to generate the prediction. What is noteworthy about this approach is the fact that the positions of query points are taken into account in the design of the estimator and that performance improves when multiple query points are processed simultaneously. Tipping (2001) proposed a sparse Bayesian learning approach, which produces probabilistic predictions and automatically detects nuisance parameters, and the Relevance Vector Machine that can be viewed as stochastic formulation of an SVM. A Bayesian treatment of SVM-based regression can also be found in the work of Chu et al. (2004). Its advantages include reduced computational complexity over Gaussian Process Regression (GPR), reviewed below, and robustness against outliers. Inspired by Factor Analysis Regression, Ting et al. (2006) propose a Bayesian regression algorithm that is robust to ill-conditioned data, detects relevant features and identifies input and output noise.

An approach that has attracted a lot of attention is the use of Gaussian Processes (GPs) for regression. Williams and Rasmussen (1996) observed that Bayesian analysis of neural networks is difficult due to complex prior distributions over functions resulting even from simple priors over weights. Instead, if one uses Gaussian processes as priors over the functions, then Bayesian analysis can be carried out exactly. Despite the speed up due to GPs, faster implementations were still needed for practical applications. A sparse greedy GP regression algorithm was presented by Smola and Bartlett (2001) who approximate the MAP estimate by expanding in terms of a small set of kernels. Csató and Opper (2002) described an alternative sparse representation for GP regression models. It operates in an online fashion and maintains a sparse basis which is dynamically updated as more data become available.

Lawrence et al. (1996) compared a global approach using a multi-layer perceptron with a linear local approximation model. They found that the local model performed better when the density of the input data deviated a lot from being uniform. Furthermore, the local model allowed for incremental learning and cross-validation. On the other hand, it showed poorer generalization, slower performance after training and required more memory, since all input data had to be stored. The

global model performed better in higher dimensions, where data sparsity becomes a serious problem for the local alternative. Wedge et al. (2006) bring together the advantages of global and local approaches using a hybrid network architecture that combines RBFs and sigmoid neural networks. It first identifies global features of the system before adding local details via the RBFs.

Schaal and Atkeson (1998) proposed a nonparametric, local, incremental learning approach based on receptive field weighted regression. The approach is truly local since the parameters for each model and the size and shape of each receptive field are learned independently. The provided mechanisms for the addition and pruning of local models enable incremental learning as new data points become available.

Atkeson et al. (1997) survey local weighted learning methods and identify the issues that must be taken into account. These include the selection of the distance metric, the weighting function, prediction assessment and robustness to noise. The authors argue that in certain cases no values of the parameters of a global model can provide a good approximation of the true function. In these cases, a local approximation using a simpler, even linear model, is a better approach than increasing the complexity of the global model. Along these lines, Vijayakumar and Schaal (2000) proposed locally weighted projection regression, an algorithm based on successive univariate regressions along projections of the data in directions given by the gradient of the underlying function.

We opt for a local approach and address the problem as an extension of manifold learning. Note, however, that we are not limited to functions that are strictly manifolds. Using tensor voting, we are able to reliably estimate the normal and tangent space at each sample, as described in the following section. These estimates allow us to perform nonlinear interpolation and generate outputs for unobserved inputs, even under severe noise corruption.

3. Tensor Voting in High-Dimensional Spaces

The tensor voting framework, in its preliminary version (Guy and Medioni, 1996), is an implementation of two Gestalt principles, namely proximity and good continuation, for grouping generic tokens in 2-D. The 2-D domain has always been the main focus of research in perceptual organization, beginning with the research of Köhler (1920), Wertheimer (1923) and Koffka (1935). The generalization of perceptual organization to 3-D is relatively straightforward, since salient groupings can be detected by the human visual system in 3-D based on the same principles. Guy and Medioni (1997) extended tensor voting to three dimensions. The term saliency here refers to *structural saliency*, which, according to Shashua and Ullman (1988) is the property of structures to stand out due to the configuration of local elements. That is, the local elements of the structure are not salient in isolation, but instead the arrangement of the elements is what makes the structure salient. The saliency of each element is estimated by accumulating *votes* cast from its neighbors. Tensor voting is a pairwise operation in which elements cast and collect votes in local neighborhoods. Each vote is a tensor and encodes the orientation the receiver would have according to the voter, if the voter and receiver belonged in the same structure. According to the Gestalt theory, simple figures are preferable to complex alternatives, if no evidence favors the latter. The evidence in tensor voting are the position and preferred orientation, if available, of the voter and the position of the receiver. Given this information, we show examples of votes cast by an oriented voter in 2-D in Figure 1. The voter V is a point on a horizontal curve and its normal is represented by the orange arrow. (Details on the representation can be found in Section 3.1). The other points, R_1-R_4, act as receivers. The simplest curve, the one with minimum total curvature, that passes through an oriented voter and

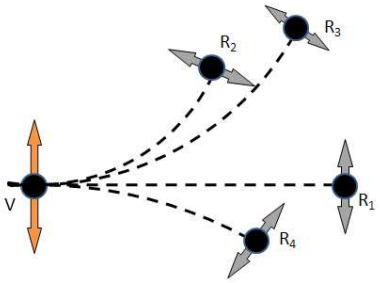

Figure 1: Illustration of tensor voting in 2-D. The voter is an oriented curve element V on a horizontal curve whose normal is represented by the orange arrow. The four receivers R_1-R_4 collect votes from V. (In practice, they would also cast votes to V and among themselves, but this is omitted here.) Each receiver is connected to V by a circular arc which is the simplest structure that can be inferred from two points, one of which is oriented. The gray votes at the receivers indicate the curve normal the receivers should have according to the voter.

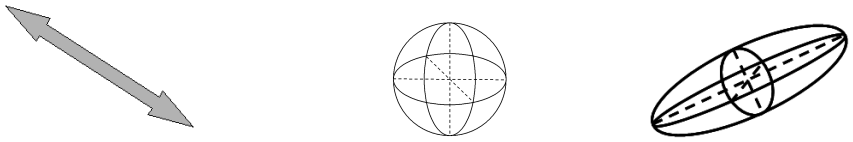
a receiver is a circular arc, for which curvature is constant. Therefore, we connect the voter and receiver by a circular arc which is tangent at the voter and passes through the receiver and define the vote cast as the normal to this arc at the location of the receiver. The votes shown as gray arrows in Figure 1 represent the orientations the receivers would have according to the voter V. The magnitude of the votes decays with distance and curvature. It will be defined formally in Section 3.2. Voting from all possible types of voters, such as surface or curve elements in 3-D, can be derived from the fundamental case of a curve element voter in 2-D (Medioni et al., 2000). Tensor voting is based on strictly local computations in the neighborhoods of the inputs. The size of these neighborhoods is controlled by the only critical parameter in the framework: the scale of voting σ. The scale parameter is introduced in Eq. 3. By determining the size of the neighborhoods, scale regulates the amount of smoothness and provides a knob to the user for balancing fidelity to the data and noise reduction.

Regardless of the computational feasibility of an implementation, the same grouping principles apply to spaces with even higher dimensions. For instance, Tang et al. (2001) observed that pixel correspondences can be viewed as points in the 8-D space of free parameters of the fundamental matrix. Correct correspondences align to form a hyperplane in that space, while wrong correspondences are randomly distributed. By applying tensor voting in 8-D, Tang et al. were able to infer the dominant hyperplane and the desired parameters of the fundamental matrix. Storage and computation requirements, however, soon become prohibitively high as the dimensionality of the space increases. Even though the applicability of tensor voting as a manifold learning technique seems to have merit, the generalization of the implementation of Medioni et al. (2000) is not practical, mostly due to computational complexity and storage requirements in N dimensions. The bottleneck is the generation and storage of voting fields, the number of which is equal to the dimensionality of the space.

In this section, we describe the tensor voting framework beginning with data representation and proceeding to the voting mechanism and vote analysis. The representation and vote analysis schemes are N-D extensions of the original implementation (Medioni et al., 2000). The novelty of



(a) Oriented or *stick* tensor (b) Unoriented or *ball* tensor (c) Generic tensor

Figure 2: Examples of tensors in 3-D. The tensor on the left has only one non-zero eigenvalue and encodes a preference for an orientation parallel to the eigenvector corresponding to that eigenvalue. The eigenvalues of the tensor in the middle are all equal, and thus the tensor does not encode a preference for a particular orientation. The tensor on the right is a generic 3-D tensor.

our work is a new formulation of the voting process that is practical for spaces of dimensionality up to a few hundreds. Efficiency is considerably higher than the preliminary version of this formulation presented in Mordohai and Medioni (2005), where we focused on dimensionality estimation.

3.1 Data Representation

The representation of a token (a generic data point) is a second order, symmetric, non-negative definite tensor, which is equivalent to an $N \times N$ matrix and an ellipsoid in an N-D space. All tensors in this paper are second order, symmetric and non-negative definite, so any reference to a tensor automatically implies these properties. Three examples of tensors, in 3-D, can be seen in Figure 2. A tensor represents the structure of a manifold going through the point by encoding the normals to the manifold as eigenvectors of the tensor that correspond to non-zero eigenvalues, and the tangents as eigenvectors that correspond to zero eigenvalues. (Note that eigenvectors and vectors in general in this paper are column vectors.) For example, a point in an N-D hyperplane has one normal and $N-1$ tangents, and thus is represented by a tensor with one non-zero eigenvalue associated with an eigenvector parallel to the hyperplane's normal. The remaining $N-1$ eigenvalues are zero. A point belonging to a 2-D manifold in N-D is represented by two tangents and $N-2$ normals, and thus is represented by a tensor with two zero eigenvalues associated with the eigenvectors that span the tangent space of the manifold. The tensor also has $N-2$ non-zero, equal eigenvalues whose corresponding eigenvectors span the manifold's normal space. Two special cases of tensors are: the *stick* tensor that has only one non-zero eigenvalue and represents perfect certainty for a hyperplane normal to the eigenvector that corresponds to the non-zero eigenvalue; and the *ball* tensor that has all eigenvalues equal and non-zero which represents perfect uncertainty in orientation, or, in other words, just the presence of an unoriented point.

The tensors can be formed by the summation of the direct products ($\vec{n}\vec{n}^T$) of the eigenvectors that span the normal space of the manifold. The tensor at a point on a manifold of dimensionality d, with $\vec{n}_i$ being the unit vectors that span the normal space, can be computed as follows:

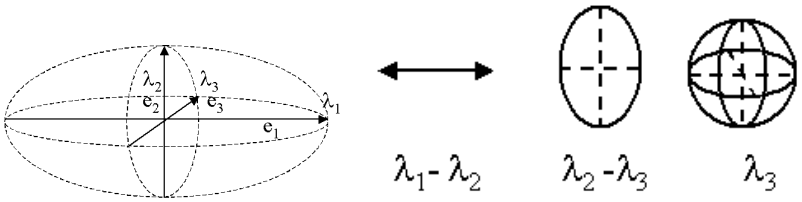
$$T = \sum_{i=1}^{d} \vec{n}_i \vec{n}_i^T . \tag{1}$$

An unoriented point can be represented by a *ball* tensor which contains all possible normals and is encoded as the $N \times N$ identity matrix. Any point on a manifold of known dimensionality and orientation can be encoded in this representation by appropriately constructed tensors, according to Eq. 1.

On the other hand, given an N-D second order, symmetric, non-negative definite tensor, the type of structure encoded in it can be inferred by examining its eigensystem. Any such tensor can be decomposed as in the following equation:

$$\begin{aligned}\mathbf{T} &= \sum_{d=1}^{N} \lambda_d \hat{e}_d \hat{e}_d^T = \\ &= (\lambda_1 - \lambda_2)\hat{e}_1\hat{e}_1^T + (\lambda_2 - \lambda_3)(\hat{e}_1\hat{e}_1^T + \hat{e}_2\hat{e}_2^T) + ... + \lambda_N(\hat{e}_1\hat{e}_1^T + \hat{e}_2\hat{e}_2^T + ... + \hat{e}_N\hat{e}_N^T) \\ &= \sum_{d=1}^{N-1} [(\lambda_d - \lambda_{d+1}) \sum_{k=1}^{d} \hat{e}_d\hat{e}_d^T] + \lambda_N(\hat{e}_1\hat{e}_1^T + ... + \hat{e}_N\hat{e}_N^T)\end{aligned} \tag{2}$$

where λ_d are the eigenvalues in descending order of magnitude and $\hat{e}_d$ are the corresponding eigenvectors. The tensor simultaneously encodes *all* possible types of structure. The confidence, or *saliency* in perceptual organization terms, of the type that has d normals is encoded in the difference $\lambda_d - \lambda_{d+1}$, or λ_N for the ball tensor. If only one of these eigenvalue differences is not zero, then the tensor encodes a single type of structure. Otherwise, more than one type can be present at the location of the tensor, each having a saliency value given by the appropriate difference between consecutive eigenvalues of λ_N. An illustration of tensor decomposition in 3-D can be seen in Figure 3.



(a) Generic 3-D tensor (b) Elementary 3-D tensors

Figure 3: Tensor decomposition in 3-D. A generic tensor can be decomposed into the stick, plate and ball components that have a normal subspace of rank one, two and three respectively.

3.2 The Voting Process

After the inputs have been encoded with tensors, the information they contain is propagated to their neighbors via a voting operation. Given a tensor at A and a tensor at B, the vote the token at A (the *voter*) casts to B (the *receiver*) has the orientation the receiver would have, if both the voter and receiver belong to the same structure. The magnitude of the vote is a function of the confidence we have that the voter and receiver indeed belong to the same structure.

3.2.1 STICK VOTING

We first examine the case of a voter associated with a *stick* tensor, that is the normal space is a single vector in N-D. We claim that, in the absence of other information, the arc of the *osculating circle* (the circle that shares the same normal as a curve at the given point) at A that goes through B is the most likely smooth path between A and B, since it minimizes total curvature. The center of the circle is denoted by C in Figure 4(a). (For visualization purposes, the illustrations are for the 2-D and 3-D cases.) In case of straight continuation from A to B, the osculating circle degenerates to a straight line. Similar use of circular arcs can also be found in Parent and Zucker (1989), Saund (1992), Sarkar and Boyer (1994) and Yen and Finkel (1998). The vote is also a stick tensor and is generated as described in Section 3 according to the following equation:

$$\begin{aligned}
\mathbf{S}_{vote}(s,\theta,\kappa) &= e^{-(\frac{s^2+c\kappa^2}{\sigma^2})} \begin{bmatrix} -\sin(2\theta) \\ \cos(2\theta) \end{bmatrix} [-\sin(2\theta) \;\; \cos(2\theta)], \qquad (3)\\
\theta &= \arcsin(\frac{\vec{v}^T \hat{e}_1}{\|\vec{v}\|}),\\
s &= \frac{\theta\|\vec{v}\|}{\sin(\theta)},\\
\kappa &= \frac{2\sin(\theta)}{\|\vec{v}\|}.
\end{aligned}$$

In the above equation, s is the length of the arc between the voter and receiver, and κ is its curvature (which can be computed from the radius AC of the osculating circle in Figure 4(a)), σ is the scale of voting, and c is a constant, which controls the degree of decay with curvature. The constant c is a function of the scale and is optimized to make the extension of two orthogonal line segments to from a right angle equally likely to the completion of the contour with a rounded corner (Guy and Medioni, 1996). Its value is given by: $c = \frac{-16log(0.1)\times(\sigma-1)}{\pi^2}$. The scale σ essentially controls the range within which tokens can influence other tokens. It can also be viewed as a measure of smoothness that regulates the inevitable trade-off between over-smoothing and over-fitting. Small values preserve details better, but are more vulnerable to noise and over-fitting. Large values produce smoother approximations that are more robust to noise. As shown in Section 7, the results are very stable with respect to the scale. Note that σ is the only free parameter in the framework.

The vote as defined above is on the plane defined by A, B and the normal at A. Regardless of the dimensionality of the space, stick vote generation always takes place in a 2-D subspace defined by the position of the voter and the receiver and the orientation of the voter. (This explains why Eq. 3 is defined in a 2-D space.) Stick vote computation is identical in any space between 2 and N dimensions. After the vote has been computed, it has to be transformed to the N-D space and aligned to the voter by a rotation and translation. For simplicity, we also use the notation:

$$\mathbf{S}_{vote}(A,B,\vec{n}) = \mathbf{S}(s(A,B,\vec{n}),\theta(A,B,\vec{n}),\kappa(A,B,\vec{n})) \qquad (4)$$

to denote the stick vote from A to B with $\vec{n}$ being the normal at A. $s(A,B,\vec{n})$, $\theta(A,B,\vec{n})$ and $\kappa(A,B,\vec{n})$ are the resulting values of the parameters of Eq. 3 given A,B and $\vec{n}$.

According to the Gestalt principles we wish to enforce, the magnitude of the vote should be a function of proximity and smooth continuation. Thus the influence from a point to another attenuates with distance, to minimize interference from unrelated points; and curvature, to favor straight

continuation over curved alternatives. Moreover, no votes are cast if the receiver is at an angle larger than 45° with respect to the tangent of the osculating circle at the voter. Similar restrictions on regions of influence also appear in Heitger and von der Heydt (1993), Yen and Finkel (1998) and Li (1998) to prevent high-curvature connections without support from the data. Votes corresponding to such connections would have been very weak regardless of the restriction since their magnitude is attenuated due to curvature. The saliency decay function (Gaussian) of Eq. 3 has infinite support, but for practical purposes the field is truncated so that negligible votes do not have to be computed. For all experiments shown here, we limited voting neighborhoods to the extent in which the magnitude of a vote is more than 3% of the magnitude of the voter. Both truncation beyond 45° and truncation beyond a certain distance are not critical choices, but are made to eliminate the computation of insignificant votes.

3.2.2 N-D FORMULATION OF TENSOR VOTING

We have shown that stick vote computation is identical up to a simple transformation from 2-D to N-D. Now we turn our attention to votes generated by voters that are not stick tensors. In the original formulation (Medioni et al., 2000) these votes can be computed by integrating the votes cast by a rotating stick tensor that spans the normal space of the voting tensor. Since the resulting integral has no closed form solution, the integration is approximated numerically by taking sample positions of the rotating stick tensor and adding the votes it generates at each point within the voting neighborhood. As a result, votes that cover the voting neighborhood are pre-computed and stored in voting fields. The advantage of this scheme is that all votes are generated based on the stick voting field. Its computational complexity, however, makes its application in high-dimensional spaces prohibitive. Voting fields are used as look-up tables to retrieve votes via interpolation between the pre-computed samples. For instance, a voting field in 10-D with k samples per axis, requires storage for k^{10} 10×10 tensors, which need to be computed via numerical integration over 10 variables. Thus, the use of pre-computed voting fields becomes impractical as dimensionality grows. At the same time, the probability of using a pre-computed vote decreases.

Here, we present a simplified vote generation scheme that allows the direct computation of votes from arbitrary tensors in arbitrary dimensions. Storage requirements are limited to storing the tensors at each sample, since explicit voting fields are not used any more. The advantage of the novel vote generation scheme is that it does not require integration. As in the original formulation, the eigenstructure of the vote represents the normal and tangent spaces that the receiver would have, if the voter and receiver belong in the same smooth structure.

3.2.3 BALL VOTING

For the generation of ball votes, we propose the following direct computation. It is based on the observation that the vote generated by a ball voter propagates the voter's preference for a straight line that connects it to the receiver (Figure 4(b)). The straight line is the simplest and smoothest continuation from a point to another point in the absence of other information. Thus, the vote generated by a ball voter is a tensor that spans the $(N-1)$-D normal space of the line and has one zero eigenvalue associated with the eigenvector that is parallel to the line. Its magnitude is a function of only the distance between the two points, since curvature is zero. Taking these observations into account, the ball vote can be constructed by subtracting the direct product of the unit vector in the direction from the voter to the receiver from a full rank tensor with equal eigenvalues (i.e., the

identity matrix). The resulting tensor is attenuated by the same Gaussian weight according to the distance between the voter and the receiver.

$$\mathbf{B}_{vote}(s) = e^{-\left(\frac{s^2}{\sigma^2}\right)} \left(I - \frac{\vec{v}\vec{v}^T}{\|\vec{v}^T\vec{v}\|} \right) \tag{5}$$

where $\vec{v}$ is a unit vector parallel to the line connecting the voter and the receiver and I is the N-D identity matrix. In this case, $s = |\vec{v}|$ and we omit θ and κ since they do not affect the computation.

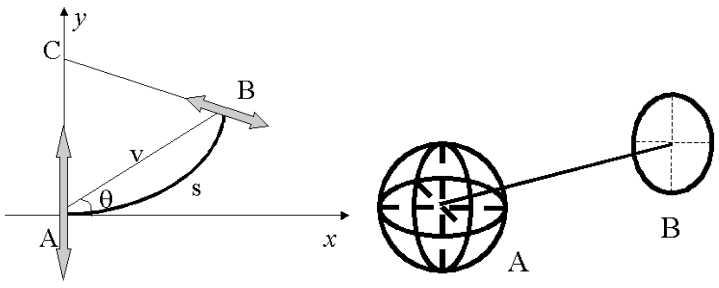
Along the lines of Equation 4, we define a simpler notation:

$$\mathbf{B}_{vote}(A,B) = \mathbf{B}_{vote}(s(A,B)) \tag{6}$$

where $s(A,B) = |\vec{v}|$.

3.2.4 VOTING BY ELEMENTARY TENSORS

To complete the description of vote generation, we need to describe the case of a tensor that has d equal eigenvalues, where d is not equal to 1 or N. (An example of such a tensor would be a curve element in 3-D, which has a rank-two normal subspace and a rank-one tangent subspace.) The description in this section also applies to ball and stick tensors, but we use the above direct computations, which are faster. Let $\vec{v}$ be the vector connecting the voting and receiving points. It can be decomposed into $\vec{v}_t$ and $\vec{v}_n$ in the tangent and normal spaces of the voter respectively. The new vote generation process is based on the observation that curvature in Eq. 3 is not a factor when θ is zero, or, in other words, if the voting stick is orthogonal to $\vec{v}_n$. We can exploit this by defining a new basis for the normal space of the voter that includes $\vec{v}_n$. The new basis is computed using the Gramm-Schmidt procedure. The vote is then constructed as the tensor addition of the votes cast by stick tensors parallel to the new basis vectors. Among those votes, only the one generated by the stick tensor parallel to $\vec{v}_n$ is not parallel to the normal space of the voter and curvature has to be considered. All other votes are a function of the length of $\vec{v}_t$ only. See Figure 5 for an illustration in 3-D. Analytically, the vote is computed as the summation of d stick votes cast by the new basis of the normal space. Let N_S denote the normal space of the voter and let $\vec{b}_i, i \in [1,d]$ be a basis for it with $\vec{b}_1$ being parallel to $\vec{v}_n$. If $S_{vote}(A,B,\vec{b})$ is the function that generates the stick vote from a



(a) Stick voting (b) Ball voting

Figure 4: Vote generation for a stick and a ball voter. The votes are functions of the position of the voter A and receiver B and the tensor of the voter.

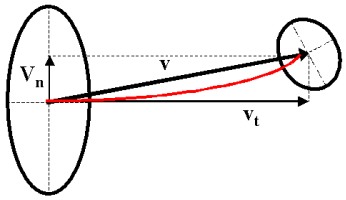


Figure 5: Vote generation for generic tensors. The voter here is a tensor with a 2-D normal subspace in 3-D. The vector connecting the voter and receiver is decomposed into $\vec{v}_n$ and $\vec{v}_t$ that lie in the normal and tangent space of the voter. A new basis that includes $\vec{v}_n$ is defined for the normal space and each basis component casts a stick vote. Only the vote generated by the orientation parallel to $\vec{v}_n$ is not parallel to the normal space. Tensor addition of the stick votes produces the combined vote.

unit stick tensor at A parallel to $\vec{b}$ to the receiver B, then the vote from a generic tensor with normal space N is given by:

$$\mathbf{V}_{vote}(A,B,\mathbf{T}_{e,d}) = S_{vote}(A,B,\vec{b}_1) + \sum_{i\in[2,d]} S_{vote}(A,B,\vec{b}_i). \tag{7}$$

In the above equation, $\mathbf{T}_{e,d}$ denotes the elementary voting tensor with d equal non-zero eigenvalues. On the right-hand side, all the terms are pure stick tensors parallel to the voters, except the first one which is affected by the curvature of the path connecting the voter and receiver. Therefore, the computation of the last $d-1$ terms is equivalent to applying the Gaussian weight to the voting sticks and adding them at the position of the receiver. Only one vote requires a full computation of orientation and magnitude. This makes the proposed scheme computationally inexpensive.

3.2.5 THE VOTING PROCESS

During the voting process (Algorithm 1), each point casts a vote to all its neighbors within the voting neighborhood. If the voters are not pure elementary tensors, that is if more than one saliency value is non-zero, they are decomposed before voting according to Eq. 2. Then, each component votes separately and the vote is weighted by $\lambda_d - \lambda_{d+1}$, except the ball component whose vote is weighted by λ_N. Besides the voting tensor $\mathbf{T}$, points also have a receiving tensor $\mathbf{R}$ that acts as vote accumulator. Votes are accumulated at each point by tensor addition, which is equivalent to matrix addition.

3.3 Vote Analysis

Vote analysis takes place after voting to determine the most likely type of structure and the orientation at each point. There are $N+1$ types of structure in an N-D space ranging from 0-D points to N-D hypervolumes.

The eigensystem of the receiving tensor $\mathbf{R}$ is computed once at the end of the voting process and the tensor is decomposed as in Eq. 2. The estimate of local intrinsic dimensionality is given by the maximum gap in the eigenvalues. Quantitative results on dimensionality estimation are presented in Section 4. In general, if the maximum eigenvalue gap is $\lambda_d - \lambda_{d+1}$, the estimated local intrinsic

dimensionality is $N-d$, and the manifold has d normals and $N-d$ tangents. Moreover, the first d eigenvectors that correspond to the largest eigenvalues are the normals to the manifold, and the remaining eigenvectors are the tangents. Outliers can be detected since all their eigenvalues are

small and no preferred structure type emerges. This happens because they are more isolated than inliers, thus they do not receive votes that consistently support any salient structure. Our past and current research has demonstrated that tensor voting is very robust against outliers.

This vote accumulation and analysis method does not optimize any explicit objective function, especially not a global one. Dimensionality emerges from the accumulation of votes, but it is not a equal to the average, nor the median, nor the majority of the dimensionalities of the voters. For instance, the accumulation of votes from elements of two or more intersecting curves in 2-D results in a rank-two normal space at the junction. If one restricts the analysis to the estimates of orientation, tensor voting can be viewed as a method for maximizing an objective at each point. The weighted (tensor) sum of all votes received is up to a constant equivalent to the weighted mean in the space of symmetric, non-negative definite, second-order tensors. This can be thought of as the tensor that maximizes the consensus among the incoming votes. In that sense, assuming dimensionality is provided by some other process, the estimated orientation at each point is the maximum likelihood estimate given the incoming votes. It should be pointed out here, that the sum is used for all subsequent computations, since the magnitude of the eigenvalues and the of the gaps between them are measures of saliency.

In all subsequent sections, the eigensystem of the accumulator tensor is used as the voter during subsequent processing steps described in the following sections.

Figure 6: 20,000 points sampled from the "Swiss Roll" data set in 3-D.

4. Dimensionality Estimation

In this section, we present experimental results in dimensionality estimation. According to Section 3.3, the intrinsic dimensionality at each point can be found as the maximum gap in the eigenvalues of the tensor after votes from its neighboring points have been collected. All inputs consist of unoriented points since no orientation information is provided and are encoded as ball tensors.

4.1 Swiss Roll

The first experiment is on the "Swiss Roll" data set, which is frequently used in the literature and is available at `http://isomap.stanford.edu/`. It contains $20,000$ points on a 2-D manifold in 3-D (Figure 6). We sample two random variables from independent uniform distributions to generate Swiss rolls with as many as $20,000$ points, as in Tenenbaum et al. (2000), and as few as $1,250$ points. We present quantitative results for 10 different instances of $1,250$, $5,000$ and $20,000$ points in Table 1 as a function of σ. The first column for each set of results shows the percentage of points with correct dimensionality estimates, that is for which $\lambda_1 - \lambda_2$ is the maximal eigenvalue gap. The

Points	1250			5000			20000		
σ	DE	NN	Time	DE	NN	Time	DE	NN	Time
1	0.5%	1.6	0.2	4.3%	3.6	0.4	22.3%	11.2	3.8
2	4.2%	3.7	0.2	22.3%	11.1	0.8	67.9%	40.8	5.4
4	21.5%	11.0	0.2	70.0%	40.7	0.8	98.0%	156.3	12.3
8	64.5%	38.3	0.2	96.9%	148.9	2.6	99.9%	587.2	36.9
12	87.4%	83.4	0.4	99.3%	324.7	5.0	99.9%	1285.4	77.4
16	94.3%	182.4	0.7	99.5%	715.7	10.1	99.8%	2838.0	164.8
20	94.9%	302.6	1.0	99.2%	1179.4	16.5	99.5%	4700.9	268.7
30	91.0%	703.6	2.3	97.0%	2750.8	37.4	97.6%	10966.5	615.2
40	83.6%	1071.7	3.6	86.7%	4271.5	57.7	87.7%	16998.2	947.3

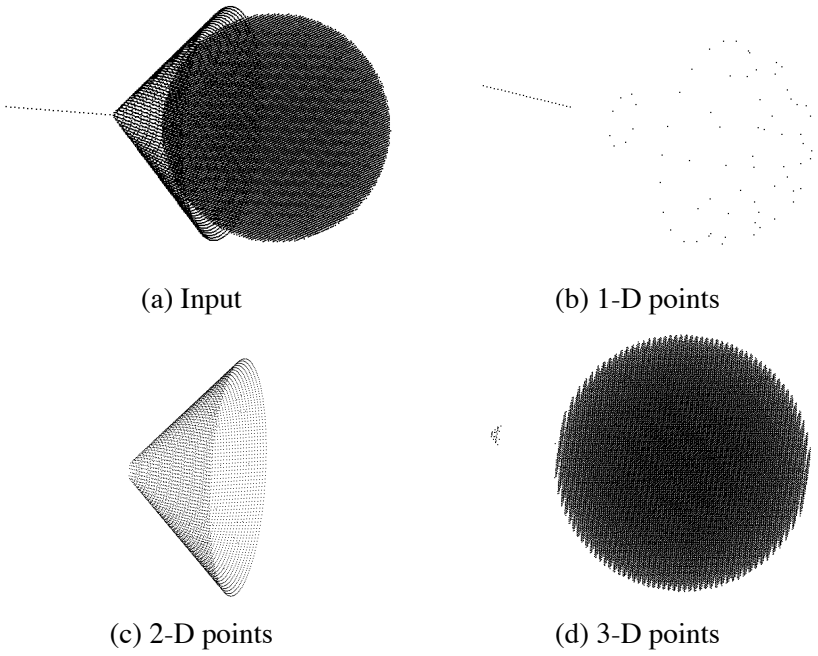
Table 1: Rate of correct dimensionality estimation (DE), average number of neighbors per point and execution times (in seconds) as functions of σ and the number of samples for the "Swiss Roll" data set. All experiments have been repeated 10 times on random samplings of the Swiss Roll function. Note that the range of scales includes extreme values as evidenced by the very high and very low numbers of neighbors in several cases.

second column shows the average number of nearest neighbors included in the voting neighborhood of each point. The third column shows processing times of a single-threaded C++ implementation running on an Intell Pentium 4 processor at $2.50GHz$. We have also repeated the experiment on 10 instances of 500 points from the Swiss Roll using the same values of the scale. Meaningful results are obtained for $\sigma > 8$. The peak of correct dimensionality estimation is at 80.3% for $\sigma = 20$.

A conclusion that can be drawn from Table 1 is that the accuracy is high and stable for a large range of values of σ, as long as a few neighbors are included in each neighborhood. The majority of neighborhoods being empty is an indication of inappropriate scale selection. Performance degrades as scale increases and the neighborhoods become too large to capture the curvature of the manifold. This robustness to large variations in parameter selection are due to the weighting of the votes according to Eqs. 3, 5 and 7 and alleviates the need for extensive parameter tuning.

4.2 Structures with Varying Dimensionality

The second data set is in 4-D and contains points sampled from three structures: a line, a 2-D cone and a 3-D hyper-sphere. The hyper-sphere is a structure with three degrees of freedom. It cannot be unfolded unless we remove a small part from it. Figure 7(a) shows the first three dimensions of the data. The data set contains a total $135,864$ points, which are encoded as ball tensors. Tensor voting is performed with $\sigma = 200$. Figures 7(b-d) show the points classified according to their dimensionality. Methods based on dimensionality reduction or methods that estimate a single dimensionality estimate for the data set would fail for this data set because of the presence of structures with different dimensionalities and because the hyper-sphere cannot be unfolded.



(a) Input (b) 1-D points

(c) 2-D points (d) 3-D points

Figure 7: Data of varying dimensionality in 4-D. (The first three dimensions of the input and the classified points are shown.) Note that the hyper-sphere is empty in 4-D, but appears as a full sphere when visualized in 3-D.

4.3 Data in High Dimensions

The data sets for this experiment were generated by sampling a few thousand points from a low-dimensional space (3- or 4-D) and mapping them to a medium dimensional space (14- to 16-D) using linear and quadratic functions. The generated points were then rotated and embedded in a 50- to 150-D space. Outliers drawn from a uniform distribution inside the bounding box of the data were added to the data set. The percentage of correct point-wise dimensionality estimates after tensor voting can be seen in Table 2.

Intrinsic Dimensionality	Linear Mappings	Quadratic Mappings	Space Dimensions	Dimensionality Estimation (%)
4	10	6	50	93.6
3	8	6	100	97.4
4	10	6	100	93.9
3	8	6	150	97.3

Table 2: Rate of correct dimensionality estimation for high dimensional data.

5. Manifold Learning

In this section we show quantitative results on estimating manifold orientation for various data sets.

Points	1250	5000	20000
σ	Orientation Error	Orientation Error	Orientation Error
1	47.2	28.1	3.1
2	28.7	3.5	**0.4**
4	4.9	**0.9**	0.5
8	**2.0**	1.3	1.1
12	2.5	2.0	1.9
16	3.5	3.1	3.0
20	5.4	4.8	4.7
30	16.9	15.0	14.9
40	28.3	26.2	25.9

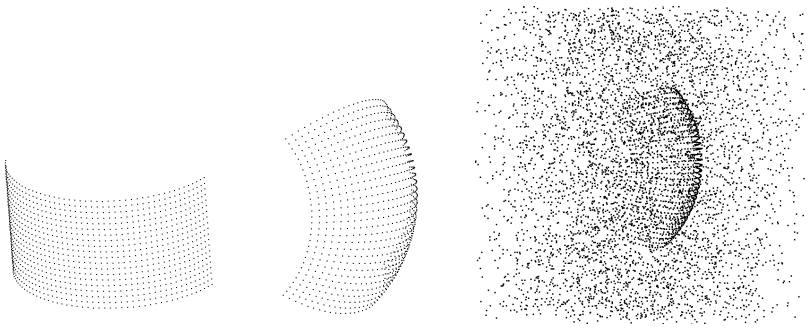
Table 3: Error (in degrees) in surface normal orientation estimation as a function of σ and the number of samples for the "Swiss Roll" data set. The error reported is the (unsigned) angle between the eigenvector corresponding to the largest eigenvalue of the estimated tensor at each point and the ground truth surface normal. See also Table 1 for processing times and the average number of points in each neighborhood.

5.1 Swiss Roll

We begin this section by completing the presentation of our experiments on the Swiss Roll data sets described in the previous section. Here we show the accuracy of normal estimation, regardless of whether the dimensionality was estimated correctly, for the experiments of Table 1. Table 3 is a complement to Table 1, which contains information on the average number of points in the voting neighborhoods and processing time that is not repeated here. The error reported is the (unsigned) angle between the eigenvector corresponding to the largest eigenvalue of the estimated tensor at each point and the ground truth surface normal. These results are over 10 different samplings for each number of points reported in the table.

For comparison, we also estimated the orientation at each point of the Swiss Roll using local PCA computed on the point's k nearest neighbors. We performed an exhaustive search over k, but only report the best results here. As for tensor voting, orientation accuracy was measured on 10 instances of each data set. The lowest errors for $1,250$, $5,000$ and $20,000$ points are 2.51°, 1.16° and 0.56° for values of k equal to 9, 10 and 13 respectively. These errors are approximately 20% larger than the lowest errors achieved by tensor voting, which are shown in bold in Table 3. It should be noted, that, unlike tensor voting, local PCA cannot be used to refine these estimates or take advantage of existing orientation estimates that may be available at the inputs.

We observe that accuracy using tensor voting is very high for a large range of scales and improves, as expected, with higher data density. Random values (around 45°) result when the neighborhood does not contain enough points for normal estimation. See Mitra et al. (2004) and Lalonde et al. (2005) for an analysis of the 3-D case based on the *Gershgorin Circle Theorem* that provides



(a) Cylinder (b) Sphere (c) Noisy sphere

Figure 8: Data sets used in Sections 5 and 6.

bounds for the eigenvalues of square matrices. The authors show how noise and curvature affect the estimation of curve and surface normals under some assumptions about the distribution of the points. The conclusions are that for large neighborhood sizes, errors caused by curvature dominate, while for small neighborhood sizes, errors due to noise dominate. (There is no noise in the data for this experiment.)

5.2 Spherical and Cylindrical Sections

Here, we present quantitative results on simple data sets in 3-D for which ground truth can be analytically computed. In Section 6, we process the same data with state of the art manifold learning algorithms and compare their results against ours. The two data sets are a section of a cylinder and a section of a sphere shown in Figure 8. The cylindrical section spans 150° and consists of 1000 points. The spherical section spans $90^\circ \times 90^\circ$ and consists of 900 points. Both are approximately uniformly sampled. The points are represented by ball tensors, assuming no information about their orientation. In the first part of the experiment, we compute local dimensionality and normal orientation as a function of scale. The results are presented in Tables 4 and 5. The results show that if the scale is not too small, dimensionality estimation is very reliable. For all scales the orientation errors are below 0.4^o.

The same experiments were performed for the spherical section in the presence of outliers. Quantitative results are shown in the following tables for a number of outliers that ranges from 900 (equal to the inliers) to 5000. The latter data set is shown in Figure 8(c). The outliers are drawn from a uniform distribution inside an extended bounding box of the data. Note that performance was evaluated only on the points that belong to the sphere and not the outliers. Larger values of the scale prove to be more robust to noise, as expected. The smallest values of the scale result in voting neighborhoods that include less than 10 points, which are insufficient. Taking this into account, performance is still good even with wrong parameter selection. Also note that one could reject the outliers by thresholding, since they have smaller eigenvalues than the inliers, and perform tensor voting again to obtain even better estimates of structure and dimensionality. Even a single pass of tensor voting, however, turns out to be very effective, especially considering that no other method can handle such a large number of outliers. Foregoing the low-dimensional embedding is a main reason that allows our method to perform well in the presence of noise, since embedding random outliers in a low-dimensional space would make their influence more detrimental. This is

σ	Average Neighbors	Orientation Error (°)	Dimensionality Estimation (%)

due to the structure imposed to them by the mapping, which makes the outliers less random, and due to the increase in their density in the low-dimensional space compared to that in the original high-dimensional space.

5.3 Data with Non-uniform Density

We also conducted two experiments on functions proposed in Wang et al. (2005). The key difficulty with these functions is the non-uniform density of the data. In the first example we attempt to estimate the tangent at the samples of:

$$x_i = [\cos(t_i) \;\; \sin(t_i)]^T \qquad t_i \in [0,\pi],\; t_{i+1} - t_i = 0.1(0.001 + |\cos(t_i)|) \tag{8}$$

Outliers	900		3000		5000

Figure 9: Input data for the two experiments proposed by Wang et al. (2005).

where the distance between consecutive samples is far from uniform. See Figure 9(a) for the inputs and the second column of Table 7 for quantitative results on tangent estimation for 152 points as a function of scale.

In the second example, which is also taken from Wang et al. (2005), points are uniformly sampled on the t-axis from the [-6, 6] interval. The output is produced by the following function:

$$x_i = [t_i \;\; 10e^{-t_i^2}]. \tag{9}$$

The points, as can be seen in Figure 9(b), are not uniformly spaced. The quantitative results on tangent estimation accuracy for 180 and 360 samples from the same interval are reported in the last two columns of Table 7. Naturally, as the sampling becomes denser, the quality of the approximation improves. What should be emphasized here is the stability of the results as a function of σ. Even with as few as 5 or 6 neighbors included in the voting neighborhood, the tangent at each point is estimated quite accurately.

σ	Eq. 8 152 points	Eq. 9 180 points	Eq. 9 360 points
10	0.60	4.52	2.45

6. Geodesic Distances and Nonlinear Interpolation

In this section, we present an algorithm that can interpolate, and thus produce new points, on the manifold and is also able to evaluate geodesic distances between points. Both of these capabilities are useful tools for many applications. The key concept is that the intrinsic distance between any two points on a manifold can be approximated by taking small steps on the manifold, collecting votes, estimating the local tangent space and advancing on it until the destination is reached. Such processes have been reported in Mordohai (2005), Dollár et al. (2007a) and Dollár et al. (2007b).

Processing begins by learning the manifold structure, as in the previous section, usually starting from unoriented points that are represented by ball tensors. Then, we select a starting point that has to be on the manifold and a target point or a desired direction from the starting point. At each step, we can project the desired direction on the tangent space of the current point and create a new point at a small distance. The tangent space of the new point is computed by collecting votes from the neighboring points, as in regular tensor voting. Note that the tensors used here are no longer balls, but the ones resulting from the previous pass of tensor voting, according to Algorithm 1, step 3. The desired direction is then projected on the tangent space of the new point and so forth until the destination is reached. The process is illustrated in Figure 10, where we start from point A and wish to reach B. We project $\vec{t}$, the vector from A to B, on the estimated tangent space of A and obtain its projection $\vec{p}$. Then, we take a small step along $\vec{p}$ to point A_1, on which we collect votes to obtain an estimate of its tangent space. The desired direction is then projected on the tangent space of each new point until the destination is reached within ε. The geodesic distance between A and B is approximated by measuring the length of the path. In the process, we have also generated a number of new points on the manifold, which may be a desirable by-product for some applications.

There are certain configurations that cannot be handled by the algorithm described above without additional precautions. One such configuration is when the source or destination point or both are in deep concavities which attract the desired direction if the step from A to A_1 is not large enough to move the path outside the concave region. A multi-scale implementation of the above scheme can overcome this problem. A few intermediate points can be marked using a large value for the step and then used as intermediate destinations with a finer step size. Under this scheme, the path

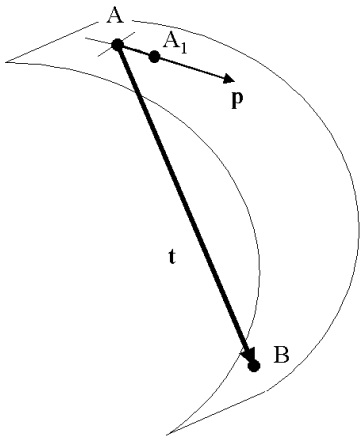

Figure 10: Nonlinear interpolation on the tangent space of a manifold.

converges to the destination and the geodesic distance is approximated accurately using a small step size. A second failure mode of the simple algorithm is for cases where the desired direction may vanish. This may occur in a manifold such as the "Swiss Roll" (Figure 6) if the destination lies on the normal space of the current point. Adding memory or inertia to the system when the desired direction vanishes, effectively addresses this situation. It should be noted that our algorithm does not handle holes and boundaries properly at its current stage of development.

6.1 Comparison with State-of-the-Art algorithms

The first experiment on manifold distance estimation is a quantitative evaluation against some of the most widely used algorithms of the literature. For the results reported in Table 8, we learn the local structure of the cylinder and sphere manifolds of the previous section using tensor voting. We also compute embeddings using LLE (Roweis and Saul, 2000), Isomap (Tenenbaum et al., 2000), Laplacian eigenmaps (Belkin and Niyogi, 2003), HLLE (Donoho and Grimes, 2003) and SDE (Weinberger and Saul, 2004). Matlab implementations for these methods can be downloaded from the following internet locations.

- LLE from `http://www.cs.toronto.edu/~roweis/lle/code.html`
- Isomap from `http://isomap.stanford.edu/`
- Laplacian Eigenmaps from `http://people.cs.uchicago.edu/~misha/ManifoldLearning/index.html`
- HLLE from `http://basis.stanford.edu/HLLE` and
- SDE from `http://www.seas.upenn.edu/~kilianw/sde/download.htm`.

We are grateful to the authors for making the code for their methods available to the community. We have also made our software publicly available at:
`http://iris.usc.edu/~medioni/download/download.htm`.

The experiment is performed as follows. We randomly select 5000 pairs of points on each manifold and attempt to measure the geodesic distance between the points of each pair in the input

space using tensor voting and in the embedding space using the other five methods. The estimated distances are compared to the ground truth: $r\Delta\theta$ for the sphere and $\sqrt{(r\Delta\theta)^2+(\Delta z)^2}$ for the cylinder. Among the above approaches, only Isomap and SDE produce isometric embeddings, and only Isomap preserves the absolute distances between the input and the embedding space. To make the evaluation fair, we compute a uniform scale that minimizes the error between the computed distances and the ground truth for all methods, except Isomap for which it is not necessary. Thus, perfect distance ratios would be awarded a perfect rating in the evaluation, even if the absolute magnitudes of the distances are meaningless in the embedding space. For all the algorithms, we tried a wide range for the number of neighbors, K. In some cases, we were not able to produce good embeddings of the data for any value of K. This occurred more frequently for the cylinder, probably due to its data density not being perfectly uniform. Errors above 20% indicate very poor performance, which is also confirmed by visual inspection of the embeddings.

Even though among the other approaches only Isomap and SDE produce isometric embeddings, while the rest produce embeddings that only preserve local structure, we think that the evaluation of the quality of manifold learning based on the computation of pairwise distances is a fair measure for the performance of all algorithms, since high quality manifold learning should minimize distortions. The distances on which we evaluate the different algorithms are both large and small, with the latter measuring the presence of local distortions. Quantitative results, in the form of the average absolute difference between the estimated and the ground truth distances as a percentage of the latter, are presented in Tables 8-10, along with the parameter that achieves the best performance for each method. In the case of tensor voting, the same scale was used for both learning the manifold and computing distances.

We also apply our method in the presence of 900, 3000 and 5000 outliers, while the inliers for the sphere and the cylinder data sets are 900 and 1000 respectively. The outliers are generated according to a uniform distribution. The error rates using tensor voting for the sphere are 0.39%, 0.47% and 0.53% respectively. The rates for the cylinder are 0.77%, 1.17% and 1.22%. Compared with the noise free case, these results demonstrate that our approach degrades slowly in the presence of outliers. The best performance achieved by any other method is 3.54% on the sphere data set with 900 outliers by Isomap. Complete results are shown in Table 9. In many cases, we were unable to achieve useful embeddings for data sets with outliers. We were not able to perform this experiment

Data Set	Sphere		Cylinder	
	K	Err(%)	K	Err(%)
LLE	18	5.08	6	26.52
Isomap	6	1.98	30	0.35
Laplacian Eigenmaps	16	11.03	10	29.36
HLLE	12	3.89	40	26.81
SDE	2	5.14	6	25.57
TV (σ)	60	0.34	50	0.62

Table 8: Error rates in distance measurement between pairs of points on the manifolds. The best result of each method is reported along with the number of neighbors used for the embedding (K), or the scale σ in the case of tensor voting (TV).

Data Set	Sphere 900	outliers	Cylinder 900	outliers
	K	Err(%)	K	Err(%)
LLE	40	60.74	6	15.40
Isomap	18	3.54	14	11.41
Laplacian Eigenmaps	6	13.97	14	27.98
HLLE	30	8.73	30	23.67
SDE		N/A		N/A
TV (σ)	70	0.39	100	0.77

Table 9: Error rates in distance measurement between pairs of points on the manifolds under outlier corruption. The best result of each method is reported along with the number of neighbors used for the embedding (K), or the scale σ in the case of tensor voting (TV). Note that HLLE fails to compute an embedding for small values of K, while SDE fails at both examples for all choices of K.

Data Set	σ	Error rate
Sphere (3000 outliers)	80	0.47
Sphere (5000 outliers)	100	0.53
Cylinder (3000 outliers)	100	1.17
Cylinder (5000 outliers)	100	1.22

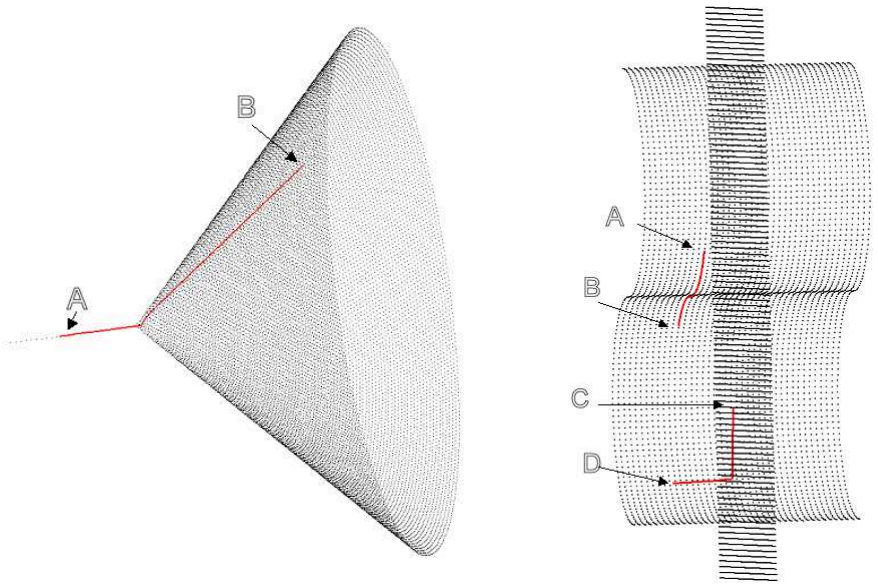
Table 10: Error rates for our approach for the experiment of Section 6.1 in the presence of 3000 and 5000 outliers.

in the presence of more than 3000 outliers with any graph-based method, probably because the graph structure is severely corrupted by the outliers.

6.2 Data Sets with Varying Dimensionality and Intersections

For the final experiment of this section, we create synthetic data in 3-D that were embedded in higher dimensions. The first data set consists of a line and a cone. The points are embedded in 50-D by three orthonormal 50-D vectors and initialized as ball tensors. Tensor voting is performed in the 50-D space and a path from point A on the line to point B on the cone is interpolated as in the previous experiment, making sure that it belongs to the local tangent space, which changes dimensionality from one to two. The data is re-projected back to 3-D for visualization in Figure 11(a).

In the second part of the experiment, we generate an intersecting S-shaped surface and a plane (a total of 11,000 points) and 30,000 outliers from a uniform distribution, and embed them in a 30-D space. Without explicitly removing the noise, we interpolate between two points on the S (A and B) and a point on the S and a point on the plane (C and D) and create the paths shown in Figure 11(b) re-projected in 3-D. The first path is curved, while the second jumps from manifold to manifold without deviating from the optimal path. (The outliers are not shown for clarity.) Processing time for 41,000



(a) Line and cone (b) S and plane

Figure 11: Nonlinear interpolation in 50-D with varying dimensionality (a) and 30-D with intersecting manifolds under noise corruption (b).

points in 30-D is 2 min. and 40 sec. on a Pentium 4 at $2.8GHz$ using voting neighborhoods that included an average of 44 points.

7. Generation of Unobserved Samples and Nonparametric Function Approximation

In this section, we build upon the results of the previous section to address function approximation. A common practice is to treat functions with multiple outputs as multiple single-output functions. We adopt this scheme here, even though nothing prohibits us from directly approximating multiple-input multiple-output functions. We assume that observations in N-D that include values for the input and output variables are available for training. The difference with the examples of the previous sections is that the queries are given as input vectors with unknown output values, and thus are of lower dimensionality than the voting space. The required module to convert this problem to that of Section 6 is one that can find a point on the manifold that corresponds to an input similar to the query. Then, in order to predict the output y of the function for an unknown input $\vec{x}$, under the assumption of local smoothness, we move on the manifold formed by the training samples until we reach the point corresponding to the given input coordinates. To ensure that we always remain on the manifold, we need to start from a point on it and proceed as in the previous section.

One way to find a suitable starting point is to find the nearest neighbor of $\vec{x}$ in the input space, which has fewer dimensions than the joint input-output (voting) space. Then, we can compute the desired direction in the low dimensional space and project it to the input-output space. If many outputs are possible for a given input (if the data have not been generated by a function in the strict sense), we have to either find neighbors at each branch of the function and produce multiple

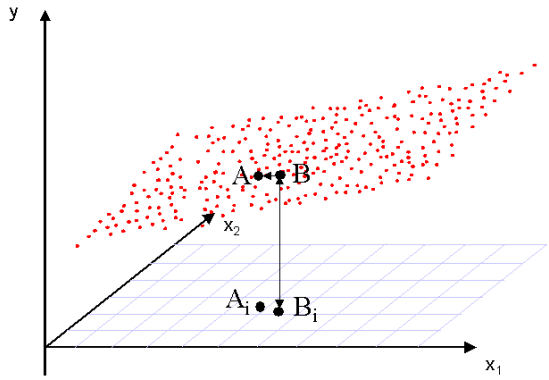


Figure 12: Interpolation to obtain output value for unknown input point A_i. B_i is the nearest neighbor in the input space and corresponds to B in the joint input-output space. We can march from B on the manifold to arrive at the desired solution A that projects on A_i in the input space.

outputs, or use other information, such as the previous state of the system, to pursue only one of the alternatives. One could find multiple nearest neighbors, run the proposed algorithm starting from each of them and produce a multi-valued answer with a probability associated with each potential output value.

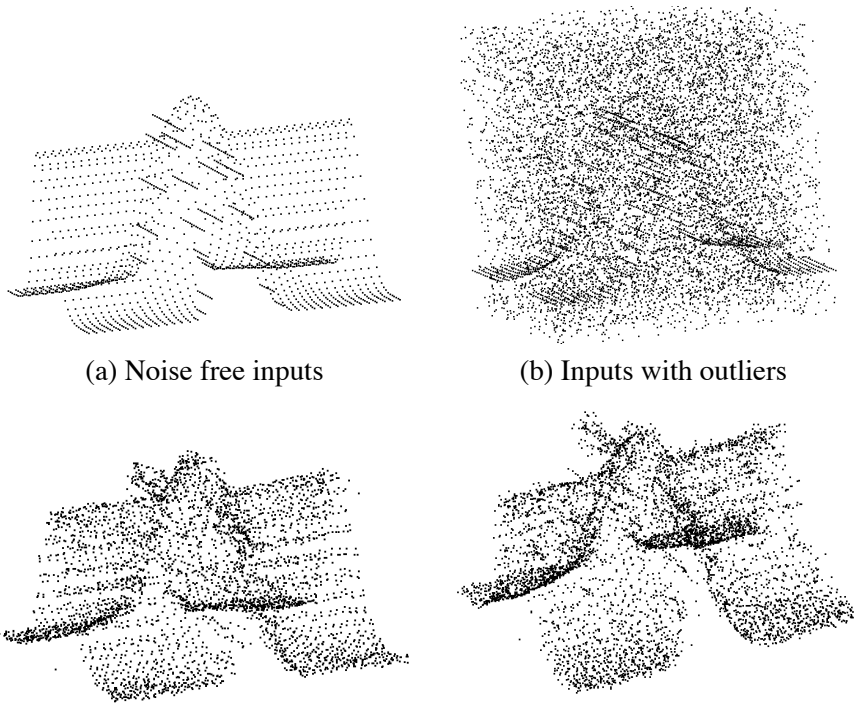
Figure 12 provides a simple illustration. We begin with a point A_i in the input space. We proceed by finding its nearest neighbor among the projections of the training data on the input space B_i. (Even if B_i is not the nearest neighbor the scheme still works but possibly requires more steps.) The sample B in the input-output space that corresponds to B_i is the starting point on the manifold. The desired direction is the projection of the A_iB_i vector on the tangent space of B. Now, we are in the case described in Section 6, where the starting point and the desired direction are known. Processing stops when the input coordinates of the point on the path from B are within ε of A_i. The corresponding point A in the input-output space is the desired interpolated sample.

As in all the experiments presented in this paper, the input points are encoded as ball tensors, since we assume that we have no knowledge of their orientation. We first attempt to approximate the following function, proposed by Schaal and Atkeson (1998):

$$y = max\{e^{-10x_1^2} \;\; e^{-50x_2^2} \;\; 1.25e^{-5(x_1^2+x_2^2)}\}. \tag{10}$$

1681 samples of y are generated by uniformly sampling the $[-1,1]\times[-1,1]$ square. We perform four experiments with increasing degree of difficulty. In all cases, after voting on the given inputs, we generate new samples by interpolating between the input points. The four configurations and noise conditions were:

- In the first experiment, we performed all operations with noise free data in 3-D.
- For the second experiment, we added 8405 outliers (five times more than the inliers) drawn from a uniform distribution in a $2\times2\times2$ cube containing the data.
- For the third experiment, we added Gaussian noise with variance 0.01 to the coordinates of all points while adding the same number of outliers as above.



(a) Noise free inputs

(b) Inputs with outliers

(c) Interpolated points with outliers and perturbation

(d) Interpolated points with outliers and perturbation in 60-D

Figure 13: Inputs and interpolated points for Eq. 10. The top row shows the noise-free inputs and the noisy input set where only 20% of the points are inliers. The bottom row shows the points generated in 3-D and 60-D respectively. In both cases the inputs were contaminated with outliers and Gaussian noise.

- Finally, we embedded the perturbed data (and the outliers) in a 60-D space, before voting and nonlinear interpolation.

The noise-free and noisy input, as well as the generated points can be seen in Figure 13. We computed the mean square error between the outputs generated by our method and Eq. 10 normalized by the variance of the noise-free data. The NMSE for all cases is reported in Table 11. Robustness against outliers is due to the fact that the inliers form a consistent surface and thus receive votes that support the correct local structure from other inliers. Outliers, on the other hand, are random and do not form any structure. They cast and receive inconsistent votes and therefore neither develop a preference for a certain manifold nor significantly disrupt the structure estimates at the inliers. They can be removed by simple thresholding since all their eigenvalues are small and almost equal, but this is not done here. Note that performance in 60-D is actually better since the interference by outliers is reduced as the dimensionality of the space increases. Tensor voting is also robust against perturbation of the coordinates as long as it is not biased to favor a certain direction. If the perturbation is zero-mean, its effects on individual votes are essentially canceled out, because they only contribute to the ball component of the accumulated tensor at each point, causing small errors in orientation estimation.

Experiment	NMSE
Noise-free	0.0041
Outliers	0.0170
Outliers & N(0, 0.01)	0.0349
Outliers & N(0, 0.01) in 60-D	0.0241

Table 11: Normalized MSE for the interpolated points of Eq. 10 under different noise conditions.

7.1 Results on Real Data

The final experiments are on real data taken from the University of California at Irvine Machine Learning Repository (Newman et al., 1998) available online at `http://www.ics.uci.edu/~mlearn/MLRepository.html` and the University of Toronto DELVE archive (`http://www.cs.toronto.edu/~delve`)(Rasmussen et al., 1996). We used the "abalone", "Boston housing" and "Computer activity" data sets. These data sets were selected because they contain data from a single class in spaces of 9, 14 and 22 dimensions respectively. In each case one variable is treated as the output and all others as inputs. Most of the input variables are continuous, but vary widely in magnitude. Since our method is based on distance relationships between the samples, we re-scaled the data so that the ratio of maximum to minimum standard deviation of the variables was approximately $10:1$, instead of the original, which for several cases exceeded $1000:1$. We split the data in training and test sets and perform tensor voting on the training data to learn the structure of the manifold. For each test sample, we begin by finding the average position of a few nearest neighbors in the $(N-1)$-D input space and then follow a path on the estimated manifold in N-D until the desired input coordinates are reached. The value of the output variable when the input variables are equal to the query is the estimate returned by our method.

In the case of the "abalone" data, we follow common practice and map the first variable from M for male, F for female and I for infant to $(1,0,0)$, $(0,1,0)$ and $(0,0,1)$ respectively. The resulting space is 12-D, with the last variable being the one we attempt to estimate. Again, we scale the data so that the variances of different variables are comparable. Following most authors, we divide the 4177 samples in training and test sets containing 3000 and 1177 samples respectively. Our results after 10 runs of the experiment with randomly selected training and test sets and a comparison with a number of other published results on the same data can be seen in Table 12. We also applied our algorithm to the "Boston housing" data set, which has been extensively used as a benchmark. It contains 506 samples of house prices as a function of 13 variables. We use training and test sets containing 481 and 25 points respectively. Due to the small size of the test set, we repeated the experiment 20 times always using as queries points that had not been included in the test set before, thus using virtually all points for queries. Error rates can be seen in Table 12. Finally, we used the "computer activity" data set from the DELVE archive (Rasmussen et al., 1996). It contains 8192 observations in a 22-D space. We used 2000 samples for training and the rest for testing.

In summary, our algorithm achieves what we think is satisfactory performance despite the fact that the data sets contain insufficient samples to describe complex manifolds. The sparseness of the data under-uses the capability of our approach to handle complex nonlinear manifolds. We observed that for certain query points there are very few similar samples in the training set. In the absence of enough samples, our algorithm may not improve the initial solution given by the nearest neighbors

of the point. These errors cause the ranking of our results in terms of RMS to be worse than in terms of mean absolute error (MAE) in Table 12.

	Abalone		Housing		Computer	
	MAE	RMS	MAE	RMS	MAE	RMS

Table 12: Mean Absolute Error (MAE) and Root Mean squared Error (RMS) for benchmark data sets. Unless otherwise noted, training and testing is performed with 3000 and 1177 samples for "abalone", 481 and 25 for "Boston housing" and 2000 and 6192 for "computer activity", respectively. Results by other methods were not generated by us. BCM is the Bayesian committee machine of Tresp (2000) and GPR1 is Gaussian process regression implemented by Tresp. 400 samples are used for training for "Boston housing" for BCM and GPR1. RVM is the relevance vector machine of Tipping (2001) and SVM is a support vector machine implemented by Tipping. Sparse GPR is the algorithm of Smola and Bartlett (2001) and GPR2 is their implementation of Gaussian process regression. 4000 samples are used for training for the "abalone" data set for Sparse GPR and GPR2. Online GPR is the algorithm of Csató and Opper (2002), BCM2 is the Bayesian committee machine implemented by Schwaighofer and Tresp (2003), while inductive and transductive SRM are algorithms from the same paper. The number of training and testing samples is not provided by the authors for Online GPR, BCM2, inductive and transductive SRM. SVR is the support vector regression of Vapnik (1995), BSVR is Bayesian support vector regression of Chu et al. (2004), GPR-ARD is Gaussian process regression using the ARD Gaussian covariance function and BSVR-ARD is BSVR using the ARD function (Chu et al., 2004).

8. Discussion

We have presented an approach for dimensionality estimation, manifold learning and function approximation that offers certain advantages over the state of the art. Tensor voting may on the surface look similar to other local, instance-based learning algorithms that propagate information from point to point, but the fact that the votes are tensors and not scalars allows them to convey considerably more information. The properties of the tensor representation, which can handle the simultaneous presence of multiple orientations and structure types, allow the reliable inference of the normal and tangent space at each point. In addition, tensor voting is very robust against outliers, as demonstrated for the 2-D and 3-D case in numerous publications including Tang and Medioni (1998) and Medioni et al. (2000). This property holds in higher dimensions, where random noise is even more scattered. See for instance the results presented in Table 11.

It should also be noted that the votes attenuate with distance and curvature. This is a more intuitive formulation than using the k nearest neighbors with equal weights, since some of them may be too far, or belong to a different part of the manifold. For both tensor voting and the methods presented in Section 2, however, the distance metric in the input space has to be meaningful. Our method is less sensitive to a somewhat incorrect selection of the distance metric since all neighbors do not contribute equally. After this choice has been made, the only free parameter in our approach is σ, the scale of voting. Small values tend to preserve details better, while large values are more robust to noise. The scale can be selected automatically by randomly sampling a few points before voting and making sure that enough points are included in their voting neighborhoods. Our results show that sensitivity with respect to scale is small, as shown in Tables 1, 3, 4-6 and 7. The number of points that can be considered sufficient is a function of the dimensionality of the space, the intrinsic dimensionality of the data, as well as noise and curvature. The two latter factors have been analyzed by Mitra et al. (2004) and Lalonde et al. (2005), using the Gershgorin Circle Theorem, for the case of curves in 2-D and surfaces in 3-D under mild restrictions on data distribution. To the best of our knowledge no similar analysis has been done for manifolds with co-dimension other than one or in high-dimensional spaces. A thorough investigation of these issues is among the objectives of our future research.

Our algorithms fail when the available observations do not suffice to represent the manifold, as for instance in the face with varying pose and illumination data set of Tenenbaum et al. (2000), where 698 instances represent a manifold in 4096-D. Global methods may be more successful in such situations. The number of sufficient samples for tensor voting cannot be easily predicted from the dimensionality of the space, since it also depends on the complexity (curvature) of the underlying manifolds. (See also the discussion above.) For instance, 486 samples in 14-D turn out to be sufficient for the "Boston housing" function approximation experiment. Nevertheless, in many practical cases the challenges are the over-abundance of data and the need for efficient processing of large data sets. Tensor voting is a well suited framework for such cases, since it can efficiently process hundreds of thousands of points in spaces of up to a few hundred dimensions.

Another important advantage of tensor voting is the absence of global computations, which makes time complexity $O(NMlogM)$, where N is the dimensionality of the space and M is the number of points. This property enables us to process data sets with very large number of points. Computation time does not become impractical as the number of points grows, assuming that more points are added to the data set in such a way that the density remains constant. In this case, the number of votes cast per point remains constant and time requirements grow linearly. Com-

plexity is adversely affected by the dimensionality of the space N, since eigen-decomposition of $N \times N$ tensors has to be performed resulting in a complexity that is cubic with respect to N due to the eigensystem computations that are $O(N^3)$. For most practical purposes, however, the number of points has to be considerably larger[2] than the dimensionality of the space ($M \gg N$) to allow structure inference. The complexity for a nearest neighbor query using the ANN k-d tree (Arya et al., 1998) is $O(NlogM)$ and one query is required for each voter. Thus the total complexity is $O(NMlogM + MN^3) \approx O(NMlogM)$. Computational complexity, therefore, is reasonable with respect to the largest parameter, which for our methods to work has to be M. Table 1 shows the effect of data set and neighborhood size on processing time. Notice that time is linear with respect to the average number of points in each neighborhood, as expected. Space requirements for M $N \times N$ tensors are $O(MN^2)$.

In terms of dimensionality estimation, we are able to obtain accurate estimates at the point level. Moreover, since the dimensionality is found as the maximum gap in the eigenvalues of the tensor at each point, no thresholds are needed. Under most other approaches, the dimensionality has to be provided, or, at best, an average intrinsic dimensionality is estimated for the entire data set, as in Bruske and Sommer (1998), Brand (2003), Kégl (2003), Weinberger and Saul (2004) and Costa and Hero (2004).

The novelty of our approach regarding manifold learning is that it is not based on dimensionality reduction. Instead, we perform tasks such as geodesic distance measurement and nonlinear interpolation in the input space. Experimental results show that we can perform these tasks in the presence of outlier noise at high accuracy, even without explicitly removing the outliers from the data. This choice also broadens the range of data sets we can process. While isometric embeddings can be achieved for a certain class of manifolds, we are able to process non-flat manifolds and even non-manifolds. The last experiment of Section 6 demonstrates our ability to work with data sets of varying dimensionality or with intersecting manifolds. To the best of our knowledge, this is impossible with any other method. If dimensionality reduction is desired due to its considerable reduction in storage requirements, a dimensionality reduction method, such as Roweis and Saul (2000), Tenenbaum et al. (2000), Belkin and Niyogi (2003), Brand (2003), Donoho and Grimes (2003) and Weinberger and Saul (2006), can be used after tensor voting. The benefits of this process are in the form of noise robustness and smooth component identification, with respect to both dimensionality and orientation, via tensor voting followed by memory savings via dimensionality reduction.

We have also presented, in Section 7, a local nonparametric approach for function approximation that combines the advantages of local methods with the efficient representation and information propagation of tensor voting. Local function approximation methods are more flexible in the type of functions they can approximate, since the properties of the function are allowed to vary throughout the space. Our approach, in particular, has no parameters that have to be selected, such as the number and type of local models to be used, besides the scale of voting. Its drawback, in line with other local methods, is higher memory requirements. We have shown that we can process challenging examples from the literature under very adverse noise conditions. As shown in the example of Eq. 10, even when more than 80% of the samples are outliers and the inliers are corrupted by noise in the form of perturbation, we are still able to correctly predict unobserved outputs. We have also shown in Table 12 promising results on publicly available data sets, despite the fact that they are not

2. While in principal three points are sufficient to define a surface, 10 points are sufficient to define a 9-D manifold and so forth, one or two orders of magnitude more points are required for practical applications in our experience.

well suited for our approach, since the number of observations they contain is hardly sufficient to define the manifold.

As mentioned above, an issue we do not fully address here is that of the selection of an appropriate distance metric. We assume that the Euclidean distance in the input coordinate system is a meaningful distance metric. This is not the case if the coordinates are not of the same type. On the other hand, a metric such as the Mahalanobis distance is not necessarily appropriate in all cases, since the data typically lie in a limited part of the input space and scaling all dimensions, including the redundant ones, to achieve equal variance would be detrimental. For the experiments shown in Section 7, we apply heuristic scaling of the coordinates when necessary. We intend to develop a systematic way based on cross-validation that automatically scales the coordinates by maximizing prediction performance for the observations that have been left out.

Our future research will focus on addressing the limitations of our current algorithm and extending its capabilities. An interpolation mechanism that takes into account holes and boundaries during geodesic distance approximation should be implemented. Additionally, in the area of function approximation, the issue of approximating functions with multiple branches for the same input value, which often appear in practical applications, has to be handled more rigorously. We also intend to develop an online, incremental version of our approach, possibly including a forgetting and an updating module, that will be able to process data as they are collected, instead of requiring the entire data set to proceed. Potential applications of our work include challenging real problems, such as the study of direct and inverse kinematics where there are typically large numbers of samples in spaces of up to a few hundred dimensions. Function approximation for complex functions, for which global models would become very complicated, is another area where our methods could be effective. Finally, one can view the proposed approach as learning data from a single class, which can serve as the groundwork for an approach for pattern recognition, data mining, supervised and unsupervised classification.

Acknowledgments

This research has been supported by the National Science Foundation grant IIS 03 29247. The authors would like to thank Adit Sahasrabudhe for his help with some of the experiments.

Abstract

Nonlinear dimensionality reduction methods are often used to visualize high-dimensional data, although the existing methods have been designed for other related tasks such as manifold learning. It has been difficult to assess the quality of visualizations since the task has not been well-defined. We give a rigorous definition for a specific visualization task, resulting in quantifiable goodness measures and new visualization methods. The task is *information retrieval* given the visualization: to find similar data based on the similarities shown on the display. The fundamental tradeoff between precision and recall of information retrieval can then be quantified in visualizations as well. The user needs to give the relative cost of missing similar points vs. retrieving dissimilar points, after which the total cost can be measured. We then introduce a new method NeRV (*neighbor retrieval visualizer*) which produces an optimal visualization by minimizing the cost. We further derive a variant for supervised visualization; class information is taken rigorously into account when computing the similarity relationships. We show empirically that the unsupervised version outperforms existing unsupervised dimensionality reduction methods in the visualization task, and the supervised version outperforms existing supervised methods.

Keywords: information retrieval, manifold learning, multidimensional scaling, nonlinear dimensionality reduction, visualization

1. Introduction

Visualization of high-dimensional data sets is one of the traditional applications of nonlinear dimensionality reduction methods. In high-dimensional data, such as experimental data where each dimension corresponds to a different measured variable, dependencies between different dimensions often restrict the data points to a manifold whose dimensionality is much lower than the dimensionality of the data space. Many methods are designed for *manifold learning*, that is, to find and unfold the lower-dimensional manifold. There has been a research boom in manifold learning since 2000, and there now exist many methods that are known to unfold at least certain kinds of manifolds successfully. Some of the successful methods include isomap (Tenenbaum et al., 2000), locally linear embedding (LLE; Roweis and Saul, 2000), Laplacian eigenmap (LE; Belkin and Niyogi, 2002a), and maximum variance unfolding (MVU; Weinberger and Saul, 2006).

It has turned out that the manifold learning methods are not necessarily good for information visualization. Several methods had severe difficulties when the output dimensionality was fixed to two for visualization purposes (Venna and Kaski, 2007a). This is natural since they have been designed to find a manifold, not to compress it into a lower dimensionality.

In this paper we discuss the specific visualization task of projecting the data to points on a two-dimensional display. Note that this task is different from manifold learning, in case the inherent dimensionality of the manifold is higher than two and the manifold cannot be represented perfectly in two dimensions. As the representation is necessarily imperfect, defining and using a *measure of goodness* of the representation is crucial. However, in spite of the large amount of research into methods for extracting manifolds, there has been very little discussion on what a good two-dimensional representation should be like and how the goodness should be measured. In a recent survey of 69 papers on dimensionality reduction from years 2000–2006 (Venna, 2007) it was found that 28 ($\approx 40\%$) of the papers only presented visualizations of toy or real data sets as a proof of quality. Most of the more quantitative approaches were based on one of two strategies. The first is to measure preservation of all pairwise distances or the order of all pairwise distances. Examples of this approach include the multidimensional scaling (MDS)-type cost functions like Sammon's cost and Stress, methods that relate the distances in the input space to the output space, and various correlation measures that assess the preservation of all pairwise distances. The other common quality assurance strategy is to classify the data in the low-dimensional space and report the classification performance.

The problem with using the above approaches to measure visualization performance is that their connection to visualization is unclear and indirect at best. Unless the purpose of the visualization is to help with a classification task, it is not obvious what the classification accuracy of a projection reveals about its goodness as a visualization. Preservation of pairwise distances, the other widely adopted principle, is a well-defined goal; it is a reasonable goal if the analyst wishes to use the visualization to assess distances between selected pairs of data points, but we argue that this is not the typical way how an analyst would use a visualization, at least in the early stages of analysis when no hypothesis about the data has yet been formed. Most approaches including ours are based on pairwise distances at heart, but we take into account the context of each pairwise distance, yielding a more natural way of evaluating visualization performance; the resulting method has a natural and rigorous interpretation which we discuss below and in the following sections.

In this paper we make rigorous the specific information visualization task of projecting a high-dimensional data set onto a two-dimensional plane for visualizing similarity relationships. This task has a very natural mapping into an information retrieval task as will be discussed in Section 2. The conceptualization as information retrieval explicitly reveals the necessary tradeoff between precision and recall, of making true similarities visible and avoiding false similarities. The tradeoff can be quantified exactly once costs have been assigned to each of the two error types, and once the total cost has been defined, it can be optimized as will be discussed in Section 3. We then show that the resulting method, called NeRV for *neighbor retrieval visualizer*, can be further extended to supervised visualization, and that both the unsupervised and supervised methods empirically outperform their alternatives. NeRV includes the previous method called stochastic neighbor embedding (SNE; Hinton and Roweis, 2002) as a special case where the tradeoff is set so that only recall is maximized; thus we give a new information retrieval interpretation to SNE.

This paper extends our earlier conference paper (Venna and Kaski, 2007b) which introduced the ideas in a preliminary form with preliminary experiments. The current paper gives the full justification and comprehensive experiments, and also introduces the supervised version of NeRV.

2. Visualization as Information Retrieval

In this section we define formally the specific visualization task; this is a novel formalization of visualization as an *information retrieval task*. We first give the definition for a simplified setup in Section 2.1, and then generalize it in Section 2.2.

2.1 Similarity Visualization with Binary Neighborhood Relationships

In the following we first define the specific visualization task and a cost function for it; we then show that the cost function is related to the traditional information retrieval measures *precision* and *recall*.

2.1.1 TASK DEFINITION: SIMILARITY VISUALIZATION

Let $\{\mathbf{x}_i\}_{i=1}^N$ be a set of input data samples, and let each sample i have an *input neighborhood* P_i, consisting of samples that are close to i. Typically, P_i might consist of all input samples (other than i itself) that fall within some radius of i, or alternatively P_i might consist of a fixed number of input samples most similar to i. In either case, let r_i be the size of the set P_i.

The *goal of similarity visualization* is to produce low-dimensional output coordinates $\{\mathbf{y}_i\}_{i=1}^N$ for the input data, usable in visual information retrieval. Given any sample i as a query, in visual information retrieval samples are retrieved based on the visualization; the retrieved result is a set Q_i of samples that are close to $\mathbf{y}_i$ in the visualization; we call Q_i the *output neighborhood*. The Q_i typically consists of all input samples j (other than i itself) whose visualization coordinates $\mathbf{y}_j$ are within some radius of $\mathbf{y}_i$ in the visualization, or alternatively Q_i might consist of a fixed number of input samples whose output coordinates are nearest to $\mathbf{y}_i$. In either case, let k_i be the number of points in the set Q_i. The number of points in Q_i may be different from the number of points in P_i; for example, if many points have been placed close to $\mathbf{y}_i$ in the visualization, then retrieving all points within a certain radius of $\mathbf{y}_i$ might yield too many retrieved points, compared to how many are neighbors in the input space. Figure 1 illustrates the setup.

The remaining question is what is a good visualization, that is, what is the cost function. Denote the number of samples that are in both Q_i and P_i by $N_{\mathrm{TP},i}$ (true positives), samples that are in Q_i but not in P_i by $N_{\mathrm{FP},i}$ (false positives), and samples that are in P_i but not Q_i by $N_{\mathrm{MISS},i}$ (misses). Assume the user has assigned a cost C_{FP} for each false positive and C_{MISS} for each miss. The total cost E_i for query i, summed over all data points, then is

$$E_i = N_{\mathrm{FP},i} C_{\mathrm{FP}} + N_{\mathrm{MISS},i} C_{\mathrm{MISS}} \,. \tag{1}$$

2.1.2 RELATIONSHIP TO PRECISION AND RECALL

The cost function of similarity visualization (1) bears a close relationship to the traditional measures of information retrieval, precision and recall. If we allow C_{MISS} to be a function of the total number of relevant points r, more specifically $C_{\mathrm{MISS}}(r_i) = C'_{\mathrm{MISS}}/r_i$, and take the cost per retrieved point by

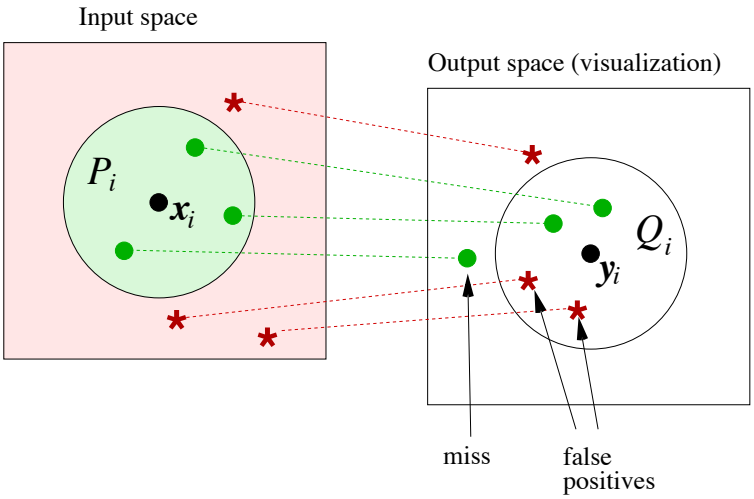

Figure 1: Diagram of the types of errors in visualization.

dividing by k_i, the total cost becomes

$$\begin{aligned} E(k_i, r_i) &= \frac{1}{k_i} E(r_i) = \frac{1}{k_i} \left(N_{\mathrm{FP},i} C_{\mathrm{FP}} + N_{\mathrm{MISS},i} C_{\mathrm{MISS}}(r_i) \right) \\ &= C_{\mathrm{FP}} \frac{N_{\mathrm{FP},i}}{k_i} + \frac{C'_{MISS}}{k_i} \frac{N_{\mathrm{MISS},i}}{r_i} \\ &= C_{\mathrm{FP}} (1 - \mathrm{precision}(i)) + \frac{C'_{MISS}}{k_i} (1 - \mathrm{recall}(i)) \, . \end{aligned}$$

The traditional definition of precision for a single query is

$$\mathrm{precision}(i) = \frac{N_{\mathrm{TP},i}}{k_i} = 1 - \frac{N_{\mathrm{FP},i}}{k_i} \, ,$$

and recall is

$$\mathrm{recall}(i) = \frac{N_{\mathrm{TP},i}}{r_i} = 1 - \frac{N_{\mathrm{MISS},i}}{r_i} \, .$$

Hence, fixing the costs C_{FP} and C_{MISS} and minimizing (1) corresponds to maximizing a specific weighted combination of precision and recall.

Finally, to assess performance of the full visualization the cost needs to be averaged over all samples (queries) which yields mean precision and recall of the visualization.

2.1.3 DISCUSSION

Given a high-dimensional data set, it is generally not possible to show all the similarity relationships within the data on a low-dimensional display; therefore, all linear or nonlinear dimensionality reduction methods need to make a tradeoff about which kinds of similarity relationships they aim to show on the display. Equation (1) fixes the tradeoff given the costs of the two kinds of errors. Figure 2 illustrates this tradeoff (computed with methods introduced in Section 3) with a toy example where a three-dimensional sphere surface is visualized in two dimensions. If we take some

query point in the visualization and retrieve a set of points close-by in the visualization, in display **A** such retrieval yields few false positives but many misses, whereas in display **B** the retrieval yields few misses but many false positives. The tradeoff can also be seen in the (mean) precision-recall curves for the two visualizations, where the number of retrieved points is varied to yield the curve. Visualization **A** reaches higher values of precision, but the precision drops much before high recall is reached. Visualization **B** has lower precision at the left end of the curve, but precision does not drop as much even when high recall is reached.

Note that in order to quantify the tradeoff, both precision and recall need to be used. This requires a rich enough retrieval model, in the sense that the number of retrieved points can be different from the number of relevant points, so that precision and recall get different values. It is well-known in information retrieval that if the numbers of relevant and retrieved items (here points) are equal, precision and recall become equal. The recent "local continuity" criterion (Equation 9 in Chen and Buja, 2009) is simply precision/recall under this constraint; we thus give a novel information retrieval interpretation of it as a side result. Such a criterion is useful but it gives only a limited view of the quality of visualizations, because it corresponds to a limited retrieval model and cannot fully quantify the precision-recall tradeoff. In this paper we will use fixed-radius neighborhoods (defined more precisely in Section 2.2) in the visualizations, which naturally yields differing numbers of retrieved and relevant points.

The simple visualization setup presented in this section is a novel formulation of visualization and useful as a clearly defined starting point. However, for practical use it has a shortcoming: the overly simple binary fixed-size neighborhoods do not take into account *grades of relevance*. The cost function does not penalize violating the original similarity ordering of neighbor samples; and the cost function penalizes all neighborhood violations with the same cost. Next we will introduce a more practical visualization setup.

2.2 Similarity Visualization with Continuous Neighborhood Relationships

We generalize the simple binary neighborhood case by defining probabilistic neighborhoods both in the (i) input and (ii) output spaces, and (iii) replacing the binary precision and recall measures with probabilistic ones. It will finally be shown that for binary neighborhoods, interpreted as a constant high probability of being a neighbor within the neighborhood set and a constant low probability elsewhere, the measures reduce to the standard precision and recall.

2.2.1 PROBABILISTIC MODEL OF RETRIEVAL

We start by defining the neighborhood in the output space, and do that by defining a probability distribution over the neighbor points. Such a distribution is interpretable as a model about how the user does the retrieval given the visualization display.

Given the location of the query point on the display, $\mathbf{y}_i$, suppose that the user selects one point at a time for inspection. Denote by $q_{j|i}$ the probability that the user chooses $\mathbf{y}_j$. If we can define such probabilities, they will define a *probabilistic model of retrieval* for the neighbors of $\mathbf{y}_i$.

The form of $q_{j|i}$ can be defined by a few axiomatic choices and a few arbitrary ones. Since the $q_{j|i}$ are a probability distribution over j for each i, they must be nonnegative and sum to one over j; therefore we can represent them as $q_{j|i} = \exp(-f_{i,j})/\sum_{k\neq i}\exp(-f_{i,k})$ where $f_{i,j} \in \mathbb{R}$. The $f_{i,j}$ should be an increasing function of distance (dissimilarity) between $\mathbf{y}_i$ and $\mathbf{y}_j$; we further assume that $f_{i,j}$ depends only on $\mathbf{y}_i$ and $\mathbf{y}_j$ and not on the other points $\mathbf{y}_k$. It remains to choose the form of

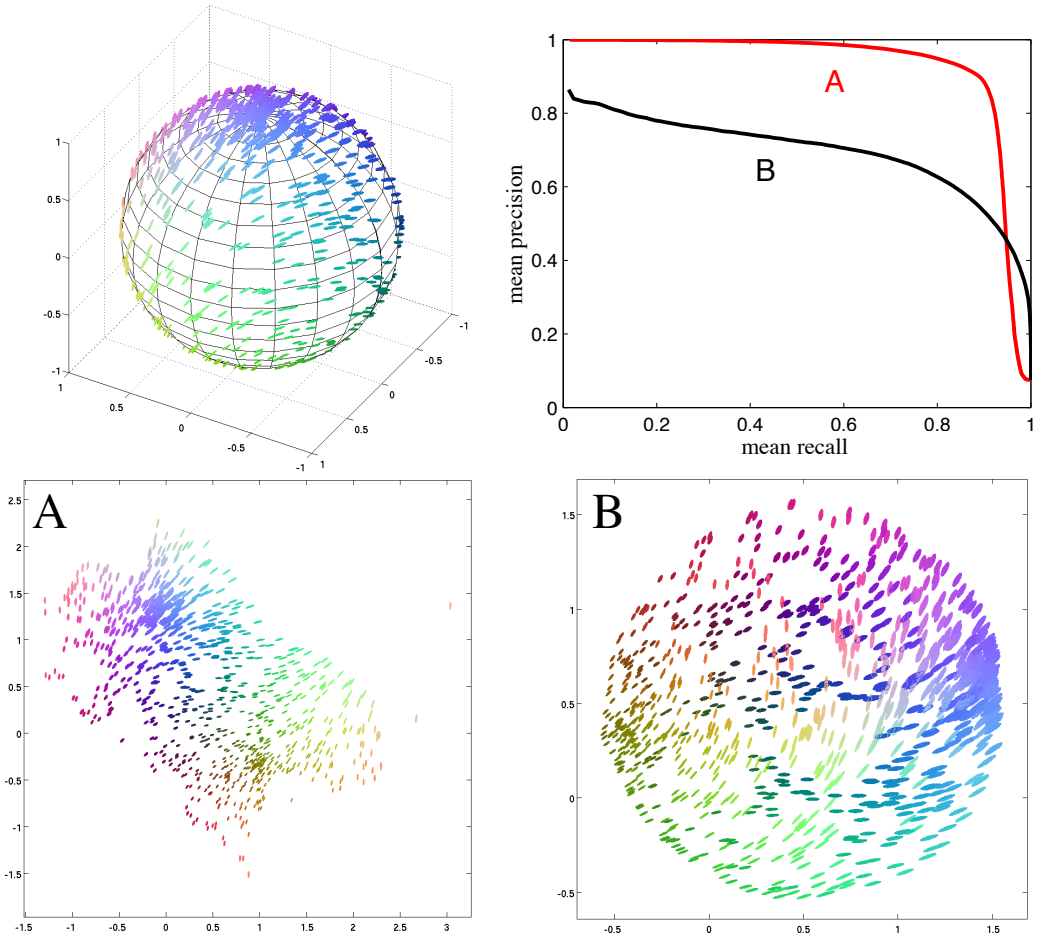

Figure 2: Demonstration of the tradeoff between false positives and misses. **Top left:** A three-dimensional data set sampled from the surface of a sphere; only the front hemisphere is shown for clarity. The glyph shapes (size, elongation, and angle) show the three-dimensional coordinates of each point; the colors in the online version show the same information. **Bottom:** Two embeddings of the data set. In the embedding **A**, the sphere has been cut open and folded out. This embedding eliminates *false positives*, but there are some *misses* because points on different sides of the tear end up far away from each other. In contrast, the embedding **B** minimizes the number of misses by simply squashing the sphere flat; this results in a large number of false positives because points on opposite sides of the sphere are mapped close to each other. **Top right:** mean precision-mean recall curves with input neighborhood size $r = 75$, as a function of the output neighborhood size k, for the two projections. The embedding **A** has better precision (yielding higher values at the left end of the curve) whereas the embedding **B** has better recall (yielding higher values at the right end of the curve).

$f_{i,j}$. In general there should not be any reason to favor any particular neighbor point, and hence the form should not depend on j. It could depend on i, however; we assume it has a simple quadratic form $f_{i,j} = ||\mathbf{y}_i - \mathbf{y}_j||^2/\sigma_i^2$ where $||\mathbf{y}_i - \mathbf{y}_j||$ is the Euclidean distance and the positive multiplier $1/\sigma_i^2$ allows the function to grow at an individual rate for each i. This yields the definition

$$q_{j|i} = \frac{\exp(-\frac{\|\mathbf{y}_i - \mathbf{y}_j\|^2}{\sigma_i^2})}{\sum_{k \neq i} \exp(-\frac{\|\mathbf{y}_i - \mathbf{y}_k\|^2}{\sigma_i^2})} \,. \tag{2}$$

2.2.2 PROBABILISTIC MODEL OF RELEVANCE

We extend the simple binary neighborhoods of input data samples to probabilistic neighborhoods as follows. Suppose that if the user was choosing the neighbors of a query point i in the original data space, she would choose point j with probability $p_{j|i}$. The $p_{j|i}$ define a *probabilistic model of relevance* for the original data, and are equivalent to a neighborhood around i: the higher the chance of choosing this neighbor, the larger its relevance to i.

We define the probability $p_{j|i}$ analogously to $q_{j|i}$, as

$$p_{j|i} = \frac{\exp(-\frac{d(\mathbf{x}_i, \mathbf{x}_j)^2}{\sigma_i^2})}{\sum_{k \neq i} \exp(-\frac{d(\mathbf{x}_i, \mathbf{x}_k)^2}{\sigma_i^2})} \,, \tag{3}$$

where $d(\cdot,\cdot)$ is a suitable difference measure in the original data, and $\mathbf{x}_i$ refers to the point in the original data that is represented by $\mathbf{y}_i$ in the visualization. Some data sets may provide the values of $d(\cdot,\cdot)$ directly; otherwise the analyst can choose a difference measure suitable for the data feature vectors. Later in this paper we will use both the simple Euclidean distance and a more complicated distance measure that incorporates additional information about the data.

Given known values of $d(\cdot,\cdot)$, the above definition of the neighborhood $p_{j|i}$ can be motivated by the same arguments as $q_{j|i}$. That is, the given form of $p_{j|i}$ is a good choice if no other information about the original neighborhoods is available. Other choices are possible too; in particular, if the data directly includes neighbor probabilities, they can simply be used as the $p_{j|i}$. Likewise, if more accurate models of user behavior are available, they can be plugged in place of $q_{j|i}$. The forms of $p_{j|i}$ and $q_{j|i}$ need not be the same.

For each point i, the scaling parameter σ_i controls how quickly the probabilities $p_{j|i}$ fall off with distance. These parameters could be fixed by prior knowledge, but without such knowledge it is reasonable to set the σ_i by specifying how much flexibility there should be about the choice of neighbors. That is, we set σ_i to a value that makes the entropy of the $p_{\cdot|i}$ distribution equal to $\log k$, where k is a rough upper limit for the number of relevant neighbors, set by the user. We use the same relative scale σ_i both in the input and output spaces (Equations 2 and 3).

2.2.3 COST FUNCTIONS

The remaining task is to measure how well the retrieval done in the output space, given the visualization, matches the true relevances defined in the input space. Both were above defined in terms of distributions, and a natural candidate for the measure is the *Kullback-Leibler divergence*, defined as

$$D(p_i, q_i) = \sum_{j \neq i} p_{j|i} \log \frac{p_{j|i}}{q_{j|i}}$$

where p_i and q_i are the neighbor distributions for a particular point i, in the input space and in the visualization respectively. For the particular probability distributions defined above the Kullback-Leibler divergence turns out to be intimately related to precision and recall. Specifically, for any query i, the Kullback-Leibler divergence $D(p_i, q_i)$ is a generalization of recall, and $D(q_i, p_i)$ is a generalization of precision; for simple "binary" neighborhood definitions, the Kullback-Leibler divergences and the precision-recall measures become equivalent. The proof is in Appendix A.

We call $D(q_i, p_i)$ *smoothed precision* and $D(p_i, q_i)$ *smoothed recall*. To evaluate a complete visualization rather than a single query, we define aggregate measures in the standard fashion: mean smoothed precision is defined as $\mathbb{E}_i[D(q_i, p_i)]$ and mean smoothed recall as $\mathbb{E}_i[D(p_i, q_i)]$, where $\mathbb{E}$ denotes expectation and the means are taken over queries (data points i).

Mean smoothed precision and recall are analogous to mean precision and recall in that we cannot in general reach the optimum of both simultaneously. We return to Figure 2 which illustrates the tradeoff for nonlinear projections of a three-dimensional sphere surface. The subfigure **A** was created by maximizing mean smoothed precision; the sphere has been cut open and folded out, which minimizes the number of false positives but also incurs some misses because some points located on opposite edges of the point cloud were originally close to each other on the sphere. The subfigure **B** was created by maximizing mean smoothed recall; the sphere is squashed flat, which minimizes the number of misses, as all the points that were close to each other in the original data are close to each other in the visualization. However, there are then a large number of false positives because opposite sides of the sphere have been mapped on top of each other, so that many points that appear close to each other in the visualization are actually originally far away from each other.

2.2.4 EASIER-TO-INTERPRET ALTERNATIVE GOODNESS MEASURES

Mean smoothed precision and recall are rigorous and well-motivated measures of visualization performance, but they have one practical shortcoming for human analysts: the errors have no upper bound, and the scale will tend to depend on the data set. The measures are very useful for comparing several visualizations of the same data, and will turn out to be useful as optimization criteria, but we would additionally like to have measures where the plain numbers are easily interpretable. We address this by introducing *mean rank-based smoothed precision and recall*: simply replace the distances in the definitions of $p_{j|i}$ and $q_{j|i}$ with ranks, so that the probability for the nearest neighbor uses a distance of 1, the probability for the second nearest neighbor a distance of 2, and so on. This imposes an upper bound on the error because the worst case scenario is that the ranks in the data set are reversed in the visualization. Dividing the errors by their upper bounds gives us measures that lie in the interval $[0, 1]$ regardless of the data and are thus much easier to interpret. The downside is that substituting ranks for distances makes the measures disregard much of the neighborhood structure in the data, so we suggest using mean rank-based smoothed precision and recall as easier-to-interpret, but less discriminating complements to, rather than replacements of, mean smoothed precision and recall.

3. Neighborhood Retrieval Visualizer (NeRV)

In Section 2 we defined similarity visualization as an information retrieval task. The quality of a visualization can be measured by the two loss functions, mean smoothed precision and recall. These measures generalize the straightforward precision and recall measures to non-binary neighborhoods. They have the further advantage of being continuous and differentiable functions of the

output visualization coordinates. It is then easy to use the measures as *optimization criteria* for a visualization method. We now introduce a visualization algorithm that optimizes visual information retrieval performance. We call the algorithm the *neighborhood retrieval visualizer* (NeRV).

As demonstrated in Figure 2, precision and recall cannot in general be minimized simultaneously, and the user has to choose which loss function (average smoothed precision or recall) is more important, by assigning a cost for misses and a cost for false positives. Once these costs have been assigned, the visualization task is simply to minimize the total cost. In practice the relative cost of false positives to misses is given as a parameter λ. The NeRV cost function then becomes

$$E_{\mathrm{NeRV}} = \lambda \mathbb{E}_i[D(p_i, q_i)] + (1-\lambda)\mathbb{E}_i[D(q_i, p_i)] \propto \lambda \sum_i \sum_{j \neq i} p_{j|i} \log \frac{p_{j|i}}{q_{j|i}} + (1-\lambda) \sum_i \sum_{j \neq i} q_{j|i} \log \frac{q_{j|i}}{p_{j|i}} \quad (4)$$

where, for example, setting λ to 0.1 indicates that the user considers an error in precision $(1-0.1)/0.1 = 9$ times as expensive as a similar error in recall.

To optimize the cost function (4) with respect to the output coordinates $\mathbf{y}_i$ of each data point, we use a standard conjugate gradient algorithm. The computational complexity of each iteration is $O(dn^2)$, where n is the number of data points and d the dimension of the projection. (In our earlier conference paper a coarse approximate algorithm was required for speed; this turned out to be unnecessary, and the $O(dn^2)$ complexity does not require any approximation.) Note that if a pairwise distance matrix in the input space is not directly provided as data, it can as usual be computed from input features; this is a one-time computation done at the start of the algorithm and takes $O(Dn^2)$ time, where D is the input dimensionality.

In general, NeRV optimizes a user-defined cost which forms a tradeoff between mean smoothed precision and mean smoothed recall. If we set $\lambda = 1$ in Equation (4), we obtain the cost function of stochastic neighbor embedding (SNE; see Hinton and Roweis, 2002). Hence we get as a side result a new interpretation of SNE as a method that maximizes mean smoothed recall.

3.0.5 PRACTICAL ADVICE ON OPTIMIZATION

After computing the distance matrix from the input data, we scale the input distances so that the average distance is equal to 1. We use a random projection onto the unit square as a starting point for the algorithm. Even this simple choice has turned out to give better results than alternatives; a more intelligent initialization, such as projecting the data using principal component analysis, can of course also be used.

To speed up convergence and avoid local minima, we apply a further initialization step: we run ten rounds of conjugate gradient (two conjugate gradient steps per round), and after each round decrease the neighborhood scaling parameters σ_i used in Equations (2) and (3). Initially, we set the σ_i to half the diameter of the input data. We decrease them linearly so that the final value makes the entropy of the $p_{j|i}$ distribution equal to an effective number of neighbors k, which is the choice recommended in Section 2.2. This initialization step has the same complexity $O(dn^2)$ per iteration as the rest of the algorithm. After this initialization phase we perform twenty standard conjugate gradient steps.

4. Using NeRV for Unsupervised Visualization

It is easy to apply NeRV for unsupervised dimensionality reduction. As in any unsupervised analysis, the analyst first chooses a suitable unsupervised similarity or distance measure for the input data; for vector-valued input data this can be the standard Euclidean distance (which we will use here), or it can be some other measure suggested by domain knowledge. Once the analyst has specified the relative importance of precision and recall by choosing a value for λ, the NeRV algorithm computes the embedding based on the distances it is given.

In this section we will make extensive experiments comparing the performance of NeRV with other dimensionality reduction methods on unsupervised visualization of several data sets, including both benchmark data sets and real-life bioinformatics data sets. In the following subsections, we describe the comparison methods and data sets, briefly discuss the experimental methodology, and present the results.

4.1 Comparison Methods for Unsupervised Visualization

For the task of unsupervised visualization we compare the performance of NeRV with the following unsupervised nonlinear dimensionality reduction methods: principal component analysis (PCA; Hotelling, 1933), metric multidimensional scaling (MDS; see Borg and Groenen, 1997), locally linear embedding (LLE; Roweis and Saul, 2000), Laplacian eigenmap (LE; Belkin and Niyogi, 2002a), Hessian-based locally linear embedding (HLLE; Donoho and Grimes, 2003), isomap (Tenenbaum et al., 2000), curvilinear component analysis (CCA; Demartines and Hérault, 1997), curvilinear distance analysis (CDA; Lee et al., 2004), maximum variance unfolding (MVU; Weinberger and Saul, 2006), landmark maximum variance unfolding (LMVU; Weinberger et al., 2005), and our previous method local MDS (LMDS; Venna and Kaski, 2006).

Principal component analysis (PCA; Hotelling, 1933) finds linear projections that maximally preserve the variance in the data. More technically, the projection directions can be found by solving for the eigenvalues and eigenvectors of the covariance matrix $\mathbf{C}_x$ of the input data points. The eigenvectors corresponding to the two or three largest eigenvalues are collected into a matrix $\mathbf{A}$, and the data points $\mathbf{x}_i$ can then be visualized by projecting them with $\mathbf{y}_i = \mathbf{A}\mathbf{x}_i$, where $\mathbf{y}_i$ is the obtained low-dimensional representation of $\mathbf{x}_i$. PCA is very closely related to linear multidimensional scaling (linear MDS, also called classical scaling; Torgerson, 1952; Gower, 1966), which tries to find low-dimensional coordinates preserving squared distances. It can be shown (Gower, 1966) that when the dimensionality of the sought solutions is the same and the distance measure is Euclidean, the projection of the original data to the PCA subspace equals the configuration of points found by linear MDS. This implies that PCA tries to preserve the squared distances between data points, and that linear MDS finds a solution that is a linear projection of the original data.

Traditional *multidimensional scaling* (MDS; see Borg and Groenen, 1997) exists in several different variants, but they all have a common goal: to find a configuration of output coordinates that preserves the pairwise distance matrix of the input data. For the comparison experiments we chose *metric MDS* which is the simplest nonlinear MDS method; its cost function (Kruskal, 1964), called the raw stress, is

$$E = \sum_{i,j} (d(\mathbf{x}_i, \mathbf{x}_j) - d(\mathbf{y}_i, \mathbf{y}_j))^2, \tag{5}$$

where $d(\mathbf{x}_i, \mathbf{x}_j)$ is the distance of points $\mathbf{x}_i$ and $\mathbf{x}_j$ in the input space and $d(\mathbf{y}_i, \mathbf{y}_j)$ is the distance of their corresponding representations (locations) $\mathbf{y}_i$ and $\mathbf{y}_j$ in the output space. This cost function is minimized with respect to the representations $\mathbf{y}_i$.

Isomap (Tenenbaum et al., 2000) is an interesting variant of MDS, which again finds a configuration of output coordinates matching a given distance matrix. The difference is that Isomap does not compute pairwise input-space distances as simple Euclidean distances but as *geodesic distances* along the manifold of the data (technically, along a graph formed by connecting all k-nearest neighbors). Given these geodesic distances the output coordinates are found by standard linear MDS. When output coordinates are found for such input distances, the manifold structure in the original data becomes unfolded; it has been shown (Bernstein et al., 2000) that this algorithm is asymptotically able to recover certain types of manifolds. We used the isomap implementation available at `http://isomap.stanford.edu` in the experiments.

Curvilinear component analysis (CCA; Demartines and Hérault, 1997) is a variant of MDS that tries to preserve only distances between points that are near each other in the visualization. This is achieved by weighting each term in the MDS cost function (5) by a coefficient that depends on the corresponding pairwise distance in the visualization. In the implementation we use, the coefficient is simply a step function that equals 1 if the distance is below a predetermined threshold and 0 if it is larger.

Curvilinear distance analysis (CDA; Lee et al., 2000, 2004) is an extension of CCA. The idea is to replace the Euclidean distances in the original space with geodesic distances in the same manner as in the isomap algorithm. Otherwise the algorithm stays the same.

Local MDS (LMDS; Venna and Kaski, 2006) is our earlier method, an extension of CCA that focuses on local proximities with a tunable cost function tradeoff. It can be seen as a first step in the development of the ideas of NeRV.

The *locally linear embedding* (LLE; Roweis and Saul, 2000) algorithm is based on the assumption that the data manifold is smooth enough and is sampled densely enough, such that each data point lies close to a locally linear subspace on the manifold. LLE makes a locally linear approximation of the whole data manifold: LLE first estimates a local coordinate system for each data point, by calculating linear coefficients that reconstruct the data point as well as possible from its k nearest neighbors. To unfold the manifold, LLE finds low-dimensional coordinates that preserve the previously estimated local coordinate systems as well as possible. Technically, LLE first minimizes the reconstruction error $E(\mathbf{W}) = \sum_i \|\mathbf{x}_i - \sum_j W_{i,j}\mathbf{x}_j\|^2$ with respect to the coefficients $W_{i,j}$, under the constraints that $W_{i,j} = 0$ if i and j are not neighbors, and $\sum_j W_{i,j} = 1$. Given the weights, the low-dimensional configuration of points is next found by minimizing $E(\mathbf{Y}) = \sum_i \|\mathbf{y}_i - \sum_j W_{i,j}\mathbf{y}_j\|^2$ with respect to the low-dimensional representation $\mathbf{y}_i$ of each data point.

The *Laplacian eigenmap* (LE; see Belkin and Niyogi, 2002a) uses a graph embedding approach. An undirected k-nearest-neighbor graph is formed, where each data point is a vertex. Points i and j are connected by an edge with weight $W_{i,j} = 1$ if j is among the k nearest neighbors of i, otherwise the edge weight is set to zero; this simple weighting method has been found to work well in practice (Belkin and Niyogi, 2002b). To find a low-dimensional embedding of the graph, the algorithm tries to put points that are connected in the graph as close to each other as possible and does not care what happens to the other points. Technically, it minimizes $\frac{1}{2}\sum_{i,j} \|\mathbf{y}_i - \mathbf{y}_j\|^2 W_{i,j} = \mathbf{y}^T\mathbf{L}\mathbf{y}$ with respect to the low-dimensional point locations $\mathbf{y}_i$, where $\mathbf{L} = \mathbf{D} - \mathbf{W}$ is the graph Laplacian and $\mathbf{D}$ is a diagonal matrix with elements $\mathrm{D}_{ii} = \sum_j W_{i,j}$. However, this cost function has an undesirable trivial solution: putting all points in the same position would minimize the cost. This can be avoided by adding suit-

able constraints. In practice the low-dimensional configuration is found by solving the generalized eigenvalue problem $\mathbf{Ly} = \lambda\mathbf{Dy}$ (Belkin and Niyogi, 2002a). The smallest eigenvalue corresponds to the trivial solution, but the eigenvectors corresponding to the next smallest eigenvalues give the Laplacian eigenmap solution.

The Laplacian eigenmap algorithm reduces to solving a generalized eigenvalue problem because the cost function that is minimized is a quadratic form involving the Laplacian matrix $\mathbf{L}$. The *Hessian-based locally linear embedding* (HLLE; Donoho and Grimes, 2003) algorithm is similar, but the Laplacian $\mathbf{L}$ is replaced by the Hessian $\mathbf{H}$.

The *maximum variance unfolding* algorithm (MVU; Weinberger and Saul, 2006) expresses dimensionality reduction as a semidefinite programming problem. One way of unfolding a folded flag is to pull its four corners apart, but not so hard as to tear the flag. MVU applies this idea to projecting a manifold: the projection maximizes variance (pulling apart) while preserving distances between neighbors (no tears). The constraint of local distance preservation can be expressed in terms of the Gram matrix $\mathbf{K}$ of the mapping. Maximizing the variance of the mapping is equivalent to maximizing the trace of $\mathbf{K}$ under a set of constraints, which, it turns out, can be done using semidefinite programming.

A notable disadvantage of MVU is the time required to solve a semidefinite program for $n \times n$ matrices when the number of data points n is large. *Landmark MVU* (LMVU; Weinberger et al., 2005) addresses this issue by significantly reducing the size of the semidefinite programming problem. Like LLE, LMVU assumes that the data manifold is sufficiently smooth and densely sampled that it is locally approximately linear. Instead of embedding all the data points directly as MVU does, LMVU randomly chooses $m \ll n$ inputs as so-called landmarks. Because of the local linearity assumption, the other data points can be approximately reconstructed from the landmarks using a linear transformation. It follows that the Gram matrix $\mathbf{K}$ can be approximated using the $m \times m$ submatrix of inner products between landmarks. Hence we only need to optimize over $m \times m$ matrices, a much smaller semidefinite program. Other recent approaches for speeding up MVU include matrix factorization based on a graph Laplacian (Weinberger et al., 2007).

In addition to the above comparison methods, other recent work on dimensionality reduction includes *minimum volume embedding* (MVE; Shaw and Jebara, 2007), which is similar to MVU, but where MVU maximizes the whole trace of the Gram matrix (the sum of all eigenvalues), MVE maximizes the sum of the first few eigenvalues and minimizes the sum of the rest, in order to preserve the largest amount of eigenspectrum energy in the few dimensions that remain after dimensionality reduction. In practice, a variational upper bound of the resulting criterion is optimized.

Very recently, a number of unsupervised methods have been compared by van der Maaten et al. (2009) in terms of classification accuracy and our old criteria trustworthiness-continuity.

4.2 Data Sets for Unsupervised Visualization

We used two synthetic benchmark data sets and four real-life data sets for our experiments.

The *plain s-curve* data set is an artificial set sampled from an S-shaped two-dimensional surface embedded in three-dimensional space. An almost perfect two-dimensional representation should be possible for a non-linear dimensionality reduction method, so this data set works as a sanity check.

The *noisy s-curve* data set is otherwise identical to the plain s-curve data set, but significant spherical normally distributed noise has been added to each data point. The result is a cloud of points where the original S-shape is difficult to discern by visual inspection.

The *faces* data set consists of ten different face images of 40 different people, for a total of 400 images. For a given subject, the images vary in terms of lighting and facial expressions. The size of each image is 64×64 pixels, with 256 grey levels per pixel. The data set is available for download at `http://www.cs.toronto.edu/~roweis/data.html`.

The *mouse gene expression* data set is a collection of gene expression profiles from different mouse tissues (Su et al., 2002). Expression of over 13,000 mouse genes had been measured in 45 tissues. We used an extremely simple filtering method, similar to that originally used by Su et al. (2002), to select the genes for visualization. Of the mouse genes clearly expressed (average difference in Affymetrix chips, AD $>$ 200) in at least one of the 45 tissues (dimensions), a random sample of 1600 genes (points) was selected. After this the variance in each tissue was normalized to unity.

The *gene expression compendium* data set is a large collection of human gene expression arrays (`http://dags.stanford.edu/cancer`; Segal et al., 2004). Since the current implementations of all methods do not tolerate missing data we removed samples with missing values altogether. First we removed genes that were missing from more than 300 arrays. Then we removed the arrays for which values were still missing. This resulted in a data set containing 1278 points and 1339 dimensions.

The *sea-water temperature time series* data set (Liitiäinen and Lendasse, 2007) is a time series of weekly temperature measurements of sea water over several years. Each data point is a time window of 52 weeks, which is shifted one week forward for the next data point. Altogether there are 823 data points and 52 dimensions.

4.3 Methodology for the Unsupervised Experiments

The performance of NeRV was compared with 11 unsupervised dimensionality reduction methods described in Section 4.1, namely principal component analysis (PCA), metric multidimensional scaling (here simply denoted MDS), locally linear embedding (LLE), Laplacian eigenmap (LE), Hessian-based locally linear embedding (HLLE), isomap, curvilinear component analysis (CCA), curvilinear distance analysis (CDA), maximum variance unfolding (MVU), landmark maximum variance unfolding (LMVU), and local MDS (LMDS). LLE, LE, HLLE, MVU, LMVU and isomap were computed with code from their developers; MDS, CCA and CDA used our code.

4.3.1 GOODNESS MEASURES

We used four pairs of performance measures to compare the methods. The first pair is *mean smoothed precision-mean smoothed recall*, that is, our new measures of visualization quality. The scale of input neighborhoods was fixed to 20 relevant neighbors (see Section 2.2).

Although we feel, as explained in Section 2, that smoothed precision and smoothed recall are more sophisticated measures of visualization performance than precision and recall, we have also plotted standard *mean precision-mean recall* curves. The curves were plotted by fixing the 20 nearest neighbors of a point in the original data as the set of relevant items, and then varying the number of neighbors retrieved from the visualization between 1 and 100, plotting mean precision and recall for each number.

Our third pair of measures are the rank-based variants of our new measures, *mean rank-based smoothed precision-mean rank-based smoothed recall*. Recall that we introduced the rank-based

variants as easier-to-interpret, but less discriminating, alternatives to mean smoothed precision and mean smoothed recall. The scale of input neighborhoods was again fixed to 20 relevant neighbors.

Our fourth pair of measures is *trustworthiness-continuity* (Kaski et al., 2003). The intuitive motivation behind these measures was the same trade-off between precision and recall as in this paper, but the measures were defined in a more ad hoc way. At the time we did not have the clear connection to information retrieval which makes NeRV particularly attractive, and we did not optimize the measures. Trustworthiness and continuity can, however, now be used as partly independent measures of visualization quality. To compute the trustworthiness and continuity, we used neighborhoods of each point containing the 20 nearest neighbors.

As a fifth measure, when data classes are available, we use *classification error* given the display, with a standard k-nearest neighbor classifier where we set $k = 5$.

4.3.2 CHOICE OF PARAMETERS

Whenever we needed to choose a parameter for any method, we used the same criterion, namely the F-measure computed from the new rank-based measures. That is, we chose the parameter yielding the largest value of $2(P \cdot R)/(P+R)$ where P and R are the mean rank-based smoothed precision and recall.

Many of the methods have a parameter k denoting the number of nearest neighbors for constructing a neighborhood graph; for each method and each data set we tested values of k ranging from 4 to 20, and chose the value that produced the best F-measure. (For MVU and LMVU we used a smaller parameter range to save computational time. For MVU k ranged from 4 to 6; for LMVU k ranged from 3 to 9.) The exceptions are local MDS (LMDS), one of our own earlier methods, and NeRV, for which we simply set k to 20 without optimizing it.

Methods that may have local optima were run five times with different random initializations and the best run (again, in terms of the F-measure) was selected.

4.4 Results of Unsupervised Visualization

We will next show visualizations for a few sets, and measure quantitatively the results of several. We begin by showing an example of a NeRV visualization for the plain S-curve data set in Figure 3. Later in this section we will show a NeRV visualization of a synthetic face data set (Figure 8), and in Section 4.6 of the *faces* data set of real face images (Figure 11). The quantitative results are spread across four figures (Figures 4–7), each of which contains results for one pair of measures and all six data sets.

We first show the curves of *mean smoothed precision-mean smoothed recall*, that is, the loss functions associated with our formalization of visualization as information retrieval. The results are shown in Figure 4. NeRV and local MDS (LMDS) form curves parameterized by λ, which ranges from 0 to 1.0 for NeRV and from 0 to 0.9 for LMDS. NeRV was clearly the best-performing method on all six data sets, which is of course to be expected since NeRV directly optimizes a linear combination of these measures. LMDS has a relatively good mean smoothed precision, but does not perform as well in terms of mean smoothed recall. Simple metric MDS also stands out as a consistently reasonably good method.

Because we formulated visualization as an information retrieval task, it is natural to also try existing measures of information retrieval performance, that is, mean precision and mean recall, even though they do not take into account grades of relevance as discussed in Section 2.1. Standard

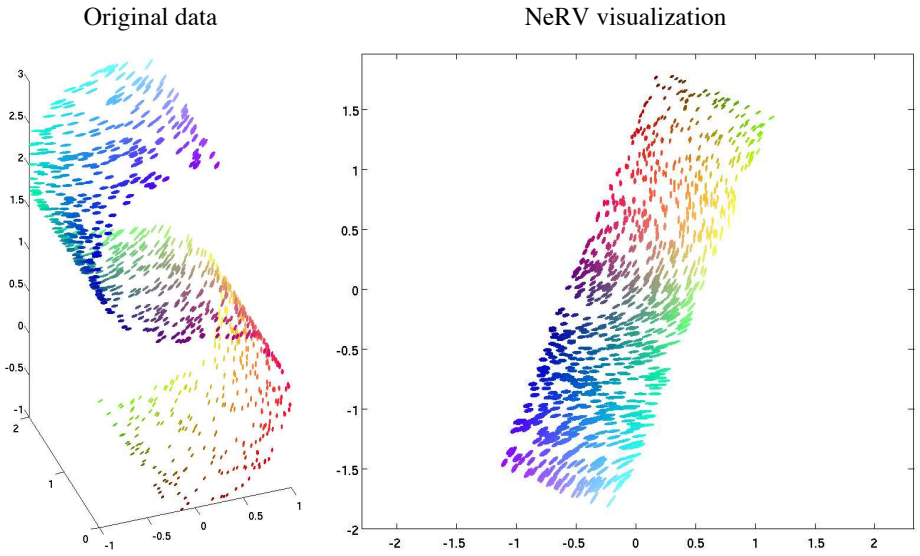

Figure 3: Left: Plain S-curve data set. The glyph shapes (size, elongation, and angle) show the three-dimensional coordinates of each point; the colors in the online version show the same information. Right: NeRV visualization (here $\lambda = 0.8$).

mean precision-mean recall curves are shown in Figure 5; for NeRV and LMDS, we show the curve for a single λ value picked by the F-measure as described in Section 4.3. Even with these coarse measures, NeRV shows excellent performance: NeRV is best on four data sets in terms of the area under the curve, CDA and CCA are each best on one data set.

Next, we plot our easier-to-interpret but less discriminating alternative measures of visualization performance. The curves of *mean rank-based smoothed precision-mean rank-based smoothed recall* are shown in Figure 6. These measures lie between 0 and 1, and may hence be easier to compare between data sets. With these measures, NeRV again performs best on all data sets; LMDS also performs well, especially on the seawater temperature data.

Finally, we plot the curves of *trustworthiness-continuity*, shown in Figure 7. The results are fairly similar to the new rank-based measures: once again NeRV performs best on all data sets and LMDS also performs well, especially on the seawater temperature data.

4.4.1 EXPERIMENT WITH A KNOWN UNDERLYING MANIFOLD

To further test how well the methods are able to recover the neighborhood structure inherent in the data we studied a synthetic face data set where a known underlying manifold defines the relevant items (neighbors) of each point. The SculptFaces data contains 698 synthetic images of a face (sized 64×64 pixels each). The pose and direction of lighting have been changed in a systematic way to create a manifold in the image space (`http://web.mit.edu/cocosci/isomap/datasets.html`; Tenenbaum et al., 2000). We used the raw pixel data as input features.

The pose and lighting parameters used to generate the images are available. These parameters define the manifold of the faces embedded in the very high-dimensional image space. For any face

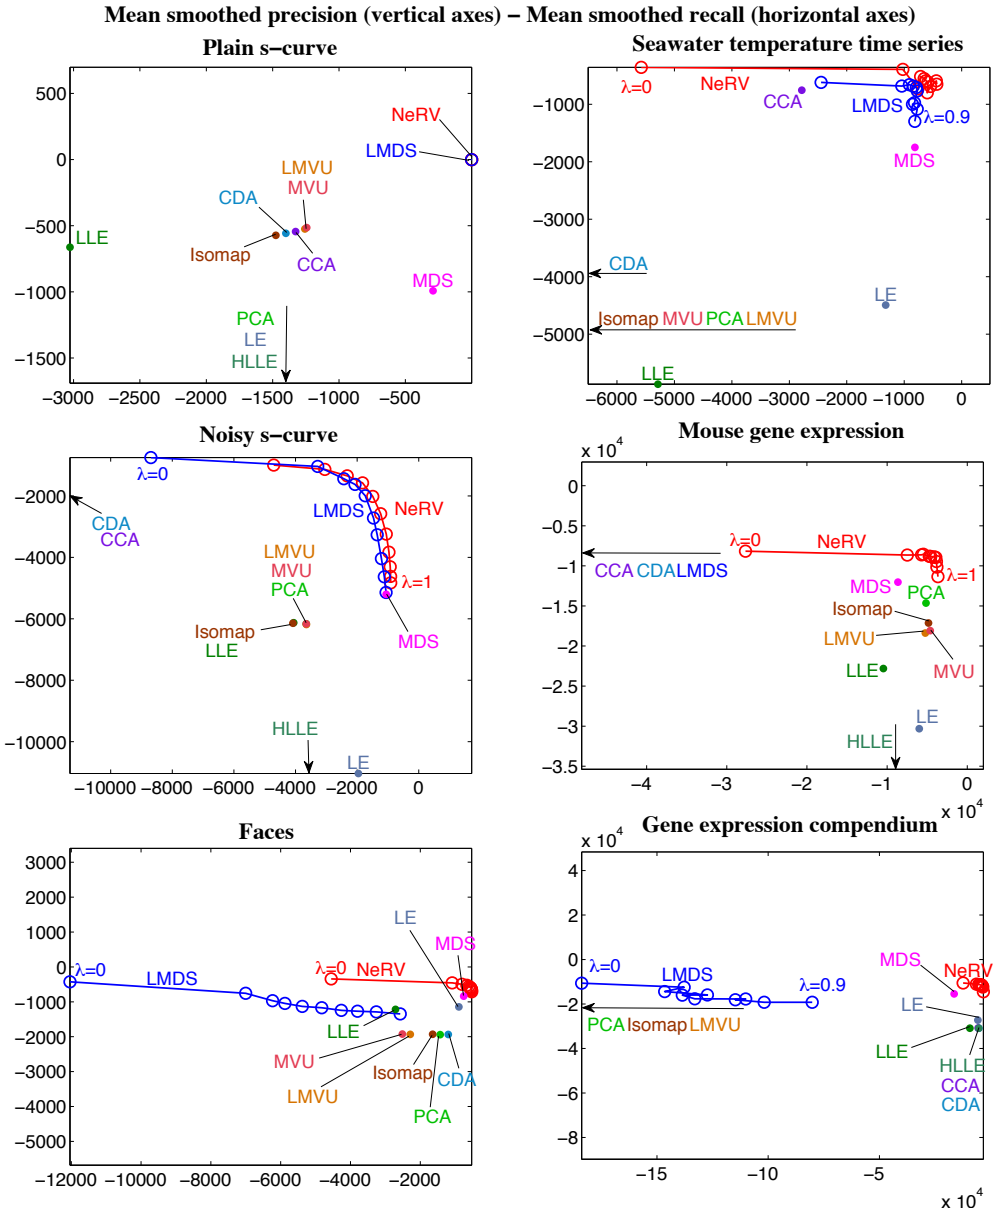

Figure 4: *Mean smoothed precision-mean smoothed recall* plotted for all six data sets. For clarity, only a few of the best-performing methods are shown for each data set. We have actually plotted $-1\cdot$(mean smoothed precision) and $-1\cdot$(mean smoothed recall) to maintain visual consistency with the plots for other measures: in each plot, the best performing methods appear in the top right corner.

image, the relevant other faces are the ones that are neighbors with respect to the pose and lighting parameters; we defined the ground truth neighborhoods using Euclidean distances in the pose and lighting space, and we fixed the scale of the ground truth neighborhoods to 20 relevant neighbors (see Section 2.2).

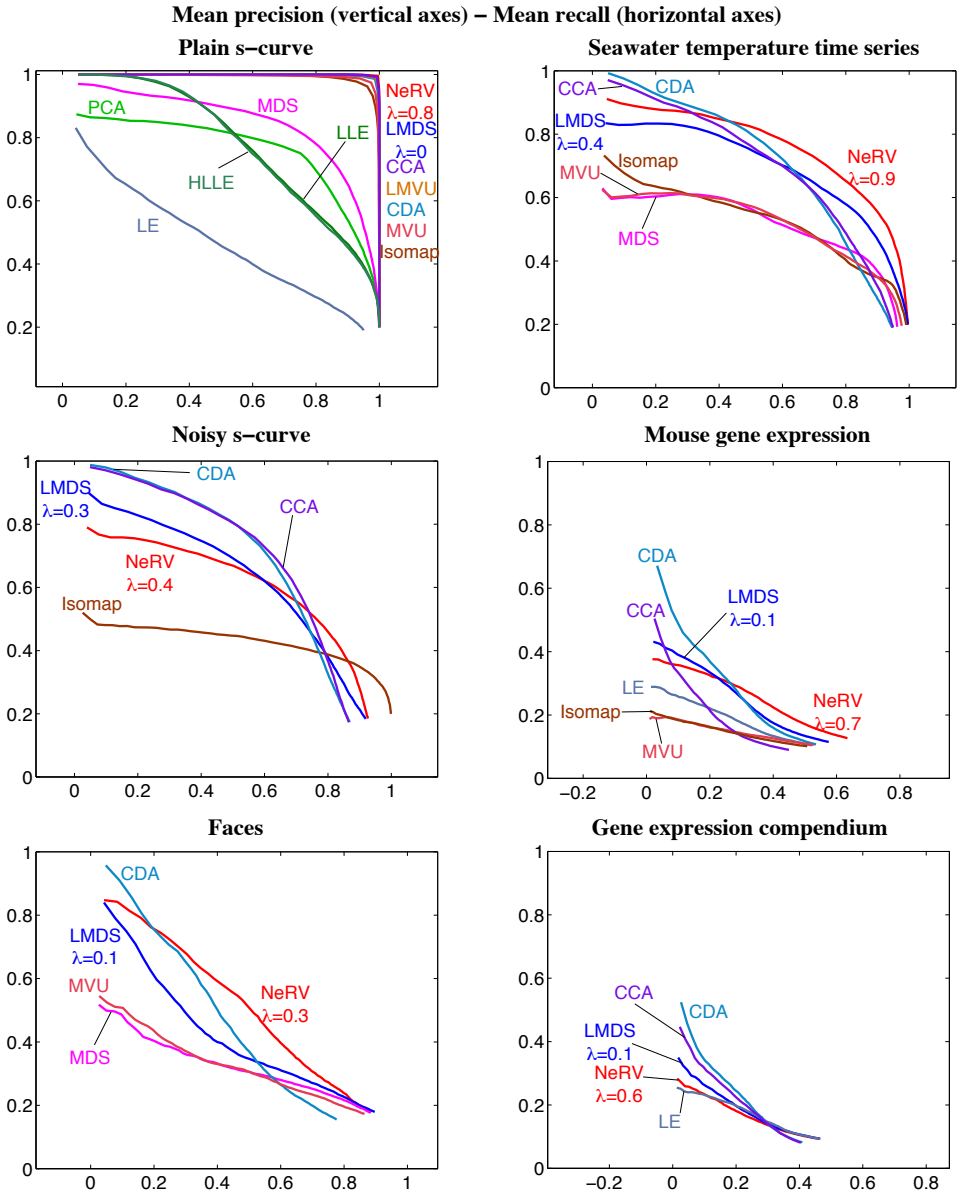

Figure 5: *Mean precision-mean recall* curves plotted for all six data sets. For clarity, only the best methods (with largest area under curve) are shown for each data set. In each plot, the best performance is in the top right corner. For NeRV and LMDS, a single λ value picked with the F-measure is shown.

We ran all methods for this data as in all experiments in this section, and then calculated four performance curves (*mean smoothed precision-mean smoothed recall*, *mean precision-mean recall*, *mean rank-based smoothed precision-mean rank-based smoothed recall*, and *trustworthiness-continuity*) using the neighborhoods in pose and lighting space as the ground truth. The results are shown in Figure 8. In spite of the very high dimensionality of the input space and the reduction of

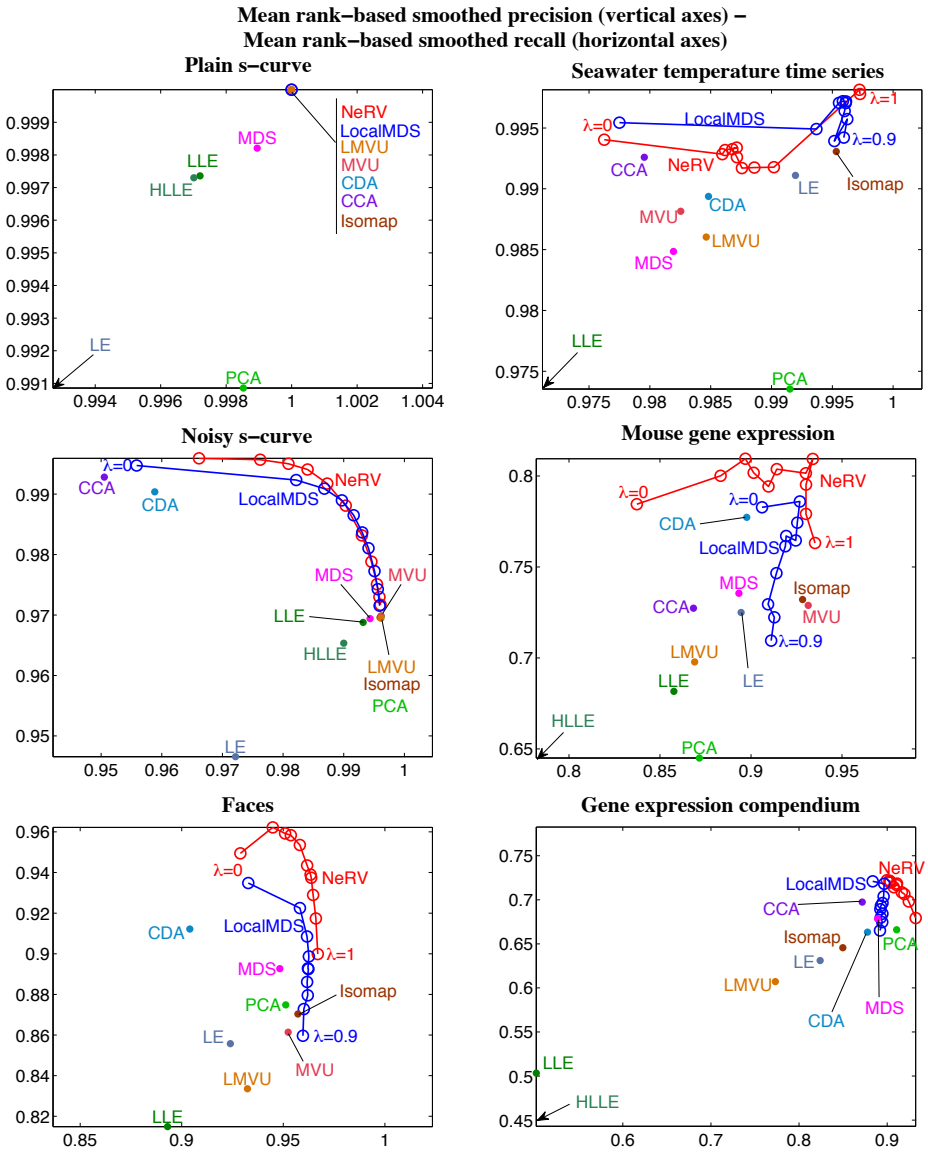

Figure 6: *Mean rank-based smoothed precision-mean rank-based smoothed recall* plotted for all six data sets. For clarity, only a few of the best performing methods are shown for each data set. We have actually plotted 1−(mean rank-based smoothed precision) and 1−(mean rank-based smoothed recall) to maintain visual consistency with the plots for other measures: in each plot, the best performance is in the top right corner.

the manifold dimension from three to two, NeRV was able to recover the structure well. NeRV is the best according to both of our proposed measures of visualization performance, mean smoothed precision and recall; MDS and local MDS also perform well. In terms of the simple mean precision and mean recall NeRV is the second best with CDA being slightly better. In terms of the rank-based measures, NeRV is the best in terms of precision; LE and MDS attain the best mean rank-based

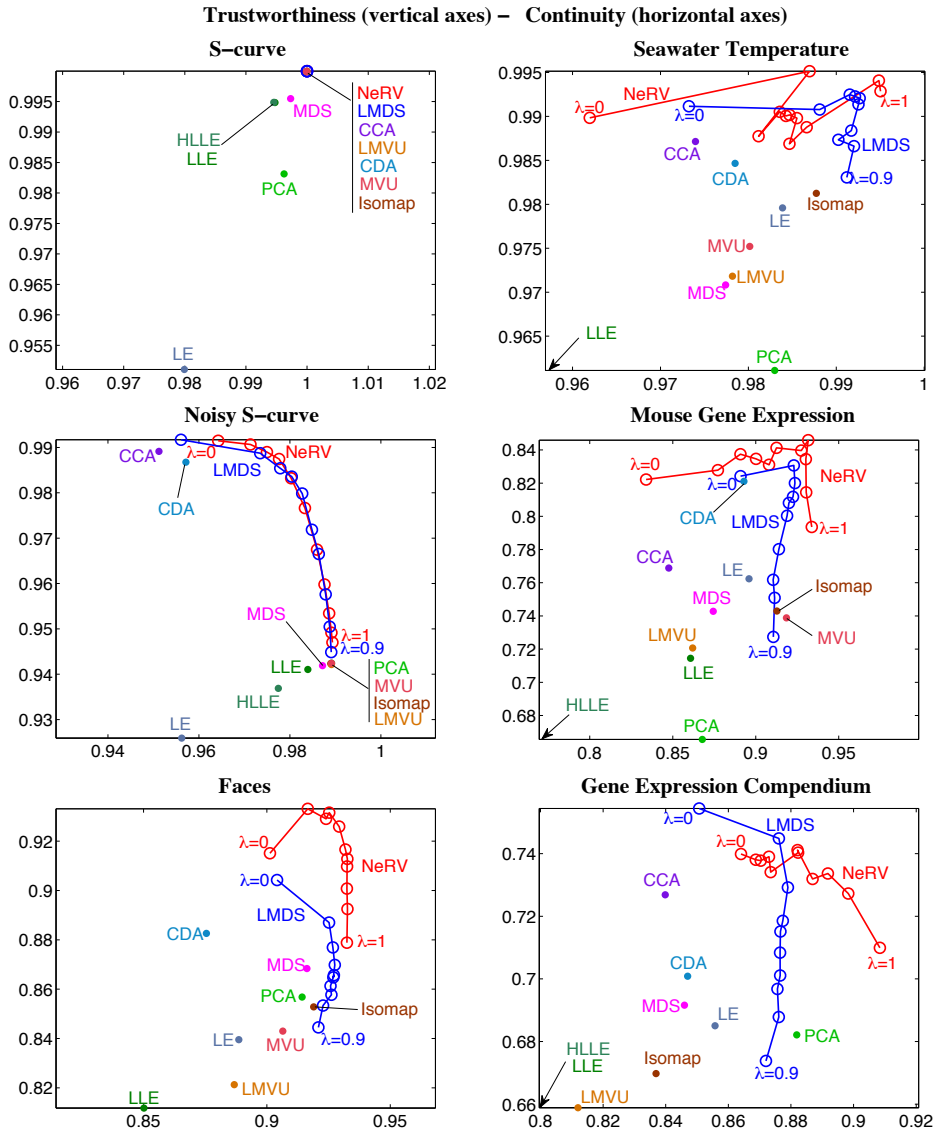

Figure 7: *Trustworthiness-continuity* plotted for all six data sets. For clarity, only a few of the best performing methods are shown for each data set. In each plot, the best performance is in the top right corner.

smoothed recall; and local MDS and CDA also perform well. When performance was measured with trustworthiness and continuity, NeRV was the best in terms of trustworthiness while MVU and Isomap attained the highest continuity.

Overall, NeRV was the best in these unsupervised visualization tasks, although it was not the best in all, and in some tasks it had tough competition.

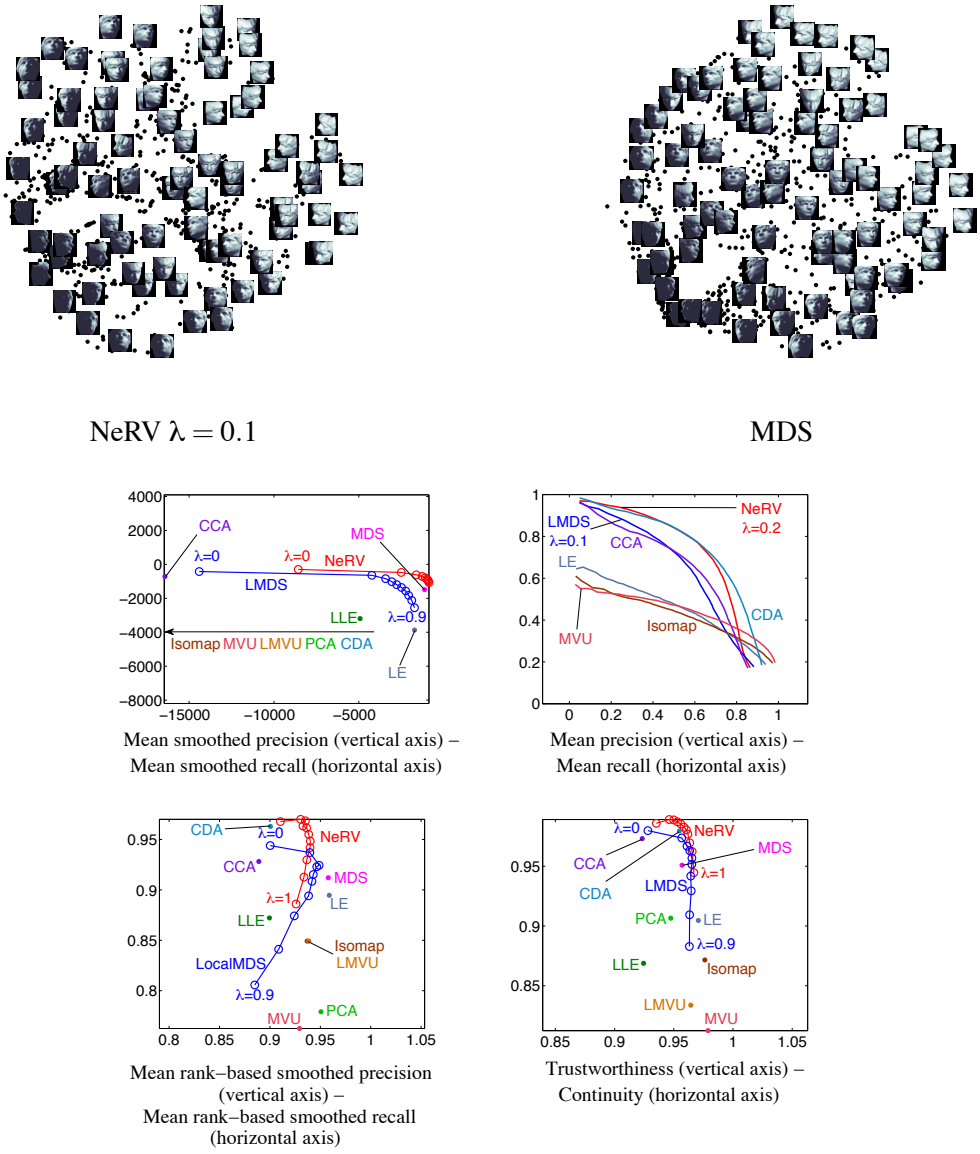

Figure 8: **Top:** Sample projections of the SculptFaces data set (NeRV vs. the best alternative). **Bottom:** How well were the ground truth neighbors in pose-lighting space retrieved from the image data, evaluated by four pairs of measures. The measures were computed the same way as before, as described in Section 4.3, but here taking the known pose and lighting information as the input data. Only the best performing methods are shown for clarity.

4.5 Comparison by Unsupervised Classification

For the data sets where a classification of samples is available, we additionally follow a traditional way to evaluate visualizations: we measure how well samples can be classified based on the visualization.

Data set	Dimensions	Classes
Letter	16	26
Phoneme	20	13
Landsat	36	6
TIMIT	12	41

Table 1: The data sets used in the unsupervised classification experiments.

Here all methods are unsupervised, that is, class labels of samples are not used in computing the visualization. The parameters of methods are again chosen as described in Section 4.3.2. Methods are evaluated by k-nearest neighbor classification accuracy (with $k = 5$), that is, each sample in the visualization is classified by majority vote of its k nearest neighbors in the visualization, and the classification is compared to the ground truth label.

We use four benchmark data sets, all of which include class labels, to compare the performances of the methods. The data sets are summarized in Table 1. For all data sets we used a randomly chosen subset of 1500 samples in the experiments, to save computation time.

The *letter recognition* data set (denoted Letter) is from the UCI Machine Learning Repository (Blake and Merz, 1998); it is a 16-dimensional data set with 26 classes, which are 4×4 images of the 26 capital letters of the alphabet. These letters are based on 20 different fonts which have been distorted to produce the final images.

The *phoneme* data set (denoted Phoneme) is taken from LVQ-PAK (Kohonen et al., 1996) and consists of phoneme samples represented by a 20-dimensional vector of features plus a class label indicating which phoneme is actually represented. There are a total of 13 classes.

The *landsat satellite* data set (denoted Landsat) is from UCI Machine Learning Repository (Blake and Merz, 1998). Each data point is a 36-dimensional vector, corresponding to a 3×3 satellite image measured in four spectral bands; the class label of the point indicates the terrain type in the image (6 possibilitities, for example red soil).

The *TIMIT* data set is taken from the DARPA TIMIT speech database (TIMIT). It is similar to the phoneme data from LVQ-PAK but the feature vectors are 12-dimensional and there are 41 classes in total.

The resulting classification error rates are shown in Table 2. NeRV is best on two out of four data sets and second best on a third set (there our old method LocalMDS is best). CDA is best on one.

4.6 NeRV, Joint Probabilities, and t-Distributions

Very recently, based on stochastic neighbor embedding (SNE), van der Maaten and Hinton (2008) have proposed a modified method called t-SNE, which has performed well in unsupervised experiments. The t-SNE makes two changes compared to SNE; in this section we describe the changes and show that the same changes can be made to NeRV, yielding a variant that we call t-NeRV. We then provide a new information retrieval interpretation for t-NeRV and t-SNE.

We start by analyzing the differences between t-SNE and the original stochastic neighbor embedding. The original SNE minimizes the sum of Kullback-Leibler divergences

$$\sum_i \sum_{j \neq i} p_{j|i} \log \frac{p_{j|i}}{q_{j|i}}$$

	Letter	Phoneme	Landsat	TIMIT
Eigenmap	0.914	0.121	0.168	0.674
LLE	n/a	0.118	0.212	0.722
Isomap	0.847	0.134	0.156	0.721
MVU	0.763	0.155	0.153	0.699
LMVU	0.819	0.208	0.151	0.787
MDS	0.823	0.189	0.151	0.705
CDA	**0.336**	0.118	0.141	0.643
CCA	0.422	0.098	0.143	0.633
NeRV	0.532	**0.079**	0.139	**0.626**
LocalMDS	0.499	0.118	**0.128**	0.637

Table 2: Error rates of k-nearest neighbor classification based on the visualization, for unsupervised visualization methods. The best results for each data set are in bold; n/a denotes that LLE did not yield a result for the Letter data. NeRV attains the lowest error rate for two data sets and second lowest error rate for one data set.

where $p_{j|i}$ and $q_{j|i}$ are defined by Equations (3) and (2). We showed in Section 2.2 that this cost function has an information retrieval interpretation: it corresponds to mean smoothed recall of retrieving neighbors of query points. The t-SNE method makes two changes which we discuss below.

4.6.1 COST FUNCTION BASED ON JOINT PROBABILITIES

The first change in t-SNE is to the cost function: t-SNE minimizes a "symmetric version" of the cost function, defined as

$$\sum_i \sum_{j \neq i} p_{i,j} \log \frac{p_{i,j}}{q_{i,j}}$$

where the $p_{i,j}$ and $q_{i,j}$ are now joint probabilities over both i and j, so that $\sum_{i,j} p_{i,j} = 1$ and similarly for $q_{i,j}$. The term "symmetric" comes from the fact that the joint probabilities are defined in a specific way for which $p_{i,j} = p_{j,i}$ and $q_{i,j} = q_{j,i}$; note that this need not be the case for all definitions of the joint probabilities.

4.6.2 DEFINITIONS OF THE JOINT PROBABILITIES

The second change in t-SNE is that the joint probabilities are defined in a manner which does not yield quite the same conditional probabilities as in Equations (3) and (2). The joint probabilities are defined as

$$p_{i,j} = \frac{1}{2n}(p_{i|j} + p_{j|i}) \tag{6}$$

where $p_{i|j}$ and $p_{j|i}$ are computed by Equation (3) and n is the total number of data points in the data set, and

$$q_{i,j} = \frac{(1 + ||\mathbf{y}_i - \mathbf{y}_j||^2)^{-1}}{\sum_{k \neq l}(1 + ||\mathbf{y}_k - \mathbf{y}_l||^2)^{-1}} \,. \tag{7}$$

The former equation is intended to ensure that, in the input space, even outlier points will have some other points as neighbors. The latter equation means that, in the visualization, the joint probability

falls off according to a (normalized) t-distribution with one degree of freedom, which is intended to help with a *crowding problem*: because the volume of a small-dimensional neighborhood grows slower than the volume of a high-dimensional one, the neighborhood ends up stretched in the visualization so that moderately distant point pairs are placed too far apart. This tends to cause clumping of the data in the center of the visualization. Since the t-distribution has heavier tails than a Gaussian, using such a distribution for the $q_{i,j}$ makes the visualization less affected by the placement of the moderately distant point pairs, and hence better able to focus on other features of the data.

4.6.3 NEW METHOD: T-NERV

We can easily apply the above-described changes to the cost function in NeRV; we call the resulting variant t-NeRV. We define the cost function as

$$E_{\text{t-NeRV}} = \lambda \sum_i \sum_{j \neq i} p_{i,j} \log \frac{p_{i,j}}{q_{i,j}} + (1-\lambda) \sum_i \sum_{j \neq i} q_{i,j} \log \frac{q_{i,j}}{p_{i,j}} = \lambda D(p,q) + (1-\lambda) D(q,p) \qquad (8)$$

where p and q are the joint distributions over i and j defined by the $p_{i,j}$ and the $q_{i,j}$, and the individual joint probabilities are given by Equations (6) and (7).

It can be shown that this changed cost function again has a natural information retrieval interpretation: it corresponds to the tradeoff between *smoothed precision* and *smoothed recall* of a *two-step information retrieval task*, where an analyst looks at a visualization and (step 1) picks a query point and then (step 2) picks a neighbor for the query point. The probability of picking a query point i depends on how many other points are close to it (that is, it depends on $\sum_j q_{i,j}$), and the probability of picking a neighbor depends as usual on the relative closenesses of the neighbors to the query. Both choices are done based on the visualization, and the choices are compared by smoothed precision and smoothed recall to the relevant pairs of queries and neighbors that are defined based on the input space. The parameter λ again controls the tradeoff between precision and recall.

The connection between the $D(p,q)$ and the recall of the two-step retrieval task can be shown by a similar proof as in Appendix A, the main difference being that conditional distributions $p_{j|i}$ and $q_{j|i}$ are replaced by joint distributions $p_{i,j}$ and $q_{i,j}$, and the sums then go over both i and j. The connection between $D(q,p)$ and precision can be shown analogously.

As a special case, setting $\lambda = 1$ in the above cost function, that is, optimizing only smoothed recall of the two-step retrieval task, yields the cost function of t-SNE. We therefore provide a novel information retrieval interpretation of t-SNE as a method that maximizes recall of query points and their neighbors.

The main conceptual difference between NeRV and t-NeRV is that in t-NeRV the probability of picking a query point in the visualization and in the input space depends on the densities in the visualization and input space respectively; in NeRV all potential query points are treated equally. Which treatment of query points should be used depends on the task of the analyst. Additionally, NeRV and t-NeRV have differences in the technical forms of the probabilities, that is, whether t-distributions or Gaussians are used etc.

The t-NeRV method can be optimized with respect to visualization coordinates $\mathbf{y}_i$ of points, by conjugate gradient optimization as in NeRV; the computational complexity is also the same.

4.6.4 COMPARISON

We briefly compare t-NeRV and NeRV on the Faces data set. The setup is the same as in the previous comparison experiments (Figures 4–7). For t-NeRV we use the effective number of neighbors $k = 40$

to compute the joint probabilities $p_{i,j}$; this corresponds to the perplexity value used by the authors of t-SNE (van der Maaten and Hinton, 2008).

Figure 9 shows the results for the four unsupervised evaluation criteria. According to the mean smoothed precision and mean smoothed recall measures, t-NeRV does worse in terms of recall. The rank-based measures indicate a similar result; however, there t-NeRV does fairly well in terms of mean rank-based smoothed precision. The trustworthiness-continuity curves are similar to the rank-based measures. The curves of mean precision versus mean recall show that t-NeRV does achieve better precision for small values of recall (i.e., for small retrieved neighborhoods), while NeRV does slightly better for larger retrieved neighborhoods. These measures correspond to the information retrieval interpretation of NeRV which is slightly different from that of t-NeRV, as discussed above. Figure 9 **E** shows mean smoothed precision/recall in the t-NeRV sense, where t-NeRV naturally performs relatively better.

Lastly, we computed k-nearest neighbor classification error rate (using $k = 5$) with respect to the identity of the persons in the images. NeRV (with $\lambda = 0.3$) attained an error rate of 0.394 and t-NeRV (with $\lambda = 0.8$) an error rate of 0.226. Here t-NeRV is better; this may be because it avoids the problem of crowding samples near the center of the visualization.

Figures 10-12 show example visualizations of the faces data set. First we show a well-performing comparison method (CDA; Figure 10); it has arranged the faces well in terms of keeping images of the same person in a single area; however, the areas of each person are diffuse and close to other persons, hence there is no strong separation between persons on the display. NeRV, here optimized to maximize precision, makes clearly tighter clusters of each person (Figure 11), which yields better retrieval of neighbor face images. However, NeRV has here placed several persons close to each other in the center of the visualization. The t-NeRV visualization, again optimized to maximize precision (Figure 12) has lessened this behavior, placing the clusters of faces more evenly.

Overall, t-NeRV is a useful alternative formulation of NeRV, and may be useful for data sets especially where crowding near the center of the visualization is an issue.

5. Using NeRV for Supervised Visualization

In this section we show how to use NeRV for supervised visualization. The key idea is simple: NeRV can be computed based on any input-space distances $d(\mathbf{x}_i, \mathbf{x}_j)$, not only the standard Euclidean distances. All that is required for supervised visualization is to compute the input-space distances in a supervised manner. The distances are then plugged into the NeRV algorithm and the visualization proceeds as usual. Note that doing the visualization modularly in two steps is an advantage, since it will be later possible to easily change the algorithm used in either step if desired.

Conveniently, rigorous methods exist for learning a supervised metric from labeled data samples. Learning of supervised metrics has recently been extensively studied for classification purposes and for some semi-supervised tasks, with both simple linear approaches and complicated nonlinear ones; see, for instance, works by Xing et al. (2003), Chang and Yeung (2004), Globerson and Roweis (2006) and Weinberger et al. (2006). Any such metric can in principle be used to compute distances for NeRV. Here we use an early one, which is flexible and can be directly plugged in the NeRV, namely the *learning metric* (Kaski et al., 2001; Kaski and Sinkkonen, 2004; Peltonen et al., 2004) which was originally proposed for data exploration tasks.

We will call NeRV computed with the supervised distances "supervised NeRV" (SNeRV). The information retrieval interpretation of NeRV carries over to SNeRV. Under certain parameter set-

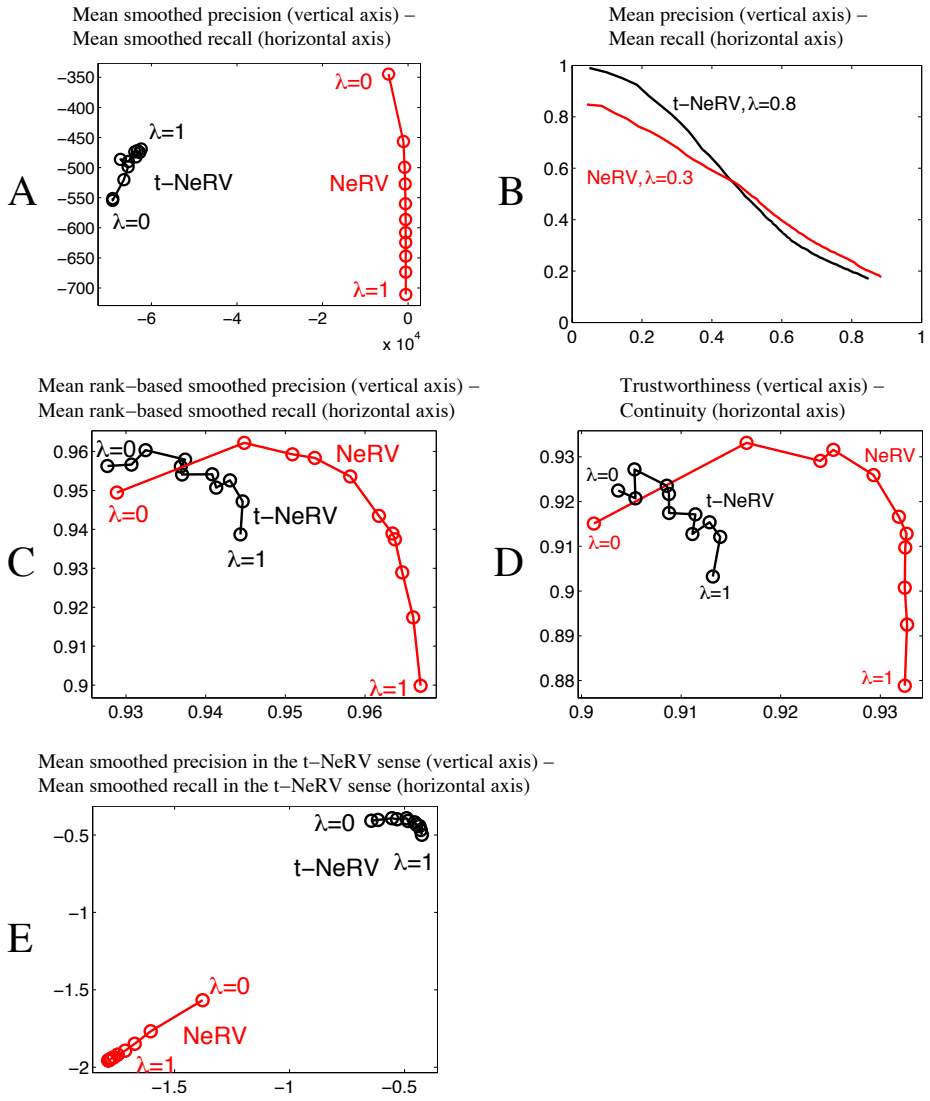

Figure 9: Comparison of NeRV and t-NeRV on the Faces data set according to the four goodness measures described in Section 4.3 (**A**-**D**), and for mean smoothed precision/recall corresponding to the information retrieval interpretation of t-NeRV (**E**; first and second terms of Eqn. 8).

tings SNeRV can be seen as a new, supervised version of stochastic neighbor embedding, but more generally it manages a flexible tradeoff between precision and recall of the information retrieval just like the unsupervised NeRV does.

SNeRV has the useful property that it can directly compute embeddings for unlabeled training points as well as labeled ones. By contrast, some supervised nonlinear dimensionality reduction methods (Geng et al., 2005; Liu et al., 2005; Song et al., 2008) only give embeddings for labeled points; for unlabeled points, the mapping is approximated for instance by interpolation or by training

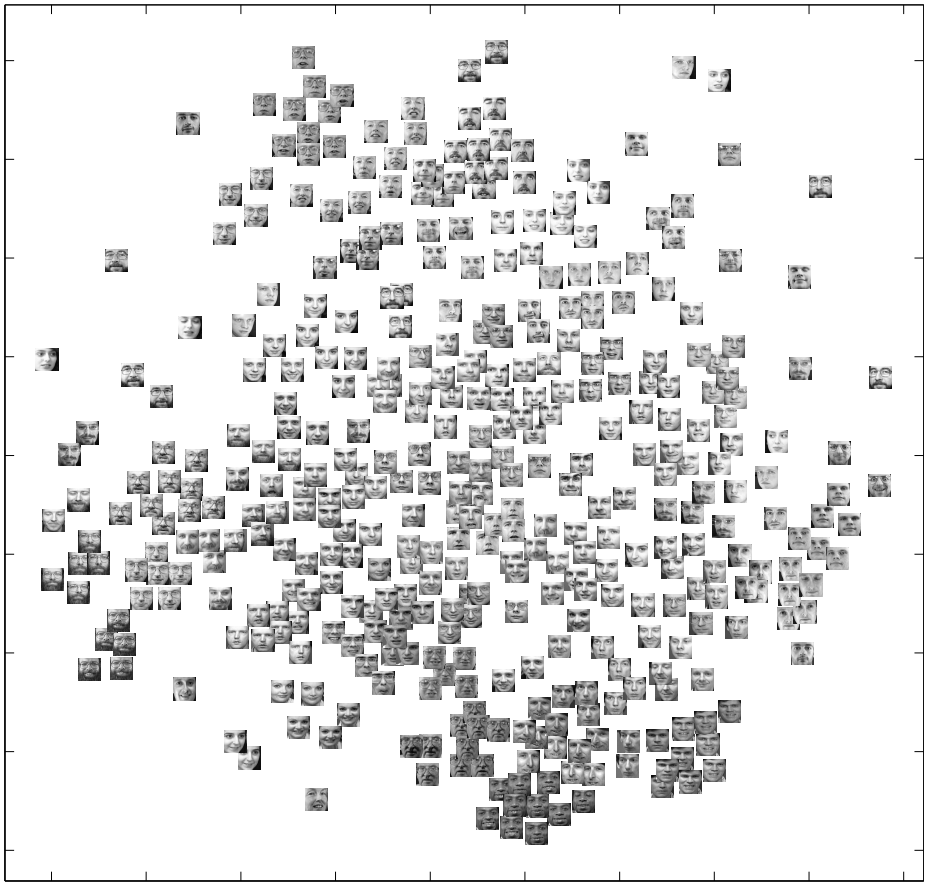

Figure 10: Example visualization of the Faces data set with CDA.

a neural network. Such approximation is not needed for SNeRV. (On the other hand, a trained neural network can embed not only unlabeled training points, but also previously unseen new points; if such generalization is desired, the same kinds of approximate mappings can be learned for SNeRV.)

In the next subsections we present the details of the distance computation, and then describe experimental comparisons showing that SNeRV outperforms several existing supervised methods.

5.1 Supervised Distances for NeRV

The input-space distances for SNeRV are computed using *learning metrics* (Kaski et al., 2001; Kaski and Sinkkonen, 2004; Peltonen et al., 2004). It is a formalism particularly suited for so-called "supervised unsupervised learning" where the final goal is still to make discoveries as in unsupervised learning, but the metric helps to focus the analysis by emphasizing useful features and, moreover, does that locally, differently for different samples. Learning metrics have previously been applied to clustering and visualization.

In brief, the learning metric is a Riemannian topology-preserving metric that measures distances in terms of changes in the class distribution. The class distribution is estimated through

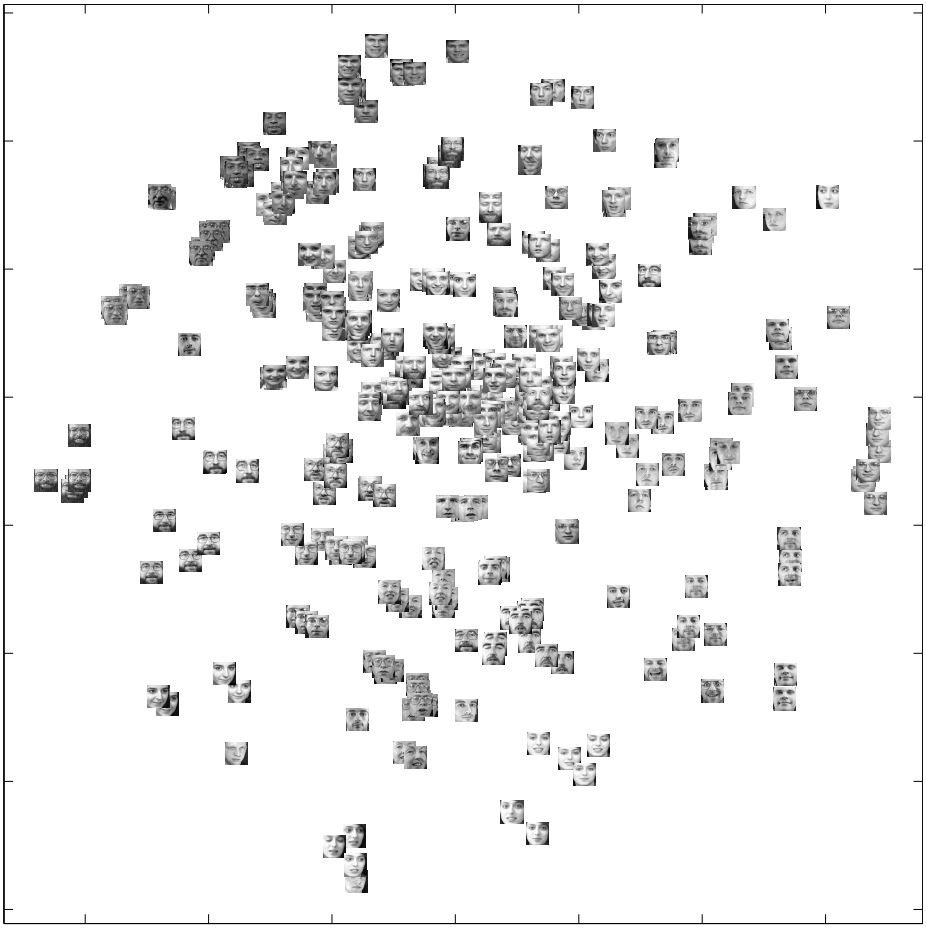

Figure 11: Example visualization of the Faces data set with NeRV, here maximizing precision (tradeoff parameter $\lambda = 0$).

conditional density estimation from labeled samples. Topology preservation helps in generalizing to new points, since class information cannot override the input space topology. In this metric, we can compute input-space distances between any two data points, and hence visualize the points with NeRV, whether they have known labels or not.

5.1.1 DEFINITION

The learning metric is a so-called Riemannian metric. Such a metric is defined in a local manner; between two (infinitesimally) close-by points it has a simple form, and this simple form is extended through path integrals to global distances.

In the learning metric, the squared distance between two close-by points $\mathbf{x}_1$ and $\mathbf{x}_2$ is given by the quadratic form

$$d_L(\mathbf{x}_1, \mathbf{x}_2)^2 = (\mathbf{x}_1 - \mathbf{x}_2)^T \mathbf{J}(\mathbf{x}_1)(\mathbf{x}_1 - \mathbf{x}_2). \tag{9}$$

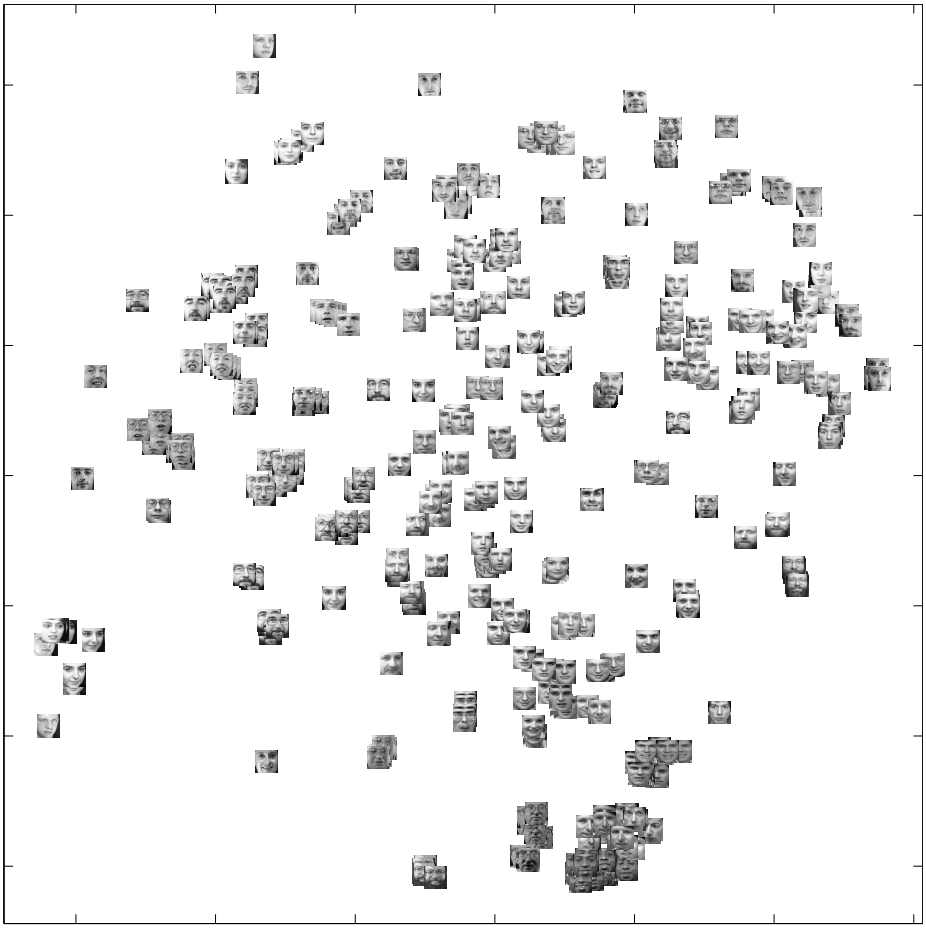

Figure 12: Example visualization of the Faces data set with t-NeRV, here maximizing precision (tradeoff parameter $\lambda = 0$).

Here $\mathbf{J}(\mathbf{x})$ is the Fisher information matrix which describes the local dependency of the conditional class distribution on the input features, that is,

$$\mathbf{J}(\mathbf{x}) = \sum_c p(c|\mathbf{x}) \left(\frac{\partial}{\partial \mathbf{x}} \log p(c|\mathbf{x}) \right) \left(\frac{\partial}{\partial \mathbf{x}} \log p(c|\mathbf{x}) \right)^T .$$

Here the c are the classes and the $p(c|\mathbf{x})$ are the conditional class probabilities at point $\mathbf{x}$. The idea is that the local distances grow the most along directions where the conditional class distribution $p(c|\mathbf{x})$ changes the most. It can be shown that the quadratic form (9) is, for close-by points, equivalent to the Kullback-Leibler divergence $D(p(c|\mathbf{x}_1), p(c|\mathbf{x}_2))$.

The general distance $d_L(\mathbf{x}_1, \mathbf{x}_2)$ between two far-away points $\mathbf{x}_1$ and $\mathbf{x}_2$ is defined in the standard fashion of Riemannian metrics: the distance is the *minimal path integral* over local distances, where the minimum is taken over all possible paths connecting $\mathbf{x}_1$ and $\mathbf{x}_2$. Notice that in a Riemannian metric, the straight path may not yield the minimum distance.

Learning metrics defined in the above manner satisfy the three criteria required of any metric: the distances d_L are nonnegative, symmetric, and satisfy the triangle inequality. Because the learning metric distances are defined as minimal path integrals they preserve the topology of the input space; roughly speaking, if the distance between two points is small, then there must be a path between them where distances are small along the entire path.

5.1.2 PRACTICAL COMPUTATION

In order to compute local distances using the Fisher information matrices $\mathbf{J}(\mathbf{x})$, we need an estimate for the conditional probability distributions $p(c|\mathbf{x})$. We learn the distributions by optimizing a discriminative mixture of labeled Gaussian densities for the data (Peltonen et al., 2004). The conditional density estimate is of the form

$$\hat{p}(c|\mathbf{x}) = \frac{\sum_{k=1}^{K} \beta_{ck} \exp(-||\mathbf{x}-\mathbf{m}_k||^2/2\sigma^2)}{\sum_{k=1}^{K} \exp(-||\mathbf{x}-\mathbf{m}_k||^2/2\sigma^2)} \tag{10}$$

where the number of Gaussians K, the centroids $\mathbf{m}_k$, the class probabilities β_{ck} and the Gaussian width σ (standard deviation) are parameters of the estimate; we require that the β_{ck} are nonnegative and that $\sum_c \beta_{ck} = 1$ for all k. The $\mathbf{m}_k$ and β_{ck} are optimized by a conjugate gradient algorithm to maximize the conditional class likelihood, and K and σ are chosen by internal cross-validation (see Section 5.3).

Given the Fisher matrices, we next need to compute the global distances between all point pairs. In most cases the minimal path integrals in the global distance definition cannot be computed analytically, and we use a graph-based approximation. We first form a fully connected graph between all known data points, where the path between each pair of points is approximated by a straight line. For these straight paths, the path integral can be computed by piecewise approximation (see Peltonen et al., 2004, for details; we use $T = 10$ pieces in all experiments). We could then use graph search (Floyd's algorithm) to find the shortest paths in the graph and use the shortest path distances as the learning metric distances. This graph approximation would take $O(n^3)$ time where n is the number of data points; note that this would not be excessive since a similar graph computation is needed in methods like isomap. However, in our experiments the straight line paths yielded about equally good results, so we simply use them, which takes only $O(n^2)$ time. Therefore SNeRV as a whole took only $O(n^2)$ time just like NeRV.

5.2 Comparison Methods for Supervised Visualization

For each data set to be visualized, the choice of supervised vs. unsupervised visualization is up to the analyst; in general, supervised embedding will preserve differences between classes better but at the expense of within-class details. In the experiments of this section we concentrate on comparing performances of supervised methods; we will compare SNeRV to three recent supervised nonlinear embedding methods.

Multiple relational embedding (MRE; Memisevic and Hinton, 2005) was proposed as an extension of stochastic neighbor embedding (Hinton and Roweis, 2002). MRE minimizes a sum of mismatches, measured by Kullback-Leibler divergence, between neighborhoods in the embedding and several different input neighborhoods: typically one of the input neighborhoods is derived from the input-space coordinates and the others are derived from auxiliary information such as labels.

MRE is able to use unlabeled data; for unlabeled points, divergences that involve neighborhoods based on labels are simply left out of the cost function.

Colored maximum variance unfolding (Song et al., 2008) is an extension of the unsupervised maximum variance unfolding. It maximizes the dependency between the embedding coordinates and the labels according to the Hilbert-Schmidt independence criterion, which is based on a cross-covariance operator. This leads to constrained optimization of the output kernel. Because of these details the method is also called maximum unfolding via Hilbert-Schmidt independence criterion (MUHSIC); we use this abbreviation.

Supervised isomap (S-Isomap; Geng et al., 2005) is an extension of the unsupervised isomap. The only difference to unsupervised isomap is a new definition of the input-space distances: roughly speaking, distances between points in different classes will grow faster than distances between same-class points. The actual embedding is done in the same way as in unsupervised isomap (described in Section 4.1). Other supervised extensions of isomap have been introduced by Li and Guo (2006) and Gu and Xu (2007).

Parametric embedding (PE; Iwata et al., 2007) represents the embedded data with a Gaussian mixture model with all Gaussians having the same covariances in the embedding space, and attempts to preserve the topology of the original data by minimizing a sum of Kullback-Leibler divergences.

Neighbourhood component analysis (NCA; Goldberger et al., 2005; see also Kaski and Peltonen, 2003, Peltonen and Kaski, 2005) is a linear and non-parametric dimensionality reduction method which learns a Mahalanobis distance measure such that, in the transformed space, k-nearest neighbor classification achieves the maximum accuracy.

5.3 Methodology for the Supervised Experiments

We used the four benchmark data sets having class information (Letter, Phoneme, Landsat, and TIMIT described in Section 4.5) to compare supervised NeRV and the five supervised visualization methods described in Section 5.2, namely multiple relational embedding (MRE), colored maximum variance unfolding (MUHSIC), supervised isomap (S-Isomap), parametric embedding (PE), and neighbourhood component analysis (NCA). We used a standard 10-fold cross-validation setup: in each fold we reserve one of the subsets for testing and use the rest of the data for training. For each data set, we use SNeRV and the comparison methods to find 2-dimensional visualizations.

In principle we could evaluate the results as in Section 4.3 for the unsupervised experiments, that is, by mean smoothed precision and recall; the only difference would be to use the supervised learning metric for the evaluation. However, unlike SNeRV, the other methods have not been formulated using the same supervised metrics. To make an unbiased comparison of the methods, we resort to a simple indirect evaluation: we evaluate the performance of the four methods by class prediction accuracy of the resulting visualizations. Although it is an indirect measure, the accuracy is a reasonable choice for unbiased comparison and has been used in several supervised dimensionality reduction papers. In more detail, we provide test point locations during training but not their labels; after the methods have computed their visualization results, we classify the test points by running a k-nearest neighbor classifier ($k = 5$) on the embedded data, and evaluate the classification error rates of the methods.

We use a standard internal 10-fold validation strategy to choose all parameters which are not optimized by their respective algorithms: each training set is subdivided into 10 folds where 9/10 of data is used for learning and 1/10 for validation; we learn visualizations with the different parameter

values; the values that yielded the best classification accuracy for the embedded validation points are then chosen and used to compute the final visualization for the whole training data.

We ran two versions of SNeRV using $\lambda = 0.1$ and $\lambda = 0.3$. The scaling parameters σ_i were set by fixing the entropy of the input neighborhoods as described in Section 2.2. Here we specified the rough upper limit for the number of relevant neighbors as $0.5 \cdot n/K$ where n is the number of data points and K is the number of mixture components used to estimate the metric; this choice roughly means that for well-separated mixture components, each data point will on average consider half of the data points from the same mixture component as relevant neighbors. A simplified validation sufficed for the number K and width σ of Gaussians: we did not need to run the embedding step but picked the values that gave best conditional class likelihood for validation points in the input space. For S-Isomap we chose its parameter α and its number of nearest neighbors using the validation sets, and trained a generalized radial basis function network to project new points, as suggested by Geng et al. (2005). For MUHSIC, the parameters are the regularization parameter ν, number of nearest neighbors, and number of eigenvectors in the graph Laplacian, and we used linear interpolation to project new points as suggested by the MUHSIC authors. For MRE the only free parameter is its neighborhood smoothness parameter σ_{MRE}. For the PE one needs to provide a conditional density estimate: we used the same one that SNeRV uses (see Equation 10) to obtain a comparison as unbiased as possible. Neighbourhood component analysis is a non-parametric method, therefore we did not need to choose any parameters for it.

5.4 Results of Supervised Visualization

Figure 13 shows the average error rate over the 10 folds as well as the standard deviation. The best two methods are SNeRV and PE, which give good results in all data sets. On two of the data sets (Letter and TIMIT) SNeRV is clearly the best; on the other two data sets (Phoneme and Landsat) SNeRV is about as good as the best of the remaining methods (S-Isomap and parametric embedding, respectively). MRE is clearly worse than the other methods, whereas MUHSIC and NCA results depend on the data set: on Letter they are the second and third worst methods after MRE, while in the other data sets they are not far from the best methods.

The value of the tradeoff parameter λ did not affect the performance of SNeRV much; both $\lambda = 0.1$ and $\lambda = 0.3$ produced good projections.

To evaluate whether the best method on each data set is statistically significantly better than the next best one, we performed a paired t-test of the performances across the 10 cross-validation folds (Table 3). The two best methods compared are always SNeRV and parametric embedding, except for the Phoneme data set for which the two best methods are SNeRV and S-Isomap. For the Letter and the TIMIT data sets SNeRV is significantly better than the next best method, while for the other two data sets the difference is not significant. In summary, all the significant differences are in favor of SNeRV.

Figure 14 presents sample visualizations of the letter recognition data set; projection results are shown for one of the 10 cross-validation folds, including both training and test points. Although there is some overlap, in general SNeRV shows distinct clusters of classes—for example, the letter "M" is a well separated cluster in the top of the figure.

Parametric embedding also manages to separate some letters, such as "A" and "I", but there is a severe overlap of classes in the center of the figure. In S-Isomap we see that there are a few very well separated clusters of classes, like the letters "W" and "N", but there is a large area with

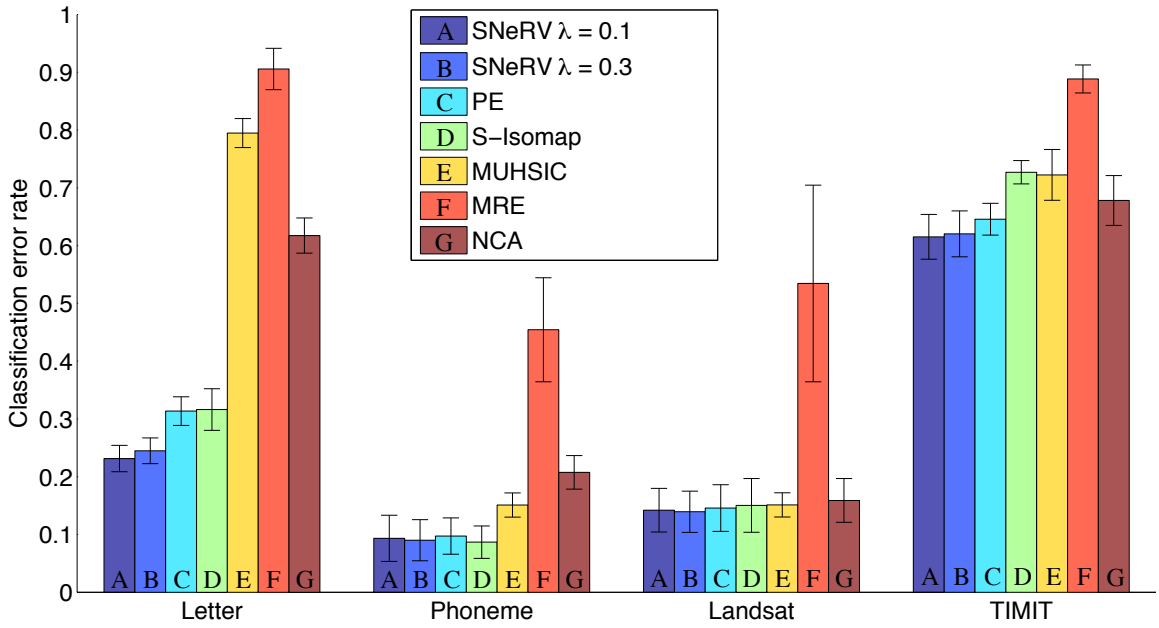

Figure 13: Performance of the supervised nonlinear embedding methods in each benchmark data set. The results are average classification error rates over 10 cross-validation folds (smaller is better), and the standard deviations are shown with error bars.

Data set	Best method	Second best	p-value
Letter	**SNeRV ($\lambda = 0.1$)**	PE	$1.8 \cdot 10^{-6}$
Phoneme	S-Isomap	SNeRV ($\lambda = 0.3$)	0.54
Landsat	SNeRV ($\lambda = 0.3$)	PE	0.28
TIMIT	**SNeRV ($\lambda = 0.1$)**	PE	$3.4 \cdot 10^{-3}$

Table 3: Statistical significance of the difference between the two best methods. The p-values are from a paired t-test of the 10-fold cross-validation results; statistically significant winners have been boldfaced.

overlapping classes near the center of the right edge of the figure. This overlap is worse than in SNeRV but still roughly comparable; by contrast, MUHSIC, MRE and NCA performed poorly on this data set, leaving most classes severely overlapped.

6. Conclusions and Discussion

By formulating the task of nonlinear projection for information visualization as an information retrieval task, we have derived a rigorously motivated pair of measures for visualization performance, *mean smoothed precision* and *mean smoothed recall*. We showed that these new measures are extensions of two traditional information retrieval measures: mean smoothed precision can be interpreted as a more sophisticated extension of mean precision, the proportion of false positives in the neigh-

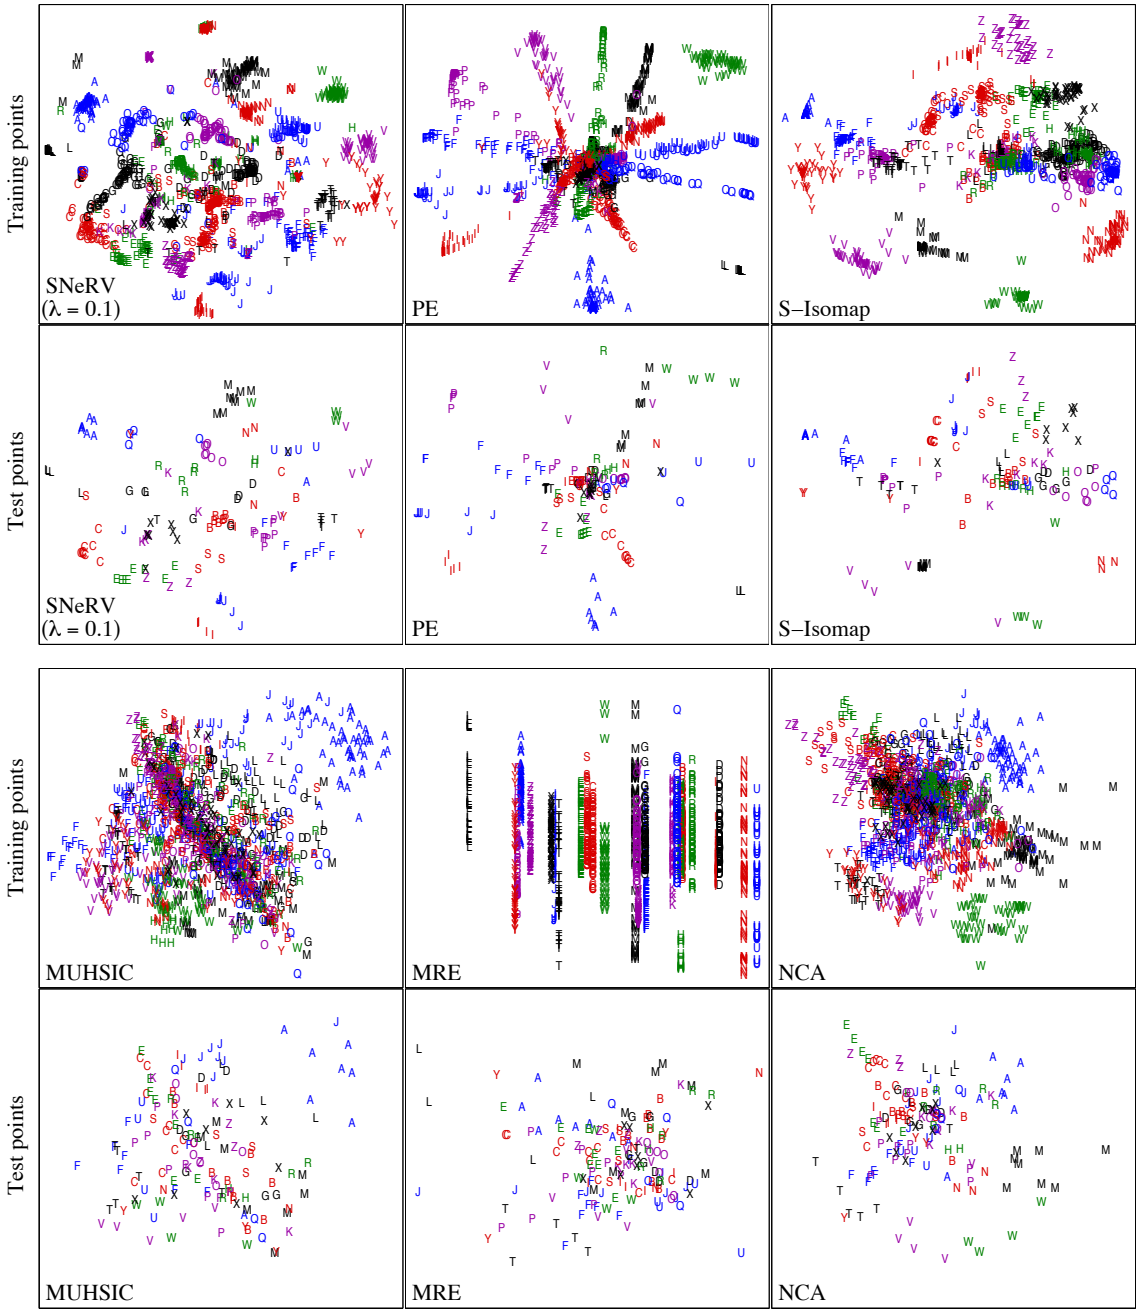

Figure 14: Visualizations of the letter recognition data set by all supervised methods.

borhood retrieved from the visualization. Analogously, mean smoothed recall is an extension of mean recall, the proportion of misses incurred by the retrieved neighborhood.

We introduced an algorithm called *neighbor retrieval visualizer* (NeRV) that optimizes the total cost, interpretable as a tradeoff between mean smoothed precision and mean smoothed recall. The tradeoff is governed by a parameter λ set by the user according to the desired cost of a miss relative

to the desired cost of a false positive. The earlier method stochastic neighbor embedding is obtained as a special case when $\lambda = 1$, optimizing mean smoothed recall.

We showed that NeRV can be used for both unsupervised and supervised visualization. For unsupervised visualization, we simply use fixed input distances; for supervised visualization we learn a supervised distance metric for the input space and plug the resulting input distances to the NeRV algorithm. In the latter case the key idea is to use supervision (labeled data) in a way that does not override the input feature space; we use a topology-preserving class-discriminative metric called the *learning metric* for the input space.

In unsupervised visualization, NeRV outperformed alternatives for most of the six data sets we tried, for four different pairs of measures, and was overall the best method. NeRV also performed well in a comparison by unsupervised classification. Many of the best manifold extraction methods perform surprisingly poorly, most likely because they have not been designed to reduce the dimensionality below the intrinsic dimensionality of the data manifold. In visualization, however, we generally have no choice but to reduce the dimensionality of the data to two or three, even if its intrinsic dimensionality is higher. NeRV is designed to find a mapping that is, in a well-defined sense, optimal for a certain type of visualization regardless of the intrinsic dimensionality of the data.

In supervised visualization, the supervised version of NeRV performed as well as or better than the best alternative method Parametric embedding; this shows that the plug-in learning metrics work well in incorporating supervision.

6.1 Discussion

NeRV models relevance using probability distributions, which makes sense if the total "amount" of relevance for any query is normalized to a fixed sum. Such normalization is desirable for any relevance measure, because for any query (point of interest) the relevance of a retrieved neighbor point should depend on its proximity relative to the proximities of other points, rather than on its absolute distance from the query point. (Our previous method, local MDS, can be thought of as an attempt to approximate NeRV without the normalization.)

The Kullback-Leibler divergences in NeRV are natural choices for measuring the difference between two probability distributions, but in principle other divergence measures could be used as well. The notions of neighbor retrieval and a probabilistic relevance model are the crucial parts of NeRV, not the specific divergence measure.

Our notion of plug-in supervised metrics could in principle be used with other methods too; other unsupervised embedding algorithms that work based on a distance matrix can also be turned into supervised versions, by plugging in learning metric distances into the distance matrix. We performed an initial experiment with Sammon's mapping (Peltonen et al., 2004); a similar idea for isomap appeared later (Weng et al., 2005). However, we believe that NeRV is an especially attractive choice for the embedding step since it has the information retrieval interpretation and it performed well empirically.

An implementation of the NeRV and local MDS algorithms as well as the *mean smoothed precision-mean smoothed recall* measures is available at `http://www.cis.hut.fi/projects/mi/software/dredviz`

Appendix A. Proof of the Connection between the Probabilistic Cost Functions and Precision and Recall

In Section 2.2 we introduced Kullback-Leibler divergences as cost functions for visual neighbor retrieval, based on probability distributions q_i and p_i which generalize the relevance model implicit in precision and recall. We will next show that in the simple case of "binary neighborhoods" the cost functions reduce to precision and recall. By "binary neighborhoods" we mean that, in both the input space and the visualization, (i) the point of interest has some number of relevant neighbors and all the other points are completely irrelevant, and (ii) the points that are relevant are all equally relevant.

In the probabilistic model the binary neighborhoods can be interpreted as follows. Let i be the point of interest, and let P_i be the set of relevant neighbors for point i in the input space. P_i can be the set of all points (other than i itself) falling inside some fixed radius from point i in the input space, or it can be the set containing some fixed number of points nearest to i in the input space. In either case, let r_i be the size of P_i.

We define that the relevant neighbors of the point of interest i have an equal non-zero probability of being chosen, and all the other points have a near-zero probability of being chosen. In other words, we define

$$p^*_{j|i} = \begin{cases} a_i \equiv \frac{1-\delta}{r_i}\,, & \text{if point } j \text{ is in } P_i \\ b_i \equiv \frac{\delta}{N-r_i-1}\,, & \text{otherwise.} \end{cases}$$

Here N is the total number of data points, and $0 < \delta \ll 0.5$ gives the irrelevant points a very small probability.

Similarly, let Q_i be the set of neighbors for point i in the visualization. Again, Q_i can be the set of all points (other than i itself) falling inside some fixed radius from point i in the visualization, or it can be the set containing some fixed number of points nearest to i in the visualization. In either case, let k_i be the size of Q_i. Note that the sizes of Q_i and P_i can be different, that is, k_i can be different from r_i.

We define the probability of choosing a neighbor from the visualization as

$$q^*_{j|i} = \begin{cases} c_i \equiv \frac{1-\delta}{k_i}\,, & \text{if point } j \text{ is in } Q_i \\ d_i \equiv \frac{\delta}{N-k_i-1}\,, & \text{otherwise.} \end{cases}$$

Consider the Kullback-Leibler divergence $D(p^*_i, q^*_i)$ for any fixed i. We now show that minimizing this divergence is equivalent to maximizing recall where point i is the query. The divergence is a sum over elements $p^*_{j|i} \log \frac{p^*_{j|i}}{q^*_{j|i}}$, thus the sum can be divided into four parts depending on which

value $p^*_{j|i}$ takes (two possibilities) and which value $q^*_{j|i}$ takes (two possibilities). We get

$$\begin{aligned}
D(p^*_i, q^*_i) = &\sum_{j\neq i, p^*_{j|i}=a_i, q^*_{j|i}=c_i} \left(a_i \log \frac{a_i}{c_i}\right) + \sum_{j\neq i, p^*_{j|i}=a_i, q^*_{j|i}=d_i} \left(a_i \log \frac{a_i}{d_i}\right) \\
&+ \sum_{j\neq i, p^*_{j|i}=b_i, q^*_{j|i}=c_i} \left(b_i \log \frac{b_i}{c_i}\right) + \sum_{j\neq i, p^*_{j|i}=b_i, q^*_{j|i}=d_i} \left(b_i \log \frac{b_i}{d_i}\right) \\
&= \left(a_i \log \frac{a_i}{c_i}\right) N_{\mathrm{TP},i} + \left(a_i \log \frac{a_i}{d_i}\right) N_{\mathrm{MISS},i} + \left(b_i \log \frac{b_i}{c_i}\right) N_{\mathrm{FP},i} + \left(b_i \log \frac{b_i}{d_i}\right) N_{\mathrm{TN},i}
\end{aligned}$$

where on the last line the terms inside parentheses are simply constant coefficients. Here $N_{\mathrm{TP},i}$ is the number of true positives for this query, that is, points for which the probability is high in both the data and the visualization. The number of misses, that is, the number of points that have a low probability in the visualization although the probability in the data is high, is $N_{\mathrm{MISS},i}$. The number of false positives (high probability in the visualization, low in the data) is $N_{\mathrm{FP},i}$. Finally the number of true negatives (low probability in both the visualization and the data) is $N_{\mathrm{TN},i}$.

It is straightforward to check that if δ is very small, then the coefficients for the misses and false positives dominate the divergence. This yields

$$\begin{aligned}
D(p^*_i, q^*_i) &\approx N_{\mathrm{MISS},i} \left(a_i \log \frac{a_i}{d_i}\right) + N_{\mathrm{FP},i} \left(b_i \log \frac{b_i}{c_i}\right) \\
&= N_{\mathrm{MISS},i} \frac{1-\delta}{r_i} \left(\log \frac{(N-k_i-1)}{\delta} + \log \frac{(1-\delta)}{r_i}\right) \\
&+ N_{\mathrm{FP},i} \frac{\delta}{N-r_i-1} \left(\log \frac{\delta}{N-r_i-1} - \log \frac{(1-\delta)}{k_i}\right) \\
&= N_{\mathrm{MISS},i} \frac{1-\delta}{r_i} \left(\log \frac{(N-k_i-1)}{r_i} + \log \frac{(1-\delta)}{\delta}\right) \\
&\qquad + N_{\mathrm{FP},i} \frac{\delta}{N-r_i-1} \left(\log \frac{k_i}{N-r_i-1} - \log \frac{(1-\delta)}{\delta}\right) . \quad (11)
\end{aligned}$$

Because the terms $\log[(1-\delta)/\delta]$ dominate the other logarithmic terms, (11) further simplifies to

$$\begin{aligned}
D(p^*_i, q^*_i) &\approx \left(N_{\mathrm{MISS},i} \frac{1-\delta}{r_i} - N_{\mathrm{FP},i} \frac{\delta}{N-r_i-1}\right) \log \frac{(1-\delta)}{\delta} \\
&\approx N_{\mathrm{MISS},i} \frac{1-\delta}{r_i} \log \frac{(1-\delta)}{\delta} = \frac{N_{\mathrm{MISS},i}}{r_i} C
\end{aligned}$$

where C is a constant that only depends on δ and not on i. Hence if we minimized this cost function, we would be maximizing the recall of the query, which is defined as

$$\mathrm{recall}(i) = \frac{N_{\mathrm{TP},i}}{r_i} = 1 - \frac{N_{\mathrm{MISS},i}}{r_i} .$$

We can analogously show that for any fixed i, minimizing $D(q^*_i, p^*_i)$ is equivalent to maximizing precision of the corresponding query.

Because $D(q^*_i, p^*_i)$ and $D(p^*_i, q^*_i)$ are equivalent to precision and recall, and p_i and q_i can be seen as more sophisticated generalizations of p^*_i and q^*_i, we interpret $D(q_i, p_i)$ and $D(p_i, q_i)$ as more sophisticated generalizations of precision and recall.

Abstract

A variational level set method is developed for the supervised classification problem. Nonlinear classifier decision boundaries are obtained by minimizing an energy functional that is composed of an empirical risk term with a margin-based loss and a geometric regularization term new to machine learning: the surface area of the decision boundary. This geometric level set classifier is analyzed in terms of consistency and complexity through the calculation of its ε-entropy. For multicategory classification, an efficient scheme is developed using a logarithmic number of decision functions in the number of classes rather than the typical linear number of decision functions. Geometric level set classification yields performance results on benchmark data sets that are competitive with well-established methods.

Keywords: level set methods, nonlinear classification, geometric regularization, consistency, complexity

1. Introduction

Variational level set methods, pioneered by Osher and Sethian (1988), have found application in fluid mechanics, computational geometry, image processing and computer vision, computer graphics, materials science, and numerous other fields, but have heretofore found little application in machine learning. The goal of this paper is to introduce a level set approach to the archetypal machine learning problem of supervised classification. We propose an implicit level set representation for classifier decision boundaries, a margin-based objective regularized by a surface area penalty, and an Euler-Lagrange descent optimization algorithm for training.

Several well-developed techniques for supervised discriminative learning exist in the literature, including the perceptron algorithm (Rosenblatt, 1958), logistic regression (Efron, 1975), and support vector machines (SVMs) (Vapnik, 1995). All of these approaches, in their basic form, produce linear decision boundaries. Nonlinear boundaries in the input space can be obtained by mapping the input space to a feature space of higher (possibly infinite) dimension by taking nonlinear functions of the input variables. Learning algorithms are then applied to the new higher-dimensional feature space by treating each dimension linearly. They retain the efficiency of the input lower-dimensional space for particular sets of nonlinear functions that admit the kernel trick (Schölkopf and Smola, 2002).

As an alternative to kernel methods for generalizing linear methods, we propose finding nonlinear decision boundaries directly in the input space. We propose an energy functional for clas-

sification that is composed of an empirical risk term that uses a margin-based loss function and a complexity term that is the length of the decision boundary for a two-dimensional input space and the surface area of the decision boundary more generally. The empirical risk term is standard in many classification methods. What is new in this work is the measurement of decision boundary complexity by surface area, an inherently geometric quantity, and the idea of using variational level set methods for optimization in discriminative learning.

We use the term *contour* to refer to a one-dimensional curve in a two-dimensional space, a two-dimensional surface in a three-dimensional space, and generally a $D-1$ dimensional hypersurface in a D-dimensional space. Classifier decision boundaries partition the input space into regions corresponding to the different class labels. If the region corresponding to one class label is composed of several unconnected pieces, then the corresponding decision boundary is composed of several unconnected pieces; we refer to this entire collection of decision boundaries as the contour. The level set representation is a flexible, implicit representation for contours that does not require knowing the number of disjoint pieces in advance. The contour is represented by a smooth, Lipschitz continuous, scalar-valued function, known as the *level set function*, whose domain is the input space. The contour is implicitly specified as the zero level set of the level set function.

Level set methods entail not only the representation, but also the minimization of an energy functional whose argument is the contour.[1] For example, in foreground-background image segmentation, a popular energy functional is mean squared error of image intensity with two different 'true' image intensities inside the contour and outside the contour. Minimizing this energy produces a good segmentation when the two regions differ in image intensity. In order to perform the minimization, a gradient descent approach is used. The first variation of the functional is found using the calculus of variations; starting from an initial contour, a gradient flow is followed iteratively to converge to a minimum. This procedure is known as *curve evolution* or *contour evolution*.

The connection between level set methods (particularly for image segmentation) and classification has been noticed before, but to the best of our knowledge, there has been little prior work in this area. Boczko et al. (2006) only hint at the idea of using level set methods for classification. Tomczyk and Szczepaniak (2005) do not consider fully general input spaces. Specifically, examples in the training and test sets must be pixels in an image with the data vector containing the spatial index of the pixel along with other variables. Cai and Sowmya (2007) do consider general feature spaces, but have a very different energy functional than our margin-based loss functional. Theirs is based on counts of training examples in grid cells and is similar to the mean squared error functional for image segmentation described earlier. Their learning is also based on one-class classification rather than standard discriminative classification, which is the framework we follow. Yip et al. (2006) use variational level set methods for density-based clustering in general feature spaces, rather than for learning classifiers.

Cremers et al. (2007) dichotomize image segmentation approaches into those that use spatially continuous representations and those that use spatially discrete representations, with level set methods being the main spatially continuous approaches. There have been methods using discrete representations that bear some ties to our methods. An example of a spatially discrete approach uses normalized graph cuts (Shi and Malik, 2000), a technique that has been used extensively in unsupervised learning for general features unrelated to images as well. Normalized decision boundary surface area is implicitly penalized in this discrete setting. Geometric notions of complexity in su-

1. In the image segmentation literature, variational energy minimization approaches often go by the name *active contours*, whether implemented using level set methods or not.

pervised classification tied to decision boundary surface area have been suggested by Ho and Basu (2002), but also defined in a discrete way related to graph cuts. In contrast, the continuous formulation we employ using level sets involves very different mathematical foundations, including explicit minimization of a criterion involving surface area. Moreover, the continuous framework—and in particular the natural way in which level set functions enter into the criterion—lead to new gradient descent algorithms to determine optimal decision boundaries. By embedding our criterion in a continuous setting, the surface area complexity term is defined intrinsically rather than being defined in terms of the graph of available training examples.

There are some other methods in the literature for finding nonlinear decision boundaries directly in the input space related to image segmentation, but these methods use neither contour evolution for optimization, nor the surface area of the decision boundary as a complexity term, as in the level set classification method proposed in this paper. A connection is drawn between classification and level set image segmentation in Scott and Nowak (2006) and Willett and Nowak (2007), but the formulation is through decision trees, not contour evolution. Tomczyk (2005), Tomczyk and Szczepaniak (2006), and Tomczyk et al. (2007) present a simulated annealing formulation given the name adaptive potential active hypercontours for finding nonlinear decision boundaries in both the classification and clustering problems; their work considers the use of radial basis functions in representing the decision boundary. Pölzlbauer et al. (2008) construct nonlinear decision boundaries in the input space from connected linear segments. In some ways, their approach is similar to active contours methods in image segmentation such as snakes that do not use the level set representation: changes in topology of the decision boundary in the optimization are difficult to handle. (The implicit level set representation takes care of topology changes naturally.)

The theory of classification with Lipschitz functions was discussed by von Luxburg and Bousquet (2004). As mentioned previously, level set functions are Lipschitz functions and the specific level set function that we use, the *signed distance function*, has a unit Lipschitz constant. Von Luxburg and Bousquet minimize the Lipschitz constant, whereas in our formulation, the Lipschitz constant is fixed. The von Luxburg and Bousquet formulation requires the specification of a subspace of Lipschitz functions over which to optimize in order to prevent overfitting, but does not resolve the question of how to select this subspace. The surface area penalty that we propose provides a natural specification for subspaces of signed distance functions.

The maximum allowable surface area parameterizes nested subspaces. We calculate the ε-entropy (Kolmogorov and Tihomirov, 1961) of these signed distance function subspaces and use the result to characterize geometric level set classification theoretically. In particular, we look at the consistency and convergence of level set classifiers as the size of the training set grows. We also look at the Rademacher complexity (Koltchinskii, 2001; Bartlett and Mendelson, 2002) of level set classifiers.

For the multicategory classification problem with $M > 2$ classes, typically binary classification methods are extended using the *one-against-all* construction (Hsu and Lin, 2002). The one-against-all scheme represents the classifier with M decision functions. We propose a more parsimonious representation of the multicategory level set classifier that uses $\log_2 M$ decision functions.[2] A collection of $\log_2 M$ level set functions can implicitly specify M regions using a binary encoding like a Venn diagram (Vese and Chan, 2002). This proposed logarithmic multicategory classification is

2. It is certainly possible to use one-against-all with the proposed level set classification methodology. In fact, there are M-category level set methods that use M level set functions (Samson et al., 2000; Paragios and Deriche, 2002), but they are less parsimonious than the approach we follow.

new, as there is no logarithmic formulation for M-category classification in the machine learning literature. The energy functional that is minimized has a multicategory empirical risk term and surface area penalties on $\log_2 M$ contours.

The level set representation of classifier decision boundaries, the surface area regularization term, the logarithmic multicategory classification scheme, and other contributions of this paper are not only interesting academically, but also practically. We compare the classification performance of geometric level set classification on several binary and multicategory data sets from the UCI Repository and find the results to be competitive with many classifiers used in practice.

Level set methods are usually implemented on a discretized grid, that is the values of the level set function are maintained and updated on a grid. In physics and image processing applications, it nearly always suffices to work in two- or three-dimensional spaces. In classification problems, however, the input data space can be high-dimensional. Implementation of level set methods for large input space dimension becomes cumbersome due to the need to store and update a grid of that large dimension. One way to address this practical limitation is to represent the level set function by a superposition of radial basis functions (RBFs) instead of on a grid (Cecil et al., 2004; Slabaugh et al., 2007; Gelas et al., 2007). We follow this implementation strategy in obtaining classification results.

In Section 2, we detail geometric level set classification in the binary case, giving the objective to be minimized and the contour evolution to perform the minimization. In Section 3, we provide theoretical analysis of the binary level set classifier given in Section 2. The main result is the calculation of the ε-entropy of the space of level set classifiers as a function of the maximum allowable decision boundary surface area; this result is then applied to characterize consistency and complexity. Section 4 goes over multicategory level set classification. In Section 5, we describe the RBF level set implementation and use that implementation to compare the classification test performance of geometric level set classification to the performance of several other classifiers. Section 6 concludes and provides a summary of the work.

2. Binary Geometric Level Set Classification

In the standard binary classification problem, we are given training data $\{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)\}$ with data vectors $\mathbf{x}_i \in \Omega \subset \mathbb{R}^D$ and class labels $y_i \in \{+1, -1\}$ drawn according to some unknown probability density function $p_{\mathbf{X},Y}(\mathbf{x}, y)$ and we would like to learn a classifier $\hat{y} : \Omega \to \{+1, -1\}$ that classifies previously unseen data vectors well. A popular approach specifies the classifier as $\hat{y}(\mathbf{x}) = \text{sign}(\varphi(\mathbf{x}))$, where φ is a scalar-valued function. This function is obtained by minimizing the empirical risk over a model class $\mathcal{F}$:

$$\min_{\varphi \in \mathcal{F}} \sum_{i=1}^{n} \mathrm{L}(y_i \varphi(\mathbf{x}_i)). \tag{1}$$

A wide variety of margin-based loss functions L are employed in different classification methods, including the logistic loss in logistic regression, the hinge loss in the SVM, and the exponential loss in boosting: $\mathrm{L}_{\text{logistic}}(z) = \log(1 + e^{-z})$, $\mathrm{L}_{\text{hinge}}(z) = \max\{0, 1 - z\}$, and $\mathrm{L}_{\text{exponential}}(z) = e^{-z}$ (Bartlett et al., 2006; Lin, 2004). The loss function on which classifiers are typically evaluated is the misclassification zero-one loss: $\mathrm{L}_{\text{zero-one}}(z) = \text{step}(-z)$, where step is the Heaviside unit step function.

Limiting the model class is a way to control the complexity of the learned classifier in order to increase its generalization ability. This is the central idea of the structural risk minimization

principle (Vapnik, 1995). A model subclass can be specified directly through a constraint in the optimization by taking $\mathcal{F}$ to be the subclass in (1). Alternatively, it may be specified through a regularization term J with weight λ:

$$\min_{\varphi\in\mathcal{F}} \sum_{i=1}^{n} \mathrm{L}(y_i\varphi(\mathbf{x}_i)) + \lambda \mathrm{J}(\varphi), \tag{2}$$

where $\mathcal{F}$ indicates a broader class within which the subclass is delineated by $\mathrm{J}(\varphi)$.

We propose a geometric regularization term novel to machine learning, the surface area of the decision boundary:

$$\mathrm{J}(\varphi) = \oint_{\varphi=0} d\mathbf{s}, \tag{3}$$

where $d\mathbf{s}$ is an infinitesimal surface area element on the decision boundary. Decision boundaries that shatter more points are more tortuous than decision boundaries that shatter fewer points. The regularization functional (3) promotes smooth, less tortuous decision boundaries. It is experimentally shown in Varshney and Willsky (2008) that with this regularization term, there is an inverse relationship between the regularization parameter λ and the Vapnik-Chervonenkis (VC) dimension of the classifier. An analytical discussion of complexity is provided in Section 3.3. The empirical risk term and regularization term must be properly balanced as the regularization term by itself drives the decision boundary to be a set of infinitesimal hyperspheres.

We now describe how to find a classifier that minimizes (2) with the new regularization term (3) using the level set methodology. As mentioned in Section 1, the level set approach implicitly represents a $(D-1)$-dimensional contour C in a D-dimensional space Ω by a scalar-valued, Lipschitz continuous function φ known as the level set function (Osher and Fedkiw, 2003). The contour is the zero level set of φ. Contour C partitions Ω into the regions $\mathcal{R}$ and $\mathcal{R}^c$, which can be simply connected, multiply connected, or composed of several components. The level set function $\varphi(\mathbf{x})$ satisfies the properties: $\varphi(\mathbf{x}) < 0$ for $\mathbf{x} \in \mathcal{R}$, $\varphi(\mathbf{x}) > 0$ for $\mathbf{x} \in \mathcal{R}^c$, and $\varphi(\mathbf{x}) = 0$ for $\mathbf{x}$ on the contour C.

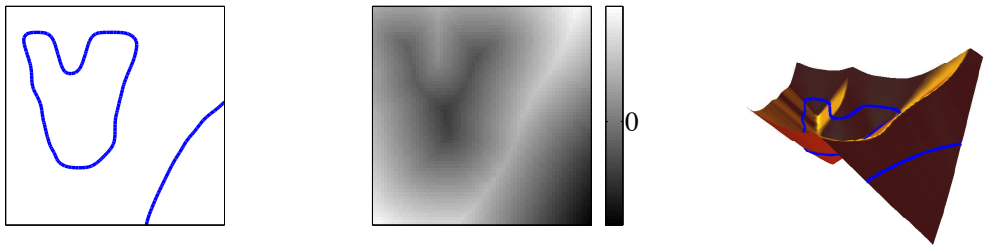
The level set function is often specialized to be the signed distance function, including in our work. The magnitude of the signed distance function at a point equals its distance to C, and its sign indicates whether it is in $\mathcal{R}$ or $\mathcal{R}^c$. The signed distance function satisfies the additional constraint that $\|\nabla\varphi(\mathbf{x})\| = 1$ and has Lipschitz constant equal to one. Illustrating the representation, a contour in a $D = 2$-dimensional space and its corresponding signed distance function are shown in Figure 1. For classification, we take $\mathcal{F}$ to be the set of all signed distance functions on the domain Ω in (2).

The general form of objective functionals in variational level set methods is

$$\mathrm{E}(C) = \int_{\mathcal{R}} g_{\mathrm{r}}(\mathbf{x}) d\mathbf{x} + \oint_{C} g_{\mathrm{b}}(C(\mathbf{s})) d\mathbf{s}, \tag{4}$$

where g_{r} is a region-based function and g_{b} is a boundary-based function. Note that the integral in the region-based functional is over $\mathcal{R}$, which is determined by C. Region-based functionals may also be integrals over $\mathcal{R}^c$, in place of or in addition to integrals over $\mathcal{R}$. In contour evolution, starting from some initial contour, the minimum of (4) is approached iteratively via a flow in the negative gradient direction. If we parameterize the iterations of the flow with a time parameter t, then it may be shown using the calculus of variations that the flow of C that implements the gradient descent is

$$\frac{\partial C}{\partial t} = -g_{\mathrm{r}}\mathbf{n} - \left(g_{\mathrm{b}}\kappa - \langle \nabla g_{\mathrm{b}}, \mathbf{n}\rangle\right)\mathbf{n}, \tag{5}$$



(a) (b) (c)

Figure 1: An illustration of the signed distance function representation of a contour with $D = 2$. The contour is shown in (a), its signed distance function is shown by shading in (b), and as a surface plot marked with the zero level set in (c).

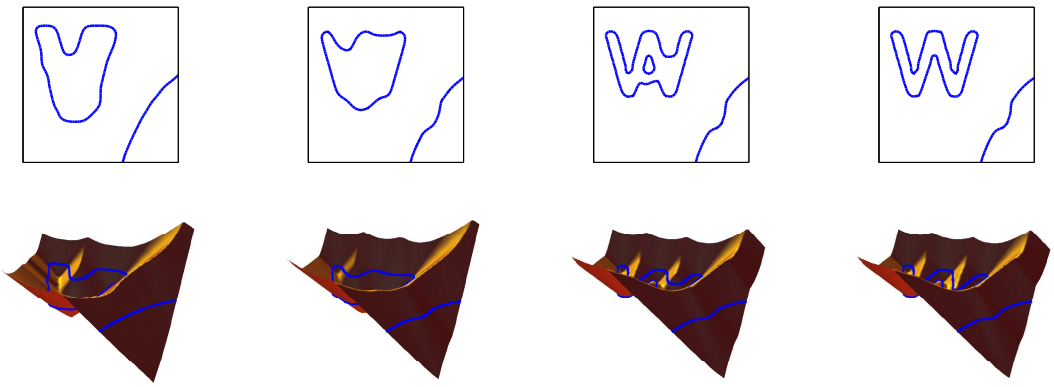


Figure 2: Iterations of an illustrative curve evolution proceeding from left to right. The top row shows the curve and the bottom row shows the corresponding signed distance function.

where $\mathbf{n}$ is the outward unit normal to C, and κ is its mean curvature (Caselles et al., 1997; Osher and Fedkiw, 2003). The mean curvature of a surface is an extrinsic measure of curvature from differential geometry that is the average of the principal curvatures. If the region-based function is integrated over $\mathcal{R}^c$, then the sign of the first term in (5) is reversed.

The flow of the contour corresponds to a flow of the signed distance function. The unit normal to the contour is $\nabla\varphi$ in terms of the signed distance function and the mean curvature is $\nabla^2\varphi$. The level set flow corresponding to (5) is

$$\frac{\partial\varphi(\mathbf{x})}{\partial t} = -g_{\mathrm{r}}(\mathbf{x})\nabla\varphi(\mathbf{x}) - \left(g_{\mathrm{b}}(\mathbf{x})\nabla^2\varphi(\mathbf{x}) - \langle\nabla g_{\mathrm{b}}(\mathbf{x}), \nabla\varphi(\mathbf{x})\rangle\right)\nabla\varphi(\mathbf{x}). \tag{6}$$

Figure 2 illustrates iterations of contour evolution.

For the classification problem, we have the following energy functional to be minimized:

$$\mathrm{E}(\varphi) = \sum_{i=1}^{n} \mathrm{L}(y_i \varphi(\mathbf{x}_i)) + \lambda \oint_C d\mathbf{s}. \tag{7}$$

The surface area regularization is a boundary-based functional with $g_\mathrm{b} = 1$ and the margin-based loss can be expressed as a region-based functional with g_r incorporating $\mathrm{L}(y_i \varphi(\mathbf{x}_i))$. Applying (4)–(6) to this energy functional yields the gradient descent flow

$$\left.\frac{\partial \varphi(\mathbf{x})}{\partial t}\right|_{\mathbf{x}=\mathbf{x}_i} = \begin{cases} \mathrm{L}(y_i \varphi(\mathbf{x}_i)) \nabla\varphi(\mathbf{x}_i) - \lambda \nabla^2 \varphi(\mathbf{x}_i) \nabla\varphi(\mathbf{x}_i), & \varphi(\mathbf{x}_i) < 0 \\ -\mathrm{L}(y_i \varphi(\mathbf{x}_i)) \nabla\varphi(\mathbf{x}_i) - \lambda \nabla^2 \varphi(\mathbf{x}_i) \nabla\varphi(\mathbf{x}_i), & \varphi(\mathbf{x}_i) > 0 \end{cases}. \tag{8}$$

In doing the contour evolution, note that we never compute the surface area of the decision boundary, which is oftentimes intractable, but just its gradient descent flow.

The derivative (8) does not take the constraint $\|\nabla\varphi\| = 1$ into account: the result of updating a signed distance function using (8) is not a signed distance function. Frequent reinitialization of the level set function as a signed distance function is important because (7) depends on the magnitude of φ, not just its sign. This reinitialization is done iteratively using (Sussman et al., 1994):

$$\frac{\partial \varphi(\mathbf{x})}{\partial t} = \mathrm{sign}(\varphi(\mathbf{x}))(1 - \|\nabla\varphi(\mathbf{x})\|).$$

With linear margin-based classifiers, including the original primal formulation of the SVM, the concept of margin is equivalent to Euclidean distance from the decision boundary in the input space. With kernel methods, however, this equivalence is lost; the quantity referred to as the margin, $y\varphi(\mathbf{x})$, is not the same as distance from $\mathbf{x}$ to the decision boundary in the input space. As discussed by Akaho (2004), oftentimes it is of interest to maximize the minimum distance to the decision boundary in the input space among all of the training examples. With the signed distance function representation, the margin $y\varphi(\mathbf{x})$ is equivalent to Euclidean distance from the decision boundary and hence is a satisfying nonlinear generalization to linear margin-based methods.

We now present two synthetic examples to illustrate this approach and its behavior. In both examples, there are $n = 1000$ points in the training set with $D = 2$. The first example has 502 points with label $y_i = -1$ and 498 points with label $y_i = +1$ and is separable by an elliptical decision boundary. The second example has 400 points with label $y_i = -1$ and 600 points with label $y_i = +1$ and is not separable by a simple shape, but has the -1 labeled points in a strip.

In these two examples, in the other examples in the rest of the paper, and in the performance results of Section 5.2, we use the logistic loss function for L in the objective (7). In these two examples, the surface area penalty has weight $\lambda = 0.5$; the value $\lambda = 0.5$ is a default parameter value that gives good performance with a variety of data sets regardless of their dimensionality D and can be used if one does not wish to optimize λ using cross-validation. Contour evolution minimization requires an initial decision boundary. In the portion of Ω where there are no training examples, we set the initial decision boundary to be a uniform grid of small components; this small seed initialization is common in level set methods. In the part of Ω where there are training examples, we use the locations and labels of the training examples to set the initial decision boundary. We assign a positive value to the initial signed distance function in locations of positively labeled examples and a negative value in locations of negatively labeled examples. The initial decision boundaries for the two examples are shown in the top left panels of Figure 3 and Figure 4.

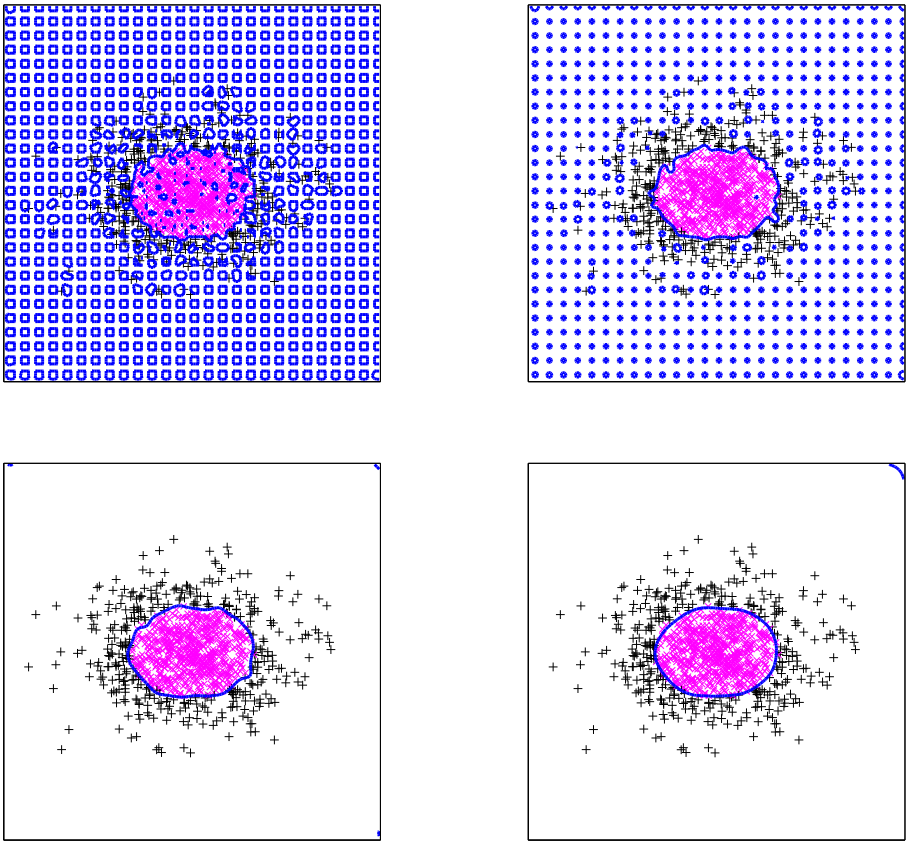

Figure 3: Curve evolution iterations with $\lambda = 0.5$ for an example training set proceeding in raster scan order starting from the top left. The magenta $\times$ markers indicate class label -1 and the black $+$ markers indicate class label $+1$. The blue line is the decision boundary.

Two intermediate iterations and the final decision boundary are also shown in Figure 3 and Figure 4. Solutions are as expected: an elliptical decision boundary and a strip-like decision boundary have been recovered. In the final decision boundaries of both examples, there is a small curved piece of the decision boundary in the top right corner of Ω where there are no training examples. This piece is an artifact of the initialization and the regularization term, and does not affect classifier performance. (The corner piece of the decision boundary is a minimal surface, a surface of zero mean curvature, which is a critical point of the surface area regularization functional (3), but not the global minimum. It is not important, assuming we have a representative training set.)

For a visual comparison of the effect of the surface area penalty weight, we show the solution decision boundaries of the geometric level set classifier for two other values of λ, 0.005 and 0.05, with the data set used in the example of Figure 4. As can be seen in comparing this figure with the bottom right panel of Figure 4, the smaller the value of λ, the longer and more tortuous the decision boundary. Small values of λ lead to overfitting.

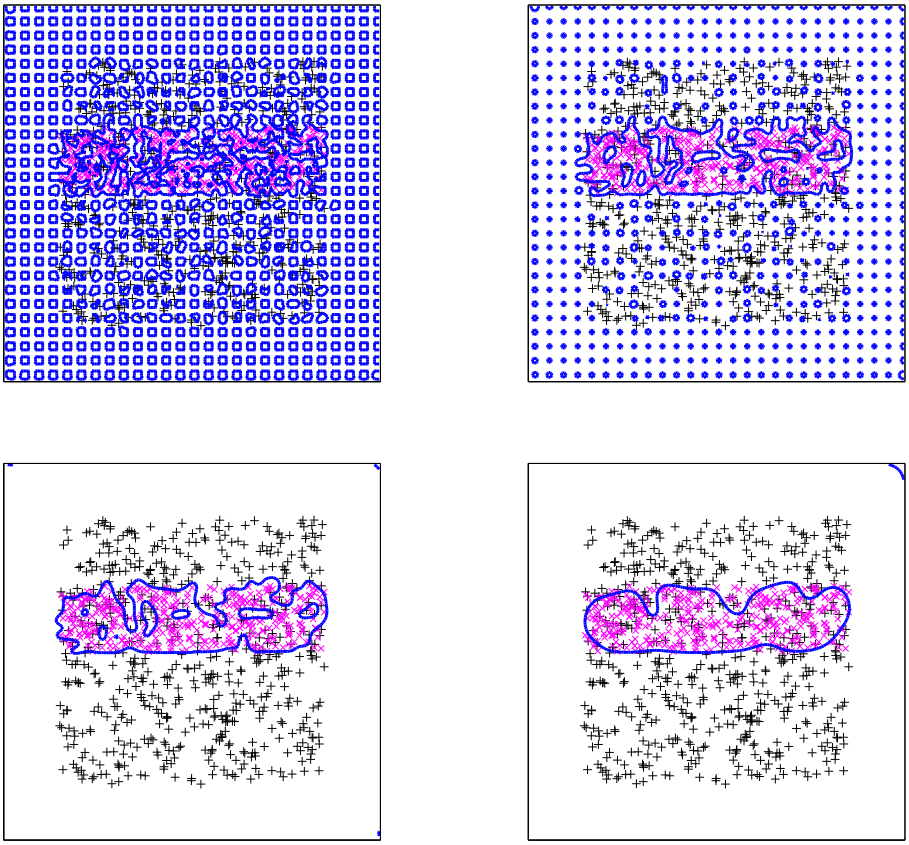

Figure 4: Curve evolution iterations with $\lambda = 0.5$ for an example training set proceeding in raster scan order starting from the top left. The magenta $\times$ markers indicate class label -1 and the black $+$ markers indicate class label $+1$. The blue line is the decision boundary.

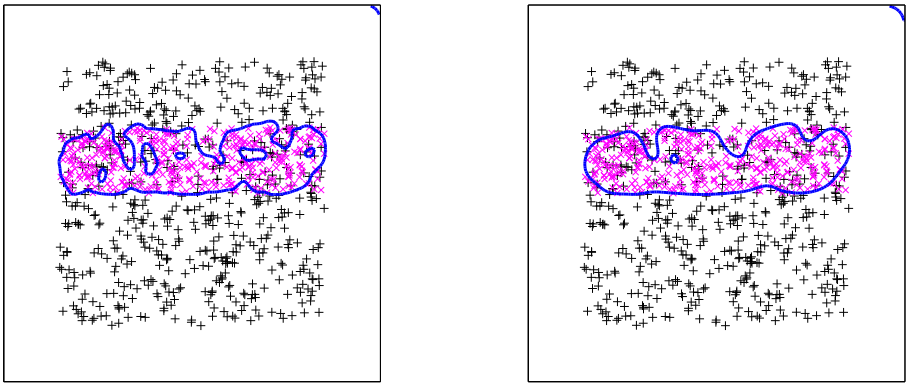
In this section, we have described the basic method for nonlinear margin-based binary classification based on level set methods and illustrated its operation on two synthetic data sets. The next two sections build upon this core binary level set classification in two directions: theoretical analysis, and multicategory classification.

3. Consistency and Complexity Analysis

In this section, we provide analytical characterizations of the consistency and complexity of the level set classifier with surface area regularization described in Section 2. The main tool used in these characterizations is ε-entropy. Once we have an expression for the ε-entropy of the set of geometric level set classifiers, we can then apply consistency and complexity results from learning theory that are based on it. The beginning of this section is devoted to finding the ε-entropy of the space of signed distance functions with a surface area constraint with respect to the uniform or L_∞ metric on



(a) (b)

Figure 5: Solution decision boundaries with (a) $\lambda = 0.005$ and (b) $\lambda = 0.05$ for an example training set. The magenta $\times$ markers indicate class label -1 and the black $+$ markers indicate class label $+1$. The blue line is the decision boundary.

functions. The end of the section gives results on classifier consistency and complexity. The main findings are that level set classifiers are consistent, and that complexity is monotonically related to the surface area constraint, and thus the regularization term can be used to prevent underfitting and overfitting.

3.1 ε-Entropy

The ε-covering number of a metric space is the minimal number of sets with radius not exceeding ε required to cover that space. The ε-entropy is the base-two logarithm of the ε-covering number. These quantities are useful values in characterizing learning (Kulkarni, 1989; Williamson et al., 2001; Lin, 2004; von Luxburg and Bousquet, 2004; Steinwart, 2005; Bartlett et al., 2006). Kolmogorov and Tihomirov (1961), Dudley (1974, 1979), and others provide ε-entropy calculations for various classes of functions and various classes of sets, but the particular class we are considering, signed distance functions with a constraint on the surface area of the zero level set, does not appear in the literature. The second and third examples in Section 2 of Kolmogorov and Tihomirov (1961) are related, and the general approach we take for obtaining the ε-entropy of level set classifiers is similar to those two examples.

In classification, it is always possible to scale and shift the data and this is often done in practice. Without losing much generality and dispensing with some bothersome bookkeeping, we consider signed distance functions defined on the unit hypercube, that is $\Omega = [0,1]^D$, and we employ the uniform or L_∞ metric, $\rho_\infty(\varphi_1,\varphi_2) = \sup_{\mathbf{x}\in\Omega} |\varphi_1(\mathbf{x}) - \varphi_2(\mathbf{x})|$. We denote the set of all signed distance functions whose zero level set has surface area less than s by $\mathcal{F}_s$, its ε-covering number with respect to the uniform metric as $N_{\rho_\infty,\varepsilon}(\mathcal{F}_s)$, and its ε-entropy as $H_{\rho_\infty,\varepsilon}(\mathcal{F}_s)$. We begin with the $D = 1$ case and then come to general D.

Figure 6a shows a signed distance function over the unit interval. Due to the $\|\nabla\varphi\| = 1$ con-

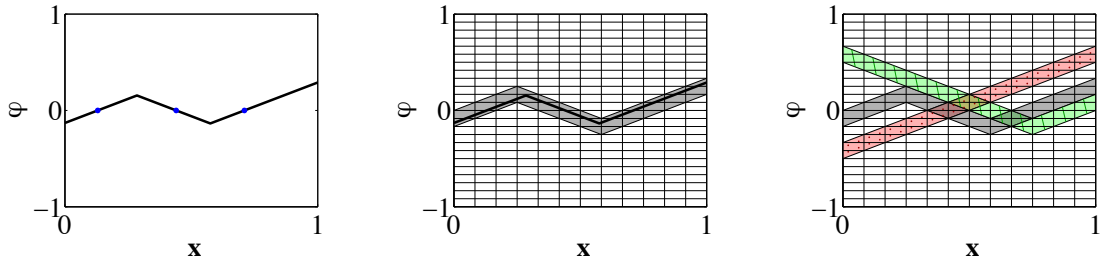


Figure 6: A $D = 1$-dimensional signed distance function in $\Omega = [0,1]$ is shown in (a), marked with its zero level set. The ε-corridor with $\varepsilon = \frac{1}{12}$ that contains the signed distance function is shown in (b), shaded in gray. The ε-corridor of (b), whose center line has three zero crossings is shown in (c), again shaded in gray, along with an ε-corridor whose center line has two zero crossings, shaded in green with stripes, and an ε-corridor whose center line has one zero crossing, shaded in red with dots.

straint, its slope is either $+1$ or -1 almost everywhere. The slope changes sign exactly once between two consecutive points in the zero level set. The signed distance function takes values in the range between positive and negative one.[3] In the $D = 1$ context, by surface area we mean the number of points in the zero level set, for example three in Figure 6a.

In finding $H_{\rho_\infty,\varepsilon}(\mathcal{F}_s)$, we will use sets known as ε-*corridors*, which are particular balls of radius ε measured using ρ_∞ in the space of signed distance functions. We use the terminology of Kolmogorov and Tihomirov (or translator Hewitt), but our definition is slightly different than theirs. An ε-corridor is a strip of height 2ε for all $\mathbf{x}$. Let us define $\nu = \lceil \varepsilon^{-1} \rceil$. At $\mathbf{x} = 0$, the bottom and top of a corridor are at $2j\varepsilon$ and $2(j+1)\varepsilon$ respectively for some integer j, where $-\nu \leq 2j < \nu$. The slope of the corridor is either $+1$ or -1 for all $\mathbf{x}$ and the slope can only change at values of $\mathbf{x}$ that are multiples of ε. Additionally, the center line of the ε-corridor is a signed distance function, changing slope halfway between consecutive points in its zero level set and only there. The ε-corridor in which the signed distance function of Figure 6a falls is indicated in Figure 6b. Other ε-corridors are shown in Figure 6c.

By construction, each signed distance function is a member of exactly one ε-corridor. This is because since at $\mathbf{x} = 0$ the bottom and top of ε-corridors are at consecutive integer multiples of 2ε and since the center line of the corridor is a signed distance function, each signed distance function starts in one ε-corridor at $\mathbf{x} = 0$ and does not escape from it in the interval $(0,1]$. Also, an ε-corridor whose center line has s points in its zero level set contains only signed distance functions with at least s points in their zero level sets.

3. There are several ways to define the signed distance function in the degenerate cases ($\mathcal{R} = \Omega$, $\mathcal{R}^c = \emptyset$) and ($\mathcal{R} = \emptyset$, $\mathcal{R}^c = \Omega$), including the assignments $-\infty$ and $+\infty$, or -1 and $+1$ (Delfour and Zolésio, 2001). For our purposes, it suffices to say that we have chosen a unique function for the $\mathcal{R} = \Omega$ case and a unique function for the $\mathcal{R}^c = \Omega$ case.

Theorem 1 *The ε-entropy of the set of signed distance functions defined over $\Omega = [0,1]$ with zero level set having less than s points is:*

$$H_{\rho_\infty,\varepsilon}(\mathcal{F}_s) = \log_2 \left(\sum_{k=1}^{s} \binom{\lceil \varepsilon^{-1} \rceil - 1}{k-1} \right) + 1.$$

Proof Since ε-corridors only change slope at multiples of ε, we can divide the abscissa into ν pieces. (Each piece has width ε except the last one if ε^{-1} is not an integer.) In each of the ν subintervals, the center line of a corridor is either wholly positive or wholly negative. Enumerating the full set of ε-corridors is equivalent to enumerating binary strings of length ν. Thus, without a constraint s, there are 2^ν ε-corridors. Since, by construction, ε-corridors tile the space of signed distance functions, $N_{\rho_\infty,\varepsilon}(\mathcal{F}) = 2^\nu$.

With the s constraint on ε-corridors, the enumeration is equivalent to twice the number of compositions of the positive integer ν by a sum of s or less positive integers. Twice because for every composition, there is one version in which the first subinterval of the corridor center is positive and one version in which it is negative. As an example, the red corridor in Figure 6c can be composed with two positive integers $(5+7)$, the green corridor by three $(7+4+1)$, and the gray corridor by four $(1+4+4+3)$. The number of compositions of ν by k positive integers is $\binom{\nu-1}{k-1}$. Note that the zero-crossings are unordered for this enumeration and that the set $\mathcal{F}_s$ includes all of the signed distance functions with surface area smaller than s as well. Therefore:

$$N_{\rho_\infty,\varepsilon}(\mathcal{F}_s) = 2 \sum_{k=1}^{s} \binom{\nu-1}{k-1}.$$

The result then follows because $H_{\rho_\infty,\varepsilon}(\mathcal{F}_s) = \log_2 N_{\rho_\infty,\varepsilon}(\mathcal{F}_s)$. ■

The combinatorial formula in Theorem 1 is difficult to work with, so we give a highly accurate approximation.

Theorem 2 *The ε-entropy of the set of signed distance functions defined over $\Omega = [0,1]$ with zero level set having less than s points is:*

$$H_{\rho_\infty,\varepsilon}(\mathcal{F}_s) \approx \lceil \varepsilon^{-1} \rceil + \log_2 \Phi \left(\frac{2s - \lceil \varepsilon^{-1} \rceil}{\sqrt{\lceil \varepsilon^{-1} \rceil - 1}} \right),$$

where Φ is the standard Gaussian cumulative distribution function (cdf).

Proof Note that for a binomial random variable Z with $(\nu-1)$ Bernoulli trials having success probability $\frac{1}{2}$:

$$\Pr[Z < z] = 2^{-\nu} \cdot 2 \sum_{k=1}^{z} \binom{\nu-1}{k-1},$$

and that $N_{\rho_\infty,\varepsilon}(\mathcal{F}_s) = 2^\nu \Pr[Z < s]$. The result follows from the de Moivre-Laplace theorem and continuity correction, which are used to approximate the binomial distribution with the Gaussian distribution. ■

The central limit theorem tells us that the approximation works well when the Bernoulli success probability is one half, which it is in our case, and when the number of trials is large, which corresponds to small ε. The continuous approximation is better in the middle of the domain, when $s \approx \nu/2$, than in the tails. However, in the tails, the calculation of the exact expression in Theorem 1 is tractable. Since Φ is a cdf taking values in the range zero to one, $\log_2 \Phi$ is nonpositive. The surface area constraint only serves to reduce the ε-entropy.

The ε-entropy calculation in Theorem 1 and Theorem 2 is for the $D = 1$ case. We now discuss the case with general D. Recall that $\Omega = [0,1]^D$. Once again, we construct ε-corridors that tile the space of signed distance functions. In the one-dimensional case, the ultimate object of interest for enumeration is a string of length ν with binary labels. In the two-dimensional case, the corresponding object is a ν-by-ν grid of ε-by-ε squares with binary labels, and in general a D-dimensional Cartesian grid of hypercubes of volume ε^D, ν on each side. The surface area of the zero level set is the number of interior faces in the Cartesian grid whose adjoining ε^D hypercubes have different binary labels.

Theorem 3 *The ε-entropy of the set of signed distance functions defined over $\Omega = [0,1]^D$ with zero level set having surface area less than s is:*

$$H_{\rho_\infty,\varepsilon}(\mathcal{F}_s) \approx \left\lceil \varepsilon^{-1} \right\rceil^D + \log_2 \Phi \left(\frac{2s - D\left(\left\lceil \varepsilon^{-1} \right\rceil - 1\right) \left\lceil \varepsilon^{-1} \right\rceil^{D-1} - 1}{\sqrt{D\left(\left\lceil \varepsilon^{-1} \right\rceil - 1\right) \left\lceil \varepsilon^{-1} \right\rceil^{D-1}}} \right),$$

where Φ is the standard Gaussian cdf.

Proof In the one-dimensional case, it is easy to see that the number of segments is ν and the number of interior faces is $\nu - 1$. For a general D-dimensional Cartesian grid with ν hypercubes on each side, the number of hypercubes is ν^D and the number of interior faces is $D(\nu-1)\nu^{D-1}$. The result follows by substituting ν^D for ν and $D(\nu-1)\nu^{D-1}$ for $\nu - 1$ in Theorem 2. ■

Theorem 2 is a special case of Theorem 3 with $D = 1$. It is common to find the dimension of the space D in the exponent of ε^{-1} in ε-entropy calculations as we do here.

The ε-entropy calculation for level set classifiers given here enables us to analytically characterize their consistency properties as the size of the training set goes to infinity in Section 3.2 through ε-entropy-based classifier consistency results. The calculation also enables us to characterize the Rademacher complexity of level set classifiers in Section 3.3 through ε-entropy-based complexity results.

3.2 Consistency

In the binary classification problem, with training set of size n drawn from $p_{\mathbf{X},Y}(\mathbf{x}, y)$, a consistent classifier is one whose probability of error converges in the limit as n goes to infinity to the probability of error of the Bayes optimal decision rule. The optimal decision rule to minimize the probability of error is $\hat{y}^*(\mathbf{x}) = \text{sign}(p_{Y|\mathbf{X}}(Y = 1|\mathbf{X} = \mathbf{x}) - \frac{1}{2})$. Introducing notation, let the probability of error achieved by this decision rule be R^*. Also denote the probability of error of a level set classifier $\text{sign}(\varphi^{(n)})$ learned from a training set of size n as $R(\text{sign}(\varphi^{(n)}))$. For consistency, it is required that $R(\text{sign}(\varphi^{(n)})) - R^*$ converge in probability to zero.

The learned classifier $\text{sign}(\varphi^{(n)})$ minimizes the energy functional (7), and consequently the properties of $R(\text{sign}(\varphi^{(n)}))$ are affected by both the margin-based loss function L and by the regularization term. Lin (2004), Steinwart (2005), and Bartlett et al. (2006) have given conditions on the loss function necessary for a margin-based classifier to be consistent. Common margin-based loss functions including the logistic loss and exponential loss meet the conditions. Lin calls a loss function that meets the necessary conditions *Fisher-consistent*. Fisher consistency of the loss function is not enough, however, to imply consistency of the classifier overall. The regularization term must also be analyzed; since the regularization term based on surface area we introduce is new, so is the following analysis.

Concentrating on the surface area regularization, we adapt Theorem 4.1 of Lin, which is based on ε-entropy. The analysis is based on the method of sieves, where sieves $\mathcal{F}_n$ are an increasing sequence of subspaces of a function space $\mathcal{F}$. In our case, $\mathcal{F}$ is the set of signed distance functions on Ω and the sieves, $\mathcal{F}_{s(n)}$, are subsets of signed distance functions whose zero level sets have surface area less than $s(n)$, that is $\oint_{\varphi=0} d\mathbf{s} < s(n)$. Such a constraint is related to the regularization expression $\text{E}(\varphi)$ given in (7) through the method of Lagrange multipliers, with λ inversely related to $s(n)$. In the following, the function $s(n)$ is increasing in n and thus the conclusions of the theorem provide asymptotic results on consistency as the strength of the regularization term decreases as more training samples are made available. The sieve estimate is:

$$\varphi^{(n)} = \arg \min_{\varphi \in \mathcal{F}_{s(n)}} \sum_{i=1}^{n} \text{L}(y_i \varphi(\mathbf{x}_i)). \tag{9}$$

Having found $H_{\rho_\infty,\varepsilon}(\mathcal{F}_s)$ in Section 3.1, we can apply Theorem 4.1 of Lin (2004), yielding the following theorem.

Theorem 4 Let L be a Fisher-consistent loss function in (9); let $\tilde{\varphi} = \arg\min_{\varphi \in \mathcal{F}} E[\text{L}(Y\varphi(\mathbf{X}))]$, where $\mathcal{F}$ is the space of signed distance functions on $[0,1]^D$; and let $\mathcal{F}_{s(n)}$ be a sequence of sieves. Then for sieve estimate $\varphi^{(n)}$, we have[4]

$$R(\text{sign}(\varphi^{(n)})) - R^* = O_P\left(\max\left\{n^{-\tau}, \inf_{\varphi \in \mathcal{F}_{s(n)}} \int (\varphi(\mathbf{x}) - \tilde{\varphi}(\mathbf{x}))^2 p_{\mathbf{X}}(\mathbf{x}) d\mathbf{x}\right\}\right),$$

where

$$\tau = \begin{cases} \frac{1}{3}, & D = 1 \\ \frac{1}{4} - \frac{\log\log n}{2\log n}, & D = 2 \\ \frac{1}{2D}, & D \geq 3 \end{cases}.$$

Proof The result is a direct application of Theorem 4.1 of Lin (2004), which is in turn an application of Theorem 1 of Shen and Wong (1994). In order to apply this theorem, we need to note two things. First, that signed distance functions on $[0,1]^D$ are bounded (by a value of 1) in the L_∞ norm. Second, that there exists an A such that $H_{\rho_\infty,\varepsilon}(\mathcal{F}_s) \leq A\varepsilon^{-D}$. Based on Theorem 3, we see that $H_{\rho_\infty,\varepsilon}(\mathcal{F}_s) \leq \nu^D$ because the logarithm of the cdf is nonpositive. Since $\nu = \lceil \varepsilon^{-1} \rceil$, if ε^{-1} is an integer, then $H_{\rho_\infty,\varepsilon}(\mathcal{F}_s) \leq \varepsilon^{-D}$ and otherwise there exists an A such that $H_{\rho_\infty,\varepsilon}(\mathcal{F}_s) \leq A\varepsilon^{-D}$. ■

4. The notation $Z_n = O_P(\zeta_n)$ means that the random variable Z_n is bounded in probability at the rate ζ_n (van der Vaart, 1998).

Clearly $n^{-\tau}$ goes to zero as n goes to infinity. Also, $\inf_{\varphi \in \mathcal{F}_{s(n)}} \int (\varphi(\mathbf{x}) - \tilde{\varphi}(\mathbf{x}))^2 p_{\mathbf{X}}(\mathbf{x}) d\mathbf{x}$ goes to zero when $s(n)$ is large enough so that the surface area constraint is no longer applicable.[5] Thus, level set classifiers are consistent.

3.3 Rademacher Complexity

The principal idea of the structural risk minimization principle is that the generalization error is the sum of an empirical risk term and a capacity term (Vapnik, 1995). The two terms should be sensibly balanced in order to achieve low generalization error. Here, we use the ε-entropy of signed distance functions constrained in decision boundary surface area to characterize the capacity term. In particular, we look at the Rademacher complexity of $\mathcal{F}_s$ as a function of s (Koltchinskii, 2001; Bartlett and Mendelson, 2002).

The Rademacher average of a class $\mathcal{F}$, denoted $\hat{R}_n(\mathcal{F})$, satisfies (von Luxburg and Bousquet, 2004):

$$\hat{R}_n(\mathcal{F}) \leq 2\varepsilon + \frac{4\sqrt{2}}{\sqrt{n}} \int_{\frac{\varepsilon}{4}}^{\infty} \sqrt{H_{\rho_{2,n},\varepsilon'}(\mathcal{F})} d\varepsilon',$$

where $\rho_{2,n}(\varphi_1, \varphi_2) = \sqrt{\frac{1}{n} \sum_{i=1}^{n} (\varphi_1(\mathbf{x}_i) - \varphi_2(\mathbf{x}_i))^2}$ is the empirical ℓ_2 metric. We found $H_{\rho_\infty,\varepsilon}(\mathcal{F}_s)$ for signed distance functions with surface area less than s in Section 3.1, and $H_{\rho_{2,n},\varepsilon}(\mathcal{F}) \leq H_{\rho_\infty,\varepsilon}(\mathcal{F})$. Thus, we can characterize the complexity of level set classifiers via the Rademacher capacity term (von Luxburg and Bousquet, 2004):

$$C_{\mathrm{Rad}}(\mathcal{F}_s, n) = 2\varepsilon + \frac{4\sqrt{2}}{\sqrt{n}} \int_{\frac{\varepsilon}{4}}^{\infty} \sqrt{H_{\rho_\infty,\varepsilon'}(\mathcal{F})} d\varepsilon'. \tag{10}$$

With $\Omega = [0,1]^D$, the upper limit of the integral in (10) is one rather than infinity because ε cannot be greater than one.

In Figure 7, we plot C_{Rad} as a function of s for three values of D, and fixed ε and n. Having a fixed ε models the discretized grid implementation of level set methods. As the value of s increases, decision boundaries with more area are available. Decision boundaries with large surface area are more complex than smoother decision boundaries with small surface area. Hence the complexity term increases as a function of s. We have also empirically found the same relationship between the VC dimension and the surface area penalty (Varshney and Willsky, 2008). Consequently, the surface area penalty can be used to control the complexity of the classifier, and prevent underfitting and overfitting. The Rademacher capacity term may be used in setting the regularization parameter λ.

4. Multicategory Geometric Level Set Classification

Thus far, we have considered binary classification. In this section, we extend level set classification to the multicategory case with $M > 2$ classes labeled $y \in \{1, \ldots, M\}$. We represent the decision boundaries using $m = \lceil \log_2 M \rceil$ signed distance functions $\{\varphi_1(\mathbf{x}), \ldots, \varphi_m(\mathbf{x})\}$. Using such a set of level set functions we can represent 2^m regions $\{\mathcal{R}_1, \mathcal{R}_2, \ldots, \mathcal{R}_{2^m}\}$ through a binary encoding

5. For a given ε, there is a maximum possible surface area; the constraint is no longer applicable when the constraint is larger than this maximum possible surface area. Also note that s and λ are inversely related.

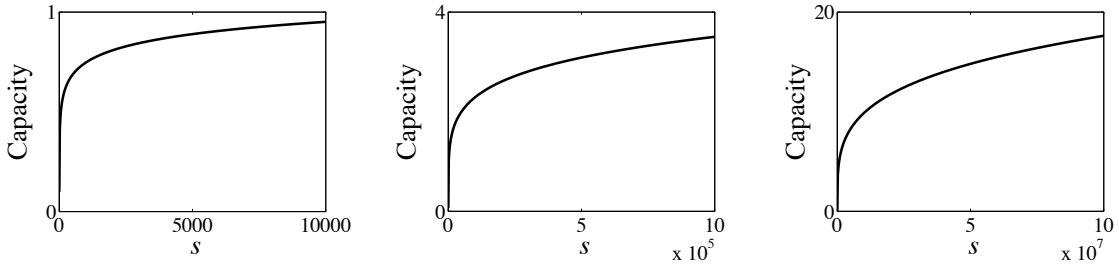

Figure 7: The Rademacher capacity term (10) as a function of s for signed distance functions on $\Omega = [0,1]^D$ with surface area less than s with (a) $D = 2$, (b) $D = 3$, and (c) $D = 4$. The values of ε and n are fixed at 0.01 and 1000 respectively.

(Vese and Chan, 2002). Thus, for $\mathbf{x} \in \mathcal{R}_1$, $(\varphi_1(\mathbf{x}) < 0) \wedge \cdots \wedge (\varphi_m(\mathbf{x}) < 0)$; for $\mathbf{x} \in \mathcal{R}_2$, $(\varphi_1(\mathbf{x}) < 0) \wedge \cdots \wedge (\varphi_{m-1}(\mathbf{x}) < 0) \wedge (\varphi_m > 0)$; and for $\mathbf{x} \in \mathcal{R}_{2^m}$, $(\varphi_1(\mathbf{x}) > 0) \wedge \cdots \wedge (\varphi_m(\mathbf{x}) > 0)$.

This binary encoding specifies the regions, but in order to apply margin-based loss functions, we also need a value for margin. In binary classification, the special encoding $y \in \{-1,+1\}$ allows $y\varphi(\mathbf{x})$ to be the argument to the loss function. For multicategory classification, the argument to the loss function is through functions $\psi_y(\mathbf{x})$, which are also specified through a binary encoding: $\psi_1(\mathbf{x}) = \max\{+\varphi_1(\mathbf{x}), \ldots, +\varphi_m(\mathbf{x})\}$, $\psi_2(\mathbf{x}) = \max\{+\varphi_1(\mathbf{x}), \ldots, +\varphi_{m-1}(\mathbf{x}), -\varphi_m(\mathbf{x})\}$, and $\psi_{2^m}(\mathbf{x}) = \max\{-\varphi_1(\mathbf{x}), \ldots, -\varphi_m(\mathbf{x})\}$. Then, the M-ary level set classification energy functional we propose is

$$\mathrm{E}(\varphi_1, \ldots, \varphi_m) = \sum_{i=1}^{n} \mathrm{L}(\psi_{y_i}(\mathbf{x}_i)) + \frac{\lambda}{m} \sum_{j=1}^{m} \oint_{\varphi_j = 0} d\mathbf{s}. \tag{11}$$

The same margin-based loss functions used in the binary case, such as the hinge and logistic loss functions, may be used in the multicategory case (Zou et al., 2006, 2008). The regularization term included in (11) is the sum of the surface areas of the zero level sets of the m signed distance functions.

The gradient descent flows for the m signed distance functions are

$$\left.\frac{\partial \varphi_1(\mathbf{x})}{\partial t}\right|_{\mathbf{x}=\mathbf{x}_i} = \begin{cases} \mathrm{L}(\psi_{y_i}(\mathbf{x}_i))\nabla\varphi_1(\mathbf{x}_i) - \frac{\lambda}{m}\nabla^2\varphi_1(\mathbf{x}_i)\nabla\varphi_1(\mathbf{x}_i), & \varphi_1(\mathbf{x}_i) < 0 \\ -\mathrm{L}(\psi_{y_i}(\mathbf{x}_i))\nabla\varphi_1(\mathbf{x}_i) - \frac{\lambda}{m}\nabla^2\varphi_1(\mathbf{x}_i)\nabla\varphi_1(\mathbf{x}_i), & \varphi_1(\mathbf{x}_i) > 0 \end{cases}$$

$$\vdots$$

$$\left.\frac{\partial \varphi_m(\mathbf{x})}{\partial t}\right|_{\mathbf{x}=\mathbf{x}_i} = \begin{cases} \mathrm{L}(\psi_{y_i}(\mathbf{x}_i))\nabla\varphi_m(\mathbf{x}_i) - \frac{\lambda}{m}\nabla^2\varphi_m(\mathbf{x}_i)\nabla\varphi_m(\mathbf{x}_i), & \varphi_m(\mathbf{x}_i) < 0 \\ -\mathrm{L}(\psi_{y_i}(\mathbf{x}_i))\nabla\varphi_m(\mathbf{x}_i) - \frac{\lambda}{m}\nabla^2\varphi_m(\mathbf{x}_i)\nabla\varphi_m(\mathbf{x}_i), & \varphi_m(\mathbf{x}_i) > 0 \end{cases}.$$

In the case $M = 2$ and $m = 1$, the energy functional and gradient flow revert back to binary level set classification described in Section 2.

The proposed multicategory classifier is different from the commonly used technique known as one-against-all (Hsu and Lin, 2002), which constructs an M-ary classifier from M binary classifiers,

both because it treats all M classes simultaneously in the objective and because the decision regions are represented by a logarithmic rather than linear number of decision functions. Zou et al. (2006) also treat all M classes simultaneously in the objective, but their multicategory kernel machines use M decision functions. In fact, to the best of our knowledge, there is no M-ary classifier representation in the literature using as few as $\lceil \log_2 M \rceil$ decision functions. Methods that combine binary classifier outputs using error-correcting codes make use of a logarithmic number of binary classifiers with a larger multiplicative constant, such as $\lceil 10 \log M \rceil$ or $\lceil 15 \log M \rceil$ (Rifkin and Klautau, 2004; Allwein et al., 2000).

We give an example showing multicategory level set classification with $M = 4$ and $D = 2$. The data set has 250 points for each of the four class labels $y_i = 1$, $y_i = 2$, $y_i = 3$, and $y_i = 4$. The classes are not perfectly separable by simple boundaries. With four classes, we use $m = 2$ signed distance functions. Figure 8 shows the evolution of the two contours, the magenta and cyan curves. The final decision region for class $y = 1$ is the portion inside both the magenta and cyan curves, and coincides with the training examples with class label 1. The final decision region for class 2 is the region inside the magenta curve but outside the cyan curve, the final decision region for class 3 is the region inside the cyan curve, but outside the magenta curve, and the final decision region for class 4 is outside both curves. The final decision boundaries are fairly smooth and partition the space with small training error.

5. Implementation and Classification Results

In this section, we describe how to implement geometric level set classification practically using RBFs and give classification performance results when applied to several real binary and multicategory data sets.

5.1 Radial Basis Function Level Set Method

There have been many developments in level set methods since the original work of Osher and Sethian (1988). One development in particular is to represent the level set function by a superposition of RBFs instead of on a grid (Cecil et al., 2004; Slabaugh et al., 2007; Gelas et al., 2007). Grid-based representation of the level set function is not amenable to classification in high-dimensional input spaces because the memory and computational requirements are exponential in the dimension of the input space. A nonparametric RBF representation, however, is tractable for classification. The RBF level set method we use to minimize the energy functionals (7) and (11) for binary and multicategory margin-based classification is most similar to that described by Gelas et al. (2007) for image processing.

The starting point of the RBF level set approach is describing the level set function $\varphi(\mathbf{x})$ via a strictly positive definite[6] RBF $\mathrm{K}(\cdot)$ as follows:

$$\varphi(\mathbf{x}) = \sum_{i=1}^{n} \alpha_i \mathrm{K}\left(\|\mathbf{x} - \mathbf{x}_i\|\right). \tag{12}$$

The zero level set of φ defined in this way is the contour C. For the classification problem, we take the centers $\mathbf{x}_i$ to be the data vectors of the training set. Then, constructing an $n \times n$ matrix $\mathbf{H}$ with

6. A more complete discussion including conditionally positive definite RBFs would add a polynomial term to (12), to span the null space of the RBF (Wendland, 2005).

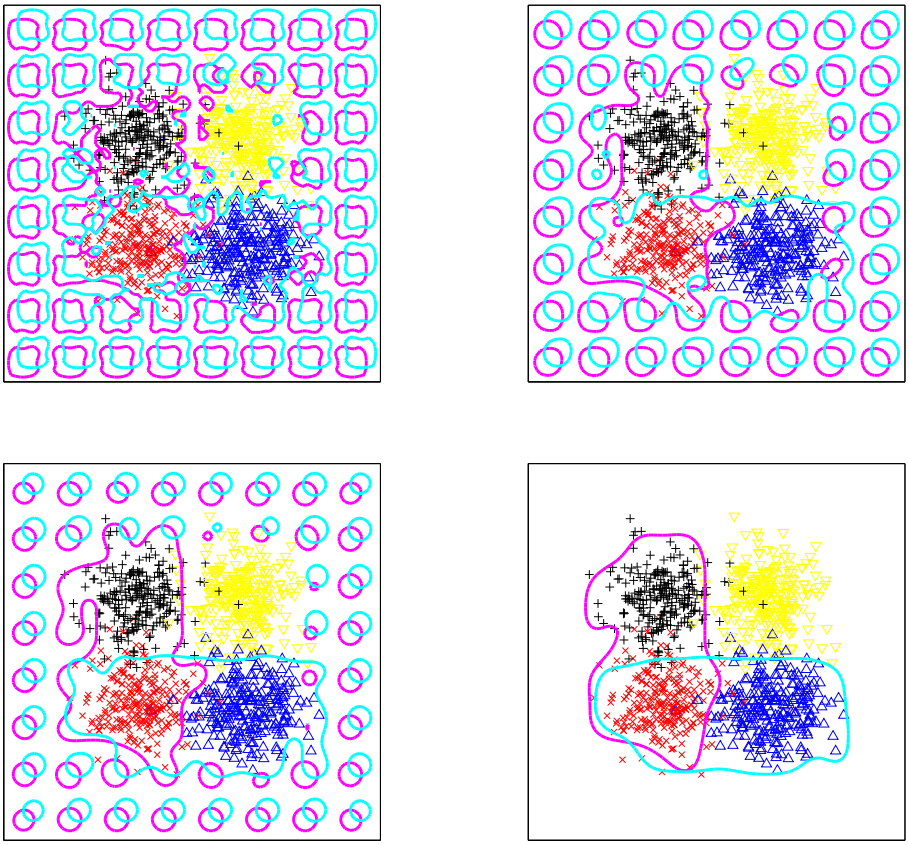

Figure 8: Curve evolution iterations with $\lambda = 0.5$ for multicategory classification proceeding in raster scan order. The red $\times$ markers indicate class label 1, the black $+$ markers indicate class label 2, the blue $\triangle$ markers indicate class label 3, and the yellow $\triangledown$ markers indicate class label 4. The magenta and cyan lines are the zero level sets of the $m = 2$ signed distance functions and together make up the decision boundary.

elements $\{\mathbf{H}\}_{ij} = \mathrm{K}(\|\mathbf{x}_i - \mathbf{x}_j\|)$, and letting $\boldsymbol{\alpha}$ be the vector of coefficients in (12), we have:

$$\begin{bmatrix} \varphi(\mathbf{x}_1) \\ \vdots \\ \varphi(\mathbf{x}_n) \end{bmatrix} = \mathbf{H}\boldsymbol{\alpha}.$$

To minimize an energy functional of C, the level set optimization is over the coefficients $\boldsymbol{\alpha}$ with $\mathbf{H}$ fixed. In order to perform contour evolution with the RBF representation, a time parameter t is introduced like in Section 2, giving:

$$\mathbf{H}\frac{d\boldsymbol{\alpha}}{dt} = \begin{bmatrix} \left.\frac{\partial\varphi(\mathbf{x})}{\partial t}\right|_{\mathbf{x}=\mathbf{x}_1} \\ \vdots \\ \left.\frac{\partial\varphi(\mathbf{x})}{\partial t}\right|_{\mathbf{x}=\mathbf{x}_n} \end{bmatrix}. \tag{13}$$

For the binary margin-based classification problem with surface area regularization that we are interested in solving, we substitute the gradient flow (8) into the right side of (13). For the multicategory classification problem, we have m level set functions as discussed in Section 4 and each one has a gradient flow to be substituted into an expression like (13).

The iteration for the contour evolution is then:

$$\boldsymbol{\alpha}^{(k+1)} = \boldsymbol{\alpha}^{(k)} - \tau\mathbf{H}^{-1}\begin{bmatrix} \left.\frac{\partial\varphi^{(k)}(\mathbf{x})}{\partial t}\right|_{\mathbf{x}=\mathbf{x}_1} \\ \vdots \\ \left.\frac{\partial\varphi^{(k)}(\mathbf{x})}{\partial t}\right|_{\mathbf{x}=\mathbf{x}_n} \end{bmatrix}, \tag{14}$$

where τ is a small step size and $\varphi^{(k)}$ comes from $\boldsymbol{\alpha}^{(k)}$. We normalize $\boldsymbol{\alpha}$ according to the ℓ_1-norm after every iteration.

The RBF-represented level set function is not a signed distance function. However, as discussed by Gelas et al. (2007), normalizing the coefficient vector $\boldsymbol{\alpha}$ with respect to the ℓ_1-norm after every iteration of (14) has a similar effect as reinitializing the level set function as a signed distance function. The Lipschitz constant of the level set function is constrained by this normalization. The analysis of Section 3 applies with minor modification for level set functions with a given Lipschitz constant and surface area constraint. The RBF level set approach is similar to kernel machines with the RBF kernel in the sense that the decision function is represented by a linear combination of RBFs. However, kernel methods in the literature minimize a reproducing kernel Hilbert space squared norm for regularization, whereas the geometric level set classifier minimizes decision boundary surface area for regularization. The regularization term and consequently inductive bias of the geometric level set classifier is new and different compared to existing kernel methods. The solution decision boundary is the zero level set of a function of the form given in (12). Of course this representation does not capture all possible functions, but, given that we use a number of RBFs equal to the number of training examples, the granularity of this representation is well-matched to the data. This is similar to the situation found in other contexts such as kernel machines using RBFs.

We initialize the decision boundary with $\boldsymbol{\alpha} = n(\mathbf{H}^{-1}\mathbf{y})/\|\mathbf{H}^{-1}\mathbf{y}\|_1$, where $\mathbf{y}$ is a vector of the n class labels in the training set. Figure 9 shows this initialization and following RBF-implemented

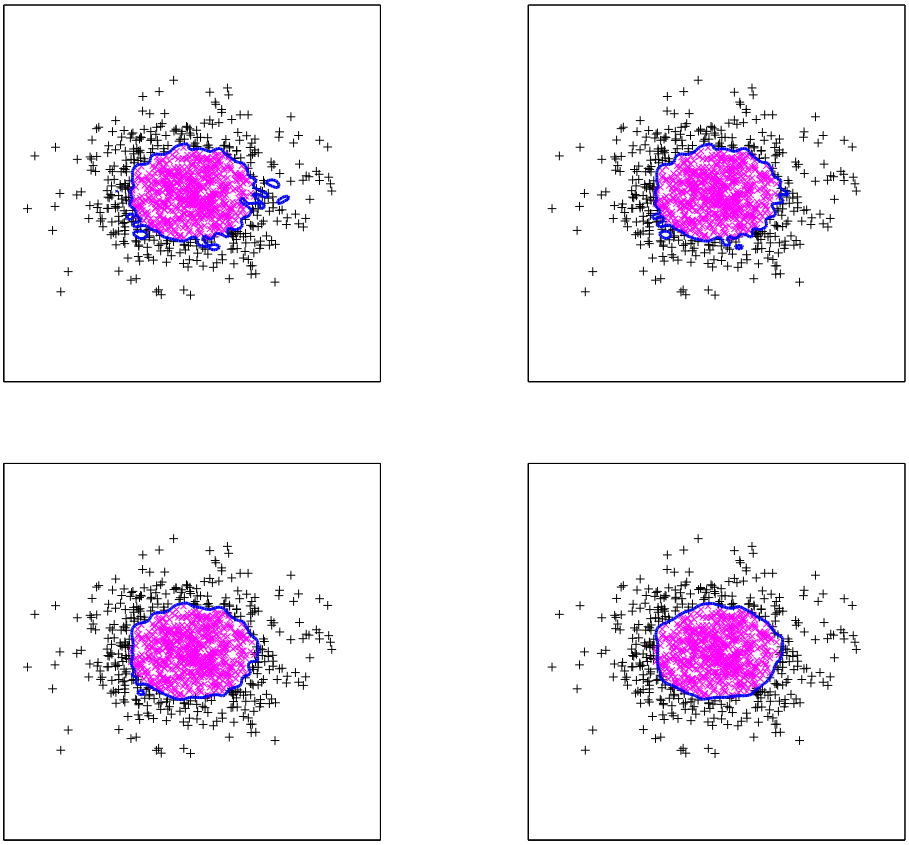

Figure 9: Curve evolution iterations with RBF implementation and $\lambda = 0.5$ for example training set proceeding in raster scan order. The magenta $\times$ markers indicate class label -1 and the black $+$ markers indicate class label $+1$. The blue line is the decision boundary.

contour evolution on the elliptically-separable data set presented in Section 2. The initial decision boundary is tortuous. It is smoothed out by the surface area penalty during the course of the contour evolution, thereby improving the generalization of the learned classifier as desired. To initialize the m vectors $\boldsymbol{\alpha}$ in M category classification, we use m length n vectors of positive and negative ones constructed from the binary encoding instead of $\mathbf{y}$.

5.2 Classification Results

We give classifier performance results on benchmark data sets from the UCI Machine Learning Repository (Asuncion and Newman, 2007) for geometric level set classification and compare them to the performance of several other classifiers, concluding that level set classification is a competitive technique. We present the tenfold cross-validation classification error performance with RBF level set implementation on four binary data sets: Pima Indians Diabetes ($n = 768$, $D = 8$), Wis-

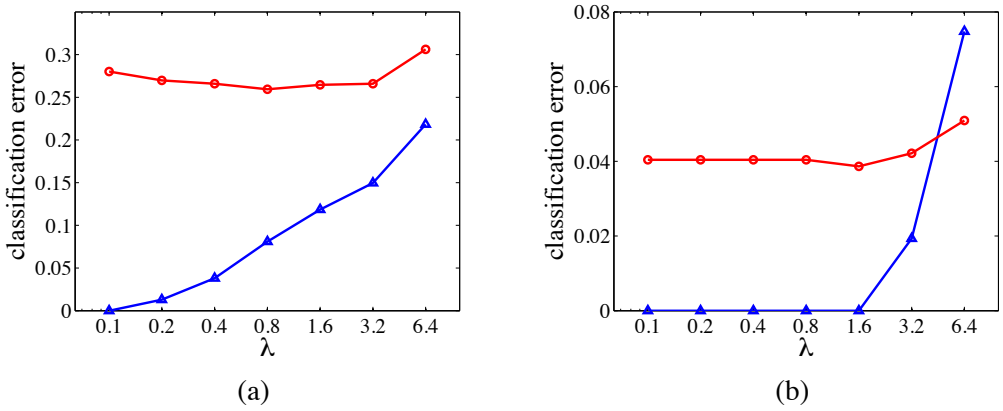

Figure 10: Tenfold cross-validation training error (blue line with triangle markers) and test error (red line with circle markers) for the (a) Pima, and (b) WDBC data sets as a function of the regularization parameter λ on a logarithmic scale.

consin Diagnostic Breast Cancer ($n = 569$, $D = 30$), BUPA Liver Disorders ($n = 345$, $D = 6$) and Johns Hopkins University Ionosphere ($n = 351$, $D = 34$), and four multicategory data sets: Wine Recognition ($n = 178$, $M = 3$, $D = 13$), Iris ($n = 150$, $M = 3$, $D = 4$), Glass Identification ($n = 214$, $M = 6$, $D = 9$), and Image Segmentation ($n = 2310$, $M = 7$, $D = 19$). For the binary data sets, there is $m = 1$ level set function, for the wine and iris data sets $m = 2$ level set functions, and for the glass and segmentation data sets $m = 3$ level set functions.

We shift and scale the data so that each of the input dimensions has zero mean and unit variance, use the RBF $K(\|\mathbf{x} - \mathbf{x}_i\|) = e^{-\|\mathbf{x}-\mathbf{x}_i\|^2}$, the logistic loss function, $\tau = 1/m$, and the initialization $\boldsymbol{\alpha} = n(\mathbf{H}^{-1}\mathbf{y})/\|\mathbf{H}^{-1}\mathbf{y}\|_1$. First, we look at classification error as a function of λ. Figure 10 shows the tenfold cross-validation training and test errors for the Pima and WDBC data sets; other data sets yield similar plots. The plots show evidence of the structural risk minimization principle and complexity analysis given in Section 3.3. For small λ (corresponding to large surface area constraint s), the model class is too complex and we see that although the training error is zero, the test error is not minimal due to overfitting. For large λ, the model class is not complex enough; the training error is large and the test error is not minimal due to underfitting. There is an intermediate value of λ that achieves the minimal test error. However, we notice that the test error is fairly insensitive to the value of λ. The test error does not change much over the plotted range.

In Table 1, we report the tenfold cross-validation test error (as a percentage) on the eight data sets and compare the performance to nine other classifiers.[7] On each of the ten folds, we set λ using cross-validation. Specifically, we perform fivefold cross-validation on the nine tenths of the full data set that is the training data for that fold. We select the λ from the set of values $\{0.2, 0.4, 0.8, 1.6, 3.2\}$ that minimizes the fivefold cross-validation test error. The performance results of the nine other

7. For lower-dimensional data sets (up to about $D = 12$), it is possible to use optimal dyadic decision trees (Scott and Nowak, 2006; Blanchard et al., 2007). We found that the results using such trees are not significantly better than those obtained using the C4.4 and C4.5 decision trees (which could be applied to all of the data sets without concern for dimensionality).

Data Set (M,D)	NB	BN	kNN	C4.4	C4.5	NBT	SVM	RBN	LLS	GLS

Table 1: Tenfold cross-validation error percentage of geometric level set classifier (GLS) with RBF level set implementation on several data sets compared to error percentages of various other classifiers reported in Cai and Sowmya (2007). The other classifiers are: naïve Bayes classifier (NB), Bayes net classifier (BN), k-nearest neighbor with inverse distance weighting (kNN), C4.4 decision tree (C4.4), C4.5 decision tree (C4.5), naïve Bayes tree classifier (NBT), SVM with polynomial kernel (SVM), radial basis function network (RBN), and learning level set classifier (LLS) of Cai and Sowmya (2007).

classifiers are as given by Cai and Sowmya (2007), who report the same tenfold cross-validation test error that we do for the geometric level set classifier. Details about parameter settings for the other nine classifiers may be found in Cai and Sowmya (2007).

The geometric level set classifier outperforms each of the other classifiers at least once among the four binary data sets, and is generally competitive overall. Level set classification is also competitive on the multicategory data sets. In fact, it gives the smallest error among all of the classifiers on the segmentation data set. The proposed classifier is competitive for data sets of both small and large dimensionality D; there is no apparent relationship between D and the performance of the geometric level set classifier in comparison to other methods.

6. Conclusion

Level set methods are powerful computational techniques that have not yet been widely adopted in machine learning. Our main goal with this contribution is to open a conduit between the application area of learning and the computational technique of level set methods. Towards that end, we have developed a nonlinear, nonparametric classifier based on level set methods that minimizes margin-based empirical risk in both the binary and multicategory cases, and is regularized by a geometric complexity penalty novel to classification. This approach is an alternative to kernel machines for learning nonlinear decision boundaries in the input space and is in some ways a more natural generalization of linear methods.

The variational level set formulation is flexible in allowing the inclusion of various geometric priors defined in the input space. The surface area regularization term is one such example, but others may also be included. Another example is an energy functional that measures feature relevance using the partial derivative of the signed distance function (Domeniconi et al., 2005), and can be used for ℓ_1-regularized feature subset selection as discussed in Varshney and Willsky (2008).

We have provided an analysis of the classifier by characterizing its ε-entropy. This characterization leads to results on consistency and complexity. We have described a multicategory level set classification procedure with a logarithmic number of decision functions, rather than the linear number that is typical in classification and decision making, through a binary encoding made possible by the level set representation.

It is a known fact that with finite training data, no one classification method is best for all data sets. Performance of classifiers may vary quite a bit depending on the data characteristics because of differing inductive biases. The classifier presented in this paper provides a new option when choosing a classifier. The results on standard data sets indicate that the level set classifier is competitive with other state-of-the-art classifiers. It would be interesting to systematically find domains in the space of data set characteristics for which the geometric level set classifier outperforms other classifiers (Ho and Basu, 2002).

Acknowledgments

Abstract

In this paper we develop a new approach to sparse principal component analysis (sparse PCA). We propose two single-unit and two block optimization formulations of the sparse PCA problem, aimed at extracting a single sparse dominant principal component of a data matrix, or more components at once, respectively. While the initial formulations involve nonconvex functions, and are therefore computationally intractable, we rewrite them into the form of an optimization program involving maximization of a convex function on a compact set. The dimension of the search space is decreased enormously if the data matrix has many more columns (variables) than rows. We then propose and analyze a simple gradient method suited for the task. It appears that our algorithm has best convergence properties in the case when either the objective function or the feasible set are strongly convex, which is the case with our single-unit formulations and can be enforced in the block case. Finally, we demonstrate numerically on a set of random and gene expression test problems that our approach outperforms existing algorithms both in quality of the obtained solution and in computational speed.

Keywords: sparse PCA, power method, gradient ascent, strongly convex sets, block algorithms

1. Introduction

Principal component analysis (PCA) is a well established tool for making sense of high dimensional data by reducing it to a smaller dimension. It has applications virtually in all areas of science—machine learning, image processing, engineering, genetics, neurocomputing, chemistry, meteorology, control theory, computer networks—to name just a few—where large data sets are encountered. It is important that having reduced dimension, the essential characteristics of the data are retained. If $A \in \mathbf{R}^{p\times n}$ is a matrix encoding p samples of n variables, with n being large, PCA aims at finding a few linear combinations of these variables, called *principal components*, which point in orthogonal directions explaining as much of the variance in the data as possible. If the variables contained in

the columns of A are centered, then the classical PCA can be written in terms of the scaled *sample covariance matrix* $\Sigma = A^T A$ as follows:

$$\text{Find} \quad z^* = \arg\max_{z^T z \leq 1} z^T \Sigma z. \tag{1}$$

Extracting one component amounts to computing the dominant eigenvector of Σ (or, equivalently, dominant right singular vector of A). Full PCA involves the computation of the singular value decomposition (SVD) of A. Principal components are, in general, combinations of all the input variables, that is, the *loading vector* z^* is not expected to have many zero coefficients. In most applications, however, the original variables have concrete physical meaning and PCA then appears especially interpretable if the extracted components are composed only from a small number of the original variables. In the case of gene expression data, for instance, each variable represents the expression level of a particular gene. A good analysis tool for biological interpretation should be capable to highlight "simple" structures in the genome—structures expected to involve a few genes only—that explain a significant amount of the specific biological processes encoded in the data. Components that are linear combinations of a small number of variables are, quite naturally, usually easier to interpret. It is clear, however, that with this additional goal, some of the explained variance has to be sacrificed. The objective of *sparse principal component analysis* (sparse PCA) is to find a reasonable *trade-off* between these conflicting goals. One would like to explain *as much* variability in the data as possible, using components constructed from *as few* variables as possible. This is the classical trade-off between *statistical fidelity* and *interpretability*.

For about a decade, sparse PCA has been a topic of active research. Historically, the first suggested approaches were based on ad-hoc methods involving post-processing of the components obtained from classical PCA. For example, Jolliffe (1995) consider using various rotation techniques to find sparse loading vectors in the subspace identified by PCA. Cadima and Jolliffe (1995) proposed to simply set to zero the PCA loadings which are in absolute value smaller than some threshold constant.

In recent years, more involved approaches have been put forward—approaches that consider the conflicting goals of explaining variability and achieving representation sparsity simultaneously. These methods usually cast the sparse PCA problem in the form of an optimization program, aiming at maximizing explained variance penalized for the number of non-zero loadings. For instance, the SCoTLASS algorithm proposed by Jolliffe et al. (2003) aims at maximizing the Rayleigh quotient of the covariance matrix of the data under the ℓ_1-norm based Lasso penalty (Tibshirani, 1996). Zou et al. (2006) formulate sparse PCA as a regression-type optimization problem and impose the Lasso penalty on the regression coefficients. d'Aspremont et al. (2007) in their DSPCA algorithm exploit convex optimization tools to solve a convex relaxation of the sparse PCA problem. Shen and Huang (2008) adapt the singular value decomposition (SVD) to compute low-rank matrix approximations of the data matrix under various sparsity-inducing penalties. Greedy methods, which are typical for combinatorial problems, have been investigated by Moghaddam et al. (2006). Finally, d'Aspremont et al. (2008) proposed a greedy heuristic accompanied with a certificate of optimality.

In many applications, several components need to be identified. The traditional approach consists of incorporating an existing single-unit algorithm in a deflation scheme, and computing the desired number of components sequentially (see, e.g., d'Aspremont et al. 2007). In the case of Rayleigh quotient maximization it is well-known that computing several components at once instead of computing them one-by-one by deflation with the classical power method might present

better convergence whenever the largest eigenvalues of the underlying matrix are close to each other (see, e.g., Parlett 1980). Therefore, block approaches for sparse PCA are expected to be more efficient on ill-posed problems.

In this paper we consider two single-unit (Section 2.1 and 2.2) and two block formulations (Section 2.3 and 2.4) of sparse PCA, aimed at extracting m sparse principal components, with $m = 1$ in the former case and $p \geq m > 1$ in the latter. Each of these two groups comes in two variants, depending on the type of penalty we use to enforce sparsity—either ℓ_1 or ℓ_0 (cardinality).[1] Although we assume a direct access to the data matrix A, these formulations also hold when only the covariance matrix Σ is available, provided that a factorization of the form $\Sigma = A^T A$ is identified (e.g., by eigenvalue decomposition or by Cholesky decomposition).

While our basic formulations involve maximization of a *nonconvex* function on a space of dimension involving n, we construct *reformulations* that cast the problem into the form of maximization of a *convex* function on the unit Euclidean sphere in $\mathbf{R}^p$ (in the $m = 1$ case) or the *Stiefel manifold*[2] in $\mathbf{R}^{p\times m}$ (in the $m > 1$ case). The advantage of the reformulation becomes apparent when trying to solve problems with many variables ($n \gg p$), since we manage to avoid searching a space of large dimension.[3] At the same time, due to the convexity of the new cost function we are able to propose and *analyze* the iteration-complexity of a simple gradient-type scheme, which appears to be well suited for problems of this form. In particular, we study (Section 3) a first-order method for solving an optimization problem of the form

$$f^* = \max_{x\in Q} f(x), \tag{P}$$

where Q is a compact subset of a finite-dimensional vector space and f is convex. It appears that our method has best theoretical convergence properties when either f or Q are strongly convex, which is the case in the single unit case (unit ball is strongly convex) and can be enforced in the block case by adding a strongly convex regularizing term to the objective function, constant on the feasible set. We do not, however, prove any results concerning the quality of the obtained solution. Even the goal of obtaining a local maximizer is in general unattainable, and we must be content with convergence to a stationary point.

In the particular case when Q is the unit Euclidean ball in $\mathbf{R}^p$ and $f(x) = x^T Cx$ for some $p \times p$ symmetric positive definite matrix C, our gradient scheme specializes to the *power method*, which aims at maximizing the *Rayleigh quotient*

$$R(x) = \frac{x^T Cx}{x^T x}$$

and thus at computing the largest eigenvalue, and the corresponding eigenvector, of C.

By applying our general gradient scheme to our sparse PCA reformulations of the form (P), we obtain algorithms (Section 4) with per-iteration computational cost $O(npm)$.

We demonstrate on random Gaussian (Section 5.1) and gene expression data related to breast cancer (Section 5.2) that our methods are very efficient in practice. While achieving a balance between the explained variance and sparsity which is the same as or superior to the existing methods,

1. Our single-unit cardinality-penalized formulation is identical to that of d'Aspremont et al. (2008).
2. Stiefel manifold is the set of rectangular matrices with orthonormal columns.
3. Note that in the case $p > n$, it is recommended to factor the covariance matrix as $\Sigma = A^T A$ with $A \in \mathbf{R}^{n\times n}$, such that the dimension p in the reformulations equals at most n.

they are faster, often converging before some of the other algorithms manage to initialize. Additionally, in the case of gene expression data our approach seems to extract components with strongest biological content.

1.1 Notation

For convenience of the reader, and at the expense of redundancy, some of the less standard notation below is also introduced at the appropriate place in the text where it is used. Parameters $m \leq p \leq n$ are actual values of dimensions of spaces used in the paper. In the definitions below, we use these actual values (i.e., n, p and m) if the corresponding object we define is used in the text exclusively with them; otherwise we make use of the dummy variables k (representing p or n in the text) and l (representing m, p or n in the text).

Given a vector $y \in \mathbf{R}^k$, its j^{th} coordinate is denoted by y_j. With an abuse of notation, we may use subscripts to indicate a sequence of vectors, such as $y_1, y_2, \ldots, y_l$. In that case the j^{th} coordinates of these vectors are denoted by $y_{1j}, y_{2j}, \ldots, y_{lj}$. By y_i we refer to the i^{th} column of $Y \in \mathbf{R}^{k\times l}$. Consequently, the element of Y at position (i, j) can be written as y_{ij}.

By $\mathbf{E}$ we refer to a finite-dimensional vector space; $\mathbf{E}^*$ is its conjugate space, that is, the space of all linear functionals on $\mathbf{E}$. By $\langle s, x\rangle$ we denote the action of $s \in \mathbf{E}^*$ on $x \in \mathbf{E}$. For a self-adjoint positive definite linear operator $G : \mathbf{E} \to \mathbf{E}^*$ we define a pair of norms on $\mathbf{E}$ and $\mathbf{E}^*$ as follows

$$\begin{aligned} \|x\| &\stackrel{\text{def}}{=} \langle Gx, x\rangle^{1/2}, \quad x \in \mathbf{E}, \\ \|s\|_* &\stackrel{\text{def}}{=} \langle s, G^{-1}s\rangle^{1/2}, \quad s \in \mathbf{E}^*. \end{aligned} \tag{2}$$

Although the theory in Section 3 is developed in this general setting, the sparse PCA applications considered in this paper require either the choice $\mathbf{E} = \mathbf{E}^* = \mathbf{R}^p$ (see Section 3.3 and problems (8) and (13) in Section 2) or $\mathbf{E} = \mathbf{E}^* = \mathbf{R}^{p\times m}$ (see Section 3.4 and problems (16) and (20) in Section 2). In both cases we will let G be the corresponding identity operator for which we obtain

$$\langle x, y\rangle = \sum_i x_i y_i, \quad \|x\| = \langle x, x\rangle^{1/2} = \left(\sum_i x_i^2\right)^{1/2} = \|x\|_2, \quad x, y \in \mathbf{R}^p, \quad \text{and}$$

$$\langle X, Y\rangle = \operatorname{Tr} X^T Y, \quad \|X\| = \langle X, X\rangle^{1/2} = \left(\sum_{ij} x_{ij}^2\right)^{1/2} = \|X\|_F, \quad X, Y \in \mathbf{R}^{p\times m}.$$

Thus in the vector setting we work with the *standard Euclidean norm* and in the matrix setting with the *Frobenius norm*. The symbol Tr denotes the trace of its argument.

Furthermore, for $z \in \mathbf{R}^n$ we write $\|z\|_1 = \sum_i |z_i|$ (ℓ_1 norm) and by $\|z\|_0$ (ℓ_0 "norm") we refer to the number of nonzero coefficients, or *cardinality*, of z. By $\mathbf{S}^p$ we refer to the space of all $p \times p$ symmetric matrices; $\mathbf{S}^p_+$ (resp. $\mathbf{S}^p_{++}$) refers to the positive semidefinite (resp. definite) cone. Eigenvalues of matrix Y are denoted by $\lambda_i(Y)$, largest eigenvalue by $\lambda_{\max}(Y)$. Analogous notation with the symbol σ refers to singular values.

By $\mathcal{B}^k = \{y \in \mathbf{R}^k \mid y^T y \leq 1\}$ (resp. $\mathcal{S}^k = \{y \in \mathbf{R}^k \mid y^T y = 1\}$) we refer to the unit Euclidean ball (resp. sphere) in $\mathbf{R}^k$. If we write $\mathcal{B}$ and $\mathcal{S}$, then these are the corresponding objects in $\mathbf{E}$. The space of $n \times m$ matrices with unit-norm columns will be denoted by

$$[\mathcal{S}^n]^m = \{Y \in \mathbf{R}^{n\times m} \mid \operatorname{Diag}(Y^T Y) = I_m\},$$

where Diag$(\cdot)$ represents the diagonal matrix obtained by extracting the diagonal of the argument. *Stiefel manifold* is the set of rectangular matrices of fixed size with orthonormal columns:

$$\mathcal{S}_m^p = \{Y \in \mathbf{R}^{p\times m} \mid Y^T Y = I_m\}.$$

For $t \in \mathbf{R}$ we will further write $\text{sign}(t)$ for the sign of the argument and $t_+ = \max\{0,t\}$.

2. Some Formulations of the Sparse PCA Problem

In this section we propose four formulations of the sparse PCA problem, all in the form of the general optimization framework (P). The first two deal with the single-unit sparse PCA problem and the remaining two are their generalizations to the block case.

2.1 Single-unit Sparse PCA via ℓ_1-Penalty

Let us consider the optimization problem

$$\phi_{\ell_1}(\gamma) \stackrel{\text{def}}{=} \max_{z\in\mathcal{B}^n} \sqrt{z^T\Sigma z} - \gamma\|z\|_1, \tag{3}$$

with sparsity-controlling parameter $\gamma \geq 0$ and sample covariance matrix $\Sigma = A^T A$.

The solution $z^*(\gamma)$ of (3) in the case $\gamma = 0$ is equal to the right singular vector corresponding to $\sigma_{\max}(A)$, the largest singular value of A. It is the first principal component of the data matrix A. The optimal value of the problem is thus equal to

$$\phi_{\ell_1}(0) = (\lambda_{\max}(A^T A))^{1/2} = \sigma_{\max}(A).$$

Note that there is no reason to expect this vector to be sparse. On the other hand, for large enough γ, we will necessarily have $z^*(\gamma) = 0$, obtaining maximal sparsity. Indeed, since

$$\max_{z\neq 0} \frac{\|Az\|_2}{\|z\|_1} = \max_{z\neq 0} \frac{\|\sum_i z_i a_i\|_2}{\|z\|_1} \leq \max_{z\neq 0} \frac{\sum_i |z_i|\|a_i\|_2}{\sum_i |z_i|} = \max_i \|a_i\|_2 = \|a_{i^*}\|_2,$$

we get $\|Az\|_2 - \gamma\|z\|_1 < 0$ for all nonzero vectors z whenever γ is chosen to be strictly bigger than $\|a_{i^*}\|_2$. From now on we will assume that

$$\gamma < \|a_{i^*}\|_2. \tag{4}$$

Note that there is a trade-off between the value $\|Az^*(\gamma)\|_2$ and the sparsity of the solution $z^*(\gamma)$. The penalty parameter γ is introduced to "continuously" interpolate between the two extreme cases described above, with values in the interval $[0, \|a_{i^*}\|_2)$. It depends on the particular application whether sparsity is valued more than the explained variance, or vice versa, and to what extent. Due to these considerations, we will consider the solution of (3) to be a sparse principal component of A.

2.1.1 REFORMULATION

The reader will observe that the objective function in (3) is not convex, nor concave, and that the feasible set is of a high dimension if $p \ll n$. It turns out that these shortcomings are overcome by

considering the following reformulation:

$$\begin{aligned}\phi_{\ell_1}(\gamma) &= \max_{z\in\mathcal{B}^n} \|Az\|_2 - \gamma\|z\|_1 \\ &= \max_{z\in\mathcal{B}^n}\max_{x\in\mathcal{B}^p} x^T Az - \gamma\|z\|_1 \qquad (5)\\ &= \max_{x\in\mathcal{B}^p}\max_{z\in\mathcal{B}^n} \sum_{i=1}^n z_i(a_i^T x) - \gamma|z_i| \\ &= \max_{x\in\mathcal{B}^p}\max_{z'\in\mathcal{B}^n} \sum_{i=1}^n |z_i'|(|a_i^T x| - \gamma), \qquad (6)\end{aligned}$$

where $z_i = \mathrm{sign}(a_i^T x)z_i'$. In view of (4), there is some $x \in \mathcal{B}^n$ for which $a_i^T x > \gamma$. Fixing such x, solving the inner maximization problem for z' and then translating back to z, we obtain the closed-form solution

$$z_i^* = z_i^*(\gamma) = \frac{\mathrm{sign}(a_i^T x)[|a_i^T x| - \gamma]_+}{\sqrt{\sum_{k=1}^n [|a_k^T x| - \gamma]_+^2}}, \quad i = 1,\ldots,n. \qquad (7)$$

Problem (6) can therefore be written in the form

$$\boxed{\phi_{\ell_1}^2(\gamma) = \max_{x\in\mathcal{S}^p} \sum_{i=1}^n [|a_i^T x| - \gamma]_+^2.} \qquad (8)$$

Note that the objective function is differentiable and convex, and hence all local and global maxima must lie on the boundary, that is, on the unit Euclidean sphere $\mathcal{S}^p$. Also, in the case when $p \ll n$, formulation (8) requires to search a space of a much lower dimension than the initial problem (3).

2.1.2 SPARSITY

In view of (7), an optimal solution x^* of (8) defines a sparsity pattern of the vector z^*. In fact, the coefficients of z^* indexed by

$$I = \{i \mid |a_i^T x^*| > \gamma\}$$

are active while all others must be zero. Geometrically, active indices correspond to the defining hyperplanes of the polytope

$$\mathcal{D} = \{x \in \mathbf{R}^p \mid |a_i^T x| \le 1\}$$

that are (strictly) crossed by the line joining the origin and the point x^*/γ. Note that it is possible to say something about the sparsity of the solution even without the knowledge of x^*:

$$\gamma \ge \|a_i\|_2 \quad \Rightarrow \quad z_i^*(\gamma) = 0, \qquad i = 1,\ldots,n. \qquad (9)$$

2.2 Single-unit Sparse PCA via Cardinality Penalty

Instead of the ℓ_1-penalization, the authors of d'Aspremont et al. (2008) consider the formulation

$$\phi_{\ell_0}(\gamma) \stackrel{\mathrm{def}}{=} \max_{z\in\mathcal{B}^n} z^T\Sigma z - \gamma\,\|z\|_0, \qquad (10)$$

which directly penalizes the number of nonzero components (cardinality) of the vector z.

2.2.1 REFORMULATION

The reasoning of the previous section suggests the reformulation

$$\phi_{\ell_0}(\gamma) = \max_{x\in\mathcal{B}^p} \max_{z\in\mathcal{B}^n} (x^T A z)^2 - \gamma \|z\|_0, \tag{11}$$

where the maximization with respect to $z \in \mathcal{B}^n$ for a fixed $x \in \mathcal{B}^p$ has the closed form solution

$$z_i^* = z_i^*(\gamma) = \frac{[\mathrm{sign}((a_i^T x)^2 - \gamma)]_+ a_i^T x}{\sqrt{\sum_{k=1}^n [\mathrm{sign}((a_k^T x)^2 - \gamma)]_+ (a_k^T x)^2}}, \quad i = 1, \ldots, n. \tag{12}$$

In analogy with the ℓ_1 case, this derivation assumes that

$$\gamma < \|a_{i^*}\|_2^2,$$

so that there is $x \in \mathcal{B}^n$ such that $(a_i^T x)^2 - \gamma > 0$. Otherwise $z^* = 0$ is optimal. Formula (12) is easily obtained by analyzing (11) separately for fixed cardinality values of z. Hence, problem (10) can be cast in the following form

$$\boxed{\phi_{\ell_0}(\gamma) = \max_{x\in\mathcal{S}^p} \sum_{i=1}^n [(a_i^T x)^2 - \gamma]_+.} \tag{13}$$

Again, the objective function is convex, albeit nonsmooth, and the new search space is of particular interest if $p \ll n$. A different derivation of (13) for the $n = p$ case can be found in d'Aspremont et al. (2008).

2.2.2 SPARSITY

Given a solution x^* of (13), the set of active indices of z^* is given by

$$I = \{i \mid (a_i^T x^*)^2 > \gamma\}.$$

Geometrically, active indices correspond to the defining hyperplanes of the polytope

$$\mathcal{D} = \{x \in \mathbf{R}^p \mid |a_i^T x| \le 1\}$$

that are (strictly) crossed by the line joining the origin and the point $x^*/\sqrt{\gamma}$. As in the ℓ_1 case, we have

$$\gamma \ge \|a_i\|_2^2 \quad \Rightarrow \quad z_i^*(\gamma) = 0, \qquad i = 1, \ldots, n. \tag{14}$$

2.3 Block Sparse PCA via ℓ_1-Penalty

Consider the following block generalization of (5),

$$\phi_{\ell_1,m}(\gamma) \stackrel{\mathrm{def}}{=} \max_{\substack{X\in\mathcal{S}_m^p \\ Z\in[\mathcal{S}^n]^m}} \mathrm{Tr}(X^T A Z N) - \sum_{j=1}^m \gamma_j \sum_{i=1}^n |z_{ij}|, \tag{15}$$

where the m-dimensional vector $\gamma = [\gamma_1, \ldots, \gamma_m]^T$ is nonnegative and $N = \mathrm{Diag}(\mu_1, \ldots, \mu_m)$, with positive entries on the diagonal. The dimension m corresponds to the number of extracted components and is assumed to be smaller or equal to the rank of the data matrix, that is, $m \le \mathrm{Rank}(A)$.

Each parameter γ_j controls the sparsity of the corresponding component. It will be shown below that under some conditions on the parameters μ_j, the case $\gamma = 0$ recovers PCA. In that particular instance, any solution Z^* of (15) has orthonormal columns, although this is not explicitly enforced. For positive γ_j, the columns of Z^* are not expected to be orthogonal anymore. Most existing algorithms for computing several sparse principal components, for example, Zou et al. (2006), d'Aspremont et al. (2007) and Shen and Huang (2008), also do not impose orthogonal loading directions. Simultaneously enforcing sparsity and orthogonality seems to be a hard (and perhaps questionable) task.

2.3.1 REFORMULATION

Since problem (15) is completely decoupled in the columns of Z, that is,

$$\phi_{\ell_1,m}(\gamma) = \max_{X \in \mathcal{S}_m^p} \sum_{j=1}^{m} \max_{z_j \in \mathcal{S}^n} \mu_j x_j^T A z_j - \gamma_j \|z_j\|_1,$$

the closed-form solution (7) of (5) is easily adapted to the block formulation (15):

$$z_{ij}^* = z_{ij}^*(\gamma_j) = \frac{\operatorname{sign}(a_i^T x_j)[\mu_j |a_i^T x_j| - \gamma_j]_+}{\sqrt{\sum_{k=1}^n [\mu_j |a_k^T x_j| - \gamma_j]_+^2}}.$$

This leads to the reformulation

$$\boxed{\phi_{\ell_1,m}^2(\gamma) = \max_{X \in \mathcal{S}_m^p} \sum_{j=1}^{m} \sum_{i=1}^{n} [\mu_j |a_i^T x_j| - \gamma_j]_+^2,} \tag{16}$$

which maximizes a convex function $f : \mathbf{R}^{p \times m} \to \mathbf{R}$ on the Stiefel manifold $\mathcal{S}_m^p$.

2.3.2 SPARSITY

A solution X^* of (16) again defines the sparsity pattern of the matrix Z^*: the entry z_{ij}^* is active if

$$\mu_j |a_i^T x_j^*| > \gamma_j,$$

and equal to zero otherwise. For all $\gamma_j > \mu_j \max_i \|a_i\|_2$, the trivial solution $Z^* = 0$ is optimal.

2.3.3 BLOCK PCA

For $\gamma = 0$, problem (16) can be equivalently written in the form

$$\phi_{\ell_1,m}^2(0) = \max_{X \in \mathcal{S}_m^p} \operatorname{Tr}(X^T A A^T X N^2), \tag{17}$$

which has been well studied (see, e.g., Brockett 1991 and Absil et al. 2008). The solutions of (17) span the dominant m-dimensional invariant subspace of the matrix AA^T. Furthermore, if the parameters μ_j are all distinct, the columns of X^* are the m dominant eigenvectors of AA^T, that is, the m dominant left-eigenvectors of the data matrix A. The columns of the solution Z^* of (15) are thus the m dominant right singular vectors of A, that is, the PCA loading vectors. Such a matrix N

with distinct diagonal elements enforces the objective function in (17) to have isolated maximizers. In fact, if $N = I_m$, any point X^*U with X^* a solution of (17) and $U \in \mathcal{S}_m^m$ is also a solution of (17). In the case of sparse PCA, that is, $\gamma > 0$, the penalty term already ensures isolated maximizers, such that the diagonal elements of N do not have to be distinct. However, as it will be briefly illustrated in the forthcoming numerical experiments (Section 5), having distinct elements on the diagonal of N pushes towards sparse loading vectors that are more orthogonal.

2.4 Block Sparse PCA via Cardinality Penalty

The single-unit cardinality-penalized case can also be naturally extended to the block case:

$$\phi_{\ell_0,m}(\gamma) \stackrel{\text{def}}{=} \max_{\substack{X \in \mathcal{S}_m^p \\ Z \in [\mathcal{S}^n]^m}} \operatorname{Tr}(\operatorname{Diag}(X^T AZN)^2) - \sum_{j=1}^{m} \gamma_j \|z_j\|_0, \tag{18}$$

where the sparsity inducing vector $\gamma = [\gamma_1, \ldots, \gamma_m]^T$ is nonnegative and $N = \operatorname{Diag}(\mu_1, \ldots, \mu_m)$ with positive entries on the diagonal. In the case $\gamma = 0$, problem (20) is equivalent to (17), and therefore corresponds to PCA, provided that all μ_j are distinct.

2.4.1 REFORMULATION

Again, this block formulation is completely decoupled in the columns of Z,

$$\phi_{\ell_0,m}(\gamma) = \max_{X \in \mathcal{S}_m^p} \sum_{j=1}^{m} \max_{z_j \in \mathcal{S}^n} (\mu_j x_j^T A z_j)^2 - \gamma_j \|z_j\|_0,$$

so that the solution (12) of the single unit case provides the optimal columns z_i:

$$z_{ij}^* = z_{ij}^*(\gamma_j) = \frac{[\operatorname{sign}((\mu_j a_i^T x_j)^2 - \gamma_j)]_+ \mu_j a_i^T x_j}{\sqrt{\sum_{k=1}^{n} [\operatorname{sign}((\mu_j a_k^T x_j)^2 - \gamma_j)]_+ \mu_j^2 (a_k^T x_j)^2}}. \tag{19}$$

The reformulation of problem (18) is thus

$$\boxed{\phi_{\ell_0,m}(\gamma) = \max_{X \in \mathcal{S}_m^p} \sum_{j=1}^{m} \sum_{i=1}^{n} [(\mu_j a_i^T x_j)^2 - \gamma_j]_+,} \tag{20}$$

which maximizes a convex function $f : \mathbf{R}^{p \times m} \to \mathbf{R}$ on the Stiefel manifold $\mathcal{S}_m^p$.

2.4.2 SPARSITY

For a solution X^* of (20), the active entries z_{ij}^* of Z^* are given by the condition

$$(\mu_j a_i^T x_j^*)^2 > \gamma_j.$$

Hence for all $\gamma_j > \mu_j^2 \max_i \|a_i\|_2^2$, the optimal solution of (18) is $Z^* = 0$.

3. A Gradient Method for Maximizing Convex Functions

By $\mathbf{E}$ we denote an arbitrary finite-dimensional vector space; $\mathbf{E}^*$ is its conjugate, that is, the space of all linear functionals on $\mathbf{E}$. We equip these spaces with norms given by (2).

In this section we propose and analyze a simple gradient-type method for maximizing a convex function $f : \mathbf{E} \to \mathbf{R}$ on a compact set Q:

$$\boxed{f^* = \max_{x \in Q} f(x).} \tag{21}$$

Unless explicitly stated otherwise, we will *not* assume f to be differentiable. By $f'(x)$ we denote any subgradient of function f at x. By $\partial f(x)$ we denote its subdifferential.

At any point $x \in Q$ we introduce some measure for the first-order optimality conditions:

$$\Delta(x) \stackrel{\text{def}}{=} \max_{y \in Q} \langle f'(x), y - x \rangle.$$

It is clear that

$$\Delta(x) \geq 0, \tag{22}$$

with equality only at those points x where the gradient $f'(x)$ belongs to the normal cone to the set $\mathrm{Conv}(Q)$ at x.[4]

3.1 Algorithm

Consider the following simple algorithmic scheme.

Algorithm 1: Gradient scheme

input : $x_0 \in Q$
output: x_k (approximate solution of (21))
begin
  $k \longleftarrow 0$
  repeat
    $x_{k+1} \in \mathrm{Arg\,max}\{f(x_k) + \langle f'(x_k), y - x_k \rangle \mid y \in Q\}$
    $k \longleftarrow k + 1$
  until *a stopping criterion is satisfied*
end

Note that for example in the special case $Q = r\mathcal{S} \stackrel{\text{def}}{=} \{x \in \mathbf{E} \mid \|x\| = r\}$ or $Q = r\mathcal{B} \stackrel{\text{def}}{=} \{x \in \mathbf{E} \mid \|x\| \leq r\}$, the main step of Algorithm 1 can be written in an explicit form:

$$x_{k+1} = r \frac{G^{-1} f'(x_k)}{\|f'(x_k)\|_*}. \tag{23}$$

4. The normal cone to the set $\mathrm{Conv}(Q)$ at $x \in Q$ is *smaller* than the normal cone to the set Q. Therefore, the optimality condition $\Delta(x) = 0$ is *stronger* than the standard one.

3.2 Analysis

Our first convergence result is straightforward. Denote $\Delta_k \stackrel{\text{def}}{=} \min_{0\le i\le k} \Delta(x_i)$.

Theorem 1 *Let sequence $\{x_k\}_{k=0}^{\infty}$ be generated by Algorithm 1 as applied to a convex function f. Then the sequence $\{f(x_k)\}_{k=0}^{\infty}$ is monotonically increasing and $\lim_{k\to\infty} \Delta(x_k) = 0$. Moreover,*

$$\Delta_k \le \frac{f^* - f(x_0)}{k+1}.$$

Proof From convexity of f we immediately get

$$f(x_{k+1}) \ge f(x_k) + \langle f'(x_k), x_{k+1} - x_k\rangle = f(x_k) + \Delta(x_k),$$

and therefore, $f(x_{k+1}) \ge f(x_k)$ for all k. By summing up these inequalities for $k = 0, 1, \ldots, N-1$, we obtain

$$f^* - f(x_0) \ge f(x_k) - f(x_0) \ge \sum_{i=0}^{k} \Delta(x_i),$$

and the result follows. ■

For a sharper analysis, we need some technical assumptions on f and Q.

Assumption 1 *The norms of the subgradients of f are bounded from below on Q by a positive constant, that is,*

$$\delta_f \stackrel{def}{=} \min_{\substack{x\in Q \\ f'(x)\in\partial f(x)}} \|f'(x)\|_* > 0.$$

This assumption is not too binding because of the following result.

Proposition 2 *Assume that there exists a point $x' \notin Q$ such that $f(x') < f(x)$ for all $x \in Q$. Then*

$$\delta_f \ge \left[\min_{x\in Q} f(x) - f(x')\right] / \left[\max_{x\in Q} \|x - x'\|\right] > 0.$$

Proof Because f is convex, for any $x \in Q$ we have

$$0 < f(x) - f(x') \le \langle f'(x), x - x'\rangle \le \|f'(x)\|_* \|x - x'\|.$$

■

For our next convergence result we need to assume either strong convexity of f or strong convexity of the set $\mathrm{Conv}(Q)$.

Assumption 2 *Function f is* strongly convex, *that is, there exists a constant $\sigma_f > 0$ such that for any $x, y \in \mathbf{E}$*

$$f(y) \ge f(x) + \langle f'(x), y - x\rangle + \frac{\sigma_f}{2}\|y - x\|^2. \tag{24}$$

Note that convex functions satisfy inequality (24) with *convexity parameter* $\sigma_f = 0$.

Assumption 3 *The set* $\mathrm{Conv}(Q)$ *is* strongly convex*, that is, there is a constant* $\sigma_Q > 0$ *such that for any* $x, y \in \mathrm{Conv}(Q)$ *and* $\alpha \in [0,1]$ *the following inclusion holds:*

$$\alpha x + (1-\alpha)y + \frac{\sigma_Q}{2}\alpha(1-\alpha)\|x-y\|^2 \mathcal{S} \subset \mathrm{Conv}(Q). \tag{25}$$

Note that any set Q satisfies inclusion (25) with *convexity parameter* $\sigma_Q = 0$.

It can be shown (see Appendix A), that level sets of strongly convex functions with Lipschitz continuous gradient are again strongly convex. An example of such a function is the simple quadratic $x \mapsto \|x\|^2$. The level sets of this function correspond to Euclidean balls of varying sizes.

As we will see in Theorem 4, a better analysis of Algorithm 1 is possible if $\mathrm{Conv}(Q)$, the convex hull of the feasible set of problem (21), is strongly convex. Note that in the case of the two formulations (8) and (13) of the sparse PCA problem, the feasible set Q is the unit Euclidean sphere. Since the convex hull of the unit sphere is the unit ball, which is a strongly convex set, the feasible set of our sparse PCA formulations satisfies Assumption 3.

In the special case $Q = r\mathcal{S}$ for some $r > 0$, there is a simple proof that Assumption 3 holds with $\sigma_Q = \frac{1}{r}$. Indeed, for any $x, y \in \mathbf{E}$ and $\alpha \in [0,1]$, we have

$$\begin{aligned} \|\alpha x + (1-\alpha)y\|^2 &= \alpha^2\|x\|^2 + (1-\alpha)^2\|y\|^2 + 2\alpha(1-\alpha)\langle Gx, y\rangle \\ &= \alpha\|x\|^2 + (1-\alpha)\|y\|^2 - \alpha(1-\alpha)\|x-y\|^2. \end{aligned}$$

Thus, for $x, y \in r\mathcal{S}$ we obtain

$$\|\alpha x + (1-\alpha)y\| = \left[r^2 - \alpha(1-\alpha)\|x-y\|^2\right]^{1/2} \leq r - \frac{1}{2r}\alpha(1-\alpha)\|x-y\|^2.$$

Hence, we can take $\sigma_Q = \frac{1}{r}$.

The relevance of Assumption 3 is justified by the following technical observation.

Proposition 3 *If* f *is convex, then for any two subsequent iterates* x_k, x_{k+1} *of Algorithm 1*

$$\Delta(x_k) \geq \frac{\sigma_Q}{2}\|f'(x_k)\|_*\|x_{k+1} - x_k\|^2.$$

Proof We have noted in (22) that for convex f we have $\Delta(x_k) \geq 0$. We can thus concentrate on the situation when $\sigma_Q > 0$ and $f'(x_k) \neq 0$. Note that

$$\langle f'(x_k), x_{k+1} - y\rangle \geq 0 \quad \text{for all} \quad y \in \mathrm{Conv}(Q).$$

We will use this inequality with

$$y = y_\alpha \stackrel{\text{def}}{=} x_k + \alpha(x_{k+1} - x_k) + \frac{\sigma_Q}{2}\alpha(1-\alpha)\|x_{k+1} - x_k\|^2 \frac{G^{-1}f'(x_k)}{\|f'(x_k)\|_*}, \quad \alpha \in [0,1].$$

In view of (25), $y_\alpha \in \mathrm{Conv}(Q)$, and therefore

$$0 \geq \langle f'(x_k), y_\alpha - x_{k+1}\rangle = (1-\alpha)\langle f'(x_k), x_k - x_{k+1}\rangle + \frac{\sigma_Q}{2}\alpha(1-\alpha)\|x_{k+1} - x_k\|^2\|f'(x_k)\|_*.$$

Since α is an arbitrary value from $[0,1]$, the result follows. ■

We are now ready to refine our analysis of Algorithm 1.

Theorem 4 (Stepsize Convergence) *Let f be convex ($\sigma_f \geq 0$), and let either Assumption 2 ($\sigma_f > 0$) or Assumptions 1 ($\delta_f > 0$) and 3 ($\delta_Q > 0$) be satisfied. If $\{x_k\}$ is the sequence of points generated by Algorithm 1, then*

$$\sum_{k=0}^{\infty} \|x_{k+1} - x_k\|^2 \leq \frac{2(f^* - f(x_0))}{\sigma_Q \delta_f + \sigma_f}. \tag{26}$$

Proof Since f is convex, Proposition 3 gives

$$f(x_{k+1}) - f(x_k) \geq \Delta(x_k) + \frac{\sigma_f}{2}\|x_{k+1} - x_k\|^2 \geq \frac{1}{2}(\sigma_Q \delta_f + \sigma_f)\|x_{k+1} - x_k\|^2.$$

The additional assumptions of the theorem ensure that $\sigma_Q \delta_f + \delta_f > 0$. It remains to add the inequalities up for $k \geq 0$. ■

Theorem 4 gives an upper estimate on the number of iterations it takes for Algorithm 1 to produce a step of small size. Indeed,

$$k \geq \frac{2(f^* - f(x_0))}{\sigma_Q \delta_f + \sigma_f} \frac{1}{\varepsilon^2} - 1 \quad \Rightarrow \quad \min_{0 \leq i \leq k} \|x_{i+1} - x_i\| \leq \varepsilon.$$

It can be illustrated on simple examples that it is not in general possible to guarantee that the algorithm will produce iterates converging to a local maximizer. However, Theorem 4 guarantees that the set of the limit points is connected, and that all of them satisfy the first-order optimality condition. Also notice that, started from a local minimizer, the method will not move away.

3.2.1 TERMINATION

A reasonable stopping criterion for Algorithm 1 is the following: terminate once the relative change of the objective function becomes small:

$$\frac{f(x_{k+1}) - f(x_k)}{f(x_k)} \leq \varepsilon, \qquad \text{or equivalently,} \qquad f(x_{k+1}) \leq (1+\varepsilon) f(x_k).$$

3.3 Maximization with Spherical Constraints

Consider $\mathbf{E} = \mathbf{E}^* = \mathbf{R}^p$ with $G = I_p$ and $\langle s, x \rangle = \sum_i s_i x_i$, and let

$$Q = r\mathcal{S}^p = \{x \in \mathbf{R}^p \mid \|x\| = r\}.$$

Problem (21) takes on the form

$$\boxed{f^* = \max_{x \in r\mathcal{S}^p} f(x).} \tag{27}$$

Since Q is strongly convex ($\sigma_Q = \frac{1}{r}$), Theorem 4 is meaningful for any convex function f ($\sigma_f \geq 0$). The main step of Algorithm 1 can be written down explicitly (see (23)):

$$x_{k+1} = r \frac{f'(x_k)}{\|f'(x_k)\|_2}.$$

The following examples illustrate the connection of Algorithm 1 to classical methods.

Example 5 (Power Method) *In the special case of a quadratic objective function* $f(x) = \frac{1}{2}x^TCx$ *for some* $C \in \mathbf{S}^p_{++}$ *on the unit sphere* ($r = 1$)*, we have*

$$f^* = \tfrac{1}{2}\lambda_{max}(C),$$

and Algorithm 1 is equivalent to the power iteration method *for computing the largest eigenvalue of* C *(Golub and Van Loan, 1996). Hence for* $Q = \mathcal{S}^p$*, we can think of our scheme as a generalization of the power method. Indeed, our algorithm performs the following iteration:*

$$x_{k+1} = \frac{Cx_k}{\|Cx_k\|}, \quad k \geq 0.$$

Note that both δ_f *and* σ_f *are equal to the smallest eigenvalue of* C*, and hence the right-hand side of (26) is equal to*

$$\frac{\lambda_{max}(C) - x_0^TCx_0}{2\lambda_{min}(C)}. \tag{28}$$

Example 6 (Shifted Power Method) *If* C *is not positive semidefinite in the previous example, the objective function is not convex and our results are not applicable. However, this complication can be circumvented by instead running the algorithm with the shifted quadratic function*

$$\hat{f}(x) = \frac{1}{2}x^T(C + \omega I_p)x,$$

where $\omega > 0$ *satisfies* $\hat{C} = \omega I_p + C \in \mathbf{S}^p_{++}$*. On the feasible set, this change only adds a constant term to the objective function. The method, however, produces different sequence of iterates. Note that the constants* δ_f *and* σ_f *are also affected and, correspondingly, the estimate (28).*

The example above illustrates an easy "trick" to turn a convex convex objective function into a strongly convex one: one simply adds to the original objective function a strongly convex function that is constant on the boundary of the feasible set. The two formulations are equivalent since the objective functions differ only by a constant on the domain of interest. However, there is a clear trade-off. If the second term dominates the first term (say, by choosing very large ω), the algorithm will tend to treat the objective as a quadratic, and will hence tend to terminate in fewer iterations, nearer to the starting iterate. In the limit case, the method will not move away from the initial iterate.

3.4 Maximization with Orthonormality Constraints

Consider $\mathbf{E} = \mathbf{E}^* = \mathbf{R}^{p\times m}$, the space of $p \times m$ real matrices, with $m \leq p$. Note that for $m = 1$ we recover the setting of the previous section. We assume this space is equipped with the trace inner product: $\langle X, Y\rangle = \mathrm{Tr}(X^TY)$. The induced norm, denoted by $\|X\|_F \stackrel{\text{def}}{=} \langle X, X\rangle^{1/2}$, is the Frobenius norm (we let G be the identity operator). We can now consider various feasible sets, the simplest being a ball or a sphere. Due to nature of applications in this paper, let us concentrate on the situation when Q is a special subset of the sphere with radius $r = \sqrt{m}$, the Stiefel manifold:

$$Q = \mathcal{S}^p_m = \{X \in \mathbf{R}^{p\times m} \mid X^TX = I_m\}.$$

Problem (21) then takes on the following form:

$$\boxed{f^* = \max_{X\in\mathcal{S}^p_m} f(X).}$$

Using the duality of the nuclear and spectral matrix norms and Proposition 7 below it can be shown that $\mathrm{Conv}(Q)$ is equal to the unit spectral ball. It can be then further deduced that this set is not strongly convex ($\sigma_Q = 0$) and as a consequence, Theorem 4 is meaningful only if f is strongly convex ($\sigma_f > 0$). Of course, Theorem 1 applies also in the $\sigma_f = 0$ case.

At every iteration, Algorithm 1 needs to maximize a linear function over the Stiefel manifold. In the text that follows, it will be convenient to use the symbol $\mathrm{Polar}(C)$ for the U factor of the *polar decomposition* of matrix $C \in \mathbf{R}^{p\times m}$:

$$C = UP, \qquad U \in \mathcal{S}_m^p, \qquad P \in \mathbf{S}_+^m.$$

The complexity of the polar decomposition is $O(pm^2)$, with $p \geq m$. In view of the Proposition 7, the main step of Algorithm 1 can be written in the form

$$x_{k+1} = \mathrm{Polar}(f'(x_k)).$$

Proposition 7 *Let $C \in \mathbf{R}^{p\times m}$, with $m \leq p$, and denote by $\sigma_i(C)$, $i = 1,\ldots,m$, the singular values of C. Then*

$$\max_{X\in\mathcal{S}_m^p} \langle C, X\rangle = \sum_{i=1}^m \sigma_i(C) \qquad (= \|C\|_* = \mathrm{Tr}[(C^TC)^{1/2}]), \tag{29}$$

with maximizer $X^* = \mathrm{Polar}(C)$. If C is of full rank, then $\mathrm{Polar}(C) = C(C^TC)^{-1/2}$.

Proof Existence of the polar factorization in the nonsquare case is covered by Theorem 7.3.2 in Horn and Johnson (1985). Let $C = V\Sigma W^T$ be the singular value decomposition (SVD) of A; that is, V is $p \times p$ orthonormal, W is $m \times m$ orthonormal, and Σ is $p \times m$ diagonal with values $\sigma_i(A)$ on the diagonal. Then

$$\begin{aligned}
\max_{X\in\mathcal{S}_m^p} \langle C, X\rangle &= \max_{X\in\mathcal{S}_m^p} \langle V\Sigma W^T, X\rangle \\
&= \max_{X\in\mathcal{S}_m^p} \langle \Sigma, V^TXW\rangle \\
&= \max_{Z\in\mathcal{S}_m^p} \langle \Sigma, Z\rangle = \max_{Z\in\mathcal{S}_m^p} \sum_{i=1}^m \sigma_i(C) z_{ii} \leq \sum_i^m \sigma_i(C).
\end{aligned}$$

The third equality follows since the function $X \mapsto V^TXW$ maps $\mathcal{S}_m^p$ onto itself. Both factors of the polar decomposition of C can be easily read-off from the SVD. Indeed, if we let V' be the submatrix of V consisting of its first m columns and Σ' be the principal $m \times m$ submatrix of Σ, that is, a diagonal matrix with values $\sigma_i(C)$ on its diagonal, then $C = V'\Sigma'W^T = (V'W^T)(W\Sigma'W^T)$ and we can put $U = V'W^T$ and $P = W\Sigma'W^T$. To establish (29) it remains to note that

$$\langle C, U\rangle = \mathrm{Tr}\, P = \sum_i \lambda_i(P) = \sum_i \sigma_i(P) = \mathrm{Tr}(P^TP)^{1/2} = \mathrm{Tr}(C^TC)^{1/2} = \sum_i \sigma_i(C).$$

Finally, since $C^TC = PU^TUP = P^2$, we have $P = (C^TC)^{1/2}$, and in the full rank case we obtain $X^* = U = CP^{-1} = C(C^TC)^{-1/2}$. ■

Note that the block sparse PCA formulations (16) and (20) conform to this setting. Here is one more example:

Example 8 (Rectangular Procrustes Problem) *Let $C, X \in \mathbf{R}^{p\times m}$ and $D \in \mathbf{R}^{p\times p}$ and consider the following problem:*

$$\min\{\|C - DX\|_F^2 \mid X^T X = I_m\}. \tag{30}$$

Since $\|C-DX\|_F^2 = \|C\|_F^2 + \langle DX, DX\rangle - 2\langle CD, X\rangle$, by a similar shifting technique as in the previous example we can cast problem (30) in the following form

$$\max\{\omega\|X\|_F^2 - \langle DX, DX\rangle + 2\langle CD, X\rangle \mid X^T X = I_m\}.$$

For $\omega > 0$ large enough, the new objective function will be strongly convex. In this case our algorithm becomes similar to the gradient method proposed in Fraikin et al. (2008).

The standard Procrustes problem in the literature is a special case of (30) with $p = m$.

4. Algorithms for Sparse PCA

The solutions of the sparse PCA formulations of Section 2 provide locally optimal patterns of zeros and nonzeros for a vector $z \in \mathcal{S}^n$ (in the single-unit case) or a matrix $Z \in [\mathcal{S}^n]^m$ (in the block case). The sparsity-inducing penalty term used in these formulations biases however the values assigned to the nonzero entries, which should be readjusted by considering the sole objective of maximum variance. An algorithm for sparse PCA combines thus a method that identifies a "good" pattern of sparsity with a method that fills the active entries. In the sequel, we discuss the general block sparse PCA problem. The single-unit case is recovered in the particular case $m = 1$.

4.1 Methods for Pattern-finding

The application of our general method (Algorithm 1) to the four sparse PCA formulations of Section 2, that is, (8), (13), (16) and (20), leads to Algorithms 2, 3, 4 and 5 below, that provide a locally optimal pattern of sparsity for a matrix $Z \in [\mathcal{S}^n]^m$. This pattern is defined as a binary matrix $P \in \{0,1\}^{n\times m}$ such that $p_{ij} = 1$ if the loading z_{ij} is active and $p_{ij} = 0$ otherwise. So P is an indicator of the coefficients of Z that are zeroed by our method. The computational complexity of the single-unit algorithms (Algorithms 2 and 3) is $O(np)$ operations per iteration. The block algorithms (Algorithms 4 and 5) have complexity $O(npm)$ per iteration.

These algorithms need to be initialized at a point for which the associated sparsity pattern has *at least one* active element. In case of the single-unit algorithms, such an initial iterate $x \in \mathcal{S}^p$ is chosen parallel to the column of A with the largest norm, that is,

$$x = \frac{a_{i^*}}{\|a_{i^*}\|_2}, \quad \text{where} \quad i^* = \arg\max_i \|a_i\|_2. \tag{31}$$

For the block algorithms, a suitable initial iterate $X \in \mathcal{S}_m^p$ is constructed in a block-wise manner as $X = [x|X_\perp]$, where x is the unit-norm vector (31) and $X_\perp \in \mathcal{S}_{m-1}^p$ is orthogonal to x, that is, $x^T X_\perp = 0$.

The nonnegative parameters γ have to be chosen below the upper bounds derived in Section 2 and which are summarized in Table 1. Increasing the value of these parameters leads to solutions of smaller cardinality. There is however not explicit relationship between γ and the resulting cardinality. Since the proposed algorithms are fast, one can afford some trials and errors to reach a targeted cardinality. We however see it as an advantage not to enforce a fixed cardinality, since this information is often unknown a priori. As illustrated in the forthcoming numerical experiments (Section 5),

Algorithm 2	Single-unit ℓ_1	$\gamma \leq \max_i \|a_i\|_2$
Algorithm 3	Single-unit ℓ_0	$\gamma \leq \max_i \|a_i\|_2^2$
Algorithm 4	Block ℓ_1	$\gamma_j \leq \mu_j \max_i \|a_i\|_2$
Algorithm 5	Block ℓ_0	$\gamma_j \leq \mu_j^2 \max_i \|a_i\|_2^2$

Table 1: Theoretical upper-bounds on the sparsity parameters γ.

our algorithms are able to recover cardinalities that are best adapted to the model that underlies the data.

As previously explained, the parameters μ_j required by the block algorithms can be either identical (e.g., equal to one) or distinct (e.g., $\mu_j = \frac{1}{j}$). Since distinct μ_j leads to orthogonal loading vectors in the PCA case (i.e., $\gamma = 0$), they are expected to push towards orthogonality also in the sparse PCA case. Nevertheless, unless otherwise stated, the technical parameters μ_j will be set to one in what follows.

Let us finally mention that the input matrix A of these algorithms can be the data matrix itself as well as any matrix such that the factorization $\Sigma = A^T A$ of the covariance matrix holds. This property is very valuable when there is no access to the data and only the covariance matrix is available, or when the number of samples is greater than the number of variables. In this last case, the dimension p can be reduced to at most n by computing an eigenvalue decomposition or a Cholesky decomposition of the covariance matrix, for instance.

Algorithm 2: Single-unit sparse PCA method based on the ℓ_1-penalty (8)

input : Data matrix $A \in \mathbf{R}^{p \times n}$
Sparsity-controlling parameter $\gamma \geq 0$
Initial iterate $x \in \mathcal{S}^p$
output: A locally optimal sparsity pattern P
begin
  repeat
    $x \longleftarrow \sum_{i=1}^n [|a_i^T x| - \gamma]_+ \operatorname{sign}(a_i^T x) a_i$
    $x \longleftarrow \frac{x}{\|x\|}$
  until *a stopping criterion is satisfied*
  Construct vector $P \in \{0,1\}^n$ such that $\begin{cases} p_i = 1 & \text{if } |a_i^T x| > \gamma \\ p_i = 0 & \text{otherwise.} \end{cases}$
end

4.2 Post-processing

Once a "good" sparsity pattern P has been identified, the active entries of Z still have to be filled. To this end, we consider the optimization problem,

$$(X^*, Z^*) \stackrel{\text{def}}{=} \arg \max_{\substack{X \in \mathcal{S}_m^p \\ Z \in [\mathcal{S}^n]^m \\ Z_{P'} = 0}} \operatorname{Tr}(X^T A Z N), \tag{32}$$

Algorithm 3: Single-unit sparse PCA algorithm based on the ℓ_0-penalty (13)

input : Data matrix $A \in \mathbf{R}^{p\times n}$
Sparsity-controlling parameter $\gamma \geq 0$
Initial iterate $x \in \mathcal{S}^p$
output: A locally optimal sparsity pattern P
begin
  repeat
    $x \longleftarrow \sum_{i=1}^{n} [\mathrm{sign}((a_i^T x)^2 - \gamma)]_+ \, a_i^T x \, a_i$
    $x \longleftarrow \frac{x}{\|x\|}$
  until *a stopping criterion is satisfied*
  Construct vector $P \in \{0,1\}^n$ such that $\begin{cases} p_i = 1 & \text{if } (a_i^T x)^2 > \gamma \\ p_i = 0 & \text{otherwise.} \end{cases}$
end

Algorithm 4: Block sparse PCA algorithm based on the ℓ_1-penalty (16)

input : Data matrix $A \in \mathbf{R}^{p\times n}$
Sparsity-controlling vector $[\gamma_1, \ldots \gamma_m]^T \geq 0$
Parameters $\mu_1, \ldots, \mu_m > 0$
Initial iterate $X \in \mathcal{S}_m^p$
output: A locally optimal sparsity pattern P
begin
  repeat
    for $j = 1, \ldots, m$ **do**
      $x_j \longleftarrow \sum_{i=1}^{n} \mu_j [\mu_j |a_i^T x_j| - \gamma_j]_+ \, \mathrm{sign}(a_i^T x) a_i$
    $X \longleftarrow \mathrm{Polar}(X)$
  until *a stopping criterion is satisfied*
  Construct matrix $P \in \{0,1\}^{n\times m}$ such that $\begin{cases} p_{ij} = 1 & \text{if } \mu_j |a_i^T x_j| > \gamma_j \\ p_{ij} = 0 & \text{otherwise.} \end{cases}$
end

where $P' \in \{0,1\}^{n\times m}$ is the complement of P, $Z_{P'}$ denotes the entries of Z that are constrained to zero and $N = \mathrm{Diag}(\mu_1, \ldots, \mu_m)$ with strictly positive μ_i. Problem (32) assigns the active part of the loading vectors Z to maximize the variance explained by the resulting components. Without loss of generality, each column of P is assumed to contain active elements.

In the single-unit case $m = 1$, an explicit solution of (32) is available,

$$\begin{aligned} X^* &= u, \\ Z_P^* &= v \text{ and } Z_{P'}^* = 0, \end{aligned} \tag{33}$$

where σuv^T with $\sigma > 0$, $u \in \mathcal{B}^p$ and $v \in \mathcal{B}^{\|P\|_0}$ is a rank one singular value decomposition of the matrix A_P, that corresponds to the submatrix of A containing the columns related to the active entries. The post-processing (33) is equivalent to the *variational renormalization* proposed by Moghaddam et al. (2006).

Algorithm 5: Block sparse PCA algorithm based on the ℓ_0-penalty (20)

input : Data matrix $A \in \mathbf{R}^{p\times n}$
Sparsity-controlling vector $[\gamma_1,\dots\gamma_m]^T \geq 0$
Parameters $\mu_1,\dots,\mu_m > 0$
Initial iterate $X \in \mathcal{S}_m^p$
output: A locally optimal sparsity pattern P
begin
  repeat
    for $j = 1,\dots,m$ **do**
      $x_j \longleftarrow \sum_{i=1}^n \mu_j^2[\mathrm{sign}((\mu_j a_i^T x_j)^2 - \gamma_j)]_+ \, a_i^T x_j \, a_i$
    $X \longleftarrow \mathrm{Polar}(X)$
  until *a stopping criterion is satisfied*
  Construct matrix $P \in \{0,1\}^{n\times m}$ such that $\begin{cases} p_{ij} = 1 & \text{if } (\mu_j a_i^T x_j)^2 > \gamma_j \\ p_{ij} = 0 & \text{otherwise.} \end{cases}$
end

Although an exact solution of (32) is hard to compute in the block case $m > 1$, a local maximizer can be efficiently computed by optimizing alternatively with respect to one variable while keeping the other ones fixed. The following lemmas provide an explicit solution to each of these subproblems.

Lemma 9 *For a fixed $Z \in [\mathcal{S}^n]^m$, a solution X^* of*

$$\max_{X\in\mathcal{S}_m^p} \mathrm{Tr}(X^T AZN)$$

is provided by the U factor of the polar decomposition of the product AZN.

Proof See Proposition 7. ■

Lemma 10 *The solution*

$$Z^* \stackrel{def}{=} \arg \max_{\substack{Z\in[\mathcal{S}^n]^m \\ Z_{P'}=0}} \mathrm{Tr}(X^T AZN), \tag{34}$$

is at any point $X \in \mathcal{S}_m^p$ defined by the two conditions $Z_P^* = (A^T XND)_P$ and $Z_{P'}^* = 0$, where D is a positive diagonal matrix that normalizes each column of Z^* to unit norm, that is,

$$D \;=\; \mathrm{Diag}(NX^T AA^T XN)^{-\frac{1}{2}}.$$

Proof The Lagrangian of the optimization problem (34) is

$$\mathcal{L}(Z,\Lambda_1,\Lambda_2) = \mathrm{Tr}(X^T AZN) - \mathrm{Tr}(\Lambda_1(Z^T Z - I_m)) - \mathrm{Tr}(\Lambda_2^T Z),$$

where the Lagrangian multipliers $\Lambda_1 \in \mathbf{R}^{m\times m}$ and $\Lambda_2 \in \mathbf{R}^{n\times m}$ have the following properties: Λ_1 is an invertible diagonal matrix and $(\Lambda_2)_P = 0$. The first order optimality conditions of (34) are thus

$$\begin{aligned} A^T XN - 2Z\Lambda_1 - \Lambda_2 &= 0 \\ \mathrm{Diag}(Z^T Z) &= I_m \\ Z_P &= 0. \end{aligned}$$

Hence, any stationary point Z^* of (34) satisfies $Z^*_P = (A^T XND)_P$ and $Z^*_{P'} = 0$, where D is a diagonal matrix that normalizes the columns of Z^* to unit norm. The second order optimality condition imposes the diagonal matrix D to be positive. Such a D is unique and given by $D = \mathrm{Diag}(NX^T AA^T XN)^{-\frac{1}{2}}$. ■

The alternating optimization scheme is summarized in Algorithm 6, which computes a local solution of (32). A judicious initialization is provided by an accumulation point of the algorithm for pattern-finding, that is, Algorithms 4 and 5.

Algorithm 6: Alternating optimization scheme for solving (32)

input : Data matrix $A \in \mathbf{R}^{p\times n}$
Sparsity pattern $P \in \{0,1\}^{n\times m}$
Matrix $N = \mathrm{Diag}(\mu_1, \ldots, \mu_m)$
Initial iterate $X \in \mathcal{S}^p_m$
output: A local minimizer (X, Z) of (32)
begin
  repeat
    $Z \longleftarrow A^T XN$
    $Z \longleftarrow Z\ \mathrm{Diag}(Z^T Z)^{-\frac{1}{2}}$
    $Z_{\bar{P}} \longleftarrow 0$
    $X \longleftarrow \mathrm{Polar}(AZN)$
  until *a stopping criterion is satisfied*
end

It should be noted that Algorithm 6 is a postprocessing heuristic that, strictly speaking, is required only for the ℓ_1 block formulation (Algorithm 4). In fact, since the cardinality penalty only depends on the sparsity pattern P and not on the actual values assigned to Z_P, a solution (X^*, Z^*) of Algorithms 3 or 5 is also a local maximizer of (32) for the resulting pattern P. This explicit solution provides a good alternative to Algorithm 6. In the single unit case with ℓ_1 penalty (Algorithm 2), the solution (33) is available.

4.3 Sparse PCA Algorithms

To sum up, in this paper we propose four sparse PCA algorithms, each combining a method to identify a "good" sparsity pattern with a method to fill the active entries of the m loading vectors.

They are summarized in Table 2. The MATLAB code of these GPower[5] algorithms is available on the authors' websites.[6]

	Computation of P	Computation of Z_P
GPower_{ℓ_1}	Algorithm 2	Equation (33)
GPower_{ℓ_0}	Algorithm 3	Equation (12)
$\mathsf{GPower}_{\ell_1,m}$	Algorithm 4	Algorithm 6
$\mathsf{GPower}_{\ell_0,m}$	Algorithm 5	Equation (19)

Table 2: New algorithms for sparse PCA.

4.4 Deflation Scheme

For the sake of completeness, we recall a classical deflation process for computing m sparse principal components with a single-unit algorithm (d'Aspremont et al., 2007). Let $z \in \mathbf{R}^n$ be a unit-norm sparse loading vector of the data A. Subsequent directions can be sequentially obtained by computing a dominant sparse component of the residual matrix $A - xz^T$, where $x = Az$ is the vector that solves

$$\min_{x \in \mathbf{R}^p} \|A - xz^T\|_F.$$

Further deflation techniques for sparse PCA have been proposed by Mackey (2008).

4.5 Connection with Existing Sparse PCA Methods

As previously mentioned, our ℓ_0-based single-unit algorithm GPower_{ℓ_0} rests on the same reformulation (13) as the greedy algorithm proposed by d'Aspremont et al. (2008).

There is also a clear connection between both single-unit algorithms GPower_{ℓ_1} and GPower_{ℓ_0} and the rSVD algorithms of Shen and Huang (2008), which solve the optimization problems

$$\min_{\substack{z \in \mathbf{R}^n \\ x \in \mathcal{S}^p}} \|A - xz^T\|_F^2 + 2\gamma\|z\|_1 \quad \text{and} \quad \min_{\substack{z \in \mathbf{R}^n \\ x \in \mathcal{S}^p}} \|A - xz^T\|_F^2 + \gamma\|z\|_0$$

by alternating optimization over one variable (either x or z) while fixing the other one. It can be shown that an update on x amounts to the iterations of Algorithms 2 and 3, depending on the penalty type. Although rSVD and GPower were derived differently, it turns out that, except for the initialization and post-processing phases, the algorithms *are identical*. There are, however, several benefits to our approach: 1) we are able to analyze convergence properties of the method, 2) we show that the core algorithm can be derived as a special case of a generalization of the power method (and hence more applications are possible), 3) we give generalizations from single unit case to block case, 4) our approach uncovers the possibility of a very useful initialization technique, 5) we equip the method with a practical postprocessing phase, 6) we provide a link with the formulation of d'Aspremont et al. (2008).

5. Our algorithms are named GPower where the "G" stands for *generalized* or *gradient*.
6. Websites are `http://www.inma.ucl.ac.be/~richtarik` and `http://www.montefiore.ulg.ac.be/~journee`.

5. Numerical Experiments

In this section, we evaluate the proposed power algorithms against existing sparse PCA methods. Three competing methods are considered in this study: a greedy scheme aimed at computing a local maximizer of (10) (Approximate Greedy Search Algorithm, d'Aspremont et al. (2008)), the SPCA algorithm (Zou et al., 2006) and the sPCA-rSVD algorithm (Shen and Huang, 2008). We do not include the DSPCA algorithm (d'Aspremont et al., 2007) in our numerical study. This method solves a convex relaxation of the sparse PCA problem and has a large per-iteration computational complexity of $O(n^3)$ compared to the other methods. Table 3 lists the considered algorithms.

GPower$_{\ell_1}$	Single-unit sparse PCA via ℓ_1-penalty
GPower$_{\ell_0}$	Single-unit sparse PCA via ℓ_0-penalty
GPower$_{\ell_1,m}$	Block sparse PCA via ℓ_1-penalty
GPower$_{\ell_0,m}$	Block sparse PCA via ℓ_0-penalty
Greedy	Greedy method
SPCA	SPCA algorithm
rSVD$_{\ell_1}$	sPCA-rSVD algorithm with an ℓ_1-penalty ("soft thresholding")
rSVD$_{\ell_0}$	sPCA-rSVD algorithm with an ℓ_0-penalty ("hard thresholding")

Table 3: Sparse PCA algorithms we compare in this section.

These algorithms are compared on random data (Sections 5.1 and 5.2) as well as on real data (Sections 5.3 and 5.4). All numerical experiments are performed in MATLAB. The parameter ε in the stopping criterion of the GPower algorithms has been fixed to 10^{-4}. MATLAB implementations of the SPCA algorithm and the greedy algorithm have been rendered available by Zou et al. (2006) and d'Aspremont et al. (2008). We have, however, implemented the sPCA-rSVD algorithm on our own (Algorithm 1 in Shen and Huang 2008), and use it with the same stopping criterion as for the GPower algorithms. This algorithm initializes with the best rank-one approximation of the data matrix. This is done by a first run of the algorithm with the sparsity-inducing parameter γ that is set to zero.

Given a data matrix $A \in \mathbf{R}^{p\times n}$, the considered sparse PCA algorithms provide m unit-norm sparse loading vectors stored in the matrix $Z \in [\mathcal{S}^n]^m$. The samples of the associated components are provided by the m columns of the product AZ. The variance explained by these m components is an important comparison criterion of the algorithms. In the simple case $m = 1$, the variance explained by the component Az is

$$\mathrm{Var}(z) = z^T A^T A z.$$

When z corresponds to the first principal loading vector, the variance is $\mathrm{Var}(z) = \sigma_{\max}(A)^2$. In the case $m > 1$, the derived components are likely to be correlated. Hence, summing up the variance explained individually by each of the components overestimates the variance explained simultaneously by all the components. This motivates the notion of *adjusted variance* proposed by Zou et al. (2006). The adjusted variance of the m components $Y = AZ$ is defined as

$$\mathrm{AdjVar}\ Z = \mathrm{Tr}\, R^2,$$

where $Y = QR$ is the QR decomposition of the components sample matrix Y ($Q \in \mathcal{S}_m^p$ and R is an $m \times m$ upper triangular matrix).

5.1 Random Data Drawn from a Sparse PCA Model

In this section, we follow the procedure proposed by Shen and Huang (2008) to generate random data with a covariance matrix having sparse eigenvectors. To this end, a covariance matrix is first synthesized through the eigenvalue decomposition $\Sigma = VDV^T$, where the first m columns of $V \in \mathbf{R}^{n\times n}$ are pre-specified sparse orthonormal vectors. A data matrix $A \in \mathbf{R}^{p\times n}$ is then generated by drawing p samples from a zero-mean normal distribution with covariance matrix Σ, that is, $A \sim N(0,\Sigma)$.

Consider a setup with $n = 500, m = 2$ and $p = 50$, where the two orthonormal eigenvectors are specified as follows

$$\left\{\begin{array}{rcll} v_{1i} &=& \frac{1}{\sqrt{10}} & \text{for} \quad i = 1,\ldots,10, \\ v_{1i} &=& 0 & \text{otherwise,} \end{array}\right. \qquad \left\{\begin{array}{rcll} v_{2i} &=& \frac{1}{\sqrt{10}} & \text{for} \quad i = 11,\ldots,20, \\ v_{2i} &=& 0 & \text{otherwise,} \end{array}\right.$$

The remaining eigenvectors $v_j,\ j > 2$, are chosen arbitrarily, and the eigenvalues are fixed at the following values

$$\left\{\begin{array}{rcll} d_{11} &=& 400 & \\ d_{22} &=& 300 & \\ d_{jj} &=& 1, & \text{for} \quad j = 3,\ldots,500. \end{array}\right.$$

We generate 500 data matrices $A \in \mathbf{R}^{p\times n}$ and employ the four GPower algorithms as well as Greedy to compute two unit-norm sparse loading vectors $z_1, z_2 \in \mathbf{R}^{500}$, which are hoped to be close to v_1 and v_2. We consider the model underlying the data to be *successfully identified* (or *recovered*) when both quantities $|v_1^T z_1|$ and $|v_2^T z_2|$ are greater than 0.99.

Two simple alternative strategies are compared for choosing the sparsity-inducing parameters γ_1 and γ_2 required by the GPower algorithms. First, we choose them uniformly at random, between the theoretical bounds. Second, we fix them to reasonable a priori values; in particular, the midpoints of the corresponding admissible interval. For the block algorithm GPower$_{\ell_1,m}$, the parameter γ_2 is fixed at 10 percent of the corresponding upper bound. This value was chosen by limited trial and error to give good results for the particular data analyzed. We do not intend to suggest that this is a recommended choice in general. The values of the sparsity-inducing parameters for the ℓ_0-based GPower algorithms are systematically chosen as the squares of the values chosen for their ℓ_1 counterparts. More details on the selection of γ_1 and γ_2 are provided in Table 4. Concerning the parameters μ_1 and μ_2 used by the block algorithms, both situations $\mu_1 = \mu_2$ and $\mu_1 > \mu_2$ have been considered. Note that Greedy requires to specify the targeted cardinalities as an input, that is, ten nonzeros entries for both loading vectors.

In Table 5, we provide the average of the scalar products $|z_1^T z_2|$, $|v_1^T z_1|$ and $|v_2^T z_2|$ for 500 data matrices with the covariance matrix Σ. The proportion of successful identification of the vectors v_1 and v_2 is also given. The table shows that the GPower algorithms are robust with respect to the choice of the sparsity inducing parameters γ. Good values of γ_1 and γ_2 are easily found by trial and error. The chances of recovery of the sparse model underlying the data are rather good, and some versions of the algorithms successfully recover the sparse model even when the parameters γ are chosen at random. The GPower algorithms do not appear to be as successful as Greedy, which managed to correctly identify vectors v_1 and v_2 in all tests. Note that while the latter method requires the exact knowledge of the cardinality of each component, the GPower algorithms find the sparse model that fits the data best without this information. This property of the GPower algorithms is

Algorithm	Random	Fixed
GPower$_{\ell_1}$	γ_1 uniform distrib. on $[0, \max_i \|a_i\|_2]$ γ_2 uniform distrib. on $[0, \max_i \|a'_i\|_2]$	$\gamma_1 = \frac{1}{2}\max_i \|a_i\|_2$ $\gamma_2 = \frac{1}{2}\max_i \|a'_i\|_2$
GPower$_{\ell_0}$	$\sqrt{\gamma_1}$ uniform distrib. on $[0, \max_i \|a_i\|_2]$ $\sqrt{\gamma_2}$ uniform distrib. on $[0, \max_i \|a'_i\|_2]$	$\gamma_1 = \frac{1}{4}\max_i \|a_i\|_2^2$ $\gamma_2 = \frac{1}{4}\max_i \|a'_i\|_2^2$

Table 4: Details on the random and fixed choices of the sparsity-inducing parameters γ_1 and γ_2 leading to the results displayed in Table 5. Matrix A' used in the case of the single-unit algorithms denotes the residual matrix after one deflation step.

valuable in real-data settings, where little or nothing is known a priori about the cardinality of the components.

Looking at the values reported in Table 5, we observe that the block GPower algorithms are more likely to obtain loading vectors that are "more orthogonal" when using parameters μ_j which are distinct.

Algorithm	γ	$\lvert z_1^T z_2\rvert$	$\lvert v_1^T z_1\rvert$	$\lvert v_2^T z_2\rvert$	Chance of success

Table 5: Average of the quantities $\lvert z_1^T z_2\rvert$, $\lvert v_1^T z_1\rvert$, $\lvert v_2^T z_2\rvert$ and proportion of successful identifications of the two dominant sparse eigenvectors of Σ by extracting two sparse principal components from 500 data matrices. The Greedy algorithm requires prior knowledge of the cardinalities of each component, while the GPower algorithms are very likely to identify the underlying sparse model without this information.

Table 5 does not include results for the SPCA algorithm because of our limited experience with it and the absence of such experiments in the literature. However, in view of the connections developed in Section 4.5, we do expect that the rSVD methods will exhibit similar flexibility to sparsity parameter tuning.

5.2 Random Data without Underlying Sparse PCA Model

All random data matrices $A \in \mathbf{R}^{p\times n}$ considered in this section are generated according to a Gaussian distribution, with zero mean and unit variance.

5.2.1 TRADE-OFF CURVES

Let us first compare the single-unit algorithms, which provide a unit-norm sparse loading vector $z \in \mathbf{R}^n$. We first plot the variance explained by the extracted component against the cardinality of the resulting loading vector z. For each algorithm, the sparsity-inducing parameter is incrementally increased to obtain loading vectors z with a cardinality that decreases from n to 1. The results displayed in Figure 1 are averages of computations on 100 random matrices with dimensions $p = 100$ and $n = 300$. The considered sparse PCA methods aggregate in two groups: GPower$_{\ell_1}$, GPower$_{\ell_0}$, Greedy and rSVD$_{\ell_0}$ outperform the SPCA and rSVD$_{\ell_1}$. It seems that these latter methods perform worse because of the ℓ_1 penalty term used in them. If one, however, post-processes the active part of z according to (33), as we do in GPower$_{\ell_1}$, all sparse PCA methods reach the same performance.

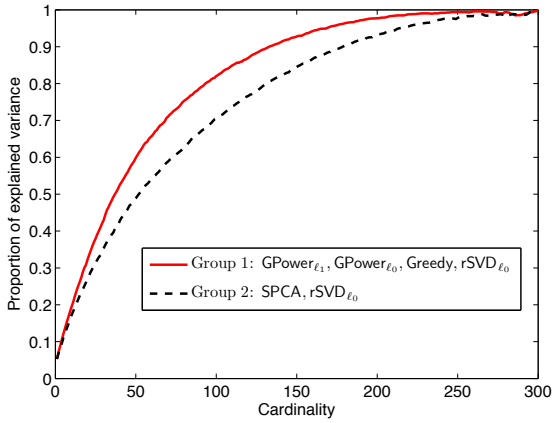

Figure 1: **Trade-off curves** between explained variance and cardinality. The vertical axis is the ratio $\mathrm{Var}(z_{\mathrm{sPCA}})/\mathrm{Var}(z_{\mathrm{PCA}})$, where the loading vector z_{sPCA} is computed by sparse PCA and z_{PCA} is the first principal loading vector. The considered algorithms aggregate in two groups: GPower$_{\ell_1}$, GPower$_{\ell_0}$, Greedy and rSVD$_{\ell_0}$ (top curve), and SPCA and rSVD$_{\ell_1}$ (bottom curve). For a fixed cardinality value, the methods of the first group explain more variance.

5.2.2 CONTROLLING SPARSITY WITH γ

Among the considered methods, the greedy approach is the only one to directly control the cardinality of the solution, that is, the desired cardinality is an input of the algorithm. The other methods require a parameter controlling the trade-off between variance and cardinality. Increasing this parameter leads to solutions with smaller cardinality, but the resulting number of nonzero elements can not be precisely predicted. In Figure 2, we plot the average relationship between the parameter γ and the resulting cardinality of the loading vector z for the two algorithms GPower$_{\ell_1}$ and GPower$_{\ell_0}$. In view of (9) (resp. (14)), the entries i of the loading vector z obtained by the GPower$_{\ell_1}$ (resp. GPower$_{\ell_0}$) algorithm satisfying

$$\|a_i\|_2 \leq \gamma \quad \text{(resp. } \|a_i\|_2^2 \leq \gamma\text{)} \tag{35}$$

have to be zero. Taking into account the distribution of the norms of the columns of A, this provides for every γ a theoretical upper bound on the expected cardinality of the resulting vector z.

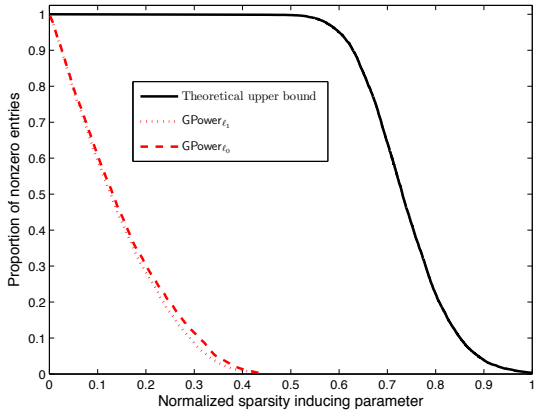

Figure 2: Dependence of cardinality on the value of the sparsity-inducing parameter γ. In case of the GPower$_{\ell_1}$ algorithm, the horizontal axis shows $\gamma/\|a_{i^*}\|_2$, whereas for the GPower$_{\ell_0}$ algorithm, we use $\sqrt{\gamma}/\|a_{i^*}\|_2$. The theoretical upper bound is therefore identical for both methods. The plots are averages based on 100 test problems of size $p = 100$ and $n = 300$.

5.2.3 GREEDY VERSUS THE REST

From the experiments reported above, Greedy and the GPower methods appear to have similar performance in terms of quality of the obtained solution. Moreover, Greedy computes a full path of solutions up to a chosen cardinality, and does not have to deal with the issue of tuning the sparsity parameter γ. The price of this significant advantage of Greedy is its heavy computational load. In order to compare the empirical computational complexities of different algorithms, we display in Figure 3 the average time required to extract one sparse component from Gaussian matrices of dimensions $p = 100$ and $n = 300$. One immediately notices that the greedy method slows down significantly as cardinality increases, whereas the speed of the other considered algorithms does not depend on cardinality. Since on average Greedy is much slower than the other methods, even for

low cardinalities, and because we aim at large-scale applications where the computational load of Greedy would be prohibitive, we discard it from the following numerical experiments.

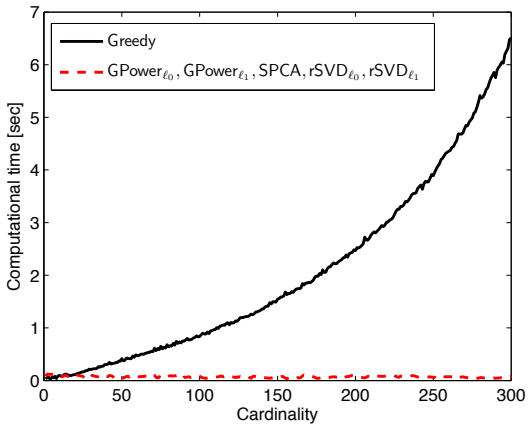

Figure 3: The computational complexity of Greedy grows significantly with cardinality of the resulting loading vector. The speed of the other methods is unaffected by the cardinality target. The single dashed line is representative of the speed of the methods GPower$_{\ell_1}$, GPower$_{\ell_0}$, SPCA, rSVD$_{\ell_0}$, rSVD$_{\ell_0}$ in this test.

5.2.4 SPEED AND SCALING TEST

In Tables 6 and 7 we compare the speed of the remaining algorithms. Table 6 deals with problems with a fixed aspect ratio $n/p = 10$, whereas in Table 7, p is fixed at 500, and exponentially increasing values of n are considered. For the GPower$_{\ell_1}$ method, the sparsity inducing parameter γ was set to 10% of the upper bound $\gamma_{\max} = \|a_{i^*}\|_2$. For the GPower$_{\ell_0}$ method, γ was set to 1% of $\gamma_{\max} = \|a_{i^*}\|_2^2$ in order to aim for solutions of comparable cardinalities (see (35)). These two parameters have also been used for the rSVD$_{\ell_1}$ and the rSVD$_{\ell_0}$ methods, respectively. Concerning SPCA, the sparsity parameter has been chosen by trial and error to get, on average, solutions with similar cardinalities as obtained by the other methods. The values displayed in Tables 6 and 7 correspond to the average running times of the algorithms on 100 test instances for each problem size. In both tables, the new methods GPower$_{\ell_1}$ and GPower$_{\ell_0}$ are the fastest. The difference in speed between GPower$_{\ell_1}$ and GPower$_{\ell_0}$ results from different approaches to fill the active part of z: GPower$_{\ell_1}$ requires to compute a rank-one approximation of a submatrix of A (see Equation (33)), whereas the explicit solution (12) is available to GPower$_{\ell_0}$. The linear complexity of the algorithms in the problem size n is clearly visible in Table 7.

5.2.5 DIFFERENT CONVERGENCE MECHANISMS

Figure 4 illustrates how the trade-off between explained variance and sparsity evolves in the time of computation for the two methods GPower$_{\ell_1}$ and rSVD$_{\ell_1}$. In case of the GPower$_{\ell_1}$ algorithm, the initialization point (31) provides a good approximation of the final cardinality. This method then works on maximizing the variance while keeping the sparsity at a low level throughout. The rSVD$_{\ell_1}$

$p \times n$	100×1000	250×2500	500×5000	750×7500	1000×10000
GPower$_{\ell_1}$	0.10	0.86	2.45	4.28	5.86
GPower$_{\ell_0}$	0.03	0.42	1.21	2.07	2.85
SPCA	0.24	2.92	14.5	40.7	82.2
rSVD$_{\ell_1}$	0.19	2.42	3.97	7.51	9.59
rSVD$_{\ell_0}$	0.18	2.14	3.85	6.94	8.34

Table 6: Average computational time for the extraction of one component (in seconds).

$p \times n$	500×1000	500×2000	500×4000	500×8000	500×16000
GPower$_{\ell_1}$	0.42	0.92	2.00	4.00	8.54
GPower$_{\ell_0}$	0.18	0.42	0.96	2.14	4.55
SPCA	5.20	7.20	12.0	22.6	44.7
rSVD$_{\ell_1}$	1.05	2.12	3.63	7.43	14.4
rSVD$_{\ell_0}$	1.02	1.97	3.45	6.58	13.2

Table 7: Average computational time for the extraction of one component (in seconds).

algorithm, in contrast, works in two steps. First, it maximizes the variance, without enforcing sparsity. This corresponds to computing the first principal component and requires thus a first run of the algorithm with random initialization and a sparsity inducing parameter set at zero. In the second run, this parameter is set to a positive value and the method works to rapidly decrease cardinality at the expense of only a modest decrease in explained variance. So, the new algorithm GPower$_{\ell_1}$ performs faster primarily because it combines the two phases into one, simultaneously optimizing the trade-off between variance and sparsity.

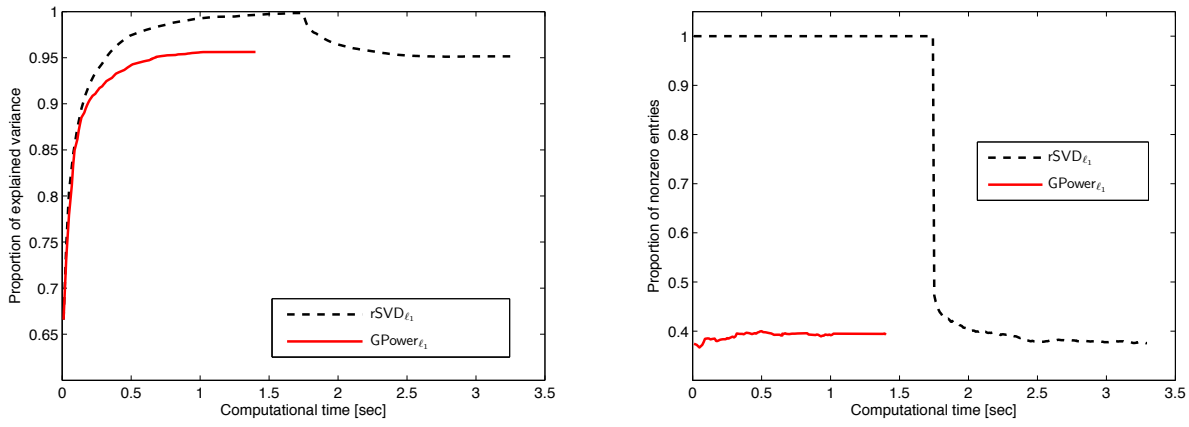

Figure 4: Evolution of explained variance (left) and cardinality (right) in time for the methods GPower$_{\ell_1}$ and rSVD$_{\ell_1}$ run on a test problem of size $p = 250$ and $n = 2500$. The rSVD$_{\ell_1}$ algorithm first solves unconstrained PCA, whereas GPower$_{\ell_1}$ immediately optimizes the trade-off between variance and sparsity.

5.2.6 EXTRACTING MORE COMPONENTS

Similar numerical experiments, which include the methods $\mathsf{GPower}_{\ell_1,m}$ and $\mathsf{GPower}_{\ell_0,m}$, have been conducted for the extraction of more than one component. A deflation scheme is used by the non-block methods to sequentially compute m components. These experiments lead to similar conclusions as in the single-unit case, that is, the methods GPower_{ℓ_1}, GPower_{ℓ_0}, $\mathsf{GPower}_{\ell_1,m}$, $\mathsf{GPower}_{\ell_0,m}$ and rSVD_{ℓ_0} outperform the SPCA and rSVD_{ℓ_1} approaches in terms of variance explained at a fixed cardinality. Again, these last two methods can be improved by postprocessing the resulting loading vectors with Algorithm 6, as it is done for $\mathsf{GPower}_{\ell_1,m}$. The average running times for problems of various sizes are listed in Table 8. The new power-like methods are significantly faster on all instances.

$p \times n$	50×500	100×1000	250×2500	500×5000	750×7500
GPower_{ℓ_1}	0.22	0.56	4.62	12.6	20.4
GPower_{ℓ_0}	0.06	0.17	2.15	6.16	10.3
$\mathsf{GPower}_{\ell_1,m}$	0.09	0.28	3.50	12.4	23.0
$\mathsf{GPower}_{\ell_0,m}$	0.05	0.14	2.39	7.7	12.4
SPCA	0.61	1.47	13.4	48.3	113.3
rSVD_{ℓ_1}	0.29	1.12	7.72	22.6	46.1
rSVD_{ℓ_0}	0.28	1.03	7.21	20.7	41.2

Table 8: Average computational time for the extraction of $m = 5$ components (in seconds).

5.2.7 COST AND BENEFITS OF THE POST-PROCESSING PHASE

Figure 5 illustrates the evolution of the relative increase of computational time as well as the relative improvement in terms of explained variance due to the post-processing phase for increasing values of γ. Only methods with iterative post-processing algorithms are considered, that is, GPower_{ℓ_1} (left-hand plot) and $\mathsf{GPower}_{\ell_1,m}$ (right-hand plot). In the single unit case, the post-processing phase, which amounts to a rank-one SVD of the truncated data matrix A_P, becomes less costly as the level of sparsity increases. As expected, the improvement of variance increases when γ gets larger, that is, when the ℓ_1-penalty biases more and more the values assigned to the non-zero entries of the vector z. A similar observation holds in the block case, excepted that the relative excess of computational time took by the post-processing increases with γ. This difference with the single-unit case results from the fact that the post-processing in the block case deals with sparse matrices of possibly large dimension, whereas in the single-unit case the problem is easily rewritten in terms of a full vector with a dimension that equals the number of nonzero elements. Overall, the postprocessing uses less that 10% of the time needed by the main routine, to improve the explained variance by up to 30%.

5.3 Pitprops Data

The "pitprops" data, which stores 180 observations of 13 variables, has been a standard benchmark to evaluate algorithms for sparse PCA (see, e.g., Jolliffe et al. 2003; Zou et al. 2006; Moghaddam et al. 2006; Shen and Huang 2008). Following these previous studies, we use the GPower algorithms to compute *six* sparse principal components of the data. For such more-samples-than-variables settings, it is customary to first factor the covariance matrix as $\Sigma = A^T A$ with $A \in \mathbf{R}^{13\times 13}$, such that the dimension p is virtually reduced to 13. This operation can be readily done through the eigenvalue decomposition of Σ.

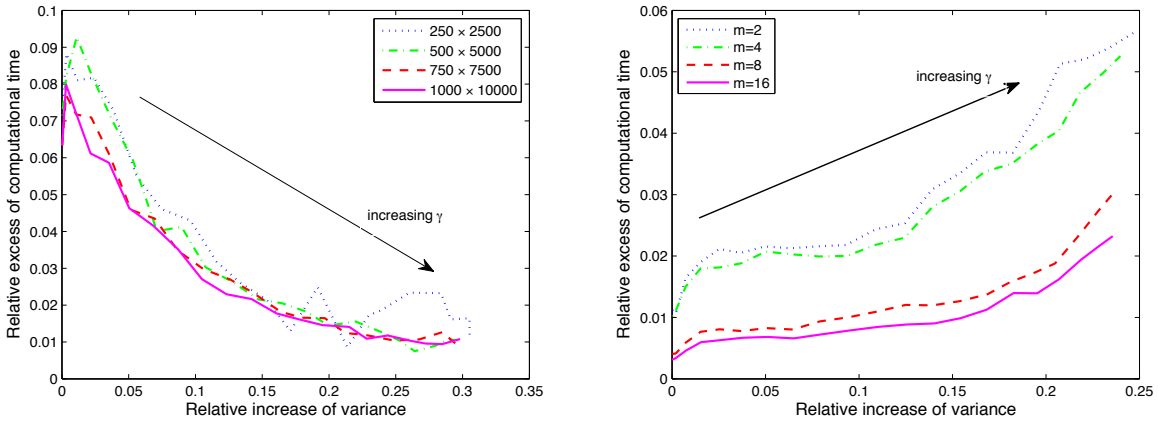

Figure 5: Effects of post-processing in the case of the algorithms GPower$_{\ell_1}$ (left-hand plot) and GPower$_{\ell_1,m}$ (right-hand plot) for increasing values of γ. In both plots, the horizontal axis is the percent increase of variance achieved by the postprocessing phase and the vertical axis is the percent increase in computational time due to post-processing. For GPower$_{\ell_1}$, several problem sizes are considered, whereas the curves for GPower$_{\ell_1,m}$ relate to matrices of dimension 500-by-5000 for several numbers m of extracted components. Each curve is an average on 25 random Gaussian data matrices.

In Table 9, we provide the total cardinality and the proportion of adjusted variance explained by six components computed with SPCA, rSVD$_{\ell_1}$, Greedy as well as our GPower algorithms. The results concerning SPCA, rSVD$_{\ell_1}$, Greedy correspond to the patterns of zeros and nonzeros proposed by Zou et al. (2006), Shen and Huang (2008) and Moghaddam et al. (2006), respectively. For fair comparison, the pattern related to SPCA and rSVD$_{\ell_1}$ have been post-processed with the approach proposed in Section 4.2. Concerning the Gpower algorithms, we fix the six parameters γ_j at the same ratio of their respective upper-bounds. For the block algorithm GPower$_{\ell_1,m}$, experiments have been conducted in both cases "identical μ_j" and "distinct μ_j".

Table 9 illustrates that better patterns can be identified with the GPower algorithms, that is, patterns that explain more variance with the same cardinality (and sometimes even with a smaller one). These results are furthermore likely to be improved by a fine tuning of the six parameters γ_j (i.e., by choosing them independently from each others).

5.4 Analysis of Gene Expression Data

Gene expression data results from DNA microarrays and provide the expression level of thousands of genes across several hundreds of experiments. The interpretation of these huge databases remains a challenge. Of particular interest is the identification of genes that are systematically coexpressed under similar experimental conditions. We refer to Riva et al. (2005) and references therein for more details on microarrays and gene expression data. PCA has been intensively applied in this context (e.g., Alter et al. 2003). Further methods for dimension reduction, such as independent component analysis (Liebermeister, 2002) or nonnegative matrix factorization (Brunet et al., 2004), have also

Method	Parameters	Total cardinality	Prop. of explained variance
rSVD$_{\ell_1}$	see Shen and Huang (2008)	25	0.7924
SPCA	see Zou et al. (2006)	18	0.7680
Greedy	cardinalities: 6-2-3-1-1-1	14	0.7150
	cardinalities: 5-2-2-1-1-1	12	0.5406
GPower$_{\ell_1}$	$\gamma_j/\bar{\gamma}_j = 0.22$, for $j = 1,\ldots,6$	25	0.8083
	$\gamma_j/\bar{\gamma}_j = 0.28$	18	0.7674
	$\gamma_j/\bar{\gamma}_j = 0.30$	15	0.7542
	$\gamma_j/\bar{\gamma}_j = 0.40$	13	0.7172
	$\gamma_j/\bar{\gamma}_j = 0.50$	11	0.6042
GPower$_{\ell_1,m}$	$\gamma_j/\bar{\gamma}_j = 0.17$, for $j = 1,\ldots,6$	25	0.7733
with $\mu_j = 1$	$\gamma_j/\bar{\gamma}_j = 0.25$	17	0.7708
	$\gamma_j/\bar{\gamma}_j = 0.3$	14	0.7508
	$\gamma_j/\bar{\gamma}_j = 0.4$	13	0.7076
	$\gamma_j/\bar{\gamma}_j = 0.45$	11	0.6603
GPower$_{\ell_1,m}$	$\gamma_j/\bar{\gamma}_j = 0.18$, for $j = 1,\ldots,6$	25	0.8111
	$\gamma_j/\bar{\gamma}_j = 0.25$	18	0.7849
with $\mu_j = \frac{1}{j}$	$\gamma_j/\bar{\gamma}_j = 0.30$	15	0.7610
	$\gamma_j/\bar{\gamma}_j = 0.35$	13	0.7323
	$\gamma_j/\bar{\gamma}_j = 0.40$	12	0.6656

Table 9: Extraction of 6 components from the pitprops data. For GPower$_{\ell_1}$, one defines the upper-bounds $\bar{\gamma}_j = \max_i \|a_i^{(j)}\|_2$, where $A^{(j)}$ is the residual data matrix after $j-1$ deflation steps. For GPower$_{\ell_1,m}$, the upper-bounds are $\bar{\gamma}_j = \mu_j \max_i \|a_i\|_2$.

been used on gene expression data. Sparse PCA, which extracts components involving a few genes only, is expected to enhance interpretation.

5.4.1 DATA SETS

The results below focus on four major data sets related to breast cancer. They are briefly detailed in Table 10.[7] Each sparse PCA algorithm computes ten components from these data sets, that is, $m = 10$.

Study	Samples (p)	Genes (n)	Reference
Vijver	295	13319	van de Vijver et al. (2002)
Wang	285	14913	Wang et al. (2005)
Naderi	135	8278	Naderi et al. (2007)
JRH-2	101	14223	Sotiriou et al. (2006)

Table 10: Breast cancer cohorts.

7. The normalized data sets have been kindly provided by Andrew Teschendorff.

5.4.2 SPEED

The average computational time required by the sparse PCA algorithms on each data set is displayed in Table 11. The indicated times are averages on all the computations performed to obtain cardinality ranging from n down to 1.

	Vijver	Wang	Naderi	JRH-2
GPower$_{\ell_1}$	5.92	5.33	2.15	2.69
GPower$_{\ell_0}$	4.86	4.93	1.33	1.73
GPower$_{\ell_1,m}$	5.40	4.37	1.77	1.14
GPower$_{\ell_0,m}$	5.61	7.21	2.25	1.47
SPCA	77.7	82.1	26.7	11.2
rSVD$_{\ell_1}$	10.19	9.97	3.96	4.43
rSVD$_{\ell_0}$	9.51	9.23	3.46	3.61

Table 11: Average computational times (in seconds) for the extraction of $m = 10$ components.

5.4.3 TRADE-OFF CURVES

Figure 6 plots the proportion of adjusted variance versus the cardinality for the "Vijver" data set. The other data sets have similar plots. As for the random test problems, this performance criterion does not discriminate among the different algorithms. All methods have in fact the same performance, provided that the SPCA and rSVD$_{\ell_1}$ approaches are used with postprocessing by Algorithm 6.

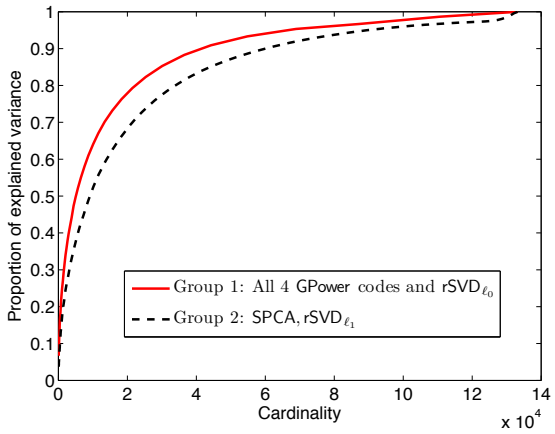

Figure 6: **Trade-off curves** between explained variance and cardinality for the "Vijver" data set. The vertical axis is the ratio $\mathrm{AdjVar}(Z_{\mathrm{sPCA}})/\mathrm{AdjVar}(Z_{\mathrm{PCA}})$, where the loading vectors Z_{sPCA} are computed by sparse PCA and Z_{PCA} are the m first principal loading vectors.

5.4.4 INTERPRETABILITY

A more interesting performance criterion is to estimate the biological interpretability of the extracted components. The *pathway enrichment index* (PEI) proposed by Teschendorff et al. (2007)

measures the statistical significance of the overlap between two kinds of gene sets. The first sets are inferred from the computed components by retaining the most expressed genes, whereas the second sets result from biological knowledge. For instance, metabolic pathways provide sets of genes known to participate together when a certain biological function is required. An alternative is given by the regulatory motifs: genes tagged with an identical motif are likely to be coexpressed. One expects sparse PCA methods to recover some of these biologically significant sets. Table 12 displays the PEI based on 536 metabolic pathways related to cancer. The PEI is the fraction of these 536 sets presenting a statistically significant overlap with the genes inferred from the sparse principal components. The values in Table 12 correspond to the largest PEI obtained among all possible cardinalities. Similarly, Table 13 is based on 173 motifs. More details on the selected pathways and motifs can be found in Teschendorff et al. (2007). This analysis clearly indicates that the sparse PCA methods perform much better than PCA in this context. Furthermore, the new GPower algorithms, and especially the block formulations, provide largest PEI values for both types of biological information. In terms of biological interpretability, they systematically outperform previously published algorithms.

6. Conclusion

We have proposed two single-unit and two block formulations of the sparse PCA problem and constructed reformulations with several favorable properties. First, the reformulated problems are of the form of maximization of a convex function on a compact set, with the feasible set being either a unit Euclidean sphere or the Stiefel manifold. This structure allows for the design and iteration complexity analysis of a simple gradient scheme which applied to our sparse PCA setting results in

four new algorithms for computing sparse principal components of a matrix $A \in \mathbf{R}^{p\times n}$. Second, our algorithms appear to be faster if either the objective function or the feasible set are strongly convex, which holds in the single-unit case and can be enforced in the block case. Third, the dimension of the feasible sets does not depend on n but on p and on the number m of components to be extracted. This is a highly desirable property if $p \ll n$. Last but not least, on random and real-life biological data, our methods systematically outperform the existing algorithms both in speed and trade-off performance. Finally, in the case of the biological data, the components obtained by our block algorithms deliver the richest biological interpretation as compared to the components extracted by the other methods.

Appendix A.

In this appendix we characterize a class of functions with strongly convex level sets. First we need to collect some basic preliminary facts. All the inequalities of Proposition 11 are well-known in the literature.

Proposition 11 *(i) If f is a strongly convex function with convexity parameter σ_f, then for all x, y and $0 \leq \alpha \leq 1$,*

$$f(\alpha x + (1-\alpha)y) \leq \alpha f(x) + (1-\alpha)f(y) - \frac{\sigma_f}{2}\alpha(1-\alpha)\|x-y\|^2. \tag{36}$$

(ii) If f is a convex differentiable function and its gradient is Lipschitz continuous with constant L_f, then for all x and h,

$$f(x+h) \leq f(x) + \langle f'(x), h\rangle + \frac{L_f}{2}\|h\|^2, \tag{37}$$

and

$$\|f'(x)\|_* \leq \sqrt{2L_f(f(x)-f_*)}, \tag{38}$$

where $f_* \stackrel{def}{=} \min_{x\in\mathbf{E}} f(x)$.

We are now ready for the main result of this section.

Theorem 12 (Strongly Convex Level Sets) *Let $f : \mathbf{E} \to \mathbf{R}$ be a nonnegative strongly convex function with convexity parameter $\sigma_f > 0$. Also assume f has a Lipschitz continuous gradient with Lipschitz constant $L_f > 0$. Then for any $\omega > 0$, the set*

$$Q_\omega \stackrel{def}{=} \{x \mid f(x) \leq \omega\}$$

is strongly convex with convexity parameter

$$\sigma_{Q_\omega} = \frac{\sigma_f}{\sqrt{2\omega L_f}}.$$

Proof Consider any $x, y \in Q_\omega$, scalar $0 \leq \alpha \leq 1$ and let $z_\alpha = \alpha x + (1-\alpha)y$. Notice that by convexity, $f(z_\alpha) \leq \omega$. For any $u \in \mathbf{E}$,

$$\begin{aligned}
f(z_\alpha + u) &\stackrel{(37)}{\leq} f(z_\alpha) + \langle f'(z_\alpha), u\rangle + \frac{L_f}{2}\|u\|^2 \\
&\leq f(z_\alpha) + \|f'(z_\alpha)\|\|u\| + \frac{L_f}{2}\|u\|^2 \\
&\stackrel{(38)}{\leq} f(z_\alpha) + \sqrt{2L_f f(z_\alpha)}\|u\| + \frac{L_f}{2}\|u\|^2 \\
&= \left(\sqrt{f(z_\alpha)} + \sqrt{\tfrac{L_f}{2}}\|u\|\right)^2 \\
&\stackrel{(36)}{\leq} \left(\sqrt{\omega - \beta} + \sqrt{\tfrac{L_f}{2}}\|u\|\right)^2,
\end{aligned}$$

where

$$\beta = \frac{\sigma_f}{2}\alpha(1-\alpha)\|x-y\|^2. \tag{39}$$

In view of (25), it remains to show that the last displayed expression is bounded above by ω whenever u is of the form

$$u = \frac{\sigma_{Q_\omega}}{2}\alpha(1-\alpha)\|x-y\|^2 s = \frac{\sigma_f}{2\sqrt{2\omega L_f}}\alpha(1-\alpha)\|x-y\|^2 s, \tag{40}$$

for some $s \in \mathcal{S}$. However, this follows directly from concavity of the scalar function $g(t) = \sqrt{t}$:

$$\begin{aligned}
\sqrt{\omega - \beta} = g(\omega - \beta) &\leq g(\omega) - \langle g'(\omega), \beta\rangle \\
&= \sqrt{\omega} - \frac{\beta}{2\sqrt{\omega}} \\
&\stackrel{(39)}{\leq} \sqrt{\omega} - \frac{\sigma_f}{4\sqrt{\omega}}\alpha(1-\alpha)\|x-y\|^2 \\
&\stackrel{(40)}{\leq} \sqrt{\omega} - \sqrt{\frac{L_f}{2}}\|u\|.
\end{aligned}$$

■

Example 13 *Let $f(x) = \|x\|^2$. Note that $\sigma_f = L_f = 2$. If we let $\omega = r^2$, then*

$$Q_\omega = \{x \mid f(x) \leq \omega\} = \{x \mid \|x\| \leq r\} = r \cdot \mathcal{B}.$$

We have shown before (see the discussion immediately following Assumption 3), that the strong convexity parameter of this set is $\sigma_{Q_\omega} = \frac{1}{r}$. Note that we recover this as a special case of Theorem 12:

$$\sigma_{Q_\omega} = \frac{\sigma_f}{\sqrt{2\omega L_f}} = \frac{1}{r}.$$

Abstract

Convolution kernels for trees provide simple means for learning with tree-structured data. The computation time of tree kernels is quadratic in the size of the trees, since all pairs of nodes need to be compared. Thus, large parse trees, obtained from HTML documents or structured network data, render convolution kernels inapplicable. In this article, we propose an effective approximation technique for parse tree kernels. The approximate tree kernels (ATKs) limit kernel computation to a sparse subset of relevant subtrees and discard redundant structures, such that training and testing of kernel-based learning methods are significantly accelerated. We devise linear programming approaches for identifying such subsets for supervised and unsupervised learning tasks, respectively. Empirically, the approximate tree kernels attain run-time improvements up to three orders of magnitude while preserving the predictive accuracy of regular tree kernels. For unsupervised tasks, the approximate tree kernels even lead to more accurate predictions by identifying relevant dimensions in feature space.

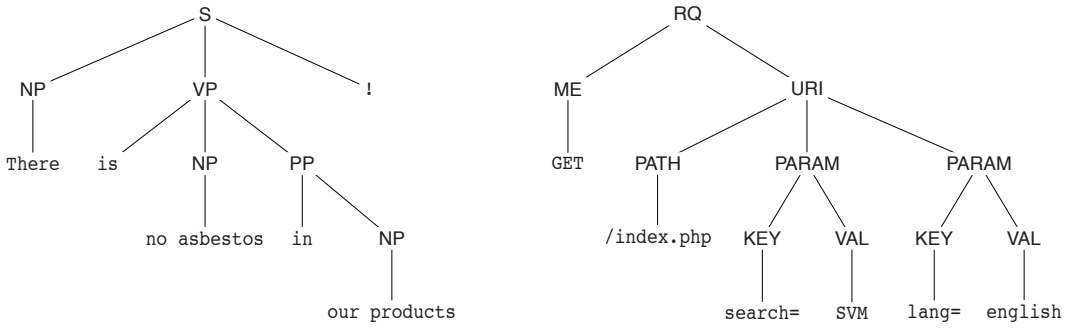
Keywords: tree kernels, approximation, kernel methods, convolution kernels

1. Introduction

Learning from tree-structured data is an elementary problem in machine learning, as trees arise naturally in many real-world applications. Exemplary applications involve parse trees in natural language processing, HTML documents in information retrieval, molecule structures in computational chemistry, and structured network data in computer security (e.g., Manning and Schütze, 1999; Kashima and Koyanagi, 2002; Moschitti, 2006b; Cilia and Moschitti, 2007; Düssel et al., 2008; Rieck et al., 2008; Bockermann et al., 2009).

In general, trees carry hierarchical information reflecting the underlying dependency structure of a domain at hand—an appropriate representation of which is often indispensable for learning accurate prediction models. For instance, shallow representations of trees such as flat feature vectors often fail to capture the underlying dependencies. Thus, the prevalent tools for learning with structured data are kernel functions, which implicitly assess pairwise similarities of structured objects and thereby avoid explicit representations (see Müller et al., 2001; Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004). Kernel functions for structured data can be constructed using the convolution of local kernels defined over sub-structures (Haussler, 1999). A prominent example for such a convolution is the parse tree kernel proposed by Collins and Duffy (2002) which determines the similarity of trees by counting shared subtrees.

The computation of parse tree kernels, however, is inherently quadratic in the number of tree nodes, as it builds on dynamic programming to compute the contribution of shared subtrees. Allocating and updating tables for dynamic programming is feasible for small tree sizes, say less than 200 nodes, so that tree kernels have been widely applied in natural language processing, for example, for question classification (Zhang and Lee, 2003) and parse tree reranking (Collins and Duffy, 2002). Figure 1(a) shows an exemplary parse tree of natural language text. Large trees involve computations that exhaust available resources in terms of memory and run-time. For example, the computation of a parse tree kernel for two HTML documents comprising 10,000 nodes each, requires about 1 gigabyte of memory and takes over 100 seconds on a recent computer system. Given that kernel computations are performed millions of times in large-scale learning, it is evident that regular tree kernels are an inappropriate choice in many learning tasks.



(a) Parse tree for a sentence

(b) Parse tree for a HTTP request

Figure 1: Parse trees for natural language text and the HTTP network protocol.

The limitation of regular tree kernels becomes apparent when considering learning tasks based on formal grammars, such as web spam detection. In web spam detection one seeks to find arrays of linked fraudulent web pages, so-called link farms, that deteriorate the performance of search engines by manipulating search results (e.g., Wu and Davison, 2005; Drost and Scheffer, 2005; Castillo et al., 2006). Besides being densely linked, these web pages share an important property: they are generated automatically according to templates. Hence, a promising approach for web spam detection is the analysis of structure in web pages using parse trees of HTML documents. Unfortunately, HTML documents can grow almost arbitrarily large and render the computation of conventional tree kernels impossible.

Moreover, tree-structured data also arises as part of unsupervised learning problems, such as clustering and anomaly detection. For instance, a critical task in computer security is the automatic detection of novel network attacks (Eskin et al., 2002). Current detection techniques fail to cope with the increasing amount and diversity of network threats, as they depend on manually generated detection rules. As an alternative, one-class learning methods have been successfully employed for identifying anomalies in the context of intrusion detection (e.g., Eskin et al., 2002; Kruegel and Vigna, 2003; Rieck and Laskov, 2007). Due to the already mentioned run-time constraints these approaches focus on shallow features, although efficient methods for extracting syntactical structure from network data are available (e.g., Pang et al., 2006; Borisov et al., 2007; Wondracek et al., 2008). Similar to natural language, network protocols are defined in terms of grammars and individual communication can be represented as parse trees, see Figure 1(b).

To alleviate the limitations of regular tree kernels, we propose *approximate tree kernels* (ATKs) which approximate the kernel computation and thereby allow for efficient learning with arbitrary sized trees in supervised and in unsupervised settings. The efficacy gained by approximate tree kernels rests on a two-stage process: A sparse set of relevant subtrees rooted at appropriate grammar symbols is determined from a small sample of trees, *prior* to subsequent training and testing processes. By decoupling the selection of symbols from the kernel computation, both, run-time and memory requirements are significantly reduced. In the supervised setting, the subset of symbols is optimized with respect to its ability to discriminate between the involved classes, while for the unsupervised setting the optimization is performed with respect to node occurrences in order to minimize the expected run-time. The corresponding optimization problems are translated into linear programs that can be efficiently solved with standard techniques.

Experiments conducted on question classification, web spam detection and network intrusion detection demonstrate the expressiveness and efficiency of our novel approximate kernels. Throughout all our experiments, approximate tree kernels are significantly faster than regular convolution kernels. Depending on the size of the trees, we observe run-time and memory improvements up to 3 orders of magnitude. Furthermore, the approximate tree kernels not only consistently yield the same predictive performance as regular tree kernels, but even outperform their exact counterparts in some tasks by identifying informative dimensions in feature space.

The remainder of this article is organized as follows. We introduce regular parse tree kernels in Section 2 and present our main contribution, the approximate tree kernels, in Section 3. We study the characteristics of approximate kernels on artificial data in Section 4 and report on real-world applications in Section 5. Finally, Section 6 concludes.

2. Kernels for Parse Trees

Let $G = (S, P, s)$ be a grammar with production rules P and a start symbol s defined over a set S of non-terminal and terminal symbols (Hopcroft and Motwani, 2001). A tree X is called a parse tree of G if X is derived by assembling productions $p \in P$ such that every node $x \in X$ is labeled with a symbol $\ell(x) \in S$. To navigate in a parse tree, we address the i-th child of a node x by x_i and denote the number of children by $|x|$. The number of nodes in X is indicated by $|X|$ and the set of all possible trees is given by $\mathcal{X}$.

A kernel $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a symmetric and positive semi-definite function, which implicitly computes an inner product in a reproducing kernel Hilbert space (Vapnik, 1995). A generic technique for defining kernel functions over structured data is the convolution of local kernels defined

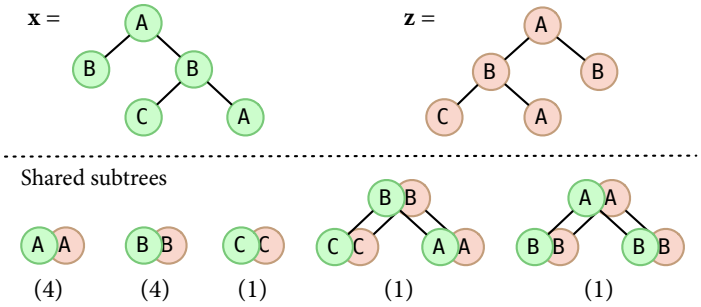


Figure 2: Shared subtrees in two parse trees. The numbers in brackets indicate the number of occurrences for each shared subtree pair.

over sub-structures (Haussler, 1999). Collins and Duffy (2002) apply this concept to parse trees by counting shared subtrees. Given two parse trees X and Z, their *parse tree kernel* is given by

$$k(X,Z) = \sum_{x \in X} \sum_{z \in Z} c(x,z), \tag{1}$$

where the counting function c recursively determines the number of shared subtrees rooted in the tree nodes x and z.

The function c is defined as $c(x,z) = 0$ if x and z are not derived from the same production and $c(x,z) = \lambda$ if x and z are leave nodes of the same production. In all other cases, the definition of the counting function c follows a recursive rule given by

$$c(x,z) = \lambda \prod_{i=1}^{|x|} (1 + c(x_i, z_i)) . \tag{2}$$

The trade-off parameter $0 < \lambda \leq 1$ balances the contribution of subtrees, such that small values of λ decay the contribution of lower nodes in large subtrees (see Collins and Duffy, 2002). Figure 2 illustrates two simple parse trees and the corresponding shared subtrees.

Several extensions and refinements of the parse tree kernel have been proposed in the literature to increase its expressiveness for specific learning tasks. For example, setting the constant term in the product of Equation (2) to zero restricts the counting function to take only complete subtrees into account (Vishwanathan and Smola, 2003). Kashima and Koyanagi (2002) extend the counting function to generic trees—not necessarily derived from a grammar—by considering ordered subsets of child nodes for computing the kernel. Further extensions to the counting function proposed by Moschitti (2006b) allow for controlling the vertical as well as the horizontal contribution of subtree counts. Moreover, Moschitti and Zanzotto (2007) extend the parse tree kernel to operate on pairs of trees for deriving relations between sentences in tasks such as textual entailment recognition. However, all of the above mentioned extensions depend on dynamic programming over all pairs of nodes and thus yield prohibitive run-time and memory requirements if large trees are considered.

Selecting discriminative subtrees for tree kernels has been first studied by Suzuki et al. (2004) in the domain of natural language processing. A feature selection procedure based on statistical tests is embedded in the dynamic programming, such that relevant substructures are identified during computation of the parse tree kernel (see also Suzuki and Isozaki, 2005). While this procedure

significantly improves the expressiveness of corresponding tree kernels, the entanglement of feature selection and dynamic programming unfortunately prevents any improvement of run-time and memory requirements over regular tree kernels.

First steps toward run-time improvement of tree kernels have been devised by Moschitti (2006a), who introduces an alternative algorithm limiting computation to node pairs with matching grammar symbols. Although this extension reduces the run-time, it does not alleviate prohibitive memory requirements, as counts for all possible node pairs need to be stored. Also note, that for large trees with $|X| \gg |S|$, only a minor speed-up is gained, since only a small fraction of node pairs can be discarded from the kernel computation. Nevertheless, this algorithm is an efficient approach when learning with small trees as in natural language processing.

3. Approximate Tree Kernels

The previous section argues that the computation of regular tree kernels using dynamic programming is infeasible for large tree structures. In this section we introduce approximate tree kernels to significantly decrease this computational burden. Our approximation of tree kernels is based on the observation that trees often contain redundant parts that are not only irrelevant for the learning task but also slow-down the kernel computation unnecessarily. As an example for redundancy in trees let us consider the task of web spam detection. While few HTML elements, such as header and meta tags, are indicative for web spam templates, the majority of formatting tags is irrelevant and may even harm performance. We exploit this observation by restricting the kernel computation to a sparse set of subtrees rooted in only a few grammar symbols.

In general, selecting relevant subtrees for the kernel computation requires efficient means for enumerating subtrees. The amount of generic subtrees contained in a single parse tree is exponential in the number of nodes and thus intractable for large tree structures. Consequently, we refrain from exhaustive enumeration and limit the selection to subtrees rooted at particular grammar symbols. We introduce a selection function $\omega : S \to \{0,1\}$, which controls whether subtrees rooted in nodes with the symbol $s \in S$ contribute to the convolution ($\omega(s) = 1$) or not ($\omega(s) = 0$). By means of ω, approximate tree kernels are defined as follows.

Definition 1 *Given a selection function $\omega : S \to \{0,1\}$, the approximate tree kernel is defined as*

$$\hat{k}_\omega(X,Z) = \sum_{s \in S} \omega(s) \sum_{\substack{x \in X \\ \ell(x)=s}} \sum_{\substack{z \in Z \\ \ell(z)=s}} \tilde{c}(x,z), \tag{3}$$

where the approximate counting function $\tilde{c}$ is defined as (i) $\tilde{c}(x,z) = 0$ if x and z are not derived from the same production, (ii) $\tilde{c}(x,z) = 0$ if x or z has not been selected, that is, $\omega(\ell(x)) = 0$ or $\omega(\ell(z)) = 0$, and (iii) $c(x,z) = \lambda$ if x and z are leave nodes of the same production. In all other cases, the approximate counting function $\tilde{c}$ is defined as

$$\tilde{c}(x,z) = \lambda \prod_{i=1}^{|x|} (1 + \tilde{c}(x_i, z_i)) .$$

For the task at hand, the selection function ω needs to be adapted to the tree data before the resulting approximate tree kernel can be applied together with learning algorithms. Note that the exact parse tree kernel in Equation (1) is obtained as a special case of Equation (3) if $\omega(s) = 1$ for all symbols $s \in S$. Irrespectively of the actual choice of ω, Proposition 2 shows that the approximate kernel $\hat{k}$ is a valid kernel function.

Proposition 2 *The approximate tree kernel in Definition 1 is a kernel function.*

Proof Let $\phi(X)$ be the vector of frequencies of all subtrees occurring in X as defined by Collins and Duffy (2002). Then, by definition, $\hat{k}_\omega$ can always be written as

$$\hat{k}_\omega(X,Z) = \langle P_\omega \phi(X), P_\omega \phi(Z) \rangle,$$

where P_ω projects the dimensions of $\phi(X)$ on the subtrees rooted in symbols selected by ω. For any ω, the projection P_ω is independent of the actual X and Z, and hence $\hat{k}_\omega$ is a valid kernel. ■

Proposition 2 allows to view approximate tree kernels as feature selection techniques. If the selection function effectively identifies relevant symbols, the dimensionality of the feature space is reduced and the kernel provides access to a refined data representation. We will address this point in Section 4 and 5 where we study eigendecompositions in the induced features spaces. Additionally, we note that the approximate tree kernel realizes a run-time speed-up by a factor of q_ω, which depends on the number of selected symbols in ω and the amount of subtrees rooted at these symbols. For two particular trees X, Z we can state the following simple proposition.

Proposition 3 *The approximate tree kernel $\hat{k}_\omega(X,Z)$ can be computed q_ω times faster than $k(X,Z)$.*

Proof Let $\#_s(X)$ denote the occurrences of nodes $x \in X$ with $\ell(x) = s$. Then the speed-up q_ω realized by $\hat{k}_\omega$ is lower bounded by

$$q_\omega \geq \frac{\sum_{s \in S} \#_s(X) \, \#_s(Z)}{\sum_{s \in S} \omega(s) \, \#_s(X) \, \#_s(Z)} \tag{4}$$

as all nodes with identical symbols in X and Z are paired. For the trivial case where for all elements $\omega(s) = 1$, the factor q_ω equals 1 and the run-time is identical to the parse tree kernel. In all other cases $q_\omega > 1$ holds since at least one symbol is discarded from the denominator in Equation (4). ■

The quality of $\hat{k}_\omega$ and also q_ω depend on the actual choice of ω. If the selection function ω discards redundant and irrelevant subtrees from the kernel computation the approximate kernel can not only be computed faster but also preserves the discriminative expressiveness of the regular tree kernel. Sections 3.1 and 3.2 deal with adapting ω for supervised and unsupervised learning tasks, respectively. Although, the resulting optimization problems are quadratic in the number of instances, selecting symbols can be performed on a small fraction of the data prior to the actual learning process; hence, performance gains achieved in the latter are not affected by the initial selection process. We show in Section 5 that reasonable approximations can be achieved for moderate sample sizes.

3.1 The Supervised Setting

In the supervised setting, we are given n labeled parse trees $(X_1, y_1), \ldots, (X_n, y_n)$ with $y_i \in \mathcal{Y}$. For binary classification we may have $\mathcal{Y} = \{-1, 1\}$ while a multi-class scenario with κ classes gives rise to the set $\mathcal{Y} = \{1, 2, \ldots, \kappa\}$. In the supervised case, the aim of the approximation is to preserve the discriminative power of the regular kernel by selecting a sparse but expressive subset of grammar symbols. We first note that Y with elements $[Y_{ij}]_{i,j=1,\ldots,n}$ given by

$$Y_{ij} = [\![y_i = y_j]\!] - [\![y_i \neq y_j]\!], \tag{5}$$

represents an optimal kernel matrix where $[\![u]\!]$ is an indicator function returning 1 if u is true and 0 otherwise. For binary classification problems, Equation (5) can also be computed by the outer product $Y = yy^{\mathsf{T}}$, where $y = (y_1, \ldots, y_n)^{\mathsf{T}}$.

Inspired by kernel target alignment (Cristianini et al., 2001), a simple measure of the similarity of the approximate kernel $\hat{K}_\omega = [\hat{k}_\omega(X_i, X_j)]_{i,j=1,\ldots,n}$ and the optimal Y is provided by the Frobenius inner product $\langle \cdot, \cdot \rangle_{\mathcal{F}}$ that is defined as $\langle A, B \rangle_{\mathcal{F}} = \sum_{ij} a_{ij} b_{ij}$. We have,

$$\langle Y, \hat{K}_\omega \rangle_{\mathcal{F}} = \sum_{y_i = y_j} \hat{k}_{ij} - \sum_{y_i \neq y_j} \hat{k}_{ij}. \tag{6}$$

The right hand side of Equation (6) measures the within class (first term) and the between class (second term) similarity. Approximate kernels that discriminate well between the involved classes realize large values of $\langle Y, \hat{K}_\omega \rangle_{\mathcal{F}}$, hence maximizing Equation (6) with respect to ω suffices for finding approximate kernels with high discriminative power.

We arrive at the following integer linear program that has to be maximized with respect to ω to align $\hat{K}_\omega$ to the labels y,

$$\max_{\omega \in \{0,1\}^{|S|}} \quad \sum_{\substack{i,j=1 \\ i \neq j}}^{n} y_i y_j \hat{k}_\omega(X_i, X_j). \tag{7}$$

Note that we exclude diagonal elements, that is, $\hat{k}_\omega(X_i, X_i)$, from Equation (7), as the large self-similarity induced by the parse tree kernel impacts numerical stability on large tree structures (see Collins and Duffy, 2002).

Optimizing Equation (7) directly will inevitably reproduce the regular convolution kernel as all subtrees contribute positively to the kernel computation. As a remedy, we restrict the number of supporting symbols of the approximation by a pre-defined constant N. Moreover, instead of optimizing the integer program directly, we propose to use a relaxed variant thereof, where a threshold is used to discretize ω. Consequently, we obtain the following relaxed linear program that can be solved with standard solvers.

Optimization Problem 1 (Supervised Setting) *Given a labeled training sample of size n and let $N \in \mathbb{N}$. The optimal selection function ω^* can be computed by solving*

$$\begin{aligned} \omega^* = \operatorname*{argmax}_{\omega \in [0,1]^{|S|}} \quad & \sum_{\substack{i,j=1 \\ i \neq j}}^{n} y_i y_j \sum_{s \in S} \omega(s) \sum_{\substack{x \in X_i \\ \ell(x) = s}} \sum_{\substack{z \in X_j \\ \ell(z) = s}} \tilde{c}(x, z) \\ \textit{subject to} \quad & \sum_{s \in S} \omega(s) \leq N, \end{aligned} \tag{8}$$

where the counting function $\tilde{c}$ is given in Definition (3).

3.2 The Unsupervised Setting

Optimization Problem 1 identifies N symbols providing the highest discriminative power given a labeled training set. In the absence of labels, for instance in an anomaly detection task, the operational goal needs to be changed. In these cases, the only accessible information for finding ω are the tree structures themselves. Large trees are often characterized by redundant substructures that strongly impact run-time performance while encoding only little information. Moreover, syntactical

structure present in all trees of a data set do not provide any information suitable for learning. As a consequence, we seek a selection of symbols using a constraint on the expected run-time and thereby implicitly discard redundant and costly structures with small contribution to the kernel value.

Given unlabeled parse trees $X_1, X_2, \ldots, X_n$, we introduce a function $f(s)$ which measures the average frequency of node comparisons for the symbol s in the training set, defined as

$$f(s) = \frac{1}{n^2} \sum_{i,j=1}^{n} \#_s(X_i) \#_s(X_j). \tag{9}$$

Using the average comparison frequency f, we bound the expected run-time of the approximate kernel by $\rho \in (0,1]$, the ratio of expected node comparisons with respect to the exact parse tree kernel. The following optimization problem details the computation of the optimal ω^* for unsupervised settings.

Optimization Problem 2 (Unsupervised Setting) *Given an unlabeled training sample of size n and a comparison ratio $\rho \in (0,1]$.*

$$\begin{aligned} \omega^* = \operatorname*{argmax}_{\omega \in [0,1]^{|S|}} & \sum_{\substack{i,j=1 \\ i \neq j}}^{n} \sum_{s \in S} \omega(s) \sum_{\substack{x \in X_i \\ \ell(x)=s}} \sum_{\substack{z \in X_j \\ \ell(z)=s}} \tilde{c}(x,z) \\ \textit{subject to} \quad & \frac{\sum_{s \in S} \omega(s) f(s)}{\sum_{s \in S} f(s)} \leq \rho, \end{aligned} \tag{10}$$

where the counting function $\tilde{c}$ is given in Definition 3 and f defined as in Equation (9).

The optimal selection function ω^* gives rise to a tree kernel that approximates the regular kernel as close as possible, while on average considering a fraction of ρ node pairs for computing the similarities. Analogously to the supervised setting, we solve the relaxed variant of the integer program and use a threshold to discretize the resulting ω.

3.3 Extensions

The supervised and unsupervised formulations in Optimization Problem 1 and 2 build on different constraints for determining a selection of appropriate symbols. Depending on the learning task at hand, these constraints are exchangeable, such that approximate tree kernels in supervised settings may also be restricted to the ratio ρ of expected node comparisons and the unsupervised formulation can be alternatively conditioned on a fixed number of symbols N. Both constraints may even be applied jointly to limit expected run-time and the number of selected symbols. For our presentation, we have chosen a constraint on the number of symbols in the supervised setting, as it provides an intuitive measure for the degree of approximation. By contrast, we employ a constraint on the expected number of node comparisons in the unsupervised formulation, as in the absence of labels, it is easier to bound the run-time, irrespective of the number of selected symbols.

Further extensions incorporating prior knowledge into the proposed approximations are straight forward. For instance, the approximation procedure can be refined using logical compounds based on conjunctions and disjunctions of symbols. If the activation of symbol s_j requires the activation of s_{j+1}, the constraint $\omega(s_j) - \omega(s_{j+1}) = 0$ can be included in Equation (8) and (10). A conjunction (AND) of m symbols can then be efficiently encoded by $m-1$ additional constraints as

$$\forall_{j=1}^{m-1} \omega(s_j) - \omega(s_{j+1}) = 0.$$

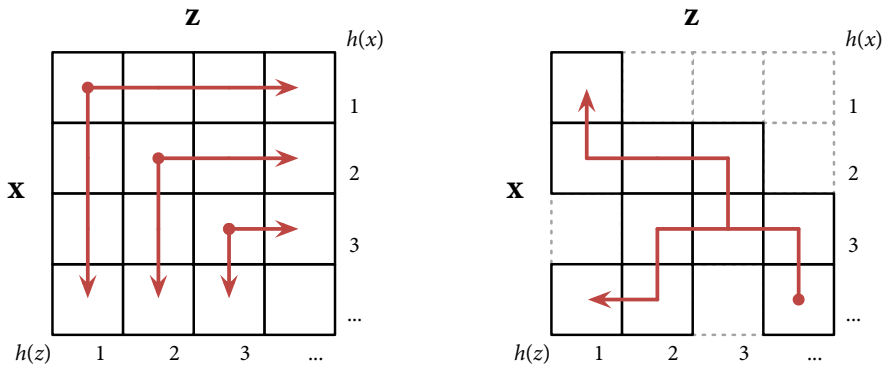
For a disjunction (OR) of symbols $s_j, \ldots, s_{j+m}$ the following constraint guarantees that at least one representative of the group is active in the solution

$$\omega(s_j) + \omega(s_{j+1}) + \ldots + \omega(s_{j+m}) \geq 1. \tag{11}$$

Alternatively, Equation (11) can be turned into an exclusive disjunction (XOR) of symbols by changing the inequality into an equality constraint.

3.4 Implementation

A standard technique for computing tree kernels is dynamic programming, where a table of $|X| \times |Z|$ elements is used to store the counts of subtrees during recursive evaluations. The kernel computation is then carried out in either a systematic or a structural fashion, where intermediate results are stored in the table as sketched in Figure 3. The systematic variant processes the subtrees with ascending height, such that at a particular height, all counts for lower subtrees can be looked up in the table (Shawe-Taylor and Cristianini, 2004). For the structural variant, the dynamic programming table acts as a cache, which stores previous results when computing the recursive counting directly (Moschitti, 2006a). This latter approach has the advantage that only matching subtrees are considered and mismatching nodes do not contribute to the run-time as in the systematic variant.



(a) Systematic mode (b) Structural mode

Figure 3: Dynamic programming for tree kernels. The convolution of subtree counts is computed in a systematic (Shawe-Taylor and Cristianini, 2004) or structural manner (Moschitti, 2006a). The term $h(x)$ denotes the height of the subtree rooted in $x \in X$.

We now provide details on an implementation of approximate tree kernels using the structural approach. The inputs of our implementation are parse trees X, Z and a selection function ω which has been determined in advance using the supervised or unsupervised approximation (Optimization Problems 1 and 2). The implementation proceeds by first generating pairs of matching nodes from the trees X, Z, similarly to the algorithm proposed by Moschitti (2006a). However, pairs whose symbols are not selected by ω are omitted. The computation of the tree kernel is then carried out by looping over the node pairs and counting the number of shared subtrees rooted at each pair. An exemplary implementation of the approximate kernel is given in Algorithms 1, 2 and 3.

Algorithm 1 Approximate Tree Kernel

```
1: function KERNEL(X, Z, ω)
2:     L ← GENERATEPAIRS(X, Z, ω)
3:     k ← 0
4:     for (x, z) ← L do                          ▷ Loop over selected pairs of nodes
5:         k ← k + COUNT(x, z)
6:     return k
```

Algorithm 1 realizes a generic tree kernel, which determines the number of shared subtrees by looping over a list of node pairs. Algorithm 2 shows the corresponding analogue of the counting function in Equation (2) which is called during each iteration of the loop. While the standard implementation of the parse tree kernel (e.g., Shawe-Taylor and Cristianini, 2004; Moschitti, 2006a) uses a dynamic programming table to store the contribution of subtree counts, we employ a hash table denoted by H. A hash table guarantees constant reading and writing of intermediate results yet it grows with the number of selected node pairs and thereby reduces memory in comparison to a standard table of all possible pairs. Note that if all symbols in ω are selected, H realizes the standard dynamic programming approach.

Algorithm 2 Counting Function

```
1: function COUNT(x, z)
2:     if x and z have different productions then
3:         return 0
4:     if x or z is a leaf node then
5:         return λ
6:     if (x, z) stored in hash table H then
7:         return H(x, z)                         ▷ Read dynamic programming cell
8:     c ← 1
9:     for i ← 1 to |x| do
10:        c ← c · (1 + COUNT(x_i, z_i))
11:    H(x, z) ← λc                               ▷ Write dynamic programming cell
12:    return H(x, z)
```

Algorithm 3 implements the function for generating pairs of nodes with selected symbols. The function first sorts the tree nodes using a predefined order in line 2–3. For our implementation we apply a standard lexicographic sorting on the symbols of nodes. Algorithm 3 then proceeds by generating a set of matching node pairs L, satisfying the invariant that included pairs $(x,z) \in L$ have matching symbols (i.e., $\ell(x) = \ell(z)$) and are selected via ω (i.e., $\omega(x) = 1$). The generation of pairs is realized analogously to merging sorted arrays (see Knuth, 1973). The function removes elements from the lists of sorted nodes N_X and N_Z in parallel until a matching and selected pair (x,z) is discovered. With a slight abuse of notation, all available node pairs (a,b) with label $\ell(x)$ are then added to L and removed from N_X and N_Z in lines 12–14 of Algorithm 3.

Algorithm 3 Node Pair Generation

```
1: function GENERATEPAIRS(X, Z, ω)
2:     N_X ← SORTNODES(X)
3:     N_Z ← SORTNODES(Z)
4:     while N_X and N_Z not empty do
5:         x ← head of N_X
6:         z ← head of N_Z
7:         if ℓ(x) < ℓ(z) or ω(x) = 0 then
8:             remove x from N_X                    ▷ x mismatches or not selected
9:         else if ℓ(x) > ℓ(z) or ω(z) = 0 then
10:            remove z from N_Z                    ▷ y mismatches or not selected
11:        else
12:            N ← { (a,b) ∈ N_X × N_Z with label ℓ(x) }
13:            L ← L ∪ N                            ▷ Add all pairs with label ℓ(x)
14:            remove N from N_X and N_Z
15:    return L
```

3.5 Application Setup

In contrast to previous work on feature selection for tree kernels (see Suzuki et al., 2004), the efficiency of our approximate tree kernels is rooted in *decoupling* the selection of symbols from later application of the learned kernel function. In particular, our tree kernels are applied in a two-stage process as detailed in the following.

1. *Selection stage*. In the first stage, a sparse selection ω of grammar symbols is determined on a sample of tree data, where depending on the learning setting either Optimization Problem 1 or 2 is solved by linear programming. As solving both problems involves computing exact tree kernels, the selection is optimized on a small fraction of the trees. To limit memory requirements, the sample may be further filtered to contain only trees of reasonable sizes.

2. *Application stage*. In the subsequent application stage, the approximate tree kernels are employed together with learning algorithms using the efficient implementation detailed in the previous section. The optimized ω reduces the run-time and memory requirements of the kernel computation, such that learning with trees of almost arbitrary size becomes feasible.

The approximate tree kernels involve the parameter λ as defined in Equation (2). The parameter controls the contribution of subtrees; values close to zero emphasize shallow subtrees and $\lambda = 1$ corresponds to a uniform weighting of all subtrees. To avoid repeatedly solving Optimization Problem 1 or 2 for different values of λ, we fix $\lambda = 1$ in the selection stage and perform model selection only in the application stage for $\lambda \in [10^{-4}, 10^{0}]$. This procedure ensures that the approximate tree kernels are first determined over equally weighted subtrees, hence allowing for an unbiased optimization in the selection phase. A potential refinement of λ is postponed to the application stage to exploit performance gains of the approximate tree kernel. Note that if prior knowledge is available, this may be reflected by a different choice of λ in the selection stage.

4. Experiments on Artificial Data

Before studying the expressiveness and performance of approximate tree kernels in real-word applications, we aim at gaining insights into the approximation process. We thus conduct experiments using artificial data generated by the following probabilistic grammar, where A, B, C, D denote non-terminal symbols and a, b terminal symbols. The start symbol is S.

$$S \xrightarrow{[1.0]} A\ B \tag{*1}$$
$$A \xrightarrow{[0.2|0.2|0.6]} A\ A \mid C\ D \mid a \tag{*2}$$
$$B \xrightarrow{[0.2|0.2|0.6]} B\ B \mid D\ C \mid b \tag{*3}$$
$$C \xrightarrow{[0.3|0.3|0.3]} A\ B \mid A \mid B \tag{*4}$$
$$D \xrightarrow{[0.3|0.3|0.3]} B\ A \mid A \mid B \tag{*5}$$

Parse trees are generated from the above grammar by applying the rule $S \to AB$ and randomly choosing matching production rules according to their probabilities until all branches end in terminal nodes. Recursions are included in (*2)–(*5) to ensure that symbols occur at different positions and depths in the parse trees.

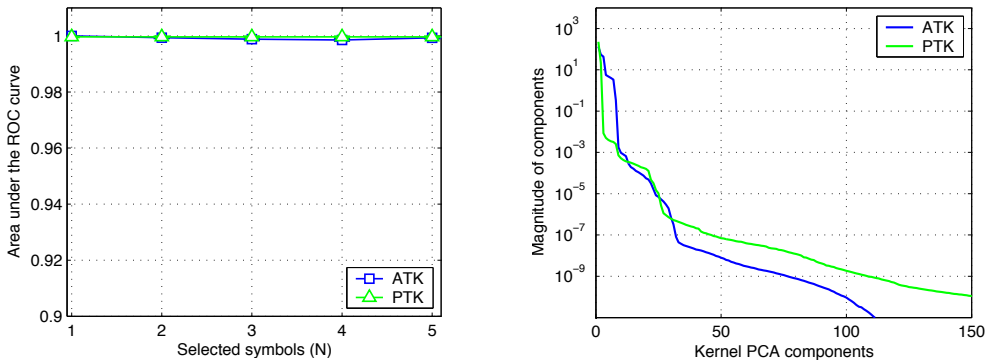
4.1 A Supervised Learning Task

To generate a simple supervised classification task, we assign the first rule in (*4) as an indicator of the positive class and the first rule in (*5) as one of the negative class. We then prepare our data set, such that one but not two of the rules are contained in each parse tree. That is, positive examples possess the rule $C \to AB$ and negative instances exhibit the rule $D \to BA$. Note that due to the symmetric design of the production rules, the two classes can not be distinguished from the symbols C and D alone but from the respective production rules.

Using this setup, we generate training, validation, and test sets consisting of 500 positive and negative trees each. We then apply the two-stage process detailed in Section 3.5: First, the selection function ω is adapted by solving Optimization Problem 1 using a sample of 250 randomly drawn trees from the training set. Second, a Support Vector Machine (SVM) is trained on the training data and applied to the test set, where the optimal regularization parameter of the SVM and the depth parameter λ are selected using the validation set. We report on averages over 10 repetitions and error bars indicate standard errors.

The classification performance of the SVM for the two kernel functions is depicted in Figure 4, where the number of selected symbols N for the approximate kernel is given on the x-axis and the attained area under the ROC curve (AUC) is shown on the y-axis. The parse tree kernel (PTK) leads to a perfect discrimination between the two classes, yet the approximate tree kernel (ATK) performs equally well, irrespectively of the number of selected symbols. That is, the approximation captures the discriminant subtrees rooted at either the symbol C or D in all settings. This selection of discriminative subtrees is also reflected in the optimal value of the depth parameter λ determined during the model selection. While for the exact tree kernel the optimal λ is 10^{-2}, the approximate kernel yields best results with $\lambda = 10^{-3}$, thus putting emphasis on shallow subtrees and the discriminative production rules rooted at C and D.

To analyze the feature space induced by the selection of subtrees, we perform a kernel principle component analysis (PCA) (see Schölkopf et al., 1998; Braun et al., 2008) for the exact and the



(a) Classification performance (b) Kernel PCA plot for $N = 1$

Figure 4: Classification performance and kernel PCA plot for the supervised toy data.

approximate tree kernel. Figure 4(b) shows the sorted magnitudes of the principal components in feature space. Although the differences are marginal, comparing the spectra allows for viewing the approximate kernel as a denoised variant of the regular parse tree kernel. The variance of smaller components is shifted towards leading principle components, resulting in a dimensionality reduction in feature space (see Mika et al., 1999).

4.2 An Unsupervised Learning Task

In order to obtain an unsupervised learning task, we modify the artificial grammar to reflect the notion of anomaly detection. First, we incorporate redundancy into the grammar by increasing the probability of irrelevant production rules in (*4)–(*5) as follows

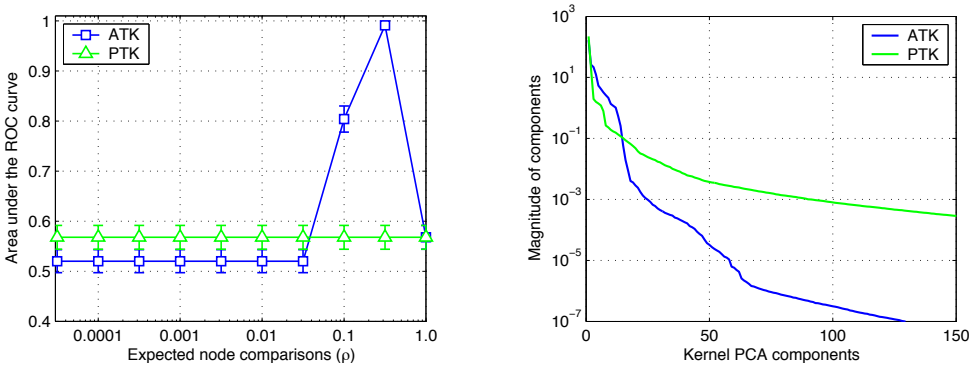
$$C \xrightarrow{[0.1|0.4|0.4]} A\ B \mid A \mid B \qquad (*4)$$

$$D \xrightarrow{[0.1|0.4|0.4]} B\ A \mid A \mid B \qquad (*5)$$

Second, we sample the parse trees such that training, validation, and testing sets contain 99% positive and 1% negative instances each, thus matching the anomaly detection scenario. We pursue the same two-stage procedure as in the previous section but first solve Optimization Problem 2 for adapting the approximate tree kernel to the unlabeled data and then employ a one-class SVM (Schölkopf et al., 1999) for training and testing.

Figure 5(a) shows the detection performance for the parse tree kernel and the approximate tree kernel for varying values of ρ. The parse tree kernel reaches an AUC value of 57%. Surprisingly, we observe a substantial gain in performance for the approximate kernel, leading to an almost perfect separation of the two classes for $\rho = 0.3$. Moreover, for the approximate kernel shallow subtrees are sufficient for detection of anomalies which is indicated by an optimal $\lambda = 10^{-3}$, whereas for the exact kernel subtrees of all depths need to be considered due to an optimal $\lambda = 1$.

The high detection performances can be explained by considering a kernel PCA of the two tree kernels in Figure 5(b). The redundant production rules introduce irrelevant and noisy dimensions into the feature space induced by the parse tree kernel. Clearly, for $\rho = 0.3$, the approximate tree kernel effectively reduces the intrinsic dimensionality by shifting the variance towards leading



(a) Detection performance (b) Kernel PCA plot for $\rho = 0.3$

Figure 5: Detection performance and kernel PCA plot for the unsupervised toy data.

components. Compared to the exact kernel, the resulting eigenspectrum of the approximate kernel possesses more explanatory and fewer noisy components.

5. Real-world Experiments

We now proceed to study the expressiveness, stability, and run-time performance of approximate tree kernels in real-world applications, namely supervised learning tasks dealing with question classification and web spam detection, respectively, and an unsupervised learning task on intrusion detection for HTTP and FTP traffic. In all experiments we employ the exact parse tree kernel and state-of-the-art implementations as baseline methods.

- **Question Classification.** Question classification is an important step for automatic answering of questions (Voorhees, 2004). The task is to categorize a user-supplied question into predefined semantic categories. We employ the data collection by Li and Roth (2002) consisting of 6,000 English questions assigned to six classes (abbreviation, entity, description, human, location, numeric value). Each question is transformed to a respective parse tree using the MEI Parser[1] (Charniak, 1999). For simplicity, we learn a discrimination between the category "entity" (1,339 instances) and all other categories using a two-class Support Vector Machine (SVM).

- **Web Spam Detection.** Web spam refers to fraudulent HTML documents, which yield high ranks in search engines through massive amounts of links. The detection of so-called link farms is essential for providing proper search results and protecting users from fraud. We use the web spam data as described by Castillo et al. (2006). The collection consists of HTML documents from normal and spam websites in the UK. All sites are examined by humans and manually annotated. We use a fault-tolerant HTML parser[2] to obtain parse trees from HTML documents. From the top 20 sites of both classes we sample 5,000 parse trees covering 974 web spam documents and 4,026 normal HTML pages. Again, we use a two-class SVM as the underlying learning algorithm.

1. Maximum-Entropy-Inspired Parser, see `ftp://ftp.cs.brown.edu/pub/nlparser`.
2. Beautiful Soup Parser, see `http://www.crummy.com/software/BeautifulSoup`.

- **Intrusion Detection.** Intrusion detection aims to automatically identify unknown attacks in network traffic. As labels for such data are hard to obtain, unsupervised learning has been a major focus in intrusion detection research (e.g., Eskin et al., 2002; Kruegel and Vigna, 2003; Rieck and Laskov, 2007; Laskov et al., 2008). Thus, for our experiments we employ a one-class SVM (Schölkopf et al., 1999) in the variant of Tax and Duin (1999) to detect anomalies in network traffic of the protocols HTTP and FTP. Network traffic for HTTP is recorded at the Fraunhofer FIRST institute, while FTP traffic is obtained from the Lawrence Berkeley National Laboratory [3] (see Paxson and Pang, 2003). Both traffic traces cover a period of 10 days. Attacks are additionally injected into the traffic using popular hacking tools.[4] The network data is converted to parse trees using the protocol grammars provided in the specifications (see Fielding et al., 1999; Postel and Reynolds, 1985). From the generated parse trees for each protocol we sample 5,000 instances and add 89 attacks for HTTP and 62 for FTP, respectively. This setting is similar to the data sets used in the DARPA intrusion detection evaluation (Lippmann et al., 2000).

Figure 6 shows the distribution of tree sizes in terms of nodes for each of the three learning tasks. For question classification, the largest tree comprises 113 nodes, while several parse trees in the web spam and intrusion detection data consist of more than 5,000 nodes.

For each learning task, we pursue the two-stage procedure described in Section 3.5 and conduct the following experimental procedure: parse trees are randomly drawn from each data set and split into training, validation and test partitions consisting of 1,000 trees each. If not stated otherwise, we first draw 250 instances at random from the training set for the selection stage, where we solve Optimization Problem 1 or 2 with fixed $\lambda = 1$. In the application stage, the resulting approximate kernels are then compared to exact kernels using SVMs as underlying learning methods. Model selection is performed for the regularization parameter of the SVM and the depth parameter λ. We measure the area under the ROC curve of the resulting classifiers and report on averages over 10 repetitions with error bars indicate standard errors. In all experiments we make use of the LIBSVM library developed by Chang and Lin (2000).

5.1 Results for Question Classification

We first study the expressiveness of the approximate tree kernel and the exact parse tree kernel for the question classification task. We thus vary the number of selected symbols in Optimization Problem 1 and report on the achieved classification performance for the approximate tree kernel for varying N and the exact tree kernel in Figure 7(a).

As expected, the approximation becomes more accurate for increasing values of N, meaning that the more symbols are included in the approximation, the better is the resulting discrimination. However, the curve saturates to the performance of the regular parse tree kernel for selecting 7 and more symbols. The selected symbols are NP, VP, PP, S1, SBARQ, SQ, and TERM. The symbols NP, PP, and VP capture the coarse semantics of the considered text, while SBARQ and SQ correspond to the typical structure of questions. Finally, the symbol TERM corresponds to terminal symbols and contains the actual sequence of tokens including interrogative pronouns. The optimal depth λ for the approximate kernel is again lower with 10^{-2} in comparison to the optimal value of 10^{-1} for the exact kernel, as discriminative substructures are close to the selected symbols.

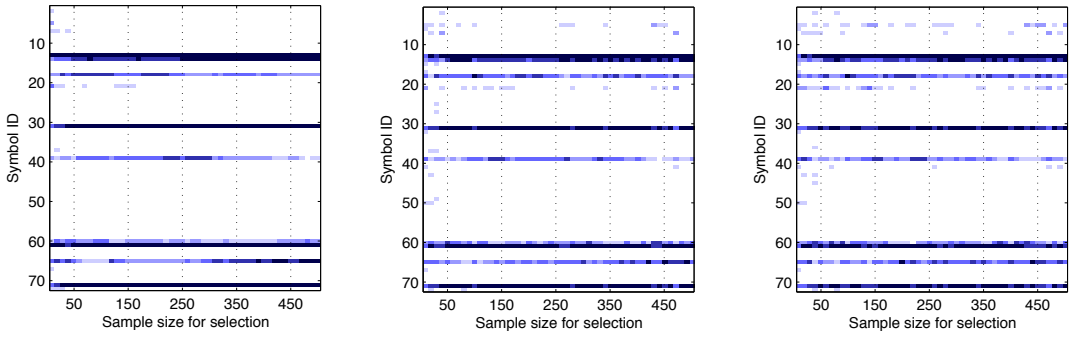
Figure 7: Classification performance and kernel PCA plot for the question classification task.

Figure 7(b) shows the eigenspectra of the parse tree kernel and its approximate variant with the above 7 selected symbols. Even though the proposed kernel is only an approximation of the regular tree kernel, their eigenspectra are nearly identical. That is, the approximate tree kernel leads to a nearly identical feature space to its exact counterpart.

The above experiments demonstrate the ability of the approximation to select discriminative symbols, yet it is not clear how the expressiveness of the approximate kernels depends on the re-



(a) Selection (b) Selection with 5% label noise (c) Selection with 10% label noise

Figure 8: Stability plot for the question classification task.

duced sample size in the selection stage. To examine this issue, we keep $N = 7$ fixed and vary the amount of data supplied for adapting the approximate tree kernel. Figure 8(a) displays the assignments of the selection function ω, where the size of the provided data is shown on the x-axis and the IDs of the grammar symbols are listed on the y-axis. The intensity of each point reflects the average number of times the corresponding symbol has been chosen in five repetitions. The selection remains stable for sample sizes of 150 parse trees, where consistently the correct 7 symbols are identified. Even if label noise is injected in the data, the approximation remains stable if at least 150 trees are considered for the selection as depicted in Figure 8(b) and 8(c).

The results on question classification show that exploiting the redundancy in parse trees can be beneficial even when dealing with small trees. Approximate tree kernels identify a simplified representation that proves robust against label noise and leads to the same classification rate compared to regular parse tree kernels.

5.2 Results for Web Spam Detection

We now study approximate tree kernels for web spam detection. Unfortunately, training SVMs using the exact parse tree kernel proves intractable for many large trees in the data due to their excessive memory requirements. We thus exclude trees from the web spam data set with more than 1,500 nodes for the following experiments. Again, we vary the number of symbols to be selected and measure the corresponding AUC value over 10 repetitions.

The results are shown in Figure 9(a). The approximation is consistently on par with the regular parse tree kernel for four and more selected labels, as the differences in this interval are not significant. However, the best result is obtained for selecting only two symbols. The approximation picks the tags HTML and BODY. We credit this finding to the usage of templates in spam websites inducing a strict order of high-level tags in the documents. In particular, header and meta tags occurring in subtrees below the HTML tag are effective for detecting spam templates. As a consequence, the optimal $\lambda = 10^{-1}$ for the approximate kernel effectively captures discriminative features reflecting web spam templates rooted at the HTML and BODY tag. The eigendecomposition of the two kernels in Figure 9(b) hardly show any differences. As for the question classification task, the exact and approximate tree kernels share the same expressiveness.

Figure 10 shows the stability of the selection function for varying amounts of data considered in the selection stage where N is fixed to 2. The selection saturates for samples containing at least 120

Figure 10: Stability plot for the web spam detection task.

parse trees and the two symbols HTML and BODY are chosen consistently. Moreover, the selection of symbols for web spam detection proves robust against label noise. Even for a noise ratio of 10% which corresponds to flipping every tenth label, the same symbols are selected. This result confirms the property of web spam to be generated from templates which provides a strong feature for discrimination even in presence of label noise.

5.3 Results for Intrusion Detection

In this section, we study the expressiveness of approximate kernels for unsupervised intrusion detection. Since label information is not available, we adapt the selection function to the data using Optimization Problem 2. The resulting approximate tree kernels are then employed together with a one-class SVM for the detection of attacks in HTTP and FTP parse trees. To determine the impact of the approximation on the detection performance, we vary the number of expected node comparisons, that is, variable ρ in Optimization Problem 2. We again exclude trees comprising more than 1,500 nodes due to prohibitive memory requirements for the exact tree kernel.

Figures 11 (HTTP) and 12 (FTP) show the observed detection rates on the left for the approximate and the exact tree kernel. Clearly, the approximate tree kernel performs identically to its exact counterpart if the ratio of node comparisons ρ equals 100%. However, when the number of

Figure 12: Detection performance and analysis of the intrusion detection task (FTP).

comparisons is restricted to only a fraction, the approximate kernel significantly outperforms the exact parse tree kernel and leads to a superior detection rate. The approximate tree kernel realizes an AUC improvement of 1% for HTTP data. For the FTP protocol, the differences are more severe: the approximate kernel outperforms its exact counterpart and yields an AUC improvement of 20%. The optimal depth parameter λ for the approximate kernel is 10^{-2} for HTTP and 10^{-2} for FTP, while the exact tree kernel requires $\lambda = 10^{-1}$ in the optimal setting. This result demonstrates that the approximation identifies relevant grammar symbols by focusing on shallow subtrees comprising discriminative patterns.

These gains in performance can be explained by looking at the respective eigenspectra, depicted in Figures 11(b) and 12(b). Compared to the regular kernel, the approximate kernel yields remarkably fewer noisy components. This is particularly the case for FTP traffic. Moreover, the variance is shifted toward only a few leading components. The approximate tree kernel performs a dimensionality reduction by suppressing noisy and redundant parts of the feature space. For HTTP traffic, such redundancy is for instance induced by common web browsers like Internet Explorer and Mozilla Firefox whose header attributes constitute a good portion of the resulting parse trees. This syntactical information is delusive in the context of intrusion detection and hence their removal

improves the detection performance. Note that the observed gain in performance is achieved using only less than 10% of the grammar symbols. That is, the approximation is not only more accurate than the exact parse tree kernel but also concisely represented.

5.4 Run-time Performance

As we have seen in the previous sections, approximate kernels can lead to a concise description of the task at hand by selecting discriminative substructures in data. In this section we compare the run-time and memory requirements of the approximate tree kernel with state-of-the-art implementations of the exact tree kernels. We first measure the time for selection, training, and testing phases using SVMs as underlying learning methods. For all data sets, we use 250 randomly drawn trees in the selection stage where training and test sets consist of 1,000 instances each. Again, we exclude large trees with more than 1,500 nodes because of excessive memory requirements.

Selection stage on 250 parse trees	
Question classification	17s $\pm$0
Web spam detection	144s $\pm$28
Intrusion detection (HTTP)	43s $\pm$7
Intrusion detection (FTP)	31s $\pm$2

Table 1: Selection stage prior to training and testing phase.

The run-time for the selection of symbols prior to application of the SVMs are presented in Table 1. For all three data sets, a selection is determined in less than 3 minutes, demonstrating the advantage of phrasing the selection as a simple linear program. Table 5.4 lists the training and testing times using the approximate tree kernel (ATK) and a fast implementation for the exact tree kernel (PTK2) devised by Moschitti (2006a). As expected, the size of the trees influences the observed results. For the small trees in the question classification task we record run-time improvements by a factor of 1.7 while larger trees in the other tasks give rise to speed-up factors between $2.8 - 13.8$. Note that the total run-time of the application stage is only marginally affected by the initial selection stage that is performed only once prior to the learning process. For example, in the task of web spam detection a speed-up of roughly 10 is attained for the full experimental evaluation, as the selection is performed once, whereas 25 runs of training and testing are necessary for model selection.

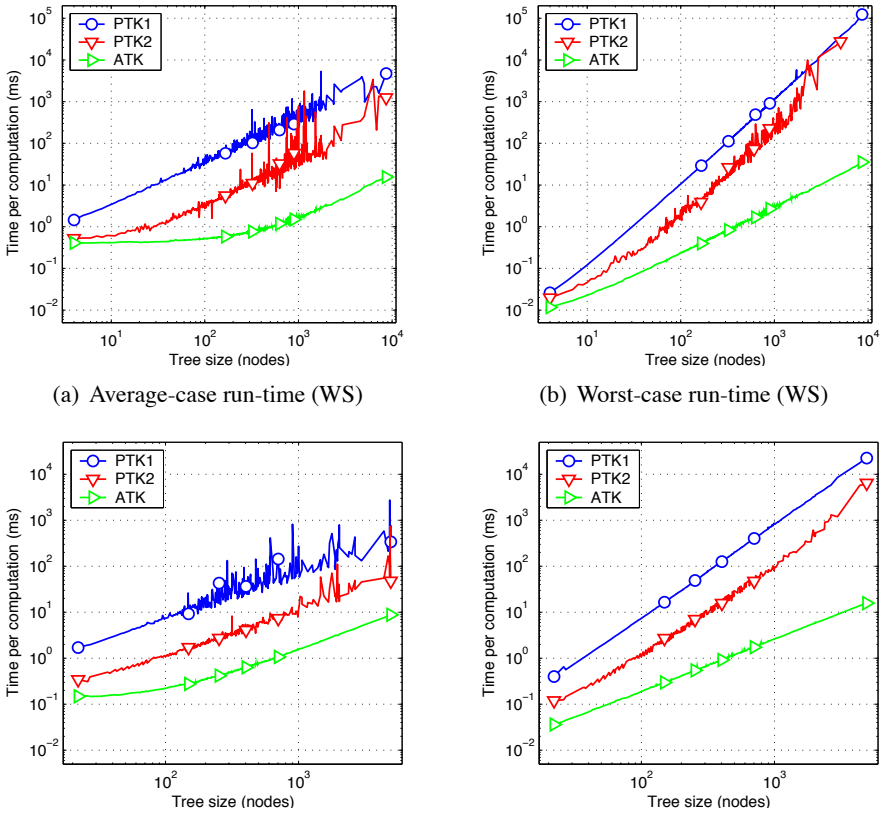
However, the interpretability of the results reported in Table 5.4 is limited because parse trees containing more than 1,500 nodes have been excluded from the experiment and the true performance gain induced by approximate tree kernels cannot be estimated. Moreover, the reported training and testing times refer to a particular learning method and cannot be transferred to other methods and applications, such as clustering and regression tasks. To address these issues, we study the run-time performance and memory consumption of tree kernels explicitly—independently of a particular learning method. Notice that for these experiments we include parse trees of all sizes. As baselines, we include a standard implementation of the parse tree kernel (PTK1) detailed by Shawe-Taylor and Cristianini (2004) and the improved variant (PTK2) proposed by Moschitti (2006a).

For each kernel, we estimate the average run-time and memory requirements by computing kernels between reference trees of fixed sizes and 100 randomly drawn trees. We also consider the worst-case scenario for each data set, which occurs if kernels are computed between identical parse trees, thus realizing the maximal number of matching node pairs. We focus in our experiments on

	ATK	*PTK2*	*Speed-up*
Training time on 1,000 parse trees			
Question classification	42s ±4	72s ±7	1.7×
Web spam detection	111s ±17	1,487s ±435	13.4×
Intrusion detection (HTTP)	123s ±20	349s ±80	2.8×
Intrusion detection (FTP)	125s ±14	517s ±129	5.8×
Testing time on 1,000 parse trees			
Question classification	40s ±4	70s ±2	1.8×
Web spam detection	112s ±18	1,542s ±471	13.8×
Intrusion detection (HTTP)	81s ±14	225s ±71	2.8×
Intrusion detection (FTP)	107s ±15	455s ±112	4.1×

Table 2: Training and testing time of SVMs using the exact and the approximate tree kernel.

the learning tasks of web spam and intrusion detection (HTTP), where results for question classification and FTP are analogous.



(a) Average-case run-time (WS)

(b) Worst-case run-time (WS)

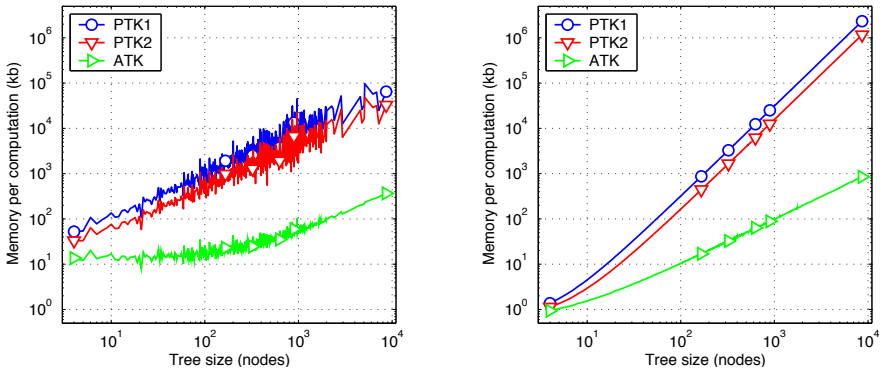
(c) Average-case run-time (ID)

(d) Worst-case run-time (ID)

Figure 13: Run-times for web spam (WS) and intrusion detection (ID).

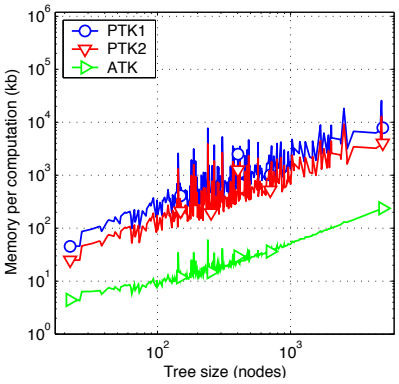
Figure 13 illustrates the run-time performance of the approximate and the two exact tree kernels. The run-time is given in milliseconds (ms) per kernel computation on the y-axis and the size of the

considered trees is shown on the x-axis. Both axes are presented in log-scale. Although the improved variant by Moschitti (PTK2) is significantly faster than the standard implementation, neither of the two show compelling run-times in both tasks. For both implementations of the regular tree kernel, a single kernel computation can take more than 10 seconds, thus rendering large-scale applications infeasible. By contrast, the approximate tree kernel computes similarities between trees up to three orders of magnitude faster and yields a worst-case computation time of less than 40 ms for the web spam detection task and less than 20 ms for the intrusion detection task. The worst-case analysis shows that the exact tree kernel scales quadratically in the number of nodes whereas the approximate tree kernel is computed in sub-quadratic time in the size of the trees.

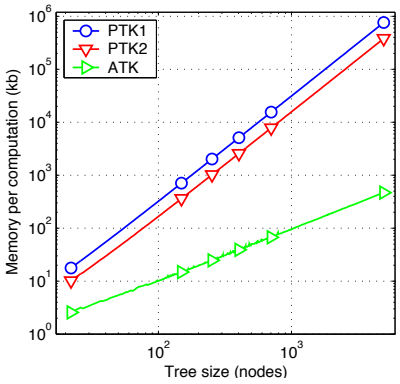


(a) Average-case memory (WS)

(b) Worst-case memory (WS)



(c) Average-case memory (ID))



(d) Worst-case memory (ID)

Figure 14: Memory requirements for web spam (WS) and intrusion detection (ID).

Figure 14 reports on average and worst-case memory requirements for the web spam detection and intrusion detection task. The memory consumption in kilobytes is depicted on the y-axis and the size of the considered trees is shown on the x-axis. Both axes are given in logarithmic scale. In all figures, the curves of the approximate kernel are significantly below the variants of the parse tree kernel. The allocated memory for the regular tree kernel exceeds 1 gigabytes in both learning tasks, which is clearly prohibitive for a single kernel computation. In contrast the approximate tree kernel requires at most 800 kilobytes. For the worst-case estimation, the memory consumption of the exact kernel scales quadratically in the number of tree nodes while the approximate tree kernel scales sub-quadratically due to the sparse selection of symbols.

6. Conclusions

Learning with large trees render regular parse tree kernels inapplicable due to quadratic run-time and memory requirements. As a remedy, we propose to approximate regular tree kernels. Our approach splits into a selection and an application stage. In the selection stage, the computation of tree kernels is narrowed to a sparse subset of subtrees rooted in appropriate grammar symbols. The symbols are chosen according to their discriminative power for supervised settings and to minimize the expected number of node comparisons for unsupervised settings, respectively. We derive linear programming approaches to identify such symbols, where the resulting optimization problems can be solved with standard techniques. In the subsequent application stage, learning algorithms benefit from the initial selection because run-time and memory requirements for the kernel computation are significantly reduced.

We evaluate the approximate trees kernels with SVMs as underlying learning algorithms for question classification, web spam detection and intrusion detection. In all experiments, the approximate tree kernels not only replicate the predictive performances of exact kernels but also provide concise representations by operating on only 2–10% of the available grammar symbols. The resulting approximate kernels lead to significant improvements in terms of run-time and memory requirements. For large trees, the approximation reduces a single kernel computation from 1 gigabyte to less than 800 kilobytes, accompanied by run-time improvements up to three orders of magnitude. We also observe improvements for parse trees generated for sentences in natural language, however, at a smaller scale. The most dramatic results are obtained for intrusion detection. Here, a kernel PCA shows that approximate tree kernels effectively identify relevant dimensions in feature space and discard redundant and noisy subspaces from the kernel computation. Consequently, the approximate kernels perform more efficiently and more accurately than their exact counterparts achieving AUC improvements of up to 20%.

To the best of our knowledge, we present the first efficient approach to learning with large trees containing thousands of nodes. In view of the many large-scale applications comprising structured data , the presented work provides means for efficient and accurate learning with large structures. Although we focus on classification, approximate tree kernels are easily leveraged to other kernel-based learning tasks, such as regression and clustering, using the introduced techniques. Moreover, the devised approximate tree kernels build on the concept of convolution over local kernel functions. Our future work will focus on transferring attained performance gains to the framework of convolution kernels, aiming at rendering learning with various types of complex structured data feasible in large-scale applications.

Acknowledgments

The authors would like to thank the anonymous reviewers for helpful comments and suggestions. Furthermore, we like to thank Patrick Düssel and René Gerstenberger for providing efficient implementations of network protocol parsers. The authors gratefully acknowledge the funding from the Bundesministerium für Bildung und Forschung under the project REMIND (FKZ 01-IS07007A) and from the FP7-ICT Program of the European Community under the PASCAL2 Network of Excellence, ICT-216886. Abstract

The problem is sequence prediction in the following setting. A sequence $x_1,\dots,x_n,\dots$ of discrete-valued observations is generated according to some unknown probabilistic law (measure) μ. After observing each outcome, it is required to give the conditional probabilities of the next observation. The measure μ belongs to an arbitrary but known class $\mathcal{C}$ of stochastic process measures. We are interested in predictors ρ whose conditional probabilities converge (in some sense) to the "true" μ-conditional probabilities, if any $\mu \in \mathcal{C}$ is chosen to generate the sequence. The contribution of this work is in characterizing the families $\mathcal{C}$ for which such predictors exist, and in providing a specific and simple form in which to look for a solution. We show that if any predictor works, then there exists a Bayesian predictor, whose prior is discrete, and which works too. We also find several sufficient and necessary conditions for the existence of a predictor, in terms of topological characterizations of the family $\mathcal{C}$, as well as in terms of local behaviour of the measures in $\mathcal{C}$, which in some cases lead to procedures for constructing such predictors.

It should be emphasized that the framework is completely general: the stochastic processes considered are not required to be i.i.d., stationary, or to belong to any parametric or countable family.

Keywords: sequence prediction, time series, online prediction, Bayesian prediction

1. Introduction

Given a sequence $x_1,\dots,x_n$ of observations $x_i \in \mathcal{X}$, where $\mathcal{X}$ is a finite set, we want to predict what are the probabilities of observing $x_{n+1} = x$ for each $x \in \mathcal{X}$, or, more generally, probabilities of observing different $x_{n+1},\dots,x_{n+h}$, before x_{n+1} is revealed, after which the process continues. It is assumed that the sequence is generated by some unknown stochastic process μ, a probability measure on the space of one-way infinite sequences $\mathcal{X}^\infty$. The goal is to have a predictor whose predicted probabilities converge (in a certain sense) to the correct ones (that is, to μ-conditional probabilities). In general this goal is impossible to achieve if nothing is known about the measure μ generating the sequence. In other words, one cannot have a predictor whose error goes to zero for any measure μ. The problem becomes tractable if we assume that the measure μ generating the data belongs to some known class $\mathcal{C}$. The questions addressed in this work are a part of the following general problem: given an arbitrary set $\mathcal{C}$ of measures, how can we find a predictor that performs well when the data is generated by any $\mu \in \mathcal{C}$, and whether it is possible to find such a predictor at all. An example of a generic property of a class $\mathcal{C}$ that allows for construction of a predictor, is that $\mathcal{C}$ is countable. Clearly, this condition is very strong. An example, important from the applications

point of view, of a class $\mathcal{C}$ of measures for which predictors are known, is the class of all stationary measures. The general question, however, is very far from being answered.

The contribution of this work to solving this question is, first, in that we provide a specific form in which to look for a predictor. More precisely, we show that if a predictor that predicts every $\mu \in \mathcal{C}$ exists, then such a predictor can also be obtained as a weighted sum of countably many elements of $\mathcal{C}$. This result can also be viewed as a justification of the Bayesian approach to sequence prediction: if there exists a predictor which predicts well every measure in the class, then there exists a Bayesian predictor (with a rather simple prior) that has this property too. In this respect it is important to note that the result obtained about such a Bayesian predictor is pointwise (holds for every μ in $\mathcal{C}$), and stretches far beyond the set its prior is concentrated on. Next, we derive some characterizations of families $\mathcal{C}$ for which a predictor exist. We first analyze what is furnished by the notion of separability, when a suitable topology can be found: we find that it is a sufficient but not always a necessary condition. We then derive some sufficient conditions for the existence of a predictor which are based on local (truncated to the first n observation) behaviour of measures in the class $\mathcal{C}$. Necessary conditions cannot be obtained in this way (as we demonstrate), but sufficient conditions, along with rates of convergence and construction of predictors, can be found.

The *motivation* for studying predictors for arbitrary classes $\mathcal{C}$ of processes is two-fold. First of all, prediction is a basic ingredient for constructing intelligent systems. Indeed, in order to be able to find optimal behaviour in an unknown environment, an intelligent agent must be able, at the very least, to predict how the environment is going to behave (or, to be more precise, how relevant parts of the environment are going to behave). Since the response of the environment may in general depend on the actions of the agent, this response is necessarily non-stationary for explorative agents. Therefore, one cannot readily use prediction methods developed for stationary environments, but rather has to find predictors for the classes of processes that can appear as a possible response of the environment.

Apart from this, the problem of prediction itself has numerous applications in such diverse fields as data compression, market analysis, bioinformatics, and many others. It seems clear that prediction methods constructed for one application cannot be expected to be optimal when applied to another. Therefore, an important question is how to develop specific prediction algorithms for each of the domains.

1.1 Prior Work

As it was mentioned, if the class $\mathcal{C}$ of measures is countable (that is, if $\mathcal{C}$ can be represented as $\mathcal{C} := \{\mu_k : k \in \mathbb{N}\}$), then there exists a predictor which performs well for any $\mu \in \mathcal{C}$. Such a predictor can be obtained as a Bayesian mixture $\rho_S := \sum_{k\in\mathbb{N}} w_k \mu_k$, where w_k are summable positive real weights, and it has very strong predictive properties; in particular, ρ_S predicts every $\mu \in \mathcal{C}$ in total variation distance, as follows from the result of Blackwell and Dubins (1962). Total variation distance measures the difference in (predicted and true) conditional probabilities of all future events, that is, not only the probabilities of the next observations, but also of observations that are arbitrary far off in the future (see formal definitions below). In the context of sequence prediction the measure ρ_S was first studied by Solomonoff (1978). Since then, the idea of taking a convex combination of a finite or countable class of measures (or predictors) to obtain a predictor permeates most of the research on sequential prediction (see, for example, Cesa-Bianchi and Lugosi, 2006) and more general learning problems (Hutter, 2005; Ryabko and Hutter, 2008a). In practice it is clear that, on

the one hand, countable models are not sufficient, since already the class $\mu_p, p \in [0,1]$ of Bernoulli i.i.d. processes, where p is the probability of 0, is not countable. On the other hand, prediction in total variation can be too strong to require; predicting probabilities of the next observation may be sufficient, maybe even not on every step but in the Cesaro sense. A key observation here is that a predictor $\rho_S = \sum w_k \mu_k$ may be a good predictor not only when the data is generated by one of the processes $\mu_k, k \in \mathbb{N}$, but when it comes from a much larger class. Let us consider this point in more detail. Fix for simplicity $\mathcal{X} = \{0,1\}$. The Laplace predictor

$$\lambda(x_{n+1} = 0 | x_1, \ldots, x_n) = \frac{\#\{i \leq n : x_i = 0\} + 1}{n + |\mathcal{X}|} \tag{1}$$

predicts any Bernoulli i.i.d. process: although convergence in total variation distance of conditional probabilities does not hold, predicted probabilities of the next outcome converge to the correct ones. Moreover, generalizing the Laplace predictor, a predictor λ_k can be constructed for the class M_k of all k-order Markov measures, for any given k. As was found by Ryabko (1988), the combination $\rho_R := \sum w_k \lambda_k$ is a good predictor not only for the set $\cup_{k \in \mathbb{N}} M_k$ of all finite-memory processes, but also for any measure μ coming from a much larger class: that of all stationary measures on $\mathcal{X}^\infty$. Here prediction is possible only in the Cesaro sense (more precisely, ρ_R predicts every stationary process in expected time-average Kullback-Leibler divergence, see definitions below). The Laplace predictor itself can be obtained as a Bayes mixture over all Bernoulli i.i.d. measures with uniform prior on the parameter p (the probability of 0). However, as was observed in Hutter (2007) (and as is easy to see), the same (asymptotic) predictive properties are possessed by a Bayes mixture with a countably supported prior which is dense in $[0,1]$ (e.g., taking $\rho := \sum w_k \delta_k$ where $\delta_k, k \in \mathbb{N}$ ranges over all Bernoulli i.i.d. measures with rational probability of 0). For a given k, the set of k-order Markov processes is parametrized by finitely many $[0,1]$-valued parameters. Taking a dense subset of the values of these parameters, and a mixture of the corresponding measures, results in a predictor for the class of k-order Markov processes. Mixing over these (for all $k \in \mathbb{N}$) yields, as in Ryabko (1988), a predictor for the class of all stationary processes. Thus, for the mentioned classes of processes, a predictor can be obtained as a Bayes mixture of countably many measures in the class. An additional reason why this kind of analysis is interesting is because of the difficulties arising in trying to construct Bayesian predictors for classes of processes that can not be easily parametrized. Indeed, a natural way to obtain a predictor for a class $\mathcal{C}$ of stochastic processes is to take a Bayesian mixture of the class. To do this, one needs to define the structure of a probability space on $\mathcal{C}$. If the class $\mathcal{C}$ is well parametrized, as is the case with the set of all Bernoulli i.i.d. process, then one can integrate with respect to the parametrization. In general, when the problem lacks a natural parametrization, although one can define the structure of the probability space on the set of (all) stochastic process measures in many different ways, the results one can obtain will then be with probability 1 with respect to the prior distribution (see, for example, Jackson et al., 1999). Pointwise consistency cannot be assured (see, for example, Diaconis and Freedman, 1986) in this case, meaning that some (well-defined) Bayesian predictors are not consistent on some (large) subset of $\mathcal{C}$. Results with prior probability 1 can be hard to interpret if one is not sure that the structure of the probability space defined on the set $\mathcal{C}$ is indeed a natural one for the problem at hand (whereas if one does have a natural parametrization, then usually results for every value of the parameter can be obtained, as in the case with Bernoulli i.i.d. processes mentioned above). The results of the present work show that when a predictor exists it can indeed be given as a Bayesian predictor, which predicts every (and not almost every) measure in the class, while its support is only a countable set.

A related question is formulated as a question about two individual measures, rather than about a class of measures and a predictor. Namely, one can ask under which conditions one stochastic process predicts another. In Blackwell and Dubins (1962) it was shown that if one measure is absolutely continuous with respect to another, than the latter predicts the former (the conditional probabilities converge in a very strong sense). In Ryabko and Hutter (2007, 2008b) a weaker form of convergence of probabilities (in particular, convergence of expected average KL divergence) is obtained under weaker assumptions.

1.2 The Results

First, we show that if there is a predictor that performs well for every measure coming from a class $\mathcal{C}$ of processes, then a predictor can also be obtained as a convex combination $\sum_{k\in\mathbb{N}} w_k\mu_k$ for some $\mu_k \in \mathcal{C}$ and some $w_k > 0$, $k \in \mathbb{N}$. This holds if the prediction quality is measured by either total variation distance, or expected average KL divergence: one measure of performance that is very strong, the other rather weak. The analysis for the total variation case relies on the fact that if ρ predicts μ in total variation distance, then μ is absolutely continuous with respect to ρ, so that $\rho(x_{1..n})/\mu(x_{1..n})$ converges to a positive number with μ-probability 1 and with a positive ρ-probability. However, if we settle for a weaker measure of performance, such as expected average KL divergence, measures $\mu \in \mathcal{C}$ are typically singular with respect to a predictor ρ. Nevertheless, since ρ predicts μ we can show that $\rho(x_{1..n})/\mu(x_{1..n})$ decreases subexponentially with n (with high probability or in expectation); then we can use this ratio as an analogue of the density for each time step n, and find a convex combination of countably many measures from $\mathcal{C}$ that has desired predictive properties for each n. Combining these predictors for all n results in a predictor that predicts every $\mu \in \mathcal{C}$ in average KL divergence. The proof techniques developed have a potential to be used in solving other questions concerning sequence prediction, in particular, the general question of how to find a predictor for an arbitrary class $\mathcal{C}$ of measures.

We then exhibit some sufficient conditions on the class $\mathcal{C}$, under which a predictor for all measures in $\mathcal{C}$ exists. It is important to note that none of these conditions relies on a parametrization of any kind. The conditions presented are of two types: conditions on asymptotic behaviour of measures in $\mathcal{C}$, and on their local (restricted to first n observations) behaviour. Conditions of the first type concern separability of $\mathcal{C}$ with respect to the total variation distance and the expected average KL divergence. We show that in the case of total variation separability is a necessary and sufficient condition for the existence of a predictor, whereas in the case of expected average KL divergence it is sufficient but is not necessary.

The conditions of the second kind concern the "capacity" of the sets $\mathcal{C}^n := \{\mu^n : \mu \in \mathcal{C}\}$, $n \in \mathbb{N}$, where μ^n is the measure μ restricted to the first n observations. Intuitively, if $\mathcal{C}^n$ is small (in some sense), then prediction is possible. We measure the capacity of $\mathcal{C}^n$ in two ways. The first way is to find the maximum probability given to each sequence $x_1,\dots,x_n$ by some measure in the class, and then take a sum over $x_1,\dots,x_n$. Denoting the obtained quantity c_n, one can show that it grows polynomially in n for some important classes of processes, such as i.i.d. or Markov processes. We show that, in general, if c_n grows subexponentially then a predictor exists that predicts any measure in $\mathcal{C}$ in expected average KL divergence. On the other hand, exponentially growing c_n are not sufficient for prediction. A more refined way to measure the capacity of $\mathcal{C}^n$ is using a concept of channel capacity from information theory, which was developed for a closely related problem of finding optimal codes for a class of sources. We extend corresponding results from information

theory to show that sublinear growth of channel capacity is sufficient for the existence of a predictor, in the sense of expected average divergence. Moreover, the obtained bounds on the divergence are optimal up to an additive logarithmic term.

The rest of the paper is organized as follows. Section 2 introduces the notation and definitions. In Section 3 we show that if any predictor works than there is a Bayesian one that works, while in Section 4 we provide several characterizations of predictable classes of processes. Section 4.1 is concerned with separability, while Section 4.2 analyzes conditions based on local behaviour of measures. Finally, Section 5 provides outlook and discussion.

As running examples that illustrate the results of each section we use countable classes of measures, the family of all Bernoulli i.i.d. processes, and that of all stationary processes.

2. Preliminaries

Let $\mathcal{X}$ be a finite set. The notation $x_{1..n}$ is used for $x_1,\dots,x_n$. We consider stochastic processes (probability measures) on $(\mathcal{X}^\infty,\mathcal{F})$, where $\mathcal{F}$ is the sigma-field generated by the cylinder sets $[x_{1..n}]$, $x_i\in\mathcal{X}, n\in\mathbb{N}$, where $[x_{1..n}]$ is the set of all infinite sequences that start with $x_{1..n}$. Since we are only interested in those measures on $(\mathcal{X}^\infty,\mathcal{F})$ which are probability measures (the measure of $\mathcal{X}^\infty$ equals 1), we call them simply *measures*. For a finite set A denote $|A|$ its cardinality. We use $\mathbf{E}_\mu$ for expectation with respect to a measure μ.

Next we introduce the criteria of the quality of prediction used in this paper. For two measures μ and ρ we are interested in how different the μ- and ρ-conditional probabilities are, given a data sample $x_{1..n}$. Introduce the *(conditional) total variation* distance

$$v(\mu,\rho,x_{1..n}) := \sup_{A\in\mathcal{F}} |\mu(A|x_{1..n})-\rho(A|x_{1..n})|.$$

Definition 1 *We say that ρ predicts μ in total variation if*

$$v(\mu,\rho,x_{1..n})\to 0 \ \mu\text{-a.s.}$$

This convergence is rather strong. In particular, it means that ρ-conditional probabilities of arbitrary far-off events converge to μ-conditional probabilities. Moreover, ρ predicts μ in total variation if Blackwell and Dubins (1962) and only if Kalai and Lehrer (1994) μ is absolutely continuous with respect to ρ:

Theorem 2 (Blackwell and Dubins, 1962; Kalai and Lehrer, 1994) *If ρ, μ are arbitrary probability measures on $(\mathcal{X}^\infty,\mathcal{F})$, then ρ predicts μ in total variation if and only if μ is absolutely continuous with respect to ρ.*

Thus, for a class $\mathcal{C}$ of measures there is a predictor ρ that predicts every $\mu\in\mathcal{C}$ in total variation if and only if every $\mu\in\mathcal{C}$ has a density with respect to ρ. Although such sets of processes are rather large, they do not include even such basic examples as the set of all Bernoulli i.i.d. processes. That is, there is no ρ that would predict in total variation every Bernoulli i.i.d. process measure δ_p, $p\in[0,1]$, where p is the probability of 0. Therefore, perhaps for many (if not most) practical applications this measure of the quality of prediction is too strong, and one is interested in weaker measures of performance.

For two measures μ and ρ introduce the *expected cumulative Kullback-Leibler divergence (KL divergence)* as

$$d_n(\mu,\rho) := \mathbf{E}_\mu \sum_{t=1}^{n} \sum_{a\in\mathcal{X}} \mu(x_t = a|x_{1..t-1}) \log \frac{\mu(x_t = a|x_{1..t-1})}{\rho(x_t = a|x_{1..t-1})}.$$

In words, we take the expected (over data) average (over time) KL divergence between μ- and ρ-conditional (on the past data) probability distributions of the next outcome.

Definition 3 *We say that ρ predicts μ in expected average KL divergence if*

$$\frac{1}{n} d_n(\mu,\rho) \to 0.$$

This measure of performance is much weaker, in the sense that it requires good predictions only one step ahead, and not on every step but only on average; also, the convergence is not with probability 1, but in expectation. With prediction quality so measured, predictors exist for relatively large classes of measures; most notably, Ryabko (1988) provides a predictor which predicts every stationary process in expected average KL divergence. A simple but useful identity that we will need (in the context of sequence prediction introduced also by Ryabko, 1988) is the following

$$d_n(\mu,\rho) = -\sum_{x_{1..n}\in\mathcal{X}^n} \mu(x_{1..n}) \log \frac{\rho(x_{1..n})}{\mu(x_{1..n})}, \tag{2}$$

where on the right-hand side we have simply the KL divergence between measures μ and ρ restricted to the first n observations.

Thus, the results of this work will be established with respect to two very different measures of prediction quality, one of which is very strong and the other rather weak. This suggests that the facts established reflect some fundamental properties of the problem of prediction, rather than those pertinent to particular measures of performance. On the other hand, it remains open to extend the results below to different measures of performance.

3. Fully Nonparametric Bayes Predictors

In this section we show that if there is a predictor that predicts every μ in some class $\mathcal{C}$, then there is a Bayesian mixture of countably many elements from $\mathcal{C}$ that predicts every $\mu \in \mathcal{C}$ too. This is established for the two notions of prediction quality that were introduced: total variation and expected average KL divergence. After the theorems we present some examples of families of measures for which predictors exist.

Theorem 4 *Let $\mathcal{C}$ be a set of probability measures on $(\mathcal{X}^\infty, \mathcal{F})$. If there is a measure ρ such that ρ predicts every $\mu \in \mathcal{C}$ in total variation, then there is a sequence $\mu_k \in \mathcal{C}$, $k \in \mathbb{N}$ such that the measure $\nu := \sum_{k\in\mathbb{N}} w_k \mu_k$ predicts every $\mu \in \mathcal{C}$ in total variation, where w_k are any positive weights that sum to 1.*

This relatively simple fact can be proven in different ways, relying on the mentioned equivalence (Blackwell and Dubins, 1962; Kalai and Lehrer, 1994) of the statements "ρ predicts μ in total variation distance" and "μ is absolutely continuous with respect to ρ." The proof presented below is not the shortest possible, but it uses ideas and techniques that are then generalized to the case

of prediction in expected average KL-divergence, which is more involved, since in all interesting cases all measures $\mu \in \mathcal{C}$ are singular with respect to any predictor that predicts all of them. Another proof of Theorem 4 can be obtained from Theorem 7 in the next section. Yet another way would be to derive it from algebraic properties of the relation of absolute continuity, given in Plesner and Rokhlin (1946).

Proof We break the (relatively easy) proof of this theorem into three steps, which will make the proof of the next theorem more understandable.

Step 1: densities. For any $\mu \in \mathcal{C}$, since ρ predicts μ in total variation, by Theorem 2, μ has a density (Radon-Nikodym derivative) f_μ with respect to ρ. Thus, for the (measurable) set T_μ of all sequences $x_1, x_2, ... \in \mathcal{X}^\infty$ on which $f_\mu(x_{1,2,...}) > 0$ (the limit $\lim_{n\to\infty} \frac{\rho(x_{1..n})}{\mu(x_{1..n})}$ exists and is finite and positive) we have $\mu(T_\mu) = 1$ and $\rho(T_\mu) > 0$. Next we will construct a sequence of measures $\mu_k \in \mathcal{C}$, $k \in \mathbb{N}$ such that the union of the sets T_{μ_k} has probability 1 with respect to every $\mu \in \mathcal{C}$, and will show that this is a sequence of measures whose existence is asserted in the theorem statement.

Step 2: a countable cover and the resulting predictor. Let $\varepsilon_k := 2^{-k}$ and let $m_1 := \sup_{\mu\in\mathcal{C}} \rho(T_\mu)$. Clearly, $m_1 > 0$. Find any $\mu_1 \in \mathcal{C}$ such that $\rho(T_{\mu_1}) \geq m_1 - \varepsilon_1$, and let $T_1 = T_{\mu_1}$. For $k > 1$ define $m_k := \sup_{\mu\in\mathcal{C}} \rho(T_\mu \backslash T_{k-1})$. If $m_k = 0$ then define $T_k := T_{k-1}$, otherwise find any μ_k such that $\rho(T_{\mu_k} \backslash T_{k-1}) \geq m_k - \varepsilon_k$, and let $T_k := T_{k-1} \cup T_{\mu_k}$. Define the predictor ν as $\nu := \sum_{k\in\mathbb{N}} w_k \mu_k$.

Step 3: ν predicts every $\mu \in \mathcal{C}$. Since the sets $T_1, T_2 \backslash T_1, \ldots, T_k \backslash T_{k-1}, \ldots$ are disjoint, we must have $\rho(T_k \backslash T_{k-1}) \to 0$, so that $m_k \to 0$ (since $m_k \leq \rho(T_k \backslash T_{k-1}) + \varepsilon_k \to 0$). Let

$$T := \cup_{k\in\mathbb{N}} T_k.$$

Fix any $\mu \in \mathcal{C}$. Suppose that $\mu(T_\mu \backslash T) > 0$. Since μ is absolutely continuous with respect to ρ, we must have $\rho(T_\mu \backslash T) > 0$. Then for every $k > 1$ we have

$$m_k = \sup_{\mu'\in\mathcal{C}} \rho(T_{\mu'} \backslash T_{k-1}) \geq \rho(T_\mu \backslash T_{k-1}) \geq \rho(T_\mu \backslash T) > 0,$$

which contradicts $m_k \to 0$. Thus, we have shown that

$$\mu(T \cap T_\mu) = 1. \tag{3}$$

Let us show that every $\mu \in \mathcal{C}$ is absolutely continuous with respect to ν. Indeed, fix any $\mu \in \mathcal{C}$ and suppose $\mu(A) > 0$ for some $A \in \mathcal{F}$. Then from (3) we have $\mu(A \cap T) > 0$, and, by absolute continuity of μ with respect to ρ, also $\rho(A \cap T) > 0$. Since $T = \cup_{k\in\mathbb{N}} T_k$, we must have $\rho(A \cap T_k) > 0$ for some $k \in \mathbb{N}$. Since on the set T_k the measure μ_k has non-zero density f_{μ_k} with respect to ρ, we must have $\mu_k(A \cap T_k) > 0$. (Indeed, $\mu_k(A \cap T_k) = \int_{A\cap T_k} f_{\mu_k} d\rho > 0$.) Hence,

$$\nu(A \cap T_k) \geq w_k \mu_k(A \cap T_k) > 0,$$

so that $\nu(A) > 0$. Thus, μ is absolutely continuous with respect to ν, and so, by Theorem 2, ν predicts μ in total variation distance. ■

Thus, examples of families $\mathcal{C}$ for which there is a ρ that predicts every $\mu \in \mathcal{C}$ in total variation, are limited to families of measures which have a density with respect to some measure ρ. On the one hand, from statistical point of view, such families are rather large: the assumption that the probabilistic law in question has a density with respect to some (nice) measure is a standard one

in statistics. It should also be mentioned that such families can easily be uncountable. On the other hand, even such basic examples as the set of all Bernoulli i.i.d. measures does not allow for a predictor that predicts every measure in total variation. Indeed, all these processes are singular with respect to one another; in particular, each of the non-overlapping sets T_p of all sequences which have limiting fraction p of 0s has probability 1 with respect to one of the measures and 0 with respect to all others; since there are uncountably many of these measures, there is no measure ρ with respect to which they all would have a density (since such a measure should have $\rho(T_p) > 0$ for all p) . As it was mentioned, predicting in total variation distance means predicting with arbitrarily growing horizon (Kalai and Lehrer, 1994), while prediction in expected average KL divergence is only concerned with the probabilities of the next observation, and only on time and data average. For the latter measure of prediction quality, consistent predictors exist not only for the class of all Bernoulli processes, but also for the class of all stationary processes (Ryabko, 1988). The next theorem establishes the result similar to Theorem 4 for expected average KL divergence.

Theorem 5 *Let $\mathcal{C}$ be a set of probability measures on $(\mathcal{X}^\infty, \mathcal{F})$. If there is a measure ρ such that ρ predicts every $\mu \in \mathcal{C}$ in expected average KL divergence, then there exist a sequence $\mu_k \in \mathcal{C}, k \in \mathbb{N}$ and a sequence $w_k > 0, k \in \mathbb{N}$, such that $\sum_{k,\in\mathbb{N}} w_k = 1$, and the measure $\nu := \sum_{k\in\mathbb{N}} w_k \mu_k$ predicts every $\mu \in \mathcal{C}$ in expected average KL divergence.*

A difference worth noting with respect to the formulation of Theorem 4 (apart from a different measure of divergence) is in that in the latter the weights w_k can be chosen arbitrarily, while in Theorem 5 this is not the case. In general, the statement "$\sum_{k\in\mathbb{N}} w_k \nu_k$ predicts μ in expected average KL divergence for some choice of w_k, $k \in \mathbb{N}$" does not imply "$\sum_{k\in\mathbb{N}} w'_k \nu_k$ predicts μ in expected average KL divergence for every summable sequence of positive $w'_k, k \in \mathbb{N}$," while the implication trivially holds true if the expected average KL divergence is replaced by the total variation. This is illustrated in the last example of this section. An interesting related question (which is beyond the scope of this paper) is how to chose the weights to optimize the behaviour of a predictor before asymptotic.

The idea of the proof of Theorem 5 is as follows. For every μ and every n we consider the sets T^n_μ of those $x_{1..n}$ on which μ is greater than ρ. These sets have to have (from some n on) a high probability with respect to μ. Then since ρ predicts μ in expected average KL divergence, the ρ-probability of these sets cannot decrease exponentially fast (that is, it has to be quite large). (The sequences $\mu(x_{1..n})/\rho(x_{1..n}), n \in \mathbb{N}$ will play the role of densities of the proof of Theorem 4, and the sets T^n_μ the role of sets T_μ on which the density is non-zero.) We then use, for each given n, the same scheme to cover the set $\mathcal{X}^n$ with countably many T^n_μ, as was used in the proof of Theorem 4 to construct a countable covering of the set $\mathcal{X}^\infty$, obtaining for each n a predictor ν_n. Then the predictor ν is obtained as $\sum_{n\in\mathbb{N}} w_n \nu_n$, where the weights decrease subexponentially. The latter fact ensures that, although the weights depend on n, they still play no role asymptotically. The technically most involved part of the proof is to show that the sets T^n_μ in asymptotic have sufficiently large weights in those countable covers that we construct for each n. This is used to demonstrate the implication "if a set has a high μ probability, then its ρ-probability does not decrease too fast, provided some regularity conditions." The proof is broken into the same steps as the (simpler) proof of Theorem 4, to make the analogy explicit and the proof more understandable.

Proof Define the weights $w_k := wk^{-2}$, where w is the normalizer $6/\pi^2$.

Step 1: densities. Define the sets

$$T_\mu^n := \left\{ x_{1..n} \in \mathcal{X}^n : \mu(x_{1..n}) \geq \frac{1}{n}\rho(x_{1..n}) \right\}. \tag{4}$$

Using Markov's inequality, we derive

$$\mu(\mathcal{X}^n \backslash T_\mu^n) = \mu\left(\frac{\rho(x_{1..n})}{\mu(x_{1..n})} > n \right) \leq \frac{1}{n} E_\mu \frac{\rho(x_{1..n})}{\mu(x_{1..n})} = \frac{1}{n}, \tag{5}$$

so that $\mu(T_\mu^n) \to 1$. (Note that if μ is singular with respect to ρ, as is typically the case, then $\frac{\rho(x_{1..n})}{\mu(x_{1..n})}$ converges to 0 μ-a.e. and one can replace $\frac{1}{n}$ in (4) by 1, while still having $\mu(T_\mu^n) \to 1$.)

Step 2n: a countable cover, time n. Fix an $n \in \mathbb{N}$. Define $m_1^n := \max_{\mu \in \mathcal{C}} \rho(T_\mu^n)$ (since $\mathcal{X}^n$ are finite all suprema are reached). Find any μ_1^n such that $\rho_1^n(T_{\mu_1^n}^n) = m_1^n$ and let $T_1^n := T_{\mu_1^n}^n$. For $k > 1$, let $m_k^n := \max_{\mu \in \mathcal{C}} \rho(T_\mu^n \backslash T_{k-1}^n)$. If $m_k^n > 0$, let μ_k^n be any $\mu \in \mathcal{C}$ such that $\rho(T_{\mu_k^n}^n \backslash T_{k-1}^n) = m_k^n$, and let $T_k^n := T_{k-1}^n \cup T_{\mu_k^n}^n$; otherwise let $T_k^n := T_{k-1}^n$. Observe that (for each n) there is only a finite number of positive m_k^n, since the set $\mathcal{X}^n$ is finite; let K_n be the largest index k such that $m_k^n > 0$. Let

$$\nu_n := \sum_{k=1}^{K_n} w_k \mu_k^n.$$

As a result of this construction, for every $n \in \mathbb{N}$ every $k \leq K_n$ and every $x_{1..n} \in T_k^n$ using (4) we obtain

$$\nu_n(x_{1..n}) \geq w_k \frac{1}{n} \rho(x_{1..n}). \tag{6}$$

Step 2: the resulting predictor. Finally, define

$$\nu := \frac{1}{2}\gamma + \frac{1}{2} \sum_{n \in \mathbb{N}} w_n \nu_n, \tag{7}$$

where γ is the i.i.d. measure with equal probabilities of all $x \in \mathcal{X}$ (that is, $\gamma(x_{1..n}) = |\mathcal{X}|^{-n}$ for every $n \in \mathbb{N}$ and every $x_{1..n} \in \mathcal{X}^n$). We will show that ν predicts every $\mu \in \mathcal{C}$, and then in the end of the proof (Step r) we will show how to replace γ by a combination of a countable set of elements of $\mathcal{C}$ (in fact, γ is just a regularizer which ensures that ν-probability of any word is never too close to 0).

Step 3: ν predicts every $\mu \in \mathcal{C}$. Fix any $\mu \in \mathcal{C}$. Introduce the parameters $\varepsilon_\mu^n \in (0,1)$, $n \in \mathbb{N}$, to be defined later, and let $j_\mu^n := 1/\varepsilon_\mu^n$. Observe that $\rho(T_k^n \backslash T_{k-1}^n) \geq \rho(T_{k+1}^n \backslash T_k^n)$, for any $k > 1$ and any $n \in \mathbb{N}$, by definition of these sets. Since the sets $T_k^n \backslash T_{k-1}^n$, $k \in \mathbb{N}$ are disjoint, we obtain $\rho(T_k^n \backslash T_{k-1}^n) \leq 1/k$. Hence, $\rho(T_\mu^n \backslash T_j^n) \leq \varepsilon_\mu^n$ for some $j \leq j_\mu^n$, since otherwise $m_j^n = \max_{\mu \in \mathcal{C}} \rho(T_\mu^n \backslash T_{j_\mu^n}^n) > \varepsilon_\mu^n$ so that $\rho(T_{j_\mu^n+1}^n \backslash T_{j_\mu^n}^n) > \varepsilon_\mu^n = 1/j_\mu^n$, which is a contradiction. Thus,

$$\rho(T_\mu^n \backslash T_{j_\mu^n}^n) \leq \varepsilon_\mu^n. \tag{8}$$

We can upper-bound $\mu(T^n_\mu \backslash T^n_{j^n_\mu})$ as follows. First, observe that

$$d_n(\mu,\rho) = -\sum_{x_{1..n}\in T^n_\mu \cap T^n_{j^n_\mu}} \mu(x_{1..n}) \log \frac{\rho(x_{1..n})}{\mu(x_{1..n})} - \sum_{x_{1..n}\in T^n_\mu \backslash T^n_{j^n_\mu}} \mu(x_{1..n}) \log \frac{\rho(x_{1..n})}{\mu(x_{1..n})} - \sum_{x_{1..n}\in \mathcal{X}^n \backslash T^n_\mu} \mu(x_{1..n}) \log \frac{\rho(x_{1..n})}{\mu(x_{1..n})} = I + II + III. \quad (9)$$

Then, from (4) we get

$$I \geq -\log n. \quad (10)$$

Observe that for every $n \in \mathbb{N}$ and every set $A \subset \mathcal{X}^n$, using Jensen's inequality we can obtain

$$-\sum_{x_{1..n}\in A} \mu(x_{1..n}) \log \frac{\rho(x_{1..n})}{\mu(x_{1..n})} = -\mu(A) \sum_{x_{1..n}\in A} \frac{1}{\mu(A)} \mu(x_{1..n}) \log \frac{\rho(x_{1..n})}{\mu(x_{1..n})} \geq -\mu(A) \log \frac{\rho(A)}{\mu(A)} \geq -\mu(A) \log \rho(A) - \frac{1}{2}. \quad (11)$$

Thus, from (11) and (8) we get

$$II \geq -\mu(T^n_\mu \backslash T^n_{j^n_\mu}) \log \rho(T^n_\mu \backslash T^n_{j^n_\mu}) - 1/2 \geq -\mu(T^n_\mu \backslash T^n_{j^n_\mu}) \log \varepsilon^n_\mu - 1/2. \quad (12)$$

Furthermore,

$$III \geq \sum_{x_{1..n}\in \mathcal{X}^n \backslash T^n_\mu} \mu(x_{1..n}) \log \mu(x_{1..n}) \geq \mu(\mathcal{X}^n \backslash T^n_\mu) \log \frac{\mu(\mathcal{X}^n \backslash T^n_\mu)}{|\mathcal{X}^n \backslash T^n_\mu|} \geq -\frac{1}{2} - \mu(\mathcal{X}^n \backslash T^n_\mu) n \log |\mathcal{X}| \geq -\frac{1}{2} - \log |\mathcal{X}|, \quad (13)$$

where in the second inequality we have used the fact that entropy is maximized when all events are equiprobable, in the third one we used $|\mathcal{X}^n \backslash T^n_\mu| \leq |\mathcal{X}|^n$, while the last inequality follows from (5). Combining (9) with the bounds (10), (12) and (13) we obtain

$$d_n(\mu,\rho) \geq -\log n - \mu(T^n_\mu \backslash T^n_{j^n_\mu}) \log \varepsilon^n_\mu - 1 - \log |\mathcal{X}|,$$

so that

$$\mu(T^n_\mu \backslash T^n_{j^n_\mu}) \leq \frac{1}{-\log \varepsilon^n_\mu} \Big(d_n(\mu,\rho) + \log n + 1 + \log |\mathcal{X}| \Big). \quad (14)$$

Since $d_n(\mu,\rho) = o(n)$, we can define the parameters ε^n_μ in such a way that $-\log \varepsilon^n_\mu = o(n)$ while at the same time the bound (14) gives $\mu(T^n_\mu \backslash T^n_{j^n_\mu}) = o(1)$. Fix such a choice of ε^n_μ. Then, using $\mu(T^n_\mu) \to 1$, we can conclude

$$\mu(\mathcal{X}^n \backslash T^n_{j^n_\mu}) \leq \mu(\mathcal{X}^n \backslash T^n_\mu) + \mu(T^n_\mu \backslash T^n_{j^n_\mu}) = o(1). \quad (15)$$

We proceed with the proof of $d_n(\mu,\nu)=o(n)$. For any $x_{1..n}\in T^n_{j^n_\mu}$ we have

$$\nu(x_{1..n})\geq\frac{1}{2}w_n\nu_n(x_{1..n})\geq\frac{1}{2}w_nw_{j^n_\mu}\frac{1}{n}\rho(x_{1..n})=\frac{w_nw}{2n}(\varepsilon^n_\mu)^2\rho(x_{1..n}),\tag{16}$$

where the first inequality follows from (7), the second from (6), and in the equality we have used $w_{j^n_\mu}=w/(j^n_\mu)^2$ and $j^n_\mu=1/\varepsilon^\mu_n$. Next we use the decomposition

$$d_n(\mu,\nu)=-\sum_{x_{1..n}\in T^n_{j^n_\mu}}\mu(x_{1..n})\log\frac{\nu(x_{1..n})}{\mu(x_{1..n})}-\sum_{x_{1..n}\in\mathcal{X}^n\setminus T^n_{j^n_\mu}}\mu(x_{1..n})\log\frac{\nu(x_{1..n})}{\mu(x_{1..n})}=I+II.\tag{17}$$

From (16) we find

$$\begin{aligned}I&\leq-\log\left(\frac{w_nw}{2n}(\varepsilon^n_\mu)^2\right)-\sum_{x_{1..n}\in T^n_{j^n_\mu}}\mu(x_{1..n})\log\frac{\rho(x_{1..n})}{\mu(x_{1..n})}\\&=(1+3\log n-2\log\varepsilon^n_\mu-2\log w)+\left(d_n(\mu,\rho)+\sum_{x_{1..n}\in\mathcal{X}^n\setminus T^n_{j^n_\mu}}\mu(x_{1..n})\log\frac{\rho(x_{1..n})}{\mu(x_{1..n})}\right)\\&\leq o(n)-\sum_{x_{1..n}\in\mathcal{X}^n\setminus T^n_{j^n_\mu}}\mu(x_{1..n})\log\mu(x_{1..n})\\&\leq o(n)+\mu(\mathcal{X}^n\setminus T^n_{j^n_\mu})n\log|\mathcal{X}|=o(n),\end{aligned}\tag{18}$$

where in the second inequality we have used $-\log\varepsilon^n_\mu=o(n)$ and $d_n(\mu,\rho)=o(n)$, in the last inequality we have again used the fact that the entropy is maximized when all events are equiprobable, while the last equality follows from (15). Moreover, from (7) we find

$$II\leq\log 2-\sum_{x_{1..n}\in\mathcal{X}^n\setminus T^n_{j^n_\mu}}\mu(x_{1..n})\log\frac{\gamma(x_{1..n})}{\mu(x_{1..n})}\leq 1+n\mu(\mathcal{X}^n\setminus T^n_{j^n_\mu})\log|\mathcal{X}|=o(n),\tag{19}$$

where in the last inequality we have used $\gamma(x_{1..n})=|\mathcal{X}|^{-n}$ and $\mu(x_{1..n})\leq 1$, and the last equality follows from (15).

From (17), (18) and (19) we conclude $\frac{1}{n}d_n(\nu,\mu)\to 0$.

Step r: the regularizer γ. It remains to show that the i.i.d. regularizer γ in the definition of ν (7), can be replaced by a convex combination of a countably many elements from $\mathcal{C}$. Indeed, for each $n\in\mathbb{N}$, denote

$$A_n:=\{x_{1..n}\in\mathcal{X}^n:\exists\mu\in\mathcal{C}\,\mu(x_{1..n})\neq 0\},$$

and let for each $x_{1..n}\in\mathcal{X}^n$ the measure $\mu_{x_{1..n}}$ be any measure from $\mathcal{C}$ such that $\mu_{x_{1..n}}(x_{1..n})\geq\frac{1}{2}\sup_{\mu\in\mathcal{C}}\mu(x_{1..n})$. Define

$$\gamma'_n(x'_{1..n}):=\frac{1}{|A_n|}\sum_{x_{1..n}\in A_n}\mu_{x_{1..n}}(x'_{1..n}),$$

for each $x'_{1..n}\in A^n$, $n\in\mathbb{N}$, and let $\gamma':=\sum_{k\in\mathbb{N}}w_k\gamma'_k$. For every $\mu\in\mathcal{C}$ we have

$$\gamma'(x_{1..n})\geq w_n|A_n|^{-1}\mu_{x_{1..n}}(x_{1..n})\geq\frac{1}{2}w_n|\mathcal{X}|^{-n}\mu(x_{1..n})$$

for every $n \in \mathbb{N}$ and every $x_{1..n} \in A_n$, which clearly suffices to establish the bound $II = o(n)$ as in (19). ■

Example: countable classes of measures. A very simple but rich example of a class $\mathcal{C}$ that satisfies the conditions of both the theorems above, is any countable family $\mathcal{C} = \{\mu_k : k \in \mathbb{N}\}$ of measures. In this case, any mixture predictor $\rho := \sum_{k\in\mathbb{N}} w_k \mu_k$ predicts all $\mu \in \mathcal{C}$ both in total variation and in expected average KL divergence. A particular instance, that has gained much attention in the literature, is the family of all computable measures. Although countable, this family of processes is rather rich. The problem of predicting all computable measures was introduced in Solomonoff (1978), where a mixture predictor was proposed.

Example: Bernoulli i.i.d. processes. Consider the class $\mathcal{C}_B = \{\mu_p : p \in [0,1]\}$ of all Bernoulli i.i.d. processes: $\mu_p(x_k = 0) = p$ independently for all $k \in \mathbb{N}$. Clearly, this family is uncountable. Moreover, each set

$$T_p := \{x \in \mathcal{X}^\infty : \text{ the limiting fraction of 0s in } x \text{ equals } p\},$$

has probability 1 with respect to μ_p and probability 0 with respect to any $\mu_{p'} : p' \neq p$. Since the sets T_p, $p \in [0,1]$ are non-overlapping, there is no measure ρ for which $\rho(T_p) > 0$ for all $p \in [0,1]$. That is, there is no measure ρ with respect to which all μ_p are absolutely continuous. Therefore, by Theorem 2, a predictor that predicts any $\mu \in \mathcal{C}_B$ in total variation does not exist, demonstrating that this notion of prediction is rather strong. However, we know (e.g., Krichevsky, 1993) that the Laplace predictor (1) predicts every Bernoulli i.i.d. process in expected average KL divergence (and not only). Hence, Theorem 4 implies that there is a countable mixture predictor for this family too. Let us find such a predictor. Let $\mu_q : q \in Q$ be the family of all Bernoulli i.i.d. measures with rational probability of 0, and let $\rho := \sum_{q\in Q} w_q \mu_q$, where w_q are arbitrary positive weights that sum to 1. Let μ_p be any Bernoulli i.i.d. process. Let $h(p,q)$ denote the divergence $p\log(p/q) + (1-p)\log(1-p/1-q)$. For each ε we can find a $q \in Q$ such that $h(p,q) < \varepsilon$. Then

$$\frac{1}{n} d_n(\mu_p, \rho) = \frac{1}{n}\mathbf{E}_{\mu_p} \log \frac{\log \mu_p(x_{1..n})}{\log \rho(x_{1..n})} \leq \frac{1}{n}\mathbf{E}_{\mu_p} \log \frac{\log \mu_p(x_{1..n})}{w_q \log \mu_q(x_{1..n})}$$
$$= -\frac{\log w_q}{n} + h(p,q) \leq \varepsilon + o(1). \quad (20)$$

Since this holds for each ε, we conclude that $\frac{1}{n} d_n(\mu_p, \rho) \to 0$ and ρ predicts every $\mu \in \mathcal{C}_B$ in expected average KL divergence.

Example: stationary processes. In Ryabko (1988) a predictor ρ_R was constructed which predicts every stationary process $\rho \in \mathcal{C}_S$ in expected average KL divergence. (This predictor is obtained as a mixture of predictors for k-order Markov sources, for all $k \in \mathbb{N}$.) Therefore, Theorem 5 implies that there is also a countable mixture predictor for this family of processes. Such a predictor can be constructed as follows (the proof in this example is based on the proof in Ryabko and Astola, 2006, Appendix 1). Observe that the family $\mathcal{C}_k$ of k-order stationary binary-valued Markov processes is parametrized by 2^k $[0,1]$-valued parameters: probability of observing 0 after observing $x_{1..k}$, for each $x_{1..k} \in \mathcal{X}^k$. For each $k \in \mathbb{N}$ let μ_q^k, $q \in Q^{2^k}$ be the (countable) family of all stationary k-order Markov processes with rational values of all the parameters. We will show that any predictor $\nu := \sum_{k\in\mathbb{N}} \sum_{q\in Q^{2^k}} w_k w_q \mu_q^k$, where w_k, $k \in \mathbb{N}$ and $w_q, q \in Q^{2^k}$, $k \in \mathbb{N}$ are any sequences of positive real weights that sum to 1, predicts every stationary $\mu \in \mathcal{C}_S$ in expected average KL divergence. For

$\mu \in \mathcal{C}_S$ and $k \in \mathbb{N}$ define the k-order conditional Shannon entropy $h_k(\mu) := \mathbf{E}_\mu \log \mu(x_{k+1}|x_{1..k})$. We have $h_{k+1}(\mu) \geq h_k(\mu)$ for every $k \in \mathbb{N}$ and $\mu \in \mathcal{C}_S$, and the limit

$$h_\infty(\mu) := \lim_{k\to\infty} h_k(\mu) \tag{21}$$

is called the limit Shannon entropy; see, for example, Gallager (1968). Fix some $\mu \in \mathcal{C}_S$. It is easy to see that for every $\varepsilon > 0$ and every $k \in \mathbb{N}$ we can find a k-order stationary Markov measure $\mu^k_{q_\varepsilon}$, $q_\varepsilon \in Q^{2^k}$ with rational values of the parameters, such that

$$\mathbf{E}_\mu \log \frac{\mu(x_{k+1}|x_{1..k})}{\mu^k_{q_\varepsilon}(x_{k+1}|x_{1..k})} < \varepsilon. \tag{22}$$

We have

$$\begin{aligned}
\frac{1}{n} d_n(\mu,\nu) &\leq -\frac{\log w_k w_{q_\varepsilon}}{n} + \frac{1}{n} d_n(\mu,\mu^k_{q_\varepsilon}) \\
&= O(k/n) + \frac{1}{n}\mathbf{E}_\mu \log \mu(x_{1..n}) - \frac{1}{n}\mathbf{E}_\mu \log \mu^k_{q_\varepsilon}(x_{1..n}) \\
&= o(1) + h_\infty(\mu) - \frac{1}{n}\mathbf{E}_\mu \sum_{k=1}^{n} \log \mu^k_{q_\varepsilon}(x_t|x_{1..t-1}) \\
&= o(1) + h_\infty(\mu) - \frac{1}{n}\mathbf{E}_\mu \sum_{t=1}^{k} \log \mu^k_{q_\varepsilon}(x_t|x_{1..t-1}) - \frac{n-k}{n}\mathbf{E}_\mu \log \mu^k_{q_\varepsilon}(x_{k+1}|x_{1..k}) \\
&\leq o(1) + h_\infty(\mu) - \frac{n-k}{n}(h_k(\mu) - \varepsilon),
\end{aligned} \tag{23}$$

where the first inequality is derived analogously to (20), the first equality follows from (2), the second equality follows from the Shannon-McMillan-Breiman theorem (e.g., Gallager, 1968), that states that $\frac{1}{n}\log\mu(x_{1..n}) \to h_\infty(\mu)$ in expectation (and a.s.) for every $\mu \in \mathcal{C}_S$, and (2); in the third equality we have used the fact that $\mu^k_{q_\varepsilon}$ is k-order Markov and μ is stationary, whereas the last inequality follows from (22). Finally, since the choice of k and ε was arbitrary, from (23) and (21) we obtain $\lim_{n\to\infty} \frac{1}{n} d_n(\mu,\nu) = 0$.

Example: weights may matter. Finally, we provide an example that illustrates the difference between the formulations of Theorems 4 and 5: in the latter the weights are not arbitrary. We will construct a sequence of measures $\nu_k, k \in \mathbb{N}$, a measure μ, and two sequences of positive weights w_k and w'_k with $\sum_{k\in\mathbb{N}} w_k = \sum_{k\in\mathbb{N}} w'_k = 1$, for which $\nu := \sum_{k\in\mathbb{N}} w_k \nu_k$ predicts μ in expected average KL divergence, but $\nu' := \sum_{k\in\mathbb{N}} w'_k \nu_k$ does not. Let ν_k be a deterministic measure that first outputs k 0s and then only 1s, $k \in \mathbb{N}$. Let $w_k = w/k^2$ with $w = 6/\pi^2$ and $w'_k = 2^{-k}$. Finally, let μ be a deterministic measure that outputs only 0s. We have $d_n(\mu,\nu) = -\log(\sum_{k\geq n} w_k) \leq -\log(wn^{-2}) = o(n)$, but $d_n(\mu,\nu') = -\log(\sum_{k\geq n} w'_k) = -\log(2^{-n+1}) = n-1 \neq o(n)$, proving the claim.

4. Characterizing Predictable Classes

Knowing that a mixture of a countable subset gives a predictor if there is one, a notion that naturally comes to mind, when trying to characterize families of processes for which a predictor exists, is separability. Can we say that there is a predictor for a class $\mathcal{C}$ of measures if and only if $\mathcal{C}$ is separable? Of course, to talk about separability we need a suitable topology on the space of all

measures, or at least on $\mathcal{C}$. If the formulated questions were to have a positive answer, we would need a different topology for each of the notions of predictive quality that we consider. Sometimes these measures of predictive quality indeed define a nice enough structure of a probability space, but sometimes they do not. The question whether there exists a topology on $\mathcal{C}$, separability with respect to which is equivalent to the existence of a predictor, is already more vague and less appealing. Nonetheless, in the case of total variation distance we obviously have a candidate topology: that of total variation distance, and indeed separability with respect to this topology is equivalent to the existence of a predictor, as the next theorem shows. This theorem also implies Theorem 4, thereby providing an alternative proof for the latter. In the case of expected average KL divergence the situation is different. While one can introduce a topology based on it, separability with respect to this topology turns out to be a sufficient but not a necessary condition for the existence of a predictor, as is shown in Theorem 9.

4.1 Separability

Definition 6 (unconditional total variation distance) *Introduce the (unconditional) total variation distance*

$$v(\mu,\rho) := \sup_{A\in\mathcal{F}} |\mu(A)-\rho(A)|.$$

Theorem 7 *Let $\mathcal{C}$ be a set of probability measures on $(\mathcal{X}^\infty,\mathcal{F})$. There is a measure ρ such that ρ predicts every $\mu\in\mathcal{C}$ in total variation if and only if $\mathcal{C}$ is separable with respect to the topology of total variation distance. In this case, any measure ν of the form $\nu=\sum_{k=1}^\infty w_k\mu_k$, where $\{\mu_k : k\in\mathbb{N}\}$ is any dense countable subset of $\mathcal{C}$ and w_k are any positive weights that sum to 1, predicts every $\mu\in\mathcal{C}$ in total variation.*

Proof *Sufficiency and the mixture predictor.* Let $\mathcal{C}$ be separable in total variation distance, and let $\mathcal{D}=\{\nu_k : k\in\mathbb{N}\}$ be its dense countable subset. We have to show that $\nu:=\sum_{k\in\mathbb{N}} w_k\nu_k$, where w_k are any positive real weights that sum to 1, predicts every $\mu\in\mathcal{C}$ in total variation. To do this, it is enough to show that $\mu(A)>0$ implies $\nu(A)>0$ for every $A\in\mathcal{F}$ and every $\mu\in\mathcal{C}$. Indeed, let A be such that $\mu(A)=\varepsilon>0$. Since $\mathcal{D}$ is dense in $\mathcal{C}$, there is a $k\in\mathbb{N}$ such that $v(\mu,\nu_k)<\varepsilon/2$. Hence $\nu_k(A)\geq\mu(A)-v(\mu,\nu_k)\geq\varepsilon/2$ and $\nu(A)\geq w_k\nu_k(A)\geq w_k\varepsilon/2>0$.

Necessity. For any $\mu\in\mathcal{C}$, since ρ predicts μ in total variation, μ has a density (Radon-Nikodym derivative) f_μ with respect to ρ. We can define L_1 distance with respect to ρ as $L_1^\rho(\mu,\nu)=\int_{\mathcal{X}^\infty}|f_\mu-f_\nu|d\rho$. The set of all measures that have a density with respect to ρ, is separable with respect to this distance (for example, a dense countable subset can be constructed based on measures whose densities are step-functions, that take only rational values, see, e.g., Kolmogorov and Fomin, 1975); therefore, its subset $\mathcal{C}$ is also separable. Let $\mathcal{D}$ be any dense countable subset of $\mathcal{C}$. Thus, for every $\mu\in\mathcal{C}$ and every ε there is a $\mu'\in\mathcal{D}$ such that $L_1^\rho(\mu,\mu')<\varepsilon$. For every measurable set A we have

$$|\mu(A)-\mu'(A)|=\left|\int_A f_\mu d\rho-\int_A f_{\mu'}d\rho\right|\leq\int_A|f_\mu-f_{\mu'}|d\rho\leq\int_{\mathcal{X}^\infty}|f_\mu-f_{\mu'}|d\rho<\varepsilon.$$

Therefore, $v(\mu,\mu')=\sup_{A\in\mathcal{F}}|\mu(A)-\mu'(A)|<\varepsilon$, and the set $\mathcal{C}$ is separable in total variation distance. ■

Definition 8 (asymptotic KL "distance" D) *Define asymptotic expected average KL divergence between measures μ and ρ as*

$$D(\mu,\rho)=\limsup_{n\to\infty}\frac{1}{n}d_n(\mu,\rho). \tag{24}$$

Theorem 9 *For any set $\mathcal{C}$ of probability measures on $(\mathcal{X}^\infty,\mathcal{F})$, separability with respect to the asymptotic expected average KL divergence D is a sufficient but not a necessary condition for the existence of a predictor:*

(i) If there exists a countable set $\mathcal{D}:=\{\nu_k : k\in\mathbb{N}\}\subset\mathcal{C}$, such that for every $\mu\in\mathcal{C}$ and every $\varepsilon>0$ there is a measure $\mu'\in\mathcal{D}$, such that $D(\mu,\mu')<\varepsilon$, then every measure ν of the form $\nu=\sum_{k=1}^\infty w_k\mu_k$, where w_k are any positive weights that sum to 1, predicts every $\mu\in\mathcal{C}$ in expected average KL divergence.

(ii) There is an uncountable set $\mathcal{C}$ of measures, and a measure ν, such that ν predicts every $\mu\in\mathcal{C}$ in expected average KL divergence, but $\mu_1\neq\mu_2$ implies $D(\mu_1,\mu_2)=\infty$ for every $\mu_1,\mu_2\in\mathcal{C}$; in particular, $\mathcal{C}$ is not separable with respect to D.

Proof *(i)* Fix $\mu\in\mathcal{C}$. For every $\varepsilon>0$ pick $k\in\mathbb{N}$ such that $D(\mu,\nu_k)<\varepsilon$. We have

$$d_n(\mu,\nu)=\mathbf{E}_\mu\log\frac{\mu(x_{1..n})}{\nu(x_{1..n})}\le\mathbf{E}_\mu\log\frac{\mu(x_{1..n})}{w_k\nu_k(x_{1..n})}=-\log w_k+d_n(\mu,\nu_k)\le n\varepsilon+o(n).$$

Since this holds for every ε, we conclude $\frac{1}{n}d_n(\mu,\nu)\to 0$.

(ii) Let $\mathcal{C}$ be the set of all deterministic sequences (measures concentrated on just one sequence) such that the number of 0s in the first n symbols is less than $\sqrt{n}$. Clearly, this set is uncountable. It is easy to check that $\mu_1\neq\mu_2$ implies $D(\mu_1,\mu_2)=\infty$ for every $\mu_1,\mu_2\in\mathcal{C}$, but the predictor ν, given by $\nu(x_n=0):=1/n$ independently for different n, predicts every $\mu\in\mathcal{C}$ in expected average KL divergence. ■

Examples. Basically, the examples of the preceding section carry over here. Indeed, the example of countable families is trivially also an example of separable (with respect to either of the considered topologies) family. For Bernoulli i.i.d. and k-order Markov processes, the (countable) sets of processes that have rational values of the parameters, considered in the previous section, are dense both in the topology of the parametrization and with respect to the asymptotic average divergence D. It is also easy to check from the arguments presented in the corresponding example of Section 3, that the family of all k-order stationary Markov processes with rational values of the parameters, where we take all $k\in\mathbb{N}$, is dense with respect to D in the set $\mathcal{C}_S$ of all stationary processes, so that $\mathcal{C}_S$ is separable with respect to D. Thus, the sufficient but not necessary condition of separability is satisfied in this case. On the other hand, neither of these latter families is separable with respect to the topology of total variation distance.

4.2 Conditions Based on the Local Behaviour of Measures

Next we provide some sufficient conditions for the existence of a predictor based on local characteristics of the class of measures, that is, measures truncated to the first n observations. First of all, it must be noted that necessary and sufficient conditions cannot be obtained this way. The basic

example is that of a family $\mathcal{C}_0$ of all deterministic sequences that are 0 from some time on. This is a countable class of measures which is very easy to predict. Yet, the class of measures on $\mathcal{X}^n$, obtained by truncating all measures in $\mathcal{C}_0$ to the first n observations, coincides with what would be obtained by truncating all deterministic measures to the first n observations, the latter class being obviously not predictable at all (see also examples below). Nevertheless, considering this kind of local behaviour of measures, one can obtain not only sufficient conditions for the existence of a predictor, but also rates of convergence of the prediction error. It also gives some ideas of how to construct predictors, for the cases when the sufficient conditions obtained are met.

For a class $\mathcal{C}$ of stochastic processes and a sequence $x_{1..n} \in \mathcal{X}^n$ introduce the coefficients

$$c_{x_{1..n}}(\mathcal{C}) := \sup_{\mu\in\mathcal{C}} \mu(x_{1..n}).$$

Define also the normalizer

$$c_n(\mathcal{C}) := \sum_{x_{1..n}\in\mathcal{X}^n} c_{x_{1..n}}(\mathcal{C}).$$

Definition 10 (NML estimate) *The normalized maximum likelihood estimator λ is defined (e.g., Krichevsky, 1993) as*

$$\lambda_{\mathcal{C}}(x_{1..n}) := \frac{1}{c_n(\mathcal{C})} c_{x_{1..n}}(\mathcal{C}),$$

for each $x_{1..n} \in \mathcal{X}^n$.

The family $\lambda_{\mathcal{C}}(x_{1..n})$ (indexed by n) in general does not immediately define a stochastic process over $\mathcal{X}^\infty$ ($\lambda_{\mathcal{C}}$ are not consistent for different n); thus, in particular, using average KL divergence for measuring prediction quality would not make sense, since

$$d_n(\mu(\cdot|x_{1..n-1}), \lambda_{\mathcal{C}}(\cdot|x_{1..n-1}))$$

can be negative, as the following example shows.

Example: negative d_n for NML estimates. Let the processes $\mu_i, i \in \{1,\dots,4\}$ be defined on the steps $n = 1,2$ as follows. $\mu_1(00) = \mu_2(01) = \mu_4(11) = 1$, while $\mu_3(01) = \mu_3(00) = 1/2$. We have $\lambda_{\mathcal{C}}(1) = \lambda_{\mathcal{C}}(0) = 1/2$, while $\lambda_{\mathcal{C}}(00) = \lambda_{\mathcal{C}}(01) = \lambda_{\mathcal{C}}(11) = 1/3$. If we define $\lambda_{\mathcal{C}}(x|y) = \lambda_{\mathcal{C}}(yx)/\lambda_{\mathcal{C}}(y)$, we obtain $\lambda_{\mathcal{C}}(1|0) = \lambda_{\mathcal{C}}(0|0) = 2/3$. Then $d_2(\mu_3(\cdot|0), \lambda_{\mathcal{C}}(\cdot|0)) = \log 3/4 < 0$.

Yet, by taking an appropriate mixture, it is still possible to construct a predictor (a stochastic process) based on λ, that predicts all the measures in the class.

Definition 11 (predictor ρ_c) *Let $w := 6/\pi^2$ and let $w_k := \frac{w}{k^2}$. Define a measure μ_k as follows. On the first k steps it is defined as $\lambda_{\mathcal{C}}$, and for $n > k$ it outputs only zeros with probability 1; so, $\mu_k(x_{1..k}) = \lambda_{\mathcal{C}}(x_{1..k})$ and $\mu_k(x_n = 0) = 1$ for $n > k$. Define the measure ρ_c as*

$$\rho_c = \sum_{k=1}^{\infty} w_k \mu_k.$$

Thus, we have taken the normalized maximum likelihood estimates λ_n for each n and continued them arbitrarily (actually, by a deterministic sequence) to obtain a sequence of measures on $(\mathcal{X}^\infty, \mathcal{F})$ that can be summed.

Theorem 12 *For any set $\mathcal{C}$ of probability measures on $(\mathcal{X}^\infty, \mathcal{F})$, the predictor ρ_c defined above satisfies*

$$\frac{1}{n} d_n(\mu, \rho_c) \le \frac{\log c_n(\mathcal{C})}{n} + O\left(\frac{\log n}{n}\right); \tag{25}$$

in particular, if

$$\log c_n(\mathcal{C}) = o(n), \tag{26}$$

then ρ_c predicts every $\mu \in \mathcal{C}$ in expected average KL divergence.

Proof Indeed,

$$\begin{aligned}\frac{1}{n} d_n(\mu, \rho_c) = \frac{1}{n} \mathbf{E} \log \frac{\mu(x_{1..n})}{\rho_c(x_{1..n})} &\le \frac{1}{n} \mathbf{E} \log \frac{\mu(x_{1..n})}{w_n \mu_n(x_{1..n})} \\ &\le \frac{1}{n} \log \frac{c_n(\mathcal{C})}{w_n} = \frac{1}{n}(\log c_n(\mathcal{C}) + 2\log n + \log w). \end{aligned} \tag{27}$$

■

Example: i.i.d., finite-memory. To illustrate the applicability of the theorem we first consider the class of i.i.d. processes $\mathcal{C}_B$ over the binary alphabet $\mathcal{X} = \{0,1\}$. It is easy to see that, for each $x_1, \dots, x_n$,

$$\sup_{\mu \in \mathcal{C}_B} \mu(x_{1..n}) = (k/n)^k (1 - k/n)^{n-k},$$

where $k = \#\{i \le n : x_i = 0\}$ is the number of 0s in $x_1, \dots, x_n$. For the constants $c_n(\mathcal{C})$ we can derive

$$\begin{aligned} c_n(C) = \sum_{x_{1..n} \in \mathcal{X}^n} \sup_{\mu \in \mathcal{C}_B} \mu(x_{1..n}) &= \sum_{x_{1..n} \in \mathcal{X}^n} (k/n)^k (1 - k/n)^{n-k} \\ &= \sum_{k=0}^{n} \binom{n}{k} (k/n)^k (1 - k/n)^{n-k} \le \sum_{k=0}^{n} \sum_{t=0}^{n} \binom{n}{k} (k/n)^t (1 - k/n)^{n-t} = n + 1, \end{aligned}$$

so that $c_n(C) \le n + 1$.

In general, for the class $\mathcal{C}_k$ of *processes with memory k* over a finite space $\mathcal{X}$ we can get polynomial $c_n(\mathcal{C})$ (see, for example, Krichevsky, 1993, and also Ryabko and Hutter, 2007). Thus, with respect to finite-memory processes, the conditions of Theorem 12 leave ample space for the growth of $c_n(\mathcal{C})$, since (26) allows subexponential growth of $c_n(\mathcal{C})$. Moreover, these conditions are tight, as the following example shows.

Example: exponential coefficients are not sufficient. Observe that the condition (26) cannot be relaxed further, in the sense that exponential coefficients c_n are not sufficient for prediction. Indeed, for the class of all deterministic processes (that is, each process from the class produces some fixed sequence of observations with probability 1) we have $c_n = 2^n$, while obviously for this class a predictor does not exist.

Example: stationary processes. For the set of all stationary processes we can obtain $c_n(C) \ge 2^n/n$ (as is easy to see by considering periodic n-order Markov processes, for each $n \in \mathbb{N}$), so that the conditions of Theorem 12 are not satisfied. This cannot be fixed, since uniform rates of convergence cannot be obtained for this family of processes, as was shown in Ryabko (1988).

4.2.1 OPTIMAL RATES OF CONVERGENCE

A natural question that arises with respect to the bound (25) is whether it can be matched by a lower bound. This question is closely related to the optimality of the normalized maximum likelihood estimates used in the construction of the predictor. In general, since NML estimates are not optimal, neither are the rates of convergence in (25). To obtain (close to) optimal rates one has to consider a different measure of capacity.

To do so, we make the following connection to a problem in information theory. Let $\mathcal{P}(\mathcal{X}^\infty)$ be the set of all stochastic processes (probability measures) on the space $(\mathcal{X}^\infty, \mathcal{F})$, and let $\mathcal{P}(\mathcal{X})$ be the set of probability distributions over a (finite) set $\mathcal{X}$. For a class $\mathcal{C}$ of measures we are interested in a predictor that has a small (or minimal) worst-case (with respect to the class $\mathcal{C}$) probability of error. Thus, we are interested in the quantity

$$\inf_{\rho\in\mathcal{P}(\mathcal{X}^\infty)} \sup_{\mu\in\mathcal{C}} D(\mu,\rho), \tag{28}$$

where the infimum is taken over all stochastic processes ρ, and D is the asymptotic expected average KL divergence (24). (In particular, we are interested in the conditions under which the quantity (28) equals zero.) This problem has been studied for the case when the probability measures are over a finite set $\mathcal{X}$, and D is replaced simply by the KL divergence d between the measures. Thus, the problem was to find the probability measure ρ (if it exists) on which the following minimax is attained

$$R(A) := \inf_{\rho\in\mathcal{P}(\mathcal{X})} \sup_{\mu\in A} d(\mu,\rho), \tag{29}$$

where $A \subset \mathcal{P}(\mathcal{X})$. This problem is closely related to the problem of finding the best code for the class of sources A, which was its original motivation. The normalized maximum likelihood distribution considered above does not in general lead to the optimum solution for this problem. The optimum solution is obtained through the result that relates the minimax (29) to the so-called channel capacity.

Definition 13 (Channel capacity) *For a set A of measures on a finite set $\mathcal{X}$ the* channel capacity *of A is defined as*

$$C(A) := \sup_{P\in\mathcal{P}_0(A)} \sum_{\mu\in S(P)} P(\mu) d(\mu,\rho_P),$$

where $\mathcal{P}_0(A)$ is the set of all probability distributions on A that have a finite support, $S(P)$ is the (finite) support of a distribution $P\in\mathcal{P}_0(A)$, and $\rho_P = \sum_{\mu\in S(P)} P(\mu)\mu$.

It is shown in Ryabko (1979) and Gallager (1976 (revised 1979) that $C(A) = R(A)$, thus reducing the problem of finding a minimax to an optimization problem. For probability measures over infinite spaces this result ($R(A) = C(A)$) was generalized by Haussler (1997), but the divergence between probability distributions is measured by KL divergence (and not asymptotic average KL divergence), which gives infinite $R(A)$, for example, already for the class of i.i.d. processes.

However, truncating measures in a class $\mathcal{C}$ to the first n observations, we can use the results about channel capacity to analyze the predictive properties of the class. Moreover, the rates of convergence that can be obtained along these lines are close to optimal. In order to pass from measures minimizing the divergence for each individual n to a process that minimizes the divergence for all n we use the same idea as when constructing the process ρ_c.

Theorem 14 *Let $\mathcal{C}$ be a set of measures on $(\mathcal{X}^\infty, \mathcal{F})$, and let $\mathcal{C}^n$ be the class of measures from $\mathcal{C}$ restricted to $\mathcal{X}^n$. There exists a measure ρ_C such that*

$$\frac{1}{n} d_n(\mu, \rho_C) \le \frac{C(\mathcal{C}^n)}{n} + O\left(\frac{\log n}{n}\right);$$

in particular, if $C(\mathcal{C}^n)/n \to 0$, then ρ_C predicts every $\mu \in \mathcal{C}$ in expected average KL divergence. Moreover, for any measure ρ_C and every $\varepsilon > 0$ there exists $\mu \in \mathcal{C}$ such that

$$\frac{1}{n} d_n(\mu, \rho_C) \ge \frac{C(\mathcal{C}^n)}{n} - \varepsilon.$$

Proof As shown in Gallager (1976 (revised 1979), for each n there exists a sequence ν_k^n, $k \in \mathbb{N}$ of measures on $\mathcal{X}^n$ such that

$$\lim_{k\to\infty} \sup_{\mu\in\mathcal{C}^n} d_n(\mu, \nu_k^n) \to C(\mathcal{C}^n).$$

For each $n \in \mathbb{N}$ find an index k_n such that

$$|\sup_{\mu\in\mathcal{C}^n} d_n(\mu, \nu_{k_n}^n) - C(\mathcal{C}^n)| \le 1.$$

Define the measure ρ_n as follows. On the first n symbols it coincides with $\nu_{k_n}^n$ and $\rho_n(x_m = 0) = 1$ for $m > n$. Finally, set $\rho_C = \sum_{n=1}^\infty w_n \rho_n$, where $w_k = \frac{w}{n^2}, w = 6/\pi^2$. We have to show that $\lim_{n\to\infty} \frac{1}{n} d_n(\mu, \rho_C) = 0$ for every $\mu \in \mathcal{C}$. Indeed, similarly to (27), we have

$$\begin{aligned}\frac{1}{n} d_n(\mu, \rho_C) &= \frac{1}{n} \mathbf{E}_\mu \log \frac{\mu(x_{1..n})}{\rho_C(x_{1..n})} \\ &\le \frac{\log w_k^{-1}}{n} + \frac{1}{n} \mathbf{E}_\mu \log \frac{\mu(x_{1..n})}{\rho_n(x_{1..n})} \le \frac{\log w + 2\log n}{n} + \frac{1}{n} d_n(\mu, \rho_n) \\ &\le o(1) + \frac{C(\mathcal{C}^n)}{n}.\end{aligned}$$

The second statement follows from the fact (Ryabko, 1979; Gallager, 1976 (revised 1979) that $C(\mathcal{C}^n) = R(\mathcal{C}^n)$ (cf. (29)). ■

Thus, if the channel capacity $C(\mathcal{C}^n)$ grows sublinearly, a predictor can be constructed for the class of processes $\mathcal{C}$. In this case the problem of constructing the predictor is reduced to finding the channel capacities for different n and finding the corresponding measures on which they are attained or approached.

Examples. For the class of all Bernoulli i.i.d. processes, the channel capacity $C(\mathcal{C}_B^n)$ is known to be $O(\log n)$ (Krichevsky, 1993). For the family of all stationary processes it is $O(n)$, so that the conditions of Theorem 14 are satisfied for the former but not for the latter.

We also remark that the requirement of a sublinear channel capacity cannot be relaxed, in the sense that a linear channel capacity is not sufficient for prediction, since it is the maximal possible capacity for a set of measures on $\mathcal{X}^n$, achieved, for example, on the set of all measures, or on the set of all deterministic sequences.

5. Discussion

The first possible extension of the results of the paper that comes to mind is to find out whether the same holds for other measures of performance, such as prediction in KL divergence without time-averaging, or with probability 1 rather then in expectation, or with respect to other measures of prediction error, such as absolute distance. (See Ryabko and Hutter, 2007 for a discussion of different measures of performance and relations between them.) Maybe the same results can be obtained in more general formulations, for example, using f-divergences of Csiszar (1967).

More generally, the questions we addressed in this work are a part of a larger problem: given an arbitrary class $\mathcal{C}$ of stochastic processes, find the best predictor for it. We have considered two subproblems: first, in which form to look for a predictor if one exists. Here we have shown that if any predictor works then a Bayesian one works too. The second one is to characterize families of processes for which a predictor exists. Here we have analyzed what the notion of separability furnishes in this respect, as well as identified some simple sufficient conditions based on the local behaviour of measures in the class. Another approach would be to identify the conditions which two measures μ and ρ have to satisfy in order for ρ to predict μ. For prediction in total variation such conditions have been identified (Blackwell and Dubins, 1962; Kalai and Lehrer, 1994) and, in particular, in the context of the present work, they turn out to be very useful. Kalai and Lehrer (1994) also provide some characterization for the case of a weaker notion of prediction: difference between conditional probabilities of the next (several) outcomes (weak merging of opinions). In Ryabko and Hutter (2008b) some sufficient conditions are found for the case of prediction in expected average KL divergence, and prediction in average KL divergence with probability 1. Of course, another very natural approach to the general problem posed above is to try and find predictors (in the form of algorithms) for some particular classes of processes which are of practical interest. Towards this end, we have found a rather simple form that some solution to this question has if a solution exists: a Bayesian predictor whose prior is concentrated on a countable set. We have also identified some sufficient conditions under which a predictor can actually be constructed (e.g., using NML estimates). However, the larger question of how to construct an optimal predictor for an arbitrary given family of processes, remains open.

Taking an even more general perspective, one can consider the problem of finding the best response to the actions of a (stochastic) environment, which itself responds to the actions of a learner. Allowing into consideration environments that change their behaviour in response to the action of the learner, clearly makes the problem much more difficult, but it also dramatically extends the range of applications. For this general problem one can pose the same questions: given a set $\mathcal{C}$ of environments, how can we construct a learner that is (asymptotically) optimal if any environment from $\mathcal{C}$ is chosen to generate the data? One can consider Bayesian learners for this formulation too (Hutter, 2005); it would be interesting to find out whether one can show that, when there is a learner which is optimal in every environment from $\mathcal{C}$, then there is a Bayesian learner with a countably supported prior that has this property too.

Editor: Aapo Hyvärinen

Abstract

In multivariate regression models we have the opportunity to look for hidden structure unrelated to the observed predictors. However, when one fits a model involving such latent variables it is important to be able to tell if the structure is real, or just an artifact of correlation in the regression errors. We develop a new statistical test based on random rotations for verifying the existence of latent variables. The rotations are carefully constructed to rotate orthogonally to the column space of the regression model. We find that only non-Gaussian latent variables are detectable, a finding that parallels a well known phenomenon in independent components analysis. We base our test on a measure of non-Gaussianity in the histogram of the principal eigenvector components instead of on the eigenvalue. The method finds and verifies some latent dichotomies in the microarray data from the AGEMAP consortium.

Keywords: independent components analysis, Kronecker covariance, latent variables, projection pursuit, transposable data

1. Introduction

The problem we consider here is one of verifying statistically that an apparent latent variable is real. The context is a microarray study, although the ideas are applicable for other high throughput biological settings, and more generally for problems where a large number of mutually correlated variables has been observed.

To fix ideas, suppose we have a matrix $Y \in \mathbb{R}^{n\times N}$ of gene expression data. Each of N genes has been measured on n microarrays. We can often assume that the n arrays come from statistically independent trials, but the N genes on any single array have a rich and unknown correlation structure. There is also an $n \times p$ matrix X of predictor variables to relate to the genes ($p < n$). We are interested in which of the predictors significantly affect the response.

The motivating context is the AGEMAP project of Zahn et al. (2007) for which $n = 40$, $N = 8932$, and $p = 3$, a project whose primary goal is to find which genes are statistically correlated with age. The covariate matrix $X \in \mathbb{R}^{n\times 3}$ has columns for intercept, age, and sex. In matrix form, we model $Y = XB + E$ where B is a p-by-N matrix of regression coefficients and E is an n-by-N matrix of Gaussian or approximately Gaussian errors.

The residuals from the linear model showed a sharp dichotomy, splitting the n AGEMAP subjects into two groups. The split could not be explained by the measured variables and it strongly suggests the presence of a binary latent variable. Binary and other latent variables can arise when

the microarray data are generated at different times, by different technicians, or at different sites. Sometimes a suspected latent variable can be confirmed by looking more closely at the data or lab notes. At that point we might identify the cause and use it as an ordinary regression variable. In other cases we may not be able to pinpoint the cause, but we still want statistical confirmation that it is real. When we are confident that the variable is real then it makes sense to use a model that includes one or more latent variables.

A natural way to test for a latent variable is to compute a singular value decomposition of the residual matrix $\widehat{E} = Y - X\widehat{B}$ and decide that a latent variable is present when the largest singular value of $\widehat{E}$ is sufficiently large. Equivalently, such a test is based on the eigenvalues of the covariance matrix of the rows of $\widehat{E}$. As we show below, a test based on those eigenvalues cannot work when the rows of E are correlated Gaussian random vectors. Adding a Gaussian latent variable simply changes the covariance structure and hence is not detectable. The situation is similar to that faced in independent components analysis (Hyvarinen et al., 2001) which becomes degenerate for Gaussian components.

While the eigenvalues offer no possibility to confirm the presence of a latent variable in correlated Gaussian noise, the eigenvectors of the covariance matrix do. Our tests are based on eigenvectors, rejecting the null hypothesis when the components of an eigenvector differ significantly from what we would get with Gaussian errors. Such measures have been derived for exploratory projection pursuit by Friedman (1987), although it is important to note that Friedman's measures by themselves do not measure of statistical significance. We cannot apply standard tests of Gaussianity such as the Anderson-Darling test, because such tests require an IID sample and the components of the eigenvector are not IID. Instead we show how to use a test based on random rotations of the data. When the noise is independent across observations and comes from a multivariate Gaussian distribution, then under the null hypothesis of no latent variable, random rotations don't change the distribution of our test statistic. Importantly, our test is still valid when there are arbitrary correlations between the columns of E.

Rotation tests have been used before, by Langsrud (2005). Our main contribution is to extend rotation tests to the context of regression for the explicit purpose of detecting latent variables. We show how to apply rotations orthogonally to a given linear model and we combine rotation tests with measures of non-Gaussianity of eigenvectors.

Our principal focus is on testing for the presence versus the absence of one latent variable. The regression model is usually used when we expect no latent variables. The presence of even one latent variable would make it reasonable to switch to a factor model. We also consider sequential tests for the correct number of latent variables when there is at least one of them.

The outline of the paper is as follows: Section 2 introduces the AGEMAP data as a motivating example and introduces the regression model mixing measured and latent predictors. Section 3 develops rotation tests for the existence of latent structure in the residual matrix from a regression. The tests surveyed in Langsrud (2005) need to be modified in order to rotate orthogonally to the regression model. We also show that Gaussian latent vectors cannot be detected, and then present some test statistics for non-Gaussian latent vectors. Section 4 presents numerical simulations on examples where we know the structure. The test is able to identify large latent variables and we find that it gives reliable p-values when no latent variables are present. Section 5 discusses fitting and validating latent variables for the AGEMAP data. Section 6 presents our conclusions.

2. Background

Here we describe the AGEMAP data and introduce regression models that include both measured and latent variables.

2.1 The AGEMAP Data

The motivating application arises from the AGEMAP (Zahn et al., 2007) study of aging in mice. AGEMAP is a large microarray study conducted at the National Institute on Aging and analyzed in collaboration with the Kim lab in Stanford's department of developmental biology. The primary focus of the AGEMAP analysis was to find which genes have expression levels that change with age.

Mice of ages 1, 6, 16, and 24 months were included. There were five male mice at each age and five female mice at each age. For each of these 40 mice, 16 microarrays were prepared, one for each of 16 tissues. The tissues considered were: adrenenal glands, bone marrow, cerebellum, cerebrum, eye, gonad (ovaries/testis), heart, hippocampus, kidney, liver, lung, muscle, spleen, spinal cord, striatum, and thymus.

From each of the $40 \times 16 = 640$ microarrays, values for 8932 genes were obtained. The microarrays had more than 8932 probes, but data from multiple probes corresponding to any single gene have been averaged.

We arrange the data into tissue specific matrices $Y^{(k)}$ for $k = 1, \ldots, 16$. Each $Y^{(k)}$ has 8932 columns. The matrix $Y^{(k)}$ has n_k rows, one for each sample of tissue type k. The values of n_k are unequal due to missing data. We have $32 \le n_k \le 40$ and the average sample size is 38.625. The entry $Y_{ij}^{(k)}$ is the logarithm of the expression value for mouse i and gene j in tissue k.

2.2 Regression with Measured and Latent Variables

For a single tissue type we can drop the superscript k. Zahn et al. (2007) used multiple regression analysis to investigate the effects of aging on gene expression. The regression model for gene j is

$$Y_{ij} = \beta_{0j} + \beta_{1j} A_i + \beta_{2j} S_i + \varepsilon_{ij}, \quad 1 \le i \le n \tag{1}$$

where Y_{ij} is log expression, A_i is the age in months of mouse i, and S_i is 1 if mouse i is female and is 0 otherwise. The random error term is denoted by ε_{ij}. We write all N regression models simultaneously as

$$Y = XB + E$$

where B is a p by N matrix of regression coefficients and E is an n by N matrix of random noise. The n by p design matrix X has a column for each covariate.

Now suppose that there is a latent variable taking the value U_i for the array of the ith mouse. Then adding the latent variable to the regression (1) yields

$$Y_{ij} = \beta_{0j} + \beta_{1j} A_i + \beta_{2j} S_i + \gamma_j U_i + \varepsilon_{ij}, \quad 1 \le i \le n,$$

where both γ_j and U_i are unknown. In matrix notation we have

$$Y = XB + U\Gamma + E \tag{2}$$

where $U \in \mathbb{R}^{n\times 1}$ and $\Gamma \in \mathbb{R}^{1\times N}$. If there are ℓ latent variables then the model remains as shown in (2), except that now $U \in \mathbb{R}^{n\times \ell}$ and $\Gamma \in \mathbb{R}^{\ell\times N}$.

Each individual regression includes more parameters than observations, having n latent values U_i and a coefficient γ_j. But in aggregate only $\ell(N+n)$ parameters are added to the regression for Nn observations, so the model is not saturated for small ℓ.

2.3 Forcing Identifiability

The latent variable model in (2) is not identifiable. To see why, note that if we were to replace U by $U + X\theta$ and B by $B - \theta\Gamma$, for some $\theta \in \mathbb{R}^{p\times N}$ then we would get the same residuals. A similar indeterminacy arises from replacing U by UC and Γ by $C^{-1}\Gamma$ for an invertible $C \in \mathbb{R}^{p\times p}$. We will sometimes assume that the latent variables U satisfy $X^\mathsf{T}U = 0$, $U^\mathsf{T}U = I_\ell$, and $\Gamma^\mathsf{T}\Gamma = D = \mathrm{diag}(d_1,\ldots,d_\ell)$ where $d_1 > d_2 > \cdots > d_\ell > 0$. This makes the model identifiable apart from the signs of the columns of U. Those can be specified by making the first nonzero value in each column positive. The existence of a latent term is not affected by identifiability of U, so we won't have to force U to be identifiable to detect a latent variable. We will also assume that $X^\mathsf{T}X$ has full rank p (this can be easily arranged by removing redundant predictors).

2.4 Noise Model and Estimation

In this section we describe the noise matrix E. One construction would be to assume that the entries of E are all independent and normally distributed with mean 0 and a different variance for each gene. We do not believe that the normality assumption causes serious difficulty for the AGEMAP data. But, assuming zero correlations among genes on the same array is not tenable. We assume instead that the rows of E are independent draws from the $\mathcal{N}(0,\Sigma_N)$ distribution where $\Sigma_N \in \mathbb{R}^{N\times N}$ is a gene-gene covariance matrix.

We will make frequent use of Kronecker notation. The random matrix $S \sim \mathcal{N}(M, A\otimes B)$ if its elements have a joint normal distribution with $\mathbb{E}(S_{ij}) = M_{ij}$ and $\mathrm{Cov}(S_{ij}, S_{kl}) = A_{ik}B_{jl}$ for matrices M, A, and B of appropriate dimensionality.

Our model for the error is that $E \sim \mathcal{N}(0, I_n \otimes \Sigma_N)$. Then model (2) may be written as

$$Y \sim \mathcal{N}(XB + U\Gamma, I_n \otimes \Sigma_N).$$

The identifiability restrictions of Section 2.3 are as before. It will often be simpler to introduce an $n \times N$ matrix Z with IID $\mathcal{N}(0,1)$ entries and note that

$$Y \overset{d}{=} XB + U\Gamma + Z\Sigma_N^{\mathsf{T}/2} \tag{3}$$

where $\Sigma_N^{1/2} \in \mathbb{R}^{N\times N}$ satisfies $\Sigma_N^{1/2}(\Sigma_N^{1/2})^\mathsf{T} = \Sigma_N$ and $\Sigma_N^{\mathsf{T}/2}$ is a shorthand for $(\Sigma_N^{1/2})^\mathsf{T}$. Similarly $A^{-\mathsf{T}}$ means $(A^{-1})^\mathsf{T}$ for invertible A.

Because of our orthogonality constraint, $X^\mathsf{T}U = 0$, the least squares estimate of B is unaffected by the latent variable. That is $\widehat{B} = (X^\mathsf{T}X)^{-1}X^\mathsf{T}Y$. We find that $\widehat{B}$ is normally distributed with $\mathbb{E}(\widehat{B}) = B$ and the covariance between $\hat\beta_{ij}$ and $\hat\beta_{kl}$ is $((X^\mathsf{T}X)^{-1})_{ik}(\Sigma_N)_{jl}$. We summarize this via

$$\widehat{B} \sim \mathcal{N}(B, (X^\mathsf{T}X)^{-1} \otimes \Sigma_N).$$

We can estimate the latent term $\widehat{U}\widehat{\Gamma}$ from the residual matrix $\widehat{E} = Y - X\widehat{B}$. The least squares estimates correspond to Principal Components Analysis (PCA), and can be gotten from truncating

the singular value decomposition of $\widehat{E}$ to ℓ terms. This least squares procedure has been described by Gabriel (1978), who also incorporates column based covariates analogous to the row based ones in X. Another alternative is to use Independent Components Analysis (ICA). If there is some prior knowledge about the distribution of the possible latent factors, this knowledge can be used in the estimation procedure, for example by choosing a particular test statistic to use in Section 3.

3. Rotation Tests for Structure in the Residual Matrix

We have two tasks when dealing with a latent term. The primary task is to determine whether any latent structure exists in the residual matrix $Y - X\widehat{B}$. A secondary task is to estimate that latent structure when we believe it exists.

The main complication is that Σ_N, the noise covariance, is unknown. When Σ_N is known, we can multiply both sides (3) from the right by $(\Sigma_N^{\mathsf{T}/2})^{-1}$ and obtain a model with the same regression variables, the same number of factors, and errors that are IID $\mathcal{N}(0,1)$. Then if $n \gg N$ classical methods due first to Gollob (1968) and refined by Mandel (1971) based on nested hypothesis testing, may be applied. If instead $n \ll N$ the resulting IID $\mathcal{N}(0,1)$ errors can be handled by recent developments in random matrix theory due to Baik and Silverstein (2006) and Paul (2007a). For example, in this setting Rao and Edelman (2008) apply an approach based on the Akaike information criterion (AIC).

Most methods for identifying latent structure only look at the singular values of the residual matrix $\widehat{E}$. Since the correlation in the residuals is nontrivial and unknown, our setting leads us to consider other functions of $\widehat{E}$.

We will use the following elementary formula. If $W \sim \mathcal{N}(0, \Psi \otimes \Phi)$ then

$$BWC^{\mathsf{T}} \sim \mathcal{N}(0, (B\Psi B^{\mathsf{T}}) \otimes (C\Phi C^{\mathsf{T}})), \tag{4}$$

so long as the product matrix BWC^{T} is well defined.

3.1 Rotations Under the Null Hypothesis

Under the null hypothesis of no latent variable, our error term is $E \sim \mathcal{N}(0, I \otimes \Sigma_N)$. For any $n \times n$ orthogonal matrix $\mathbb{O}$, we find that $\mathbb{O}E \sim \mathcal{N}(0, [\mathbb{O}I\mathbb{O}^{\mathsf{T}}] \otimes \Sigma_N) = \mathcal{N}(0, I \otimes \Sigma_N)$ so that $\mathbb{O}E \stackrel{d}{=} E$. The original residual matrix, E, and the rotated residual matrix, $\mathbb{O}E$ have the same distribution. This fact provides our starting point.

We refer to orthogonal matrices as rotations. A stricter usage of the term requires $\det(\mathbb{O}) = 1$ but following Langsrud (2005) we allow $\det(\mathbb{O}) = -1$ as well. Such reflections, as they are sometimes called, also preserve the distribution of E so they are worth including. In a rotation test we compare some aspect of the data to its value under repeated random rotations of the data. Such rotation tests are analogous to the more familiar permutation tests. Rotation tests were first introduced by Wedderburn (1975) and Heiberger (1978). A recent survey appears in Langsrud (2005) who focuses on multiple testing issues.

Here we give a self-contained derivation of rotation tests for multiple regression. The regression context requires us to make some modifications to the method.

The data are $Y = XB + E$ with $E \stackrel{d}{=} U\Gamma + Z\Sigma_N^{\mathsf{T}/2}$ where Z_{ij} are IID $\mathcal{N}(0,1)$. The matrix X has rank $p < n$ and hat matrix $H = X(X^{\mathsf{T}}X)^{-1}X^{\mathsf{T}}$. The residual matrix is $\widehat{E} = (I-H)Y = (I-H)XB + (I-H)E = (I-H)E$. We will apply many random rotations to $\widehat{E}$. This is mathematically equivalent

to rotating both X and Y each time, and then taking the residuals from the rotated variables, but of course it is faster to simply rotate the residuals. To prove equivalence:

Proposition 1 *For integers $n > p > 0$ and $N \geq 1$, let $X \in \mathbb{R}^{n\times p}$, $Y \in \mathbb{R}^{n\times N}$, $B \in \mathbb{R}^{p\times N}$ and $E \in \mathbb{R}^{n\times N}$ satisfy $Y = XB + E$. Suppose that $H = X(X^\mathsf{T}X)^{-1}X^\mathsf{T}$ has rank p. Let $\mathbb{O} \in \mathbb{R}^{n\times n}$ be an orthogonal matrix. Put $\widetilde{Y} = \mathbb{O}Y$, $\widetilde{X} = \mathbb{O}X$, $\widetilde{H} = \widetilde{X}(\widetilde{X}^\mathsf{T}\widetilde{X})^{-1}\widetilde{X}^\mathsf{T}$ and $\widetilde{E} = (I - \widetilde{H})\widetilde{Y}$. Then $\widetilde{E} = \mathbb{O}(I-H)Y$.*

Proof The rotated hat matrix satisfies $\widetilde{H} = \mathbb{O}X(X^\mathsf{T}\mathbb{O}^\mathsf{T}\mathbb{O}X)^{-1}X^\mathsf{T}\mathbb{O}^\mathsf{T} = \mathbb{O}H\mathbb{O}^\mathsf{T}$. The new residual is $\widetilde{E} = \widetilde{Y} - \widetilde{H}\widetilde{Y}$. Now $\widetilde{H}\widetilde{Y} = \mathbb{O}H\mathbb{O}^\mathsf{T}\mathbb{O}Y = \mathbb{O}HY$. Finally $\widetilde{E} = \mathbb{O}Y - \mathbb{O}HY = \mathbb{O}(I-H)Y$. ■

In the regression context, randomly rotating the residuals does not generally preserve their distribution. First because $(I-H)(I-H)^\mathsf{T} = (I-H)$, we find that under the null hypothesis ($U = 0$):

$$\widehat{E} \sim \mathcal{N}(0, (I-H)\otimes\Sigma_N).$$

But then, for the rotated residual we have

$$\mathbb{O}\widehat{E} \sim \mathcal{N}(0, [\mathbb{O}(I-H)\mathbb{O}^\mathsf{T}]\otimes\Sigma_N),$$

by Equation (4). These distributions do not usually coincide.

We will fix this problem by restricting attention to a special subset of rotation matrices. The desired rotations $\mathbb{O}$ satisfy $\mathbb{O}H\mathbb{O}^\mathsf{T} = H$ (equivalently $\mathbb{O}(I-H)\mathbb{O}^\mathsf{T} = (I-H)$) for then the rotation does not change the distribution of $\widehat{E}$. The rotations we want will fix X but rotate the space orthogonal to X. Specific construction details follow.

Because H has p eigenvalues equal to 1 and $n-p$ eigenvalues equal to 0 we may write it as $H = Q_1Q_1^\mathsf{T}$ where $Q_1 \in \mathbb{R}^{n\times p}$ satisfies $Q_1^\mathsf{T}Q_1 = I_p$. Let $Q_2 \in \mathbb{R}^{n\times(n-p)}$ be a matrix such that $Q = \begin{pmatrix} Q_1 & Q_2 \end{pmatrix}$ is orthogonal. For our construction, we let $\mathbb{O}_* \in \mathbb{R}^{(n-p)\times(n-p)}$ be an orthogonal matrix and then take

$$\mathbb{O} = Q_1Q_1^\mathsf{T} + Q_2\mathbb{O}_*Q_2^\mathsf{T}. \tag{5}$$

The matrices produced by Equation (5) are orthogonal and satisfy $\mathbb{O}H\mathbb{O}^\mathsf{T} = H$. We summarize as follows:

Proposition 2 *Let $Y \sim \mathcal{N}(XB, I_n\otimes\Sigma_N)$ where $X \in \mathbb{R}^{n\times p}$ has rank $p < n$ and $B \in \mathbb{R}^{p\times N}$. Let $\widehat{E} = (I-H)Y$ where $H = X(X^\mathsf{T}X)^{-1}X^\mathsf{T}$ and let $\widetilde{E} = \mathbb{O}\widehat{E}$ where $\mathbb{O}$ satisfies* (5)*. Then both $\widehat{E}$ and $\widetilde{E}$ have the $\mathcal{N}(0, (I-H)\otimes\Sigma_N)$ distribution.*

Proof Let $E = Y - XB \sim \mathcal{N}(0, I_n\otimes\Sigma_N)$. Then $\widehat{E} = (I-H)Y = (I-H)E \sim \mathcal{N}(0, (I-H)\otimes\Sigma_N)$ as above. Now suppose that $\mathbb{O}$ satisfies (5). Then $\widetilde{E} = \mathbb{O}(I-H)E \sim \mathcal{N}(0, [\mathbb{O}(I-H)\mathbb{O}^\mathsf{T}]\otimes\Sigma_N)$. Next

$$\begin{aligned}
\mathbb{O}(I-H)\mathbb{O}^\mathsf{T} &= \left(Q_1Q_1^\mathsf{T} + Q_2\mathbb{O}_*Q_2^\mathsf{T}\right)(I-H)\left(Q_1Q_1^\mathsf{T} + Q_2\mathbb{O}_*Q_2^\mathsf{T}\right)\\
&= \left(Q_1Q_1^\mathsf{T} + Q_2\mathbb{O}_*Q_2^\mathsf{T}\right)Q_2Q_2^\mathsf{T}\left(Q_1Q_1^\mathsf{T} + Q_2\mathbb{O}_*^\mathsf{T}Q_2^\mathsf{T}\right)\\
&= Q_2\mathbb{O}_*\mathbb{O}_*^\mathsf{T}Q_2^\mathsf{T}\\
&= I-H,
\end{aligned}$$

and so $\widetilde{E} \overset{d}{=} \widehat{E}$. ■

To complete this section we show that Equation (5) generates all of the desired rotations.

Proposition 3 *Let $Q = \begin{pmatrix} Q_1 & Q_2 \end{pmatrix} \in \mathbb{R}^{n\times n}$ be an orthogonal matrix, where $Q_1 \in \mathbb{R}^{n\times p}$ for $n > p > 0$. Let $\mathbb{O} \in \mathbb{R}^{n\times n}$ be an orthogonal matrix and write $H = Q_1 Q_1^\mathsf{T}$. If $\mathbb{O}H\mathbb{O}^\mathsf{T} = H$ then $\mathbb{O} = Q_1\mathbb{O}_\circ Q_1^\mathsf{T} + Q_2\mathbb{O}_* Q_2^\mathsf{T}$ where $\mathbb{O}_\circ \in \mathbb{R}^{p\times p}$ and $\mathbb{O}_* \in \mathbb{R}^{(n-p)\times(n-p)}$ are orthogonal matrices.*

Proof First, any orthogonal matrix $\mathbb{O}$ can be written as $\mathbb{O} = QPQ^\mathsf{T}$ where

$$P = \begin{pmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{pmatrix}$$

is orthogonal, and partitioned with $P_{11} \in \mathbb{R}^{p\times p}$, $P_{22} \in \mathbb{R}^{(n-p)\times(n-p)}$ and so on. We may take $P = Q^\mathsf{T}\mathbb{O}Q$. Now $\mathbb{O}H\mathbb{O}^\mathsf{T} = QPQ^\mathsf{T}Q_1Q_1^\mathsf{T}QP^\mathsf{T}Q^\mathsf{T} = FF^\mathsf{T}$where

$$F = QPQ^\mathsf{T}Q_1 = \begin{pmatrix} Q_1 & Q_2 \end{pmatrix}\begin{pmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{pmatrix}\begin{pmatrix} Q_1^\mathsf{T} \\ Q_2^\mathsf{T} \end{pmatrix} Q_1 = Q_1P_{11} + Q_2P_{21}.$$

Assume that $\mathbb{O}H\mathbb{O}^\mathsf{T} = H$. Then $Q_1^\mathsf{T}\mathbb{O}H\mathbb{O}^\mathsf{T}Q_1 = I_p$ so that $(Q_1^\mathsf{T}F)(Q_1^\mathsf{T}F)^\mathsf{T} = I_p$. But $Q_1^\mathsf{T}F = P_{11}$. Therefore $P_{11}P_{11}^\mathsf{T} = I_p$, or in other words P_{11} is an orthogonal matrix. The columns of P_{11} are unit vectors and so are those of P. Therefore $P_{21} = 0$. Similarly $P_{12} = 0$ and P_{22} is an orthogonal matrix. Taking $\mathbb{O}_\circ = P_{11}$ and $\mathbb{O}_* = P_{22}$ completes the proof. ■

From Proposition 3 we see that the suitable rotations take the form $\mathbb{O} = Q_1\mathbb{O}_\circ Q_1^\mathsf{T} + Q_2\mathbb{O}_* Q_2^\mathsf{T}$. In Equation (5), we only use $\mathbb{O}_\circ = I_p$. We don't need to vary that part of the rotation because in our application we work with

$$\mathbb{O}(I-H) = \mathbb{O}Q_2Q_2^\mathsf{T} = (Q_1\mathbb{O}_\circ Q_1^\mathsf{T} + Q_2\mathbb{O}_* Q_2^\mathsf{T})Q_2Q_2^\mathsf{T} = Q_2\mathbb{O}_* Q_2^\mathsf{T}.$$

The choice of $\mathbb{O}_\circ$ does not affect the value of $\widetilde{E} = \mathbb{O}(I-H)Y$, and so we may simply take $\mathbb{O}_\circ = I_p$.

3.2 Testing for the Existence of Structure

Here we construct a test for latent structure in the residual matrix. The null hypothesis is $H_0 : U = 0$ and the alternative is $H_1 : U \neq 0$. We will construct a rotation test by modifying the rotation tests in Langsrud (2005). As in the discussion of the randomization tests in Lehmann and Romano (2005) we find a group of rotations. It is easy to show that $O_H = \{Q_1Q_1^\mathsf{T} + Q_2\mathbb{O}_*Q_2^\mathsf{T} \mid \mathbb{O}_* \in \mathbb{R}^{(n-p)\times(n-p)}, \mathbb{O}_*^\mathsf{T}\mathbb{O}_* = I_{n-p}\}$ is a group under multiplication, because orthogonal $r-p$ by $r-p$ matrices are a group. Southworth et al. (2009) give a cautionary note on randomizations without a group structure.

Proposition 2 allows us to perform a test of the hypothesis as follows: let $T : \mathbb{R}^{n\times N} \to \mathbb{R}$ be any statistic of the residual matrix. Specific examples are given in Section 3.4. We generate independent n by n random rotations $\mathbb{O}_1, \ldots, \mathbb{O}_{R-1}$ uniformly from O_H. Then, construct a p-value as

$$\hat{p} = \frac{1}{R}\Big(1 + \sum_{i=1}^{R-1} 1\{T(\mathbb{O}_i\widehat{E}) \geq T(\widehat{E})\}\Big). \tag{6}$$

Since under the null hypothesis $\mathbb{O}_i\widehat{E}$ and $\widehat{E}$ have the same distribution and since O_H is a group, this gives us a valid p-value. The leading 1 in $\hat{p}$ counts the observed $\widehat{E}$ and prevents us from claiming $\hat{p}$ below $1/R$ if we have only seen R rotations (including the original one).

3.3 Gaussian Alternative

Here we show that when Σ_N is unknown, a Gaussian latent variable cannot be detected. This was remarked on by Snee (1982) and it is well known in the independent component analysis community; see Hyvarinen et al. (2001).

To see how the problem manifests, consider the model in (3) with just one latent variable with entries $U_i \sim \mathcal{N}(0,1)$ independently of Z. The regression model XB is assumed nonrandom. To focus on essentials we do not initially impose the normalization $U^\mathsf{T}U = I_\ell$.

Proposition 4 *For positive integers N, n, and ℓ, let $Z \sim \mathcal{N}(0, I_n \otimes I_N)$ independently of $U \sim \mathcal{N}(0, I_n \otimes I_\ell)$. Let $\Gamma \in \mathbb{R}^{\ell\times N}$. Then $U\Gamma + Z\Sigma_N^{\mathsf{T}/2} \overset{d}{=} Z\widetilde{\Sigma}_N^{\mathsf{T}/2}$ where $\widetilde{\Sigma}_N = \Sigma_N + \Gamma^\mathsf{T}\Gamma$.*

Proof We only need to show that $U\Gamma + Z\Sigma_N^{\mathsf{T}/2}$ has the same distribution as $Z\widetilde{\Sigma}_N^{\mathsf{T}/2}$. The matrix $U\Gamma + Z\Sigma_N^{\mathsf{T}/2}$ has independent identically distributed rows from $\mathcal{N}(0, \Sigma_N + \Gamma^\mathsf{T}\Gamma)$. Therefore $U\Gamma + Z\Sigma_N^{\mathsf{T}/2}$ has representation $\widetilde{Z}\widetilde{\Sigma}_N^{\mathsf{T}/2}$ where $\widetilde{Z} \in \mathbb{R}^{N\times n}$ has IID entries from $\mathcal{N}(0,1)$. This $\widetilde{Z}$ has the same distribution as Z. ■

If we do normalize U then nothing essential changes. We replace U by UC for a random normalizing matrix $C \in \mathbb{R}^{\ell\times\ell}$ that is independent of Z (that is, $UC \sim \mathcal{N}(0, I_n \otimes I_\ell)$ and $U^\mathsf{T}U = I$). Then we compensate by replacing Γ by $C^{-1}\Gamma$ and get $U\Gamma + Z\Sigma_N^{\mathsf{T}/2} \overset{d}{=} Z\widetilde{\Sigma}_N$ where $\widetilde{\Sigma}_N = \Sigma_N + \Gamma^\mathsf{T}C^{-\mathsf{T}}C^{-1}\Gamma$ is now random.

The implication of Proposition 4 is that if we don't know anything about Σ_N, or Γ, then a Gaussian latent variable is impossible to detect. There is no mathematical difference between a Gaussian latent vector and a changed correlation structure. Put another way, such latent variables are already well accounted for in the correlation structure.

Latent variables of practical interest typically exhibit non-Gaussian traits like clumping or outliers. Also, if a latent variable corresponds to a roughly-linear time trend, then it will be nearly uniformly distributed if the points are sampled at regular time intervals. Therefore this restriction still leaves many interesting testing problems.

3.4 Choice of the Test Statistic, T

Since a Gaussian latent variable is covered by the correlation model and is not detectable, any effective test statistic T must be tuned for non-Gaussian latent variables. A non-Gaussian latent variable makes for an error term $U\Gamma + Z\Sigma_N^{\mathsf{T}/2}$ that does not have a rotationally invariant distribution.

In principle any function $T(E)$ can be used. However, the choice of T will often be dictated by what we deem to be interesting structure. Here we describe four different possibilities for T. We first apply a simplification procedure to reduce E to a vector $u(E)$. Then, we apply a function to reduce u to a scalar. The end result is a scalar-valued function $T(E)$.

We would like $u(E)$ to be representative of latent structure in E. An obvious choice is the first left singular vector of E, which corresponds to the first principal component of E. A second choice is to apply ICA to E, treating the columns as mixtures of n-dimensional sources, and have $u(E)$ be the first estimated source. In both cases $u(E)$ is a unit vector.

We cannot simply use a test for normality of the components of $u(E)$, such as the Anderson-Darling test, because the components we get are not independent $\mathcal{N}(0,1)$ even under H_0.

Instead, we propose two functions for reducing $u = u(E)$ to a scalar. The first is the L^1 norm of the vector:

$$T_{L^1}(u) = \sum_{i=1}^{n} |u_i|.$$

As a point of reference, for independent $u_i \sim \mathcal{N}(0, \frac{1}{n})$ we would get $T_{L^1} \doteq \sqrt{2n/\pi}$. So, the expected L^1 norm of a uniformly distributed n-dimensional unit vector is approximately $\sqrt{2n/\pi} \doteq 0.798\sqrt{n}$. Larger values of T_{L^1} correspond to distributions whose expected absolute value is large compared to their root mean square. Uniform distributions on $[-1,1]$ or $\{-1,1\}$ behave this way. Conversely, small values of T_{L^1} arise from very heavy tailed distributions like the Cauchy which have outliers.

The rotation based p-value (6) is sensitive to large values of T_{L^1} and should therefore catch dichotomies and light tailed latent variables. To detect heavy tailed alternatives we could use (6) with $1/T_{L^1}$. Because we are potentially interested in both kinds of non-Gaussian latent structure we take

$$\hat{p} = \frac{2}{R} \min\left(1 + \sum_{i=1}^{R-1} 1\{\widetilde{T}_i \geq \widehat{T}\},\ 1 + \sum_{i=1}^{R-1} 1\{\widetilde{T}_i \leq \widehat{T}\}\right), \tag{7}$$

where $\widehat{T} = T(\widehat{E})$ and $\widetilde{T}_i = T(\mathbb{O}_i \widehat{E})$ and $T(\cdot)$ subsumes all the computation in T_{L^1}. The leading 2 in (7) compensates for using the more extreme of two tails.

The second test statistic comes from Exploratory Projection Pursuit (Friedman, 1987). T_{EPP} is a distance measure on densities, represented as a Legendre-series and then truncated to 4 terms:

$$T_{\text{EPP}}(u) = \sum_{j=1}^{4} \left(j + \frac{1}{2}\right) \left(\mathbb{E}P_j(R)\right)^2$$

where, P_j is the j-th Legendre polynomial, R is a random variable uniformly distributed over the discrete set $\{2\Phi(u_i) - 1\}_{i=1}^n$, Φ is the cumulative distribution function of the $\mathcal{N}(0,1)$ distribution, and $\mathbb{E}$ denotes expectation over the randomness in R. The Legendre polynomials can be computed using the recurrence relation

$$\begin{aligned} P_0(x) &= 1, \\ P_1(x) &= x, \quad \text{and}, \\ (j+1)P_{j+1}(x) &= (2j+1)xP_j(x) - jP_{j-1}(x). \end{aligned}$$

In computing T_{EPP} we use

$$\mathbb{E}P_j(R) = \frac{1}{n} \sum_{i=1}^{n} P_j(2\Phi(u_i) - 1).$$

T_{EPP} is designed to be close to 0 when the histogram of u looks Gaussian, and it gets bigger the more "non-Gaussian" u is. The full derivation of T_{EPP} is given by Friedman (1987).

Because only large values of T_{EPP} are interesting we use (6) directly without making a two-tailed modification.

We can combine PCA or ICA with $T_{\text{EPP}}(u)$ or $T_{L^1}(u)$ and get four different test statistics. We write $T_{\text{EPP}}(E)$ or $T_{L^1}(E)$ when the context dictating PCA or ICA for u is clear. The choice of T is independent of the procedure for estimating the latent variable. In particular, it is possible to detect the existence of latent structure in $\widehat{E}$ using a PCA-based test statistic and then fit the structure using ICA. Indeed, in simulations it turns out to be better to use PCA for u. This will be further explored in Section 4.

3.5 Identifying the Rank of the Latent Term

When we are able to reject the null hypothesis we conclude that some latent structure exists, but we do not know the rank of U. To estimate the number of latent variables we consider a sequential approach, based on subtracting estimated latent variables and looking for latent structure in the residuals.

First, we fit the model $\widehat{Y}_0 = X_0\widehat{B}_0$ and get the residual matrix $\widehat{E}_0$. The subscripts denote a model with 0 latent terms. Next, we test for latent structure in $\widehat{E}_0$. If we determine that any structure exists, we fit a single latent variable $\hat{u}_1$.

At this stage, we treat $\hat{u}_1$ as a known covariate. We create a new covariate matrix $X_1 = [X_0 \;\; \hat{u}_1]$ by appending $\hat{u}_1$ as a column onto the old covariate matrix. Now, we fit the a new model $\widehat{Y}_1 = X_1\widehat{B}_1$ and get a new residual matrix $\widehat{E}_1$. We proceed in a sequential matter: test for structure in $\widehat{E}_i$; upon identifying structure, fit a single latent variable, treat it as a covariate, and get a new residual matrix $\widehat{E}_{i+1}$. We stop when there is no latent structure in $\widehat{E}_i$.

In the context of PCA, fitting $\hat{u}_2$ sequentially after adjusting $\widehat{E}$ for $\hat{u}_1$ is equivalent to fitting $\hat{u}_1$ and $\hat{u}_2$ simultaneously. For other estimation methods, this equivalence may not hold. The procedure we describe is still valid, but there may be some loss in power. If this is a concern, the practitioner can adjust the testing procedure accordingly.

One has to be careful when testing for more than one latent term. In particular, for some settings when $n \ll N$, it is impossible to consistently estimate the latent variables $\hat{u}_i$. When we do not have a good estimate of $\hat{u}_i$, treating it as a known covariate will introduce a potentially serious error. When this happens, only the p-value for the first term is reliable. This point is illustrated in the example of Section 4.3, where the error in the p-value distribution was small.

3.6 Caveats

When we reject the null hypothesis, then either there is strong enough latent structure in the data, or the noise is far from Gaussian. Therefore, rejecting the null hypothesis is *necessary* to deem latent structure to be real, but not sufficient. Often there is ambiguity between what constitutes non-Gaussianity and what can be explained by a latent variable. An outlier can be modeled using a latent variable that has support on a single observation. Bi-modal noise can be re-cast as a clumping latent effect.

3.7 Related Work

Rank determination methods have been the subject of much interest in crop science. For a recent survey see Crossa and Cornelius (2002). Those methods tend to focus on the amount of variance explained by the first principal component. In an eigen-analysis of $Y - X\widehat{B}$, they focus on the size of the eigenvalues. There has been considerable difficulty with getting tests to have the right level, as described for example by dos S Dias and Krzanowski (2003). The core problem is that there is no good way to count the degrees of freedom for such data sets, despite recent progress in random matrix theory including El Karoui (2007), Paul (2007b), and Nadler (2007). Owen and Perry (2009) apply a cross-validation-based approach to rank determination for the truncated SVD and non-negative matrix factorization. That work requires independent noise, not the correlated noise we consider here. Efron (2009) uses permutations to test whether some microarrays are independent of each other.

4. Empirical Testing

In this section we examine the performance of rotation tests on constructed examples where we know the answer. Some readers may prefer to read the real data example of Section 5 first. In our constructed examples, the response satisfies

$$Y \sim \mathcal{N}(XB + U\Gamma, I_n \otimes \Sigma_N),$$

with parameters described below.

4.1 Microarray Model

This example is designed to resemble microarray studies. We take $p = 2, n = 20$ and $N = 256$. This value of N is small, to allow a larger number of simulated cases. The matrix X has a first column of 1s. The second column has values $1, \ldots, n$. We take B to be a $p \times N$ matrix of 0s. Having $B = 0$ is no loss of generality, because the analysis works on residuals after regression on X and the residuals are unaffected by B.

We construct latent variables $U \in \mathbb{R}^{n\times 3}$. The first latent variable, u_1, is the first column of U and has independent elements distributed as Cauchy random variables. The second latent variable, u_2, has elements which are either -1 or 1 with equal probability. The third latent variable, u_3, has elements that are independent and exponentially distributed with mean 1. Thus, u_1 is an "outlier" effect, u_2 is a "clumping" effect, and u_3 is some other latent effect.

The latent coefficient matrix, Γ, has independent elements distributed as $\mathcal{N}(0,1)$. We do not think that non-normal Γ would make the signal artificially easy to detect, but taking Gaussian Γ removes any such worry. As described, U, Γ, and X do not satisfy the identifiability conditions of Section 2.3. The existence of an unnormalized latent variable implies that a normalized one exists, and so the testing problem is unaffected.

For Σ_N we need a 256×256 correlation matrix. The true correlation patterns for microarray data are not known. The sample sizes to date are far too small to allow confident description of the patterns. Owen (2005) looks at what gene-gene correlations are like in real data. We mimic two features of microarray data. First, genes are often thought to belong to relatively small clusters. Second, the mean of the squared estimated off-diagonal sample correlations is often seen to be a small multiple of $1/n$. The value $1/n$ is very close to what we would expect in the event that all true correlations were zero. To encode the first property, we take

$$\Sigma_{ij} = \begin{cases} 1 & i = j, \\ \rho & \lfloor (i-1)/32 \rfloor = \lfloor (j-1)/32 \rfloor, \quad \& \quad i \neq j, \\ \rho & i - j \equiv 0 \bmod 32, \quad \& \quad i \neq j, \\ 0 & \text{else.} \end{cases}$$

In words, gene i belongs to two clusters: one cluster of 8 genes corresponding to the least-significant digit of $i-1$ in base 32, and one cluster of 32 genes corresponding to the most-significant digit of $i-1$ in base 32. Gene i has 38 non-zero correlations with other genes. The value of $\rho > 0$ is chosen so that signal is about 30% of the noise:

$$\frac{\sum_{i=1}^N \sum_{j=1}^N \Sigma_{ij}^2 - N}{N(N-1)/n} = 0.30.$$

Thus $38\rho^2 = (N-1)/(0.30\,n)$ so $\rho = \sqrt{0.30\,(N-1)/(38n)} \doteq 0.317$.

4.2 Rotation Tests

The true model has three latent variables. We are interested in what happens when testing for the first, second, third, and fourth latent terms. We look at two different choices for the test statistic: T_{EPP} in conjunction with PCA, and T_{EPP} in conjunction with ICA. The results are summarized in ROC curves in Figure 1.

The upper-right panel shows the results from testing the residual matrix after one latent term has been removed. Here, we see that testing with u_{PCA} results in about 75% of the replicates having estimated p-values less than 0.2, while testing with u_{ICA}, results in about 55%. Generally, the PCA test gave us higher power. We also found that FastICA can get stuck in a local minimum. This is what lead to its surprisingly poor performance in the upper left panel. The latent variables of the randomly-rotated data are more non-Gaussian than the latent variable estimated from the original data.

The lower-right panel shows the estimated p-values after three latent terms have been fit and removed from the residual matrix. As expected, the estimated p-values are close to the specified false-positive rates. Comparing the lower left panel to the others, we see, unsurprisingly that the smallest latent vector is hardest to detect while the largest is easiest to detect. Finally, testing for a fourth latent variable gives us a uniform p-value, which is exactly what we want since there are only three latent terms.

A word is in order about how we removed the first latent variable when testing for the presence of the second. We tried removing vectors as estimated by PCA and also by ICA. There was not much difference in performance, and PCA has the computational advantage that the estimated second vector does not change when we remove the first. Therefore when testing for the k'th vector, whether by ICA or PCA, we always used PCA to remove the first $k-1$ of them.

4.3 Testing Under and Near the Null Hypothesis

In the previous simulation, the signal-to-noise ratio between the latent effect terms and the random error is relatively high, and so the p-values for non-existent latent terms are faithful. In this simulation, we demonstrate that the p-values for testing for multiple latent variables are slightly liberal if the signal strength is too weak, but these p-values are still within tolerable accuracy.

We generate an $n \times N$ data matrix Y according to the model

$$Y = (N\lambda)^{1/2} u\gamma^{\mathsf{T}} + Z\Sigma_N^{\mathsf{T}/2},$$

with $n = 20$ and $N = 200$. There is a single latent variable u which has elements equal to -1 or $+1$ with equal probability. The coefficient vector γ is a uniformly distributed random unit vector in $\mathbb{R}^N$. The noise covariance Σ_N is a diagonal matrix with $(\Sigma_N)_{ii}$ independent from all other entries and exponentially-distributed with mean 1; $\Sigma_N^{1/2}$ is its square root. The noise variable matrix Z has IID $\mathcal{N}(0,1)$ elements. We choose λ to be a fixed scalar, specified below.

The theory in Section 3.2 tells us that the p-value from a rotation test of a single latent term is uniformly-distributed when $\lambda = 0$. However, it tells us nothing about p-values for a second term. Regardless of the value of λ, we would like them to be uniformly distributed, so that the test is faithful to the specified false positive rate. The issue is whether errors in the estimated first latent vector spoil the test for the second. Results in Onatski (2007) suggest that as the sample size goes to infinity, p-values from the second and higher terms will be faithful when we fit with PCA. Our sample size is only 20, so we do an empirical test.

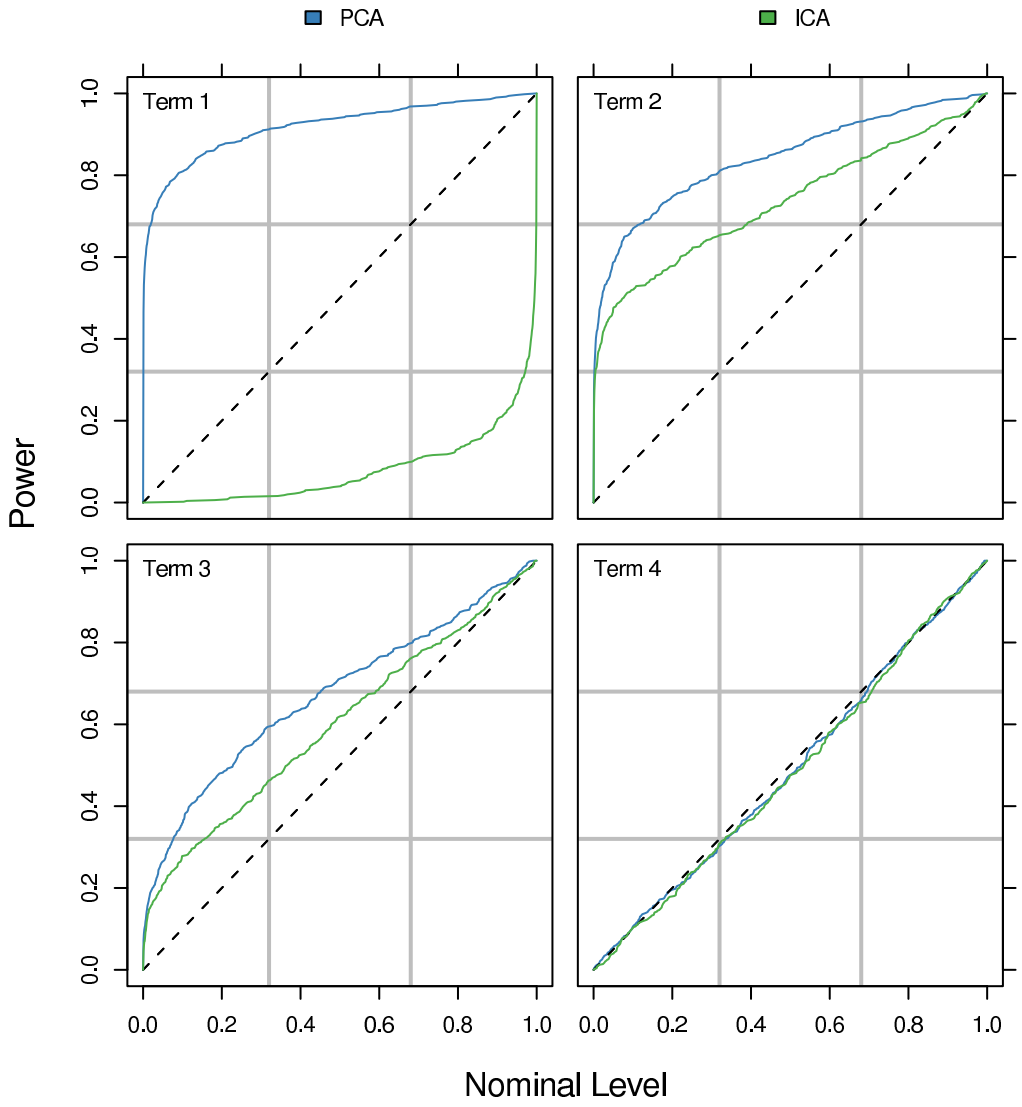

Figure 1: MULTI-FACTOR ROTATION TESTS WITH PCA AND ICA. We simulate data from a model with three latent terms and then apply rotation tests for latent structure. The test statistic is $T_{\mathrm{EPP}}(u)$ applied to either the first principal component u_{PCA}, or the first independent component u_{ICA} (via FastICA) of the residual matrix. The plots show estimated ROC curves after $0, 1, 2$, or 3 principal components have been fit and removed. The x axis of each plot is the specified false-positive rate. The y axis is the proportion of replicates with an estimated p-value below that level, using 500 total replicates of the data set. The plots are discussed further in the text.

For all λ in the set $\{0, 0.5, 1, 5, 10, 50, 100, 500, 1000\}$, we perform the following simulation, which we repeat 1000 times:

1) Generate data Y as described above.

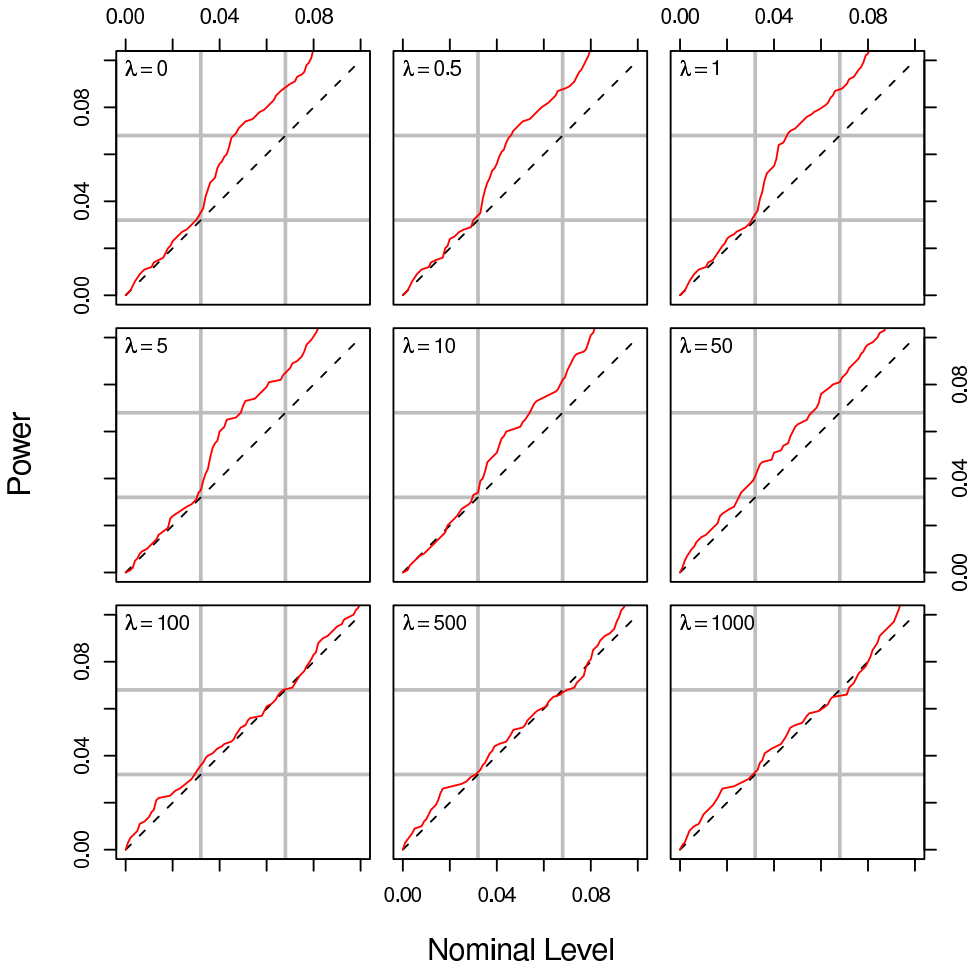

Figure 2: TESTING FOR A NON-EXISTENT SECOND TERM. We estimate a factor generated according to $(N\lambda)^{1/2}u\gamma^{\mathsf{T}}$ and then test for a second term. Depending on the factor strength (which is related to our ability to estimate), the p-values for validating the second term may be slightly liberal. This seems to be the case for $\lambda \leq 50$. For $\lambda \geq 100$, the p-values appear to be faithful.

2) Fit a single latent variable $\hat{u}$, using the first term in the SVD of Y.
3) Construct the matrix of residuals as $\widehat{E} = Y - \hat{u}\hat{u}^{\mathsf{T}}Y$.
4) Test for the existence of more latent terms using a PCA-based rotation test using T_{EPP} as our test statistic and treating $\hat{u}$ as a known covariate. Record the p-value estimated from 999 random rotations.

We would like to assess the implications of treating $\hat{u}$ as a known covariate. When λ is big, this is a reasonable assumption since the term is easy to estimate, but when λ is small this is not the case.

We summarize the results in Figure 2. We can see that for $\lambda \leq 50$, the small p-values are slightly liberal. When $\lambda \geq 100$, the p-values appear to be faithful. When the first latent variable is strong, then we have a reliable test for the second.

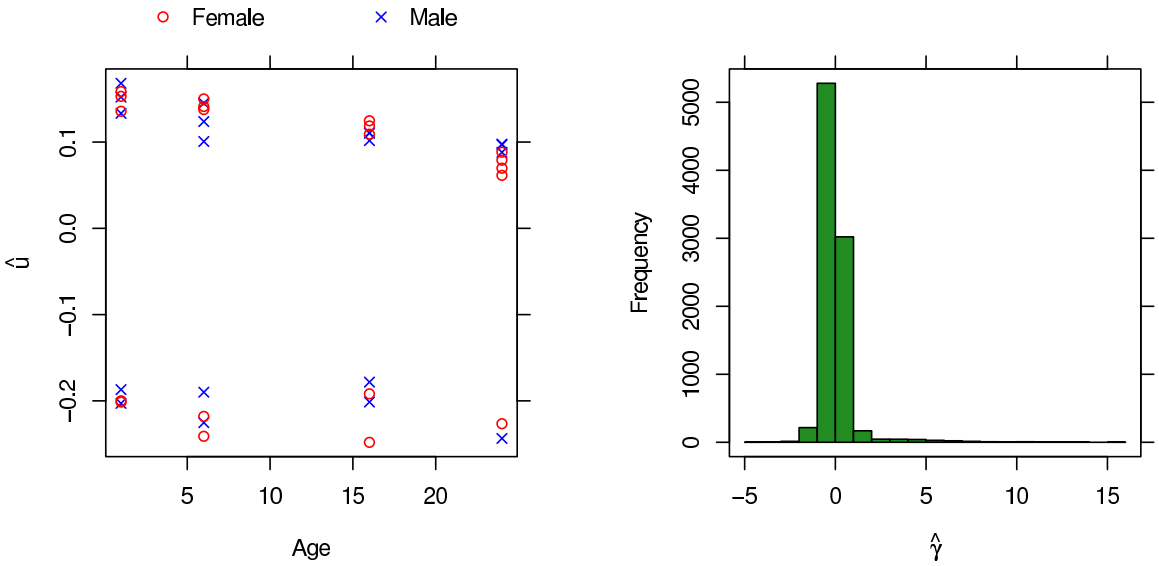

Figure 3: CEREBELLUM LATENT VARIABLE. The left plot shows the latent variable estimated for the cerebellum in each of 39 mice plotted versus the ages of those mice. We can see an apparent dichotomy that is unrelated to gender. The right plot shows a histogram of the regression coefficients for the latent variable. The long tail of the histogram indicates that a large number of genes (about 100) are related to the dichotomy.

5. Latent Variables for the AGEMAP Mice

Now that we have seen how rotation tests work in simulations, we apply them to the data described in the beginning of the paper. Recall that in the AGEMAP data set there are 16 tissue types and 32–40 mice per tissue with known age and sex. Here we will see patterns that certainly appear unlikely to be artifacts. Then we verify them by the rotation test.

We fit 16 regression models of gene activation on age and sex with one latent variable, one for each tissue. The result is that for each tissue type from $k = 1, \ldots, 16$, we have an estimated latent variables vector $U^{(k)} \in \mathbb{R}^{n_k}$.

The latent variables for tissue 2 (the cerebellum) have a striking pattern. There is one value $\widehat{U}_i^{(2)}$ for each of $n_2 = 39$ mice for which a cerebellum array was available. Figure 3 shows that latent variable plotted versus age and with plot symbols encoding the sex of the mouse. It is clear that the mice are split into two different groups, one with a high value of the latent variable and one low.

Often when one sees two distinct groups in microarray data, they correspond to male versus female samples, and certain genes that are sex related, such as on those on the Y chromosome in males or Xist genes that silence a second X chromosome for females. That cannot be the case here because the estimated latent variable is orthogonal to both the sex and age variables by construction, meaning the sum of its coefficients over male samples must equal the negative of the sum over females.

There are high and low values for the latent variable for the cerebellum. The second panel of Figure 4 shows the histogram of these latent values. It is clearly bimodal. The other 15 panels in Figure 4 show the corresponding histograms for the other 15 tissues.

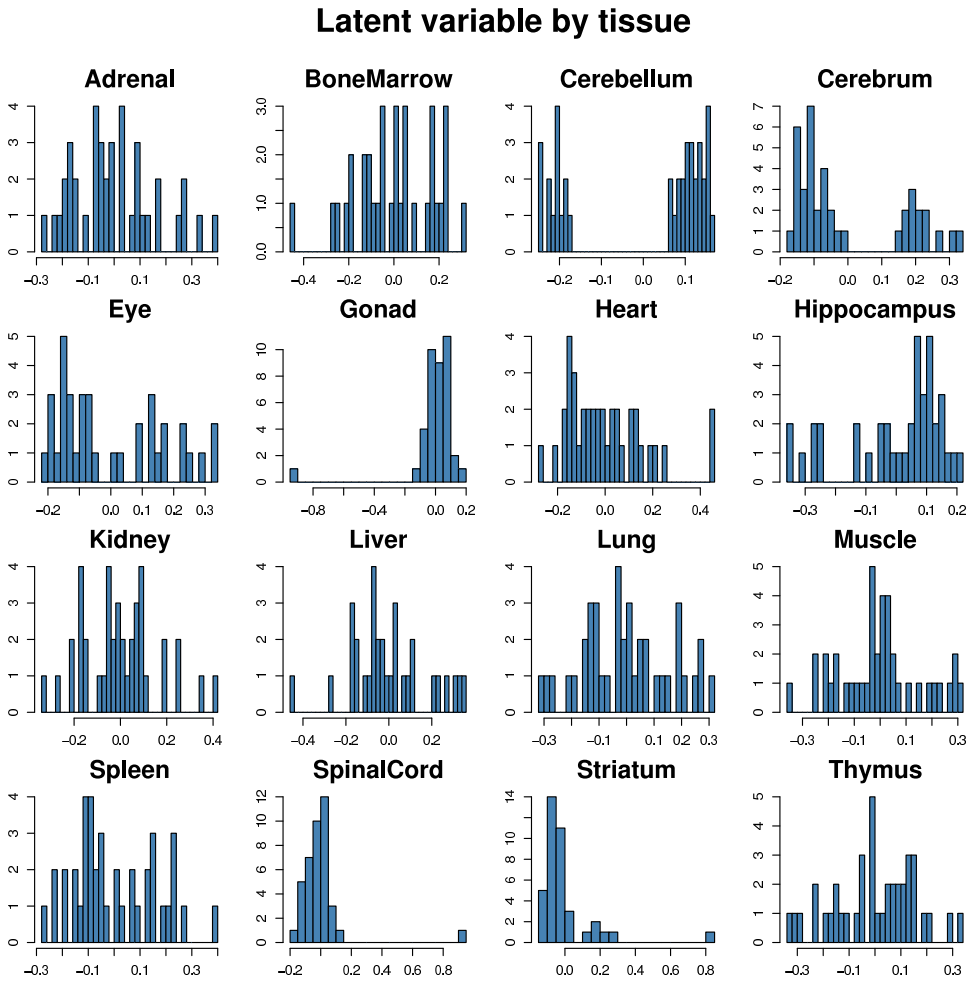

Figure 4: LATENT VARIABLES BY TISSUE. This figure shows histograms of the latent variables found in microarray data from 16 mouse tissues. In each histogram the latent variable values from up to 40 mice are given.

Some of the other histograms have interesting and interpretable structure too. The histograms for spinal tissue, gonad and striatum all show outliers. The biggest latent effect in these tissues is that the expression of one mouse was quite different from the other mice and that difference is reflected in a large number of genes. It is not simply one unusual animal. Three different mice were the outliers in the three different tissues.

The histogram for the cerebrum shows an apparent dichotomy, similar to but less pronounced than the one for the cerebellum. For both of these tissues, the latent variable is splitting the mice into two groups. Both dichotomies are somewhat imbalanced with one group roughly twice as large as the other. Such an effect would be explainable if the same latent factor were affecting both of these brain tissues. Figure 5 plots the estimated latent variable from the cerebrum versus that for the cerebellum. There is one point for each of the 39 mice in which both tissues were measured.

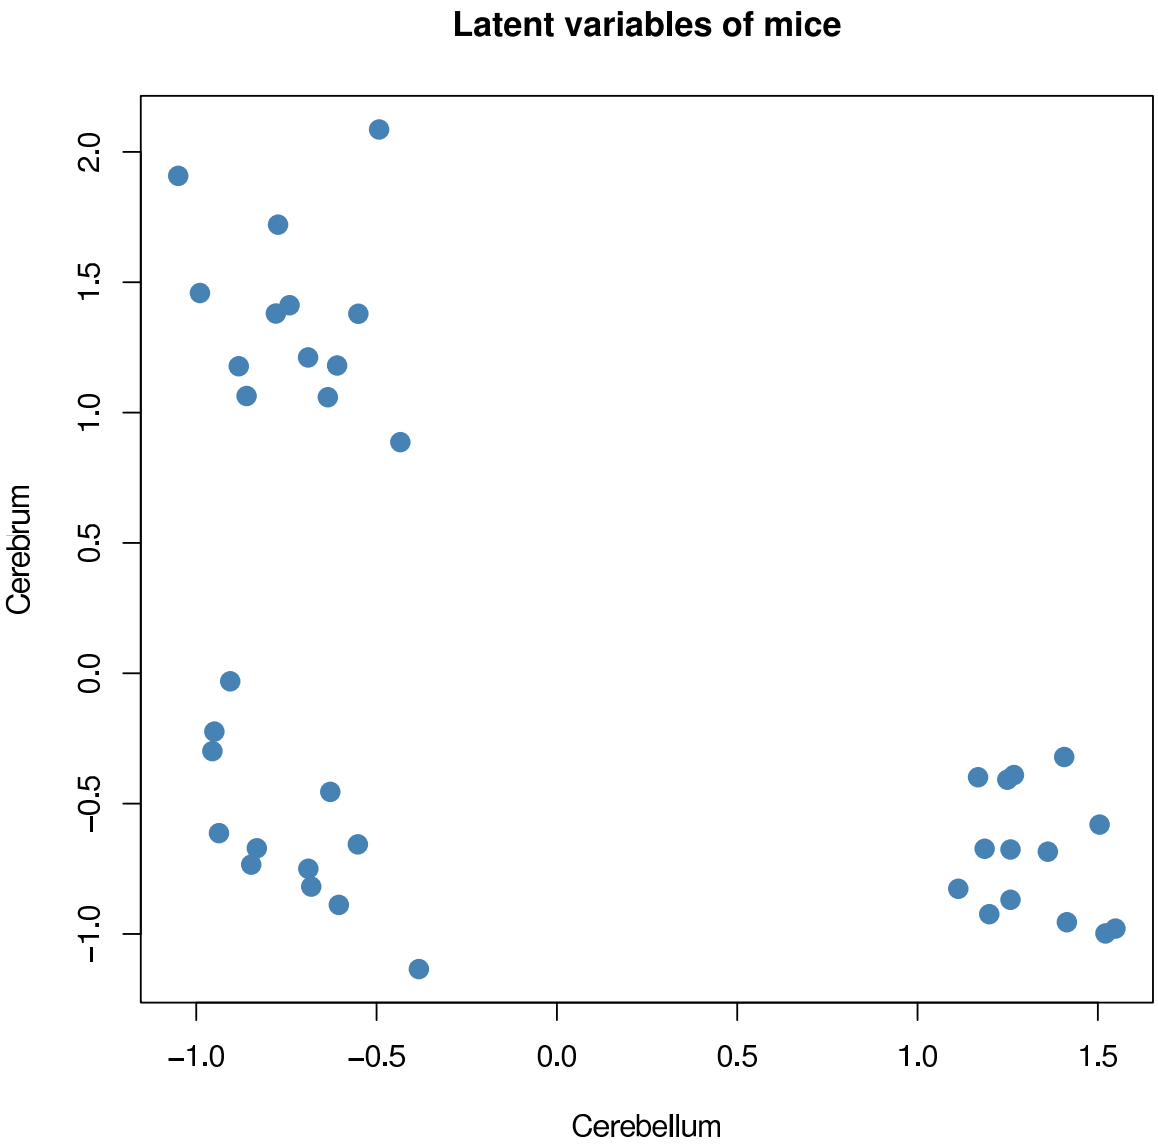

Figure 5: LATENT VARIABLES OF MICE. This figure plots the latent variable from the cerebrum versus that from the cerebellum for the 39 mice for which both arrays were available. There appear to be three kinds of mice in this population.

Figure 5 shows that the apparent dichotomy in the cerebrum is not the same as the one in the cerebellum. The pattern is not a simple double dichotomy either. Rather there appears to be a trichotomy. It is visually striking that there are no mice in the upper right hand corner of Figure 5. The counts of the four corners of Figure 5 are set out in Table 1.

About one third of the mice have the rare cerebellum type, one third have the rare cerebrum type and the remaining mice the common form for both tissues. Were the types independent we would expect about one ninth of the mice to be rare for both. A p value based on Fisher's exact test is

Count	Common cerebellum	Rare cerebellum
Rare cerebrum	13	0
Common cerebrum	12	14

Table 1: Counts of mice in the corners of Figure 5.

0.00094. While we can't be sure that the next mouse won't be the rare type for both brain parts, the failure to observe one here is statistically significant.

Although we don't have laboratory notes to identify the meaning of these groupings, the fact that the joint behavior of two dichotomies from different tissues forms such an interesting pattern lends additional support to the rotation results.

We applied rotation tests for all 16 tissues in the AGEMAP data set using two different measures of non-normality.

We demonstrate the calculation of p-values for the spleen and cerebellum data in Figure 6. The rotation distributions for the other 15 tissues have approximately the same shape, so we do not display them here. Instead, we summarize the results in Table 2. The estimated latent variables for the cerebellum, cerebrum, and eye tissues exhibited dichotomies. This shows up in significantly high values of T_{L^1} and T_{EPP}. The gonad, spinal cord, and striatum latent variables have clear outliers, which manifest as a significantly low values of T_{L^1}, and a significantly high values of T_{EPP}. The spleen latent variable potentially has an outlier at age 5 months, and is found to be marginally significant according to T_{EPP}, and not significant according to T_{L^1}. The discrepancy is because of the two- versus one-tailed p-value.

The only case where T_{L^1} and T_{EPP} give drastically different results is with the latent variable estimated from the hippocampus data. Using T_{L^1}, the variable is nowhere near significant ($\hat{p} = 0.586$), but using T_{EPP}, the variable is unquestionably significant ($\hat{p} < 0.001$). T_{EPP} finds the skewed histogram interesting, while T_{L^1} does not. A possible explanation for why the latent variable is insignificant according to T_{L^1} is this: T_{L^1} is simultaneously measuring presence of outliers and presence of clumping. Outliers correspond to low values of T_{L^1}, and clumping corresponds to high values of T_{L^1}. In the hippocampus data, we see both outliers *and* clumping. The two features "cancel out", giving a moderate value of T_{L^1}. T_{EPP}, on the other hand, does not distinguish between the different kinds of non-Gaussianity. The two features act in tandem to give a high value of the test statistic.

6. Conclusions

We find that it is possible to test for latent variables in correlated Gaussian noise by a rotation test using a projection pursuit index applied to the components of the first singular vector, instead of the usual test based on the size of the largest singular value. This test detects the lack of rotational invariance of the matrix of errors. The rotations must be done orthogonally to the regression variables. Testing for one latent variable is theoretically justified and reliable. Testing for additional terms is possible, but can give somewhat liberal p-values if the signal strength is too weak.

For microarray data, a normal distribution is often a very reasonable model. Some researchers apply transformations for the explicit purpose of making the data more normally distributed. For data that is not close to normally distributed a strategy of looking for latent variables by measuring how non-Gaussian they are is not recommended. It might uncover eigenvectors with especially

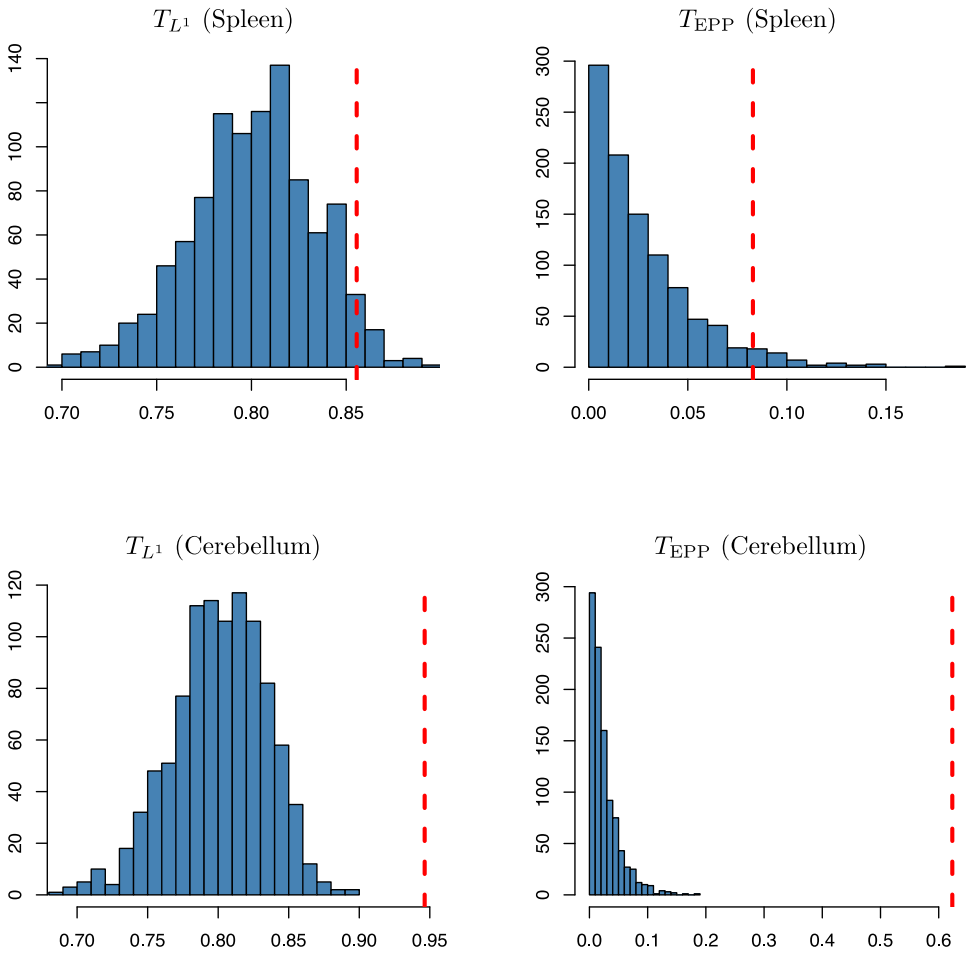

Figure 6: This figure shows histograms of 1000 realizations of the test statistics T_{L^1} and T_{EPP} after applying random rotations to the estimated latent variable. The top row comes from the spleen data, and the bottom row from the cerebellum. The dashed line shows the value of the test statistic at the observed data. In the top-left plot, the area in the right tail is 0.049, giving a two-sided p-value of 0.098. In the top-right plot, the tail area and the one-sided p-value are equal to 0.045. Formal descriptions of the p-values can be found in Equations (6) and (7). The latent variable is found to be barely significant at the 0.05 level according to T_{EPP}, but not according to T_{L^1}. In the bottom plots, the observed data falls at the extreme of the rotation histograms, and is found to be strongly significant in both cases.

non-Gaussian components but their interpretation is more difficult without a Gaussian background to compare them to.

Our original interest was to see if thousands of genes could be used to define a genomic "true age" of a sample of mouse tissue as a latent variable in the residuals from a regression that did not include age. It turned out that the dominant latent variable bore no resemblance to chronological

Table 2: Test statistics and p-values from the rotation tests applied to the AGEMAP data. In all cases, 1000 random rotation were used to construct the a reference histogram, and approximate p-values were estimated. Significant results at the 0.05 level are marked with a single asterisk. In instances where the observed test statistic was at the extreme end of the histogram, we have marked the p-values with two asterisks. In the second column of the table, we indicate how much of the residual is explained by the latent term. We can see that high R^2 does not necessarily indicate significance according to the rotation test. A Bonferroni correction for multiple testing would multiply the p-values by 32 and would find most of the same latent variables significant.

age. We never uncovered a biological explanation for the dichotomies and other latent variables that we saw. But, the rotation tests confirm that these striking anomalies would not arise from correlated Gaussian noise. Several of the tissues did not have apparent latent variables. Accordingly results like those in Table 2 help one focus on where to search for physical causes underlying apparent latent variables.

It may happen that a latent variable is statistically significant when judged by a rotation test but only explains a negligible amount of the response variation. This seems unlikely to happen in practice and did not happen for the AGEMAP data, according to the R^2 column in Table 2. But, when it does happen one can always declare the variable statistically but not practically significant.

It is natural to ask if rotation tests extend to nonlinear models. Our method is strongly geared to linear models because of the way we construct our rotations, so we see no straightforward extension.

Abstract

Much recent research has been devoted to learning algorithms for deep architectures such as Deep Belief Networks and stacks of auto-encoder variants, with impressive results obtained in several areas, mostly on vision and language data sets. The best results obtained on supervised learning tasks involve an unsupervised learning component, usually in an unsupervised pre-training phase. Even though these new algorithms have enabled training deep models, many questions remain as to the nature of this difficult learning problem. The main question investigated here is the following: how does unsupervised pre-training work? Answering this questions is important if learning in deep architectures is to be further improved. We propose several explanatory hypotheses and test them through extensive simulations. We empirically show the influence of pre-training with respect to architecture depth, model capacity, and number of training examples. The experiments confirm and clarify the advantage of unsupervised pre-training. The results suggest that unsupervised pre-training guides the learning towards basins of attraction of minima that support better generalization from the training data set; the evidence from these results supports a regularization explanation for the effect of pre-training.

Keywords: deep architectures, unsupervised pre-training, deep belief networks, stacked denoising auto-encoders, non-convex optimization

1. Introduction

Deep learning methods aim at learning feature hierarchies with features from higher levels of the hierarchy formed by the composition of lower level features. They include learning methods for a wide array of *deep architectures* (Bengio, 2009 provides a survey), including neural networks with many hidden layers (Bengio et al., 2007; Ranzato et al., 2007; Vincent et al., 2008; Collobert and Weston, 2008) and graphical models with many levels of hidden variables (Hinton et al., 2006),

∗. Part of this work was done while Dumitru Erhan was at Google Research.

among others (Zhu et al., 2009; Weston et al., 2008). Theoretical results (Yao, 1985; Håstad, 1986; Håstad and Goldmann, 1991; Bengio et al., 2006), reviewed and discussed by Bengio and LeCun (2007), suggest that in order to learn the kind of complicated functions that can represent high-level abstractions (e.g., in vision, language, and other AI-level tasks), one may need *deep architectures*. The recent surge in experimental work in the field seems to support this notion, accumulating evidence that in challenging AI-related tasks—such as computer vision (Bengio et al., 2007; Ranzato et al., 2007; Larochelle et al., 2007; Ranzato et al., 2008; Lee et al., 2009; Mobahi et al., 2009; Osindero and Hinton, 2008), natural language processing (NLP) (Collobert and Weston, 2008; Weston et al., 2008), robotics (Hadsell et al., 2008), or information retrieval (Salakhutdinov and Hinton, 2007; Salakhutdinov et al., 2007)—deep learning methods significantly out-perform comparable but shallow competitors, and often match or beat the state-of-the-art.

These recent demonstrations of the potential of deep learning algorithms were achieved despite the serious challenge of training models with many layers of adaptive parameters. In virtually all instances of deep learning, the objective function is a highly non-convex function of the parameters, with the potential for many distinct *local minima* in the model parameter space. The principal difficulty is that not all of these minima provide equivalent generalization errors and, we suggest, that for deep architectures, the standard training schemes (based on random initialization) tend to place the parameters in regions of the parameters space that generalize poorly—as was frequently observed empirically but rarely reported (Bengio and LeCun, 2007).

The breakthrough to effective training strategies for deep architectures came in 2006 with the algorithms for training deep belief networks (DBN) (Hinton et al., 2006) and stacked auto-encoders (Ranzato et al., 2007; Bengio et al., 2007), which are all based on a similar approach: greedy layer-wise unsupervised pre-training followed by supervised fine-tuning. Each layer is pre-trained with an unsupervised learning algorithm, learning a nonlinear transformation of its input (the output of the previous layer) that captures the main variations in its input. This unsupervised pre-training sets the stage for a final training phase where the deep architecture is fine-tuned with respect to a supervised training criterion with gradient-based optimization. While the improvement in performance of trained deep models offered by the pre-training strategy is impressive, little is understood about the mechanisms underlying this success.

The objective of this paper is to explore, through extensive experimentation, how unsupervised pre-training works to render learning deep architectures more effective and why they appear to work so much better than traditional neural network training methods. There are a few reasonable hypotheses why unsupervised pre-training might work. One possibility is that unsupervised pre-training acts as a kind of network pre-conditioner, putting the parameter values in the appropriate range for further supervised training. Another possibility, suggested by Bengio et al. (2007), is that unsupervised pre-training initializes the model to a point in parameter space that somehow renders the optimization process more effective, in the sense of achieving a lower minimum of the empirical cost function.

Here, we argue that our experiments support a view of unsupervised pre-training as an unusual form of *regularization*: minimizing variance and introducing bias towards configurations of the parameter space that are useful for unsupervised learning. This perspective places unsupervised pre-training well within the family of recently developed semi-supervised methods. The unsupervised pre-training approach is, however, unique among semi-supervised training strategies in that it acts by defining a particular initialization point for standard supervised training rather than either modifying the supervised objective function (Barron, 1991) or explicitly imposing constraints on the parame-

ters throughout training (Lasserre et al., 2006). This type of initialization-as-regularization strategy has precedence in the neural networks literature, in the shape of the early stopping idea (Sjöberg and Ljung, 1995; Amari et al., 1997), and in the Hidden Markov Models (HMM) community (Bahl et al., 1986; Povey and Woodland, 2002) where it was found that first training an HMM as a generative model was essential (as an initialization step) before fine-tuning it discriminatively. We suggest that, in the highly non-convex situation of training a deep architecture, defining a particular initialization point *implicitly* imposes constraints on the parameters in that it specifies which minima (out of a very large number of possible minima) of the cost function are allowed. In this way, it may be possible to think of unsupervised pre-training as being related to the approach of Lasserre et al. (2006).

Another important and distinct property of the unsupervised pre-training strategy is that in the standard situation of training using stochastic gradient descent, the beneficial generalization effects due to pre-training do not appear to diminish as the number of labeled examples grows very large. We argue that this is a consequence of the combination of the non-convexity (multi-modality) of the objective function and the dependency of the stochastic gradient descent method on example ordering. We find that early changes in the parameters have a greater impact on the final region (basin of attraction of the descent procedure) in which the learner ends up. In particular, unsupervised pre-training sets the parameter in a region from which better basins of attraction can be reached, in terms of generalization. Hence, although unsupervised pre-training is a regularizer, it can have a positive effect on the training objective when the number of training examples is large.

As previously stated, this paper is concerned with an experimental assessment of the various competing hypotheses regarding the role of unsupervised pre-training in the recent success of deep learning methods. To this end, we present a series of experiments design to pit these hypotheses against one another in an attempt to resolve some of the mystery surrounding the effectiveness of unsupervised pre-training.

In the first set of experiments (in Section 6), we establish the effect of unsupervised pre-training on improving the generalization error of trained deep architectures. In this section we also exploit dimensionality reduction techniques to illustrate how unsupervised pre-training affects the location of minima in parameter space.

In the second set of experiments (in Section 7), we directly compare the two alternative hypotheses (pre-training as a pre-conditioner; and pre-training as an optimization scheme) against the hypothesis that unsupervised pre-training is a regularization strategy. In the final set of experiments, (in Section 8), we explore the role of unsupervised pre-training in the online learning setting, where the number of available training examples grows very large. In these experiments, we test key aspects of our hypothesis relating to the topology of the cost function and the role of unsupervised pre-training in manipulating the region of parameter space from which supervised training is initiated.

Before delving into the experiments, we begin with a more in-depth view of the challenges in training deep architectures and how we believe unsupervised pre-training works towards overcoming these challenges.

2. The Challenges of Deep Learning

In this section, we present a perspective on why standard training of deep models through gradient backpropagation appears to be so difficult. First, it is important to establish what we mean in stating that training is difficult.

We believe the central challenge in training deep architectures is dealing with the strong dependencies that exist during training between the parameters across layers. One way to conceive the difficulty of the problem is that we must simultaneously:

1. adapt the lower layers in order to provide adequate input to the final (end of training) setting of the upper layers

2. adapt the upper layers to make good use of the final (end of training) setting of the lower layers.

The second problem is easy on its own (i.e., when the final setting of the other layers is known). It is not clear how difficult is the first one, and we conjecture that a particular difficulty arises when both sets of layers must be learned jointly, as the gradient of the objective function is limited to a local measure given the current setting of other parameters. Furthermore, because with enough capacity the top two layers can easily overfit the training set, training error does not necessarily reveal the difficulty in optimizing the lower layers. As shown in our experiments here, the standard training schemes tend to place the parameters in regions of the parameters space that generalize poorly.

A separate but related issue appears if we focus our consideration of traditional training methods for deep architectures on stochastic gradient descent. A sequence of examples along with an online gradient descent procedure defines a trajectory in parameter space, which converges in some sense (the error does not improve anymore, maybe because we are near a local minimum). The hypothesis is that small perturbations of that trajectory (either by initialization or by changes in which examples are seen when) have more effect early on. Early in the process of following the stochastic gradient, changes in the weights tend to increase their magnitude and, consequently, the amount of non-linearity of the network increases. As this happens, the set of regions accessible by stochastic gradient descent on samples of the training distribution becomes smaller. Early on in training small perturbations allow the model parameters to switch from one basin to a nearby one, whereas later on (typically with larger parameter values), it is unlikely to "escape" from such a basin of attraction. Hence the early examples can have a larger influence and, in practice, trap the model parameters in particular regions of parameter space that correspond to the specific and arbitrary ordering of the training examples.[1] An important consequence of this phenomenon is that even in the presence of a very large (effectively infinite) amounts of supervised data, stochastic gradient descent is subject to a degree of *overfitting* to the training data presented early in the training process. In that sense, unsupervised pre-training interacts intimately with the optimization process, and when the number of training examples becomes large, its positive effect is seen not only on generalization error but also on training error.

1. This process seems similar to the "critical period" phenomena observed in neuroscience and psychology (Bornstein, 1987).

3. Unsupervised Pre-training Acts as a Regularizer

As stated in the introduction, we believe that greedy layer-wise unsupervised pre-training overcomes the challenges of deep learning by introducing a useful prior to the *supervised fine-tuning* training procedure. We claim that the regularization effect is a consequence of the pre-training procedure establishing an initialization point of the fine-tuning procedure inside a region of parameter space in which the parameters are henceforth restricted. The parameters are restricted to a relatively small volume of parameter space that is delineated by the boundary of the *local basin of attraction* of the supervised fine-tuning cost function.

The pre-training procedure increases the magnitude of the weights and in standard deep models, with a sigmoidal nonlinearity, this has the effect of rendering both the function more nonlinear and the cost function locally more complicated with more topological features such as peaks, troughs and plateaus. The existence of these topological features renders the parameter space locally more difficult to travel significant distances via a gradient descent procedure. This is the core of the restrictive property imposed by the pre-training procedure and hence the basis of its regularizing properties.

But unsupervised pre-training restricts the parameters to particular regions: those that correspond to capturing structure in the input distribution $P(X)$. To simply state that unsupervised pre-training is a regularization strategy somewhat undermines the significance of its effectiveness. Not all regularizers are created equal and, in comparison to standard regularization schemes such as L_1 and L_2 parameter penalization, unsupervised pre-training is dramatically effective. We believe the credit for its success can be attributed to the unsupervised training criteria optimized during unsupervised pre-training.

During each phase of the greedy unsupervised training strategy, layers are trained to represent the dominant factors of variation extant in the data. This has the effect of leveraging knowledge of X to form, at each layer, a representation of X consisting of statistically reliable features of X that can then be used to predict the output (usually a class label) Y. This perspective places unsupervised pre-training well within the family of learning strategies collectively know as semi-supervised methods. As with other recent work demonstrating the effectiveness of semi-supervised methods in regularizing model parameters, we claim that the effectiveness of the unsupervised pre-training strategy is limited to the extent that learning $P(X)$ is helpful in learning $P(Y|X)$. Here, we find transformations of X—learned features—that are predictive of the main factors of variation in $P(X)$, and when the pre-training strategy is effective,[2] some of these learned features of X are also predictive of Y. In the context of deep learning, the greedy unsupervised strategy may also have a special function. To some degree it resolves the problem of simultaneously learning the parameters at all layers (mentioned in Section 2) by introducing a proxy criterion. This proxy criterion encourages significant factors of variation, present in the input data, to be represented in intermediate layers.

To clarify this line of reasoning, we can formalize the effect of unsupervised pre-training in inducing a prior distribution over the parameters. Let us assume that parameters are forced to be chosen in a bounded region $\mathcal{S} \subset \mathbb{R}^d$. Let $\mathcal{S}$ be split in regions $\{R_k\}$ that are the basins of attraction of descent procedures in the training error (note that $\{R_k\}$ depends on the training set, but the dependency decreases as the number of examples increases). We have $\cup_k R_k = \mathcal{S}$ and $R_i \cap R_j = \emptyset$ for $i \neq j$. Let $v_k = \int 1_{\theta \in R_k} d\theta$ be the volume associated with region R_k (where θ are our model's

2. Acting as a form of (data-dependent) "prior" on the parameters, as we are about to formalize.

parameters). Let r_k be the probability that a purely random initialization (according to our initialization procedure, which factorizes across parameters) lands in R_k, and let π_k be the probability that pre-training (following a random initialization) lands in R_k, that is, $\sum_k r_k = \sum_k \pi_k = 1$. We can now take into account the initialization procedure as a regularization term:

$$\text{regularizer} = -\log P(\theta).$$

For pre-trained models, the prior is

$$P_{\text{pre-training}}(\theta) = \sum_k 1_{\theta \in R_k} \pi_k / v_k.$$

For the models without unsupervised pre-training, the prior is

$$P_{\text{no-pre-training}}(\theta) = \sum_k 1_{\theta \in R_k} r_k / v_k.$$

One can verify that $P_{\text{pre-training}}(\theta \in R_k) = \pi_k$ and $P_{\text{no-pre-training}}(\theta \in R_k) = r_k$. When π_k is tiny, the penalty is high when $\theta \in R_k$, with unsupervised pre-training. The derivative of this regularizer is zero almost everywhere because we have chosen a uniform prior inside each region R_k. Hence, to take the regularizer into account, and having a generative model $P_{\text{pre-training}}(\theta)$ for θ (i.e., this is the unsupervised pre-training procedure), it is reasonable to sample an initial θ from it (knowing that from this point on the penalty will not increase during the iterative minimization of the training criterion), and this is exactly how the pre-trained models are obtained in our experiments.

Note that this formalization is just an illustration: it is there to simply show how one could conceptually think of an initialization point as a regularizer and should not be taken as a literal interpretation of how regularization is explicitly achieved, since we do not have an analytic formula for computing the π_k's and v_k's. Instead these are implicitly defined by the whole unsupervised pre-training procedure.

4. Previous Relevant Work

We start with an overview of the literature on semi-supervised learning (SSL), since the SSL framework is essentially the one in which we operate as well.

4.1 Related Semi-Supervised Methods

It has been recognized for some time that generative models are less prone to overfitting than discriminant ones (Ng and Jordan, 2002). Consider input variable X and target variable Y. Whereas a discriminant model focuses on $P(Y|X)$, a generative model focuses on $P(X,Y)$ (often parametrized as $P(X|Y)P(Y)$), that is, it also cares about getting $P(X)$ right, which can reduce the freedom of fitting the data when the ultimate goal is only to predict Y given X.

Exploiting information about $P(X)$ to improve generalization of a classifier has been the driving idea behind semi-supervised learning (Chapelle et al., 2006). For example, one can use unsupervised learning to map X into a representation (also called embedding) such that two examples $\mathbf{x}_1$ and $\mathbf{x}_2$ that belong to the same cluster (or are reachable through a short path going through neighboring examples in the training set) end up having nearby embeddings. One can then use supervised learning (e.g., a linear classifier) in that new space and achieve better generalization in many cases (Belkin

and Niyogi, 2002; Chapelle et al., 2003). A long-standing variant of this approach is the application of Principal Components Analysis as a pre-processing step before applying a classifier (on the projected data). In these models the data is first transformed in a new representation using unsupervised learning, and a supervised classifier is stacked on top, learning to map the data in this new representation into class predictions.

Instead of having separate unsupervised and supervised components in the model, one can consider models in which $P(X)$ (or $P(X,Y)$) and $P(Y|X)$ share parameters (or whose parameters are connected in some way), and one can trade-off the supervised criterion $-\log P(Y|X)$ with the unsupervised or generative one ($-\log P(X)$ or $-\log P(X,Y)$). It can then be seen that the generative criterion corresponds to a particular form of prior (Lasserre et al., 2006), namely that the structure of $P(X)$ is connected to the structure of $P(Y|X)$ in a way that is captured by the shared parametrization. By controlling how much of the generative criterion is included in the total criterion, one can find a better trade-off than with a purely generative or a purely discriminative training criterion (Lasserre et al., 2006; Larochelle and Bengio, 2008).

In the context of deep architectures, a very interesting application of these ideas involves adding an unsupervised embedding criterion at each layer (or only one intermediate layer) to a traditional supervised criterion (Weston et al., 2008). This has been shown to be a powerful semi-supervised learning strategy, and is an alternative to the kind of algorithms described and evaluated in this paper, which also combine unsupervised learning with supervised learning.

In the context of scarcity of labelled data (and abundance of unlabelled data), deep architectures have shown promise as well. Salakhutdinov and Hinton (2008) describe a method for learning the covariance matrix of a Gaussian Process, in which the usage of unlabelled examples for modeling $P(X)$ improves $P(Y|X)$ quite significantly. Note that such a result is to be expected: with few labelled samples, modeling $P(X)$ usually helps. Our results show that even in the context of *abundant labelled data*, unsupervised pre-training still has a pronounced positive effect on generalization: a somewhat surprising conclusion.

4.2 Early Stopping as a Form of Regularization

We stated that pre-training as initialization can be seen as restricting the optimization procedure to a relatively small volume of parameter space that corresponds to a local basin of attraction of the supervised cost function. Early stopping can be seen as having a similar effect, by constraining the optimization procedure to a region of the parameter space that is close to the initial configuration of parameters. With τ the number of training iterations and η the learning rate used in the update procedure, $\tau\eta$ can be seen as the reciprocal of a regularization parameter. Indeed, restricting either quantity restricts the area of parameter space reachable from the starting point. In the case of the optimization of a simple linear model (initialized at the origin) using a quadratic error function and simple gradient descent, early stopping will have a similar effect to traditional regularization.

Thus, in both pre-training and early stopping, the parameters of the supervised cost function are constrained to be close to their initial values.[3] A more formal treatment of early stopping as regularization is given by Sjöberg and Ljung (1995) and Amari et al. (1997). There is no equivalent treatment of pre-training, but this paper sheds some light on the effects of such initialization in the case of deep architectures.

3. In the case of pre-training the "initial values" of the parameters for the supervised phase are those that were obtained at the end of pre-training.

5. Experimental Setup and Methodology

In this section, we describe the setting in which we test the hypothesis introduced in Section 3 and previously proposed hypotheses. The section includes a description of the deep architectures used, the data sets and the details necessary to reproduce our results.

5.1 Models

All of the successful methods (Hinton et al., 2006; Hinton and Salakhutdinov, 2006; Bengio et al., 2007; Ranzato et al., 2007; Vincent et al., 2008; Weston et al., 2008; Ranzato et al., 2008; Lee et al., 2008) in the literature for training deep architectures have something in common: they rely on an unsupervised learning algorithm that provides a training signal at the level of a single layer. Most work in two main phases. In a first phase, *unsupervised pre-training*, all layers are initialized using this layer-wise unsupervised learning signal. In a second phase, *fine-tuning*, a global training criterion (a prediction error, using labels in the case of a supervised task) is minimized. In the algorithms initially proposed (Hinton et al., 2006; Bengio et al., 2007; Ranzato et al., 2007), the unsupervised pre-training is done in a greedy layer-wise fashion: at stage k, the k-th layer is trained (with respect to an unsupervised criterion) using as input the output of the previous layer, and while the previous layers are kept fixed.

We shall consider two deep architectures as representatives of two families of models encountered in the deep learning literature.

5.1.1 DEEP BELIEF NETWORKS

The first model is the Deep Belief Net (DBN) by Hinton et al. (2006), obtained by training and stacking several layers of Restricted Boltzmann Machines (RBM) in a greedy manner. Once this stack of RBMs is trained, it can be used to initialize a multi-layer neural network for classification.

An RBM with n hidden units is a Markov Random Field (MRF) for the joint distribution between hidden variables h_i and observed variables x_j such that $P(\mathbf{h}|\mathbf{x})$ and $P(\mathbf{x}|\mathbf{h})$ factorize, that is, $P(\mathbf{h}|\mathbf{x}) = \prod_i P(h_i|\mathbf{x})$ and $P(\mathbf{x}|\mathbf{h}) = \prod_j P(x_j|\mathbf{h})$. The sufficient statistics of the MRF are typically h_i, x_j and $h_i x_j$, which gives rise to the following joint distribution:

$$P(\mathbf{x},\mathbf{h}) \propto e^{\mathbf{h}'W\mathbf{x}+b'\mathbf{x}+c'\mathbf{h}}$$

with corresponding parameters $\theta = (W,b,c)$ (with $'$ denoting transpose, c_i associated with h_i, b_j with x_j, and W_{ij} with $h_i x_j$). If we restrict h_i and x_j to be binary units, it is straightforward to show that

$$\begin{aligned} P(\mathbf{x}|\mathbf{h}) &= \prod_j P(x_j|\mathbf{h}) \quad \text{with} \\ P(x_j = 1|\mathbf{h}) &= \text{sigmoid}(b_j + \sum_i W_{ij} h_i). \end{aligned}$$

where $\text{sigmoid}(\mathbf{a}) = 1/(1+\exp(-\mathbf{a}))$ (applied element-wise on a vector $\mathbf{a}$), and $P(\mathbf{h}|\mathbf{x})$ also has a similar form:

$$\begin{aligned} P(\mathbf{h}|\mathbf{x}) &= \prod_i P(h_i|\mathbf{x}) \quad \text{with} \\ P(h_i = 1|\mathbf{x}) &= \text{sigmoid}(c_i + \sum_j W_{ij} x_j). \end{aligned}$$

The RBM form can be generalized to other conditional distributions besides the binomial, including continuous variables. Welling et al. (2005) describe a generalization of RBM models to conditional distributions from the exponential family.

RBM models can be trained by approximate stochastic gradient descent. Although $P(\mathbf{x})$ is not tractable in an RBM, the Contrastive Divergence estimator (Hinton, 2002) is a good stochastic approximation of $\frac{\partial \log P(\mathbf{x})}{\partial \theta}$, in that it very often has the same sign (Bengio and Delalleau, 2009).

A DBN is a multi-layer generative model with layer variables h_0 (the input or visible layer), h_1, h_2, etc. The top two layers have a joint distribution which is an RBM, and $P(h_k|h_{k+1})$ are parametrized in the same way as for an RBM. Hence a 2-layer DBN is an RBM, and a stack of RBMs share parametrization with a corresponding DBN. The contrastive divergence update direction can be used to initialize each layer of a DBN as an RBM, as follows. Consider the first layer of the DBN trained as an RBM P_1 with hidden layer h_1 and visible layer v_1. We can train a second RBM P_2 that models (in its visible layer) the samples h_1 from $P_1(h_1|v_1)$ when v_1 is sampled from the training data set. It can be shown that this maximizes a lower bound on the log-likelihood of the DBN. The number of layers can be increased greedily, with the newly added top layer trained as an RBM to model the samples produced by chaining the posteriors $P(h_k|h_{k-1})$ of the lower layers (starting from h_0 from the training data set).

The parameters of a DBN or of a stack of RBMs also correspond to the parameters of a deterministic feed-forward multi-layer neural network. The i-th unit of the k-th layer of the neural network outputs $\hat{h}_{ki} = \text{sigmoid}(c_{ki} + \sum_j W_{kij}\hat{h}_{k-1,j})$, using the parameters c_k and W_k of the k-th layer of the DBN. Hence, once the stack of RBMs or the DBN is trained, one can use those parameters to initialize the first layers of a corresponding multi-layer neural network. One or more additional layers can be added to map the top-level features $\hat{h}_k$ to the predictions associated with a target variable (here the probabilities associated with each class in a classification task). Bengio (2009) provides more details on RBMs and DBNs, and a survey of related models and deep architectures.

5.1.2 STACKED DENOISING AUTO-ENCODERS

The second model, by Vincent et al. (2008), is the so-called Stacked Denoising Auto-Encoder (SDAE). It borrows the greedy principle from DBNs, but uses denoising auto-encoders as a building block for unsupervised modeling. An auto-encoder learns an encoder $h(\cdot)$ and a decoder $g(\cdot)$ whose composition approaches the identity for examples in the training set, that is, $g(h(\mathbf{x})) \approx \mathbf{x}$ for $\mathbf{x}$ in the training set.

Assuming that some constraint prevents $g(h(\cdot))$ from being the identity for arbitrary arguments, the auto-encoder has to capture statistical structure in the training set in order to minimize reconstruction error. However, with a high capacity code ($h(\mathbf{x})$ has too many dimensions), a regular auto-encoder could potentially learn a trivial encoding. Note that there is an intimate connection between minimizing reconstruction error for auto-encoders and contrastive divergence training for RBMs, as both can be shown to approximate a log-likelihood gradient (Bengio and Delalleau, 2009).

The *denoising auto-encoder* (Vincent et al., 2008; Seung, 1998; LeCun, 1987; Gallinari et al., 1987) is a stochastic variant of the ordinary auto-encoder with the distinctive property that even with a high capacity model, it cannot learn the identity mapping. A denoising autoencoder is explicitly trained to denoise a corrupted version of its input. Its training criterion can also be viewed as a variational lower bound on the likelihood of a specific generative model. It has been shown on an array of data sets to perform significantly better than ordinary auto-encoders and similarly or better

than RBMs when stacked into a deep supervised architecture (Vincent et al., 2008). Another way to prevent regular auto-encoders with more code units than inputs to learn the identity is to restrict the capacity of the representation by imposing sparsity on the code (Ranzato et al., 2007, 2008).

We now summarize the training algorithm of the Stacked Denoising Auto-Encoders. More details are given by Vincent et al. (2008). Each denoising auto-encoder operates on its inputs $\mathbf{x}$, either the raw inputs or the outputs of the previous layer. The denoising auto-encoder is trained to reconstruct $\mathbf{x}$ from a stochastically corrupted (noisy) transformation of it. The output of each denoising auto-encoder is the "code vector" $h(\mathbf{x})$, not to confuse with the reconstruction obtained by applying the decoder to that code vector. In our experiments $h(\mathbf{x}) = \text{sigmoid}(\mathbf{b} + W\mathbf{x})$ is an ordinary neural network layer, with hidden unit biases $\mathbf{b}$, and weight matrix W. Let $C(\mathbf{x})$ represent a stochastic corruption of $\mathbf{x}$. As done by Vincent et al. (2008), we set $C_i(\mathbf{x}) = x_i$ or 0, with a random subset (of a fixed size) selected for zeroing. We have also considered a salt and pepper noise, where we select a random subset of a fixed size and set $C_i(\mathbf{x}) = \text{Bernoulli}(0.5)$. The denoised "reconstruction" is obtained from the noisy input with $\hat{\mathbf{x}} = \text{sigmoid}(\mathbf{c} + W^T h(C(\mathbf{x})))$, using biases $\mathbf{c}$ and the transpose of the feed-forward weights W. In the experiments on images, both the raw input x_i and its reconstruction $\hat{x}_i$ for a particular pixel i can be interpreted as a Bernoulli probability for that pixel: the probability of painting the pixel as black at that location. We denote $\text{CE}(\mathbf{x}||\hat{\mathbf{x}}) = \sum_i \text{CE}(x_i||\hat{x}_i)$ the sum of the component-wise cross-entropy between the Bernoulli probability distributions associated with each element of $\mathbf{x}$ and its reconstruction probabilities $\hat{\mathbf{x}}$: $\text{CE}(\mathbf{x}||\hat{\mathbf{x}}) = -\sum_i (x_i \log \hat{x}_i + (1 - x_i) \log (1 - \hat{x}_i))$. The Bernoulli model only makes sense when the input components and their reconstruction are in $[0, 1]$; another option is to use a Gaussian model, which corresponds to a Mean Squared Error (MSE) criterion.

With either DBN or SDAE, an output logistic regression layer is added after unsupervised training. This layer uses softmax (multinomial logistic regression) units to estimate $P(\text{class}|\mathbf{x}) = \text{softmax}_{\text{class}}(\mathbf{a})$, where a_i is a linear combination of outputs from the top hidden layer. The whole network is then trained as usual for multi-layer perceptrons, to minimize the output (negative log-likelihood) prediction error.

5.2 Data Sets

We experimented on three data sets, with the motivation that our experiments would help understand previously presented results with deep architectures, which were mostly with the MNIST data set and variations (Hinton et al., 2006; Bengio et al., 2007; Ranzato et al., 2007; Larochelle et al., 2007; Vincent et al., 2008):

MNIST the digit classification data set by LeCun et al. (1998), containing 60,000 training and 10,000 testing examples of 28x28 handwritten digits in gray-scale.

InfiniteMNIST a data set by Loosli et al. (2007), which is an extension of `MNIST` from which one can obtain a quasi-infinite number of examples. The samples are obtained by performing random elastic deformations of the original `MNIST` digits. In this data set, there is only one set of examples, and the models will be compared by their (online) performance on it.

Shapeset is a synthetic data set with a controlled range of geometric invariances. The underlying task is binary classification of 10×10 images of triangles and squares. The examples show

images of shapes with many variations, such as size, orientation and gray-level. The data set is composed of 50000 training, 10000 validation and 10000 test images.[4]

5.3 Setup

The models used are

1. Deep Belief Networks containing Bernoulli RBM layers,
2. Stacked Denoising Auto-Encoders with Bernoulli input units, and
3. standard feed-forward multi-layer neural networks,

each with 1–5 hidden layers. Each hidden layer contains the same number of hidden units, which is a hyperparameter. The other hyperparameters are the unsupervised and supervised learning rates, the L_2 penalty / weight decay,[5] and the fraction of stochastically corrupted inputs (for the SDAE). For `MNIST`, the number of supervised and unsupervised passes through the data (epochs) is 50 and 50 per layer, respectively. With `InfiniteMNIST`, we perform 2.5 million unsupervised updates followed by 7.5 million supervised updates.[6] The standard feed-forward networks are trained using 10 million supervised updates. For `MNIST`, model selection is done by choosing the hyperparameters that optimize the supervised (classification) error on the validation set. For `InfiniteMNIST`, we use the average online error over the last million examples for hyperparameter selection. In all cases, purely stochastic gradient updates are applied.

The experiments involve the training of deep architectures with a variable number of layers with and without unsupervised pre-training. For a given layer, weights are initialized using random samples from uniform$[-1/\sqrt{k}, 1/\sqrt{k}]$, where k is the number of connections that a unit receives from the previous layer (the fan-in). Either supervised gradient descent or unsupervised pre-training follows.

In most cases (for `MNIST`), we first launched a number of experiments using a cross-product of hyperparameter values[7] applied to 10 different random initialization seeds. We then selected the hyperparameter sets giving the best validation error for each combination of model (with or without pre-training), number of layers, and number of training iterations. Using these hyper-parameters, we launched experiments using an additional 400 initialization seeds. For `InfiniteMNIST`, only one seed is considered (an arbitrarily chosen value).

In the discussions below we sometimes use the word **apparent local minimum** to mean the solution obtained after training, when no further noticeable progress seems achievable by stochastic gradient descent. It is possible that these are not really near a true local minimum (there could be a tiny ravine towards significant improvement, not accessible by gradient descent), but it is clear that these end-points represent regions where gradient descent is stuck. Note also that when we write of number of layers it is to be understood as the number of *hidden* layers in the network.

4. The data set can be downloaded from `http://www.iro.umontreal.ca/~lisa/twiki/bin/view.cgi/Public/ShapesetDataForJMLR`.
5. A penalizing term $\lambda||\theta||_2^2$ is added to the supervised objective, where θ are the weights of the network, and λ is a hyper-parameter modulating the strength of the penalty.
6. The number of examples was chosen to be as large as possible, while still allowing for the exploration a variety of hyper-parameters.
7. Number of hidden units $\in \{400, 800, 1200\}$; learning rate $\in \{0.1, 0.05, 0.02, 0.01, 0.005\}$; ℓ_2 penalty coefficient $\lambda \in \{10^{-4}, 10^{-5}, 10^{-6}, 0\}$; pre-training learning rate $\in \{0.01, 0.005, 0.002, 0.001, 0.0005\}$; corruption probability $\in \{0.0, 0.1, 0.25, 0.4\}$; tied weights $\in \{\text{yes}, \text{no}\}$.

6. The Effect of Unsupervised Pre-training

We start by a presentation of large-scale simulations that were intended to confirm some of the previously published results about deep architectures. In the process of analyzing them, we start making connections to our hypotheses and motivate the experiments that follow.

6.1 Better Generalization

When choosing the number of units per layer, the learning rate and the number of training iterations to optimize classification error on the validation set, unsupervised pre-training gives substantially lower test classification error than no pre-training, for the same depth or for smaller depth on various vision data sets (Ranzato et al., 2007; Bengio et al., 2007; Larochelle et al., 2009, 2007; Vincent et al., 2008) no larger than the MNIST digit data set (experiments reported from 10,000 to 50,000 training examples).

Such work was performed with only one or a handful of different random initialization seeds, so one of the goals of this study was to ascertain the effect of the random seed used when initializing ordinary neural networks (deep or shallow) and the pre-training procedure. For this purpose, between 50 and 400 different seeds were used to obtain the graphics on MNIST.

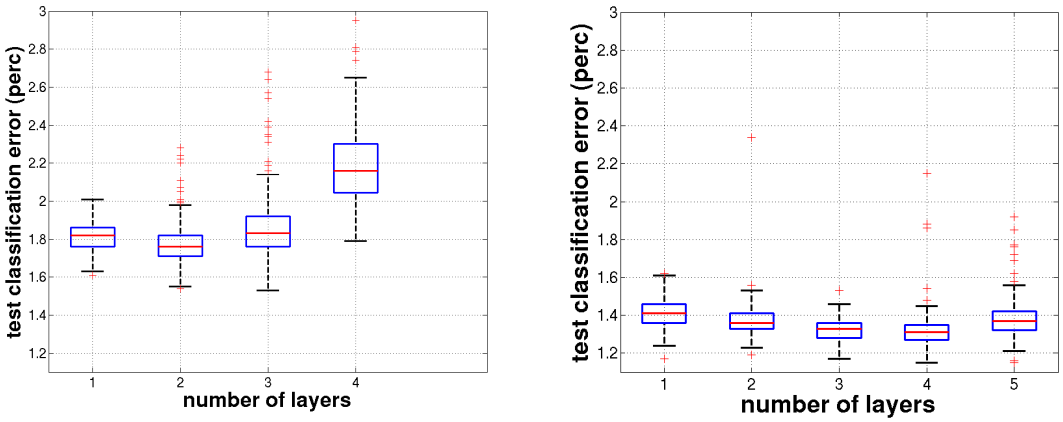

Figure 1: Effect of depth on performance for a model trained (**left**) without unsupervised pre-training and (**right**) with unsupervised pre-training, for 1 to 5 hidden layers (networks with 5 layers failed to converge to a solution, without the use of unsupervised pre-training). Experiments on MNIST. Box plots show the distribution of errors associated with 400 different initialization seeds (top and bottom quartiles in box, plus outliers beyond top and bottom quartiles). Other hyperparameters are optimized away (on the validation set). *Increasing depth seems to increase the probability of finding poor apparent local minima*.

Figure 1 shows the resulting distribution of test classification error, obtained with and without pre-training, as we increase the depth of the network. Figure 2 shows these distributions as histograms in the case of 1 and 4 layers. As can be seen in Figure 1, unsupervised pre-training allows

classification error to go down steadily as we move from 1 to 4 hidden layers, whereas without pre-training the error goes up after 2 hidden layers. It should also be noted that we were unable to effectively train 5-layer models without use of unsupervised pre-training. Not only is the error obtained on average with unsupervised pre-training systematically lower than without the pre-training, it appears also more robust to the random initialization. With unsupervised pre-training the variance stays at about the same level up to 4 hidden layers, with the number of bad outliers growing slowly.

Contrast this with the case without pre-training: the variance and number of bad outliers grows sharply as we increase the number of layers beyond 2. The gain obtained with unsupervised pre-training is more pronounced as we increase the number of layers, as is the gain in robustness to random initialization. This can be seen in Figure 2. The increase in error variance and mean for deeper architectures without pre-training suggests that **increasing depth increases the probability of finding poor apparent local minima** when starting from random initialization. It is also interesting to note the low variance and small spread of errors obtained with 400 seeds with unsupervised pre-training: it suggests that **unsupervised pre-training is robust with respect to the random initialization seed** (the one used to initialize parameters before pre-training).

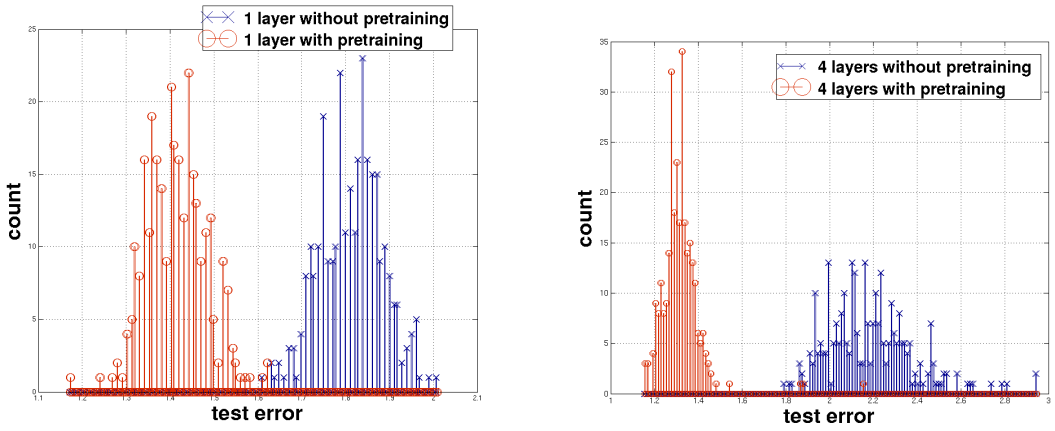

Figure 2: Histograms presenting the test errors obtained on `MNIST` using models trained with or without pre-training (400 different initializations each). **Left**: 1 hidden layer. **Right**: 4 hidden layers.

These experiments show that the variance of final test error with respect to initialization random seed is larger without pre-training, and this effect is magnified for deeper architectures. It should however be noted that there is a limit to the success of this technique: performance degrades for 5 layers on this problem.

6.2 Visualization of Features

Figure 3 shows the weights (called filters) of the first layer of the DBN before and after supervised fine-tuning. For visualizing what units do on the 2nd and 3rd layer, we used the activation maximization technique described by Erhan et al. (2009): to visualize what a unit responds most to, the method looks for the bounded input pattern that maximizes the activation of a given unit. This is an

optimization problem which is solved by performing gradient ascent in the space of the inputs, to find a local maximum of the activation function. Interestingly, nearly the same maximal activation input pattern is recovered from most random initializations of the input pattern.

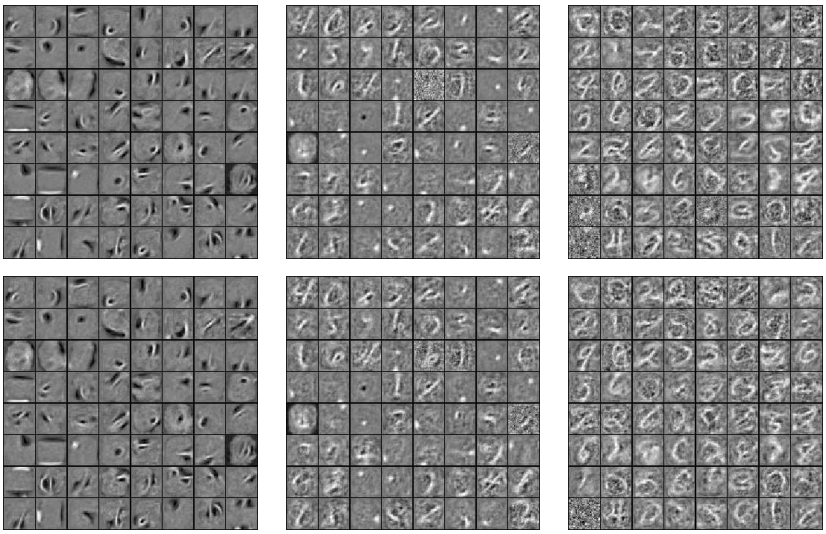

Figure 3: Visualization of filters learned by a DBN trained on `InfiniteMNIST`. The top figures contain a visualization of filters after pre-training, while the bottoms ones picture the same units after supervised fine-tuning; from left to right: units from the 1st, 2nd and 3rd layers, respectively.

For comparison, we have also visualized the filters of a network for 1–3 layers in which no pre-training was performed (Figure 4). While the first layer filters do seem to correspond to localized features, 2nd and 3rd layers are not as interpretable anymore. Qualitatively speaking, filters from the bottom row of Figure 3 and those from Figure 4 have little in common, which is an interesting conclusion in itself. In addition, there seems to be more interesting visual structures in the features learned in networks with unsupervised pre-training.

Several interesting conclusions can be drawn from Figure 3. First, supervised fine-tuning (after unsupervised pre-training), even with 7.5 million updates, does not change the weights in a significant way (at least visually): they seem stuck in a certain region of weight space, and the sign of weights does not change after fine-tuning (hence the same pattern is seen visually). Second, different layers change differently: the first layer changes least, while supervised training has more effect when performed on the 3rd layer. Such observations are consistent with the predictions made by our hypothesis: namely that the early dynamics of stochastic gradient descent, the dynamics induced by unsupervised pre-training, can "lock" the training in a region of the parameter space that is essentially inaccessible for models that are trained in a purely supervised way.

Finally, the features increase in complexity as we add more layers. First layer weights seem to encode basic stroke-like detectors, second layer weights seem to detect digit parts, while top layer weights detect entire digits. The features are more complicated as we add more layers, and displaying only one image for each "feature" does not do justice to the non-linear nature of that

feature. For example, it does not show the *set of patterns* on which the feature is highly active (or highly inactive).

While Figures 3–4 show only the filters obtained on `InfiniteMNIST`, the visualizations are similar when applied on `MNIST`. Likewise, the features obtained with SDAE result in qualitatively similar conclusions; Erhan et al. (2009) gives more details.

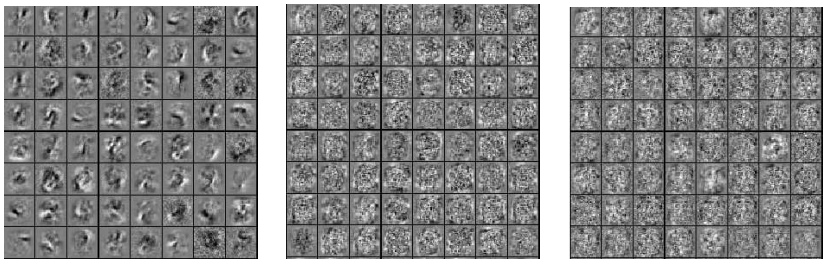

Figure 4: Visualization of filters learned by a network without pre-training, trained on `InfiniteMNIST`. The filters are shown after supervised training; from left to right: units from the 1st, 2nd and 3rd layers, respectively.

6.3 Visualization of Model Trajectories During Learning

Visualizing the learned features allows for a qualitative comparison of the training strategies for deep architectures. However it is not useful for investigating how these strategies are influenced by random initialization, as the features learned from multiple initializations look similar. If it was possible for us to visualize a variety of models at the same time, it would allow us to explore our hypothesis, and ascertain to what degree and how the set of pre-trained models (for different random seeds) is far from the set of models without pre-training. Do these two sets cover very different regions in parameter space? Are parameter trajectories getting stuck in many different apparent local minima?

Unfortunately, it is not possible to directly compare parameter values of two architectures, because many permutations of the same parameters give rise to the same model. However, one can take a functional approximation approach in which we compare the function (from input to output) represented by each network, rather than comparing the parameters. The function is the infinite ordered set of output values associated with all possible inputs, and it can be approximated with a finite number of inputs (preferably plausible ones). To visualize the trajectories followed during training, we use the following procedure. For a given model, we compute and concatenate all its outputs on the test set examples as one long vector summarizing where it stands in "function space". We get one such vector for each partially trained model (at each training iteration). This allows us to plot many learning trajectories, one for each initialization seed, with or without pre-training. Using a dimensionality reduction algorithm we then map these vectors to a two-dimensional space for visualization.[8] Figures 5 and 6 present the results using dimensionality reduction techniques that

8. Note that we can and do project the models with and without pre-training at the same time, so as to visualize them in the same space.

focus respectively on local[9] and global structure.[10] Each point is colored according to the training iteration, to help follow the trajectory movement.

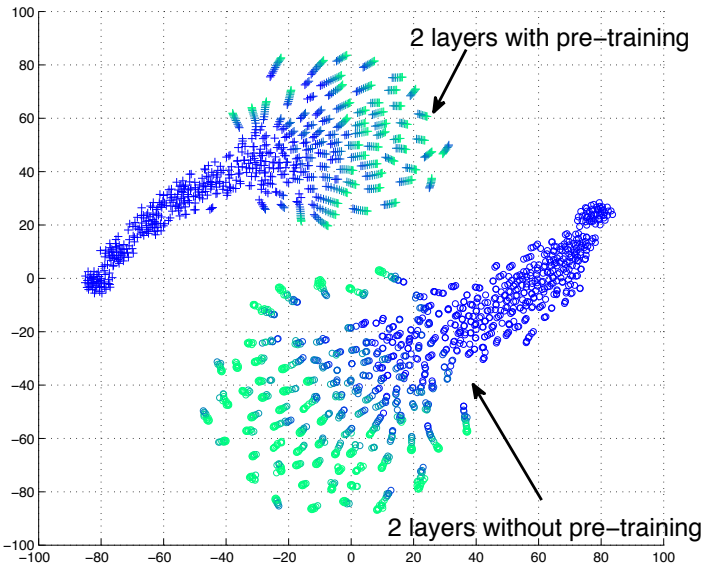

Figure 5: 2D visualizations with tSNE of the functions represented by 50 networks with and 50 networks without pre-training, as supervised training proceeds over MNIST. See Section 6.3 for an explanation. Color from dark blue to cyan and red indicates a progression in training iterations (training is longer without pre-training). The plot shows models with 2 hidden layers but results are similar with other depths.

What seems to come out of these visualizations is the following:

1. The pre-trained and not pre-trained models start and *stay* in different regions of function space.

2. From the visualization focusing on local structure (Figure 5) we see that all trajectories of a given type (with pre-training or without) initially move together. However, at some point (after about 7 epochs) the different trajectories (corresponding to different random seeds) diverge (slowing down into elongated jets) and never get back close to each other (this is more true for trajectories of networks without pre-training). This suggests that each trajectory moves into a different apparent local minimum.[11]

9. t-Distributed Stochastic Neighbor Embedding, or tSNE, by van der Maaten and Hinton (2008), with the default parameters available in the public implementation: `http://ict.ewi.tudelft.nl/~lvandermaaten/t-SNE.html`.
10. Isomap by Tenenbaum et al. (2000), with one connected component.
11. One may wonder if the divergence points correspond to a turning point in terms of overfitting. As shall be seen in Figure 8, the test error does not improve much after the 7th epoch, which reinforces this hypothesis.

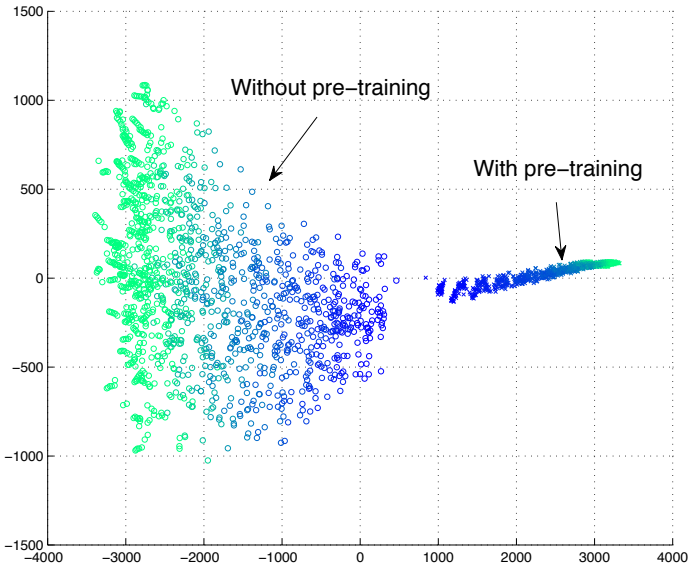

Figure 6: 2D visualization with ISOMAP of the functions represented by 50 networks with and 50 networks without pre-training, as supervised training proceeds over MNIST. See Section 6.3 for an explanation. Color from dark blue to cyan indicates a progression in training iterations (training is longer without pre-training). The plot shows models with 2 hidden layers but results are similar with other depths.

3. From the visualization focusing on global structure (Figure 6), we see the pre-trained models live in a disjoint and much smaller region of space than the not pre-trained models. In fact, from the standpoint of the functions found without pre-training, the pre-trained solutions look all the same, and their self-similarity increases (variance across seeds decreases) during training, while the opposite is observed without pre-training. This is consistent with the formalization of pre-training from Section 3, in which we described a theoretical justification for viewing unsupervised pre-training as a regularizer; there, the probabilities of pre-traininig parameters landing in a basin of attraction is small.

The visualizations of the training trajectories do seem to confirm our suspicions. It is difficult to guarantee that each trajectory actually does end up in a different local minimum (corresponding to a different function and not only to different parameters). However, all tests performed (visual inspection of trajectories in function space, but also estimation of second derivatives in the directions of all the estimated eigenvectors of the Jacobian not reported in details here) were consistent with that interpretation.

We have also analyzed models obtained at the end of training, to visualize the training criterion in the neighborhood of the parameter vector θ^* obtained. This is achieved by randomly sampling a direction v (from the stochastic gradient directions) and by plotting the training criterion around

θ^* in that direction, that is, at $\theta = \theta^* + \alpha v$, for $\alpha \in \{-2.5, -2.4, \ldots, -0.1, 0, 0.1, \ldots 2.4, 2.5\}$, and v normalized ($||v|| = 1$). This analysis is visualized in Figure 7. The error curves look close to quadratic and we seem to be near a local minimum in all directions investigated, as opposed to a saddle point or a plateau. A more definite answer could be given by computing the full Hessian eigenspectrum, which would be expensive. Figure 7 also suggests that the error landscape is a bit flatter in the case of unsupervised pre-training, and flatter for deeper architectures.

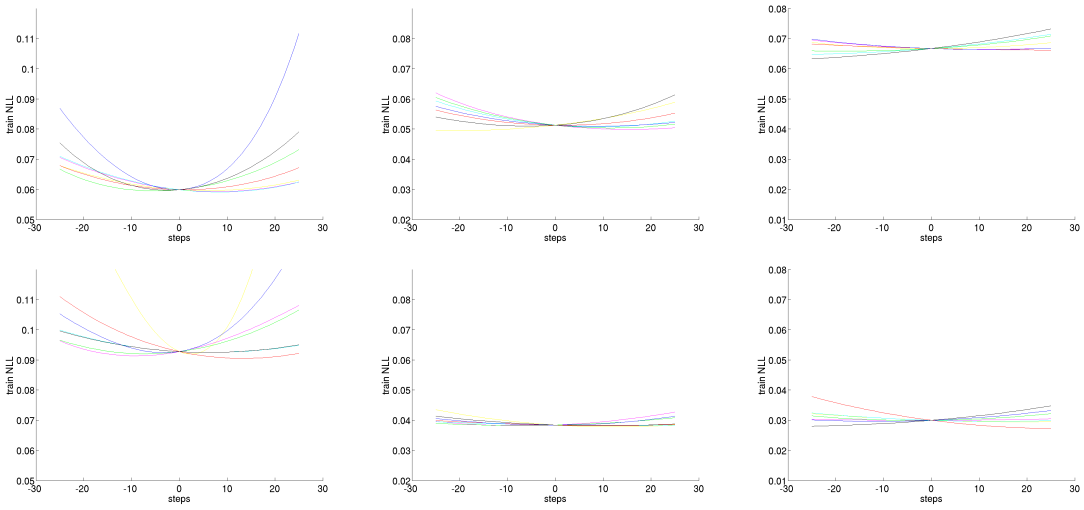

Figure 7: Training errors obtained on `Shapeset` when stepping in parameter space around a converged model in 7 random gradient directions (stepsize of 0.1). **Top**: no pre-training. **Bottom**: with unsupervised pre-training. **Left**: 1 hidden layer. **Middle**: 2 hidden layers. **Right**: 3 hidden layers. Compare also with Figure 8, where 1-layer networks with unsupervised pre-training obtain higher training errors.

6.4 Implications

The series of results presented so far show a picture that is consistent with our hypothesis. Better generalization that seems to be robust to random initializations is indeed achieved by pre-trained models, which indicates that unsupervised learning of $P(X)$ is helpful in learning $P(Y|X)$. The function space landscapes that we visualized point to the fact that there are many apparent local minima. The pre-trained models seem to end up in distinct regions of these error landscapes (and, implicitly, in different parts of the parameter space). This is both seen from the function space trajectories and from the fact that the visualizations of the learned features are qualitatively very different from those obtained by models without pre-training.

7. The Role of Unsupervised Pre-training

The observations so far in this paper confirm that starting the supervised optimization from pre-trained weights rather than from randomly initialized weights consistently yields better performing

classifiers on MNIST. To better understand where this advantage came from, it is important to realize that the *supervised objective being optimized is exactly the same in both cases*. The gradient-based optimization procedure is also the same. The only thing that differs is the starting point in parameter space: either picked at random or obtained after unsupervised pre-training (which also starts from a random initialization).

Deep architectures, since they are built from the composition of several layers of non-linearities, yield an error surface that is non-convex and hard to optimize, with the suspected presence of many local minima (as also shown by the above visualizations). A gradient-based optimization should thus end in the apparent local minimum of whatever *basin of attraction* we started from. From this perspective, the advantage of unsupervised pre-training could be that it puts us in a region of parameter space where basins of attraction run deeper than when picking starting parameters at random. The advantage would be due to a better **optimization**.

Now it might also be the case that unsupervised pre-training puts us in a region of parameter space in which training error is not necessarily better than when starting at random (or possibly worse), but which systematically yields better generalization (test error). Such behavior would be indicative of a **regularization** effect. Note that the two forms of explanation are *not necessarily mutually exclusive*.

Finally, a very simple explanation could be the most obvious one: namely the disparity in the magnitude of the weights (or more generally, the marginal distribution of the weights) at the start of the supervised training phase. We shall analyze (and rule out) this hypothesis first.

7.1 Experiment 1: Does Pre-training Provide a Better Conditioning Process for Supervised Learning?

Typically gradient descent training of the deep model is initialized with randomly assigned weights, small enough to be in the linear region of the parameter space (close to zero for most neural network and DBN models). It is reasonable to ask if the advantage imparted by having an initial unsupervised pre-training phase is simply due to the weights being larger and therefore somehow providing a better "conditioning" of the initial values for the optimization process; we wanted to rule out this possibility.

By conditioning, we mean the range and marginal distribution from which we draw initial weights. In other words, could we get the same performance advantage as unsupervised pre-training if we were still drawing the initial weights independently, but from a more suitable distribution than the uniform$[-1/\sqrt{k}, 1/\sqrt{k}]$? To verify this, we performed unsupervised pre-training, and computed marginal histograms for each layer's pre-trained weights and biases (one histogram per each layer's weights and biases). We then resampled new "initial" random weights and biases according to these histograms (independently for each parameter), and performed fine-tuning from there. The resulting parameters have the same marginal statistics as those obtained after unsupervised pre-training, but not the same joint distribution.

Two scenarios can be imagined. In the first, the initialization from marginals would lead to significantly better performance than the standard initialization (when no pre-training is used). This would mean that unsupervised pre-training does provide a better marginal conditioning of

the weights. In the second scenario, the marginals would lead to performance similar to or worse than that without pre-training.[12]

initialization.	Uniform	Histogram	Unsup.pre-tr.
1 layer	1.81 ± 0.07	1.94 ± 0.09	1.41 ± 0.07
2 layers	1.77 ± 0.10	1.69 ± 0.11	1.37 ± 0.09

Table 1: Effect of various initialization strategies on 1 and 2-layer architectures: independent uniform densities (one per parameter), independent densities from the marginals after unsupervised pre-training, or unsupervised pre-training (which samples the parameters in a highly dependent way so that they collaborate to make up good denoising auto-encoders.) Experiments on `MNIST`, numbers are mean and standard deviation of test errors (across different initialization seeds).

What we observe in Table 1 seems to fall within the first scenario. However, while initializing the weights to match the marginal distributions at the end of pre-training appears to slightly improve the generalization error on MNIST for 2 hidden layers, the difference is not significant and it is far from fully accounting for the discrepancy between the pre-trained and non-pre-trained results.

This experiment constitutes evidence against the preconditioning hypothesis, but does not exclude either the optimization hypothesis or the regularization hypothesis.

7.2 Experiment 2: The Effect of Pre-training on Training Error

The optimization and regularization hypotheses diverge on their prediction on how unsupervised pre-training should affect the training error: the former predicts that unsupervised pre-training should result in a lower training error, while the latter predicts the opposite. To ascertain the influence of these two possible explanatory factors, we looked at the test cost (Negative Log Likelihood on test data) obtained as a function of the training cost, along the trajectory followed in parameter space by the optimization procedure. Figure 8 shows 400 of these curves started from a point in parameter space obtained from random initialization, that is, without pre-training (blue), and 400 started from pre-trained parameters (red).

The experiments were performed for networks with 1, 2 and 3 hidden layers. As can be seen in Figure 8, while for 1 hidden layer, unsupervised pre-training reaches lower training cost than no pre-training, hinting towards a better optimization, this is not necessarily the case for the deeper networks. The remarkable observation is rather that, *at a same training cost level, the pre-trained models systematically yield a lower test cost* than the randomly initialized ones. The advantage appears to be one of *better generalization rather than merely a better optimization procedure*.

This brings us to the following result: unsupervised pre-training appears to have a similar effect to that of a good regularizer or a good "prior" on the parameters, even though no explicit regularization term is apparent in the cost being optimized. As we stated in the hypothesis, it might be reasoned that restricting the possible starting points in parameter space to those that minimize the unsupervised pre-training criterion (as with the SDAE), does in effect restrict the set of possible

12. We observed that the distribution of weights after unsupervised pre-training is fat-tailed. It is conceivable that sampling from such a distribution in order to initialize a deep architecture might actually *hurt* the performance of a deep architecture (compared to random initialization from a uniform distribution).

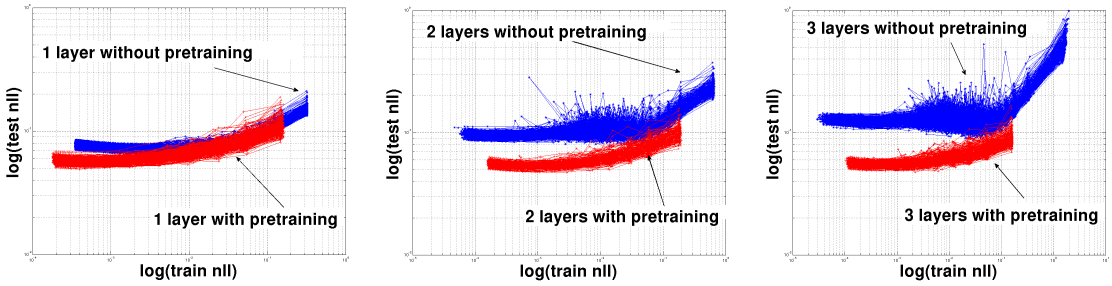

Figure 8: Evolution without pre-training (blue) and with pre-training (red) on MNIST of the log of the test NLL plotted against the log of the train NLL as training proceeds. Each of the 2×400 curves represents a different initialization. The errors are measured after each pass over the data. The rightmost points were measured after the first pass of gradient updates. Since training error tends to decrease during training, the trajectories run from right (high training error) to left (low training error). Trajectories moving up (as we go leftward) indicate a form of overfitting. All trajectories are plotted on top of each other.

final configurations for parameter values. Like regularizers in general, unsupervised pre-training (in this case, with denoising auto-encoders) might thus be seen as decreasing the variance and introducing a bias (towards parameter configurations suitable for performing denoising). Unlike ordinary regularizers, unsupervised pre-training does so in a data-dependent manner.

7.3 Experiment 3: The Influence of the Layer Size

Another signature characteristic of regularization is that the effectiveness of regularization increases as capacity (e.g., the number of hidden units) increases, effectively trading off one constraint on the model complexity for another. In this experiment we explore the relationship between the number of units per layer and the effectiveness of unsupervised pre-training. The hypothesis that unsupervised pre-training acts as a regularizer would suggest that we should see a trend of increasing effectiveness of unsupervised pre-training as the number of units per layer are increased.

We trained models on MNIST with and without pre-training using increasing layer sizes: 25, 50, 100, 200, 400, 800 units per layer. Results are shown in Figure 9. Qualitatively similar results were obtained on *Shapeset*. In the case of SDAE, we were expecting the denoising pre-training procedure to help classification performance most for large layers; this is because the denoising pre-training allows useful representations to be learned in the over-complete case, in which a layer is larger than its input (Vincent et al., 2008). What we observe is a more systematic effect: while unsupervised pre-training helps for larger layers and deeper networks, it also appears to hurt for too small networks.

Figure 9 also shows that DBNs behave qualitatively like SDAEs, in the sense that unsupervised pre-training architectures with smaller layers hurts performance. Experiments on InfiniteMNIST reveal results that are qualitatively the same. Such an experiment seemingly points to a re-verification of the regularization hypothesis. In this case, it would seem that unsupervised pre-training acts as an additional regularizer for both DBN and SDAE models—on top of the regularization provided by

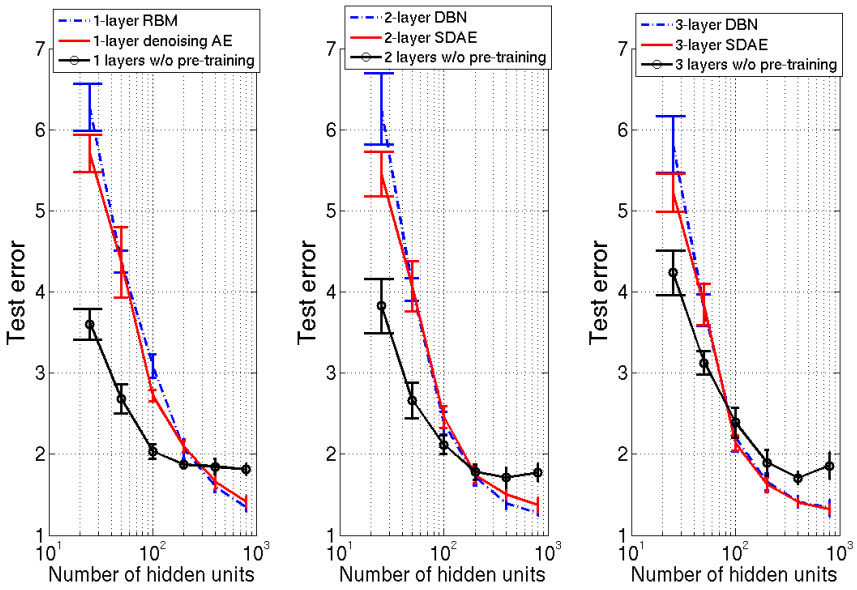

Figure 9: Effect of layer size on the changes brought by unsupervised pre-training, for networks with 1, 2 or 3 hidden layers. Experiments on MNIST. Error bars have a height of two standard deviations (over initialization seed). Pre-training hurts for smaller layer sizes and shallower networks, but it helps for all depths for larger networks.

the small size of the hidden layers. As the model size decreases from 800 hidden units, the generalization error increases, and it increases more with unsupervised pre-training presumably because of the extra regularization effect: small networks have a limited capacity already so further restricting it (or introducing an additional bias) can harm generalization. Such a result seems incompatible with a pure optimization effect. We also obtain the result that DBNs and SDAEs seem to have qualitatively similar effects as pre-training strategies.

The effect can be explained in terms of the role of unsupervised pre-training as promoting input transformations (in the hidden layers) that are useful at capturing the main variations in the input distribution $P(X)$. It may be that only a small subset of these variations are relevant for predicting the class label Y. When the hidden layers are small it is less likely that the transformations for predicting Y are included in the lot learned by unsupervised pre-training.

7.4 Experiment 4: Challenging the Optimization Hypothesis

Experiments 1–3 results are consistent with the regularization hypothesis and Experiments 2–3 would appear to directly support the regularization hypothesis over the alternative—that unsupervised pre-training aids in optimizing the deep model objective function.

In the literature there is some support for the optimization hypothesis. Bengio et al. (2007) constrained the top layer of a deep network to have 20 units and measured the training error of networks with and without pre-training. The idea was to prevent the networks from overfitting the training error simply with the top hidden layer, thus to make it clearer whether some optimization

effect (of the lower layers) was going on. The reported training and test errors were lower for pre-trained networks. One problem with the experimental paradigm used by Bengio et al. (2007) is their use of early stopping. This is problematic because, as previously mentioned, early stopping is itself a regularizer, and it can influence greatly the training error that is obtained. It is conceivable that if Bengio et al. (2007) had run the models to convergence, the results could have been different. We needed to verify this.

Figure 10 shows what happens without early stopping. The training error is still higher for pre-trained networks even though the generalization error is lower. This result now favors the regularization hypothesis against the optimization story. What may have happened is that early stopping prevented the networks without pre-training from moving too much towards their apparent local minimum.

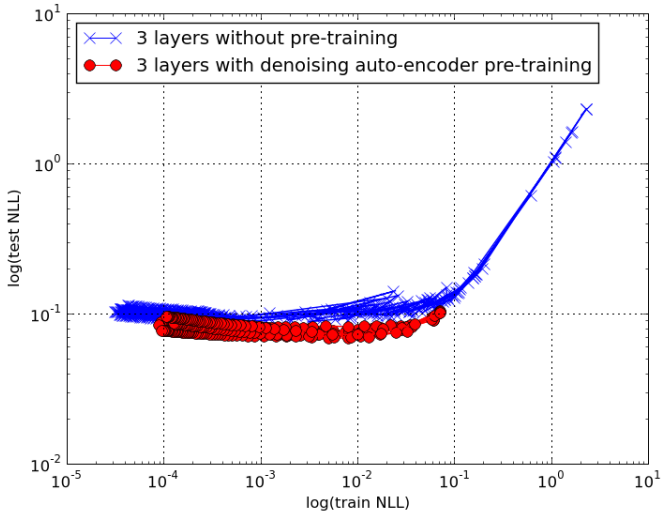

Figure 10: For `MNIST`, a plot of the log(train NLL) vs. log(test NLL) at each epoch of training. The top layer is constrained to 20 units.

7.5 Experiment 5: Comparing pre-training to L_1 and L_2 regularization

An alternative hypothesis would be that classical ways of regularizing could perhaps achieve the same effect as unsupervised pre-training. We investigated the effect of L_1 and L_2 regularization (i.e., adding a $||\theta||_1$ or $||\theta||_2^2$ term to the supervised objective function) in a network without pre-training. We found that while in the case of `MNIST` a small penalty can in principle help, the gain is nowhere near as large as it is with pre-training. For `InfiniteMNIST`, the optimal amount of L_1 and L_2 regularization is zero.[13]

13. Which is consistent with the classical view of regularization, in which its effect should diminish as we add more and more data.

This is not an entirely surprising finding: not all regularizers are created equal and these results are consistent with the literature on semi-supervised training that shows that unsupervised learning can be exploited as a particularly effective form of regularization.

7.6 Summary of Findings: Experiments 1-5

So far, the results obtained from the previous experiments point towards a pretty clear explanation of the effect of unsupervised pre-training: namely, that its effect is a regularization effect. We have seen that it is not simply sufficient to sample random weights with the same magnitude: the (data-dependent) unsupervised initialization is crucial. We have also observed that canonical regularizers (L_1/L_2 penalties on the weights) do not achieve the same level of performance.

The most compelling pieces of evidence in support of the regularization hypothesis are Figures 8 and 9. The alternative explanation—that unsupervised pre-training has an optimization effect—suggested by Bengio et al. (2007) doesn't seem to be supported by our experimental setup.

8. The Online Learning Setting

Our hypothesis included not only the statistical/phenomenological hypothesis that unsupervised pre-training acted as a regularizer, but also contains a mechanism for how such behavior arises both as a consequence of the dynamic nature of training—following a stochastic gradient through two phases of training and as a consequence of the non-convexity of the supervised objective function.

In our hypothesis, we posited that early examples induce changes in the magnitude of the weights that increase the amount of non-linearity of the network, which in turn decreases the number of regions accessible to the stochastic gradient descent procedure. This means that the early examples (be they pre-training examples or otherwise) determine the basin of attraction for the remainder of training; this also means that the early examples have a disproportionate influence on the configuration of parameters of the trained models.

One consequence to the hypothesized mechanism is that we would predict that in the online learning setting with unbounded or very large data sets, the behavior of unsupervised pre-training would diverge from the behavior of a canonical regularizer (L_1/L_2). This is because the effectiveness of a canonical regularizer **decreases** as the data set grows, whereas the effectiveness of unsupervised pre-training as a regularizer is **maintained** as the data set grows.

Note that stochastic gradient descent in online learning is a stochastic gradient descent optimization of the generalization error, so good online error in principle implies that we are optimizing well the generalization error. Indeed, each gradient $\frac{\partial L(x,y)}{\partial \theta}$ for example (x,y) (with $L(x,y)$ the supervised loss with input x and label y) sampled from the true generating distribution $P(x,y)$ is an unbiased Monte-Carlo estimator of the true gradient of generalization error, that is, $\sum_y \int_x \frac{\partial L(x,y)}{\partial \theta} P(x,y)dx$.

In this section we empirically challenge this aspect of the hypothesis and show that the evidence does indeed support our hypothesis over what is more typically expected from a regularizer.

8.1 Experiment 6: Effect of Pre-training with Very Large Data Sets

The results presented here are perhaps the most surprising findings of this paper. Figure 11 shows the online classification error (on the next block of examples, as a moving average) for 6 architectures that are trained on `InfiniteMNIST`: 1 and 3-layer DBNs, 1 and 3-layer SDAE, as well as 1 and 3-layer networks without pre-training.

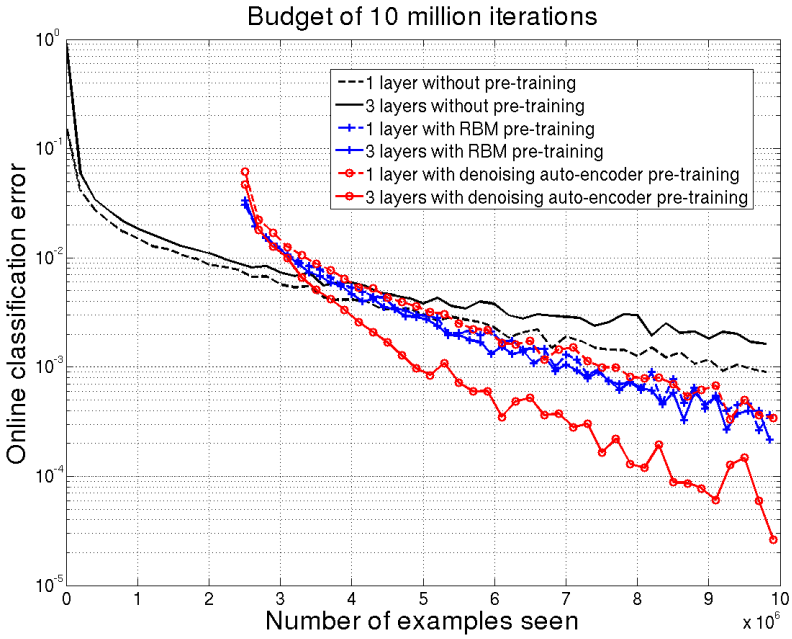

Figure 11: Comparison between 1 and 3-layer networks trained on `InfiniteMNIST`. Online classification error, computed as an average over a block of last 100,000 errors.

We can draw several observations from these experiments. First, 3-layer networks without pre-training are worse at generalization, compared to the 1-layer equivalent. This confirms the hypothesis that even in an online setting, optimization of deep networks is harder than shallow ones. Second, 3-layer SDAE models seem to generalize better than 3-layer DBNs. Finally and most importantly, the pre-training advantage does not vanish as the number of training examples increases, on the contrary.

Note that the number of hidden units of each model is a hyperparameter.[14] So theoretical results suggest that 1-layer networks without pre-training should in principle be able to represent the input distribution as capacity and data grow. Instead, without pre-training, the networks are not able to take advantage of the additional capacity, which again points towards the optimization explanation. It is clear, however, that **the starting point of the non-convex optimization matters**, even for networks that are seemingly "easier" to optimize (1-layer ones), which supports our hypothesis.

Another experiment that shows the effects of large-scale online stochastic non-convex optimization is shown in Figure 12. In the setting of `InfiniteMNIST`, we compute the error on the *training set*, in the same order that we presented the examples to the models. We observe several interesting results: first, note that both models are better at classifying more recently seen examples. This is a natural effect of stochastic gradient descent with a constant learning rate (which gives exponentially more weight to recent examples). Note also that examples at the beginning of training are essentially like test examples for both models, in terms of error. Finally, we observe that the pre-trained

14. This number was chosen individually for each model s.t. the error on the last 1 million examples is minimized. In practice, this meant 2000 units for 1-layer networks and 1000 units/layer for 3-layer networks.

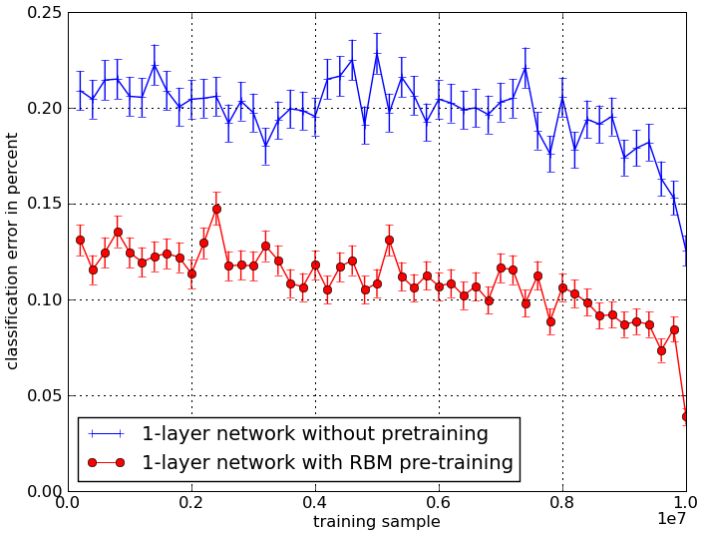

Figure 12: Error of 1-layer network with RBM pre-training and without, on the 10 million examples used for training it. The errors are calculated in the same order (from left to right, above) as the examples were presented during training. Each error bar corresponds to a block of consecutive training examples.

model is better across the board *on the training set*. This fits well with the optimization hypothesis, since it shows that unsupervised pre-training has an optimization effect.

What happens in this setting is that the training and generalization errors converge as the empirical distribution (defined by the training set) converges to the true data distribution. These results show that the effectiveness of unsupervised pre-training does not diminish with increasing data set sizes. This would be unexpected from a superficial understanding of unsupervised pre-training as a regularization method. However it is entirely consistent with our interpretation, stated in our hypothesis, of the role of unsupervised pre-training in the online setting with stochastic gradient descent training on a non-convex objective function.

8.2 Experiment 7: The Effect of Example Ordering

The hypothesized mechanism implies, due to the dynamics of learning—the increase in weight magnitude and non-linearity as training proceeds, as well as the dependence of the basin of attraction on early data—that, when training with stochastic gradient descent, we should see increased sensitivity to early examples. In the case of `InfiniteMNIST` we operate in an online stochastic optimization regime, where we try to find a local minimum of a highly non-convex objective function. It is then interesting to study to what extent the outcome of this optimization is influenced by the examples seen at different points during training, and whether the early examples have a stronger influence (which would not be the case with a convex objective).

To quantify the variance of the outcome with respect to training samples at different points during training, and to compare these variances for models with and without pre-training, we proceeded with the following experiment. Given a data set with 10 million examples, we vary (by resampling)

the first million examples (across 10 different random draws, sampling a different set of 1 million examples each time) and keep the other ones fixed. After training the (10) models, we measure the variance (across the 10 draws) of the *output* of the networks on a fixed test set (i.e., we measure the variance in function space). We then vary the next million examples in the same fashion, and so on, to see how much each of the ten parts of the training set influenced the final function.

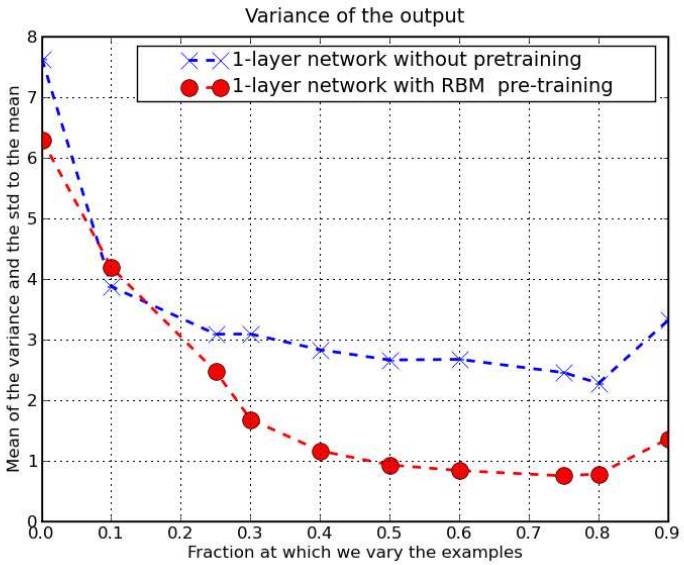

Figure 13: Variance of the output of a trained network with 1 layer. The variance is computed as a function of the point at which we vary the training samples. Note that the 0.25 mark corresponds to the start of pre-training.

Figure 13 shows the outcome of such an analysis. The samples at the beginning[15] do seem to influence the output of the networks more than the ones at the end. However, this variance is *lower* for the networks that have been pre-trained. In addition to that, one should note that the variance of pre-trained network at 0.25 (i.e., the variance of the output as a function of the first samples used for supervised training) is *lower* than the variance of the supervised network at 0.0. Such results imply that unsupervised pre-training can be seen as a sort of variance reduction technique, consistent with a regularization hypothesis. Finally, both networks are more influenced by the *last examples* used for optimization, which is simply due to the fact that we use stochastic gradient with a constant learning rate, where the most recent examples' gradient has a greater influence.

These results are consistent with what our hypothesis predicts: both the fact that early examples have greater influence (i.e., the variance is higher) and that pre-trained models seem to reduce this variance are in agreement with what we would have expected.

15. Which are *unsupervised* examples, for the red curve, until the 0.25 mark in Figure 13.

8.3 Experiment 8: Pre-training only k layers

From Figure 11 we can see that unsupervised pre-training makes quite a difference for 3 layers, on `InfiniteMNIST`. In Figure 14 we explore the link between depth and unsupervised pre-training in more detail. The setup is as follows: for both `MNIST` and `InfiniteMNIST` we pre-train only the bottom k layers and randomly initialize the top $n-k$ layers in the usual way. In this experiment, $n = 3$ and we vary k from 0 (which corresponds to a network with no pre-training) to $k = n$ (which corresponds to the normal pre-trained case).

For `MNIST`, we plot the log(train NLL) vs. log(test NLL) trajectories, where each point corresponds to a measurement after a certain number of epochs. The trajectories go roughly from the right to left and from top to bottom, corresponding to the lowering of the training and test errors. We can also see that models overfit from a certain point onwards.

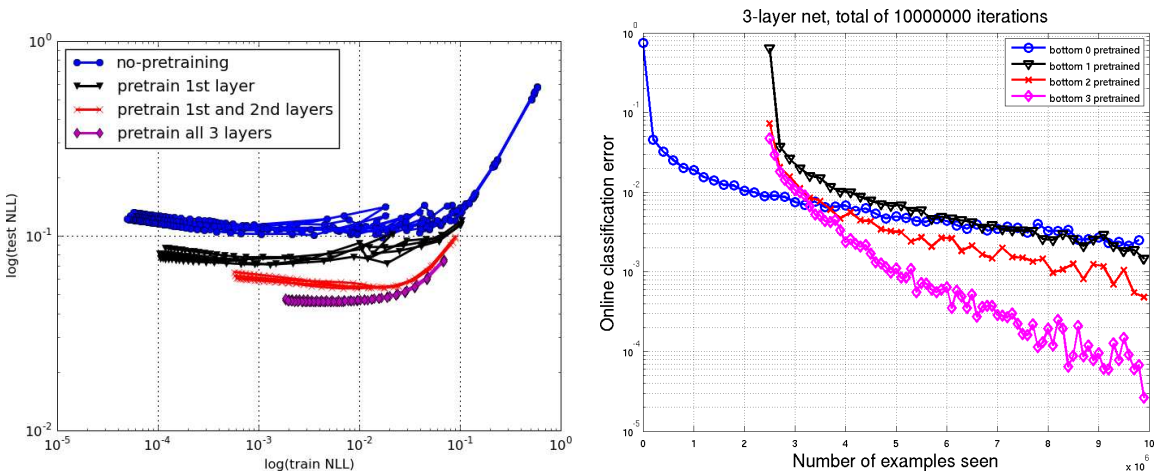

Figure 14: *On the left*: for `MNIST`, a plot of the log(train NLL) vs. log(test NLL) at each epoch of training. We pre-train the first layer, the first two layers and all three layers using RBMs and randomly initialize the other layers; we also compare with the network whose layers are all randomly initialized. *On the right*: `InfiniteMNIST`, the online classification error. We pre-train the first layer, the first two layers or all three layers using denoising auto-encoders and leave the rest of the network randomly initialized.

For `InfiniteMNIST`, we simply show the online error. The results are ambiguous w.r.t the difficulty of optimizing the lower layers versus the higher ones. We would have expected that the largest incremental benefit came from pre-training the first layer or first two layers. It is true for the first two layers, but not the first. As we pre-train more layers, the models become better at generalization. In the case of the finite `MNIST`, note how the final training error (after the same number of epochs) becomes *worse* with pre-training of more layers. This clearly brings additional support to the regularization explanation.

9. Discussion and Conclusions

We have shown that unsupervised pre-training adds robustness to a deep architecture. The same set of results also suggests that increasing the depth of an architecture that is not pre-trained increases the probability of finding poor apparent local minima. Pre-trained networks give consistently better generalization. Our visualizations point to the observations that pre-trained networks learn qualitatively different features (if networks are visualized in the weight space) compared to networks without pre-training. Moreover, the trajectories of networks with different initialization seeds seem to fall into many distinct apparent local minima, which are again different (and seemingly far apart) depending on whether we use pre-training or not.

We have shown that unsupervised pre-training is not simply a way of getting a good initial marginal distribution, and that it captures more intricate dependencies between parameters. One of our findings is that deep networks with unsupervised pre-training seem to exhibit some properties of a regularizer: with small enough layers, pre-trained deep architectures are systematically worse than randomly initialized deep architectures. Moreover, when the layers are big enough, the pre-trained models obtain worse training errors, but better generalization performance. Additionally, we have re-done an experiment which purportedly showed that unsupervised pre-training can be explained with an optimization hypothesis and observed a regularization effect instead. We also showed that classical regularization techniques (such as L_1/L_2 penalties on the network weights) cannot achieve the same performance as unsupervised pre-training, and that the effect of unsupervised pre-training does not go away with more training data, so if unsupervised pre-training is a regularizer, it is certainly of a rather different kind.

The two unsupervised pre-training strategies considered—denoising auto-encoders and Restricted Boltzmann Machines—seem to produce qualitatively similar observations. We have observed that, surprisingly, the pre-training advantage is present even in the case of really large training sets, pointing towards the conclusion that the starting point in the non-convex optimization problem is indeed quite important; a fact confirmed by our visualizations of filters at various levels in the network. Finally, the other important set of results show that unsupervised pre-training acts like a variance reduction technique, yet a network with pre-training has a lower training error on a very large data set, which supports an optimization interpretation of the effect of pre-training.

How do we make sense of all these results? The contradiction between what looks like regularization effects and what looks like optimization effects appears, on the surface, unresolved. Instead of sticking to these labels, we attempted to draw a hypothesis, described in Section 3 about the dynamics of learning in an architecture that is trained using two phases (unsupervised pre-training and supervised fine-tuning), which we believe to be consistent with all the above results.

This hypothesis suggests that there are consequences of the non-convexity of the supervised objective function, which we observed in various ways throughout our experiments. One of these consequences is that early examples have a big influence on the outcome of training and this is one of the reasons why in a large-scale setting the influence of unsupervised pre-training is still present. Throughout this paper, we have delved on the idea that the basin of attraction induced by the early examples (in conjunction with unsupervised pre-training) is, for all practical purposes, a basin from which supervised training does not escape.

This effect can be observed from the various visualizations and performance evaluations that we made. *Unsupervised pre-training,* **as a regularizer** *that only influences the starting point of supervised training, has an effect that, contrary to classical regularizers, does not disappear with*

more data (at least as far as we can see from our results). Basically, unsupervised pre-training favors hidden units that compute features of the input X that correspond to major factors of variation in the true $P(X)$. Assuming that some of these are near features useful at predicting variations in Y, unsupervised pre-training sets up the parameters near a solution of low predictive generalization error.

One of the main messages that our results imply is that the optimization of a non-convex objective function with stochastic gradient descent presents challenges for analysis, especially in a regime with large amounts of data. Our analysis so far shows that it is possible for networks that are trained in such a regime to be influenced more by early examples. This can pose problems in scenarios where we would like our networks to be able to capture more of the information in later examples, that is, when training from very large data sets and trying to capture a lot of information from them.

One interesting realization is that with a small training set, we do not usually put a lot of importance on minimizing the training error, because overfitting is a major issue; the training error is not a good way to distinguish between the generalization performance of two models. In that setting, unsupervised pre-training helps to find apparent local minima that have better generalization error. With a large training set, as we saw in Figure 12, the empirical and true distributions converge. In such a scenario, *finding a better apparent local minimum will matter and stronger (better) optimization strategies should have a significant impact on generalization when the training set is very large*. Note also that it would be interesting to extend our experimental techniques to the problem of training deep auto-encoders (with a bottleneck), where previous results (Hinton and Salakhutdinov, 2006) show that not only test error but also training error is greatly reduced by unsupervised pre-training, which is a strong indicator of an optimization effect. We hypothesize that the presence of the bottleneck is a crucial element that distinguishes the deep auto-encoders from the deep classifiers studied here.

In spite of months of CPU time on a cluster devoted to the experiments described here (which is orders of magnitude more than most previous work in this area), more could certainly be done to better understand these effects. Our original goal was to have well-controlled experiments with well understood data sets. It was not to advance a particular algorithm but rather to try to better understand a phenomenon that has been well documented elsewhere. Nonetheless, our results are limited by the data sets used and it is plausible that different conclusions could be drawn, should the same experiments be carried out on other data.

Our results suggest that optimization in deep networks is a complicated problem that is influenced in great part by the early examples during training. Future work should clarify this hypothesis. If it is true and we want our learners to capture really complicated distributions from very large training sets, it may mean that we should consider learning algorithms that reduce the effect of the early examples, allowing parameters to escape from the attractors in which current learning dynamics get stuck.

The observations reported here suggest more detailed explanations than those already discussed, which could be tested in future work. We hypothesize that the factors of variation present in the input distribution are disentangled more and more as we go from the input layer to higher-levels of the feature hierarchy. This is coherent with observations of increasing invariance to geometric transformations in DBNs trained on images (Goodfellow et al., 2009), as well as by visualizing the variations in input images generated by sampling from the model (Hinton, 2007; Susskind et al., 2008), or when considering the preferred input associated with different units at different depths (Lee et al.,

2009; Erhan et al., 2009). As a result, during early stages of learning, the upper layers (those that typically learn quickly) would have access to a more robust representation of the input and are less likely to be hindered by the entangling of factors variations present in the input. If this disentangling hypothesis is correct, it would help to explain how unsupervised pre-training can address the chicken-and-egg issue explained in Section 2: the lower layers of a supervised deep architecture need the upper layers to define what they should extract, and vice-versa. Instead, the lower layers can extract robust and disentangled representations of the factors of variation and the upper layers select and combine the appropriate factors (sometimes not all at the top hidden layer). Note that as factors of variation are disentangled, it could also happen that some of them are not propagated upward (before fine-tuning), because RBMs do not try to represent in their hidden layer input bits that are independent.

To further explain why smaller hidden layers yield worse performance with pre-training than without (Figure 9), one may hypothesize further that, for some data sets, the leading factors of variation present in $P(X)$ (presumably the only ones captured in a smaller layer) are less predictive of Y than random projections[16] can be, precisely because of the hypothesized disentangling effect. With enough hidden units, unsupervised pre-training may extract among the larger set of learned features some that are highly predictive of Y (more so than random projections). This additional hypothesis could be tested by measuring the mutual information between each hidden unit and the object categories (as done by Lee et al., 2009), as the number of hidden units is varied (like in Figure 9). It is expected that the unit with the most mutual information will be less informative with pre-training when the number of hidden units is too small, and more informative with pre-training when the number of hidden units is large enough.

Under the hypothesis that we have proposed in Section 3, the following result is unaccounted for: in Figure 8(a), training error is lower with pre-training when there is only one hidden layer, but worse with more layers. This may be explained by the following additional hypothesis. Although each layer extracts information about Y in some of its features, it is not guaranteed that all of that information is preserved when moving to higher layers. One may suspect this in particular for RBMs, which would not encode in their hidden layer any input bits that would be marginally independent of the others, because these bits would be explained by the visible biases: perfect disentangling of Y from the other factors of variation in X may yield marginally independent bits about Y. Although supervised fine-tuning should help to bubble up that information towards the output layer, it might be more difficult to do so for deeper networks, explaining the above-stated feature of Figure 8. Instead, in the case of a single hidden layer, less information about Y would have been dropped (if at all), making the job of the supervised output layer easier. This is consistent with earlier results (Larochelle et al., 2009) showing that for several data sets supervised fine-tuning significantly improves classification error, when the output layer only takes input from the top hidden layer. This hypothesis is also consistent with the observation made here (Figure 1) that unsupervised pre-training actually does not help (and can hurt) for too deep networks.

In addition to exploring the above hypotheses, future work should include an investigation of the connection between the results presented in this paper and by Hinton and Salakhutdinov (2006), where it seems to be hard to obtain a good training reconstruction error with deep auto-encoders (in an unsupervised setting) without performing pre-training. Other avenues for future work include the analysis and understanding of deep semi-supervised techniques where one does not separate

16. Meaning the random initialization of hidden layers.

between the pre-training phase and the supervised phase, such as work by Weston et al. (2008) and Larochelle and Bengio (2008). Such algorithms fall more squarely into the realm of semi-supervised methods. We expect that analyses similar to the ones we performed would be potentially harder, but perhaps revealing as well.

Many open questions remain towards understanding and improving deep architectures. Our conviction is that devising improved strategies for learning in deep architectures requires a more profound understanding of the difficulties that we face with them. This work helps with such understanding via extensive simulations and puts forward a hypothesis explaining the mechanisms behind unsupervised pre-training, which is well supported by our results.

Abstract

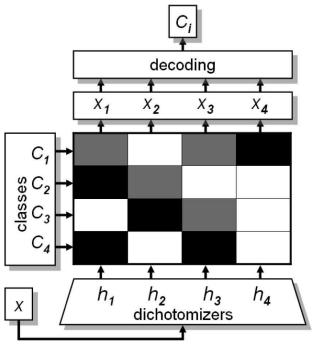
In this paper, we present an open source Error-Correcting Output Codes (ECOC) library. The ECOC framework is a powerful tool to deal with multi-class categorization problems. This library contains both state-of-the-art coding (one-versus-one, one-versus-all, dense random, sparse random, DECOC, forest-ECOC, and ECOC-ONE) and decoding designs (hamming, euclidean, inverse hamming, laplacian, β-density, attenuated, loss-based, probabilistic kernel-based, and loss-weighted) with the parameters defined by the authors, as well as the option to include your own coding, decoding, and base classifier.

Keywords: error-correcting output codes, multi-class classification, coding, decoding, open source, matlab, octave

1. Error-Correcting Output Codes

The Error-Correcting Output Codes (ECOC) framework (Dietterich and Bakiri, 1995) is a simple but powerful framework to deal with the multi-class categorization problem based on the embedding of binary classifiers. Given a set of N_c classes, the basis of the ECOC framework consists of designing a codeword for each of the classes. These codewords encode the membership information of each class for a given binary problem. Arranging the codewords as rows of a matrix, we obtain a "coding matrix" M_c, where $M_c \in \{-1,0,1\}^{N_c \times n}$, being n the length of the codewords codifying each class. From the point of view of learning, M_c is constructed by considering n binary problems, each one corresponding to a column of the matrix M_c. Each of these binary problems (or dichotomizers) splits the set of classes in two partitions (coded by +1 or -1 in M_c according to their class set membership, or 0 if the class is not considered by the current binary problem). Then, at the decoding step, applying the n trained binary classifiers, a code is obtained for each data point in the test set. This code is compared to the base codewords of each class defined in the matrix M_c, and the data point is assigned to the class with the "closest" codeword. Several decoding strategies have been proposed in literature. The reader is referred to Escalera et al. (2008) for a more detailed review. An example of an ECOC design is described in Fig. 1.

The ECOC designs are independent of the base classifier applied. They involve error-correcting properties (Dietterich and Bakiri, 1995) and have shown to be able to reduce the bias and variance produced by the learning algorithm (Kong and Dietterich, 1995). Because of these reasons, ECOCs have been widely used to deal with multi-class categorization problems.



ECOC coding design for a 4-class problem. White, black, and grey positions corresponds to the symbols +1, -1, and 0, respectively. Once the four binary problems are learnt, at the decoding step a new test sample X is tested by the n classifiers. Then, the new codeword $x = \{x_1,..,x_n\}$ is compared with the class codewords $\{C_1,..C_4\}$, classifying the new sample by the class c_i which codeword minimizes the decoding measure.

Figure 1: ECOC design example.

2. Library Algorithms

The ECOCs library is a Matlab/Octave code under the open source GPL license (gpl) with the implementation of the state-of-the-art coding and decoding ECOC designs. A main function defines the multi-class data, coding, decoding, and base classifier. A list of parameters are also included in order to tune the different strategies. In addition to the implemented coding and decoding designs, which are described in the following section, the user can include his own coding, decoding, and base classifier as defined in the user guide.

2.1 Implemented Coding Designs

The ECOC designs of the ECOC library cover the state-of-the-art of coding strategies, mainly divided in two main groups: problem-independent approaches, which do not take into account the distribution of the data to define the coding matrix, and the problem-dependent designs, where information of the particular domain is used to guide the coding design.

2.1.1 PROBLEM-INDEPENDENT ECOC DESIGNS

• One-versus-all (Rifkin and Klautau, 2004): N_c dichotomizers are learnt for N_c classes, where each one splits one class from the rest of classes.

• One-versus-one (Nilsson, 1965): $n = N_c(N_c-1)/2$ dichotomizers are learnt for N_c classes, splitting each possible pair of classes.

• Dense Random (Allwein et al., 2002): $n = 10 \cdot \log N_c$ dichotomizers are suggested to be learnt for N_c classes, where $P(-1) = 1 - P(+1)$, being $P(-1)$ and $P(+1)$ the probability of the symbols -1 and +1 to appear, respectively. Then, from a set of defined random matrices, the one which maximizes a decoding measure among all possible rows of M_c is selected.

• Sparse Random (Escalera et al., 2009): $n = 15 \cdot \log N_c$ dichotomizers are suggested to be learnt for N_c classes, where $P(0) = 1 - P(-1) - P(+1)$, defining a set of random matrices M_c and selecting the one which maximizes a decoding measure among all possible rows of M_c.

2.1.2 PROBLEM-DEPENDENT ECOC DESIGNS

• DECOC (Pujol et al., 2006): problem-dependent design that uses $n = N_c - 1$ dichotomizers. The partitions of the problem are learnt by means of a binary tree structure using exhaustive search or a $SFFS$ criterion. Finally, each internal node of the tree is embedded as a column in M_c.

• Forest-ECOC (Escalera et al., 2007): problem-dependent design that uses $n = (N_c - 1) \cdot T$ dichotomizers, where T stands for the number of binary tree structures to be embedded. This approach extends the variability of the classifiers of the DECOC design by including extra dichotomizers.

• ECOC-ONE (Pujol et al., 2008): problem-dependent design that uses $n = 2 \cdot N_c$ suggested dichotomizers. A validation sub-set is used to extend any initial matrix M_c and to increase its generalization by including new dichotomizers that focus on difficult to split classes.

2.2 Implemented Decoding Designs

The software comes with a complete set of ECOC decoding strategies. The notation used refers to that used in (Escalera et al., 2008):

• Hamming decoding: $HD(x, y_i) = \sum_{j=1}^{n} (1 - \text{sign}(x^j \cdot y_i^j))/2$, being x a test codeword and y_i a codeword from M_c corresponding to class C_i.

• Inverse Hamming decoding: $IHD(x, y_i) = \max(\Delta^{-1} D^T)$, where $\Delta(i_1, i_2) = HD(y_{i_1}, y_{i_2})$, and D is the vector of Hamming decoding values of the test codeword x for each of the base codewords y_i.

• Euclidean decoding: $ED(x, y_i) = \sqrt{\sum_{j=1}^{n} (x^j - y_i^j)^2}$.

• Attenuated Euclidean decoding: $AED(x, y_i) = \sqrt{\sum_{j=1}^{n} \mid y_i^j \mid\mid x^j \mid (x^j - y_i^j)^2}$.

• Loss-based decoding: $LB(\rho, y_i) = \sum_{j=1}^{n} L(y_i^j \cdot f^j(\rho))$, where ρ is a test sample, L is a loss-function, and f is a real-valued function $f : \mathcal{R}^n \rightarrow \mathcal{R}$.

• Probabilistic-based decoding:
$PD(y_i, x) = -log\left(\prod_{j \in [1,..,n]: M_c(i,j) \neq 0} P(x^j = M_c(i, j) | f^j) + K\right)$, where K is a constant factor that collects the probability mass dispersed on the invalid codes, and the probability $P(x^j = M_c(i, j) | f^j)$ is estimated by means of $P(x^j = y_i^j | f^j) = \frac{1}{1 + \mathbf{e}^{y_i^j (\upsilon^j f^j + \omega^j)}}$, where vectors υ and ω are obtained by solving an optimization problem (Passerini et al., 2004).

• Laplacian decoding: $LAP(x, y_i) = \frac{\alpha_i + 1}{\alpha_i + \beta_i + K}$, where α_i is the number of matched positions between x and y_i, β_i is the number of miss-matches without considering the positions coded by 0, and K is an integer value that codifies the number of classes considered by the classifier.

• Pessimistic β-Density Distribution decoding: accuracy s_i : $\int_{\nu_i - s_i}^{\nu_i} \psi_i(\nu, \alpha_i, \beta_i) d\nu = \frac{1}{3}$, where $\psi_i(\nu, \alpha_i, \beta_i) = \frac{1}{K} \nu^{\alpha_i} (1 - \nu)^{\beta_i}$, ψ_i is the β-Density Distribution between a codeword x and a class codeword y_i for class c_i, and $\nu \in \mathcal{R} : [0, 1]$.

• Loss-Weighted decoding: $LW(\rho, i) = \sum_{j=1}^{n} M_W(i, j) L(y_i^j \cdot f(\rho, j))$, where $M_W(i, j) = \frac{H(i,j)}{\sum_{j=1}^{n} H(i,j)}$, $H(i, j) = \frac{1}{m_i} \sum_{k=1}^{m_i} \varphi(h^j(\rho_k^i), i, j), \varphi(x^j, i, j) = \begin{cases} 1, & \text{if } x^j = y_i^j, \\ 0, & \text{otherwise.} \end{cases}$, m_i is the number of training samples from class C_i, and ρ_k^i is the kth sample from class C_i.

3. Implementation Details

The ECOCs Library comes with detailed documentation. A user guide describes the usage of the software. All the strategies and parameters used in the functions and files are described in detail. The user guide also presents examples of variable setting and execution, including a demo file.

About the computational complexity, the training and testing time depends on the data size, coding and decoding algorithms, as well as the base classifier used in the ECOC design.

Abstract

Traditional analysis methods for single-trial classification of electro-encephalography (EEG) focus on two types of paradigms: phase-locked methods, in which the amplitude of the signal is used as the feature for classification, that is, event related potentials; and second-order methods, in which the feature of interest is the power of the signal, that is, event related (de)synchronization. The process of deciding which paradigm to use is *ad hoc* and is driven by assumptions regarding the underlying neural generators. Here we propose a method that provides an unified framework for the analysis of EEG, combining first and second-order spatial and temporal features based on a bilinear model. Evaluation of the proposed method on simulated data shows that the technique outperforms state-of-the art techniques for single-trial classification for a broad range of signal-to-noise ratios. Evaluations on human EEG—including one benchmark data set from the Brain Computer Interface (BCI) competition—show statistically significant gains in classification accuracy, with a reduction in overall classification error from 26%-28% to 19%.

Keywords: regularization, classification, bilinear decomposition, neural signals, brain computer interface

1. Introduction

The work presented in this paper is motivated by the analysis of functional brain imaging signals recorded via electroencephalography (EEG). EEG is measured across time and typically at multiple scalp locations, providing a spatio-temporal data set of the underlying neural activity. In addition, these measurements are often taken over multiple repetitions or trials, where trials may differ in the type of stimulus presented, the task given to the subject, or the subject's response. Analysis of these

signals is often expressed as a single-trial classification problem. The goal for the classifier is to determine from the EEG data which stimulus was presented or how the subject responded. Many of these classification techniques were originally developed in the context of Brain Computer Interfaces (BCI) but are now more widely used to interpret activity associated with neural processing.

In the case of BCI algorithms (Wolpaw et al., 2002; Birbaumer et al., 1999; Blankertz et al., 2002, 2003) the aim is to decode brain activity on a single-trial basis in order to provide a direct control pathway between a user's intentions and a computer. Such an interface could provide "locked in patients" a more direct and natural control over a neuroprosthesis or other computer applications (Birbaumer et al., 1999). Furthermore, by providing an additional communication channel for healthy individuals, BCI systems can be used to increase productivity and efficiency in high-throughput tasks (Gerson et al., 2006; Parra et al., 2008).

Single-trial discriminant analysis has also been used as a research tool to study the neural correlates of behavior. By extracting activity that differs maximally between two experimental conditions, the typically low signal-to-noise ratio of EEG can be overcome. The resulting discriminant components can be used to identify the spatial origin and time course of stimulus/response specific activity, while the improved SNR can be leveraged to correlate variability of neural activity across trials to behavioral variability and behavioral performance (Philiastides et al., 2006; Gerson et al., 2006; Philiastides and Sajda, 2006) In essence, discriminant analysis adds to the existing set of multi-variate statistical tools commonly used in neuroscience research (ANOVA, Hoteling T^2, Wilks' Λ test, etc.).

1.1 Traditional EEG Analysis

In EEG the signal-to-noise ratio (SNR) of individual channels is low, often at, or below -20dB. To overcome this limitation, all analysis methods perform some form of averaging, either across repeated trials, across time, or across electrodes. Traditional EEG analysis averages signals across many repeated trials for each individual electrode. Typical in this case is to average the measured potentials following stimulus presentation, thereby canceling uncorrelated noise that is not reproducible from one trial to the next. This averaged activity, called an event related potential (ERP), captures activity that is time-locked to the stimulus presentation but cancels induced oscillatory activity that is not locked in phase to the timing of the stimulus. Alternatively, many studies compute the oscillatory activity in specific frequency bands by filtering and squaring the signal prior to averaging. Induced changes in oscillatory activity are termed event related synchronization or desynchronization (ERS/ERD) Pfurtscheller and da Silva (1999).

Surprisingly, discriminant analysis methods developed thus far by the machine learning community have followed this dichotomy: First order methods in which the amplitude of the EEG signal is considered to be the feature of interest in classification—corresponding to ERP—and second-order methods in which the power of the feature is considered to be of importance for classification—corresponding to ERS/ERD. First order methods include temporal filtering and thresholding (Birbaumer et al., 1999), Fisher linear discriminants (Parra et al., 2005; Blankertz et al., 2002), hierarchical linear classifiers (Gerson et al., 2006) and bilinear discriminant analysis (Dyrholm et al., 2007; Tomioka and Aihara, 2007). Second-order methods include logistic regression with a quadratic term (Tomioka et al., 2007) and the well known common spatial patterns method (CSP) (Ramoser et al., 2000) and its variants: common spatio-spectral patterns (CSSP) (Lemm et al., 2005), and common sparse spectral spatial patterns (CSSSP) (Dornhege et al., 2006).

In the past, the process for choosing features for classification has been *ad hoc* and driven primarily by prior knowledge and/or assumptions regarding the underlying neurophysiology and task. From a machine-learning point of view, it seems limiting to commit *a priori* to only one type of feature. Instead, it would be desirable for the analysis method to extract the relevant neurophysiological activity *de novo* with minimal prior expectations.

In this paper we present a new framework that combines both first and second-order features in the analysis of EEG. Through a bilinear formulation, the method can simultaneously identify spatial linear components as well as temporal modulation of activity. These spatio-temporal components are identified such that their first and second-order statistics are maximally different between two conditions. Further, through the bilinear formulation, the method exploits the spatio-temporal nature of the EEG signals and provides a reduced parametrization of the high dimensional data space. We show that a broad set of state-of-the-art EEG analysis methods can be characterized as special cases under this bilinear framework. Simulated EEG data is then used to evaluate performance of the different methods under varying signal strengths. We conclude the paper with a performance comparison on human EEG. In all instances the performance of the present method is comparable or superior to the existing state-of-the-art.

2. Second-Order Bilinear Discriminant Analysis

To introduce the new method we start by formally defining the classification problem in EEG. We then present the bilinear model, discuss interpretation in the context of EEG, and establish a link to current analysis methods. The section concludes with the optimization criterion and regularization approaches. As the title of this section suggests, we termed our method Second-Order Bilinear Discriminant Analysis (SOBDA).

2.1 Problem Setting

Suppose that we are given examples of brain activity as a set of trials $\{\mathbf{X}_n, y_n\}_{n=1}^N, \mathbf{X}_n \in \mathbb{R}^{D\times T}, y_n \in \{-1,1\}$, where for each example n the matrix $\mathbf{X}_n$ corresponds to the EEG signal with D channels and T time samples and y_n indicates the class to which this example corresponds. The class label may indicated one of two conditions, that is, imagined right or left hand movement, stimulus or non-stimulus control conditions, etc. Given these examples the task is then to predict the class label y for a new trial with data $\mathbf{X}$.

2.2 Second-order Bilinear Model

To solve this problem we propose the following discriminant function

$$f(\mathbf{X};\theta) = C\,\mathrm{Trace}\left(\mathbf{U}^\top\mathbf{X}\mathbf{V}\right) + (1-C)\,\mathrm{Trace}\left(\Lambda\mathbf{A}^\top\mathbf{X}\mathbf{B}\mathbf{B}^\top\mathbf{X}^\top\mathbf{A}\right) + w_o\,, \tag{1}$$

where the parameters are $\theta = \{\mathbf{U}\in\mathbb{R}^{D\times R}, \mathbf{V}\in\mathbb{R}^{T\times R}, \mathbf{A}\in\mathbb{R}^{D\times K}\,\mathbf{B}\in\mathbb{R}^{T\times T'}, w_o\in\mathbb{R}, \Lambda\in diag(K)|\ \lambda_{ii}\in\{-1,+1\}, C\in[0,1]$. Some of these parameters may be specified using prior knowledge as will be discussed later. The scalars R, K and T' are chosen by the user and denote the rank of matrix $\mathbf{U}$,$\mathbf{V}$ $\mathbf{A}$ and $\mathbf{B}$. Typically we use $T' = T$. The goal will be to use the N examples to optimize these parameters such that the discriminant function takes on positive values for examples with $y_n = +1$ and negative values for $y_n = -1$. To accomplish this we will use a standard probabilistic

formalism—logistic regression—which will permit us to incorporate regularization criteria as prior probabilities on the parameter as will be explained in Sections 2.6 and 2.8.

2.3 Interpretation and Rationale of the Model

The discriminant criterion defined in (1) is the sum of a linear and a quadratic term, each combining bilinear components of the EEG signal. The first term can be interpreted as a spatio-temporal projection of the signal that captures the first-order statistics of the signal. Specifically, the columns $\mathbf{u}_r$ of $\mathbf{U}$ represent R linear projections in space (rows of $\mathbf{X}$). Similarly, each of the R columns of $\mathbf{v}_k$ in matrix $\mathbf{V}$ represent linear projections in time (columns of $\mathbf{X}$). By re-writing the term as:

$$\text{Trace}(\mathbf{U}^\top \mathbf{X}\mathbf{V}) = \text{Trace}(\mathbf{V}\mathbf{U}^\top \mathbf{X}) = \text{Trace}(\mathbf{W}^\top \mathbf{X}),$$

where we defined, $\mathbf{W} = \mathbf{U}\mathbf{V}^\top$, it is easy to see that the bilinear projection is a linear combination of elements of $\mathbf{X}$ with a rank-R constraint on $\mathbf{W}$. This expression is linear in $\mathbf{X}$ and thus captures directly the amplitude of the signal. In particular, the polarity of the signal (positive evoked response versus negative evoked response) will contribute to discrimination if it is consistent across trials. This term, therefore, captures phase-locked event related potential in the EEG signal. This bilinear projection reduces the number of model parameters of $\mathbf{W}$ from $D \times T$ dimensions to $R \times (D+T)$ which is a significant dimensionality reduction that alleviates the problem of over-fitting in parameters estimation given the small training set size. This projection assumes that the generators of class-dependent variances in the data have a low-rank contribution to each data matrix $\mathbf{X}$. This holds true in EEG data, where an electrical current source which is spatially static in the brain will give a rank-one contribution to the spatio-temporal $\mathbf{X}$ (Dyrholm and Parra, 2006).

The second term of Equation (1) is the power of spatially and temporally weighted signals and thus captures the second-order statistics of the signal. As before, each column of matrix $\mathbf{A}$ and $\mathbf{B}$ represent components that project the data in space and time respectively. Depending on the structure one enforces in matrix $\mathbf{B}$, different interpretations of the model can be achieved. In the general case where no structure on $\mathbf{B}$ is assumed, the model captures a linear combination of the elements of a rank-T' second-order matrix of the signal $\mathbf{X}\mathbf{B}(\mathbf{X}\mathbf{B})^\top$. In the case where Toeplitz structure is enforced on $\mathbf{B}$ (see Section 2.7), then $\mathbf{B}$ defines a temporal filter on the signal and the model captures powers of the filtered signal. Further, by allowing $\mathbf{B}$ to be learned from the data, we may be able to identify new frequency bands that have so far not been identified in novel experimental paradigms. The spatial weights $\mathbf{A}$ together with the Trace operation ensure that the power is measured, not in individual electrodes, but in some component space that may reflect activity distributed across several electrodes. The diagonal matrix Λ partitions the K spatial components (i.e., K columns of $\mathbf{A}$) into those that contribute power positively and those that contribute power negatively to the total sum. Since each column of $\mathbf{A}$ measures the power from different sources, then by multiplying the expression with Λ we capture the difference in power between different spatial components. As motivation consider the task of distinguishing between imagined left versus right hand movements. It is known that imagining a movement of the left hand reduces oscillatory activity over the motor cortex of the right hemisphere, while an imagined right-hand movement reduces oscillations over the left motor cortex. Each of these cortical areas will be captured by a different spatial distribution in the EEG. If we limit the columns of $\mathbf{A}$ to two, then these columns may capture the power of oscillatory activity over the right and left motor cortex respectively. One would like one of these two terms to contribute positively providing evidence of the observation belonging to the first class,

while the second should contribute negatively, supporting the observations coming from the second class. This can be achieved with the proper choice of Λ. Finally, the parameter C defines a convex combination of the first-order term and the second-order term. $C = 1$ indicates that the discriminant activity is dominated by the first-order features; $C = 0$ indicates that the activity is dominated by second-order features, and any value in between denotes the importance of one component versus the other.

2.4 Incorporating Prior Knowledge into the Model

Realizing that the parameters of the SOBDA model have a physical meaning (i.e., $\mathbf{u}_r$ and $\mathbf{a}_r$ map the sensor signal to a current-source space, $\mathbf{v}_r$ are temporal weight on a source signal and $\mathbf{b}_r$ can be arranged to represent a temporal filter) it becomes intuitive for the experimenter to incorporate prior knowledge of an experimental setup in the model. If the signal of interest is known to be in a specific frequency band, one can fix matrix $\mathbf{B}$ to capture only the desired frequency band. For example, $\mathbf{B}$ can be fixed to a Toeplitz matrix with coefficients corresponding to an 8Hz-12Hz band-pass filter, then the second-order term is able to extract power in the alpha-band which is known to be modulated during motor related tasks. It is often the case that experimenters have a hypothesis about the temporal profile of the signal of interest, for example the P300 signal or the N170 are known EEG responses with a positive peak at 300ms or negative peak at 170ms and are associated with surprise or processing of faces respectively. In such a scenario the experimenter can fix the temporal profile parameter $\mathbf{V}$ to emphasize time samples around the expected location of the peak activity and optimize over the rest of the parameters. The model also provides the ability to integrate information from fMRI studies. fMRI has high spatial resolution and can provide locations within the brain that may be known to participate in the processing during a particular experimental paradigm. This location information can be incorporated into the present model by fixing the spatial parameters $\mathbf{u}_r$ and $\mathbf{a}$ to reflect a localized source (often approximated as a current dipole). The remaining temporal parameters of the model can then be optimized.

2.5 SOBDA as a Generalized EEG Analysis Framework

The present model provides a generic framework that encompasses a number of popular EEG analysis techniques. The following list identifies some of the algorithms and how they relate to the model used in the SOBDA framework:

- Set $C = 1, R = 1$ and choose temporal component $\mathbf{v}$ to select a time window of interest (i.e., set $v_j = 1$ if j is inside the window of interest,$v_j = 0$ otherwise). Learn the spatial filters $\mathbf{u}$. This exactly corresponds to averaging over time and classifying in the sensor space as in Parra et al. (2002, 2005)

- Set $C = 1$ and select some $R > 1$ and choose the component vectors $\mathbf{v}_r$ to select multiple time windows of interest as in 1. Learn for each temporal window the corresponding spatial vector $\mathbf{u}_r$ from examples separately and then combine these components by learning a linear combination of the elements. This corresponds to the multiple window hierarchical classifier as in Gerson et al. (2006) and Parra et al. (2008)

- Set $C = 1, R = D$ while constraining $\mathbf{U}$ to be a diagonal matrix and select, separately for each channel, the time window $\mathbf{v}_r$ which is most discriminative. Then train the diagonal terms of

$\mathbf{U}$ resulting in a latency dependent spatial filter (Luo and Sajda, 2006a). Alternatively, in the first step, use feature selection to find the right set of time windows $\mathbf{v}_r$ simultaneously for all channels (Luo and Sajda, 2006b).

- Set $C = 1$,$R = 1$ and learn the spatial and temporal components $\mathbf{u}, \mathbf{v}$ simultaneously. This reduces to the rank-one bilinear discriminant as in Dyrholm and Parra (2006)

- Select $C = 1$ and some $R > 1$ and learn all columns of the spatial and temporal projection matrix $\mathbf{U}$ and $\mathbf{V}$ simultaneously. This results in the *Bilinear Discriminant Component Analysis (BDCA)* (Dyrholm et al., 2007).

- Set $C = 0$, $K = 2$ and fix $\mathbf{B}$ to a Toeplitz structure encoding a specific frequency band and set the diagonal of Λ to be $[1 - 1]$. Then learn the spatial component $\mathbf{A}$. This then reduces to the logistic regression with a quadratic term (Tomioka et al., 2007) which is related to the Common Spatial Patters (CSP) algorithm of Ramoser et al. (2000).

- Define $\hat{\mathbf{X}}$ to be the concatenation of $\mathbf{X}$ with itself delayed in time by τ samples, where τ is specified by the user, fix $\mathbf{B}$ to a Toeplitz structure, $C = 0$, and $\mathbf{A} \in \mathbb{R}^{2D \times 2}$, learn the matrix $\mathbf{A}$. This configuration can be related to the Common Spatio-Spectral Pattern algorithm of Lemm et al. (2005).

2.6 Logistic Regression

To optimize the model parameters $\mathbf{U}, \mathbf{V}, \mathbf{A}$ and $\mathbf{B}$ we use a Logistic Regression (LR) formalism. The probabilistic formalism is particularly convenient when imposing additional statistical properties on the coefficients such as smoothness or sparseness. In addition, in our experience, linear LR performs well in strongly overlapping high-dimensional data-sets and is insensitive to outliers, the later being of particular concern when including quadratic features.

Under the Logistic Regression model the probability that a trial belongs to class y after seeing data $\mathbf{X}$ is given by the class posterior probability

$$P(y|\mathbf{X};\theta) = \frac{1}{1 + e^{-yf(\mathbf{X};\theta)}}\,.$$

With this definition, the discriminant criterion given by the log-odds ratio of the posterior class probability

$$\log \frac{P(y=+1|\mathbf{X})}{P(y=-1|\mathbf{X})} = f(\mathbf{X};\theta)\,,$$

is simply the discriminant function which we chose to define in (1) as a sum of linear and quadratic terms. The Likelihood of observing the N examples under this model is then given by

$$L(\theta) = -\sum_{n=1}^{N} \log(1 + e^{-y_n f(\mathbf{X}_n;\theta)})\,. \tag{2}$$

Training consists of maximizing this likelihood using a gradient assent algorithm. Analytic gradi-

ents of the log likelihood (2) with respect to the various parameters are given by:

$$\begin{aligned}
\frac{\partial L(\theta)}{\partial \mathbf{u}_r} &= C\sum_{n=1}^{N} y_n \pi_n \mathbf{X}_n \mathbf{v}_r\,, \\
\frac{\partial L(\theta)}{\partial \mathbf{v}_r} &= C\sum_{n=1}^{N} y_n \pi_n \mathbf{u}_r \mathbf{X}_n\,, \\
\frac{\partial L(\theta)}{\partial \mathbf{a}_r} &= 2(1-C)\lambda_r \sum_{n=1}^{N} y_n \pi_n \mathbf{X}_n \mathbf{B}\mathbf{B}^\top \mathbf{X}_n^\top \mathbf{a}_r\,, \qquad (3) \\
\frac{\partial L(\theta)}{\partial \mathbf{b}_t} &= 2(1-C)\sum_{n=1}^{N} y_n \pi_n \mathbf{X}^\top \mathbf{A}\Lambda\mathbf{A}^\top \mathbf{X}\mathbf{b}_t\,, \qquad (4)
\end{aligned}$$

where we define

$$\pi_n = 1 - P(y_n|\mathbf{X}_n) = \frac{e^{-y_n f(\mathbf{X}_n;\theta)}}{1+e^{-y_n f(\mathbf{X}_n;\theta)}}\,,$$

and $\mathbf{u}_i, \mathbf{v}_i, \mathbf{a}_i$ and $\mathbf{b}_i$ correspond to the i_{th} columns of $\mathbf{U}, \mathbf{V}, \mathbf{A}$ and $\mathbf{B}$ respectively.

2.7 Enforcing Structure on B

If matrix $\mathbf{B}$ is constrained to have a circular Toeplitz structure then it can be represented as $\mathbf{B} = \mathbf{F}^{-1}\mathbf{D}\mathbf{F}$, where $\mathbf{F}$ denotes the orthonormal Fourier matrix with $\mathbf{F}^H = \mathbf{F}^{-1}$, and $\mathbf{D}$ is a diagonal complex-valued matrix of Fourier coefficients. In such a case we can re-write Equations (3) and (4) as

$$\begin{aligned}
\frac{\partial L(\theta)}{\partial \mathbf{a}_r} &= 2(1-C)\sum_{n=1}^{N} y_n \pi_n \mathbf{X}_n \mathbf{F}^{\mathrm{H}} \mathbf{D}\mathbf{D}^{\mathrm{H}} \mathbf{F}\mathbf{X}_n^\top \mathbf{a}_r\,. \\
\frac{\partial L(\theta)}{\partial d_i} &= 2(1-C)\sum_{n=1}^{N} y_n \pi_n \left(\mathbf{F}\mathbf{X}_n^\top \mathbf{A}\Lambda\mathbf{A}^\top \mathbf{X}_n \mathbf{F}^{\mathrm{H}}\right)_{ii} d_i\,.
\end{aligned}$$

and the parameters are now optimized with respect to Fourier coefficients $d_i = (\mathbf{D})_{i,i}$. An iterative gradient descent optimization procedure can be used to solve the minimization above.

This way of modeling $\mathbf{B}$ opens up a new perspective on the capabilities of the model. These last two equations are equally applicable for any choice of orthonormal basis $\mathbf{F}$. For example, the columns of $\mathbf{F}$ can represent a set of wavelet basis vectors. We note that a wavelet basis can be thought of as time-frequency representation of the signal; hence, proper selection of a wavelet basis allows for the method to not only capture the stationary power of the signal, but also the local changes in power within the T samples of matrix $\mathbf{X}$.

2.8 Regularization

Due to the high dimensional space in which the model lies and the limited samples available during training (typically in the order of 100), a maximum likelihood estimate of the parameters will over-train the data and have poor generalization performance. To ensure good generalization performance additional regularization criteria are required. The probabilistic formulation of Logistic Regression can incorporate regularization terms as prior probabilities resulting in maximum a posteriori (MAP) estimates.

We choose Gaussian process priors (Rasmussen and Williams, 2005) on the various parameters of the model and ensure smoothness by choosing the proper covariance matrices. Spatial and temporal smoothness is typically a valid assumption in EEG (Penny et al., 2005). Specifically, the spatial components of the model (i.e., columns of $\mathbf{U}$, and $\mathbf{A}$) follow a normal distribution with $\mathbf{u}_i \sim \mathcal{N}(\mathbf{0}, \mathbf{K}_u)$, $\mathbf{a}_i \sim \mathcal{N}(\mathbf{0}, \mathbf{K}_a)$ where the covariance matrices $\mathbf{K}_u$ and $\mathbf{K}_a$ define the degree and form of the smoothness of $\mathbf{u}$ and $\mathbf{a}$. This is done through choice of covariance function: Let r be a spatial or temporal measure in context of $\mathbf{X}$. For instance r is a measure of spatial distance between data acquisition sensors, or a measure of time difference between two samples in the data. Then a covariance function $k(r)$ expresses the degree of correlation between any two points with that given distance. For example, a class of covariance functions that has been suggested for modeling smoothness in physical processes, the Matérn class, is given by:

$$\mathrm{k}_{\text{Matérn}}(r) = \frac{2^{1-\nu}}{\Gamma(\nu)} \left(\frac{\sqrt{2\nu} r}{l} \right)^{\nu} \mathrm{B}\left(\frac{\sqrt{2\nu} r}{1} \right) ,$$

where l is a length-scale parameter, and ν is a shape parameter. Parameter l can be roughly though of as the distance within which points are significantly correlated (Rasmussen and Williams, 2005). The parameter ν defines the degree of ripple. The covariance matrix $\mathbf{K}$ is then built by evaluating the covariance function

$$(\mathbf{K})_{ij} = \sigma^2 \mathrm{k}_{\text{Matérn}}(r_{ij})$$

where $r_{i,j}$ denotes the physical distance of sensor-i from sensor-j, and σ^2 defines the overall scale parameter. Similarly, the Gaussian prior can be used on the columns of the temporal matrix $\mathbf{V}$ (i.e., $mv \sim \mathcal{N}(\mathbf{0}, \mathbf{K}_v)$). The Matérn function was preferred because it allows for a low parametrization of the covariance matrix (two parameters define the entire covariance), but also because of the physical and intuitive interpretation of its parameters. Specifically the parameter l is associated with the physical concept of distance between measurements (either in space or time). This understanding of the parameters is useful since it allows for an educated search strategy in setting the proper values for these parameters.

Regularizing logistic regression amounts to minimizing the negative log-likelihood plus the negative log-priors, which can be written as:

$$\arg \min_{\mathbf{U},\mathbf{V},\mathbf{A},\mathbf{B},w_o} -L(\theta) + \frac{1}{2} \left(\sum_{r=1}^{R} \mathbf{u}_r^\top \mathbf{K}_u^{-1} \mathbf{u}_r + \mathbf{v}_r^\top \mathbf{K}_v^{-1} \mathbf{v}_r + \sum_{k=1}^{K} \mathbf{a}_k^\top \mathbf{K}_a^{-1} \mathbf{a}_k + \sum_{t=1}^{T'} \mathbf{b}_t^\top \mathbf{K}_t^{-1} \mathbf{b}_t \right) , \qquad (5)$$

where we ignored constants that have no effect in the optimization. The covariances of these priors are given by $\mathbf{K}_u, \mathbf{K}_a \in \mathbb{R}^{D \times D}$ and $\mathbf{K}_v, \mathbf{K}_b \in \mathbb{R}^{T \times T}$ and control the smoothness of the parameter space. In the case of the spectral regularization we use the identity matrix for the covariance, $\mathbf{K}_b = \sigma^2 \mathbf{I}$, since the smoothness assumption does not necessarily hold in the spectral domain.

Following Rasmussen and Williams (2005) the shape parameter was chosen to be $\nu = 100$ for the spatial components and $\nu = 2.5$ for the temporal components. Reasonable choices for the length-scale parameter l may be 25ms, 50ms or 100ms and in space 1cm, 2cm, and 3cm. Cross-validation was used to select among these choices. The overall scale parameters σ were chose to be the same for space and time components, but allowed to take on separate values for the first and second order component. We used a line-search procedure in combination with cross-validation to select appropriate values for σ.

2.9 Optimization

Optimization (5) is achieved using a coordinate decent type algorithm (Nielsen, 2005) with parameters $\mathbf{U}, \mathbf{V}$ and $\mathbf{A}, \mathbf{B}$ optimized separately. We obtain analytic expressions for both the gradient and the Hessian of the function, however, in the optimization only the gradient information is used.[1] We first optimize the parameters $\mathbf{U}$ and $\mathbf{V}$, then optimize parameters $\mathbf{A}$ and $\mathbf{B}$ and finally perform a line search to determine the value of C.

Given that the optimization function is non-convex, the gradient decent method only finds local minima. In fact, the performance of SOBDA is particularly sensitive to the starting conditions of the spectral parameter $\mathbf{d}$ (parameter $\mathbf{d}$ enters the model when enforcing a Toeplitz structure on $\mathbf{B}$, see section 2.7.), while it is quite robust to the choice of initial conditions for the remaining parameters $\mathbf{U}$, $\mathbf{V}$ and $\mathbf{A}$. A common technique in global optimization is to use parameter seeding and multiple runs of the optimization procedure. For most parameters it was sufficient to try a few random initial starting points. However, for the spectral parameter we found it important to initialize to a frequency band that was expected to carry useful information, for example, 8Hz-30Hz. Note that the present learning task falls into the class of bi-convex optimization problems for which efficient algorithms have been developed (Floudas, 1997).

3. Results

We evaluated our algorithm on 3300 simulated data sets as well as 6 real EEG recordings, including a data set used in the Brain Computer Interface Competitions II (Blankertz et al., 2004). The simulation aims to quantify the algorithm's performance on a broad spectrum of conditions and various noise levels, as well as to compare the extracted spatial, temporal and frequency components with ground truth. The evaluation on real data set compares the cross-validation performance of the proposed method with three popular methods used in EEG analysis and BCI. Results show that our method outperformed these methods, decreasing the overall classification error rates from 26%-28% to 19%. For the data set of the BCI competition we also report performance results on the independent test set and compare to the previous results.

The three methods we will compare with are Bilinear Discriminant Component Analysis (BDCA) (Dyrholm et al., 2007), Common Spatial Patterns (CSP) (Ramoser et al., 2000), and Matrix Logistic Regression (MLR) (Tomioka et al., 2007). For the evaluation on the 6 real EEG data sets, we further compare our method to the trace norm regularized Matrix Logistic Regression (sMLR) (Tomioka and Aihara, 2007). These may be considered current state-of-the art methods in EEG single-trial analysis. In our evaluation we use a rank one approximation for the BDCA as in Dyrholm et al. (2007). We implemented CSP following the description of Ramoser et al. (2000). We used two spatial patterns (SP) and employ a logistic regression classifier on the resulting SP. In the case of MLR we use the rank-2 approximation as described in the corresponding paper (Tomioka et al., 2007). For sMLR we used the implementation provide in Tomioka and Aihara (2007). Since CSP,MLR and sMLR require the data to be band-pass filtered to the frequency of interest, data sets where filtered in the range of 8Hz-30Hz for these two methods. For our algorithm we use rank-1 for the first-order parameters $\mathbf{U}$ and $\mathbf{V}$ with $R = 1$. For the spatial parameter $\mathbf{A}$ we set $K = 2$ allowing for two spatial patterns, while we enforce a Toeplitz structure on $\mathbf{B}$. We initialize the parameters

1. We discard the Hessian information because of its computational cost and the non-convexity of the optimization function. The Hessian of a non-convex function would need to be approximated by a positive definite matrix in each iteration.

$\mathbf{U}, \mathbf{V}$ and $\mathbf{A}$ by a random assignment. While we initialize the matrix $\mathbf{B}$ to encode a band-pass filter in the range of $8Hz - 30Hz$ as in the case of CSP, MLR, sMLR. As discussed in Section 2.7, enforcing a Toeplitz structure on $\mathbf{B}$ implies a representation of $\mathbf{B}$ in the form $\mathbf{B} = \mathbf{F}^{-1}\mathbf{D}\mathbf{F}$, where $\mathbf{F}$ denotes the orthonormal Fourier matrix with $\mathbf{F}^{\mathrm{H}} = \mathbf{F}^{-1}$, and $\mathbf{D}$ is a diagonal complex-valued matrix of Fourier coefficients. In our implementation, we optimize the coefficients of the matrix $\mathbf{D}$ instead of $\mathbf{B}$ directly.

3.1 Simulated EEG Data

Simulated data for a two-class problem was generated using standard EEG simulation software (GmbH, 2006). This software can generate electrode measurements under the assumption of dipolar current sources in the brain. We used 3 dipoles at three different locations, with one dipole used to generate evoked response activity, one dipole to generate induced oscillatory activity, and one dipole to generate unrelated noise/interference. The first dipole's component simulates a P300 evoked response potential (ERP) signal. We used a half-sinusoid lasting 125ms with the peak positioned at 300ms after trial-onset and a trial-to-trial Gaussian temporal jitter with standard deviation of 10ms. The second dipole's component simulates ERS/ERD in the frequency band of 8Hz to 30Hz. A variable signal in this frequency band was generated by bandpass filtering an uncorrelated Gaussian process. The third dipole was used to generate noise in the source space representing brain activity that is not related to the evoked/induced activity. Electric potentials at $D = 31$ electrode locations were generated corresponding to 500ms of EEG signal sampled at 100Hz ($T = 50$ samples). In addition to this rank-one noise we added noise to each sensor representing other sources of noise (muscle activity, skin potentials, inductive noise, amplifier noise, etc.). All noise sources were white. Trials belonging to the first class ($y_n = +1$) contained the ERP and ERD/ERS source signals scaled appropriately to achieve a specified SNR for each data set. The second class was generated by only including the noise with no ERP or ERD/ERS activity. A data set is specified by indicating the SNR for the ERP component and the SNR for the ERD/ERS component. A total of 500 trials for each class were generated for each classification problem. The SNR of the ERP component is in the range of -33dB to -13dB, and in the range of -22dB to -10dB for the oscillatory component. This is a very broad range in terms of SNR. We note that -20dB translates to the signal being 10 times smaller than the noise. ERP signals are known to be as low as $-20dB$ so this evaluation captures some extreme cases of SNR. We generated 35 data sets for each combination of SNR resulting to a total of 3300 data sets.

3.2 Performance Results on Simulated Data

The simulation results are summarized in Figure 1. The top two rows show the performance of each of the methods as a function of the SNR. The contours of the classification performance for each method as a function of the SNR of the first-order and the second-order components are shown. It is clear that BDCA performance is only affected by the noise in the linear term while CSP and MLR performance only changes as a function of the second-order component's SNR. SOBDA however, uses both first and second-order terms, hence performs well in data sets where at least one of the components has reasonable SNR. This finding confirms that SOBDA performs well in a broader range of SNRs than the other three competitive methods. The third row in 1 shows the difference in classification performance between SOBDA vs (BDCA,CSP,MLR).

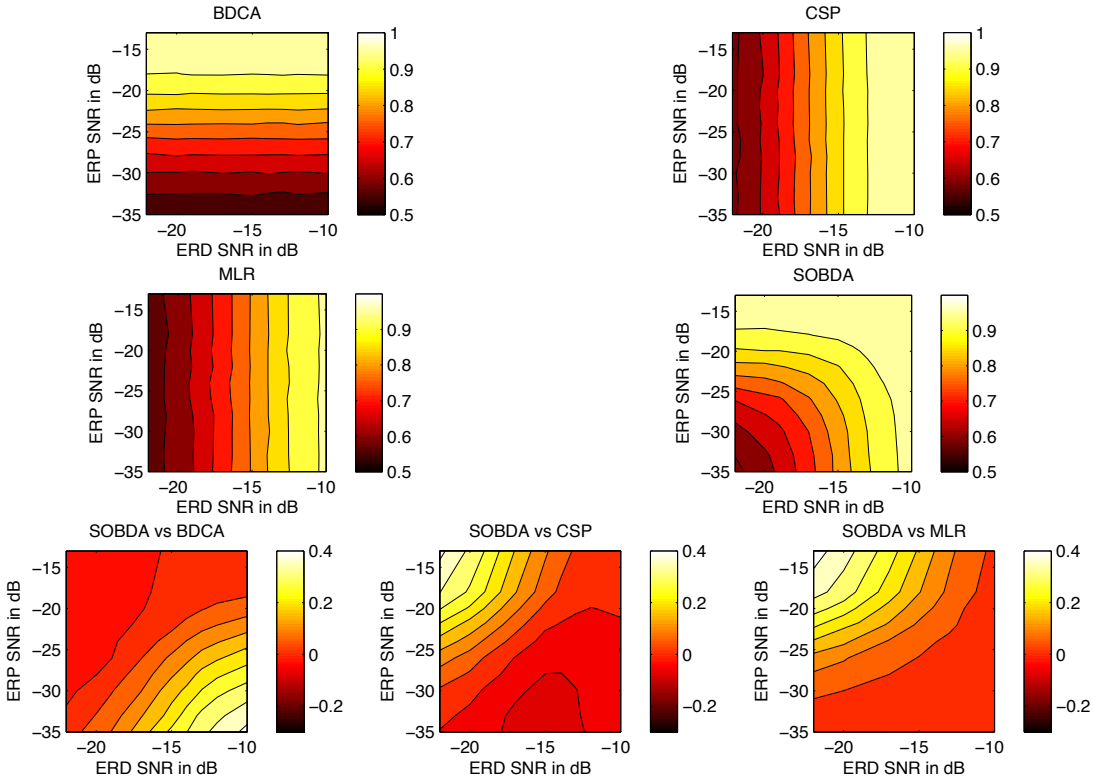

Figure 1: Performance results on simulated data. *Second and third row:* Probability of correct classification (Pc) as a function of the component's SNR. SOBDA equi-performance contours span larger area in the SNR space than any of the other three algorithms. *Third row:* Difference in Pc performance between SOBDA and each of the three methods as a function of components SNR.

As a decomposition method, SOBDA extracts spatial, temporal and frequency components. The advantage of simulated data is that we can now compare the extracted information to ground truth. The component recovered for one of the data sets at $-22dB$ and $-15dB$ is shown in figure 2. The first row shows the extracted temporal component $\mathbf{U}$ and the frequency component $\mathbf{d}$.[2] We can see that the method extracted a temporal component with a peak at 300ms which is exactly the signal used in the simulation data design. Similarly, the frequency band extracted shows a higher amplitude in the range of 8Hz-30Hz which is the band used to generate the oscillatory component. The spatial components extracted and the corresponding dipole used in the model generation are shown in rows two and three in the figure. It is clear that the topography of the extracted components is similar for the first and second-order components. The last column of the figure captures the second-order oscillatory component and the dipole of the rank one noise. Visual inspection allows one to give neurological interpretations to the extracted components. Further, the results can be used as input to

2. $\mathbf{d}$ the vector of diagonal elements of matrix $\mathbf{D}$, such that $\mathbf{B} = \mathbf{F}^{\mathrm{H}}\mathbf{D}\mathbf{F}$

a source localization algorithm, or as a guide to reduce the number of electrodes in a brain computer interface.

3.2.1 GENERIC INITIALIZATION OF FREQUENCY COMPONENT

In the evaluation presented above, we initialized the matrix $\mathbf{B}$ to encode a band-pass in the range of 8Hz - 30Hz as it was the case for CSP and MLR. In this section we demonstrate the ability of the proposed SOBDA in cases where no initialization information is available. Specifically, we evaluated the SOBDA algorithm on a simulated data set using the process described above, but this time we initialize matrix B to a high-pass filter with cut of frequency at 1 Hz. High pass filtering is a standard preprocessing steps in EEG that removes the DC power. Figure 3 shows the temporal and frequency component obtained from SOBDA. As it is evident from the figure, the resulting frequency component has higher weights for frequencies in the band 8Hz-30Hz, which is the band used to generate the power component in the simulated data. Thus the proposed method is able optimize the frequency band even in cases where we use a generic initialization of the matrix $\mathbf{B}$.

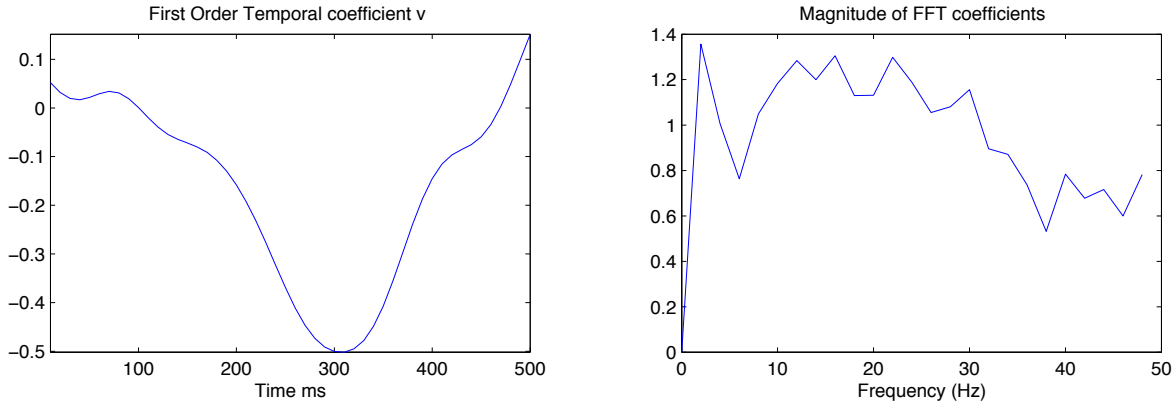

Figure 3: Discriminant coefficients on simulated data set with first-order SNR at $-22dB$ and second-order SNR at $-15dB$. The Fourier coefficients were initialized to a high-pass filter with cut off frequency at 1 Hz *Left figure:* Extracted temporal weight of linear term.*Right figure:* Magnitude of the Fourier coefficients in $\mathbf{D}$, such that $\mathbf{B} = \mathbf{F}^{\mathrm{H}}\mathbf{D}\mathbf{F}$.

3.3 Human Subject EEG

To evaluate the performance of the proposed method on real data we first applied the algorithm to an EEG data set that was made available through The BCI Competition 2003 (Blankertz et al., 2004, Data Set IV). EEG was recorded on 28 channels for a single subject performing "self-paced key typing", that is, pressing with the index and little fingers corresponding keys in a self-chosen order and timing. Key-presses occurred at an average speed of 1 key per second. Trial matrices were extracted by epoching the data starting 630ms before each key-press. A total of 416 epochs were recorded, each of length 500ms. For the competition, the first 316 epochs were used for classifier training, while the remaining 100 epochs were used as a test set. Data was recorded at 1000Hz with a pass-band between 0.05 and 200Hz, then down sampled to 100Hz sampling rate.

For this experiment, the matrix $\mathbf{B}$ was fixed to a Toeplitz structure that encodes a 10Hz-33Hz bandpass filter and only the parameters $\mathbf{U}, \mathbf{V}, \mathbf{A}$ and w_0 were trained. The number of columns of $\mathbf{U}$ and $\mathbf{V}$ were set to $R = 1$ and the number of columns for $\mathbf{A}$ was set to $K = 2$. The selection of these parameters is motivated by the task at hand. Specifically, we are looking for one ERP components associated with the *readiness* potential that is, the slow increase in amplitude before an actual hand movement. In the case of the second-order term involving the parameter $\mathbf{A}$ we set $K = 2$ because we are interested in finding the modulation of oscillatory activity associated with the different movements of the movements of the hands. Hands and fingers are represented in somato-sensory cortex covering different areas and will hence modulate activity in distinct spatial profiles. In order to detect the power difference of these two components we set, $\Lambda = [1,0;0,-1]$, in agreement with the original approach of Wolpaw et al. (2002).

The temporal filter was selected based on prior knowledge of the relevant frequency band. This demonstrates the flexibility of our approach to either incorporate prior knowledge when available or extract it from data otherwise. Regularization parameters where chosen via a five fold-cross validation procedure as described in Section 2.8.

Benchmark performance was measured on the test set which had not been used during either training or cross-validation. The number of misclassified trials in the test set was 13 which places

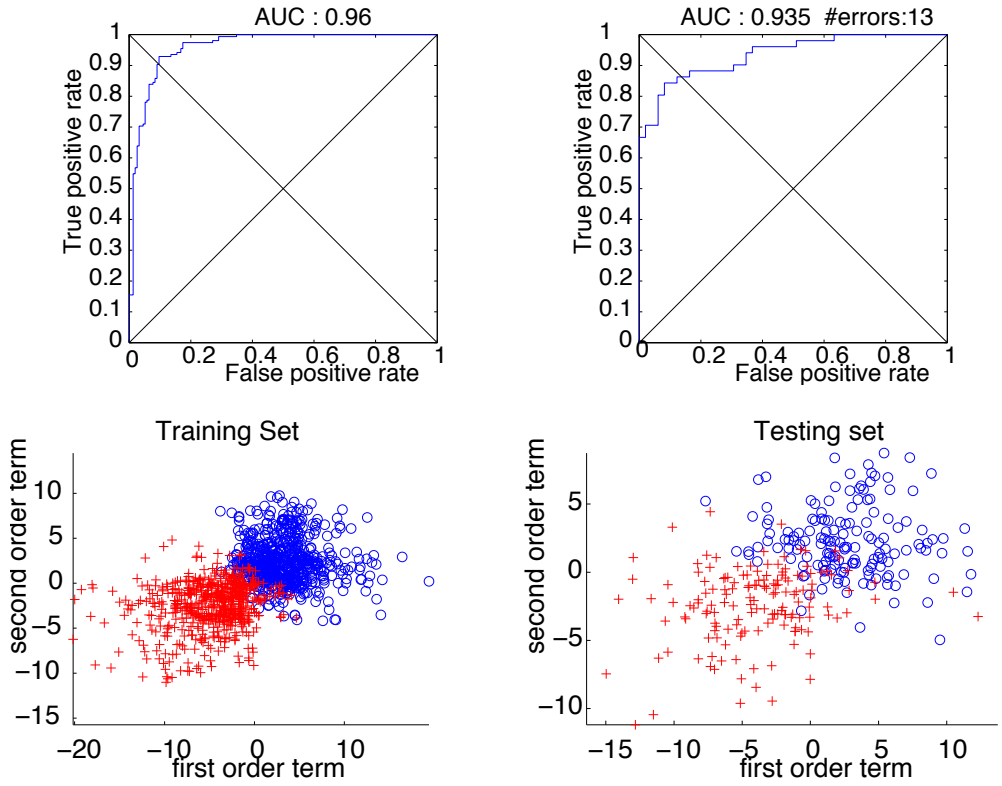

Figure 4: Results on human EEG for BCI. *Top row:* Cross-validation performance shown as ROC curve with area under the curve of 0.96 for the benchmark data set (left) and 0.93 for the independent test set (right). There were a total of 13 errors on unseen data, which is less than any of the results previously reported. *Bottom row:* Scatter plot of the first-order term vs second-order term of the model, on the training and testing set for the benchmark data set ('+' left key, and 'o' right key). It is clear that the two types of features contain independent information that can help improve the classification performance.

our method in a new first place ranking, based on the results of the competition (Blankertz et al., 2004). The receiver-operator characteristic curve (ROC) for cross-validation and for the independent test set are shown in Figure 4. The Figure also shows the contribution of the linear and quadratic terms for every trial for the two types of key-presses.

To further validate our method we performed our own EEG recordings asking subjects now to respond with the left and right index fingers. We obtain five more data sets with the same number of electrodes. For each data set and each algorithm we performed 20 repetitions of a five-fold cross-validation procedure. Each repetition uses a different partitioning of the data. For the cross-validation evaluation of these data sets, we initialized (but did not fix) matrix $\mathbf{B}$ to a Toeplitz structure that encodes a 10Hz-33Hz bandpass filter and trained over all parameters $\mathbf{U}, \mathbf{V}, \mathbf{A}, \mathbf{B}$ and w_0.[3] The number of columns of $\mathbf{U}$ and $\mathbf{V}$ were set to 1, where two columns were used for $\mathbf{A}$. This corresponds to the parameter configuration of $R = 1, K = 2$ and $T' = T$.

3. We remind the reader that in the actual implementation we optimize the Fourier coefficients $\mathbf{D}$ instead of matrix $\mathbf{B}$

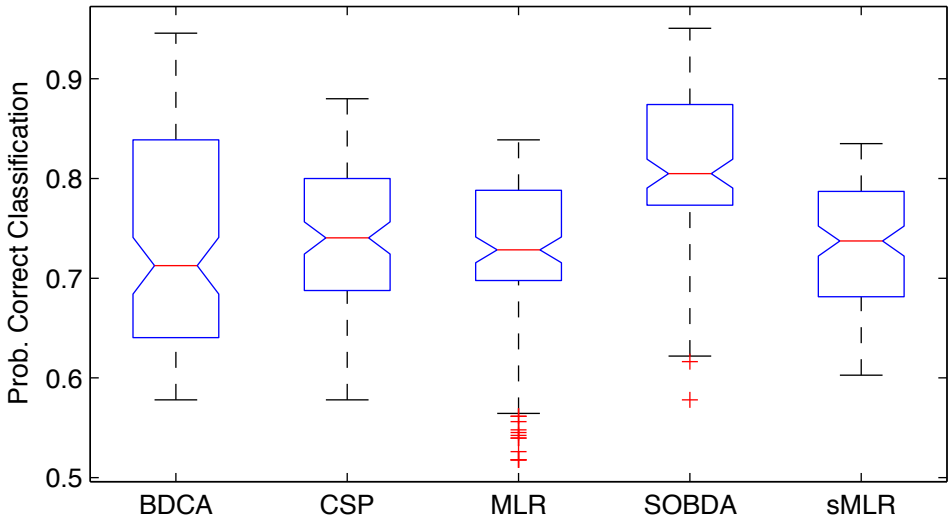

Figure 5: Estimate of the spread of the probability of correct identification from multiple cross-validation repetitions. Lines show lower quartile, median, and upper quartile values for each of the methods on all data sets. + symbols represent outliers.

Figure 5 shows performance distribution across these bootstrap repetitions using a standard boxplot. The mean performance and standard deviation of each data set and algorithm are summarized in table 1. The reduction in the overall classification error is from 26%-28% to 19%. In the mean, SOBDA outperforms competitive methods in five out of the six data sets, while achieving a comparable performance on data set 2. The performance optained with SOBDA is comparable to performance gains that may be obtained by combining existing first and second order methods (e.g., CSP and BDCA—data not shown).

Figure 6 shows the extracted components for 3 of the 6 data sets. We note that in all three cases the extracted components follow the general shape of the pre-motor or readiness potential (a.k.a. Bereitschafts potential) which known to precede a voluntary muscle movement. In addition, for two of the data sets, the frequency weightings suggest that alpha band activity also provides discriminant information for this task. This finding is consistent with the changes in the μ rhythm—that is, alpha-band activity localized over the motor cortex and associated with motor planning and execution. This demonstrates the ability of our method to learn first and second-order features that are consistent with, and can be linked to existing knowledge of the underlying neuronal signal generators.

Experiment	BDCA	CSP	MLR	SOBDA	sMLR
1	0.84 ± 0.011	0.8 ± 0.017	0.82 ± 0.011	$\mathbf{0.88 \pm 0.013}$	0.78 ± 0.0089
2	0.69 ± 0.037	$\mathbf{0.84 \pm 0.017}$	0.77 ± 0.028	0.83 ± 0.021	0.82 ± 0.012
3	$\mathbf{0.63 \pm 0.018}$	0.62 ± 0.016	0.55 ± 0.02	$\mathbf{0.63 \pm 0.017}$	0.62 ± 0.015
4	0.72 ± 0.021	0.78 ± 0.015	0.77 ± 0.015	$\mathbf{0.79 \pm 0.018}$	0.76 ± 0.021
5	0.64 ± 0.018	0.7 ± 0.022	0.7 ± 0.011	$\mathbf{0.78 \pm 0.013}$	0.73 ± 0.0097
6	0.93 ± 0.01	0.7 ± 0.016	0.72 ± 0.01	$\mathbf{0.94 \pm 0.0089}$	0.68 ± 0.0056
Mean	0.7412	0.7388	0.7213	0.8068	0.7316

Table 1: Probability of correct identification for the six EEG data sets obtained by each of the four methods. The last row indicates the percentage of decrease in the classification error achieved by SOBDA compared to each one of the methods. $\pm$ range indicates one standard deviation for results of multiple cross-validation repetitions.

4. Rank-Selection

In our results, we selected the rank for the parameters $\mathbf{U}$ and $\mathbf{V}$ to be one (i.e., $R = 1$) and the rank for the parameter $\mathbf{A}$ to be two (i.e., $K = 2$). The selection of these parameters was motivated in Section 3.3. Specifically, in the current experimental paradigm, we are looking for one ERP components associated with the *readiness* potential, that is, the slow increase in amplitude before an actual hand movement. The search for a single component suggests setting $R = 1$, one spatio-temporal component. In the case of the second-order term involving the parameter $\mathbf{A}$ we set the $K = 2$ because we are interested in finding two components corresponding to the two different spatial profiles of the two classes. To validate our selection for these parameters, we preformed repeated cross-validation evaluation of our algorithm for different configurations of the parameters R and K. The parameter R was tested for values $\{1,2,3,4\}$ while parameter K was tested for $\{2,4\}$. The results of this evaluation are summarized in Figure 7. The Figure 7.a shows the mean cross-validation performance of the SOBDA algorithm across all real-EEG data sets for all configurations of the parameters R and K. It is evident from this figure that configuration $R = 1, K = 2$ corresponds to the best selection for these parameters on average for these data sets. The Figure 7.b shows the cross-validation performance of the SOBDA algorithm for each data set separately and for all configuration of the parameters R and K. The cross-validation procedure can be used to determine or validate the configuration of parameters R and K in cases were no prior knowledge is available about the signal of interest.

5. Conclusion

In this paper we presented a new method called Second-Order Bilinear Discriminant Analysis (SOBDA) for analyzing EEG signals on a single-trial basis. The method combines linear and quadratic features thus encompassing and extending a number of existing EEG analysis methods. We evaluated the SOBDA algorithm in both simulated and real human EEG data sets. We show a reduction in the classification error on human EEG when comparing our method to the state-of-the-art. The results on simulated data characterize the operational range of these algorithms in terms of SNR and shows that the proposed algorithm operates well where other methods fail. The parametrization

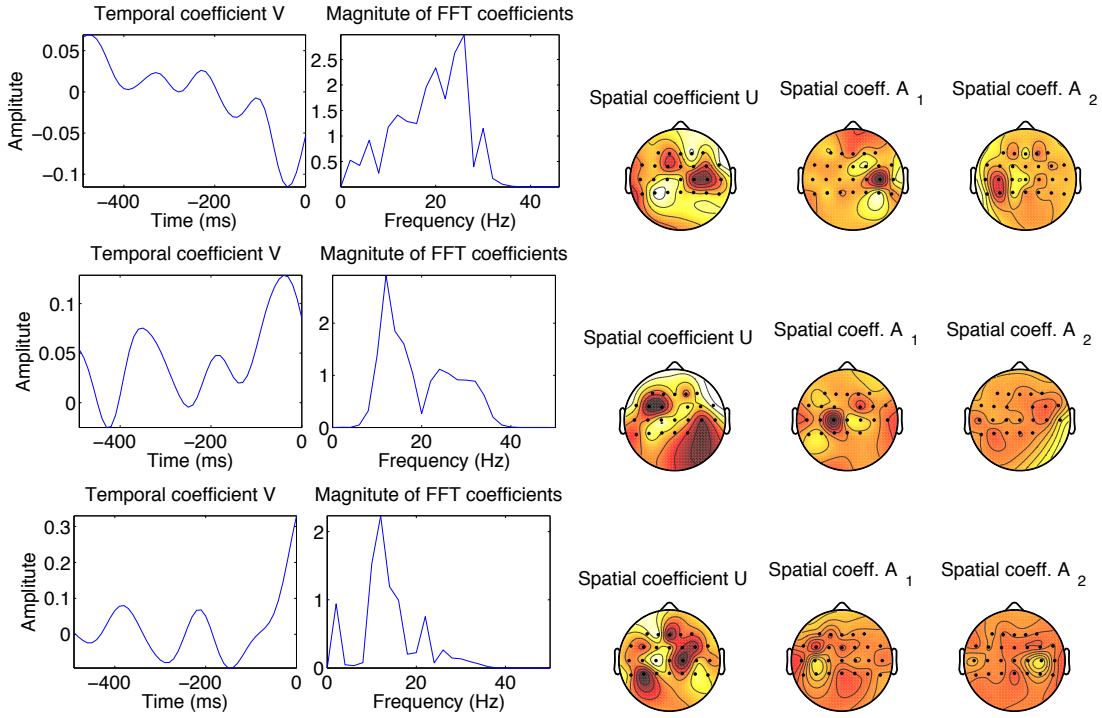

Figure 6: Extracted components in EEG for data sets 6, 4, and 3. *Left:* Temporal weights of linear component (first column) and and frequency weights of quadratic component (second column). *Right:* Spatial weights of linear component (third column) and two spatial weights for second-order spatial components (fourth and fifth column).

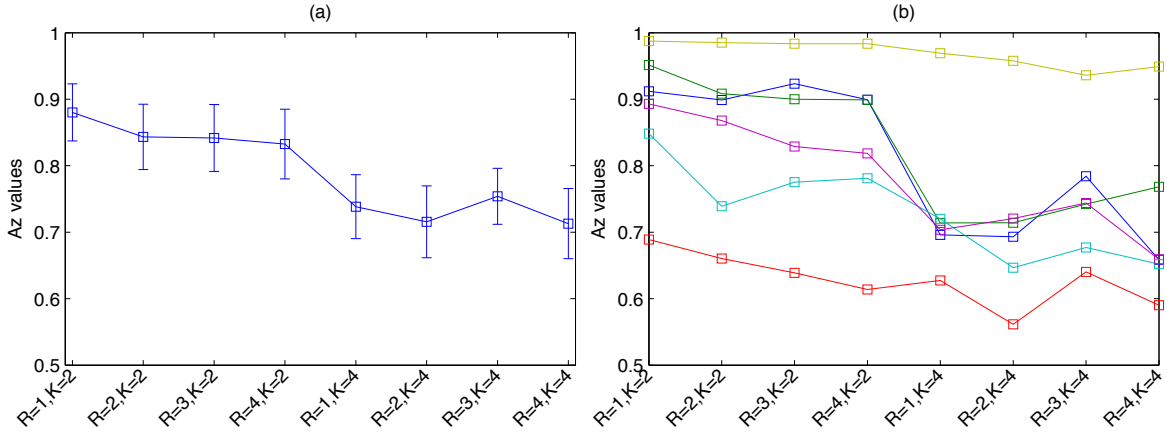

Figure 7: Cross-validation performance of SOBDA on the six real-EEG data sets used in the evaluation, at various configuration of the parameters R and K. of the discriminant criterion is intuitive, allowing one to incorporate prior knowledge as well as to derive spatial, temporal, and spectral information about the underlying neurological activity.

6. Derivations

In this section we derive the analytic gradient formulas of the negative log-likelihood function defined in (2). In general the gradient with respect to any of the variables can be expressed as:

$$\begin{aligned}\frac{\partial L(\theta)}{\partial \theta} &= -\sum_{n=1}^{N} \frac{\partial \log(1+e^{-y_n f(\mathbf{X}_n;\theta)})}{\partial \theta} \\ &= -\sum_{n=1}^{N} \frac{1}{1+e^{-y_n f(\mathbf{X};\theta)}} \frac{\partial\{1+e^{-y_n f(\mathbf{X}_n;\theta)}\}}{\partial \theta} \\ &= \sum_{n=1}^{N} y_n \frac{e^{-y_n f(\mathbf{X};\theta)}}{1+e^{-y_n f(\mathbf{X};\theta)}} \frac{\partial f(\mathbf{X}_n;\theta)}{\partial \theta},\end{aligned}$$

Now one has to take the specific derivatives with respect to each of the variables in θ is:

The gradient with respect to $\mathbf{u}_r$, the rth column of $\mathbf{U}$.

$$\begin{aligned}\frac{\partial\{f(\mathbf{X}_n;\theta)+w0\}}{\partial \mathbf{u}_r} &= C\frac{\partial\{\mathrm{Trace}\,\mathbf{U}^\top \mathbf{X}_n \mathbf{V}\}}{\partial \mathbf{u}_r} \\ &= C\frac{\partial\{\sum_{r'=1}^{R} \mathbf{u}_{r'}^\top \mathbf{X}_n \mathbf{v}_{r'}\}}{\partial \mathbf{u}_r} \\ &= C\mathbf{X}_n \mathbf{v}_r\,.\end{aligned}$$

The gradient with respect to $\mathbf{v}_r$, the *rth* column of $\mathbf{V}$ is:

$$\begin{aligned}\frac{\partial\{f(\mathbf{X}_n;\theta)+w0\}}{\partial \mathbf{v}_r} &= C\frac{\partial\{\mathrm{Trace}\,\mathbf{U}^\top \mathbf{X}_n \mathbf{V}\}}{\partial \mathbf{v}_r} \\ &= C\frac{\partial\{\sum_{r'=1}^{R} \mathbf{u}_{r'}^\top \mathbf{X}_n \mathbf{v}_{r'}\}}{\partial \mathbf{v}_r} \\ &= C\mathbf{u}_r^\top \mathbf{X}_n\,.\end{aligned}$$

The gradient with respect to $\mathbf{a}_r$, the *rth* column of $\mathbf{A}$ is:
