We examined the following methods: principal component analysis—PCA (Jolliffe, 2002), independent component analysis—ICA (Hyvärinen and Oja, 2000), stochastic neighbor embedding—SNE (Hinton and Roweis, 2003), isomap (Tenenbaum et al., 2000), and diffusion maps (Lafon and Lee, 2006; Nadler et al., 2006). Figure 10 depicts the relationship between the percentage of the original number of features maintained by the DR methods and S_{N_k}, for several high-dimensional real data sets (musk1, mfeat-factors, and spectrometer; see Table 1) and i.i.d. uniform random data (with Euclidean distance, $k = 10$, and the same number of neighbors used for isomap and diffusion maps). For PCA, ICA, SNE, and the real data sets, looking from right to left, S_{N_k} stays relatively constant until a small percentage of features is left, after which it suddenly drops (Figure 10(a–c)). It can be said that this is the point where the intrinsic dimensionality of data sets is reached, and further reduction of dimensionality may incur loss of valuable information. Such behavior is in contrast with the case of i.i.d. uniform random data (full black line in Figure 10(a–c)), where S_{N_k} steadily and steeply reduces with the decreasing number of randomly selected features (dimensionality reduction is not meaningful in this case), because intrinsic and embedded dimensionalities are equal. Since PCA is equivalent to metric multidimensional scaling (MDS) when Euclidean distances are used (Tenenbaum et al., 2000), and SNE is a variant of MDS which favors the preservation of distances between nearby points, we can roughly regard the notion of intrinsic dimensionality used in this paper as the minimal number of features needed to account for all *pairwise distances* within a data set. Although ICA does not attempt to explicitly preserve pairwise distances, combinations of independent components produce skewness of N_k which behaves in a way that is similar to the skewness observed with PCA and SNE.

On the other hand, isomap and diffusion maps replace the original distances with distances derived from a neighborhood graph. It can be observed in Figure 10(d,e) that such replacement generally reduces S_{N_k}, but in most cases does not alleviate it completely. With the decreasing number of features, however, S_{N_k} of real data sets in Figure 10(d,e) still behaves in a manner more similar to S_{N_k} of real data sets for PCA, ICA, and SNE (Figure 10(a–c)) than i.i.d. random data (dash-dot black line in Figure 10(d,e)).

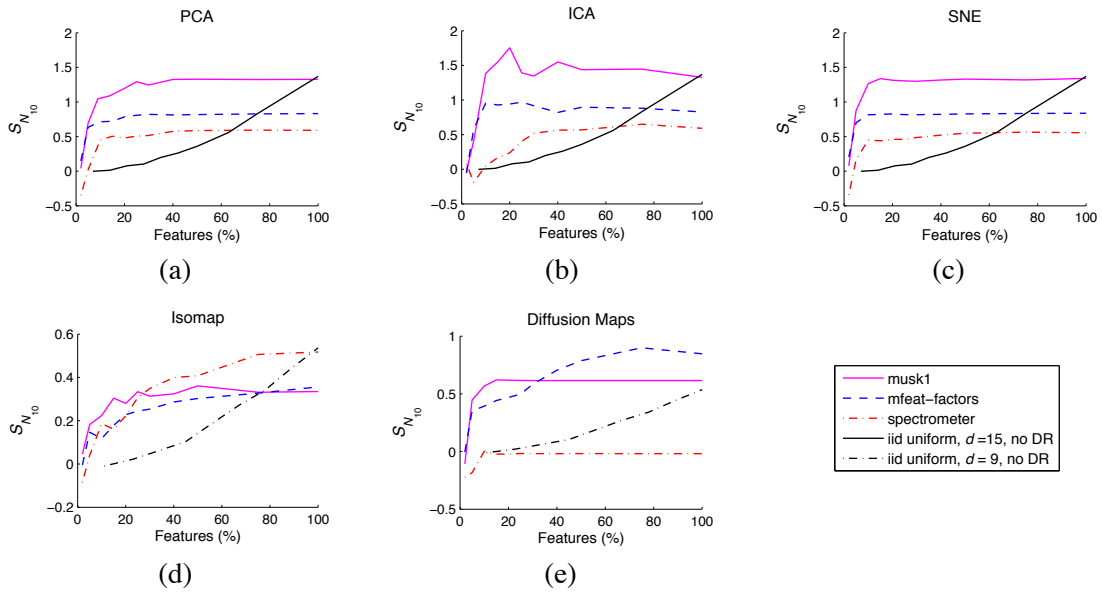

Figure 10: Skewness of N_{10} in relation to the percentage of the original number of features maintained by dimensionality reduction, for real and i.i.d. uniform random data and (a) principal component analysis—PCA, (b) independent component analysis—ICA, (c) stochastic neighbor embedding—SNE, (d) isomap, and (e) diffusion maps.

The above observations signify that, if distances are not explicitly altered (as with isomap and diffusion maps DR methods), that is, if one cares about preserving the original distances, dimensionality reduction may not have a significant effect on hubness when the number of features is above the intrinsic dimensionality. This observation is useful in most practical cases because if dimensionality is reduced below intrinsic dimensionality, loss of information can occur. If one still chooses to apply aggressive dimensionality reduction and let the resulting number of features fall below intrinsic dimensionality, it can be expected of pairwise distances and nearest-neighbor relations between points in the data set to be altered, and hubness to be reduced or even lost. Whether these effects should be actively avoided or sought really depends on the application domain and task at hand, that is, whether and to what degree the original pairwise distances represent valuable information, and how useful are the new distances and neighborhoods after dimensionality reduction.

7. The Impact of Hubness on Machine Learning

The impact of hubness on machine-learning applications has not been thoroughly investigated so far. In this section we examine a wide range of commonly used machine-learning methods for supervised (Section 7.1), semi-supervised (Section 7.2), and unsupervised learning (Section 7.3), that either directly or indirectly use distances in the process of building a model. Our main objective is to demonstrate that hubs (as well as their opposites, antihubs) can have a significant effect on these methods. The presented results highlight the need to take hubs into account in a way equivalent to other factors, such as the existence of outliers, the role of which has been well studied.

7.1 Supervised Learning

To investigate possible implications of hubness on supervised learning, we first study the interaction of k-occurrences with information provided by labels (Section 7.1.1). We then move on to examine the effects of hubness on several well-known classification algorithms in Section 7.1.2.

7.1.1 "GOOD" AND "BAD" k-OCCURRENCES

When labels are present, k-occurrences can be distinguished based on whether labels of neighbors match. We define the number of *"bad" k-occurrences* of $\mathbf{x}$, $BN_k(\mathbf{x})$, as the number of points from data set D for which $\mathbf{x}$ is among the first k NNs, and the labels of $\mathbf{x}$ and the points in question *do not match*. Conversely, $GN_k(\mathbf{x})$, the number of *"good" k-occurrences* of $\mathbf{x}$, is the number of such points where labels do match. Naturally, for every $\mathbf{x} \in D$, $N_k(\mathbf{x}) = BN_k(\mathbf{x}) + GN_k(\mathbf{x})$.

To account for labels, Table 1 includes $\widetilde{BN}_{10}$ (14th column), the sum of all observed "bad" k-occurrences of a data set normalized by $\sum_{\mathbf{x}} N_{10}(\mathbf{x}) = 10n$. This measure is intended to express the total amount of "bad" k-occurrences within a data set. Also, to express the amount of information that "regular" k-occurrences contain about "bad" k-occurrences in a particular data set, $C_{BN_{10}}^{N_{10}}$ (15th column) denotes the Spearman correlation between BN_{10} and N_{10} vectors. The motivation behind this measure is to express the degree to which BN_k and N_k follow a similar distribution.

"Bad" hubs, that is, points with high BN_k, are of particular interest to supervised learning because they carry more information about the location of the decision boundaries than other points, and affect classification algorithms in different ways (as will be described in Section 7.1.2). To understand the origins of "bad" hubs in real data, we rely on the notion of the *cluster assumption* from semi-supervised learning (Chapelle et al., 2006), which roughly states that most pairs of points in a high density region (cluster) should be of the same class. To measure the degree to which the cluster assumption is violated in a particular data set, we simply define the *cluster assumption violation* (CAV) coefficient as follows. Let a be the number of pairs of points which are in different classes but in the same cluster, and b the number of pairs of points which are in the same class and cluster. Then, we define

$$\mathrm{CAV} = \frac{a}{a+b},$$

which gives a number in the $[0,1]$ range, higher if there is more violation. To reduce the sensitivity of CAV to the number of clusters (too low and it will be overly pessimistic, too high and it will be overly optimistic), we choose the number of clusters to be 3 times the number of classes of a particular data set. Clustering is performed with K-means.

For all examined real data sets, we computed the Spearman correlation between the total amount of "bad" k-occurrences, $\widetilde{BN}_{10}$, and CAV (16th column of Table 1) and found it strong (0.85, see Table 2). Another significant correlation (0.39) is observed between $C_{BN_{10}}^{N_{10}}$ and intrinsic dimensionality. In contrast, $\widetilde{BN}_{10}$ and CAV are not correlated with intrinsic dimensionality nor with the skewness of N_{10}. The latter fact indicates that high dimensionality and skewness of N_k are not sufficient to induce "bad" hubs. Instead, based on the former fact, we can argue that there are two, mostly independent, forces at work: violation of the cluster assumption on one hand, and high intrinsic dimensionality on the other. "Bad" hubs originate from putting the two together; that is, the consequences of violating the cluster assumption can be more severe in high dimensions than in low dimensions, not in terms of the total amount of "bad" k-occurrences, but in terms of their distribution, since strong regular hubs are now more prone to "pick up" bad k-occurrences than non-hub points. This is supported by

the positive correlation between $C_{BN_{10}}^{N_{10}}$ and intrinsic dimensionality, meaning that in high dimensions BN_k tends to follow a more similar distribution to N_k than in low dimensions.

7.1.2 INFLUENCE ON CLASSIFICATION ALGORITHMS

We now examine how skewness of N_k and the existence of ("bad") hubs affects well-known classification techniques, focusing on the k-nearest neighbor classifier (k-NN), support vector machines (SVM), and AdaBoost. We demonstrate our findings on a selection of data sets from Table 1 which have relatively high (intrinsic) dimensionality, and a non-negligible amount of "badness" ($\widetilde{BN}_k$) and cluster assumption violation (CAV). Generally, the examined classification algorithms (including semi-supervised learning from Section 7.2) exhibit similar behavior on other data sets from Table 1 with the aforementioned properties, and also with various different values of k (in the general range 1–50, as we focused on values of k which are significantly smaller than the number of points in a data set).

k-nearest neighbor classifier. The k-nearest neighbor classifier is negatively affected by the presence of "bad" hubs, because they provide erroneous class information to many other points. To validate this assumption, we devised a simple weighting scheme. For each point $\mathbf{x}$, we compute its standardized "bad" hubness score:

$$h_B(\mathbf{x},k) = \frac{BN_k(\mathbf{x}) - \mu_{BN_k}}{\sigma_{BN_k}},$$

where μ_{BN_k} and σ_{BN_k} are the mean and standard deviation of BN_k, respectively. During majority voting in the k-NN classification phase, when point $\mathbf{x}$ participates in the k-NN list of the point being classified, the vote of $\mathbf{x}$ is weighted by

$$w_k(\mathbf{x}) = \exp(-h_B(\mathbf{x},k)),$$

thus lowering the influence of "bad" hubs on the classification decision. Figure 11 compares the resulting accuracy of k-NN classifier with and without this weighting scheme for six data sets from Table 1. Leave-one-out cross-validation is performed, with Euclidean distance being used for determining nearest neighbors. The k value for N_k is naturally set to the k value used by the k-NN classifier, and $h_B(\mathbf{x},k)$ is recomputed for the training set of each fold. The reduced accuracy of the unweighted scheme signifies the negative influence of "bad" hubs.

Although "bad" hubs tend to carry more information about the location of class boundaries than other points, the "model" created by the k-NN classifier places the emphasis on describing non-borderline regions of the space occupied by each class. For this reason, it can be said that "bad" hubs are truly bad for k-NN classification, creating the need to penalize their influence on the classification decision. On the other hand, for classifiers that explicitly model the borders between classes, such as support vector machines, "bad" hubs can represent points which contribute information to the model in a positive way, as will be discussed next.

Support vector machines. We consider SVMs with the RBF (Gaussian) kernel of the form:

$$K(\mathbf{x},\mathbf{y}) = \exp\left(-\gamma\|\mathbf{x}-\mathbf{y}\|^2\right),$$

where γ is a data-dependent constant. $K(\mathbf{x},\mathbf{y})$ is a smooth monotone function of Euclidean distance between points. Therefore, N_k values in the kernel space are exactly the same as in the original

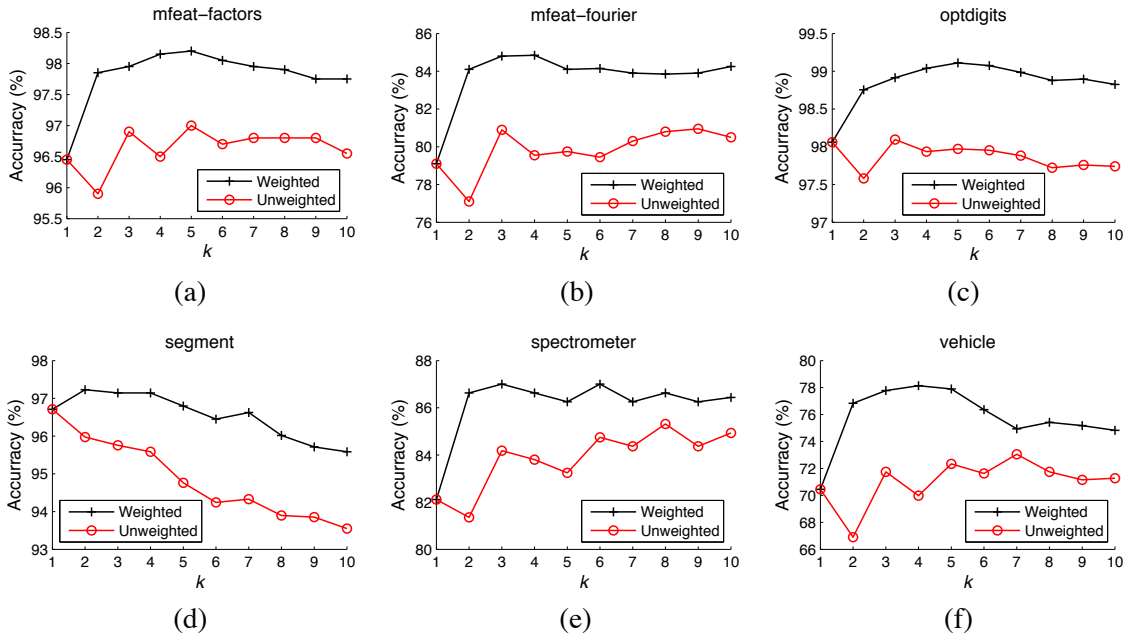

Figure 11: Accuracy of k-NN classifier with and without the weighting scheme.

space.[22] To examine the influence of "bad" hubs on SVMs, Figure 12 illustrates 10-fold cross-validation accuracy results of SVM trained using sequential minimal optimization (Platt, 1999; Keerthi et al., 2001), when points are progressively removed from the training sets: (i) by decreasing BN_k ($k = 5$), and (ii) at random. Accuracy drops with removal by BN_k, indicating that bad hubs are important for support vector machines. The difference in SVM accuracy between random removal and removal by BN_k becomes consistently significant at some stage of progressive removal, as denoted by the dashed vertical lines in the plots, according to the paired t-test at 0.05 significance level.[23]

The reason behind the above observation is that for high-dimensional data, points with high BN_k can comprise good support vectors. Table 3 exemplifies this point by listing the normalized average ranks of support vectors in the 10-fold cross-validation models with regards to decreasing BN_k. The ranks are in the range $[0,1]$, with the value 0.5 expected from a random set of points. Lower values of the ranks indicate that the support vectors, on average, tend to have high BN_k. The table also lists the values of the γ parameter of the RBF kernel, as determined by independent experiments involving 9-fold cross-validation.

AdaBoost. Boosting algorithms take into account the "importance" of points in the training set for classification by weak learners, usually by assigning and updating weights of individual points—the higher the weight, the more attention is to be paid to the point by subsequently trained weak learners. We consider the AdaBoost.MH algorithm (Schapire and Singer, 1999) in conjunction with

22. Centering the kernel matrix changes the N_k of points in the kernel space, but we observed that the overall distribution (that is, its skewness) does not become radically different. Therefore, the following arguments still hold for centered kernels, providing N_k is computed in the kernel space.
23. Since random removal was performed in 20 runs, fold-wise accuracies for statistical testing were obtained in this case by averaging over the runs.

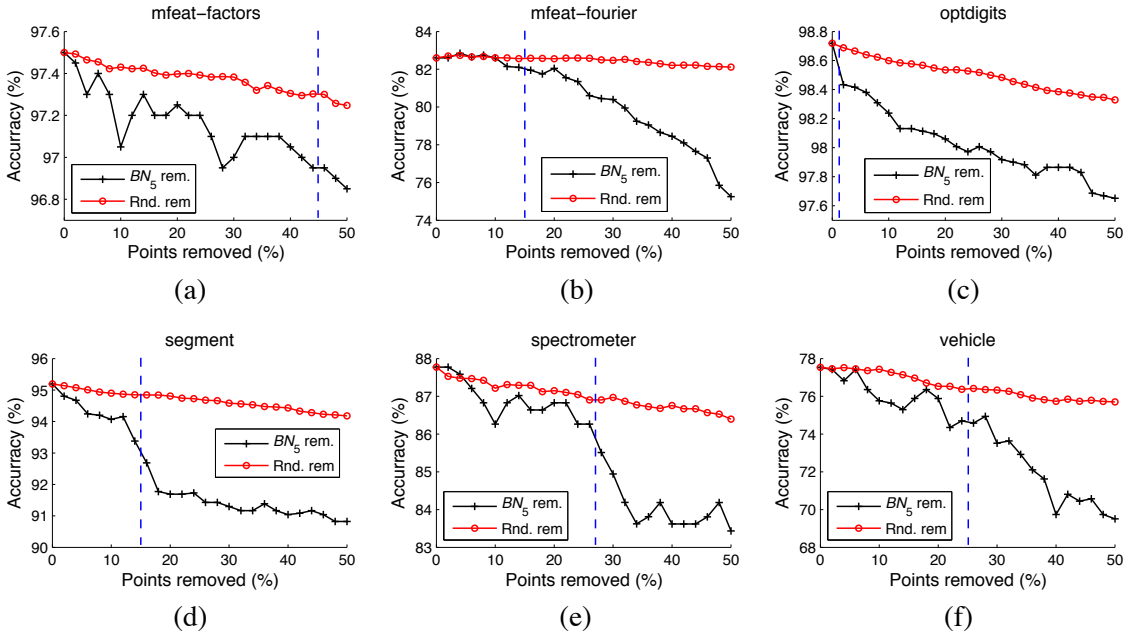

Figure 12: Accuracy of SVM with RBF kernel and points being removed from the training sets by decreasing BN_5, and at random (averaged over 20 runs).

Data set	γ	SV rank	Data set	γ	SV rank
mfeat-factors	0.005	0.218	segment	0.3	0.272
mfeat-fourier	0.02	0.381	spectrometer	0.005	0.383
optdigits	0.02	0.189	vehicle	0.07	0.464

Table 3: Normalized average support vector ranks with regards to decreasing BN_5.

CART trees (Breiman et al., 1984) with the maximal depth of three.[24] We define for each point $\mathbf{x}$ its *standardized hubness* score:

$$h(\mathbf{x},k) = \frac{N_k(\mathbf{x}) - \mu_{N_k}}{\sigma_{N_k}}, \tag{24}$$

where μ_{N_k}, σ_{N_k} are the mean and standard deviation of N_k, respectively. We set the initial weight of each point $\mathbf{x}$ in the training set to

$$w_k(\mathbf{x}) = \frac{1}{1+|h(\mathbf{x},k)|},$$

normalized by the sum over all points, for an empirically determined value of k. The motivation behind the weighting scheme is to assign less importance to both hubs and outliers than other points (this is why we take the absolute value of $h(\mathbf{x},k)$).

Figure 13 illustrates on six classification problems from Table 1 how the weighting scheme helps AdaBoost achieve better generalization in fewer iterations. The data sets were split into training,

24. More precisely, we use the binary "Real AdaBoost" algorithm and the one-vs-all scheme to handle multi-class problems, which is equivalent to the original AdaBoost.MH (Friedman et al., 2000).

validation, and test sets with size ratio 2:1:1, parameter k was chosen based on classification accuracy on the validation sets, and accuracies on the test sets are reported. While it is known that AdaBoost is sensitive to outliers (Rätsch et al., 2001), improved accuracy suggests that hubs should be regarded in an analogous manner, that is, both hubs and antihubs are intrinsically more difficult to classify correctly, and the attention of the weak learners should initially be focused on "regular" points. The discussion from Section 4.4, about hubs corresponding to probabilistic outliers in high-dimensional data, offers an explanation for the observed good performance of the weighting scheme, as both hubs and antihubs can be regarded as (probabilistic) outliers.

To provide further support, Figure 14 depicts binned accuracies of unweighted AdaBoost trained in one fifth of the iterations shown in Figure 13, for points sorted by decreasing N_k. It illustrates how in earlier phases of ensemble training the generalization power with hubs and/or antihubs is worse than with regular points. Moreover, for the considered data sets it is actually the hubs that appear to cause more problems for AdaBoost than antihubs (that is, distance-based outliers).

7.2 Semi-Supervised Learning

Semi-supervised learning algorithms make use of data distribution information provided by unlabeled examples during the process of building a classifier model. An important family of approaches are graph-based methods, which represent data as nodes of a graph, the edges of which are weighted by pairwise distances of incident nodes (Chapelle et al., 2006).

We consider the well-known algorithm by Zhu et al. (2003), whose strategy involves computing a real-valued function f on graph nodes, and assign labels to nodes based on its values. Function f, which exhibits harmonic properties, is obtained by optimizing a quadratic energy function that involves graph edge weights, with the probability distribution on the space of functions f formed using Gaussian fields. For data points $\mathbf{x}, \mathbf{y} \in \mathbb{R}^d$ we consider edge weights assigned by the radial basis function (RBF) of the following form:

$$W(\mathbf{x}, \mathbf{y}) = \exp\left(-\frac{\|\mathbf{x}-\mathbf{y}\|^2}{\sigma^2}\right),$$

where σ is a data-dependent constant. Therefore, large edge weights are assigned between nodes that are close to one another with respect to Euclidean distance.

Taking into account the properties of hubs and antihubs discussed in previous sections, for high-dimensional data sets it can be expected of hubs to be closer to many other points than "regular" points are, and thus carry larger edge weights and be more influential in the process of determining the optimal function f. Conversely, antihubs are positioned farther away from other points, and are expected to bear less influence on the computation of f. Therefore, following an approach that resembles active learning, selecting the initial labeled point set from hubs could be more beneficial in terms of classification accuracy than arbitrarily selecting the initial points to be labeled. On the other extreme, picking the initial labeled point set from the ranks of antihubs could be expected to have a detrimental effect on accuracy.

To validate the above hypothesis, we evaluated the accuracy of the harmonic function algorithm by Zhu et al. (2003) on multiple high-dimensional data sets from Table 1, for labeled set sizes ranging from 1% to 10% of the original data set size, with the test set consisting of all remaining unlabeled points. Because the setting is semi-supervised, we compute the N_k scores of points based on complete data sets, instead of only training sets which was the case in Section 7.1.2. Based on

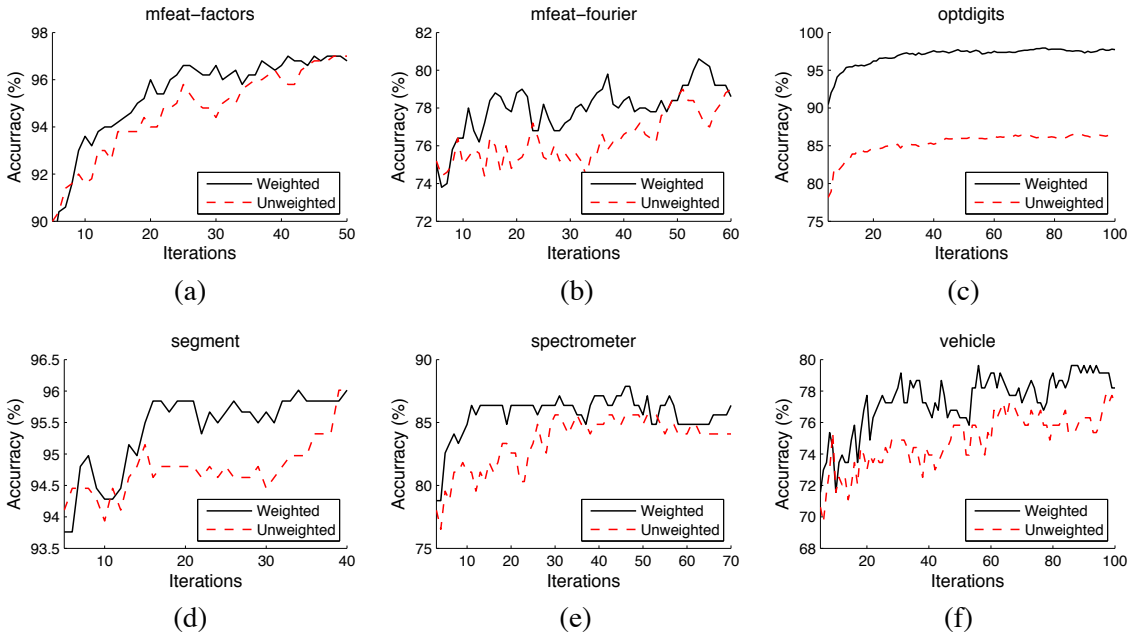

Figure 13: Accuracy of AdaBoost with and without the weighting scheme: (a) $k = 20$, (b) $k = 15$, (c) $k = 10$, (d) $k = 20$, (e) $k = 20$, (f) $k = 40$.

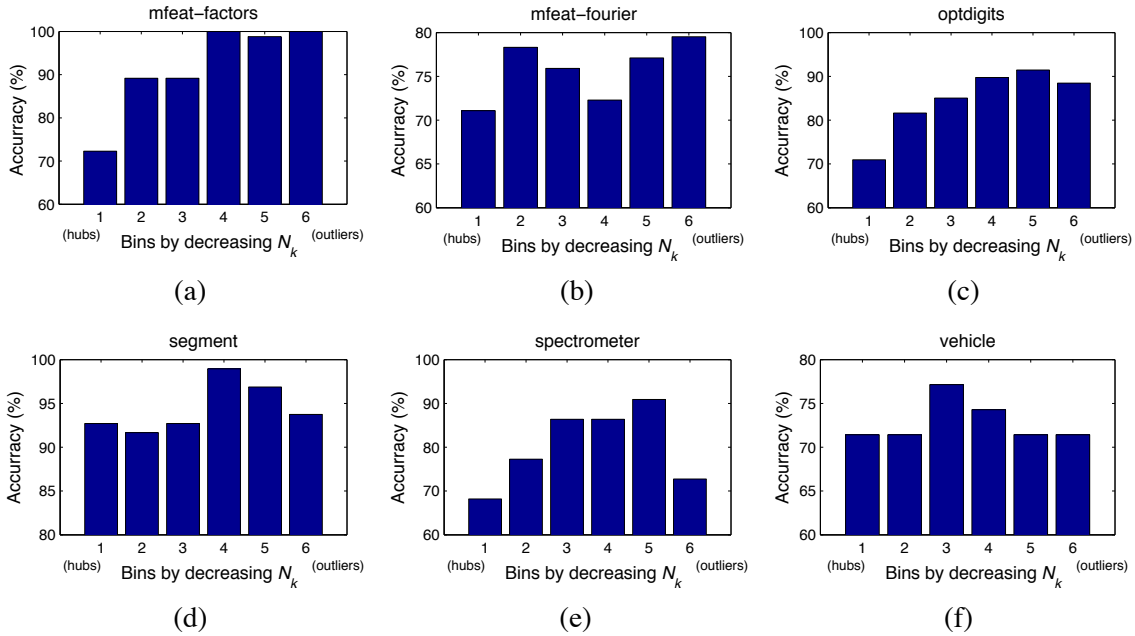

Figure 14: Binned accuracy of AdaBoost by decreasing N_k, at one fifth of the iterations shown in Figure 13.

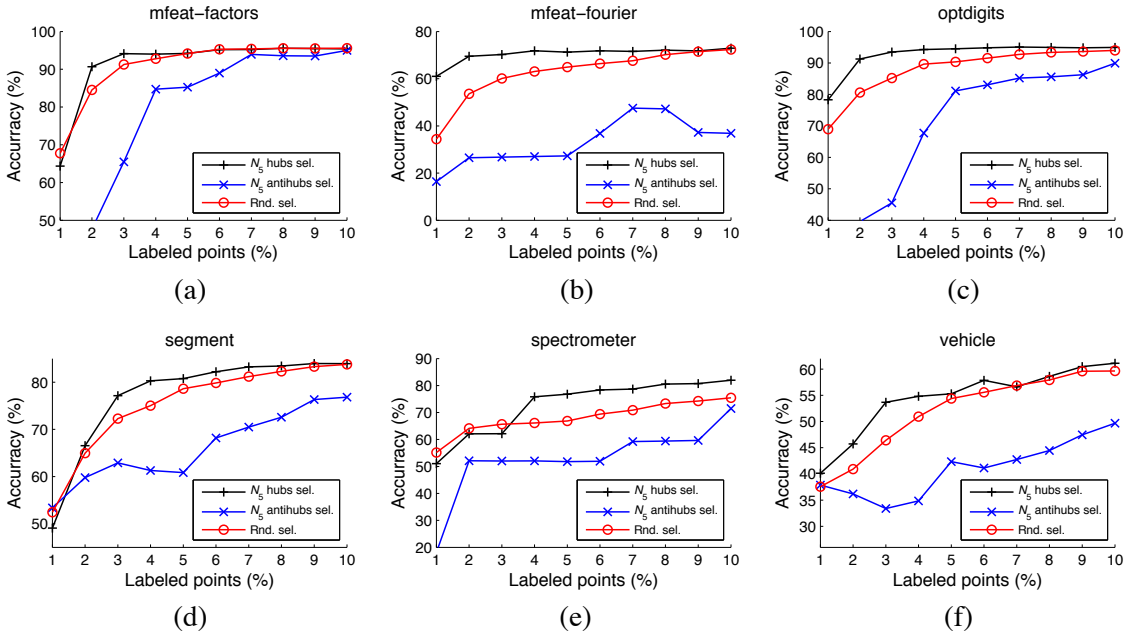

Figure 15: Accuracy of the semi-supervised algorithm by Zhu et al. (2003) with respect to the initial labeled set size as a percentage of the original data set size. Labeled points are selected in the order of decreasing N_5 (hubs first), increasing N_5 (antihubs first), and in random order. Sigma values of the RBF are: (a) $\sigma = 2.9$, (b) $\sigma = 2$, (c) $\sigma = 2.1$, (d) $\sigma = 0.9$, (e) $\sigma = 1.8$, and (f) $\sigma = 0.7$.

the N_k scores ($k = 5$), Figure 15 plots classification accuracies for labeled points selected in the order of decreasing N_5 (we choose to take hub labels first), in the order of increasing N_5 (antihub labels are taken first), and in random order (where we report accuracies averaged over 10 runs).[25] It can be seen that when the number of labeled points is low in comparison to the size of the data sets, taking hub labels first generally produces better classification accuracy. On the other hand, when assigning initial labels to antihubs, accuracy becomes significantly worse, with a much larger labeled set size required for the accuracy to reach that of randomly selected labeled points.

7.3 Unsupervised Learning

This section will discuss the interaction of the hubness phenomenon with unsupervised learning, specifically the tasks of clustering (Section 7.3.1) and outlier detection (Section 7.3.2).

7.3.1 CLUSTERING

The main objectives of (distance-based) clustering algorithms are to minimize intra-cluster distance and maximize inter-cluster distance. The skewness of k-occurrences in high-dimensional data influences both objectives.

25. We determined the σ values of the RBF function in a separate experiment involving 10 runs of random selection of points for the labeled set, the size of which is 10% of the original data set.

Intra-cluster distance may be increased due to points with low k-occurrences. As discussed in Section 4.4, such points are far from all the rest, acting as distance-based outliers. Distance-based outliers and their influence on clustering are well-studied subjects (Tan et al., 2005): outliers do not cluster well because they have high intra-cluster distance, thus they are often discovered and eliminated beforehand. The existence of outliers is attributed to various reasons (for example, erroneous measurements). Nevertheless, the skewness of N_k suggests that in high-dimensional data outliers are also expected due to inherent properties of vector space. Section 7.3.2 will provide further discussion on this point.

Inter-cluster distance, on the other hand, may be reduced due to points with high k-occurrences, that is, hubs. Like outliers, hubs do not cluster well, but for a different reason: they have low inter-cluster distance, because they are close to many points, thus also to points from other clusters. In contrast to outliers, the influence of hubs on clustering has not attracted significant attention.

To examine the influence of both outliers and hubs, we used the popular silhouette coefficients (SC) (Tan et al., 2005). For the ith point, let a_i be the average distance to all points in its cluster (a_i corresponds to intra-cluster distance), and b_i the minimum average distance to points from other clusters (b_i corresponds to inter-cluster distance). The SC of the ith point is $(b_i - a_i)/\max(a_i, b_i)$, ranging between -1 and 1 (higher values are preferred). The SC of a set of points is obtained by averaging the silhouette coefficients of the individual points.

We examined several clustering algorithms, and report results for the spectral algorithm of Meilă and Shi (2001) and Euclidean distance, with similar results obtained for classical K-means, as well as the spectral clustering algorithm by Ng et al. (2002) in conjunction with K-means and the algorithm by Meilă and Shi (2001). For a given data set, we set the number of clusters, K, to the number of classes (specified in Table 1). We select as hubs those points $\mathbf{x}$ with $h(\mathbf{x},k) > 2$, that is, $N_k(\mathbf{x})$ more than two standard deviations higher than the mean (note that $h(\mathbf{x},k)$, defined by Equation 24, ignores labels). Let n_h be the number of hubs selected. Next, we select as outliers the n_h points with the lowest k-occurrences. Finally, we randomly select n_h points from the remaining points (we report averages for 100 different selections). To compare hubs and antihubs against random points, we measure the *relative SC* of hubs (antihubs): the mean SC of hubs (antihubs) divided by the mean SC of random points. For several data sets from Table 1, Figure 16 depicts with bars the relative silhouette coefficients.[26] As expected, outliers have relative SC lower than one, meaning that they cluster worse than random points. Notably, the same holds for hubs, too.[27]

To gain further insight, Figure 16 plots with lines (referring to the right vertical axes) the relative mean values of a_i and b_i for hubs and outliers (dividing with those of randomly selected points). Outliers have high relative a_i values, indicating higher intra-cluster distance. Hubs, in contrast, have low relative b_i values, indicating reduced inter-cluster distance. In conclusion, when clustering high-dimensional data, hubs should receive analogous attention as outliers.

7.3.2 OUTLIER DETECTION

This section will briefly discuss possible implications of high dimensionality on distance-based outlier detection, in light of the findings concerning the hubness phenomenon presented in previous sections. Section 4.4 already discussed the correspondence of antihubs with distance-based outliers

26. Data sets were selected due to their high (intrinsic) dimensionality—similar observations can be made with other high-dimensional data sets from Table 1.
27. The statistical significance of differences between the SC of hubs and randomly selected points has been verified with the paired t-test at 0.05 significance level.

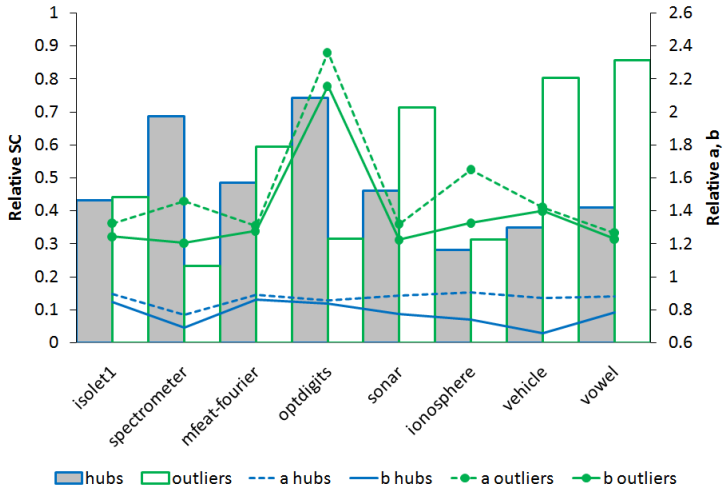

Figure 16: Relative silhouette coefficients for hubs (gray filled bars) and outliers (empty bars). Relative values for a and b coefficients are also plotted (referring to the right vertical axes).

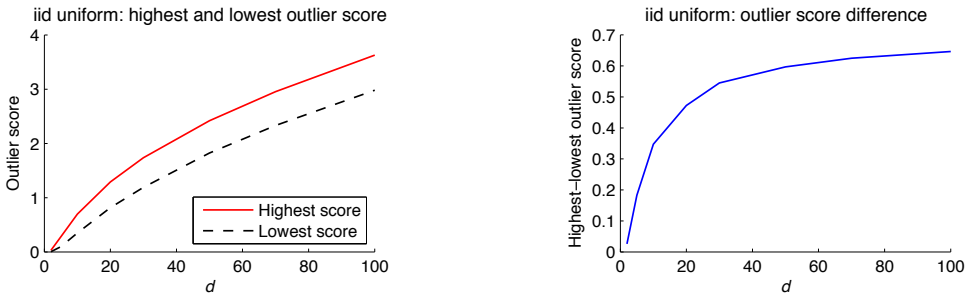
in high dimensions, and demonstrated on real data the negative correlation between N_k and a commonly used outlier score—distance to the kth nearest neighbor. On the other hand, a prevailing view of the effect of high dimensionality on distance-based outlier detection is that, due to distance concentration, every point seems to be an equally good outlier, thus hindering outlier-detection algorithms (Aggarwal and Yu, 2001). Based on the observations regarding hubness and the behavior of distances discussed earlier, we believe that the true problem actually lies in the opposite extreme: high dimensionality induces antihubs that can represent "artificial" outliers. This is because, from the point of view of common distance-based outlier scoring schemes, antihubs may appear to be stronger outliers in high dimensions than in low dimensions, only due to the effects of increasing dimensionality of data.

To illustrate the above discussion, Figure 17(a) plots for i.i.d. uniform random data the highest and lowest outlier score (distance to the kth NN, $k = 5$) with respect to increasing d ($n = 10000$ points, averages over 10 runs are reported). In accordance with the asymptotic behavior of all pairwise distances discussed in previous sections, both scores increase with d. However, as Figure 17(b) shows, the *difference* between the two scores also increases. This implies that a point could be considered a distance-based outlier only because of high dimensionality, since outliers are not expected for any other reason in i.i.d. uniform data (we already demonstrated that such a point would most likely be an antihub). As a consequence, outlier-detection methods based on measuring distances between points may need to be adjusted to account for the (intrinsic) dimensionality of data, in order to prevent dimensionality-induced false positives.

8. Conclusion

In this paper we explored an aspect of the curse of dimensionality that is manifested through the phenomenon of hubness—the tendency of high-dimensional data sets to contain hubs, in the sense of popular nearest neighbors of other points. To the best of our knowledge, hubs and the effects they



(a) (b)

Figure 17: (a) Highest and lowest distance to the 5th nearest neighbor in i.i.d. uniform random data, with respect to increasing d. (b) The difference between the two distances.

have on machine-learning techniques have not been thoroughly studied subjects. Through theoretical and empirical analysis involving synthetic and real data sets we demonstrated the emergence of the phenomenon and explained its origins, showing that it is an inherent property of data distributions in high-dimensional vector space that depends on the intrinsic, rather than embedding dimensionality of data. We also discussed the interaction of hubness with dimensionality reduction. Moreover, we explored the impact of hubness on a wide range of machine-learning tasks that directly or indirectly make use of distances between points, belonging to supervised, semi-supervised, and unsupervised learning families, demonstrating the need to take hubness into account in an equivalent degree to other factors, like the existence of outliers.

Besides application areas that involve audio and image data (Aucouturier and Pachet, 2007; Doddington et al., 1998; Berenzweig, 2007; Hicklin et al., 2005), identifying hubness within data and methods from other fields can be considered an important aspect of future work, as well as designing application-specific methods to mitigate or take advantage of the phenomenon. We already established the existence of hubness and its dependence on data dimensionality on collaborative filtering data with commonly used variants of cosine distance (Nanopoulos et al., 2009), time-series data sets in the context of k-NN classification involving dynamic time warping (DTW) distance (Radovanović et al., 2010b), text data within several variations of the classical vector space model for information retrieval (Radovanović et al., 2010a), and audio data for music information retrieval using spectral similarity measures (Karydis et al., 2010). In the immediate future we plan to perform a more detailed investigation of hubness in the fields of outlier detection and image mining. Another application area that could directly benefit from an investigation into hubness are reverse k-NN queries (which retrieve data points that have the query point $\mathbf{q}$ as one of their k nearest neighbors, Tao et al., 2007).

One concern we elected not to include into the scope of this paper is the efficiency of computing N_k. It would be interesting to explore the interaction between approximate k-NN graphs (Chen et al., 2009) and hubness, in both directions: to what degree do approximate k-NN graphs preserve hubness information, and can hubness information be used to enhance the computation of approximate k-NN graphs for high-dimensional data (in terms of both speed and accuracy).

Possible directions for future work within different aspects of machine learning include a more formal and theoretical study of the interplay between hubness and various distance-based machine-

learning models, possibly leading to approaches that account for the phenomenon at a deeper level. Supervised learning methods may deserve special attention, as it was also observed in another study (Caruana et al., 2008) that the k-NN classifier and boosted decision trees can experience problems in high dimensions. Further directions of research may involve determining whether the phenomenon is applicable to probabilistic models, (unboosted) decision trees, and other techniques not explicitly based on distances between points; and also to algorithms that operate within general metric spaces. Since we determined that for K-means clustering of high-dimensional data hubs tend to be close to cluster centers, it would be interesting to explore whether this can be used to improve iterative clustering algorithms, like K-means or self-organizing maps (Kohonen, 2001). Nearest-neighbor clustering (Bubeck and von Luxburg, 2009) of high-dimensional data may also directly benefit from hubness information. Topics that could also be worth further study are the interplay of hubness with learned metrics (Weinberger and Saul, 2009) and dimensionality reduction, including supervised (Vlassis et al., 2002; Geng et al., 2005), semi-supervised (Zhang et al., 2007), and unsupervised approaches (van der Maaten et al., 2009; Kumar, 2009). Finally, as we determined high correlation between intrinsic dimensionality and the skewness of N_k, it would be interesting to see whether some measure of skewness of the distribution of N_k can be used for estimation of the intrinsic dimensionality of a data set.

Acknowledgments

We would like to thank the authors of all software packages, libraries, and resources used in this research: Matlab with the Statistics Toolbox, Dimensionality Reduction Toolbox (van der Maaten, 2007), the FastICA package (Gävert et al., 2005), GML AdaBoost Toolbox (Vezhnevets, 2006), code for semi-supervised learning with the basic harmonic function (Zhu et al., 2003), SpectraLIB package for symmetric spectral clustering (Verma, 2003; Meilă and Shi, 2001), MatlabBGL graph library (Gleich, 2008); the Weka machine-learning toolkit (Witten and Frank, 2005), and Wolfram Mathematica with invaluable online resources MathWorld (mathworld.wolfram.com/) and the Wolfram Functions Site (functions.wolfram.com/).

We would like to express our gratitude to the action editor, Ulrike von Luxburg, and the anonymous reviewers, for helping to significantly improve the article with their detailed and thoughtful comments. We are also indebted to Zagorka Lozanov-Crvenković for helpful discussions and suggestions regarding the mathematical aspects of the paper.

Editor: Soeren Sonnenburg

Abstract

WEKA is a popular machine learning workbench with a development life of nearly two decades. This article provides an overview of the factors that we believe to be important to its success. Rather than focussing on the software's functionality, we review aspects of project management and historical development decisions that likely had an impact on the uptake of the project.

Keywords: machine learning software, open source software

1. Introduction

We present a brief account of the WEKA 3 software, which is distributed under the GNU General Public License, followed by some lessons learned over the period spanning its development and maintenance. We also include a brief historical mention of its predecessors.

WEKA contains implementations of algorithms for classification, clustering, and association rule mining, along with graphical user interfaces and visualization utilities for data exploration and algorithm evaluation. This article shares some background on software design and management decisions, in the hope that it may prove useful to others involved in the development of open-source machine learning software. Hall et al. (2009) give an overview of the system; more comprehensive sources of information are Witten and Frank's book *Data Mining* (2005) and the user manuals included in the software distribution.[1] Online sources, including the WEKA Wiki pages[2] and the API, provide the most complete coverage. The *wekalist* mailing list is a forum for discussion of WEKA-related queries, with nearly 3000 subscribers.

2. What is WEKA?

WEKA is a machine learning workbench that supports many activities of machine learning practitioners.

1. Available from `http://www.cs.waikato.ac.nz/ml/weka`.
2. Available at `http://weka.wikispaces.com/`.

2.1 Basic Functionality

Here is a summary of WEKA's main features.

- *Data preprocessing*. As well as a native file format (ARFF), WEKA supports various other formats (for instance CSV, Matlab ASCII files), and database connectivity through JDBC. Data can be filtered by a large number of methods (over 75), ranging from removing particular attributes to advanced operations such as principal component analysis.

- *Classification*. One of WEKA's drawing cards is the more than 100 classification methods it contains. Classifiers are divided into "Bayesian" methods (Naive Bayes, Bayesian nets, etc.), lazy methods (nearest neighbor and variants), rule-based methods (decision tables, OneR, RIPPER), tree learners (C4.5, Naive Bayes trees, M5), function-based learners (linear regression, SVMs, Gaussian processes), and miscellaneous methods. Furthermore, WEKA includes meta-classifiers like bagging, boosting, stacking; multiple instance classifiers; and interfaces for classifiers implemented in Groovy and Jython.

- *Clustering*. Unsupervised learning is supported by several clustering schemes, including EM-based mixture models, k-means, and various hierarchical clustering algorithms. Though not as many methods are available as for classification, most of the classic algorithms are included.

- *Attribute selection*. The set of attributes used is essential for classification performance. Various selection criteria and search methods are available.

- *Data visualization*. Data can be inspected visually by plotting attribute values against the class, or against other attribute values. Classifier output can be compared to training data in order to detect outliers and observe classifier characteristics and decision boundaries. For specific methods there are specialized tools for visualization, such as a tree viewer for any method that produces classification trees, a Bayes network viewer with automatic layout, and a dendrogram viewer for hierarchical clustering.

WEKA also includes support for association rule mining, comparing classifiers, data set generation, facilities for annotated documentation generation for source code, distribution estimation, and data conversion.

2.2 Graphical User Interfaces

WEKA's functionality can be accessed through various graphical user interfaces, principally the Explorer, and Experimenter interfaces shown in Figure 1, but also the Knowledge Flow interface. The most popular interface, the Explorer, allows quick exploration of data and supports all the main items mentioned above—data loading and filtering, classification, clustering, attribute selection and various forms of visualization—in an interactive fashion.

The Experimenter is a tool for setting up machine learning experiments that evaluate classification and regression methods. It allows easy comparison of performance, and can tabulate summaries in ways that are easy to incorporate into publications. Experiments can be set up to run in parallel over different computers in a network so that multiple repetitions of cross validation (the default method of performance analysis) can be distributed over multiple machines.

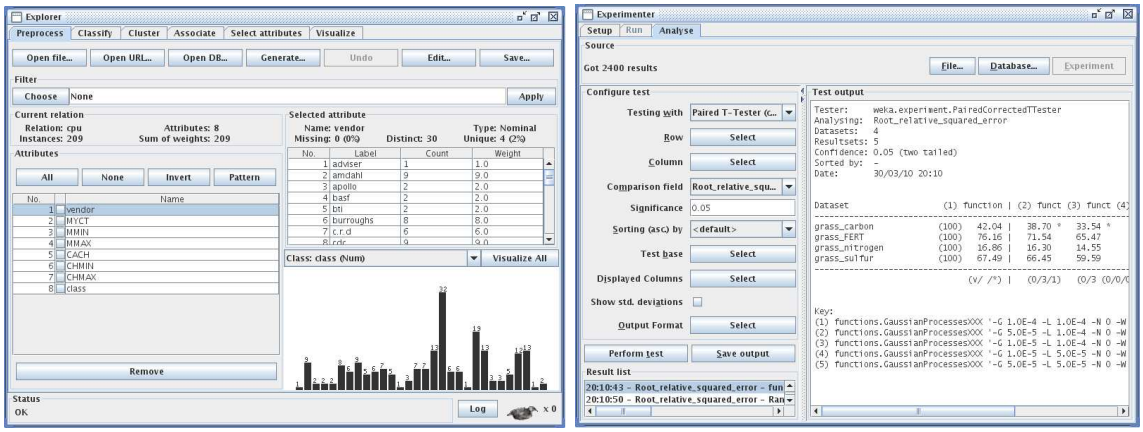

Figure 1: The Explorer and Experimenter interfaces.

The Knowledge Flow interface is a Java Beans application that allows the same kind of data exploration, processing and visualization as the Explorer (along with some extras), but in a workflow-oriented system. The user can define a workflow specifying how data is loaded, preprocessed, evaluated and visualized, which can be repeated multiple times. This makes it easy to optimize the workflow by tweaking parameters of algorithms, or to apply it to other data sources. In the Explorer, on the other hand, the individual steps must be invoked manually, one at a time. This is a rather tedious process, and is prone to errors such as omitting preprocessing steps.

WEKA also includes some specialized graphical interfaces, such as a Bayes network editor that focuses on Bayes network learning and inference, an SQL viewer for interaction with databases, and an ARFF data file viewer and editor.

All functionality and some more specialized functions can be accessed from a command line interface, so WEKA can be used without a windowing system.

2.3 Extending WEKA

One of WEKA's major strengths is that it is easily extended with customized or new classifiers, clusterers, attribute selection methods, and other components. For instance, all that is needed to add a new classifier is a class that derives from the `Classifier` class and implements the `buildClassifier` method for learning, and a `classifyInstance` method for testing/predicting the value for a data point. The code fragment in Figure 2 shows a minimal implementation of a classifier that returns the mean or mode of the class in the training set (double values are used to store indices of nominal attribute values).

Any new class is picked up by the graphical user interfaces through Java introspection: no further coding is needed to deploy it from WEKA's graphical user interfaces. This makes it easy to evaluate how new algorithms perform compared to any of the existing ones, which explains WEKA's popularity among machine learning researchers.

Besides being easy to extend, WEKA includes a wide range of support for adding functionality to basic implementations. For instance, a classifier can have various optional settings by implementing a pre-defined interface for option handling. Each option can be documented using a tool-tip text

```
package weka.classifiers.misc;

import weka.classifiers.Classifier;
import weka.core.*;

public class NewClassifier extends Classifier {
        double m_fMean;

        public void buildClassifier(Instances data) throws Exception {
                m_fMean = data.meanOrMode(data.classIndex());
        }

        public double classifyInstance(Instance instance) throws Exception {
                return m_fMean;
        }

}
```

Figure 2: Classifier code example.

method, which is picked up by the *help* dialogs of the graphical user interfaces. Classes typically implement methods described in papers, and this provenance metadata can be captured in a method that is used to generate documentation. Some methods only apply to certain kinds of data, such as numeric class values or discrete attribute values. A 'capabilities' mechanism allows classes to identify what kind of data is acceptable by any method, and the graphical user interfaces incorporate this by making methods available only if they are able to process the data at hand.

There are many projects that build on top WEKA, about fifty of which are listed on the WEKA Wiki.

3. Origins

The Machine Learning project at Waikato was launched in 1993 with a successful grant application to the New Zealand Foundation for Research, Science, and Technology. The underlying intention behind the request was not so much to further a specific agenda in machine learning research as to create a research culture in a small and obscure computer science department that brought different people together. Machine learning was selected because of prior expertise and its potential applicability to agriculture, New Zealand's core industry; the grant was justified in terms of applications research rather than the development of new learning techniques.

This gave the research team a license to incorporate and reimplement existing methods, and work soon began on a workbench, written in C, that was intended to provide a common interface to a growing collection of machine learning algorithms. It contained some learning algorithms written mostly in C, data I/O and pre-processing tools, also written in C, and graphical user interfaces written in TCL/TK. The number of learning algorithms was limited and they came from different sources; wrapper shell scripts were employed to bind them into the framework. The acronym WEKA for "Waikato Environment for Knowledge Analysis" was coined, and the system gradually became known in the international ML community, along with another machine learning library in C++ from the University of Stanford called MLC++, developed by Kohavi et al. (1997).[3]

3. MLC++ is now distributed by Silicon Graphics at `http://www.sgi.com/Technology/mlc`.

Because of dependencies on other libraries, mainly related to the graphical user interfaces, the software became increasingly unwieldy and hard to maintain. In 1997 work began on reimplementing WEKA from scratch in Java into what we now term WEKA 3. One of the authors, Eibe Frank, had earlier decided to adopt Java to implement algorithm prototypes, abandoning C++ because Java development was rapid and debugging was dramatically simplified. This positive experience, the promise of platform independence through virtual machine technology, and the fact that, as part of the research code, classes for reading WEKA's standard ARFF file format into appropriate data structures already existed, led to the decision to re-write WEKA in Java.

Many of the classes in today's code archive (including, for example, J48, the WEKA implementation of Quinlan's C4.5) date from mid-1997. Rapid early development was stimulated by the need to teach a course on machine learning at the University of Calgary during a Fall 1997 sabbatical visit by Witten, along with several students, including Frank. The Java version was called JAWS for "Java Weka system" to avoid confusion with WEKA itself, and after some debate was changed to WEKA in March 1999. The first paper written using this system was Frank and Witten (1998), written in late 1997. By the end of 1998 WEKA included packages for classifiers, association rule learners, filters, and evaluation, as well as a core package. Several methods that were relatively advanced for the day, such as bagging, were in place, as well as old chestnuts like instance-based learning and Naive Bayes. Attribute selection was added soon afterwards, in 1999.

Work began on the first edition of the *Data Mining* book in 1997, based on earlier notes for Witten's courses at the University of Waikato, and a proposal was submitted to Morgan Kaufmann late that year. It finally appeared in 1999 (though for reasons that are not clear to us the official publication date is 2000). WEKA was seen as an important adjunct to the book, and the original title, *Practical machine learning*, was changed to *Data Mining: Practical machine learning tools and techniques with Java* to reflect this. The term "data mining" was prepended primarily for marketing reasons. The WEKA software described in that edition was command-line oriented and the book makes no mention of a graphical user interface, for which design began in 1999. By the time the second edition appeared in 2005 the interactive versions of WEKA—the Explorer, Experimenter, and Knowledge Flow interface—were mature and well-tested pieces of software.

4. How Did WEKA Become Widely Adopted?

The size of the mailing list, the volume of downloads, and the number of academic papers citing WEKA-based results show that the software is widely deployed. It is used in the machine learning and data mining community as an educational tool for teaching both applications and technical internals of machine learning algorithms, and as a research tool for developing and empirically comparing new techniques. It is applied increasingly widely in other academic fields, and in commercial settings. We are often asked what is the secret of WEKA's success, and here we speculate on reasons for the software's broad uptake. An obvious one is that it is free and open-source software. However, there are several other factors, many of which are exposed by the above brief historical review.

4.1 Portability

Pre-Java versions of WEKA were limited to UNIX operating systems and distributions were made available for Linux, Solaris, and SGI. The present popularity of the software owes much to the existence of Java Virtual Machines for all important platforms, along with the fact that all code

necessary to compile and run WEKA is included in the distribution. The lack of dependency on externally-maintained libraries makes maintenance of the code base much easier.

The decision to rewrite WEKA from scratch in Java may seem obvious in hindsight, but was a large step into the unknown at the time. For one thing, portability seemed less important in the days when everyone we knew was using Unix! More importantly, in 1997 no-one could forsee that Java would turn out to be such a suitable platform. Just-in-time compilation was unknown (Sun's Java 1.2, which included a just-in-time compiler, was introduced in December 1998). Fully-interpreted execution suffered a substantial performance hit compared to C++. And deficiencies in early Java technology still affect the WEKA code today: the original design of the basic data structures was clean, object-oriented, and elegant, but the performance penalty incurred by extensive use of objects led to a less generic array-based representation, where all data is stored in arrays of doubles. Many of the design characteristics of WEKA that seem inelegant are due to pragmatic decisions based on the Java technology available at the time.

Later versions of the Java Virtual Machine virtually eliminated the performance gap from C++ through just-in-time compilation and adaptive optimization. Although there still persists a perception that execution of Java code is too slow for scientific computing, this is not our experience and does not appear to be shared by the WEKA community.

4.2 Graphical User Interface

Early releases of the WEKA 3 software were command-line driven and did not include graphical user interfaces. Although many experienced users still shun them, the graphical interfaces undoubtedly contributed to the popularity of WEKA. The introduction of the Explorer in particular has made the software more accessible to users who want to employ machine learning in practice. It has allowed many universities (including our own) to offer courses in applied machine learning and data mining, and has certainly contributed to WEKA's popularity for commercial and industrial use. Again, while obvious in hindsight, the development of graphical user interfaces was a significant risk, because valuable programming effort had to be diverted from the main job of implementing learning algorithms into relatively superficial areas of presentation and interaction.

The WEKA 3 graphical user interface development benefited from the fact that the core system was already up and running, and relatively mature—as evidenced by the first edition of *Data Mining*—before any work began on interactive interfaces. The early WEKA project probably suffered from attempting to develop interactive interfaces (in TCL/TK) at the same time as the basic algorithms and data structures were being commissioned, a mistake that was avoided in the later system.

4.3 The *Data Mining* Book

The first stable release of the WEKA 3 software coincided with the publication of the first edition of *Data Mining* by Witten and Frank, which contained a chapter describing it, both interactively via the command-line and programmatically via the API and extension of superclasses. There has been a symbiotic relationship between the software and the book: users of the software are likely to consult the book and readers of the book are likely to try out the software. The combination of a book explaining the core algorithms in a corresponding piece of free software is particularly suitable for education. It seems likely that the feedback loop between the readership of the book and the users of the software has bolstered the size of both populations. The early existence of a

companion book, unusual for open source software, is particularly valuable for machine learning because the techniques involved are quite simple and easy to explain, but by no means obvious.

4.4 Extensibility

WEKA can be used both for educational purposes and as a research platform. New algorithms can easily be incorporated and compared to existing ones on a collection of data sets. As noted earlier, only two methods from the `Classifier` superclass need be implemented to come up with a classifier that takes advantage of all the infrastructure in WEKA, including I/O, evaluation, and so-called "meta" algorithms.

4.5 Documentation

In recent years there has been a dramatic growth in the volume of WEKA-related online documentation—notably as part of the WEKA Wiki. This, in conjunction with the information in the mailing list archives, provides a wealth of information for all users. The existence of a steadily increasing, knowledgeable and enthusiastic user community, and the combined knowledge they share, has played a significant role in the success of the software.

4.6 Comprehensiveness

Perhaps the foremost reason for the adoption of WEKA 3 by the research community has been the inclusion of faithful reimplementations of classic benchmark methods, in particular the C4.5 decision tree learner (Quinlan, 1992), but also other algorithms such as the RIPPER rule learner (Cohen, 1995). The original implementations of these algorithms were already very successful software projects in themselves. Bringing them together in a common framework has been a strong drawing card.

4.7 Support

"Given sufficient funding, anyone could have done that!" is a refrain often heard from sceptics. We were lucky to receive an initial research grant for *applied* machine learning research from a New Zealand funding agency that approved of our aspirations to investigate the application of this technology in agricultural domains. Yet it is hard to reconcile the practical need to win academic credit for research publications with the production of usable software, particularly when there is a constantly growing pressure to commercialize. We continued to apply for, and receive, follow-on funding from the same source, but—particularly as time went on—this compelled us to channel much of our research in the direction of target applications rather than basic research in machine learning.

5. Maintaining the Project

A software project can only become and remain successful if it is consistently maintained to a high standard. It has been our experience that this requires a group of people who are continually involved in the management and development of the software for an extended period of time, spanning several years. The core development team of WEKA has always been small and close-knit: having a small team helps maintain code quality and overall coherence.

Development of the software would not have been possible without financial support from the New Zealand government in the form of successive research grants by the Foundation for Research, Science and Technology, which have been awarded over a significant period of time—from 1993 to 2007. Over the years, work on the project has been done by a couple of academic staff, who were involved in the longer term and fitted it in with their teaching and research duties, and a succession of one (or one and a half) full-time equivalent research programmers. A fair amount of work was undertaken by students on casual contracts or as part of their studies. The community also contributed many algorithm implementations that are included in the WEKA distribution, along with some patches for the basic framework.

The project has always had a policy of maintaining close control of what became part of the software. Only a handful of developers have ever had write access to the source code repository. The drawback of this policy is reduced functionality; the advantages are improved code quality, ease of maintenance, and greater coherence for both developer and end user. When new algorithm implementations were considered for inclusion, we generally insisted on a backing publication describing the new method. In a few cases we have rejected submitted code, despite publication, when our experiments revealed that the method did not appear to improve on what was already present in WEKA.

The research contract that sponsored WEKA development required some measure of commercialization, and a few commercial licenses to parts of the WEKA code base owned by the University of Waikato have been sold. It eventually became clear that the succession of research contracts had a finite life span, and support by a commercial organization was necessary to keep WEKA healthy. Since 2007, Pentaho Corporation, a company that provides open-source business intelligence software and support, has contributed substantially to the maintenance of WEKA by hiring one of the chief developers and providing online help. As part of the requirement to commercialize the software, it has been necessary to maintain a branch in the source code repository that only contains code owned by the University of Waikato, an onerous but necessary facet of project maintenance.

6. Concluding Remarks

Obviously, in almost two decades of project development, many mistakes were made—but most were quickly corrected. One, mentioned above, regards the premature design of interactive interfaces, where WEKA 3 benefited from a strategic error made in the early WEKA project. Below are two instances of how adoption might have been strengthened had the project been managed differently.

One of the most challenging aspects of managing open source software development is to decide what to include in the software. Although careful control of contributions has substantial benefits, it limits community involvement (Bacon, 2009). A package-based architecture (such as that adopted by the R Development Team, 2009) provides a better platform for more widespread ownership and development. Under such a scheme, packages maintained by their developers can be loaded into the system on demand, opening it up to greater diversity and flexibility. A recent development in WEKA is the inclusion of package management, so that packages can easily be added to a given installation.[4] The project would probably have benefited by moving in this direction earlier.

We have learned that mailing lists for open source software are easier to maintain if the users are researchers rather than teachers. WEKA's widespread role in education has led to a repetitive

4. Currently in the development version only.

and distracting deluge of basic questions. Requests from students all over the world for assistance with their assignments and projects present a significant (and growing) problem; moreover, students often depart from proper mailing-list etiquette. It would have been better to identify the clientele for WEKA as a teaching tool, and offer a one-stop-shop for software, documentation and help that is distinct from the support infrastructure used by researchers.

All in all, WEKA has been a resounding success which we believe has significantly advanced the application of machine learning techniques in today's world. One of the most satisfying aspects of participating in the project is that the software has been incorporated into, and spawned, many other open-source projects.

Acknowledgments

We gratefully acknowledge the input of all contributors to the WEKA project, and want in particular to mention significant early contributions to the WEKA 3 codebase by Len Trigg and many later contributions by Richard Kirkby, Ashraf Kibriya and Xin Xu.

Dual Averaging Methods for Regularized Stochastic Learning and Online Optimization

Lin Xiao LIN.XIAO@MICROSOFT.COM

Editor: Sham Kakade

Abstract

We consider regularized stochastic learning and online optimization problems, where the objective function is the sum of two convex terms: one is the loss function of the learning task, and the other is a simple regularization term such as ℓ_1-norm for promoting sparsity. We develop extensions of Nesterov's dual averaging method, that can exploit the regularization structure in an online setting. At each iteration of these methods, the learning variables are adjusted by solving a simple minimization problem that involves the running average of all past subgradients of the loss function and the whole regularization term, not just its subgradient. In the case of ℓ_1-regularization, our method is particularly effective in obtaining sparse solutions. We show that these methods achieve the optimal convergence rates or regret bounds that are standard in the literature on stochastic and online convex optimization. For stochastic learning problems in which the loss functions have Lipschitz continuous gradients, we also present an accelerated version of the dual averaging method.

Keywords: stochastic learning, online optimization, ℓ_1-regularization, structural convex optimization, dual averaging methods, accelerated gradient methods

1. Introduction

In machine learning, online algorithms operate by repetitively drawing random examples, one at a time, and adjusting the learning variables using simple calculations that are usually based on the single example only. The low computational complexity (per iteration) of online algorithms is often associated with their slow convergence and low accuracy in solving the underlying optimization problems. As argued by Bottou and Bousquet (2008), the combined low complexity and low accuracy, together with other tradeoffs in statistical learning theory, still make online algorithms favorite choices for solving large-scale learning problems. Nevertheless, traditional online algorithms, such as stochastic gradient descent, have limited capability of exploiting problem structure in solving *regularized* learning problems. As a result, their low accuracy often makes it hard to obtain the desired regularization effects, for example, sparsity under ℓ_1-regularization.

In this paper, we develop a new class of online algorithms, the *regularized dual averaging* (RDA) methods, that can exploit the regularization structure more effectively in an online setting. In this section, we describe the two types of problems that we consider, and explain the motivation of our work.

1.1 Regularized Stochastic Learning

The regularized stochastic learning problems we consider are of the following form:

$$\underset{w}{\text{minimize}} \quad \Big\{ \phi(w) \triangleq \mathbf{E}_z f(w,z) + \Psi(w) \Big\} \tag{1}$$

where $w \in \mathbf{R}^n$ is the optimization variable (often called *weights* in learning problems), $z = (x,y)$ is an input-output pair of data drawn from an (unknown) underlying distribution, $f(w,z)$ is the loss function of using w and x to predict y, and $\Psi(w)$ is a regularization term. We assume $\Psi(w)$ is a closed convex function (Rockafellar, 1970, Section 7), and its effective domain, $\operatorname{dom}\Psi = \{w \in \mathbf{R}^n \,|\, \Psi(w) < +\infty\}$, is closed. We also assume that $f(w,z)$ is convex in w for each z, and it is subdifferentiable (a subgradient always exists) on $\operatorname{dom}\Psi$. Examples of the loss function $f(w,z)$ include:

- Least-squares: $x \in \mathbf{R}^n$, $y \in \mathbf{R}$, and $f(w,(x,y)) = (y - w^T x)^2$.
- Hinge loss: $x \in \mathbf{R}^n$, $y \in \{+1,-1\}$, and $f(w,(x,y)) = \max\{0, 1 - y(w^T x)\}$.
- Logistic regression: $x \in \mathbf{R}^n$, $y \in \{+1,-1\}$, and $f(w,(x,y)) = \log\big(1 + \exp\big(-y(w^T x)\big)\big)$.

Examples of the regularization term $\Psi(w)$ include:

- ℓ_1-regularization: $\Psi(w) = \lambda \|w\|_1$ with $\lambda > 0$. With ℓ_1-regularization, we hope to get a relatively sparse solution, that is, with many entries of the weight vector w being zeroes.
- ℓ_2-regularization: $\Psi(w) = (\sigma/2)\|w\|_2^2$, with $\sigma > 0$. When ℓ_2-regularization is used with the hinge loss function, we have the standard setup of support vector machines.
- Convex constraints: $\Psi(w)$ is the indicator function of a closed convex set C, that is,

$$\Psi(w) = I_C(w) \triangleq \begin{cases} 0, & \text{if } w \in C, \\ +\infty, & \text{otherwise.} \end{cases}$$

We can also consider mixed regularizations such as $\Psi(w) = \lambda\|w\|_1 + (\sigma/2)\|w\|_2^2$. These examples cover a wide range of practical problems in machine learning.

A common approach for solving stochastic learning problems is to approximate the expected loss function $\phi(w)$ by using a finite set of independent observations $z_1, \ldots, z_T$, and solve the following problem to minimize the empirical loss:

$$\underset{w}{\text{minimize}} \quad \frac{1}{T} \sum_{t=1}^{T} f(w, z_t) + \Psi(w). \tag{2}$$

By our assumptions, this is a convex optimization problem. Depending on the structure of particular problems, they can be solved efficiently by interior-point methods (e.g., Ferris and Munson, 2003; Koh et al., 2007), quasi-Newton methods (e.g., Andrew and Gao, 2007), or accelerated first-order methods (Nesterov, 2007; Tseng, 2008; Beck and Teboulle, 2009). However, this *batch optimization* approach may not scale well for very large problems: even with first-order methods, evaluating one single gradient of the objective function in (2) requires going through the whole data set.

In this paper, we consider *online algorithms* that process samples sequentially as they become available. More specifically, we draw a sequence of i.i.d. samples $z_1, z_2, z_3, \ldots$, and use them to

calculate a sequence $w_1, w_2, w_3, \ldots$. Suppose at time t, we have the most up-to-date weight vector w_t. Whenever z_t is available, we can evaluate the loss $f(w_t, z_t)$, and also a subgradient $g_t \in \partial f(w_t, z_t)$ (here $\partial f(w,z)$ denotes the subdifferential of $f(w,z)$ with respect to w). Then we compute w_{t+1} based on these information.

The most widely used online algorithm is the *stochastic gradient descent* (SGD) method. Consider the general case $\Psi(w) = I_C(w) + \psi(w)$, where $I_C(w)$ is a "hard" set constraint and $\psi(w)$ is a "soft" regularization. The SGD method takes the form

$$w_{t+1} = \Pi_C\big(w_t - \alpha_t\,(g_t + \xi_t)\big), \tag{3}$$

where α_t is an appropriate stepsize, ξ_t is a subgradient of ψ at w_t, and $\Pi_C(\cdot)$ denotes Euclidean projection onto the set $\mathcal{C}$. The SGD method belongs to the general scheme of *stochastic approximation*, which can be traced back to Robbins and Monro (1951) and Kiefer and Wolfowitz (1952). In general we are also allowed to use all previous information to compute w_{t+1}, and even second-order derivatives if the loss functions are smooth.

In a stochastic online setting, each weight vector w_t is a random variable that depends on $\{z_1, \ldots, z_{t-1}\}$, and so is the objective value $\phi(w_t)$. Assume an optimal solution $w^\star$ to the problem (1) exists, and let $\phi^\star = \phi(w^\star)$. The goal of online algorithms is to generate a sequence $\{w_t\}_{t=1}^\infty$ such that

$$\lim_{t\to\infty} \mathbf{E}\,\phi(w_t) = \phi^\star,$$

and hopefully with reasonable convergence rate. This is the case for the SGD method (3) if we choose the stepsize $\alpha_t = c/\sqrt{t}$, where c is a positive constant. The corresponding convergence rate is $O(1/\sqrt{t})$, which is indeed best possible for subgradient schemes with a *black-box* model, even in the case of deterministic optimization (Nemirovsky and Yudin, 1983). Despite such slow convergence and the associated low accuracy in the solutions (compared with batch optimization using, for example, interior-point methods), the SGD method has been very popular in the machine learning community due to its capability of scaling with very large data sets and good generalization performances observed in practice (e.g., Bottou and LeCun, 2004; Zhang, 2004; Shalev-Shwartz et al., 2007).

Nevertheless, a main drawback of the SGD method is its lack of capability in exploiting problem structure, especially for problems with explicit regularization. More specifically, the SGD method (3) treats the soft regularization $\psi(w)$ as a general convex function, and only uses its subgradient in computing the next weight vector. In this case, we can simply lump $\psi(w)$ into $f(w, z_t)$ and treat them as a single loss function. Although in theory the algorithm converges to an optimal solution (in expectation) as t goes to infinity, in practice it is usually stopped far before that. Even in the case of convergence in expectation, we still face (possibly big) variations in the solution due to the stochastic nature of the algorithm. Therefore, the regularization effect we hope to have by solving the problem (1) may be elusive for any particular solution generated by (3) based on finite random samples.

An important example and main motivation for this paper is ℓ_1-regularized stochastic learning, where $\Psi(w) = \lambda\|w\|_1$. In the case of batch learning, the empirical minimization problem (2) can be solved to very high precision, for example, by interior-point methods. Therefore simply rounding the weights with very small magnitudes toward zero is usually enough to produce desired sparsity. As a result, ℓ_1-regularization has been very effective in obtaining sparse solutions using the batch optimization approach in statistical learning (e.g., Tibshirani, 1996) and signal processing

(e.g., Chen et al., 1998). In contrast, the SGD method (3) hardly generates any sparse solution, and its inherent low accuracy makes the simple rounding approach very unreliable. Several principled soft-thresholding or truncation methods have been developed to address this problem (e.g., Langford et al., 2009; Duchi and Singer, 2009), but the levels of sparsity in their solutions are still unsatisfactory compared with the corresponding batch solutions.

In this paper, we develop *regularized dual averaging* (RDA) methods that can exploit the structure of (1) more effectively in a stochastic online setting. More specifically, each iteration of the RDA methods takes the form

$$w_{t+1} = \arg\min_{w} \left\{ \frac{1}{t} \sum_{\tau=1}^{t} \langle g_\tau, w \rangle + \Psi(w) + \frac{\beta_t}{t} h(w) \right\}, \tag{4}$$

where $h(w)$ is an auxiliary strongly convex function, and $\{\beta_t\}_{t\geq 1}$ is a nonnegative and nondecreasing input sequence, which determines the convergence properties of the algorithm. Essentially, at each iteration, this method minimizes the sum of three terms: a linear function obtained by averaging all previous subgradients (the dual average), the original regularization function $\Psi(w)$, and an additional strongly convex regularization term $(\beta_t/t)h(w)$. The RDA method is an extension of the *simple dual averaging* scheme of Nesterov (2009), which is equivalent to letting $\Psi(w)$ be the indicator function of a closed convex set.

For the RDA method to be practically efficient, we assume that the functions $\Psi(w)$ and $h(w)$ are *simple*, meaning that we are able to find a closed-form solution for the minimization problem in (4). Then the computational effort per iteration is only $O(n)$, the same as the SGD method. This assumption indeed holds in many cases. For example, if we let $\Psi(w) = \lambda\|w\|_1$ and $h(w) = (1/2)\|w\|_2^2$, then w_{t+1} has an entry-wise closed-from solution. This solution uses a much more aggressive truncation threshold than previous methods, thus results in significantly improved sparsity (see discussions in Section 5).

In terms of iteration complexity, we show that if $\beta_t = \Theta(\sqrt{t})$, that is, with order exactly $\sqrt{t}$, then the RDA method (4) has the standard convergence rate

$$\mathbf{E}\,\phi(\bar{w}_t) - \phi^\star \leq O\left(\frac{G}{\sqrt{t}}\right),$$

where $\bar{w}_t = (1/t)\sum_{\tau=1}^{t} w_\tau$ is the *primal average*, and G is a uniform upper bound on the norms of the subgradients g_t. If the regularization term $\Psi(w)$ is strongly convex, then setting $\beta_t \leq O(\ln t)$ gives a faster convergence rate $O(\ln t/t)$.

For stochastic optimization problems in which the loss functions $f(w,z)$ are all differentiable and have Lipschitz continuous gradients, we also develop an accelerated version of the RDA method that has the convergence rate

$$\mathbf{E}\,\phi(w_t) - \phi^\star \leq O(1)\left(\frac{L}{t^2} + \frac{Q}{\sqrt{t}}\right),$$

where L is the Lipschitz constant of the gradients, and Q^2 is an upper bound on the variances of the stochastic gradients. In addition to convergence in expectation, we show that the same orders of convergence rates hold with high probability.

1.2 Regularized Online Optimization

In *online optimization*, we use an online algorithm to generate a sequence of decisions w_t, one at a time, for $t = 1, 2, 3, \ldots$. At each time t, a previously unknown cost function f_t is revealed, and we encounter a loss $f_t(w_t)$. We assume that the cost functions f_t are convex for all $t \geq 1$. The goal of the online algorithm is to ensure that the total cost up to each time t, $\sum_{\tau=1}^{t} f_\tau(w_\tau)$, is not much larger than $\min_w \sum_{\tau=1}^{t} f_\tau(w)$, the smallest total cost of any fixed decision w from hindsight. The difference between these two cost is called the *regret* of the online algorithm. Applications of online optimization include online prediction of time series and sequential investment (e.g., Cesa-Bianchi and Lugosi, 2006).

In regularized online optimization, we add a convex regularization term $\Psi(w)$ to each cost function. The regret with respect to any fixed decision $w \in \operatorname{dom}\Psi$ is

$$R_t(w) \triangleq \sum_{\tau=1}^{t} \big(f_\tau(w_\tau) + \Psi(w_\tau)\big) - \sum_{\tau=1}^{t} \big(f_\tau(w) + \Psi(w)\big). \tag{5}$$

As in the stochastic setting, the online algorithm can query a subgradient $g_t \in \partial f_t(w_t)$ at each step, and possibly use all previous information, to compute the next decision w_{t+1}. It turns out that the simple subgradient method (3) is well suited for online optimization: with a stepsize $\alpha_t = \Theta(1/\sqrt{t})$, it has a regret $R_t(w) \leq O(\sqrt{t})$ for all $w \in \operatorname{dom}\Psi$ (Zinkevich, 2003). This regret bound cannot be improved in general for convex cost functions. However, if the cost functions are strongly convex, say with convexity parameter σ, then the same algorithm with stepsize $\alpha_t = 1/(\sigma t)$ gives an $O(\ln t)$ regret bound (e.g., Hazan et al., 2006; Bartlett et al., 2008).

Similar to the discussions on regularized stochastic learning, the online subgradient method (3) in general lacks the capability of exploiting the regularization structure. In this paper, we show that the same RDA method (4) can effectively exploit such structure in an online setting, and ensure the $O(\sqrt{t})$ regret bound with $\beta_t = \Theta(\sqrt{t})$. For strongly convex regularizations, setting $\beta_t = O(\ln t)$ yields the improved regret bound $O(\ln t)$.

Since there is no specifications on the probability distribution of the sequence of functions, nor assumptions like mutual independence, online optimization can be considered as a more general framework than stochastic learning. In this paper, we will first establish regret bounds of the RDA method for solving online optimization problems, then use them to derive convergence rates for solving stochastic learning problems.

1.3 Outline of Contents

The methods we develop apply to more general settings than $\mathbf{R}^n$ with Euclidean geometry. In Section 1.4, we introduce the necessary notations and definitions associated with a general finite-dimensional real vector space.

In Section 2, we present the generic RDA method for solving both the stochastic learning and online optimization problems, and give several concrete examples of the method.

In Section 3, we present the precise regret bounds of the RDA method for solving regularized online optimization problems.

In Section 4, we derive convergence rates of the RDA method for solving regularized stochastic learning problems. In addition to the rates of convergence in expectation, we also give associated high probability bounds.

In Section 5, we explain the connections of the RDA method to several related work, and analyze its capability of generating better sparse solutions than other methods.

In Section 6, we give an enhanced version of the ℓ_1-RDA method, and present computational experiments on the MNIST handwritten data set (LeCun et al., 1998). Our experiments show that the RDA method is capable of generate sparse solutions that are comparable to those obtained by batch learning using interior-point methods.

In Section 7, we discuss the RDA methods in the context of *structural convex optimization* and their connections to incremental subgradient methods. As an extension, we develop an accelerated version of the RDA method for stochastic optimization problems with smooth loss functions. We also discuss in detail the p-norm based RDA methods.

Appendices A-D contain technical proofs of our main results.

1.4 Notations and Generalities

Let $\mathcal{E}$ be a finite-dimensional real vector space, endowed with a norm $\|\cdot\|$. This norm defines a systems of balls: $\mathcal{B}(w,r) = \{u \in \mathcal{E} \,|\, \|u-w\| \le r\}$. Let $\mathcal{E}^*$ be the vector space of all linear functions on $\mathcal{E}$, and let $\langle s, w\rangle$ denote the value of $s \in \mathcal{E}^*$ at $w \in \mathcal{E}$. The dual space $\mathcal{E}^*$ is endowed with the dual norm $\|s\|_* = \max_{\|w\|\le 1} \langle s, w\rangle$.

A function $h : \mathcal{E} \to \mathbf{R} \cup \{+\infty\}$ is called *strongly convex* with respect to the norm $\|\cdot\|$ if there exists a constant $\sigma > 0$ such that

$$h(\alpha w + (1-\alpha)u) \le \alpha h(w) + (1-\alpha)h(u) - \frac{\sigma}{2}\alpha(1-\alpha)\|w-u\|^2, \qquad \forall\, w, u \in \operatorname{dom} h.$$

The constant σ is called the *convexity parameter*, or the *modulus* of strong convexity. Let $\operatorname{rint} \mathcal{C}$ denote the *relative interior* of a convex set $\mathcal{C}$ (Rockafellar, 1970, Section 6). If h is strongly convex with modulus σ, then for any $w \in \operatorname{dom} h$ and $u \in \operatorname{rint}(\operatorname{dom} h)$,

$$h(w) \ge h(u) + \langle s, w-u\rangle + \frac{\sigma}{2}\|w-u\|^2, \qquad \forall\, s \in \partial h(u).$$

See, for example, Goebel and Rockafellar (2008) and Juditsky and Nemirovski (2008).

In the special case of the coordinate vector space $\mathcal{E} = \mathbf{R}^n$, we have $\mathcal{E} = \mathcal{E}^*$, and the standard inner product $\langle s, w\rangle = s^T w = \sum_{i=1}^n s^{(i)} w^{(i)}$, where $w^{(i)}$ denotes the i-th coordinate of w. For the standard Euclidean norm, $\|w\| = \|w\|_2 = \sqrt{\langle w, w\rangle}$ and $\|s\|_* = \|s\|_2$. For any $w_0 \in \mathbf{R}^n$, the function $h(w) = (\sigma/2)\|w - w_0\|_2^2$ is strongly convex with modulus σ.

For another example, consider the ℓ_1-norm $\|w\| = \|w\|_1 = \sum_{i=1}^n |w^{(i)}|$ and its associated dual norm $\|w\|_* = \|w\|_\infty = \max_{1\le i\le n} |w^{(i)}|$. Let $\mathcal{S}_n$ be the standard simplex in $\mathbf{R}^n$, that is, $\mathcal{S}_n = \left\{w \in \mathbf{R}^n_+ \,|\, \sum_{i=1}^n w^{(i)} = 1\right\}$. Then the negative entropy function

$$h(w) = \sum_{i=1}^n w^{(i)} \ln w^{(i)} + \ln n, \tag{6}$$

with $\operatorname{dom} h = \mathcal{S}_n$, is strongly convex with respect to $\|\cdot\|_1$ with modulus 1 (see, e.g., Nesterov, 2005, Lemma 3). In this case, the unique minimizer of h is $w_0 = (1/n, \ldots, 1/n)$.

For a closed proper convex function Ψ, we use $\operatorname{Arg\,min}_w \Psi(w)$ to denote the (convex) set of minimizing solutions. If a convex function h has a unique minimizer, for example, when h is strongly convex, then we use $\arg\min_w h(w)$ to denote that single point.

Algorithm 1 Regularized dual averaging (RDA) method

input:

- an auxiliary function $h(w)$ that is strongly convex on $\operatorname{dom}\Psi$ and also satisfies

$$\arg\min_w h(w) \in \operatorname{Arg}\min_w \Psi(w). \tag{7}$$

- a nonnegative and nondecreasing sequence $\{\beta_t\}_{t\geq 1}$.

initialize: set $w_1 = \arg\min_w h(w)$ and $\bar{g}_0 = 0$.

for $t = 1, 2, 3, \ldots$ **do**

1. Given the function f_t, compute a subgradient $g_t \in \partial f_t(w_t)$.
2. Update the average subgradient:

$$\bar{g}_t = \frac{t-1}{t}\bar{g}_{t-1} + \frac{1}{t}g_t.$$

3. Compute the next weight vector:

$$w_{t+1} = \arg\min_w \left\{ \langle \bar{g}_t, w\rangle + \Psi(w) + \frac{\beta_t}{t}h(w) \right\}. \tag{8}$$

end for

2. Regularized Dual Averaging Method

In this section, we present the generic RDA method (Algorithm 1) for solving regularized stochastic learning and online optimization problems, and give several concrete examples. To unify notation, we use $f_t(w)$ to denote the cost function at each step t. For stochastic learning problems, we simply let $f_t(w) = f(w, z_t)$.

At the input to the RDA method, we need an auxiliary function h that is strongly convex on $\operatorname{dom}\Psi$. The condition (7) requires that its unique minimizer must also minimize the regularization function Ψ. This can be done, for example, by first choosing a starting point $w_0 \in \operatorname{Arg}\min_w \Psi(w)$ and an arbitrary strongly convex function $h'(w)$, then letting

$$h(w) = h'(w) - h'(w_0) - \langle \nabla h'(w_0), w - w_0\rangle.$$

In other words, $h(w)$ is the *Bregman divergence* from w_0 induced by $h'(w)$. If h' is not differentiable, but subdifferentiable at w_0, we can replace $\nabla h'(w_0)$ with a subgradient. The input sequence $\{\beta_t\}_{t\geq 1}$ determines the convergence rate, or regret bound, of the algorithm.

There are three steps in each iteration of the RDA method. Step 1 is to compute a subgradient of f_t at w_t, which is standard for all subgradient or gradient based methods. Step 2 is the online version of computing the average subgradient:

$$\bar{g}_t = \frac{1}{t}\sum_{\tau=1}^{t} g_\tau.$$

The name *dual averaging* comes from the fact that the subgradients live in the dual space $\mathcal{E}^*$.

Step 3 is most interesting and worth further explanation. In particular, the efficiency in computing w_{t+1} determines how useful the method is in practice. For this reason, we assume the regularization functions $\Psi(w)$ and $h(w)$ are *simple*. This means the minimization problem in (8) can be solved with little effort, especially if we are able to find a closed-form solution for w_{t+1}. At first sight, this assumption seems to be quite restrictive. However, the examples below show that this indeed is the case for many important learning problems in practice.

2.1 RDA Methods with General Convex Regularization

For a general convex regularization Ψ, we can choose any positive sequence $\{\beta_t\}_{t\geq 1}$ that is order exactly $\sqrt{t}$, to obtain an $O(1/\sqrt{t})$ convergence rate for stochastic learning, or an $O(\sqrt{t})$ regret bound for online optimization. We will state the formal convergence theorems in Sections 3 and 4. Here, we give several concrete examples. To be more specific, we choose a parameter $\gamma > 0$ and use the sequence

$$\beta_t = \gamma\sqrt{t}, \qquad t = 1, 2, 3, \ldots.$$

- *Nesterov's dual averaging method*. Let $\Psi(w)$ be the indicator function of a closed convex set $\mathcal{C}$. This recovers the *simple dual averaging* scheme in Nesterov (2009). If we choose $h(w) = (1/2)\|w\|_2^2$, then the Equation (8) yields

$$w_{t+1} = \Pi_{\mathcal{C}}\left(-\frac{\sqrt{t}}{\gamma}\bar{g}_t\right) = \Pi_{\mathcal{C}}\left(-\frac{1}{\gamma\sqrt{t}}\sum_{\tau=1}^{t} g_\tau\right). \tag{9}$$

  When $\mathcal{C} = \{w \in \mathbf{R}^n \,|\, \|w\|_1 \leq \delta\}$ for some $\delta > 0$, we have "hard" ℓ_1-regularization. In this case, although there is no closed-form solution for w_{t+1}, efficient algorithms for projection onto the ℓ_1-ball can be found, for example, in Duchi et al. (2008).

- *"Soft" ℓ_1-regularization*. Let $\Psi(w) = \lambda\|w\|_1$ for some $\lambda > 0$, and $h(w) = (1/2)\|w\|_2^2$. In this case, w_{t+1} has a closed-form solution (see Appendix A for the derivation):

$$w_{t+1}^{(i)} = \begin{cases} 0 & \text{if } \left|\bar{g}_t^{(i)}\right| \leq \lambda, \\ -\dfrac{\sqrt{t}}{\gamma}\left(\bar{g}_t^{(i)} - \lambda\,\mathrm{sgn}\left(\bar{g}_t^{(i)}\right)\right) & \text{otherwise,} \end{cases} \qquad i = 1, \ldots, n. \tag{10}$$

  Here $\mathrm{sgn}(\cdot)$ is the *sign* or *signum* function, that is, $\mathrm{sgn}(\omega)$ equals 1 if $\omega > 0$, -1 if $\omega < 0$, and 0 if $\omega = 0$. Whenever a component of $\bar{g}_t$ is less than λ in magnitude, the corresponding component of w_{t+1} is set to zero. Further extensions of the ℓ_1-RDA method, and associated computational experiments, are given in Section 6.

- *Exponentiated dual averaging method*. Let $\Psi(w)$ be the indicator function of the standard simplex $\mathcal{S}_n$, and $h(w)$ be the negative entropy function defined in (6). In this case,

$$w_{t+1}^{(i)} = \frac{1}{Z_{t+1}}\exp\left(-\frac{\sqrt{t}}{\gamma}\bar{g}_t^{(i)}\right), \qquad i = 1, \ldots, n,$$

  where Z_{t+1} is a normalization parameter such that $\sum_{i=1}^n w_{t+1}^{(i)} = 1$. This is the dual averaging version of the exponentiated gradient algorithm (Kivinen and Warmuth, 1997); see also Tseng and Bertsekas (1993) and Juditsky et al. (2005). We note that this example is also covered by Nesterov's dual averaging method.

We discuss in detail the special case of p-norm RDA method in Section 7.2. Several other examples, including ℓ_∞-norm and a hybrid ℓ_1/ℓ_2-norm (*Berhu*) regularization, also admit closed-form solutions for w_{t+1}. Their solutions are similar in form to those obtained in the context of the FOBOS algorithm in Duchi and Singer (2009).

2.2 RDA Methods with Strongly Convex Regularization

If the regularization term $\Psi(w)$ is strongly convex, we can use any nonnegative and nondecreasing sequence $\{\beta_t\}_{t\geq 1}$ that grows no faster than $O(\ln t)$, to obtain an $O(\ln t/t)$ convergence rate for stochastic learning, or an $O(\ln t)$ regret bound for online optimization. For simplicity, in the following examples, we use the zero sequence $\beta_t = 0$ for all $t \geq 1$. In this case, we do not need the auxiliary function $h(w)$, and the Equation (8) becomes

$$w_{t+1} = \arg\min_w \left\{ \langle \bar{g}_t, w \rangle + \Psi(w) \right\}.$$

- *ℓ_2^2-regularization*. Let $\Psi(w) = (\sigma/2)\|w\|_2^2$ for some $\sigma > 0$. In this case,

$$w_{t+1} = -\frac{1}{\sigma}\bar{g}_t = -\frac{1}{\sigma t}\sum_{\tau=1}^{t} g_\tau.$$

- *Mixed ℓ_1/ℓ_2^2-regularization*. Let $\Psi(w) = \lambda\|w\|_1 + (\sigma/2)\|w\|_2^2$ with $\lambda > 0$ and $\sigma > 0$. In this case, we have

$$w_{t+1}^{(i)} = \begin{cases} 0 & \text{if } |\bar{g}_t^{(i)}| \leq \lambda, \\ -\frac{1}{\sigma}\left(\bar{g}_t^{(i)} - \lambda \operatorname{sgn}\left(\bar{g}_t^{(i)}\right)\right) & \text{otherwise,} \end{cases} \qquad i = 1, \ldots, n.$$

- *Kullback-Leibler (KL) divergence regularization*. Let $\Psi(w) = \sigma D_{\mathrm{KL}}(w\|p)$, where the given probability distribution $p \in \operatorname{rint} \mathcal{S}_n$, and

$$D_{\mathrm{KL}}(w\|p) \triangleq \sum_{i=1}^{n} w^{(i)} \ln\left(\frac{w^{(i)}}{p^{(i)}}\right).$$

  Here $D_{\mathrm{KL}}(w\|p)$ is strongly convex with respect to $\|w\|_1$ with modulus 1. In this case,

$$w_{t+1}^{(i)} = \frac{1}{Z_{t+1}} p^{(i)} \exp\left(-\frac{1}{\sigma}\bar{g}_t^{(i)}\right),$$

  where Z_{t+1} is a normalization parameter such that $\sum_{i=1}^{n} w_{t+1}^{(i)} = 1$. KL divergence regularization has the *pseudo-sparsity* effect, meaning that most elements in w can be replaced by elements in the constant vector p without significantly increasing the loss function (e.g., Bradley and Bagnell, 2009).

3. Regret Bounds for Online Optimization

In this section, we give the precise regret bounds of the RDA method for solving regularized online optimization problems. The convergence rates for stochastic learning problems can be established based on these regret bounds, and will be given in the next section. For clarity, we gather here the general assumptions used throughout this paper:

- The regularization term $\Psi(w)$ is a closed proper convex function, and $\operatorname{dom}\Psi$ is closed. The symbol σ is dedicated to the convexity parameter of Ψ. Without loss of generality, we assume $\min_w \Psi(w) = 0$.
- For each $t \geq 1$, the function $f_t(w)$ is convex and subdifferentiable on $\operatorname{dom}\Psi$.
- The function $h(w)$ is strongly convex on $\operatorname{dom}\Psi$, and subdifferentiable on $\operatorname{rint}(\operatorname{dom}\Psi)$. Without loss of generality, assume $h(w)$ has convexity parameter 1 and $\min_w h(w) = 0$.

We will not repeat these general assumptions when stating our formal results later.

To facilitate regret analysis, we first give a few definitions. For any constant $D > 0$, we define the set

$$\mathcal{F}_D \triangleq \left\{ w \in \operatorname{dom}\Psi \;\middle|\; h(w) \leq D^2 \right\},$$

and let

$$\Gamma_D = \sup_{w \in \mathcal{F}_D} \inf_{g \in \partial\Psi(w)} \|g\|_*. \tag{11}$$

We use the convention $\inf_{g\in\emptyset} \|g\|_* = +\infty$, where $\emptyset$ denotes the empty set. As a result, if Ψ is not subdifferentiable everywhere on $\mathcal{F}_D$, that is, if $\partial\Psi(w) = \emptyset$ at some $w \in \mathcal{F}_D$, then we have $\Gamma_D = +\infty$. Note that Γ_D is not a Lipschitz-type constant which would be required to be an upper bound on all the subgradients; instead, we only require that at least one subgradient is bounded in norm by Γ_D at every point in the set $\mathcal{F}_D$.

We assume that the sequence of subgradients $\{g_t\}_{t\geq 1}$ generated by Algorithm 1 is bounded, that is, there exist a constant G such that

$$\|g_t\|_* \leq G, \quad \forall t \geq 1. \tag{12}$$

This is true, for example, if $\operatorname{dom}\Psi$ is compact and each f_t has Lipschitz-continuous gradient on $\operatorname{dom}\Psi$. We require that the input sequence $\{\beta_t\}_{t\geq 1}$ be chosen such that

$$\max\{\sigma, \beta_1\} > 0, \tag{13}$$

where σ is the convexity parameter of $\Psi(w)$. For convenience, we let $\beta_0 = \max\{\sigma, \beta_1\}$ and define the sequence of *regret bounds*

$$\Delta_t \triangleq \beta_t D^2 + \frac{G^2}{2} \sum_{\tau=0}^{t-1} \frac{1}{\sigma\tau + \beta_\tau} + \frac{2(\beta_0 - \beta_1)G^2}{(\beta_1 + \sigma)^2}, \qquad t = 1, 2, 3, \ldots, \tag{14}$$

where D is the constant used in the definition of $\mathcal{F}_D$. We could always set $\beta_1 \geq \sigma$, so that $\beta_0 = \beta_1$ and therefore the term $2(\beta_0 - \beta_1)G^2/(\beta_1 + \sigma)^2$ vanishes in the definition (14). However, when $\sigma > 0$, we would like to keep the flexibility of setting $\beta_t = 0$ for all $t \geq 1$, as we did in Section 2.2.

Theorem 1 *Let the sequences $\{w_t\}_{t\geq 1}$ and $\{g_t\}_{t\geq 1}$ be generated by Algorithm 1, and assume (12) and (13) hold. Then for any $t \geq 1$ and any $w \in \mathcal{F}_D$, we have:*

(a) The regret defined in (5) is bounded by Δ_t, that is,

$$R_t(w) \leq \Delta_t. \tag{15}$$

(b) The primal variables are bounded as

$$\|w_{t+1} - w\|^2 \leq \frac{2}{\sigma t + \beta_t}\big(\Delta_t - R_t(w)\big). \tag{16}$$

(c) If w is an interior point, that is, $\mathcal{B}(w,r) \subset \mathcal{F}_D$ for some $r > 0$, then

$$\|\bar{g}_t\|_* \leq \Gamma_D - \frac{1}{2}\sigma r + \frac{1}{rt}\big(\Delta_t - R_t(w)\big). \tag{17}$$

In Theorem 1, the bounds on $\|w_{t+1} - w\|^2$ and $\|\bar{g}_t\|_*$ depend on the regret $R_t(w)$. More precisely, they depend on $\Delta_t - R_t(w)$, which is the *slack* of the regret bound in (15). A smaller slack is equivalent to a larger regret $R_t(w)$, which means w is a better *fixed* solution for the online optimization problem (the best one gives the largest regret); correspondingly, the inequality (16) gives a tighter bound on $\|w_{t+1} - w\|^2$. In (17), the left-hand side $\|\bar{g}_t\|_*$ does not depend on any particular interior point w to compare with, but the right-hand side depends on both $R_t(w)$ and how far w is from the boundary of $\mathcal{F}_D$. The tightest bound on $\|\bar{g}_t\|_*$ can be obtained by taking the infimum of the right-hand side over all $w \in \operatorname{int} \mathcal{F}_D$. We further elaborate on part (c) through the following two examples:

- Consider the case when Ψ is the indicator function of a closed convex set $\mathcal{C}$. In this case, $\sigma = 0$ and $\partial\Psi(w)$ is the *normal cone* to $\mathcal{C}$ at w (Rockafellar, 1970, Section 23). By the definition (11), we have $\Gamma_D = 0$ because the zero vector is a subgradient at every $w \in \mathcal{C}$, even though the normal cones can be unbounded at the boundary of $\mathcal{C}$. In this case, if $\mathcal{B}(w,r) \subset \mathcal{F}_D$ for some $r > 0$, then (17) simplifies to

$$\|\bar{g}_t\|_* \leq \frac{1}{rt}\big(\Delta_t - R_t(w)\big).$$

- Consider the function $\Psi(w) = \sigma D_{\mathrm{KL}}(w\|p)$ with $\operatorname{dom}\Psi = \mathcal{S}_n$ (assuming $p \in \operatorname{rint}\mathcal{S}_n$). In this case, $\operatorname{dom}\Psi$, and hence $\mathcal{F}_D$, have empty interior. Therefore the bound in part (c) does not apply. In fact, the quantity Γ_D can be unbounded anyway. In particular, the subdifferentials of Ψ at the relative boundary of $\mathcal{S}_n$ are all empty. In the relative interior of $\mathcal{S}_n$, the subgradients (actually gradients) of Ψ always exist, but can become unbounded for points approaching the relative boundary. Nevertheless, the bounds in parts (a) and (b) still hold.

The proof of Theorem 1 is given in Appendix B. In the rest of this section, we discuss more concrete regret bounds depending on whether or not Ψ is strongly convex.

3.1 Regret Bound with General Convex Regularization

For a general convex regularization term Ψ, any nonnegative and nondecreasing sequence $\beta_t = \Theta(\sqrt{t})$ gives an $O(\sqrt{t})$ regret bound. Here we give detailed analysis for the sequence used in Section 2.1. More specifically, we choose a constant $\gamma > 0$ and let

$$\beta_t = \gamma\sqrt{t}, \qquad \forall\, t \geq 1. \tag{18}$$

We have the following corollary of Theorem 1.

Corollary 2 *Let the sequences $\{w_t\}_{t\geq 1}$ and $\{g_t\}_{t\geq 1}$ be generated by Algorithm 1 using $\{\beta_t\}_{t\geq 1}$ defined in (18), and assume (12) holds. Then for any $t \geq 1$ and any $w \in \mathcal{F}_D$:*

(a) The regret is bounded as

$$R_t(w) \leq \left(\gamma D^2 + \frac{G^2}{\gamma}\right)\sqrt{t}.$$

(b) The primal variables are bounded as

$$\frac{1}{2}\|w_{t+1} - w\|^2 \leq D^2 + \frac{G^2}{\gamma^2} - \frac{1}{\gamma\sqrt{t}}R_t(w).$$

(c) If w is an interior point, that is, $\mathcal{B}(w,r) \subset \mathcal{F}_D$ for some $r > 0$, then

$$\|\bar{g}_t\|_* \leq \Gamma_D + \left(\gamma D^2 + \frac{G^2}{\gamma}\right)\frac{1}{r\sqrt{t}} - \frac{1}{rt}R_t(w).$$

Proof To simplify regret analysis, let $\gamma \geq \sigma$. Therefore $\beta_0 = \beta_1 = \gamma$. Then Δ_t defined in (14) becomes

$$\Delta_t = \gamma\sqrt{t}D^2 + \frac{G^2}{2\gamma}\left(1 + \sum_{\tau=1}^{t-1}\frac{1}{\sqrt{\tau}}\right).$$

Next using the inequality

$$\sum_{\tau=1}^{t-1}\frac{1}{\sqrt{\tau}} \leq 1 + \int_1^t \frac{1}{\sqrt{\tau}}d\tau = 2\sqrt{t} - 1,$$

we get

$$\Delta_t \leq \gamma\sqrt{t}D^2 + \frac{G^2}{2\gamma}\left(1 + \left(2\sqrt{t} - 1\right)\right) = \left(\gamma D^2 + \frac{G^2}{\gamma}\right)\sqrt{t}.$$

Combining the above inequality and the conclusions of Theorem 1 proves the corollary. ■

The regret bound in Corollary 2 is essentially the same as the *online gradient descent* method of Zinkevich (2003), which has the form (3), with the stepsize $\alpha_t = 1/(\gamma\sqrt{t})$. The main advantage of the RDA method is its capability of exploiting the regularization structure, as shown in Section 2. The parameters D and G are not used explicitly in the algorithm. However, we need good estimates of them for choosing a reasonable value for γ. The best γ that minimizes the expression $\gamma D^2 + G^2/\gamma$ is

$$\gamma^\star = \frac{G}{D},$$

which leads to the simplified regret bound

$$R_t(w) \leq 2GD\sqrt{t}.$$

If the total number of online iterations T is known in advance, then using a constant stepsize in the classical gradient method (3), say

$$\alpha_t = \frac{1}{\gamma^\star}\sqrt{\frac{2}{T}} = \frac{D}{G}\sqrt{\frac{2}{T}}, \qquad \forall t = 1,\ldots,T, \tag{19}$$

gives a slightly improved bound $R_T(w) \leq \sqrt{2}GD\sqrt{T}$ (see, e.g., Nemirovski et al., 2009).

The bound in part (b) does not converge to zero. This result is still interesting because there is no special caution taken in the RDA method, more specifically in (8), to ensure the boundedness of the sequence w_t. In the case $\Psi(w) = 0$, as pointed out by Nesterov (2009), this may even look surprising since we are minimizing over $\mathcal{E}$ the sum of a linear function and a regularization term $(\gamma/\sqrt{t})h(w)$ that eventually goes to zero.

Part (c) gives a bound on the norm of the dual average. If $\Psi(w)$ is the indicator function of a closed convex set, then $\Gamma_D = 0$ and part (c) shows that $\bar{g}_t$ actually converges to zero if there exist an interior w in $\mathcal{F}_D$ such that $R_t(w) \geq 0$. However, a properly scaled version of $\bar{g}_t$, $-(\sqrt{t}/\gamma)\bar{g}_t$, tracks the optimal solution; see the examples in Section 2.1.

3.2 Regret Bounds with Strongly Convex Regularization

If the regularization function $\Psi(w)$ is strongly convex, that is, with a convexity parameter $\sigma > 0$, then any nonnegative, nondecreasing sequence that satisfies $\beta_t \leq O(\ln t)$ will give an $O(\ln t)$ regret bound. If $\{\beta_t\}_{t\geq 1}$ is not the all zero sequence, we can simply choose the auxiliary function $h(w) = (1/\sigma)\Psi(w)$. Here are several possibilities:

- *Positive constant sequences*. For simplicity, let $\beta_t = \sigma$ for $t \geq 0$. In this case,

$$\Delta_t = \sigma D^2 + \frac{G^2}{2\sigma}\sum_{\tau=0}^{t-1}\frac{1}{\tau+1} \leq \sigma D^2 + \frac{G^2}{2\sigma}(1+\ln t).$$

- *Logarithmic sequences*. Let $\beta_t = \sigma(1+\ln t)$ for $t \geq 1$. In this case, $\beta_0 = \beta_1 = \sigma$ and

$$\Delta_t = \sigma(1+\ln t)D^2 + \frac{G^2}{2\sigma}\left(1 + \sum_{\tau=1}^{t-1}\frac{1}{\tau+1+\ln\tau}\right) \leq \left(\sigma D^2 + \frac{G^2}{2\sigma}\right)(1+\ln t).$$

- *The zero sequence*. Let $\beta_t = 0$ for $t \geq 1$. In this case, $\beta_0 = \sigma$ and

$$\Delta_t = \frac{G^2}{2\sigma}\left(1 + \sum_{\tau=1}^{t-1}\frac{1}{\tau}\right) + \frac{2G^2}{\sigma} \leq \frac{G^2}{2\sigma}(6+\ln t). \tag{20}$$

Notice that in this last case, the regret bound does not depend on D.

When Ψ is strongly convex, we also conclude that, given two different points u and v, the regrets $R_t(u)$ and $R_t(v)$ cannot be nonnegative simultaneously if t is large enough. To see this, we notice that if $R_t(u)$ and $R_t(v)$ are nonnegative simultaneously for some t, then part (b) of Theorem 1 implies

$$\|w_{t+1} - u\|^2 \leq O\left(\frac{\ln t}{t}\right), \qquad \text{and} \qquad \|w_{t+1} - v\|^2 \leq O\left(\frac{\ln t}{t}\right),$$

which again implies

$$\|u - v\|^2 \leq (\|w_{t+1} - u\| + \|w_{t+1} - v\|)^2 \leq O\left(\frac{\ln t}{t}\right).$$

Therefore, if the event $R_t(u) \geq 0$ and $R_t(v) \geq 0$ happens for infinitely many t, we must have $u = v$. If $u \neq v$, then eventually at least one of the regrets associated with them will become negative. However, it is possible to construct sequences of functions f_t such that the points with nonnegative regrets do not converge to a fixed point.

4. Convergence Rates for Stochastic Learning

In this section, we give convergence rates of the RDA method when it is used to solve the regularized stochastic learning problem (1), and also the related high probability bounds. These rates and bounds are established not for the individual w_t's generated by the RDA method, but rather for the *primal average*

$$\bar{w}_t = \frac{1}{t}\sum_{\tau=1}^{t} w_\tau, \qquad t \geq 1.$$

4.1 Rate of Convergence in Expectation

Theorem 3 *Assume there exists an optimal solution $w^\star$ to the problem (1) that satisfies $h(w^\star) \leq D^2$ for some $D > 0$, and let $\phi^\star = \phi(w^\star)$. Let the sequences $\{w_t\}_{t\geq 1}$ and $\{g_t\}_{t\geq 1}$ be generated by Algorithm 1, and assume (12) holds. Then for any $t \geq 1$, we have:*

(a) The expected cost associated with the random variable $\bar{w}_t$ is bounded as

$$\mathbf{E}\,\phi(\bar{w}_t) - \phi^\star \leq \frac{1}{t}\Delta_t.$$

(b) The primal variables are bounded as

$$\mathbf{E}\,\|w_{t+1} - w^\star\|^2 \leq \frac{2}{\sigma t + \beta_t}\Delta_t.$$

(c) If $w^\star$ is an interior point, that is, $\mathcal{B}(w^\star, r) \subset \mathcal{F}_D$ for some $r > 0$, then

$$\mathbf{E}\|\bar{g}_t\|_* \leq \Gamma_D - \frac{1}{2}\sigma r + \frac{1}{rt}\Delta_t.$$

Proof First, we substitute all $f_\tau(\cdot)$ by $f(\cdot, z_\tau)$ in the definition of the regret

$$R_t(w^\star) = \sum_{\tau=1}^{t} \big(f(w_\tau, z_\tau) + \Psi(w_\tau)\big) - \sum_{\tau=1}^{t} \big(f(w^\star, z_\tau) + \Psi(w^\star)\big).$$

Let $\mathbf{z}[t]$ denote the collection of i.i.d. random variables $(z_1, \ldots, z_t)$. All the expectations in Theorem 3 are taken with respect to $\mathbf{z}[t]$, that is, the symbol $\mathbf{E}$ can be written more explicitly as $\mathbf{E}_{\mathbf{z}[t]}$. We note that the random variable w_τ, where $1 \le \tau \le t$, is a function of $(z_1, \ldots, z_{\tau-1})$, and is independent of $(z_\tau, \ldots, z_t)$. Therefore

$$\mathbf{E}_{\mathbf{z}[t]}\big(f(w_\tau, z_\tau) + \Psi(w_\tau)\big) = \mathbf{E}_{\mathbf{z}[\tau-1]}\big(\mathbf{E}_{z_\tau} f(w_\tau, z_\tau) + \Psi(w_\tau)\big) = \mathbf{E}_{\mathbf{z}[\tau-1]}\phi(w_\tau) = \mathbf{E}_{\mathbf{z}[t]}\phi(w_\tau),$$

and

$$\mathbf{E}_{\mathbf{z}[t]}\big(f(w^\star, z_\tau) + \Psi(w^\star)\big) = \mathbf{E}_{z_\tau} f(w^\star, z_\tau) + \Psi(w^\star) = \phi(w^\star) = \phi^\star.$$

Since $\phi^\star = \phi(w^\star) = \min_w \phi(w)$, we have

$$\mathbf{E}_{\mathbf{z}[t]} R_t(w^\star) = \sum_{\tau=1}^{t} \mathbf{E}_{\mathbf{z}[t]}\phi(w_\tau) - t\phi^\star \ge 0. \tag{21}$$

By convexity of ϕ, we have

$$\phi(\bar{w}_t) = \phi\left(\frac{1}{t}\sum_{\tau=1}^{t} w_\tau\right) \le \frac{1}{t}\sum_{\tau=1}^{t} \phi(w_\tau)$$

Taking expectation with respect to $\mathbf{z}[t]$ and subtracting $\phi^\star$, we have

$$\mathbf{E}_{\mathbf{z}[t]}\phi(\bar{w}_t) - \phi^\star \le \frac{1}{t}\left(\sum_{\tau=1}^{t} \mathbf{E}_{\mathbf{z}[t]}\phi(\bar{w}_\tau) - t\phi^\star\right) = \frac{1}{t}\mathbf{E}_{\mathbf{z}[t]} R_t(w^\star).$$

Then part (a) follows from that of Theorem 1, which states that $R_t(w^\star) \le \Delta_t$ for all realizations of $\mathbf{z}[t]$. Similarly, parts (b) and (c) follow from those of Theorem 1 and (21). ■

Specific convergence rates can be obtained in parallel with the regret bounds discussed in Sections 3.1 and 3.2. We only need to divide every regret bound by t to obtain the corresponding rate of convergence in expectation. More specifically, using appropriate sequences $\{\beta_t\}_{t\ge1}$, we have $\mathbf{E}\phi(\bar{w}_t)$ converging to $\phi^\star$ with rate $O(1/\sqrt{t})$ for general convex regularization, and $O(\ln t/t)$ for strongly convex regularization.

The bound in part (b) applies to both the case $\sigma = 0$ and the case $\sigma > 0$. For the latter, we can derive a slightly different and more specific bound. When Ψ has convexity parameter $\sigma > 0$, so is the function ϕ. Therefore,

$$\phi(w_t) \ge \phi(w^\star) + \langle s, w_t - w^\star\rangle + \frac{\sigma}{2}\|w_t - w^\star\|^2, \qquad \forall s \in \partial\phi(w^\star).$$

Since $w^\star$ is the minimizer of ϕ, we must have $0 \in \partial\phi(w^\star)$ (Rockafellar, 1970, Section 27). Setting $s = 0$ in the above inequality and rearranging terms, we have

$$\|w_t - w^\star\|^2 \le \frac{2}{\sigma}\left(\phi(w_t) - \phi^\star\right).$$

Taking expectation of both sides of the above inequality leads to

$$\mathbf{E}\|w_t - w^\star\|^2 \leq \frac{2}{\sigma}\left(\mathbf{E}\phi(w_t) - \phi^\star\right) \leq \frac{2}{\sigma t}\Delta_t, \tag{22}$$

where in the last step we used part (a) of Theorem 3. This bound directly relate w_t to Δ_t.

Next we take a closer look at the quantity $\mathbf{E}\|\bar{w}_t - w^\star\|^2$. By convexity of $\|\cdot\|^2$, we have

$$\mathbf{E}\|\bar{w}_t - w^\star\|^2 \leq \frac{1}{t}\sum_{\tau=1}^{t}\mathbf{E}\|w_\tau - w^\star\|^2 \tag{23}$$

If $\sigma = 0$, then it is simply bounded by a constant because each $\mathbf{E}\|w_\tau - w^\star\|^2$ for $1 \leq \tau \leq t$ is bounded by a constant. When $\sigma > 0$, the optimal solution $w^\star$ is unique, and we have:

Corollary 4 *If Ψ is strongly convex with convexity parameter $\sigma > 0$ and $\beta_t = O(\ln t)$, then*

$$\mathbf{E}\|\bar{w}_t - w^\star\|^2 \leq O\left(\frac{(\ln t)^2}{t}\right).$$

Proof For the ease of presentation, we consider the case $\beta_t = 0$ for all $t \geq 1$. Substituting the bound on Δ_t in (20) into the inequality (22) gives

$$\mathbf{E}\|w_t - w^\star\|^2 \leq \frac{(6 + \ln t)\,G^2}{t\,\sigma^2}, \qquad \forall t \geq 1.$$

Then by (23),

$$\mathbf{E}\|\bar{w}_t - w^\star\|^2 \leq \frac{1}{t}\sum_{\tau=1}^{t}\left(\frac{6}{\tau} + \frac{\ln\tau}{\tau}\right)\frac{G^2}{\sigma^2} \leq \frac{1}{t}\left(6(1+\ln t) + \frac{1}{2}(\ln t)^2\right)\frac{G^2}{\sigma^2}.$$

In other words, $\mathbf{E}\|\bar{w}_t - w^\star\|^2$ converges to zero with rate $O((\ln t)^2/t)$. This can be shown for any $\beta_t = O(\ln t)$; see Section 3.2 for other choices of β_t. ■

As a further note, the conclusions in Theorem 3 still hold if the assumption (12) is weakened to

$$\mathbf{E}\,\|g_t\|_*^2 \leq G^2, \qquad \forall t \geq 1. \tag{24}$$

However, we need (12) in order to prove the high probability bounds presented next.

4.2 High Probability Bounds

For stochastic learning problems, in addition to the rates of convergence in expectation, it is often desirable to obtain confidence level bounds for approximate solutions. For this purpose, we start from part (a) of Theorem 3, which states $\mathbf{E}\phi(w_t) - \phi^\star \leq (1/t)\Delta_t$. By Markov's inequality, we have for any $\varepsilon > 0$,

$$\mathrm{Prob}\big(\phi(\bar{w}_t) - \phi^\star > \varepsilon\big) \leq \frac{\Delta_t}{\varepsilon t}. \tag{25}$$

This bound holds even with the weakened assumption (24). However, it is possible to have much tighter bounds under more restrictive assumptions. To this end, we have the following result.

Theorem 5 *Assume there exist constants D and G such that $h(w^\star) \le D^2$, and $h(w_t) \le D^2$ and $\|g_t\|_* \le G$ for all $t \ge 1$. Then for any $\delta \in (0,1)$, we have, with probability at least $1-\delta$,*

$$\phi(\bar{w}_t) - \phi^\star \le \frac{\Delta_t}{t} + \frac{8GD\sqrt{\ln(1/\delta)}}{\sqrt{t}}, \qquad \forall t \ge 1. \tag{26}$$

Theorem 5 is proved in Appendix C.

From our results in Section 3.1, with the input sequence $\beta_t = \gamma\sqrt{t}$ for all $t \ge 1$, we have $\Delta_t = O(\sqrt{t})$ regardless of $\sigma = 0$ or $\sigma > 0$. Therefore, $\phi(\bar{w}_t) - \phi^\star = O(1/\sqrt{t})$ with high probability. To simplify further discussion, let $\gamma = G/D$, hence $\Delta_t \le 2GD\sqrt{t}$ (see Section 3.1). In this case, if $\delta \le 1/e \approx 0.368$, then with probability at least $1-\delta$,

$$\phi(\bar{w}_t) - \phi^\star \le \frac{10GD\sqrt{\ln(1/\delta)}}{\sqrt{t}}.$$

Letting $\varepsilon = 10GD\sqrt{\ln(1/\delta)}/\sqrt{t}$, then the above bound is equivalent to

$$\text{Prob}\left(\phi(\bar{w}_t) - \phi^\star > \varepsilon\right) \le \exp\left(-\frac{\varepsilon^2 t}{(10GD)^2}\right),$$

which is much tighter than the one in (25). It follows that for any chosen accuracy ε and $0 < \delta \le 1/e$, the sample size

$$t \ge \frac{(10GD)^2 \ln(1/\delta)}{\varepsilon^2}$$

guarantees that, with probability at least $1-\delta$, $\bar{w}_t$ is an ε-optimal solution of the original stochastic optimization problem (1).

When Ψ is strongly convex ($\sigma > 0$), our results in Section 3.2 show that we can obtain regret bounds $\Delta_t = O(\ln t)$ using $\beta_t = O(\ln t)$. However, the high probability bound in Theorem 5 does not improve: we still have $\phi(\bar{w}_t) - \phi^\star = O(1/\sqrt{t})$, not $O(\ln t/t)$. The reason is that the concentration inequality (Azuma, 1967) used in proving Theorem 5 cannot take advantage of the strong-convexity property. By using a refined concentration inequality due to Freedman (1975), Kakade and Tewari (2009, Theorem 2) showed that for strongly convex stochastic learning problems, with probability at least $1 - 4\delta \ln t$,

$$\phi(\bar{w}_t) - \phi^\star \le \frac{R_t(w^\star)}{t} + 4\frac{\sqrt{R_t(w^\star)}}{t}\sqrt{\frac{G^2\ln(1/\delta)}{\sigma}} + \max\left\{\frac{16G^2}{\sigma}, 6B\right\}\frac{\ln(1/\delta)}{t}.$$

In our context, the constant B is an upper bound on $f(w,z) + \Phi(w)$ for $w \in \mathcal{F}_D$. Using the regret bound $R(w^\star) \le \Delta_t$, this gives

$$\phi(\bar{w}_t) - \phi^\star \le \frac{\Delta_t}{t} + O\left(\frac{\sqrt{\Delta_t \ln(1/\delta)}}{t} + \frac{\ln(1/\delta)}{t}\right).$$

Here the constants hidden in the O-notation are determined by G, σ and D. Plugging in $\Delta_t = O(\ln t)$, we have $\phi(\bar{w}_t) - \phi^\star = O(\ln t/t)$ with high probability. The additional penalty of getting the high probability bound, compared with the rate of convergence in expectation, is only $O(\sqrt{\ln t}/t)$.

5. Related Work

As we pointed out in Section 2.1, if Ψ is the indicator function of a convex set $\mathcal{C}$, then the RDA method recovers the simple dual averaging scheme in Nesterov (2009). This special case also belongs to a more general primal-dual algorithmic framework developed by Shalev-Shwartz and Singer (2006), which can be expressed equivalently in our notation:

$$w_{t+1} = \arg\min_{w \in \mathcal{C}} \left\{ \frac{1}{\gamma\sqrt{t}} \left\langle \sum_{\tau=1}^{t} d_\tau^t, w \right\rangle + h(w) \right\},$$

where $(d_1^t, \ldots, d_t^t)$ is the set of dual variables that can be chosen at time t. The simple dual averaging scheme (9) is in fact the *passive* extreme of their framework in which the dual variables are simply chosen as the subgradients and do not change over time, that is,

$$d_\tau^t = g_\tau, \qquad \forall \tau \le t, \qquad \forall t \ge 1. \tag{27}$$

However, with the addition of a general regularization term $\Psi(w)$ as in (4), the convergence analysis and $O(\sqrt{t})$ regret bound of the RDA method do *not* follow directly as corollaries of either Nesterov (2009) or Shalev-Shwartz and Singer (2006). Our analysis in Appendix B extends the framework of Nesterov (2009).

Shalev-Shwartz and Kakade (2009) extended the primal-dual framework of Shalev-Shwartz and Singer (2006) to strongly convex functions and obtained $O(\ln t)$ regret bound. In the context of this paper, their algorithm takes the form

$$w_{t+1} = \arg\min_{w \in \mathcal{C}} \left\{ \frac{1}{\sigma t} \left\langle \sum_{\tau=1}^{t} d_\tau^t, w \right\rangle + h(w) \right\},$$

where σ is the convexity parameter of Ψ, and $h(w) = (1/\sigma)\Psi(w)$. The passive extreme of this method, with the dual variables chosen in (27), is equivalent to a special case of the RDA method with $\beta_t = 0$ for all $t \ge 1$.

Other than improving the iteration complexity, the idea of treating the regularization explicitly in each step of a subgradient-based method (instead of lumping it together with the loss function and taking their subgradients) is mainly motivated by practical considerations, such as obtaining sparse solutions. In the case of ℓ_1-regularization, this leads to soft-thresholding type of algorithms, in both batch learning (e.g., Figueiredo et al., 2007; Wright et al., 2009; Bredies and Lorenz, 2008; Beck and Teboulle, 2009) and the online setting (e.g., Langford et al., 2009; Duchi and Singer, 2009; Shalev-Shwartz and Tewari, 2009). Most of these algorithms can be viewed as extensions of classical gradient methods (including mirror-descent methods) in which the new iterate is obtained by stepping from the current iterate along a single subgradient, and then followed by a truncation. Other types of algorithms include an interior-point based stochastic approximation scheme by Carbonetto et al. (2009), and Balakrishnan and Madigan (2008), where a modified shrinkage algorithm is developed based on sequential quadratic approximations of the loss function.

The main point of this paper, is to show that dual-averaging based methods can be more effective in exploiting the regularization structure, especially in a stochastic or online setting. To demonstrate this point, we compare the RDA method with the FOBOS method studied in Duchi and Singer (2009). In an online setting, each iteration of the FOBOS method consists of the following two

steps:

$$w_{t+\frac{1}{2}} = w_t - \alpha_t g_t,$$
$$w_{t+1} = \arg\min_w \left\{ \frac{1}{2} \left\| w - w_{t+\frac{1}{2}} \right\|_2^2 + \alpha_t \Psi(w) \right\}.$$

For convergence with optimal rates, the stepsize α_t is set to be $\Theta(1/\sqrt{t})$ for general convex regularizations and $\Theta(1/t)$ if Ψ is strongly convex. This method is based on a technique known as *forward-backward splitting*, which was first proposed by Lions and Mercier (1979) and later analyzed by Chen and Rockafellar (1997) and Tseng (2000). For easy comparison with the RDA method, we rewrite the FOBOS method in an equivalent form

$$w_{t+1} = \arg\min_w \left\{ \langle g_t, w \rangle + \Psi(w) + \frac{1}{2\alpha_t} \|w - w_t\|_2^2 \right\}. \tag{28}$$

Compared with this form of the FOBOS method, the RDA method (8) uses the average subgradient $\bar{g}_t$ instead of the current subgradient g_t; it uses a global proximal function, say $h(w) = (1/2)\|w\|_2^2$, instead of its local Bregman divergence $(1/2)\|w - w_t\|_2^2$; moreover, the coefficient for the proximal function is $\beta_t/t = \Theta(1/\sqrt{t})$ instead of $1/\alpha_t = \Theta(\sqrt{t})$ for general convex regularization, and $O(\ln t/t)$ instead of $\Theta(t)$ for strongly convex regularization. Although these two methods have the same order of iteration complexity, the differences list above contribute to quite different properties of their solutions.

These differences can be better understood in the special case of ℓ_1-regularization, that is, when $\Psi(w) = \lambda\|w\|_1$. In this case, the FOBOS method is equivalent to a special case of the *Truncated Gradient* (TG) method of Langford et al. (2009). The TG method truncates the solutions obtained by the standard SGD method every K steps; more specifically,

$$w_{t+1}^{(i)} = \begin{cases} \text{trnc}\left(w_t^{(i)} - \alpha_t g_t^{(i)}, \lambda_t^{\text{TG}}, \theta \right) & \text{if } \text{mod}(t,K) = 0, \\ w_t^{(i)} - \alpha_t g_t^{(i)} & \text{otherwise}, \end{cases} \tag{29}$$

where $\lambda_t^{\text{TG}} = \alpha_t \lambda K$, $\text{mod}(t,K)$ is the remainder on division of t by K, and

$$\text{trnc}(\omega, \lambda_t^{\text{TG}}, \theta) = \begin{cases} 0 & \text{if } |\omega| \le \lambda_t^{\text{TG}}, \\ \omega - \lambda_t^{\text{TG}} \,\text{sgn}(\omega) & \text{if } \lambda_t^{\text{TG}} < |\omega| \le \theta, \\ \omega & \text{if } |\omega| > \theta. \end{cases}$$

When $K = 1$ and $\theta = +\infty$, the TG method is the same as the FOBOS method (28) with ℓ_1-regularization. Now comparing the truncation threshold λ_t^{TG} and the threshold λ used in the ℓ_1-RDA method (10): with $\alpha_t = \Theta(1/\sqrt{t})$, we have $\lambda_t^{\text{TG}} = \Theta(1/\sqrt{t})\lambda$. This $\Theta(1/\sqrt{t})$ discount factor is also common for other previous work that use soft-thresholding, including Shalev-Shwartz and Tewari (2009). It is clear that the RDA method uses a much more aggressive truncation threshold, thus is able to generate significantly more sparse solutions. This is confirmed by our computational experiments in the next section.

Most recently, Duchi et al. (2010) developed a family of subgradient methods that can adaptively modifying the proximal function (squared Mahalanobis norms) at each iteration, in order to better incorporate learned knowledge about geometry of the data. Their methods include extensions for both the mirror-descent type of algorithms like (28) and the RDA methods studied in this paper.

Algorithm 2 Enhanced ℓ_1-RDA method

Input: $\gamma > 0, \rho \geq 0$

Initialize: $w_1 = 0, \bar{g}_0 = 0$.

for $t = 1, 2, 3, \ldots$ **do**

1. Given the function f_t, compute subgradient $g_t \in \partial f_t(w_t)$.
2. Compute the dual average
$$\bar{g}_t = \frac{t-1}{t}\bar{g}_{t-1} + \frac{1}{t}g_t.$$
3. Let $\lambda_t^{\mathrm{RDA}} = \lambda + \gamma\rho/\sqrt{t}$, and compute w_{t+1} entry-wise:
$$w_{t+1}^{(i)} = \begin{cases} 0 & \text{if } \left|\bar{g}_t^{(i)}\right| \leq \lambda_t^{\mathrm{RDA}}, \\ -\dfrac{\sqrt{t}}{\gamma}\left(\bar{g}_t^{(i)} - \lambda_t^{\mathrm{RDA}}\mathrm{sgn}\left(\bar{g}_t^{(i)}\right)\right) & \text{otherwise,} \end{cases} \quad i = 1, \ldots, n. \tag{30}$$

end for

6. Computational Experiments with ℓ_1-Regularization

In this section, we provide computational experiments of the ℓ_1-RDA method on the MNIST data set of handwritten digits (LeCun et al., 1998). Our purpose here is mainly to illustrate the basic characteristics of the ℓ_1-RDA method, rather than comprehensive performance evaluation on a wide range of data sets. First, we describe a variant of the ℓ_1-RDA method that is capable of getting enhanced sparsity in the solution.

6.1 Enhanced ℓ_1-RDA Method

The enhanced ℓ_1-RDA method shown in Algorithm 2 is a special case of Algorithm 1. It is derived by setting $\Psi(w) = \lambda\|w\|_1$, $\beta_t = \gamma\sqrt{t}$, and replacing $h(w)$ with a parameterized version

$$h_\rho(w) = \frac{1}{2}\|w\|_2^2 + \rho\|w\|_1, \tag{31}$$

where $\rho \geq 0$ is a *sparsity-enhancing* parameter. Note that $h_\rho(w)$ is strongly convex with modulus 1 for any $\rho \geq 0$. Hence the convergence rate of this algorithm is the same as if we choose $h(w) = (1/2)\|w\|_2^2$. In this case, the Equation (8) becomes

$$\begin{aligned} w_{t+1} &= \arg\min_w \left\{ \langle \bar{g}_t, w\rangle + \lambda\|w\|_1 + \frac{\gamma}{\sqrt{t}}\left(\frac{1}{2}\|w\|_2^2 + \rho\|w\|_1\right)\right\} \\ &= \arg\min_w \left\{ \langle \bar{g}_t, w\rangle + \lambda_t^{\mathrm{RDA}}\|w\|_1 + \frac{\gamma}{2\sqrt{t}}\|w\|_2^2\right\}, \end{aligned}$$

where $\lambda_t^{\mathrm{RDA}} = \lambda + \gamma\rho/\sqrt{t}$. The above minimization problem has a closed-form solution given in (30) (see Appendix A for the derivation). By letting $\rho > 0$, the effective truncation threshold λ_t^{RDA} is larger than λ, especially in the initial phase of the online process. For problems without explicit ℓ_1-regularization in the objective function, that is, when $\lambda = 0$, this still gives a diminishing truncation threshold $\gamma\rho/\sqrt{t}$.

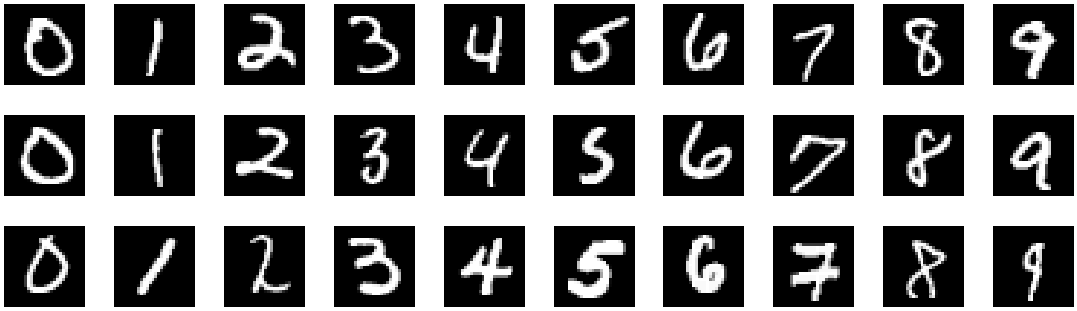

Figure 1: Sample images from the MNIST data set, with gray-scale from 0 to 255.

We can also restrict ℓ_1-regularization on part of the optimization variables only. For example, in support vector machines or logistic regression, we usually want the bias terms to be free of regularization. In this case, we can simply replace λ_t^{RDA} by 0 for the corresponding coordinates in (30).

6.2 Experiments on the MNIST Data Set

Each image in the MNIST data set is represented by a 28×28 gray-scale pixel-map, for a total of 784 features. Each of the 10 digits has roughly 6,000 training examples and 1,000 testing examples. Some of the samples are shown in Figure 1. From the perspective of using stochastic and online algorithms, the number of features and size of the data set are considered very small. Nevertheless, we choose this data set because the computational results are easy to visualize. No preprocessing of the data is employed.

We use ℓ_1-regularized logistic regression to do binary classification on each of the 45 pairs of digits. More specifically, let $z = (x, y)$ where $x \in \mathbf{R}^{784}$ represents a gray-scale image and $y \in \{+1, -1\}$ is the binary label, and let $w = (\tilde{w}, b)$ where $\tilde{w} \in \mathbf{R}^{784}$ and b is the bias. Then the loss function and regularization term in (1) are

$$f(w,z) = \log\left(1 + \exp\left(-y(\tilde{w}^T x + b)\right)\right), \qquad \Psi(w) = \lambda \|\tilde{w}\|_1.$$

Note that we do not apply regularization on the bias term b. In the experiments, we compare the (enhanced) ℓ_1-RDA method (Algorithm 2) with the SGD method

$$w_{t+1}^{(i)} = w_t^{(i)} - \alpha_t \left(g_t^{(i)} + \lambda \operatorname{sgn}(w_t^{(i)})\right), \qquad i = 1, \ldots, n,$$

and the TG method (29) with $\theta = \infty$. These three online algorithms have similar convergence rates and the same order of computational cost per iteration. We also compare them with the batch optimization approach, more specifically solving the empirical minimization problem (2) using an efficient interior-point method (IPM) of Koh et al. (2007).

Each pair of digits have about 12,000 training examples and 2,000 testing examples. We use online algorithms to go through the (randomly permuted) data only once, therefore the algorithms stop at $T = 12{,}000$. We vary the regularization parameter λ from 0.01 to 10. As a reference, the maximum λ for the batch optimization case (Koh et al., 2007) is mostly in the range of $30 - 50$ (beyond which the optimal weights are all zeros). In the ℓ_1-RDA method, we use $\gamma = 5{,}000$, and set ρ to

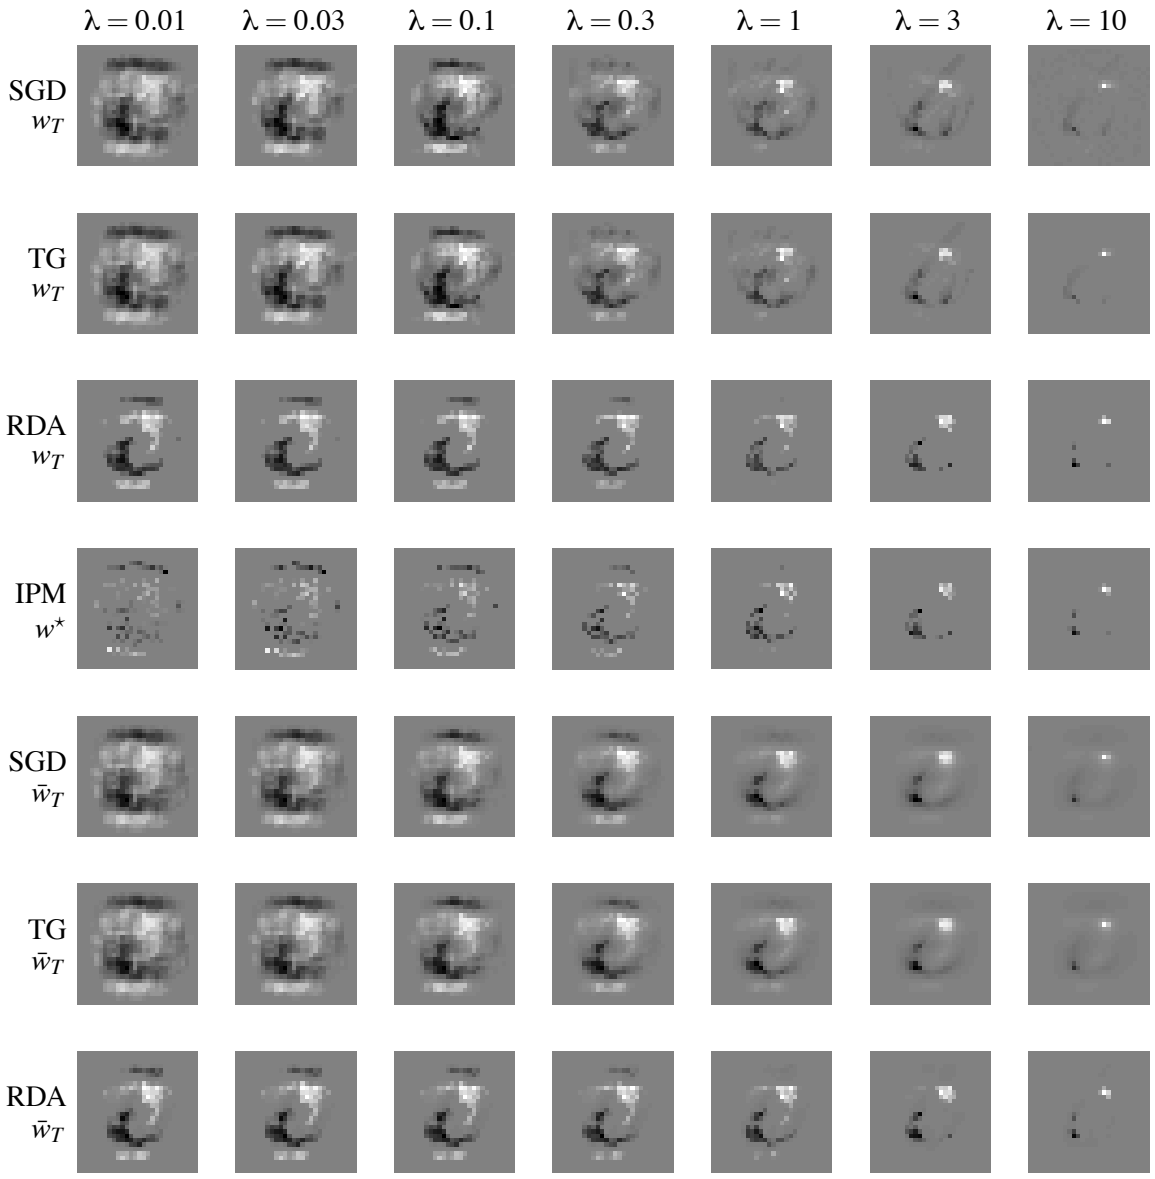

Figure 2: Sparsity patterns of w_T and $\bar{w}_T$ for classifying the digits 6 and 7 when varying the parameter λ from 0.01 to 10 in ℓ_1-regularized logistic regression. The background gray represents the value zero, bright spots represent positive values and dark spots represent negative values. Each column corresponds to a value of λ labeled at the top. The top three rows are the weights w_T (without averaging) from the last iteration of the three online algorithms; the middle row shows optimal solutions of the batch optimization problem solved by interior-point method (IPM); the bottom three rows show the averaged weights $\bar{w}_T$ in the three online algorithms. Both the TG and RDA methods were run with parameters for enhanced ℓ_1-regularization, that is, $K = 10$ for TG and $\gamma\rho = 25$ for RDA.

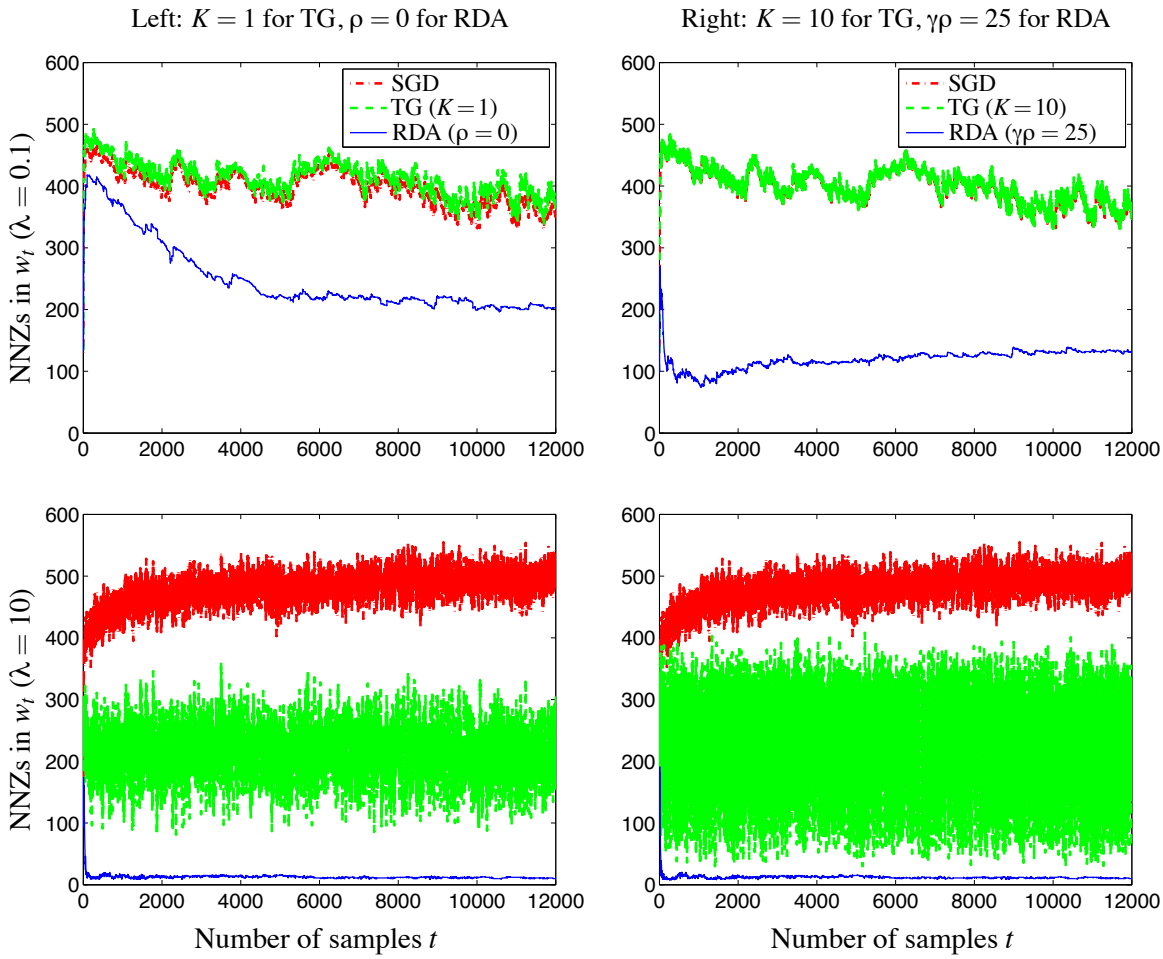

Figure 3: Number of non-zeros (NNZs) in w_t for the three online algorithms (classifying the pair 6 and 7). The left column shows SGD, TG with $K = 1$, and RDA with $\rho = 0$; the right column shows SGD, TG with $K = 10$, and RDA with $\gamma\rho = 25$. The same curves for SGD are plotted in both columns for clear comparison. The two rows correspond to $\lambda = 0.1$ and $\lambda = 10$, respectively.

be either 0 for basic regularization, or 0.005 (effectively $\gamma\rho = 25$) for enhanced regularization effect. These parameters are chosen by cross-validation. For the SGD and TG methods, we use a constant stepsize $\alpha = (1/\gamma)\sqrt{2/T}$ for comparable convergence rate; see (19) and related discussions. In the TG method, the period K is set to be either 1 for basic regularization (same as FOBOS), or 10 for periodic enhanced regularization effect.

Figure 2 shows the sparsity patterns of the solutions w_T and $\bar{w}_T$ for classifying the digits 6 and 7. The algorithmic parameters used are: $K = 10$ for the TG method, and $\gamma\rho = 25$ for the RDA method. It is clear that the RDA method gives more sparse solutions than both SGD and TG methods. The sparsity pattern obtained by the RDA method is very similar to the batch optimization results solved by IPM, especially for larger λ.

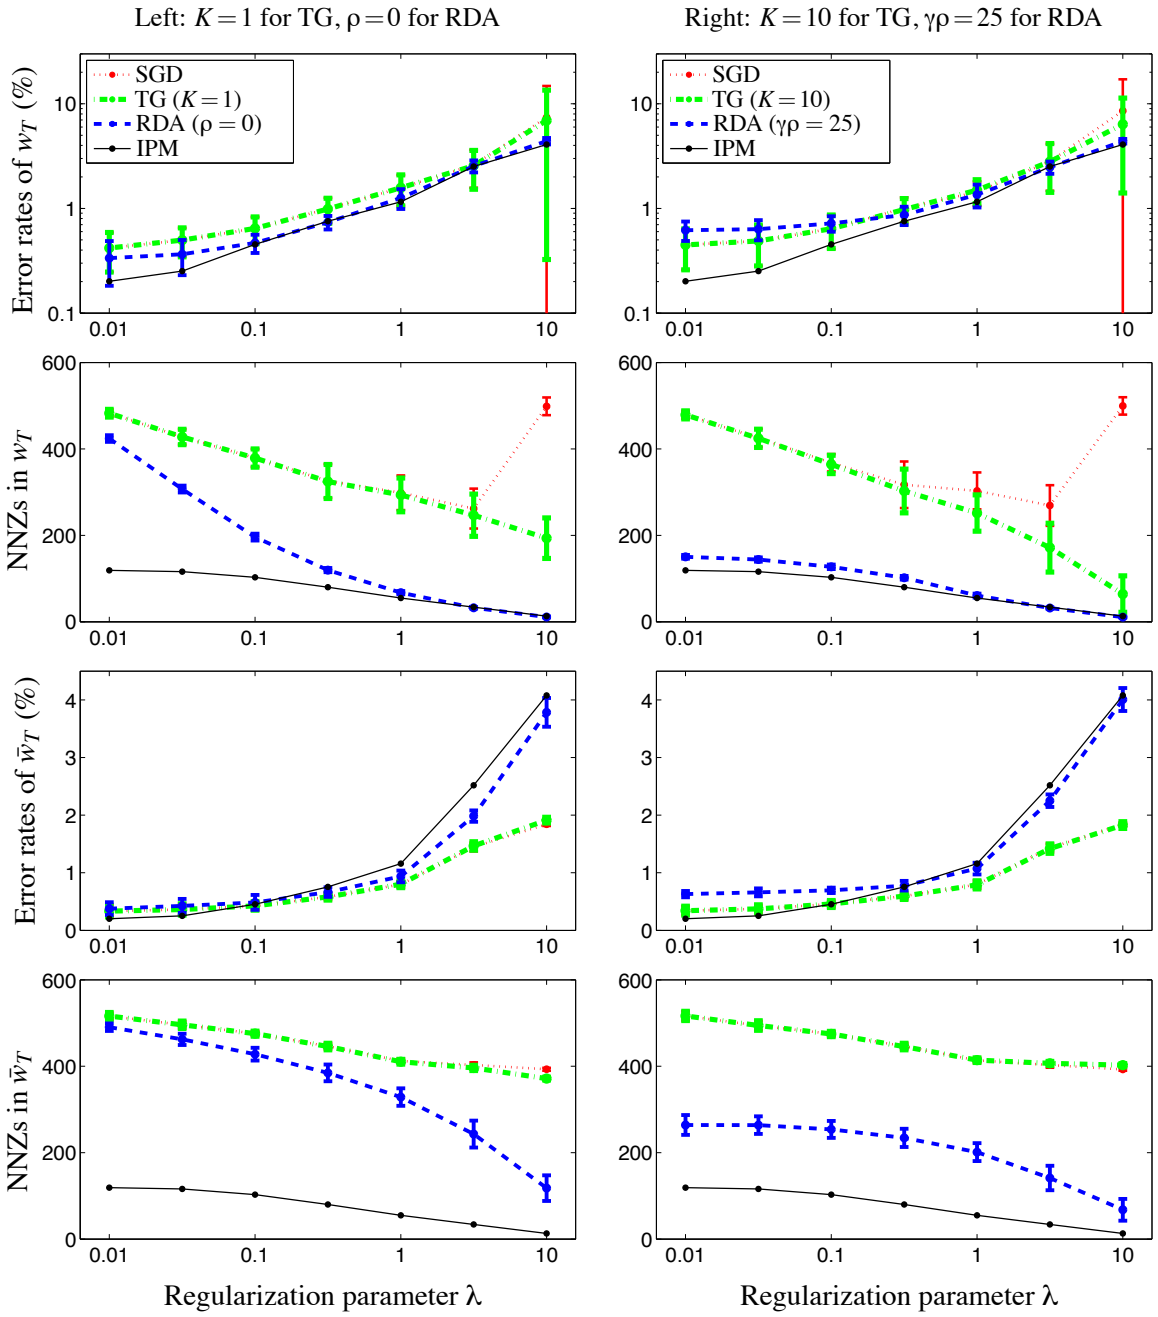

Figure 4: Tradeoffs between testing error rates and NNZs in solutions when varying λ from 0.01 to 10 (for classifying 6 and 7). The left column shows SGD, TG with $K=1$, RDA with $\rho=0$, and IPM. The right column shows SGD, TG with $K=10$, RDA with $\gamma\rho=25$, and IPM. The same curves for SGD and IPM are plotted in both columns for clear comparison. The top two rows shows the testing error rates and NNZs of the final weights w_T, and the bottom two rows are for the averaged weights $\bar{w}_T$. All horizontal axes have logarithmic scale. For vertical axes, only the two plots in the first row have logarithmic scale.

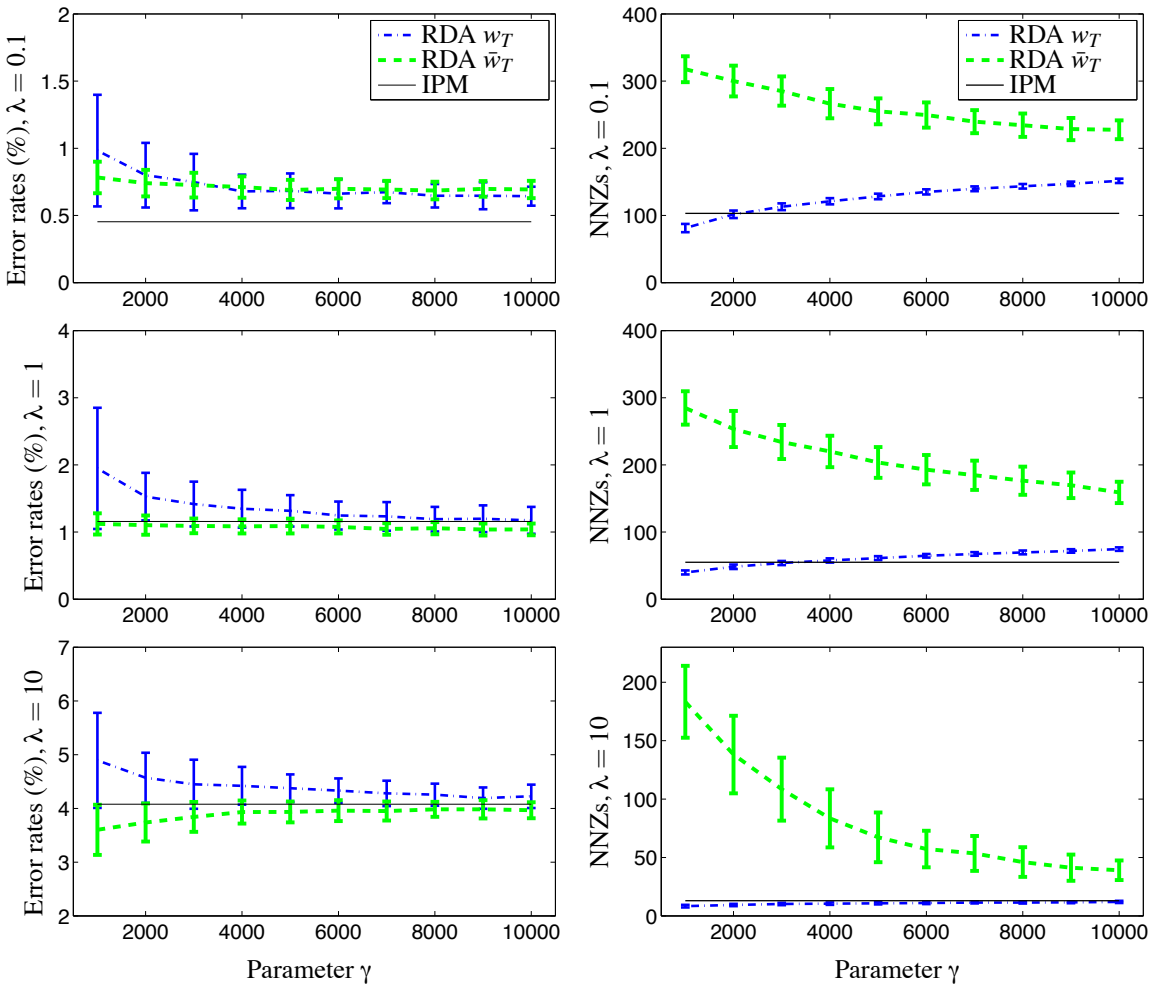

Figure 5: Testing error rates and NNZs in solutions for the RDA method when varying the parameter γ from 1,000 to 10,000, and setting ρ such that $\gamma\rho = 25$. The three rows show results for $\lambda = 0.1$, 1, and 10, respectively. The corresponding batch optimization results found by IPM are shown as a horizontal line in each plot.

To have a better understanding of the behaviors of the algorithms, we plot the number of non-zeros (NNZs) in w_t in Figure 3. Only the RDA method and TG with $K = 1$ give explicit zero weights using soft-thresholding at every step. In order to count the NNZs in all other cases, we have to set a small threshold for rounding the weights to zero. Considering that the magnitudes of the largest weights in Figure 2 are mostly on the order of 10^{-3}, we set 10^{-5} as the threshold and verified that rounding elements less than 10^{-5} to zero does not affect the testing errors. Note that we do not truncate the weights for RDA and TG with $K = 1$ further, even if some of their components are below 10^{-5}. It can be seen that the RDA method maintains a much more sparse w_t than the other online algorithms. While the TG method generates more sparse solutions than the SGD method when λ is large, the NNZs in w_t oscillates with a very big range. The oscillation becomes more severe with $K = 10$. In contrast, the RDA method demonstrates a much more smooth behavior

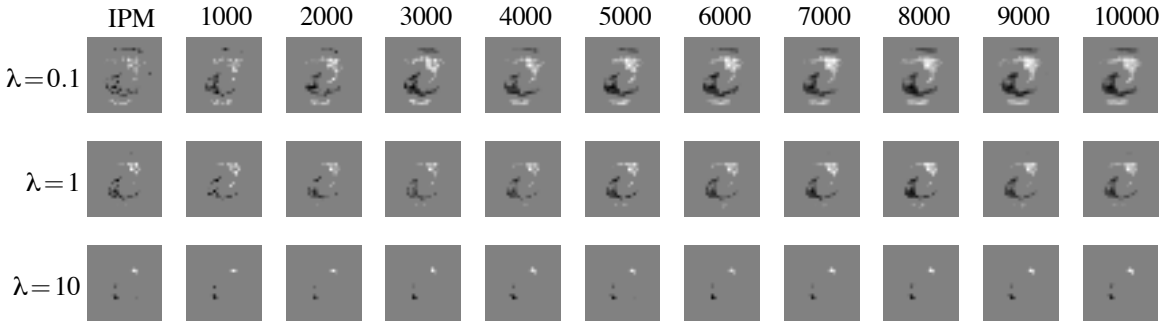

Figure 6: Sparsity patterns of w_T by varying the parameter γ in the RDA method from 1,000 to 10,000 (for classifying the pair 6 and 7). The first column shows results of batch optimization using IPM, and the other 10 columns show results of RDA method using γ labeled at the top.

of the NNZs. For the RDA method, the effect of enhanced regularization using $\gamma\rho = 25$ is more pronounced for relatively small λ.

Next we illustrate the tradeoffs between sparsity and testing error rates. Figure 4 shows that the solutions obtained by the RDA method match the batch optimization results very well. Since the performance of the online algorithms vary when the training data are given in different random sequences (permutations), we run them on 100 randomly permuted sequences of the same training set, and plot the means and standard deviations shown as error bars. For the SGD and TG methods, the testing error rates of w_T vary a lot for different random sequences. In contrast, the RDA method demonstrates very robust performance (small standard deviations) for w_T, even though the theorems only give convergence bound for the averaged weight $\bar{w}_T$. For large values of λ, the averaged weights $\bar{w}_T$ obtained by SGD and TG methods actually have much smaller error rates than those of RDA and batch optimization. This can be explained by the limitation of the SGD and TG methods in obtaining sparse solutions: these lower error rates are obtained with much more nonzero features than used by the RDA and batch optimization methods.

Figure 5 shows the results of choosing different values for the parameter γ in the RDA method. We see that smaller values of γ, which corresponds to faster learning rates, lead to more sparse w_T and higher testing error rates; larger values of γ result in less sparse w_T with lower testing error rates. But interestingly, the effects on the averaged solution $\bar{w}_T$ is almost opposite: smaller values of γ lead to less sparse $\bar{w}_T$ (in this case, we count the NNZs using the rounding threshold 10^{-5}). For large regularization parameter λ, smaller values of γ also give lower testing error rates. Figure 6 shows the sparsity patterns of w_T when varying γ from 1,000 to 10,000. We see that smaller values of γ give more sparse w_T, which are also more scattered like the batch optimization solution by IPM.

Figure 7 shows summary of classification results for all the 45 pairs of digits. For clarity, we only show results of the ℓ_1-RDA method and batch optimization using IPM. We see that the solutions obtained by the ℓ_1-RDA method demonstrate very similar tradeoffs between sparsity and testing error rates as rendered by the batch optimization solutions.

Finally, we note that one of the main reasons for regularization in machine learning is to prevent overfitting, meaning that appropriate amount of regularization may actually reduce the testing error rate. In order to investigate the possibility of overfitting, we also conducted experiments by subsam-

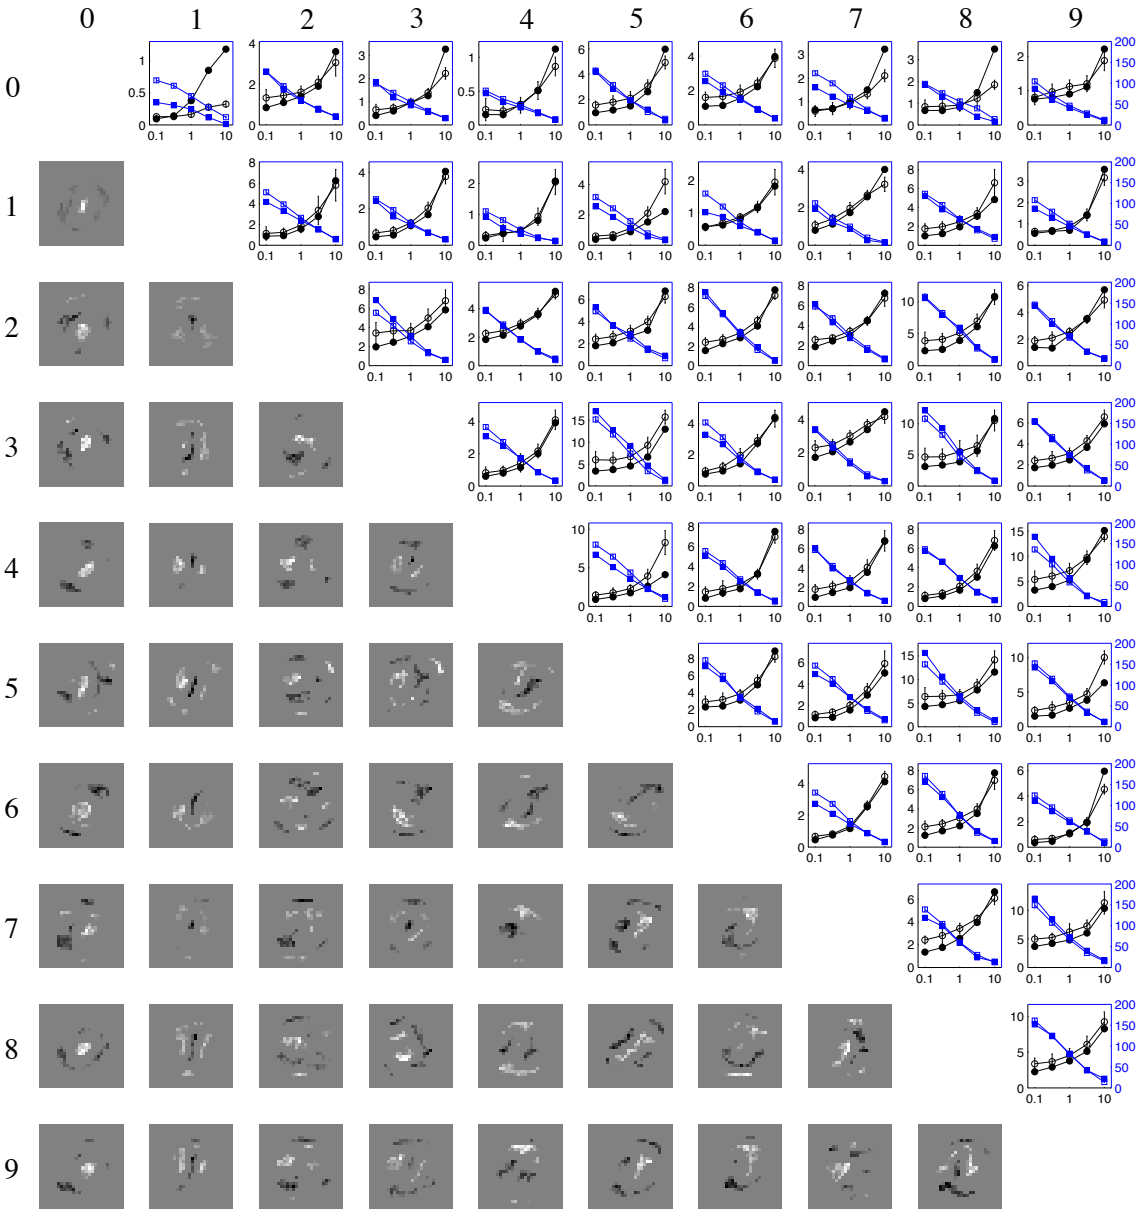

Figure 7: Binary classification for all 45 pairs of digits. The images in the lower-left triangular area show sparsity patterns of w_T with $\lambda = 1$, obtained by the ℓ_1-RDA method with $\gamma = 5000$ and $\rho = 0.005$. The plots in the upper-right triangular area show tradeoffs between sparsity and testing error rates, by varying λ from 0.1 to 10. The solid circles and solid squares show error rates and NNZs in w_T, respectively, using IPM for batch optimization. The hollow circles and hollow squares show error rates and NNZs of w_T, respectively, using the ℓ_1-RDA method. The vertical bars centered at hollow circles and squares show standard deviations by running on 100 different random permutations of the same training data. The scales of the error rates (in percentages) are marked on the left vertical axes, and the scales of the NNZs are marked on the right-most vertical axes.

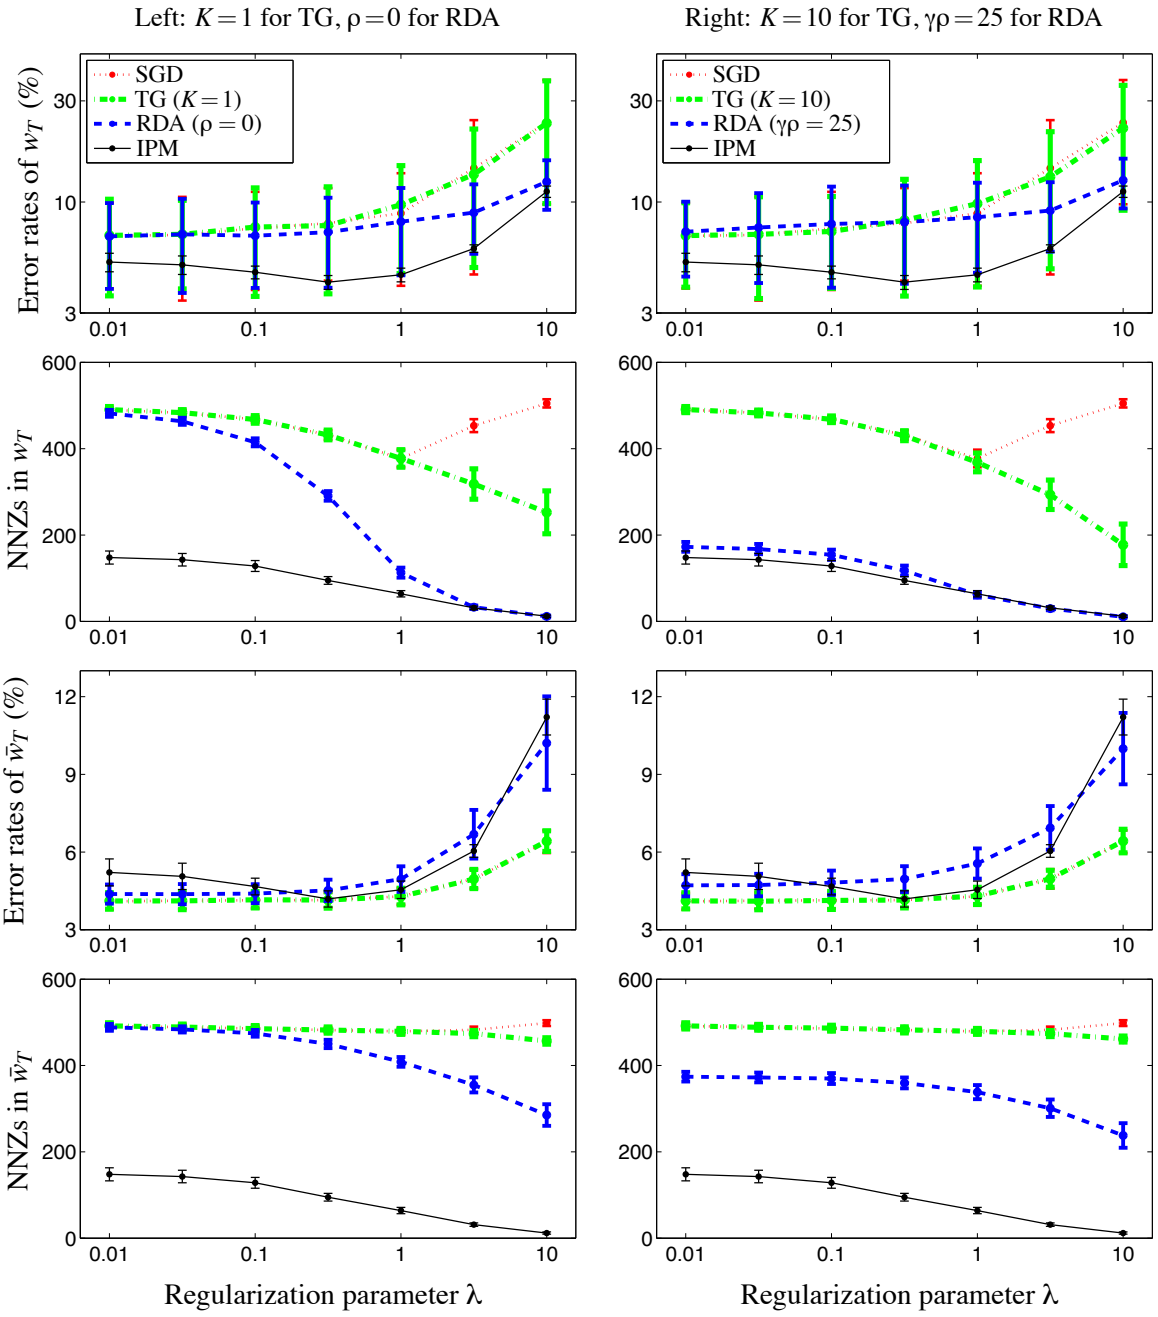

Figure 8: Tradeoffs between testing error rates and NNZs in solutions when varying λ from 0.01 to 10 (for classifying 3 and 8). In order to investigate overfitting, we used 1/10 subsampling of the training data. The error bars show standard deviations of using 10 sets of subsamples. For the three online algorithms, we averaged results on 10 random permutations for each of the 10 subsets. The left column shows SGD, TG with $K=1$, RDA with $\rho=0$, and IPM. The right column shows SGD, TG with $K=10$, RDA with $\gamma\rho=25$, and IPM. The same curves for SGD and IPM are plotted in both columns for clear comparison.

pling the training set. More specifically, we randomly partition the training sets in 10 subsets, and use each subset for training but still test on the whole testing set. The same algorithmic parameters γ and ρ are used as before. Figure 8 shows the results of classifying the more difficult pair 3 and 8. We see that overfitting does occur for batch optimization using IPM. Online algorithms, thanks for their low accuracy in solving the optimization problems, are mostly immune from overfitting.

7. Discussions and Extensions

This paper is inspired by several work in the emerging area of *structural convex optimization* (Nesterov, 2008). The key idea is that by exploiting problem structure that are beyond the conventional black-box model (where only function values and gradient information are allowed), much more efficient first-order methods can be developed for solving structural convex optimization problems. Consider the following problem with two separate parts in the objective function:

$$\underset{w}{\text{minimize}} \quad f(w) + \Psi(w) \tag{32}$$

where the function f is convex and differentiable on $\operatorname{dom}\Psi$, its gradient $\nabla f(w)$ is Lipschitz-continuous with constant L, and the function Ψ is a closed proper convex function. Since Ψ in general can be non-differentiable, the best convergence rate for gradient-type methods that are based on the black-box model is $O(1/\sqrt{t})$ (Nemirovsky and Yudin, 1983). However, if the function Ψ is *simple*, meaning that we are able to find closed-form solution for the auxiliary optimization problem

$$\underset{w}{\text{minimize}} \quad \left\{ f(u) + \langle \nabla f(u), w-u \rangle + \frac{L}{2}\|w-u\|_2^2 + \Psi(w) \right\}, \tag{33}$$

then it is possible to develop accelerated gradient methods that have the convergence rate $O(1/t^2)$ (Nesterov, 1983, 2004; Tseng, 2008; Beck and Teboulle, 2009). Accelerated first-order methods have also been developed for solving large-scale conic optimization problems (Auslender and Teboulle, 2006; Lan et al., 2009; Lu, 2009).

The story is a bit different for stochastic optimization. In this case, the convergence rate $O(1/\sqrt{t})$ cannot be improved in general for convex loss functions with a black-box model. When the loss function $f(w,z)$ have better properties such as differentiability, higher orders of smoothness, and strong convexity, it is tempting to expect that better convergence rates can be achieved. Although these better properties of $f(w,z)$ are inherited by the expected function $\varphi(w) \triangleq \mathbf{E}_z f(w,z)$, almost none of them can really help (Nesterov and Vial, 2008, Section 4). One exception is when the objective function is strongly convex. In this case, the convergence rate for stochastic optimization problems can be improved to $O(\ln t/t)$ (e.g., Nesterov and Vial, 2008), or even $O(1/t)$ (e.g., Polyak and Juditsky, 1992; Nemirovski et al., 2009). For online convex optimization problems, the regret bound can be improved to $O(\ln t)$ (Hazan et al., 2006; Bartlett et al., 2008). But these are still far short of the best complexity result for deterministic optimization with strong convexity assumptions; see, for example, Nesterov (2004, Chapter 2) and Nesterov (2007).

We discuss further the case with a stronger smoothness assumption on the stochastic objective functions. In particular, let $f(w,z)$ be differentiable with respect to w for each z, and the gradient, denoted $g(w,z)$, be Lipschitz continuous. In other words, there exists a constant L such that for any fixed z,

$$\|g(v,z) - g(w,z)\|_* \le L\|v-w\|, \qquad \forall\, v,w \in \operatorname{dom}\Psi. \tag{34}$$

Let $\varphi(w) = \mathbf{E}_z f(w,z)$. Then φ is differentiable and $\nabla\varphi(w) = \mathbf{E}_z g(w,z)$ (e.g., Rockafellar and Wets, 1982). By Jensen's inequality, $\nabla\varphi(w)$ is also Lipschitz continuous with the same constant L. For the regularization function Ψ, we assume there is a constant G_Ψ such that

$$|\Psi(v) - \Psi(w)| \leq G_\Psi \|v - w\|, \qquad \forall\, v, w \in \operatorname{dom}\Psi.$$

In a black-box model, for any query point w, we are only allowed to query a stochastic gradient $g(w,z)$ and a subgradient of $\Psi(w)$. We assume the stochastic gradients have bounded variance; more specifically, let there be a constant Q such that

$$\mathbf{E}_z \|g(w,z) - \nabla\varphi(w)\|_*^2 \leq Q^2, \qquad \forall\, w \in \operatorname{dom}\Psi. \tag{35}$$

Under these assumptions and the black-box model, the optimal convergence rate for solving the problem (1), according to the complexity theory of Nemirovsky and Yudin (1983), is

$$\mathbf{E}\,\phi(w_t) - \phi^\star \leq O(1)\left(\frac{L}{t^2} + \frac{G_\Psi + Q}{\sqrt{t}}\right).$$

Lan (2010) developed an accelerated mirror-descent stochastic approximation method to achieve this rate. The stochastic nature of the algorithm dictates that the term $O(1)(Q/\sqrt{t})$ is inevitable in the convergence bound. However, by using structural optimization techniques similar to (33), it is possible to eliminate the term $O(1)(G_\Psi/\sqrt{t})$ and achieve

$$\mathbf{E}\phi(w_t) - \phi^\star \leq O(1)\left(\frac{L}{t^2} + \frac{Q}{\sqrt{t}}\right). \tag{36}$$

Such a result was obtained by Hu et al. (2009). Their algorithm can be viewed as an accelerated version of the FOBOS method (28). In each iteration of their method, the regularization term $\Psi(w)$ is discounted by a factor of $\Theta(t^{-3/2})$. In terms of obtaining the desired regularization effects (see discussions in Section 5), this is even worse than the $\Theta(t^{-1/2})$ discount factor in the FOBOS method. For the case of ℓ_1-regularization, this means using an even smaller truncation threshold $\Theta(t^{-3/2})\lambda$. Next, we give an accelerated version of the RDA method, which achieves the same improved convergence rate (36), but also maintains the desired property of using the undiscounted regularization at each iteration.

7.1 Accelerated RDA Method for Stochastic Optimization

Nesterov (2005) developed an accelerated version of the dual averaging method for solving smooth convex optimization problems, where the uniform average of all past gradients is replaced by an weighted average that emphasizes more recent gradients. Several variations (Nesterov, 2007; Tseng, 2008) were also developed for minimizing composite objective functions of the form (32). They all have a convergence rate $O(L/t^2)$.

Algorithm 3 is our extension of Nesterov's method for solving stochastic optimization problems of the form (1). At the input, it needs a strongly convex function h and two positive sequences $\{\alpha_t\}_{t\geq 1}$ and $\{\beta_t\}_{t\geq 0}$. At each iteration $t \geq 1$, it computes three primal vectors u_t, v_t, w_t, and a dual vector $\tilde{g}_t$. Among them, u_t is the point for querying a stochastic gradient, $\tilde{g}_t$ is an weighted average of all past stochastic gradients, v_t is the solution of an auxiliary minimization problem that involves $\tilde{g}_t$ and the regularization term $\Psi(w)$, and w_t is the output vector. The computational effort

Algorithm 3 Accelerated RDA method

Input:

- a strongly convex function $h(w)$ with modulus 1 on $\mathrm{dom}\,\Psi$.
- two positive sequences $\{\alpha_t\}_{t\geq 1}$ and $\{\beta_t\}_{t\geq 0}$.

Initialize: set $w_0 = v_0 = \arg\min_w h(w)$, $A_0 = 0$, and $\tilde{g}_0 = 0$.

for $t = 1, 2, 3, \ldots$ **do**

1. Calculate the coefficients

$$A_t = A_{t-1} + \alpha_t, \qquad \theta_t = \frac{\alpha_t}{A_t}.$$

2. Compute the query point

$$u_t = (1-\theta_t) w_{t-1} + \theta_t v_{t-1}.$$

3. Query stochastic gradient $g_t = g(u_t, z_t)$, and update the weighted average $\tilde{g}_t$:

$$\tilde{g}_t = (1-\theta_t)\tilde{g}_{t-1} + \theta_t g_t.$$

4. Solve for the exploration point

$$v_t = \arg\min_w \left\{ \langle \tilde{g}_t, w \rangle + \Psi(w) + \frac{L+\beta_t}{A_t} h(w) \right\}$$

5. Compute w_t by interpolation

$$w_t = (1-\theta_t) w_{t-1} + \theta_t v_t.$$

end for

per iteration is on the same order as Algorithm 1. The additional costs are mainly the two vector interpolations (convex combinations) for computing u_t and w_t. The following theorem gives an estimate of its convergence rate.

Theorem 6 *Assume the conditions (34) and (35) hold, and the problem (1) has an optimal solution $w^\star$ with optimal value $\phi^\star$. In Algorithm 3, if the sequence $\{\alpha_t\}_{t\geq 1}$ and its accumulative sums $A_t = A_{t-1} + \alpha_t$ satisfy the condition $\alpha_t^2 \leq A_t$ for all $t \geq 1$, then*

$$\mathbf{E}\,\phi(w_t) - \phi^\star \leq \frac{L}{A_t} h(w^\star) + \frac{1}{A_t}\left(\beta_t h(w^\star) + Q^2 \sum_{\tau=1}^{t} \frac{\alpha_\tau^2}{2\beta_{\tau-1}} \right).$$

The proof of this theorem is given in Appendix D.

If we choose the two input sequences as

$$\alpha_t = 1, \qquad \forall t \geq 1,$$
$$\beta_t = \gamma\sqrt{t+1}, \qquad \forall t \geq 0,$$

then $A_t = t$, $\theta_t = 1/t$, and $\tilde{g}_t = \bar{g}_t$ is the uniform average of all past gradients. In this case, the minimization problem in Step 4 is very similar to that in Step 3 of Algorithm 1. Let D^2 be an upper

bound on $h(w^\star)$ and set $\gamma = Q/D$. Then we have

$$\mathbf{E}\phi(w_t) - \phi^\star \le \frac{LD^2}{t} + \frac{2QD}{\sqrt{t}}.$$

To achieve the optimal convergence rate stated in (36), we choose

$$\alpha_t = \frac{t}{2}, \qquad \forall t \ge 1, \tag{37}$$

$$\beta_t = \gamma\frac{(t+1)^{3/2}}{2}, \qquad \forall t \ge 0. \tag{38}$$

In this case,

$$A_t = \sum_{\tau=1}^{t}\alpha_\tau = \frac{t(t+1)}{4}, \qquad \theta_t = \frac{\alpha_t}{A_t} = \frac{2}{t+1}, \qquad \forall t \ge 1.$$

It is easy to verify that the condition $\alpha_t^2 \le A_t$ is satisfied. The following corollary is proved in Appendix D.1.

Corollary 7 *Assume the conditions (34) and (35) hold, and $h(w^\star) \le D^2$. If the two input sequences in Algorithm 3 are chosen as in (37) and (38) with $\gamma = Q/D$, then*

$$\mathbf{E}\phi(w_t) - \phi^\star \le \frac{4LD^2}{t^2} + \frac{4QD}{\sqrt{t}}.$$

We can also give high probability bound under more restrictive assumptions. Instead of requiring the deterministic condition $\|g(w,z) - \nabla\varphi(w)\|_*^2 \le Q^2$ for all z and all $w \in \operatorname{dom}\Psi$, we adopt a weaker condition used in Nemirovski et al. (2009) and Lan (2010):

$$\mathbf{E}\left[\exp\left(\frac{\|g(w,z) - \nabla\varphi(w)\|_*^2}{Q^2}\right)\right] \le \exp(1), \qquad \forall w \in \operatorname{dom}\Psi. \tag{39}$$

It is not hard to see that this implies (35) by using Jensen's inequality.

Theorem 8 *Suppose $\operatorname{dom}\Psi$ is compact, say $h(w) \le D^2$ for all $w \in \operatorname{dom}\Psi$, and let the assumptions (34) and (39) hold. If the two input sequences in Algorithm 3 are chosen as in (37) and (38) with $\gamma = Q/D$, then for any $\delta \in (0,1)$, with probability at least $1-\delta$,*

$$\phi(w_t) - \phi^\star \le \frac{4LD^2}{t^2} + \frac{4QD}{\sqrt{t}} + \frac{QD}{\sqrt{t}}\left(\ln(2/\delta) + 2\sqrt{\ln(2/\delta)}\right)$$

Compared with the bound on expectation, the additional penalty in the high probability bound depends only on Q, not L. This theorem is proved in Appendix D.2.

In the special case of deterministic optimization, that is, when $Q = 0$, we have $\gamma = Q/D = 0$ and $\beta_t = 0$ for all $t \ge 0$. Then Algorithm 3 reduces to a variant of Nesterov's method given in Tseng (2008, Section 4), which has convergence rate $\phi(w_t) - \phi^\star \le 4LD^2/t^2$.

For stochastic optimization problems, the above theoretical bounds show that the algorithm can be very effective when Q is much smaller than LD. One way to make this happen is to use a mini-batch approach. More specifically, at each iteration of Algorithm 3, let g_t itself be the average of the stochastic gradients at a small batch of samples computed at u_t. We leave the empirical studies of Algorithm 3 and other accelerated schemes for future investigation.

7.2 The p-Norm RDA Methods

The p-norm RDA methods are special cases of Algorithm 1 in which the auxiliary functions h (*not* the regularization functions Ψ) are squared p-norms. They offer more flexibility than 2-norm based RDA methods in adapting to the geometry of the learning problems.

Recall that for $p \geq 1$, the p-norm of $w \in \mathbf{R}^n$ is defined as $\|w\|_p = \left(\sum_{i=1}^n |w^{(i)}|^p\right)^{1/p}$. If p and q satisfy the equality $1/p + 1/q = 1$, then the norms $\|w\|_p$ and $\|g\|_q$ are dual to each other. Moreover, the pair of functions $(1/2)\|w\|_p^2$ and $(1/2)\|g\|_q^2$ are conjugate functions of each other. As a result, their gradient mappings are a pair of inverse mappings. More formally, let $p \in (1,2]$ and $q = p/(p-1)$, and define the mapping $\vartheta : \mathcal{E} \to \mathcal{E}^*$ with

$$\vartheta_i(w) = \nabla_i \left(\frac{1}{2}\|w\|_p^2\right) = \frac{\operatorname{sgn}\left(w^{(i)}\right)\left|w^{(i)}\right|^{p-1}}{\|w\|_p^{p-2}}, \qquad i = 1, \ldots, n,$$

and the inverse mapping $\vartheta^{-1} : \mathcal{E}^* \to \mathcal{E}$ with

$$\vartheta_i^{-1}(g) = \nabla_i \left(\frac{1}{2}\|g\|_q^2\right) = \frac{\operatorname{sgn}\left(g^{(i)}\right)\left|g^{(i)}\right|^{q-1}}{\|g\|_q^{q-2}}, \qquad i = 1, \ldots, n.$$

These mappings are often called *link functions* in machine learning (e.g., Gentile, 2003).

Again we focus on the ℓ_1-RDA case with $\Psi(w) = \lambda\|w\|_1$. For any $p \in (1,2]$, the function $(1/2)\|w\|_p^2$ is strongly convex with respect to $\|\cdot\|_p$ with the convexity parameter $p-1$ (e.g., Juditsky and Nemirovski, 2008). In order to have an auxiliary strongly convex function h with convexity parameter 1, we define

$$h(w) = \frac{1}{2(p-1)}\|w\|_p^2.$$

Using $\beta_t = \gamma\sqrt{t}$ for some $\gamma > 0$,, the Equation (8) in Algorithm 1 becomes

$$w_{t+1} = \arg\min_w \left\{ \langle \bar{g}_t, w \rangle + \lambda\|w\|_1 + \frac{\gamma}{\sqrt{t}} \frac{1}{2(p-1)}\|w\|_p^2 \right\}.$$

The optimality condition of the above minimization problem (Rockafellar, 1970, Section 27) states that there exists a subgradient $s \in \partial\|w_{t+1}\|_1$ such that

$$\bar{g}_t + \lambda s + \frac{\gamma}{(p-1)\sqrt{t}}\vartheta(w_{t+1}) = 0.$$

Following similar arguments as in Appendix A, we find that it has a closed-form solution

$$w_{t+1} = \vartheta^{-1}\left(\hat{g}_t\right),$$

where the elements of $\hat{g}_t$ are given as

$$\hat{g}_t^{(i)} = \begin{cases} 0 & \text{if } \left|\bar{g}_t^{(i)}\right| \leq \lambda, \\ -\dfrac{(p-1)\sqrt{t}}{\gamma}\left(\bar{g}_t^{(i)} - \lambda \operatorname{sgn}\left(\bar{g}_t^{(i)}\right)\right) & \text{otherwise,} \end{cases} \qquad i = 1, \ldots, n.$$

When $p = q = 2$, ϑ and ϑ^{-1} are identity maps and the solution is the same as (10). If p is close to 1 ($q \gg 2$), the map ϑ^{-1} penalizes small entries of the truncated vector $\hat{g}_t$ to be even smaller.

As an interesting property of the map ϑ^{-1}, we always have $\|w_{t+1}\|_p = \|\hat{g}_t\|_q$ (e.g., Gentile, 2003, Lemma 1).

In terms of regret bound or convergence rate, our results in Sections 3 and 4 apply directly. More specifically, for stochastic learning problems, let $D_p^2 = (1/2(p-1))\|w^\star\|_p^2$, and G_q be an upper bound on $\|g_t\|_q$ for all $t \geq 1$. Then by Corollary 2 and Theorem 3,

$$\mathbf{E}\,\phi(\bar{w}_t) - \phi^\star \leq \left(\gamma D_p^2 + \frac{G_q^2}{\gamma}\right)\frac{1}{\sqrt{t}}.$$

The optimal choice of γ is $\gamma^\star = G_q/D_p$, which results in

$$\mathbf{E}\,\phi(\bar{w}_t) - \phi^\star \leq \sqrt{\frac{2}{p-1}}\frac{G_q\|w^\star\|_p}{\sqrt{t}} = \sqrt{2(q-1)}\frac{G_q\|w^\star\|_p}{\sqrt{t}}.$$

In order to gain further insight, we transform the convergence bound in terms of ℓ_∞ and ℓ_1 norms. Let G_∞ be an upper bound on $\|g_t\|_\infty$, that is,

$$\left|g_t^{(i)}\right| \leq G_\infty, \qquad \forall\, i = 1,\ldots,n, \qquad \forall\, t \geq 1.$$

Then $\|g_t\|_q \leq G_\infty n^{1/q}$. If we choose $q = \ln n$ (assuming $n \geq e^2$ so that $q \geq 2$), then $\|g_t\|_q \leq G_\infty n^{1/\ln n} = G_\infty e$. Next we substitute $G_\infty e$ for G_q and use the fact $\|w^\star\|_p \leq \|w^\star\|_1$, then

$$\mathbf{E}\,\phi(\bar{w}_t) - \phi^\star \leq \sqrt{2(\ln n - 1)}\,\frac{eG_\infty\|w^\star\|_1}{\sqrt{t}} = O\left(\frac{\sqrt{\ln n}\,G_\infty\|w^\star\|_1}{\sqrt{t}}\right).$$

For 2-norm based RDA method, we have $\|g_t\|_2 \leq G_\infty\sqrt{n}$, thus

$$\mathbf{E}\,\phi(\bar{w}_t) - \phi^\star \leq \frac{\sqrt{2n}\,G_\infty\|w^\star\|_2}{\sqrt{t}}.$$

Therefore, for learning problems in which the features are dense (i.e., G_2 close to $G_\infty\sqrt{n}$) and $w^\star$ is indeed very sparse (i.e., $\|w^\star\|_2$ close to $\|w^\star\|_1$), using the p-norm RDA method, with $p = \ln n/(\ln n - 1)$, can lead to faster convergence.

The above analysis of convergence rates matches that for the p-norm based SMIDAS (Stochastic MIrror Descent Algorithm made Sparse) algorithm developed in Shalev-Shwartz and Tewari (2009). However, like other algorithms of the mirror-descent type, including TG (Langford et al., 2009) and FOBOS (Duchi and Singer, 2009), SMIDAS uses a truncation threshold $\Theta(1/\sqrt{t})\lambda$ in obtaining sparse solutions. In contrast, the p-norm based RDA method uses a much more aggressive threshold λ. This is their major difference.

The accelerated RDA method (Algorithm 3) also works in the p-norm setting.

7.3 Connection with Incremental Subgradient Methods

As an intermediate model between deterministic and stochastic optimization problems, consider the problem

$$\underset{w}{\text{minimize}} \quad \sum_{k=1}^{m} f_k(w) + \Psi(w), \tag{40}$$

which can be considered as a special case of (1) where the random variable z has a uniform distribution on a finite support; more specifically, $f_k(w) = (1/m)f(w,z_k)$ for $k = 1,\ldots,m$. The unregularized version, that is, with $\Psi(w) = 0$, has been addressed by *incremental subgradient methods* (e.g., Tseng, 1998; Nedić and Bertsekas, 2001). At each iteration of such methods, a step is taken along the negative subgradient of a single function f_k, which is chosen either in a round-robin manner or randomly with uniform distribution. The randomized version is equivalent to the SGD method. The RDA methods are well suited for solving the regularized version (40).

Randomized incremental subgradient methods with Markov jumps have also been developed for solving (40) with $\Psi(w) = 0$ (Johansson et al., 2009; Ram et al., 2009). In such methods, the functions f_k are picked randomly but not independently: they follow the transition probabilities of a Markov chain that has the uniform distribution. It would be very interesting to investigate the convergence of the RDA methods when the random examples are drawn according to a Markovian chain. This is particularly attractive for online learning problems where the assumption of i.i.d. samples does not hold.

Acknowledgments

The author is grateful to John Duchi for careful reading of a previous draft and pointing out that the regret analysis for general convex regularizations and for strongly convex regularizations can be unified. The author thanks John Platt for encouragement and suggestions for improving the computational experiments, and Paul Tseng and Zhaosong Lu for helpful discussions on minimizing composite objective functions. He also would like to thank the anonymous referees for their valuable comments.

Appendix A. Closed-form Solution for ℓ_1-RDA Method

For RDA method with ℓ_1-regularization, we set $\Psi(w) = \lambda\|w\|_1$ and use $h(w) = (1/2)\|w\|_2^2$, or use $h_\rho(w)$ in (31) for enhanced regularization effect. In such cases, the minimization problem in step 3 of Algorithm 1 can be decomposed into n independent scalar minimization problems, each of the form

$$\underset{\omega\in\mathbf{R}}{\text{minimize}} \quad \eta_t\omega + \lambda_t|\omega| + \frac{\gamma_t}{2}\omega^2,$$

where the coefficients $\lambda_t > 0$, $\gamma_t > 0$, and η_t can be arbitrary. This is an unconstrained nonsmooth optimization problem. Its optimality condition (Rockafellar, 1970, Section 27) states that $\omega^\star$ is an optimal solution if and only if there exists $\xi \in \partial|\omega^\star|$ such that

$$\eta_t + \lambda_t\xi + \gamma_t\omega^\star = 0. \tag{41}$$

The subdifferential of $|\omega|$ is

$$\partial|\omega| = \begin{cases} \{\xi\in\mathbf{R} \mid -1 \le \xi \le 1\} & \text{if } \omega = 0, \\ \{1\} & \text{if } \omega > 0, \\ \{-1\} & \text{if } \omega < 0. \end{cases}$$

We discuss the solution to (41) in three different cases:

- If $|\eta_t| \leq \lambda_t$, then $\omega^\star = 0$ and $\xi = -\eta_t/\lambda_t \in \partial|0|$ satisfy (41). We also show that there is no solution other than $\omega^\star = 0$. If $\omega > 0$, then $\xi = 1$, and

$$\eta_t + \lambda_t + \gamma_t \omega > \eta_t + \lambda_t \geq 0.$$

  Similarly, if $\omega < 0$, then $\xi = -1$, and

$$\eta_t - \lambda_t + \gamma_t \omega < \eta_t - \lambda_t \leq 0.$$

  In either cases when $\omega \neq 0$, the optimality condition (41) cannot be satisfied.

- If $\eta_t > \lambda_t > 0$, we must have $\omega^\star < 0$ and $\xi = -1$. More specifically,

$$\omega^\star = -\frac{1}{\gamma_t}(\eta_t - \lambda_t).$$

- If $\eta_t < -\lambda_t < 0$, we must have $\omega^\star > 0$ and $\xi = 1$. More specifically,

$$\omega^\star = -\frac{1}{\gamma_t}(\eta_t + \lambda_t).$$

The above discussions can be summarized as

$$\omega^\star = \begin{cases} 0 & \text{if } |\eta_t| \leq \lambda_t, \\ -\dfrac{1}{\gamma_t}\big(\eta_t - \lambda_t \operatorname{sgn}(\eta_t)\big) & \text{otherwise.} \end{cases}$$

This is the closed-form solution for each component of w_{t+1} in the ℓ_1-RDA method.

Appendix B. Regret Analysis of RDA Method

In this Appendix, we prove Theorem 1. First, let s_t denote the sum of the subgradients obtained up to time t in the RDA method, that is,

$$s_t = \sum_{\tau=1}^{t} g_\tau = t\bar{g}_t, \tag{42}$$

with the initialization $s_0 = 0$. Then the Equation (8) in Algorithm 1 is equivalent to

$$w_{t+1} = \arg\min_w \big\{ \langle s_t, w \rangle + t\Psi(w) + \beta_t h(w) \big\}. \tag{43}$$

This extends the *simple dual averaging* scheme of Nesterov (2009), where $\Psi(w)$ reduces to the indicator function of a closed convex set. Compared with the analysis in Nesterov (2009), the assumption (7), Lemma 11 and Lemma 12 (below) are new essentials that make the proof work. We also provide refined bounds on the primal and dual variables that relate to the regret with respect to an arbitrary comparison point; see part (b) and (c) of Theorem 1. It seems that the *weighted dual averaging* scheme of Nesterov (2009) cannot be extended when Ψ is a nontrivial regularization function.

B.1 Conjugate Functions and Their Properties

Let w_0 be the unique minimizer of $h(w)$. By the assumption (7), we have

$$w_0 = \arg\min_w h(w) \in \operatorname{Arg\,min}_w \Psi(w).$$

Let $\{\beta_t\}_{t\geq 1}$ be the input sequence to Algorithm 1, which is nonnegative and nondecreasing. In accordance with the assumption (13), we let

$$\beta_0 = \max\{\sigma, \beta_1\} > 0, \tag{44}$$

where σ be the convexity parameter of $\Psi(w)$. For each $t \geq 0$, we define two conjugate-type functions:

$$U_t(s) = \max_{w\in\mathcal{F}_D} \big\{\langle s, w - w_0\rangle - t\Psi(w)\big\}, \tag{45}$$

$$V_t(s) = \max_{w} \big\{\langle s, w - w_0\rangle - t\Psi(w) - \beta_t h(w)\big\}, \tag{46}$$

where $\mathcal{F}_D = \big\{w \in \operatorname{dom}\Psi \,|\, h(w) \leq D^2\big\}$. The maximum in (45) is always achieved because $\mathcal{F}_D$ is a nonempty compact set (which always contains w_0). Because of (44), we have $\sigma t + \beta_t \geq \beta_0 > 0$ for all $t \geq 0$, which means the functions $t\Psi(w) + \beta_t h(w)$ are all strongly convex. Therefore, the maximum in (46) is always achieved, and the maximizer is unique. As a result, we have $\operatorname{dom} U_t = \operatorname{dom} V_t = \mathcal{E}^*$ for all $t \geq 0$. Moreover, by the assumption $\Psi(w_0) = h(w_0) = 0$, both of the functions are nonnegative.

The lemma below is similar to Lemma 2 of Nesterov (2009), but with our new definitions of U_t and V_t. We include the proof for completeness.

Lemma 9 *For any $s \in \mathcal{E}^*$ and $t \geq 0$, we have*

$$U_t(s) \leq V_t(s) + \beta_t D^2.$$

Proof Starting with the definition of $U_t(s)$ and using $\mathcal{F}_D = \{w \in \operatorname{dom}\Psi \,|\, h(w) \leq D^2\}$,

$$\begin{aligned}
U_t(s) &= \max_{w\in\mathcal{F}_D} \{\langle s, w - w_0\rangle - t\Psi(w)\} \\
&= \max_w \min_{\beta\geq 0} \big\{\langle s, w - w_0\rangle - t\Psi(w) + \beta(D^2 - h(w))\big\} \\
&\leq \min_{\beta\geq 0} \max_w \big\{\langle s, w - w_0\rangle - t\Psi(w) + \beta(D^2 - h(w))\big\} \\
&\leq \max_w \big\{\langle s, w - w_0\rangle - t\Psi(w) + \beta_t(D^2 - h(w))\big\} \\
&= V_t(s) + \beta_t D^2.
\end{aligned}$$

For the second equality and the first inequality above, we used standard duality arguments and the max-min inequality; see, for example, Boyd and Vandenberghe (2004, Section 5.4.1). ■

Let $\pi_t(s)$ denote the unique maximizer in the definition of $V_t(s)$; in other words,

$$\begin{aligned}
\pi_t(s) &= \arg\max_w \big\{\langle s, w - w_0\rangle - t\Psi(w) - \beta_t h(w)\big\} \\
&= \arg\min_w \big\{\langle -s, w\rangle + t\Psi(w) + \beta_t h(w)\big\}.
\end{aligned}$$

Comparing with the Equation (43), we have

$$w_{t+1} = \pi_t(-s_t), \qquad \forall t \geq 0.$$

Lemma 10 *The function V_t is convex and differentiable. Its gradient is given by*

$$\nabla V_t(s) = \pi_t(s) - w_0 \tag{47}$$

Moreover, the gradient is Lipschitz continuous with constant $1/(\sigma t + \beta_t)$; that is

$$\|\nabla V_t(s_1) - \nabla V_t(s_2)\| \leq \frac{1}{\sigma t + \beta_t}\|s_1 - s_2\|_*, \qquad \forall s_1, s_2 \in \mathcal{E}^*.$$

Proof Because the function $t\Psi(w) + \beta_t h(w)$ is a strongly convex with convexity parameter $\sigma t + \beta_t$, this lemma follows from classical results in convex analysis; see, for example, Hiriart-Urruty and Lemaréchal (2001, Chapter E, Theorem 4.2.1), or Nesterov (2005, Theorem 1). ■

A direct consequence of Lemma 10 is the following inequality:

$$V_t(s+g) \leq V_t(s) + \langle g, \nabla V_t(s)\rangle + \frac{1}{2(\sigma t + \beta_t)}\|g\|_*^2, \quad \forall s, g \in \mathcal{E}^*. \tag{48}$$

For a proof, see, for example, Nesterov (2004, Theorem 2.1.5).

Lemma 11 *For each $t \geq 1$, we have*

$$V_t(-s_t) + \Psi(w_{t+1}) \leq V_{t-1}(-s_t) + (\beta_{t-1} - \beta_t)h(w_{t+1}).$$

Proof We start with the definition of $V_{t-1}(-s_t)$:

$$\begin{aligned} V_{t-1}(-s_t) &= \max_w \{\langle -s_t, w - w_0\rangle - (t-1)\Psi(w) - \beta_{t-1}h(w)\} \\ &\geq \langle -s_t, w_{t+1} - w_0\rangle - (t-1)\Psi(w_{t+1}) - \beta_{t-1}h(w_{t+1}) \\ &= \big\{\langle -s_t, w_{t+1} - w_0\rangle - t\Psi(w_{t+1}) - \beta_t h(w_{t+1})\big\} + \Psi(w_{t+1}) + (\beta_t - \beta_{t-1})h(w_{t+1}). \end{aligned}$$

Comparing with (43) and (46), we recognize that the expression in the last braces above is precisely $V_t(-s_t)$. Making the substitution and rearranging terms give the desired result. ■

Since by assumption $h(w_{t+1}) \geq 0$ and the sequence $\{\beta_t\}_{t\geq 1}$ is nondecreasing, we have

$$V_t(-s_t) + \Psi(w_{t+1}) \leq V_{t-1}(-s_t), \quad \forall t \geq 2. \tag{49}$$

For $t = 1$, Lemma (11) gives

$$V_1(-s_1) + \Psi(w_2) \leq V_0(-s_1) + (\beta_0 - \beta_1)h(w_2). \tag{50}$$

Since it may happen that $\beta_0 > \beta_1$, we need the following upper bound on $h(w_2)$.

Lemma 12 *Assume* $\max\{\sigma, \beta_1\} > 0$, *and let* $h(w) = (1/\sigma)\Psi(w)$ *if* $\sigma > 0$. *Then*

$$h(w_2) \leq \frac{2\|g_1\|_*^2}{(\beta_1+\sigma)^2}. \tag{51}$$

Proof For $t = 1$, we have $w_1 = w_0, \Psi(w_1) = \Psi(w_0) = 0, h(w_1) = h(w_0) = 0$, and $\bar{g}_1 = g_1$. Since w_2 is the minimizer in (43) for $t = 1$, we have

$$\langle g_1, w_2\rangle + \Psi(w_2) + \beta_1 h(w_2) \leq \langle g_1, w_1\rangle + \Psi(w_1) + \beta_1 h(w_1) = \langle g_1, w_1\rangle.$$

Therefore,

$$\Psi(w_2) + \beta_1 h(w_2) \leq \langle g_1, w_1 - w_2\rangle \leq \|g_1\|_*\|w_2 - w_1\|.$$

On the other hand, by strong convexity of $\Psi(w)$ and $h(w)$, we have

$$\Psi(w_2) + \beta_1 h(w_2) \geq \frac{\sigma+\beta_1}{2}\|w_2 - w_1\|^2.$$

Combining the last two inequalities together, we have

$$\Psi(w_2) + \beta_1 h(w_2) \leq \frac{2\|g_1\|_*^2}{\sigma+\beta_1}.$$

By assumption, if $\sigma = 0$, we must have $\beta_1 > 0$. In this case, since $\Psi(w_2) \geq 0$, we have

$$\beta_1 h(w_2) \leq \Psi(w_2) + \beta_1 h(w_2) \leq \frac{2\|g_1\|_*^2}{\beta_1} \quad \Longrightarrow \quad h(w_2) \leq \frac{2\|g_1\|_*^2}{\beta_1^2} = \frac{2\|g_1\|_*^2}{(\sigma+\beta_1)^2}.$$

If $\sigma > 0$, we have $\Psi(w) = \sigma h(w)$ by assumption, and therefore

$$\Psi(w_2) + \beta_1 h(w_2) = (\sigma+\beta_1)h(w_2) \leq \frac{2\|g_1\|_*^2}{\sigma+\beta_1},$$

which also results in (51). ■

B.2 Bounding the Regret

To measure the quality of the solutions $w_1, \ldots, w_t$, we define the following *gap* sequence:

$$\delta_t = \max_{w\in\mathcal{F}_D}\left\{\sum_{\tau=1}^{t}\big(\langle g_\tau, w_\tau - w\rangle + \Psi(w_\tau)\big) - t\Psi(w)\right\}, \quad t = 1,2,3,\ldots. \tag{52}$$

The gap δ_t is an upper bound on the regret $R_t(w)$ for all $w \in \mathcal{F}_D$. To see this, we use the assumption $w \in \mathcal{F}_D$ and convexity of $f_t(w)$ in the following:

$$\begin{aligned}
\delta_t &\geq \sum_{\tau=1}^{t}\big(\langle g_\tau, w_\tau - w\rangle + \Psi(w_\tau)\big) - t\Psi(w) \\
&\geq \sum_{\tau=1}^{t}\big(f_\tau(w_\tau) - f_\tau(w) + \Psi(w_\tau)\big) - t\Psi(w) \\
&= \sum_{\tau=1}^{t}\big(f_\tau(w_\tau) + \Psi(w_\tau)\big) - \sum_{\tau=1}^{t}\big(f_\tau(w) + \Psi(w)\big) = R_t(w).
\end{aligned} \tag{53}$$

We can also derive an upper bound on δ_t. For this purpose, we add and subtract the sum $\sum_{\tau=1}^{t}\langle g_\tau, w_0\rangle$ in the definition (52), which leads to

$$\delta_t = \sum_{\tau=1}^{t}\big(\langle g_\tau, w_\tau - w_0\rangle + \Psi(w_\tau)\big) + \max_{w\in\mathcal{F}_D}\big\{\langle s_t, w_0 - w\rangle - t\Psi(w)\big\}. \tag{54}$$

We observe that the maximization term in (54) is in fact $U_t(-s_t)$. Therefore, by applying Lemma 9, we have

$$\delta_t \le \sum_{\tau=1}^{t}\big(\langle g_\tau, w_\tau - w_0\rangle + \Psi(w_\tau)\big) + V_t(-s_t) + \beta_t D^2. \tag{55}$$

Next, we show that Δ_t defined in (14) is an upper bound for the right-hand side of the inequality (55). For any $\tau \ge 2$, we have

$$\begin{aligned}
V_\tau(-s_\tau) + \Psi(w_{\tau+1}) &\le V_{\tau-1}(-s_\tau) \\
&= V_{\tau-1}(-s_{\tau-1} - g_\tau) \\
&\le V_{\tau-1}(-s_{\tau-1}) + \langle -g_\tau, \nabla V_{\tau-1}(-s_{\tau-1})\rangle + \frac{\|g_\tau\|_*^2}{2(\sigma(\tau-1)+\beta_{\tau-1})} \\
&= V_{\tau-1}(-s_{\tau-1}) + \langle -g_\tau, w_\tau - w_0\rangle + \frac{\|g_\tau\|_*^2}{2(\sigma(\tau-1)+\beta_{\tau-1})},
\end{aligned}$$

where the four steps above used (49), (42), (48), and (47), respectively. Therefore,

$$\langle g_\tau, w_\tau - w_0\rangle + \Psi(w_{\tau+1}) \le V_{\tau-1}(-s_{\tau-1}) - V_\tau(-s_\tau) + \frac{\|g_\tau\|_*^2}{2(\sigma(\tau-1)+\beta_{\tau-1})}, \quad \forall \tau \ge 2.$$

For $\tau = 1$, we have a similar inequality

$$\langle g_1, w_1 - w_0\rangle + \Psi(w_2) \le V_0(-s_0) - V_1(-s_1) + \frac{\|g_1\|_*^2}{2\beta_0} + (\beta_0 - \beta_1)h(w_2),$$

where the additional term $(\beta_0 - \beta_1)h(w_2)$ comes from using (50). Summing the above inequalities for $\tau = 1,\ldots,t$, and noting that $V_0(-s_0) = V_0(0) = 0$, we arrive at

$$\sum_{\tau=1}^{t}\big(\langle g_\tau, w_\tau - w_0\rangle + \Psi(w_{\tau+1})\big) + V_t(-s_t) \le (\beta_0 - \beta_1)h(w_2) + \frac{1}{2}\sum_{\tau=1}^{t}\frac{\|g_\tau\|_*^2}{\sigma(\tau-1)+\beta_{\tau-1}}.$$

Using $w_1 = w_0 \in \operatorname{Arg\,min}_w \Psi(w)$, we have $\Psi(w_{t+1}) \ge \Psi(w_0) = \Psi(w_1)$. Therefore, adding the nonpositive quantity $\Psi(w_1) - \Psi(w_{t+1})$ to the left-hand side of the above inequality yields

$$\sum_{\tau=1}^{t}\big(\langle g_\tau, w_\tau - w_0\rangle + \Psi(w_\tau)\big) + V_t(-s_t) \le (\beta_0 - \beta_1)h(w_2) + \frac{1}{2}\sum_{\tau=1}^{t}\frac{\|g_\tau\|_*^2}{\sigma(\tau-1)+\beta_{\tau-1}}. \tag{56}$$

Combining the inequalities (53), (55) and (56), and using Lemma 12,

$$R_t(w) \le \delta_t \le \beta_t D^2 + \frac{1}{2}\sum_{\tau=1}^{t}\frac{\|g_\tau\|_*^2}{\sigma(\tau-1)+\beta_{\tau-1}} + \frac{2(\beta_0-\beta_1)\|g_1\|_*^2}{(\beta_1+\sigma)^2}.$$

Finally using the assumption (12) and the definition of Δ_t in (14), we conclude

$$R_t(w) \le \delta_t \le \Delta_t.$$

This proves the regret bound (15).

B.3 Bounding the Primal Variable

We start with the optimality condition for the minimization problem in (43): there exist subgradients $b_{t+1} \in \partial\Psi(w_{t+1})$ and $d_{t+1} \in \partial h(w_{t+1})$ such that

$$\langle s_t + t b_{t+1} + \beta_t d_{t+1},\ w - w_{t+1} \rangle \geq 0, \quad \forall w \in \operatorname{dom}\Psi. \tag{57}$$

By the strong convexity of h and Ψ, we have for any $w \in \operatorname{dom}\Psi$,

$$\Psi(w) \geq \Psi(w_{t+1}) + \langle b_{t+1}, w - w_{t+1} \rangle + \frac{\sigma}{2}\|w_{t+1} - w\|^2, \tag{58}$$

$$h(w) \geq h(w_{t+1}) + \langle d_{t+1}, w - w_{t+1} \rangle + \frac{1}{2}\|w_{t+1} - w\|^2. \tag{59}$$

We multiply both sides of the inequality (58) by t, multiply both sides of the inequality (59) by β_t, and then add them together. This gives

$$\begin{aligned}\frac{1}{2}(\sigma t + \beta_t)\|w_{t+1} - w\|^2 \leq{}& \beta_t h(w) - \beta_t h(w_{t+1}) - \langle t b_{t+1} + \beta_t d_{t+1}, w - w_{t+1} \rangle \\ &+ t\Psi(w) - t\Psi(w_{t+1}).\end{aligned}$$

Using the optimality condition (57), we have

$$\begin{aligned}\frac{1}{2}(\sigma t + \beta_t)\|w_{t+1} - w\|^2 &\leq \beta_t h(w) - \beta_t h(w_{t+1}) + \langle s_t, w - w_{t+1} \rangle + t\Psi(w) - t\Psi(w_{t+1}) \\ &= \beta_t h(w) + \left\{ \langle -s_t, w_{t+1} - w_0 \rangle - t\Psi(w_{t+1}) - \beta_t h(w_{t+1}) \right\} \\ &\quad + t\Psi(w) + \langle s_t, w - w_0 \rangle.\end{aligned}$$

Using (43), we recognize that the collection in the braces is precisely $V_t(-s_t)$. Therefore

$$\frac{1}{2}(\sigma t + \beta_t)\|w_{t+1} - w\|^2 \leq \beta_t h(w) + V_t(-s_t) + t\Psi(w) + \langle s_t, w - w_0 \rangle. \tag{60}$$

Now we expand the last term $\langle s_t, w - w_0 \rangle$ using the definition of s_t:

$$\langle s_t, w - w_0 \rangle = \sum_{\tau=1}^{t} \langle g_\tau, w - w_0 \rangle = \sum_{\tau=1}^{t} \langle g_\tau, w_\tau - w_0 \rangle + \sum_{\tau=1}^{t} \langle g_\tau, w - w_\tau \rangle.$$

By further adding and subtracting $\sum_{\tau=1}^{t} \Psi(w_\tau)$, the right-hand side of (60) becomes

$$\beta_t h(w) + \left\{ V_t(-s_t) + \sum_{\tau=1}^{t} \left(\langle g_\tau, w_\tau - w_0 \rangle + \Psi(w_\tau) \right) \right\} + \sum_{\tau=1}^{t} \langle g_\tau, w - w_\tau \rangle + t\Psi(w) - \sum_{\tau=1}^{t} \Psi(w_\tau).$$

We recognize that the expression in the braces above is exactly the left-hand side in (56). Furthermore, by convexity of f_τ for $\tau \geq 1$,

$$\begin{aligned}\sum_{\tau=1}^{t} \langle g_\tau, w - w_\tau \rangle + t\Psi(w) - \sum_{\tau=1}^{t} \Psi(w_\tau) &\leq \sum_{\tau=1}^{t} \left(f_\tau(w) - f_\tau(w_\tau) \right) + t\Psi(w) - \sum_{\tau=1}^{t} \Psi(w_\tau) \\ &= \sum_{\tau=1}^{t} \left(f_\tau(w) + \Psi(w) \right) - \sum_{\tau=1}^{t} \left(f_\tau(w_\tau) + \Psi(w_\tau) \right) \\ &= -R_t(w).\end{aligned}$$

Putting everything together, and using (56), we have

$$\frac{1}{2}(\sigma t+\beta_t)\|w_{t+1}-w\|^2 \le \beta_t h(w)+(\beta_0-\beta_1)h(w_2)+\frac{1}{2}\sum_{\tau=1}^{t}\frac{\|g_\tau\|_*^2}{\sigma(\tau-1)+\beta_{\tau-1}}-R_t(w).$$

Finally, using $w\in\mathcal{F}_D$, Lemma 12 and the assumption (12), we conclude

$$\frac{1}{2}(\sigma t+\beta_t)\|w_{t+1}-w\|^2 \le \Delta_t - R_t(w),$$

which is the same as (16).

B.4 Bounding the Dual Average

First notice that (54) still holds if we replace w_0 with an arbitrary, fixed $w\in\mathcal{F}_D$, that is,

$$\delta_t=\sum_{\tau=1}^{t}\big(\langle g_\tau, w_\tau-w\rangle+\Psi(w_\tau)\big)+\max_{u\in\mathcal{F}_D}\big\{\langle s_t, w-u\rangle - t\Psi(u)\big\}.$$

By convexity of f_τ for $\tau\ge 1$, we have

$$\begin{aligned}
\delta_t &\ge \sum_{\tau=1}^{t}\big(f_\tau(w_\tau)-f_\tau(w)+\Psi(w_\tau)\big)+\max_{u\in\mathcal{F}_D}\big\{\langle s_t, w-u\rangle - t\Psi(u)\big\}\\
&= \sum_{\tau=1}^{t}\big(f_\tau(w_\tau)+\Psi(w_\tau)-f_\tau(w)-\Psi(w)\big)+\max_{u\in\mathcal{F}_D}\big\{\langle s_t, w-u\rangle - t\big(\Psi(u)-\Psi(w)\big)\big\}\\
&= R_t(w)+\max_{u\in\mathcal{F}_D}\big\{\langle s_t, w-u\rangle - t\big(\Psi(u)-\Psi(w)\big)\big\}. \qquad (61)
\end{aligned}$$

Let $d(u)$ denote a subgradient of Ψ at u with minimum norm, that is,

$$d(u)=\operatorname*{arg\,min}_{g\in\partial\Psi(u)}\|g\|_*. \qquad (62)$$

Since Ψ has convexity parameter σ, we have

$$\Psi(w)-\Psi(u)\ge\langle d(u), w-u\rangle+\frac{\sigma}{2}\|w-u\|^2.$$

Therefore,

$$\begin{aligned}
\delta_t &\ge R_t(w)+\max_{u\in\mathcal{F}_D}\left\{\langle s_t, w-u\rangle + t\langle d(u), w-u\rangle+\frac{\sigma t}{2}\|w-u\|^2\right\}\\
&\ge R_t(w)+\max_{u\in\mathcal{B}(w,r)}\left\{\langle s_t, w-u\rangle + t\langle d(u), w-u\rangle+\frac{\sigma t}{2}\|w-u\|^2\right\},
\end{aligned}$$

where in the last inequality, we used the assumption $\mathcal{B}(w,r)\subset\mathcal{F}_D$ for some $r>0$. Let $u^\star$ be the maximizer of $\langle s_t, w-u\rangle$ within the set $B(w,r)$, that is,

$$u^\star=\operatorname*{arg\,max}_{u\in B(w,r)}\big\{\langle s_t, w-u\rangle\big\}.$$

Then $\|w-u^\star\| = r$ and

$$\langle s_t, w-u^\star\rangle = \|w-u^\star\|\|s_t\|_* = r\|s_t\|_*.$$

So we can continue with the inequality:

$$\begin{aligned}
\delta_t &\geq R_t(w) + \langle s_t, w-u^\star\rangle + t\langle d(u^\star), w-u^\star\rangle + \frac{\sigma t}{2}\|w-u^\star\|^2 \\
&= R_t(w) + r\|s_t\|_* + t\langle d(u^\star), w-u^\star\rangle + \frac{1}{2}\sigma t r^2 \\
&\geq R_t(w) + r\|s_t\|_* - t\|d(u^\star)\|_*\|w-u^\star\| + \frac{1}{2}\sigma t r^2 \\
&\geq R_t(w) + r\|s_t\|_* - rt\Gamma_D + \frac{1}{2}\sigma t r^2
\end{aligned}$$

where in the last inequality, we used $\|d(u^\star)\|_* \leq \Gamma_D$, which is due to (62) and (11). Therefore

$$\|s_t\|_* \leq t\Gamma_D - \frac{1}{2}\sigma t r + \frac{1}{r}\big(\delta_t - R_t(w)\big).$$

Finally, we have (17) by noting $\delta_t \leq \Delta_t$ and $s_t = t\bar{g}$.

Appendix C. Proof of High Probability Bounds

In this Appendix, we prove Theorem 5. First let $\varphi(w) = \mathbf{E}_z f(w,z)$, then by definition $\phi(w) = \varphi(w) + \Psi(w)$. Let $\hat{g}_t$ be the conditional expectation of g_t given w_t, that is,

$$\hat{g}_t = \mathbf{E}[g_t \,|\, w_t] = \mathbf{E}\big[g_t \,|\, \mathbf{z}[t-1]\big].$$

Since $g_t \in \partial f(w_t, z_t)$, we have $\hat{g}_t \in \partial\varphi(w_t)$ (e.g., Rockafellar and Wets, 1982). By the definition of δ_t in (52), for any $w^\star \in \mathcal{F}_D$,

$$\begin{aligned}
\delta_t &\geq \sum_{\tau=1}^{t}\Big(\langle g_\tau, w_\tau - w^\star\rangle + \Psi(w_\tau)\Big) - t\Psi(w^\star) \\
&= \sum_{\tau=1}^{t}\Big(\langle \hat{g}_\tau, w_\tau - w^\star\rangle + \Psi(w_\tau)\Big) - t\Psi(w^\star) + \sum_{\tau=1}^{t}\langle g_\tau - \hat{g}_\tau, w_\tau - w^\star\rangle \\
&\geq \sum_{\tau=1}^{t}\Big(\varphi(w_\tau) - \varphi(w^\star) + \Psi(w_\tau)\Big) - t\Psi(w^\star) + \sum_{\tau=1}^{t}\langle g_\tau - \hat{g}_\tau, w_\tau - w^\star\rangle \\
&= \sum_{\tau=1}^{t}\big(\phi(w_\tau) - \phi(w^\star)\big) + \sum_{\tau=1}^{t}\langle g_\tau - \hat{g}_\tau, w_\tau - w^\star\rangle. \qquad (63)
\end{aligned}$$

where in the second inequality above we used convexity of φ. Now define the random variables

$$\xi_\tau = \langle g_\tau - \hat{g}_\tau, w^\star - w_\tau\rangle, \qquad \forall \tau \geq 1.$$

Combining (63) and the result $\delta_t \leq \Delta_t$ leads to

$$\sum_{\tau=1}^{t}\big(\phi(w_\tau) - \phi(w^\star)\big) \leq \Delta_t + \sum_{\tau=1}^{t}\xi_\tau. \qquad (64)$$

Since w_t is a deterministic function of $\mathbf{z}[t-1]$ and $\hat{g}_t = \mathbf{E}[g_t \,|\, w_t]$, we have

$$\mathbf{E}\big[\xi_\tau \,\big|\, \mathbf{z}[\tau-1]\big] = 0.$$

Therefore the sum $\sum_{\tau=1}^t \xi_\tau$ is a martingale. By the assumptions $h(w_\tau) \le D^2$ and $\|g_\tau\|_* \le L$ for all w_τ, we have

$$\|w - w_\tau\| \le \|w - w_0\| + \|w_\tau - w_0\| \le (2h(w))^{1/2} + (2h(w_\tau))^{1/2} \le 2\sqrt{2}D,$$

and $\|g_\tau - G_\tau\|_* \le \|g_\tau\|_* + \|G_\tau\|_* \le 2L$. Therefore,

$$|\xi_\tau| \le \|g_\tau - G_\tau\|_* \|w - w_\tau\| \le 4\sqrt{2}LD$$

So the sequence of random variables $\{\xi_\tau\}_{\tau=1}^t$ form a bounded martingale difference. Now by Hoeffding-Azuma inequality (Azuma, 1967), we have

$$\text{Prob}\left(\sum_{\tau=1}^t \xi_\tau \ge \Theta\right) \le \exp\left(\frac{-\Theta^2}{2t(4\sqrt{2}LD)^2}\right) = \exp\left(-\frac{\Theta^2}{64L^2D^2t}\right), \qquad \forall\, \Theta > 0.$$

Let $\Omega = \Theta/(8LD\sqrt{t})$, we have

$$\text{Prob}\left(\sum_{\tau=1}^t \xi_\tau \ge 8LD\sqrt{t}\,\Omega\right) \le \exp(-\Omega^2).$$

Now combining with (64) yields

$$\text{Prob}\left(\phi(\bar{w}_t) - \phi^\star \ge \frac{\Delta_t}{t} + \frac{8LD\Omega}{\sqrt{t}}\right) \le \exp(-\Omega^2).$$

Setting $\delta = \exp(-\Omega^2)$ gives the desired result (26).

Appendix D. Convergence Analysis of Accelerated RDA Method

In this appendix, we prove Theorem 6. We will need the following lemma.

Lemma 13 *Let ψ be a closed proper convex function, and h be strongly convex on* $\text{dom}\,\psi$ *with convexity parameter σ_h. If*

$$v = \arg\min_w \big\{\psi(w) + h(w)\big\}, \tag{65}$$

then

$$\psi(w) + h(w) \ge \psi(v) + h(v) + \frac{\sigma_h}{2}\|w - v\|^2, \qquad \forall\, w \in \text{dom}\,\psi.$$

Proof By the optimality condition for (65), there exist $b \in \partial\psi(v)$ and $d \in \partial h(v)$ such that

$$\langle b + d, w - v\rangle \ge 0, \qquad \forall\, w \in \text{dom}\,\psi.$$

Since ψ is convex and h is strongly convex, we have

$$\begin{aligned}
\psi(w) &\ge \psi(v) + \langle b, w - v\rangle, \\
h(w) &\ge h(v) + \langle d, w - v\rangle + \frac{\sigma_h}{2}\|w - v\|^2.
\end{aligned}$$

The lemma is proved by combining the three inequalities above. ■

In Lemma 13, we do not assume differentiability of either ψ or h. Similar results assuming differentiability have appeared in, for example, Chen and Teboulle (1993) and Tseng (2008), where the term $(\sigma_h/2)\|w-v\|^2$ was replaced by the Bregman divergence induced by h.

Our proof combines several techniques appeared separately in Nesterov (2005), Tseng (2008), Lan (2010), and Nemirovski et al. (2009). First, let $\varphi(w) = \mathbf{E}_z f(w,z)$. For every $t \geq 1$, define the following two functions:

$$\ell_t(w) = \varphi(u_t) + \langle \nabla\varphi(u_t), w-u_t\rangle + \Psi(w),$$
$$\hat{\ell}_t(w) = \varphi(u_t) + \langle g_t, w-u_t\rangle + \Psi(w).$$

Note that $\ell_t(w)$ is a lower bound of $\phi(w)$ for all $t \geq 1$. Let $q_t = g_t - \nabla\varphi(u_t)$, then

$$\hat{\ell}_t(w) = \ell_t(w) + \langle q_t, w-u_t\rangle.$$

For each $t \geq 1$, we also define the function

$$\psi_t(w) = \sum_{\tau=1}^{t} \alpha_\tau \hat{\ell}_\tau(w).$$

For convenience, let $\psi_0(w) = 0$. Then step 4 in Algorithm 3 is equivalent to

$$v_t = \arg\min_w \big\{\psi_t(w) + (L+\beta_t)h(w)\big\}. \tag{66}$$

Since $\nabla\varphi$ is Lipschitz continuous with a constant L (see discussions following (34)), we have

$$\varphi(w_t) \leq \varphi(u_t) + \langle \nabla\varphi(u_t), w_t-u_t\rangle + \frac{L}{2}\|w_t-u_t\|^2.$$

Adding $\Psi(w_t)$ to both sides of the above inequality yields

$$\begin{aligned}
\phi(w_t) &\leq \ell_t(w_t) + \frac{L}{2}\|w_t-u_t\|^2 \\
&= \ell_t\big((1-\theta_t)w_{t-1} + \theta_t v_t\big) + \frac{L}{2}\big\|(1-\theta_t)w_{t-1} + \theta_t v_t - u_t\big\|^2 \\
&\leq (1-\theta_t)\ell_t(w_{t-1}) + \theta_t\ell_t(v_t) + \frac{L}{2}\big\|\theta_t v_t - \theta_t v_{t-1}\big\|^2 \\
&= (1-\theta_t)\ell_t(w_{t-1}) + \theta_t\hat{\ell}_t(v_t) - \theta_t\langle q_t, v_t-u_t\rangle + \theta_t^2\frac{L}{2}\big\|v_t-v_{t-1}\big\|^2 \\
&= (1-\theta_t)\ell_t(w_{t-1}) + \frac{1}{A_t}\left(\alpha_t\hat{\ell}_t(v_t) + \frac{\alpha_t^2}{A_t}\frac{L}{2}\big\|v_t-v_{t-1}\big\|^2\right) - \theta_t\langle q_t, v_t-u_t\rangle \\
&\leq (1-\theta_t)\phi(w_{t-1}) + \frac{1}{A_t}\left(\alpha_t\hat{\ell}_t(v_t) + \frac{L}{2}\big\|v_t-v_{t-1}\big\|^2\right) - \theta_t\langle q_t, v_t-u_t\rangle.
\end{aligned}$$

In the second inequality above, we used convexity of ℓ_t and $u_t = (1-\theta_t)w_{t-1} + \theta_t v_{t-1}$, and in the last inequality above, we used $\ell_t(w) \leq \phi(w)$ and the assumption $\alpha_t^2 \leq A_t$. Multiplying both sides of

the above inequality by A_t and noticing $A_t(1-\theta_t) = A_t - \alpha_t = A_{t-1}$, we have

$$\begin{aligned}
A_t\phi(w_t) &\le A_{t-1}\phi(w_{t-1}) + \alpha_t\hat{\ell}_t(v_t) + \frac{L}{2}\left\|v_t - v_{t-1}\right\|^2 - \alpha_t\langle q_t, v_t - u_t\rangle \\
&= A_{t-1}\phi(w_{t-1}) + \alpha_t\hat{\ell}_t(v_t) + \frac{L+\beta_{t-1}}{2}\left\|v_t - v_{t-1}\right\|^2 - \frac{\beta_{t-1}}{2}\left\|v_t - v_{t-1}\right\|^2 \\
&\quad - \alpha_t\langle q_t, v_t - v_{t-1}\rangle - \alpha_t\langle q_t, v_{t-1} - u_t\rangle \\
&\le A_{t-1}\phi(w_{t-1}) + \alpha_t\hat{\ell}_t(v_t) + \frac{L+\beta_{t-1}}{2}\left\|v_t - v_{t-1}\right\|^2 - \frac{\beta_{t-1}}{2}\left\|v_t - v_{t-1}\right\|^2 \\
&\quad + \alpha_t\|q_t\|_*\|v_t - v_{t-1}\| - \alpha_t\langle q_t, v_{t-1} - u_t\rangle.
\end{aligned}$$

Now using the inequality

$$bc - \frac{a}{2}c^2 \le \frac{b^2}{2a}, \qquad \forall a > 0,$$

with $a = \beta_{t-1}$, $b = \alpha_t\|q_t\|_*$, and $c = \|v_t - v_{t-1}\|$, we have

$$A_t\phi(w_t) \le A_{t-1}\phi(w_{t-1}) + \alpha_t\hat{\ell}_t(v_t) + \frac{L+\beta_{t-1}}{2}\left\|v_t - v_{t-1}\right\|^2 + \frac{\alpha_t^2\|q_t\|_*^2}{2\beta_{t-1}} - \alpha_t\langle q_t, v_{t-1} - u_t\rangle.$$

By (66), v_{t-1} is the minimizer of $\psi_{t-1}(v) + (L+\beta_{t-1})h(v)$. Then by Lemma 13, we have

$$\psi_{t-1}(v_t) + (L+\beta_{t-1})h(v_t) \ge \psi_{t-1}(v_{t-1}) + (L+\beta_{t-1})h(v_{t-1}) + \frac{L+\beta_{t-1}}{2}\left\|v_t - v_{t-1}\right\|^2,$$

therefore,

$$\begin{aligned}
A_t\phi(w_t) - \psi_t(v_t) - (L+\beta_{t-1})h(v_t) \le{}& A_{t-1}\phi(w_{t-1}) - \psi_{t-1}(v_{t-1}) - (L+\beta_{t-1})h(v_{t-1}) \\
&+ \frac{\alpha_t^2\|q_t\|_*^2}{2\beta_{t-1}} - \alpha_t\langle q_t, v_{t-1} - u_t\rangle.
\end{aligned}$$

Since $\beta_t \ge \beta_{t-1}$ and $h(v_t) \ge 0$, we can replace the β_{t-1} on the left-hand side with β_t:

$$\begin{aligned}
A_t\phi(w_t) - \psi_t(v_t) - (L+\beta_t)h(v_t) \le{}& A_{t-1}\phi(w_{t-1}) - \psi_{t-1}(v_{t-1}) - (L+\beta_{t-1})h(v_{t-1}) \\
&+ \frac{\alpha_t^2\|q_t\|_*^2}{2\beta_{t-1}} - \alpha_t\langle q_t, v_{t-1} - u_t\rangle.
\end{aligned}$$

Summing the above inequality from $\tau = 1$ to t results in

$$\begin{aligned}
A_t\phi(w_t) \le{}& \psi_t(v_t) + (L+\beta_t)h(v_t) + A_0\phi(w_0) - \psi_0(v_0) - (L+\beta_0)h(v_0) \\
&+ \sum_{\tau=1}^{t}\frac{\alpha_\tau^2\|q_\tau\|_*^2}{2\beta_{\tau-1}} + \sum_{\tau=1}^{t}\alpha_\tau\langle q_\tau, u_\tau - v_{\tau-1}\rangle.
\end{aligned}$$

Using $A_0 = 0, \psi_0(v_0) = 0, h(v_0) = 0$, and (66), we have

$$\begin{aligned}
A_t\phi(w_t) &\le \psi_t(w^\star) + (L+\beta_t)h(w^\star) + \sum_{\tau=1}^{t} \frac{\alpha_\tau^2 \|q_\tau\|_*^2}{2\beta_{\tau-1}} + \sum_{\tau=1}^{t} \alpha_\tau \langle q_\tau, u_\tau - v_{\tau-1}\rangle \\
&= \sum_{\tau=1}^{t} \alpha_\tau \hat{\ell}_\tau(w^\star) + (L+\beta_t)h(w^\star) + \sum_{\tau=1}^{t} \frac{\alpha_\tau^2 \|q_\tau\|_*^2}{2\beta_{\tau-1}} + \sum_{\tau=1}^{t} \alpha_\tau \langle q_\tau, u_\tau - v_{\tau-1}\rangle \\
&= \sum_{\tau=1}^{t} \alpha_\tau \big(\ell_\tau(w^\star) + \langle q_\tau, w^\star - u_\tau\rangle\big) + (L+\beta_t)h(w^\star) + \sum_{\tau=1}^{t} \frac{\alpha_\tau^2 \|q_\tau\|_*^2}{2\beta_{\tau-1}} \\
&\quad + \sum_{\tau=1}^{t} \alpha_\tau \langle q_\tau, u_\tau - v_{\tau-1}\rangle \\
&= \sum_{\tau=1}^{t} \alpha_\tau \ell_\tau(w^\star) + (L+\beta_t)h(w^\star) + \sum_{\tau=1}^{t} \frac{\alpha_\tau^2 \|q_\tau\|_*^2}{2\beta_{\tau-1}} + \sum_{\tau=1}^{t} \alpha_\tau \langle q_\tau, w^\star - v_{\tau-1}\rangle.
\end{aligned}$$

Next, by $\ell_\tau(w^\star) \le \phi(w^\star)$ for all $\tau \ge 1$ and $A_t = \sum_{\tau=1}^{t} \alpha_\tau$, we have

$$A_t\phi(w_t) \le A_t\phi(w^\star) + (L+\beta_t)h(w^\star) + \sum_{\tau=1}^{t} \frac{\alpha_\tau^2 \|q_\tau\|_*^2}{2\beta_{\tau-1}} + \sum_{\tau=1}^{t} \alpha_\tau \langle q_\tau, w^\star - v_{\tau-1}\rangle. \tag{67}$$

Since $\mathbf{E}\big[q_\tau | \mathbf{z}[\tau-1]\big] = 0$ and q_τ is independent of $v_{\tau-1}$, we have $\mathbf{E}\big[\langle q_\tau, w^\star - v_{\tau-1}\rangle | \mathbf{z}[\tau-1]\big] = 0$. Together with the assumption $\mathbf{E}\|q_\tau\|_*^2 \le Q^2$ for all $\tau \ge 1$, we conclude

$$\mathbf{E}\,\phi(w_t) - \phi(w^\star) \le \frac{L+\beta_t}{A_t} h(w^\star) + \frac{1}{A_t}\left(\frac{Q^2}{2} \sum_{\tau=1}^{t} \frac{\alpha_\tau^2}{\beta_{\tau-1}}\right).$$

By rearranging terms on the right-hand side, this finishes the proof for Theorem 6.

D.1 Proof of Corollary 7

Using the two input sequences given in (37) and (38), we have

$$\sum_{\tau=1}^{t} \frac{\alpha_\tau^2}{2\beta_{\tau-1}} = \frac{1}{4\gamma} \sum_{\tau=1}^{t} \tau^{1/2} \le \frac{1}{4\gamma} \int_0^{t+1} \tau^{1/2} d\tau = \frac{(t+1)^{3/2}}{6\gamma}. \tag{68}$$

Plugging them into the conclusion of Theorem 6 gives

$$\mathbf{E}\phi(w_t) - \phi^\star \le \frac{4L}{t(t+1)} h(w^\star) + \frac{(t+1)^{1/2}}{t}\left(2\gamma h(w^\star) + \frac{2Q^2}{3\gamma}\right).$$

Next we use the assumption $h(w^\star) \le D^2$ and let $\gamma = Q/D$. Then

$$\mathbf{E}\phi(w_t) - \phi^\star \le \frac{4LD^2}{t(t+1)} + \frac{(t+1)^{1/2}}{t} \frac{8QD}{3} \le \frac{4LD}{t^2} + \frac{4QD}{\sqrt{t}}.$$

D.2 Proof of Theorem 8

We start with the inequality (67). We will first show high probability bounds for the two summations on the right-hand side of (67) that involve the stochastic quantities q_τ, and then combine them to prove Theorem 8. We need the following result on large-deviation bound for martingales, which can be viewed as an extension to the Hoeffding-Azuma inequality.

Lemma 14 *(Lan et al., 2008, Lemma 6) Let $z_1, z_2, \ldots$ be a sequence of i.i.d. random variables and let $\mathbf{z}[t]$ denote the collection $[z_1, \ldots, z_t]$. If $\xi_t = \xi_t(\mathbf{z}[t])$ are deterministic Borel functions of $\mathbf{z}[t]$ such that the conditional expectations $\mathbf{E}\big[\xi_t \,|\, \mathbf{z}[t-1]\big] = 0$ almost surely and*

$$\mathbf{E}\big[\exp(\xi_t^2/\nu_t^2) \,|\, \mathbf{z}[t-1]\big] \le \exp(1) \tag{69}$$

almost surely, where $\nu_t > 0$ are deterministic. Then for all $t \ge 1$,

$$\text{Prob}\left(\sum_{\tau=1}^{t} \xi_\tau > \Omega \sqrt{\sum_{\tau=1}^{t} \nu_\tau^2}\right) \le \exp\left(-\frac{\Omega^2}{3}\right), \qquad \forall\, \Omega \ge 0.$$

Lemma 15 *Let $\xi_t = \alpha_t \langle q_t, w^\star - v_{t-1}\rangle$. Then for all $t \ge 1$ and any $\Omega > 0$,*

$$\text{Prob}\left(\sum_{\tau=1}^{t} \xi_\tau > \Omega QD \sqrt{\frac{2}{3}(t+1)^3}\right) \le \exp(-\Omega^2/3).$$

Proof Since $\mathbf{E}\big[q_t \,|\, \mathbf{z}[t-1]\big] = 0$ and q_t is independent of $w^\star$ and v_{t-1}, we have

$$\mathbf{E}\big[\xi_t \big| \mathbf{z}[t-1]\big] = \mathbf{E}\big[\alpha_t \langle q_t, w^\star - v_{t-1}\rangle \big| \mathbf{z}[t-1]\big] = 0.$$

Therefore, $\sum_{\tau=1}^{t} \xi_\tau$ is a martingale. By the assumption $(1/2)\|w\|^2 \le h(w) \le D^2$ for all $w \in \text{dom}\,\Psi$, we have $\|w\| \le \sqrt{2}D$ for all $w \in \text{dom}\,\Psi$, and therefore

$$|\xi_t| \le \alpha_t \|q_t\|_* \|w^\star - v_{t-1}\| \le \alpha_t \|q_t\|_* \big(\|w^\star\| + \|v_{t-1}\|\big) \le \alpha_t \|q_t\|_* 2\sqrt{2}D.$$

Using the assumption $\mathbf{E}\big[\exp\big(\|q_t\|_*^2/Q^2\big)\big] \le \exp(1)$, we have

$$\mathbf{E}\left[\exp\left(\frac{\xi_t^2}{(8\alpha_t^2 Q^2 D^2)^2}\right)\Big| \mathbf{z}[t-1]\right] \le \mathbf{E}\left[\exp\left(\frac{(\alpha_t \|q_t\|_* 2\sqrt{2}D)^2}{8\alpha_t^2 Q^2 D^2}\right)\Big| \mathbf{z}[t-1]\right] \le \exp(1).$$

Therefore the condition (69) holds with $\nu_t^2 = 8\alpha_t^2 Q^2 D^2$. We bound $\sum_{\tau=1}^{t} \nu_\tau^2$ as follows:

$$\sum_{\tau=1}^{t} \nu_\tau^2 \le 8Q^2D^2 \sum_{\tau=1}^{t} \alpha_\tau^2 = 2Q^2D^2 \sum_{\tau=1}^{t} \tau^2 \le 2Q^2D^2 \int_0^{t+1} \tau^2 d\tau = \frac{2Q^2D^2}{3}(t+1)^3.$$

Then applying Lemma 14 gives the desired result. ■

Lemma 16 *For all $t \ge 1$ and any $\Lambda > 0$,*

$$\text{Prob}\left(\sum_{\tau=1}^{t} \frac{\alpha_\tau^2}{2\beta_{\tau-1}} \|q_\tau\|_*^2 > (1+\Lambda)\frac{Q^2}{6\gamma}(t+1)^{3/2}\right) \le \exp(-\Lambda).$$

Proof For any given $t \geq 1$, let

$$\Theta_t = \sum_{\tau=1}^{t} \frac{\alpha_\tau^2}{2\beta_{\tau-1}},$$

and

$$\eta_\tau = \frac{\alpha_\tau^2}{2\beta_{\tau-1}} \frac{1}{\Theta_t}, \qquad \tau = 1, \ldots, t.$$

Therefore $\sum_{\tau=1}^{t} \eta_\tau = 1$. By convexity of the function $\exp(\cdot)$,

$$\exp\left(\sum_{\tau=1}^{t} \eta_\tau \frac{\|q_\tau\|_*^2}{Q^2} \right) \leq \sum_{\tau=1}^{t} \eta_\tau \exp\left(\frac{\|q_\tau\|_*^2}{Q^2} \right).$$

Taking expectation and using the assumption (39),

$$\mathbf{E}\exp\left(\sum_{\tau=1}^{t} \eta_\tau \frac{\|q_\tau\|_*^2}{Q^2} \right) \leq \sum_{\tau=1}^{t} \eta_\tau \mathbf{E}\exp\left(\frac{\|q_\tau\|_*^2}{Q^2} \right) \leq \sum_{\tau=1}^{t} \eta_\tau \exp(1) = \exp(1).$$

By Markov's inequality,

$$\mathrm{Prob}\left(\exp\left(\sum_{\tau=1}^{t} \eta_\tau \frac{\|q_\tau\|_*^2}{Q^2} \right) > \exp(1+\Lambda) \right) \leq \frac{\exp(1)}{\exp(1+\Lambda)} = \exp(-\Lambda),$$

which is the same as

$$\mathrm{Prob}\left(\sum_{\tau=1}^{t} \frac{\alpha_\tau^2}{2\beta_{\tau-1}} \|q_\tau\|_*^2 > (1+\Lambda)\Theta_t Q^2 \right) \leq \exp(-\Lambda).$$

Then using the upper bound on Θ_t derived in (68) gives the desired result. ■

Combining Lemma 15, Lemma 16, and the inequality (67), we have

$$\begin{aligned} &\mathrm{Prob}\left(A_t(\phi(w_t) - \phi^\star) > (L+\beta_t)h(w^\star) + (1+\Lambda)\frac{Q^2}{6\gamma}(t+1)^{3/2} + \Omega QD\sqrt{\frac{2}{3}}(t+1)^{3/2} \right) \\ &\quad \leq \exp(-\Lambda) + \exp\left(-\frac{\Omega^2}{3} \right). \end{aligned}$$

Plugging in $A_t = t(t+1)/4$, $\beta_t = (\gamma/2)(t+1)^{3/2}$, and letting $\gamma = Q/D$, $\Omega = \sqrt{3\Lambda}$, we get

$$\mathrm{Prob}\left(\phi(w_t) - \phi^\star > \frac{4LD^2}{t(t+1)} + \left(\frac{8QD}{3} + \frac{2\Lambda QD}{3} + \sqrt{2\Lambda}QD \right) \frac{(t+1)^{1/2}}{t} \right) \leq 2\exp(-\Lambda).$$

Then using the fact $\sqrt{(t+1)/t} \leq \sqrt{2} \leq 3/2$ for all $t \geq 1$ results in

$$\mathrm{Prob}\left(\phi(w_t) - \phi^\star > \frac{4LD^2}{t^2} + \frac{4QD}{\sqrt{t}} + \frac{(\Lambda + 2\sqrt{\Lambda})QD}{\sqrt{t}} \right) \leq 2\exp(-\Lambda).$$

Finally, let $\delta = 2\exp(-\Lambda)$, hence $\Lambda = \ln(2/\delta)$. Then with probability at least $1-\delta$,

$$\phi(w_t) - \phi^\star \leq \frac{4LD^2}{t^2} + \frac{4QD}{\sqrt{t}} + \frac{QD}{\sqrt{t}}\left(\ln(2/\delta) + 2\sqrt{\ln(2/\delta)} \right).$$

This finishes the proof of Theorem 8.

Abstract

Maximum likelihood estimators are often of limited practical use due to the intensive computation they require. We propose a family of alternative estimators that maximize a stochastic variation of the composite likelihood function. Each of the estimators resolve the computation-accuracy trade-off differently, and taken together they span a continuous spectrum of computation-accuracy trade-off resolutions. We prove the consistency of the estimators, provide formulas for their asymptotic variance, statistical robustness, and computational complexity. We discuss experimental results in the context of Boltzmann machines and conditional random fields. The theoretical and experimental studies demonstrate the effectiveness of the estimators when the computational resources are insufficient. They also demonstrate that in some cases reduced computational complexity is associated with robustness thereby increasing statistical accuracy.

Keywords: Markov random fields, composite likelihood, maximum likelihood estimation

1. Introduction

Maximum likelihood estimation is by far the most popular point estimation technique in machine learning and statistics. Assuming that the data consists of n, m-dimensional vectors

$$D = (X^{(1)}, \ldots, X^{(n)}), \quad X^{(i)} \in \mathbb{R}^m, \tag{1}$$

and is sampled iid from a parametric distribution p_{θ_0} with $\theta_0 \in \Theta \subset \mathbb{R}^r$, a maximum likelihood estimator (MLE) $\hat{\theta}_n^{\text{ml}}$ is a maximizer of the log-likelihood function

$$\ell_n(\theta; D) = \sum_{i=1}^{n} \log p_\theta(X^{(i)}), \tag{2}$$
$$\hat{\theta}_n^{\text{ml}} = \arg\max_{\theta \in \Theta} \ell_n(\theta; D).$$

The use of the MLE is motivated by its consistency,[1] that is, $\hat{\theta}_n^{\text{ml}} \to \theta_0$ as $n \to \infty$ with probability 1 (Ferguson, 1996). The consistency property ensures that as the number n of samples grows, the estimator will converge to the true parameter θ_0 governing the data generation process.

An even stronger motivation for the use of the MLE is that it has an asymptotically normal distribution with mean vector θ_0 and variance matrix $(nI(\theta_0))^{-1}$. More formally, we have the

1. The consistency $\hat{\theta}_n^{\text{ml}} \to \theta_0$ with probability 1 is sometimes called strong consistency in order to differentiate it from the weaker notion of consistency in probability $P(|\hat{\theta}_n^{\text{ml}} - \theta_0| < \varepsilon) \to 0$.

following convergence in distribution as $n \to \infty$ (Ferguson, 1996)

$$\sqrt{n}\,(\hat{\theta}_n^{\mathrm{ml}} - \theta_0) \rightsquigarrow N(0, I^{-1}(\theta_0)), \tag{3}$$

where $I(\theta)$ is the $r \times r$ Fisher information matrix

$$I(\theta) = \mathsf{E}_{p_\theta}\{\nabla \log p_\theta(X)(\nabla \log p_\theta(X))^\top\}$$

with ∇f representing the $r \times 1$ gradient vector of $f(\theta)$ with respect to θ. The convergence (3) is especially striking since according to the Cramer-Rao lower bound, the asymptotic variance $(nI(\theta_0))^{-1}$ of the MLE is the smallest possible variance for any estimator. Since it achieves the lowest possible asymptotic variance, the MLE (and other estimators which share this property) is said to be asymptotically efficient.

The consistency and asymptotic efficiency of the MLE motivate its use in many circumstances. Unfortunately, in some situations the maximization or even evaluation of the log-likelihood (2) and its derivatives is impossible due to computational considerations. For instance this is the situation in many high dimensional exponential family distributions, including Markov random fields whose graphical structure contains cycles. This has lead to the proposal of alternative estimators under the premise that a loss of asymptotic efficiency is acceptable—in return for reduced computational complexity.

In contrast to asymptotic efficiency, we view consistency as a less negotiable property and prefer to avoid inconsistent estimators if at all possible. This common viewpoint in statistics is somewhat at odds with recent advances in the machine learning literature promoting non-consistent estimators, for example using variational techniques (Jordan et al., 1999). Nevertheless, we feel that there is a consensus regarding the benefits of having consistent estimators over non-consistent ones.

In this paper, we propose a family of estimators, for use in situations where the computation of the MLE is intractable. In contrast to many previously proposed approximate estimators, our estimators are statistically consistent and admit a precise quantification of both computational complexity and statistical accuracy through their asymptotic variance. Due to the continuous parameterization of the estimator family, we obtain an effective framework for achieving a predefined problem-specific balance between computational tractability and statistical accuracy. We also demonstrate that in some cases reduced computational complexity may in fact act as a regularizer, increasing robustness and therefore accomplishing both reduced computation and increased accuracy. This "win-win" situation conflicts with the conventional wisdom stating that moving from the MLE to pseudo likelihood and other related estimators result in a computational win but a statistical loss. Nevertheless we show that this occurs in some practical situations.

For the sake of concreteness, we focus on the case of estimating the parameters associated with Markov random fields. In this case, we provide a detailed discussion of the accuracy-complexity tradeoff. We include experiments on both simulated and real world data for several models including the Boltzmann machine, conditional random fields, and the Boltzmann linear chain model. Appendix B outlines a road-map of figures and the corresponding exposition.

2. Related Work

There is a large body of work dedicated to tractable learning techniques. Two popular categories are Markov chain Monte Carlo (MCMC) and variational methods. MCMC is a general purpose

technique for approximating expectations and can be used to approximate the normalization term and other intractable portions of the log-likelihood and its gradient (Casella and Robert, 2004). Variational methods are techniques for conducting inference and learning based on tractable bounds (Jordan et al., 1999). A similar approach would be to conduct maximum likelihood estimation for a simpler model that is tractable.

Despite the substantial work on MCMC and variational methods, there are little practical results concerning the convergence and approximation rate of the resulting parameter estimators. Variational techniques are sometimes inconsistent and it is hard to analyze their asymptotic statistical behavior. In the case of MCMC, a number of asymptotic results exist (Casella and Robert, 2004), but since MCMC plays a role inside each gradient descent or EM iteration it is hard to analyze the asymptotic behavior of the resulting parameter estimates. An advantage of our framework is that we are able to directly characterize the asymptotic behavior of the estimator and relate it to the amount of computational savings.

Our work draws on the composite likelihood method for parameter estimation proposed by Lindsay (1988) which in turn generalized the pseudo likelihood of Besag (1974). A selection of more recent studies on pseudo and composite likelihood are Arnold and Strauss (1991), Liang and Yu (2003), Varin and Vidoni (2005), Sutton and McCallum (2007) and Hjort and Varin (2008). Most of the recent studies in this area examine the behavior of the pseudo or composite likelihood in a particular modeling situation. We believe that the present paper is the first to systematically examine statistical and computational tradeoffs in a general quantitative framework. Possible exceptions include the experimental study of texture generation by Zhu and Liu (2002), the work of Xing et al. (2003) which focused on inference rather than parameter estimation, and the examination of generalization performance of small- and large- scale learning systems by Bottou and Bousquet (2008). The work of Liang and Jordan (2008) is also interesting in that the authors employ composite likelihood m-estimators and asymptotic arguments to compare the risk of discriminative and generative models. However, our work differs in theme and technique—we explore the tradeoff between computation and accuracy by way of a fundamentally different estimator.

Composite likelihood techniques, and consequently our work, can be thought of as local contrastive objectives (i.e., pseudo likelihood, contrastive divergence). Vickrey et al. (2010) present a non-local alternative in which the objective is not restricted to using the training label, but rather any assignment.

3. Stochastic Composite Likelihood

In many cases, the absence of a closed form expression for the normalization term prevents the computation of the log-likelihood (2) and its derivatives thereby severely limiting the use of the MLE. A popular example is Markov random fields, wherein the computation of the normalization term is often intractable (see Section 6 for more details). In this paper we propose alternative estimators based on the maximization of a stochastic variation of the composite likelihood.

We denote multiple samples using superscripts and individual dimensions using subscripts. Thus $X_j^{(r)}$ refers to the j-dimension of the r sample. Following standard convention we refer to random variables (RV) using uppercase letters and their corresponding values using lowercase letters. We also use the standard notations for extracting a subset of the dimensions of a random

variable

$$X_S \stackrel{\text{def}}{=} \{X_i : i \in S\}, \qquad X_{-j} \stackrel{\text{def}}{=} \{X_i : i \neq j\}. \tag{4}$$

We start by reviewing the pseudo log-likelihood function (Besag, 1974) associated with the data D (1),

$$p\ell_n(\theta; D) \stackrel{\text{def}}{=} \sum_{i=1}^{n} \sum_{j=1}^{m} \log p_\theta(X_j^{(i)} | X_{-j}^{(i)}). \tag{5}$$

The maximum pseudo likelihood estimator (MPLE) $\hat{\theta}_n^{\text{mpl}}$ is consistent, that is, $\hat{\theta}_n^{\text{mpl}} \to \theta_0$ with probability 1, but possesses considerably higher asymptotic variance than the MLE's $(nI(\theta_0))^{-1}$. Its main advantage is that it does not require the computation of the normalization term as it cancels out in the probability ratio defining conditional distributions

$$p_\theta(X_j | X_{-j}) = p_\theta(X_j | \{X_k : k \neq j\}) = \frac{p_\theta(X)}{\sum_{x_j} p_\theta(X_1, \ldots, X_{j-1}, X_j = x_j, X_{j+1}, \ldots, X_m)}.$$

The MLE and MPLE represent two different ways of resolving the tradeoff between asymptotic variance and computational complexity. The MLE has low asymptotic variance but high computational complexity while the MPLE has higher asymptotic variance but low computational complexity. It is desirable to obtain additional estimators realizing alternative resolutions of the accuracy complexity tradeoff. To this end we define the stochastic composite likelihood whose maximization provides a family of consistent estimators with statistical accuracy and computational complexity spanning the entire accuracy-complexity spectrum.

Stochastic composite likelihood generalizes the likelihood and pseudo likelihood functions by constructing an objective function that is a stochastic sum of likelihood objects. We start by defining the notion of m-pairs and likelihood objects and then proceed to stochastic composite likelihood.

Definition 1 *An m-pair (A,B) is a pair of sets $A,B \subset \{1,\ldots,m\}$ satisfying $A \neq \emptyset = A \cap B$. The likelihood object associated with an m-pair (A,B) and X is $S_\theta(A,B) \stackrel{\text{def}}{=} \log p_\theta(X_A | X_B)$ where X_S is defined in* (4)*. The composite log-likelihood function (Lindsay, 1988) is a collection of likelihood objects defined by a finite sequence of m-pairs $(A_1,B_1),\ldots,(A_k,B_k)$*

$$c\ell_n(\theta; D) \stackrel{\text{def}}{=} \sum_{i=1}^{n} \sum_{j=1}^{k} \log p_\theta(X_{A_j}^{(i)} | X_{B_j}^{(i)}). \tag{6}$$

There is a certain lack of flexibility associated with the composite likelihood framework as each likelihood object is either selected or not for the entire sample $X^{(1)},\ldots,X^{(n)}$. There is no allowance for some objects to be selected more frequently than others. For example, available computational resources may allow the computation of the log-likelihood for 20% of the samples, and the pseudo likelihood for the remaining 80%. In the case of composite likelihood if we select the full likelihood component (or the pseudo likelihood or any other likelihood object) then this component is applied to all samples indiscriminately.

In SCL, different likelihood objects $S_\theta(A_j,B_j)$ may be selected for different samples with the possibility of some likelihood objects being selected for only a small fraction of the data samples.

The selection may be non-coordinated, in which case each component is selected or not independently of the other components. Or it may be coordinated in which case the selection of one component depends on the selection of the other ones. For example, we may wish to avoid selecting a pseudo likelihood component for a certain sample $X^{(i)}$ if the full likelihood component was already selected for it.

Another important advantage of stochastic selection is that the discrete parameterization of (6) defined by the sequence $(A_1,B_1),\ldots,(A_k,B_k)$ is less convenient for theoretical analysis. Each component is either selected or not, turning the problem of optimally selecting components into a hard combinatorial problem. The stochastic composite likelihood, which is defined below, enjoys continuous parameterization leading to more convenient optimization techniques and convergence analysis.

Definition 2 *Consider a finite sequence of m-pairs* $(A_1,B_1),\ldots,(A_k,B_k)$*, a data set* $D=(X^{(1)},\ldots,X^{(n)})$*,* $\beta\in\mathbb{R}_+^k$*, and n iid, length k, binary random vectors* $Z^{(1)},\ldots,Z^{(n)}\overset{\text{i.i.d.}}{\sim}P(Z)$ *with* $\lambda_j\overset{\text{def}}{=}E(Z_j)>0$*. The stochastic composite log-likelihood (SCL) is*

$$sc\ell_n(\theta;D,Z)\overset{\text{def}}{=}\frac{1}{n}\sum_{i=1}^{n}m_\theta(X^{(i)},Z^{(i)}),\quad \textit{where}$$

$$m_\theta(X,Z)\overset{\text{def}}{=}\sum_{j=1}^{k}\beta_j Z_j\log p_\theta(X_{A_j}|X_{B_j}), \tag{7}$$

where, for brevity, we typically omit D,Z *in favor of* $sc\ell_n(\theta)$*.*

In other words, the SCL is a stochastic extension of (6) where for each sample $X^{(i)},i=1,\ldots,n$, the likelihood objects $S(A_1,B_1),\ldots,S(A_k,B_k)$ are either selected or not, depending on the values of the binary random variables $Z_1^{(i)},\ldots,Z_k^{(i)}$ and weighted by the constants $\beta_1,\ldots,\beta_k$. Note that $Z_j^{(i)}$ may in general depend on $Z_r^{(i)}$ but not on $Z_r^{(l)}$ or on $X^{(i)}$.

When we focus on examining different models for $P(Z)$ we sometimes parameterize it, for example by λ, that is, $P_\lambda(Z)$. This reuse of λ (it is also used in Definition 2) is a notational abuse. We accept it, however, as in most of the cases that we consider $\lambda_1,\ldots,\lambda_k$ from Definition 2 either form the parameter vector for $P(Z)$ or are part of it. Often we refer to a particular λ as a "policy" in order to emphasize its role as a "knob" in selecting particular m-pairs.

Some illustrative examples follow.

Independence. Factorizing $P_\lambda(Z_1,\ldots,Z_k)=\prod_j P_{\lambda_j}(Z_j)$ leads to $Z_j^{(i)}\sim\text{Ber}(\lambda_j)$ with complete independence among the indicator variables. For each sample $X^{(i)}$, each likelihood object $S(A_j,B_j)$ is selected or not independently with probability λ_j.

Multinomial. A multinomial model $Z\sim\text{Mult}(1,\lambda)$ implies that for each sample $Z^{(i)}$ a multivariate Bernoulli experiment is conducted with precisely one likelihood object being selected depending on the selection probabilities $\lambda_1,\ldots,\lambda_k$.

Product of Multinomials. A product of multinomials is formed by a partition of the dimensions to l disjoint subsets $\{1,\ldots,m\}=C_1\cup\cdots C_l$ where $Z_{C_i}\sim\text{Mult}(1,(\lambda_j:j\in C_i))$, that is,

$$P(Z)=\prod_{i=1}^{c}P_i\left(\{Z_j:j\in C_i\}\right),\qquad\text{where } P_i \text{ is } \text{Mult}(1,(\lambda_j:j\in C_l)).$$

Loglinear Models. The distribution $P(Z)$ follows a hierarchical loglinear model (Bishop et al., 1975). This case subsumes the other cases above.

In analogy to the MLE and the MPLE, the maximum SCL estimator (MSCLE) $\hat{\theta}_n^{\text{msl}}$ estimates θ_0 by maximizing the SCL function. In contrast to the log-likelihood and pseudo log-likelihood functions, the SCL function and its maximizer are random variables that depend on the indicator variables $Z^{(1)},\ldots,Z^{(n)}$ in addition to the data D. As such, its behavior should be summarized by examining the limit $n\to\infty$. Doing so eliminates the dependency on particular realizations of $Z^{(1)},\ldots,Z^{(n)}$ in favor of the the expected frequencies $\lambda_j = \mathsf{E}_{P(Z)}Z_j$ which are non-random constants.

The statistical accuracy and computational complexity of the SCL estimator are continuous functions of the parameters (β,λ) (component weights and selection probabilities respectively) which vary continuously throughout their domain $(\lambda,\beta)\in\Lambda\times\mathbb{R}_+^k$. Choosing appropriate values of (λ,β) retrieves the special cases of MLE, MPLE, maximum composite likelihood with each selection being associated with a distinct statistical accuracy and computational complexity. The SCL framework allows selections of many more values of (λ,β) realizing a wide continuous spectrum of estimators, each resolving the accuracy-complexity tradeoff differently.

We include below a demonstration of the SCL framework in a simple low dimensional case. In the following sections we discuss in detail the statistical behavior of the MSCLE and its computational complexity. We conclude the paper with several experimental studies.

3.1 Boltzmann Machine Example

Before proceeding we illustrate the SCL framework using a simple example involving a Boltzmann machine (Hinton and Sejnowski, 1983). Section 8.1 describes the specifics of this model. We consider in detail three SCL policies: full likelihood (FL), pseudo likelihood (PL), and a stochastic combination of first and second order pseudo likelihood with the first order components $p(X_i|X_{-i})$ selected with probability λ and the second order components $p(X_i,X_j|X_{\{i,j\}^c})$ selected with probability $1-\lambda$.

Denoting the number of (binary) graph vertices, or nodes, by m, and the number of examples by n, the computational complexity of the FL function measured in FLOP[2] counts is $O\big(\binom{m}{2}(2^m+n)\big)$ (for the log-likelihood) and $O\big(\binom{m}{2}^2 2^m + n\binom{m}{2}\big)$ for the log-likelihood gradient.[3] The exponential growth in m prevents such computations for large graphs.

The k-order PL function offers a practical alternative to FL (1-order PL corresponds to the traditional pseudo likelihood and 2-order PL its analog, $p(X_{\{i,j\}}|X_{\{i,j\}^c})$). The complexity of computing the corresponding SCL function is $O\big(\binom{m}{2}(\binom{m}{k}2^k+n)\big)$ for the objective function and $O\big(\binom{m}{2}^2\binom{m}{k}2^k + n\binom{m}{2}\big)$ for its gradient. The slower complexity growth of the k-order PL (polynomial in m instead of exponential) is offset by its reduced statistical accuracy, which we measure using the normalized asymptotic variance

$$\text{eff}(\hat{\theta}_n) = \frac{\det(\text{Asymp Var}(\hat{\theta}_n))}{\det(\text{Asymp Var}(\hat{\theta}_n^{\text{ml}}))} \tag{8}$$

2. FLOP is the number of FLoating point OPerations.
3. With memoization the complexity of the gradient can be reduced to $O\big(\binom{m}{2}2^m + n\binom{m}{2}\big)$ (at the cost of exponential 2^m storage). Note that this is only a polynomial improvement to an exponential complexity hence we lose no insight by making naive assumptions.

which is bounded from below by 1 (due to Cramer Rao lower bound) and its deviation from 1 reflects its inefficiency relative to the MLE.

The MLE thus achieves the best accuracy but it is computationally intractable. The first order and second order PL have higher asymptotic variance but are easier to compute. The SCL framework enables adding many more estimators filling in the gaps between ML, 1-order PL, 2-order PL, etc.

We illustrate three SCL functions in the context of a simple Boltzmann machine (five binary nodes, fourteen samples $X^{(1)},\ldots,X^{(14)}$, $\theta^{\text{true}} = (-1,-1,-1,-1,-1,1,1,1,1,1))$ in Figure 1. The top box refers to the full likelihood policy, that is, maximum likelihood. For each of the fourteen samples, the FL component is computed and their aggregation forms the SCL function which in this case equals the log-likelihood. The selection of the FL component for each sample is illustrated using a diamond box. The values under the boxes reflect the FLOP counts needed to compute the components and the total complexity associated with computing the entire SCL or log-likelihood is listed on the right. As mentioned above, the normalized asymptotic variance (8) is 1.

The pseudo likelihood function (5) is illustrated in the second box where each row correspond to one of the five PL components. As each of the five PL component is selected for each of the samples we have diamond boxes covering the entire 5×14 array. The shade of the diamond boxes reflects the complexity required to compute them enabling an easy comparison to the FL components in the top of the figure (note how the FL boxes are much darker than the PL boxes). The numbers at the bottom of each column reflect the FLOP marginal count for each of the fourteen samples and the numbers to the right of the rows reflect the FLOP marginal count for each of the PL components. In this case the FLOP count is less than half the FLOP count of the FL in top box (this reduction in complexity obtained by replacing FL with PL will increase dramatically for graphs with more than 5 nodes) but the asymptotic variance is 83% higher.[4]

The third SCL policy reflects a stochastic combination of first and second order pseudo likelihood components. Each first order component is selected with probability λ and each second order component is selected with probability $1-\lambda$. The result is a collection of 5 1-order PL components and 10 2-order components with only some of them selected for each of the fourteen samples. Again diamond boxes correspond to selected components which are shaded according to their FLOP complexity. The per-component FLOP marginals and per example FLOP marginals are listed as the bottom row and right-most column. The total complexity is somewhere between FL and PL and the asymptotic variance is reduced from the PL's 183% to 148%.

Additional insight may be gained at this point by considering Figure 3 which plots several SCL estimators as points in the plane whose x and y coordinates correspond to normalized asymptotic variance and computational complexity respectively. We turn at this point to considering the statistical properties of the SCL estimators.

4. Consistency and Asymptotic Variance of $\hat{\theta}_n^{\text{msl}}$

A nice property of the SCL framework is enabling mathematical characterization of the statistical properties of the estimator $\hat{\theta}_n^{\text{msl}}$. In this section we examine the conditions for consistency of the MSCLE and its asymptotic distribution and in the next section we consider robustness. The propositions below constitute novel generalizations of some well-known results in classical statistics. Proofs may be found in Appendix A. For simplicity, we assume that X is discrete and $p_\theta(x) > 0$.

4. The asymptotic variance of SCL functions is computed using formulas derived in the next section.

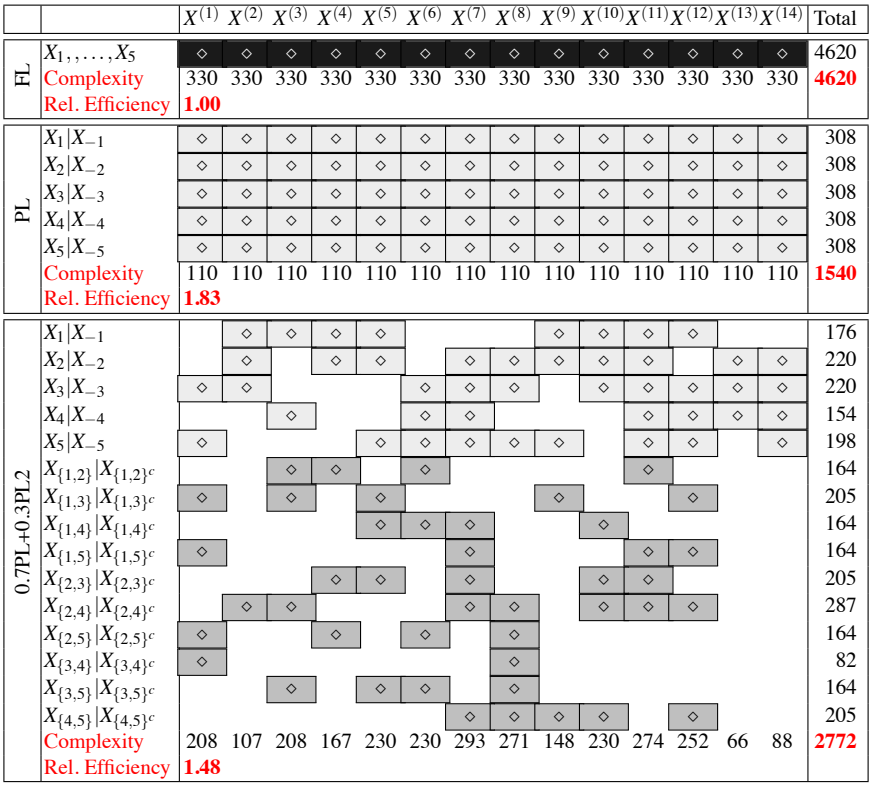

Figure 1: Sample runs of three different SCL policies for 14 examples $X^{(1)},\ldots,X^{(14)}$ drawn from a 5 binary node Boltzmann machine ($\theta^{\text{true}} = (-1,-1,-1,-1,-1,1,1,1,1,1)$). The policies are full likelihood (FL, top), pseudo likelihood (PL, middle), and a stochastic combination of first and second order pseudo likelihood with the first order components selected with probability 0.7 and the second order components with probability 0.3 (bottom).

The sample runs for the policies are illustrated by placing a diamond box in table entries corresponding to selected likelihood objects (rows corresponding to likelihood objects and columns to $X^{(1)},\ldots,X^{(14)}$). The FLOP counts of each likelihood object determines the shade of the diamond boxes while the total FLOP counts per example and per likelihood objects are displayed as table marginals (bottom row and right column for each policy). We also display the total FLOP count and the normalized asymptotic variance (8).

Even in the simple case of 5 nodes, FL is the most complex policy with PL requiring a third of the FL computation. 0.7PL+0.3PL2 is somewhere in between. The situation is reversed for the estimation accuracy-FL achieves the lowest possible normalized asymptotic variance of 1, PL is almost twice that, and 0.7PL+0.3PL2 somewhere in the middle. The SCL framework spans the accuracy-complexity spectrum. Choosing the right λ value obtains an estimator that suits available computational resources and required accuracy.

Definition 3 *A sequence of m-pairs $(A_1,B_1),\ldots,(A_k,B_k)$ is m-pair identifiable, or simply identifiable, of p_θ if the map $\{p_\theta(X_{A_j}|X_{B_j}) : j=1,\ldots,k\} \mapsto p_\theta(X)$ is injective. In other words, there exists only a single collection of conditionals $\{p_\theta(X_{A_j}|X_{B_j}) : j=1,\ldots,k\}$ that does not contradict the joint $p_\theta(X)$.*

Proposition 1 *Let $\Theta \subset \mathbb{R}^r$ be an open set, $p_\theta(x) > 0$ and continuous and smooth in θ, and $(A_1,B_1),\ldots,(A_k,B_k)$ be a sequence of m-pairs for which $\{(A_j,B_j) : \forall j$ such that $\lambda_j > 0\}$ ensures identifiability. Then the sequence of SCL maximizers is strongly consistent, that is,*

$$P\left(\lim_{n\to\infty} \hat{\theta}_n = \theta_0\right) = 1.$$

The above proposition indicates that to guarantee consistency, the sequence of m-pairs needs to satisfy Definition 3. It can be shown that a selection equivalent to the pseudo likelihood function, that is,

$$\mathcal{S} = \{(A_1,B_1),\ldots,(A_m,B_m)\} \quad \text{where} \quad A_i = \{i\}, B_i = \{1,\ldots,m\} \setminus A_i \tag{9}$$

ensures identifiability and consequently the consistency of the MSCLE estimator. Furthermore, every selection of m-pairs that subsumes $\mathcal{S}$ in (9) similarly guarantees identifiability and consistency.

The proposition below establishes the asymptotic normality of the MSCLE $\hat{\theta}_n$. The asymptotic variance enables the comparison of SCL functions with different parameterizations (λ,β).

Proposition 2 *Making the assumptions of Proposition 1 as well as convexity of $\Theta \subset \mathbb{R}^r$ we have the following convergence in distribution*

$$\sqrt{n}(\hat{\theta}_n^{msl} - \theta_0) \rightsquigarrow N(0, \Upsilon\Sigma\Upsilon)$$

where

$$\Upsilon^{-1} = \sum_{j=1}^{k} \beta_j\lambda_j \mathit{Var}_{\theta_0}(\nabla S_{\theta_0}(A_j,B_j)),$$

$$\Sigma = \mathit{Var}_{\theta_0}\left(\sum_{j=1}^{k} \beta_j\lambda_j \nabla S_{\theta_0}(A_j,B_j)\right).$$

The notation $\mathsf{Var}_{\theta_0}(Y)$ represents the covariance matrix of the random vector Y under p_{θ_0} while the notations $\xrightarrow{p}, \rightsquigarrow$ in the proof below denote convergences in probability and in distribution (Ferguson, 1996). ∇ represents the gradient vector with respect to θ.

When θ is a vector the asymptotic variance is a matrix. To facilitate comparison between different estimators we follow the convention of using the determinant, and in some cases the trace, to measure the statistical accuracy. See Chapter 4 of Serfling (1980) for some heuristic arguments for doing so. Figures 1,2,3 provide the asymptotic variance for some SCL estimators and describe how it can be used to gain insight into which estimator to use.

The fact that $\sqrt{n}(\hat{\theta}_n - \theta_0)$ converges in distribution to a Gaussian with zero mean (for the MLE and similarly for SCL estimators as we show above) implies that the estimator's asymptotic behavior, up to $n^{-1/2}$ order, is determined exclusively by the asymptotic variance. That means that the estimator is essentially unbiased up to that order. Higher order statistical analysis (obtained using

Taylor series with more terms) show that the bias decays in the faster rate of n^{-1} (Cox and Snell, 1968). We thus follow the statistical convention of conducting first order asymptotic analysis and concentrate on the estimator's asymptotic variance.

The statistical accuracy of the SCL estimator depends on β (weight parameters) and λ (selection parameter). It is thus desirable to use the results in this section in determining what values of β, λ to use. Directly using the asymptotic variance is not possible in practice as it depends on the unknown quantity θ_0. However, it is possible to estimate the asymptotic variance using the training data. We describe this in Section 7.

5. Robustness of $\hat{\theta}_n^{\mathbf{msl}}$

We observed in our experiments (see Section 8) that the SCL estimator sometimes performed better on a held-out test set than did the maximum likelihood estimator. This phenomenon seems to be in contradiction to the fact that the asymptotic variance of the MLE is lower than that of the SCL maximizer. This is explained by the fact that in some cases the true model generating the data does not lie within the parametric family $\{p_\theta : \theta \in \Theta\}$ under consideration. For example, many graphical models (HMM, CRF, LDA, etc.) make conditional independence assumptions that are often violated in practice. In such cases the SCL estimator acts as a regularizer achieving better test set performance than the non-regularized MLE. We provide below a theoretical account of this phenomenon using the language of m-estimators and statistical robustness. Our notation follows the one in van der Vaart (1998).

We assume that the model generating the data is outside the model family $P(X) \notin \{p_\theta : \theta \in \Theta\}$ and we extend the notation of $m_\theta(X,Z)$ in (7) with,

$$\begin{aligned}
\psi_\theta(X,Z) &\stackrel{\text{def}}{=} \nabla m_\theta(X,Z), \\
\dot{\psi}_\theta(X,Z) &\stackrel{\text{def}}{=} \nabla^2 m_\theta(X,Z), \text{ and} \\
\Psi_n(\theta) &\stackrel{\text{def}}{=} \frac{1}{n}\sum_{i=1}^{n} \psi_\theta(X^{(i)},Z^{(i)}),
\end{aligned}$$

noting that $\dot{\psi}_\theta(X,Z)$ is a matrix of second order derivatives.

Proposition 3 below generalizes the consistency result by asserting that $\hat{\theta}_n \to \theta_0$ where θ_0 is the point on $\{p_\theta : \theta \in \Theta\}$ that is closest to the true model P, as defined by

$$\theta_0 = \arg\max_{\theta\in\Theta} M(\theta) \quad \text{where} \quad M(\theta) \stackrel{\text{def}}{=} -\sum_{j=1}^{k} \beta_j \lambda_j D(P(X_{A_j}|X_{B_j})||p_\theta(X_{A_j}|X_{B_j})),$$

or equivalently, θ_0 satisfies

$$\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_{\theta_0}(X,Z) = 0.$$

When the SCL function reverts to the log-likelihood function, θ_0 becomes the KL projection of the true model P onto the parametric family $\{p_\theta : \theta \in \Theta\}$.

Proposition 3 *Assuming the conditions in Proposition 1 as well as* $\sup_{\theta:\|\theta-\theta_0\|\geq\varepsilon} M(\theta) < M(\theta_0)$ *for all* $\varepsilon > 0$ *we have* $\hat{\theta}_n^{msl} \to \theta_0$ *as* $n \to \infty$ *with probability 1.*

The added condition maintains that θ_0 is a well separated maximum point of M. In other words it asserts that only values close to θ_0 may yield a value of M that is close to the maximum $M(\theta_0)$. This condition is satisfied in the case of most exponential family models.

Proposition 4 *Assuming the conditions of Proposition 2 as well as* $E_{P(X)}E_{P(Z)}\|\psi_{\theta_0}(X,Z)\|^2 < \infty$, $E_{P(X)}E_{P(Z)}\psi_{\theta_0}(X)$ *exists and is non-singular,* $|\ddot{\Psi}_{ij}| = |\partial^2\psi_\theta(x)/\partial\theta_i\theta_j| < g(x)$ *for all* i, j *and* θ *in a neighborhood of* θ_0 *for some integrable* g*, we have*

$$\sqrt{n}(\hat{\theta}_n - \theta_0) = -(E_{P(X)}E_{P(Z)}\psi_{\theta_0})^{-1}\frac{1}{\sqrt{n}}\sum_{i=1}^{n}\psi_{\theta_0}(X^{(i)},Z^{(i)}) + o_P(1) \tag{10}$$

or equivalently

$$\hat{\theta}_n = \theta_0 - (E_{P(X)}E_{P(Z)}\psi_{\theta_0})^{-1}\frac{1}{n}\sum_{i=1}^{n}\psi_{\theta_0}(X^{(i)},Z^{(i)}) + o_P\left(\frac{1}{\sqrt{n}}\right). \tag{11}$$

Above, $f_n = o_P(g_n)$ means f_n/g_n converges to 0 with probability 1.

Corollary 1 *Assuming the conditions specified in Proposition 4 we have*

$$\sqrt{n}(\hat{\theta}_n - \theta_0) \rightsquigarrow N(0, (E_{P(X)}E_{P(Z)}\psi_{\theta_0})^{-1}(E_{P(X)}E_{P(Z)}\psi_{\theta_0}\psi_{\theta_0}^{\top})(E_{P(X)}E_{P(Z)}\psi_{\theta_0})^{-1}). \tag{12}$$

Equation (11) means that asymptotically, $\hat{\theta}_n$ behaves as θ_0 plus the average of iid RVs. As mentioned in van der Vaart (1998) this fact may be used to obtain a convenient expression for the asymptotic influence function, which measures the effect of adding a new observation to an existing large data set. Neglecting the remainder in (10) we have

$$\begin{aligned}
I(x,z) &\stackrel{\text{def}}{=} \hat{\theta}_n(X^{(1)},\ldots,X^{(n-1)},x,Z^{(1)},\ldots,Z^{(n-1)},z) - \hat{\theta}_{n-1}(X^{(1)},\ldots,X^{(n-1)},Z^{(1)},\ldots,Z^{(n-1)}) \\
&\approx -(\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_{\theta_0})^{-1}\left(\frac{1}{n}\sum_{i=1}^{n-1}\psi_{\theta_0}(X^{(i)},Z^{(i)}) + \frac{1}{n}\psi_{\theta_0}(w,z) - \frac{1}{n-1}\sum_{i=1}^{n-1}\psi_{\theta_0}(X^{(i)},Z^{(i)})\right) \\
&= -(\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_{\theta_0})^{-1}\frac{1}{n}\psi_{\theta_0}(w,z) + (\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_{\theta_0})^{-1}\frac{1}{n(n-1)}\sum_{i=1}^{n-1}\psi_{\theta_0}(X^{(i)},Z^{(i)}) \\
&= -\frac{1}{n}(\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_{\theta_0})^{-1}\psi_{\theta_0}(w,z) + o_P\left(\frac{1}{n}\right).
\end{aligned} \tag{13}$$

Corollary 1 and Equation (13) measure the statistical behavior of the estimator when the true distribution is outside the model family. In these cases it is possible that a computationally efficient SCL maximizer will result in higher statistical accuracy as well. This "win-win" situation of improving in both accuracy and complexity over the MLE is confirmed by our experiments in Section 8.

We finally note that the above analysis is not limited to misspecified models. For example, the influence function may be used to detect the robustness of $\hat{\theta}_n$ to outliers or rare events (it is desirable to be robust to such occurrences even if the model is not misspecified).

6. Stochastic Composite Likelihood for Markov Random Fields

Markov random fields (MRF) are some of the more popular statistical models for complex high dimensional data. Approaches based on pseudo likelihood and composite likelihood are naturally well-suited in this case due to the cancellation of the normalization term in the probability ratios defining conditional distributions. More specifically, a MRF with respect to a graph $G = (V,E)$, $V = \{1,\ldots,m\}$ with a clique set $\mathcal{C}$ is given by the following exponential family model

$$p_\theta(x) = \exp\left(\sum_{C\in\mathcal{C}} \theta_C f_C(x_C) - \log Z(\theta)\right),$$
$$Z(\theta) = \sum_x \exp\left(\sum_{C\in\mathcal{C}} \theta_c f_C(x_C)\right). \tag{14}$$

The primary bottlenecks in obtaining the maximum likelihood are the computations $\log Z(\theta)$ and $\nabla \log Z(\theta)$. Their computational complexity is exponential in the graph's treewidth and for many cyclic graphs, such as the Ising model or the Boltzmann machine, it is exponential in $|V| = m$.

In contrast, the conditional distributions that form the composite likelihood of (14) are given by (note the cancellation of $Z(\theta)$)

$$p_\theta(x_A|x_B) = \frac{\sum_{x'_{(A\cup B)^c}} \exp\left(\sum_{C\in\mathcal{C}} \theta_C f_C((x_A,x_B,x'_{(A\cup B)^c})_C)\right)}{\sum_{x'_{(A\cup B)^c}} \sum_{x''_A} \exp\left(\sum_{C\in\mathcal{C}} \theta_C f_C((x''_A,x_B,x'_{(A\cup B)^c})_C)\right)}. \tag{15}$$

whose computation is substantially faster. Specifically, The computation of (15) depends on the size of the sets A and $(A\cup B)^c$ and their intersections with the cliques in $\mathcal{C}$. In general, selecting small $|A_j|$ and $B_j = (A_j)^c$ leads to efficient computation of the composite likelihood and its gradient. For example, in the case of $|A_j| = l, |B_j| = m-l$ with $l \ll m$ we have that $k \leq m!/(l!(m-l)!)$ and the complexity of computing the $c\ell(\theta)$ function and its gradient may be shown to require time that is at most exponential in l and polynomial in m.

7. Automatic Selection of β

As Proposition 2 indicates, the weight vector β and selection probabilities λ play an important role in the statistical accuracy of the estimator through its asymptotic variance. The computational complexity, on the other hand, is determined by λ independently of β. Conceptually, we are interested in resolving the accuracy-complexity tradeoff jointly for both β,λ before estimating θ by maximizing the SCL function. However, since the computational complexity depends only on λ we propose the following simplified problem: Select λ based on available computational resources, and then given λ, select the β (and θ) that will achieve optimal statistical accuracy.

Selecting β that minimizes the asymptotic variance is somewhat ambiguous as $\Upsilon\Sigma\Upsilon$ in Proposition 2 is an $r\times r$ positive semidefinite matrix. A common solution is to consider the determinant as a one dimensional measure of the size of the variance matrix,[5] and minimize

$$J(\beta) = \log\det(\Upsilon\Sigma\Upsilon) = \log\det\Sigma + 2\log\det\Upsilon. \tag{16}$$

5. See Chapter 4 of Serfling (1980) for a heuristic discussion motivating this measure.

A major complication with selecting β based on the optimization of (16) is that it depends on the true parameter value θ_0 which is not known at training time. This may be resolved, however, by noting that (16) is composed of covariance matrices under θ_0 which may be estimated using empirical covariances over the training set. To facilitate fast computation of the optimal β we also propose to replace the determinant in (16) with the product of the diagonal elements. Such an approximation is motivated by Hadamard's inequality (which states that for symmetric matrices $\det(M) \leq \prod_i M_{ii}$) and by Geršgorin's circle theorem (see below). This approximation works well in practice as we observe in the experiments section. We also note that the procedure described below involves only simple statistics that may be computed on the fly and does not contribute significant additional computation (nor do they require significant memory).

More specifically, we denote $K^{(ij)} = \mathsf{Cov}_{\theta_0}(\nabla S_{\theta_0}(A_i, B_i), \nabla S_{\theta_0}(A_j, B_j))$ with entries $K^{(ij)}_{st}$, and approximate the log det terms in (16) using

$$\log\det\Upsilon = -\log\det\sum_{j=1}^{k}\beta_j\lambda_j K^{(jj)} \approx -\sum_{l=1}^{r}\log\sum_{j=1}^{k}\beta_j\lambda_j K^{(jj)}_{ll}$$

$$\log\det\Sigma = \log\det\mathsf{Var}_{\theta_0}\left(\sum_{j=1}^{k}\beta_j\lambda_j\nabla S_{\theta_0}(A_j, B_j)\right) = \log\det\sum_{i=1}^{k}\sum_{j=1}^{k}\beta_i\lambda_i\beta_j\lambda_j K^{(ij)}$$

$$\approx \sum_{l=1}^{r}\log\sum_{i=1}^{k}\sum_{j=1}^{k}\beta_i\lambda_i\beta_j\lambda_j K^{(ij)}_{ll}.$$

We denote (assuming A is a $n \times n$ matrix) for $i \in \{1,\ldots,n\}$, $R_i(A) = \sum_{j\neq i}\left|A_{ij}\right|$ and let $D(A_{ii}, R_i(A))$ (D_i where unambiguous) be the closed disc centered at A_{ii} with radius $R_i(A)$. Such a disc is called a Geršgorin disc. The result below states that for matrices that are close to diagonal, the eigenvalues are close to the diagonal elements making our approximation accurate.

Theorem 1 (Geršgorin's circle theorem, for example, Horn and Johnson, 1990) *Every eigenvalue of A lies within at least one of the Geršgorin discs $D(A_{ii}, R_i(A))$. Furthermore, if the union of k discs is disjoint from the union of the remaining $n-k$ discs, then the former union contains exactly k and the latter $n-k$ eigenvalues of A.*

Algorithm 1 solves for θ, β jointly using alternating optimization. The second optimization problem $J(\beta;\cdot)$ is done using the approximation above and may be computed with minimal additional computation. The components of this objective are typically freely available when $sc\ell$ is minimized with Newton-type methods. In practice we found that such an approach leads to a selection of β that is close to optimal, despite loose convergence criteria for the minimization of the $sc\ell$ objective (see Sec. 8.3 and Figures 14, 20 for results).

8. Experiments

We demonstrate the asymptotic properties of $\hat{\theta}^{\mathrm{msl}}_n$ and explore the complexity-accuracy tradeoff for three different models-Boltzmann machine, linear Boltzmann MRF and conditional random fields. In terms of data sets, we consider synthetic data as well as data sets from sentiment prediction and text chunking domains.

In Appendix B we list all figures by subject. The basic road-map is to explore SCL for a theoretical Boltzmann machine and then to explore two data sets using both generative and discriminative models. We also demonstrate the effectiveness of the β heuristic for these experiments.

Algorithm 1 Calculate $\hat{\theta}^{msl}$

Require: $\{X_i\}_{i\in I}$ and $\lambda, \beta^{(0)}$
1: $t \leftarrow 1$
2: **while** $t <$ MAXITS **do**
3: $\quad \theta^{(t)} \leftarrow \arg\min sc\ell(\theta; \{X_i\}_{i\in I}, \lambda, \beta^{(t-1)})$
4: $\quad$ **if** converged **then**
5: $\quad\quad$ **return** θ
6: $\quad$ **end if**
7: $\quad \beta^{(t)} \leftarrow \arg\min J(\beta; \{K^{(ij)}\}_{(i,j)\in J}, \lambda, \theta)$
8: $\quad t \leftarrow t+1$
9: **end while**
10: **return false**

8.1 Toy Example: Boltzmann Machines

We illustrate the improvement in asymptotic variance of the MSCLE associated with adding higher order Boltzmann machine likelihood components with increasingly higher probability. The Boltzmann machine can be parameterized as,

$$p_\theta(x) = \exp\left(\sum_{i<j} \theta_{ij} x_i x_j - \log\psi(\theta)\right), \quad x \in \{0,1\}^m.$$

To be able to accurately compute the asymptotic variance we use $m = 5$ with θ being a $\binom{5}{2}$ dimensional vector with half the components $+1$ and half -1. Since the asymptotic variance of $\hat{\theta}_n^{\text{msl}}$ is a matrix we summarize its size using either its trace or determinant.

Figure 2 displays the asymptotic variance, relative to the minimal variance of the MLE, for the cases of full likelihood (FL), pseudo likelihood ($|A_j| = 1$) PL1, stochastic combination of pseudo likelihood and 2nd order pseudo likelihood ($|A_j| = 2$) components λPL2 $+ (1-\lambda)$PL1, stochastic combination of 2nd order pseudo likelihood and 3rd order pseudo likelihood ($|A_j| = 3$) components λPL3 $+ (1-\lambda)$PL2, and stochastic combination of 3rd order pseudo likelihood and 4th order pseudo likelihood ($|A_j| = 4$) components λPL4 $+ (1-\lambda)$PL3.

The graph demonstrates the computation-accuracy tradeoff as follows: (a) pseudo likelihood is the fastest but also the least accurate, (b) full likelihood is the slowest but the most accurate, (c) adding higher order components reduces the asymptotic variance but also requires more computation, (d) the variance reduces with the increase in the selection probability λ of the higher order component, and (e) adding 4th order components brings the variance very close the lower limit and with each successive improvement becoming smaller and smaller according to a law of diminishing returns.

Figure 3 displays the asymptotic accuracy and complexity for different SCL policies for $m = 9$ binary valued vertices of a Boltzmann machine. We explore three polices in which we denote pseudo likelihood components of size, or order, k. These policies include: $\lambda_1\beta_1$PL1 $+ \lambda_2(1-\beta_1)$PL2, $\lambda_1\beta_1$PL1 $+ \lambda_2(1-\beta_1)$PL3, $\lambda_1\beta_1$PL2 $+ \lambda_2(1-\beta_1)$PL3 (for multiple values of $\lambda_1, \lambda_2, \beta_1$). By taking different linear combinations of various sized pseudo likelihood components, we span a continuous spectrum of accuracy-complexity resolutions. The lower part of the diagram is the boundary of the achievable region (the optimal but unachievable place is the bottom left corner). SCL policies that

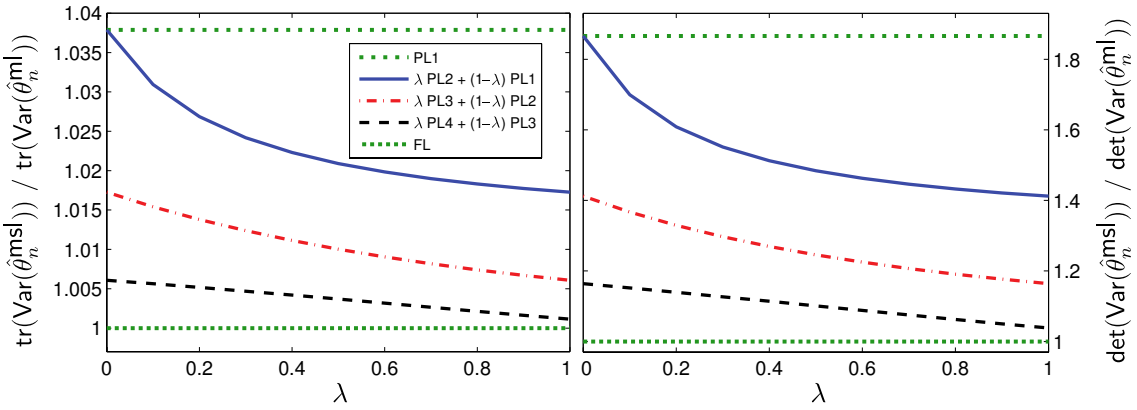

Figure 2: Asymptotic variance matrix, as measured by trace (left) and determinant (right), as a function of the selection probabilities for different stochastic versions of the SCL function.

lie to the right and top of that boundary may be improved by selecting a policy below and to the left of it.

8.2 Local Sentiment Prediction

Our first real world data set experiment involves local sentiment prediction using a conditional MRF model. The data set consisted of 249 movie review documents having an average of 30.5 sentences each with an average of 12.3 words from a 12633 word vocabulary. Each sentence was manually labeled as one of five sentimental designations: very negative, negative, objective, positive, or very positive. As described in Mao and Lebanon (2007) (where more information may be found) we considered the task of predicting the local sentiment flow within these documents using regularized conditional random fields (CRFs) (see Figure 4 for a graphical diagram of the model in the case of four sentences).

As is common practice, we curtail overfitting through a L_2 regularizer, $\exp\{-(2n\sigma^2)^{-1}||\theta||_2^2\}$, which is strong when σ^2 is small and weak when σ^2 is large. We consider σ^2 a hyper-parameter and select it through cross-validation, unless noted otherwise.

Figure 5 shows the contour plots of train and test log-likelihood as a function of the SCL parameters: weight β and selection probability λ. The likelihood components were mixtures of full and pseudo ($|A_j| = 1$) likelihood (rows 1,3) and pseudo and 2nd order pseudo ($|A_j| = 2$) likelihood (rows 2,4). A_j identifies a set of labels corresponding to adjacent sentences over which the probabilistic query is evaluated. Results were averaged over 100 cross validation iterations with 50% train-test split. We used BFGS quasi-Newton method for maximizing the regularized SCL functions. The figure demonstrates how the train log-likelihood increases with increasing the weight and selection probability of full likelihood in rows 1,3 and of 2nd order pseudo likelihood in rows 2,4. This increase in train log-likelihood is also correlated with an increase in computational complexity as higher order likelihood components require more computation. Note however, that the test set behavior in the third and fourth rows shows an improvement in prediction accuracy associated with

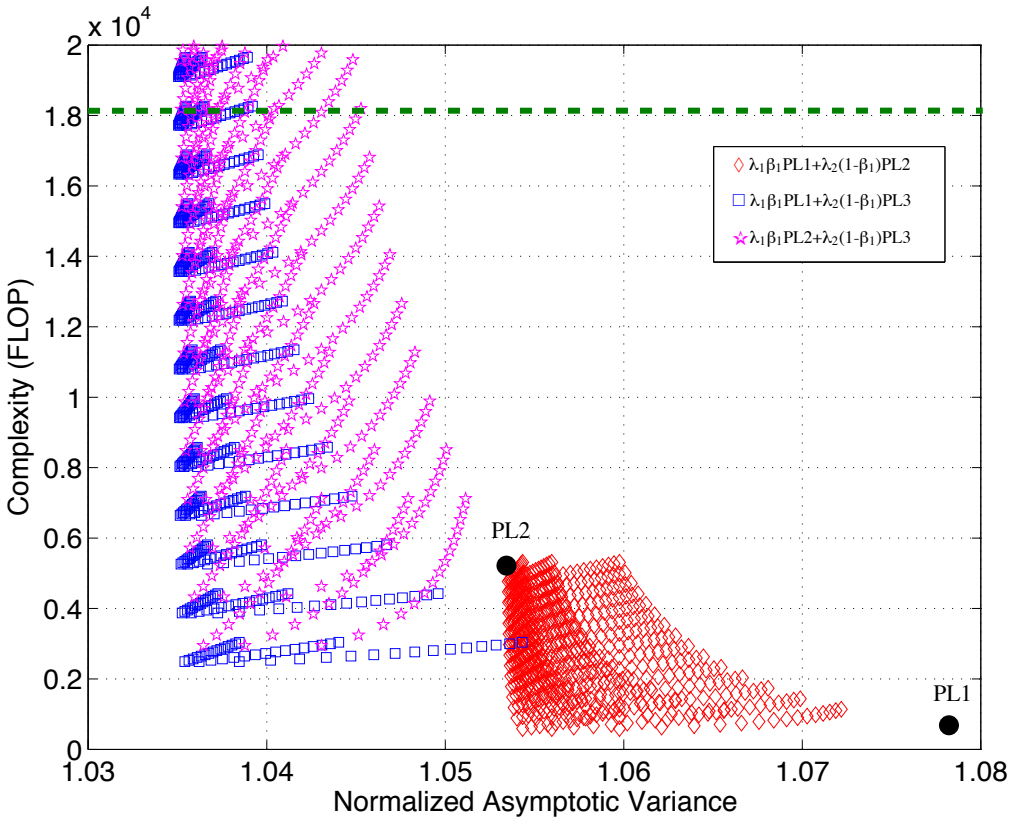

Figure 3: Computation-accuracy diagram for three SCL families:$\lambda_1\beta_1\text{PL1} + \lambda_2(1-\beta_1)\text{PL2}$, $\lambda_1\beta_1\text{PL1} + \lambda_2(1-\beta_1)\text{PL3}$, $\lambda_1\beta_1\text{PL2} + \lambda_2(1-\beta_1)\text{PL3}$ (for multiple values of $\lambda_1, \lambda_2, \beta_1$) for the Boltzmann machine with 9 binary nodes. The pure policies PL1 and PL2 are indicated by black circles and the computational complexity of the full likelihood indicated by a dashed line (corresponding normalized asymptotic variance is 1). The PL3 pure policy is beyond the scale of the diagram. As the graph size increases, the computational cost increases dramatically, in particular for the full likelihood policy and to a lesser extent for the pseudo likelihood policy.

decreasing the influence of full likelihood in favor of pseudo likelihood. The fact that this happens for (relatively) weak regularization, $\sigma^2 = 10$, and indicates that lower order pseudo likelihood has a regularization effect which improves prediction accuracy when the model is not regularized enough. We have encountered this phenomenon in other experiments as well and we will discuss it further in the following subsections.

Figure 6 displays the complexity and negative log-likelihoods (left:train, right:test) of different SCL estimators, sweeping through λ and β, as points in a two dimensional space. The shaded area near the origin is unachievable as no SCL estimator can achieve high accuracy and low computation at the same time. The optimal location in this 2D plane is the curved boundary of the

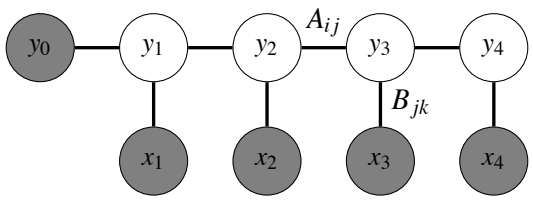

Figure 4: Graphical representation of a four token conditional random field (CRF). A, B are weight matrices and represent state-to-state transitions and state-to-observation outputs. Shading indicates the variable is conditioned upon while no shading indicates the variable is generated by the model.

achievable region with the exact position on that boundary depending on the required solution of the computation-accuracy tradeoff.

8.3 Text Chunking

This experiment consists of using sequential MRFs to divide sentences into "text chunks," that is, syntactically correlated sub-sequences, such as noun and verb phrases. Chunking is a crucial step towards full parsing. For example,[6] the sentence:

> He reckons the current account deficit will narrow to only # 1.8 billion in September.

could be divided as:

> [NP He] [VP reckons] [NP the current account deficit] [VP will narrow] [PP to] [NP only # 1.8 billion] [PP in] [NP September].

where NP, VP, and PP indicate noun phrase, verb phrase, and prepositional phrase.

We used the publicly available CoNLL-2000 shared task data set. It consists of labeled partitions of a subset of the Wall Street Journal (WSJ) corpus. Our training sets consisted of sampling 100 sentences without replacement from the the CoNLL-2000 training set (211,727 tokens from WSJ Sections 15-18). The test set was the same as the CoNLL-2000 testing partition (47,377 tokens from WSJ Section 20). Each of the possible 21,589 tokens, that is, words, numbers, punctuation, etc., are tagged by one of 11 chunk types and an O label indicating the token is not part of any chunk. Chunk labels are prepended with flags indicating that the token begins (B-) or is inside (I-) the phrase. Figure 7 lists all labels and respective frequencies. In addition to labeled tokens, the data set contains a part-of-speech (POS) column. These tags were automatically generated by the Brill tagger and must be incorporated into any model/feature set accordingly.

In the following, we explore this task using various SCL selection policies on two related, but fundamentally different sequential MRFs: Boltzmann chain MRFs and CRFs.

8.3.1 BOLTZMANN CHAIN MRF

Boltzmann chains are a generative MRF that are closely related to hidden Markov models (HMM). See MacKay (1996) for a discussion on the relationship between Boltzmann chain MRFs and

6. Taken from the CoNLL-2000 shared task, `http://www.cnts.ua.ac.be/conll2000/chunking/`.

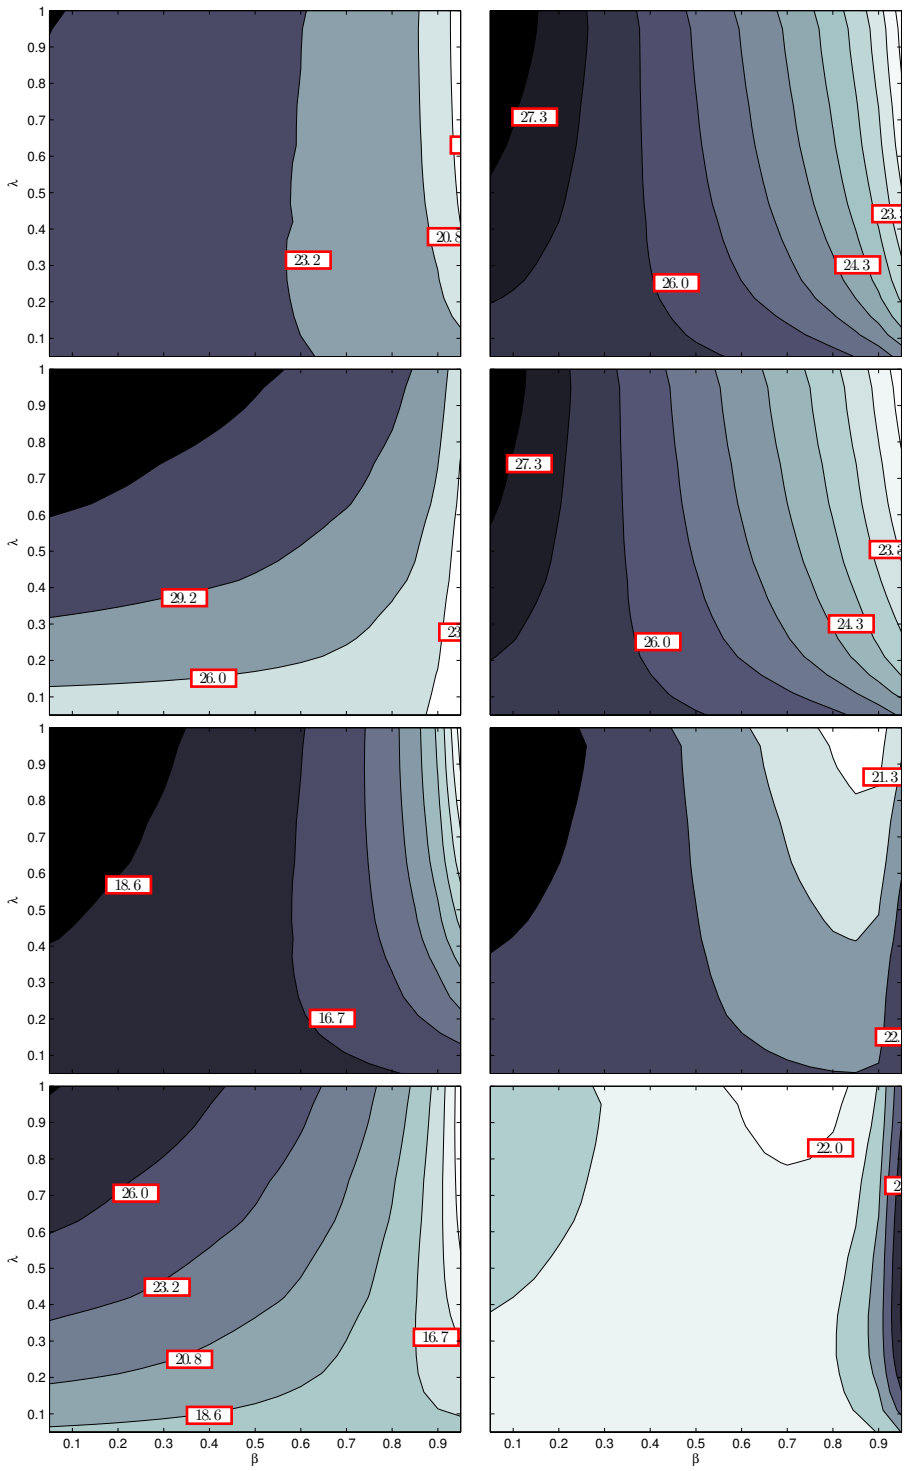

Figure 5: Train (left column) and test (right column) neg. log-likelihood contours for maximum SCL estimators for the CRF model. L_2 regularization, $\exp\{-(2n\sigma^2)^{-1}||\theta||_2^2\}$, parameters are $\sigma^2 = 1$ (rows 1,2) and $\sigma^2 = 10$ (rows 3,4). Rows 1,3 are stochastic mixtures of full (FL) and pseudo (PL1) log-likelihood components while rows 2,4 are PL1 and 2nd order pseudo (PL2). Note that weaker regularization resulted in higher accuracy at lower computation.

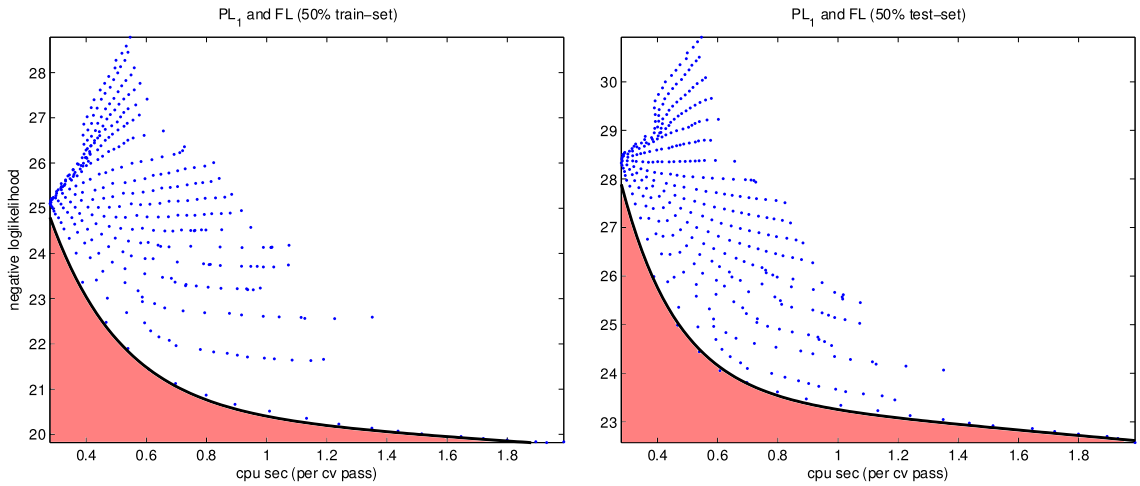

Figure 6: Scatter plot representing complexity and negative log-likelihood (left:train, right:test) of SCL functions for CRFs with L2 regularization parameter $\sigma^2 = 1/2$. The points represent different stochastic combinations of full and pseudo likelihood components. The shaded region represents impossible accuracy/complexity demands. Since the boundary of the obtainable region is empirical, the optimal beta always lies on this boundary. By varying λ, β we are able to smoothly span complexity (wall seconds) and accuracy.

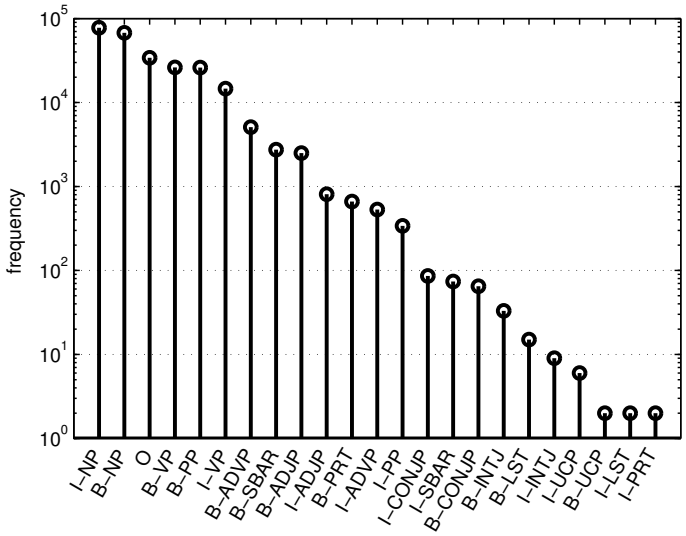

Figure 7: Label counts in CoNLL-2000 data set. Phrases such as noun (NP), verb (VP), and prepositional (PP) are demarcated by a "begin" tag (B-) and an "inside" tag (I-). Non-phrase entities are denoted as "other" (O).

HMMs. We consider SCL components of the form $p(X_2, Y_2|Y_1, Y_3)$, $p(X_2, X_3, Y_2, Y_3|Y_1, Y_4)$ which we refer to as first and second order pseudo likelihood (with higher order components generalizing in a straightforward manner).

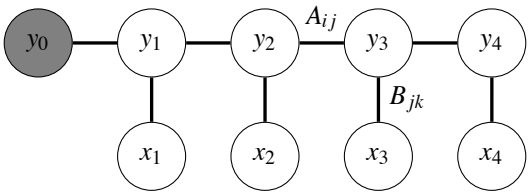

Figure 8: Graphical representation of a four token Boltzmann chain. A, B are weight matrices and represent preference in particular state-to-state transitions and state-to-feature emissions. Only the start state is conditioned upon while all others are generative.

The nature of the Boltzmann chain constrains our feature set to only encode the particular token present at each position, or time index. In doing so we avoid having to model additional dependencies across time steps and dramatically reduce computational complexity. Although SCL is precisely motivated by high treewidth graphs, we wish to include the full likelihood for demonstrative purposes—in practice, this is often not possible. Although POS tags are available we do not include them in these features since the dependence they share on neighboring tokens and other POS tags is unclear. For these reasons our time-sliced feature vector, x_i, has only a single-entry one and cardinality matching the size of the vocabulary (21,589 tokens).

As in Section 8.2, we control overfitting through a L_2 regularizer, $\exp\{-(2n\sigma^2)^{-1}||\theta||_2^2\}$, which is strong when σ^2 is small and weak when σ^2 is large. Here again we choose σ^2 via cross-validation unless otherwise noted. More often though, we show results for several representative σ^2 to demonstrate the roles of λ and β in $\hat{\theta}_n^{msl}$.

Figures 9 and 10 depict train and test negative log-likelihood, that is, perplexity, for the SCL estimator $\hat{\theta}_{100}^{msl}$ with a pseudo/full likelihood selection policy (PL1/FL). As is our convention, weight β and selection probability λ correspond to the higher order component, in this case full likelihood. The lower order pseudo likelihood component is always selected and has weight $1-\beta$. As expected the test set perplexity dominates the train-set perplexity. As was the situation in Sec. 8.2, we note that the lower order component serves to regularize the full likelihood, as evident by the abnormally large σ^2.

We next demonstrate the effect of using a 1st order/2nd order pseudo likelihood selection policy (PL1/PL2). Recall, our notion of pseudo likelihood never entails conditioning on x, although in principle it could. Figures 11 and 12 show how the policy responds to varying both λ and β. Figure 13 depicts the empirical tradeoff between accuracy and complexity. Figure 14 highlights the effectiveness of the β heuristic. See captions for additional comments.

8.3.2 CRFs

Conditional random fields are the discriminative counterpart of Boltzmann chains (cf. Figures 4 and 8). Since x is not jointly modeled with y, we are free to include features with non-independence across time steps without significantly increasing the computational complexity. Here our notion of

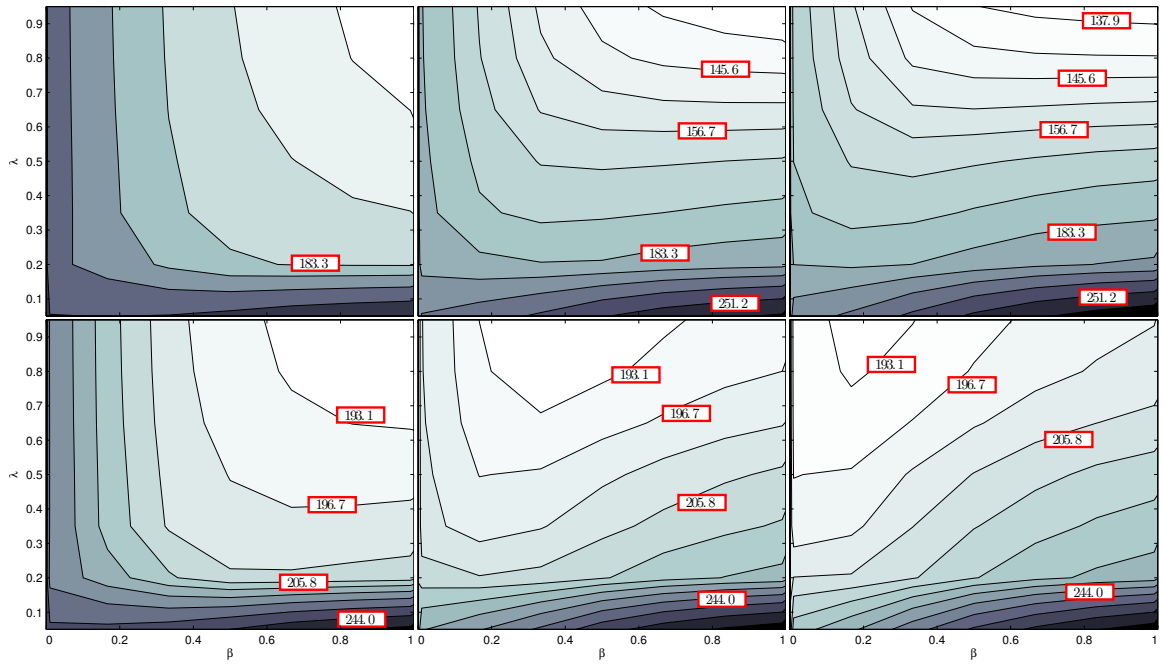

Figure 9: Train set (top) and test set (bottom) negative log-likelihood (perplexity) for the Boltzmann chain MRF with pseudo/full likelihood selection policy (PL1/FL). The x-axis, β, corresponds to relative weight placed on FL and and the y-axis, λ, corresponds to the probability of selecting FL. PL1 is selected with probability 1 and weight $1-\beta$. Contours and labels are fixed across columns. Results averaged over several cross-validation folds, that is, resampling both the train set and the PL1/FL policy. Columns from left to right correspond to weaker regularization, $\sigma^2 = \{500, 2500, 5000\}$. The best achievable test set perplexity is about 190.

Unsurprisingly the test set perplexity dominates the train set perplexity at each σ^2 (column). For a desired level of accuracy (contour) there exists a computationally favorable regularizer. Hence $\hat{\theta}_n^{msl}$ acts as both a regularizer and mechanism for controlling accuracy and complexity.

pseudo likelihood is more traditional, for example, $p(Y_2|Y_1, Y, 3, X_2)$ and $p(Y_2, Y_3|Y_1, Y, 4, X_2, X_3)$ are valid 1st and 2nd order pseudo likelihood components.

We employ a subset of the features outlined in Sha and Pereira (2003) which proved competitive for the CoNLL-2000 shared task. Our feature vector was based on seven feature categories, resulting in a total of 273,571 binary features (i.e., $\sum_i f_i(x_t) = 7$). The feature categories consisted of word unigrams, POS unigrams, word bigrams (forward and backward), and POS bigrams (forward and backward) as well as a stopword indicator (and its complement) as defined by Lewis et al. (2004). The set of possible feature/label pairs is much larger than our set—we use only those features supported by the CoNLL-2000 data set, that is, those which occur at least once. Thus we modeled 297,041 feature/label pairs and 847 transitions for a total of 297,888 parameters. As before, we use

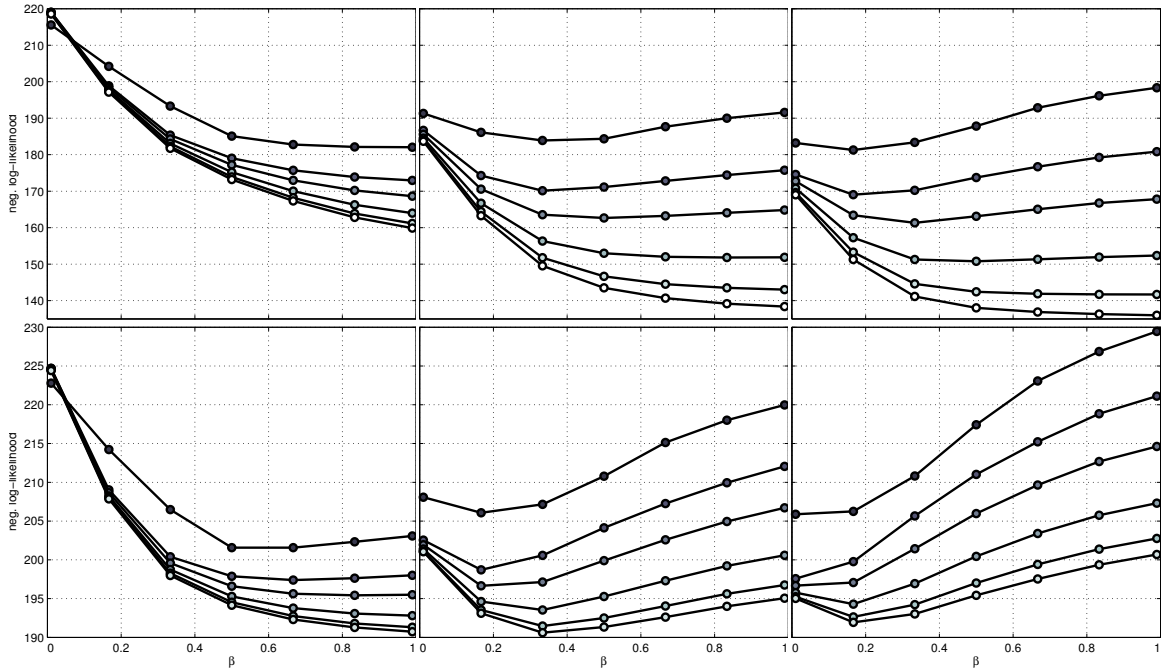

Figure 10: Train set and test set perplexities for the Boltzmann chain MRF with PL1/FL selection policy (see above layout description). The x-axis is again β and the y-axis perplexity. Lighter shading indicates FL is selected with increasing frequency. Note that as the regularizer is weakened the range in perplexity spanned by λ increases and the lower bound decreases. This indicates that the approximating power of $\hat{\theta}_n^{msl}$ increases when unencumbered by the regularizer and highlights its secondary role as a regularizer.

the L_2 regularizer, $\exp\{-(2\sigma^2)^{-1}||\theta||_2^2\}$, which is strong when σ^2 is small and weak when σ^2 is large.

We demonstrate learning on two selection policies: pseudo/full likelihood (Figures 15 and 16) and 1st/2nd order pseudo likelihood (Figures 17 and 18). In both selection polices we note a significant difference from the Boltzmann chain, β has less impact on both train and test perplexity. Intuitively, this seems reasonable as the component likelihood range and variance are constrained by the conditional nature of CRFs. Figure 19 demonstrates the empirical accuracy/complexity tradeoff and Figure 20 depicts the effectiveness of the β heuristic. See captions for further comments.

8.4 Complexity/Regularization Win-Win

It is interesting to contrast the test log-likelihood behavior in the case of mild and stronger L_2 regularization. In the case of weaker or no regularization, the test log-likelihood shows different behavior than the train log-likelihood. Adding a lower order component such as pseudo likelihood acts as a regularizer that prevents overfitting. Thus, in cases that are prone to overfitting reducing higher order likelihood components improves both performance as well as complexity. This represents a win-win situation in contrast to the classical view where the MLE has the lowest variance and adding lower order components reduces complexity but increases the variance.

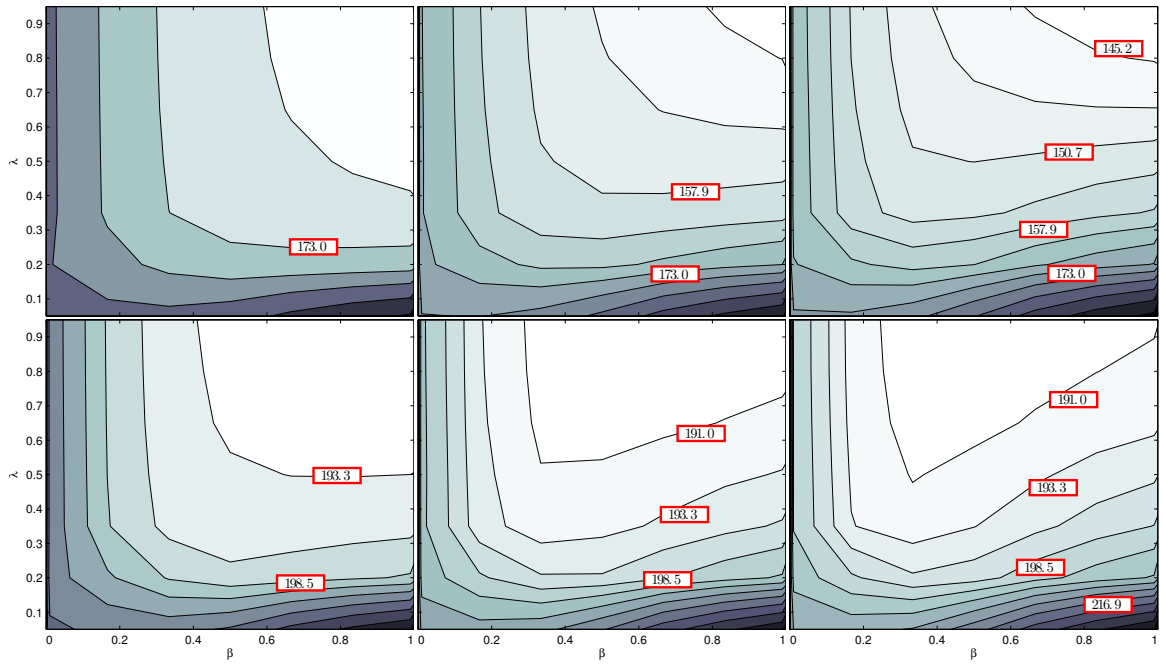

Figure 11: Train set (top) and test set (bottom) perplexity for the Boltzmann chain MRF with 1st/2nd order pseudo likelihood selection policy (PL1/PL2). The x-axis corresponds to PL2 weight and the y-axis the probability of its selection. PL1 is selected with probability 1 and weight $1-\beta$. Columns from left to right correspond to $\sigma^2 = \{5000, 10000, 15000\}$. See Figure 9 for more details. The best achievable test set perplexity is about 189.5.

In comparing these results to PL1/FL, we note that the test set contours exhibit less perplexity for larger areas. In particular, perplexity is lower at smaller λ values, meaning a computational saving over PL1/FL at a given level of accuracy.

In Figure 5 we note this phenomenon when comparing $\sigma^2 = 1$ to $\sigma^2 = 10$ across the selection policies PL1/FL and PL1/PL2. That is, the weaker regularization and more restrictive selection policy, that is, PL1/PL2, is able to achieve comparable test set perplexity.

For the text chunking experiments, we observe a striking win-win when using the Boltzmann chain MRF, Figures 9 and 11. Notice that as regularization is decreased (comparing from left to right), the contours are pulled closer to the x-axis. This means that we are achieving the same perplexity at reduced levels of computational complexity. The CRF however, only exhibits the win-win to a minor extent. We delve deeper into why this is might be the case in the following section.

8.5 λ, σ^2 Interplay

Throughout these experiments we fixed σ^2 and either swept over (λ, β) or used the heuristic to evaluate $(\lambda, \beta(\lambda))$. Motivated by the sometimes weak win-win (cf. Section 8.4) we now consider

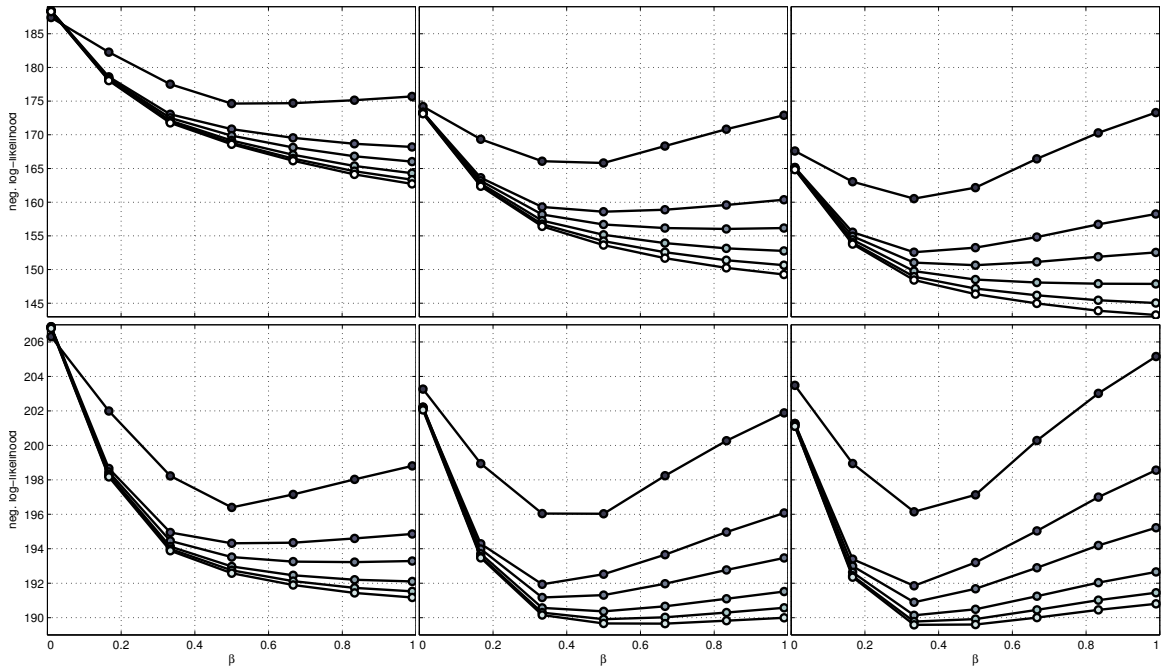

Figure 12: Train (top) and test (bottom) perplexities for the Boltzmann chain MRF with PL1/PL2 selection policy (x-axis:PL2 weight, y-axis:perplexity; see above and previous).

PL1/PL2 outperforms PL1/FL (Fig. 10) test perplexity despite PL1/FL including FL as a special case (i.e., $(\lambda,\beta) = (1,1)$). We speculate that the regularizer's indirect connection to the training samples precludes it from preventing certain types of overfitting. See Sec. 8.4 for more discussion.

how the optimal σ^2 changes as a function of λ. In Figure 21 we used the β heuristic to evaluate train and test perplexity over a (λ,σ^2) grid. We used CRFs and the text chunking task as outlined in Section 8.3.2.

For the PL1/FL policy, we observe that for small enough λ the optimal σ^2, that is, the σ^2 with smallest test perplexity, has considerable range. At some point there are enough samples of the higher-order component to stabilize the choice of regularizer, noting that it is still weaker than the optimal full likelihood regularizer. Conversely, the PL1/PL2 regularizer has an essentially constant optimal regularizer which is relatively much weaker.

As a result, we believe that the lack of win-win for the chunking CRF follows from two effects. In the case of the PL1/FL policy the contour plots are misleading since there is no single σ^2 that performs well across all $\lambda \in [0,1]$. For the PL1/PL2 there is simply little change in regularization necessary across λ.

9. Discussion

The proposed estimator family facilitates computationally efficient estimation in complex graphical models. In particular, different (β,λ) parameterizations of the stochastic composite likelihood en-

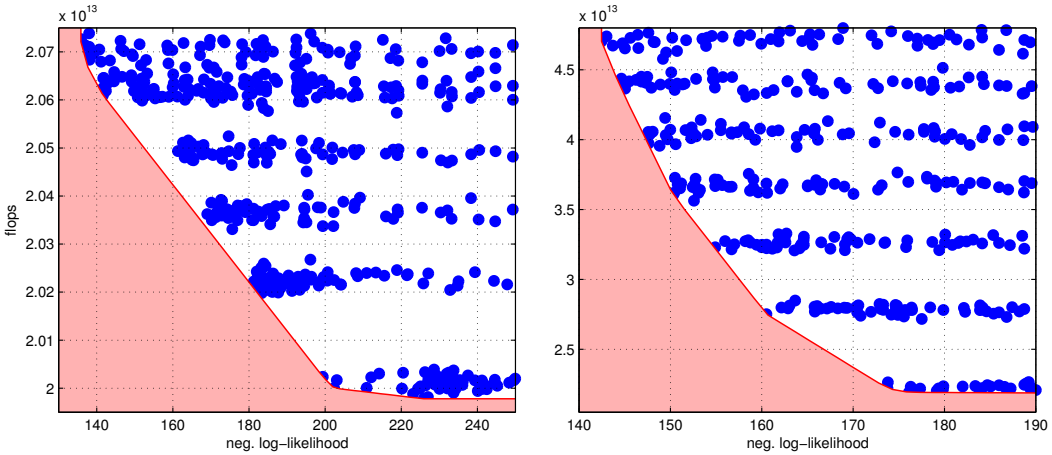

Figure 13: Accuracy and complexity tradeoff for the Boltzmann chain MRF with PL1/FL (left) and PL1/PL2 (right) selection policies. Each point represents the negative log-likelihood (perplexity) and the number of flops required to evaluate the composite likelihood and its gradient under a particular instantiation of the selection policy. The shaded region is the convex hull of the points and represents empirically unobtainable combinations of computational complexity and accuracy. Particularly interesting is the difference between policies and against the discriminative CRF, cf. Figure 19.

ables the resolution of the complexity-accuracy tradeoff in a domain and problem specific manner. The framework is generally suited for Markov random fields, including conditional graphical models and is theoretically motivated. When the model is prone to overfit, stochastically mixing lower order components with higher order ones acts as a regularizer and results in a win-win situation of improving test-set accuracy and reducing computational complexity at the same time.

It is interesting to note that the SCL framework may be generalized to random m-estimators beyond likelihood objects. That is, instead of a fixed m-function we may consider a linear combination of stochastic objects (appearing or not with some probability). Such estimators go beyond traditional m-estimator but may be analyzed using techniques similar to the ones developed in this paper. Although not a random m-estimator, the work of Dillon et al. (2010) borrows SCL concepts to facilitate budgeted semi-supervised learning. This too would benefit from a random m-estimator interpretation and indeed many machine learning tasks may fit nicely into such a framework.

The SCL framework may be useful for a wide variety of intractable graphical models. Besides the examples presented here, it may be particularly suited for large scale models from statistical physics, exponential random graph models, and models from computational biology. A particularly nice feature is that the above computation may be trivially parallelized thus leading to effective computation on large clusters and cloud computing.

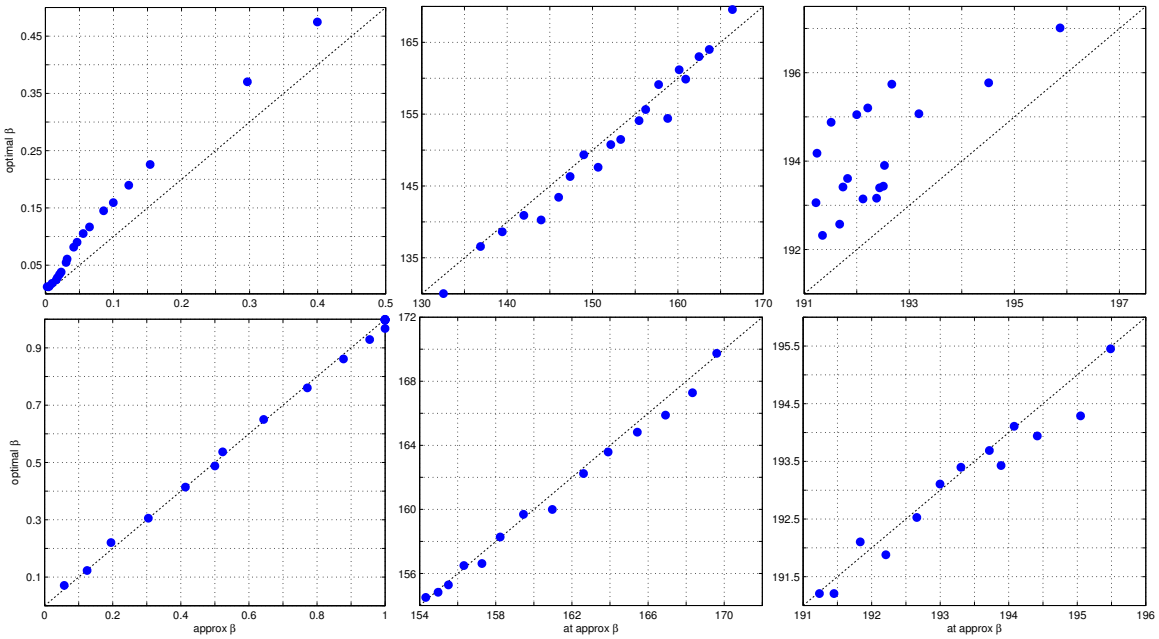

Figure 14: Demonstration of the effectiveness of the β heuristic, that is, using $\hat{\theta}^{msl}$ as a plug-in estimate for θ_0 to periodically re-estimate β during gradient descent. Results are for the Boltzmann chain with PL1/FL (top) and PL1/PL2 (bottom) selection policies. The x-axis is the value at the heuristically found β and the y-axis the value at the optimal β. The optimal β was found by evaluating over a β grid and choosing that with the smallest train set perplexity. The first column depicts the best performing β against the heuristic β. The second and third columns depict the training and testing perplexities (resp.) at the best performing β and heuristically found β. For all three columns, we assess the effectiveness of the heuristic by its nearness to the diagonal (dashed line).

For the PL1/PL2 policy the heuristic closely matched the optimal (all bottom row points are on diagonal). The heuristic out-performed the optimal on the test set and had slightly higher perplexity on the training set. It is a positive result, albeit somewhat surprising, and is attributable to either coarseness in the grid or improved generalization by accounting for variability in $\hat{\theta}^{msl}$.

Acknowledgments

The authors acknowledge useful discussion with P. Liang, M. Welling, P. Smyth, S.-C. Zhu, and C. Sutton. The presentation of the paper was substantially improved following useful feedback from Fernando Pereira and the anonymous referees.

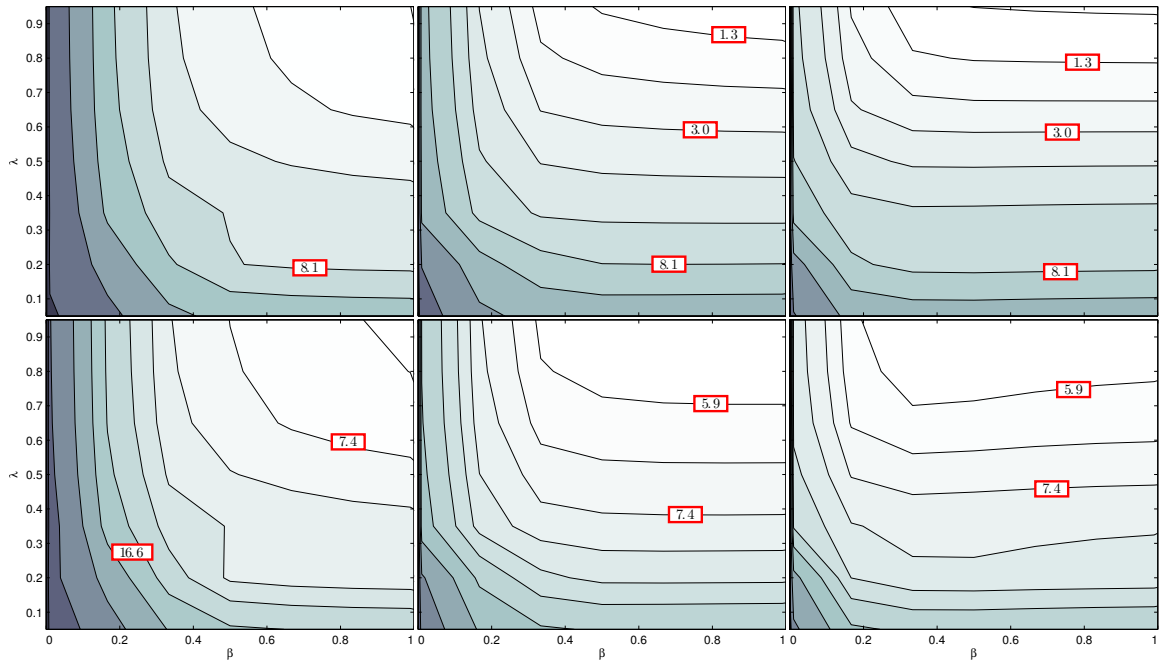

Figure 15: Train set (top) and test set (bottom) perplexity for the CRF with pseudo/full likelihood selection policy (PL1/FL). The x-axis corresponds to FL weight and the y-axis the probability of its selection. PL1 is selected with probability 1 and weight $1-\beta$. Columns from left to right correspond to $\sigma^2 = \{100, 1000, 5000\}$. See Figure 9 for more details. The best achievable test set perplexity is about 5.5.

Although we cannot directly compare CRFs to its generative counterpart, we observe some strikingly different trends. It is immediately clear that the CRF is less sensitive to the relative weighting of components than is the Boltzmann chain. This is partially attributable to a smaller range of the objective—the CRF is already conditional hence the per-component perplexity range is reduced.

Appendix A. Proofs

The proofs below generalize the classical consistency and asymptotic efficiency of the MLE (Ferguson, 1996) and the corresponding results for *m*-estimators (van der Vaart, 1998). They follow similar lines as the proofs in Ferguson (1996) and van der Vaart (1998), with the necessary modifications due to the stochasticity of the SCL function. We assume below that $p_\theta(X) > 0$ and that X is a discrete and finite RV.

The following lemma generalizes Shannon's inequality (Cover and Thomas, 2005) for the KL divergence. We will use it to prove consistency of the SCL estimator.

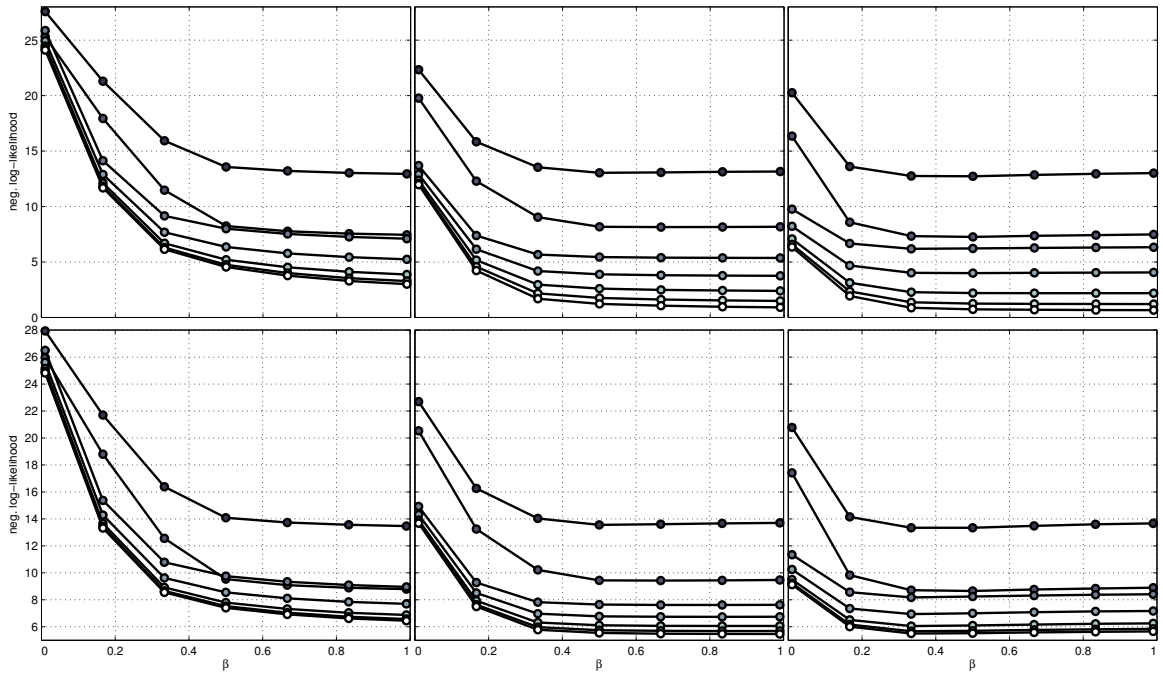

Figure 16: Train (top) and test (bottom) perplexities for a CRF with PL1/FL selection policy (x-axis:FL weight, y-axis:perplexity; see above and Fig. 10).

Perhaps more evidently here than above, we note that the significance of a particular β is less than that of the Boltzmann chain. However, for large enough σ^2, the optimal $\beta \neq 1$. This indicates the dual role of PL1 as a regularizer. Moreover, the left panel calls attention to the interplay between β, λ, and σ^2. See Sec. 8.5 for more discussion.

Lemma 1 *Let* $(A_1,B_1),\ldots,(A_k,B_k)$ *be a sequence of m-pairs that ensures identifiability of* $p_\theta, \theta \in \Theta$ *and* $\alpha_1,\ldots,\alpha_k$ *positive constants. Then*

$$\sum_{j=1}^{k} \alpha_k D(p_\theta(X_{A_j}|X_{B_j}) \,||\, p_{\theta'}(X_{A_j}|X_{B_j})) \geq 0$$

where equality holds iff $\theta = \theta'$.

Proof The inequality follows from applying Jensen's inequality for each conditional KL divergence

$$\begin{aligned} -D(p_\theta(X_{A_j}|X_{B_j}) \,||\, p_{\theta'}(X_{A_j}|X_{B_j})) = \mathsf{E}_{p_\theta} \log \frac{p_{\theta'}(X_{A_j}|X_{B_j})}{p_\theta(X_{A_j}|X_{B_j})} &\leq \log E_{p_\theta} \frac{p_{\theta'}(X_{A_j}|X_{B_j})}{p_\theta(X_{A_j}|X_{B_j})} \\ &= \log 1 = 0. \end{aligned}$$

For equality to hold we need each term to be 0 which follows only if $p_\theta(X_{A_j}|X_{B_j}) \equiv p_{\theta'}(X_{A_j}|X_{B_j})$ for all j which, assuming identifiability, holds iff $\theta = \theta'$. ■

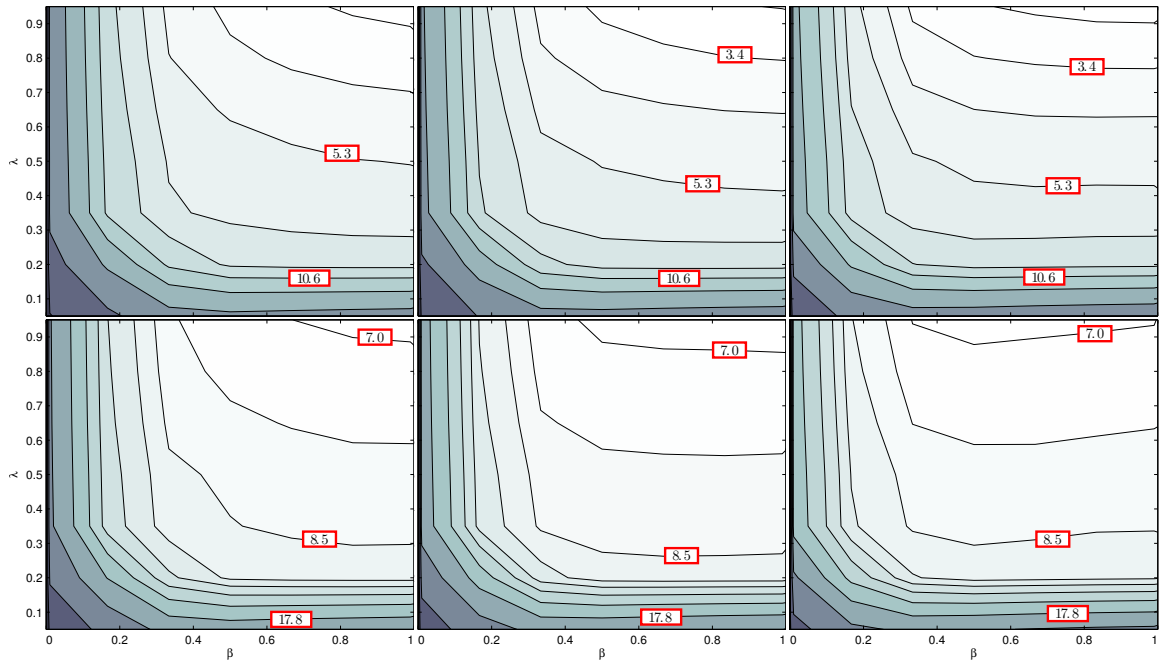

Figure 17: Train set (top) and test set (bottom) perplexity for a CRF with 1st/2nd order pseudo likelihood selection policy (PL1/PL2). The x-axis, β, represents the relative weight placed on PL2 and the y-axis, λ, the probability of selecting PL2. PL1 is selected with probability 1. Columns from left to right correspond to weaker regularization, $\sigma^2 = \{10000, 20000, 40000\}$. See Figure 15 for more details.

Proposition 5 *Let $\Theta \subset \mathbb{R}^r$ be an open set, $p_\theta(x) > 0$ and continuous and smooth in θ, and $(A_1, B_1), \ldots, (A_k, B_k)$ be a sequence of m-pairs for which $\{(A_j, B_j) : \forall j$ such that $\lambda_j > 0\}$ ensures identifiability. Then the sequence of SCL maximizers is strongly consistent, that is,*

$$P\left(\lim_{n\to\infty} \hat{\theta}_n = \theta_0\right) = 1.$$

Proof The SCL function, modified slightly by a linear combination with a term that is constant in θ is

$$sc\ell'(\theta) = \frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{k} \beta_j \left(Z_{ij} \log p_\theta(X_{A_j}^{(i)} | X_{B_j}^{(i)}) - \lambda_j \log p_{\theta_0}(X_{A_j}^{(i)} | X_{B_j}^{(i)})\right).$$

By the strong law of large numbers, the above expression converges as $n \to \infty$ to its expectation

$$\mu(\theta) = -\sum_{j=1}^{k} \beta_j \lambda_j D(p_{\theta_0}(X_{A_j} | X_{B_j}) \,||\, p_\theta(X_{A_j} | X_{B_j})).$$

If we restrict ourselves to the compact set $S = \{\theta : c_1 \le \|\theta - \theta_0\| \le c_2\}$ then

$$\sup_{\theta \in S} \sup_{Z} \left| \sum_{j=1}^{k} Z_j \beta_j \log p_\theta(X_{A_j} | X_{B_j}) - \lambda_j \beta_j \log p_{\theta_0}(X_{A_j} | X_{B_j}) \right| < K(x) < \infty$$

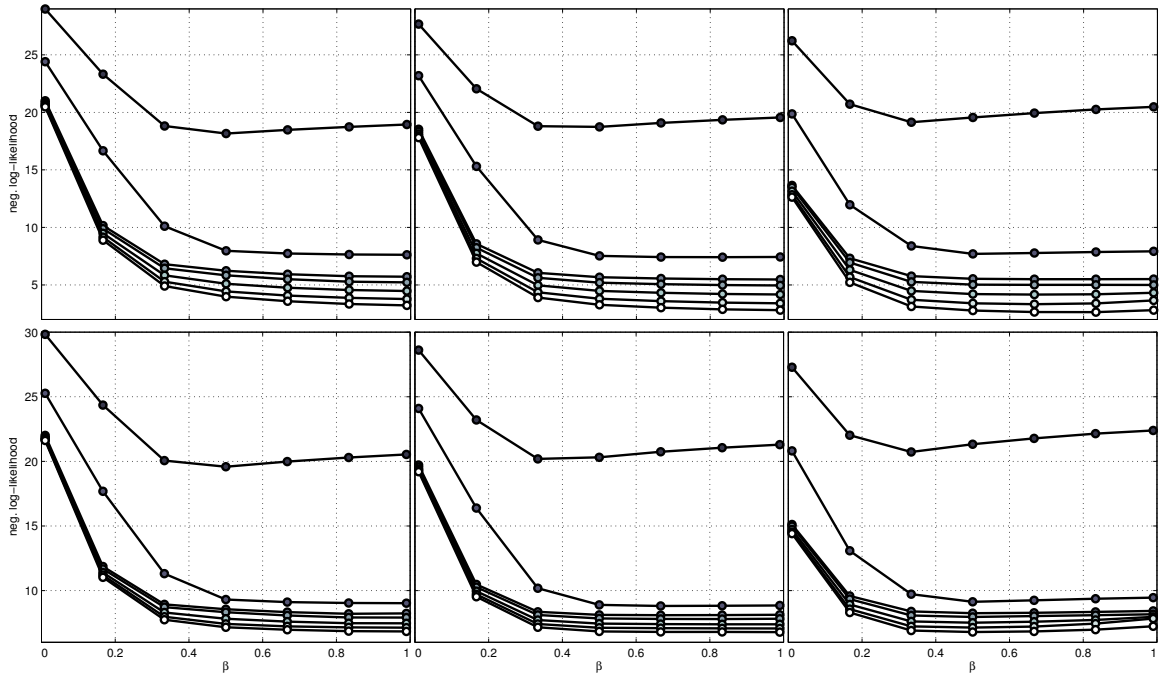

Figure 18: Train (top) and test (bottom) perplexities for a CRF with PL1/PL2 selection policy (x-axis:PL2 weight, y-axis:perplexity; see above and Fig. 10).

Although increasing λ only brings minor improvement to both the training and testing perplexities, it is worth noting that the test perplexity meets that of the PL1/FL. Still though, the overall lack of resolution here suggests that smaller values of λ would better span a range of perplexities and at reduced computational cost.

where $K(x)$ is a function satisfying $\mathsf{E}K(X) < \infty$. As a result, the conditions for the uniform strong law of large numbers (Ferguson, 1996) hold on S leading to

$$P\left\{\lim_{n\to\infty}\sup_{\theta\in S}|scl'(\theta)-\mu(\theta)|=0\right\}=1. \tag{17}$$

By Proposition 1, $\mu(\theta)$ is non-positive and is zero iff $\theta=\theta_0$. Since the function $\mu(\theta)$ is continuous it attains its negative supremum on the compact S: $\sup_{\theta\in S}\mu(\theta)<0$. Combining this fact with (17) we have that there exists N such that for all $n>N$ the SCL maximizers on S achieves strictly negative values of $sc\ell'(\theta)$ with probability 1. However, since $sc\ell'(\theta)$ can be made to achieve values arbitrarily close to zero under $\theta=\theta_0$, we have that $\hat{\theta}_n^{\text{msl}}\notin S$ for $n>N$. Since c_1,c_2 were chosen arbitrarily $\hat{\theta}_n^{\text{msl}}\to\theta_0$ with probability 1. ■

Proposition 6 *Making the assumptions of Proposition 1 as well as convexity of $\Theta\subset\mathbb{R}^r$ we have the following convergence in distribution*

$$\sqrt{n}(\hat{\theta}_n^{msl}-\theta_0)\rightsquigarrow N(0,\Upsilon\Sigma\Upsilon)$$

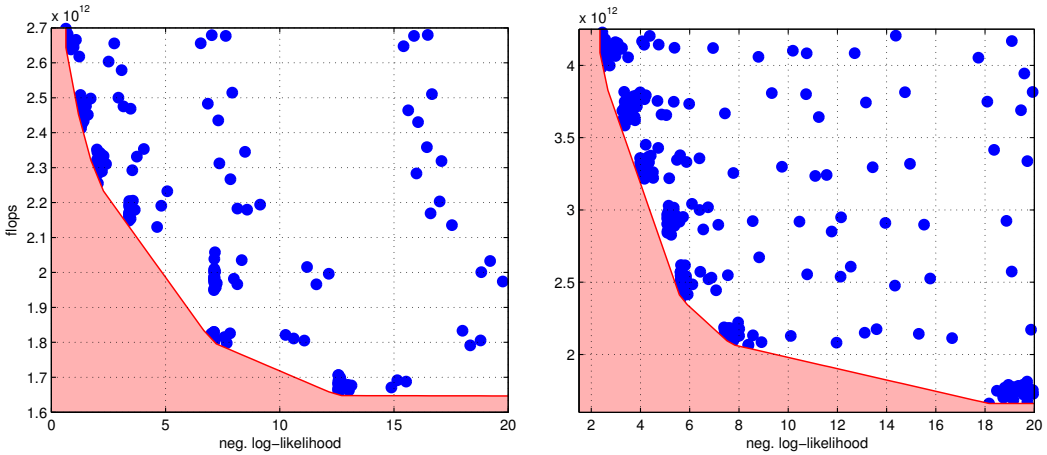

Figure 19: Accuracy and complexity tradeoff for the CRF with PL1/FL (left) and PL1/PL2 (right) selection policies. Each point represents the negative log-likelihood (perplexity) and the number of flops required to evaluate the composite likelihood and its gradient under a particular instance of the selection policy. The shaded region is the convex hull of the points and represents empirically unobtainable combinations of computational complexity and accuracy. σ^2. Particularly interesting is the difference between policies and against the generative Boltzmann chain, cf. Figure 13.

where

$$\Upsilon^{-1} = \sum_{j=1}^{k} \beta_j \lambda_j \mathsf{Var}_{\theta_0}(\nabla S_{\theta_0}(A_j, B_j))$$

$$\Sigma = \mathsf{Var}_{\theta_0}\left(\sum_{j=1}^{k} \beta_j \lambda_j \nabla S_{\theta_0}(A_j, B_j)\right).$$

The notation $\mathsf{Var}_{\theta_0}(Y)$ represents the covariance matrix of the random vector Y under p_{θ_0} while the notations $\xrightarrow{\mathrm{p}}, \rightsquigarrow$ in the proof below denote convergences in probability and in distribution (Ferguson, 1996).

Proof By the mean value theorem and convexity of Θ there exists $\eta \in (0,1)$ for which $\theta' = \theta_0 + \eta(\hat{\theta}_n^{\mathrm{msl}} - \theta_0)$ and

$$\nabla sc\ell_n(\hat{\theta}_n^{\mathrm{msl}}) = \nabla sc\ell_n(\theta_0) + \nabla^2 sc\ell_n(\theta')(\hat{\theta}_n^{\mathrm{msl}} - \theta_0)$$

where $\nabla f(\theta)$ and $\nabla^2 f(\theta)$ are the $r \times 1$ gradient vector and $r \times r$ matrix of second order derivatives of $f(\theta)$. Since $\hat{\theta}_n$ maximizes the SCL, $\nabla sc\ell_n(\hat{\theta}_n^{\mathrm{msl}}) = 0$ and

$$\sqrt{n}(\hat{\theta}_n^{\mathrm{msl}} - \theta_0) = -\sqrt{n}(\nabla^2 sc\ell_n(\theta'))^{-1} \nabla sc\ell_n(\theta_0). \tag{18}$$

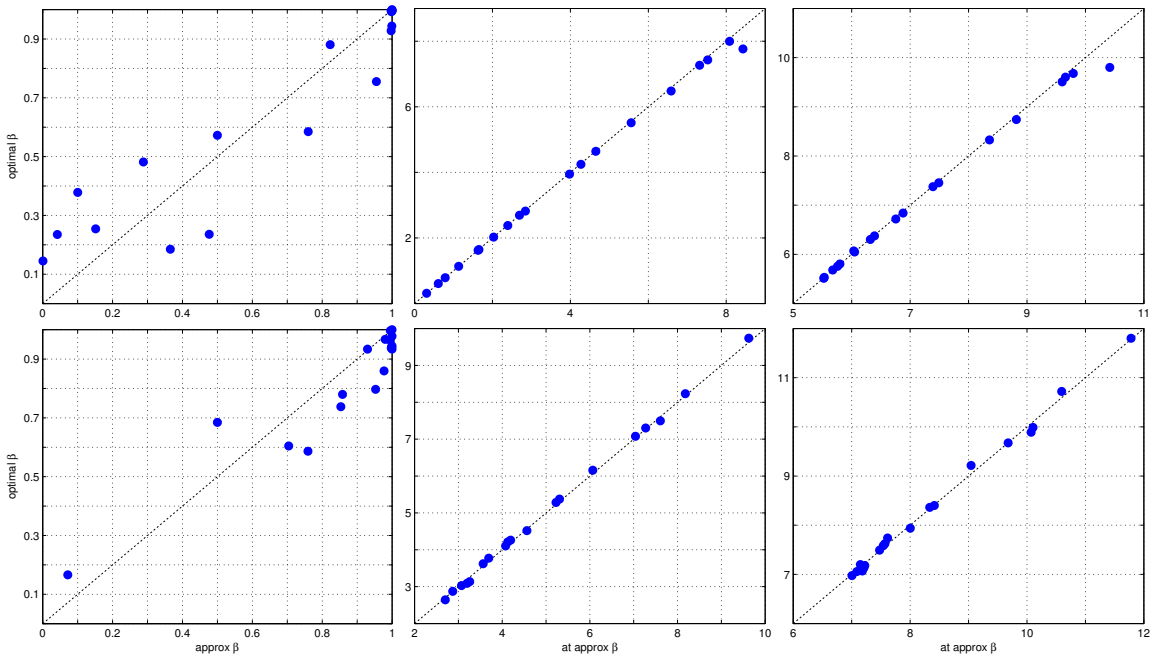

Figure 20: Demonstration of the effectiveness of the β heuristic. Results are for the CRF with PL1/FL (top) and PL1/PL2 (bottom) selection policies. The x-axis is the value at the heuristically found β and the y-axis the value at the optimal β. The first column depicts the best performing β against the heuristic β. The second and third columns depict the training and testing perplexities (resp.) at the best performing β and heuristically found β. For all three columns, we assess the effectiveness of the heuristic by its nearness to the diagonal (dashed line). See Fig. 14 for more details.

The optimal and heuristic β match train and test perplexities for both policies. The actual β value however does not seem to match as well as the Boltzmann chain. However, if we note the flatness of the β grid (cf. Fig. 16 and 18) this result is unsurprising and can be disregarded as an indication of the heuristic's performance.

By Proposition 1 we have $\hat{\theta}_n^{\text{msl}} \xrightarrow{\text{p}} \theta_0$ which implies that $\theta' \xrightarrow{\text{p}} \theta_0$ as well. Furthermore, by the law of large numbers and the fact that if $W_n \xrightarrow{\text{p}} W$ then $g(W_n) \xrightarrow{\text{p}} g(W)$ for continuous g,

$$\begin{aligned}(\nabla^2 sc\ell_n(\theta'))^{-1} &\xrightarrow{\text{p}} (\nabla^2 sc\ell_n(\theta_0))^{-1} \\ &\xrightarrow{\text{p}} \left(\sum_{j=1}^{k} \beta_j \lambda_j \mathsf{E}_{\theta_0} \nabla^2 S_{\theta_0}(A_j, B_j)\right)^{-1} \\ &= -\left(\sum_{j=1}^{k} \beta_j \lambda_j \mathsf{Var}_{\theta_0}(\nabla S_{\theta_0}(A_j, B_j))\right)^{-1}.\end{aligned} \tag{19}$$

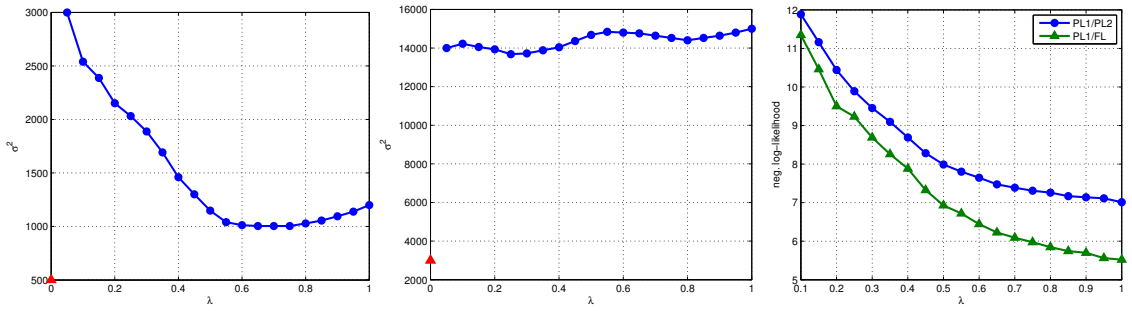

Figure 21: Optimal regularization parameter as a function of $(\lambda, \hat{\beta}(\lambda))$ for PL1/FL (left) and PL1/PL2 (center) CRF selection policies. In the left figure, PL1/FL, λ represents the probability of including FL into the objective. A few FL samples add uncertainty to the objective thus a weaker regularizer is preferable. As more FL samples are incorporated, this effect diminishes but still acts to regularize since the full likelihood (only) best regularization is $\sigma^2 = 500$ (red triangle). The center figure, PL1/PL2, exhibits only a minor change as λ (the probability of incorporating PL2) is increased. It is however, best served by a much weaker regularizer than PL2 alone (red triangle).

The right figure depicts the test-set perplexity as a function of λ using the optimal σ^2 (small λ values were clipped as their performance is quite poor). Note that the perplexity is lowest when both components are always selected ($\lambda = 1$) and that the PL1/FL policy outperforms the PL1/PL2 policy as expected.

For the remaining term in (18) we have

$$\sqrt{n}\nabla sc\ell_n(\theta_0) = \sum_{j=1}^{k} \beta_j \sqrt{n} \frac{1}{n} \sum_{i=1}^{n} W_{ij}$$

where the random vectors $W_{ij} = Z_{ij}\nabla \log p_\theta(X_{A_j}^{(i)} | X_{B_j}^{(i)})$ have expectation 0 and variance matrix $\mathsf{Var}_{\theta_0}(W_{ij}) = \lambda_j \mathsf{Var}_{\theta_0}(\nabla S_{\theta_0}(A_j, B_j))$. By the central limit theorem

$$\sqrt{n}\frac{1}{n}\sum_{i=1}^{n} W_{ij} \rightsquigarrow N\left(0, \lambda_j \mathsf{Var}_{\theta_0}(\nabla S_{\theta_0}(A_j, B_j))\right).$$

The sum $\sqrt{n}\nabla sc\ell_n(\theta_0) = \sum_{j=1}^{k} \beta_j \sqrt{n} \frac{1}{n} \sum_{i=1}^{n} W_{ij}$ is asymptotically Gaussian as well with mean zero since it converges to a sum of Gaussian distributions with mean zero. Since in the general case the random variables $\sqrt{n}\frac{1}{n}\sum_{i=1}^{n} W_{ij}$, $j = 1, \ldots, k$ are correlated, the asymptotic variance matrix of $\sqrt{n}\nabla sc\ell_n(\theta_0)$ needs to account for cross covariance terms leading to

$$\sqrt{n}\nabla sc\ell_n(\theta_0) \rightsquigarrow N\left(0, \mathsf{Var}_{\theta_0}\left(\sum_{j=1}^{k} \beta_j \lambda_j \nabla S_{\theta_0}(A_j, B_j)\right)\right). \tag{20}$$

We finish the proof by combining (18), (19) and (20) using Slutsky's theorem. ■

Recall our notation for the case that the true model $P \notin \{p_\theta : \theta \in \Theta\}$.

$$\psi_\theta(X,Z) \stackrel{\text{def}}{=} \nabla m_\theta(X,Z)$$
$$\dot{\psi}_\theta(X,Z) \stackrel{\text{def}}{=} \nabla^2 m_\theta(X,Z) \quad \text{(matrix of second order derivatives)}$$
$$\Psi_n(\theta) \stackrel{\text{def}}{=} \frac{1}{n}\sum_{i=1}^{n} \psi_\theta(X^{(i)},Z^{(i)}).$$

Proposition 7 *Assuming the conditions in Proposition 1 as well as* $\sup_{\theta:\|\theta-\theta_0\|\geq\varepsilon} M(\theta) < M(\theta_0)$ *for all* $\varepsilon > 0$ *we have* $\hat{\theta}_n^{msl} \to \theta_0$ *as* $n \to \infty$ *with probability 1.*

Proof We assert

$$P\left\{\lim_{n\to\infty} \sup_{\theta\in S} |scl'(\theta) - \mu(\theta)| = 0\right\} = 1. \tag{21}$$

on the compact set $S = \{\theta : c_1 \leq \|\theta - \theta_0\| \leq c_2\}$ as in the proof of Proposition 1. We proceed similarly along the lines of Proposition 1, with the necessary modification due to the fact that the true model is outside the parametric family.

Since the function $\mu(\theta)$ is continuous it attains its negative supremum on the compact S: $\sup_{\theta\in S}\mu(\theta) < \mu(\theta_0) \geq 0$. Combining this fact with (21) we have that there exists N such that for all $n > N$ the SCL maximizers on S achieves strictly negative values of $sc\ell'(\theta)$ with probability 1.

However, since $sc\ell'(\theta)$ can be made to achieve values arbitrarily close to $\mu(\theta_0)$ as $\hat{\theta}_n \to \theta_0$, we have that $\hat{\theta}_n^{\text{msl}} \notin S$ for $n > N$. Since c_1, c_2 were chosen arbitrarily $\hat{\theta}_n^{\text{msl}} \to \theta_0$ with probability 1. ■

Proposition 8 *Assuming the conditions of Proposition 2 as well as* $E_{P(X)}E_{P(Z)}\|\psi_{\theta_0}(X,Z)\|^2 < \infty$, $E_{P(X)}E_{P(Z)}\dot{\psi}_{\theta_0}(X)$ *exists and is non-singular,* $|\ddot{\Psi}_{ij}| = |\partial^2\psi_\theta(x)/\partial\theta_i\theta_j| < g(x)$ *for all* i, j *and* θ *in a neighborhood of* θ_0 *for some integrable* g*, we have*

$$\sqrt{n}(\hat{\theta}_n - \theta_0) = -(E_{P(X)}E_{P(Z)}\dot{\psi}_{\theta_0})^{-1}\frac{1}{\sqrt{n}}\sum_{i=1}^{n}\psi_{\theta_0}(X^{(i)},Z^{(i)}) + o_P(1)$$

or equivalently

$$\hat{\theta}_n = \theta_0 - (E_{P(X)}E_{P(Z)}\dot{\psi}_{\theta_0})^{-1}\frac{1}{n}\sum_{i=1}^{n}\psi_{\theta_0}(X^{(i)},Z^{(i)}) + o_P\left(\frac{1}{\sqrt{n}}\right).$$

Proof By Taylor's theorem there exists a random vector $\tilde{\theta}_n$ on the line segment between θ_0 and $\hat{\theta}_n$ for which

$$0 = \Psi_n(\hat{\theta}_n) = \Psi_n(\theta_0) + \dot{\Psi}_n(\theta_0)(\hat{\theta}_n - \theta_0) + \frac{1}{2}(\hat{\theta}_n - \theta_0)^\top \ddot{\Psi}_n(\tilde{\theta}_n)(\hat{\theta}_n - \theta_0).$$

which we re-arrange as

$$\begin{aligned}\sqrt{n}\dot{\Psi}_n(\theta_0)(\hat{\theta}_n - \theta_0) + \sqrt{n}\frac{1}{2}(\hat{\theta}_n - \theta_0)^\top\ddot{\Psi}_n(\tilde{\theta}_n)(\hat{\theta}_n - \theta_0) &= -\sqrt{n}\Psi_n(\hat{\theta}_n) \\ &= -\sqrt{n}\Psi_n(\theta_0) + o_P(1)\end{aligned} \tag{22}$$

where the second equality follows from the fact that $\hat{\theta}_n \xrightarrow{\text{p}} \theta_0$ and continuous functions preserves converges in probability.

Since $\dot{\Psi}_n(\theta_0)$ converges by the law of large numbers to $\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_\theta(X,Z)$ and $\ddot{\Psi}_n(\tilde{\theta}_n)$ converges to a matrix of bounded values in the neighborhood of θ_0 (for large n), the lhs of (22) is

$$\sqrt{n}\left(\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_\theta(X,Z) + o_P(1) + \frac{1}{2}(\hat{\theta}_n - \theta_0)O_P(1)\right)(\hat{\theta}_n - \theta_0)$$
$$= \sqrt{n}(\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_\theta(X,Z) + o_P(1))(\hat{\theta}_n - \theta_0)$$

since $\hat{\theta}_n - \theta_0 = o_P(1)$ and $o_P(1)O_p(1) = o_P(1)$ (the notation $O_P(1)$ denotes stochastically bounded and it applies to $\ddot{\Psi}_n(\tilde{\theta}_n)$ as described above). Putting it together we have

$$\sqrt{n}(\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_\theta(X,Z) + o_P(1))(\hat{\theta}_n - \theta_0) = -\sqrt{n}\Psi_n(\theta_0) + o_P(1).$$

Since the matrix $\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_\theta(X,Z) + o_P(1)$ converges to a non-singular matrix, multiplying the equation above by its inverse finishes the proof. ■

Corollary 2 *Assuming the conditions specified in Proposition 4 we have*

$$\sqrt{n}(\hat{\theta}_n - \theta_0) \rightsquigarrow N(0, (\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_{\theta_0})^{-1}(\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_{\theta_0}\psi_{\theta_0}^\top)(\mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_{\theta_0})^{-1}).$$

Proof Equation (12) follows from (10) by noticing that due to the central limit theorem $\Psi_n(\theta_0)$ (as it is an average of n iid RVs with expectation 0)

$$\sqrt{n} \cdot \frac{1}{n}\sum_{i=1}^{n} \psi_{\theta_0}(X^{(i)}, Z^{(i)}) \rightsquigarrow N(0, \mathsf{E}_{P(X)}\mathsf{E}_{P(Z)}\psi_{\theta_0}\psi_{\theta_0}^\top).$$

Substituting this in the right hand side of (10) and accounting for the modified variance due to the matrix inverse results in (12). ■

Abstract

The problem of characterizing learnability is the most basic question of statistical learning theory. A fundamental and long-standing answer, at least for the case of supervised classification and regression, is that learnability is equivalent to uniform convergence of the empirical risk to the population risk, and that if a problem is learnable, it is learnable via empirical risk minimization. In this paper, we consider the General Learning Setting (introduced by Vapnik), which includes most statistical learning problems as special cases. We show that in this setting, there are non-trivial learning problems where uniform convergence does not hold, empirical risk minimization fails, and yet they are learnable using alternative mechanisms. Instead of uniform convergence, we identify stability as the key necessary and sufficient condition for learnability. Moreover, we show that the conditions for learnability in the general setting are significantly more complex than in supervised classification and regression.

Keywords: statistical learning theory, learnability, uniform convergence, stability, stochastic convex optimization

1. Introduction

We consider the General Setting of Learning introduced by Vapnik (1995) where we would like to minimize a population risk functional (stochastic objective)

$$F(\mathbf{h}) = \mathbb{E}_{Z\sim\mathcal{D}}[f(\mathbf{h};Z)] \tag{1}$$

over some hypothesis class $\mathcal{H}$, where the distribution $\mathcal{D}$ of Z is unknown, based on i.i.d. sample $z_1,\ldots,z_m$ drawn from $\mathcal{D}$ (and full knowledge of f and $\mathcal{H}$). This General Setting subsumes supervised classification and regression, certain unsupervised learning problems, density estimation and more. For example, in supervised learning $z=(\mathbf{x},y)$ is an instance-label pair, $\mathbf{h}$ is a predictor, and $f(h;(\mathbf{x},y)) = \text{loss}(h(\mathbf{x}),y)$ is the loss functional. See Section 2 for formal definitions and further examples.

In the context of this general setting, we are concerned with the question of statistical "learnability". That is, when can Equation (1) be minimized to within arbitrary precision based only on a finite sample $z_1,\ldots,z_m$, as $m\to\infty$? We are not concerned here with computational aspects of this problem, that is, whether this approximate minimization can be carried out efficiently, but only whether it is statistically possible to do so based only on the sample $z_1,\ldots,z_m$.

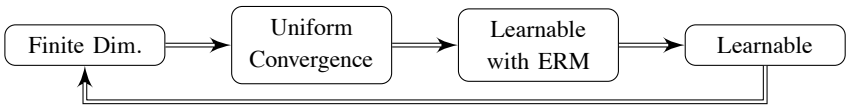
For supervised classification and regression problems, it is well known that a problem is learnable if and only if the empirical risks

$$F_S(\mathbf{h}) = \frac{1}{m}\sum_{i=1}^{m} f(\mathbf{h}, z_i)$$

for all $\mathbf{h} \in \mathcal{H}$ converge uniformly to the population risk (Blumer et al., 1989; Alon et al., 1997). If uniform convergence holds, then the empirical risk minimizer (ERM) is *consistent*, that is, the population risk of the ERM converges to the optimal population risk, and the problem is learnable using the ERM. We therefore have:

- A necessary and sufficient condition for learnability, namely uniform convergence of the empirical risks. Furthermore, this can be shown to be equivalent to a combinatorial condition: having finite VC-dimension in the case of classification, and having finite fat-shattering dimensions in the case of regression.
- A complete understanding of *how* to learn: since learnability is equivalent to learnability by ERM, we can focus our attention solely on empirical risk minimizers.

The situation, for supervised classification and regression, can be depicted as follows:



Other than uniform convergence, certain notions of stability have also been suggested as an explicit condition for learnability. Intuitively, stability notions focus on particular algorithms, or learning rules, and measure their sensitivity to perturbations in the training set. In particular, it is known that stability of the ERM is *sufficient* for learnability. In Mukherjee et al. (2006), it is argued that stability is also a *necessary* for learnability. However, that argument relied on the assumption that uniform convergence is equivalent to learnability. Therefore, stability was shown to characterize learnability only in situations where uniform convergence characterizes learnability anyway.

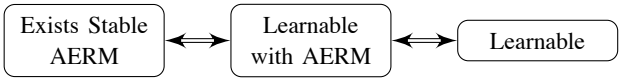
The equivalence of uniform convergence and learnability was formally established only in the supervised classification and regression setting. In the more general setting, the "rightward" implications in the diagram above still hold: finite fat-shattering dimensions, uniform convergence, as well as ERM stability, are indeed sufficient conditions for learnability using the ERM. As for the reverse implication, Vapnik showed that a notion of "non-trivial" or "strict" learnability with the ERM is indeed equivalent to uniform convergence of the empirical risks. This notion was meant to exclude certain "trivial" learning problems, which are learnable without uniform convergence (see Section 3.1). Even in such problems, learnability is still possible by empirical risk minimization. Thus, it would seem that in the General Learning Setting, as in supervised classification and regression, a problem is learnable if and only if it is learnable by empirical risk minimization.

In this paper we show that the situation in the General Learning Setting is actually much more complex. In particular, in Section 4.1 we show an example of a learning problem in the General Learning Setting, which is learnable (using an online algorithm and an online-to-batch conversion), but which is *not* learnable using empirical risk minimization. To the best of our knowledge this is the first example shown of this type.

Furthermore, in Section 4.2 we show a modified example which *is* learnable using empirical risk minimization, but for which the empirical risks of the hypotheses do *not* converge uniformly to their expectations, not even locally for hypotheses very close to the true hypothesis. We argue that unlike the examples discussed in Section 3.1, this example is far from being "trivial". We use this example to discuss how Vapnik's notion of "strict" learnability with the ERM is too strict, and precludes cases which are far from trivial and in which learnability with empirical risk minimization is *not* equivalent to uniform convergence.

Having shown that learnability does not imply learnability with the ERM, and learnability with the ERM does not imply uniform convergence (unlike supervised classification and regression), we proceed in Section 5 to characterize learnability in the General Learning Setting, unveiling stability as a key notion.

In particular, we show that for learnable problems, even when they are not learnable with ERM, they are always learnable with some learning rule which is "asymptotically ERM" and (AERM - see precise definition in Section 2). Moreover, such an AERM must be stable (under a suitable notion of stability). Namely, we have the following characterization of learnability in the General Learning Setting:



Note that this characterization holds even for learnable problems with no uniform convergence. In this sense, stability emerges as a strictly more powerful notion than uniform convergence for characterizing learnability.

Other than this, we also discuss several related results, which above all imply that the conditions for learnability in the General Learning Setting are substantially different and more complex than in supervised classification and regression.

Our results point not to a specific learning rule (such as an ERM), but rather to a class of learning rules (AERM learning rules) as possible candidates for learning. In Section 6, we explore how our results can be strengthened if we allow randomized learning rules. In particular, randomization allows us to pinpoint not a general class of learning rules, but rather a specific (though highly impractical) learning rule, which learns if and only if the problem is learnable.

Throughout most of the paper we discuss learning rates (as a function of the sample size), but do not pay much attention to the confidence at which the learning rule succeeds (i.e., the dependence of the sample size on the allowed probability of failure). This issue is addressed Section 7, and again we show that in the General Learning Setting, things can behave rather differently than in supervised classification and regression.

In summary, this paper opens a door to the complexity of learnability in the General Learning Setting, and provides some understanding of the situation, including highlighting the important role of stability. Many gaps in our understanding remain, and we hope that future progress will close some of these gaps, as well as connect the theoretical insights gained to machine learning as used in practice.

This paper is partially based on the results obtained in Shalev-Shwartz et al. (2009a) and Shalev-Shwartz et al. (2009b).

2. The General Learning Setting: Formal Definition and Notation

In this paper we focus on the General Learning Setting, which was introduced by Vapnik (1995) as a unifying framework for the problem of statistical learning from empirical data.

The General Learning Setting deals with *learning problems*. Formally, a learning problem is specified by a hypothesis class $\mathcal{H}$, an instance set $\mathcal{Z}$ (with a sigma-algebra), and an objective function (e.g., "loss" or "cost") $f : \mathcal{H} \times \mathcal{Z} \to \mathbb{R}$. Throughout this paper we assume the function is bounded by some constant B, that is $|f(\mathbf{h};\mathbf{z})| \leq B$ for all $\mathbf{h} \in \mathcal{H}$ and $z \in \mathcal{Z}$.

Given a distribution $\mathcal{D}$ on $\mathcal{Z}$, the quality of each hypothesis $\mathbf{h} \in \mathcal{H}$ is measured by its *risk* $F(\mathbf{h})$, which is defined as $\mathbb{E}_{\mathbf{z}\sim\mathcal{D}}[f(\mathbf{h};\mathbf{z})]$. While $\mathcal{H}$, $\mathcal{Z}$ and $f(\mathbf{h};\mathbf{z})$ are known to the learner, we assume that $\mathcal{D}$ is unknown. Ideally, we would like to pick $\mathbf{h} \in \mathcal{H}$ whose risk is as close as possible to $\inf_{\mathbf{h}\in\mathcal{H}} F(\mathbf{h})$. Since the underlying distribution $\mathcal{D}$ is unknown, we cannot do this directly, but instead need to rely on a finite empirical *training sample* $S = \{\mathbf{z}_1, \ldots, \mathbf{z}_m\}$. On this sample, we apply a *learning rule* to pick a hypothesis . Formally, a learning rule is a mapping $\mathbf{A} : \cup_{m=1}^{\infty} \mathcal{Z}^m \to \mathcal{H}$ from sequences of instances in $\mathcal{Z}$ to hypotheses. We refer to sequences $S = \{\mathbf{z}_1, \ldots, \mathbf{z}_m\}$ as "sample sets", but it is important to remember that the order and multiplicity of instances may be significant. A learning rule that does not depend on the order of the instances in the training sample is said to be *symmetric*. We will generally consider samples $S \sim \mathcal{D}^m$ of m i.i.d. draws from $\mathcal{D}$.

This framework is sufficiently general to include a large portion of the statistical learning and optimization problems we are aware of, such as:

- **Binary Classification:** Let $\mathcal{Z} = \mathcal{X} \times \{0,1\}$, let $\mathcal{H}$ be a set of functions $\mathbf{h} : \mathcal{X} \mapsto \{0,1\}$, and let $f(\mathbf{h};(\mathbf{x},y)) = \mathbb{1}_{\{\mathbf{h}(\mathbf{x}) \neq y\}}$. Here, $f(\cdot)$ is simply the $0-1$ loss function, measuring whether the binary hypothesis $\mathbf{h}(\cdot)$ misclassified the example $(\mathbf{x},y)$.

- **Regression:** Let $\mathcal{Z} = \mathcal{X} \times \mathcal{Y}$ where $\mathcal{X}$ and $\mathcal{Y}$ are bounded subsets of $\mathbb{R}^n$ and $\mathbb{R}$ respectively, let $\mathcal{H}$ be a set of bounded functions $\mathbf{h} : \mathcal{X}^n \mapsto \mathbb{R}$, and let $f(\mathbf{h};(\mathbf{x},y)) = (\mathbf{h}(\mathbf{x}) - y)^2$. Here, $f(\cdot)$ is simply the squared loss function.

- **Large Margin Classification in a Reproducing Kernel Hilbert Space (RKHS):** Let $\mathcal{Z} = \mathcal{X} \times \{0,1\}$, where $\mathcal{X}$ is a bounded subset of an RKHS, let $\mathcal{H}$ be another bounded subset of the RKHS, and let $f(\mathbf{h};(\mathbf{x},y)) = \max\{0, 1 - y\langle \mathbf{x}, \mathbf{h}\rangle\}$. Here, $f(\cdot)$ is the well known hinge loss function, and our goal is to perform margin-based linear classification in the RKHS.

- **K-Means Clustering in Euclidean Space:** Let $\mathcal{Z} = \mathbb{R}^n$, let $\mathcal{H}$ be all subsets of $\mathbb{R}^n$ of size k, and let $f(\mathbf{h};\mathbf{z}) = \min_{\mathbf{c} \in \mathbf{h}} \|\mathbf{c} - \mathbf{z}\|^2$. Here, each $\mathbf{h}$ represents a set of k centroids, and $f(\cdot)$ measures the Euclidean distance squared between an instance $\mathbf{z}$ and its nearest centroid, according to the hypothesis $\mathbf{h}$.

- **Density Estimation:** Let $\mathcal{Z}$ be a subset of $\mathbb{R}^n$, let $\mathcal{H}$ be a set of bounded probability densities on $\mathcal{Z}$, and let $f(\mathbf{h};\mathbf{z}) = -\log(\mathbf{h}(\mathbf{z}))$. Here, $f(\cdot)$ is simply the negative log-likelihood of an instance $\mathbf{z}$ according to the hypothesis density $\mathbf{h}$. Note that to ensure boundedness of $f(\cdot)$, we need to assume that $\mathbf{h}(\mathbf{z})$ is lower bounded by a positive constant for all $\mathbf{z} \in \mathcal{Z}$.

- **Stochastic Convex Optimization in Hilbert Spaces:** Let $\mathcal{Z}$ be an arbitrary measurable set, let $\mathcal{H}$ be a closed, convex and bounded subset of a Hilbert space, and let $f(\mathbf{h};\mathbf{z})$ be Lipschitz-continuous and convex w.r.t. its first argument. Here, we want to approximately minimize the objective function $\mathbb{E}_{\mathbf{z}\sim\mathcal{D}}[f(\mathbf{h};\mathbf{z})]$, where the distribution over $\mathcal{Z}$ is unknown, based on an empirical sample $\mathbf{z}_1,\ldots,\mathbf{z}_m$.

Our overall goal in this setting is to pick a hypothesis $\mathbf{h} \in \mathcal{H}$ with approximately minimal possible risk, based on a finite sample. Generally, we expect the approximation to get better with the sample size. Learning rules which allow us to choose such hypotheses are said to be *consistent*. Formally, we say a rule $\mathbf{A}$ is consistent with rate $\varepsilon_{\text{cons}}(m)$ under distribution $\mathcal{D}$ if for all m,

$$\mathbb{E}_{S\sim\mathcal{D}^m}[F(\mathbf{A}(S)) - F^*] \leq \varepsilon_{\text{cons}}(m), \tag{2}$$

where we denote $F^* = \inf_{\mathbf{h}\in\mathcal{H}} F(\mathbf{h})$ (here and whenever talking about a "rate" $\varepsilon(m)$, we require it to be monotone decreasing with $\varepsilon_{\text{cons}}(m) \overset{m\to\infty}{\longrightarrow} 0$).

However, since $\mathcal{D}$ is unknown, we cannot choose a learning rule based on $\mathcal{D}$. Instead, we will ask for a stronger requirement, namely that the rule is consistent with rate $\varepsilon_{\text{cons}}(m)$ under *all* distributions $\mathcal{D}$ over $\mathcal{Z}$. This leads to the following central definition:

Definition 1 *A learning problem is* learnable*, if there exist a learning rule* $\mathbf{A}$ *and a monotonically decreasing sequence* $\varepsilon_{\text{cons}}(m)$*, such that* $\varepsilon_{\text{cons}}(m) \overset{m\to\infty}{\longrightarrow} 0$*, and*

$$\forall \mathcal{D}, \quad \mathbb{E}_{S\sim\mathcal{D}^m}[F(\mathbf{A}(S)) - F^*] \leq \varepsilon_{\text{cons}}(m).$$

A learning rule $\mathbf{A}$ *for which this holds is denoted as a* universally consistent *learning rule*.

This definition of learnability, requiring a uniform rate for all distributions, is the relevant notion for studying learnability of a hypothesis class. It is a direct generalization of agnostic PAC-learnability (Kearns et al., 1992) to Vapnik"s General Setting of Learning as studied by Haussler (1992) and others.

A possible approach to learning is to minimize the *empirical risk* $F_S(\mathbf{h})$ over a sample S, defined as

$$F_S(\mathbf{h}) = \frac{1}{m}\sum_{\mathbf{z}\in S} f(\mathbf{h};\mathbf{z}).$$

$\mathcal{Z}$,$\mathbf{z}$	Instance domain and a specific instance.
$\mathcal{H}$,$\mathbf{h}$	Hypothesis class and a specific hypothesis.
$f(\mathbf{h},\mathbf{z})$	Loss of hypothesis $\mathbf{h}$ on instance $\mathbf{z}$
B	$\sup_{\mathbf{h},\mathbf{z}} \lvert f(\mathbf{h};\mathbf{z})\rvert$
$\mathcal{D}$	Underlying distribution on instance domain $\mathcal{Z}$
S	Empirical sample $\mathbf{z}_1,\ldots,\mathbf{z}_m$, sampled i.i.d. from $\mathcal{D}$
m	Size of empirical sample S
$\mathbf{A}(S)$	Learning rule $\mathbf{A}$ applied on empirical sample S
$\varepsilon_{\text{cons}}(m)$	Rate of consistency for a learning rule
$F(\mathbf{h})$	Risk of hypothesis $\mathbf{h}$, $\mathbb{E}_{\mathbf{z}\sim\mathcal{D}}[f(\mathbf{h};\mathbf{z})]$
F^*	$\inf_{\mathbf{h}\in\mathcal{H}} F(\mathbf{h})$
$F_S(\mathbf{h})$	Empirical risk of hypothesis $\mathbf{h}$ on sample S, $\frac{1}{m}\sum_{\mathbf{z}\in S} f(\mathbf{h};\mathbf{z})$
$\hat{\mathbf{h}}_S$	An ERM hypothesis, $F_S(\hat{\mathbf{h}}_S) = \inf_{\mathbf{h}\in\mathcal{H}} F_S(\mathbf{h})$
$\varepsilon_{\text{erm}}(m)$	Rate of AERM for a learning rule
$\varepsilon_{\text{stable}}(m)$	Rate of stability for a learning rule
$\varepsilon_{\text{gen}}(m)$	Rate of generalization for a learning rule

Table 1: Table of Notation

We say that a rule $\mathbf{A}$ is an *ERM (Empirical Risk Minimizer)* if it minimizes the empirical risk

$$F_S(\mathbf{A}(S)) = F_S(\hat{\mathbf{h}}_S) = \inf_{\mathbf{h}\in\mathcal{H}} F_S(\mathbf{h}).$$

where we use $F_S(\hat{\mathbf{h}}_S) = \inf_{\mathbf{h}\in\mathcal{H}} F_S(\mathbf{h})$ to refer to the minimal empirical risk. But since there might be several hypotheses minimizing the empirical risk, $\hat{\mathbf{h}}_S$ does not refer to a specific hypotheses and there might be many rules which are all ERM.

We say that a rule $\mathbf{A}$ is an *AERM (Asymptotic Empirical Risk Minimizer)* with rate $\varepsilon_{\text{erm}}(m)$ under distribution $\mathcal{D}$ if:

$$\mathbb{E}_{S\sim\mathcal{D}^m}\left[F_S(\mathbf{A}(S)) - F_S(\hat{\mathbf{h}}_S)\right] \leq \varepsilon_{\text{erm}}(m)$$

A learning rule is *universally an AERM* with rate $\varepsilon_{\text{erm}}(m)$, if it is an AERM with rate $\varepsilon_{\text{erm}}(m)$ under all distributions $\mathcal{D}$ over $\mathcal{Z}$. A learning rule is an *always AERM* with rate $\varepsilon_{\text{erm}}(m)$, if for *any* sample S of size m, it holds that $F_S(\mathbf{A}(S)) - F_S(\hat{\mathbf{h}}_S) \leq \varepsilon_{\text{erm}}(m)$.

We say a rule $\mathbf{A}$ *generalizes* with rate $\varepsilon_{\text{gen}}(m)$ under distribution $\mathcal{D}$ if for all m,

$$\mathbb{E}_{S\sim\mathcal{D}^m}\left[\lvert F(\mathbf{A}(S)) - F_S(\mathbf{A}(S))\rvert\right] \leq \varepsilon_{\text{gen}}(m).$$

A rule *universally generalizes* with rate $\varepsilon_{\text{gen}}(m)$ if it generalizes with rate $\varepsilon_{\text{gen}}(m)$ under all distributions $\mathcal{D}$ over $\mathcal{Z}$.

We note that other authors sometimes define "consistent", and thus also "learnable" as a combination of our notions of "consistent" and "generalizing".

In the above definitions, we choose to use convergence in expectation, and defined the rates as rates on the expectation. Since the objective f is bounded, convergence in expectation is equivalent to convergence in probability. Furthermore, using Markov's inequality we can translate a rate of the form $\mathbb{E}[\lvert X\rvert] \leq \varepsilon(m)$ to a "low confidence" guarantee $\mathbb{P}[\lvert X\rvert > \varepsilon(m)/\delta] \leq \delta$. See Section 7 for a further discussion on this issue.

3. Background: Characterization of Learnability

Before presenting our results, we begin with a review of the known connections between learnability, stability, and uniform convergence, highlighting the issues which will be of importance later on.

3.1 Learnability and Uniform Convergence

As discussed in the introduction, a central notion for characterizing learnability is uniform convergence. Formally, we say that uniform convergence holds for a learning problem, if the empirical risks of hypotheses in the hypothesis class converges to their population risk uniformly, with a distribution-independent rate:

$$\sup_{\mathcal{D}} \mathbb{E}_{S\sim\mathcal{D}^m}\left[\sup_{\mathbf{h}\in\mathcal{H}} |F(\mathbf{h}) - F_S(\mathbf{h})|\right] \stackrel{m\to\infty}{\longrightarrow} 0.$$

It is straightforward to show that if uniform convergence holds, then a problem can be learned with the ERM learning rule.

For binary classification problems (where $\mathcal{Z} = \mathcal{X} \times \{0,1\}$, each hypothesis is a mapping from $\mathcal{X}$ to $\{0,1\}$, and $f(\mathbf{h};(\mathbf{x},y)) = \mathbb{1}_{\{\mathbf{h}(\mathbf{x})\neq y\}}$), Vapnik and Chervonenkis (1971) showed that the finiteness of a simple combinatorial measure known as the VC-dimension implies uniform convergence. Furthermore, it can be shown that binary classification problems with infinite VC-dimension are not learnable in a distribution-independent sense. This establishes the condition of having finite VC-dimension, and thus also uniform convergence, as a necessary and sufficient condition for learnability.

Such a characterization can also be extended to regression, such as regression with squared loss, where $\mathbf{h}$ is now a real-valued function, and $f(\mathbf{h};(\mathbf{x},y)) = (\mathbf{h}(\mathbf{x}) - y)^2$. The property of having finite fat-shattering dimension at all finite scales now replaces the property of having finite VC-dimension, but the basic equivalence still holds: a problem is learnable if and only if uniform convergence holds (Alon et al., 1997, see also Anthony and Bartlet, 1999, Chapter 19). These results are usually based on clever reductions to binary classification. However, the General Learning Setting that we consider is much more general than classification and regression, and includes setting where a reduction to binary classification is impossible.

To justify the necessity of uniform convergence even in the General Learning Setting, Vapnik attempted to show that in this setting, learnability with the ERM learning rule is equivalent to uniform convergence (Vapnik, 1998). Vapnik noted that this result does not hold, due to "trivial" situations. In particular, consider the case where we take an arbitrary learning problem (with hypothesis class $\mathcal{H}$), and add to $\mathcal{H}$ a single hypothesis $\tilde{\mathbf{h}}$ such that $f(\tilde{\mathbf{h}},\mathbf{z}) < \inf_{\mathbf{h}\in\mathcal{H}} f(\mathbf{h},\mathbf{z})$ for all $\mathbf{z} \in \mathcal{Z}$ (see figure 1 below). This learning problem is now trivially learnable, with the ERM learning rule which always picks $\tilde{\mathbf{h}}$. Note that no assumptions whatsoever are made on $\mathcal{H}$ - in particular, it can be arbitrarily complex, with no uniform convergence or any other particular property. Note also that such a phenomenon is not possible in the binary classification setting, where $f(h;(\mathbf{x},y)) = \mathbb{1}_{\{\mathbf{h}(\mathbf{x})\neq y\}}$, since on any (x,y) we will have hypotheses with $f(h;(\mathbf{x},y)) = f(\tilde{h};(\mathbf{x},y))$ and thus if $\mathcal{H}$ is very complex (has infinite VC dimension) then on every training set there will be many hypotheses with zero empirical error.

To exclude such "trivial" cases, Vapnik introduced a stronger notion of consistency, termed as "strict consistency", which in our notation is defined as

$$\forall c \in \mathbb{R}, \quad \inf_{\mathbf{h}:F(\mathbf{h})\geq c} F_S(\mathbf{h}) \stackrel{m\to\infty}{\longrightarrow} \inf_{\mathbf{h}:F(\mathbf{h})\geq c} F(\mathbf{h}) \ ,$$

where the convergence is in probability. The intuition is that we require the empirical risk of the ERM to converge to the lowest possible risk, even after discarding all the "good" hypotheses whose risk is smaller than some threshold. Vapnik then showed that such strict consistency of the ERM is in fact equivalent to (one-sided) uniform convergence, of the form

$$\sup_{\mathbf{h}\in\mathcal{H}} \left(F(\mathbf{h}) - F_S(\mathbf{h})\right) \stackrel{m\to\infty}{\longrightarrow} 0$$

in probability. Note that this equivalence holds for every distribution separately, and does not rely on universal consistency of the ERM.

These results seem to imply that up to "trivial" situations, a uniform convergence property indeed characterizes learnability, at least using the ERM learning rule. However, as we will see later on, the situation is in fact not that simple.

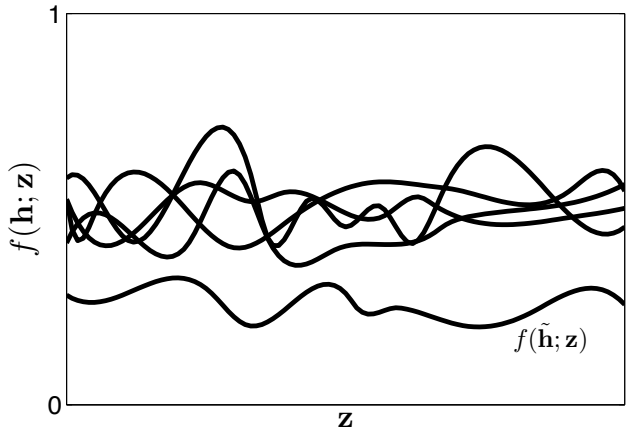


Figure 1: An example of a "trivial" learning situation. Each line represents some $\mathbf{h} \in \mathcal{H}$, and shows the value of $f(\mathbf{h},\mathbf{z})$ for all $\mathbf{z} \in \mathcal{Z}$. The hypothesis $\tilde{\mathbf{h}}$ dominates any other hypothesis (e.g., $f(\tilde{\mathbf{h}};\mathbf{z}) < f(\mathbf{h};\mathbf{z})$ uniformly for all $\mathbf{z}$), and thus the problem is learnable without uniform convergence or any other property of $\mathcal{H}$.

3.2 Learnability and Stability

Instead of focusing on the hypothesis class, and ensuring uniform convergence of the empirical risks of hypothesis in this class, an alternative approach is to directly control the variance of the learning rule. Here, it is not the complexity of the hypothesis class which matters, but rather the way that the learning rule explores this hypothesis class. This alternative approach leads to the notion of stability in learning. It is important to note that stability is a property of a learning rule, not of the hypothesis class.

In the context of modern learning theory,[1] the use of stability can be traced back at least to the work of Rogers and Wagner (1978), which noted that the sensitivity of a learning algorithm with regard to small changes in the sample controls the variance of the leave-one-out estimate. The authors used this observation to obtain generalization bounds (w.r.t. the leave-one-out estimate) for the k-nearest neighbor algorithm. It is interesting to note that a uniform convergence approach for analyzing this algorithm simply cannot work, because the "hypothesis class" in this case has unbounded complexity. These results were later extended to other "local" learning algorithms (see Devroye et al., 1996 and references therein). In addition, practical methods have been developed to introduce stability into learning algorithms, in particular the Bagging technique introduced by Breiman (1996).

Over the last decade, stability was studied as a generic condition for learnability. Kearns and Ron (1999) showed that an algorithm operating on a hypothesis class with finite VC dimension is also stable (under a certain definition of stability). Bousquet and Elisseeff (2002) introduced a strong notion of stability (denoted as *uniform stability*) and showed that it is a sufficient condition for learnability, satisfied by popular learning algorithms such as regularized linear classifiers and regressors in Hilbert spaces (including several variants of SVM). Kutin and Niyogi (2002) introduced several weaker variants of stability, and showed how they are sufficient to obtain generalization bounds for algorithms stable in their sense.

The papers above mainly considered stability as a *sufficient* condition for learnability. A more recent line of work (Rakhlin et al., 2005; Mukherjee et al., 2006) studied stability as a *necessary* condition for learnability. However, the line of argument is specific to settings where uniform convergence holds and is

1. In a more general mathematical context, stability has been around for much longer. The necessity of stability for so-called inverse problems to be well posed was first recognized by Hadamard (1902). The idea of regularization (that is, introducing stability into ill-posed inverse problems) became widely known through the works of Tikhonov (1943) and Phillips (1962). We return to the notion of regularization later on.

necessary for learning. With this assumption, it is possible to show that the ERM algorithm is stable, and thus stability is also a necessary condition for learning. However, as we will see later on in our paper, uniform convergence is in fact not necessary for learning in the General Learning Setting, and stability plays there a key role which has nothing to do with uniform convergence.

Finally, it is important to note that the results cited above make use of many different definitions of stability, which unfortunately are not always comparable. All of them measure stability as the amount of change in the algorithm's output as a function of small changes to the sample on which the algorithm is run. However, "amount of change to the output" and "small changes to the sample" can be defined in many different ways. "Amount of change to the output" can mean change in risk, change in loss with respect to particular examples, or supremum of change in loss over all examples. "Small changes to the sample" usually mean either deleting one example or replacing it with another one (and even here, one can talk about removing/replacing one instance at random, or in some arbitrary manner). Finally, this measure of change can be measured with respect to any arbitrary sample, in expectation over samples drawn from the underlying distribution; or in high probability over samples. For further discussion of this issue, see Appendix A.

4. Gaps Between Learnability, Uniform Convergence and ERM

In this section, we study a special case of the General Learning Setting, where there is a real gap between learnability and uniform convergence, in the sense that there are non-trivial problems where no uniform convergence holds (not even in a local sense), but they are still learnable. Moreover, some of these problems are learnable with an ERM (again, without any uniform convergence), and some are not learnable with an ERM, but rather with a different mechanism. We also discuss why this peculiar behavior does not formally contradict Vapnik's results on the equivalence of strict consistency of the ERM and uniform convergence, as well as the important role that regularization seems to play here, but in a different way than in standard theory.

4.1 Learnability without Uniform Convergence : Stochastic Convex Optimization

A stochastic convex optimization problem is a special case of the General Learning Setting discussed above, with the added constraints that the objective function $f(\mathbf{h};\mathbf{z})$ is Lipschitz-continuous and convex in $\mathbf{h}$ for every $\mathbf{z}$, and that $\mathcal{H}$ is closed, convex and bounded. We will focus here on problems where $\mathcal{H}$ is a subset of a Hilbert space. A special case is the familiar linear prediction setting, where $\mathbf{z} = (\mathbf{x}, y)$ is an instance-label pair, each hypothesis $\mathbf{h}$ belongs to a subset $\mathcal{H}$ of a Hilbert space, and $f(\mathbf{h};\mathbf{x},y) = \ell(\langle \mathbf{h}, \phi(\mathbf{x})\rangle, y)$ for some feature mapping ϕ and a loss function $\ell : \mathbb{R} \times \mathcal{Y} \to \mathbb{R}$, which is convex w.r.t. its first argument.

The situation in which the stochastic dependence on $\mathbf{h}$ is linear, as in the preceding example, is fairly well understood. When the domain $\mathcal{H}$ and the mapping ϕ are bounded, we have uniform convergence, in the sense that $|F(\mathbf{h}) - F_S(\mathbf{h})|$ is uniformly bounded over all $\mathbf{h} \in \mathcal{H}$ (see Sridharan et al., 2008). This uniform convergence of $F_S(\mathbf{h})$ to $F(\mathbf{h})$ justifies choosing the empirical minimizer $\hat{\mathbf{h}}_S = \arg\min_{\mathbf{h}} F_S(\mathbf{h})$, and guarantees that the expected value of $F(\hat{\mathbf{h}}_S)$ converges to the optimal value $F^* = \inf_{\mathbf{h}} F(\mathbf{h})$.

Even if the dependence on $\mathbf{h}$ is not linear, it is still possible to establish uniform convergence (using covering number arguments) provided that $\mathcal{H}$ is finite dimensional. Unfortunately, when we turn to infinite dimensional hypothesis spaces, uniform convergence might not hold and the problem might not be learnable with empirical minimization. Surprisingly, it turns out that this does not imply that the problem is unlearnable. We will show that using a regularization mechanism, it is possible to devise a learning algorithm for any stochastic convex optimization problem, even when uniform convergence does not hold. This mechanism is fundamentally related to the idea of stability, and will be a good starting point for our more general treatment of stability and learnability in the next section of the paper.

We now turn to discuss our first concrete example. Consider the convex stochastic optimization problem given by

$$f^{(3)}(\mathbf{h};(\mathbf{x},\alpha)) \;=\; \|\alpha * (\mathbf{h}-\mathbf{x})\| \;=\; \sqrt{\sum_i \alpha^2[i](\mathbf{h}[i]-\mathbf{x}[i])^2}\,, \tag{3}$$

where for now we let $\mathcal{H}$ to be the d-dimensional unit sphere $\mathcal{H} = \left\{\mathbf{h} \in \mathbb{R}^d : \|\mathbf{h}\| \leq 1\right\}$, we let $\mathbf{z} = (\mathbf{x}, \alpha)$ with $\alpha \in [0,1]^d$ and $\mathbf{x} \in \mathcal{H}$, and we define $u * v$ to be an element-wise product. We will first consider a sequence of problems, where $d = 2^m$ for any sample size m, and establish that we cannot expect a convergence rate which is independent of the dimensionality d. We then formalize this example in infinite dimensions.

One can think of the problem in Equation (3) as that of finding the "center" of an unknown distribution over $\mathbf{x} \in \mathbb{R}^d$, where we also have stochastic per-coordinate "confidence" measures $\alpha[i]$. We will actually focus on the case where some coordinates are missing, namely that $\alpha[i] = 0$.

Consider the following distribution over $(\mathbf{x}, \alpha)$: $\mathbf{x} = 0$ with probability one, and α is uniform over $\{0,1\}^d$. That is, $\alpha[i]$ are i.i.d. uniform Bernoulli. For a random sample $(\mathbf{x}_1, \alpha_1), \ldots, (\mathbf{x}_m, \alpha_m)$ if $d > 2^m$ then we have that with probability greater than $1 - e^{-1} > 0.63$, there exists a coordinate $j \in 1 \ldots d$ such that all confidence vectors α_i in the sample are zero on the coordinate j, that is $\alpha_i[j] = 0$ for all $i = 1..m$. Let $\mathbf{e}_j \in \mathcal{H}$ be the standard basis vector corresponding to this coordinate. Then

$$F_S^{(3)}(\mathbf{e}_j) \;=\; \frac{1}{m}\sum_{i=1}^{m} \left\|\alpha_i * (\mathbf{e}_j - 0)\right\| \;=\; \frac{1}{m}\sum_{i=1}^{m} |\alpha_i[j]| \;=\; 0,$$

where $F_S^{(3)}(\cdot)$ denotes the empirical risk w.r.t. the function $f^{(3)}(\cdot)$. On the other hand, letting $F^{(3)}(\cdot)$ denote the actual risk w.r.t. $f^{(3)}(\cdot)$, we have

$$F^{(3)}(\mathbf{e}_j) \;=\; \mathbb{E}_{\mathbf{x},\alpha}\left[\left\|\alpha * (\mathbf{e}_j - 0)\right\|\right] \;=\; \mathbb{E}_{\mathbf{x},\alpha}\left[|\alpha[j]|\right] \;=\; 1/2.$$

Therefore, for any m, we can construct a convex Lipschitz-continuous objective in a high enough dimension such that with probability at least 0.63 over the sample, $\sup_{\mathbf{h}} \left|F^{(3)}(\mathbf{h}) - F_S^{(3)}(\mathbf{h})\right| \geq 1/2$. Furthermore, since $f(\cdot;\cdot)$ is non-negative, we have that $\mathbf{e}_j$ is an empirical minimizer, but its expected value $F^{(3)}(\mathbf{e}_j) = 1/2$ is far from the optimal expected value $\min_{\mathbf{h}} F^{(3)}(\mathbf{h}) = F^{(3)}(0) = 0$.

To formalize the example in a sample-size independent way, take $\mathcal{H}$ to be the unit sphere of an infinite-dimensional Hilbert space with orthonormal basis $\mathbf{e}_1, \mathbf{e}_2, \ldots$, where for $\mathbf{v} \in \mathcal{H}$, we refer to its coordinates $\mathbf{v}[j] = \langle \mathbf{v}, \mathbf{e}_j \rangle$ w.r.t this basis. The confidences α are now a mapping of each coordinate to $[0,1]$. That is, an infinite sequence of reals in $[0,1]$. The element-wise product operation $\alpha * \mathbf{v}$ is defined with respect to this basis and the objective function $f^{(3)}(\cdot)$ of Equation (3) is well defined in this infinite-dimensional space.

We again take a distribution over $z = (\mathbf{x}, \alpha)$ where $\mathbf{x} = 0$ and α is an infinite i.i.d. sequence of uniform Bernoulli random variables (that is, a Bernoulli process with each α_i uniform over $\{0,1\}$ and independent of all other α_j). Now, for any finite sample there is almost surely a coordinate j with $\alpha_i[j] = 0$ for all i, and so we a.s. have an empirical minimizer $F_S^{(3)}(\mathbf{e}_j) = 0$ with $F^{(3)}(\mathbf{e}_j) = 1/2 > 0 = F^{(3)}(0)$.

As a result, we see that the empirical values $F_S^{(3)}(\mathbf{h})$ do not converge uniformly to their expectations, and empirical minimization is not guaranteed to solve the problem. Moreover, it is possible to construct a sharper counterexample, in which the *unique* empirical minimizer $\hat{\mathbf{h}}_S$ is far from having optimal expected value. To do so, we augment $f^{(3)}(\cdot)$ by a small term which ensures its empirical minimizer is unique, and far from the origin. Consider:

$$f^{(4)}(\mathbf{h}; (\mathbf{x}, \alpha)) = f^{(3)}(\mathbf{h}; (\mathbf{x}, \alpha)) + \varepsilon \sum_i 2^{-i} (\mathbf{h}[i] - 1)^2 \tag{4}$$

where $\varepsilon = 0.01$. The objective is still convex and $(1+\varepsilon)$-Lipschitz. Furthermore, since the additional term is strictly convex, we have that $f^{(4)}(\mathbf{h}; \mathbf{z})$ is strictly convex w.r.t. $\mathbf{h}$ and so the empirical minimizer is unique.

Consider the same distribution over z: $\mathbf{x} = 0$ while $\alpha[i]$ are i.i.d. uniform zero or one. The empirical minimizer is the minimizer of $F_S^{(4)}(\mathbf{h})$ subject to the constraints $\|\mathbf{h}\| \leq 1$. Identifying the solution to this constrained optimization problem is tricky, but fortunately not necessary. It is enough to show that the optimum of the *unconstrained* optimization problem $h^*_{\mathrm{UC}} = \arg\min F_S^{(4)}(\mathbf{h})$ (without constraining $\mathbf{h} \in \mathcal{H}$) has norm $\|\mathbf{h}^*_{\mathrm{UC}}\| \geq 1$. Notice that in the unconstrained problem, whenever $\alpha_i[j] = 0$ for all $i = 1..n$, only the second term of $f^{(4)}$ depends on $\mathbf{h}[j]$ and we have $\mathbf{h}^*_{\mathrm{UC}}[j] = 1$. Since this happens a.s. for some coordinate j,

we can conclude that the solution to the constrained optimization problem lies on the boundary of $\mathcal{H}$, that is $\left\|\hat{\mathbf{h}}_S\right\| = 1$. But for such a solution we have

$$F^{(4)}(\hat{\mathbf{h}}_S) \geq \mathbb{E}_\alpha\left[\sqrt{\sum_i \alpha[i]\hat{\mathbf{h}}_S^2[i]}\right] \geq \mathbb{E}_\alpha\left[\sum_i \alpha[i]\hat{\mathbf{h}}_S^2[i]\right] = \sum_i \hat{\mathbf{h}}_S^2[i]\mathbb{E}_\alpha\left[\alpha[i]\right] = \frac{1}{2}\left\|\hat{\mathbf{h}}_S\right\|^2 = \frac{1}{2},$$

while $F^* \leq F(0) = \varepsilon$.

In conclusion, no matter how big the sample size is, the unique empirical minimizer $\hat{\mathbf{h}}_S$ of the stochastic convex optimization problem in Equation (4) is a.s. much worse than the population optimum, $F(\hat{\mathbf{h}}_S) \geq \frac{1}{2} > \varepsilon \geq F^*$, and certainly does not converge to it.

4.2 Learnability via Stability

At this point, we have seen an example in the stochastic convex optimization framework where uniform convergence does not hold, and the ERM algorithm fails. Surprisingly, we will now show that such problems are in fact learnable using an alternative mechanism which has nothing to do with uniform convergence.

Given a stochastic convex optimization problem with an objective function $f(\mathbf{h};\mathbf{z})$, consider a *regularized* version of it: instead of minimizing the expected risk $\mathbb{E}_\mathbf{z}\left[f(\mathbf{h};\mathbf{z})\right]$ over $\mathbf{h} \in \mathcal{H}$, we will try to minimize

$$\mathbb{E}_\mathbf{z}\left[f(\mathbf{h};\mathbf{z}) + \frac{\lambda}{2}\left\|\mathbf{h}\right\|^2\right]$$

for some $\lambda > 0$. Notice that this is simply a stochastic convex optimization problem w.r.t. the objective function $f(\mathbf{h};\mathbf{z}) + \frac{\lambda}{2}\left\|\mathbf{h}\right\|^2$. We will show that this regularized problem *is* learnable using the ERM algorithm (namely, by attempting to minimize $\frac{1}{m}\sum_i f(\mathbf{h};\mathbf{z}_i) + \frac{\lambda}{2}\left\|\mathbf{h}\right\|^2$), by showing that the ERM algorithm is *stable*. By taking $\lambda \to 0$ at an appropriate rate as the sample size increases, we are able to solve the original stochastic problem optimization problem, w.r.t. $f(\mathbf{h};\mathbf{z})$.

The key characteristic of the regularized objective function we need is that it is λ-*strongly convex*. Formally, we say that a real function $g(\cdot)$ over a domain $\mathcal{H}$ in a Hilbert space is λ-strongly convex (where $\lambda \geq 0$), if the function $g(\cdot) - \frac{\lambda}{2}\left\|\cdot\right\|^2$ is convex. In this case, it is easy to verify that if $\mathbf{h}$ minimizes g then

$$\forall \mathbf{h}',\ g(\mathbf{h}') - g(\mathbf{h}) \geq \tfrac{\lambda}{2}\left\|\mathbf{h}' - \mathbf{h}\right\|^2 .$$

When $\lambda = 0$, strong convexity corresponds to standard convexity. In particular, it is immediate from the definition that $f(\mathbf{h};\mathbf{z}) + \frac{\lambda}{2}\left\|\mathbf{h}\right\|^2$ is λ-strongly convex w.r.t. $\mathbf{h}$ (assuming $f(\mathbf{h};\mathbf{z})$ is convex).

The arguments above are formalized in the following two theorems:

Theorem 2 *Consider a stochastic convex optimization problem such that $f(\mathbf{h};\mathbf{z})$ is λ-strongly convex and L-Lipschitz with respect to $\mathbf{h} \in \mathcal{H}$. Let $\mathbf{z}_1,\ldots,\mathbf{z}_m$ be an i.i.d. sample and let $\hat{\mathbf{h}}_S$ be the empirical minimizer. Then, with probability at least $1-\delta$ over the sample we have*

$$F(\hat{\mathbf{h}}_S) - F^* \ \leq\ \frac{4L^2}{\delta\lambda m} .$$

Theorem 3 *Let $f : \mathcal{H} \times \mathcal{Z} \to \mathbb{R}$ be such that $\mathcal{H}$ is bounded by B and $f(\mathbf{h},\mathbf{z})$ is convex and L-Lipschitz with respect to $\mathbf{h}$. Let $\mathbf{z}_1,\ldots,\mathbf{z}_m$ be an i.i.d. sample and let $\hat{\mathbf{h}}_\lambda$ be the minimizer of*

$$\hat{\mathbf{h}}_\lambda = \min_{\mathbf{h}\in\mathcal{H}}\left(\frac{1}{m}\sum_{i=1}^m f(\mathbf{h},\mathbf{z}_i) + \tfrac{\lambda}{2}\left\|\mathbf{h}\right\|^2\right) \tag{5}$$

with $\lambda = \sqrt{\frac{16L^2}{\delta B^2 m}}$. Then, with probability at least $1-\delta$ we have

$$F(\hat{\mathbf{h}}_\lambda) - F^* \ \leq\ 4\sqrt{\frac{L^2B^2}{\delta m}}\left(1 + \frac{8}{\delta m}\right) .$$

Proof [Proof of Theorem 2] To prove the theorem, we use a stability argument. Denote

$$F_S^{(i)}(\mathbf{h}) = \frac{1}{m}\left(f(\mathbf{h},\mathbf{z}_i') + \sum_{j\neq i} f(\mathbf{h},\mathbf{z}_j)\right).$$

the empirical average with $\mathbf{z}_i$ replaced by an independently and identically drawn $\mathbf{z}_i'$, and consider its minimizer:

$$\hat{\mathbf{h}}_S^{(i)} = \arg\min_{\mathbf{h}\in\mathcal{H}} F_S^{(i)}(\mathbf{h}).$$

We first use strong convexity and Lipschitz-continuity to establish that empirical minimization is stable in the following sense:

$$\forall \mathbf{z}\in\mathbb{Z},\quad \left|f(\hat{\mathbf{h}}_S,\mathbf{z}) - f(\hat{\mathbf{h}}_S^{(i)},\mathbf{z})\right| \leq \tfrac{4L^2}{\lambda m}\,. \tag{6}$$

We have that

$$\begin{aligned}
&F_S(\hat{\mathbf{h}}_S^{(i)}) - F_S(\hat{\mathbf{h}}_S)\\
&= \frac{f(\hat{\mathbf{h}}_S^{(i)},\mathbf{z}_i) - f(\hat{\mathbf{h}}_S,\mathbf{z}_i)}{m} + \frac{\sum_{j\neq i}\left(f(\hat{\mathbf{h}}_S^{(i)},\mathbf{z}_j) - f(\hat{\mathbf{h}}_S,\mathbf{z}_j)\right)}{m}\\
&= \frac{f(\hat{\mathbf{h}}_S^{(i)},\mathbf{z}_i) - f(\hat{\mathbf{h}}_S,\mathbf{z}_i)}{m} + \frac{f(\hat{\mathbf{h}}_S,\mathbf{z}_i') - f(\hat{\mathbf{h}}_S^{(i)},\mathbf{z}_i')}{m}\\
&\quad + \left(F_S^{(i)}(\hat{\mathbf{h}}_S^{(i)}) - F_S^{(i)}(\hat{\mathbf{h}}_S)\right)\\
&\leq \frac{|f(\hat{\mathbf{h}}_S^{(i)},\mathbf{z}_i) - f(\hat{\mathbf{h}}_S,\mathbf{z}_i)|}{m} + \frac{|f(\hat{\mathbf{h}}_S,\mathbf{z}_i') - f(\hat{\mathbf{h}}_S^{(i)},\mathbf{z}_i')|}{m}\\
&\leq \frac{2L}{m}\left\|\hat{\mathbf{h}}_S^{(i)} - \hat{\mathbf{h}}_S\right\|
\end{aligned} \tag{7}$$

where the first inequality follows from the fact that $\hat{\mathbf{h}}_S^{(i)}$ is the minimizer of $F_S^{(i)}(\mathbf{h})$ and for the second inequality we use Lipschitz continuity. But from strong convexity of $F_S(\mathbf{h})$ and the fact that $\hat{\mathbf{h}}_S$ minimizes $F_S(\mathbf{h})$ we also have that

$$F_S(\hat{\mathbf{h}}_S^{(i)}) \geq F_S(\hat{\mathbf{h}}_S) + \tfrac{\lambda}{2}\left\|\hat{\mathbf{h}}_S^{(i)} - \hat{\mathbf{h}}_S\right\|^2. \tag{8}$$

Combining Equation (8) with Equation (7) we get $\left\|\hat{\mathbf{h}}_S^{(i)} - \hat{\mathbf{h}}_S\right\| \leq 4L/(\lambda m)$ and combining this with Lipschitz continuity of f we obtain that Equation (6) holds. Later on in this paper, we show that a stable ERM is sufficient for learnability. More formally, Equation (6) implies that the ERM is uniform-RO stability (Definition 4) with rate $\varepsilon_{\text{stable}}(m) = 4L^2/(\lambda m)$ and therefore Theorem 8 implies that the ERM is consistent with rate $\leq \varepsilon_{\text{stable}}(m)$, namely

$$\mathbb{E}_{S\sim\mathcal{D}^m}\left[F(\hat{\mathbf{h}}_S) - F^*\right] \leq \tfrac{4L^2}{\lambda m}\,.$$

Since the random variable in the expectation is non-negative, the theorem follows by Markov's inequality. ■

We now turn to the proof of Theorem 3.

Proof [Proof of Theorem 3] Let $r(\mathbf{h};\mathbf{z}) = \frac{\lambda}{2}\|\mathbf{h}\|^2 + f(\mathbf{h};\mathbf{z})$ and let $R(\mathbf{h}) = \mathbb{E}_{\mathbf{z}}[r(\mathbf{h},\mathbf{z})]$. Note that $\hat{\mathbf{h}}_\lambda$ is the empirical minimizer for the stochastic optimization problem defined by $r(\mathbf{h};\mathbf{z})$.

We apply Theorem 2 to $r(\mathbf{h};\mathbf{z})$, to this end note that since f is L-Lipschitz and $\forall \mathbf{h}\in\mathcal{H},\ \|\mathbf{h}\|\leq B$ we see that r is in fact $L+\lambda B$-Lipschitz. Applying Theorem 2, we see that

$$\tfrac{\lambda}{2}\left\|\hat{\mathbf{h}}_\lambda\right\|^2 + F(\hat{\mathbf{h}}_\lambda) = R(\hat{\mathbf{h}}_\lambda) \leq \inf_{\mathbf{h}} R(\mathbf{h}) + \frac{4(L+\lambda B)^2}{\delta\lambda m}$$

Now note that $\inf_{\mathbf{h}} R(\mathbf{h}) \leq \inf_{\mathbf{h}} F(\mathbf{h}) + \frac{\lambda}{2}B^2 = F^* + \frac{\lambda}{2}B^2$, and so we get that

$$\begin{aligned} F(\hat{\mathbf{h}}_\lambda) &\leq F^* + \frac{\lambda}{2}B^2 + \frac{4(L+\lambda B)^2}{\delta\lambda m} \\ &\leq F^* + \frac{\lambda}{2}B^2 + \frac{8L^2}{\delta\lambda m} + \frac{8\lambda B^2}{\delta m} \end{aligned}$$

Plugging in the value of λ given in the theorem statement we see that

$$F(\hat{\mathbf{h}}_\lambda) \leq F^* + 4\sqrt{\frac{L^2B^2}{\delta m}} + \frac{32}{\delta m}\sqrt{\frac{L^2B^2}{\delta m}}$$

This gives us the required bound. ■

From the above theorem, we see that regularization is essential for convex stochastic optimization. It is important to note that even for the strongly convex optimization problem in Theorem 2, where the ERM algorithm does work, it is not due to uniform convergence. To see this, consider augmenting the objective function $f^{(3)}(\cdot)$ from Equation (3) with a strongly convex term:

$$f^{(9)}(\mathbf{h};\mathbf{x},\alpha) = f^{(3)}(\mathbf{h};\mathbf{x},\alpha) + \frac{\lambda}{2}\|\mathbf{h}\|^2. \tag{9}$$

The modified objective $f^{(9)}(\cdot;\cdot)$ is λ-strongly convex and $(1+\lambda)$-Lipschitz over $\mathcal{H} = \{\mathbf{h} : \|\mathbf{h}\| \leq 1\}$ and thus satisfies the conditions of Theorem 2. Now, consider the same distribution over $z = (\mathbf{x},\alpha)$ used earlier: $\mathbf{x} = 0$ and α is an i.i.d. sequence of uniform zero/one Bernoulli variables. Recall that almost surely we have a coordinate j that is never "observed", namely such that $\forall_i \alpha_i[j] = 0$. Consider a vector $t\mathbf{e}_j$ of magnitude $0 < t \leq 1$ in the direction of this coordinate. We have that $F_S^{(9)}(t\mathbf{e}_j) = \frac{\lambda}{2}t^2$ (where $F_S^{(9)}(\cdot)$ is the empirical risk w.r.t. $f^{(9)}(\cdot)$) but $F^{(9)}(t\mathbf{e}_j) = \frac{1}{2}t + \frac{\lambda}{2}t^2$. Hence, letting $F^{(9)}(\cdot)$ denote the risk w.r.t. $f^{(9)}(\cdot)$, we have that $F^{(9)}(t\mathbf{e}_j) - F_S^{(9)}(t\mathbf{e}_j) = t/2$. In particular, we can set $t = 1$ and establish $\sup_{\mathbf{h}\in\mathcal{H}}(F^{(9)}(\mathbf{h}) - F_S^{(9)}(\mathbf{h})) \geq \frac{1}{2}$ regardless of the sample size.

We see then that the empirical averages $F_S^{(9)}(\mathbf{h})$ do *not* converge uniformly to their expectations. Moreover, the example above shows that there is no uniform convergence even in a local sense, namely over all hypotheses whose risk is close enough to F^*, or those close enough to the minimizer of $f^{(9)}(\mathbf{h};\mathbf{x},\alpha)$.

Finally, we note that the learning algorithm we have discussed here is mainly for pedagogical reasons. A different generic algorithm for stochastic convex optimization is already known in the literature, by combining Zinkevich's algorithm (Zinkevich, 2003) for online convex optimization, with an online-to-batch conversion (e.g., Cesa-Bianchi et al., 2004). While different than our algorithm, Shalev-Shwartz (2007) showed that Zinkevich's online learning algorithm can be viewed as approximate coordinate ascent optimization of the dual of the regularized problem Equation (5). Thus, this algorithm still uses the same mechanisms of regularization and stability. Also, we note that the algorithm also enjoys bounds which depend only logarithmically on $1/\delta$, while the bounds we have obtained above depend linearly on $1/\delta$. However, we suspect that the dependence on δ in Theorem 2 can be improved to $\log(1/\delta)$. For instance, such bounds has been obtained whenever the objective function is a generalized linear function of h (Sridharan et al., 2008).

4.3 How to Interpret Regularization: Uniform Convergence vs Stability

The technique of regularizing the objective function by adding a "bias" term is old and well known. In particular, adding $\|\mathbf{h}\|^2$ is the so-called Tikhonov Regularization technique, which has been known for more than half a century (see Tikhonov, 1943). However, the role of regularization in our case is very different than in familiar settings such as ℓ_2 regularization in SVMs and ℓ_1 regularization in LASSO. In those settings regularization serves to constrain our domain to a low-complexity domain (e.g., low-norm predictors), where

we rely on uniform convergence. In fact, almost all learning guarantees that we are aware of can be expressed in terms of some sort of uniform convergence.

In our case, constraining the norm of $\mathbf{h}$ does *not* ensure uniform convergence. Consider the example $f^{(3)}(\cdot)$ we have seen earlier. Even over a restricted domain $\mathcal{H}_r = \{\mathbf{h} : \|\mathbf{h}\| \leq r\}$, for arbitrarily small $r > 0$, the empirical averages $F_S(\mathbf{h})$ do *not* uniformly converge to $F(\mathbf{h})$. Furthermore, consider replacing the regularization term $\lambda \|\mathbf{h}\|^2$ with a constraint on the norm of $\|\mathbf{h}\|$, namely, solving the problem

$$\tilde{\mathbf{h}}_r = \arg\min_{\|\mathbf{h}\| \leq r} F_S(\mathbf{h})$$

We cannot solve the stochastic optimization problem by setting r in a distribution-independent way (i.e., without knowing the solution...). To see this, note that when $\mathbf{x} = 0$ a.s. we must have $r \to 0$ to ensure $F(\tilde{\mathbf{h}}_r) \to F^*$. However, if $\mathbf{x} = \mathbf{e}_1$ a.s., we must set $r \to 1$. No constraint will work for all distributions over $\mathbb{Z} = (\mathcal{X}, \alpha)$! This sharply contrasts with traditional uses of regularization, where learning guarantees are typically stated in terms of a constraint on the norm rather than in terms of a parameter such as λ, and adding a regularization term of the form $\frac{\lambda}{2} \|\mathbf{h}\|^2$ is viewed as a proxy for bounding the norm $\|\mathbf{h}\|$.

4.4 Contradiction to Vapnik?

In Section 3.1, we discussed how Vapnik showed that uniform convergence is in fact necessary for learnability with the ERM. At first glance, this might seem confusing in light of the examples presented above, where we have problems learnable with the ERM without uniform convergence whatsoever.

The solution for this apparent paradox is that our examples are not "strictly consistent" in Vapnik's sense. Recall that in order to exclude "trivial" cases, Vapnik defined strict consistency of empirical minimization as (in our notation):

$$\forall c \in \mathbb{R}, \quad \inf_{\mathbf{h}:F(\mathbf{h}) \geq c} F_S(\mathbf{h}) \longrightarrow \inf_{\mathbf{h}:F(\mathbf{h}) \geq c} F(\mathbf{h}) \ , \tag{10}$$

where the convergence is in probability. This condition indeed ensures that $F(\hat{\mathbf{h}}_S) \xrightarrow{P} F^*$. Vapnik's Key Theorem on Learning Theory (Vapnik, 1998, Theorem 3.1) then states that *strict* consistency of empirical minimization is equivalent to one-sided[2] uniform convergence. In the example presented above, even though Theorem 2 establishes $F^{(9)}(\hat{\mathbf{h}}_S) \xrightarrow{P} F^*$, the consistency isn't "strict" by the definition above. To see this, for any $c > 0$, consider the vector $t\mathbf{e}_j$ (where $\forall_i \alpha_i[j] = 0$) with $t = 2c$. We have $F^{(9)}(t\mathbf{e}_j) = \frac{1}{2}t + \frac{\lambda}{2}t^2 > c$ but $F_S^{(9)}(t\mathbf{e}_j) = \frac{\lambda}{2}t^2 = 2\lambda c^2$. Focusing on $\lambda = \frac{1}{2}$ we get:

$$\inf_{F^{(9)}(\mathbf{h}) \geq c} F_S^{(9)}(\mathbf{h}) \leq c^2$$

almost surely for any sample size m, violating the strict consistency requirement Equation (10).

We emphasize that stochastic convex optimization is far from "trivial" in that there is no dominating hypothesis that will always be selected. Although for convenience of analysis we took $\mathbf{x} = 0$, one should think of situations in which $\mathbf{x}$ is stochastic with an unknown distribution. This shows that uniform convergence is a sufficient, but not at all necessary, condition for consistency of empirical minimization in non-trivial settings.

5. Learnability in the General Learning Setting: the role of Stability

In the previous section, we have shown that in the General Learning Setting, it is possible for problems to be learnable without uniform convergence, in sharp contrast to previously considered settings. The key underlying mechanism which allowed us to learn is stability. In this section, we study the connection between learnability and stability in greater depth, and show that stability can in fact *characterize* learnability. Also, we will see how various "common knowledge facts", which we usually take for granted and are based on a

2. "One-sided" meaning requiring only $\sup(F(\mathbf{h}) - F_S(\mathbf{h})) \longrightarrow 0$, rather then $\sup|F(\mathbf{h}) - F_S(\mathbf{h})| \longrightarrow 0$.

"uniform convergence equivalent to learnability" assumption, do not hold in the General Learning Setting, and things can be much more delicate.

We will refer to settings where learnability is equivalent to uniform convergence as "supervised classification" settings. While supervised classification does not encompass all settings where this equivalence holds, most equivalence results refer to it either explicitly or implicitly (by reduction to a classification problem).

5.1 Stability : Definitions

We start by giving the exact definition of the stability notions that we will use. As discussed earlier, there are many possible stability measures, some of which can be used to obtain results of a similar flavor to the ones below. The definition we use seems to be the most convenient for the goal of characterizing learnability in the General Learning Setting. In Appendix A, we provide a few illustrating examples to the subtle differences that can arise from slight variations in the stability measure.

Our two stability notions are based on replacing one of the training sample instances. For a sample S of size m, let $S^{(i)} = \{\mathbf{z}_1, ..., \mathbf{z}_{i-1}, \mathbf{z}'_i, \mathbf{z}_{i+1}, ..., \mathbf{z}_m\}$ be a sample obtained by replacing the i-th observation of S with some different instance $\mathbf{z}'_i$. When not discussed explicitly, the nature of how $\mathbf{z}'_i$ is obtained should be obvious from context.

Definition 4 *A rule* $\mathbf{A}$ *is* **uniform-RO stable**[3] *with rate* $\varepsilon_{\text{stable}}(m)$*, if for all possible* $S^{(i)}$ *and any* $\mathbf{z}' \in \mathcal{Z}$*,*

$$\frac{1}{m}\sum_{i=1}^{m}\left|f(\mathbf{A}(S^{(i)});\mathbf{z}') - f(\mathbf{A}(S);\mathbf{z}')\right| \leq \varepsilon_{\text{stable}}(m).$$

Definition 5 *A rule* $\mathbf{A}$ *is* **average-RO stable** *with rate* $\varepsilon_{\text{stable}}(m)$ *under distributions* $\mathcal{D}$ *if*

$$\left|\frac{1}{m}\sum_{i=1}^{m}\mathbb{E}_{S\sim\mathcal{D}^m,(\mathbf{z}'_1,...,\mathbf{z}'_m)\sim\mathcal{D}^m}\left[f(\mathbf{A}(S^{(i)});\mathbf{z}'_i) - f(\mathbf{A}(S);\mathbf{z}'_i)\right]\right| \leq \varepsilon_{\text{stable}}(m).$$

Note that this definition corresponds to assuming that the expected empirical risk of the learning rule converges to the expected risk - see Lemma 11.

We say that a rule is *universally* stable with rate $\varepsilon_{\text{stable}}(m)$, if the stability property holds with rate $\varepsilon_{\text{stable}}(m)$ for all distributions.

Claim 6 *Uniform-RO stability with rate* $\varepsilon_{\text{stable}}(m)$ *implies average-RO stability with rate* $\varepsilon_{\text{stable}}(m)$*.*

5.2 Characterizing Learnability : Main Results

Our overall goal is to characterize learnable problems (namely, problems for which there exists a universally consistent learning rule, as in Equation (2)). That means finding some condition which is both *necessary* and *sufficient* for learnability. In the uniform convergence setting, such a condition is the stability of the ERM (under any of several possible stability measures, including both variants of RO-stability defined above). This is still sufficient for learnability in the General Learning Setting, but far from being necessary, as we have seen in Section 4.

The most important result in this section is a condition which is necessary and sufficient for learnability in the General Learning Setting:

Theorem 7 *A learning problem is learnable if and only if there exists a uniform-RO stable, universally AERM learning rule.*

In particular, if there exists a $\varepsilon_{\text{cons}}(m)$*-universally consistent rule, then there exists a rule that is* $\varepsilon_{\text{stable}}(m)$*-uniform-RO stable and universally* $\varepsilon_{\text{erm}}(m)$*-AERM where:*

$$\varepsilon_{\text{erm}}(m) = 3\varepsilon_{\text{cons}}(m^{1/4}) + \tfrac{8B}{\sqrt{m}} \ ,$$
$$\varepsilon_{\text{stable}}(m) = \tfrac{2B}{\sqrt{m}}.$$

3. RO is short for "replace-one".

In the opposite direction, if a learning rule is $\varepsilon_{\text{stable}}(m)$*-uniform-RO stable and universally* $\varepsilon_{\text{erm}}(m)$*-AERM, then it is universally consistent with rate*

$$\varepsilon_{\text{cons}}(m) \leq \varepsilon_{\text{stable}}(m) + \varepsilon_{\text{erm}}(m)$$

Thus, while we have seen in Section 4 that the ERM rule might fail for learning problems which are in fact learnable, there is always an AERM rule which will work. In other words, when designing learning rules, we might need to look beyond empirical risk minimization, but not beyond AERM learning rules. On the downside, we must choose our AERM carefully, since not any AERM will work. This contrasts with supervised classification, where any AERM will work if the problem is learnable at all.

How do we go about proving this assertion? The easier part is showing sufficiency. Namely, that a stable AERM must be consistent (and generalizing). In fact, this holds both separately for any particular distribution $\mathcal{D}$s, and uniformly over all distributions:

Theorem 8 *If a rule is an AERM with rate* $\varepsilon_{\text{erm}}(m)$ *and average-RO stable (or uniform-RO stable) with rate* $\varepsilon_{\text{stable}}(m)$ *under* $\mathcal{D}$*, then it is consistent and generalizes under* $\mathcal{D}$ *with rates*

$$\varepsilon_{\text{cons}}(m) \leq \varepsilon_{\text{stable}}(m) + \varepsilon_{\text{erm}}(m)$$
$$\varepsilon_{\text{gen}}(m) \leq \varepsilon_{\text{stable}}(m) + 2\varepsilon_{\text{erm}}(m) + \tfrac{2B}{\sqrt{m}}$$

The second part of Theorem 7 follows as a direct corollary. We note that close variants of Theorem 8 has already appeared in previous literature (e.g., Mukherjee et al., 2006 and Rakhlin et al., 2005).

The harder part is showing that a uniform-RO stable AERM is *necessary* for learnability. This is done in several steps.

First, we show that consistent AERMs have to be average-RO stable:

Theorem 9 *For an AERM, the following are equivalent:*
- *Universal average-RO stability.*
- *Universal consistency.*
- *Universal generalization.*

The exact conversion rate of Theorem 9 is specified in the corresponding proof (Section 5.3), and are all polynomial. In particular, an $\varepsilon_{\text{cons}}$-universal consistent ε_{erm}-AERM is average-RO stable with rate

$$\varepsilon_{\text{stable}}(m) \leq \varepsilon_{\text{erm}}(m) + 3\varepsilon_{\text{cons}}(m^{1/4}) + \tfrac{4B}{\sqrt{m}}.$$

Next, we show that if we seek universally consistent and generalizing learning rules, then we must consider only AERMs:

Theorem 10 *If a rule* $\mathbf{A}$ *is universally consistent with rate* $\varepsilon_{\text{cons}}(m)$ *and generalizing with rate* $\varepsilon_{\text{gen}}(m)$*, then it is universally an AERM with rate*

$$\varepsilon_{\text{erm}}(m) \leq \varepsilon_{\text{gen}}(m) + 3\varepsilon_{\text{cons}}(m^{1/4}) + \frac{4B}{\sqrt{m}}$$

Now, recall that learnability is defined as the existence of some universally consistent learning rule. Such a rule might not be generalizing, stable or even an AERM (see example 2 below). However, it turns out that if a universally consistent learning rule exist, then there is *another* learning rule for the same problem, which is generalizing (Lemma 20). Thus, by Theorems 9-10, this rule must also be average-RO stable AERM. In fact, by another application of Lemma 20, such an AERM must also be uniform-RO stable, leading to Theorem 7.

5.3 Detailed Results and Proofs

We first establish that for AERMs, average-RO stability and generalization are equivalent.

5.3.1 EQUIVALENCE OF STABILITY AND GENERALIZATION

It will be convenient to work with a weaker version of generalization as an intermediate step: We say a rule **A on-average generalizes** with rate $\varepsilon_{\text{oag}}(m)$ under distribution $\mathcal{D}$ if for all m,

$$|\mathbb{E}_{S\sim\mathcal{D}^m}[F(\mathbf{A}(S)) - F_S(\mathbf{A}(S))]| \leq \varepsilon_{\text{oag}}(m). \tag{11}$$

It is straightforward to see that generalization implies on-average generalization with the same rate. We show that for AERMs, the converse is also true, and also that on-average generalization is equivalent to average-RO stability. This establishes the equivalence between generalization and average-RO stability (for AERMs).

Lemma 11 (on-average generalization $\Leftrightarrow$ average-RO stability) *If* $\mathbf{A}$ *is on-average generalizing with rate* $\varepsilon_{\text{oag}}(m)$ *then it is average-RO stable with rate* $\varepsilon_{\text{oag}}(m)$. *If* $\mathbf{A}$ *is average-RO stable with rate* $\varepsilon_{\text{stable}}(m)$ *then it is on-average generalizing with rate* $\varepsilon_{\text{stable}}(m)$.

Proof For any i, $\mathbf{z}_i$ and $\mathbf{z}'_i$ are both drawn i.i.d. from $\mathcal{D}$, we have that

$$\mathbb{E}_{S\sim\mathcal{D}^m}[f(\mathbf{A}(S);\mathbf{z}_i)] = \mathbb{E}_{S\sim\mathcal{D}^m,\mathbf{z}'_i\sim\mathcal{D}}\left[f(\mathbf{A}(S^{(i)});\mathbf{z}'_i)\right].$$

Hence,

$$\begin{aligned}
\mathbb{E}_{S\sim\mathcal{D}^m}[F_S(\mathbf{A}(S))] &= \mathbb{E}_{S\sim\mathcal{D}^m}\left[\frac{1}{m}\sum_{i=1}^m f(\mathbf{A}(S);\mathbf{z}_i)\right] \\
&= \frac{1}{m}\sum_{i=1}^m \mathbb{E}_{S\sim\mathcal{D}^m}[f(\mathbf{A}(S);\mathbf{z}_i)] \\
&= \frac{1}{m}\sum_{i=1}^m \mathbb{E}_{S\sim\mathcal{D}^m,\mathbf{z}'_i\sim\mathcal{D}}\left[f(\mathbf{A}(S^{(i)});\mathbf{z}'_i)\right]
\end{aligned}$$

Also note that $F(\mathbf{A}(S)) = \mathbb{E}_{\mathbf{z}'_i\sim\mathcal{D}}[f(\mathbf{A}(S);\mathbf{z}'_i)] = \frac{1}{m}\sum_{i=1}^m \mathbb{E}_{\mathbf{z}'_i\sim\mathcal{D}}[f(\mathbf{A}(S);\mathbf{z}'_i)]$. Hence we can conclude that

$$\mathbb{E}_{S\sim\mathcal{D}^m}[F(\mathbf{A}(S)) - F_S(\mathbf{A}(S))] = \frac{1}{m}\sum_{i=1}^m \mathbb{E}_{S\sim\mathcal{D}^m,(\mathbf{z}'_1,\ldots,\mathbf{z}'_m)\sim\mathcal{D}^m}\left[f(\mathbf{A}(S);\mathbf{z}'_i) - f(\mathbf{A}(S^{(i)});\mathbf{z}'_i)\right]$$

Hence we have the required result. ■

For the next result, we will need the following two short utility lemmas.

Utility Lemma 12 *For i.i.d.* X_i, $|X_i| \leq B$ *and* $X = \frac{1}{m}\sum_{i=1}^m X_i$ *we have* $\mathbb{E}[|X - \mathbb{E}[X]|] \leq B/\sqrt{m}$.

Proof $\mathbb{E}[|X - \mathbb{E}[X]|] \leq \sqrt{\mathbb{E}\left[|X - \mathbb{E}[X]|^2\right]} \leq \sqrt{\text{Var}[X]} = \sqrt{\text{Var}[X_i]/m} \leq B/\sqrt{m}$. ■

Utility Lemma 13 *Let* X, Y *be random variables s.t.* $X \leq Y$ *almost surely. Then* $\mathbb{E}[|X|] \leq |\mathbb{E}[X]| + 2\mathbb{E}[|Y|]$.

Proof

$$\mathbb{E}[|X|] = \mathbb{E}[|(Y-X) - Y|] \leq \mathbb{E}[Y - X] + \mathbb{E}[|Y|] \leq |\mathbb{E}[X]| + 2|\mathbb{E}[Y]|.$$

■

Lemma 14 (AERM + on-average generalization ⇒ generalization) *If* $\mathbf{A}$ *is an AERM with rate* $\varepsilon_{\text{erm}}(m)$ *and on-average generalizes with rate* $\varepsilon_{\text{oag}}(m)$ *under* $\mathcal{D}$*, then* $\mathbf{A}$ *generalizes with rate* $\varepsilon_{\text{oag}}(m)+2\varepsilon_{\text{erm}}(m)+\frac{2B}{\sqrt{m}}$ *under* $\mathcal{D}$*.*

Proof Recall that $F^* = \inf_{\mathbf{h}\in\mathcal{H}} F(\mathbf{h})$. For an arbitrarily small $\nu > 0$, let $\mathbf{h}_\nu$ be a fixed hypothesis such that $F(\mathbf{h}_\nu) \leq F^* + \nu$. Using respective optimalities of $\hat{\mathbf{h}}_S$ and F^* we can bound:

$$\begin{aligned}
&F_S(\mathbf{A}(S)) - F(\mathbf{A}(S)) \\
&= F_S(\mathbf{A}(S)) - F_S(\hat{\mathbf{h}}_S) + F_S(\hat{\mathbf{h}}_S) - F_S(\mathbf{h}_\nu) + F_S(\mathbf{h}_\nu) - F(\mathbf{h}_\nu) + F(\mathbf{h}_\nu) - F(\mathbf{A}(S)) \\
&\leq F_S(\mathbf{A}(S)) - F_S(\hat{\mathbf{h}}_S) + F_S(\mathbf{h}_\nu) - F(\mathbf{h}_\nu) + \nu = Y_\nu
\end{aligned}$$

Where the final equality defines a new random variable Y_ν. By Lemma 12 and the AERM guarantee we have $\mathbb{E}[|Y_\nu|] \leq \varepsilon_{\text{erm}}(m) + B/\sqrt{m} + \nu$. From Lemma 13 we can conclude that

$$\mathbb{E}\left[\left|F_S(\mathbf{A}(S)) - F(\mathbf{A}(S))\right|\right] \leq \left|\mathbb{E}\left[F_S(\mathbf{A}(S)) - F(\mathbf{A}(S))\right]\right| + 2\mathbb{E}\left[|Y_\nu|\right] \leq \varepsilon_{\text{oag}}(m) + 2\varepsilon_{\text{erm}}(m) + \tfrac{2B}{\sqrt{m}} + \nu.$$

Notice that the l.h.s. is a fixed quantity which does not depend on ν. Therefore, we can take ν in the r.h.s. to zero, and the result follows. ■

Combining Lemma 11 and Lemma 14, we have now **established the stability↔generalization parts of Theorem 8 and Theorem 9** (in fact, even a slightly stronger converse than in Theorem 9, as it does not require universality).

5.3.2 A SUFFICIENT CONDITION FOR CONSISTENCY

It is fairly straightforward to see that generalization (or even on-average generalization) of an AERM implies its consistency:

Lemma 15 (AERM+generalization⇒consistency) *If* $\mathbf{A}$ *is AERM with rate* $\varepsilon_{\text{erm}}(m)$ *and it on-average generalizes with rate* $\varepsilon_{\text{oag}}(m)$ *under* $\mathcal{D}$ *then it is consistent with rate* $\varepsilon_{\text{oag}}(m) + \varepsilon_{\text{erm}}(m)$ *under* $\mathcal{D}$*.*

Proof For any $\nu > 0$, let $\mathbf{h}_\nu$ be a hypothesis such that $F(\mathbf{h}_\nu) \leq F^* + \nu$. We have

$$\begin{aligned}
&\mathbb{E}\left[F(\mathbf{A}(S)) - F^*\right] = \mathbb{E}\left[F(\mathbf{A}(S)) - F_S(\mathbf{h}_\nu) + \nu\right] \\
&= \mathbb{E}\left[F(\mathbf{A}(S)) - F_S(\mathbf{A}(S))\right] + \mathbb{E}\left[F_S(\mathbf{A}(S)) - F_S(\mathbf{h}_\nu)\right] + \nu \\
&\leq \mathbb{E}\left[F(\mathbf{A}(S)) - F_S(\mathbf{A}(S))\right] + \mathbb{E}\left[F_S(\mathbf{A}(S)) - F_S(\hat{\mathbf{h}}_S)\right] + \nu \\
&\leq \varepsilon_{\text{oag}}(m) + \varepsilon_{\text{erm}}(m) + \nu.
\end{aligned}$$

Since this upper bound holds for any ν, we can take ν to zero, and the result follows. ■

Combined with the results of Lemma 11, this completes the **proof of Theorem 8** and the **stability → consistency and generalization → consistency parts of Theorem 9**.

5.3.3 CONVERSE DIRECTION

Lemma 11 already provides a converse result, establishing that stability is necessary for generalization. However, as it will turn out, in order to establish that stability is also necessary for *universal consistency*, we must prove that universal consistency of an AERM implies *universal* generalization. The assumption of *universal* consistency for the AERM is crucial here: mere consistency of an AERM with respect to a specific distribution does *not* imply generalization nor stability with respect to that distribution. The following example briefly illustrates this point.

Example 1 *There exists a learning problem and a distribution on the instance space, such that the ERM (or any AERM) is consistent with rate* $\varepsilon_{\text{cons}}(m) = 0$*, but does not generalize and is not average-RO stable (namely,* $\varepsilon_{\text{gen}}(m), \varepsilon_{\text{stable}}(m) = \Omega(1)$*).*

Proof Let the instance space be $[0,1]$, the hypothesis space consist of all finite subsets of $[0,1]$, and define the objective function as $f(\mathbf{h}, z) = \mathbb{1}_{[z \notin \mathbf{h}]}$. Consider any continuous distribution on the instance space. Since the underlying distribution $\mathcal{D}$ is continuous, we have $F(\mathbf{h}) = 1$ for any hypothesis h. Therefore, any learning rule (including any AERM) will be consistent with $F(\mathbf{A}(S)) = 1$. On the other hand, the ERM here always achieves $F_S(\hat{\mathbf{h}}_S) = 0$, so any AERM cannot generalize, or even on-average-generalize (by Lemma 14), hence cannot be average-RO stable (by Lemma 11). ■

The main tool we use to prove our desired converse result is the following lemma. It is here that we crucially use the universal consistency assumption (i.e., consistency with respect to *any* distribution). Intuitively, it states that if a problem is learnable at all, then although the ERM rule might fail, its empirical risk is a consistent estimator of the minimal achievable risk.

Lemma 16 (Main Converse Lemma) *If a problem is learnable, namely there exists a universally consistent rule* $\mathbf{A}$ *with rate* $\varepsilon_{\text{cons}}(m)$*, then under any distribution,*

$$\mathbb{E}\left[\left|F_S(\hat{\mathbf{h}}_S) - F^*\right|\right] \leq \varepsilon_{\text{emp}}(m) \qquad \textit{where} \tag{12}$$

$$\varepsilon_{\text{emp}}(m) = 2\varepsilon_{\text{cons}}(m') + \tfrac{2B}{\sqrt{m}} + \tfrac{2Bm'^2}{m}$$

for any m' *such that* $2 \leq m' \leq m/2$.

Proof Let $I = \{I_1, \ldots, I_{m'}\}$ be a random sample of m' indexes in the range $1..m$ where each I_i is independently uniformly distributed, and I is independent of S. Let $S' = \{z_{I_i}\}_{i=1}^{m'}$, that is, a sample of size m' drawn from the uniform distribution over samples in S (with replacements). We first bound the probability that I has no repeated indexes ("duplicates"):

$$\mathbb{P}\left[I \text{ has duplicates}\right] \leq \frac{\sum_{i=1}^{m'}(i-1)}{m} \leq \frac{m'^2}{2m} \tag{13}$$

Conditioned on not having duplicates in I, the sample S' is actually distributed according to $\mathcal{D}^{m'}$, that is, can be viewed as a sample from the original distribution. We therefore have by universal consistency:

$$\mathbb{E}\left[\left|F(\mathbf{A}(S')) - F^*\right| \,\middle|\, \text{no dups}\right] \leq \varepsilon_{\text{cons}}(m') \tag{14}$$

But viewed as a sample drawn from the uniform distribution over instances in S, we also have:

$$\mathbb{E}_{S'}\left[\left|F_S(\mathbf{A}(S')) - F_S(\hat{\mathbf{h}}_S)\right|\right] \leq \varepsilon_{\text{cons}}(m') \tag{15}$$

Conditioned on having no duplications in I, the set of those samples in S not chosen by I (i.e., $S \setminus S'$) is independent of S', and $|S \setminus S'| = m - m'$, and so by Lemma 12:

$$\mathbb{E}_S\left[\left|F(\mathbf{A}(S')) - F_{S\setminus S'}(\mathbf{A}(S'))\right|\right] \leq \frac{B}{\sqrt{m-m'}} \tag{16}$$

Finally, if there are no duplicates, then for any hypothesis, and in particular for $\mathbf{A}(S')$ we have:

$$\left|F_S(\mathbf{A}(S')) - F_{S\setminus S'}(\mathbf{A}(S'))\right| \leq \frac{2Bm'}{m} \tag{17}$$

Combining Equation (14),Equation (15),Equation (16) and Equation (17), accounting for a maximal discrepancy of B when we do have duplicates, and assuming $2 \leq m' \leq m/2$, we get the desired bound. ■

Equipped with Lemma 16, we are now ready to show that universal consistency of an AERM implies universal generalization and that any universally consistent and generalizing rule must be an AERM. What we show is actually a bit stronger: that if a problem is learnable, and so Lemma 16 holds, then for any distribution $\mathcal{D}$ separately, consistency of an AERM under $\mathcal{D}$ implies generalization under $\mathcal{D}$ and also any consistent and generalizing rule under $\mathcal{D}$ must be an AERM.

Lemma 17 (learnable+AERM+consistent⇒generalizing) *If Equation (12) in Lemma 16 holds with rate $\varepsilon_{\text{emp}}(m)$, and $\mathbf{A}$ is an ε_{erm}-AERM and $\varepsilon_{\text{cons}}$-consistent under $\mathcal{D}$, then it is generalizing under $\mathcal{D}$ with rate $\varepsilon_{\text{emp}}(m)+\varepsilon_{\text{erm}}(m)+\varepsilon_{\text{cons}}(m)$.*

Proof

$$\begin{aligned}\mathbb{E}\left[\left|F_S(\mathbf{A}(S))-F(\mathbf{A}(S))\right|\right] &\leq \mathbb{E}\left[\left|F_S(\mathbf{A}(S))-F_S(\hat{\mathbf{h}}_S)\right|\right]+\mathbb{E}\left[\left|F^*-F(\mathbf{A}(S))\right|\right]+\mathbb{E}\left[\left|F_S(\hat{\mathbf{h}}_S)-F^*\right|\right] \\ &\leq \varepsilon_{\text{erm}}(m)+\varepsilon_{\text{cons}}(m)+\varepsilon_{\text{emp}}(m)\ .\end{aligned}$$

■

Lemma 18 (learnable+consistent+generalizing⇒AERM) *If Equation (12) in Lemma 16 holds with rate $\varepsilon_{\text{emp}}(m)$, and $\mathbf{A}$ is $\varepsilon_{\text{cons}}$-consistent and ε_{gen}-generalizing under $\mathcal{D}$, then it is AERM under $\mathcal{D}$ with rate $\varepsilon_{\text{emp}}(m)+\varepsilon_{\text{gen}}(m)+\varepsilon_{\text{cons}}(m)$.*

Proof

$$\begin{aligned}\mathbb{E}\left[\left|F_S(\mathbf{A}(S))-F_S(\hat{\mathbf{h}}_S)\right|\right] &\leq \mathbb{E}\left[\left|F_S(\mathbf{A}(S))-F(\mathbf{A}(S))\right|\right]+\mathbb{E}\left[\left|F(\mathbf{A}(S))-F^*\right|\right]+\mathbb{E}\left[\left|F^*-F_S(\hat{\mathbf{h}}_S)\right|\right] \\ &\leq \varepsilon_{\text{gen}}(m)+\varepsilon_{\text{cons}}(m)+\varepsilon_{\text{emp}}(m)\ .\end{aligned}$$

■

Lemma 17 establishes that universal consistency of an AERM implies universal generalization, and thus **completes the proof of Theorem 9**. Lemma 18 **establishes Theorem 10**. To get the rates in Section 5.2, we use $m' = m^{1/4}$ in Lemma 16.

Lemma 15, Lemma 17 and Lemma 18 together establish an interesting relationship:

Corollary 19 *For a (universally) learnable problem, for any distribution $\mathcal{D}$ and learning rule $\mathbf{A}$, any two of the following imply the third :*

- $\mathbf{A}$ *is an AERM under $\mathcal{D}$.*
- $\mathbf{A}$ *is consistent under $\mathcal{D}$.*
- $\mathbf{A}$ *generalizes under $\mathcal{D}$.*

Note, however, that any one property by itself is possible, even universally:

- In Section 4.1, we have discussed an example where the ERM learning rule is neither consistent nor generalizing, despite the problem being learnable.
- In the next subsection (Example 2) we demonstrate a universally consistent learning rule which is neither generalizing nor an AERM.
- A rule returning a fixed hypothesis always generalizes, but of course need not be consistent nor an AERM.

In contrast, for learnable supervised classification problems, it is not possible for a learning rule to be just universally consistent, without being an AERM and without generalization. Nor is it possible for a learning rule to be a universal AERM for a learnable problem, without being generalizing and consistent.

Corollary 19 can also provide a *certificate* of non-learnability. In other words, for the problem in Example 1 we show a specific distribution for which there is a consistent AERM that does not generalize. We can conclude that there is *no* universally consistent learning rule for the problem, otherwise the corollary is violated.

5.3.4 EXISTENCE OF A STABLE RULE

Theorem 9 and Theorem 10, which we just completed proving, already establish that for AERMs, universal consistency is equivalent to universal average-RO stability. Existence of a universally average-RO stable AERM is thus sufficient for learnability. In order to prove that it is also necessary, it is enough to show that existence of a universally consistent learning rule implies existence of a universally consistent AERM. This AERM must then be average-RO stable by Theorem 9.

We actually show how to transform a consistent rule to a consistent and generalizing rule (Lemma 20 below). If this rule is universally consistent, then by Lemma 18 we can then conclude it must be an AERM, and by Lemma 11 it must be average-RO stable.

Lemma 20 *For any rule* $\mathbf{A}$ *there exists a rule* $\mathbf{A}'$*, such that:*

- $\mathbf{A}'$ *universally generalizes with rate* $\frac{3B}{\sqrt{m}}$.
- *For any* $\mathcal{D}$*, if* $\mathbf{A}$ *is* $\varepsilon_{\text{cons}}$*-consistent under* $\mathcal{D}$ *then* $\mathbf{A}'$ *is* $\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)$ *consistent under* $\mathcal{D}$.
- $\mathbf{A}'$ *is uniformly-RO-stable with rate* $\frac{2B}{\sqrt{m}}$.

Proof For a sample S of size m, let S' be a sub-sample consisting of some $\lfloor\sqrt{m}\rfloor$ observation in S. To simplify the presentation, assume that $\lfloor\sqrt{m}\rfloor$ is an integer. Define $\mathbf{A}'(S) = \mathbf{A}(S')$. That is, $\mathbf{A}'$ applies A to only $\sqrt{m}$ of the observation in S.

$\mathbf{A}'$ *generalizes:* We can decompose:

$$F_S(\mathbf{A}(S')) - F(\mathbf{A}(S')) = \tfrac{1}{\sqrt{m}}(F_{S'}(\mathbf{A}(S')) - F(\mathbf{A}(S'))) + (1-\tfrac{1}{\sqrt{m}})(F_{S\setminus S'}(\mathbf{A}(S')) - F(\mathbf{A}(S')))$$

The first term can be bounded by $2B/\sqrt{m}$. As for the second term, $S \setminus S'$ is statistically independent of S' and so we can use Lemma 12 to bound its expected magnitude to obtain:

$$\mathbb{E}\left[\left|F_S(\mathbf{A}(S')) - F(\mathbf{A}(S'))\right|\right] \leq \tfrac{2B}{\sqrt{m}} + (1-\tfrac{1}{\sqrt{m}})\tfrac{B}{\sqrt{m-\sqrt{m}}} \leq \tfrac{3B}{\sqrt{m}}$$

$\mathbf{A}'$ *is consistent:* If $\mathbf{A}$ is consistent, then:

$$\mathbb{E}\left[F(\mathbf{A}'(S)) - \inf_{\mathbf{h}\in\mathcal{H}} F(\mathbf{h})\right] = \mathbb{E}\left[F(\mathbf{A}(S')) - \inf_{\mathbf{h}\in\mathcal{H}} F(\mathbf{h})\right] \leq \varepsilon_{\text{cons}}(\sqrt{m})$$

$\mathbf{A}'$ *is uniformly-RO-stable:* Since $\mathbf{A}'$ only uses the first $\sqrt{m}$ samples of S, for any $i > \sqrt{m}$ we have $\mathbf{A}'(S^{(i)}) = \mathbf{A}'(S)$ and so:

$$\frac{1}{m}\sum_{i=1}^{m}\left|f(\mathbf{A}'(S^{(i)});\mathbf{z}') - f(\mathbf{A}'(S);\mathbf{z}')\right| = \frac{1}{m}\sum_{i=1}^{\sqrt{m}}\left|f(\mathbf{A}'(S^{(i)});\mathbf{z}') - f(\mathbf{A}'(S);\mathbf{z}')\right| \leq \frac{2B}{\sqrt{m}}$$

■

Proof of Converse in Theorem 7 If there exists a universally consistent rule with rate $\varepsilon_{\text{cons}}(m)$, by Lemma 20 there exists $\mathbf{A}'$ which is $\varepsilon_{\text{cons}}(\sqrt{m})$- universally consistent, $\frac{2B}{\sqrt{m}}$-generalizing and $\frac{2B}{\sqrt{m}}$-uniformly-RO-stable.

Further by Lemma 18 and Lemma 16 (with $m' = m^{1/4}$), we can conclude that A' is ε_{erm}-universally AERM where,

$$\varepsilon_{\text{erm}}(m) \leq 3\varepsilon_{\text{cons}}(m^{1/4}) + \frac{8B}{\sqrt{m}}.$$

Hence we get the specified rate for the converse direction. To see that if there exists a rule that is a universal AERM and stable it is consistent, we simply use Lemma 15.

As a final note, the following example shows that while learnability is equivalent to the existence of stable and consistent AERM's (Theorem 7 and Theorem 9), there might still exist other learning rules, which are neither stable, nor generalize, nor AERM's. In this sense, our results characterize learnability, but do not characterize all learning rules which "work".

Example 2 *There exists a learning problem with a universally consistent learning rule, which is not average-RO stable, generalizing nor an AERM.*

Proof Let the instance space be $[0,1]$. Let the hypothesis space consist of all finite subsets of $[0,1]$, and the objective function be the indicator function $f(\mathbf{h},z) = \mathbb{1}_{[z\in\mathbf{h}]}$. Consider the following learning rule: given a sample $S \subseteq [0,1]$, the learning rule checks if there are any two identical instances in the sample. If so, the learning rule returns the empty set $\emptyset$. Otherwise, it returns the sample.

Consider any continuous distribution on $[0,1]$. In that case, the probability of having two identical instances is 0. Therefore, the learning rule always returns a countable non-empty set $\mathbf{A}(S)$, with $F_S(\mathbf{A}(S)) = 1$, while $F_S(\emptyset) = 0$ (so it is not an AERM) and $F(\mathbf{A}(S)) = 0$ (so it does not generalize). Also, $f(\mathbf{A}(S), z_i) = 1$ while $f(\mathbf{A}(S^{(i)}), z_i) = 0$ with probability 1, so it is not average-RO stable either.

However, the learning rule is universally consistent. If the underlying distribution is continuous on $[0,1]$, then the returned hypothesis is S, which is countable hence , $F(S) = 0 = \inf_{\mathbf{h}} F(\mathbf{h})$. For discrete distributions, let M_1 denote the proportion of instances in the sample which appear exactly once, and let M_0 be the probability mass of instances which did not appear in the sample. Using (McAllester and Schapire, 2000, Theorem 3), we have that for any δ, it holds with probability at least $1-\delta$ over a sample of size m that

$$|M_0 - M_1| \leq O\left(\frac{\log(m/\delta)}{\sqrt{m}}\right),$$

uniformly for any discrete distribution. If this occurs, then either $M_1 < 1$, or $M_0 \geq 1 - O(\log(m/\delta)/\sqrt{m})$. But in the first event, we get duplicate instances in the sample, so the returned hypothesis is the optimal $\emptyset$, and in the second case, the returned hypothesis is the sample, which has a total probability mass of at most $O(\log(m/\delta)/\sqrt{m})$, and therefore $F(\mathbf{A}(S)) \leq O(\log(m/\delta)/\sqrt{m})$. As a result, regardless of the underlying distribution, with probability of at least $1-\delta$ over the sample,

$$F(\mathbf{A}(S)) \leq O\left(\frac{\log(m/\delta)}{\sqrt{m}}\right).$$

Since the r.h.s. converges to 0 with m for any δ, it is easy to see that the learning rule is universally consistent. ■

6. Randomization, Convexification, and a Generic Learning Algorithm

The strongest result we were able to obtain for characterizing learnability so far is Theorem 7, which stated that a problem is learnable if and only if there exists a universally uniform-RO stable AERM. In fact, this result was obtained under the assumption that the learning rule $\mathbf{A}$ is deterministic: given a fixed sample S, $\mathbf{A}$ returns a single specific hypothesis $\mathbf{h}$. However, we might relax this assumption and also consider *randomized* learning rules: given any fixed S, $\mathbf{A}(S)$ returns a distribution over the hypothesis class $\mathcal{H}$.

With this relaxation, we will see that we can obtain a stronger version of Theorem 7, and even provide a generic learning algorithm (at least for computationally unbounded learners) which successfully learns any learnable problem.

6.1 Stronger Results with Randomized Learning Rules

For simplicity, we will override the notations $f(\mathbf{A}(S),\mathbf{z})$, $F(\mathbf{A}(S))$ and $F_S(\mathbf{A}(S))$ to mean $\mathbb{E}_{\mathbf{h}\sim\mathbf{A}(S)}[f(\mathbf{h},\mathbf{z})]$, $\mathbb{E}_{\mathbf{h}\sim\mathbf{A}(S)}[F(\mathbf{h})]$ and $\mathbb{E}_{\mathbf{h}\sim\mathbf{A}(S)}[F_S(\mathbf{h})]$. In other words, $\mathbf{A}$ returns a distribution over $\mathcal{H}$ and $f(\mathbf{A}(S),\mathbf{z})$ for some fixed $S,\mathbf{z}$ is the expected loss of a random hypothesis picked according to that distribution, with respect to $\mathbf{z}$. Similarly, $F(\mathbf{A}(S))$ for some fixed S is the expected generalization error, and $F_S(\mathbf{A}(S))$ is the expected empirical risk on the fixed sample S. With this slight abuse of notation, all our previous definitions hold. For instance, we still define a learning rule $\mathbf{A}$ to be consistent with rate $\varepsilon_{\text{cons}}(m)$ if $\mathbb{E}_{S\sim\mathcal{D}^m}[F(\mathbf{A}(S))-F^*]\leq\varepsilon_{\text{cons}}(m)$, only now we actually mean

$$\mathbb{E}_{S\sim\mathcal{D}^m}\left[\mathbb{E}_{\mathbf{h}\sim\mathbf{A}(S)}[F(\mathbf{h})-F^*]\right]\leq\varepsilon_{\text{cons}}(m).$$

The definitions for AERM, generalization etc. also hold with this subtle change in meaning.

An alternative way to view randomization is as a method to *linearize* the learning problem. In other words, randomization implicitly replaces the arbitrary hypothesis class $\mathcal{H}$ by the space of probability distributions over $\mathcal{H}$,

$$\mathcal{M}=\left\{\alpha:\mathcal{H}\to[0,1]\ \text{ s.t. }\int\alpha[\mathbf{h}]=1\right\},$$

and replaces the arbitrary function $f(\mathbf{h};\mathbf{z})$ by a *linear* function in its first argument

$$f(\alpha;\mathbf{z})=\mathbb{E}_{\mathbf{h}\sim\alpha}[f(\mathbf{h},\mathbf{z})]=\int f(\mathbf{h};\mathbf{z})\alpha[\mathbf{h}]\ .$$

Linearity of the loss and convexity of $\mathcal{M}$ are the key mechanism which allows us to obtain our stronger results. Moreover, if the learning problem is already convex (i.e., f is convex and $\mathcal{H}$ is covex), we can achieve the same results using a deterministic learning rule, as the following claim demonstrates:

Claim 21 *Assume that the hypothesis class $\mathcal{H}$ is convex subset of a vector space, such that $\mathbb{E}_{\mathbf{h}\sim\mathbf{A}(S)}[\mathbf{h}]$ is a well-defined element of $\mathcal{H}$ for any S. Moreover, assume that $f(\mathbf{h};\mathbf{z})$ is convex in $\mathbf{h}$. Then from any (possibly randomized) learning rule $\mathbf{A}$, it is possible to construct a deterministic learning rule $\mathbf{A}'$, such that $f(\mathbf{A}'(S),\mathbf{z})\leq f(\mathbf{A}(S),\mathbf{z})$ for any $S,\mathbf{z}$. As a result, it also holds that $F_S(\mathbf{A}'(S))\leq F_S(\mathbf{A}(S))$ and $F(\mathbf{A}'(S))\leq F(\mathbf{A}(S))$.*

Proof Given a sample S, define $\mathbf{A}'(S;\mathbf{z})$ as the single hypothesis $\mathbb{E}_{\mathbf{h}\sim\mathbf{A}(S)}[\mathbf{h}]$. The proof of the theorem is immediate by Jensen's inequality: since $f()$ is convex in its first argument,

$$f(\mathbf{A}'(S);\mathbf{z})=f(\mathbb{E}_{\mathbf{h}\sim\mathbf{A}(S)}[\mathbf{h}],\mathbf{z})\leq\mathbb{E}_{\mathbf{h}\sim\mathbf{A}(S)}[f(\mathbf{h},\mathbf{z})],$$

where the r.h.s. is in fact $f(\mathbf{A}(S),\mathbf{z})$ by the abuse of notation we have defined previously. ■

Although linearization is the real mechanism at play here, we find it more convenient to display our results and proofs in the language of randomized learning rules.

Allowing randomization allows us to obtain results with respect to the following very strong notion of stability:[4]

Definition 22 *A rule $\mathbf{A}$ is* **strongly-uniform-RO stable** *with rate $\varepsilon_{\text{stable}}(m)$ if for all samples S of m points, for all i, and any $\mathbf{z}',\mathbf{z}'_i\in\mathcal{Z}$, it holds that*

$$\left|f(\mathbf{A}(S^{(i)});\mathbf{z}')-f(\mathbf{A}(S);\mathbf{z}')\right|\leq\varepsilon_{\text{stable}}(m).$$

The strengthening of Theorem 7 that we will prove here is the following:

4. This definition of stability is very similar to the so-called "uniform stability", discussed in Bousquet and Elisseeff (2002), although Bousquet and Elisseeff (2002) consider deterministic learning rules. See Appendix A for more details.

Theorem 23 *A learning problem is learnable if and only if there exists a (possibly randomized) learning rule which is an always AERM and strongly-uniform-RO stable.*

Compared to Theorem 7, we have replaced universal AERM by the stronger notion of an always AERM, and uniform-RO stability by strongly-uniform-RO stability. This makes the result strong enough to formulate a generic learning algorithm, as we will see later on.

The theorem is an immediate consequence of Theorem 7 and the following lemma:

Lemma 24 *For any deterministic learning rule* $\mathbf{A}$*, there exists a randomized learning rule* $\mathbf{A}'$ *such that:*

- *For any* $\mathcal{D}$*, if* $\mathbf{A}$ *is* $\varepsilon_{\text{cons}}$*-consistent under* $\mathcal{D}$ *then* $\mathbf{A}'$ *is* $\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)$ *consistent under* $\mathcal{D}$*.*
- $\mathbf{A}'$ *universally generalizes with rate* $4B/\sqrt{m}$*.*
- *If* $\mathbf{A}$ *is uniform-RO stable with rate* $\varepsilon_{\text{stable}}(m)$*, then* $\mathbf{A}'$ *is strongly-uniform-RO stable with rate* $\varepsilon_{\text{stable}}(\lfloor\sqrt{m}\rfloor)$*.*
- *If* $\mathbf{A}$ *is universally* $\varepsilon_{\text{cons}}$*-consistent, then* $\mathbf{A}'$ *is an always AERM with rate* $2\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)$*.*

Moreover, $\mathbf{A}'$ *is a symmetric learning rule (it does not depend on the order of elements in the sample on which it is applied).*

Proof Consider the learning rule A' which given a sample S, returns a uniform distribution over $A(S')$, where S' ranges over all subsets of S of size $\lfloor\sqrt{m}\rfloor$.

The fact that $\mathbf{A}'$ is symmetric is trivial. We now prove the other assertions in the lemma.

$\mathbf{A}'$ *is consistent:* First note that $F(\mathbf{A}'(S)) = \mathbb{E}_{S'}\left[F(\mathbf{A}(S'))\right]$, and so:

$$\mathbb{E}_S\left[\left|F(\mathbf{A}'(S)) - F^*\right|\right] \;\le\; \mathbb{E}_{S,S'}\left[\left|F(\mathbf{A}(S')) - F^*\right|\right] \;=\; \mathbb{E}_{[S']}\left[\mathbb{E}_{S|[S']}\left[\left|F(\mathbf{A}(S')) - F^*\right|\right]\right]$$

where $[S']$ designates a choice of indices for S'. This decomposition of the random choice of S' (e.g., first deciding on the indices and only then sampling S) allows us think of $[S']$ and S as statistically independent. Given a fixed choice of indices $[S']$, S' is simply an i.i.d. sample of size $\lfloor\sqrt{m}\rfloor$. Therefore, if $\mathbf{A}$ is consistent, $|F(\mathbf{A}(S')) - F^*| \le \varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)$, this holds for any possible fixed $[S']$, and therefore

$$\mathbb{E}_{[S']}\left[\mathbb{E}_{S|[S']}\left[\left|F(\mathbf{A}(S')) - F^*\right|\right]\right] \;=\; \mathbb{E}_{[S']}\left[\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)\right] \;\le\; \varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor).$$

$\mathbf{A}'$ *generalizes:* For convenience, let $b(S,S') = |F_S(\mathbf{A}(S')) - F(\mathbf{A}(S'))|$. Using similar arguments and notation as above:

$$\begin{aligned}
&\mathbb{E}_S\left[\left|F_S(\mathbf{A}'(S)) - F(\mathbf{A}'(S))\right|\right] \\
&\le \mathbb{E}_{[S']}\left[\mathbb{E}_{S|[S']}\left[b(S,S')\right]\right] \\
&\le \mathbb{E}_{[S']}\left[\mathbb{E}_{S|[S']}\left[\frac{\lfloor\sqrt{m}\rfloor}{m} b(S',S')\right] \;+\; \mathbb{E}_{S|[S']}\left[\left(1 - \frac{\lfloor\sqrt{m}\rfloor}{m}\right) b(S\setminus S', S')\right]\right] \\
&\le \mathbb{E}_{[S']}\left[\frac{\lfloor\sqrt{m}\rfloor}{m} 2B + \left(1 - \frac{\lfloor\sqrt{m}\rfloor}{m}\right) \frac{B}{\sqrt{m - \lfloor\sqrt{m}\rfloor} + 1}\right],
\end{aligned}$$

where the last line follows from Lemma 12 and the fact that $b(S,S') \le 2B$ for any S, S'. It is not hard to show that the expression above is at most $4B/\sqrt{m}$, assuming $m \ge 1$.

$\mathbf{A}'$ *is strongly-uniform-RO stable:* For any sample S, any i and replacement instance $\mathbf{z}_i$, and any instance $\mathbf{z}'$, we have that

$$\left|f(\mathbf{A}'(S^{(i)}); \mathbf{z}') - f(\mathbf{A}'(S); \mathbf{z}')\right| \;\le\; \mathbb{E}_{S'}\left[\left|f(\mathbf{A}(S'^{(i)}); \mathbf{z}') - f(\mathbf{A}(S'); \mathbf{z}')\right|\right],$$

where we take $S'^{(i)}$ in the expectation to mean S' if $i \notin [S']$. Notice that if $i \notin [S']$, then $f(\mathbf{A}(S'^{(i)});\mathbf{z}_i) - f(\mathbf{A}(S');\mathbf{z}_i)$ is trivially 0. Thus, we can upper bound the expression above by

$$\mathbb{E}_{S'}\left[\left|f(\mathbf{A}(S'^{i});\mathbf{z}') - f(\mathbf{A}(S');\mathbf{z}')\right| \;\middle|\; i \in [S']\right].$$

Since S' is chosen uniformly over all $\lfloor\sqrt{m}\rfloor$-subsets of S, all permutations of $[S']$ are equally happen to occur, and therefore the above is equal to

$$\mathbb{E}_{S'}\left[\frac{1}{\lfloor\sqrt{m}\rfloor}\sum_{j\in S'}\left|f(\mathbf{A}(S'^{(j)});\mathbf{z}') - f(\mathbf{A}(S');\mathbf{z}')\right|\right] \;\leq\; \mathbb{E}_{S'}\left[\varepsilon_{\text{stable}}(\lfloor\sqrt{m}\rfloor)\right] \;=\; \varepsilon_{\text{stable}}(\lfloor\sqrt{m}\rfloor).$$

$\mathbf{A}'$ *is an always AERM:* For any fixed sample S, we note that

$$\begin{aligned}|F_S(\mathbf{A}'(S)) - F_S(\hat{\mathbf{h}}_S)| \;&=\; \mathbb{E}_{S'}\left[F_S(\mathbf{A}(S')) - F_S(\hat{\mathbf{h}}_S)\right]\\ &= \mathbb{E}_{S'\sim\mathcal{U}(S)^{\lfloor\sqrt{m}\rfloor}}\left[F_S(\mathbf{A}(S')) - F_S(\hat{\mathbf{h}}_S) \mid \text{no dups}\right],\end{aligned}$$

where $\mathcal{U}(S)^{\lfloor\sqrt{m}\rfloor}$ signifies the distribution of i.i.d. samples of size $\lfloor\sqrt{m}\rfloor$, picked uniformly at random (with replacement) from $\lfloor\sqrt{m}\rfloor$, and 'no dups' signifies the event that no element in S was picked twice. By the law of total expectation, this is at most

$$\frac{\mathbb{E}_{S'\sim\mathcal{U}(S)^{\lfloor\sqrt{m}\rfloor}}\left[F_S(\mathbf{A}(S')) - F_S(\hat{\mathbf{h}}_S)\right]}{\mathbb{P}\left[\text{no dups}\right]}.$$

Since the learning rule $\mathbf{A}$ is universally consistent, it is in particular consistent with respect to the distribution $\mathcal{U}(S)$, and therefore the expectation in the expression above is at most $\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)$. As to $\mathbb{P}\left[\text{no dups}\right]$, an analysis identical to the one performed in the proof of Lemma 16 (see Equation (13)) implies that it is at least $1-(\lfloor\sqrt{m}\rfloor)^2/m \geq 1/2$. Overall, we get that $F_S(\mathbf{A}'(S)) - F_S(\hat{\mathbf{h}}_S) \leq 2\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)$, so in particular

$$\frac{\mathbb{E}_{S'\sim\mathcal{U}(S)^{\lfloor\sqrt{m}\rfloor}}\left[F_S(\mathbf{A}(S')) - F_S(\hat{\mathbf{h}}_S)\right]}{\mathbb{P}\left[\text{no dups}\right]} \leq 2\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor),$$

from which the claim follows.

■

6.2 A Generic Learning Algorithm

Recall that a symmetric learning rule $\mathbf{A}$ is such that $\mathbf{A}(S) = \mathbf{A}(S')$ whenever S, S' are identical samples up to permutation. When we deal with randomized learning rules, we assume that the distribution of $\mathbf{A}(S)$ is identical to the distribution of $\mathbf{A}(S')$. Also, let $\bar{\mathcal{H}}$ denote the set of all distributions on $\mathcal{H}$. An element $\bar{\mathbf{h}} \in \bar{H}$ will be thought of as a possible outcome of a randomized learning rule.

Consider the following learning rule: given a sample size m, find a minimizer over all symmetric[5] functions $\mathbf{A} : \mathcal{Z}^m \to \bar{\mathcal{H}}$ of

$$\sup_{S\in\mathcal{Z}^m}\left(F_S(\mathbf{A}(S)) - F_S(\hat{\mathbf{h}}_S)\right) \;+\; \sup_{S\in\mathcal{Z}^m,\mathbf{z}'}\left|f(\mathbf{A}(S);\mathbf{z}') - f(\mathbf{A}(S^{(i)});\mathbf{z}')\right|, \tag{18}$$

with i being an arbitrary fixed element in $\{1,\ldots,m\}$. Once such a function $\mathbf{A}$ is found, return $\mathbf{A}_m(S)$.

5. The algorithm would still work, with slight modifications, if we minimize over all functions - symmetric or not. However, the search space would be larger.

Theorem 25 *If a learning problem is learnable (namely, there exist a universally consistent learning rule with rate $\varepsilon_{\text{cons}}(m)$), the learning algorithm described above is universally consistent with rate*

$$4\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)+\frac{8B}{\sqrt{m}}.$$

Proof By Lemma 24, if a learning problem is learnable, there exists a (possibly randomized) symmetric learning rule $\mathbf{A}'$, which is an always AERM and strongly-uniform-RO stable. More specifically, we have that

$$\sup_{S\in\mathcal{Z}^m}\left(F_S(\mathbf{A}'(S))-F_S(\hat{\mathbf{h}}_S)\right)\leq 2\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor),$$

as well as

$$\sup_{S\in\mathcal{Z}^m,\mathbf{z}'}\left|f(\mathbf{A}'(S);\mathbf{z}')-f(\mathbf{A}'(S^{(i)});\mathbf{z}')\right|\leq\frac{4B}{\sqrt{m}}.$$

In particular, there exists some symmetric $\mathbf{A}:Z^m\to\bar{\mathcal{H}}$, for which the expression in Equation (18) is at most

$$2\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)+\frac{4B}{\sqrt{m}}.$$

Therefore, by definition, the $\mathbf{A}$ found satisfies

$$\sup_{S\in\mathcal{Z}^m}\left(F_S(\mathbf{A}_m(S))-F_S(\hat{\mathbf{h}}_S)\right)\ \leq\ 2\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)+\frac{4B}{\sqrt{m}},\tag{19}$$

as well as

$$\sup_{S\in\mathcal{Z}^m}\left|f(\mathbf{A}_m(S);\mathbf{z}')-f(\mathbf{A}_m(S^{(i)});\mathbf{z}')\right|\ \leq\ 2\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)+\frac{4B}{\sqrt{m}}.\tag{20}$$

In Theorem 9, we have seen that a universally average-RO stable AERM learning rule has to be universally consistent. The inequalities above essentially say that $\mathbf{A}$ is in fact both strongly-uniform-RO stable (and in particular, universally average-RO stable) and an AERM, and thus is a universally consistent learning rule. Formally speaking, this is not entirely accurate, because $\mathbf{A}$ is defined only with respect to samples of size m, and hence is not formally a learning rule which can be applied to samples of any size. However, the analysis we have done earlier in fact carries through also for learning rules $\mathbf{A}$ which are defined just on a specific sample size m. In particular, the analysis of Lemma 11 and Lemma 15 hold verbatim for $\mathbf{A}$ (with trivial modifications due to the fact that $\mathbf{A}$ is randomized), and together imply that since Equation (19) and Equation (20) hold, then

$$\mathbb{E}\left[F(\mathbf{A}(S))-F^*\right]\leq 4\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)+\frac{8B}{\sqrt{m}}.$$

Therefore, our learning algorithm is consistent with rate $4\varepsilon_{\text{cons}}(\lfloor\sqrt{m}\rfloor)+\frac{8B}{\sqrt{m}}$. ■

The main drawback of the algorithm we described is that it is completely infeasible: in practice, we cannot hope to efficiently perform minimization of Equation (18) over all functions from $\mathcal{Z}^m$ to $\bar{\mathcal{H}}$. Nevertheless, we believe it is conceptually important for three reasons: First, it hints that generic methods to develop learning algorithms might be possible in the General Learning Setting (similar to the more specific supervised classification setting); Second, it shows that stability might play a crucial role in the way such methods will work; And third, that stability might act in a similar manner to regularization. Indeed, Equation (18) can be seen as a "regularized ERM" in the space of learning rules (i.e., functions from samples to hypotheses): if we take just the first term in Equation (18), $\sup_{S\in\mathcal{Z}^m}\left(F_S(\mathbf{A}(S))-F_S(\hat{\mathbf{h}}_S)\right)$, then its minimizer is trivially the ERM learning rule. If we take just the second term in Equation (18), $\sup_{S\in\mathcal{Z}^m,\mathbf{z}}\left|f(\mathbf{A}(S);\mathbf{z}')-f(\mathbf{A}(S^{(i)});\mathbf{z}')\right|$, then its minimizers are trivial learning rules which return the same hypothesis irrespective of the training sample. Minimizing a sum of both terms forces us to choose a learning rule which is an "almost"-ERM but also stable - a learning rule which must exist if the problem is learnable at all, as Theorem 23 proves.

In any case, using these results and intuitions to design a generic, *practical* method to learn in the General Learning Setting - remains a very interesting open problem.

7. High Confidence Learnability

So far, we have presented all our results in terms of expectation: namely, the rate at which the expected risk converges to the lowest possible risk. By Markov's inequality, we can always convert these bounds to bounds which hold with probability $1-\delta$ over the sample, and the bounds depend linearly on $1/\delta$. However, in supervised classification, if we have learnability at all, then we have learnability at rates which are logarithmic in $1/\delta$. Can such results be attained in the General Learning Setting?

Fortunately, there is a generic method already known in the literature ("Boosting the Confidence", see Schapire, 1989) which allows us to convert any learning algorithm with linear dependence on δ to an algorithm with logarithmic dependence on $1/\delta$, at a certain price in terms of the sample complexity. This technique is reviewed below.

Moreover, we show that such conversions can in fact be necessary: we give a learning problem which is learnable with an ERM algorithm, and the ERM is stable, but the dependence on the confidence parameter δ cannot be better than linear. This shows that both learnability and stability (under our definitions) of the ERM learning rule are not sufficient to ensure logarithmic dependence on $1/\delta$. Also, this gives a nice illustration to the fundamental differences between the General Learning Setting and supervised classification, where in the latter case learnability implies logarithmic dependence on $1/\delta$.

Theorem 26 *Let* $\mathbf{A}$ *be a universally consistent learning rule with rate* $\varepsilon_{\text{cons}}(m)$*, namely that*

$$\mathbb{E}_{S\sim\mathcal{D}^m}\left[F(\mathbf{A}(S))-F^*\right]\leq\varepsilon_{\text{cons}}(m). \tag{21}$$

Then there exists another universally consistent learning rule $\mathbf{A}'$ *such that with probability at least* $1-\delta$ *over a sample* S *of size* m*,*

$$F(\mathbf{A}'(S))-F^*\leq e\varepsilon_{\text{cons}}\left(\frac{m}{\log(2/\delta)+1}\right)+2B\sqrt{\frac{\log(2/\delta)+\log(\log(2/\delta))}{2m}}$$

Proof Applying Markov's inequality on Equation (21), we have with probability at least $1-1/e$ over a sample S of size m that

$$F(\mathbf{A}(S))-F^*\leq e\varepsilon_{\text{cons}}(m). \tag{22}$$

Now, define the learning rule $\mathbf{A}'$ as follows: given a sample of size m, split it randomly into $a+1$ parts $S_1,\ldots,S_{a+1}$ of size $m/(a+1)$ each (where a is a constant to be determined later). Apply $\mathbf{A}$ separately on $S_1,\ldots,S_a$, to create a hypotheses $\mathbf{A}(S_1),\ldots,\mathbf{A}(S_a)$. Now, return the hypothesis $\mathbf{A}(S_t)$ which minimizes $F_{S_{a+1}}(\mathbf{A}(S_t))$ (namely, the hypothesis with lowest empirical risk on S_{a+1}), where ties are broken arbitrarily. By Equation (22), we have for any S_t separately that with probability at least $1-1/e$,

$$F(\mathbf{A}(S_t))-F^*\leq e\varepsilon_{\text{cons}}\left(\frac{m}{a+1}\right).$$

Since $F(\mathbf{A}(S_1)),\ldots,F(\mathbf{A}(S_a))$ are independent random variables, we have that with probability at least $1-(1/e)^a$, there exists at least one S_t such that

$$F(\mathbf{A}(S_t))-F^*\leq e\varepsilon_{\text{cons}}\left(\frac{m}{a+1}\right).$$

Assume w.l.o.g. that this holds for S_1. Using Hoeffding's inequality and a union bound, it also holds with probability at least $1-\delta_1$ over S that

$$F_{S_{a+1}}(\mathbf{A}(S_1))-F(\mathbf{A}(S_1))\leq B\sqrt{\frac{\log(2a/\delta_1)}{2m}},$$

and also

$$F(\mathbf{A}(S_t))-F_{S_{a+1}}(\mathbf{A}(S_t))\leq B\sqrt{\frac{\log(2a/\delta_1)}{2m}}$$

simultaneously for every $t = 2,\ldots,a$. If this happens, it means that we will pick a hypothesis whose risk is at most $2B\sqrt{\log(2a/\delta_1)/2m}$ larger than $F(\mathbf{A}(S_1))$. Overall, we have that with probability at least $1-\delta_1-(1/e)^a$,

$$F(\mathbf{A}'(S)) - F^* \leq e\varepsilon_{\text{cons}}\left(\frac{m}{a+1}\right) + 2B\sqrt{\frac{\log(2a/\delta_1)}{2m}}\ .$$

Picking $a = \log(2/\delta)$ and $\delta_1 = \delta/2$, we get that with probability at least $1-\delta$,

$$F(\mathbf{A}'(S)) - F^* \leq e\varepsilon_{\text{cons}}\left(\frac{m}{\log(2/\delta)+1}\right) + 2B\sqrt{\frac{\log(4/\delta)+\log(\log(4/\delta))}{2m}}$$

as required. ■

After we have seen how to convert a low-confidence learning rule (linear in δ) to a high-confidence learning rule (logarithmic in δ), we show that such conversions might actually be necessary, in sharp contrast to supervised classification.

Example 3 *There exists a learning problem where any ERM algorithm is universally consistent and average-RO stable with rates $\Theta(1/\sqrt{m})$, but for any ERM algorithm,*

$$\mathbb{P}\left[F(\hat{\mathbf{h}}_S) - F^* = 1\right] = \Theta\left(\frac{1}{\sqrt{m}}\right). \tag{23}$$

The $\Theta(\cdot)$ notation hides only absolute constants.

This example implies that no high-confidence bound is possible, at least without foregoing polynomial dependence on m. To see this, note that a high-confidence result corresponds to $\mathbb{P}\left[F(\hat{\mathbf{h}}_S) - F^*\right] > \varepsilon)$ decreasing exponentially in m for any fixed $\varepsilon > 0$, while in the case above we only have convergence at the rate of $1/\sqrt{m}$.

Proof Consider the instance space $\mathcal{X}\times\mathcal{Y}\times\mathcal{Z} = [0,1]\times\{-1,+1\}\times\{-1,+1\}$, with any joint distribution such that $p(y,z|x)$ for any x is uniform on $\{-1,+1\}^2$, and the marginal distribution on $\mathcal{X}$ is continuous.

Consider the hypothesis class $\mathcal{H} = \mathcal{G}\cup\mathcal{B}$, where $\mathcal{G}$ consists of the constant function 1 and the constant function -1 over $[0,1]$, and $\mathcal{B}$ consists of all functions $\mathbf{h} : [0,1] \mapsto \{-1,0,+1\}$, such that each $\mathbf{h}(\cdot)$ equals 0 on all but a non-empty finite subset of $[0,1]$, and is uniformly either $+1$ or -1 on this finite subset.

Finally, define the objective function as

$$f(\mathbf{h},(x,y,z)) = \left(\mathbf{1}(\mathbf{h}\in\mathcal{G})y + \frac{\mathbf{1}(\mathbf{h}\in\mathcal{B})z}{2|\mathbf{h}|}\right)\mathbf{h}(x) + \mathbf{1}(\mathbf{h}(x)=0),$$

where $|\mathbf{h}| = |\{x\in[0,1] : \mathbf{h}(x)\neq 0\}|$ (namely, the number of points in $[0,1]$ on which the function $h(\cdot)$ is not zero). For $\mathbf{h}\in\mathcal{G}$, where the number of such points is infinite, we take $|\mathbf{h}| = \infty$.

First, notice that for any $\mathbf{h}\in\mathcal{G}$, $F(\mathbf{h}) = 0$, and for any $\mathbf{h}\in B$, $F(\mathbf{h}) = 1$. Thus, we can think of $\mathcal{G}$ as the set of "good" hypotheses, and $\mathcal{B}$ as the set of 'bad" hypotheses. Our goal is to show that any ERM will pick a hypothesis from $\mathcal{B}$ with probability $\Theta(1/\sqrt{m})$.

We need to do a bit of case-by-case analysis. Let $(x_1,y_1,z_1),\ldots,(x_m,y_m,z_m)$ be the sample. If $\sum_{i=1}^m y_i \neq 0$, then using hypotheses in G, it is possible to achieve an empirical risk of

$$-\left|\sum_{i=1}^m y_i\right| \leq -1,$$

while using hypotheses in B, it is only possible to achieve an empirical risk of

$$\frac{\sum_{i=1}^m z_i\mathbf{h}(x_i)}{2|\mathbf{h}|} + \sum_{i=1}^m \mathbf{1}(\mathbf{h}(x_i)=0) \geq -\frac{1}{2}.$$

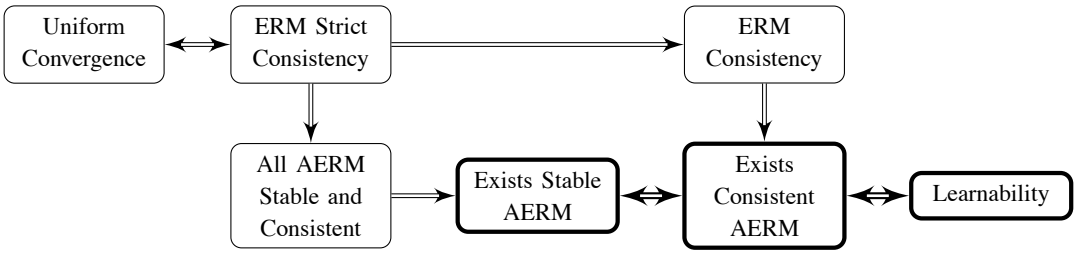

Figure 2: Implications of various properties of learning problems. Consistency refers to univeral consistency and stability refers to universal uniform-RO stability.

Thus, with probability $1-\Theta(1/\sqrt{m})$ (the probability that $\sum_{i=1}^{m} y_i \neq 0$ in the sample), any ERM algorithm will pick $\hat{\mathbf{h}}_S \in G$.

If $\sum_{i=1}^{m} y_i = 0$, then any $\mathbf{h} \in G$ achieves an empirical objective value of 0. On the other hand, unless $\sum_{i=1}^{m} z_i = 0$, we can choose some $\mathbf{h} \in B$, which is non-zero on all points in the sample, and achieves an empirical risk smaller than 0. The probability that $\sum_{i=1}^{m} y_i = 0$ and $\sum_{i=1}^{m} z_i \neq 0$ is $\Theta(1/\sqrt{m})(1-\Theta(1/\sqrt{m}))$, or $\Theta(1/\sqrt{m})$.

So we have that any ERM picks $\hat{\mathbf{h}}_S \in G$ with probability $1-\Theta(1/\sqrt{m})$, and some $\hat{\mathbf{h}}_S \in B$ with probability $\Theta(1/\sqrt{m})$, from which the consistency rate and Equation (23) in the theorem statement follows. Finally, note that replacing a single instance in the training set will lead to the ERM picking a different hypothesis, only if $\sum_{i=1}^{m} y_i = 0$ before or after the replacement. The probability for getting a training set where this happens is $O(1/\sqrt{m})$, and from this it is easy to see that the ERM is average-RO stable with rate $O(1/\sqrt{m})$. ■

8. Discussion and Conclusions

In the familiar setting of supervised classification problems, the question of learnability is reduced to that of uniform convergence of empirical risks to their expectations. Therefore, for the purposes of establishing learnability, there is no need to look beyond the ERM.

In this paper, we showed that in the General Learning Setting, which includes more general problems, this equivalence does not hold, and the situation is substantially more complex. ERM might work without any uniform convergence, and learnability might be possible only with a non-ERM algorithm. We are therefore in need of a new understanding of the question of learnability, that applies more broadly than just to supervised classification.

In studying learnability in the General Setting, Vapnik (1995) focuses solely on empirical risk minimization, which we have seen to be insufficient for understanding learnability. Furthermore, for empirical risk minimization, Vapnik establishes uniform convergence as a necessary and sufficient condition not for ERM consistency, but rather for *strict* consistency of the ERM. We have seen that even in rather non-trivial problems, where the ERM is consistent and generalizes, strict consistency does not hold. This perhaps gives an indication that strict consistency might be too strict.

On the other hand, we have seen that stability is both a sufficient and necessary condition for learning, even in the General Learning Setting where uniform convergence fails to characterize learnability. A previous stability-based characterization (Mukherjee et al., 2006) relied on uniform convergence and thus applied only to restricted setting. Extending the characterization beyond these settings is particularly interesting, since for supervised classification the question of learnability is already essentially solved. This also allows us to frame stability as the core condition guaranteeing learnability, with uniform convergence only a sufficient, but not necessary, condition for stability (see Figure 2).

In studying the question of learnability and its relation to stability, we encountered several differences between this more general setting, and settings such as supervised classification where learnability is equivalent to uniform convergence. We summarize some of these distinctions:

- Perhaps the most important distinction is that in the General Setting learnability might be possible only with a non-ERM. In this paper we establish that if a problem is learnable, although it might not be learnable with an ERM, it must be learnable with some AERM. And so, in the General Setting we must look beyond empirical risk minimization, but not beyond asymptotic empirical risk minimization.

- In supervised classification, if one AERM is universally consistent then all AERMs are universally consistent. In the General Setting we must choose the AERM carefully.

- In supervised classification, a universally consistent rule must also generalize and be AERM. In the General Setting, a universally consistent rule need not generalize nor be an AERM, as example 2 demonstrates. However, Theorem 10 establishes that, even in the General Setting, if a rule is universally consistent *and* generalizing then it must be an AERM. This gives us another reason to not look beyond asymptotic empirical risk minimization, even in the General Setting.

  The above distinctions can also be seen through Corollary 19, which is concerned with the relationship between AERM, consistency and generalization in learnable problems. In the General Setting, any two conditions imply the other, but it is possible for any one condition to exist without the others. In supervised classification, if a problem is learnable then generalization always holds (for any rule), and so universal consistency and AERM imply each other.
- In supervised classification, ERM inconsistency for some distribution is enough to establish non-learnability. Establishing non-learnability in the General Setting is trickier, since one must consider all AERMs. We show how Corollary 19 can provide a *certificate* for non-learnability, in the form of a rule that is consistent and an AERM for some specific distribution, but does not generalize (Example 1).

- In supervised classification, any learnable problem is learnable with an ERM, *and* the ERM "works" with high-confidence (namely, $F(\hat{\mathbf{h}}_S) - F^*$ can be bounded with probability $1-\delta$ by an expression with logarithmic dependence on $1/\delta$). In Section 7 we have seen that in the General Learning Setting, even if the ERM is universally consistent, high-confidence bounds for the ERM might be impossible to obtain.

We have begun exploring the issue of learnability in the General Setting, and uncovered important relationships between learnability and stability. But many problems are left open, some of which are listed below.

First, is it possible to come up with well-known machine learning applications, where learnability is achievable despite uniform convergence failing to hold?

In Section 6.2, we have managed to obtain a completely generic learning algorithm: an algorithm which in principle allows us to learn any learnable problem. However, the algorithm suffers from the severe drawback that in general, it requires unbounded computational power. Can we derive an efficient algorithm, or characterize classes of learning problems where our algorithm, or some other generic learning algorithm using the notion of stability, can be executed efficiently? For instance, can we always learn using a regularized ERM learning rule?

On a related vein, it would be interesting to develop learning algorithms (perhaps for specific settings rather than generic learning problems) which directly use stability in order to learn. Convex regularization is one such mechanism, as discussed in Section 4. Are there other mechanisms, which use the notion of stability in a different way?

Another issue is that even the existence of uniform-RO stable AERM (or strongly-uniform-RO stable, always-AERM allowing for convexity/randomization) is not as elegant and simple as having finite VC dimension or fat-shattering dimension. It would be very interesting to derive equivalent but more "combinatorial" conditions for learnability.

Yet another open question: We showed that existence of an uniform-RO stable AERM is necessary and sufficient for learnability (Theorem 7). However, it is possible that learnability is an equivalent to the existence of an AERM with a stronger notion of stability, without resorting to convexity/randomization as we

have done in Section 6.2. This might perhaps lead to generic learning algorithms which perform minimization over a search space more feasible than the one our algorithm (in Section 6.2) uses.

Finally, we do not know whether it is enough to consider symmetric learning rules: that is, learning rules which do not depend on the order of the instances in the training sample. Intuitively, this should be true, since the instances were sampled i.i.d. Can our characterization of learnability (e.g., existence of a uniform-RO stable AERM learning rule) be strengthened to existence of symmetric uniform-RO stable AERM learning rule, without allowing convexity/randomization?

Acknowledgments

We would like to thank Leon Bottou, Vladimir Vapnik and Tong Zhang for helpful discussions. We would also like to thank the anonymous reviewers for their detailed and helpful comments.

Appendix A. Alternative Notions of Stability

In this appendix, we discuss how our definition of stability compares to previous definitions in the literature, as well as demonstrate how subtleties involved in the precise choice of the definition can have a significant effect on the results which can be obtained.

A.1 Previous Definitions in the Literature

The existing literature on stability in learning, briefly surveyed in Section 3.2, uses many different stability measures. All of them measure the amount of change in the algorithm's output as a function of small changes to the sample on which the algorithm is run. However, they differ in how "output", "amount of change to the output", and "small changes to the sample" are defined. In Section 5, we used three stability measures. Roughly speaking, one measure (average-RO stability) is the expected change in the objective value on a particular instance, after that instance is replaced with a different instance. The second measure and third measure (uniform-RO stability and strongly-uniform-RO stability respectively) basically deal with the maximal possible change in the objective value with respect to a particular instance, by replacing a single instance in the training set. However, instead of measuring the objective value on a specific instance, we could have measured the change in the risk of the returned hypothesis, or any other distance measure between hypotheses. Instead of replacing an instance, we could have talked about adding or removing one instance from the sample, either in expectation or in some arbitrary manner. Such variations are common in the literature.

To relate our stability definitions to the ones in the literature, we note that our definitions of uniform-RO stability and strongly-uniform-RO stability are somewhat similar to uniform stability (Bousquet and Elisseeff, 2002), which in our notation is defined as $\sup_{S,\mathbf{z}} \max_i |f(\mathbf{A}(S;\mathbf{z})) - f(\mathbf{A}(S^{\setminus i});\mathbf{z})|$, where $S^{\setminus i}$ is the training sample S with instance $\mathbf{z}_i$ removed. Compared to uniform-RO stability, here we measure maximal change over any particular instance, rather than average change over all instances in the training sample. Also, we deal with removing an instance rather than replacing it. Strongly-uniform-RO stability is more similar, with the only formal difference being removal vs. replacement of an instance. However, the results for uniform stability mostly assume deterministic learning rules, while in this paper we have used strongly-uniform-RO stability solely in the context of randomized learning rules. For deterministic learning rules, the differences outlined above are sufficient to make uniform stability a strictly stronger requirement than uniform-RO stability, since it is easy to come up with learning problems and (non-symmetric) learning rules which are uniform-RO stable but not uniformly stable. Moreover, we show in this paper that uniform-RO stable AERM's characterize learnability, while it is well known that uniformly stable AERM's are not necessary for learnability (see Kutin and Niyogi, 2002). For the same reason, our notion of strongly-uniform-RO stability is apparently too strong to characterize learnability when we deal with deterministic learning rules, as opposed to randomized learning rules.

Our definition of average-RO stable is similar to "average stability" defined in Rakhlin et al. (2005), which in our notation is defined as $\mathbb{E}_{S\sim\mathcal{D}^m,\mathbf{z}'_1}\left[f(\mathbf{A}(S^{(i)});\mathbf{z}_1)-f(\mathbf{A}(S);\mathbf{z}_1)\right]$. Compared to average-RO stability, the main difference is that the change in the objective value is measured with respect to $\mathbf{z}_1$ rather than an average over $\mathbf{z}_i$ for all i, and stems from the assumption there that the learning algorithm is symmetric. Notice that in this paper we do not make such an assumption.

For an elaborate study on other stability notions and their relationships, see Kutin and Niyogi (2002).

Unfortunately, many of the stability notions in the literature are incomparable, and even slight changes in the definition radically affect their behavior. We go into this in much more detail in the following subsections.

A.2 LOO Stability vs. RO Stability

The stability definitions we have used in this paper are all based on the idea of replacing one instance in the training sample by another instance (e.g., "RO" or "replace-one" stability). An alternative set of definitions can be obtained based on *removing* one instance in the training sample (e.g., "LOO" or "leave-one-out" stability). In fact, these were the definitions used in our preliminary paper (Shalev-Shwartz et al., 2009b). Despite seeming like a small change, it turns out there is a considerable discrepancy in terms of the obtainable results, compared to RO stability. In this subsection, we wish to discuss these discrepancies, as well as show how small changes to the stability definition can materially affect its strength.

Specifically, we consider the following four LOO stability measures, each slightly weaker than the previous one. The first and last are similar to our notion of uniform-RO stability and average-RO stability respectively. However, we emphasize that RO stability and LOO stability are in general incomparable notions, as we shall see later on. Also, we note that some of these definitions appeared in previous literature. For instance, the notion of "all-i-LOO" below has been studied by several authors under different names (Bousquet and Elisseeff, 2002; Mukherjee et al., 2006; Rakhlin et al., 2005). The notation $S^{\setminus i}$ below refer to a training sample S with instance $\mathbf{z}_i$ removed.

Definition 27 *A rule* $\mathbf{A}$ *is* **uniform-LOO stable** *with rate* $\varepsilon_{\text{stable}}(m)$ *if for all samples* S *of* m *points and for all* i*:*

$$\left|f(\mathbf{A}(S^{\setminus i});\mathbf{z}_i)-f(\mathbf{A}(S);\mathbf{z}_i)\right|\leq\varepsilon_{\text{stable}}(m).$$

Definition 28 *A rule* $\mathbf{A}$ *is* **all-i-LOO stable** *with rate* $\varepsilon_{\text{stable}}(m)$ *under distribution* $\mathcal{D}$ *if for all* i*:*

$$\mathbb{E}_{S\sim\mathcal{D}^m}\left[\left|f(\mathbf{A}(S^{\setminus i});\mathbf{z}_i)-f(\mathbf{A}(S);\mathbf{z}_i)\right|\right]\leq\varepsilon_{\text{stable}}(m).$$

Definition 29 *A rule* $\mathbf{A}$ *is* **LOO stable** *with rate* $\varepsilon_{\text{stable}}(m)$ *under distribution* $\mathcal{D}$ *if*

$$\frac{1}{m}\sum_{i=1}^{m}\mathbb{E}_{S\sim\mathcal{D}^m}\left[\left|f(\mathbf{A}(S^{\setminus i});\mathbf{z}_i)-f(\mathbf{A}(S);\mathbf{z}_i)\right|\right]\leq\varepsilon_{\text{stable}}(m).$$

Definition 30 *A rule* $\mathbf{A}$ *is* **on-average-LOO stable** *with rate* $\varepsilon_{\text{stable}}(m)$ *under distribution* $\mathcal{D}$ *if*

$$\left|\frac{1}{m}\sum_{i=1}^{m}\mathbb{E}_{S\sim\mathcal{D}^m}\left[f(\mathbf{A}(S^{\setminus i});\mathbf{z}_i)-f(\mathbf{A}(S);\mathbf{z}_i)\right]\right|\leq\varepsilon_{\text{stable}}(m).$$

While some of the definitions above might look rather similar, we show below that each one is strictly stronger than the other. Example 6 is interesting in its own right, since it presents a learning problem and an AERM that is universally consistent, but not LOO stable. While this is possible in the General Learning Setting, in supervised classification every such AERM has to be LOO stable (this is essentially proven in Mukherjee et al., 2006).

Example 4 *There exists a learning problem with a universally consistent and all-i-LOO stable learning rule, but there is no universally consistent and uniform LOO stable learning rule.*

Proof This example is taken from Kutin and Niyogi (2002). Consider the hypothesis space $\{0,1\}$, the instance space $\{0,1\}$, and the objective function $f(\mathbf{h},z) = |h-z|$.

It is straightforward to verify that an ERM is a universally consistent learning rule. It is also universally all-i-LOO stable, because removing an instance can change the hypothesis only if the original sample had an equal number of 0's and 1's (plus or minus one), which happens with probability at most $O(1/\sqrt{m})$ where m is the sample size. However, it is not hard to see that the only uniform LOO stable learning rule, at least for large enough sample sizes, is a constant rule which always returns the same hypothesis h regardless of the sample. Such a learning rule is obviously not universally consistent. ■

Example 5 *There exists a learning problem with a universally consistent and LOO-stable AERM, which is not symmetric and is not all-i-LOO stable.*

Proof Let the instance space be $[0,1]$, the hypothesis space $[0,1] \cup 2$, and the objective function $f(h,z) = \mathbb{1}_{\{h=z\}}$. Consider the following learning rule $\mathbf{A}$: given a sample, check if the value z_1 appears more than once in the sample. If no, return z_1, otherwise return 2.

Since $F_S(2) = 0$, and z_1 returns only if this value constitutes $1/m$ of the sample, the rule above is an AERM with rate $\varepsilon_{\text{erm}}(m) = 1/m$. To see universal consistency, let $\mathbb{P}[z_1] = p$. With probability $(1-p)^{m-2}$, $z_1 \notin \{z_2,\ldots,z_m\}$, and the returned hypothesis is z_1, with $F(z_1) = p$. Otherwise, the returned hypothesis is 2, with $F(2) = 0$. Hence $\mathbb{E}_S[F(\mathbf{A}(S))] \leq p(1-p)^{m-2}$, which can be easily verified to be at most $1/(m-1)$, so the learning rule is consistent with rate $\varepsilon_{\text{cons}}(m) \leq 1/(m-1)$. To see LOO-stability, notice that our learning hypothesis can change by deleting z_i, $i > 1$, only if z_i is the only instance in $z_2,\ldots,z_m$ equal to z_1. So $\varepsilon_{\text{stable}}(m) \leq 2/m$ (in fact, LOO-stability holds even without the expectation). However, this learning rule is not all-i-LOO-stable. For instance, for any continuous distribution, $|f(\mathbf{A}(S^{\setminus 1}),z_1) - f(\mathbf{A}(S),z_1)| = 1$ with probability 1, so it obviously cannot be all-i-LOO-stable with respect to $i = 1$. ■

Example 6 *There exists a learning problem with a universally consistent (and on-average-LOO stable) AERM, which is not LOO stable.*

Proof Let the instance space, hypothesis space and objective function be as in Example 4. Consider the following learning rule, based on a sample $S = (z_1,\ldots,z_m)$: if $\sum_i \mathbb{1}_{\{z_i=1\}}/m > 1/2 + \sqrt{\log(4)/2m}$, return 1. If $\sum_i \mathbb{1}_{\{z_i=1\}}/m < 1/2 - \sqrt{\log(4)/2m}$, return 0. Otherwise, return $\text{Parity}(S) = (z_1 + \ldots z_m) \bmod 2$.

This learning rule is an AERM, with $\varepsilon_{\text{erm}}(m) = \sqrt{2\log(4)/m}$. Since we have only two hypotheses, we have uniform convergence of $F_S(\cdot)$ to $F(\cdot)$ for any hypothesis. Therefore, our learning rule universally generalizes (with rate $\varepsilon_{\text{gen}}(m) = \sqrt{\log(4/\delta)/2m}$), and by Theorem 9, this implies that the learning rule is also universally consistent and on-average-LOO stable.

However, the learning rule is not LOO stable. Consider the uniform distribution on the instance space. By Hoeffding's inequality, $|\sum_i \mathbb{1}_{\{z_i=1\}}/m - 1/2| \leq \sqrt{\log(4)/2m}$ with probability at least $1/2$ for any sample size m. In that case, the returned hypothesis is the parity function (even when we remove an instance from the sample, assuming $m \geq 3$). When this happens, it is not hard to see that for any i,

$$f(\mathbf{A}(S),z_i) - f(\mathbf{A}(S^{\setminus i}),z_i) = \mathbb{1}_{\{z_i=1\}}(-1)^{\text{Parity(S)}}.$$

This implies that

$$\begin{aligned}
&\mathbb{E}\left[\frac{1}{m}\sum_{i=1}^{m}\left|\left(f(\mathbf{A}(S^{\setminus i});\mathbf{z}_i)-f(\mathbf{A}(S);\mathbf{z}_i)\right)\right|\right] \qquad (24)\\
&\geq \frac{1}{2}\mathbb{E}\left[\frac{1}{m}\sum_{i=1}^{m}\mathbb{1}_{\{z_i=1\}}\left|\sqrt{\frac{\log(4)}{2m}}\geq\left|\sum_{i=1}^{m}\frac{\mathbb{1}_{\{z_i=1\}}}{m}-\frac{1}{2}\right|\right|\right]\\
&\geq \frac{1}{2}\left(\frac{1}{2}-\sqrt{\frac{\log(4)}{2m}}\right) \;\longrightarrow\; \frac{1}{4}\ ,
\end{aligned}$$

which does not converge to zero with the sample size m. Therefore, the learning rule is not LOO stable. ■

Note that the proof implies that on-average-LOO stability cannot be replaced even by something between on-average-LOO stability and LOO stability. For instance, a natural candidate would be

$$\mathbb{E}_{S\sim\mathcal{D}^m}\left[\left|\frac{1}{m}\sum_{i=1}^{m}\left(f(\mathbf{A}(S^{\setminus i});\mathbf{z}_i)-f(\mathbf{A}(S);\mathbf{z}_i)\right)\right|\right], \qquad (25)$$

where the absolute value is now over the entire sum, but inside the expectation. In the example used in the proof, Equation (25) is still lower bounded by Equation (24), which does not converge to zero with the sample size.

After showing that the hierarchy of definitions above is indeed strict, we turn to the question of what can be characterized in terms of LOO stability. In Shalev-Shwartz et al. (2009b), we show a version of Theorem 7, which asserts that a problem is learnable if and only if there is an on-average-LOO stable AERM. However, on-average-LOO stability is qualitatively much weaker than the notion of uniform-RO stability used in Theorem 7 (see Definition 4). Rather, we would expect to prove a version of the theorem with the notion of uniform-LOO stability or at least LOO stability, which are more analogous to uniform-RO stability. However, the proof of Theorem 7 does not work for these stability definitions (technically, this is because the proof relies on the sample size remaining constant, which is true for replacement stability, but not when we remove an instance as in LOO stability). We do not know if one can prove a version of Theorem 7 with an LOO stability notion stronger than on-average-LOO stability.

On the plus side, LOO stability allows us to prove the following interesting result, specific to ERM learning rules.

Theorem 31 *For an ERM the following are equivalent:*

- *Universal LOO stability.*
- *Universal consistency.*
- *Universal generalization.*

In particular, the theorem implies that LOO stability is a necessary property for consistent ERM learning rules. This parallels Theorem 9, which dealt with AERM's in general, and used RO stability. As before, we do not know how to obtain something akin to Theorem 9 with RO stability.

Proof Lemma 15 and Lemma 17 from Section 5.3.3 already tell us that for ERM's, universal consistency is equivalent to universal generalization. Moreover, Lemma 14 implies that for ERM's, generalization is equivalent to on-average generalization (see Equation (11) for the exact definition). Thus, is left to prove that for ERM's, generalization implies LOO stability, and LOO stability implies on-average generalization. stability.

First, suppose the ERM learning rule is generalizing with rate $\varepsilon_{\text{gen}}(m)$. Note that $f(\hat{\mathbf{h}}_{S^{\setminus i}}; z_i) - f(\hat{\mathbf{h}}_S; z_i)$ is always nonnegative. Therefore the LOO stability of the ERM can be upper bounded as follows:

$$\begin{aligned}
&\frac{1}{m}\sum_{i=1}^{m}\mathbb{E}\left[\left|f(\hat{\mathbf{h}}_{S^{\setminus i}}; z_i) - f(\hat{\mathbf{h}}_S; z_i)\right|\right] \\
&= \frac{1}{m}\sum_{i=1}^{m}\mathbb{E}\left[f(\hat{\mathbf{h}}_{S^{\setminus i}}; z_i) - f(\hat{\mathbf{h}}_S; z_i)\right] \\
&= \frac{1}{m}\sum_{i=1}^{m}\mathbb{E}\left[F(\hat{\mathbf{h}}_{S^{\setminus i}})\right] - \mathbb{E}\left[\frac{1}{m}\sum_{i=1}^{m} f(\hat{\mathbf{h}}_S; z_i)\right] \\
&\leq \frac{1}{m}\sum_{i=1}^{m}\mathbb{E}\left[F_{S^{\setminus i}}(\hat{\mathbf{h}}_{S^{\setminus i}}) + \varepsilon_{\text{gen}}(m-1)\right] - \mathbb{E}\left[F_S(\hat{\mathbf{h}}_S)\right] \\
&= \varepsilon_{\text{gen}}(m-1) + \mathbb{E}\left[\frac{1}{m}\sum_{i=1}^{m} F_{S^{\setminus i}}(\hat{\mathbf{h}}_{S^{\setminus i}}) - F_S(\hat{\mathbf{h}}_S)\right] \\
&\leq \varepsilon_{\text{gen}}(m-1).
\end{aligned}$$

For the opposite direction, suppose the ERM learning rule is LOO stable with rate $\varepsilon_{\text{stable}}(m)$. Notice that we can get any sample of size $m-1$ by picking a sample S of size m and discarding any instance i. Therefore, the on-average generalization rate of the ERM for samples of size $m-1$ is equal to the following:

$$\begin{aligned}
&\left|\mathbb{E}\left[F(\hat{\mathbf{h}}_{S^{\setminus i}}) - F_{S^{\setminus i}}(\hat{\mathbf{h}}_{S^{\setminus i}})\right]\right| \\
&= \left|\frac{1}{m}\sum_{i=1}^{m}\mathbb{E}\left[F(\hat{\mathbf{h}}_{S^{\setminus i}}) - F_{S^{\setminus i}}(\hat{\mathbf{h}}_{S^{\setminus i}})\right]\right| \\
&= \left|\frac{1}{m}\sum_{i=1}^{m}\mathbb{E}\left[f(\hat{\mathbf{h}}_{S^{\setminus i}}; z_i)\right] - \frac{1}{m}\sum_{i=1}^{m}\mathbb{E}\left[F_{S^{\setminus i}}(\hat{\mathbf{h}}_{S^{\setminus i}})\right]\right|
\end{aligned}$$

Now, note that for the ERM's of S and $S^{\setminus i}$ we have $\left|F_{S^{\setminus i}}(\hat{\mathbf{h}}_{S^{\setminus i}}) - F_S(\hat{\mathbf{h}}_S)\right| \leq \frac{2B}{m}$. Therefore, we can upper bound the above by

$$\begin{aligned}
&\left|\frac{1}{m}\sum_{i=1}^{m}\mathbb{E}\left[f(\hat{\mathbf{h}}_{S^{\setminus i}}; z_i)\right] - \mathbb{E}\left[F_S(\hat{\mathbf{h}}_S)\right]\right| + \frac{2B}{m} \\
&= \left|\frac{1}{m}\sum_{i=1}^{m}\mathbb{E}\left[f(\hat{\mathbf{h}}_{S^{\setminus i}}; z_i) - f(\hat{\mathbf{h}}_{S,}; z_i)\right]\right| \\
&\leq \varepsilon_{\text{stable}}(m)
\end{aligned}$$

using the assumption that the learning rule is $\varepsilon_{\text{stable}}(m)$-stable. ■

Abstract

An algorithm is presented for topology selection in graphical models of autoregressive Gaussian time series. The graph topology of the model represents the sparsity pattern of the inverse spectrum of the time series and characterizes conditional independence relations between the variables. The method proposed in the paper is based on an ℓ_1-type nonsmooth regularization of the conditional maximum likelihood estimation problem. We show that this reduces to a convex optimization problem and describe a large-scale algorithm that solves the dual problem via the gradient projection method. Results of experiments with randomly generated and real data sets are also included.

Keywords: graphical models, time series, topology selection, convex optimization

1. Introduction

We consider graphical models of autoregressive (AR) Gaussian processes

$$x(t) = -\sum_{k=1}^{p} A_k x(t-k) + w(t), \qquad w(t) \sim \mathcal{N}(0,\Sigma) \tag{1}$$

where $x(t) \in \mathbf{R}^n$, and $w(t) \in \mathbf{R}^n$ is Gaussian white noise. A graphical model of the time series is an undirected graph with n nodes, one for each component $x_i(t)$, and an edge connecting nodes i and j if the components $x_i(t)$ and $x_j(t)$ are *conditionally dependent*, given the other components of the time series. The conditional independence property has a simple characterization (which holds for general Gaussian stationary processes) in terms of the spectrum of the process: $x_i(t)$ and $x_j(t)$ are independent, conditional on the other $n-2$ components of $x(t)$, if and only if

$$(S(\omega)^{-1})_{ij} = 0$$

for all ω, where $S(\omega)$ is the spectral density matrix (Brillinger, 1981, Chapter 8; Dahlhaus, 2000). This characterization allows us to include the conditional independence relations in an estimation problem by placing sparsity constraints on the inverse spectral density matrix.

In Songsiri et al. (2009) a convex optimization method was discussed for estimating the model parameters A_k, Σ from data, given the graph of conditional independence relations. The method is

based on solving the convex optimization problem

$$\begin{array}{ll} \text{minimize} & -\log\det X_{00} + \mathbf{tr}(CX) \\ \text{subject to} & Y_k = \sum_{i=0}^{p-k} X_{i,i+k}, \quad k = 0,1,\ldots,p, \\ & (Y_k)_{ij} = 0, \quad (i,j) \in \mathcal{V}, \quad k = 0,1,\ldots,p, \\ & X \succeq 0. \end{array} \tag{2}$$

Here C is the sample covariance matrix and $\mathcal{V}$ is the set of conditionally independent pairs of variables. The optimization variables are $X \in \mathbf{S}^{n(p+1)}$ (the symmetric matrices of order $n(p+1)$), $Y_0 \in \mathbf{S}^n$, and $Y_k \in \mathbf{R}^{n\times n}$, $k = 1,2,\ldots,p$. X_{ij} denotes the $n \times n$ subblock of X in position i, j, where the indices i and j run from 0 to p. It was shown that if the sample covariance matrix C is block-Toeplitz, then problem (2) is equivalent to the conditional maximum likelihood (ML) estimation problem, and the ML estimates for A_k and Σ are easily obtained from the optimal solution X. If C is not block-Toeplitz, the problem is a relaxation and in general not equivalent to the conditional ML problem. However in practice, the relaxation often happens to be exact (Songsiri et al., 2009). This will be discussed in more detail in §2.3.

In this paper we consider the more general problem of estimating the model parameters *and* the topology of the graphical model. The topology selection problem can be solved by enumerating all topologies, solving the ML estimation problem for each topology, and ranking them via information-theoretic criteria such as the Akaike or Bayes information criteria (Eichler, 2006; Songsiri et al., 2009). However this combinatorial approach is clearly limited to small graphs. The goal of this paper is to present an efficient alternative based on convex optimization.

Topology selection for graphical models of time series is of interest in many applications (see Dahlhaus et al., 1997; Eichler et al., 2003; Salvador et al., 2005; Gather et al., 2002; Timmer et al., 2000; Feiler et al., 2005; Friedman et al., 2008). A common approach is to formulate hypothesis testing problems to decide about the presence or absence of edges. Dahlhaus (2000) derives a statistical test for the existence of an edge in the graph, based on the maximum of a nonparametric estimate of the normalized inverse spectrum (see also Dahlhaus et al., 1997; Eichler et al., 2003; Salvador et al., 2005; Gather et al., 2002; Timmer et al., 2000; Feiler et al., 2005; Fried and Didelez, 2003). Eichler (2008) presents a more general approach by introducing a hypothesis test based on the norm of some suitable function of the spectral density matrix. A related problem was studied by Bach and Jordan (2004). They use an efficient search procedure to learn the graph structure from sample estimates of the joint spectral density matrix.

If $p = 0$, the problem (2) reduces to

$$\begin{array}{ll} \text{minimize} & -\log\det X + \mathbf{tr}(CX) \\ \text{subject to} & X_{ij} = 0, \quad (i,j) \in \mathcal{V} \end{array} \tag{3}$$

with variable $X \in \mathbf{S}^n$. (Throughout the paper we take the set of positive definite matrices as the domain of the function $\log\det X$, so (3) includes an implicit constraint $X \succ 0$.) Problem (3) is known as the *covariance selection* problem, that is, the problem of computing the ML estimate of the inverse covariance matrix $X = \Sigma^{-1}$ of a multivariate Gaussian variable $\mathcal{N}(0,\Sigma)$, subject to conditional independence constraints (which, for a normal distribution, correspond to zeros in the inverse covariance); see Dempster (1972) and Lauritzen (1996, §5.2). Recently, new heuristic methods for topology selection in large Gaussian graphical models have been developed. These methods are

based on augmenting the ML objective with an ℓ_1-norm regularization term, that is, on solving

$$\text{minimize} \quad -\log\det X + \mathbf{tr}(CX) + \gamma \textstyle\sum_{ij} |X_{ij}| \tag{4}$$

(see Dahl et al., 2005; Meinshausen and Bühlmann, 2006; Banerjee et al., 2008; Ravikumar et al., 2008; Friedman et al., 2008; Lu, 2009, 2010). The optimization problem (4) is convex but has $n(n+1)/2$ variables (the elements of X) and is nondifferentiable, so it can be challenging to solve when n is large. Several large-scale methods have been proposed. Banerjee et al. (2008) apply a block coordinate descent method to the dual problem. Each step of this method reduces to solving a quadratic program with box constraints. They also apply Nesterov's optimal gradient method (Nesterov, 2005) to a smooth approximation of (4). Friedman et al. (2008) observe that the dual of the subproblems in the coordinate descent algorithm can be regarded as a lasso-type problem and solved with a method called graphical lasso. Scheinberg and Rish (2009) consider a coordinate ascent method applied to the primal problem. A method based on column-wise updates is given by Rothman et al. (2008). A related problem is explored in Yuan and Lin (2007) where the authors make a connection between (4) and more general determinant maximization problems (Vandenberghe et al., 1998), and solve the problem using interior-point methods. Lu (2009) observes that the dual of (4) is a smooth problem and applies Nesterov's method (Nesterov, 2005) directly to the dual. The algorithm is further extended by Lu (2010) and compared with a projected spectral gradient method. Another closely related paper is Duchi et al. (2008) in which the gradient projection method is applied to the dual problem.

The main purpose of this paper is to develop an efficient method for topology selection in AR models, based on augmenting the estimation problem (2) with a convex regularization term, similar to the ℓ_1-norm regularization used in (4). We also discuss first-order methods for solving the resulting large-scale and nondifferentiable convex optimization problem.

The paper is organized as follows. In Section 2 we review the definition of conditional independence in time series and summarize the results from Songsiri et al. (2009). In Section 3 we set up the topology selection problem as a regularized ML problem and discuss its properties. Examples and applications are presented in Sections 4 and 5. We conclude in Section 6 with a discussion of gradient projection algorithms for solving large instances of the regularized ML estimation problem.

1.1 Notation

$\mathbf{S}^n$ is the set of real symmetric matrices of order n. $\mathbf{S}^n_+$ and $\mathbf{S}^n_{++}$ are the sets of symmetric positive semidefinite, respectively, positive definite, matrices of order n. $\mathbf{R}^{m\times n}$ is the set of $m\times n$-matrices. $\mathbf{M}^{n,p}$ is the set of matrices

$$X = \begin{bmatrix} X_0 & X_1 & \cdots & X_p \end{bmatrix}$$

with $X_0 \in \mathbf{S}^n$ and $X_1,\ldots,X_p \in \mathbf{R}^{n\times n}$. The standard trace inner product $\langle X,Y\rangle = \mathbf{tr}(X^TY)$ is used for the three vector spaces $\mathbf{S}^n, \mathbf{R}^{m\times n}, \mathbf{M}^{n,p}$. For a symmetric matrix X, the inequalities $X \succeq 0$ and $X \succ 0$ mean X is positive semidefinite, resp., positive definite. Row and column indices of submatrices in a block matrix start at 0. If X is a matrix with (block) entries X_{ij}, then $X_{i:j,k:l}$ will denote the submatrix formed by rows i through j and columns k through l:

$$X_{i:j,k:l} = \begin{bmatrix} X_{ik} & X_{i,k+1} & \cdots & X_{il} \\ X_{i+1,k} & X_{i+1,k+1} & \cdots & X_{i+1,l} \\ \vdots & \vdots & & \vdots \\ X_{jk} & X_{j,k+1} & \cdots & X_{j,l} \end{bmatrix}.$$

The linear mapping $\mathrm{T} : \mathbf{M}^{n,p} \to \mathbf{S}^{n(p+1)}$ constructs a symmetric block Toeplitz matrix from its first block row: if $X = \begin{bmatrix} X_0 & X_1 & \cdots & X_p \end{bmatrix} \in \mathbf{M}^{n,p}$, then

$$\mathrm{T}(X) = \begin{bmatrix} X_0 & X_1 & \cdots & X_p \\ X_1^T & X_0 & \cdots & X_{p-1} \\ \vdots & \vdots & \ddots & \vdots \\ X_p^T & X_{p-1}^T & \cdots & X_0 \end{bmatrix}. \tag{5}$$

The adjoint of T is a mapping $\mathrm{D} : \mathbf{S}^{n(p+1)} \to \mathbf{M}^{n,p}$ defined as follows. If $S \in \mathbf{S}^{n(p+1)}$ is partitioned as

$$S = \begin{bmatrix} S_{00} & S_{01} & \cdots & S_{0p} \\ S_{01}^T & S_{11} & \cdots & S_{1p} \\ \vdots & \vdots & & \vdots \\ S_{0p}^T & S_{1p}^T & \cdots & S_{pp} \end{bmatrix},$$

then $\mathrm{D}(S) = \begin{bmatrix} \mathrm{D}_0(S) & \mathrm{D}_1(S) & \cdots & \mathrm{D}_p(S) \end{bmatrix}$ where

$$\mathrm{D}_0(S) = \sum_{i=0}^{p} S_{ii}, \qquad \mathrm{D}_k(S) = 2\sum_{i=0}^{p-k} S_{i,i+k}, \quad k = 1, \ldots, p. \tag{6}$$

A symmetric sparsity pattern of a sparse matrix X of order n will be associated with the positions $\mathcal{V} \subseteq \{1,\ldots,n\} \times \{1,\ldots,n\}$ of its zero entries. We assume $(i,i) \notin \mathcal{V}$ for $i = 1,\ldots,n$, that is, the diagonal entries are not included among the zeros. $\mathrm{P}_{\mathcal{V}}(X)$ denotes the projection of a matrix $X \in \mathbf{S}^n$ or $X \in \mathbf{R}^{n\times n}$ on the complement of the sparsity pattern $\mathcal{V}$:

$$\mathrm{P}_{\mathcal{V}}(X)_{ij} = \begin{cases} X_{ij} & (i,j) \in \mathcal{V} \\ 0 & \text{otherwise.} \end{cases} \tag{7}$$

The same notation is used for $\mathrm{P}_{\mathcal{V}}$ as a mapping from $\mathbf{R}^{n\times n} \to \mathbf{R}^{n\times n}$ and as a mapping from $\mathbf{S}^n \to \mathbf{S}^n$. In both cases, $\mathrm{P}_{\mathcal{V}}$ is self-adjoint. If X is an $r \times s$ block matrix with i,j block X_{ij}, and each block is square of order n, then $\mathrm{P}_{\mathcal{V}}(X)$ denotes the $r \times s$ block matrix with i,j block $\mathrm{P}_{\mathcal{V}}(X)_{ij} = \mathrm{P}_{\mathcal{V}}(X_{ij})$. Similarly, $\mathrm{P}_{\mathcal{V}}(X)$ with $X \in \mathbf{M}^{n,p}$ denotes

$$\begin{bmatrix} \mathrm{P}_{\mathcal{V}}(X_0) & \mathrm{P}_{\mathcal{V}}(X_1) & \cdots & \mathrm{P}_{\mathcal{V}}(X_p) \end{bmatrix}.$$

The subscript $\mathcal{V}$ in $\mathrm{P}_{\mathcal{V}}$ is omitted if the sparsity pattern is clear from the context.

2. Graphical Models of Autoregressive Gaussian Processes

In this section we describe the conditional independence property for Gaussian time series, review the maximum likelihood estimation of AR models, and provide a convex formulation for the estimation problem with conditional independence constraints.

2.1 Conditional Independence

Let $x(t)$ be an n-dimensional stationary zero-mean Gaussian process with spectrum $S(\omega)$:

$$S(\omega) = \sum_{k=-\infty}^{\infty} R_k e^{-\mathrm{j}k\omega}$$

where $R_k = \mathbf{E}x(t+k)x(t)^T$ and $\mathrm{j} = \sqrt{-1}$. We assume that $S(\omega)$ is invertible for all ω. Two components $x_i(t)$ and $x_j(t)$ of $x(t)$ are conditionally independent (i.e., conditional on the other components of $x(t)$) if

$$(S(\omega)^{-1})_{ij} = 0$$

for all ω (Brillinger, 1981; Dahlhaus, 2000). If we denote by $\mathcal{V}$ the set of index pairs i, j of conditionally independent variables, then we can use the projection operator $\mathrm{P} = \mathrm{P}_{\mathcal{V}}$ defined in (7) to express the conditional independence relations as

$$\mathrm{P}(S(\omega)^{-1}) = 0. \tag{8}$$

In a graphical model of the process, the index set $\mathcal{V}$ is the set of missing edges in the graph.

To apply this result to AR processes (1) we need to express the inverse spectrum in terms of the model parameters. The notation will simplify if we first normalize the input covariance and use the model

$$B_0 x(t) = -\sum_{k=1}^{p} B_k x(t-k) + v(t), \qquad v(t) \sim \mathcal{N}(0, I), \tag{9}$$

where $B_0 \in \mathbf{S}^n_{++}$ and $B_k \in \mathbf{R}^{n\times n}$, $k = 1, \ldots, p$. If Σ is nonsingular, the two models are equivalent, and related as $B_0 = \Sigma^{-1/2}$, $B_k = \Sigma^{-1/2} A_k$ for $k \geq 1$. The inverse spectrum $S(\omega)$ of the process (9) is a trigonometric matrix polynomial

$$S(\omega)^{-1} = Y_0 + \frac{1}{2}\sum_{k=1}^{p} (e^{-\mathrm{j}k\omega} Y_k + e^{\mathrm{j}k\omega} Y_k^T) \tag{10}$$

where $Y_0 = \sum_{l=0}^{p} B_l^T B_l$, and $Y_k = 2\sum_{l=0}^{p-k} B_l^T B_{k+l}$ for $k = 1, \ldots, p$. If we define $B = \begin{bmatrix} B_0 & B_1 & \cdots & B_p \end{bmatrix}$, we can use the operator D defined in (6) to express Y_k as

$$\begin{bmatrix} Y_0 & Y_1 & \cdots & Y_p \end{bmatrix} = \mathrm{D}(B^T B).$$

The expression (10) shows that $(S(\omega)^{-1})_{ij}$ is identically zero if and only if the i, j and j, i entries of Y_k are zero for $k = 0, \ldots, p$. The conditional independence condition (8) is therefore equivalent to a quadratic equation in the model parameters B_k:

$$\mathrm{P}\left(\mathrm{D}(B^T B)\right) = 0. \tag{11}$$

(Recall from the Notation section that if Y is a block matrix with square submatrices Y_k of order n, then $\mathrm{P}(Y)$ denotes the block matrix with submatrices $\mathrm{P}(Y_k)$.)

2.2 Conditional Maximum Likelihood Estimation

We now consider the problem of estimating the model parameters B from an observed sequence $\tilde{x}(1), \tilde{x}(2), \ldots, \tilde{x}(N)$ of the AR process, subject to known conditional independence constraints (11). In Songsiri et al. (2009) the estimation problem was formulated as the optimization problem

$$\begin{array}{ll} \text{minimize} & -2\log\det B_0 + \mathbf{tr}(CB^T B) \\ \text{subject to} & \mathrm{P}(\mathrm{D}(B^T B)) = 0. \end{array} \tag{12}$$

The matrix $C \in \mathbf{S}_+^{n(p+1)}$ is a sample estimate of the covariance matrix, that is, its blocks C_{ij}, $i \leq j$, are estimates of the covariances $R_{j-i} = \mathbf{E}x(t+j-i)x(t)^T$, calculated from the observed sequence. Two choices of C are common. The first choice is the *non-windowed estimate*

$$C = \frac{1}{N-p}HH^T, \qquad H = \begin{bmatrix} \tilde{x}(p+1) & \tilde{x}(p+2) & \cdots & \tilde{x}(N) \\ \tilde{x}(p) & \tilde{x}(p+1) & \cdots & \tilde{x}(N-1) \\ \vdots & \vdots & & \vdots \\ \tilde{x}(1) & \tilde{x}(2) & \cdots & \tilde{x}(N-p) \end{bmatrix}. \tag{13}$$

With this choice the estimation problem (12) can be interpreted as a maximum likelihood problem. Indeed, from (9), the conditional density of a sequence $x(t_1), x(t_1+1), \ldots x(t_2)$, given $x(t_1-p), \ldots, x(t_1-1)$, is given by

$$\left(\frac{\det B_0}{(2\pi)^{n/2}}\right)^{t_2-t_1+1} \exp\left(-\frac{1}{2}\sum_{t=t_1}^{t_2} \mathbf{x}(t)^T B^T B \mathbf{x}(t)\right),$$

where $\mathbf{x}(t)$ denotes the $n(p+1)$-vector $\mathbf{x}(t) = (x(t), x(t-1), \ldots, x(t-p))$. From this it can be shown that the cost function in (12) with C defined as in (13), is essentially the negative conditional log-likelihood function of the observed sequence $\tilde{x}(p+1)$, $\tilde{x}(p+2)$, $\ldots$, $\tilde{x}(N)$, given $\tilde{x}(1)$, $\ldots$, $\tilde{x}(p)$. We therefore refer to (12) as the *conditional maximum likelihood problem*. For AR processes, the conditional ML formulation is substantially simpler and more often used than the exact ML formulation. Moreover, when the data length N is sufficiently large compared to p, the difference between the exact and conditional ML formulations is small.

The second choice for C is the *windowed estimate*

$$C = \frac{1}{N}HH^T, \tag{14}$$

where

$$H = \begin{bmatrix} \tilde{x}(1) & \tilde{x}(2) & \cdots & \tilde{x}(p+1) & \cdots & \tilde{x}(N) & 0 & \cdots & 0 \\ 0 & \tilde{x}(1) & \cdots & \tilde{x}(p) & \cdots & \tilde{x}(N-1) & \tilde{x}(N) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots & & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \tilde{x}(1) & \cdots & \tilde{x}(N-p) & \tilde{x}(N-p+1) & \cdots & \tilde{x}(N) \end{bmatrix}.$$

The windowed estimate C is block-Toeplitz, and this guarantees several useful properties of the resulting model B (for example, stability; see Songsiri et al., 2009). In practice, the differences between the windowed and non-windowed estimates are small when $N \gg p$.

We will assume that C is positive definite. If n is small compared to N, this is a reasonable assumption but not guaranteed to be true. (As a counterexample, assume $\tilde{x}(1)$, $\ldots$, $\tilde{x}(n)$ are the first n unit vectors and the remainder of the sequence is zero. The matrix C in (14) then has rank $n+p$.) If C is not positive definite, it may be necessary to add a small multiple of the identity. This is equivalent to a quadratic regularization term proportional to $\|B\|_F^2$ in the objective of (12).

When there are no sparsity constraints in (12), the solution can be found by setting the gradient of the cost function equal to zero, which gives

$$\begin{bmatrix} C_{00} & C_{01} & \cdots & C_{0p} \\ C_{10} & C_{11} & \cdots & C_{1p} \\ \vdots & \vdots & \ddots & \vdots \\ C_{p0} & C_{p1} & \cdots & C_{pp} \end{bmatrix} \begin{bmatrix} B_0 \\ B_1^T \\ \vdots \\ B_p^T \end{bmatrix} = \begin{bmatrix} B_0^{-1} \\ 0 \\ \vdots \\ 0 \end{bmatrix}.$$

Written in terms of the original variables $\Sigma = B_0^{-2}$, $A_k = B_0^{-1}B_k$, this gives

$$\begin{bmatrix} C_{00} & C_{01} & \cdots & C_{0p} \\ C_{10} & C_{11} & \cdots & C_{1p} \\ \vdots & \vdots & \ddots & \vdots \\ C_{p0} & C_{p1} & \cdots & C_{pp} \end{bmatrix} \begin{bmatrix} I \\ A_1^T \\ \vdots \\ A_p^T \end{bmatrix} = \begin{bmatrix} \Sigma \\ 0 \\ \vdots \\ 0 \end{bmatrix}, \tag{15}$$

with unknowns $\Sigma = B_0^{-2}$, $A_k = B_0^{-1}B_k$. The bottom p equations form a set of linear equations from which $A_1, \ldots, A_p$ can be determined. Plugging in the solution in the first equation gives Σ. Later in the paper we will refer to the solution as the *least-squares estimate* because the bottom p equations can be interpreted as normal equations for the least-squares problem

$$\text{minimize} \quad \mathbf{tr}(ACA^T)$$

with variable $A = \begin{bmatrix} I & A_1 & \cdots & A_p \end{bmatrix}$. This method is also known as the *covariance method* if C is the non-windowed sample covariance (13), and as the *correlation method* if C is the windowed sample covariance (14) (see Stoica and Moses, 1997).

2.3 Convex Formulation

The optimization problem (12) is non-convex because of the quadratic equality constraint. A convex relaxation is

$$\begin{array}{ll} \text{minimize} & -\log\det X_{00} + \mathbf{tr}(CX) \\ \text{subject to} & \mathrm{P}(\mathrm{D}(X)) = 0 \\ & X \succeq 0 \end{array} \tag{16}$$

with variable $X \in \mathbf{S}^{n(p+1)}$. The relaxation is exact, that is, the two problems (16) and (12) are equivalent, if the optimal solution X of (16) has rank n. In that case, the solution B of (16) can be calculated by factoring X as $X = B^T B$.

A condition for exactness of the relaxation follows from the dual problem of (16), which is

$$\begin{array}{ll} \text{maximize} & \log\det W + n \\ \text{subject to} & \begin{bmatrix} W & 0 \\ 0 & 0 \end{bmatrix} \preceq C + \mathrm{T}(\mathrm{P}(Z)), \end{array} \tag{17}$$

with variables $W \in \mathbf{S}^n$ and $Z \in \mathbf{M}^{n,p}$ (for the derivation, see Songsiri et al., 2009). The variable Z is the Lagrange multiplier associated with the equality constraint in (16); the slack matrix in the inequality in (17) is the multiplier associated with the primal inequality $X \succeq 0$. To find the relation between primal and dual solutions, we first note that the primal and dual problems are strictly feasible: $X = I$ is strictly feasible in the primal problem (16), since by assumption $\mathcal{V}$ does not contain any diagonal entries; in the dual problem $Z = 0$ and a sufficiently small positive definite W are strictly feasible, because $C \succ 0$ by assumption. From convex duality, strict primal and dual feasibility imply that the primal and dual problems are solvable, and that their optimal solutions are related by the optimality conditions

$$X_{00}^{-1} = W, \qquad \mathbf{tr}\left(X\left(C + \mathrm{T}(\mathrm{P}(Z)) - \begin{bmatrix} W & 0 \\ 0 & 0 \end{bmatrix}\right)\right) = 0 \tag{18}$$

(Boyd and Vandenberghe, 2004, Chapter 5). The second condition is known as *complementary slackness* between the optimal X and the dual variable associated with the inequality $X \succeq 0$. From these optimality conditions, it can be shown that the relaxation is exact when the trailing principal submatrix of order np in the matrix $C + \mathrm{T}(\mathrm{P}(Z)) \in \mathbf{S}^{n(p+1)}$ is positive definite at the optimum, that is,

$$(C + \mathrm{T}(\mathrm{P}(Z)))_{1:p,1:p} \succ 0. \tag{19}$$

Under this condition, the rank of

$$C + \mathrm{T}(\mathrm{P}(Z)) - \begin{bmatrix} W & 0 \\ 0 & 0 \end{bmatrix}$$

is at least np. Since X has order $n(p+1)$, the two conditions in (18) imply that the optimal X has rank n.

In general it is difficult to guarantee a priori that the condition (19) holds at optimum. However, when C is block-Toeplitz, then (19) can be shown to hold for all dual feasible Z. This follows from the following easily established property of block-Toeplitz matrices: if $V \in \mathbf{S}^{n(p+1)}$ is a symmetric block-Toeplitz matrix with $n \times n$ blocks V_{ij}, and

$$V = \begin{bmatrix} V_{00} & V_{0,1:p} \\ V_{1:p,0} & V_{1:p,1:p} \end{bmatrix} \succeq \begin{bmatrix} W & 0 \\ 0 & 0 \end{bmatrix}$$

for some $W \succ 0$, then V is positive definite (see Songsiri et al., 2009, §3.3.3). We therefore conclude that for positive definite block-Toeplitz C (for example, the windowed sample covariance (14) or the true covariance), the problems (12) and (16) are *equivalent*. For general non-block-Toeplitz C (for example, the non-windowed sample covariance (13)), we cannot guarantee that (19) holds at the optimum. However, we can note that the non-windowed sample covariance approaches a block-Toeplitz matrix as $N \to \infty$. It is therefore not surprising that even for the non-windowed estimate, the relaxation is often exact, as was observed in the experimental results in Songsiri et al. (2009).

3. Topology Selection Via Nonsmooth Regularization

In the previous section we have described a convex formulation of the (conditional) ML estimation problem with given conditional independence constraints, that is, a given graph topology. In many applications the topology is not known, and needs to be discovered from the data. Information theoretic model selection criteria such as the Akaike, second-order Akaike, or Bayes information criteria can be used for this purpose. They require enumerating all possible topologies, solving the ML problem for each topology, and ranking the ML estimates according to their information criterion score. These scores are defined as

$$\mathrm{AIC} = -2\mathcal{L} + 2k, \qquad \mathrm{AIC_c} = -2\mathcal{L} + \frac{2Nk}{N-k-1}, \qquad \mathrm{BIC} = -2\mathcal{L} + k\log N \tag{20}$$

where $\mathcal{L}$ is the log-likelihood of the ML estimate, N is the sample size, and k is the effective number of parameters. In our application, $\mathcal{L}$ is given by

$$\mathcal{L} = \frac{N-p}{2}\left(\log\det X_{00} - \mathbf{tr}(CX)\right)$$

where X is the optimal solution of (16), and we use for k the total number of parameters in the estimation problem,

$$k = \frac{n(n+1)}{2} - |\mathcal{V}| + p(n^2 - 2|\mathcal{V}|),$$

where $|\mathcal{V}|$ is the number of conditionally independent pairs of variables. This topology selection method based on information-theoretic criteria is feasible if the number of possible topologies is not too large, but quickly becomes intractable even for small values of n. In this section and the next we describe a more scalable approach based on a convex optimization problem that extends the ℓ_1-norm heuristic (4) for sparse covariance selection.

3.1 Regularized ML Problem

In analogy with the convex heuristic for covariance selection (4), we can formulate a regularized ML problem by adding a nonsmooth ℓ_1-type penalty:

$$\begin{array}{ll} \text{minimize} & -\log\det X_{00} + \mathbf{tr}(CX) + \gamma h(\mathrm{D}(X)) \\ \text{subject to} & X \succeq 0, \end{array} \tag{21}$$

where $\gamma > 0$ is a weighting parameter. The penalty $h : \mathbf{M}^{n,p} \to \mathbf{R}$ is a convex function, chosen to encourage a sparse solution X with a common, symmetric sparsity pattern for the $p+1$ blocks of $\mathrm{D}(X)$. We will use the penalty function

$$h_\infty(Y) = \sum_{j>i} \max\left\{ \left|(Y_0)_{ij}\right|, \max_{k=1,\ldots,p} \left|(Y_k)_{ij}\right|, \max_{k=1,\ldots,p} \left|(Y_k)_{ji}\right| \right\} \tag{22}$$

that is, a sum of the ℓ_∞-norms of vectors of i,j and j,i-entries of the coefficients Y_k. In the examples (Section 4) we will also discuss penalty functions defined as sums of ℓ_α-norms, with $\alpha = 1, 2$.

Regularization with a convex sum-of-norms penalty is a popular technique for achieving sparsity of groups of variables. Examples from statistics are the *composite absolute penalties* (CAP) (Zhao et al., 2009) and the *group lasso* (Yuan and Lin, 2006; Kim et al., 2006). When $p = 0$ and $X \in \mathbf{S}^n$ in (21) the penalty term reduces to $\sum_{i>j} |X_{ij}|$ and we obtain problem (4), studied in Banerjee et al. (2008), Lu (2009) and Friedman et al. (2008), with the minor difference that we do not penalize the diagonal entries of X.

We now derive the dual problem of (21) which will be important in Section 6. To simplify the derivation we introduce a variable $Y = \mathrm{D}(X)$ and write the problem as

$$\begin{array}{ll} \text{minimize} & -\log\det X_{00} + \mathbf{tr}(CX) + \gamma h_\infty(Y) \\ \text{subject to} & Y = \mathrm{D}(X) \\ & X \succeq 0. \end{array}$$

If we use a multiplier $Z \in \mathbf{M}^{n,p}$ for the equality constraint $Y = \mathrm{D}(X)$ and a multiplier $U \in \mathbf{S}^{n(p+1)}$ for the inequality $X \succeq 0$, the Lagrangian of the problem is

$$\begin{aligned} L(X,Y,Z,U) &= -\log\det X_{00} + \mathbf{tr}(CX) + \gamma h_\infty(Y) - \mathbf{tr}(UX) + \mathbf{tr}(Z^T(\mathrm{D}(X) - Y)) \\ &= -\log\det X_{00} + \mathbf{tr}((C + \mathrm{T}(Z) - U)X) + \gamma h_\infty(Y) - \mathbf{tr}(Z^T Y). \end{aligned} \tag{23}$$

(Recall that the mappings T and D defined in (5) and (6) are adjoints, that is, $\mathbf{tr}(Z^T \mathrm{D}(X)) = \mathbf{tr}(\mathrm{T}(Z)X)$.) The dual function is the infimum of the Lagrangian over X and Y. We first minimize over Y. The nonlinear penalty term does not depend on the diagonal entries of the blocks Y_k. The minimization over the diagonal entries of Y_k is therefore unbounded below unless

$$\mathbf{diag}(Z_k) = 0, \quad k = 0, 1, \ldots, p. \tag{24}$$

The minimization over the off-diagonal part of the blocks Y_k decomposes into independent minimizations of the functions

$$-\sum_{k=0}^{p} ((Z_k)_{ij}(Y_k)_{ij} + (Z_k)_{ji}(Y_k)_{ji}) + \gamma \max\left\{ |(Y_0)_{ij}|, \max_{k=1,\ldots,p} |(Y_k)_{ij}|, \max_{k=1,\ldots,p} |(Y_k)_{ji}| \right\}$$

for each element i, j with $i > j$. This expression is unbounded below unless

$$2|(Z_0)_{ij}| + \sum_{k=1}^{p} (|(Z_k)_{ij}| + |(Z_k)_{ji}|) \leq \gamma, \quad i \neq j, \tag{25}$$

and, if this condition holds, the infimum over Y is zero. The result of the partial minimization of the Lagrangian over Y can be summarized as

$$\inf_Y L(X,Y,Z,U) = \begin{cases} -\log\det X_{00} + \mathbf{tr}((C + \mathrm{T}(Z) - U)X) & (24), (25) \\ -\infty & \text{otherwise.} \end{cases}$$

Next, we carry out the minimization over X. The terms in X_{00} are bounded below if and only if $(C + \mathrm{T}(Z) - U)_{00} \succ 0$, and if this holds, they are minimized by $X_{00} = (C + \mathrm{T}(Z) - U)_{00}^{-1}$. The Lagrangian is linear in the other blocks X_{ij}, and therefore bounded below (and identically zero) only if $(C + \mathrm{T}(Z) - U)_{ij} = 0$ for blocks $(i, j) \neq (0, 0)$. This gives a third set of dual feasibility conditions:

$$(C + \mathrm{T}(Z) - U)_{00} \succ 0, \qquad (C + \mathrm{T}(Z) - U)_{ij} = 0, \quad (i, j) \neq 0, \tag{26}$$

and an expression for the dual function

$$g(Z,U) = \inf_{X,Y} L(X,Y,Z,U) = \begin{cases} \log\det(C + \mathrm{T}(Z) - U)_{00} + n & (24), (25), (26) \\ -\infty & \text{otherwise.} \end{cases}$$

The dual problem is to maximize $g(Z,U)$ subject to $U \succeq 0$. If we add a variable $W = C_{00} + Z_0 - U_{00}$ and eliminate the slack variable U, we can express the dual problem as

$$\begin{array}{ll} \text{maximize} & \log\det W + n \\ \text{subject to} & \begin{bmatrix} W & 0 \\ 0 & 0 \end{bmatrix} \preceq C + \mathrm{T}(Z) \\ & \sum_{k=0}^{p} (|(Z_k)_{ij}| + |(Z_k)_{ji}|) \leq \gamma, \quad i \neq j \\ & \mathbf{diag}(Z_k) = 0, \quad k = 0, \ldots, p. \end{array} \tag{27}$$

The variables are $W \in \mathbf{S}^n$ and $Z \in \mathbf{M}^{n,p}$. When $p = 0$, the problem reduces to

$$\begin{array}{ll} \text{maximize} & \log\det(C + Z) + n \\ \text{subject to} & |Z_{ij}| \leq \gamma/2, \quad i \neq j \\ & \mathbf{diag}(Z) = 0, \end{array}$$

Except for the equality constraint, this is the problem considered in Lu (2009) and Duchi et al. (2008).

If a sum of ℓ_α-norms

$$h_\alpha(Y) = \sum_{j>i} \left(\sum_{k=0}^{p} (|(Y_k)_{ij}|^\alpha + |(Y_k)_{ji}|^\alpha) \right)^{1/\alpha} \tag{28}$$

is used as penalty function in (21), the second constraint in the corresponding dual problem (27) is replaced by

$$\left(\sum_{k=0}^{p} \left(|(Z_k)_{ij}|^\beta + |(Z_k)_{ji}|^\beta \right) \right)^{1/\beta} \leq \gamma, \quad i \neq j$$

with $\beta = \alpha/(\alpha-1)$.

3.2 Optimality Conditions

The primal problem (21) is always strictly feasible ($X = I$ is strictly feasible). The dual problem (21) is strictly feasible if $C \succ 0$ (we can take $Z = 0$ and W positive definite and sufficiently small). It follows that the primal and dual problems are solvable, have equal optimal values, and that their solutions are characterized by the following set of necessary and sufficient optimality (or KKT) conditions.

Primal feasibility. X and Y satisfy

$$X \succeq 0, \qquad X_{00} \succ 0, \qquad Y = \mathrm{D}(X).$$

Dual feasibility. W and Z satisfy

$$W \succ 0, \qquad C + \mathrm{T}(Z) \succeq \begin{bmatrix} W & 0 \\ 0 & 0 \end{bmatrix},$$

$$\sum_{k=0}^{p} (|(Z_k)_{ij}| + |(Z_k)_{ji}|) \leq \gamma, \quad i \neq j, \qquad \mathbf{diag}(Z_k) = 0, \quad k = 0, 1, \ldots p.$$

Zero duality gap. The Lagrangian evaluated at the primal and dual optimal solutions is equal to the primal objective at the optimal X, Y, and equal to the dual objective evaluated at the optimal W, Z. From (23), we have equality between the Lagrangian and the primal objective if $\mathbf{tr}(UX) = 0$. Therefore the complementary slackness condition

$$\mathbf{tr}\left(X \left(C + \mathrm{T}(Z) - \begin{bmatrix} W & 0 \\ 0 & 0 \end{bmatrix} \right) \right) = 0 \tag{29}$$

holds at the optimum. Equality between the Lagrangian and the dual objective requires that the primal optimal X, Y minimize the Lagrangian evaluated at the dual optimal W, Z. Reviewing the derivation of the dual problem, we see that X_{00} minimizes the Lagrangian if

$$X_{00}^{-1} = W. \tag{30}$$

To express the conditions from the minimization over Y, we define

$$t_{ij} = \max\left\{ |(Y_0)_{ij}|, \max_{k=1,\ldots,p} |(Y_k)_{ij}|, \max_{k=1,\ldots,p} |(Y_k)_{ji}| \right\}.$$

Then we see that Y minimizes the Lagrangian if for all $i \neq j$, we either have

$$\sum_{k=0}^{p} (|(Z_k)_{ij}| + |(Z_k)_{ji}|) < \gamma,$$

or we have $\sum_{k=0}^{p}(|(Z_k)_{ij}| + |(Z_k)_{ji}|) = \gamma$ and

$$(Z_k)_{ij} = 0,\ |(Y_k)_{ij}| \leq t_{ij} \quad \text{or} \quad (Z_k)_{ij} < 0,\ (Y_k)_{ij} = -t_{ij} \quad \text{or} \quad (Z_k)_{ij} > 0,\ (Y_k)_{ij} = t_{ij}$$

for $k = 0, \ldots, p$.

The conditions (29)–(30) show that the optimal X has rank n under the same conditions as for the problem with given sparsity pattern (16). If

$$(C + \mathrm{T}(Z))_{1:p,1:p} \succ 0$$

then the optimal X has rank n, and this is always the case if C is block-Toeplitz. Under these conditions, the optimization problem (21) is equivalent to a regularized (conditional) ML estimation problem for the model parameters B:

$$\text{minimize} \quad -2\log\det B_0 + \mathbf{tr}(CB^TB) + \gamma h_\infty(\mathrm{D}(B^TB)).$$

4. Examples with Randomly Generated Data

Our interest in the regularized ML formulation (21) is motivated by the fact that the resulting AR model typically has a sparse inverse spectrum $S(\omega)^{-1}$. Since the regularized problem is convex, it is interesting as an efficient heuristic for topology selection. In this section we illustrate several aspects of this approach using experiments with randomly generated data. In Section 5 we will apply the method to real data sets. Numerical algorithms for solving the regularized problem (21) are discussed in Section 6.

4.1 Method

We first explain in greater detail how we will use the results of the regularized ML problem for model selection.

4.1.1 CHOICE OF REGULARIZATION PARAMETER γ

The sparsity in the inverse spectrum of the solution of the regularized ML problem is controlled by the weighting coefficient γ. As γ varies, the sparsity pattern varies from dense (γ small) to diagonal (γ large). Several authors have discussed the choice of γ in the context of covariance selection (i.e., heuristics based on solving problem (4) or closely related problems). A common approach is to select γ via cross-validation; see, for example, Friedman et al. (2008), Huang et al. (2006) and Banerjee et al. (2008). Meinshausen and Bühlmann (2006) give explicit formulas for γ based

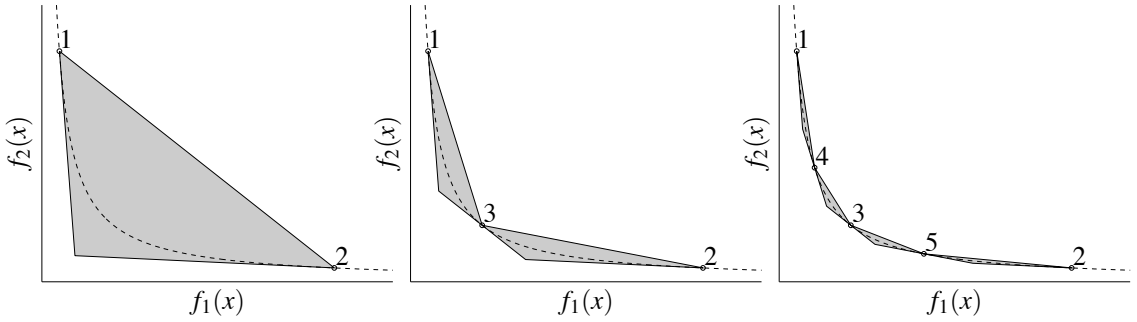

Figure 1: Method for approximating the trade-off curve between two convex objectives.

on a statistical analysis of the probability of errors in the topology (see also Yuan and Lin, 2007; Banerjee et al., 2008). Asadi et al. (2009) consider γ as a random variable and use a maximum a posteriori probability (MAP) estimation to choose γ and the covariance matrix.

In the examples of this section we will use the following method for selecting γ. We first compute the entire trade-off curve between the two terms in the objective of (21), that is, between the log-likelihood and the penalty function $h_\infty(\mathrm{D}(X))$. The trade-off curve can be computed by solving (21) for a number of different values of γ (see below). We collect the topologies of the solutions along the trade-off curve, and solve the ML problem (16) for each of these topologies. We then rank the models using the Bayes information criterion (BIC), as discussed at the beginning of Section 3, and select the model with the lowest score. In this approach, the convex heuristic is used as a preprocessing step to reduce the number of topologies that are examined using the BIC, and to filter out topologies that are unlikely to be competitive.

4.1.2 TRACING TRADE-OFF CURVES

The trade-off curves are computed by solving (21) for a sequence of values of γ. To obtain an accurate estimate of the curve with only a small number of values γ we use a method which is illustrated in Figure 1 for a generic trade-off between two convex cost functions f_1 and f_2. We first solve the scalarized problem

$$\text{minimize} \quad f_1(x) + \gamma f_2(x) \tag{31}$$

for two positive values γ_1, γ_2 near the opposite ends of the trade-off curve. This gives the points labeled 1 and 2 on the trade-off curve. The values of γ_1 and γ_2 also define the slopes of straight lines that support the trade-off curve at points 1 and 2. Since the trade-off curve is convex, we can conclude that the curve between 1 and 2 lies somewhere in the shaded triangular region. As γ_3, we choose the value that corresponds to the slope of the straight line between 1 and 2. Solving problem (31) with $\gamma = \gamma_3$ gives point 3 on the trade-off curve and a straight line that supports the curve at point 3. The trade-off curve between points 1 and 2 is now known to lie in the union of the two shaded triangles. Next, we solve the problem (31) for a value γ_4 corresponding to the slope of the straight line between points 1 and 3, and a value γ_5 corresponding to the slope of the straight line between 3 and 2. In this example, we obtain fairly accurate upper and lower bounds of the actual trade-off curve after solving five scalarized problems (31).

4.1.3 THRESHOLDING

With a proper value of γ, the regularized ML problem (21) has a sparse solution Y, resulting in a sparse inverse spectrum $S(\omega)^{-1}$. When solved with a limited accuracy, the entries of Y are not exactly zero. We will use the following method to determine the topology from the computed solution.

We calculate the inverse spectrum $S(\omega)^{-1}$ and normalize it by scaling its rows and columns so that the diagonal is one:

$$R(\omega) = \mathbf{diag}(S(\omega)^{-1})^{-1/2} S(\omega)^{-1} \mathbf{diag}(S(\omega)^{-1})^{-1/2}.$$

The normalized inverse spectrum $R(\omega)$ is known as the *partial coherence* (Brillinger, 1981; Dahlhaus, 2000). Its entries are between 0 and 1 in magnitude, and measure the conditional dependence between the corresponding variables, after removing the linear effects from the other variables. In the static case ($p = 0$), $R(\omega)$ reduces to the normalized concentration matrix. To estimate the graph topology we compare the L_∞-norms of the entries of $R(\omega)$,

$$\rho_{ij} = \sup_{\omega} |R(\omega)_{ij}|$$

with a given threshold. This thresholding step is similar to thresholding in other sparse methods, for example the thresholded lasso and Dantzig estimators in Lounici (2008).

To simplify the interpretation we will use the same threshold value (10^{-1}) in all the experiments, that is, we remove edge (i, j) from the graph if $\rho_{ij} \leq 10^{-1}$.

4.2 Experiment 1

In the first series of experiments we generate AR models with sparse inverse spectra by setting $B_0 = I$ and randomly choosing sparse lower triangular matrices B_k with entries ± 0.5. The random trials are continued until a stable AR model is found. The AR process is then used to generate N samples of the time series. The model dimensions are $n = 20$ and $p = 2$.

4.2.1 TOPOLOGY SELECTION

We first illustrate the basic topology selection method outlined above using the correct model order ($p = 2$). The sample size is $N = 512$.

Figure 2 shows the trade-off curve between the penalty $h_\infty(\mathrm{D}(X))$ and the log-likelihood $\mathcal{L}(X)$. We calculate the inverse spectra (10) for the computed points on the trade-off curve, and apply a threshold to them (as explained above, by setting entries with $\rho_{ij} \leq 10^{-1}$ to zero). The resulting topologies are shown in Figure 3. The patterns range from quite dense (small γ) to very sparse (large γ). The sparsity of the densest solution ($\gamma = 10^{-5}$) is identical to the sparsity of the least-squares estimate (i.e., the solution of the equations (15) with C given in (13) or, equivalently, the ML solution of (12) without the sparsity constraints). For each of the nine sparsity patterns, we solve the ML problem subject to sparsity constraints (16). We rank the nine solutions using the $\mathrm{AIC_c}$ and BIC scores defined in (20). Figure 4 shows the two scores and the negative log-likelihood as functions of γ. The models that minimize the $\mathrm{AIC_c}$/BIC scores turn out to be the same in this example (the models for $\gamma = 0.15$) and the corresponding topology is shown in Figure 5 (left). Only seven entries are misclassified (six entries are misclassified as zeros; one as nonzero). The sparsity pattern in the middle is the topology estimated by thresholding the partial coherence spectrum of

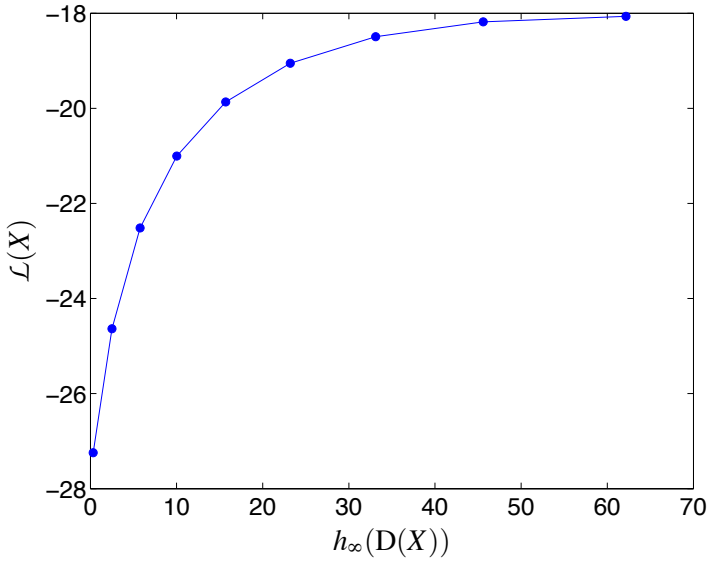

Figure 2: Trade-off curve between the log-likelihood $\mathcal{L}(X)$ and $h_\infty(\mathrm{D}(X))$.

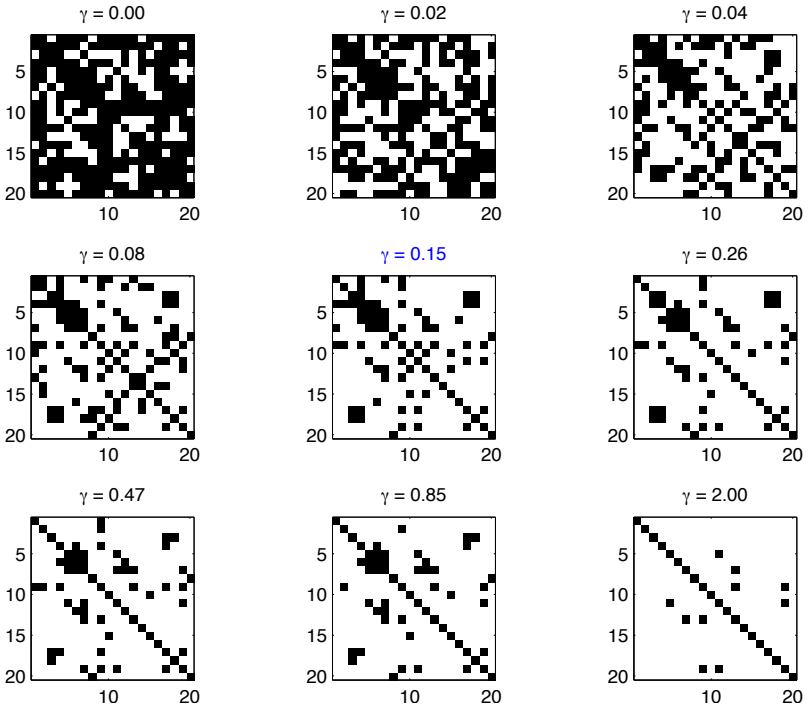

Figure 3: Topologies of solutions along the tradeoff curve in Figure 2 (ordered from right to left on the tradeoff curve).

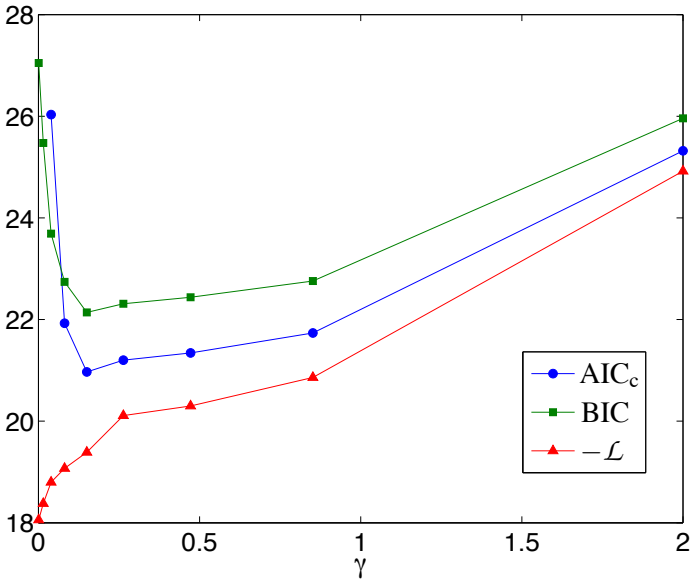

Figure 4: AIC$_c$ and BIC scores, and maximized log-likelihood for solutions on the trade-off curve in Figure 2.

the least-squares solution with the correct model order ($p = 2$). This pattern is computed by solving the ML problem (12) without constraints, and then thresholding the partial coherence (using the same threshold value 0.1 as in the other experiments). The difference between the two patterns clearly shows the benefits of the nonsmooth regularization for estimating a sparse topology. The sparsity pattern on the right of Figure 5 is obtained from the covariance selection method with ℓ_1-norm regularization (i.e., by setting $p = 0$ in the regularized ML problem (21)) and thresholding the partial coherence. Ignoring the model dynamics substantially increased the error in the topology selection.

4.2.2 COMPARISON WITH OTHER TYPES OF REGULARIZATION

To compare the quality of the sparse models with the models obtained from other estimation methods we evaluate the Kullback-Leibler (KL) divergence (Bach and Jordan, 2004) between the true and the estimated spectra as a function of the sample size N for the following six methods.

1. ML estimation without conditional independence constraints (or least-squares estimate). This is the solution of (12) without the constraints, and it can be computed by solving the normal equations (15).

2. ML estimation with conditional independence constraints determined by thresholding the partial coherence matrix of the least-squares estimate (solution 1).

3. ML estimation with Tikhonov regularization and without conditional independence constraints. Tikhonov regularization (also known as *ridge regression* or ℓ_2-regularization) is widely used in statistics and estimation (Hastie et al., 2009, §3.4). A Tikhonov-regularized ML estimate

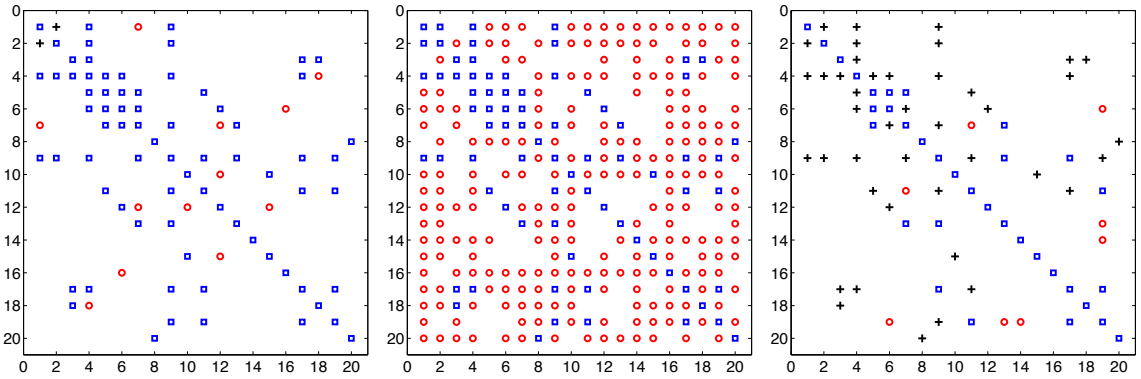

Figure 5: *Left*. The sparsity pattern from the regularized ML problem with $\gamma = 0.15$. *Middle*. The sparsity pattern estimated from the least-squares solution. *Right*. The sparsity pattern from the regularized ML problem for a static model ($p = 0$). The blue squares are the correctly identified nonzero entries (true positives). The red circles are the entries that are misclassified as nonzero (false positives). The black crosses are entries that are misclassified as zeros (false negatives).

is the solution of

$$\text{minimize} \quad -2\log\det B_0 + \mathbf{tr}(CB^TB) + \gamma\|B\|_F^2.$$

The solution can be computed from the normal equations (15) with C replaced by $C+\gamma I$. The solution of this problem can therefore also be viewed as a ML estimate using a perturbed sample covariance matrix $C+\gamma I$. In the experiment, the value of γ is determined by performing a five-fold cross-validation (Hastie et al., 2009, §7.10).

4. ML estimation with conditional independence constraints determined by thresholding the inverse spectral density for the Tikhonov estimate (solution 3).

5. Regularized ML estimation with h_∞-penalty. This is the solution of problem (21) with penalty function (22).

6. ML estimation with conditional independence constraints determined by thresholding the inverse spectral density for the h_∞-regularized ML estimate (solution 5).

The total number of variables in this example is $n(n+1)/2 + pn^2 = 1010$ variables. We show the results in Figure 6 in two different settings: with small sample sizes ($N < 1010$) and with moderate to large sample sizes ($N \geq 1010$). We can note that for small sample sizes N the constrained ML estimates (models 2,4,6) are not better than the unconstrained estimates (models 1,3,5), and much worse in the case of the Tikhonov-regularized estimates. This can be explained by large errors in the estimated topology. For larger N the constrained estimates are consistently better than the unconstrained models, and for very large N the three constrained ML estimates give the same accuracy. For small and moderate N we also see that model 6 (ML estimate for the topology selected via nonsmooth regularization) is much more accurate than the other methods.

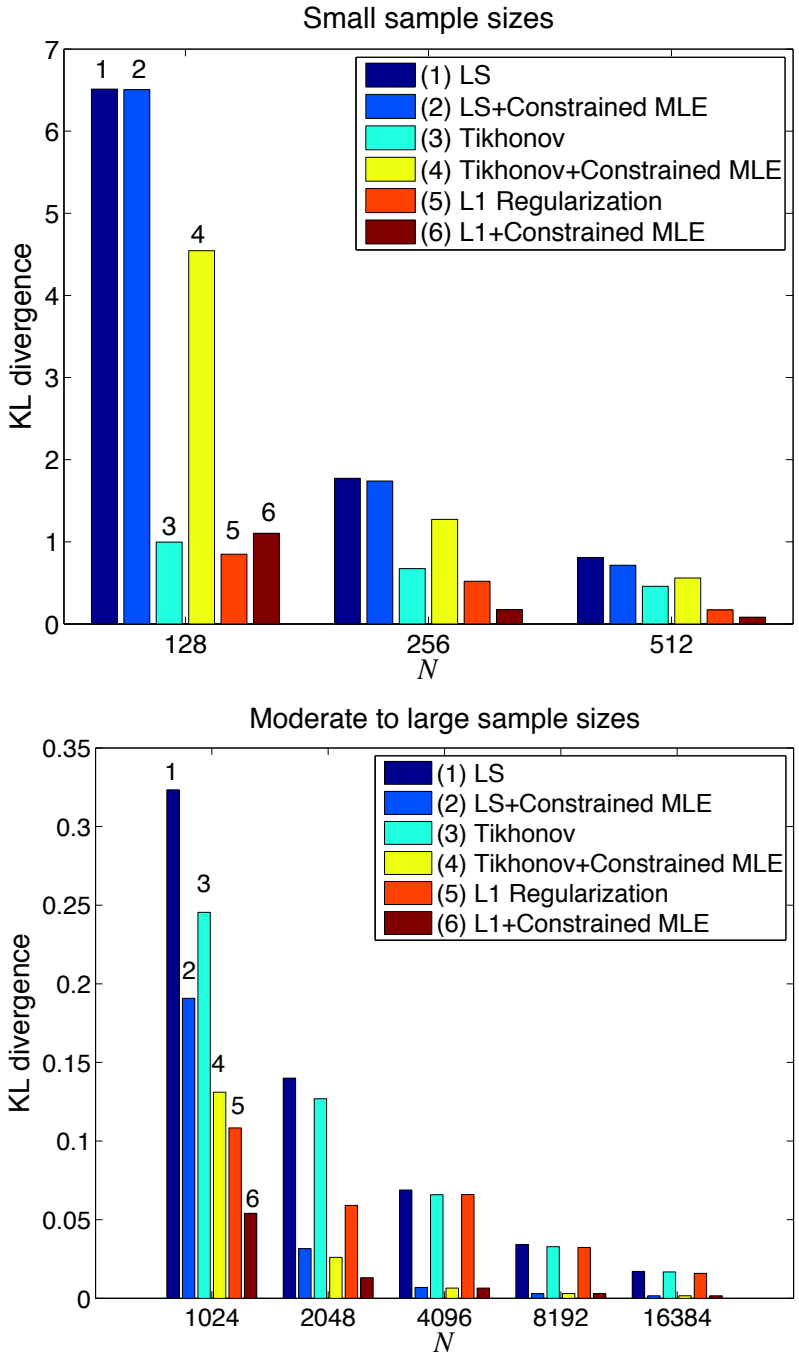

Figure 6: KL divergence between estimated AR models and the true model $(n = 20, p = 2)$ versus the number of samples N. We compare six methods: (1) least-squares estimate, (2) constrained ML estimate with topology estimated by thresholding solution 1, (3) ML estimate with Tikhonov regularization, (4) constrained ML estimate with topology estimated by thresholding solution 3, (5) regularized ML estimate with h_∞-penalty, (6) constrained ML estimate with topology estimated by thresholding solution 5.

4.2.3 ERRORS IN TOPOLOGY AS A FUNCTION OF SAMPLE SIZE

In the last figure (Figure 7) we examine how fast the error in the topology selection decreases with increasing sample length N for three topology selection methods: LS estimation followed by thresholding, ML estimation with Tikhonov regularization followed by thresholding, and ML estimation with nonsmooth regularization followed by thresholding. For each sample size N we show the errors averaged over 50 sample sequences (i.e., 50 different sample covariance matrices C). "False positives" refers to entries that are incorrectly classified as nonzeros (i.e., incorrectly added edges in the graphical model). "False negatives" are entries that are incorrectly classified as zeros (i.e., incorrectly deleted edges). The top graphs in Figure 7 show the fraction of false positives and false negatives versus the sample size. The bottom graphs show the total fraction of misclassified entries. We compare the three methods listed above. As can be seen, the total error in the estimated topology is reduced in the regularized estimates, and the errors decrease more rapidly when we regularize with the sum-of-norms penalty h_∞.

4.3 Experiment 2

In the second experiment we compare different penalty functions h for the regularized ML problem (21): the 'sum-of-ℓ_∞-norms' penalty h_∞ defined in (22), the 'sum-of-ℓ_2-norms' penalty h_2 defined in (28) with $\alpha = 2$, and the 'sum-of-ℓ_1-norms' penalty h_1 defined in (28) with $\alpha = 1$. These penalty functions all yield models with a sparse inverse spectrum

$$S(\omega)^{-1} = Y_0 + \frac{1}{2}\sum_{k=1}^{p}(e^{-\mathrm{j}k\omega}Y_k + e^{\mathrm{j}k\omega}Y_k^T),$$

but have different degrees of sparsity for the entries $(Y_k)_{ij}$ within each group i, j.

The data are generated by randomly choosing sparse coefficients Y_k of an inverse spectrum (10). For each (i, j) of nonzero locations in $S(\omega)^{-1}$, we select random values $(Y_k)_{ij}$ with about the same magnitude for all k. If necessary, a multiple of the identity matrix is added to Y_0 to guarantee the positiveness of the spectrum. An AR realization of the spectrum is then computed by spectral factorization and used to generate sample time series. The model dimensions are $n = 5$, $p = 7$.

Figure 8 shows typical values for the estimated coefficients $(Y_k)_{ij}$. The three penalty functions all give the same topology, but a different sparsity with the same group i, j of coefficients. The sparsity within each group is largest for the h_1-penalty and smallest for the h_∞-penalty.

Table 1 shows the results of topology selection with the three penalties, for sample size $N = 512$ and averaged over 50 sample sequences. The h_∞-penalty gives the models with the smallest KL divergence and smallest error in topology. This is to be expected, given the distribution of the nonzero coefficients $(Y_k)_{ij}$ in the AR models that were used to generate the data. The results also agree with a comparison of different norms in a composite penalty function (Zhao et al., 2009). In general the best choice of norm will depend on how the coefficients are distributed within each group.

5. Applications

This section presents two examples of real data sets to demonstrate how topology selection can facilitate studies of relationship in multivariate time series.

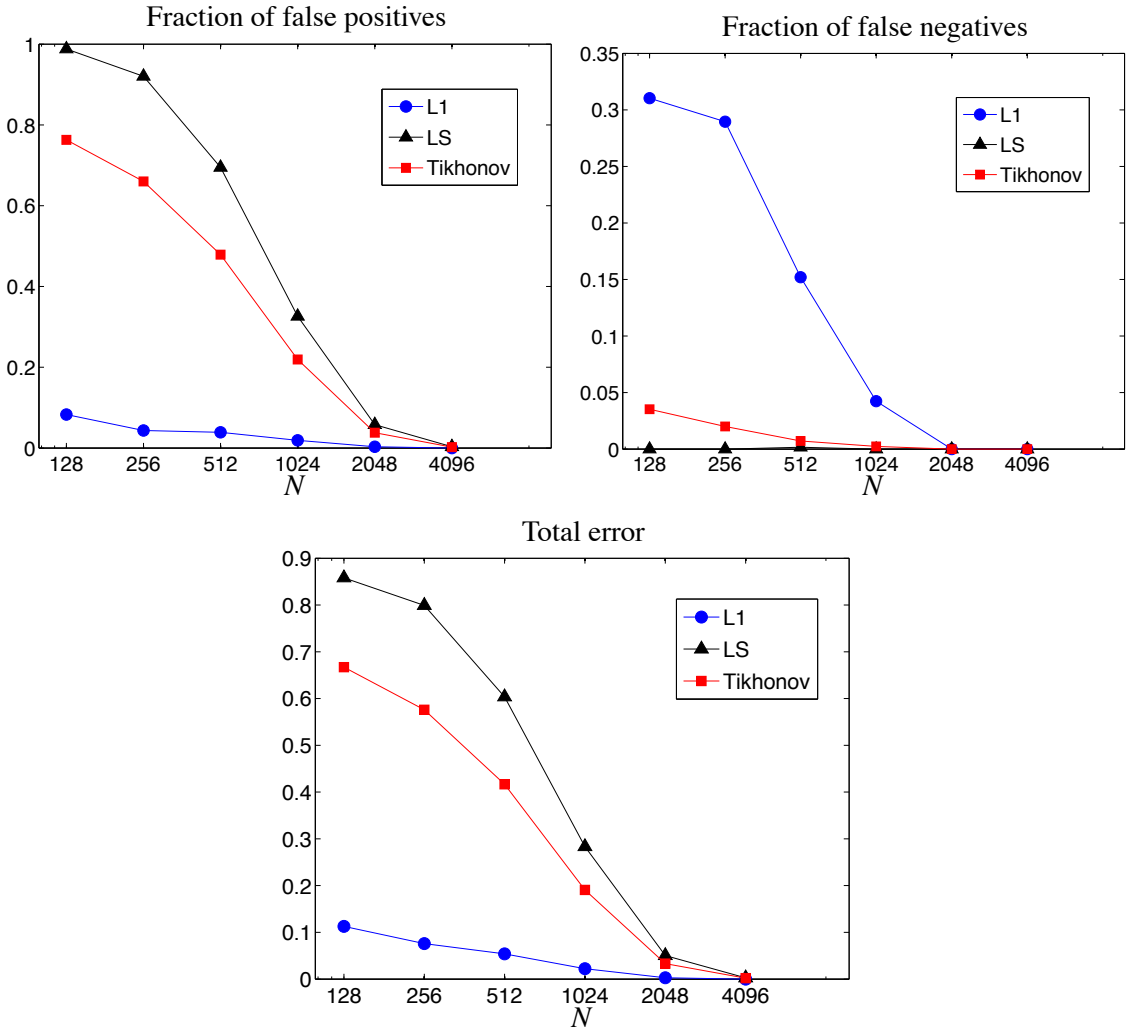

Figure 7: *Top left*. Fraction of incorrectly added edges in the estimated graph (number of upper triangular nonzeros in the estimated pattern that are incorrect, divided by the number of upper triangular zeros in the correct pattern). *Top right*. Fraction of incorrectly removed edges in the estimated graph (number of upper triangular zeros in the estimated pattern that are incorrect, divided by the number of upper triangular nonzeros in the correct pattern). *Bottom*. The combined classification error computed as the sum of the false positives and false negatives divided by the number of upper triangular entries in the pattern.

5.1 Functional Magnetic Resonance Imaging (fMRI) Data

In this section we apply the topology selection method to a functional magnetic resonance imaging (fMRI) time series. We use the StarPlus fMRI data set[1] (Mitchell et al., 2004), which was analyzed

1. StarPlus data can be found at `www.cs.cmu.edu/afs/cs.cmu.edu/project/theo-81/www/`.

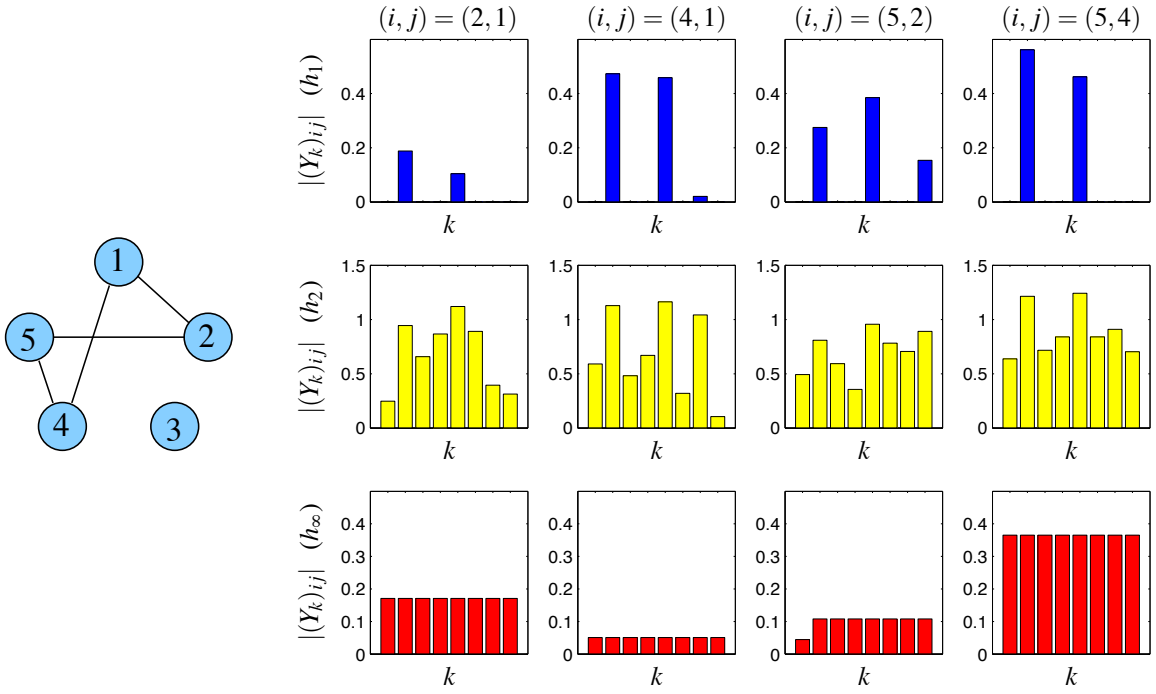

Figure 8: Nonzero coefficients $|(Y_k)_{ij}|$ for regularized ML estimates with penalty h_α, for $\alpha = 1, 2, \infty$.

Dimensions	KL divergence			Error in topology (%)		
	h_1	h_2	h_∞	h_1	h_2	h_∞
$n = 20, p = 2$	0.24	0.22	**0.21**	11.8	11.9	11.6
$n = 20, p = 4$	0.33	0.24	**0.19**	1.65	1.19	0.51
$n = 30, p = 2$	0.40	0.35	**0.30**	9.95	8.83	7.96
$n = 30, p = 4$	0.59	0.46	**0.40**	5.18	3.97	3.53

Table 1: Accuracy of topology selection methods with penalty h_α for $\alpha = 1, 2, \infty$. The table shows the average KL divergence with respect to the true model and the average percentage error in the estimated topology (defined as the sum of the false positives and false negatives divided by the number of upper triangular entries in the pattern), averaged over 50 instances.

using covariance selection in Scheinberg and Rish (2009). The data consists of 80 time series (runs) of brain image scans. In half of the 80 runs the input stimulus shown to the subject is a picture; in the other half it is a sentence. Each run contains 16 images, resulting in 640 images for each input. Mitchell et al. (2004) suggest a region of interest (ROI) of 1718 voxels. To reduce the dimension we took averages over groups of voxels in the ROI and considered four reduced graphs with $n = 7$, 50, 100, and 190 nodes, respectively.

We fit two different AR models, one for each input. The AR model orders selected by the BIC are shown in Table 2. As the problem size (n) becomes larger, the BIC tends to pick a static model

Input	$n=7$	$n=50$	$n=100$	$n=190$
Picture	$p=1$	$p=1$	$p=0$	$p=0$
Sentence	$p=1$	$p=1$	$p=0$	$p=0$

Table 2: AR model orders for the fMRI data set.

Input	Static models ($p=0$)			Time series models ($p=1$)		
	ℓ_1	Tikhonov	LS	ℓ_1	Tikhonov	LS
Picture	991	4116	4203	**0**	13467	13465
Sentence	922	4021	4131	**0**	13240	13238

Table 3: Relative BIC scores of six models fitted to two fMRI time series of size $n=50$. The 'static' models are Gaussian graphical models (i.e., AR models of order $p=0$), the time series models are AR models of order $p=1$. The models are constrained ML estimates with topologies estimated using three different methods: Regularized ML estimate with h_α-penalty, Tikhonov-regularized ML estimate, and the least-squares estimate. The BIC scores are relative to the score of the best model (time series models of regularized ML estimate with h_α-penalty).

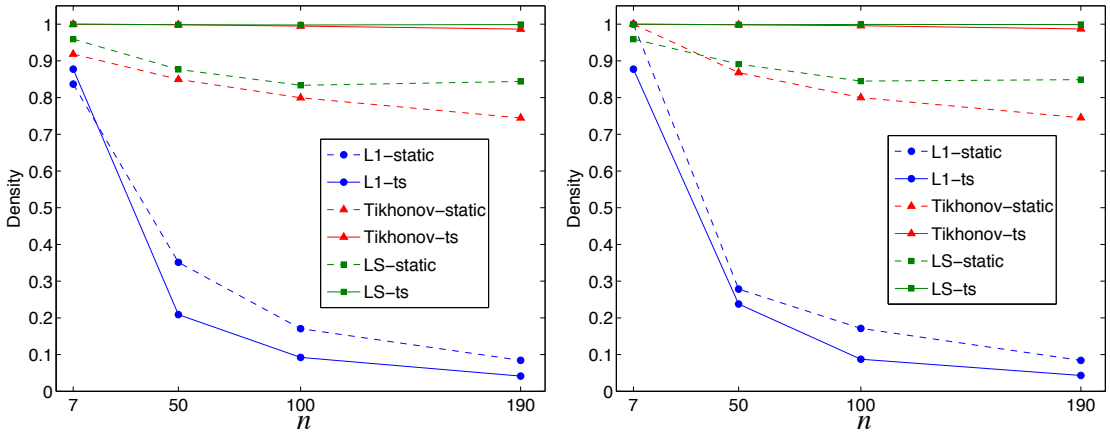

Figure 9: Density of the graphical models of fMRI data for 'picture' stimulus (*left*) and for 'sentence' stimulus (*right*). The density is computed as the number of nonzero entries in the estimated inverse spectrum divided by n^2.

($p=0$). Table 3 shows the BIC scores of different models for the experiment with size $n=50$.

The topologies selected by the BIC are the regularized ML estimates with h_∞-penalty. Figure 9 shows the sparsity of the estimated graphs from the least-squares, Tikhonov-regularized ML, and h_∞-regularized ML methods. The plots show that the h_∞-regularization produces much sparser graphs than the other two methods.

To get an idea of the accuracy of the estimated network structure, we validated the result with a simple classification experiment. For each input we keep one fMRI run as a test problem and use

model order	$n = 7$	$n = 50$	$n = 100$	$n = 190$
$p = 0$	0.21	0.16	**0.11**	**0.06**
$p = 1$	**0.20**	**0.16**	0.16	0.11

Table 4: Classification error of fMRI data versus model size. The error is the number of runs for which the stimulus input is correctly identified divided by the total number of runs (40).

the 39 remaining runs to estimate a sparse AR model. The two models are then used to guess the inputs shown to the subject during the test run. The classification algorithm computes the likelihood of each input, based on the two models, and selects the input with the highest likelihood. We repeat this for each of the 40 choices of test run. Table 4 shows the classification error versus the number of nodes in the graph. We see that the classification is quite successful and achieves an error in the range 6–20%. The error tends to be smaller if we use less averaging (larger n). We also note that for each n, the AR model of order p chosen in Table 2 also performs slightly better in the classification experiment.

5.2 International Stock Market Data

We consider a multivariate time series of 17 stock market indices: the S&P 5000 composite index (U.S.), Toronto stock exchange 300 index (Canada), the All ordinary composite stock index (Australia), the Nikkei 225 stock index (Japan), the Hang Seng stock composite index (Hong Kong), the FTSE 100 share index (United Kingdom), the Frankfurt DAX 30 composite index (German), the CAC 40 stock composite index (France), MIBTEL index (Italy), the Zurich Swiss Market composite index (Switzerland), the Amsterdam exchange index (Netherlands), the Austrian traded index (Austria), IBEX 35 (Spain), BEL 20 (Belgium), the OMX Helsinki 25 index (Finland), the Portugese stock index (Portugal), the Irish stock exchange index (Ireland). The data were stock index closing prices recorded from June 3, 1997 to June 30, 1999 and obtained from `www.globalfinancialdata.com`. The data were converted to US dollars. Missing data due to national holidays were replaced by the most recent values. For each market we use as variable the return between trading day $k-1$ and k, defined as

$$r_k = 100 \log(\pi_k / \pi_{k-1}),$$

where π_k is the closing price on day k. This results in 17-dimensional time series of length 540. Similar time series for a smaller number of markets were analyzed in Bessler and Yang (2003) and Abdelwahab et al. (2008).

We solve the h_∞-regularized ML problem with model orders ranging from $p = 0$ to $p = 3$, and for each value collect the topologies along the trade-off curve, as in the previous examples. The AIC_c and BIC criteria were then used to select a model. Both criteria selected a model of order $p = 1$ and the same sparsity pattern (corresponding to a value $\gamma = 0.34$). Figure 10 (right) shows ρ_{ij}, the maximum magnitude of the partial coherence of the model, and compares it with a thresholded nonparametric estimate obtained with Welch's method (Proakis, 2001) and the constrained ML model with topology obtained by thresholding the least-squares estimate. We note that the graph topologies suggested by the nonparametric and least-squares estimates are much denser than the regularized ML estimate.

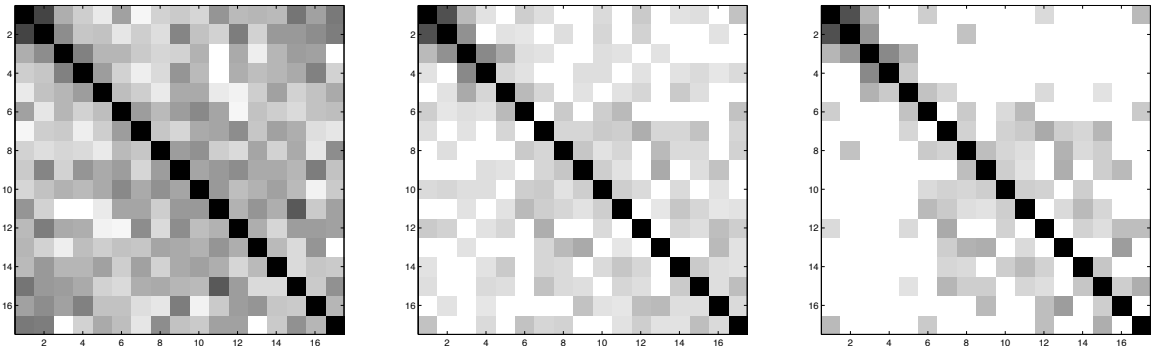

Figure 10: The maximum magnitude ρ_{ij} of the partial coherence for three models of the stock exchange data. *Left:* Thresholded nonparametric sample estimate using Welch's method. *Middle:* Constrained ML estimate with topology determined from the LS solution. *Right:* Constrained ML estimate with topology determined from the h_∞-regularized ML estimate.

Figure 11 shows the graphical model estimated by the h_∞-regularized ML problem. The thickness of the edges is proportional to ρ_{ij}. We recognize many connections that can be explained from geographic proximity or economic ties between the countries. For example, we see strong connections between the U.S. and Canada, between Australia, Japan, and Hong Kong, between Hong Kong and U.K., between the southern European countries, et cetera. Overall the graphical model seems plausible, and the experiment suggests that the topology selection method is quite effective.

6. First-order Optimization Algorithms

In the preceding sections we have considered four convex optimization problems. The constrained ML estimation problem (16) and its dual (17) have differentiable objectives and linear equality and matrix inequality constraints. The regularized ML problem (21) also includes a nondifferentiable term in the objective, and its dual (27) has a differentiable objective but constraints that involve nondifferentiable functions. These optimization problems can be solved by interior-point methods, for example, the path-following methods developed for convex determinant maximization problems (Toh, 1999; Vandenberghe et al., 1998). In practice, however, the problems are often too large for interior-point methods because they involve matrix variables (X or Z) of high dimension. In this section we therefore investigate less expensive first-order algorithms applied to a reformulation of the dual problems (17) and (27). The dual approach avoids several difficulties that arise in first-order methods applied to the primal problems: the complicated constraints in the constrained ML problem (16), the fact that its objective, which is also the first term in the objective of the regularized ML problem (21), is not strictly convex, the nondifferentiability of the penalty term in (21), and, most important, the fact the solution X has low rank and therefore lies on the boundary of the feasible set. (For the regularized ML problem (21), these difficulties could be addressed as in the covariance selection method of Banerjee et al. (2008), by applying Nesterov's fast gradient method to an approximation of the primal problem with a smoothed objective and a closed bounded constraint set (Nesterov, 2005). In our limited experience, with a fixed and conservative choice of

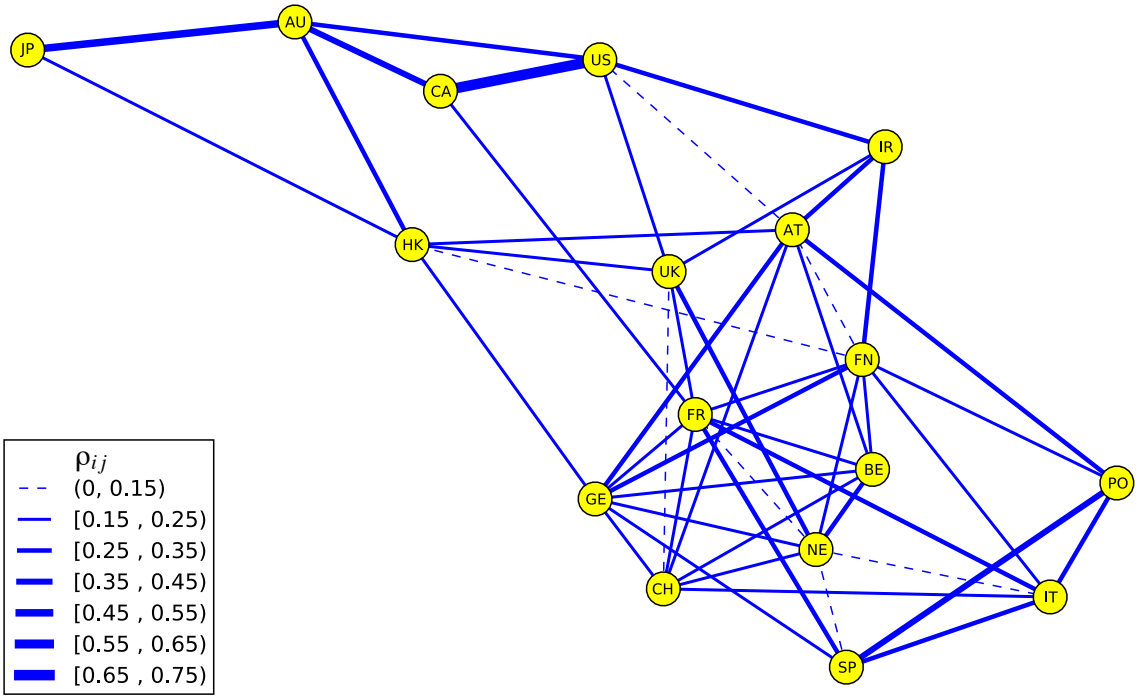

Figure 11: A graphical model of stock market data. The strength of connections is represented by the width of the blue links, which is proportional to $\rho_{ij} = \sup_\omega |R(\omega)_{ij}|$ if it is greater than 0.15.

the smoothing and bounding parameters, this algorithm was slower than the dual gradient projection method described in this section, so we will not pursue it here.)

6.1 Reformulated Dual Problems

To reformulate the dual problems we eliminate the variable W in (17) and (27). Let $V = C + \mathrm{T}(\mathrm{P}(Z))$, respectively, $V = C + \mathrm{T}(Z)$. The inequality

$$V - \begin{bmatrix} W & 0 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} V_{00} - W & V_{1:p,0}^T \\ V_{1:p,0} & V_{1:p,1:p} \end{bmatrix} \succeq 0,$$

is equivalent to

$$V_{1:p,1:p} \succeq 0, \qquad \mathrm{range}(V_{1:p,0}) \subseteq \mathrm{range}(V_{1:p,1:p}), \qquad V_{00} - V_{1:p,0}^T V_{1:p,1:p}^\dagger V_{1:p,0} \succeq W, \tag{32}$$

where $V_{1:p,1:p}^\dagger$ is the pseudo-inverse of $V_{1:p,1:p}$. If $V \succeq 0$, then the matrix W with maximum determinant that satisfies (32) is equal to $V_{00} - V_{1:p,0}^T V_{1:p,1:p}^\dagger V_{1:p,0}$, the *Schur complement* of $V_{1:p,1:p}$ in V. This observation allows us to eliminate W from (17) and (27). Problem (17) can be written as an unconstrained problem

$$\text{maximize} \quad -\phi(C + \mathrm{T}(\mathrm{P}(Z))), \tag{33}$$

and problem (27) as a problem with simple constraints

$$\begin{array}{ll} \text{maximize} & -\phi(C+\mathrm{T}(Z)) \\ \text{subject to} & \sum_{k=0}^{p}(|(Z_k)_{ij}|+|(Z_k)_{ji}|) \leq \gamma, \quad i \neq j \\ & \mathbf{diag}(Z_k) = 0, \quad k = 0,\ldots,p. \end{array} \tag{34}$$

Here $\phi : \mathbf{S}^{n(p+1)} \to \mathbf{R}$ is defined as

$$\phi(V) = -\log\det\left(V_{00} - V_{1:p,0}^T V_{1:p,1:p}^\dagger V_{1:p,0}\right) - n,$$

with domain $\mathbf{dom}\,\phi = \{V \in \mathbf{S}_+^{n(p+1)} \mid V_{00} - V_{1:p,0}^T V_{1:p,1:p}^\dagger V_{1:p,0} \succ 0\}$. This function is convex, since it can be expressed as

$$\phi(V) = \inf\left\{ -\log\det W \;\middle|\; \left[\begin{array}{cc} W & 0 \\ 0 & 0 \end{array}\right] \preceq V \right\} - n,$$

and convexity of this expression follows from results in convex analysis (Boyd and Vandenberghe, 2004, §3.2.5). It is also a smooth function on the interior of its domain and its gradient at a positive definite V can be expressed as

$$\nabla\phi(V) = -V^{-1} + \left[\begin{array}{cc} 0 & 0 \\ 0 & V_{1:p,1:p}^{-1} \end{array}\right]. \tag{35}$$

This can be seen, for example, from the identity $\det V = \det V_{1:p,1:p} \det(V_{00} - V_{1:p,0}^T V_{1:p,1:p}^{-1} V_{1:p,0})$, which gives $\phi(V) = -\log\det V + \log\det V_{1:p,1:p} - n$, and the fact that the gradient of $\log\det X$ is X^{-1}.

If $V = C + \mathrm{T}(\mathrm{P}(Z)) \succ 0$ at the optimum of (33) then the primal optimal solution can be computed from Z via the expressions

$$X = V^{-1} - \left[\begin{array}{cc} 0 & 0 \\ 0 & V_{1:p,1:p}^{-1} \end{array}\right] = \left[\begin{array}{c} -I \\ V_{1:p,1:p}^{-1} V_{1:p,0} \end{array}\right] W^{-1} \left[\begin{array}{c} -I \\ V_{1:p,1:p}^{-1} V_{1:p,0} \end{array}\right]^T \tag{36}$$

where $V = C + \mathrm{T}(\mathrm{P}(Z))$ and $W = V_{00} - V_{1:p,0}^T V_{1:p,1:p}^{-1} V_{1:p,0}$. The expression for X follows from the optimality condition (18) and the identities

$$V = \left[\begin{array}{cc} V_{00} - V_{1:p,0}^T V_{1:p,1:p}^{-1} V_{1:p,0} & 0 \\ 0 & 0 \end{array}\right] + \left[\begin{array}{c} V_{1:p,0}^T V_{1:p,1:p}^{-1} \\ I \end{array}\right] V_{1:p,1:p} \left[\begin{array}{c} V_{1:p,0}^T V_{1:p,1:p}^{-1} \\ I \end{array}\right]^T,$$

$$V^{-1} = \left[\begin{array}{cc} 0 & 0 \\ 0 & V_{1:p,1:p}^{-1} \end{array}\right] + \left[\begin{array}{c} -I \\ V_{1:p,1:p}^{-1} V_{1:p,0} \end{array}\right] (V_{00} - V_{1:p,0}^T V_{1:p,1:p}^{-1} V_{1:p,0})^{-1} \left[\begin{array}{c} -I \\ V_{1:p,1:p}^{-1} V_{1:p,0} \end{array}\right]^T. \tag{37}$$

The formula for V^{-1} also provides an alternative form of the gradient (35).

Similarly, if $C + \mathrm{T}(Z) \succ 0$ at the optimum of (34) then the primal optimal X can be computed from (36) with $V = C + \mathrm{T}(Z)$.

The reformulated dual problems are interesting because they can often be solved by gradient algorithms for unconstrained optimization or gradient projection algorithms for problems with simple constraints. To explain this, we again distinguish between Toeplitz and non-Toeplitz C. If C is

block-Toeplitz, then it can be shown that the functions $\phi(C+\mathrm{T}(\mathrm{P}(Z)))$ and $\phi(C+\mathrm{T}(Z))$ are *closed* convex functions (i.e., with closed sublevel sets) and that their domains are open. Consider the function ϕ restricted to the set of block-Toeplitz matrices, that is, $\phi(\mathrm{T}(R))$, where $R \in \mathbf{M}^{n,p}$. By definition, R is in the domain of $\phi(\mathrm{T}(R))$ if $\mathrm{T}(R) \succeq 0$ and there exists a positive definite W with

$$\mathrm{T}(R) \succeq \begin{bmatrix} W & 0 \\ 0 & 0 \end{bmatrix}.$$

From the property of block-Toeplitz matrices mentioned in Section 2.3, this implies $\mathrm{T}(R) \succ 0$. In other words, the domain of $\phi(\mathrm{T}(R))$ is the open set $\{R \mid \mathrm{T}(R) \succ 0\}$. By a similar argument, if a sequence of matrices R in the domain of $\phi(\mathrm{T}(R))$ converges to a point $\bar{R}$ in the boundary of the domain, then the Schur complement of $\mathrm{T}(\bar{R})_{1:p,1:p}$ in $\mathrm{T}(\bar{R})$ must be singular, and hence $\phi(\mathrm{T}(R)) \to \infty$. For a continuous function with an open domain this is equivalent to closedness (Boyd and Vandenberghe, 2004, p.639).

If C is not block-Toeplitz, then the functions $\phi(C+\mathrm{T}(\mathrm{P}(Z)))$ and $\phi(C+\mathrm{T}(Z))$ are not necessarily closed, and their domains not necessarily open. One implication is that it is possible that the optimal solution of (33) or (34) is at a point in the boundary of the domain of the cost function, that is, a point where $C+\mathrm{T}(\mathrm{P}(Z))$ or $C+\mathrm{T}(Z)$ are singular. However in practice, C is usually approximately block-Toeplitz and one can expect that the functions are often closed. Moreover, in order to apply unconstrained minimization algorithms it is sufficient that the algorithm is started at a point $Z^{(0)}$ for which the sublevel set $\{Z \mid \phi(C+\mathrm{T}(\mathrm{P}(Z))) \leq \phi(C+\mathrm{T}(\mathrm{P}(Z^{(0)})))\}$ is closed. This condition is considerably weaker than the requirement that all sublevel sets are closed.

6.2 Gradient Projection Algorithms

We now present some details on first-order algorithms for the reformulated dual problems. We focus on the constrained problem (34) since the unconstrained problem (33) can be handled as a special case. We first describe a version of the classical gradient projection with a backtracking line search (Polyak, 1987; Bertsekas, 1999). To simplify the notation we will use a generic problem format

$$\begin{array}{ll} \text{minimize} & f(x) \\ \text{subject to} & x \in \mathcal{C} \end{array}$$

where $f : \mathbf{R}^n \to \mathbf{R}$ is convex and continuously differentiable with an open domain, and $\mathcal{C}$ is a closed convex set. We assume that a feasible point $x^{(0)}$ is known and that the sublevel set

$$\mathcal{S} = \{x \in \mathbf{dom}\, f \cap \mathcal{C} \mid f(x) \leq f(x^{(0)})\}$$

is closed and bounded. The closedness assumption is satisfied if f is a closed function. (See the previous paragraph on the validity of this assumption for problems (33) and (34).) We assume that projections on $\mathcal{C}$ are inexpensive and we denote the projection operator by $\mathcal{P}$:

$$\mathcal{P}(y) = \operatorname*{argmin}_{x \in \mathcal{C}} \|x-y\|_2.$$

The *gradient map* associated with f and $\mathcal{C}$ is defined as

$$G_t(x) = \frac{1}{t}\left(x - \mathcal{P}(x - t\nabla f(x))\right)$$

for $t > 0$. For an unconstrained problem, the gradient map is $G_t(x) = \nabla f(x)$, independent of t.

6.2.1 BASIC GRADIENT PROJECTION

The basic gradient projection method starts at $x^{(0)}$ and continues the iteration

$$\begin{aligned} x^{(k)} &= \mathcal{P}\left(x^{(k-1)} - t_k \nabla f(x^{(k-1)})\right) \\ &= x^{(k-1)} - t_k G_{t_k}(x^{(k-1)}) \end{aligned} \tag{38}$$

until a stopping criterion is satisfied. A classical convergence result states that $x^{(k)}$ converges to an optimal solution if t_k is fixed and equal to $1/L$, where L is a constant that satisfies

$$\|\nabla f(u) - \nabla f(v)\|_2 \leq L\|u - v\|_2 \quad \forall u, v \in \mathcal{S}, \tag{39}$$

(Polyak, 1987, §7.2.1). Although our assumptions ($\mathcal{S}$ is closed and bounded, and $\mathbf{dom}\, f$ is open) imply that the Lipschitz condition (39) holds for some constant $L > 0$, its value is not known in practice, so the fixed step size rule $t_k = 1/L$ cannot be used. We therefore determine t_k using a backtracking search (Beck and Teboulle, 2009). The step size search algorithm in iteration k starts at a value $t_k := \bar{t}_k$ where

$$\bar{t}_k = \min\left\{\frac{s^T s}{s^T y}, t_{\max}\right\}, \tag{40}$$

where

$$s = x^{(k-1)} - x^{(k-2)}, \qquad y = \nabla f(x^{(k-1)}) - \nabla f(x^{(k-2)}),$$

and $t_{\max}$ is a positive constant. (In the first iteration we initialize the step size as $t_1 = t_{\max}$.) The search then repeats the update $t_k := \beta t_k$ (where $\beta \in (0,1)$ is an algorithm parameter) until $x^{(k-1)} - t_k G_{t_k}(x^{(k-1)}) \in \mathbf{dom}\, f$ and

$$f(x^{(k-1)} - t_k G_{t_k}(x^{(k-1)})) \leq f(x^{(k-1)}) - t_k \nabla f(x^{(k-1)})^T G_{t_k}(x^{(k-1)}) + \frac{t_k}{2}\|G_{t_k}(x^{(k-1)})\|_2^2. \tag{41}$$

The resulting step size t_k is used in the update to $x^{(k)}$ in (38). Note that the trial points

$$x^{(k-1)} - t_k G_{t_k}(x^{(k-1)}) = \mathcal{P}\left(x^{(k-1)} - t_k \nabla f(x^{(k-1)})\right)$$

generated during the step size search are not necessarily on a straight line. The trajectory is sometimes referred to as the *projection arc* (Bertsekas, 1999, §2.3).

The step length $\|s\|_2^2/s^T y$ is known as the *Barzilai-Borwein* step size and forms the basis of *spectral gradient* methods (Barzilai and Borwein, 1988; Birgin et al., 2003; Figueiredo et al., 2007; Wright et al., 2009). It can be motivated by the easily established fact that $\|s\|_2^2/s^T y \geq 1/L$ if f satisfies (39), so it is a readily computed upper bound for $1/L$.

6.2.2 VARIATIONS

The basic gradient projection method can be varied in several ways, some of which will be compared in the numerical experiments below. To avoid computing a projection for each trial step size t_k in the step size search, we can replace the gradient update with

$$x^{(k)} = x^{(k-1)} - t_k G_{\bar{t}_k}(x^{(k-1)}) \tag{42}$$

where $\bar{t}_k$ is held fixed at the value (40) and t_k is determined by a backtracking search: we take $t_k := \bar{t}_k$ and then backtrack ($t_k := \beta t_k$) until $x^{(k-1)} - t_k G_{\bar{t}_k}(x^{(k-1)}) \in \mathbf{dom}\, f$ and

$$f(x^{(k-1)} - t_k G_{\bar{t}_k}(x^{(k-1)})) \leq f(x^{(k-1)}) - t_k \nabla f(x^{(k-1)})^T G_{\bar{t}_k}(x^{(k-1)}) + \frac{t_k}{2} \|G_{\bar{t}_k}(x^{(k-1)})\|_2^2. \tag{43}$$

In this method the trial points during the step size selection follow a straight line, and each step only requires a function evaluation.

Many alternatives to the step size rules (38) and (42) are available in the literature, for example, the Armijo rule (Bertsekas, 1999, §2.3), and conditions that allow non-monotone convergence (Birgin et al., 2000; Lu and Zhang, 2009). In our experiments these variations gave similar results as the step size rules outlined above.

Another attractive class of gradient projection algorithms are the optimal first-order methods originated by Nesterov (Nesterov, 2004; Tseng, 2008; Beck and Teboulle, 2009). For functions whose gradient is Lipschitz continuous on $\mathcal{C}$, these algorithms have a better complexity than the classical gradient projection method (at most $O(\sqrt{1/\varepsilon})$ iterations are needed to reach an accuracy ε, as opposed to $O(1/\varepsilon)$ for the gradient projection method). These theoretical complexity results are valid if a constant step size $t_k = 1/L$ is used where L is the Lipschitz constant for the gradient, or if the step sizes form an nonincreasing sequence ($t_{k+1} \leq t_k$) determined by a backtracking line search (Beck and Teboulle, 2009; Tseng, 2008). The assumption that the gradient is Lipschitz continuous on $\mathcal{C}$ does not hold for the problem considered here, and it is not clear if the convergence analysis can be extended to the case when the gradient is Lipschitz continuous only on the initial sublevel set. Nevertheless, an implementation with a backtracking line search worked well in our experiments (see next section).

6.2.3 IMPLEMENTATION DETAILS

The most important steps in the gradient projection algorithms applied to (33) are the evaluations of the gradient of the objective function and the projections on the set defined by the constraints. We now explain these two steps and the stopping criterion in more detail.

The gradient (35) of ϕ at a point V can be evaluated from a Cholesky factorization $V = L^T L$ with L lower triangular. If we partition L as

$$L = \begin{bmatrix} L_{00} & 0 \\ L_{1:p,0} & L_{1:p,1:p} \end{bmatrix}$$

then

$$\nabla\phi(V) = \begin{bmatrix} I \\ -L_{1:p,1:p}^{-1} L_{1:p,0} \end{bmatrix} L_{00}^{-1} L_{00}^{-T} \begin{bmatrix} I \\ -L_{1:p,1:p}^{-1} L_{1:p,0} \end{bmatrix}^T.$$

The projection $\mathcal{P}(U)$ of a matrix $U \in \mathbf{M}^{p,n}$ on the set defined by the constraints in (34) can be efficiently computed as follows. Clearly, the diagonal entries of $\mathcal{P}(U)_k$ are zero for $k = 0, \ldots, p$. To find the off-diagonal entries we can solve an independent problem

$$\begin{array}{ll} \text{minimize} & 2((Z_0)_{ij} - (U_0)_{ij})^2 + \sum_{k=1}^{p} \left(((Z_k)_{ij} - (U_k)_{ij})^2 + ((Z_k)_{ji} - (U_k)_{ji})^2\right) \\ \text{subject to} & \sum_{k=0}^{p} (|(Z_k)_{ij}| + |(Z_k)_{ji}|) \leq \gamma \end{array}$$

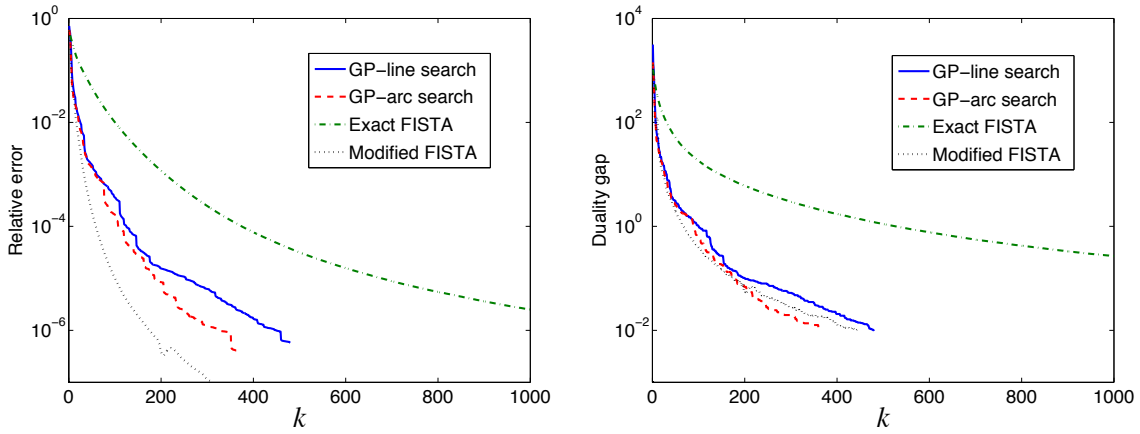

Figure 12: Convergence of gradient projection algorithms. *Left:* Relative error $(f(Z^{(k)})-f^\star)/|f^\star|$ versus the number of iterations. *Right:* Duality gap versus the number of iterations.

for each i,j with $j>i$. This is the problem of projecting a vector on the ℓ_1-norm ball. The solution is easily derived from duality and can be calculated by applying to the entries $(U_k)_{ij}$ the shrinkage operation familiar in sparse optimization (see, for example, Tibshirani, 1996).

The following stopping criterion will be used in the experiments. At each iteration, we compute X in (36) from the current iterate Z. This matrix X is primal feasible, as can be seen from the identity (37) and the fact that $C+\mathrm{T}(Z)\succ 0$. By taking the Schur complement of $(C+\mathrm{T}(Z))_{1:p,1:p}$ we also find a dual feasible W in (27). The duality gap between this primal feasible X and the dual feasible Z,W is

$$\begin{aligned}\eta &= -\log\det X_{00}+\mathbf{tr}(CX)+\gamma h(\mathrm{D}(X))-\log\det W-n\\ &= \mathbf{tr}(CX)-n+\gamma h(\mathrm{D}(X))\\ &= \mathbf{tr}((C+\mathrm{T}(Z))X)-n-\mathbf{tr}(X\,\mathrm{T}(Z))+\gamma h(\mathrm{D}(X))\\ &= -\mathbf{tr}(X\,\mathrm{T}(Z))+\gamma h(\mathrm{D}(X)).\end{aligned}$$

We terminate when the duality gap is below a given tolerance.

6.3 Numerical Example

We generate AR models as in the experiment described in Section 4.2. In the first experiment, the model dimensions are $n=300$, $p=2$, $N=2n(p+1)$. The true inverse spectrum has 10428 non-zero entries in the upper triangular part (a density of about 12%). The penalty parameter γ is set at $\gamma=0.1$. The variable Z in the reformulated dual problem (34) is a matrix in $\mathbf{M}^{300,2}$, so the problem has $n(n+1)/2+pn^2=225150$ optimization variables. We start the gradient projection algorithm at a strictly feasible $Z^{(0)}=0$, and terminate when the duality gap is below 10^{-2} (the optimal value is on the order of hundreds).

Figure 12 shows the relative error $(f(Z^{(k)})-f^\star)/|f^\star|$ where $f(Z)=\phi(C+\mathrm{T}(\mathrm{P}(Z)))$ and $f^\star$ is the optimal value. It also shows the duality gap $\eta^{(k)}$ versus the iteration number for a typical instance. 'GP with arc search' refers to the gradient projection method (38) with step size rule (41).

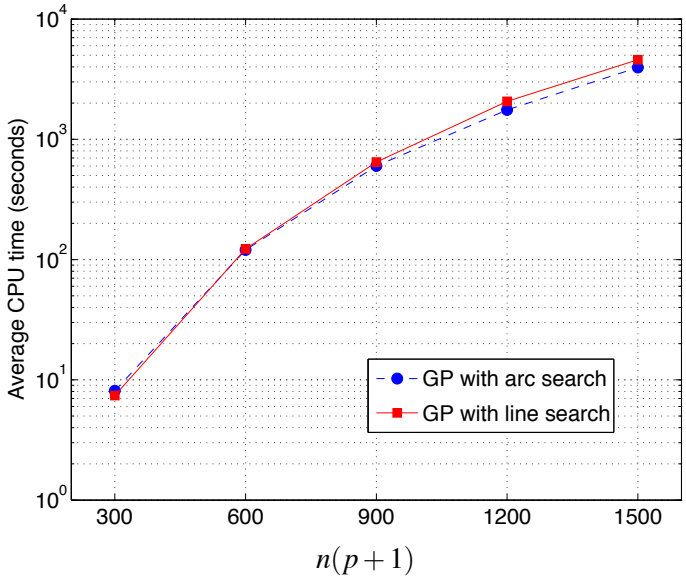

Figure 13: Average CPU times (averaged over 10 runs) of the gradient projection algorithm versus the problem size. The algorithm stops when the duality gap is less than 10^{-1}. The red squares correspond to 'GP with line search' and the blue squares correspond to 'GP with arc search'.

'GP with line search' refers to the gradient projection method (42) with step size rule (43). The step size searches required at most 15 backtracking steps to find an acceptable step size. As can be seen, a solution with a moderate accuracy (relative error in the range 10^{-4}–10^{-3}) is obtained after a number of iterations that is only a fraction of the problem size. The convergence of the 'arc search' method is slightly faster, but it should be kept in mind that this method is more expensive than the 'line search'.

The 'Exact FISTA' method is the gradient projection algorithm with backtracking line search from Beck and Teboulle (2009) using monotonically decreasing step sizes ($t_k \leq t_{k-1}$, as required by the theory in Beck and Teboulle 2009). As can be seen the convergence was not faster than the classical gradient projection method. A heuristic modification in which the step sizes are not forced to be nonincreasing, but at each iteration the line searche is initialized at the Barzilai and Borwein steplength (40), was often about five times faster. This algorithm is referred to as 'Modified FISTA' in the figure.

Figure 13 shows the CPU time versus problem size on a 3GHz Intel Pentium(R) 4 processor with 2.94 GB of RAM, for the 'GP with arc search' and 'GP with line search' algorithms. The test problems are generated as in the previous experiment, with $p = 2$ and varying n. The algorithms stop when it achieves a duality gap less than $\varepsilon = 0.1$. This yields a solution with a moderate accuracy (relative gap in the range 10^{-4}–10^{-3}). The plot shows that the times needed to solving the regularized ML estimation using both algorithms are fairly comparable with a slight advantage for 'GP with arc search' when n is large. Although the backtracking steps in the arc search method are more expensive, the gradient projection method with this step size selection required fewer iterations in most cases.

7. Conclusion

We have presented a convex optimization method for topology selection in graphical models of autoregressive Gaussian processes. The method is based on augmenting the maximum likelihood estimation problem with an ℓ_1-type penalty function, chosen to promote sparsity in the inverse spectrum. By tracing the trade-off curve between the log-likelihood and the penalty function, we obtain a small set of sparse graph topologies, that can then be ranked according to information-theoretic criteria such as the AIC or BIC. This procedure avoids the combinatorial complexity of enumerating all possible topologies, and produces accurate results for smaller sample sizes than methods based on empirical or least-squares estimates. To solve the large, nonsmooth convex optimization problems that result from this formulation, we have investigated a gradient projection method applied to a reformulated dual problem. Experiments with randomly generated examples, and an analysis of an fMRI time series and a time series of international stock market indices were included to confirm the effectiveness of this approach.

Abstract

We present a polynomial update time algorithm for the inductive inference of a large class of context-free languages using the paradigm of positive data and a membership oracle. We achieve this result by moving to a novel representation, called Contextual Binary Feature Grammars (CBFGs), which are capable of representing richly structured context-free languages as well as some context sensitive languages. These representations explicitly model the lattice structure of the *distribution* of a set of substrings and can be inferred using a generalisation of distributional learning. This formalism is an attempt to bridge the gap between simple learnable classes and the sorts of highly expressive representations necessary for linguistic representation: it allows the learnability of a large class of context-free languages, that includes all regular languages and those context-free languages that satisfy two simple constraints. The formalism and the algorithm seem well suited to natural language and in particular to the modeling of first language acquisition. Preliminary experimental results confirm the effectiveness of this approach.

Keywords: grammatical inference, context-free language, positive data only, membership queries

1. Introduction

In natural language processing, many applications require the learning of powerful grammatical models. One of the central concerns of generative linguistics is the definition of an adequate formalism that needs to satisfy two different objectives. On the one hand, such a formalism must be expressive enough to describe natural languages. On the other hand, it has to be sufficiently constrained to be learnable from the sort of linguistic data available to the child learner (Chomsky, 1986). In this context, there are two possible research strategies. One is to take a descriptively adequate formalism such as *Tree Adjoining Grammars* (Joshi and Schabes, 1997) or some other mildly context sensitive grammatical formalism and try to construct learning algorithms for that class. However, such a strategy is unlikely to be successful because classes that are so powerful are difficult to handle from a machine learning point of view. The other approach, which we adopt

in this paper, consists in switching to a formalism that is in some sense intrinsically learnable, and seeing whether we can represent linguistically interesting formal languages in that representation.

Grammatical inference is the machine learning domain which aims at studying learnability of formal languages. While many learnability results have been obtained for regular languages (Angluin, 1987; Carrasco and Oncina, 1994), this class is not sufficient to correctly represent natural languages. The next class of languages to consider is the class of context-free languages (CFL). Unfortunately, there exists no learnability results for the whole class. This may be explained by the fact that this class relies on syntactic properties instead of intrinsic properties of the language like the notion of residuals for regular languages (Denis et al., 2004). Thus, most of the approaches proposed in the literature are either based on heuristics (Nakamura and Matsumoto, 2005; Langley and Stromsten, 2000) or are theoretically well founded but concern very restricted subclasses of context-free languages (Eyraud et al., 2007; Yokomori, 2003; Higuera and Oncina, 2002). Some of these approaches are built from the idea of *distributional learning*,[1] normally attributed to Harris (1954). The basic principle—as we reinterpret it in our work—is to look at the set of contexts that a substring can occur in. The distribution of a substring is the linguistic way of referring to this set of contexts. This idea has formed the basis of many heuristic algorithms for learning context-free grammars (see Adriaans, 2002 for instance). However, a recent approach by Clark and Eyraud (2007), has presented an accurate formalisation of distributional learning. From this formulation, a provably correct algorithm for context-free grammatical inference was given in the identification in the limit framework, albeit for a very limited subclass of languages, the substitutable languages. From a more general point of view, the central insight is that it is not necessary to find the non-terminals of the context-free grammar (CFG): it is enough to be able to represent the congruence classes of a sufficiently large set of substrings of the language and to be able to compute how they combine. This result was extended to a PAC-learning result under a number of different assumptions (Clark, 2006) for a larger class of languages, and also to a family of classes of learnable languages (Yoshinaka, 2008).

Despite their theoretical bases, these results are still too limited to form the basis for models for natural language. There are two significant limitations to this work: first it uses a very crude measure for determining the syntactic congruence, and secondly the number of congruence classes required will in real cases be prohibitively large. If each non-terminal corresponds to a single congruence class (the NTS languages Boasson and Senizergues, 1985), then the problem may be tractable. However in general the contexts of different non-terminals overlap enormously: for instance the contexts of adjective phrases and noun phrases in English both contain contexts of the form (*"it is"*, *"."*). Problems of lexical ambiguity also cause trouble. Thus for a CFG it may be the case that the number of congruence classes corresponding to each non-terminal may be exponentially large (in the size of the grammar). But the situation in natural language is even worse: the CFG itself may have an exponentially large number of non-terminals to start off with! Conventional CFGs are simply not sufficiently expressive to be cognitively plausible representations of natural language: to write a CFG requires a multiplication of the numbers of non-terminals to handle phenomena like *subject verb agreement*, *gender features*, *displaced constituents*, etc. This requires the use of a formalism like GPSG (Generalised Phrase Structure Grammar) (Gazdar et al., 1985) to write a meta-grammar—a compact way of specifying a very large CFG with richly structured non-terminals.

1. Note here that the word distributional does not refer to stochastic distributions, but to the occurrence of strings into contexts. The distribution of a string corresponds to all the possible contexts in which the string can appear.

Thus we cannot hope to learn natural languages by learning one congruence class at a time: it is vital to use a more structured representation.

This is the objective of the approach introduced in this article: for the first time, we can bridge the gap between theoretically well founded grammatical inference methods and the sorts of structured representations required for modeling natural languages.

In this paper, we present a family of representations for highly structured context-free languages and show how they can be learned. This is a paper in learning, but superficially it may appear to be a paper about grammatical representations: much of the work is done by switching to a more tractable formalism, a move which is familiar to many in machine learning. From a machine learning point of view, it is a commonplace that switching to a better representation—for example, through a non-linear map into some feature space—may make a hard problem very easy.

The contributions of this paper are as follows: we present in Section 3 a rich grammatical formalism, which we call *Contextual Binary Feature Grammars* (CBFG). This grammar formalism is defined using a set of contexts which play the role of features with a strict semantics attached to these features. Though not completely original, since it is closely related to a number of other formalisms such as Range Concatenation Grammars (Boullier, 2000), it is of independent interest. We consider then the case when the contextual features assigned to a string correspond to the contexts that the string can occur in, in the language defined by the grammar. When this property holds, we call it an *exact CBFG*. The crucial point here is that for languages that can be defined by an exact CBFG, the underlying structure of the representation relies on intrinsic properties of the language easily observable on samples by looking at context sets.

The learning algorithm is defined in Section 4. We provide some conditions, both on the context sets and the learning set, to ensure the learnability of languages that can be represented by CBFG. We prove that this algorithm can identify in the limit this restricted class of CBFGs from positive data and a membership oracle.

Some experiments are provided in Section 5: these experiments are intended to demonstrate that even quite naive algorithms based on this are efficient and effective at learning context-free languages.

Section 6 contains a theoretical study on the expressiveness of CBFG representations. We investigate the links with the classical Chomsky hierarchy, some well known grammatical representations used in natural language processing. An important result about the expressive power of the class of CBFG is obtained: it contains all the context-free languages and some non context-free languages. This makes this representation a good candidate for representing natural languages. However exact CBFG do not include all context-free languages but do include some non context-free ones, thus they are orthogonal with the classic Chomsky hierarchy and can represent a large class of languages. This expressiveness is strengthened by the fact that exact CBFG contains most of the existing learnable classes of languages.

2. Basic Definitions and Notations

We begin by some standard notations and definitions used all along the paper.

We consider a finite alphabet Σ as a finite non-empty set of symbols also called letters. A string (also called word) u over Σ is a finite sequence of letters $u = u_1 \cdots u_n$. Let $|u|$ denote the length of u. The set of all strings over Σ is denoted by Σ^*, corresponding to the free monoid generated by Σ. λ denotes the empty string and $\Sigma^+ = \Sigma^* \backslash \{\lambda\}$. A language L is any subset $L \subseteq \Sigma^*$.

We will write the concatenation of u and v as uv, and similarly for sets of strings. $u \in \Sigma^*$ is a substring of $v \in \Sigma^*$ if there are strings $l, r \in \Sigma^*$ such that $v = lur$. Define $Sub(u)$ to be the set of non-empty substrings of u. For a set of strings S define $Sub(S) = \bigcup_{u \in S} Sub(u)$.

A context is an element of $\Sigma^* \times \Sigma^*$. For a string u and a context $f = (l, r)$ we write $f \odot u = lur$; the insertion or wrapping operation. We extend this to sets of strings and contexts in the natural way. We define by $Con(w) = \{(l, r) | \exists u \in \Sigma^+ : lur = w\}$, that is, the set of all contexts of a word w. Similarly, for a set of strings, we define: $Con(S) = \bigcup_{w \in S} Con(w)$.

We give now a formal definition of the set of contexts since it represents a notion often used in the paper.

Definition 1 *The set of contexts, or context distribution, of a string u in a language L is, $C_L(u) = \{(l, r) \in \Sigma^* \times \Sigma^* | lur \in L\}$. We will often drop the subscript where there is no ambiguity.*

Definition 2 *Two strings u and v are syntactically congruent with respect to a language L, denoted $u \equiv_L v$, if and only if $C_L(u) = C_L(v)$.*

The equivalence classes under this relation are the *congruence* classes of the language.

After these basic definitions and notations, we recall here the definition of a context-free grammar which is a class which is close to the language class studied in this paper.

Definition 3 *A context-free grammar (CFG) is a quadruple $G = (\Sigma, V, P, S)$. Σ is a finite alphabet of terminal symbols, V is a set of non terminals s.t. $\Sigma \cap V = \emptyset$, $P \subseteq V \times (V \cup \Sigma)^+$ is a finite set of productions, $S \in V$ is the start symbol.*

We denote a production of P: $N \to \alpha$ with $N \in V$ and $\alpha \in (V \cup \Sigma)^+$. We will write $uNv \Rightarrow_G u\alpha v$ if there is a production $N \to \alpha$ in G. $\overset{*}{\Rightarrow}_G$ denotes the reflexive transitive closure of $\Rightarrow_G$.

The language defined by a CFG G is $L(G) = \{w \in \Sigma^* | S \overset{*}{\Rightarrow}_G w\}$. In the following, we will consider the CFG are represented in the *Chomsky normal form* (CNF), that is, with right hand side of production rules composed of exactly two non terminals or with exactly one terminal symbol.

In general we will assume that λ is not a member of any language.

3. Contextual Binary Feature Grammars (CBFG)

Distributional learning, in our view, involves explicitly modeling the distribution of the substrings of the language—we would like to model $C_L(w)$. Clearly a crucial element of this distribution is the empty context (λ, λ): $(\lambda, \lambda) \in C_L(w)$ if and only if $w \in L$. Our goal is to construct a representation that allows us to recursively compute a representation of the distribution of a string w, $C_L(w)$, from the (representations of) the distributions of its substrings.

The representation by *contextual binary feature grammars* relies on the inclusion relation between sets of contexts of language L. In order to introduce this formalism, we propose, for a start, to present some preliminary results on context inclusion. These results will lead us to define a relevant representation for modeling these inclusion dependencies by the notion of *contextual binary feature grammars*.

3.1 Preliminary Results about Context Inclusion

The objective of this section is to give some information about contexts that will help to give an intuition about the representation. The basic insight behind CBFGs is that there is a relation between

the contexts of a string w and the contexts of its substrings. This is given by the following trivial lemma:

Lemma 4 *For any language L and for any strings u, u', v, v' if $C(u) = C(u')$ and $C(v) = C(v')$, then $C(uv) = C(u'v')$.*

Proof We write out the proof completely as the ideas will be used later on. Suppose we have u, v, u', v' that satisfy the conditions. If $(l, r) \in C(uv)$, then $(l, vr) \in C(u)$ and thus $(l, vr) \in C(u')$. As a consequence, $(lu', r) \in C(v)$ and then $(lu', r) \in C(v')$ which implies that $(l, r) \in C(u'v')$. Symmetrically, by using the same arguments, we can show that $(l, r) \in C(u'v')$ implies (l, r) in $C(uv)$. Thus $C(uv) = C(u'v')$. ■

This establishes that the syntactic monoid $\Sigma^* / \equiv_L$ is well-defined; from a learnability point of view this means that if we want to compute the contexts of a string w we can look for a split into two strings uv where u is congruent to u' and v is congruent to v'; if we can do this and we know how u' and v' combine, then we know that the contexts of uv will be exactly the contexts of $u'v'$. There is also a slightly stronger result:

Lemma 5 *For any language L and for any strings u, u', v, v' if $C(u) \subseteq C(u')$ and $C(v) \subseteq C(v')$, then $C(uv) \subseteq C(u'v')$.*

Proof See proof of Lemma 4. ■

$C(u) \subseteq C(u')$ means that we can replace any occurrence in a sentence of u with a u', without affecting the grammaticality, but not necessarily vice versa. Note that none of these strings need to correspond to non-terminals: this is valid for any fragment of a sentence.

We will give a simplified example from English syntax: the pronoun "*it*" can occur everywhere that the pronoun "*him*" can, but not vice versa.[2] Thus given a sentence "*I gave him away*", we can substitute "*him*" for "*it*", to get the grammatical sentence "*I gave it away*", but we cannot reverse the process. For example, given the sentence "*it is raining*", we cannot substitute "*him*" for "*it*", as we will get the ungrammatical sentence "*him is raining*". Thus we observe $C(him) \subsetneq C(it)$.

Looking at Lemma 5 we can also say that, if we have some finite set of strings K, where we know the contexts, then:

Corollary 6 *For any language L and for any set of strings K, we have:*

$$C(w) \supseteq \bigcup_{\substack{u',v': \\ u'v'=w}} \bigcup_{\substack{u \in K: \\ C(u) \subseteq C(u')}} \bigcup_{\substack{v \in K: \\ C(v) \subseteq C(v')}} C(uv).$$

This is the basis of our representation: a word w is characterised by its set of contexts. We can compute the representation of w, from the representation of its parts u', v', by looking at all of the other matching strings u and v where we understand how they combine (with subset inclusion). Rather than representing just the congruence classes, we will represent the lattice structure of the set of contexts using subset inclusion; sometimes called Dobrušin-domination (Marcus, 1967).

The key relationships are given by context set inclusion. *Contextual binary feature grammars* allow a proper definition of the combination of context inclusion.

2. This example does not account for a number of syntactic and semantic phenomena, particularly the distribution of reflexive anaphors.

3.2 Contextual Binary Feature Grammars

The formalism of *contextual binary feature grammars* has some resemblance with *Generalized Phrase Structure Grammar (GPSG)* (Gazdar et al., 1985), and most importantly the class of *Range Concatenation Grammars (RCG)* (Boullier, 2000); these relationships will be detailed in Section 6. As we will see later, note that our formalism defines a class orthogonal to the class of context-free grammars, indeed the use of subsets inclusion allows to model non context-free languages.

Definition 7 *A Contextual Binary Feature Grammar (CBFG) G is a tuple* $\langle F, P, P_L, \Sigma \rangle$*:*

- F *is a finite set of contexts, (i.e.,* $F \subset \Sigma^* \times \Sigma^*$*) called features, where we write* $E = 2^F$ *for the power set of* F *defining the categories of the grammar, and where* $(\lambda, \lambda) \in F$*.*
- $P \subseteq E \times E \times E$ *is a finite set of productions that we write* $x \to yz$ *where* $x, y, z \in E$*,*
- $P_L \subseteq E \times \Sigma$ *is a set of lexical rules, written* $x \to a$*,*
- Σ *denotes the alphabet.*

Given a CBFG G we can recursively define a function f_G from $\Sigma^* \to E$ as follows:

$$
\begin{aligned}
& f_G(\lambda) = \emptyset, \\
& f_G(w) = \bigcup_{(c \to w) \in P_L} c && \text{iff } |w| = 1, \\
& f_G(w) = \bigcup_{u,v:uv=w} \; \bigcup_{\substack{x \to yz \in P: \\ y \subseteq f_G(u) \wedge \\ z \subseteq f_G(v)}} x && \text{iff } |w| > 1.
\end{aligned}
$$

Given a CBFG G and a string w it is possible to compute $f_G(w)$ in time $O(|F||P||w|^3)$ using standard dynamic programming techniques. A straightforward modification of the Cocke-Kasami-Younger algorithm for parsing Context-Free Grammars will suffice.

Thus a CBFG, G, defines for every string u a set of contexts $f_G(u)$: this will be a representation of the context distribution. $f_G(u)$ will be a subset of F: we will want $f_G(u)$ to approximate $C_L(u) \cap F$. The natural way to define the membership of a string w in $L(G)$ is to have the context $(\lambda, \lambda) \in f_G(w)$.

Definition 8 *The language defined by a CBFG G is the set of all strings that are assigned the empty context:* $L(G) = \{u | (\lambda, \lambda) \in f_G(u)\}$.

We give here more explanation about the function f_G. A rule $x \to yz$ is applied to analyse a string w if there is a split or *cut* of the string w into two strings u and v such that $uv = w$ s.t. $y \subseteq f_G(u)$ and $z \subseteq f_G(v)$—recall that y and z are sets of features.

One way of viewing a production $x \to yz$ is as an implication: if two strings u and v are such that they have the features y and z, then their concatenation will have the features x. As features correspond to contexts, intuitively, the relation given by the production rule is linked with Lemma 5: x is included in the set of features of $w = uv$. From this relationship, for any $(l, r) \in x$ we have $lwr \in L(G)$.

The complete computation of f_G is then justified by Corollary 6: $f_G(w)$ defines all the possible contextual features associated by G to w with all the possible cuts $uv = w$ (i.e., all the possible derivations).

Note the relation between the third clause above and Corollary 6. In general we will apply more than one production at each step of the analysis.

We will discuss the relation between this class and the class of CFGs in some detail in Section 6. For the moment, we will just make the following points. First, the representation is quite close to that of a CFG where the non-terminals correspond to sets of contexts (subsets of F). There are, however, crucial differences: the very fact that they are represented by sets means that the non-terminals are no longer atomic symbols but rather structures; the formalism can combine different rules together at each step. Secondly, the function f_G can combine different parsing paths. It is not the case that every feature assigned to w must come from the same split of w into u and v. Rather some features could come from one split, and some from another: these two sets of features can be combined in a single derivation even though they come from different splits (which correspond to different derivation trees in CFG). It is this property that takes the class of languages out of the class of context-free languages. In the special case where all of the productions involve only singleton sets then this will reduce to a CFG—the non-terminals will correspond to the individual features, and $f_G(w)$ will correspond to the set of non-terminals that can derive the string w.

Clearly by the definition of $L(G)$ we are forcing a correspondence between the occurrence of the context (λ,λ) in $C_L(w)$ and the occurrence of the feature (λ,λ) in $f_G(w)$. But ideally we can also require that f_G defines exactly the possible features that can be associated to a given string according to the underlying language. Indeed, we are interested in cases where there is a correspondence between the language theoretic interpretation of a context, and the occurrence of that context as a feature in the grammar: in this case the features will be observable which will lead to learnability.

This is formalised via the following definitions.

Definition 9 *Given a finite set of contexts $F = \{(l_1,r_1), \ldots, (l_n,r_n)\}$ and a language L we can define the context feature function $F_L : \Sigma^* \to 2^F$ which is just the function $u \mapsto \{(l,r) \in F | lur \in L\} = C_L(u) \cap F$.*

Using this definition, we now need a correspondence between the language theoretic context feature function F_L and the representation in our CBFG, f_G.

Definition 10 *A CBFG G is* exact *if for all $u \in \Sigma^*$, $f_G(u) = F_{L(G)}(u)$.*

Example. Let $L = \{a^n b^n | n > 0\}$. Let $\langle F, (\lambda,\lambda), P, P_L, \Sigma\rangle$ a CBFG s.t.

$$F = \{(\lambda,\lambda), (a,\lambda), (aab,\lambda), (\lambda,b), (\lambda,abb)\}.$$

The lexical productions in P_L are:

$$\{(\lambda,b), (\lambda,abb)\} \to a, and$$

$$\{(a,\lambda), (aab,\lambda)\} \to b.$$

Note that these lexical productions are of the form $x \to a$, where x is a subset of F, that is to say, a set of features. The rule $\{(\lambda,b), (\lambda,abb)\} \to a$ therefore says that the letter a will be assigned both

of the features/contexts (λ, b) and (λ, abb). Since this is the only lexical rule for a, we will have that $f_G(a) = \{(\lambda, b), (\lambda, abb)\}$. The productions in P, denoted by $x \to yz$, where x, y, z are again sets of contexts, are defined as:

$$\{(\lambda,\lambda)\} \to \{(\lambda,b)\}\{(aab,\lambda)\},$$
$$\{(\lambda,\lambda)\} \to \{(\lambda,abb)\}\{(a,\lambda)\},$$
$$\{(\lambda,b)\} \to \{(\lambda,abb)\}\{(\lambda,\lambda)\}, \textit{and}$$
$$\{(a,\lambda)\} \to \{(\lambda,\lambda)\}\{(aab,\lambda)\}.$$

In each of these rules, in this trivial case, the sets of contexts are singleton sets. In general, these productions may involve sets that have more than one element. This defines an exact CBFG for L. Indeed, the grammar assigns only (λ,λ) to the elements of the language; for all elements w of $\{a^n b^{n+1} : n > 1\}$ we have $f_G(w) = \{(a,\lambda)\} = F_L(w)$ and for all all elements w of $\{a^{n+1} b^n : n > 1\}$, $f_G(w) = \{(\lambda, b)\} = F_L(w)$; The lexical rules assign correct contexts to each letter.

Exact CBFGs are a more limited formalism than CBFGs themselves; without any limits on the interpretation of the features, we can define a class of formalisms that is equal to the class of *Conjunctive Grammars* (see Section 6.2.3). However, exactness is an important property because it allows to associate the intrinsic structure of a language to the structure of the representation. Contexts are easily observable from a sample and moreover it is only when the features correspond to the contexts that distributional learning algorithms can infer the structure of the language.

3.3 A Parsing Example

To clarify the relationship with CFG parsing, we will give a simple worked example. Consider the CBFG $G = \langle \{(\lambda,\lambda), (aab,\lambda), (\lambda,b), (\lambda,abb), (a,\lambda)\}, P, P_L, \{a,b\}\rangle$ with

$$P_L = \{ \quad \{(\lambda,b),(\lambda,abb)\} \to a, \quad \{(a,\lambda),(aab,\lambda)\} \to b \quad \}.$$

and

$$P = \{ \quad \{(\lambda,\lambda)\} \to \{(\lambda,b)\}\{(aab,\lambda)\}, \quad \{(\lambda,\lambda)\} \to \{(\lambda,abb)\}\{(a,\lambda)\}, \quad \{(\lambda,b)\} \to \{(\lambda,abb)\}\{(\lambda,\lambda)\}, \quad \{(a,\lambda)\} \to \{(\lambda,\lambda)\}\{(aab,\lambda)\} \quad \}.$$

If we want to parse a string w the usual way is to have a bottom-up approach. This means that we recursively compute the f_G function on the substrings of w in order to check whether (λ,λ) belongs to $f_G(w)$.

For example, suppose $w = aabb$. Figure 1 graphically gives the main steps of the computation of $f_G(aabb)$. Basically there are two ways to split $aabb$ that allow the derivation of the empty context: $aab|b$ and $a|abb$. The first one corresponds to the top part of the figure while the second one is drawn at the bottom. We can see for instance that the empty context belongs to $f_G(ab)$ thanks to the rule $\{(\lambda,\lambda)\} \to \{(\lambda,abb)\}\{(a,\lambda)\}$: $\{(\lambda,abb)\} \subseteq f_G(a)$ and $\{(a,\lambda)\} \subseteq f_G(b)$. But for symmetrical reasons the result can also be obtained using the rule $\{(\lambda,\lambda)\} \to \{(\lambda,b)\}\{(aab,\lambda)\}$.

As we trivially have $f_G(aa) = f_G(bb) = \emptyset$, since no right-hand side contains the concatenation of the same two features, an induction proof can be written to show that $(\lambda,\lambda) \in f_G(w) \Leftrightarrow w \in \{a^n b^n : n > 0\}$.

This is a simple example that illustrates the parsing of a string given a CBFG. This example does not fully express the power of CBFG since no element of the right hand side of a rule is composed of more than one context. A more complex example, corresponding to a context-sensitive language, will be presented in Section 6.1.3.

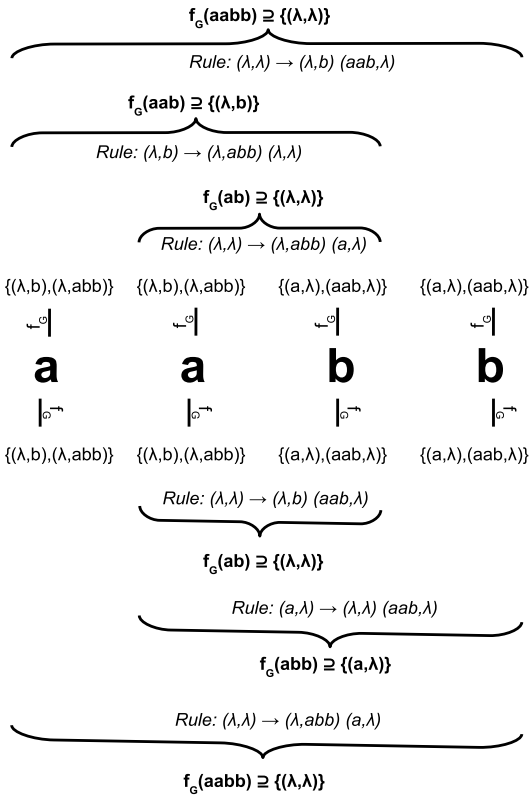

Figure 1: The two derivations to obtain (λ,λ) in $f_G(aabb)$ in the grammar G.

We stop here the presentation of the CBFG formalism and we present our learning algorithm in the next section. However, if the reader wishes to become more familiar with CBFGs a study on their expressiveness is provided in Section 6.

4. Learning Algorithm

We have carefully defined the representation so that the inference algorithm will be almost trivial. Given a set of strings, and a set of contexts, we can simply write down a CBFG that will approximate a particular language.

4.1 Building CBFGs from Sets of Strings and Contexts

Definition 11 *Let L be a language, F be a finite set of contexts such that $(\lambda,\lambda) \in F$, K a finite set of strings, $P_L = \{F_L(u) \to u | u \in K \wedge |u| = 1\}$ and $P = \{F_L(uv) \to F_L(u)F_L(v) | u, v, uv \in K\}$. We define $G_0(K,L,F)$ as the CBFG $\langle F, P, P_L, \Sigma\rangle$.*

Often K will be closed under substrings: that is, $Sub(K) = K$. This grammar is a CBFG, since K and F are finite, and so P and P_L are too by construction. In general it will not be exact.

We will call K here the *basis* for the language. The set of productions is defined merely by observation: we take the set of all productions that we observe as the concatenation of elements of the small set K.

Let us explain the construction in more detail. P_L is the set of lexical productions—analogous to rules of the form $N \to a$ in a CFG in Chomsky normal form. These rules just assign to the terminal symbols their observed distribution—this will obviously be correct in that $f_G(a) = F_L(a)$. P is the interesting set of productions: these allow us to predict the features of a string uv from the features of its part u and v. To construct P we take all triples of strings u, v, uv that are in our finite set K. We observe that u has the contexts $F_L(u)$ and v has the set of contexts $F_L(v)$: our rule then states that we can combine any string that has all of the contexts in $F_L(u)$ together with any string that has the contexts in $F_L(v)$ and the result will have all of the contexts in $F_L(uv)$.

We will now look at a simple example. Let $L = \{a^n b^n \mid n > 0\}$, F, the set of features is $\{(\lambda,\lambda),(a,\lambda),(\lambda,b)\}$ and K, the basis, is $\{a,b,ab,aa,aab\}$. For each of the elements of K we can compute the set of features that it has:

- $F_L(a)$ is just $\{(\lambda,b)\}$—this is the only one of the three contexts in F such that $f \odot a \in L$,
- $F_L(b) = \{(a,\lambda)\}$,
- $F_L(aa) = \emptyset$,
- $F_L(ab) = \{(\lambda,\lambda)\}$,
- $F_L(aab) = \{(\lambda,b)\}$.

G_0 will therefore have the following lexical productions $P_L = \{(\lambda,b)\} \to a,\ \{(a,\lambda)\} \to b$. We can now consider the productions in P. Looking at K we will see that there are only four possible triples of strings of the form uv, u, v: these are (aa,a,a), (ab,a,b), (aab,aa,b) and (aab,a,ab). Each of these will give rise to an element of P:

- The rule given by $ab = a \circ b$: $\{(\lambda,\lambda)\} \to \{(\lambda,b)\}\{(a,\lambda)\}$,
- $aa = a \circ a$ gives $\emptyset \to \{(\lambda,b)\}\{(\lambda,b)\}$,
- $aab = aa \circ b$ gives $\{(\lambda,b)\} \to \emptyset\{(a,\lambda)\}$,
- $aab = a \circ ab$ gives $\{(\lambda,b)\} \to \{(\lambda,b)\}\{(\lambda,\lambda)\}$.

Given K, F and an oracle for L we can thus simply write down a CBFG. However, in this case, the language $L(G_0)$ is not the same as L; moreover, the resulting grammar is not exact. Applying the rules for the recursive computation of f_G, we can see that $f_{G_0}(aab) = \{(\lambda,b)\}$ and $f_{G_0}(abb) = f_{G_0}(aabb) = \{(\lambda,b),(\lambda,\lambda)\}$ but $F_{L(G_0)}(abb) = \{(a,\lambda),(\lambda,b),(\lambda,\lambda)\}$ and thus G_0 is not exact. The problem here is caused by the fact that the production $\{(\lambda,b)\} \to \emptyset\{(a,\lambda)\}$ allows any string to occur in the place specified by the $\emptyset$: indeed since $\emptyset \subseteq f_{G_0}(aab)$ and $\{(a,\lambda)\} \subseteq f_{G_0}(b)$ the rule holds for $aabb$ and thus $\{(\lambda,b)\} \subseteq f_{G_0}(aabb)$. This is actually caused by the fact that there are no contexts in F that correspond to the string aa in K.

Fixing L for the moment, clearly the language defined depends on two factors: the set of strings K and the set of features F. Given K and F, and access to a membership oracle, we can write down

a CBFG with almost no computation, but we still have the problem of finding suitable K and F—it might be that searching for exactly the right combination of K and F is intractably hard. It turns out that it is also very easy to find suitable sets.

In the next section we will establish two important lemmas that show that the search for K and F is fundamentally tractable: first, that as K increases the language defined by $G_0(K,L,F)$ will increase, and secondly that as F increases the language will decrease.

Let us consider one example that illustrates these properties. Consider the language $L = \{a^n b \mid n \geq 0\} \cup \{ba^m \mid m \geq 0\} \cup \{a\}$.

First, let $K = \{a, b, ab\}$ and $F = \{(\lambda, \lambda)\}$; then, by the definition of G_0, we have the following productions:

- $\{(\lambda,\lambda)\} \to a$,
- $\{(\lambda,\lambda)\} \to b$,
- $\{(\lambda,\lambda)\} \to \{(\lambda,\lambda)\}\{(\lambda,\lambda)\}$.

It is easy to see that $L(G_0) = \Sigma^+$.

Now, suppose that $F = \{(\lambda,\lambda),(\lambda,b)\}$ with K unchanged; then, by construction G_0 will have the following productions:

- $\{(\lambda,\lambda),(\lambda,b)\} \to a$,
- $\{(\lambda,\lambda)\} \to b$,
- $\{(\lambda,\lambda)\} \to \{(\lambda,\lambda),(\lambda,b)\}\{(\lambda,\lambda)\}$.

The language defined by G_0 contains $a^n b$ and also a^n since $\{(\lambda,\lambda)\} \subset \{(\lambda,\lambda),(\lambda,b)\}$ allowing the third production to accept strings ending with an a. Thus, the language has been reduced such that $L(G_0) = \{a^n b \mid n \geq 0\} \cup \{a^m \mid m \geq 0\}$.

We continue by leaving $F = \{(\lambda,\lambda),(\lambda,b)\}$ and we enlarge K such that $K = \{a, b, ab, ba\}$. The productions in G_0 are:

- $\{(\lambda,\lambda),(\lambda,b)\} \to a$,
- $\{(\lambda,\lambda)\} \to b$,
- $\{(\lambda,\lambda)\} \to \{(\lambda,\lambda),(\lambda,b)\}\{(\lambda,\lambda)\}$; the rule given by $ab = a \circ b$,
- $\{(\lambda,\lambda)\} \to \{(\lambda,\lambda)\}\{(\lambda,\lambda),(\lambda,b)\}$; the rule given by $ba = b \circ a$.

The addition of the last rule allows the grammar to recognize ba^n and it can be easily shown that by a combination of the last two productions $a^n ba^m$ belongs to the language defined by the grammar. Then, $L(G_0)$ has been increased such that $L(G_0) = \{a^n ba^k \mid n,k \geq 0\} \cup \{a^m \mid m \geq 0\}$.

In this example, the addition of $(\lambda,b),(a,\lambda)$ and (λ,a) to F and the addition of aab and baa to K will then define the correct language. In fact this illustrates one principle of our approach: in the infinite data limit, the construction G_0 will define the correct language. In the following lemma we abuse notation and use G_0 for when we have infinite K, and F: in this lemma we let K be the set of all non-empty strings and we let F be the set of all possible contexts $(\Sigma^* \times \Sigma^*)$. Recall that in this case for every string w $C_L(w) = F_L(w)$.

Lemma 12 *For any language L, let $G = G_0(\Sigma^+, L, \Sigma^* \times \Sigma^*)$. Then for all $w \in \Sigma^+$ $f_G(w) = C_L(w)$ and therefore $L(G) = L$.*

Proof By induction on the length of w. If $|w| = 1$, and $w = a$ then there is a lexical production $C_L(a) \to a$ and by the definition of $f_G(a) = C_L(a)$. Suppose this is true for all w with $|w| \leq k$. Let w be some string of length $k+1$. Consider any split of w into u, v such that $w = uv$. $f_G(w)$ is the union over all these splits of a function. We will show that every such split will give the same result of $C_L(w)$. By inductive hypothesis $f_G(u) = C_L(u), f_G(v) = C_L(v)$. Since u, v, w are in $K = \Sigma^+$ we will also have an element of P of the form $C_L(w) \to C_L(u)C_L(v)$, so we know that $f_G(w) \supseteq F_L(w)$. We now show that f_G will not predict any extra contexts. Consider every production in P, $F_L(u'v') \to F_L(u')F_L(v')$, that applies to u, v, that is, with $F_L(u') \subseteq f_G(u) = C_L(u)$ and $F_L(v') \subseteq f_G(v) = C_L(v)$. Lemma 5 shows that in this case $F_L(u'v') \subseteq F_L(w)$ and thus we deduce that $f_G(w) \subseteq F_L(w)$, which establishes the lemma. ■

Informally if we take K to be every string and F to be every context, then we can accurately define any language. Of course, we are just interested in those cases where this can be defined finitely and we have a CBFG, in which case L will be decidable, but this infinite limit is a good check that the construction is sound.

4.2 Monotonicity Lemmas

We now prove two lemmas that show that the size of the language, and more particularly the features predicted will increase or decrease monotonically as a function of the basis K, and the feature set F, respectively. In fact, they give also a framework for approaching a target language from K and F.

Lemma 13 *Suppose we have two CBFGs defined by $G = G_0(K, L, F)$ and $G' = G_0(K, L, F')$ where $F \subseteq F'$. Then for all u, $f_G(u) \supseteq f_{G'}(u) \cap F$.*

Proof Let G' have a set of productions P', P'_L, and G have a set of productions P, P_L. Clearly if $x \to yz \in P'$ then $x \cap F \to (y \cap F)(z \cap F)$ is in P by the definition of G_0, and likewise for P_L, P'_L. By induction on $|u|$ we can show that any feature in $f_{G'}(u) \cap F$ will be in $f_G(u)$. The base case is trivial since $F'_L(a) \cap F = F_L(a)$; if it is true for all strings up to length k, then if $f \in f_{G'}(u) \cap F$; there must be a production in F' with f on the head. By the inductive hypothesis, the right hand sides of the corresponding production in P will be triggered, and so f must be in $f_G(u)$. ■

Corollary 14 *Suppose we have two CBFGs defined by $G = G_0(K, L, F)$ and $G' = G_0(K, L, F')$ where $F \subseteq F'$; then $L(G) \supseteq L(G')$.*

Proof It is sufficient to remark that if $u \in L(G')$ then $(\lambda, \lambda) \in f_{G'}(u) \subseteq f_G(u)$ and thus $u \in L(G)$. ■

Conversely, we can show that as we increase K, the language and the map f_G will increase. This is addressed by the next lemma.

Lemma 15 *Suppose we have two CBFGs defined by $G = G_0(K, L, F)$ and $G' = G_0(K', L, F)$ where $K \subseteq K'$. Then for all u, $f_{G_0(K,L,F)}(u) \subseteq f_{G_0(K',L,F)}(u)$.*

Proof Clearly the sets of productions of $G_0(K,L,F)$ will be a subset of the set of productions of $G_0(K',L,F)$, and so anything that can be derived by the first can be derived by the second, again by induction on the length of the string. ■

A simple result is that when K contains all of the substrings of a word, then $G_0(K,L,F)$ will generate all of the correct features for this word.

Lemma 16 *For any string w, if $Sub(w) \subset K$, and let $G = G_0(K,L,F)$, then $F_L(w) \subseteq f_G(w)$.*

Proof By recursion on the size of w. Let $G = G_0(K,L,F) = \langle F, P, P_L, \Sigma \rangle$. First, notice that if w is of length 1 then we have $F_L(w) \to w$ in P_L and thus the lemma holds. Then suppose that $|w| = k \geq 2$. Let u and v in Σ^+ be such that $w = uv$. As $Sub(w) \subset K$ we have u, v in K. Therefore the rule $F_L(w) \to F_L(u)F_L(v)$ belongs to P. As $|u| < |w|$ and $|v| < |w|$, by recursion we get $F_L(u) \subseteq f_G(u)$ and $F_L(v) \subseteq f_G(v)$. Thus the rule can be applied and then $F_L(w) \subseteq f_G(w)$. ■

In particular if $w \in L$, and $Sub(w) \subseteq K$, then $w \in L(G)$. This means that we can easily increase the language defined by G just by adding $Sub(w)$ to K. In general we do not need to add every element of $Sub(w)$—it is enough to have one binary bracketing.

To establish learnability, we need to prove that for a target language L, if we have a sufficiently large F then $L(G_0(K,L,F))$ will be contained within L and that if we have a sufficiently large K, then $L(G_0(K,L,F))$ will contain L.

4.3 Fiducial Feature Sets and Finite Context Property

We need to be able to prove that for any K if we have enough features then the language defined will be included within the target language L. We formalise the idea of having enough features in the following way:

Definition 17 *For a language L and a string u, a set of features F is fiducial on u if for all $v \in \Sigma^*$, $F_L(u) \subseteq F_L(v)$ implies $C_L(u) \subseteq C_L(v)$.*

Note that if F is fiducial on u and $F \subset F'$ then F' is fiducial on u. Therefore we can naturally extend this to sets of strings.

Definition 18 *For a language L and a set of strings K, a set of features F is fiducial on K if for all $u \in K$, F is fiducial on u.*

Clearly, for any string w, $C_L(w)$ will be fiducial on w; but this is vacuous—we are interested in cases where there is a finite set of contexts which is fiducial for w, but where $C_L(w)$ is infinite. If u and v are both in K then having the same features means they are syntactically congruent. However if two strings, neither of which are in K, have the same features this does not mean they are necessarily congruent (for instance if $F_L(v) = F_L(v') = \emptyset$). For non finite state languages, the set of congruence classes will be infinite, and thus we cannot have a finite fiducial set for the set of all strings in $Sub(L)$, but we can have a feature set that is correct for a finite subset of strings, or more generally for an infinite set of strings, if they fall into a finite number of congruence classes.

Let us consider our running example $L = \{a^n b^n | n > 0\}$. Take the string ab. $C_L(ab)$ is infinite and contains contexts of the form $(\lambda,\lambda),(a,b),(aa,bb)$ and so on. Consider a set with just one of these contexts, say $F = \{(a,b)\}$. This set is clearly fiducial for ab, since the only strings that will have this context are those that are congruent to ab. Consider now the string aab; clearly $\{(\lambda,b)\}$ is fiducial for aab, even though the string a, which is not congruent to aab also occurs in this context. Indeed, this does not violate fiduciality since $C_L(a) \supset C_L(aab)$. However, looking at string a, $\{(\lambda,b)\}$ is not fiducial, since aab has this context but does not include all the contexts of a such as, for example, (λ,abb).

In these trivial examples, a context set of cardinality one is sufficient to be fiducial, but this is not the case in general. Consider the finite language $L = \{ab,ac,db,ec,dx,ey\}$, and the string a. It has two contexts (λ,b) and (λ,c) neither of which is fiducial for a on its own. However, the set of both contexts is: $\{(\lambda,b),(\lambda,c)\}$ is fiducial for a.

We now define the finite context property, which is one of the two conditions that languages must satisfy to be learnable in this model; this condition is a purely language theoretic property.

Definition 19 *A language L has the Finite Context Property (FCP) if every string has a finite fiducial feature set.*

Clearly if L has the FCP, then any finite set of substrings, K, has a finite fiducial feature set which will be the union of the finite fiducial feature sets for each element of K. If $u \notin Sub(L)$ then any set of features is fiducial since $C_L(u) = \emptyset$.

We note here that all regular languages have the FCP. We refer the reader to the Section 6.1.1 about CBFG and regular languages where the Lemma 35 and the associated construction proves this claim.

We can now state the most important lemma: this lemma links up the definition of the feature map in a CBFG, with the fiducial set of features to show that only correct features will be assigned to substrings by the grammar. It states that the features assigned by the grammar will correspond to the language theoretic interpretation of them as contexts.

Lemma 20 *For any language L, given a set of strings K and a set of features F, let $G = G_0(K,L,F)$. If F is fiducial on K, then for all $w \in \Sigma^*$ $f_G(w) \subseteq F_L(w)$.*

Proof We proceed by induction on length of the string. *Base case:* strings of length 1. $f_G(w)$ will be the set of observed contexts of w, and since we have observed these contexts, they must be in the language. *Inductive step:* let w a string of length k.

Take a feature f on $f_G(w)$; by definition this must come from some production $x \to yz$ and a split u,v of w. The production must be from some elements of K, u',v' and $u'v'$ such that $y = F_L(u'), z = F_L(v')$ and $x = F_L(u'v')$. If the production applies this means that $F_L(u') = y \subseteq f_G(u) \subseteq F_L(u)$ (by inductive hypothesis), and similarly $F_L(v') \subseteq F_L(v)$. By fiduciality of F this means that $C(u') \subseteq C(u)$ and $C(v') \subseteq C(v)$. So by Lemma 5 $C(u'v') \subseteq C(uv)$. Since $f \in C(u'v')$ then $f \in C(uv) = C(w)$. Therefore, since $f \in F$ and $C(w) \cap F = F_L(w)$, $f \in F_L(w)$, and therefore $f_G(w) \subseteq F_L(w)$. ■

Corollary 21 *If F is fiducial on K then $L(G_0(K,F,L)) \subseteq L$.*

Therefore for any finite set K from an FCP language, we can find a set of features so that the language defined by those features on K is not too big.

4.4 Kernel and Finite Kernel Property

We will now show a complementary result, namely that for a sufficiently large K the language defined by G_0 will include the target language. We will start by formalising the idea that a set K is large enough, by defining the idea of a *kernel*.

Definition 22 *A finite set $K \subseteq \Sigma^*$ is a kernel for a language L, if for any set of features F, $L(G_0(K,F,L)) \supseteq L$.*

Consider again the language $L = \{a^n b^n | n \geq 0\}$. The set $K = \{a, b, ab\}$ is not a kernel, since if we have a large enough set of features, then the language defined will only be $\{ab\}$ which is a proper subset of L. However $K = \{a, b, ab, aab, abb, aabb\}$ is a kernel: no matter how large a set of features we have the language defined will always include L. Consider a language $L' = L \cup \{b^{16}\}$. In this case, a kernel for L' must include, as well as a kernel for L, some set of substrings of b^{16}: it is enough to have b^{16}, b^8, b^4, bb, b.

To prove that a set is a kernel, it suffices to show that if we consider all the possible features for building the grammar, we will contain the target language; any smaller set of features defines then a larger language. In our case, we can take the infinite set of all contexts and define productions based on the congruence classes. If F is the set of all contexts then we have $F_L(u) = C_L(u)$, thus the productions will be exactly of the form $C(uv) \to C(u)C(v)$. This is a slight abuse of notation since feature sets are normally finite.

Lemma 23 *Let $F = \Sigma^* \times \Sigma^*$; if $L(G_0(K,L,F)) \supseteq L$ then K is a kernel.*

Proof By monotonicity of F: any finite feature set will be a subset of F. ■

Not all context-free languages will have a finite kernel. For example $L = \{a^+\} \cup \{a^n b^m | n < m\}$ is clearly context-free, but does not have a finite kernel. Assume that the set K contains all strings of length less than or equal to k. Assume w.l.o.g. that the fiducial set of features for K includes all features (λ, b^i), where $i \leq k+1$. Consider the rules of the form $F_L(a^k) \to F_L(a^j)F_L(a^{k-j})$; we can see that no matter how large k is, the derived CBFG will undergenerate as a^k is not congruent to a^{k-1}.

Definition 24 *A context-free grammar $G_T = \langle V, S, P, \Sigma \rangle$ has the Finite Kernel Property (FKP) iff for every non-terminal $N \in V$ there is a finite set of strings $K(N)$ such that $a \in K(N)$ if $a \in \Sigma$ and $N \to a \in P$ and such that for all $k \in K(N), N \stackrel{*}{\Rightarrow} k$ and where for every string $w \in \Sigma^*$ such that $N \stackrel{*}{\Rightarrow} w$ there is a string $k \in K(N)$ such that $C(k) \subseteq C(w)$. A CFL L has the FKP, if there is a grammar in CNF for it with the FKP.*

Notice that all regular languages have the FKP since they have a finite number of congruence classes.

Lemma 25 *Any context-free language with the FKP has a finite kernel.*

Proof Let $G_T = \langle V, S, P, \Sigma \rangle$ be such a CNF CFG with the FKP. Define

$$K(G_T) = \bigcup_{N \in V} \left(K(N) \cup \bigcup_{X \to MN \in P} K(M)K(N) \right).$$

We claim that $K(G_T)$ is a kernel. Assume that $F = \Sigma^* \times \Sigma^*$ and let G be such that $G = G_0(K(G_T), L(G_T), F) = \langle F, (\lambda,\lambda), P, P_L, \Sigma \rangle$.

We will show, by induction on the length of derivation of w in G_T, that for all N, w if $N \stackrel{*}{\Rightarrow} w$ then there is a k in $K(N)$ such that $f_G(w) \supseteq C(k)$. If length of derivation is 1, then this is true since $|w| = 1$ and thus $w \in K(N)$: therefore $C(w) \to w \in P_L$. Suppose it is true for all derivations of length less than j. Take a derivation of length j; say $N \stackrel{*}{\Rightarrow} w$. There must be a production in G_T of the form $N \to PQ$, where $P \Rightarrow^* u$ and $Q \Rightarrow^* v$, and $w = uv$. By inductive hypothesis; we have $f_G(u) \supseteq C(k_u)$ and $f_G(v) \supseteq C(k_v)$. By construction $k_u k_v \in K(G_T)$ and then there will be a rule $C(k_u k_v) \to C(k_u)C(k_v)$ in P. Therefore $f_G(uv) \supseteq C(k_u k_v)$. Since $N \stackrel{*}{\Rightarrow} k_u k_v$ there must be some $k_{uv} \in K(N)$ such that $C(k_{uv}) \subseteq C(k_u k_v)$. Therefore $f_G(w) \supseteq C(k_u k_v) \supseteq C(k_{uv})$.

Now we can see that if $w \in L$, then $S \stackrel{*}{\Rightarrow} w$, then there is a $k \in K(S)$ such that $f_G(w) \supseteq C(k)$ and $S \stackrel{*}{\Rightarrow} k$, therefore $(\lambda,\lambda) \in f_G(w)$ since $(\lambda,\lambda) \in C(k)$, thus $w \in L(G)$ and therefore K is a kernel. ■

4.5 Learning Algorithm

Before we present the algorithm, we will discuss the learning model that we use. The class of languages that we will learn is suprafinite and thus we cannot get a positive data only identification in the limit result (Gold, 1967). Ultimately we are interested in a more realistic probabilistic learning paradigm, but for mathematical convenience it is appropriate to establish the basic results in a symbolic paradigm. The ultimate goal is to model natural languages, where negative data, or equivalence queries are generally not available or are computationally impossible. Accordingly, we have decided to use the model of positive data together with membership queries: an oracle can tell the learner whether a string is in the language or not (Angluin, 1988). The presented algorithm runs in time polynomial in the size of the sample S: since the strings are of variable length, this size must be the sum of the lengths of the strings in S, $\|S\| = \sum_{w \in S} |w|$. We should note that this is not a strong enough result: Pitt (1989) showed that any algorithm can be made polynomial, by only processing a small prefix of the data. It is hard to tighten the model sufficiently: the suggestion of de la Higuera (1997) for a polynomial characteristic set is inapplicable for representations, such as the ones in this paper, that are powerful enough to define languages whose shortest strings are exponentially long. Accordingly we do not require in this model a polynomial dependence on the size of the representation. We note that the situation is unsatisfactory, but we do not intend to propose a solution in this paper. We merely point out that the algorithm is genuinely polynomial and processes all of the data in the sample without "delaying tricks" of the type discussed by Pitt.

Definition 26 *A class of languages $\mathbb{L}$ is identifiable in the limit (IIL) from positive data and a membership oracle with polynomial time and queries iff there exist two polynomials $p(), q()$ and an algorithm A such that:*

- *Given an infinite presentation of positive examples S, where S_n is the first n examples of the presentation,*
  1. *A returns a representation $G = A(S_n)$ in time $p(\|S_n\|)$.*
  2. *A asks at most $q(\|S_n\|)$ queries to build $A(S_n)$.*
- *For each language $L \in \mathbb{L}$, for each presentation S of L, there exists an index n such that for all $N \geq n$: $A(S_N) = A(S_n)$ and $L(A(S_n)) = L$.*

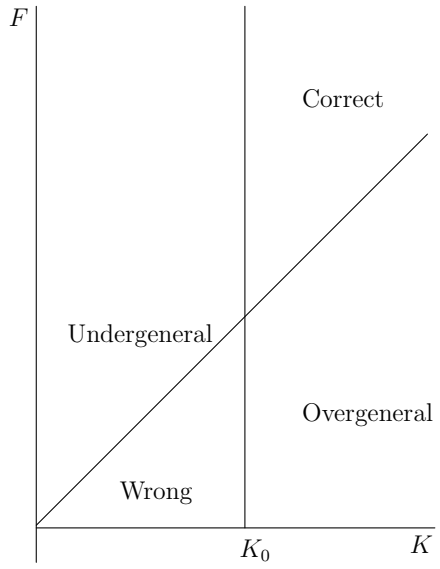

Figure 2: The relationship between K and F: The diagonal line is the line of fiduciality: above this line means that F is fiducial on K. K_0 is a kernel for the language.

Before we present the algorithm we hope that it is intuitively obvious how the approach will work. Figure 2 diagrammatically shows the relationship between K and F. When we have a large enough K, we will be to the right of the vertical line; when we have enough features for that K we will be above the diagonal line. Thus the basis of the algorithm is to move to the right, until we have enough data, and then to move up vertically, increasing the feature set until we have a fiducial set.

We can now define our learning algorithm in Algorithm 1. Informally, D is the list of all strings that have been seen so far and G_n is the current grammar obtained with the first n strings of D. The algorithm uses two tests: one test is just to determine if the current hypothesis undergeneralises. This is trivial, since we have a positive presentation of the data, and so eventually we will be presented with a string in $L \setminus L(G_n)$. In this case we need to increase K; we accordingly increase K to the set of all substrings that we have observed so far. The second test is a bit more delicate. We want to detect if our algorithm overgeneralises. This requires us to search through a polynomially bounded set of strings looking for a string that is in $L(G_n) \setminus L$. An obvious candidate set is $Con(D) \odot Sub(D)$; but though we conjecture that this is adequate, we have not yet been able to prove that is correct, as it might be that the overgenerated string does not lie in $Con(L) \odot Sub(L)$.

Here we use a slightly stricter criterion: we try to detect whether F is fiducial for K: we search through a polynomially bounded set of strings, $Sub(D)$, to find a violation of the fiduciality condition. If we find such a violation, then we know that F is not fiducial for K, and so we increase F to the set of all contexts that we have seen so far, $Con(D)$.

In Algorithm 1, $G_0(K, O, F)$ denotes the same construction as $G_0(K, L, F)$, except that we use membership queries with the oracle O to compute F_L for each element in K. We give the identification in the limit version of the algorithm, that is, that admits an infinite positive presentation of strings in input.

Algorithm 1: CBFG learning algorithm IIL

Data: A sequence of strings $S = \{w_1, w_2 \ldots, \}$, membership oracle O
Result: A sequence of CBFGs $G_1, G_2, \ldots$
$K \leftarrow \emptyset$; $D \leftarrow \emptyset$; $F \leftarrow \{(\lambda, \lambda)\}$; $G = G_0(K, O, F)$;
for w_i **do**
  $D \leftarrow D \cup \{w_i\}$; $C \leftarrow Con(D)$; $S \leftarrow Sub(D)$;
  if $\exists w \in D \setminus L(G)$ **then**
    $K \leftarrow S$; $F \leftarrow C$;
  end
  else if $\exists v \in S, u \in K, f \in C$ *such that* $F_L(u) \subseteq F_L(v)$ *and* $f \odot u \in L$ *but* $f \odot v \notin L$ **then**
    $F \leftarrow C$;
  end
  $G = G_0(K, O, F)$;
  Output $G_i = G$;
end

Theorem 27 *Algorithm 1 runs in polynomial time in the size of the sample, and makes a polynomial number of calls to the membership oracle.*

Proof The value of D will just be the set of observed strings; $Sub(D)$ and $Con(D)$ are both polynomially bounded by the size of the sample, and therefore so are $|K|$ and $|F|$. Therefore the number of calls to the oracle is clearly polynomial, as it is bouned by $|K||F|$. Computing G_0 is also polynomial, since $|P| \leq |K|^2$, and all strings involved are in $Sub(D)$. ■

4.6 Identification in the Limit Result

In the following, we consider the class of context-free languages having the FCP and the FKP, represented by CBFG. K_n denotes the value of K at the n^{th} loop, and similarly for F, D.

Definition 28 *$\mathcal{L}_{CFG}$ is the class of all context-free languages that satisfy the FCP and the FKP.*

In what follows we assume that L is an element of this class, and that $w_1, \ldots, w_n, \ldots$ is a infinite presentation of the language. The proof is straightforward and merely requires an analysis of a few cases. We will proceed as follows: there are 4 states that the model can be in, that correspond to the four regions of the diagram in Figure 2.

1. K is a kernel and F is fiducial for K; in this case the model has converged to the correct answer. This is the region labeled *correct* in Figure 2.
2. K is a kernel and F is not fiducial for K: then $L \subseteq L(G)$, and at some later point, we will increase F to a fiducial set, and we will be in state 1: this is the region labeled *overgeneral*.
3. K is not a kernel and F is fiducial. Either $L(G) = L$, in which case we have converged to a correct answer or, if not, we will define a proper subset of the target language. In the later case we will change hypothesis at some later point, increase K to a kernel, and move to state 2 or state 1. This is the area labeled *undergeneral*.

4. K is not a kernel and F is not fiducial: in this case at some point we will move to states 1 or 2. This is the area labeled *wrong*.

We will start by making some basic statements about properties of the algorithm:

Lemma 29 *If there is some n, such that F_n is fiducial for K_n and $L(G_n) = L$, then the algorithm will not change its hypothesis: that is, for all $n > N$, $K_n = K_N, F_n = F_N$ and therefore $G_n = G_N$.*

Proof If $L(G_n)$ is correct, then the first condition of the loop will never be met; if F_n is fiducial for K_n, then the second condition will never be satisfied. ■

Lemma 30 *If there is some N such that K_N is a kernel, then for all $n > N$, $K_n = K_N$.*

Proof Immediate by definition of a kernel, and of the algorithm. ■

We now prove that if F is not fiducial then the algorithm will be able to detect this.

Lemma 31 *If there is some n such that F_n is not fiducial for K_n, then there is some index $n' \geq n$ at which F_n will be increased.*

Proof If F_n is not fiducial, then by definition there is some $u \in K$, $v \in \Sigma^+$ such that $F_L(u) \subseteq F_L(v)$, but there is an $f \in C_L(u)$ that is not in $C_L(v)$. By construction $F_L(u)$ is always non-empty, and so is $F_L(v)$. Thus $v \in Sub(L)$. Note $f \odot u \in L$, so $f \in Con(L)$. Let n' be the smallest index such that $v \in Sub(D_n)$ and $f \in Con(D_n)$: at this point, either F_n will have changed, or not, in which case it will be increased at this point. ■

We now prove that we will always get a fiducial feature set.

Lemma 32 *For any n, there is some n' such that $F_{n'}$ is fiducial for K_n.*

Proof If F_n is fiducial then $n' = n$ satisfies the condition. Assume otherwise. Let F be a finite set of contexts that is fiducial for K_n. We can assume that $F \subseteq Con(L)$. Let n_1 be the first index such that $Con(D_{n_1})$ contains F. At this point we are not sure that $F_{n_1} = Con(D_{n_1})$ since the conditions for changing the set of contexts may not be reached. Anyhow, if it is the case then F_{n_1} is fiducial, then $n_1 = n'$ satisfies the condition. If not, then by the preceding lemma, there must be some point n_2 at which we will increase the set of contexts of the current grammar; $F_{n_2} = Con(n_2)$ must contain F since $Con(D_{n_1}) \subset Con(D_{n_2})$, and is therefore fiducial, and so $n_2 = n'$ satisfies the condition. ■

Lemma 33 *For every positive presentation of an $L \in \mathcal{L}_{CFG}$, there is some n such that either the algorithm has converged to a correct grammar or K_n is a kernel.*

Proof Let m be the smallest number such that $Sub(D_m)$ is a kernel. Recall that any superset of a kernel is a kernel, and that all CFL with the FKP have a finite kernel (Lemma 25), and that such a kernel is a subset of $Sub(L)$, so such an m must exist.

Consider the grammar G_m; there are three possibilities:
1. $L(G_m) = L$, and F_m is fiducial, in which case the grammar has converged.
2. $L(G_m)$ is a proper subset of L and F_m is fiducial. Let m' be the first point at which $w_{m'}$ is in $L \setminus L(G_m)$; at this point $K_{m'}$ will be increased to include $Sub(D_m)$ and it will therefore be a kernel.
3. F_m is not fiducial: in this case by Lemma 32; there is some n at which F_n is fiducial for K_m. Either $K_n = K_m$ in which case this reduces to Case 2; or K_n is larger than K_m in which case it must be a kernel, since it will include $Sub(D_m)$ which is a kernel.

■

We now can prove the main result of the paper:

Theorem 34 *Algorithm 1 identifies in the limit the class of context-free languages with the finite context property and the finite kernel property.*

Proof By Lemma 33 there is some point at which it converges or has a kernel. If K_n is a kernel then by Lemma 32, there is some point n' at which we have a fiducial feature set. Therefore $L(G_{n'}) = L$, and the algorithm has converged. ■

4.7 Examples

We will now give a worked example of the algorithm.

Suppose $L = \{a^n b^n | n > 0\}$.

G_0 will be the empty grammar, with $K = \emptyset, F = \{(\lambda, \lambda)\}$ and an empty set of productions. $L(G_0) = \emptyset$.

1. Suppose $w_1 = ab$. $D = \{ab\}$. This is not in $L(G_0)$ so we set

   - $K = Sub(D) = \{a, b, ab\}$.
   - $F = Con(D) = \{(\lambda, \lambda), (a, \lambda), (\lambda, b)\}$.

   This gives us one production: $F_L(ab) \to F_L(a)F_L(b)$ which corresponds to $\{(\lambda, \lambda)\} \to \{(\lambda, b)\}\{(a, \lambda)\}$, and the lexical productions $\{(\lambda, b)\} \to a, \{(a, \lambda)\} \to b$. The language defined is thus $L(G_1) = \{ab\}$.

2. Suppose $w_2 = aabb$. $D = \{ab, aabb\}$. This is not in $L(G_1)$ so we set

   - $K = Sub(D) = \{a, b, ab, aa, bb, aab, abb, aabb\}$.
   - $F = Con(D) = \{(\lambda, \lambda), (a, \lambda), (\lambda, b), (aa, \lambda), (a, b), (\lambda, bb), (aab, \lambda), (aa, b), (a, bb), (\lambda, abb)\}$.

   We then have the following productions:

- $F_L(ab) \to F_L(a), F_L(b)$ which is
$$\{(\lambda,\lambda),(a,b)\} \to \{(a,bb),(\lambda,abb),(\lambda,b)\},\{(aa,b),(aab,\lambda),(a,\lambda)\}.$$
- $F_L(aab) \to F_L(a), F_L(ab)$ which is
$$\{(a,bb),(\lambda,b)\} \to \{(a,bb),(\lambda,abb),(\lambda,b)\},\{(\lambda,\lambda),(a,b)\}.$$
- $F_L(aab) \to F_L(aa), F_L(b)$ which is
$$\{(a,bb),(\lambda,b)\} \to \{(\lambda,bb)\},\{(aa,b),(aab,\lambda),(a,\lambda)\}.$$
- $F_L(bb) \to F_L(b), F_L(b)$ which is
$$\{(aa,\lambda)\} \to \{(aa,b),(aab,\lambda),(a,\lambda)\},\{(aa,b),(aab,\lambda),(a,\lambda)\}.$$
- $F_L(aa) \to F_L(a), F_L(a)$ which is
$$\{(\lambda,bb)\} \to \{(a,bb),(\lambda,abb),(\lambda,b)\},\{(a,bb),(\lambda,abb),(\lambda,b)\}.$$
- $F_L(aabb) \to F_L(a), F_L(abb)$ which is
$$\{(\lambda,\lambda),(a,b)\} \to \{(a,bb),(\lambda,abb),(\lambda,b)\},\{(aa,b),(a,\lambda)\}.$$
- $F_L(aabb) \to F_L(aa), F_L(bb)$ which is
$$\{(\lambda,\lambda),(a,b)\} \to \{(\lambda,bb)\},\{(aa,\lambda)\}.$$
- $F_L(aabb) \to F_L(aab), F_L(b)$ which is
$$\{(\lambda,\lambda),(a,b)\} \to \{(a,bb),(\lambda,b)\},\{(aa,b),(aab,\lambda),(a,\lambda)\}.$$
- $F_L(abb) \to F_L(a), F_L(bb)$ which is
$$\{(aa,b),(a,\lambda)\} \to \{(a,bb),(\lambda,abb),(\lambda,b)\},\{(aa,\lambda)\}.$$
- $F_L(abb) \to F_L(ab), F_L(b)$ which is
$$\{(aa,b),(a,\lambda)\} \to \{(\lambda,\lambda),(a,b)\},\{(aa,b),(aab,\lambda),(a,\lambda)\}.$$

and the two lexical productions:

- $F_L(a) \to a$ which is $\{(a,bb),(\lambda,abb),(\lambda,b)\} \to a$
- $F_L(b) \to b$ which is $\{(aa,b),(aab,\lambda),(a,\lambda)\} \to b$.

K is now a kernel and $L(G) = L$, but F is not fiducial for K, since (λ,bb) is not fiducial for aa (consider $aaab$).

3. Suppose $w_3 = aaabbb$. Now $|Con(D_3)| = 21$; there are now several elements of $Con(D_3)$ that are similar. For example $(\lambda,\lambda),(a,b)$ and (aa,bb) are identical but as it is harmless for the resulting grammar, it does not mind. Now we will detect that F is not fiducial: we will find $v = aaab$, $u = aa$ and $f = (\lambda,abbb)$; $F_L(aa) = \{(\lambda,bb)\} = F_L(aaab)$, but $f \odot aaab = aaababbb$ which is not in L. We will therefore increase F to be $Con(D_3)$, and then the algorithm will have converged. The final grammar will have 10 productions and 2 lexical productions; $|K| = 8$ and $|F| = 21$.

5. Practical Behavior of the Algorithm

In this section, we propose to study the behavior of our algorithm from a practical point of view. We focus more specifically on two important issues. The first one deals with the learning ability of the algorithm when the conditions for the theoretical learning result are not reached. Indeed, although the identification in the limit paradigm proves that with sufficient data it is possible to obtain exact convergence, it says nothing about the convergence when fewer learning examples are available: does the output get closer and closer to the target until it reaches it or does it stay far from the expected solution until receives enough data? The second question concerns the learning behavior of the algorithm: does it tend to over-generalise or to under-generalise?

For our experimental setup, we need to select appropriate data sets. In grammatical inference little has been done concerning benchmarking. The main available corpora are those of the on line competitions organised by the International Colloquium on Grammatical Inference. Three different competitions have recently taken place: the *Abbadingo One* (Lang et al., 1998) which was about regular languages, the *Omphalos* competition on context-free languages (Starkie et al., 2004) and the *Tenjino* competition (Starkie et al., 2006) dealing with transducers learning. Note that some of these data sets correspond to extremely hard learning problems since their main objective was to push the state of the art (some problems of the *Abbadingo One* competition are still unsolved more than ten years after its official end!)

However, these data sets can not be directly used for evaluating our algorithm because the solutions or the target models are not available. Our algorithm needs an oracle and thus we need a way to give answers to membership queries. In order to overcome this drawback, we chose to build synthetically some data sets following the experimental setup proposed by these competitions. More precisely, we decided to randomly generate target context-free grammars following what has been done for the *Omphalos* competition. Each grammar is then used either to generate training and test sets or as an oracle for answering membership queries.

In the following paragraphs we describe first the generation of the target context-free grammars, then the experimental setup with learning and test data sets used and finally the results and conclusions that can be drawn.

5.1 Generation of Target Context-free Grammars

To generate the target grammars we follow the process used for the *Omphalos* competition (Starkie et al., 2004). We built 30 different grammars randomly according the following principles. For each grammar, we first fix the number of non-terminals and terminals which are randomly chosen between 4 and 7 for the non-terminals (including the start symbol) and between 2 and 4 for terminal symbols. Then we randomly generate 20 context-free rules in Chomsky normal form such that every non-terminal appears at least once in the left hand side of a grammar rule. In order to avoid the presence of useless rules, we apply two simple procedures: if a non-terminal can not generate any terminal string, a new terminal rule generating one terminal symbol is created for this non-terminal; if a non-terminal can not be reached from the start symbol, we erase it from the grammar (i.e., we remove all the rules containing this non-terminal). From these grammars without useless rules, we force them to generate non finite languages by checking that the start symbol is used at least once in a right hand side of a grammar rule (in average this symbol appears in a right hand side of a rule more than 3 times per grammar).

The main difference with the *Omphalos* generation process is that we do not especially need non-regular languages. Indeed, one of the aim of these experiments is to give an idea on the behavior of the algorithm when its theoretical assumptions are not likely to be valid. From this standpoint, all randomly generated non-finite languages are good candidates as learning targets. However, with a similar principle used for the *Omphalos* competition, we checked that some of the generated grammars can not be easily solved by methods for regular languages. Although we can not decide if these grammars define non regular context-free languages, it ensures us that the target models are at least not too simple.

5.2 Experimental Setup

For each target grammar we generate a learning and a test sample following the *Omphalos* competition requirements. We build the learning sample by first creating a *structurally complete set* of strings for each grammar. This set is built such that for each rule of the target grammar, at least one string of the set can be derived using this rule (Parekh and Honavar, 1996). This would guarantee that the complete learning set would have the minimal amount of information for finding the structure of the grammar. We then complete this learning set by randomly generating new strings from the grammar in order to have a total of 50 examples. We chose arbitrarily this value for two reasons: first it is sufficient to ensure that each sample strictly contains a structurally complete set for each target grammar and secondly we are likely to be far from the guarantees of the identification in the limit framework.

The construction of the test set needs particular attention. Since the learning phase uses a membership oracle, when the hypothesis is being constructed, some new strings may be built and queried for the oracle by picking a substring and a context from the learning sample. Thus, even if the test set does not contain any string of the learning sample, the construction G_0 may consider some strings present in the test set. In order to avoid this drawback, that is, to guarantee that no string of the test could be seen during the construction of the CBFG, each test string has a length of at least 3 times the maximal length of the strings in the learning set, which is by construction the maximal size of the strings queried. According to this procedure, we randomly generate a test set of 1000 strings over the alphabet of terminal symbols used to define the target grammar (1000 examples is twice the size of the small test sets of the *Omphalos* competition). The test sequences are then labeled positive or negative depending on their membership to the language defined by the grammar. We repeat this process until we have the desired number of strings. The ratio between strings in the language and strings outside the language is fixed to be between 40% and 60%.

In order to study the behavior of our algorithm, we define the following setup. For each target context-free grammar, we construct a CBFG by applying the construction $G_0(K,O,F)$ with $K = Sub(S)$ and $F = Con(S)$ where S is a set of strings drawn from the learning set and using the target grammar as the oracle O for the membership queries. We generate different sets S by drawing an increasing number of learning examples (from 2 to 50) from the learning sample of the considered grammar. Then, we evaluate the learned CBFG on the test sample by measuring the accuracy of correct classification. We present the results averaged on the 30 test sets of the different target context-free grammars.

5.3 Results and Discussion

Figure 3 shows the averaged accuracy over the different target grammars according to the number of strings in the learning sample. We can note that a high correct classification rate (nearly 90%) is reached with 20 examples and with only 5 examples an accuracy of 75% is obtained. These results indicate that a relevant hypothesis can be found even with few examples. The standard deviations represented by vertical bars show a good stability of the results from learning sets of 20 strings. This confirms that our algorithm is able to learn partly correct representations even when learning sets may not have a kernel or a fiducial learning set and thus are far from the identification in the limit assumptions.

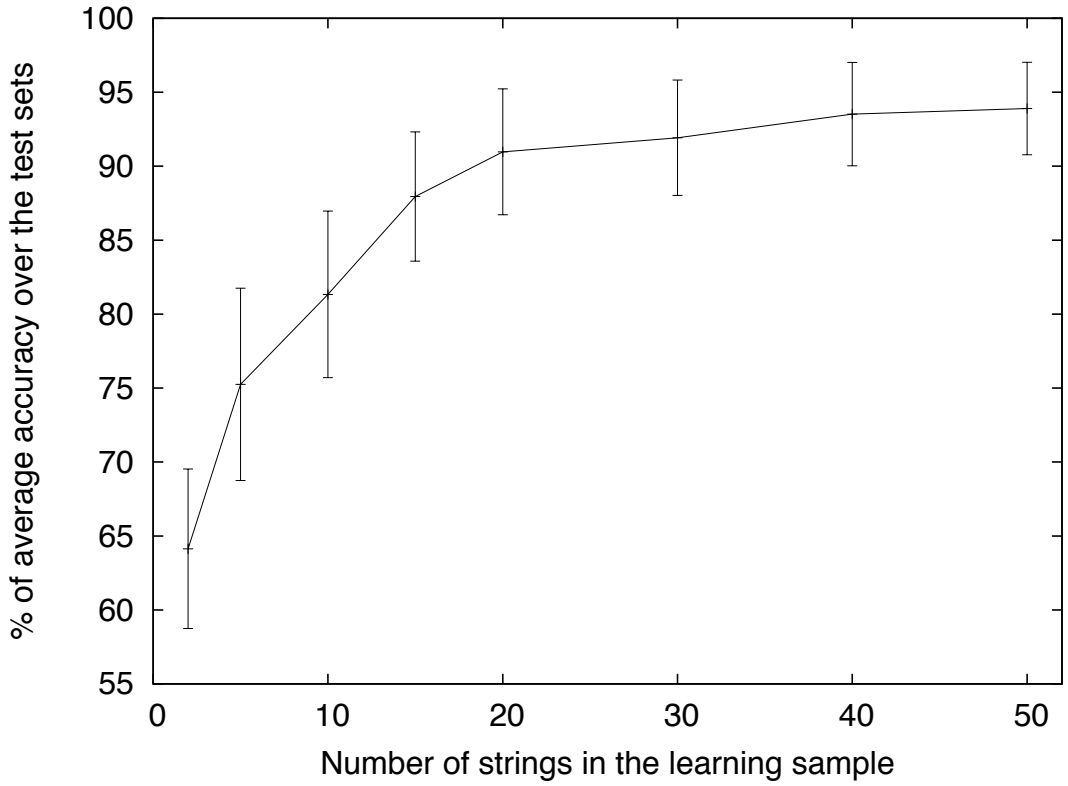

Figure 3: Evolution of the average percentage of correct classification according to the number of learning examples.

The analysis of the behavior of the algorithm in terms of false positive and false negative rates is shown in Table 1. The proportion of false negatives (i.e., positive strings classified as negative) is higher than the proportion of false positives (i.e., negative strings classified as positive), whatever the size of the learning sample is. Thus the output of the algorithm tends more to under-generalise than the converse. As it is generally admitted that over-generalisation is the main trouble when learning from positive examples, this tendency confirms that the algorithm behaves well. However, it is difficult to draw firm conclusions without a natural distribution over negative examples.

Number of strings in S	false positive	false negative
02	07.2 % $\pm$ 12.3	36.4 % $\pm$ 7.0
05	04.5 % $\pm$ 4.7	28.4 % $\pm$ 9.1
10	03.8 % $\pm$ 2.9	22.4 % $\pm$ 8.4
15	03.9 % $\pm$ 2.6	14.1 % $\pm$ 6.6
20	04.1 % $\pm$ 3.0	09.4 % $\pm$ 6.1
30	04.2 % $\pm$ 2.8	07.9 % $\pm$ 5.5
40	03.9 % $\pm$ 2.6	05.6 % $\pm$ 4.7
50	04.4 % $\pm$ 1.6	04.8 % $\pm$ 3.9

Table 1: Average percentage of false positive and false negative rates obtained over the test samples.

The preceding results show that despite its simplicity the algorithm behaved nicely during these experiments, in particular concerning over-generalisation. We focus now on the amount of queries needed by the algorithm for building the CBFG. The growth of the number of requested queries according to the average size of the learning sample is shown in Figure 4 (recall that here the size of the sample means the sum of the string lengths of the sample). While a very worst case analysis of the grammar construction used by G_0 would lead to a complexity in $O(|S|^5)$, we can observe that the number of queries seems to be quadratic, at least in the case of the grammars we consider here. However, the volume of queries used is large, which can be explained by the simplicity of the algorithm. From a practical standpoint, it is clear that much work has to be done in order to try to minimise the number of queries needed by selecting the most informative examples, but this point is out of the scope of the paper.

Finally, we can note that these experiments suffer of the lack of comparison with other approaches. This is due to the fact that, as far as we know, no other algorithm uses a positive learning sample and a membership oracle only. Indeed, since the work of Angluin about the Minimum Adequate Teacher (Angluin, 1988) all algorithms using membership queries are designed with the additional help of equivalence queries. The point of view adopted in this paper is rather theoretical since our aim was to show the relevance of CBFG representations for language learning. However, a perspective of our work is to try to avoid the use of the oracle (by using statistical or simulation methods) which will allow us to compare more easily our approach with other methods.

6. Expressiveness of CBFG

In this section, we compare the expressiveness of CBFG with other well known representations. As noted earlier, we are primarily interested in the class of exact CBFGs—these are CBFGs where the presence of a contextual feature in the representation corresponds exactly to the language theoretic interpretation of the context. The class of unrestricted CBFG is significantly larger, but less relevant.

The algorithm presented in this paper cannot learn the entire class of exact CBFGs, but we conjecture that there are more powerful algorithms that can; see Clark (2009) for some steps in this direction.

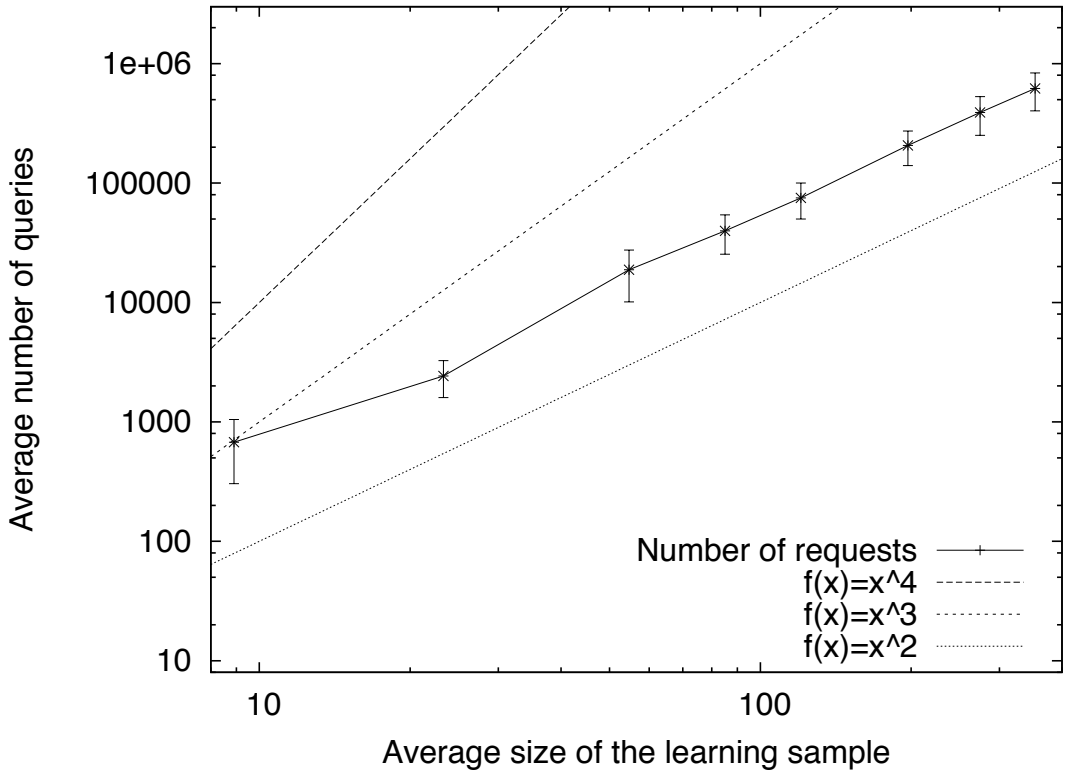

Figure 4: Growth of the number of membership queries versus the average of the total size of the learning sample (using log log scale).

6.1 Exact CBFGs and the Chomsky Hierarchy

We start by examining the class of languages defined by exact CBFGs. We will show that this class

- includes all regular languages
- does not include all context free languages
- includes some non-context-free languages.

This class is thus orthogonal to the Chomsky hierarchy.

6.1.1 REGULAR LANGUAGES

Any regular language can be defined by an exact CBFG. We will show a way of constructing an exact CBFG for any regular language. Suppose we have a regular language L: we consider the left and right residual languages:

$$u^{-1}L = \{w | uw \in L\},$$

$$Lu^{-1} = \{w | wu \in L\}.$$

For any $u \in \Sigma^*$, let $l_{min}(u)$ be the lexicographically shortest element such that $l_{min}^{-1}L = u^{-1}L$. The number of such l_{min} is finite by the Myhill-Nerode theorem, we denote by L_{min} this set, that is, $\{l_{min}(u)|u \in \Sigma^*\}$. We define symmetrically R_{min} for the right residuals ($Lr_{min}^{-1} = Lu^{-1}$).

We define the set of contexts as:

$$F(L) = L_{min} \times R_{min}.$$

$F(L)$ is clearly finite by construction.

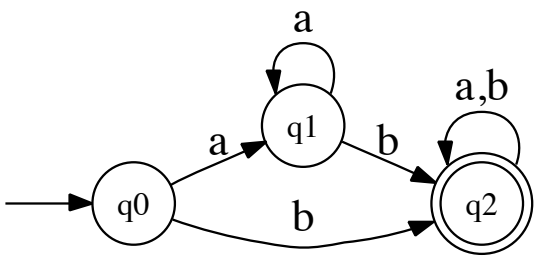

Figure 5: Example of a DFA. The left residuals are defined by $\lambda^{-1}L, a^{-1}L, b^{-1}L$ are the right ones by $L\lambda^{-1}, Lb^{-1}, Lab^{-1}$ (note here that $La^{-1} = L\lambda^{-1}$).

If we consider the regular language defined by the deterministic finite automata of Figure 5, we obtain $L_{min} = \{\lambda, a, b\}$ and $R_{min} = \{\lambda, b, ab\}$ and thus

$$F(L) = \{(\lambda,\lambda),(a,\lambda),(b,\lambda),(\lambda,b),(a,b),(b,b),(\lambda,ab),$$

$$(a,ab),(b,ab)\}.$$

By considering this set of features, we can prove the following lemma:

Lemma 35 *For any strings u, v such that $F_L(u) \supset F_L(v)$ then $C_L(u) \supset C_L(v)$.*

Proof Suppose $F_L(u) \supset F_L(v)$ and let (l,r) be a context in $C_L(v)$. Let l' be the lexicographically shortest element of $\{u : u^{-1}L = l^{-1}L\}$ and r' the lexicographically shortest element of $\{u : Lu^{-1} = Lr^{-1}\}$. By construction we have $(l',r') \in F(L)$ and $l'vr' \in L$, as $vr' \in l'^{-1}L = l^{-1}L$. $F_L(v)$ is contained in $F_L(u)$ therefore we have $l'ur' \in L$. $l'^{-1}L = l^{-1}L$ implies $lur' \in L$. As r' is congruent to r, $lur \in L$. ■

This lemma means that the set of features F is sufficient to represent context inclusion.

Note that the number of congruence classes of a regular language is finite. Each congruence class is represented by a set of contexts $F_L(u)$. Let K_L be finite set of strings formed by taking the lexicographically shortest string from each congruence class. The final grammar can be obtained by combining elements of K_L. For every pair of strings $u, v \in K_L$, we define a rule

$$F_L(uv) \to F_L(u)F_L(v)$$

and we add lexical productions of the form $F_L(a) \to a, a \in \Sigma$.

The following lemma shows the correctness and the exactness of the grammar.

Lemma 36 *For all* $w \in \Sigma^*$, $f_G(w) = F_L(w)$.

Proof *(Sketch)* The proof is in two steps: $f_G(w) \subseteq F_L(w)$ and $F_L(w) \subseteq f_G(w)$. Each step is made by induction on the length of w and uses the rules created to build the grammar, the derivation process of a CBFG and the fiduciality for the second step.

First, we show $\forall w \in \Sigma^*, f_g(w) \subseteq F_L(w)$ by induction on the length of w. For $|w| = 1$, the inclusion is trivial since all the lexical rules $F_L(a) \to a$ are included in the grammar. Suppose that a string w, $|w| = n > 1$, is parsed by the CBFG G, then there exists a cut of w in $uv = w$ and a rule $z \to xy$ in G such that $x \subseteq f_G(u)$ and $y \subseteq f_G(v)$. By induction hypothesis, $x \subseteq F_L(u)$ and $y \subseteq F_L(v)$. By construction of the grammar, there exists two strings $u', v' \in K_L$ such that u, resp. v, belongs to same congruence class than u', resp. v' and the rule $F_L(u'v') \to F_L(u')F_L(v')$ belongs to the productions of the grammar. By induction hypothesis, $x \subseteq F_L(u) = F_L(u')$ and $y \subseteq F_L(v) = F_L(v')$ and thus $f_G(w) \subseteq F_L(w)$.
Second, we prove that $\forall w \in \Sigma^*, F_L(w) \subseteq f_G(w)$ by induction on the length of w. The key point relies on the fact that when a string w is parsed by a CBFG G, there exists a cut of w into $uv = w$ (u, v $\in \Sigma^*$) and a rule $z \to xy$ in G such that $x \subseteq f_G(u)$ and $y \subseteq f_G(v)$. The rule $z \to xy$ is also obtained from a substring from the set used to build the grammar using the F_L function. By the inductive hypothesis we obtain inclusion between f_G and F_L on u and v. ■

For the language of Figure 5, the following set is sufficient to build an exact CBFG: $\{a, b, aa, ab, ba, aab, bb, bba\}$ (this corresponds to all the substrings of *aab* and *bba*). We have:

$$F_L(a) = F(L) \backslash \{(\lambda, \lambda), (a, \lambda)\} \to a,$$

$$F_L(b) = F(L) \to b,$$

$$F_L(aa) = F_L(a) \to F_L(a)F_L(a),$$

$$F_L(ab) = F(L) \to F_L(a)F_L(b) = F_L(a)F(L),$$

$$F_L(ba) = F(L) \to F_L(b)F_L(a) = F(L)F_L(a),$$

$$F_L(bb) = F(L) \to F_L(b)F_L(b) = F(L)F(L),$$

$$F_L(aab) = F_L(bba) = F_L(ab) = F_L(ba).$$

The approach presented here gives a canonical form for representing a regular language by an exact CBFG. Moreover, this is is *complete* in the sense that every context of every substring will be represented by some element of F: this CBFG will completely model the relation between contexts and substrings.

6.1.2 EXACT CBFGS DO NOT INCLUDE ALL CFLS

First, it is clear that the class of exact CBFGs includes some non-regular context-free languages: the grammar defined in Section 3.3 is an exact CBFG for the context-free and non regular language $\{a^n b^n | n > 0\}$, showing the class of exact CBFG has some elements properly in the class of CFGs.

We give now a context-free language L that can not be defined by an exact CBFG:

$$L = \{a^n b | n > 0\} \cup \{a^n c^m | m > n > 0\}.$$

Suppose that there exists an exact CBFG that recognizes it and let N be the length of the biggest feature (i.e., the longest left part of the feature). For any sufficiently large $k > N$, the sequences c^k and c^{k+1} share the same features: $F_L(c^k) = F_L(c^{k+1})$. Since the CBFG is exact we have $F_L(b) \subseteq F_L(c_k)$. Thus any derivation of $a^{k+1}b$ could be a derivation of $a^{k+1}c^k$ which does not belong to the language.

However, this restriction does not mean that the class of exact CBFG is too restrictive for modeling natural languages. Indeed, the example we have given is highly unnatural and such phenomena appear not to occur in attested natural languages.

6.1.3 CBFG AND NON CONTEXT-FREE LANGUAGES

CBFGs are more powerful than CFGs in two respects. First, CBFGs can compactly represent languages like the finite language of all $n!$ permutations of an n-letter alphabet, that have no concise representation as a CFG (Asveld, 2006). Secondly, as we now show, there are some exact CBFGs that are not context-free. In particular, we define a language closely related to the *MIX language* (consisting of strings with an equal number of a's, b's and c's in any order) which is known to be non context-free, and indeed is conjectured to be outside the class of indexed grammars (Boullier, 2003).

Let $M = \{\{a,b,c\}^+\}$, the set of all strings of length at least one that can be built on the alphabet $\{a,b,c\}$. We consider now the language

$$L = L_{abc} \cup L_{ab} \cup L_{ac} \cup \{a'a, b'b, c'c, dd', ee', ff'\} :$$

$$L_{ab} = \{wd | w \in M, |w|_a = |w|_b\},$$

$$L_{ac} = \{we | w \in M, |w|_a = |w|_c\},$$

$$L_{abc} = \{wf | w \in M, |w|_a = |w|_b = |w|_c\}.$$

In order to define a CBFG recognizing L, we have to select features (contexts) that can represent exactly the intrinsic components of the languages composing L. We propose to use the following set of features for each sublanguage:

- For L_{ab}: (λ, d) and $(\lambda, ad), (\lambda, bd)$.
- For L_{ac}: (λ, e) and $(\lambda, ae), (\lambda, ce)$.
- For L_{abc}: (λ, f').
- For the letters a', b', c', a, b, c we add: $(\lambda, a), (\lambda, b), (\lambda, c), (a', \lambda), (b', \lambda), (c', \lambda)$.
- For the letters d, e, f, d', e', f' we add; $(\lambda, d'), (\lambda, e'), (\lambda, f'), (d, \lambda), (e, \lambda), (f, \lambda)$.

Here, L_{ab} will be represented by (λ, d), but we will use $(\lambda, ad), (\lambda, bd)$ to define the internal derivations of elements of L_{ab}. The same idea holds for L_{ac} with (λ, e) and $(\lambda, ae), (\lambda, ce)$.

For the lexical rules and in order to have an exact CBFG, note the special case for a, b, c:

$$\{(\lambda, bd), (\lambda, ce), (a', \lambda)\} \to a,$$

$$\{(\lambda, ad), (b', \lambda)\} \to b,$$

$$\{(\lambda, ae), (c', \lambda)\} \to c.$$

For the nine other letters, each one is defined with only one context, for example using the rule $\{(\lambda, d')\} \to d$.

For the production rules, the most important one is: $(\lambda, \lambda) \to \{(\lambda, d), (\lambda, e)\}, \{(\lambda, f')\}$.

Indeed, this rule, with the presence of two contexts in one of categories, means that an element of the language has to be derived so that it has a prefix u such that $f_G(u) \supseteq \{(\lambda, d), (\lambda, e)\}$. This means u is both an element of L_{ab} and L_{ac}. This rule represents the language L_{abc} since $\{(\lambda, f')\}$ can only represent the letter f.

The other parts of the language will be defined by the following rules:

$$(\lambda, \lambda) \to \{(\lambda, d)\}, \{(\lambda, d')\},$$

$$(\lambda, \lambda) \to \{(\lambda, e)\}, \{(\lambda, e')\},$$

$$(\lambda, \lambda) \to \{(\lambda, a)\}, \{(\lambda, bd), (\lambda, ce), (a', \lambda)\},$$

$$(\lambda, \lambda) \to \{(\lambda, b)\}, \{(\lambda, ad), (b', \lambda)\},$$

$$(\lambda, \lambda) \to \{(\lambda, c)\}, \{(\lambda, ae), (c', \lambda)\},$$

$$(\lambda, \lambda) \to \{(\lambda, d')\}, \{(d, \lambda)\},$$

$$(\lambda, \lambda) \to \{(\lambda, e')\}, \{(e, \lambda)\},$$

$$(\lambda, \lambda) \to \{(\lambda, f')\}, \{(f, \lambda)\}.$$

This set of rules is incomplete, since for representing L_{ab}, the grammar must contain the rules ensuring to have the same number of a's and b's, and similarly for L_{ac}. To lighten the presentation here, the complete grammar is presented in Appendix.

We claim this is an exact CBFG for a context-sensitive language. L is not context-free since if we intersect L with the regular language $\Sigma^* d$, we get an instance of the non context-free MIX language (with d appended). The exactness comes from the fact that we chose the contexts in order to ensure that strings belonging to a sublanguage can not belong to another one and that the derivation of a substring will provide all the possible correct features with the help of the union of all the possible derivations.

Note that the MIX language on its own is not definable by an exact CBFG: it is only when other parts of the language can distributionally define the appropriate partial structures that we can get context sensitive languages. Far from being a limitation of this formalism (a bug), we argue this is a feature: it is only in rather exceptional circumstances that we will get properly context sensitive languages. This formalism thus potentially accounts not just for the existence of non context-free natural languages but also for their rarity.

6.2 Inexact CBFGs

We are less interested in the class of all CBFGs: these are CBFGs where the contexts are just arbitrary features and there is no relation between $f_G(u)$ and $C_L(u)$ except for the presence of (λ, λ). However, it is important to understand the language theoretic power of this class as this upper bounds the hypothesis class of the algorithm, and is easier to analyse.

6.2.1 CONTEXT-FREE GRAMMARS

First, we note that this class contains all context-free languages. Given a context-free language, that does not include the empty string, we can take a CFG in Chomsky normal form and convert it directly into a CBFG. Let V be the set of non-terminals of such a CFG. We pick an arbitrary set of distinct contexts to represent the elements of V, subject only to the constraint that S corresponds to (λ,λ). Let $C(N)$ be the context corresponding to the non-terminal N. For every production rule in the CFG of the form $N \to PQ$, we add a CBFG production $\{C(N)\} \to \{C(P)\},\{C(Q)\}$. For every production in the CFG of the form $N \to a$, we add a CBFG production to P_L of the form $\{C(N)\} \to a$. It is easy to see that this will define the same language.

6.2.2 RANGE CONCATENATION GRAMMARS

While CBFG formalism has some relationship to a context-free grammar, and some to a semi-Thue system (also known as a string rewriting system), it is not formally identical to either of these. One exact equivalence is to a restricted subset of Range Concatenation Grammars; a very powerful formalism (Boullier, 2000). We include the following relationship, but suggest that the reader unfamiliar with RCGs proceeds to the discussion of the relationship with the more familiar class of context-free grammars.

Lemma 37 *For every CBFG G, there is a non-erasing positive range concatenation grammar of arity one, in 2-var form that defines the same language.*

Proof Suppose $G = \langle F,P,P_L,\Sigma\rangle$. Define a RCG with a set of predicates equal to F and the following clauses, and the two variables U,V. For each production $x \to yz$ in P, for each $f \in x$, where $y = \{g_1,\ldots g_i\}, z = \{h_1,\ldots h_j\}$ add clauses

$$f(UV) \to g_1(U),\ldots g_i(U),h_1(V),\ldots h_j(V).$$

For each lexical production $\{f_1 \ldots f_k\} \to a$ add clauses

$$f_i(a) \to \varepsilon.$$

It is straightforward to verify that $f(w) \vdash \varepsilon$ iff $f \in f_G(w)$. ■

6.2.3 CONJUNCTIVE GRAMMAR

A tighter correspondence is to the class of Conjunctive Grammars (Okhotin, 2001), invented independently of RCGs.

Definition 38 *A conjunctive grammar is defined as a quadruple $\langle\Sigma,N,P,S\rangle$, in which: Σ is the alphabet; N is the set of non terminal symbols; P is the set of rules, each of the form $A \to \alpha_1\&\ldots\&\alpha_m$, where $A \in V$ and $\forall i < m$, $\alpha_i \in (V \cup \Sigma)^*$; $S \in N$ is the start symbol.*

In this formalism, a string w is derived from $A \in V$ iff there exists a rule $A \to \alpha_1\&\ldots\&\alpha_m$ in P and for all $i < m$, α_i derives w.

We claim that for every every language L generated by a conjunctive grammar there is a CBFG representing $L\#$ (where the special character # is not included in the original alphabet).

Suppose we have a conjunctive grammar $G = \langle \Sigma, N, P, S \rangle$ in binary normal form (as defined in Okhotin, 2003). We construct the equivalent CBFG $G' = \langle F, P', P_L, \Sigma \rangle$ as followed:

- For every letter a we add a context (l_a, r_a) to F such that $l_a a r_a \in L$;
- For every rules $X \to a$ in P, we create a rule $\{(l_a, r_a)\} \to a$ in P_L.
- For every non terminal $X \in N$, for every rule $X \to P_1 Q_1 \& \ldots \& P_n Q_n$ we add distinct contexts $\{(l_{P_i Q_i}, r_{P_i Q_i})\}$ to F, such that for all i it exists u_i, $l_{P_i Q_i} u_i r_{P_i Q_i} \in L$ and $P_i Q_i \stackrel{*}{\Rightarrow}_G u_i$;
- Let $F_{X,j} = \{(l_{P_i Q_i}, r_{P_i Q_i}) : \forall i\}$ the set of contexts corresponding to the j^{th} rule applicable to X. For all $(l_{P_i Q_i}, r_{P_i Q_i}) \in F_{X,j}$, we add to P' the rules $(l_{P_i Q_i}, r_{P_i Q_i}) \to F_{P_i,k} F_{Q_i,l}$ $(\forall k, l)$.
- We add a new context (w, λ) to F such that $S \stackrel{*}{\Rightarrow}_G w$ and $(w, \lambda) \to \#$ to P_L;
- For all j, we add to P' the rule $(\lambda, \lambda) \to F_{S,j}\{(w, \lambda)\}$.

It can be shown that this construction gives an equivalent CBFG.

7. Discussion and Conclusion

One of the main objective of our approach is to provide a framework that helps to bridge the gap between theoretical methods of grammatical inference and the structured representations required in linguistics. We provide a conclusion and a discussion of our work according to these two standpoints.

7.1 Grammatical Inference

In this paper, we have presented a new formalism the *Contextual Binary Feature Grammars* and shown its relevance for representing a large class of languages. We have proposed a learning algorithm using only membership queries and shown that this algorithm can identify in the limit the class of context-free languages satisfying the FCP and FKP assumptions. First of all, we should establish how large the class of languages with the FCP and the FKP is: it includes all finite languages and all regular languages, since the set of congruence classes is finite for finite state languages. It similarly includes the context-free substitutable languages (Clark and Eyraud, 2007), since every string in a substitutable language belongs to only one syntactic congruence class. As already stated it does not include all CFLs since not all CFLs have the FCP and/or the FKP. However it does include languages like the Dyck languages of arbitrary order, Lukacevic language and most other classic simple examples. As a special case consider the equivalence relation between contexts $f \cong_L f'$ iff $\forall u$ we have that $f \odot u \in L$ iff $f' \odot u \in L$. The class of CFLs where the context distribution of every string is a finite union of equivalence classes of contexts clearly has both the FKP and the FCP.

If we now focus on the algorithm proposed: it is relatively simple but has two main drawbacks. First, the algorithm is not conservative since once we have found the correct language, the representation may change—if the feature set found is not fiducial—until the fiduciality is reached. Second, the CBFG output by the algorithm may not be consistent with some answers provided by the oracle. Indeed, when the algorithm checks the fiduciality of the feature set F, the membership of new strings is tested. These strings do not appear in the list of learning examples given to the oracle but are built from all the possible contexts and substrings that can be extracted from this list. Then, it is

possible that, among these new strings, some of them belong to the target language but are not recognized by the current grammar. In this case, the output grammar is nevertheless not modified. We can imagine a procedure that changes the grammar by adding these new positive strings for building the CBFG, however this could lead to having to deal with an exponential number of strings. Thus, a more reasonable procedure is to wait for these strings in the positive data presentation. One proposal for future work, from these two remarks, is a new learning algorithm that overcomes these drawbacks.

One important point is whether this result can be extended to a result which also bounds the number of samples as a polynomial function of the size of the representation. A preliminary result in this direction is presented in Clark (2010), which presents a polynomial result using the Minimally Adequate Teacher model of Angluin (1987). It seems likely that it will be possible to extend that result, which uses only context-free grammars, to the class of CBFGs.

Our approach to context-free grammatical inference is based on a generalisation of distributional learning, following the work of Clark and Eyraud (2007). The current state of the art in context-free inductive inference from flat unstructured examples only has been rather limited. When learning from stochastic data or using a membership oracle, it is possible to have powerful results, if we allow exponential computation (see for example Horning, 1969). The main contribution of this paper is to show that efficient learning is possible, with an appropriate representation. We currently rely on using a membership oracle, but under suitable assumptions about distributions, it should be possible to get a PAC-learning result for this class along the lines of Clark (2006), placing some bounds on the number of features required. Another interesting and important issue is the adaptation of this approach to stochastic languages.

We have focused on context-free grammatical inference, however, we have shown that our representation is also relevant for modeling non context-free languages. Then, another perspective of this work is to study learnability results for larger classes of languages. This would allow us to compare with other formalisms such as External Contextual Grammars (Boullier, 2001; Mitrana, 2005) and other learning methods dealing with non context-free languages (Oates et al., 2006; Yoshinaka, 2009).

7.2 Linguistics

The field of grammatical inference has close relations to the study of language acquisition. Attempts to model natural languages with context-free grammars require additional machinery: natural language categories such as noun phrases contain many overlapping subclasses with features such as case, number, gender and similarly for verbal categories. Modelling this requires either an exponential explosion of the number of non-terminals employed or a switch to a richer set of features. Our formalism can be seen as a first step to integrate such features.

While we have implemented the algorithm described here, and verified that it works in accordance with theory on small artificial examples, there are a number of modifications that would need to be made before it can be applied to real grammar induction on natural language. First, the algorithm is very naive; in practice a more refined algorithm could select both the kernel and the feature set in a more sophisticated way. Secondly, considering features that correspond to individual contexts may be too narrow a definition for natural language given the well known problems of data sparseness and it will be necessary to switch to features corresponding to sets of contexts, which may overlap. Thus for example one might have features that correspond to sets of contexts of the

form $F(u,v) = \{(lu, vr) | l, r \in \Sigma^*\}$. This would take this approach closer to methods that have been shown to be effective in unsupervised learning in NLP (Klein and Manning, 2004) where typically $|u| = |v| = 1$. In any event, we think such modifications will be necessary for the acquisition of non context-free languages. Finally, at the moment the algorithm has polynomial update time, but in the worst case, there are deterministic finite state automata such that the size of the smallest kernel will be exponential in the number of states. There are, however, natural algorithms for generalising the productions by removing features from the right hand sides of the rules; this would have the effect of accelerating the convergence of the algorithm, and removing or weakening the requirement for the Finite Kernel Property.

Acknowledgments

We would like to thank Ryo Yoshinaka for very helpful discussions, and the anonymous reviewers for suggestions and comments that have greatly improved the paper. We also want to thank Jean-Marie Madiot who worked on the first version of the experiments presented in this paper.

Appendix A.

We give here an explicit exact CBFG for the following non context-free language

$$L = L_{abc} \cup L_{ab} \cup L_{ac} \cup \{a'a, b'b, c'c, dd', ee', ff'\}$$

defined on the alphabet $\Sigma = \{a, b, c, d, e, f, a', b', c', d', e', f'\}$ and such that:

$$L_{ab} = \{wd | w \in \{a,b,c\}^+, |w|_a = |w|_b\},$$

$$L_{ac} = \{we | w \in \{a,b,c\}^+, |w|_a = |w|_c\},$$
$$L_{abc} = \{wf | w \in \{a,b,c\}^+, |w|_a = |w|_b = |w|_c\}.$$

Here is the list of productions of the grammar.

$$\{(\lambda,\lambda)\} \to \{(\lambda,d),(\lambda,e)\},\{(\lambda,f')\},$$
$$\{(\lambda,\lambda)\} \to \{(\lambda,d)\},\{(\lambda,d')\},$$
$$\{(\lambda,\lambda)\} \to \{(\lambda,e)\},\{(\lambda,e')\},$$
$$\{(\lambda,\lambda)\} \to \{(\lambda,a)\},\{(\lambda,bd),(\lambda,ce),(a',\lambda)\},$$
$$\{(\lambda,\lambda)\} \to \{(\lambda,b)\},\{(\lambda,ad),(b',\lambda)\},$$
$$\{(\lambda,\lambda)\} \to \{(\lambda,c)\},\{(\lambda,ae),(c',\lambda)\},$$
$$\{(\lambda,\lambda)\} \to \{(\lambda,d')\},\{(d,\lambda)\},$$

$$\{(\lambda,\lambda)\} \rightarrow \{(\lambda,e')\},\{(e,\lambda)\},$$
$$\{(\lambda,\lambda)\} \rightarrow \{(\lambda,f')\},\{(f,\lambda)\},$$

Abstract

Continuous-time Bayesian networks is a natural structured representation language for multi-component stochastic processes that evolve continuously over time. Despite the compact representation provided by this language, inference in such models is intractable even in relatively simple structured networks. We introduce a mean field variational approximation in which we use a product of *inhomogeneous* Markov processes to approximate a joint distribution over trajectories. This variational approach leads to a globally consistent distribution, which can be efficiently queried. Additionally, it provides a lower bound on the probability of observations, thus making it attractive for learning tasks. Here we describe the theoretical foundations for the approximation, an efficient implementation that exploits the wide range of highly optimized ordinary differential equations (ODE) solvers, experimentally explore characterizations of processes for which this approximation is suitable, and show applications to a large-scale real-world inference problem.

Keywords: continuous time Markov processes, continuous time Bayesian networks, variational approximations, mean field approximation

1. Introduction

Many real-life processes can be naturally thought of as evolving continuously in time. Examples cover a diverse range, starting with classical and modern physics, but also including robotics (Ng et al., 2005), computer networks (Simma et al., 2008), social networks (Fan and Shelton, 2009), gene expression (Lipshtat et al., 2005), biological evolution (El-Hay et al., 2006), and ecological systems (Opper and Sanguinetti, 2007). A joint characteristic of all above examples is that they are complex systems composed of multiple components (e.g., many servers in a server farm and multiple residues in a protein sequence). To realistically model such processes and use them in

*. A preliminary version of this paper appeared in the Proceedings of the Twenty Fifth Conference on Uncertainty in Artificial Intelligence, 2009 (UAI 09).
†. These authors contributed equally.

making sensible predictions we need to learn how to reason about systems that are composed of multiple components and evolve continuously in time.

Generally, when an evolving system is modeled with sufficient detail, its evolution in time is Markovian; meaning that its future state it determined by its present state—whether in a deterministic or random sense—independently of its past states. A traditional approach to modeling a multi-component Markovian process is to discretize the entire time interval into regular time slices of fixed length and represent its evolution using a *Dynamic Bayesian network*, which compactly represents probabilistic transitions between consecutive time slices (Dean and Kanazawa, 1989; Murphy, 2002; Koller and Friedman, 2009). However, as thoroughly explained in Nodelman et al. (2003), discretization of a time interval often leads either to modeling inaccuracies or to an unnecessary computational overhead. Therefore, in recent years there is a growing interest in modeling and reasoning about multi-component stochastic processes in continuous time (Nodelman et al., 2002; Ng et al., 2005; Rajaram et al., 2005; Gopalratnam et al., 2005; Opper and Sanguinetti, 2007; Archambeau et al., 2007; Simma et al., 2008).

In this paper we focus on *continuous-time Markov processes* having a discrete product state space $S = S_1 \times S_2 \times \cdots \times S_D$, where D is the number of components and the size of each S_i is finite. The dynamics of such processes that are also *time-homogeneous* can be determined by a single rate matrix whose entries encode transition rates among states. However, as the size of the state space is exponential in the number of components so does the size of the transition matrix. *Continuous-time Bayesian networks* (CTBNs) provide an elegant and compact representation language for multi-component processes that have a sparse pattern of interactions (Nodelman et al., 2002). Such patterns are encoded in CTBNs using a directed graph whose nodes represent components and edges represent direct influences among them. The instantaneous dynamics of each component depends only on the state of its parents in the graph, allowing a representation whose size scales linearly with the number of components and exponentially only with the indegree of the nodes of the graph.

Inference in multi-component temporal models is a notoriously hard problem (Koller and Friedman, 2009). Similar to the situation in discrete time processes, inference in CTBNs is exponential in the number of components, even with sparse interactions (Nodelman et al., 2002). Thus, we have to resort to approximate inference methods. The recent literature has adapted several strategies from discrete graphical models to CTBNs in a manner that attempts to exploit the continuous-time representation, thereby avoiding the drawbacks of discretizing the model.

One class of approximations includes sampling-based approaches, where Fan and Shelton (2008) introduce a likelihood-weighted sampling scheme, and more recently El-Hay et al. (2008) introduce a Gibbs-sampling procedure. The complexity of the Gibbs sampling procedure has been shown to naturally adapt to the rate of each individual component. Additionally it yields more accurate answers with the investment of additional computation. However, it is hard to bound the required time in advance, tune the stopping criteria, or estimate the error of the approximation.

An alternative class of approximations is based on *variational principles*. Recently, Nodelman et al. (2005b) and Saria et al. (2007) introduced an *Expectation Propagation* approach, which can be roughly described as a local message passing scheme, where each message describes the dynamics of a single component over an interval. This message passing procedure can be efficient. Moreover it can automatically refine the number of intervals according to the complexity of the underlying system. Nonetheless, it does suffer from several caveats. On the formal level, the approximation has no convergence guarantees. Second, upon convergence, the computed marginals do not neces-

sarily form a globally consistent distribution. Third, it is restricted to approximations in the form of piecewise-homogeneous messages on each interval. Thus, the refinement of the number of intervals depends on the fit of such homogeneous approximations to the target process. Finally, the approximation of Nodelman *et al* does not provide a provable approximation on the likelihood of the observation—a crucial component in learning procedures.

Here, we develop an alternative variational approximation, which provides a different tradeoff. We use the strategy of structured variational approximations in graphical models (Jordan et al., 1999), and specifically the variational approach of Opper and Sanguinetti (2007) for approximate inference in latent Markov Jump Processes, a related class of models (see below for more elaborate comparison). The resulting procedure approximates the posterior distribution of the CTBN as a product of independent components, each of which is an inhomogeneous continuous-time Markov process. We introduce a novel representation that is both natural and allows numerically stable computations. By using this representation, we derive an iterative variational procedure that employs passing information between neighboring components as well as solving a small set of differential equations (ODEs) in each iteration. The latter allows us to employ highly optimized standard ODE solvers in the implementation. Such solvers use an adaptive step size, which as we show is more efficient than any fixed time interval approximation.

We finally describe how to extend the proposed procedure to branching processes and particularly to models of molecular evolution, which describe historical dynamics of biological sequences that employ many interacting components. Our experiments on this domain demonstrate that our procedure provides a good approximation both for the likelihood of the evidence and for the expected sufficient statistics. In particular, the approximation provides a lower-bound on the likelihood, and thus is attractive for use in learning.

The paper is organized as follows: In Section 2 we review continuous-time models and inference problems in such models. Section 3 introduces a general variational principle for inference using a novel parameterization. In Section 4 we apply this principle to a family of factored representations and show how to find an optimal approximation within this family. Section 5 discusses related work. Section 6 gives an initial evaluation. Section 7 presents branching process and further experiments, and Section 8 discusses our results.

2. Foundations

CTBNs are based on the framework of *continuous-time Markov processes (CTMPs)*. In this section we begin by briefly describing CTMPs. See, for example, Gardiner (2004) and Chung (1960) for a thorough introduction. Next we review the semantics of CTBNs. We then discuss inference problems in CTBNs and the challenges they pose.

2.1 Continuous Time Markov Processes

A *continuous-time stochastic process with state space S* is an uncountable collection of S-valued random variables $\{X^{(t)} : t \geq 0\}$ where $X^{(t)}$ describes the state of the system at time t. Systems with multiple components are described by state spaces that are Cartesian products of spaces, S_i, each representing the state of a single component. In this paper we consider a D-component stochastic process $X^{(t)} = (X_1^{(t)}, \ldots, X_D^{(t)})$ with state space $S = S_1 \times S_2 \times \ldots \times S_D$, where each S_i is finite. The states in S are denoted by vectors, $x = (x_1, \ldots, x_D)$.

A *continuous-time Markov process* is a continuous-time stochastic process in which the joint distribution of every finite subset of random variables $X^{(t_0)}, X^{(t_1)}, \ldots, X^{(t_K)}$, where $t_0 < t_1 < \cdots < t_K$, satisfies the conditional independence property, also known as the Markov property:

$$\Pr(X^{(t_K)} = x_K | X^{(t_{K-1})} = x_{K-1}, \ldots, X^{(t_0)} = x_0) = \Pr(X^{(t_K)} = x_K | X^{(t_{K-1})} = x_{K-1}).$$

In simple terms, the knowledge of the state of the system at a certain time make its states at later times independent of its states at former times. In that case the distribution of the process is fully determined by the conditional probabilities of random variable pairs $\Pr(X^{(t+s)} = y | X^{(s)} = x)$, namely, by the probability that the process is in state y at time $t+s$ given that is was in state x at time s, for all $0 \leq s < t$ and $x, y \in S$. A CTMP is called *time homogeneous* if these conditional probabilities do not depend on s but only on the length of the time interval t, thus, the distribution of the process is determined by the *Markov transition functions*,

$$p_{x,y}(t) \equiv \Pr(X^{(t+s)} = y | X^{(s)} = x), \qquad \text{for all } x, y \in S \text{ and } t \geq 0,$$

which for every fixed t can be viewed as the entries of a stochastic matrix indexed by states x and y.

Under mild assumptions on the Markov transition functions $p_{x,y}(t)$, these functions are differentiable. Their derivatives at $t = 0$,

$$q_{x,y} = \lim_{t \to 0^+} \frac{p_{x,y}(t) - \mathbf{1}_{x=y}}{t},$$

are the entries of the *rate matrix* $\mathbb{Q}$, where $\mathbf{1}$ is the indicator function. This rate matrix describes the infinitesimal transition probabilities,

$$p_{x,y}(h) = \mathbf{1}_{x=y} + q_{x,y} h + o(h), \tag{1}$$

where $o(\cdot)$ means decay to zero faster than its argument, that is $\lim_{h \downarrow 0} \frac{o(h)}{h} = 0$. Note that the off-diagonal entries of $\mathbb{Q}$ are non-negative, whereas each of its rows sums up to zero, namely,

$$q_{x,x} = -\sum_{y \neq x} q_{x,y}.$$

The derivative of the Markov transition function for t other than 0 satisfies the so-called *forward*, or *master equation*,

$$\frac{d}{dt} p_{x,y}(t) = \sum_z q_{z,y} p_{x,z}(t). \tag{2}$$

A similar characterization for the time-dependent probability distribution, $p(t)$, whose entries are defined by

$$p_x(t) = \Pr(X^{(t)} = x), \qquad x \in S,$$

is obtained by multiplying the Markov transition function by entries of the initial distribution $p(0)$ and marginalizing, resulting in

$$\frac{d}{dt} p = p\mathbb{Q}. \tag{3}$$

The solution of this ODE is

$$p(t) = p(0) \exp(t\mathbb{Q}),$$

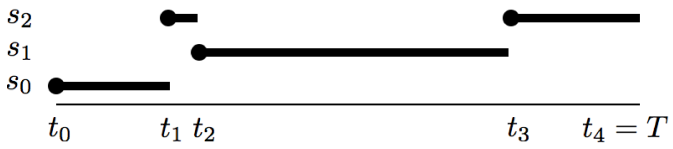

Figure 1: An example of a CTMP trajectory: The process starts at state $x_1 = s_0$, transitions to $x_2 = s_2$ at t_1, to $x_3 = s_1$ at t_2, and finally to $x_4 = s_2$ at t_3.

where $\exp(t\mathbb{Q})$ is a matrix exponential, defined for any square matrix $\mathbb{A}$ by the Taylor series,

$$\exp(\mathbb{A}) = \mathbf{I} + \sum_{k=1}^{\infty} \frac{\mathbb{A}^k}{k!} \ .$$

Applying this solution to the initial condition $p_{x'}(0) = \mathbf{1}_{x=x'}$, we can express the Markov transition function $p_{x,y}(t)$ using the rate matrix $\mathbb{Q}$ as

$$p_{x,y}(t) = [\exp(t\mathbb{Q})]_{x,y}. \tag{4}$$

Although a CTMP is an uncountable collection of random variables (the state of the system at every time t), a *trajectory* σ of $\{X^{(t)}\}_{t\geq 0}$ over a time interval $[0,T]$ can be characterized by a finite number of transitions K, a sequence of states $(x_0, x_1, \ldots, x_K)$ and a sequence of transition times $(t_0 = 0, t_1, \ldots, t_K, t_{K+1} = T)$. We denote by $\sigma(t)$ the state at time t, that is, $\sigma(t) = x_k$ for $t_k \leq t < t_{k+1}$. Figure 1 illustrates such a trajectory.

2.2 Multi-component Representation - Continuous-Time Bayesian Networks

Equation (4) indicates that the distribution of a homogeneous Markov process is fully determined by an initial distribution and a single rate matrix $\mathbb{Q}$. However, since the number of states in a D-component Markov Process is exponential in D, an explicit representation of this transition matrix is often infeasible. *Continuous-time Bayesian networks* are a compact representation of Markov processes that satisfy two assumptions. First it is assumed that only one component can change at a time, thus transition rates involving simultaneous changes of two or more components are zero. Second, the transition rate of each component i depends only on the state of some subset of components denoted $\mathbf{Pa}_i \subseteq \{1,\ldots,D\} \setminus \{i\}$ and on its own state. This dependency is represented using a directed graph, where the nodes are indexed by $\{1,\ldots,D\}$ and the parent nodes of i are $\mathbf{Pa}_i$ (Nodelman et al., 2002). With each component i we then associate a conditional rate matrix $\mathbb{Q}^{i|\mathbf{Pa}_i}_{\cdot|u_i}$ for each state u_i of $\mathbf{Pa}_i$. The off-diagonal entries $q^{i|\mathbf{Pa}_i}_{x_i,y_i|u_i}$ represent the rate at which X_i transitions from state x_i to state y_i given that its parents are in state u_i. The diagonal entries are $q^{i|\mathbf{Pa}_i}_{x_i,x_i|u_i} = -\sum_{y_i \neq x_i} q^{i|\mathbf{Pa}_i}_{x_i,y_i|u_i}$, ensuring that each row in each conditional rate matrix sums up to zero. The dynamics of $X^{(t)}$ are defined by a rate matrix $\mathbb{Q}$ with entries $q_{x,y}$, which combines the conditional rate matrices as follows:

$$q_{x,y} = \begin{cases} q^{i|\mathbf{Pa}_i}_{x_i,y_i|u_i} & \delta(x,y) = \{i\} \\ \sum_i q^{i|\mathbf{Pa}_i}_{x_i,x_i|u_i} & x = y \\ 0 & \text{otherwise,} \end{cases} \tag{5}$$

where $\delta(x,y) = \{j | x_j \neq y_j\}$ denotes the set of components in which x differs from y.

To have another perspective on CTBN's, we may consider a discrete-time approximation of the process. Let h be a sampling interval. The subset of random variables $\{X_{t_k} : k \geq 0\}$, where $t_k = kh$, is a discrete-time Markov process over a D-dimensional state-space. *Dynamic Bayesian networks (DBNs)* provide a compact modeling language for such processes, namely the conditional distribution of a DBN $\mathrm{P}_h(X^{(t_k+1)}|X^{(t_k)})$ is factorized into a product of conditional distributions of $X_i^{(t_{k+1})}$ given the state of a subset of $X^{(t_k)} \cup X^{(t_{k+1})}$. When h is sufficiently small, the CTBN can be approximated by a DBN whose parameters depend on the rate matrix $\mathbb{Q}$ of the CTBN ,

$$\mathrm{P}_h(X^{(t_{k+1})} = y | X^{(t_k)} = x) = \prod_{i=1}^{D} \mathrm{P}_h(X_i^{(t_{k+1})} = y_i | X_i^{(t_k)} = x_i, U^{(t_k)} = u_i), \tag{6}$$

where

$$\mathrm{P}_h(X_i^{(t_{k+1})} = y_i | X_i^{(t_k)} = x_i, U^{(t_k)} = u_i) = \mathbf{1}_{x_i = y_i} + q^{i|\mathbf{Pa}_i}_{x_i,y_i|u_i} h. \tag{7}$$

Each such term is the local conditional probability that $X_i^{(t_{k+1})} = y_i$ given the state of X_i and U_i at time t_k. These are valid conditional distributions, because they are non-negative and are normalized, that is

$$\sum_{y_i \in S_i} \left(\mathbf{1}_{x_i = y_i} + q^{i|\mathbf{Pa}_i}_{x_i,y_i|u_i} h \right) = 1$$

for every x_i and u_i. Note that in this discretized process, transition probabilities involving changes in more than one component are $o(h)$, as in the CTBN. Moreover, using Equations (1) and (5) we observe that

$$\Pr(X^{(t_k+1)} = y | X^{(t_k)} = x) = \mathrm{P}_h(X^{(t_k+1)} = y | X^{(t_k)} = x) + o(h).$$

(See Appendix A for detailed derivations). Therefore, the CTBN and the approximating DBN are asymptotically equivalent as $h \to 0$.

Example 1 An example of a multi-component process is the *dynamic Ising model*, which corresponds to a CTBN in which every component can be in one of two states, -1 or $+1$, and each component prefers to be in the same state as its neighbor. These models are governed by two parameters: a *coupling parameter* β (it is the inverse temperature in physical models, which determines the strength of the coupling between two neighboring components), and a *rate parameter* τ, which determines the propensity of each component to change its state. Low values of β correspond to weak coupling (high temperature). More formally, we define the conditional rate matrices as

$$q^{i|\mathbf{Pa}_i}_{x_i,y_i|u_i} = \tau \left(1 + e^{-2y_i \beta \sum_{j \in \mathbf{Pa}_i} x_j} \right)^{-1}$$

where $x_j \in \{-1, 1\}$. This model is derived by plugging the Ising grid to *Continuous-Time Markov Networks*, which are the undirected counterparts of CTBNs (El-Hay et al., 2006).

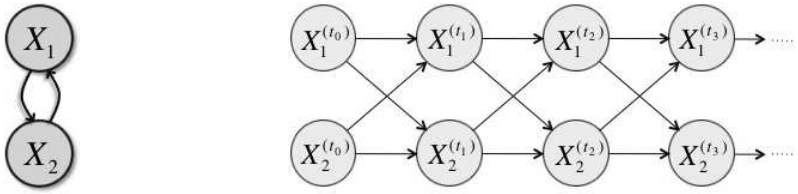
Consider a two component Ising model whose structure and corresponding DBN are shown in Figure 2. This system is symmetric, that is, the conditional rate matrices are identical for $i \in \{1,2\}$. As an example, for a specific choice of β and τ we have:

$\mathbb{Q}^{i|\mathbf{Pa}_i}_{\cdot|-1}$ =

	-	+
-	-1	1
+	10	-10

$\mathbb{Q}^{i|\mathbf{Pa}_i}_{\cdot|+1}$ =

	-	+
-	-10	10
+	1	-1



(a) (b)

Figure 2: Two representations of a two binary component dynamic process. *(a)* The associated CTBN. *(b)* The DBN corresponding to the CTBN in (a). The models are equivalent when $h \to 0$.

The local conditional distributions of the DBN can be directly inferred from Equation (7). For example

$$\mathrm{P}_h(X_1^{(t_{k+1})} = 1 | X_1^{(t_k)} = -1, X_2^{(t_k)} = 1) = 10h.$$

Here, in both components the conditional rates are higher for transitions into states that are identical to the state of their parent. Therefore, the two components have a disposition of being in the same state. To support this intuition, we examine the amalgamated rate matrix:

$$\mathbb{Q} = \begin{array}{c|cccc} & \text{--} & \text{-+} & \text{+-} & \text{++} \\ \hline \text{--} & -2 & 1 & 1 & 0 \\ \text{-+} & 10 & -20 & 0 & 10 \\ \text{+-} & 10 & 0 & -20 & 10 \\ \text{++} & 0 & 1 & 1 & -2. \end{array}$$

Clearly, transition rates into states in which both components have the same value is higher. Higher transitions rate imply higher transition probabilities, for example:

$$\begin{aligned} p_{\text{-+},\text{--}}(h) &= 10h + o(h), \\ p_{\text{--},\text{-+}}(h) &= h + o(h). \end{aligned}$$

Thus the probability of transitions into a coherent state is much higher than into an incoherent state. ∎

2.3 Inference in Continuous-time Markov Processes

Our setting is as follows: we receive evidence of the states of several or all components within a time interval $[0,T]$. The two possible types of evidence that may be given are continuous evidence, where we know the state of a subset $U \subseteq X$ continuously over some sub-interval $[t_1,t_2] \subseteq [0,T]$, and point evidence of the state of U at some point $t \in [0,T]$. For convenience we restrict our treatment to a time interval $[0,T]$ with full end-point evidence $X^{(0)} = e_0$ and $X^{(T)} = e_T$. We shall discuss the more general case in Section 5.

Given a continuous-time Bayesian network and evidence of the above type we would like to evaluate the likelihood of the evidence, $\Pr(e_0, e_T; \mathbb{Q})$ and to compute pointwise posterior probabilities of various events (e.g., $\Pr(U^{(t)} = u | e_0, e_T)$ for some $U \subseteq X$). Another class of queries are

conditional expectations of statistics that involve entire trajectories of the process. Two important examples for queries are the *sufficient statistics* required for learning. These statistics are the amount of time in which X_i is in state x_i and $\mathbf{Pa}_i$ are in state u_i, and the number of transitions that X_i underwent from x_i to y_i while its parents were in state u_i (Nodelman et al., 2003). We denote these statistics by $T^i_{x_i|u_i}$ and $M^i_{x_i,y_i|u_i}$ respectively. For example, in the trajectory of the univariate process in Figure 1, we have $T_{s_2} = t_2 - t_1 + t_4 - t_3$ and $M_{s_0,s_2} = 1$.

Exact calculation of these values is usually a computationally intractable task. For instance, calculation of marginals requires first calculating the pointwise distribution over X using a forward-backward like calculation:

$$\Pr(X^{(t)} = x | e_0, e_T) = \frac{p_{e_0,x}(t)\, p_{x,e_T}(T-t)}{p_{e_0,e_T}(T)}, \tag{8}$$

and then marginalizing

$$\Pr(U^{(t)} = u | e_0, e_T) = \sum_{x \setminus u} \Pr(X^{(t)} = x | e_0, e_T),$$

where $p_{x,y}(t) = [\exp(t\mathbb{Q})]_{x,y}$, and the size of $\mathbb{Q}$ is exponential in the number of components. Moreover, calculating expected residence times and expected number of transitions involves integration over the time interval of these quantities (Nodelman et al., 2005a):

$$\mathbf{E}[T_x] = \frac{1}{p_{e_0,e_T}(T)} \int_0^T p_{e_0,x}(t)\, p_{x,e_T}(T-t)dt,$$
$$\mathbf{E}[M_{x,y}] = \frac{1}{p_{e_0,e_T}(T)} \int_0^T p_{e_0,x}(t)\, q_{x,y}\, p_{y,e_T}(T-t)dt \quad .$$

These make this approach infeasible beyond a modest number of components, hence we have to resort to approximations.

3. Variational Principle for Continuous-Time Markov Processes

Variational approximations to structured models aim to approximate a complex distribution by a simpler one, which allows efficient inference. This problem can be viewed as an optimization problem: given a specific model and evidence, find the "best" approximation within a given class of simpler distributions. In this setting the inference is posed as a constrained optimization problem, where the constraints ensure that the parameters correspond to valid distributions consistent with the evidence. Specifically, the optimization problem is constructed by defining a lower bound to the log-likelihood of the evidence, where the gap between the bound and the true likelihood is the divergence of between the approximation and the true posterior. While the resulting problem is generally intractable, it enables us to derive approximate algorithms by approximating either the functional or the constrains that define the set of valid distributions. In this section we define the lower-bound functional in terms of a general continuous-time Markov process (that is, without assuming any network structure). Here we aim at defining a lower bound on $\ln P_{\mathbb{Q}}(e_T|e_0)$ as well as to approximating the posterior probability $P_{\mathbb{Q}}(\cdot \mid e_0, e_T)$, where $P_{\mathbb{Q}}$ is the distribution of the Markov process whose instantaneous rate-matrix is $\mathbb{Q}$. We start by examining the structure of the posterior and introducing an appropriate parameterization.

Recall that the distribution of a time-homogeneous Markov process is characterized by the conditional transition probabilities $p_{x,y}(t)$, which in turn is fully redetermined by the constant rate matrix $\mathbb{Q}$. It is not hard to see that whenever the prior distribution of a stochastic process is that of a homogeneous Markov process with rate matrix $\mathbb{Q}$, then the posterior $P_{\mathbb{Q}}(\cdot|e_0, e_T)$ is also a Markov process, albeit generally not a homogeneous one. The distribution of a continuous-time Markov processes that is not homogeneous in time is determined by conditional transition probabilities, $p_{x,y}(s, s+t)$, which depend explicitly on both initial and final times. These transition probabilities can be expressed by means of a time-dependent matrix-valued function, $\mathbb{R}(t)$, which describes instantaneous transition rates. The connection between the time-dependent rate matrix $\mathbb{R}(t)$ and the transition probabilities, $p_{x,y}(s, s+t)$ is established by the master equation,

$$\frac{d}{dt} p_{x,y}(s, s+t) = \sum_z r_{z,y}(s+t) p_{x,z}(s, s+t),$$

where $r_{z,y}(t)$ are the entries of $\mathbb{R}(t)$. This equation is a generalization of Equation (2) for inhomogeneous processes. As in the homogeneous case, it leads to a master equation for the time-dependent probability distribution,

$$\frac{d}{dt} p_x(t) = \sum_y r_{y,x}(t) p_y(t),$$

thereby generalizing Equation (3).

By the above discussion, it follows that the posterior process can be represented by a time-dependent rate matrix $\mathbb{R}(t)$. More precisely, writing the posterior transition probability using basic properties of conditional probabilities and the definition of the Markov transition function gives

$$P_{\mathbb{Q}}(X^{(t+h)} = y | X^{(t)} = x, X^{(T)} = e_T) = \frac{p_{x,y}(h) p_{y,e_T}(T - t + h)}{p_{x,e_T}(T - t)}.$$

Taking the limit $h \to 0$ we obtain the instantaneous transition rate of the posterior process

$$r_{x,y}(t) = \lim_{h \to 0} \frac{P_{\mathbb{Q}}(X^{(t+h)} = y | X^{(t)} = x, X^{(T)} = e_T)}{h} = q_{x,y} \cdot \frac{p_{y,e_T}(T - t)}{p_{x,e_T}(T - t)}. \tag{9}$$

This representation, although natural, proves problematic in the framework of deterministic evidence because as t approaches T the transition rate into the observed state tends to infinity. In particular, when $x \neq e_T$ and $y = e_T$, the posterior transition rate is $q_{x,e_T} \cdot \frac{p_{e_T,e_T}(T-t)}{p_{x,e_T}(T-t)}$. This term diverges as $t \to T$, because the numerator approaches 1 while the denominator approaches 0. We therefore consider an alternative parameterization for this inhomogeneous process that is more suitable for variational approximations.

3.1 Marginal Density Representation

Let Pr be the distribution of a Markov process, generally not time homogeneous. We define a family of functions:

$$\begin{aligned} \mu_x(t) &= \Pr(X^{(t)} = x), \\ \gamma_{x,y}(t) &= \lim_{h \downarrow 0} \frac{\Pr(X^{(t)} = x, X^{(t+h)} = y)}{h}, \ x \neq y. \end{aligned} \tag{10}$$

The function $\mu_x(t)$ is the marginal probability that $X^{(t)} = x$. The function $\gamma_{x,y}(t)$ is the probability density that X transitions from state x to y at time t. Note that this parameter is not a transition rate, but rather a product of a point-wise probability with the point-wise transition rate of the distribution, that is, the entries of the time-dependent rate matrix of an equivalent process can be defined by

$$r_{x,y}(t) = \begin{cases} \frac{\gamma_{x,y}(t)}{\mu_x(t)} & \mu_x(t) > 0, \\ 0 & \mu_x(t) = 0. \end{cases} \tag{11}$$

Hence, unlike the (inhomogeneous) rate matrix at time t, $\gamma_{x,y}(t)$ takes into account the probability of being in state x and not only the rate of transitions.

We aim to use the family of functions μ and γ as a representation of the posterior process. To do so, we need to characterize the set of constraints that these functions satisfy. We begin by constraining the marginals $\mu_x(t)$ to be valid distributions that is, $0 \leq \mu_x(t) \leq 1$ and $\sum_x \mu_x(t) = 1$. A similar constraint on the pairwise distributions implies that $\gamma_{x,y}(t) \geq 0$ for $x \neq y$. Next, we infer additional constraints from consistency properties between distributions over pairs of variables and their uni-variate marginals. Specifically, Equation (10) implies that for $x \neq y$

$$\Pr(X^{(t)} = x, X^{(t+h)} = y) = \gamma_{x,y}(t)\, h + o(h). \tag{12}$$

Plugging this identity into the consistency constraint

$$\mu_x(t) = \Pr(X^{(t)} = x) = \sum_y \Pr(X^{(t)} = x, X^{(t+h)} = y),$$

defining

$$\gamma_{x,x}(t) = -\sum_{y \neq x} \gamma_{x,y}(t)$$

and rearranging, we obtain

$$\Pr(X^{(t)} = x, X^{(t+h)} = y) = \mathbf{1}_{x=y}\mu_x(t) + \gamma_{x,y}(t)\, h + o(h), \tag{13}$$

which unlike (12) is valid for all x, y. Marginalizing (13) with respect to the second variable,

$$\Pr(X^{(t+h)} = x) = \sum_y \Pr(X^{(t)} = y, X^{(t+h)} = x),$$

we obtain a forward update rule for the uni-variate marginals

$$\mu_x(t+h) = \mu_x(t) + h \sum_y \gamma_{y,x}(t) + o(h).$$

Rearranging terms and taking the limit $h \to 0$ gives a differential equation for $\mu_x(t)$,

$$\frac{d}{dt}\mu_x(t) = \sum_y \gamma_{y,x}(t).$$

Finally, whenever $\mu_x(t) = 0$ we have $\Pr(X^{(t)} = x, X^{(t+h)} = y) = 0$, implying in that case that $\gamma_{x,y}(t) = 0$. Based on these observations we define:

Definition 1 A family $\eta = \{\mu_x(t), \gamma_{x,y}(t) : 0 \le t \le T\}$ of functions is a *Markov-consistent density set* if the following constraints are fulfilled:

$$\begin{aligned} \mu_x(t) &\geq 0, \quad \sum_x \mu_x(0) = 1, \\ \gamma_{x,y}(t) &\geq 0 \qquad \forall y \neq x, \\ \gamma_{x,x}(t) &= -\sum_{y \neq x} \gamma_{x,y}(t), \\ \frac{d}{dt}\mu_x(t) &= \sum_y \gamma_{y,x}(t), \end{aligned}$$

and $\gamma_{x,y}(t) = 0$ whenever $\mu_x(t) = 0$. We denote by $\mathcal{M}$ the set of all Markov-consistent densities. ∎

Using standard arguments we can show that there exists a correspondence between (generally inhomogeneous) Markov processes and density sets η. Specifically, given η, we construct a process by defining an inhomogeneous rate matrix $\mathbb{R}(t)$ whose entries are defined in Equation (11) and prove the following:

Lemma 2 *Let $\eta = \{\mu_x(t), \gamma_{x,y}(t) : 0 \le t \le T\}$. If $\eta \in \mathcal{M}$, then there exists a continuous-time Markov process* Pr *for which μ_x and $\gamma_{x,y}$ satisfy (10) for every t in the right-open interval [0,T).*

Proof See appendix B ■

The converse is also true: for every integrable inhomogeneous rate matrix $\mathbb{R}(t)$ the corresponding marginal density set is defined by $\frac{d}{dt}\mu_x(t) = \sum_y r_{y,x}(t)\mu_y(t)$ and $\gamma_{x,y}(t) = \mu_x(t)r_{x,y}(t)$. The processes we are interested in, however, have additional structure, as they correspond to the posterior distribution of a time-homogeneous process with end-point evidence. In that case, multiplying Equation (9) by $\mu_x(t)$ gives

$$\gamma_{x,y}(t) = \mu_x(t) \cdot q_{x,y} \cdot \frac{p_{y,e_T}(T-t)}{p_{x,e_T}(T-t)}. \tag{14}$$

Plugging in Equation (8) we obtain

$$\gamma_{x,y}(t) = \frac{p_{e_0,x}(t) \cdot q_{x,y} \cdot p_{y,e_T}(T-t)}{p_{e_0,e_T(T)}},$$

which is zero when $y \neq e_T$ and $t = T$. This additional structure implies that we should only consider a subset of $\mathcal{M}$. Specifically the representation η corresponding to the posterior distribution $P_{\mathbb{Q}}(\cdot|e_0, e_T)$ satisfies $\mu_x(0) = \mathbf{1}_{x=e_0}, \mu_x(T) = \mathbf{1}_{x=e_T}, \gamma_{x,y}(0) = 0$ for all $x \neq e_0$ and $\gamma_{x,y}(T) = 0$ for all $y \neq e_T$. We denote by $\mathcal{M}_e \subset \mathcal{M}$ the subset that contains Markov-consistent density sets satisfying these constraints. This analysis suggests that for every homogeneous rate matrix and point evidence e there is a member in $\mathcal{M}_e$ that corresponds to the posterior process. Thus, from now on we restrict our attention to density sets from $\mathcal{M}_e$.

3.2 Variational Principle

The marginal density representation allows us to state the variational principle for continuous processes, which closely tracks similar principles for discrete processes. Specifically, we define a functional of functions that are constrained to be density sets from $\mathcal{M}_e$. The maximum over this

set is the log-likelihood of the evidence and is attained for a density set that represents the posterior distribution. This formulation will serve as a basis for the mean-field approximation, which is introduced in the next section.

Define a *free energy functional*,

$$\mathcal{F}(\eta;\mathbb{Q}) = \mathcal{E}(\eta;\mathbb{Q}) + \mathcal{H}(\eta),$$

which, as we will see, measures the quality of η as an approximation of $P_{\mathbb{Q}}(\cdot|e)$. (For succinctness, we will assume that the evidence e is clear from the context.) The two terms in the functional are the *average energy*,

$$\mathcal{E}(\eta;\mathbb{Q}) = \int_0^T \sum_x \left[\mu_x(t) q_{x,x} + \sum_{y \neq x} \gamma_{x,y}(t) \ln q_{x,y} \right] dt,$$

and the *entropy*,

$$\mathcal{H}(\eta) = \int_0^T \sum_x \sum_{y \neq x} \gamma_{x,y}(t)[1 + \ln \mu_x(t) - \ln \gamma_{x,y}(t)]dt.$$

The following theorem establishes the relation of this functional to the Kullback-Leibler (KL) divergence and the likelihood of the evidence, and thus allows us to cast the variational inference into an optimization problem.

Theorem 3 *Let $\mathbb{Q}$ be a rate matrix, $e = (e_0, e_T)$ be states of X, and $\eta \in \mathcal{M}_e$. Then*

$$\mathcal{F}(\eta;\mathbb{Q}) = \ln P_{\mathbb{Q}}(e_T|e_0) - \boldsymbol{D}(P_\eta \| P_{\mathbb{Q}}(\cdot|e))$$

where P_η is the distribution corresponding to η and $\boldsymbol{D}(P_\eta \| P_{\mathbb{Q}}(\cdot|e))$ is the KL divergence between the two processes.

We conclude from the non-negativity of the KL divergence that the energy functional $\mathcal{F}(\eta;\mathbb{Q})$ is a lower bound of the log-likelihood of the evidence. The closer the approximation to the target posterior, the tighter the bound. Moreover, since the KL divergence is zero if and only if the two distributions are equal almost everywhere, finding the maximizer of this free energy is equivalent to finding the posterior distribution from which answers to different queries can be efficiently computed.

3.3 Proof of Theorem 3

We begin by examining properties of distributions of inhomogeneous Markov processes. Let $X^{(t)}$ be an inhomogeneous Markov process with rate matrix $\mathbb{R}(t)$. As in the homogeneous case, a trajectory σ of $\{X^{(t)}\}_{t \geq 0}$ over a time interval $[0,T]$ can be characterized by a finite number of transitions K, a sequence of states $(x_0, x_1, \ldots, x_K)$ and a sequence of transition times $(t_0 = 0, t_1, \ldots, t_K, t_{K+1} = T)$. We denote by Σ the set of all trajectories of $X^{[0,T]}$. The distribution over Σ can be characterized by a collection of random variables that consists of the number of transitions κ, a sequence of states $(\chi_0, \ldots, \chi_\kappa)$ and transition times $(\tau_1, \ldots, \tau_\kappa)$. Note that the number of random variables that characterize the trajectory is by itself a random variable. The density $f_{\mathbb{R}}$ of a trajectory $\sigma = \{K, x_0, \ldots, x_K, t_1, \ldots, t_K\}$ is the derivative of the joint distribution with respect to transition times, that is,

$$f_{\mathbb{R}}(\sigma) = \frac{\partial^K}{\partial t_1 \cdots \partial t_K} P_{\mathbb{R}}(\kappa = K, \chi_0 = x_0, \ldots, \chi_K = x_K, \tau_1 \leq t_1, \ldots, \tau_K \leq t_K),$$

which is given by

$$f_{\mathbb{R}}(\sigma) = p_{x_0}(0) \cdot \prod_{k=0}^{K-1} \left[e^{\int_{t_k}^{t_{k+1}} r_{x_k,x_k}(t)dt} r_{x_k,x_{k+1}}(t_{k+1}) \right] \cdot e^{\int_{t_K}^{t_{K+1}} r_{x_K,x_K}(t)dt}.$$

For example, in case $\mathbb{R}(t) = \mathbb{Q}$ is a homogeneous rate matrix this equation reduces to

$$f_{\mathbb{Q}}(\sigma) = p_{x_0}(0) \cdot \prod_{k=0}^{K-1} \left[e^{q_{x_k,x_k}(t_{k+1}-t_k)} q_{x_k,x_{k+1}} \right] \cdot e^{q_{x_K,x_K}(t_{K+1}-t_K)}.$$

The expectation of a random variable $\psi(\sigma)$ is an infinite sum (because one has to account for all possible numbers of transitions) of finite dimensional integrals,

$$\mathbf{E}_{f_{\mathbb{Q}}}[\psi] \equiv \int_{\Sigma} f_{\mathbb{R}}(\sigma)\psi(\sigma)d\sigma \equiv \sum_{K=0}^{\infty} \sum_{x_0} \cdots \sum_{x_K} \int_0^T \int_0^{t_K} \cdots \int_0^{t_2} f_{\mathbb{R}}(\sigma)\psi(\sigma)dt_1 \cdots dt_K.$$

The *KL-divergence* between two densities that correspond to two inhomogeneous Markov processes with rate matrices $\mathbb{R}(t)$ and $\mathbb{S}(t)$ is

$$\boldsymbol{D}(f_{\mathbb{R}} \| f_{\mathbb{S}}) = \int_{\Sigma} f_{\mathbb{R}}(\sigma) \ln \frac{f_{\mathbb{R}}(\sigma)}{f_{\mathbb{S}}(\sigma)} d\sigma \ . \tag{15}$$

We will use the convention $0 \ln 0 = 0$ and assume the support of $f_{\mathbb{S}}$ is contained in the support of $f_{\mathbb{R}}$. That is $f_{\mathbb{R}}(\sigma) = 0$ whenever $f_{\mathbb{S}}(\sigma) = 0$. The KL-divergence satisfies $\boldsymbol{D}(f_{\mathbb{R}} \| f_{\mathbb{S}}) \geq 0$ and is exactly zero if and only if $f_{\mathbb{R}} = f_{\mathbb{S}}$ almost everywhere (Kullback and Leibler, 1951).

Let $\eta \in \mathcal{M}_e$ be a marginal density set consistent with e. As we have seen, this density set corresponds to a Markov process with rate matrix $\mathbb{R}(t)$ whose entries are defined by Equation (11), hence we identify $f_\eta \equiv f_{\mathbb{R}}$.

Given evidence e on some event we denote $f_{\mathbb{Q}}(\sigma, e) \equiv f_{\mathbb{Q}}(\sigma) \cdot \mathbf{1}_{\sigma \models e}$, and note that

$$P_{\mathbb{Q}}(e) = \int_{\{\sigma : \sigma \models e\}} f_{\mathbb{Q}}(\sigma)d\sigma = \int_{\Sigma} f_{\mathbb{Q}}(\sigma, e)d\sigma \ ,$$

where $\sigma \models e$ is a predicate which is true if σ is consistent with the evidence. The density function of the posterior distribution $P_{\mathbb{Q}}(\cdot|e)$ satisfies $f_{\mathbb{S}}(\sigma) = \frac{f_{\mathbb{Q}}(\sigma,e)}{P_{\mathbb{Q}}(e)}$ where $\mathbb{S}(t)$ is the time-dependent rate matrix that corresponds to the posterior process.

Manipulating (15), we get

$$\boldsymbol{D}(f_\eta \| f_{\mathbb{S}}) = \int_{\Sigma} f_\eta(\sigma) \ln f_\eta(\sigma) d\sigma - \int_{\Sigma} f_\eta(\sigma) \ln f_{\mathbb{S}}(\sigma) d\sigma \equiv \mathbf{E}_{f_\eta}[\ln f_\eta(\sigma)] - \mathbf{E}_{f_\eta}[\ln f_{\mathbb{S}}(\sigma)].$$

Replacing $\ln f_{\mathbb{S}}(\sigma)$ by $\ln f_{\mathbb{Q}}(\sigma, e) - \ln P_{\mathbb{Q}}(e)$ and applying simple arithmetic operations gives

$$\ln P_{\mathbb{Q}}(e) = \mathbf{E}_{f_\eta}[\ln f_{\mathbb{Q}}(\sigma, e)] - \mathbf{E}_{f_\eta}[\ln f_\eta(\sigma)] + \boldsymbol{D}(f_\eta \| f_{\mathbb{S}}).$$

The crux of the proof is in showing that the expectations in the right-hand side satisfy

$$\mathbf{E}_{f_\eta}[\ln f_{\mathbb{Q}}(\sigma, e)] = \mathcal{E}(\eta; \mathbb{Q}),$$

and

$$-\mathbf{E}_{f_\eta}\left[\ln f_\eta(\sigma)\right] = \mathcal{H}(\eta),$$

implying that $\mathcal{F}(\eta;\mathbb{Q})$ is a lower bound on the log-probability of evidence with equality if and only if $f_\eta = f_\mathbb{Q}$ almost everywhere.

To prove these identities for the energy and entropy, we treat trajectories as functions $\sigma : \mathcal{R} \to \mathcal{R}$ where $\mathcal{R}$ is the set of real numbers by denoting $\sigma(t) \equiv X^{(t)}(\sigma)$—the state of the system at time t. Using this notation we introduce two lemmas that allow us to replace integration over a set of trajectories by a one dimensional integral, which is defined over a time variable. The first result handles expectations of functions that depend on specific states:

Lemma 4 *Let $\psi : S \times \mathcal{R} \to \mathcal{R}$ be a function, then*

$$\mathbf{E}_{f_\eta}\left[\int_0^T \psi(\sigma(t),t)dt\right] = \int_0^T \sum_x \mu_x(t)\psi(x,t)dt.$$

Proof See Appendix C.1 ■

As an example, by setting $\psi(x',t) = \mathbf{1}_{x'=x}$ we obtain that the expected residence time in state x is $\mathbf{E}_{f_\eta}[T_x] = \int_0^T \mu_x(t)dt$. The second result handles expectations of functions that depend on transitions between states:

Lemma 5 *Let $\psi(x,y,t)$ be a function from $S \times S \times \mathcal{R}$ to $\mathcal{R}$ that is continuous with respect to t and satisfies $\psi(x,x,t) = 0$, $\forall x, \forall t$ then*

$$\mathbf{E}_{f_\eta}\left[\sum_{k=1}^{K^\sigma} \psi(x_{k-1}^\sigma, x_k^\sigma, t_k^\sigma)\right] = \int_0^T \sum_x \sum_{y\neq x} \gamma_{x,y}(t)\psi(x,y,t)dt,$$

where the superscript σ stresses that K^σ, x_k^σ and t_k^σ are associated with a specific trajectory σ.

Proof See Appendix C.2 ■

Continuing the example of the previous lemma, here by setting $\psi(x',y',t) = \mathbf{1}_{x'=x}\mathbf{1}_{y'=y}\mathbf{1}_{x\neq y}$ the sums within the left hand expectation become the number of transitions in a trajectory σ. Thus, we obtain that the expected number of transitions from x to y is $\mathbf{E}_f[M_{x,y}] = \int_0^T \gamma_{x,y}(t)dt$.

We now use these lemmas to compute the expectations involved in the energy functional. Suppose $e = \{e_0, e_T\}$ is a pair of point evidence and $\eta \in \mathcal{M}_e$. Applying these lemmas with $\psi(x,t) = q_{x,x}$ and $\psi(x,y,t) = \mathbf{1}_{x\neq y} \cdot \ln q_{x,y}$ gives

$$\mathbf{E}_{f_\eta}\left[\ln f_\mathbb{Q}(\sigma,e)\right] = \int_0^T \sum_x \left[\mu_x(t)q_{x,x}(t) + \sum_{y\neq x} \gamma_{x,y}(t)\ln q_{x,y}(t)\right] dt\ .$$

Similarly, setting $\psi(x,t) = r_{x,x}(t)$ and $\psi(x,y,t) = \mathbf{1}_{x\neq y} \cdot \ln r_{x,y}(t)$, where $\mathbb{R}(t)$ is defined in Equation (11), we obtain

$$-\mathbf{E}_{f_\eta}\left[\ln f_\eta(\sigma,e)\right] = -\int_0^T \sum_x \left[\mu_x(t)\frac{\gamma_{x,x}(t)}{\mu_x(t)} + \sum_{y\neq x} \gamma_{x,y}(t)\ln\frac{\gamma_{x,y}(t)}{\mu_x(t)}\right] dt = \mathcal{H}(\eta)\ .$$

4. Factored Approximation

The variational principle we discussed is based on a representation that is as complex as the original process—the number of functions $\gamma_{x,y}(t)$ we consider is equal to the size of the original rate matrix $\mathbb{Q}$. To get a tractable inference procedure we make additional simplifying assumptions on the approximating distribution.

Given a D-component process we consider approximations that factor into products of independent processes. More precisely, we define $\mathcal{M}_e^i$ to be the continuous Markov-consistent density sets over the component X_i, that are consistent with the evidence on X_i at times 0 and T. Given a collection of density sets $\eta^1,\ldots,\eta^D$ for the different components, the product density set $\eta = \eta^1 \times \cdots \times \eta^D$ is defined as

$$\begin{aligned} \mu_x(t) &= \prod_i \mu^i_{x_i}(t), \\ \gamma_{x,y}(t) &= \begin{cases} \gamma^i_{x_i,y_i}(t)\mu_x^{\setminus i}(t) & \delta(x,y) = \{i\} \\ \sum_i \gamma^i_{x_i,x_i}(t)\mu_x^{\setminus i}(t) & x = y \\ 0 & \text{otherwise} \end{cases} \end{aligned}$$

where $\mu_x^{\setminus i}(t) = \prod_{j\neq i}\mu^j_{x_j}(t)$ is the joint distribution at time t of all the components other than the i'th (it is not hard to see that if $\eta^i \in \mathcal{M}_e^i$ for all i, then $\eta \in \mathcal{M}_e$). We define the set $\mathcal{M}_e^F$ to contain all factored density sets. From now on we assume that $\eta = \eta^1 \times \cdots \times \eta^D \in \mathcal{M}_e^F$.

Assuming that $\mathbb{Q}$ is defined by a CTBN, and that η is a factored density set, we can rewrite

$$\mathcal{E}(\eta;\mathbb{Q}) = \sum_i \int_0^T \sum_{x_i} \left[\mu^i_{x_i}(t)\mathbf{E}_{\mu^{\setminus i}(t)}\left[q_{x_i,x_i|U_i}\right] + \sum_{x_i,y_i\neq x_i} \gamma^i_{x_i,y_i}(t)\mathbf{E}_{\mu^{\setminus i}(t)}\left[\ln q_{x_i,y_i|U_i}\right] \right] dt$$

(see derivations in Appendix D). Similarly, the entropy term factors as

$$\mathcal{H}(\eta) = \sum_i \mathcal{H}(\eta^i) \ .$$

Note that terms such as $\mathbf{E}_{\mu^{\setminus i}(t)}\left[q_{x_i,x_i|U_i}\right]$ involve only $\mu^j(t)$ for $j \in \mathbf{Pa}_i$, because $\mathbf{E}_{\mu^{\setminus i}(t)}[f(U_i)] = \sum_{u_i}\mu_{u_i}(t)f(u_i)$. Therefore, this decomposition involves only local terms that either include the i'th component, or include the i'th component and its parents in the CTBN defining $\mathbb{Q}$.

To make the factored nature of the approximation explicit in the notation, we write henceforth,

$$\mathcal{F}(\eta;\mathbb{Q}) = \tilde{\mathcal{F}}(\eta^1,\ldots,\eta^D;\mathbb{Q}).$$

4.1 Fixed Point Characterization

The factored form of the functional and the independence between the different η^i allows optimization by *block ascent*, optimizing the functional with respect to each parameter set in turn. To do so, we should solve the following optimization problem:

> Fixing i, and given $\eta^1,\ldots,\eta^{i-1},\eta^{i+1},\ldots,\eta^D$, in $\mathcal{M}_e^1,\ldots\mathcal{M}_e^{i-1},\mathcal{M}_e^{i+1},\ldots,\mathcal{M}_e^D$, respectively, find
>
> $$\arg\max_{\eta^i\in\mathcal{M}_e^i} \tilde{\mathcal{F}}(\eta^1,\ldots,\eta^D;\mathbb{Q}) \ .$$

If for all i, we have a $\mu^i \in \mathcal{M}_e^i$, which is a solution to this optimization problem with respect to each component, then we have a (local) stationary point of the energy functional within $\mathcal{M}_e^F$.

To solve this optimization problem, we define a Lagrangian, which includes the constraints in the form of Definition 1. These constraints are to be enforced in a continuous fashion, and so the Lagrange multipliers $\lambda^i_{x_i}(t)$ are continuous functions of t as well. The Lagrangian is a functional of the functions $\mu^i_{x_i}(t)$, $\gamma^i_{x_i,y_i}(t)$ and $\lambda^i_{x_i}(t)$, and takes the following form

$$\mathcal{L} = \tilde{\mathcal{F}}(\eta;\mathbb{Q}) - \sum_{i=1}^{D} \int_0^T \lambda^i_{x_i}(t) \left(\frac{d}{dt}\mu^i_{x_i}(t) - \sum_{y_i} \gamma^i_{x_i,y_i}(t) \right) dt \ .$$

A necessary condition for the optimality of a density set η is the existence of λ such that (η,λ) is a *stationary point* of the Lagrangian. A stationary point of a functional satisfies the *Euler-Lagrange* equations, namely the *functional derivatives* with respect to μ, γ and λ vanish (see Appendix E for a brief review). The detailed derivation of the resulting equations is in Appendix F. Writing these equations in explicit form, we get a fixed point characterization of the solution in term of the following set of ODEs:

$$\begin{aligned} \frac{d}{dt}\mu^i_{x_i}(t) &= \sum_{y_i \neq x_i} \left(\gamma^i_{y_i,x_i}(t) - \gamma^i_{x_i,y_i}(t) \right), \\ \frac{d}{dt}\rho^i_{x_i}(t) &= -\rho^i_{x_i}(t) \left(\overline{q}^{\,i}_{x_i,x_i}(t) + \psi^i_{x_i}(t) \right) - \sum_{y_i \neq x_i} \rho^i_{y_i}(t) \tilde{q}^i_{x_i,y_i}(t) \end{aligned} \tag{16}$$

along with the following algebraic constraint

$$\rho^i_{x_i}(t)\gamma^i_{x_i,y_i}(t) = \mu^i_{x_i}(t)\tilde{q}^i_{x_i,y_i}(t)\rho^i_{y_i}(t), \ x_i \neq y_i \tag{17}$$

where ρ^i are the exponents of the Lagrange multipliers λ_i. In these equations we use the following shorthand notations for the average rates

$$\begin{aligned} \overline{q}^{\,i}_{x_i,x_i}(t) &= \mathbf{E}_{\mu^{\setminus i}(t)} \left[q^{i|\mathbf{Pa}_i}_{x_i,x_i|U_i} \right], \\ \overline{q}^{\,i}_{x_i,x_i|x_j}(t) &= \mathbf{E}_{\mu^{\setminus i}(t)} \left[q^{i|\mathbf{Pa}_i}_{x_i,x_i|U_i} \mid x_j \right], \end{aligned}$$

where $\mu^{\setminus i}(t)$ is the product distribution of $\mu^1(t),\ldots,\mu^{i-1}(t),\mu^{i+1}(t),\ldots,\mu^D(t)$. Similarly, we have the following shorthand notations for the geometrically-averaged rates,

$$\begin{aligned} \tilde{q}^i_{x_i,y_i}(t) &= \exp\left\{ \mathbf{E}_{\mu^{\setminus i}(t)} \left[\ln q^{i|\mathbf{Pa}_i}_{x_i,y_i|U_i} \right] \right\}, \\ \tilde{q}^i_{x_i,y_i|x_j}(t) &= \exp\left\{ \mathbf{E}_{\mu^{\setminus i}(t)} \left[\ln q^{i|\mathbf{Pa}_i}_{x_i,y_i|U_i} \mid x_j \right] \right\} \ . \end{aligned}$$

The last auxiliary term is

$$\psi^i_{x_i}(t) = \sum_{j \in Children_i} \sum_{x_j} \left[\mu^j_{x_j}(t) \overline{q}^{\,j}_{x_j,x_j|x_i}(t) + \sum_{x_j \neq y_j} \gamma^j_{x_j,y_j}(t) \ln \tilde{q}^j_{x_j,y_j|x_i}(t) \right] \ .$$

To uniquely solve the two differential Equations (16) for $\mu^i_{x_i}(t)$ and $\rho^i_{x_i}(t)$ we need to set boundary conditions. The boundary condition for $\mu^i_{x_i}$ is defined explicitly in $\mathcal{M}_e^F$ as

$$\mu^i_{x_i}(0) = \mathbf{1}_{x_i = e_{i,0}} \ . \tag{18}$$

The boundary condition at T is slightly more involved. The constraints in $\mathcal{M}_e^F$ imply that $\mu^i_{x_i}(T) = \mathbf{1}_{x_i=e_{i,T}}$. As stated in Section 3.1, we have that $\gamma^i_{e_{i,T},x_i}(T) = 0$ when $x_i \neq e_{i,T}$. Plugging these values into (17), and assuming that all elements of $\mathbb{Q}^{i|\mathbf{Pa}_i}$ are non-zero we get that $\rho_{x_i}(T) = 0$ for all $x_i \neq e_{i,T}$ (It might be possible to use a weaker condition that $\mathbb{Q}$ is irreducible). In addition, we notice that $\rho_{e_{i,T}}(T) \neq 0$, for otherwise the whole system of equations for ρ will collapse to 0. Finally, notice that the solution of (16,17) for μ^i and γ^i is insensitive to the multiplication of ρ^i by a constant. Thus, we can arbitrarily set $\rho_{e_{i,T}}(T) = 1$, and get the boundary condition

$$\rho^i_{x_i}(T) = \mathbf{1}_{x_i=e_{i,T}}. \tag{19}$$

Putting it all together we obtain a characterization of stationary points of the functional as stated in the following theorem:

Theorem 6 *$\eta^i \in \mathcal{M}_e^i$ is a stationary point (e.g., local maxima) of $\tilde{\mathcal{F}}(\eta^1,\ldots,\eta^D;\mathbb{Q})$ subject to the constraints of Definition 1 if and only if it satisfies (16–19).*

Proof see Appendix F ■

It is straightforward to extend this result to show that at a maximum with respect to all the component densities, this fixed-point characterization must hold for all components simultaneously.

Example 2 Consider the case of a single component, for which our procedure should be exact, as no simplifying assumptions are made on the density set. In that case, the averaged rates $\overline{q}^i$ and the geometrically-averaged rates $\tilde{q}^i$ both reduce to the unaveraged rates q, and $\psi \equiv 0$. Thus, the system of equations to be solved is

$$\frac{d}{dt}\mu_x(t) = \sum_{y\neq x}\left(\gamma_{y,x}(t) - \gamma_{x,y}(t)\right),$$
$$\frac{d}{dt}\rho_x(t) = -\sum_y q_{x,y}\rho_y(t),$$

along with the algebraic equation

$$\rho_x(t)\gamma_{x,y}(t) = \mu_x(t)q_{x,y}\rho_y(t), \qquad y \neq x.$$

These equations have a simple intuitive interpretation. First, the backward propagation rule for ρ_x implies that

$$\rho_x(t) = \Pr(e_T|X^{(t)} = x).$$

To prove this identity, we recall the notation $p_{x,y}(h) \equiv \Pr(X^{(t+h)} = y|X^{(t)} = x)$ and write the discretized propagation rule

$$\Pr(e_T|X^{(t)} = x) = \sum_y p_{x,y}(h)\cdot\Pr(e_T|X^{(t+h)} = y) \ .$$

Using the definition of q (Equation 1), rearranging, dividing by h and taking the limit $h \to 0$ gives

$$\frac{d}{dt}\Pr(e_T|X^{(t)} = x) = -\sum_y q_{x,y}\cdot\Pr(e_T|X^{(t)} = y),$$

which is identical to the differential equation for ρ. Second, dividing the above algebraic equation by $\rho_x(t)$ whenever it is greater than zero we obtain

$$\gamma_{x,y}(t) = \mu_x(t) q_{x,y} \frac{\rho_y(t)}{\rho_x(t)}. \tag{20}$$

Thus, we reconstructed Equation (14).

This analysis suggest that this system of ODEs is similar to forward-backward propagation, except that unlike classical forward propagation, here the forward propagation already takes into account the backward messages to directly compute the posterior. Given this interpretation, it is clear that integrating $\rho_x(t)$ from T to 0 followed by integrating $\mu_x(t)$ from 0 to T computes the exact posterior of the processes.

This interpretation of $\rho_x(t)$ also allows us to understand the role of $\gamma_{x,y}(t)$. Equation (20) suggests that the instantaneous rate combines the original rate with the relative likelihood of the evidence at T given y and x. If y is much more likely to lead to the final state, then the rates are biased toward y. Conversely, if y is unlikely to lead to the evidence the rate of transitions to it are lower. This observation also explains why the forward propagation of μ_x will reach the observed $\mu_x(T)$ even though we did not impose it explicitly. ∎

Example 3 Let us return to the two-component Ising chain in Example 1 with initial state $X_1^{(0)} = -1$ and $X_2^{(0)} = 1$, and a reversed state at the final time, $X_1^{(T)} = 1$ and $X_2^{(T)} = -1$. For a large value of β, this evidence is unlikely as at both end points the components are in a undesired configurations. The exact posterior is one that assigns higher probabilities to trajectories where one of the components switches relatively fast to match the other, and then toward the end of the interval, they separate to match the evidence. Since the model is symmetric, these trajectories are either ones in which both components are most of the time in state -1, or ones where both are most of the time in state 1 (Figure 3(a)). Due to symmetry, the marginal probability of each component is around 0.5 throughout most of the interval. The variational approximation cannot capture the dependency between the two components, and thus converges to one of two local maxima, corresponding to the two potential subsets of trajectories (Figure 3(b)). Examining the value of ρ^i, we see that close to the end of the interval they bias the instantaneous rates significantly. For example, as t approaches 1, $\rho_1^1(t)/\rho_{-1}^1(t)$ approaches infinity and so does the instantaneous rate $\gamma_{-1,1}^1(t)/\mu_{-1}^1(t)$, thereby forcing X_1 to switch to state 1 (Figure 3(c)).

This example also allows to examine the implications of modeling the posterior by inhomogeneous Markov processes. In principle, we might have used as an approximation Markov processes with homogeneous rates, and conditioned on the evidence. To examine whether our approximation behaves in this manner, we notice that in the single component case we have

$$q_{x,y} = \frac{\rho_x(t)\gamma_{x,y}(t)}{\rho_y(t)\mu_x(t)},$$

which should be constant.

Consider the analogous quantity in the multi-component case: $\tilde{q}^i_{x_i,y_i}(t)$, the geometric average of the rate of X_i, given the probability of parents state. Not surprisingly, this is exactly a mean field approximation, where the influence of interacting components is approximated by their average influence. Since the distribution of the parents (in the two-component system, the other component)

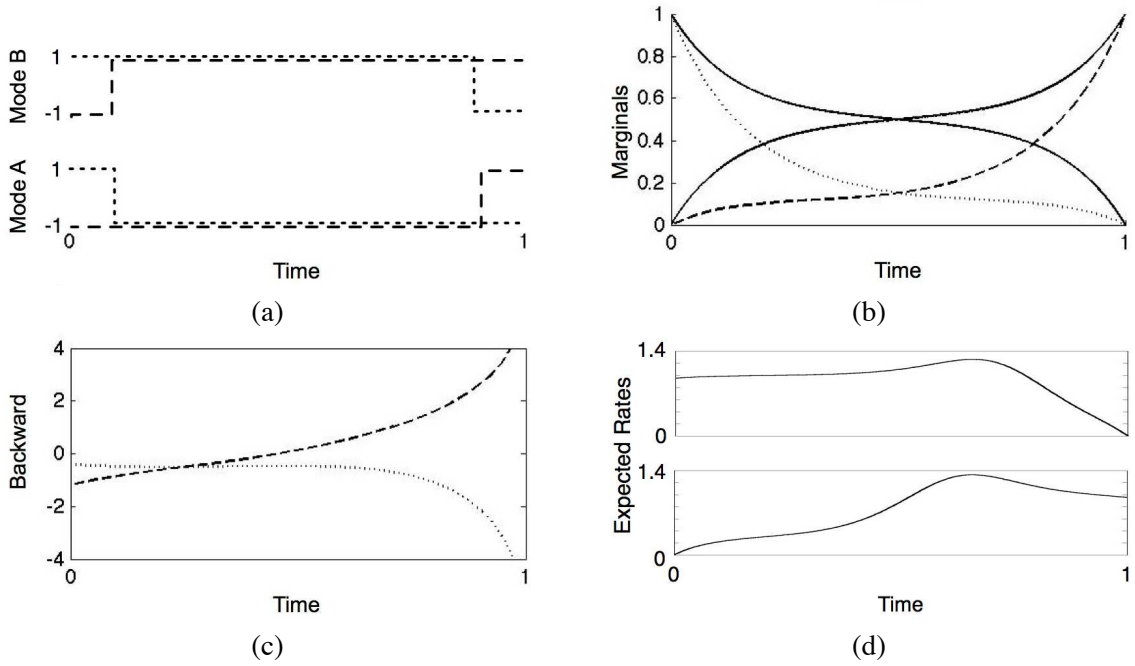


Figure 3: Numerical results for the two-component Ising chain described in Example 3 where the first component starts in state -1 and ends at time $T = 1$ in state 1. The second component has the opposite behavior. *(a)* Two likely trajectories depicting the two modes of the model. *(b)* Exact (solid) and approximate (dashed/dotted) marginals $\mu_1^i(t)$. *(c)* The log ratio $\log \rho_1^i(t)/\rho_{-1}^i(t)$. *(d)* The expected rates $\tilde{q}_{1,-1}^1(t)$ and $\tilde{q}_{-1,1}^1(t)$ of component X_1 of the Ising chain in Example 1. We can notice that the averaged rates are highly non-constant, and so cannot be approximated well with a constant rate matrix.

changes in time, these rates change continuously, especially near the end of the time interval. This suggests that a piecewise homogeneous approximation cannot capture the dynamics without a loss in accuracy. As expected in a dynamic process, we can see in Figure 3(d) that the inhomogeneous transition rates are very erratic. In particular, the rates of X_1 spike at the transition point selected by the mean field approximation. This can be interpreted as putting most of the weight of the distribution on trajectories which transition from state -1 to 1 at that point. ∎

4.2 Optimization Procedure

If $\mathbb{Q}$ is irreducible, then $\rho_{x_i}^i$ and $\mu_{x_i}^i$ are non-zero throughout the open interval $(0,T)$. As a result, we can solve (17) to express γ_{x_i,y_i}^i as a function of μ^i and ρ^i, thus eliminating it from (16) to get evolution equations solely in terms of μ^i and ρ^i. Abstracting the details, we obtain a set of ODEs of the form

$$\frac{d}{dt}\rho^i(t) = \alpha(\rho^i(t), \mu^{\setminus i}(t)) \qquad \rho^i(T) = \text{given},$$
$$\frac{d}{dt}\mu^i(t) = \beta(\mu^i(t), \rho^i(t), \mu^{\setminus i}(t)) \quad \mu^i(0) = \text{given}.$$

where α and β are defined by the right-hand side of the differential equations (16). Since the evolution of ρ^i does not depend on μ^i, we can integrate backward from time T to solve for ρ^i. Then, integrating forward from time 0, we compute μ^i. After performing a single iteration of backward-forward integration, we obtain a solution that satisfies the fixed-point equation (16) for the i'th component (this is not surprising once we have identified our procedure to be a variation of a standard forward-backward algorithm for a single component). Such a solution will be a local maximum of the functional w.r.t. to η^i (reaching a local minimum or a saddle point requires very specific initialization points).

This suggests that we can use the standard procedure of asynchronous updates, where we update each component in a round-robin fashion. Since each of these single-component updates converges in one backward-forward step, and since it reaches a local maximum, each step improves the value of the free energy over the previous one. As the free energy functional is bounded by the probability of the evidence, this procedure will always converge, and the rate of the free energy increase can be used to test for convergence.

Potentially, there can be many scheduling possibilities. In our implementation the update scheduling is simply random. A better choice would be to update the component which would maximally increase the value of the functional in that iteration. This idea is similar to the scheduling of Elidan et al. (2006), who approximate the change in the beliefs by bounding the *residuals* of the messages, which give an approximation of the benefit of updating each component.

Another issue is the initialization of this procedure. Since the iteration on the i'th component depends on $\mu^{\setminus i}$, we need to initialize μ by some legal assignment. To do so, we create a fictional rate matrix $\tilde{\mathbb{Q}}_i$ for each component and initialize μ^i to be the posterior of the process given the evidence $e_{i,0}$ and $e_{i,T}$. As a reasonable initial guess, we choose at random one of the conditional rates $\mathbb{Q}^{i|u_i}$ using some random assignment u_i to determine the fictional rate matrix.

The general optimization procedure is summarized in the following algorithm:

For each i, initialize μ^i using some legal marginal function.
while *not converged* **do**

1. *Pick a component $i \in \{1,\ldots,D\}$.*
2. *Update $\rho^i(t)$ by solving the ρ^i backward differential equation in (16).*
3. *Update $\mu^i(t)$ and $\gamma^i(t)$ by solving the μ^i forward differential equation in (16) and using the algebraic equation in (17).*

end

Algorithm 1: Mean field approximation in continuous-time Bayesian networks

4.3 Exploiting Continuous-Time Representation

The continuous-time update equations allow us to use standard ODE methods with an adaptive step size (here we use the Runge-Kutta-Fehlberg (4,5) method). At the price of some overhead, these procedures automatically tune the trade-off between error and time granularity. Moreover, this overhead is usually negligible compared to the saving in computation time, because adaptive integration can be more efficient than *any* fixed step size integration by an order of magnitude (Press et al., 2007).

To further save computations, we note that while standard integration methods involve only initial boundary conditions at $t = 0$, the solution of μ^i is also known at $t = T$. Therefore, we stop the adaptive integration when $\mu^i(t) \approx \mu^i(T)$ and t is close enough to T. This modification reduces the number of computed points significantly because the derivative of μ^i tends to grow near the boundary, resulting in a smaller step size.

The adaptive solver selects different time points for the evaluation of each component. Therefore, updates of η^i require access to marginal density sets of neighboring components at time points that differ from their evaluation points. To allow efficient interpolation, we use a piecewise linear approximation of η whose boundary points are determined by the evaluation points that are chosen by the adaptive integrator.

5. Perspectives and Related Work

Variational approximations for different types of continuous-time processes have been recently proposed. Examples include systems with discrete hidden components (Opper and Sanguinetti, 2007); continuous-state processes (Archambeau et al., 2007); hybrid models involving both discrete and continuous-time components (Sanguinetti et al., 2009; Opper and Sanguinetti, 2010); and spatiotemporal processes (Ruttor and Opper, 2010; Dewar et al., 2010). All these models assume noisy observations in a finite number of time points. In this work we focus on structured discrete-state processes with noiseless evidence.

Our approach is motivated by results of Opper and Sanguinetti (2007) who developed a variational principle for a related model. Their model is similar to an HMM, in which the hidden chain is a continuous-time Markov process and there are (noisy) observations at discrete points along the process. They describe a variational principle and discuss the form of the functional when the approximation is a product of independent processes. There are two main differences between the setting of Opper and Sanguinetti and ours. First, we show how to exploit the structure of the target CTBN to reduce the complexity of the approximation. These simplifications imply that the update of the i'th process depends only on its Markov blanket in the CTBN, allowing us to develop efficient approximations for large models. Second, and more importantly, the structure of the evidence in our setting is quite different, as we assume deterministic evidence at the end of intervals. This setting typically leads to a posterior Markov process in which the instantaneous rates used by Opper and Sanguinetti diverge toward the end point—the rates of transition into the observed state go to infinity, leading to numerical problems at the end points. We circumvent this problem by using the marginal density representation which is much more stable numerically.

Taking the general perspective of Wainwright and Jordan (2008), the representation of the distribution uses the natural sufficient statistics. In the case of a continuous-time Markov process, the sufficient statistics are T_x, the time spent in state x, and $M_{x,y}$, the number of transitions from state x to y. In a discrete-time model, we can capture the statistics for every random variable. In a continuous-time model, however, we need to consider the time derivative of the statistics. Indeed, as shown in Section 3.3 we have

$$\frac{d}{dt}\mathbf{E}\left[T_x(t)\right] = \mu_x(t) \quad \text{and} \quad \frac{d}{dt}\mathbf{E}\left[M_{x,y}(t)\right] = \gamma_{x,y}(t).$$

Thus, our marginal density sets η provide what we consider a natural formulation for variational approaches to continuous-time Markov processes.

Our presentation focused on evidence at two ends of an interval. Our formulation easily extends to deal with more elaborate types of evidence: (1) If we do not observe the initial state of the i'th component, we can set $\mu^i_x(0)$ to be the prior probability of $X^{(0)} = x$. Similarly, if we do not observe X_i at time T, we set $\rho^i_x(T) = 1$ as initial data for the backward step. (2) In a CTBN where one (or more) components are fully observed throughout some interval, we simply set μ^i for these components to be a distribution that assigns all the probability mass to the observed trajectory. Similarly, if we observe different components at different times, we may update each component on a different time interval. Consequently, maintaining for each component a marginal distribution μ^i throughout the interval of interest, we can update the other ones using their evidence patterns.

6. Evaluation on Ising Chains

To gain better insight into the quality of our procedure, we performed numerical tests on models that challenge the approximation. Specifically, we use Ising chains with the parameterization introduced in Example 1, where we explore regimes defined by the degree of coupling between the components (the parameter β) and the rate of transitions (the parameter τ). We evaluate the error in two ways. The first is by the difference between the true log-likelihood and our estimate. The second is by the average relative error in the estimate of different expected sufficient statistics defined by $\sum_j |\hat{\theta}_j - \theta_j|/\theta_j$, where θ_j is exact value of the j'th expected sufficient statistics and $\hat{\theta}_j$ is the approximation. To obtain a stable estimate the average is taken over all $\theta_j > 0.05 \max_{j'} \theta_{j'}$.

Applying our procedure on an Ising chain with 8 components, for which we can still perform exact inference, we evaluated the relative error for different choices of β and τ. The evidence in this experiment is $e_0 = \{+,+,+,+,+,+,-,-\}$, $T = 0.64$ and $e_T = \{-,-,-,+,+,+,+,+\}$. As shown in Figure 4(a), the error is larger when τ and β are large. In the case of a weak coupling (small β), the posterior is almost factored, and our approximation is accurate. In models with few transitions (small τ), most of the mass of the posterior is concentrated on a few canonical "types" of trajectories that can be captured by the approximation (as in Example 3). At high transition rates, the components tend to transition often, and in a coordinated manner, which leads to a posterior that is hard to approximate by a product distribution. Moreover, the resulting free energy landscape is rough with many local maxima. Examining the error in likelihood estimates (Figure 4(b),(c)) we see a similar trend.

Next, we examine the run time of our approximation when using fairly standard ODE solver with few optimizations and tunings. The run time is dominated by the time needed to perform the backward-forward integration when updating a single component, and by the number of such updates until convergence. Examining the run time for different choices of β and τ (Figure 5), we see that the run time of our procedure scales linearly with the number of components in the chain. The differences among the different curves suggest that the runtime is affected by the choice of parameters, which in turn affect the smoothness of the posterior density sets.

7. Evaluation on Branching Processes

The above-mentioned experimental results indicate that our approximation is accurate when reasoning about weakly-coupled components, or about time intervals involving few transitions (low transition rates). Unfortunately, in many domains we face strongly-coupled components. For example, we are interested in modeling the evolution of biological sequences (DNA, RNA, and proteins).

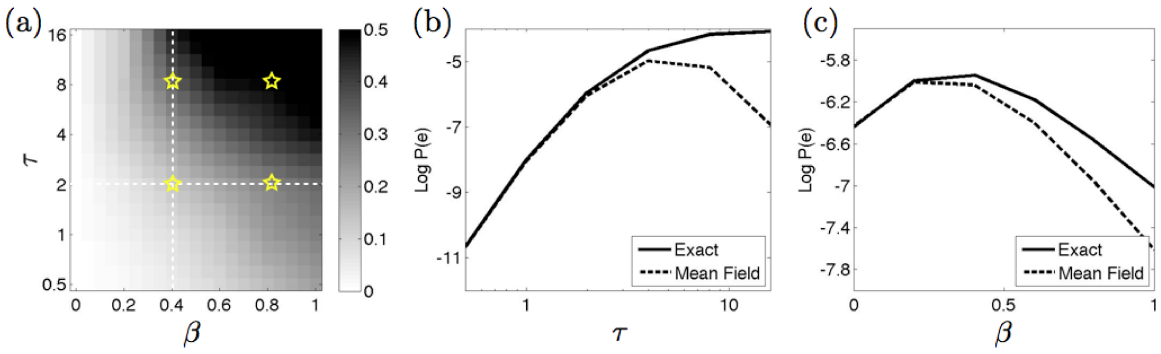

Figure 4: *(a)* Relative error as a function of the coupling parameter β (*x*-axis) and transition rates τ (*y*-axis) for an 8-component Ising chain. *(b)* Comparison of true vs. estimated likelihood as a function of the rate parameter τ. *(c)* Comparison of true vs. likelihood as a function of the coupling parameter β.

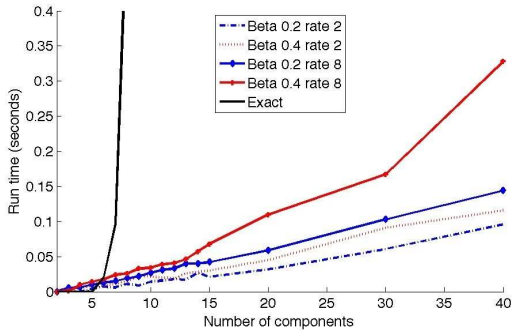

Figure 5: Evaluation of the run time of the approximation versus the run time of exact inference as a function of the number of components.

In such systems, we have a *phylogenetic tree* that represents the branching process that leads to current day sequences (see Figure 6).

It is common in sequence evolution to model this process as a continuous-time Markov process over a tree (Felsenstein, 2004). More precisely, the evolution along each branch is a standard continuous-time Markov process, and branching is modeled by a replication, after which each replica evolves independently along its sub-branch. Common applications are forced to assume that each character in the sequence evolves independently of the other.

In some situations, assuming an independent evolution of each character is highly unreasonable. Consider the evolution of an RNA sequence that folds onto itself to form a functional structure, as in Figure 7(a). This folding is mediated by complementary base-pairing (A-U, C-G, etc) that stabilizes the structure. During evolution, we expect to see compensatory mutations. That is, if a *A* changes into *C* then its based-paired *U* will change into a *G* soon thereafter. To capture such

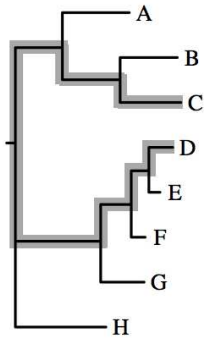

Figure 6: An example of a phylogenetic tree. Branch lengths denote time intervals between events. The interval used for the comparison with non-branching processes is highlighted.

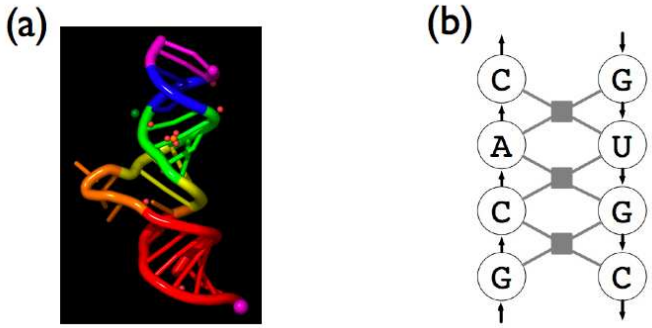

Figure 7: *(a)* Structure of an RNA molecule. The 3 dimensional structure dictates the dependencies between the different positions. *(b)* The form of the energy function for encoding RNA folding, superimposed on a fragment of a folded structure; each gray box denotes a term that involves four nucleotides.

coordinated changes, we need to consider the joint evolution of the different characters. In the case of RNA structure, the stability of the structure is determined by *stacking potentials* that measure the stability of two adjacent pairs of interacting nucleotides. Thus, if we consider a factor network to represent the energy of a fold, it will have structure as shown in Figure 7(b). We can convert this factor graph into a CTBN using procedures that consider the energy function as a fitness criteria in evolution (El-Hay et al., 2006; Yu and Thorne, 2006). Unfortunately, inference in such models suffers from computational blowup, and so the few studies that deal with it explicitly resort to sampling procedures (Yu and Thorne, 2006).

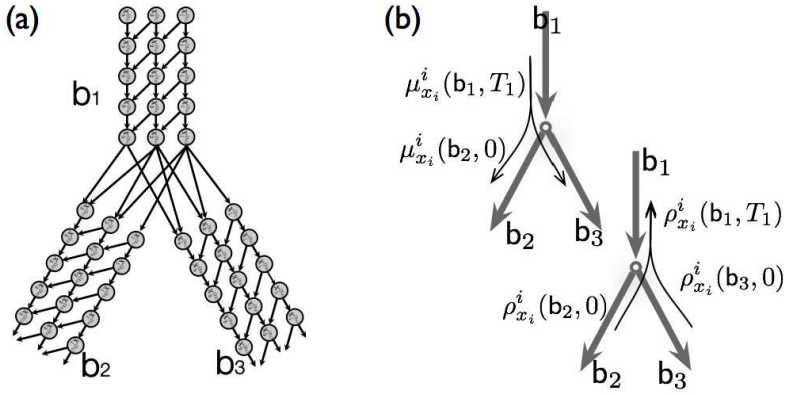

Figure 8: Structure of the branching process. *(a)* The discretized CTBN underlying the process in an intersection. *(b)* Illustration of the ODE updates on a directed tree, updating $\rho^i(t)$ backwards using (21) and $\mu^i(t)$ forwards using (22).

7.1 Representation

To consider phylogenetic trees, we should take a common approach in evolutionary analysis, in which inference of the tree topology and branch lengths is performed separately from inference of sequence dynamics. Thus, we need to extend our framework to deal with branching processes, where the branching points are fixed and known. In a linear-time model, we view the process as a map from $[0,T]$ into random variables $X^{(t)}$. In the case of a tree, we view the process as a map from a point $\mathsf{t} = \langle \mathsf{b}, t \rangle$ on a tree $\mathcal{T}$ (defined by branch b and the time t within it) into a random variable $X^{(\mathsf{t})}$. Similarly, we generalize the definition of the Markov-consistent density set η to include functions on trees. We define continuity of functions on trees in the obvious manner.

To gain intuition on this process we return to the discrete case, where our branching process can be viewed as a branching of the Dynamic Bayesian Network from one branch to two separate branches at the vertex, as in Figure 8(a).

7.2 Inference on Trees

The variational approximation on trees is thus similar to the one on intervals. Within each branch, we deal with the same update formulas as in linear time. We denote by $\mu^i_{x_i}(\mathsf{b},t)$ and $\rho^i_{x_i}(\mathsf{b},t)$ the messages computed on branch b at time t. The only changes occur at vertices, where we cannot use the Euler-Lagrange equations (Appendix E), therefore we must derive the propagation equations using a different method.

The following proposition establishes the update equations for the parameters $\mu^i(t)$ and $\rho^i(t)$ at the vertices, as depicted in Figure 8(b):

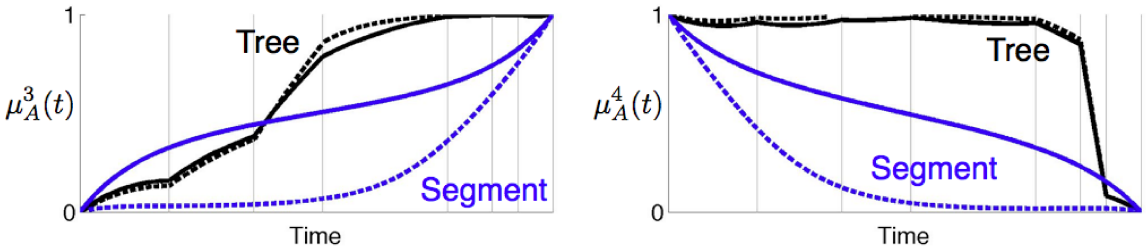

Figure 9: Comparison of exact vs. approximate inference along the highlighted path from C to D in the tree of Figure 6 with and without additional evidence at other leaves. In the latter case the problem is equivalent to inference on a linear segment. Exact marginals are shown in solid lines, whereas approximate marginals are in dashed lines. The horizontal gray lines indicate branch points along the path. Notice that evidence at the leaves result in discontinuities of the derivatives at such points. The two panels show two different components.

Proposition 7 *Given a vertex T with an incoming branch b_1 and two outgoing branches $\mathsf{b}_2, \mathsf{b}_3$. The following are the correct updates for our parameters $\mu^i_{x_i}(t)$ and $\rho^i_{x_i}(t)$:*

$$\rho^i_{x_i}(\mathsf{b}_1, T) = \rho^i_{x_i}(\mathsf{b}_2, 0)\rho^i_{x_i}(\mathsf{b}_3, 0), \tag{21}$$

$$\mu^i_{x_i}(\mathsf{b}_k, 0) = \mu^i_{x_i}(\mathsf{b}_1, T) \qquad k = 2, 3. \tag{22}$$

Proof See Appendix G ■

Using Proposition 7 we can set the updates of the different parameters in the branching process according to (21–22). In the backward propagation of ρ^i, the value at the end of b_1 is the product of the values at the start of the two outgoing branches. This is the natural operation when we recall the interpretation of ρ^i as the probability of the downstream evidence given the current state (which is its exact meaning in a single component process): the downstream evidence of b_2 is independent of the downstream evidence of b_3, given the state of the process at the vertex $\langle \mathsf{b}_1, T \rangle$. The forward propagation of μ^i simply uses the value at the end of the incoming branch as initial value for the outgoing branches.

When switching to trees, we essentially increase the amount of evidence about intermediate states. Consider for example the tree of Figure 6 with an Ising chain model (as in the previous subsection). We can view the span from C to D as an interval with evidence at its end. When we add evidence at the tip of other branches we gain more information about intermediate points between C and D. Even though this evidence can represent evolution from these intermediate points, they do change our information state about them. To evaluate the impact of these changes on our approximation, we considered the tree of Figure 6, and compared it to inference in the backbone between C and D (Figure 4). Comparing the true marginal to the approximate one along the main backbone (see Figure 9) we see a major difference in the quality of the approximation. The evidence in the tree leads to a much tighter approximation of the marginal distribution. A more systematic

comparison (Figure 10) demonstrates that the additional evidence reduces the magnitude of the error throughout the parameter space.

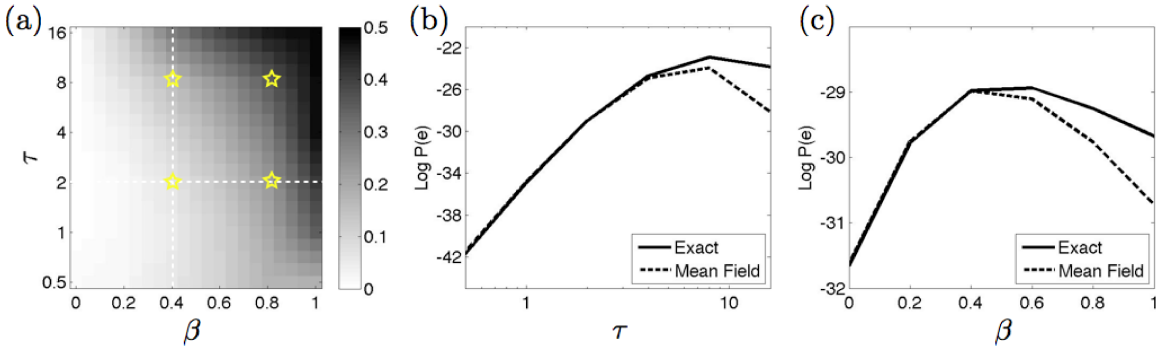

Figure 10: *(a)* Evaluation of the relative error in expected sufficient statistics for an Ising chain in branching-time; compare to Figure 4(a). *(b),(c)* Evaluation of the estimated likelihood on a tree w.r.t. the rate τ and coupling β; compare to Figure 4(b),(c).

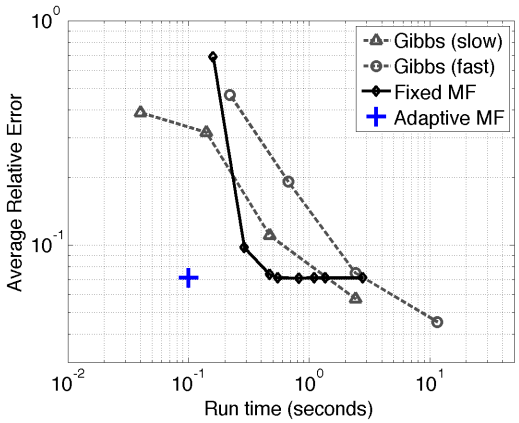

Figure 11: Evaluation of the run time vs. accuracy trade-off for several choices of parameters for mean field and Gibbs sampling on the branching process of Figure 6.

Similarly to mean-field, the Gibbs sampling procedure for CTBNs (El-Hay et al., 2008) can also be extended to deal with branching processes. Comparing our method to the Gibbs sampling procedure we see (Figure 11) that the faster mean field approach dominates the Gibbs procedure over short run times. However, as opposed to mean field, the Gibbs procedure is asymptotically unbiased, and with longer run times it ultimately prevails. This evaluation also shows that the adaptive integration procedure in our methods strikes a better trade-off than using a fixed time granularity integration.

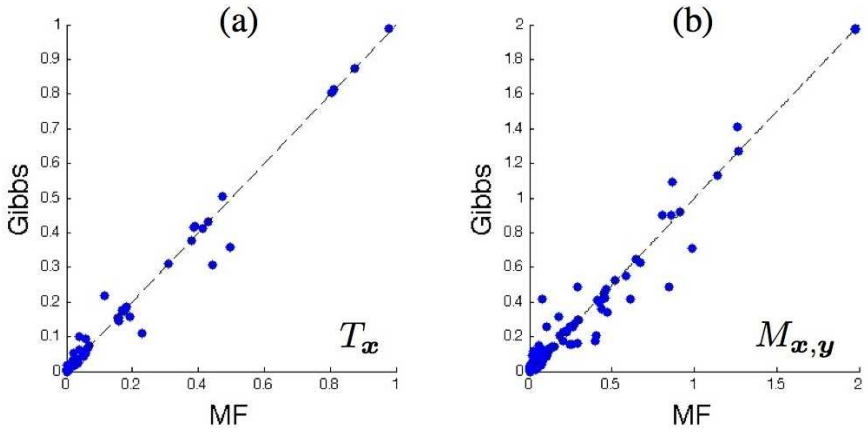

Figure 12: Comparison of estimates of expected sufficient statistics in the evolution of 18 interacting nucleotides, using a realistic model of RNA evolution. Each point is an expected value of: (a) residence time in a specific state of a component and its parents; (b) number of transition between two states. The x-axis is the estimate by the variational procedure, whereas the y-axis is the estimate by Gibbs sampling.

As a more demanding test, we applied our inference procedure to a model similar to the one introduced by Yu and Thorne (2006) for a stem of 18 interacting RNA nucleotides in 8 species in the phylogeny of Figure 6. In this model the transition rate between two sequences that differ in a single nucleotide depends on difference between their folding energy. Specifically, the transition rate from sequence x to sequence y is given by

$$q_{x,y} = 1.6\left(1 + e^{E_{\text{fold}}(y) - E_{\text{fold}}(x)}\right)^{-1}, \qquad |\delta(x,y)| = 1,$$

where E_{fold} is the folding energy of the sequence. This equation implies that transition rates are increasing monotonically with the reduction of the folding energy. Hence, this model tends to evolve into low energy states. The folding energy in turn is a sum of local stacking energies, involving quadruples of nucleotides as described by the factors in Figure 7. Denoting the subset of positions contained in each quadruple by D_k, the energy is

$$E_{\text{fold}}(x) = \sum_k E^k_{\text{fold}}(x|_{D_k}),$$

where $x|_{D_k}$ is the subset of nucleotides that belong factor k. This model is equivalent to a CTBN in which the parents of each components are the other components that share the same factors. This property follows from the fact that for any pair x and y, where $\delta(x,y) = \{i\}$, the difference between the energies of these two sequences depends only on the factors that contain i.

We compared our estimate of the expected sufficient statistics of this model to these obtained by the Gibbs sampling procedure. The Gibbs sampling estimates were chosen by running the procedure with an increasing computation time until there was no significant change in the results. The

final estimates was obtained using 5000 burn-in rounds, 10000 number of samples and 100 rounds between two consecutive samples. The results, shown in Figure 12, demonstrate that over all the two approximate inference procedures are in good agreement about the value of the expected sufficient statistics.

8. Discussion

In this paper we formulate a general variational principle for continuous-time Markov processes (by reformulating and extending the one proposed by Opper and Sanguinetti, 2007), and use it to derive an efficient procedure for inference in CTBNs. In this mean field approximation, we use a product of independent inhomogeneous processes to approximate the multi-component posterior.

Our procedure enjoys the same benefits encountered in discrete-time mean field procedure (Jordan et al., 1999): it provides a lower-bound on the likelihood of the evidence and its run time scales linearly with the number of components. Using asynchronous updates it is guaranteed to converge, and the approximation represents a consistent joint distribution. It also suffers from expected shortcomings: the functional has multiple local maxima, it cannot capture complex interactions in the posterior (Example 3). By using a time-inhomogeneous representation our approximation does capture complex patterns in the temporal progression of the marginal distribution of each component. Importantly, the continuous-time parameterization enables straightforward implementation using standard ODE integration packages that automatically tune the trade-off between time granularity and approximation quality. We show how it is extended to perform inference on phylogenetic trees, where the posterior distribution is directly affected by several evidence points, and show that it provides fairly accurate answers in the context of a real application (Figure 12).

A key development is the introduction of marginal density sets. Using this representation we reformulate and extend the variational principle proposed by Opper and Sanguinetti (2007) , which incorporates a different inhomogeneous representation. This modification allows handling direct evidence of the state of the process, as in the case of CTBNs, while keeping the representation of the approximation bounded. The extension of this principle to CTBNs follows by exploiting their networks structure. This adaptation of continuously inhomogeneous representations to CTBNs increases the flexibility of the approximation relative to the piecewise homogeneous representation of Saria et al. (2007) and, somewhat surprisingly, also significantly simplifies the resulting formulation.

The proposed representation is natural in the sense that its functions are the time-derivatives of the expected sufficient statistics that we are willing to evaluate. Hence, once finding the optimal value of the lower bound, calculating these expectations is straightforward. This representation is analogous to mean parameters which have proved powerful in variational approximations of exponential families over finite random variable sets (Wainwright and Jordan, 2008).

We believe that even in cases where evidence is indirect and noisy, the marginal density representation should comprise smoother functions than posterior rates. Intuitively, in the presence of a noisy observation the posterior probability of some state x can be very small. In such cases, the posterior transition rate form x into a state that better explains the observation might tend to a large quantity. This reasoning suggests that marginal density representations should be better handled by adaptive numerical integration algorithms. An interesting direction would be to test this conjecture empirically.

A possible extension is using our variational procedure to generate the initial distribution for the Gibbs sampling procedure and thus skip the initial burn-in phase and produce accurate samples. Another attractive aspect of this new variational approximation is its potential use for learning model parameters from data. It can be easily combined with the EM procedure for CTBNs (Nodelman et al., 2005a) to obtain a Variational-EM procedure for CTBNs, which monotonically increases the likelihood by alternating between steps that improve the approximation η (the updates discussed here) and steps that improve the model parameters θ (an M-step Nodelman et al., 2005a). Finally, marginal density sets are a particularly suitable representation for adapting richer representations such as Bethe, Kikuchi and convex approximations to non-homogeneous versions (El-Hay et al., 2010). Further work in that direction should allow bridging the gap in the wealth of inference techniques between finite domain models and continuous-time models.

Appendix A. The Relation Between CTBNs and DBNs

In this section we show that the DBN construction of Equations (6-7) is such that as h approaches 0, the distribution P_h approaches Pr. To show this, it suffice to show that

$$\lim_{h\to 0} \frac{P_h(X^{(t_{k+1})} = y | X^{(t_k)} = x) - \mathbf{1}_{x=y}}{h} = q_{x,y} \ .$$

We ensured this condition holds component-wise, and now need to show that this leads to global consistency.

Plugging Equation (7) into Equation (6), the transition probability of the DBN is

$$P_h(X^{(t_{k+1})} = y | X^{(t_k)} = x) = \prod_i \left(\mathbf{1}_{x_i=y_i} + q^{i|\mathbf{Pa}_i}_{x_i,y_i|u_i} \cdot h \right) \ .$$

Since we consider the limit as h approaches 0, any term that involves h^d with $d > 1$ is irrelevant. And thus, we can limit our attention to the constant terms and terms linear in h. Expanding the product gives

$$P_h(X^{(t_{k+1})} = y | X^{(t_k)} = x) = \prod_i \mathbf{1}_{x_i=y_i} + \sum_i q^{i|\mathbf{Pa}_i}_{x_i,y_i|u_i} \cdot h \prod_{j\neq i} \mathbf{1}_{x_j=y_j} + o(h) \ .$$

Now, $\prod_i \mathbf{1}_{x_i=y_i} = \mathbf{1}_{x=y}$. Moreover, it is easy to verify that

$$q_{x,y} = \sum_i q^{i|\mathbf{Pa}_i}_{x_i,y_i|u_i} \prod_{j\neq i} \mathbf{1}_{x_j=y_j} \ .$$

Thus,

$$P_h(X^{(t_{k+1})} = y | X^{(t_k)} = x) = \mathbf{1}_{x=y} + q_{x,y} h + o(h),$$

proving the required condition.

Appendix B. Marginal Density Sets and Markov Processes - Proof of Lemma 2

Proof Given η, we define the *inhomogeneous rate matrix* $\mathbb{R}(t)$ as in Equation (11). $\mathbb{R}(t)$ is a valid rate matrix because its off-diagonals are non-negative as they are the quotient of two non-negative functions, and because applying the requirement on $\gamma_{x,x}(t)$ in Definition 1

$$r_{x,x}(t) = \frac{\gamma_{x,x}(t)}{\mu_x(t)} = -\frac{\sum_{y \neq x} \gamma_{x,y}(t)}{\mu_x(t)} = -\sum_{y \neq x} r_{x,y}(t) \ ,$$

we see that $\mathbb{R}(t)$'s diagonals are negative and the rows sum to 0. We can use these rates with the initial value $\mu_x(0)$ to construct the Markov process P_η from the forward master equation

$$\frac{d}{dt} P_\eta(X^{(t)} = x) = \sum_y P_\eta(X^{(t)} = y) r_{y,x}(t) \ ,$$

and

$$P_\eta(X^{(0)}) = \mu(0) \ .$$

To conclude the proof we show that P_η and the marginal density set satisfy (10). First, from Definition 1 it follows that $\mu(t)$ is the solution to the master equation of $P_\eta(X^{(t)})$, because the initial values match at $t = 0$ and the time-derivatives of the two functions are identical. Thus

$$P_\eta(X^{(t)} = x) = \mu_x(t) \ .$$

Next, the equivalence of the joint probability densities can be proved:

$$\begin{aligned} \lim_{h \to 0} \frac{\Pr(X^{(t)} = x, X^{(t+h)} = y)}{h} &= \lim_{h \to 0} \frac{\mu_x(t) \Pr(X^{(t+h)} = y | \Pr(X^{(t)} = x)}{h} \\ &= \lim_{h \to 0} \frac{\mu_x(t) r_{x,y}(t) h}{h} \\ &= \mu_x(t) r_{x,y}(t) \ . \end{aligned}$$

From the definition of $r_{x,y}(t)$ and the fact that $\gamma_{x,y}(t) = 0$ whenever $\mu_x(t) = 0$, it follows that $\mu_x(t) r_{x,y}(t)$ is exactly $\gamma_{x,y}(t)$ ■

Appendix C. Expectations in Inhomogeneous Processes

This section includes the proofs of the lemmas used in the proof of the variational lower bound theorem.

C.1 Expectations of Functions of States - Proof of Lemma 4

Proof Changing the order of integration we obtain

$$\mathbf{E}_{f_\eta} \left[\int_0^T \psi(\sigma(t), t) dt \right] \equiv \int_\Sigma f_\eta(\sigma) \int_0^T \psi(\sigma(t), t) dt d\sigma = \int_0^T \int_\Sigma f_\eta(\sigma) \cdot \psi(\sigma(t), t) \, d\sigma dt \ .$$

For each $t \in T$ we decompose the inner integral according to possible states at that time:

$$\begin{aligned}\int_\Sigma f_\eta(\sigma)\cdot\psi(\sigma(t),t)\,d\sigma &= \sum_x \int_\Sigma f_\eta(\sigma)\cdot \mathbf{1}_{\sigma(t)=x}\cdot\psi(x,t)\,d\sigma \\ &= \sum_x \psi(x,t)\int_\Sigma f_\eta(\sigma)\cdot \mathbf{1}_{\sigma(t)=x}\,d\sigma \\ &= \sum_x \psi(x,t)\mu_x(t)\,.\end{aligned}$$

■

C.2 Expectations of Functions of Transitions - Proof of Lemma 5

Proof Given a trajectory σ there exists a small enough $h>0$ such that for every transition and for every $t \in (t_k-h,t_k)$ we have $\sigma(t)=x_{k-1}$ and $\sigma(t+h)=x_k$. In that case we can rewrite the sum in the expectation term as

$$\begin{aligned}\sum_{k=1}^{K^\sigma}\psi(x^\sigma_{k-1},x^\sigma_k,t^\sigma_k) &= \sum_{k=1}^{K^\sigma}\frac{1}{h}\int_{t_k-h}^{t_k}\psi(\sigma(t),\sigma(t+h),t)dt+\frac{o(h)}{h} \\ &= \frac{1}{h}\int_0^{T-h}\psi(\sigma(t),\sigma(t+h),t)dt+\frac{o(h)}{h}\,,\end{aligned}$$

where the first equality follows from continuity and the second one from the requirement that $\psi(x,x,t)=0$. Taking the limit $h\to 0$ and using this requirement again gives

$$\sum_{k=1}^{K^\sigma}\psi(x^\sigma_{k-1},x^\sigma_k,t^\sigma_k)=\frac{d}{ds}\left[\int_0^T\psi(\sigma(t),\sigma(t+s),t)dt\right]_{s=0}\,.$$

Taking expectation we obtain

$$\begin{aligned}&\int_\Sigma f(\sigma)\frac{d}{ds}\left[\int_0^T\psi(\sigma(t),\sigma(t+s),t)dt\right]_{s=0}d\sigma \\ &= \int_\Sigma f(\sigma)\frac{d}{ds}\left[\int_0^T\sum_x\sum_{y\neq x}\psi(x,y,t)\,\mathbf{1}_{\sigma(t)=x}\mathbf{1}_{\sigma(t+s)=y}\,dt\right]_{s=0}d\sigma \\ &= \frac{d}{ds}\left[\int_0^T\sum_x\sum_{y\neq x}\psi(x,y,t)\int_\Sigma f(\sigma)\,\mathbf{1}_{\sigma(t)=x}\mathbf{1}_{\sigma(t+s)=y}d\sigma\,dt\right]_{s=0}\,.\end{aligned}$$

The inner integral in the last term is a joint probability

$$\int_\Sigma f(\sigma)\mathbf{1}_{\sigma(t)=x}\mathbf{1}_{\sigma(t+s)=y}d\sigma=\Pr(X^{(t)}=x,X^{(t+s)}=y)\,.$$

Switching the order of integration and differentiation and using

$$\frac{d}{ds}\Pr(X^{(t)}=x,X^{(t+s)}=y)\Big|_{s=0}=\gamma_{xy}(t),\quad x\neq y,$$

gives the desired result. ■

Appendix D. Proof of the Factored Representation of the Energy Functional

Proof We begin with the definition of the average energy

$$\begin{aligned}\mathcal{E}(\eta;\mathbb{Q}) &= \int_0^T \sum_x \left[\mu_x(t)q_{x,x} + \sum_{y\neq x}\gamma_{x,y}(t)\ln q_{x,y}\right]dt \\ &= \int_0^T \sum_x \left[\mu_x(t)q_{x,x} + \sum_i \sum_{y_i\neq x_i}\gamma^i_{x_i,y_i}(t)\mu^{\setminus i}(t)\ln q_{x,y}\right]dt\ .\end{aligned}$$

where the equality stems from the observation that the only states y that may have $\gamma_{x,y}(t) > 0$, are those with $\delta(x,y) \leq 1$ (all the rest are 0). Thus, the enumeration over all possible states collapses into an enumeration over all components i and all states $y_i \neq x_i$. Due to the fact that we are only considering transitions in single components, we may replace the global joint density $\gamma_{x,y}$ with $\gamma^i_{x_i,y_i}\cdot\mu^{\setminus i}(t)$, as per definition.

Using (5), we can decompose the transition rates $q_{x,x}$ and $q_{x,y}$ to get

$$\begin{aligned}\mathcal{E}(\eta;\mathbb{Q}) &= \sum_i \int_0^T \sum_x \left[\mu_x(t)q_{x_i,x_i|u_i} + \sum_{y_i\neq x_i}\gamma^i_{x_i,y_i}(t)\mu^{\setminus i}(t)\ln q_{x_i,y_i|u_i}\right]dt \\ &= \sum_i \int_0^T \sum_{x_i} \left[\mu^i_{x_i}(t)\sum_{x\setminus i}\mu^{\setminus i}_{x\setminus i}(t)q_{x_i,x_i|u_i} + \sum_{y_i\neq x_i}\gamma^i_{x_i,y_i}(t)\mu^{\setminus i}_{x\setminus i}(t)\ln q_{x_i,y_i|u_i}\right]dt\ .\end{aligned}$$

To get to the last equality we use the factorization of $\mu(t)$ as a product of $\mu^i(t)$ with $\mu^{\setminus i}(t)$ and the reordering of the summation. Next we simply write the previous sum as an expectation over $X\setminus i$

$$\mathcal{E}(\eta;\mathbb{Q}) = \sum_i \int_0^T \sum_{x_i}\mu^i_{x_i}(t)\mathbf{E}_{\mu^{\setminus i}(t)}\left[q_{x_i,x_i|U_i}\right] + \sum_i \int_0^T \sum_{y_i\neq x_i}\gamma^i_{x_i,y_i}(t)\mathbf{E}_{\mu^{\setminus i}(t)}\left[\ln q_{x_i,y_i|U_i}\right]dt\ ,$$

which concludes the proof.

Turning to the entropy-like term we have:

$$\begin{aligned}\mathcal{H}(\eta) &= \int_0^T \sum_x\sum_{y\neq x}\gamma_{x,y}(t)[1+\ln\mu_x(t)-\ln\gamma_{x,y}(t)]dt \\ &= \sum_i\int_0^T \sum_x\sum_{y_i\neq x_i}\mu^{\setminus i}(t)\gamma_{x_i,y_i}(t)[1+\sum_i\ln\mu^i_{x_i}(t)-\ln\gamma_{x_i,y_i}(t)-\sum_{j\neq i}\ln\mu_{x_j}(t)]dt \\ &= \sum_i\int_0^T \sum_{x_i}\sum_{y_i\neq x_i}\gamma_{x_i,y_i}(t)[1+\ln\mu^i_{x_i}(t)-\ln\gamma_{x_i,y_i}(t)]dt \\ &= \sum_i \mathcal{H}(\eta^i)\ ,\end{aligned}$$

where, the first equality is definition of $\mathcal{H}$. The second one follows from the definition of the factored density set. The third one is obtained by algebraic manipulation and the last one is again the definition of $\mathcal{H}$. ■

Appendix E. Euler-Lagrange Equations

The problem of finding the fixed points of *functionals* whose arguments are continuous functions comes from the field of *Calculus of variations*. We briefly review the usage Euler-Lagrange equation for solving optimization problems over functionals. Additional information can be found in Gelfand and Fomin (1963).

A functional is a mapping from a vector space to its underlying field. In our case the functional is the Lagrangian introduced in Section 4, which is an integral over real-valued functions, and the underlying field is the real numbers.

Given a functional over a normed space of continuously differentiable real functions of the form

$$I[y] = \int_a^b f(t, y(t), y'(t))dt$$

where $y'(t)$ is the time-derivative of the function $y(t)$, we would like to find a function $y(t)$ that minimizes (or in our case maximizes) the functional subject to $y(a) = y_a$ and $y(b) = y_b$. In the simplest case, when there are no additional constraints, a necessary condition for y to be a local optimum is that y is a *stationary point*. Roughly, a stationary point is a function y, where $I[y]$ is insensitive to small variations in y. That is, given a function $h(t)$ where $h(a) = 0$ and $h(b) = 0$, the change of the functional $I[y+h] - I[y]$ is small relative to the norm of h. For $y(t)$ to be a stationary point, it must satisfy the *Euler-Lagrange* equations (Gelfand and Fomin, 1963)

$$\frac{\partial}{\partial y} f(t, y(t), y'(t)) - \frac{d}{dt}\left(\frac{\partial}{\partial y'} f(t, y(t), y'(t))\right) = 0 \ . \tag{23}$$

In this paper we have additional constraints describing the time derivative of μ. The generalization of the Euler-Lagrange equations to that case is straightforward. Denoting the subsidiary constraints by $g(t, y(t), y'(t)) = 0$, we simply replace $f(t, y, y')$ by $f(t, y, y') - \lambda(t)g(t, y, y')$ in Equation 23.

An example for the use of this equation is in the following proof.

Appendix F. Stationary Points of the Lagrangian - Proof of Theorem 6

Proof For convenience, we begin by rewriting the Lagrangian in explicit form: $\mathcal{L} = \int_0^T f(y(t), y'(t))dt$ where $y(t) = \langle \mu(t), \gamma(t), \lambda(t) \rangle$ is a concatenation of the parameters and Lagrange multiplier and

$$\begin{aligned} f(y(t), y'(t)) \quad = \quad & \sum_{i=1}^{D} \sum_{x_i} \Bigg[\mu^i_{x_i}(t) \mathbf{E}_{\mu^{\setminus i}(t)} \left[q_{x_i, x_i | U_i} \right] + \sum_{y_i \neq x_i} \gamma^i_{x_i, y_i}(t) \mathbf{E}_{\mu^{\setminus i}(t)} \left[\ln q_{x_i, y_i | U_i} \right] \\ & + \sum_{y_i \neq x_i} \gamma_{x_i y_i} \left[1 + \ln \mu^i_{x_i}(t) - \ln \gamma^i_{x_i y_i}(t) \right] - \lambda^i_{x_i}(t) \left(\frac{d}{dt} \mu^i_{x_i}(t) - \sum_{y_i} \gamma^i_{x_i y_i}(t) \right) \Bigg] \ . \end{aligned}$$

The Euler-Lagrange equations of the Lagrangian define its stationary points w.r.t. the parameters of each component $\mu^i(t), \gamma^i(t)$ and $\lambda^i(t)$.

First, we take the partial derivatives of f w.r.t to $\mu^i_{x_i}(t)$ as well as $\frac{d}{dt}\mu^i_{x_i}(t)$ and plug them into Equation 23. We start by handling the energy terms. These terms involve expectations in the form

$\mathbf{E}_{\mu^{\setminus j}(t)}[g(U_j)] = \sum_{u_j} \mu_{u_j}(t) g(u_j)$. The parameter $\mu^i_{x_i}(t)$ appears in these terms only when i is a parent of j and u_j is consistent with x_i. In that case $\frac{\partial}{\partial \mu^i_{x_i}} \mu_{u_j} = \mu_{u_j} / \mu^i_{x_i}$. Thus,

$$\frac{\partial}{\partial \mu^i_{x_i}} \mathbf{E}_{\mu^{\setminus j}(t)}[g(U_j)] = \mathbf{E}_{\mu^{\setminus j}(t)}[g(U_j) \mid x_i] \cdot \delta_{j \in Children_i}$$

Recalling the definitions of the averaged rates

$$\overline{q}^{\,i}_{x_i,x_i|x_j}(t) = \mathbf{E}_{\mu^{\setminus i}(t)}\left[q^{i|\mathbf{Pa}_i}_{x_i,x_i|U_i} \mid x_j\right]$$

and

$$\tilde{q}^i_{x_i,y_i|x_j}(t) = \exp\left\{\mathbf{E}_{\mu^{\setminus i}(t)}\left[\ln q^{i|\mathbf{Pa}_i}_{x_i,y_i|U_i} \mid x_j\right]\right\}$$

we obtain

$$\frac{\partial}{\partial \mu^i_{x_j}} \mathbf{E}_{\mu^{\setminus j}(t)}\left[q^j_{x_j,x_j|U_j}\right] = \delta_{j \in Children_i} \overline{q}^{\,j}_{x_j,x_j|x_i}(t)$$

and

$$\frac{\partial}{\partial \mu^i_{x_j}} \mathbf{E}_{\mu^{\setminus j}(t)}\left[\ln q^j_{x_j,x_j|U_j}\right] = \delta_{j \in Children_i} \ln \tilde{q}^j_{x_j,x_j|x_i}(t).$$

Therefore the derivative of the sum over $j \neq i$ of the energy terms is

$$\psi^i_{x_i}(t) \equiv \sum_{j \in Children_i} \sum_{x_j} \left[\mu^j_{x_j}(t) \overline{q}^{\,j}_{x_j,x_j|x_i}(t) + \sum_{x_j \neq y_j} \gamma^j_{x_j,y_j}(t) \ln \tilde{q}^j_{x_j,y_j|x_i}(t)\right] \ .$$

Additionally, the derivative of the energy term for $j = i$ is $\overline{q}^{\,i}_{x_i,x_i}(t) \equiv \mathbf{E}_{\mu^{\setminus i}(t)}\left[q_{x_i,x_i|U_i}\right]$. Next, the derivative of the entropy term is $\gamma^i_{x_i,x_i}(t)/\mu^i_{x_i}(t)$. Finally, the derivative of f with respect to $\frac{d}{dt}\mu^i_{xi}(t)$ is $-\lambda^i_{x_i}(t)$. Plugging in these derivatives into Equation (23) we obtain

$$\overline{q}^{\,i}_{x_i,x_i}(t) + \psi^i_{x_i}(t) - \frac{\gamma^i_{x_i,x_i}}{\mu^i_{x_i}(t)} + \frac{d}{dt}\lambda^i_{x_i}(t) = 0 \ . \tag{24}$$

Next, the derivative w.r.t. $\gamma^i_{x_i,y_i}(t)$ gives us

$$\ln \mu^i_{x_i}(t) + \ln \tilde{q}^i_{x_i,y_i}(t) - \ln \gamma^i_{x_i,y_i}(t) + \lambda^i_{y_i}(t) - \lambda^i_{x_i}(t) = 0 \ . \tag{25}$$

Denoting $\rho^i_{x_i}(t) = \exp\{\lambda^i_{x_i}(t)\}$, Equation (25) becomes

$$\gamma^i_{x_i,y_i}(t) = \mu^i_{x_i}(t) \tilde{q}^i_{x_i,y_i}(t) \frac{\rho^i_{y_i}(t)}{\rho^i_{x_i}(t)} \ ,$$

which is the algebraic equation of γ. Using this result and the definition of $\gamma^i_{x_i,x_i}$ we have

$$\gamma^i_{x_i,x_i}(t) = -\sum_{y_i \neq x_i} \gamma^i_{x_i,y_i}(t) = -\mu^i_{x_i}(t) \sum_{x_i,y_i} \tilde{q}^i_{x_i,y_i}(t) \frac{\rho^i_{y_i}(t)}{\rho^i_{x_i}(t)}.$$

Plugging this equality into (24) and using the identity $\frac{d}{dt}\rho^i_{x_i}(t) = \frac{d}{dt}\lambda^i_{x_i}(t)\rho^i_{x_i}(t)$ gives

$$\frac{d}{dt}\rho^i_{x_i}(t) = -\rho^i_{x_i}(t)\left(\overline{q}^{\,i}_{x_i,x_i}(t) + \psi^i_{x_i}(t)\right) - \sum_{y_i \neq x_i} \tilde{q}^i_{x_i,y_i} \rho^i_{y_i}(t) \ .$$

Thus the stationary point of the Lagrangian matches the updates of (16–17). ■

Appendix G. Proof of Proposition 7

Proof We denote the time at the vertex $t_0 = (\mathsf{b}_1, T)$, the time just before as $t_1 = (\mathsf{b}_1, T-h)$ and the times just after it on each branch $t_2 = (\mathsf{b}_2, h)$ and $t_3 = (\mathsf{b}_3, h)$, as in Figure 13.

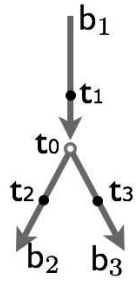

Figure 13: Branching process with discretization points of Lemma 7.

The marginals $\mu^i_{x_i}(\mathsf{b}_1, t)$ are continuous, as they are derived from the forward differential equation. To derive the propagation formula for the $\rho^i_{x_i}(t)$ requires additional care. The $\rho^i_{x_i}(t)$ have been derived from the constraints on the time-derivative of $\mu^i_{x_i}(t)$. In a vertex this constraint is threefold, as we now have the constraints on b_1

$$\frac{\mu^i_{x_i}(t_0) - \mu^i_{x_i}(t_1)}{h} = \sum_{y_i} \gamma^i_{x_i,y_i}(t_1)$$

and those on the other branches b_k for $k = 2, 3$

$$\frac{\mu^i_{x_i}(t_k) - \mu^i_{x_i}(t_0)}{h} = \sum_{y_i} \gamma^i_{x_i,y_i}(t_0) \quad .$$

The integrand of the Lagrangian corresponding to point t_0 is

$$\begin{aligned} \mathcal{L}_{|t_0} &= \tilde{\mathcal{F}}(\eta;\mathbb{Q})_{|t_0} + \lambda^0(t_1)\left(\frac{\mu^i_{x_i}(t_0) - \mu^i_{x_i}(t_1)}{h} - \sum_{y_i}\gamma^i_{x_i,y_i}(t_1)\right) \\ &- \sum_{k=2,3} \lambda^k(t_0)\left(\frac{\mu^i_{x_i}(t_k) - \mu^i_{x_i}(t_0)}{h} - \sum_{y_i}\gamma^i_{x_i,y_i}(t_0)\right) \quad , \end{aligned}$$

as this is the only integrand which involves $\mu_{x_i}(t_0)$, the derivative of the Lagrangian collapses into

$$\begin{aligned} \frac{\partial}{\partial \mu^i_{x_i}(t_0)}\mathcal{L} &= \frac{\partial}{\partial \mu^i_{x_i}(t_0)}\mathcal{L}_{|t_0} \\ &= \frac{\lambda^0(t_1)}{h} - \left(\frac{\lambda^2(t_0)}{h} + \frac{\lambda^3(t_0)}{h}\right) + \frac{\partial}{\partial \mu^i_{x_i}(t_0)}\tilde{\mathcal{F}}(\eta;\mathbb{Q})_{|t_0} = 0 \quad . \end{aligned}$$

Rearranging the previous equation and multiplying by h, we get

$$\lambda^0(t_1) = \lambda^2(t_0) + \lambda^3(t_0) + \frac{\partial}{\partial \mu^i_{x_i}(t_0)}\tilde{\mathcal{F}}(\eta;\mathbb{Q})_{|t_0} h \quad .$$

Looking at (24) we can see that as t_0 is not a leaf, and thus $\mu^i_{x_i}(t_0) > 0$ and the derivative of the functional cannot diverge. Therefore, as $h \to 0$ this term vanishes and we are left with

$$\lambda^0(t_1) = \lambda^2(t_0) + \lambda^3(t_0)$$

which after taking exponents gives (21). ■

Abstract

This work deals with four classical prediction settings, namely full information, bandit, label efficient and bandit label efficient as well as four different notions of regret: pseudo-regret, expected regret, high probability regret and tracking the best expert regret. We introduce a new forecaster, INF (Implicitly Normalized Forecaster) based on an arbitrary function ψ for which we propose a unified analysis of its pseudo-regret in the four games we consider. In particular, for $\psi(x) = \exp(\eta x) + \frac{\gamma}{K}$, INF reduces to the classical exponentially weighted average forecaster and our analysis of the pseudo-regret recovers known results while for the expected regret we slightly tighten the bounds. On the other hand with $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$, which defines a new forecaster, we are able to remove the extraneous logarithmic factor in the pseudo-regret bounds for bandits games, and thus fill in a long open gap in the characterization of the minimax rate for the pseudo-regret in the bandit game. We also provide high probability bounds depending on the cumulative reward of the optimal action.

Finally, we consider the stochastic bandit game, and prove that an appropriate modification of the upper confidence bound policy UCB1 (Auer et al., 2002a) achieves the distribution-free optimal rate while still having a distribution-dependent rate logarithmic in the number of plays.

Keywords: Bandits (adversarial and stochastic), regret bound, minimax rate, label efficient, upper confidence bound (UCB) policy, online learning, prediction with limited feedback.

1. Introduction

This section starts by defining the prediction tasks, the different regret notions that we will consider, and the different adversaries of the forecaster. We will then recap existing lower and upper regret bounds for the different settings, and give an overview of our contributions.

1.1 The Four Prediction Tasks

We consider a general prediction game where at each stage, a forecaster (or decision maker) chooses one action (or arm), and receives a reward from it. Then the forecaster receives a feedback about the rewards which he can use to make his choice at the next stage. His goal is to maximize his cumulative gain. In the simplest version, after choosing an arm the forecaster observes the rewards

*. Also at Willow, CNRS/ENS/INRIA—UMR 8548.

Parameters: the number of arms (or actions) K and the number of rounds n with $n \geq K \geq 2$.

For each round $t = 1, 2, \ldots, n$

(1) The forecaster chooses an arm $I_t \in \{1, \ldots, K\}$, possibly with the help of an external randomization.

(2) Simultaneously the adversary chooses a gain vector $g_t = (g_{1,t}, \ldots, g_{K,t}) \in [0,1]^K$ (see Section 8 for loss games or signed games).

(3) The forecaster receives the gain $g_{I_t,t}$ (without systematically observing it). He observes

- the reward vector $(g_{1,t}, \ldots, g_{K,t})$ in the **full information** game,
- the reward vector $(g_{1,t}, \ldots, g_{K,t})$ if he asks for it with the global constraint that he is not allowed to ask it more than m times for some fixed integer number $1 \leq m \leq n$. This prediction game is the **label efficient** game,
- only $g_{I_t,t}$ in the **bandit** game,
- only his obtained reward $g_{I_t,t}$ if he asks for it with the global constraint that he is not allowed to ask it more than m times for some fixed integer number $1 \leq m \leq n$. This prediction game is the **label efficient bandit** game.

Goal : The forecaster tries to maximize his cumulative gain $\sum_{t=1}^{n} g_{I_t,t}$.

Figure 1: The four prediction tasks considered in this work.

for all arms, this is the so called full information game. In the label efficient game, originally proposed by Helmbold and Panizza (1997), after choosing its action at a stage, the forecaster decides whether to ask for the rewards of the different actions at this stage, knowing that he is allowed to do it a limited number of times. Another classical setting is the bandit game where the forecaster only observes the reward of the arm he has chosen. In its original version (Robbins, 1952), this game was considered in a stochastic setting, that is, the nature draws the rewards from a fixed product-distribution. Later it was considered in an adversarial framework (Auer et al., 1995), where there is an adversary choosing the rewards on the arms. A combination of the two previous settings is the label efficient bandit game (György and Ottucsák, 2006), in which the only observed rewards are the ones obtained and asked by the forecaster, with again a limitation on the number of possible queries. These four games are described more precisely in Figure 1. Their Hannan consistency has been considered in Allenberg et al. (2006) in the case of unbounded losses. Here we will focus on regret upper bounds and minimax policies for bounded losses.

1.2 Regret and Pseudo-regret

A natural way to assess the performance of a forecaster is to compute his *regret* with respect to the best action in hindsight (see Section 7 for a more general regret in which we compare to the best

switching strategy having a fixed number of action-switches):

$$R_n = \max_{1\le i\le K} \sum_{t=1}^{n} \left(g_{i,t} - g_{I_t,t}\right).$$

A lot of attention has been drawn by the characterization of the minimax expected regret in the different games we have described. More precisely for a given game, let us write sup for the supremum over all allowed adversaries and inf for the infimum over all forecaster strategies for this game. We are interested in the quantity:

$$\inf \sup \mathbb{E} R_n,$$

where the expectation is with respect to the possible randomization of the forecaster and the adversary. Another related quantity which can be easier to handle is the *pseudo-regret*:

$$\overline{R}_n = \max_{1\le i\le K} \mathbb{E} \sum_{t=1}^{n} \left(g_{i,t} - g_{I_t,t}\right).$$

Note that, by Jensen's inequality, the pseudo-regret is always smaller than the expected regret. In Appendix D we discuss cases where the converse inequality holds (up to an additional term).

1.3 The Different Adversaries

The simplest adversary is the deterministic one. It is characterized by a fixed matrix of nK rewards corresponding to $(g_{i,t})_{1\le i\le K, 1\le t\le n}$. Another adversary is the "stochastic" one, in which the reward vectors are independent and have the same distribution.[1] This adversary is characterized by a distribution on $[0,1]^K$, corresponding to the common distribution of g_t, $t = 1,\dots,n$. A more general adversary is the fully oblivious one, in which the reward vectors are independent. Here the adversary is characterized by n distributions on $[0,1]^K$ corresponding to the distributions of $g_1,\dots,g_n$. Deterministic and stochastic adversaries are fully oblivious adversaries.

An even more general adversary is the oblivious one, in which the only constraint on the adversary is that the reward vectors are independent of the past decisions of the forecaster. The most general adversary is the one who may choose the reward vector g_t as a function of the past decisions $I_1,\dots,I_{t-1}$ (non-oblivious adversary).

1.4 Known Regret Bounds

Table 1 recaps existing lower and upper bounds on the minimax pseudo-regret and the minimax expected regret for general adversaries (i.e., possibly non-oblivious ones). For the first three lines, we refer the reader to the book (Cesa-Bianchi and Lugosi, 2006) and references within, particularly Cesa-Bianchi et al. (1997) and Cesa-Bianchi (1999) for the full information game, Cesa-Bianchi et al. (2005) for the label efficient game, Auer et al. (2002b) for the bandit game and György and Ottucsák (2006) for the label efficient bandit game. The lower bounds in the last line do not appear in the existing litterature, but we prove them in this paper. Apart from the full information game, the upper bounds are usually proved on the pseudo-regret. The upper bounds on the expected regret are obtained by using high probability bounds on the regret. The parameters of the algorithm in the

1. The term "stochastic" can be a bit misleading since the assumption is not just stochasticity but rather an i.i.d. assumption.

Label efficient game	$n\sqrt{\frac{\log K}{m}}$	$n\sqrt{\frac{\log K}{m}}$	$n\sqrt{\frac{\log K}{m}}$	$n\sqrt{\frac{\log n}{m}}$
Bandit game	$\sqrt{nK}$	$\sqrt{nK\log K}$	$\sqrt{nK}$	$\sqrt{nK\log n}$
Bandit label efficient game	$n\sqrt{\frac{K}{m}}$	$n\sqrt{\frac{K\log K}{m}}$	$n\sqrt{\frac{K}{m}}$	$n\sqrt{\frac{K\log n}{m}}$

Table 1: Existing bounds (apart from the lower bounds in the last line which are proved in this paper) on the pseudo-regret and expected regret. Except for the full information game, there are logarithmic gaps between lower and upper bounds.

latter bounds usually depend on the confidence level δ that we want to obtain. Thus to derive bounds on the expected regret we can not integrate the deviations but rather we have to take δ of order $1/n$, which leads to the gaps involving $\log(n)$. Table 1 exhibits several logarithmic gaps between upper and lower bounds on the minimax rate, namely:

- $\sqrt{\log(K)}$ gap for the minimax pseudo-regret in the bandit game as well as the label efficient bandit game.
- $\sqrt{\log(n)}$ gap for the minimax expected regret in the bandit game as well as the label efficient bandit game.
- $\sqrt{\log(n)/\log(K)}$ gap for the minimax expected regret in the label efficient game,

1.5 Contributions of This Work

We reduce the above gaps by improving the upper bounds as shown by Table 2. Different proof techniques are used and new forecasting strategies are proposed. The most original contribution is the introduction of a new forecaster, INF (Implicitly Normalized Forecaster), for which we propose a unified analysis of its regret in the four games we consider. The analysis is original (it avoids the traditional but scope-limiting argument based on the simplification of a sum of logarithms of ratios), and allows to fill in the long open gap in the bandit problems with oblivious adversaries (and with general adversaries for the pseudo-regret notion). The analysis also applies to exponentially weighted average forecasters. It allows to prove a regret bound of order $\sqrt{nKS\log(nK/S)}$ when the forecaster's strategy is compared to a strategy allowed to switch S times between arms, while the best known bound was $\sqrt{nKS\log(nK)}$ (Auer, 2002), and achieved for a different policy.

An "orthogonal" contribution is to propose a tuning of the parameters of the forecasting policies such that the high probability regret bounds holds for any confidence level (instead of holding just for a single confidence level as in previous works). Bounds on the expected regret that are deduced from these PAC ("probably approximately correct") regret bounds are better than previous bounds by a logarithmic factor in the games with limited information (see columns on $\inf\sup \mathbb{E}R_n$ in Tables 1 and 2). The arguments to obtain these bounds are not fundamentally new and rely essentially on a careful use of deviation inequalities for supermartingales. They can be used either in the standard analysis of exponentially weighted average forecasters or in the more general context of INF.

L.E. bandit with oblivious adversary	$n\sqrt{\frac{K}{m}}$	$n\sqrt{\frac{K}{m}}$	$n\sqrt{\frac{K}{m\log K}}\log(K\delta^{-1})$
L.E. bandit with general adversary	$n\sqrt{\frac{K}{m}}$	$n\sqrt{\frac{K\log K}{m}}$	$n\sqrt{\frac{K}{m\log K}}\log(K\delta^{-1})$

Table 2: New regret upper bounds proposed in this work. The high probability bounds are for a policy of the forecaster that does not depend on the confidence level δ (unlike previously known high probability bounds).

Another "orthogonal" contribution is the proposal of a new biased estimate of the rewards in bandit games, which allows to achieve high probability regret bounds depending on the performance of the optimal arm: in this new bound, the factor n is replaced by $G_{\max} = \max_{i=1,\dots,n} \sum_{t=1}^{n} g_{i,t}$. If the forecaster draws I_t according to the distribution $p_t = (p_{1,t}, \dots, p_{K,t})$, then the new biased estimate of $g_{i,t}$ is $v_{i,t} = -\frac{\mathbb{1}_{I_t=i}}{\beta}\log\left(1 - \frac{\beta g_{i,t}}{p_{i,t}}\right)$. This estimate should be compared to $v_{i,t} = g_{i,t}\frac{\mathbb{1}_{I_t=i}}{p_{i,t}}$, for which bounds in terms of $G_{\max}$ exists in expectations as shown in (Auer et al., 2002b, Section 3), and to $v_{i,t} = g_{i,t}\frac{\mathbb{1}_{I_t=i}}{p_{i,t}} + \frac{\beta}{p_{i,t}}$ for some $\beta > 0$ for which high probability bounds exist but they are expressed with the n factor, and not $G_{\max}$ (see Section 6 of Auer et al., 2002b, and Section 6.8 of Cesa-Bianchi and Lugosi, 2006).

We also propose a unified proof to obtain the lower bounds in Table 1. The contribution of this proof is two-fold. First it gives the first lower bound for the label efficient bandit game. Secondly in the case of the label efficient (full information) game it is a simpler proof than the one proposed in Cesa-Bianchi et al. (2005). Indeed in the latter proof, the authors use Birgé's version of Fano's lemma to prove the lower bound for deterministic forecasters. Then the extension to non-deterministic forecasters is done by a generalization of this information lemma and a decomposition of general forecasters into a convex combination of deterministic forecasters. The benefit from this proof technique is to be able to deal with the case $K = 2$ and $K = 3$ while the basic version of Fano's lemma does not give any information in this case. Here we propose to use Pinsker's inequality for the case $K = 2$ and $K = 3$. This allows us to use the basic version of Fano's lemma and to extend the result to non-deterministic forecasters with a simple application of Fubini's Theorem.

The last contribution of this work is also independent of the previous ones and concerns the stochastic bandit game (that is the bandit game with "stochastic" adversary). We prove that a modification of UCB1, Auer et al. (2002a), attains the optimal distribution-free rate $\sqrt{nK}$ as well as the logarithmic distribution-dependent rate. The key idea, compared to previous works, is to reduce exploration of sufficiently drawn arms.

1.6 Outline

In Section 2, we describe a new class of forecasters, called INF, for prediction games. Then we present a new forecaster inside this class, called Poly INF, for which we propose a general theorem bounding its regret. A more general statement on the regret of any INF can be found in Appendix A. Exponentially weighted average forecasters are a special case of INF as shown in Section 3. In Section 4, we prove that our forecasters and analysis recover the known results for the full information game.

Section 5 contains the core contributions of the paper, namely all the regret bounds for the limited feedback games. The interest of Poly INF appears in the bandit games where it satisfies a regret bound without a logarithmic factor, unlike exponentially weighted average forecasters. Section 6 provides high probability bounds in the bandit games that depends on the cumulative reward of the optimal arm: the factor n is replaced by $\max_{1\leq i\leq K}\sum_{t=1}^{n} g_{i,t}$. In Section 7, we consider a stronger notion of regret, when we compare ourselves to a strategy allowed to switch between arms a fixed number of times. Section 8 shows how to generalize our results when one considers losses rather than gains, or signed games.

Section 9 considers a framework fundamentally different from the previous sections, namely the stochastic multi-armed bandit problem. There we propose a new forecaster, MOSS, for which we prove an optimal distribution-free rate as well as a logarithmic distribution-dependent rate.

Appendix A contains a general regret upper bound for INF and two useful technical lemmas. Appendix B contains the unified proof of the lower bounds. Appendix C contains the proofs that have not been detailed in the main body of the paper. Finally, Appendix D gathers the different results we have obtained regarding the relation between the expected regret and the pseudo-regret.

2. The Implicitly Normalized Forecaster

In this section, we define a new class of randomized policies for the general prediction game. Let us consider a continuously differentiable function $\psi : \mathbb{R}_-^* \to \mathbb{R}_+^*$ satisfying

$$\psi' > 0, \qquad \lim_{x\to-\infty} \psi(x) < 1/K, \qquad \lim_{x\to 0} \psi(x) \geq 1. \tag{1}$$

Lemma 1 *There exists a continuously differentiable function $C : \mathbb{R}_+^K \to \mathbb{R}$ satisfying for any $x = (x_1,\ldots,x_K) \in \mathbb{R}_+^K$,*

$$\max_{1\leq i\leq K} x_i < C(x) \leq \max_{1\leq i\leq K} x_i - \psi^{-1}(1/K), \tag{2}$$

and

$$\sum_{i=1}^{K} \psi(x_i - C(x)) = 1. \tag{3}$$

Proof Consider a fixed $x = (x_1,\ldots,x_K)$. The decreasing function $\phi : c \mapsto \sum_{i=1}^K \psi(x_i - c)$ satisfies

$$\lim_{c\to \max_{1\leq i\leq K} x_i} \phi(c) > 1 \qquad \text{and} \qquad \lim_{c\to+\infty} \phi(c) < 1.$$

From the intermediate value theorem, there is a unique $C(x)$ satisfying $\phi(C(x)) = 1$. From the implicit function theorem, the mapping $x \mapsto C(x)$ is continuously differentiable. ■

INF (Implicitly Normalized Forecaster):

Parameters:

- the continuously differentiable function $\psi : \mathbb{R}_-^* \to \mathbb{R}_+^*$ satisfying (1)
- the estimates $v_{i,t}$ of $g_{i,t}$ based on the (drawn arms and) observed rewards at time t (and before time t)

Let p_1 be the uniform distribution over $\{1,\dots,K\}$.

For each round $t = 1,2,\dots,$

(1) Draw an arm I_t from the probability distribution p_t.

(2) Use the observed reward(s) to build the estimate $v_t = (v_{1,t},\dots,v_{K,t})$ of $(g_{1,t},\dots,g_{K,t})$ and let: $V_t = \sum_{s=1}^{t} v_s = (V_{1,t},\dots,V_{K,t})$.

(3) Compute the normalization constant $C_t = C(V_t)$.

(4) Compute the new probability distribution $p_{t+1} = (p_{1,t+1},\dots,p_{K,t+1})$ where

$$p_{i,t+1} = \psi(V_{i,t} - C_t).$$

Figure 2: The proposed policy for the general prediction game.

The implicitly normalized forecaster (INF) is defined in Figure 2. Equality (3) makes the fourth step in Figure 2 legitimate. From (2), $C(V_t)$ is roughly equal to $\max_{1\le i\le K} V_{i,t}$. Recall that $V_{i,t}$ is an estimate of the cumulative gain at time t for arm i. This means that INF chooses the probability assigned to arm i as a function of the (estimated) regret. Note that, in spirit, it is similar to the traditional weighted average forecaster, see for example Section 2.1 of Cesa-Bianchi and Lugosi (2006), where the probabilities are proportional to a function of the difference between the (estimated) cumulative reward of arm i and the cumulative reward of the policy, which should be, for a well-performing policy, of order $C(V_t)$.

The interesting feature of the implicit normalization is the following argument, which allows to recover the results concerning the exponentially weighted average forecasters, and more interestingly to propose a policy having a regret of order $\sqrt{nK}$ in the bandit game with oblivious adversary. First note that $\sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t}v_{i,t}$ roughly evaluates the cumulative reward $\sum_{t=1}^{n} g_{I_t,t}$ of the policy. In fact, it is exactly the cumulative gain in the bandit game when $v_{i,t} = g_{i,t}\frac{\mathbb{1}_{I_t=i}}{p_{i,t}}$, and its expectation is exactly the expected cumulative reward in the full information game when $v_{i,t} = g_{i,t}$. The argument starts with an Abel transformation and consequently is "orthogonal" to the usual argument given in

the beginning of Section C.2. Letting $V_0 = 0 \in \mathbb{R}^K$. We have

$$\begin{aligned}
\sum_{t=1}^n g_{I_t,t} &\approx \sum_{t=1}^n \sum_{i=1}^K p_{i,t} v_{i,t} \\
&= \sum_{t=1}^n \sum_{i=1}^K p_{i,t}(V_{i,t} - V_{i,t-1}) \\
&= \sum_{i=1}^K p_{i,n+1} V_{i,n} + \sum_{i=1}^K \sum_{t=1}^n V_{i,t}(p_{i,t} - p_{i,t+1}) \\
&= \sum_{i=1}^K p_{i,n+1} \left(\psi^{-1}(p_{i,n+1}) + C_n\right) + \sum_{i=1}^K \sum_{t=1}^n (\psi^{-1}(p_{i,t+1}) + C_t)(p_{i,t} - p_{i,t+1}) \\
&= C_n + \sum_{i=1}^K p_{i,n+1} \psi^{-1}(p_{i,n+1}) + \sum_{i=1}^K \sum_{t=1}^n \psi^{-1}(p_{i,t+1})(p_{i,t} - p_{i,t+1}),
\end{aligned}$$

where the remarkable simplification in the last step is closely linked to our specific class of randomized algorithms. The equality is interesting since, from (2), C_n approximates the maximum estimated cumulative reward $\max_{1\le i\le K} V_{i,n}$, which should be close to the cumulative reward of the optimal arm $\max_{1\le i\le K} G_{i,n}$, where $G_{i,n} = \sum_{t=1}^n g_{i,t}$. Since the last term in the right-hand side is

$$\sum_{i=1}^K \sum_{t=1}^n \psi^{-1}(p_{i,t+1})(p_{i,t} - p_{i,t+1}) \approx \sum_{i=1}^K \sum_{t=1}^n \int_{p_{i,t}}^{p_{i,t+1}} \psi^{-1}(u)du = \sum_{i=1}^K \int_{1/K}^{p_{i,n+1}} \psi^{-1}(u)du, \tag{4}$$

we obtain

$$\max_{1\le i\le K} G_{i,n} - \sum_{t=1}^n g_{I_t,t} \lessapprox -\sum_{i=1}^K p_{i,n+1}\psi^{-1}(p_{i,n+1}) + \sum_{i=1}^K \int_{1/K}^{p_{i,n+1}} \psi^{-1}(u)du. \tag{5}$$

The right-hand side is easy to study: it depends only on the final probability vector and has simple upper bounds for adequate choices of ψ. For instance, for $\psi(x) = \exp(\eta x) + \frac{\gamma}{K}$ with $\eta > 0$ and $\gamma \in [0,1)$, which corresponds to exponentially weighted average forecasters as we will explain in Section 3, the right-hand side is smaller than $\frac{1-\gamma}{\eta}\log\left(\frac{K}{1-\gamma}\right) + \gamma C_n$. For $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$ with $\eta > 0$, $q > 1$ and $\gamma \in [0,1)$, which will appear to be a fruitful choice, it is smaller than $\frac{q}{q-1}\eta K^{1/q} + \gamma C_n$. For sake of simplicity, we have been hiding the residual terms of (4) coming from the Taylor expansions of the primitive function of ψ^{-1}. However, these terms when added together (nK terms!) are not that small, and in fact constrain the choice of the parameters γ and η if one wishes to get the tightest bound.

The rigorous formulation of (5) is given in Theorem 27, which has been put in Appendix A for lack of readability. We propose here its specialization to the function $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$ with $\eta > 0$, $q > 1$ and $\gamma \in [0,1)$. This function obviously satisfies conditions (1). We will refer to the associated forecasting strategy as "Poly INF". Here the (normalizing) function C has no closed form expression (this is a consequence of Abel's impossibility theorem). Actually this remark holds in general, hence the name of the general policy. However this does not lead to a major computational issue since, in the interval given by (2), $C(x)$ is the unique solution of $\phi(c) = 1$, where $\phi : c \mapsto \sum_{i=1}^K \psi(x_i - c)$ is a decreasing function. We will prove that Poly INF forecaster generates nicer probability updates than the exponentially weighted average forecasteras as, for bandits games (label efficient or not), it allows to remove the extraneous $\log K$ factor in the pseudo-regret bounds and some regret bounds.

Theorem 2 (General regret bound for Poly INF) *Let* $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$ *with* $q > 1$, $\eta > 0$ *and* $\gamma \in [0,1)$. *Let* $(v_{i,t})_{1\le i\le K,\, 1\le t\le n}$ *be a sequence of nonnegative real numbers,*

$$B_t = \max_{1\le i\le K} v_{i,t}, \text{ and } B = \max_t B_t.$$

If $\gamma = 0$ *then INF satisfies:*

$$\left(\max_{1\le i\le K}\sum_{t=1}^n v_{i,t}\right) - \sum_{t=1}^n\sum_{i=1}^K p_{i,t}v_{i,t} \le \frac{q}{q-1}\eta K^{1/q} + \frac{q}{2\eta}\exp\left(2\frac{q+1}{\eta}B\right)\sum_{t=1}^n B_t^2, \tag{6}$$

and

$$\left(\max_{1\le i\le K}\sum_{t=1}^n v_{i,t}\right) - \sum_{t=1}^n\sum_{i=1}^K p_{i,t}v_{i,t} \le \frac{q}{q-1}\eta K^{1/q} + \frac{qB}{\eta}\exp\left(\frac{8qB}{\eta}\right)\sum_{t=1}^n\sum_{i=1}^K p_{i,t}v_{i,t}. \tag{7}$$

For $\gamma > 0$, *if we have* $v_{i,t} = \frac{c_t}{p_{i,t}}\mathbb{1}_{i=I_t}$ *for some random variable* c_t *taking values in* $[0,c]$ *with* $0 < c < q\eta\left(\frac{\gamma}{(q-1)K}\right)^{(q-1)/q}$, *then*

$$(1-\gamma)\left(\max_{1\le i\le K}\sum_{t=1}^n v_{i,t}\right) - (1+\gamma\zeta)\sum_{t=1}^n\sum_{i=1}^K p_{i,t}v_{i,t} \le \frac{q}{q-1}\eta K^{\frac{1}{q}}, \tag{8}$$

where

$$\zeta = \frac{1}{(q-1)K}\left(\frac{(q-1)cK\mu(1+\mu)}{2\gamma\eta}\right)^q,$$

with

$$\mu = \exp\left\{\frac{2(q+1)c}{\eta}\left(\frac{K}{\gamma}\right)^{(q-1)/q}\left(1 - \frac{c}{q\eta}\left(\frac{(q-1)K}{\gamma}\right)^{(q-1)/q}\right)^{-q}\right\}.$$

In all this work, the parameters η, q and γ will be chosen such that ζ and μ act as numerical constants. To derive concrete bounds from the above theorem, most of the work lies in relating the left-hand side with the different notions of regret we consider. This task is trivial for the pseudo-regret. To derive high probability regret bounds, deviation inequalities for supermartingales are used on top of (6) and (8) (which hold with probability one). Finally, the expected regret bounds are obtained by integration of the high probability bounds.

As long as numerical constants do not matter, one can use (7) to recover the bounds obtained from (6). The advantage of (7) over (6) is that it allows to get regret bounds where the factor n is replaced by $G_{\max} = \max_{i=1,\dots,n} G_{i,n}$.

3. Exponentially Weighted Average Forecasters

The normalization by division that weighted average forecasters perform is different from the normalization by shift of the real axis that INF performs. Nonetheless, we can recover exactly the exponentially weighted average forecasters because of the special relation of the exponential with the addition and the multiplication.

Let $\psi(x) = \exp(\eta x) + \frac{\gamma}{K}$ with $\eta > 0$ and $\gamma \in [0,1)$. Then conditions (1) are clearly satisfied and (3) is equivalent to $\exp(-\eta C(x)) = \frac{1-\gamma}{\sum_{i=1}^K \exp(\eta x_i)}$, which implies

$$p_{i,t+1} = (1-\gamma)\frac{\exp(\eta V_{i,t})}{\sum_{j=1}^K \exp(\eta V_{i,t})} + \frac{\gamma}{K}.$$

In other words, for the full information case (label efficient or not), we recover the exponentially weighted average forecaster (with $\gamma = 0$) while for the bandit game we recover EXP3. For the label efficient bandit game, it does not give us the GREEN policy proposed in Allenberg et al. (2006) but rather the straightforward modification of the exponentially weighted average forecaster to this game (György and Ottucsák, 2006). Theorem 3 below gives a unified view on this algorithm for these four games. In the following, we will refer to this algorithm as the "exponentially weighted average forecaster" whatever the game is.

Theorem 3 (Regret bound for the exponentially weighted average forecaster)
Let $\psi(x) = \exp(\eta x) + \frac{\gamma}{K}$ *with* $\eta > 0$ *and* $\gamma \in [0,1)$. *Let* $(v_{i,t})_{1\le i\le K,\, 1\le t\le n}$ *be a sequence of nonnegative real numbers,*

$$B_t = \max_{1\le i\le K} v_{i,t}, \text{ and } B = \max_{1\le t\le n} B_t.$$

Consider the increasing function $\Theta : u \mapsto \frac{e^u - 1 - u}{u^2}$ *equal to* $1/2$ *by continuity at zero. If* $\gamma = 0$ *then INF satisfies:*

$$\left(\max_{1\le i\le K} \sum_{t=1}^{n} v_{i,t}\right) - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t} \le \frac{\log K}{\eta} + \frac{\eta}{8}\sum_{t=1}^{n} B_t^2, \tag{9}$$

and

$$\left(\max_{1\le i\le K} \sum_{t=1}^{n} v_{i,t}\right) - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t} \le \frac{\log K}{\eta} + \eta B \Theta(\eta B) \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t}. \tag{10}$$

If we have

$$\gamma \ge K\eta\Theta(\eta B) \max_{i,t} p_{i,t} v_{i,t}, \tag{11}$$

then INF satisfies:

$$(1-\gamma)\left(\max_{1\le i\le K} \sum_{t=1}^{n} v_{i,t}\right) - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t} \le (1-\gamma)\frac{\log K}{\eta}. \tag{12}$$

We have the same discussion about (9) and (10) than about (6) and (7): Inequality (10) allows to prove bounds where the factor n is replaced by $G_{\max} = \max_{i=1,\dots,n} G_{i,n}$, but at the price of worsened numerical constants, when compared to (9). We illustrate this point in Theorem 4, where (13) and (14) respectively comes from (9) and (10) .

The above theorem relies on the standard argument based on the cancellation of terms in a sum of logarithms of ratios (see Section C.2). For sake of comparison, we have applied our general result for INF forecasters, that is Theorem 27 (see Appendix A). This leads to the same result with worsened constants. Precisely, $\frac{\eta}{8}$ becomes $\frac{\eta}{2}\exp(2\eta B)$ in (9) while $\Theta(\eta B)$ becomes $\frac{\exp(2B\eta)[1+\exp(2B\eta)]}{2}$ in (11). This seems to be the price for having a theorem applying to a large class of forecasters.

4. The Full Information (FI) Game

The purpose of this section is to illustrate the general regret bounds given in Theorems 2 and 3 in the simplest case, when we set $v_{i,t} = g_{i,t}$, which is possible since the rewards for all arms are observed in the full information setting. The next theorem is given explicitly to show an easy application of Inequalities (9) and (10).

Theorem 4 (Exponentially weighted average forecaster in the FI game) *Let $\psi(x) = \exp(\eta x)$ with $\eta > 0$. Let $v_{i,t} = g_{i,t}$. Then in the full information game, INF satisfies*

$$\max_{1\le i\le K} \sum_{t=1}^{n} g_{i,t} - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} g_{i,t} \le \frac{\log K}{\eta} + \frac{\eta n}{8}. \tag{13}$$

and

$$\max_{1\le i\le K} \sum_{t=1}^{n} g_{i,t} - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} g_{i,t} \le \frac{\log K}{\eta} + \eta\Theta(\eta) \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} g_{i,t}. \tag{14}$$

In particular with $\eta = \sqrt{\frac{8\log K}{n}}$, we get $\mathbb{E}R_n \le \sqrt{\frac{n}{2}\log K}$, and there exists $\eta > 0$ such that

$$\mathbb{E}R_n \le \sqrt{2\mathbb{E}G_{\max}\log K}.$$

Proof It comes from (9) and (10) since we have $B \le 1$ and $\sum_{t=1}^{n} B_t^2 \le n$. The only nontrivial result is the last inequality. It obviously holds for any η when $\mathbb{E}G_{\max} = 0$, and is achieved for $\eta = \log\left(1 + \sqrt{2(\log K)/\mathbb{E}G_{\max}}\right)$, when $\mathbb{E}G_{\max} > 0$. Indeed, by taking the expectation in (14), we get

$$\begin{aligned}\mathbb{E}\sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} g_{i,t} \ge \frac{\eta\mathbb{E}G_{\max} - \log K}{\exp(\eta) - 1} &= \log\left(1 + \sqrt{\frac{2\log K}{\mathbb{E}G_{\max}}}\right)\sqrt{\frac{(\mathbb{E}G_{\max})^3}{2\log K}} - \sqrt{\frac{\mathbb{E}G_{\max}\log K}{2}} \\ &\ge \mathbb{E}G_{\max} - 2\sqrt{\frac{\mathbb{E}G_{\max}\log K}{2}},\end{aligned}$$

where we use $\log(1+x) \ge x - \frac{x^2}{2}$ for any $x \ge 0$ in the last inequality. ■

Now we consider a new algorithm for the FI game, that is INF with $\psi(x) = \left(\frac{\eta}{-x}\right)^q$ and $v_{i,t} = g_{i,t}$.

Theorem 5 (Poly INF in the FI game) *Let $\psi(x) = \left(\frac{\eta}{-x}\right)^q$ with $\eta > 0$ and $q > 1$. Let $v_{i,t} = g_{i,t}$. Then in the full information game, INF satisfies:*

$$\max_{1\le i\le K} \sum_{t=1}^{n} g_{i,t} - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} g_{i,t} \le \frac{q}{q-1}\eta K^{1/q} + \exp\left(\frac{4q}{\eta}\right)\frac{qn}{2\eta}. \tag{15}$$

In particular with $q = 3\log K$ and $\eta = 1.8\sqrt{n\log K}$ we get

$$\mathbb{E}R_n \le 7\sqrt{n\log K}.$$

Proof It comes from (6), $q + 1 \le 2q$ and $\sum_{t=1}^{n} B_t^2 \le n$. ■

Remark 6 By using the Hoeffding-Azuma inequality (see, e.g., Lemma A.7 of Cesa-Bianchi and Lugosi, 2006), one can derive high probability bounds from (13) and (15): for instance, from (15), for any $\delta > 0$, with probability at least $1 - \delta$, Poly INF satisfies:

$$R_n \le \frac{q}{q-1}\eta K^{1/q} + \exp\left(\frac{4q}{\eta}\right)\frac{qn}{2\eta} + \sqrt{\frac{n\log(\delta^{-1})}{2}}.$$

5. The Limited Feedback Games

This section provides regret bounds for three limited feedback games: the label efficient game, the bandit game, and the mixed game, that is the label efficient bandit game.

5.1 Label Efficient Game (LE)

The variants of the LE game consider that the number of queried reward vectors is constrained either strictly or just in expectation. This section considers successively these two cases.

5.1.1 Constraint on the Expected Number of Queried Reward Vectors

As in Section 4, the purpose of this section is to show how to use INF in order to recover known minimax bounds (up to constant factors) in a slight modification of the LE game: the simple LE game, in which the requirement is that the *expected* number of queried reward vectors should be less or equal to m.

Let us consider the following policy. At each round, we draw a Bernoulli random variable Z_t, with parameter $\varepsilon = m/n$, to decide whether we ask for the gains or not. Note that we do not fulfill exactly the requirement of the LE game as we might ask a bit more than m reward vectors, but we fulfill the one of the simple LE game. We do so in order to avoid technical details and focus on the main argument of the proof. The exact LE game will be addressed in Section 5.1.2, where, in addition, we will prove bounds on the expected regret $\mathbb{E}R_n$ instead of just the pseudo-regret $\overline{R}_n$.

In this section, the estimate of $g_{i,t}$ is $v_{i,t} = \frac{g_{i,t}}{\varepsilon} Z_t$, which is observable since the rewards at time t for all arms are observed when $Z_t = 1$.

Theorem 7 (Exponentially weighted average forecaster in the simple LE game) *Let* $\psi(x) = \exp(\eta x)$ *with* $\eta = \frac{\sqrt{8m\log K}}{n}$. *Let* $v_{i,t} = \frac{g_{i,t}}{\varepsilon} Z_t$ *with* $\varepsilon = \frac{m}{n}$. *Then in the simple LE game, INF satisfies*

$$\overline{R}_n \leq n\sqrt{\frac{\log K}{2m}}.$$

Proof The first inequality comes from (9). Since we have $B_t \leq Z_t/\varepsilon$ and $v_{i,t} = \frac{g_{i,t}}{\varepsilon} Z_t$, we obtain

$$\left(\max_{1\leq i\leq K} \sum_{t=1}^{n} g_{i,t}\frac{Z_t}{\varepsilon}\right) - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} g_{i,t}\frac{Z_t}{\varepsilon} \leq \frac{\log K}{\eta} + \frac{\eta}{8\varepsilon^2}\sum_{t=1}^{n} Z_t,$$

hence, by taking the expectation of both sides,

$$\overline{R}_n = \left(\max_{1\leq i\leq K} \mathbb{E}\sum_{t=1}^{n} g_{i,t}\frac{Z_t}{\varepsilon}\right) - \mathbb{E}\sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} g_{i,t}\frac{Z_t}{\varepsilon} \leq \frac{\log K}{\eta} + \frac{n\eta}{8\varepsilon} = \frac{\log K}{\eta} + \frac{n^2\eta}{8m}.$$

Straightforward computations conclude the proof. ■

A similar result can be proved for the INF forecaster with $\psi(x) = \left(\frac{\eta}{-x}\right)^q$, $\eta > 0$ and q of order $\log K$. We do not state it since we will prove a stronger result in the next section.

5.1.2 HARD CONSTRAINT ON THE NUMBER OF QUERIED REWARD VECTORS

The goal of this section is to push the idea that by using high probability bounds as an intermediate step, one can control the expected regret $\mathbb{E}R_n = \mathbb{E}\max_{1\le i\le K}\sum_{t=1}^n \left(g_{i,t} - g_{I_t,t}\right)$ instead of just the pseudo-regret $\overline{R}_n = \max_{1\le i\le K}\mathbb{E}\sum_{t=1}^n \left(g_{i,t} - g_{I_t,t}\right)$. Most previous works have obtained results for $\overline{R}_n$. These results are interesting for oblivious opponents, that is when the adversary's choices of the rewards do not depend on the past draws and obtained rewards, since in this case Proposition 33 in Appendix D shows that one can extend bounds on the pseudo-regret $\overline{R}_n$ to the expected regret $\mathbb{E}R_n$. For non-oblivious opponents, upper bounds on $\overline{R}_n$ are rather weak statements and high probability bounds on R_n or bounds on $\mathbb{E}R_n$ are desirable. In Auer (2002) and Cesa-Bianchi and Lugosi (2006), high probability bounds on R_n have been given. Unfortunately, the policies proposed there are depending on the confidence level of the bound. As a consequence, the resulting best bound on $\mathbb{E}R_n$, obtained by choosing the policies with confidence level parameter of order $1/n$, has an extraneous $\log n$ term. Specifically, from Theorem 6.2 of Cesa-Bianchi and Lugosi (2006), one can immediately derive $\mathbb{E}R_n \le 8n\sqrt{\frac{\log(4K)+\log(n)}{m}} + 1$. The theorems of this section essentially show that the $\log n$ term can be removed.

As in Section 5.1.1, we still use a draw of a Bernoulli random variable Z_t to decide whether we ask for the gains or not. The difference is that, if $\sum_{s=1}^{t-1} Z_s \ge m$, we do not ask for the gains (as we are not allowed to do so). To avoid that this last constraint interferes in the analysis, the parameter of the Bernoulli random variable is set to $\varepsilon = \frac{3m}{4n}$ and the probability of the event $\sum_{t=1}^n Z_t > m$ is upper bounded. The estimate of $g_{i,t}$ remains $v_{i,t} = \frac{g_{i,t}}{\varepsilon} Z_t$.

Theorem 8 (Exponentially weighted average forecaster in the LE game) *Let* $\psi(x) = \exp(\eta x)$ *with* $\eta = \frac{\sqrt{m\log K}}{n}$. *Let* $v_{i,t} = \frac{g_{i,t}}{\varepsilon} Z_t$ *with* $\varepsilon = \frac{3m}{4n}$. *Then in the LE game, for any* $\delta > 0$, *with probability at least* $1-\delta$, *INF satisfies:*

$$R_n \le n\sqrt{\frac{27\log(2K\delta^{-1})}{m}},$$

and

$$\mathbb{E}R_n \le n\sqrt{\frac{27\log(6K)}{m}}.$$

Theorem 9 (Poly INF in the LE game) *Let* $\psi(x) = \left(\frac{\eta}{-x}\right)^q$ *with* $q = 3\log(2K)$ *and* $\eta = 2n\sqrt{\frac{\log(2K)}{m}}$. *Let* $v_{i,t} = \frac{g_{i,t}}{\varepsilon} Z_t$ *with* $\varepsilon = \frac{3m}{4n}$. *Then in the LE game, for any* $\delta > 0$, *with probability at least* $1-\delta$, *INF satisfies:*

$$R_n \le \left(8 - \sqrt{27}\right) n\sqrt{\frac{\log(2K)}{m}} + n\sqrt{\frac{27\log(2K\delta^{-1})}{m}},$$

and

$$\mathbb{E}R_n \le 8n\sqrt{\frac{\log(6K)}{m}}.$$

5.2 Bandit Game

This section is cut into two parts. In the first one, from Theorem 2 and Theorem 3, we derive upper bounds on the pseudo-regret $\overline{R}_n = \max_{1\le i\le K}\mathbb{E}\sum_{t=1}^n \left(g_{i,t} - g_{I_t,t}\right)$. To bound the expected regret

$\mathbb{E}R_n = \mathbb{E}\max_{1\leq i\leq K}\sum_{t=1}^n \left(g_{i,t} - g_{I_t,t}\right)$, we will then use high probability bounds on top of the use of these theorems. Since this makes the proofs more intricate, we have chosen to provide the less general results, but easier to obtain, in Section 5.2.1 and the more general ones in Section 5.2.2.

The main results here are that, by using the INF with a polynomial function ψ, we obtain an upper bound of order $\sqrt{nK}$ for $\overline{R}_n$, which imply a bound of order $\sqrt{nK}$ on $\mathbb{E}R_n$ for oblivious adversaries (Proposition 33 in Appendix D). In the general case (containing the non-oblivious opponent), we show an upper bound of order $\sqrt{nK\log K}$ on $\mathbb{E}R_n$. We conjecture that this bound cannot be improved, that is the opponent may take advantage of the past to make the player pay a regret with the extra logarithmic factor (see Remark 14).

5.2.1 BOUNDS ON THE PSEUDO-REGRET

In this section, the estimate of $g_{i,t}$ is $v_{i,t} = \frac{g_{i,t}}{p_{i,t}}\mathbb{1}_{I_t=i}$, which is observable since the reward $g_{I_t,t}$ is revealed at time t.

Theorem 10 (Exponentially weighted average forecaster in the bandit game) *Let* $\psi(x) = \exp(\eta x) + \frac{\gamma}{K}$ *with* $1 > \gamma \geq \frac{4\eta K}{5} > 0$. *Let* $v_{i,t} = \frac{g_{i,t}}{p_{i,t}}\mathbb{1}_{I_t=i}$. *Then in the bandit game, INF satisfies:*

$$\overline{R}_n \leq \frac{\log K}{\eta} + \gamma \max_{1\leq i\leq K} \mathbb{E}G_{i,n}.$$

In particular, for $\gamma = \min\left(\frac{1}{2}, \sqrt{\frac{4K\log K}{5n}}\right)$ *and* $\eta = \sqrt{\frac{5\log K}{4nK}}$, *we have*

$$\overline{R}_n \leq \sqrt{\frac{16}{5}nK\log K}.$$

Proof One simply needs to note that for $5\gamma \geq 4K\eta$, (11) is satisfied (since $B = K/\gamma$), and thus (12) can be rewritten into

$$(1-\gamma)\left(\max_{1\leq i\leq K}\sum_{t=1}^n \frac{g_{i,t}}{p_{i,t}}\mathbb{1}_{I_t=i}\right) - \sum_{t=1}^n g_{I_t,t} \leq (1-\gamma)\frac{\log K}{\eta}.$$

By taking the expectation, we get

$$\overline{R}_n \leq (1-\gamma)\frac{\log K}{\eta} + \gamma \max_{1\leq i\leq K} \mathbb{E}G_{i,n}.$$

For the numerical application, since $\overline{R}_n \leq n$, the bound is trivial $\sqrt{(4K\log K)/(5n)} < \frac{1}{2}$. Otherwise, it is a direct application of the general bound. ■

Theorem 11 (Poly INF in the bandit game) *Consider* $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$ *with* $\gamma = \min\left(\frac{1}{2}, \sqrt{\frac{3K}{n}}\right)$, $\eta = \sqrt{5n}$ *and* $q = 2$. *Let* $v_{i,t} = \frac{g_{i,t}}{p_{i,t}}\mathbb{1}_{I_t=i}$. *Then in the bandit game, INF satisfies:*

$$\overline{R}_n \leq 8\sqrt{nK}.$$

Proof The bound is trivial when $\frac{1}{2} \leq \sqrt{\frac{3K}{n}}$. So we consider hereafter that $\gamma = \sqrt{\frac{3K}{n}} < \frac{1}{2}$. By taking the expectation in (8) and letting $\bar{G}_{\max} = \max_{1\leq i\leq K} \mathbb{E}G_{i,n}$, we obtain that for $\gamma > (q-1)K(q\eta)^{q/(1-q)} > 0$ (condition coming from the condition on c for (8)),

$$(1-\gamma)\bar{G}_{\max} - (1+\gamma\zeta)\mathbb{E}\sum_{t=1}^{n} g_{I_t,t} \leq \frac{q}{q-1}\eta K^{\frac{1}{q}},$$

with

$$\zeta = \frac{1}{(q-1)K}\Big(\frac{(q-1)K\mu(1+\mu)}{2\gamma\eta}\Big)^q,$$

and

$$\mu = \exp\left\{\frac{2(q+1)}{\eta}\left(\frac{K}{\gamma}\right)^{(q-1)/q}\left(1-\frac{1}{q\eta}\left(\frac{(q-1)K}{\gamma}\right)^{(q-1)/q}\right)^{-q}\right\}.$$

We thus have

$$\overline{R}_n \leq \gamma(1+\zeta)\bar{G}_{\max} + \frac{q}{q-1}\eta K^{\frac{1}{q}} \leq \gamma(1+\zeta)n + \frac{q}{q-1}\eta K^{\frac{1}{q}}.$$

The desired inequality is trivial when $\sqrt{K/n} \geq 1/8$. So we now consider that $\sqrt{K/n} < 1/8$. For $\gamma = \sqrt{3K/n}$, $\eta = \sqrt{5n}$ and $q = 2$, the condition on γ is satisfied (since $\sqrt{K/n} < 1/8$), and we have $\frac{1}{\eta}\big(\frac{K}{\gamma}\big)^{(q-1)/q} \leq 0.121$, hence $\mu \leq 2.3$, $\zeta \leq 1$ and $\overline{R}_n \leq 8\sqrt{nK}$. ■

We have arbitrarily chosen $q = 2$ to provide an explicit upper bound. More generally, it is easy to check from the proof of Theorem 11 that for any real number $q > 1$, we obtain the convergence rate $\sqrt{nK}$, provided that γ and η are respectively taken of order $\sqrt{K/n}$ and $\sqrt{nK}/K^{1/q}$.

5.2.2 HIGH PROBABILITY BOUNDS AND BOUNDS ON THE EXPECTED REGRET

Theorems 10 and 11 provide upper bounds on $\overline{R}_n = \max_{1\leq i\leq K}\mathbb{E}\sum_{t=1}^{n}\big(g_{i,t} - g_{I_t,t}\big)$. To bound $\mathbb{E}R_n = \mathbb{E}\max_{1\leq i\leq K}\sum_{t=1}^{n}\big(g_{i,t} - g_{I_t,t}\big)$, we will use high probability bounds. First we need to modify the estimates of $g_{i,t}$ by considering $v_{i,t} = \frac{g_{i,t}}{p_{i,t}}\mathbb{1}_{I_t=i} + \frac{\beta}{p_{i,t}}$ with $0 < \beta \leq 1$, as was proposed in Auer (2002),[2] or $v_{i,t} = -\frac{\mathbb{1}_{I_t=i}}{\beta}\log\big(1 - \frac{\beta g_{i,t}}{p_{i,t}}\big)$ as we propose here.

Theorem 12 (Exponentially weighted average forecaster in the bandit game) *Consider* $\psi(x) = \exp(\eta x) + \frac{\gamma}{K}$ *with* $\gamma = \min\Big(\frac{2}{3}, 2\sqrt{\frac{K\log(3K)}{n}}\Big)$ *and* $\eta = 2\sqrt{\frac{\log(3K)}{Kn}}$. *Let* $v_{i,t} = -\frac{\mathbb{1}_{I_t=i}}{\beta}\log\big(1 - \frac{\beta g_{i,t}}{p_{i,t}}\big)$ *with* $\beta = \sqrt{\frac{\log(3K)}{2Kn}}$. *Then in the bandit game, against any adversary (possibly a non-oblivious one), for any* $\delta > 0$, *with probability at least* $1-\delta$, *INF satisfies:*

$$R_n \leq 3\sqrt{nK\log(3K)} + \sqrt{\frac{2nK}{\log(3K)}}\log(K\delta^{-1}),$$

and also $\mathbb{E}R_n \leq (3+\sqrt{2})\sqrt{nK\log(3K)}$.

2. The technical reason for this modification, which may appear surprising as it introduces a bias in the estimate of $g_{i,t}$, is that it allows to have high probability upper bounds with the correct rate on the difference $\sum_{t=1}^{n} g_{i,t} - \sum_{t=1}^{n} v_{i,t}$. A second reason for this modification (but useless for this particular section) is that it allows to track the best expert (see Section 7).

This theorem is similar to Theorem 6.10 of Cesa-Bianchi and Lugosi (2006). The main difference here is that the high probability bound holds for any confidence level, and not only for a confidence level depending on the algorithm. As a consequence, our algorithm, unlike the one proposed in previous works, satisfies both a high probability bound and an expected regret bound of order $\sqrt{nK\log(K)}$.

Theorem 13 (Poly INF in the bandit game) *Let* $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$ *with* $\eta = 2\sqrt{n}$, $q = 2$ *and* $\gamma = \min\left(\frac{1}{2}, 3\sqrt{\frac{K}{n}}\right)$. *Consider* $v_{i,t} = -\frac{\mathbb{I}_{I_t=i}}{\beta}\log\left(1 - \frac{\beta g_{i,t}}{p_{i,t}}\right)$ *with* $\beta = \frac{1}{\sqrt{2Kn}}$. *Then in the bandit game, against a deterministic adversary, for any* $\delta > 0$, *with probability at least* $1-\delta$, *INF satisfies:*

$$R_n \leq 9\sqrt{nK} + \sqrt{2nK}\log(\delta^{-1}). \tag{16}$$

Against an oblivious adversary, it satisfies

$$\mathbb{E}R_n \leq 10\sqrt{nK}. \tag{17}$$

Moreover in the general case (containing the non-oblivious opponent), with the following parameters $q = 2$, $\gamma = \min\left(\frac{1}{2}, 3\sqrt{\frac{K\log(3K)}{n}}\right)$, $\eta = 2\sqrt{\frac{n}{\log(3K)}}$ *and* $\beta = \sqrt{\frac{\log(3K)}{2nK}}$, *it satisfies with probability at least* $1-\delta$,

$$R_n \leq 9\sqrt{nK\log(3K)} + \sqrt{\frac{2nK}{\log(3K)}}\log(\delta^{-1}),$$

and

$$\mathbb{E}R_n \leq 9\sqrt{nK\log(3K)}.$$

Remark 14 *We conjecture that the order* $\sqrt{nK\log K}$ *of the bound on* $\mathbb{E}R_n$ *cannot be improved in the general case containing the non-oblivious opponent. Here is the main argument to support our conjecture. Consider an adversary choosing all rewards to be equal to one until time* $n/2$ *(say* n *is even to simplify). Then, let* $\hat{k}$ *denote the arm for which the estimate* $V_{i,n/2} = \sum_{1\leq t\leq n/2} v_{i,t}$ *of the cumulative reward of arm* i *is the smallest. After time* $n/2$, *all rewards are chosen to be equal to zero except for arm* $\hat{k}$ *for which the rewards are still chosen to be equal to* 1. *Since we believe that with high probability,* $\max_{1\leq i\leq K} V_{i,n/2} - \min_{j\in\{1,\ldots,K\}} V_{j,n/2} \geq \kappa\sqrt{nK\log K}$ *for some small enough* $\kappa > 0$, *it seems that the INF algorithm achieving a bound of order* $\sqrt{nK}$ *on* $\mathbb{E}R_n$ *in the oblivious setting will suffer an expected regret of order at least* $\sqrt{nK\log K}$. *While this does not prove the conjecture as one can design other algorithms, it makes the conjecture likely to hold.*

5.3 Label Efficient Bandit Game (LE Bandit)

The following theorems concern the simple LE bandit game, in which the requirement is that the *expected* number of queried rewards should be less or equal to m. We consider the following policy. At each round, we draw a Bernoulli random variable Z_t, with parameter $\varepsilon = m/n$, to decide whether the gain of the chosen arm is revealed or not. Note that this policy does not fulfil exactly the requirement of the LE bandit game as we might ask a bit more than m rewards, but, as was argued in Section 5.1.2, it can be modified in order to fulfil the hard constraint of the game. The theoretical guarantees are then the same (up to numerical constant factors).

Theorem 15 (Exponentially weighted average forecaster in the simple LE bandit game) *Let* $\psi(x) = \exp(\eta x) + \frac{\gamma}{K}$ *with* $\gamma = \min\left(\frac{1}{2}, \sqrt{\frac{4K\log K}{5m}}\right)$ *and* $\eta = \frac{1}{n}\sqrt{\frac{5m\log K}{4K}}$. *Let* $v_{i,t} = g_{i,t}\frac{\mathbb{I}_{I_t=i}}{p_{i,t}}\frac{Z_t}{\varepsilon}$ *with* $\varepsilon = \frac{m}{n}$. *Then in the simple LE bandit game, INF satisfies:*

$$\overline{R}_n \leq n\sqrt{\frac{16K\log K}{5m}}.$$

Proof One simply needs to note that for $5\gamma \geq \frac{4K\eta}{\varepsilon}$, (11) is satisfied, and thus by taking the expectation in (12), we get

$$\overline{R}_n \leq (1-\gamma)\frac{\log K}{\eta} + \gamma\mathbb{E}\max_{1\leq i\leq K} V_{i,n} \leq (1-\gamma)\frac{\log K}{\eta} + \gamma n.$$

We thus have

$$\overline{R}_n \leq \frac{n}{m}\left((1-\gamma)\frac{\log K}{\eta/\varepsilon} + \gamma m\right).$$

The numerical application for the term in parenthesis is then exactly the same as the one proposed in the proof of Theorem 10 (with n and η respectively replaced by m and η/ε). ■

Theorem 16 (Poly INF in the simple LE bandit game) *Let* $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$ *with* $\gamma = \min\left(\frac{1}{2}, \sqrt{\frac{3K}{m}}\right)$, $\eta = n\sqrt{\frac{5}{m}}$ *and* $q = 2$. *Let* $v_{i,t} = g_{i,t}\frac{\mathbb{I}_{I_t=i}}{p_{i,t}}\frac{Z_t}{\varepsilon}$ *with* $\varepsilon = \frac{m}{n}$. *Then in the simple LE bandit game, INF satisfies:*

$$\overline{R}_n \leq 8n\sqrt{\frac{K}{m}}.$$

Proof By taking the expectation in (8) and letting $\bar{G}_{\max} = \max_{1\leq i\leq K}\mathbb{E}G_{i,n}$, we obtain that for $\gamma > (q-1)K(q\eta\varepsilon)^{q/(1-q)} > 0$ (condition coming from the condition on c for (8)),

$$(1-\gamma)\bar{G}_{\max} - (1+\gamma\zeta)\mathbb{E}\sum_{t=1}^{n} g_{I_t,t} \leq \frac{q}{q-1}\eta K^{\frac{1}{q}},$$

with

$$\zeta = \frac{1}{(q-1)K}\Big(\frac{(q-1)K\mu(1+\mu)}{2\gamma\eta\varepsilon}\Big)^q,$$

and

$$\mu = \exp\left\{\frac{2(q+1)}{\eta\varepsilon}\left(\frac{K}{\gamma}\right)^{(q-1)/q}\left(1 - \frac{1}{q\eta}\left(\frac{(q-1)K}{\gamma}\right)^{(q-1)/q}\right)^{-q}\right\}.$$

We thus have

$$\overline{R}_n \leq \frac{n}{m}\left(\gamma(1+\zeta)m + \frac{q}{q-1}(\eta\varepsilon)K^{\frac{1}{q}}\right).$$

The numerical application for the term in parenthesis is exactly the same than the one proposed in the proof of Theorem 11 (with n and η respectively replaced by m and $\eta\varepsilon$). ■

Both previous theorems only consider the pseudo-regret. By estimating $g_{i,t}$ differently, we obtain the following result for the regret.

Theorem 17 (Poly INF in the simple LE bandit game) *Let* $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$ *with* $\eta = 2n/\sqrt{m}$, $q = 2$ *and* $\gamma = \min\left(\frac{1}{2}, 3\sqrt{\frac{K}{m}}\right)$. *Consider* $v_{i,t} = -\frac{\mathbb{I}_{I_t=i} Z_t}{\beta} \log\left(1 - \frac{\beta g_{i,t}}{\varepsilon p_{i,t}}\right)$ *with* $\beta = \frac{1}{n}\sqrt{\frac{m}{2K}}$. *Then in the simple LE bandit game, against a deterministic adversary, for any* $\delta > 0$, *with probability at least* $1-\delta$, *INF satisfies:*

$$R_n \leq 10.7n\sqrt{\frac{K}{m}} + 3.1n\sqrt{\frac{K}{m}}\log(\delta^{-1}).$$

Against an oblivious adversary, it satisfies

$$\mathbb{E}R_n \leq 13\sqrt{nK}.$$

Moreover in the general case (containing the non-oblivious opponent), with the following parameters $q = 2$, $\gamma = \min\left(\frac{1}{2}, 3\sqrt{\frac{K\log(3K)}{m}}\right)$, $\eta = 2n/\sqrt{m\log(3K)}$ *and* $\beta = \frac{1}{n}\sqrt{\frac{m\log(3K)}{2K}}$, *it satisfies with probability at least* $1-\delta$,

$$R_n \leq 10n\sqrt{\frac{K\log(3K)}{m}} + 3.5n\sqrt{\frac{K}{m\log(3K)}}\log(\delta^{-1}),$$

and

$$\mathbb{E}R_n \leq 13n\sqrt{\frac{\log(3K)}{m}}.$$

A similar result can be obtained for Exp INF, at the price of an additional logarithmic term in K against oblivious (deterministic or not) adversaries. We omit the details.

6. Regret Bounds Scaling with the Optimal Arm Rewards

In this section, we provide regret bounds for bandit games depending on the performance of the optimal arm: in these bounds, the factor n is essentially replaced by

$$G_{\max} = \max_{i=1,\ldots,n} G_{i,n},$$

where $G_{i,n} = \sum_{t=1}^n g_{i,t}$. Such a bound has been proved on the expected regret for deterministic adversaries in the seminal work of Auer et al. (2002b). Here, by using a new biased estimate of $g_{i,t}$, that is

$v_{i,t} = -\frac{\mathbb{I}_{I_t=i}}{\beta}\log\left(1 - \frac{\beta g_{i,t}}{p_{i,t}}\right)$, we obtain a bound holding with high probability and we also consider its extension to any adversary.

The bounds presented here are especially interesting when $G_{\max} \ll n$: this typically occurs in online advertizing where the different arms are the ads that can be put on the website and where the probability that a user clicks on an ad banner (and thus induces a reward to the webpage owner) is very low. For deterministic adversaries, as in the bandit game, the $\log K$ factor appearing in the exponentially weighted average forecaster regret bound disappears in the Poly INF regret bound as follows.

Theorem 18 *Let G_0 be a real number such that $G_0 \geq 81K$. Let $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$ with $\eta = 2\sqrt{G_0}$, $q = 2$ and $\gamma = 3\sqrt{\frac{K}{G_0}}$. Let $v_{i,t} = -\frac{\mathbb{I}_{I_t=i}}{\beta}\log\left(1 - \frac{\beta g_{i,t}}{p_{i,t}}\right)$ with $\beta = \frac{1}{\sqrt{2KG_0}}$. Then in the bandit game, against a deterministic adversary, for any $\delta > 0$, with probability at least $1-\delta$, INF satisfies:*

$$R_n \leq 4.5\sqrt{K\frac{G_{\max}^2}{G_0}} + 4\sqrt{KG_0} + \sqrt{2KG_0}\log(\delta^{-1}). \tag{18}$$

For fully oblivious adversaries, for any $\delta > 0$, with probability at least $1-\delta$, INF satisfies:

$$R_n \leq 4.5\sqrt{K\frac{G_{\max}^2}{G_0}} + 4\sqrt{KG_0} + \sqrt{2KG_0}\log(2\delta^{-1}) + \sqrt{8\log(2K\delta^{-1})G_{\max}}. \tag{19}$$

For the choice $G_0 = n$, the high probability upper bounds are of the order of $\sqrt{nK} + \sqrt{nK}\log(\delta^{-1})$. The interest of the theorem is to provide a policy which, for small $G_{\max}$, leads to smaller regret bounds, as long as G_0 is taken much smaller than n and but not much smaller than $G_{\max}$. For deterministic adversaries, $G_{\max}$ is nonrandom, and provided that we know its order, one has interest of taking G_0 of this order. Precisely, we have the following corollary for deterministic adversaries.

Corollary 19 *Let $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$ with $\eta = 2\sqrt{G_{\max}}$, $q = 2$ and $\gamma = \min\left(\frac{1}{2}, 3\sqrt{\frac{K}{G_{\max}}}\right)$. Consider $v_{i,t} = -\frac{\mathbb{I}_{I_t=i}}{\beta}\log\left(1 - \frac{\beta g_{i,t}}{p_{i,t}}\right)$ with $\beta = \frac{1}{\sqrt{2KG_{\max}}}$. Then in the bandit game, against a deterministic adversary, for any $\delta > 0$, with probability at least $1-\delta$, INF satisfies:*

$$R_n \leq 9\sqrt{KG_{\max}} + \sqrt{2KG_{\max}}\log(\delta^{-1}), \tag{20}$$

and

$$\mathbb{E}R_n \leq 10\sqrt{KG_{\max}}. \tag{21}$$

For more general adversaries than fully oblivious ones, we have the following result in which the $\log K$ factor reappears.

Theorem 20 *Let $G_0 \geq 81K\log(3K)$. Let $\psi(x) = \left(\frac{\eta}{-x}\right)^q + \frac{\gamma}{K}$ with $q = 2$, $\gamma = 3\sqrt{\frac{K\log(3K)}{G_0}}$ and $\eta = 2\sqrt{\frac{G_0}{\log(3K)}}$. Let $v_{i,t} = -\frac{\mathbb{I}_{I_t=i}}{\beta}\log\left(1 - \frac{\beta g_{i,t}}{p_{i,t}}\right)$ with $\beta = \sqrt{\frac{\log(3K)}{2KG_0}}$. Then in the bandit game, against any adversary (possibly a non-oblivious one), for any $\delta > 0$, with probability at least $1-\delta$, INF satisfies:*

$$R_n \leq \frac{9}{2}\sqrt{\frac{G_{\max}^2}{G_0}K\log(3K)} + 4\sqrt{\frac{KG_0}{\log(3K)}} + \sqrt{\frac{2KG_0}{\log(3K)}}\log(K\delta^{-1}).$$

This last result concerning Poly INF is similar to the following one concerning the exponentially weighted average forecaster: the advantage of Poly INF only appears when it allows to remove the $\log K$ factor.

Theorem 21 *Let $G_0 > 4K\log(3K)$. Let $\psi(x) = \exp(\eta x) + \frac{\gamma}{K}$ with $\gamma = 2\sqrt{\frac{K\log(3K)}{G_0}}$ and $\eta = 2\sqrt{\frac{\log(3K)}{KG_0}}$. Let $v_{i,t} = -\frac{\mathbb{I}_{I_t=i}}{\beta}\log\left(1 - \frac{\beta g_{i,t}}{p_{i,t}}\right)$ with $\beta = \sqrt{\frac{\log(3K)}{2KG_0}}$. Then in the bandit game, against any adversary (possibly a non-oblivious one), for any $\delta > 0$, with probability at least $1-\delta$, INF satisfies:*

$$R_n \leq \frac{5}{2}\sqrt{\frac{G_{\max}^2}{G_0}K\log(3K)} + \frac{1}{2}\sqrt{KG_0\log(3K)} + \sqrt{\frac{2KG_0}{\log(3K)}}\log(K\delta^{-1}).$$

7. Tracking the Best Expert in the Bandit Game

In the previous sections, the cumulative gain of the forecaster was compared to the cumulative gain of the best single expert. Here, it will be compared to more flexible strategies that are allowed to switch actions. We will use

$$v_{i,t} = g_{i,t}\frac{\mathbb{I}_{I_t=i}}{p_{i,t}} + \frac{\beta}{p_{i,t}},$$

with $0 < \beta \leq 1$. The β term introduces a bias in the estimate of $g_{i,t}$, that constrains the differences $\max_{1\leq i\leq K} V_{i,t} - \min_{1\leq j\leq K} V_{j,t}$ to be relatively small. This is the key property in order to track the best switching strategy, provided that the number of switches is not too large. A switching strategy is defined by a vector $(i_1,\ldots,i_n) \in \{1,\ldots,K\}^n$. Its size is defined by

$$\mathcal{S}(i_1,\ldots,i_n) = \sum_{t=1}^{n-1} \mathbb{I}_{i_{t+1}\neq i_t},$$

and its cumulative gain is

$$G_{(i_1,\ldots,i_n)} = \sum_{t=1}^{n} g_{i_t,t}.$$

The regret of a forecaster with respect to the best switching strategy with S switches is then given by:

$$R_n^S = \max_{(i_1,\ldots,i_n):\mathcal{S}(i_1,\ldots,i_n)\leq S} G_{(i_1,\ldots,i_n)} - \sum_{t=1}^{n} g_{I_t,t}.$$

Theorem 22 (INF for tracking the best expert in the bandit game)
Let $s = S\log\left(\frac{3nK}{S}\right) + 2\log K$ with the natural convention $S\log(3nK/S) = 0$ for $S = 0$. Let $v_{i,t} = g_{i,t}\frac{\mathbb{I}_{I_t=i}}{p_{i,t}} + \frac{\beta}{p_{i,t}}$ with $\beta = 3\sqrt{\frac{s}{nK}}$. Let $\psi(x) = \exp(\eta x) + \frac{\gamma}{K}$ with $\gamma = \min\left(\frac{1}{2}, \sqrt{\frac{Ks}{2n}}\right)$ and $\eta = \frac{1}{5}\sqrt{\frac{s}{nK}}$. Then in the bandit game, for any $0 \leq S \leq n-1$, for any $\delta > 0$, with probability at least $1-\delta$, INF satisfies:

$$R_n^S \leq 7\sqrt{nKs} + \sqrt{\frac{nK}{s}}\log(\delta^{-1}),$$

and

$$\mathbb{E}R_n^S \leq 7\sqrt{nKs}.$$

Note that for $S = 0$, we have $R_n^S = R_n$, and we recover an expected regret bound of order $\sqrt{nK\log K}$ similar to the one of Theorem 12.

Remark 23 Up to constant factors, the same bounds as the ones of Theorem 22 can be obtained (via a tedious proof not requiring new arguments than the ones presented in this work) for the INF forecaster using $\psi(x) = \frac{c_1}{K}\left(\frac{\sqrt{snK}}{-x}\right)^{c_3 s} + c_2\sqrt{\frac{s}{nK}}$, with $s = S\log\left(\frac{enK}{S}\right) + \log(2K)$ and appropriate constants c_1, c_2 and c_3.

8. Gains vs Losses, Unsigned Games vs Signed Games

To simplify, we have considered so far that the rewards were in $[0,1]$. Here is a trivial argument which shows how to transfer our analysis to loss games (i.e., games with only non-positive rewards), and more generally to signed games (i.e., games in which the rewards can be positive and negative). If the rewards, denoted now $g'_{i,t}$, are in some interval $[a,b]$ potentially containing zero, we set $g_{i,t} = \frac{g'_{i,t}-a}{b-a} \in [0,1]$. Then we can apply our analysis to:

$$\max_{i\in\{1,\ldots,K\}} \sum_{t=1}^{n} g_{i,t} - \sum_{t=1}^{n} g_{I_t,t} = \frac{1}{b-a}\left(\max_{i\in\{1,\ldots,K\}} \sum_{t=1}^{n} g'_{i,t} - \sum_{t=1}^{n} g'_{I_t,t}\right).$$

A less straightforward analysis can be done by looking at the INF algorithm directly applied to the observed rewards (and not to the renormalized rewards). In this case, as it was already noted in Remark 6.5 of Cesa-Bianchi and Lugosi (2006), the behavior of the algorithm may be very different for loss and gain games. However it can be proved that our analysis still holds up to constant factors (one has to go over the proofs and make appropriate modifications since for simplicity, we have presented the general results concerning INF under the assumptions that the estimates $v_{i,t}$ are nonnegative). In Section 6, we provide regret bounds scaling with the cumulative reward of the optimal arm. For this kind of results, renormalizing will not lead to regret bounds scaling with the cumulative reward before renormalization of the optimal arm, and consequently, the study of INF directly applied to the observed rewards is necessary. In particular, obtaining low regret bounds when the optimal arm has small cumulative loss would require appropriate modifications in the proof.

9. Stochastic Bandit Game

By considering the deterministic case when the rewards are $g_{i,t} = 1$ if $i = 1$ and $g_{i,t} = 0$ otherwise, it can be proved that the INF policies considered in Theorem 10 and Theorem 11 have a pseudo-regret lower bounded by $\sqrt{nK}$. In this simple setting, and more generally in most of the stochastic multi-armed bandit problems, one would like to suffer a much smaller regret.

We recall that in the stochastic bandit considered in this section, the rewards $g_{i,1},\ldots,g_{i,n}$ are independent and drawn from a fixed distribution ν_i on $[0,1]$ for each arm i, and the reward vectors $g_1,\ldots,g_n$ are independent.[3] The suboptimality of an arm i is then measured by $\Delta_i = \max_{1\le j\le K}\mu_j - \mu_i$ where μ_i is the mean of ν_i. We provide now a strategy achieving a $\sqrt{nK}$ regret in the worst case, and a much smaller regret as soon as the Δ_i of the suboptimal arms are much larger than $\sqrt{K/n}$.

Let $\widehat{\mu}_{i,s}$ be the empirical mean of arm i after s draws of this arm. Let $T_i(t)$ denote the number of times we have drawn arm i on the first t rounds. In this section, we propose a policy, called MOSS (Minimax Optimal Strategy in the Stochastic case), inspired by the UCB1 policy (Auer et al., 2002a). As in UCB1, each arm has an index measuring its performance, and at each round, we choose the arm having the highest index. The only difference with UCB1 is to use $\log\left(\frac{n}{Ks}\right)$ instead of $\log(t)$ at time t (see Figure 3). As a consequence, an arm that has been drawn more than n/K times has an index equal to the empirical mean of the rewards obtained from the arm, and when

3. Note that we do not assume independence of $g_{1,t},\ldots,g_{K,t}$ for each t. This assumption is usually made in the literature, but is often useless. In our work, assuming it would just have improved Proposition 36 by a constant factor, and would not have improved the constant in Theorem 24.

it has been drawn close to n/K times, the logarithmic term is much smaller than the one of UCB1, implying less exploration of this already intensively drawn arm.

MOSS (Minimax Optimal Strategy in the Stochastic case):

For an arm i, define its index $B_{i,s}$ by

$$B_{i,s} = \widehat{\mu}_{i,s} + \sqrt{\frac{\max\left(\log\left(\frac{n}{Ks}\right), 0\right)}{s}} \, .$$

for $s \geq 1$ and $B_{i,0} = +\infty$.

At time t, draw an arm maximizing $B_{i,T_i(t-1)}$.

Figure 3: The proposed policy for the stochastic bandit game.

Theorem 24 *Introduce* $\Delta = \min_{i \in \{1,\ldots,K\}:\Delta_i > 0} \Delta_i$. *MOSS satisfies*

$$\overline{R}_n \leq \frac{23K}{\Delta} \log\left(\max\left(\frac{110n\Delta^2}{K}, 10^4\right)\right), \tag{22}$$

and

$$\mathbb{E}R_n \leq 25\sqrt{nK}. \tag{23}$$

Besides, if there exists a unique arm with $\Delta_i = 0$, *we also have*

$$\mathbb{E}R_n \leq \frac{23K}{\Delta} \log\left(\max\left(\frac{140n\Delta^2}{K}, 10^4\right)\right). \tag{24}$$

The distribution-dependent bounds Inequalities (22) and (24) show the desired logarithmic dependence in n, while the distribution-free regret bound (23) has the minimax rate $\sqrt{nK}$.

Remark 25 The uniqueness of the optimal arm is really needed to have the logarithmic (in n) bound on the expected regret. This can be easily seen by considering a two-armed bandit in which both reward distributions are identical (and non degenerated). In this case, the pseudo-regret is equal to zero while the expected regret is of order $\sqrt{n}$. This reveals a fundamental difference between the expected regret and the pseudo-regret.

Remark 26 A careful tuning of the constants in front and inside the logarithmic term of $B_{i,s}$ and of the thresholds used in the proof leads to smaller numerical constants in the previous theorem, and in particular to $\sup \mathbb{E}R_n \leq 6\sqrt{nK}$. However, it makes the proof more intricate. So we will only prove (23).

Thanks to Gilles Stoltz for pointing us out Proposition 33. This work has been supported by the French National Research Agency (ANR) through the COSINUS program (ANR-08-COSI-004: EXPLO-RA project).

Appendix A. The General Regret Upper Bound of INF

Theorem 27 (INF regret upper bound) *For any nonnegative real numbers $v_{i,t}$, where $i \in \{1,\dots,K\}$ and $t \in \mathbb{N}^*$, we still use $v_t = (v_{1,t},\dots,v_{K,t})$ and $V_t = \sum_{s=1}^{t} v_t$, with the convention $V_0 = 0 \in \mathbb{R}_+^K$. Define $[V_{t-1}, V_t] = \{\lambda V_{t-1} + (1-\lambda)V_t : \lambda \in [0,1]\}$. Let*

$$B_t = \max_{1\le i\le K} v_{i,t},$$

$$\rho = \max_{1\le t\le n} \max_{v,w\in[V_{t-1},V_t],\, 1\le i\le K} \frac{\psi'(v_i - C(v))}{\psi'(w_i - C(w))},$$

and

$$A_t = \min\left(B_t^2 \sum_{i=1}^{K} \psi'\circ\psi^{-1}(p_{i,t}), (1+\rho^2)\sum_{i=1}^{K} \psi'\circ\psi^{-1}(p_{i,t}) v_{i,t}^2 \right).$$

Then the INF forecaster based on ψ satisfies:

$$\max_{1\le i\le K} V_{i,n} \le C_n \le \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t} - \sum_{i=1}^{K}\left(p_{i,n+1}\psi^{-1}(p_{i,n+1}) + \int_{p_{i,n+1}}^{1/K} \psi^{-1}(u)du \right) + \frac{\rho^2}{2}\sum_{t=1}^{n} A_t. \quad (25)$$

Proof Let us set $C_0 = C(V_0)$. The proof is divided into four steps.

First step: Rewriting $\sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t}v_{i,t}$.

We start with a simple Abel transformation:

$$\begin{aligned}
\sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t}v_{i,t} &= \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t}(V_{i,t}-V_{i,t-1}) \\
&= \sum_{i=1}^{K} p_{i,n+1}V_{i,n} + \sum_{i=1}^{K}\sum_{t=1}^{n} V_{i,t}(p_{i,t}-p_{i,t+1}) \\
&= \sum_{i=1}^{K} p_{i,n+1}\left(\psi^{-1}(p_{i,n+1})+C_n\right) + \sum_{i=1}^{K}\sum_{t=1}^{n}(\psi^{-1}(p_{i,t+1})+C_t)(p_{i,t}-p_{i,t+1}) \\
&= C_n + \sum_{i=1}^{K} p_{i,n+1}\psi^{-1}(p_{i,n+1}) + \sum_{i=1}^{K}\sum_{t=1}^{n}\psi^{-1}(p_{i,t+1})(p_{i,t}-p_{i,t+1})
\end{aligned}$$

where the last step comes from the fact that $\sum_{i=1}^{K} p_{i,t} = 1$.

Second step: A Taylor-Lagrange expansion.

For $x \in [0,1]$ we define $f(x) = \int_0^x \psi^{-1}(u)du$. Remark that $f'(x) = \psi^{-1}(x)$ and $f''(x) = 1/\psi'(\psi^{-1}(x))$. Then by the Taylor-Lagrange formula, we know that for any i, there exists $\tilde{p}_{i,t+1} \in [p_{i,t}, p_{i,t+1}]$ (with the convention $[a,b] = [b,a]$ when $a > b$) such that

$$f(p_{i,t}) = f(p_{i,t+1}) + (p_{i,t}-p_{i,t+1})f'(p_{i,t+1}) + \frac{(p_{i,t}-p_{i,t+1})^2}{2}f''(\tilde{p}_{i,t+1}),$$

or, in other words:

$$(p_{i,t}-p_{i,t+1})\psi^{-1}(p_{i,t+1}) = \int_{p_{i,t+1}}^{p_{i,t}} \psi^{-1}(u)du - \frac{(p_{i,t}-p_{i,t+1})^2}{2\psi'(\psi^{-1}(\tilde{p}_{i,t+1}))}.$$

Now by summing over t the first term on the right-hand side becomes $\int_{p_{i,n+1}}^{1/K} \psi^{-1}(u)du$. Moreover, since $x \to \psi(x - C(x))$ is continuous, there exists $W^{(i,t)} \in [V_t, V_{t+1}] \subset \mathbb{R}^K$ such that $\psi\left(W_i^{(i,t)} - C(W^{(i,t)})\right) = \tilde{p}_{i,t+1}$. Thus we have

$$\sum_{i=1}^{K}\sum_{t=1}^{n}\psi^{-1}(p_{i,t+1})(p_{i,t}-p_{i,t+1}) = \sum_{i=1}^{K}\int_{p_{i,n+1}}^{1/K}\psi^{-1}(u)du - \sum_{i=1}^{K}\sum_{t=1}^{n}\frac{(p_{i,t}-p_{i,t+1})^2}{2\psi'\left(W_i^{(i,t)} - C(W^{(i,t)})\right)}.$$

From the equality obtained in the first step, it gives

$$\begin{aligned}
C_n - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t}v_{i,t} = -\sum_{i=1}^{K}\left(p_{i,n+1}\psi^{-1}(p_{i,n+1}) + \int_{p_{i,n+1}}^{1/K}\psi^{-1}(u)du\right) \\
+ \sum_{i=1}^{K}\sum_{t=1}^{n}\frac{(p_{i,t}-p_{i,t+1})^2}{2\psi'\left(W_i^{(i,t)} - C(W^{(i,t)})\right)}.
\end{aligned}$$

Third step: The mean value theorem to compute $(p_{i,t+1}-p_{i,t})^2$.

It is now convenient to consider the functions f_i and h_i defined for any $x \in \mathbb{R}_+^K$ by

$$f_i(x) = \psi(x_i - C(x)) \quad \text{and} \quad h_i(x) = \psi'(x_i - C(x)).$$

We are going to bound $p_{i,t+1} - p_{i,t} = f_i(V_t) - f_i(V_{t-1})$ by using the mean value theorem. To do so we need to compute the gradient of f_i. First, we have

$$\frac{\partial f_i}{\partial x_j}(x) = \left(\mathbb{1}_{i=j} - \frac{\partial C}{\partial x_j}(x) \right) h_i(x).$$

Now, by definition of C, we have $\sum_{k=1}^K f_k(x) = 1$ and thus $\sum_{k=1}^K \frac{\partial f_k}{\partial x_j}(x) = 0$, which implies

$$\frac{\partial C}{\partial x_j}(x) = \frac{h_j(x)}{\sum_{k=1}^K h_k(x)} \qquad \text{and} \qquad \frac{\partial f_i}{\partial x_j}(x) = \left(\mathbb{1}_{i=j} - \frac{h_j(x)}{\sum_{k=1}^K h_k(x)} \right) h_i(x).$$

Now the mean value theorem says that there exists $V^{(i,t)} \in [V_{t-1}, V_t]$ such that

$$f_i(V_t) - f_i(V_{t-1}) = \sum_{j=1}^K v_{j,t} \frac{\partial f_i}{\partial x_j}(V^{(i,t)}).$$

Thus we have

$$\begin{aligned}(p_{i,t} - p_{i,t+1})^2 &= \left(\sum_{j=1}^K v_{j,t} \left(\mathbb{1}_{i=j} - \frac{h_j(V^{(i,t)})}{\sum_{k=1}^K h_k(V^{(i,t)})} \right) h_i(V^{(i,t)}) \right)^2 \\ &= h_i(V^{(i,t)})^2 \left(v_{i,t} - \frac{\sum_{j=1}^K v_{j,t} h_j(V^{(i,t)})}{\sum_{k=1}^K h_k(V^{(i,t)})} \right)^2.\end{aligned}$$

Fourth step: An almost variance term.

We introduce $\rho = \max_{v,w \in [V_{t-1}, V_t],\, 1 \le t \le n,\, 1 \le i \le K} \frac{h_i(v)}{h_i(w)}$. Thus we have

$$\begin{aligned}\sum_{i=1}^K \sum_{t=1}^n \frac{(p_{i,t} - p_{i,t+1})^2}{2\psi'\left(W_i^{(i,t)} - C(W^{(i,t)})\right)} &= \sum_{i=1}^K \sum_{t=1}^n \frac{h_i(V^{(i,t)})^2}{2h_i(W^{(i,t)})} \left(v_{i,t} - \frac{\sum_{j=1}^K v_{j,t} h_j(V^{(i,t)})}{\sum_{k=1}^K h_k(V^{(i,t)})} \right)^2 \\ &\le \frac{\rho^2}{2} \sum_{t=1}^n \sum_{i=1}^K h_i(V_{t-1}) \left(v_{i,t} - \frac{\sum_{j=1}^K v_{j,t} h_j(V^{(i,t)})}{\sum_{k=1}^K h_k(V^{(i,t)})} \right)^2.\end{aligned}$$

Now we need to control the term $\left(v_{i,t} - \frac{\sum_{j=1}^K v_{j,t} h_j(V^{(i,t)})}{\sum_{k=1}^K h_k(V^{(i,t)})} \right)^2$. Remark that since the function ψ is increasing we know that $h_i(x) \ge 0, \forall x$. Now since we have $0 \le v_{i,t} \le B_t$, we can simply bound this last term by B_t^2. A different bound can be obtained by using $(a-b)^2 \le a^2 + b^2$ when a and b have

the same sign:

$$\begin{aligned}\left(v_{i,t}-\frac{\sum_{j=1}^K v_{j,t}h_j(V^{(i,t)})}{\sum_{k=1}^K h_k(V^{(i,t)})}\right)^2 &\leq v_{i,t}^2+\left(\frac{\sum_{j=1}^K v_{j,t}h_j(V^{(i,t)})}{\sum_{k=1}^K h_k(V^{(i,t)})}\right)^2\\ &\leq v_{i,t}^2+\frac{\sum_{j=1}^K v_{j,t}^2 h_j(V^{(i,t)})}{\sum_{k=1}^K h_k(V^{(i,t)})}\\ &\leq v_{i,t}^2+\rho^2\frac{\sum_{j=1}^K v_{j,t}^2 h_j(V_{t-1})}{\sum_{k=1}^K h_k(V_{t-1})},\end{aligned}$$

where the first inequality comes from the fact that both terms are nonnegative and the second inequality comes from Jensen's inequality. As a consequence, we have

$$\begin{aligned}\sum_{i=1}^K h_i(V_{t-1})\left(v_{i,t}-\frac{\sum_{j=1}^K v_{j,t}h_j(V^{(i,t)})}{\sum_{k=1}^K h_k(V^{(i,t)})}\right)^2 &\leq \sum_{i=1}^K h_i(V_{t-1})v_{i,t}^2+\rho^2\sum_{j=1}^K h_j(V_{t-1})v_{j,t}^2\\ &\leq (1+\rho^2)\sum_{i=1}^K h_i(V_{t-1})v_{i,t}^2.\end{aligned}$$

We have so far proved

$$C_n \quad - \quad \sum_{t=1}^n\sum_{i=1}^K p_{i,t}v_{i,t} \quad \leq \quad -\sum_{i=1}^K\left(p_{i,n+1}\psi^{-1}(p_{i,n+1})+\int_{p_{i,n+1}}^{1/K}\psi^{-1}(u)du\right) \quad + \quad \frac{\rho^2}{2}\sum_{t=1}^n A_t.$$

The announced result is then obtained by using Inequality (2). ■

To apply successfully Theorem 27 (page 2807), we need to have tight upper bounds on ρ. The two following lemmas provide such bounds.

Lemma 28 (A simple bound on the quantity ρ of Theorem 27) *Let ψ be a convex function satisfying* (1) *and assume that there exists $B>0$ such that $\forall i,j,t\ |v_{i,t}-v_{j,t}|\leq B$. Then:*

$$\rho=\max_{1\leq t\leq n}\ \max_{v,w\in[V_{t-1},V_t],\,1\leq i\leq K}\frac{\psi'(v_i-C(v))}{\psi'(w_i-C(w))}\leq\sup_{x\in(-\infty,\psi^{-1}(1)]}\exp\left(B\frac{\psi''}{\psi'}(x)\right).$$

Proof Let $h_i(x)=\psi'(x_i-C(x)), m_i(x)=\psi''(x_i-C(x))$. For $\alpha\in[0,1]$ we note

$$\varphi(\alpha)=\log\left\{h_i(V_{t-1}+\alpha(V_t-V_{t-1}))\right\}.$$

Remark that we should rather note this function $\varphi_{i,t}(\alpha)$ but for sake of simplicity we omit this dependency. With these notations we have $\rho=\max_{\alpha,\beta\in[0,1];\,1\leq t\leq n,\,1\leq i\leq K}\exp(\varphi(\alpha)-\varphi(\beta))$. By the mean value theorem for any $\alpha,\beta\in[0,1]$ there exists $\xi\in[0,1]$ such that $\varphi(\alpha)-\varphi(\beta)=(\alpha-\beta)\varphi'(\xi)$. Now with the calculus done in the third step of the proof of Theorem 27 and using the notations $h_i:=h_i(V_{t-1}+\xi(V_t-V_{t-1})), m_i:=m_i(V_{t-1}+\xi(V_t-V_{t-1}))$ we obtain

$$\varphi'(\xi)=\sum_{j=1}^K(V_{j,t}-V_{j,t-1})\left(\mathbb{1}_{i=j}-\frac{h_j}{\sum_{k=1}^K h_k}\right)\frac{m_i}{h_i}=\sum_{j=1}^K\frac{(v_{i,t}-v_{j,t})h_j}{\sum_{k=1}^K h_k}\frac{m_i}{h_i}.$$

Thus we get

$$|\varphi'(\xi)| \leq \max_{1\leq i,j\leq K} |v_{i,t} - v_{j,t}| \sup_{v\in[V_{t-1},V_t]} \frac{\psi''}{\psi'}(v_i - C(v)).$$

Moreover, using that $x \to \psi(x - C(x))$ is continuous we know that there exists $\tilde{p}_{i,t+1} \in [p_{i,t}, p_{i,t+1}]$ such that $\tilde{p}_{i,t+1} = \psi(v_i - C(v))$ and thus $v_i - C(v) = \psi^{-1}(\tilde{p}_{i,t+1})$. This concludes the proof. ■

Lemma 29 (An other bound on the quantity ρ of Theorem 27) *Let ψ be a function satisfying* (1) *and assume that there exists $c > 0$ such that $0 \leq v_{i,t} \leq \frac{c}{p_{i,t}} \mathbb{I}_{i=I_t}$. We also assume that ψ'/ψ is a nondecreasing function and that there exists $a > 1$ such that $\psi\left(x + \frac{c}{\psi(x)}\right) \leq a\psi(x)$. Then:*

$$\rho \leq \sup_{x\in(-\infty,\psi^{-1}(1)]} \exp\left(ac\frac{\psi''}{\psi\times\psi'}(x)\right).$$

Proof We extract from the previous proof that $\rho \leq \max_{\xi\in[0,1];\, 1\leq t\leq n,\, 1\leq i\leq K} \exp(|\varphi'(\xi)|)$ where

$$\varphi'(\xi) = \sum_{j=1}^{K} \frac{(v_{i,t} - v_{j,t})h_j}{\sum_{k=1}^{K} h_k} \frac{m_i}{h_i}.$$

Note that, since the functions ψ and ψ'/ψ are nondecreasing, the function ψ is convex, hence $\psi'' \geq 0$ and $m_i \geq 0$. Now using our assumption on $v_{i,t}$ and since $p_{i,t} = f_i(V_{t-1})$, if $i \neq I_t$ we have:

$$|\varphi'(\xi)| \leq \frac{c\frac{h_{I_t}}{f_{I_t}(V_{t-1})}}{\sum_{k=1}^{K} h_k} \frac{m_i}{h_i} \leq c\frac{f_{I_t}(V_{t-1} + \xi(V_t - V_{t-1}))}{f_{I_t}(V_{t-1})} \times \frac{h_{I_t}}{f_{I_t}(V_{t-1} + \xi(V_t - V_{t-1}))} \times \frac{m_i}{h_i} \times \frac{1}{h_{I_t} + h_i}.$$

Noticing that for any x, y in $\mathbb{R}^*_-$, $\frac{\frac{\psi'}{\psi}(x)\times\frac{\psi''}{\psi'}(y)}{\psi'(x)+\psi'(y)} \leq \frac{\psi''(y)}{\psi'(y)\psi(y)}$, we obtain

$$|\varphi'(\xi)| \leq c\frac{f_{I_t}(V_{t-1} + \xi(V_t - V_{t-1}))}{f_{I_t}(V_{t-1})} \frac{m_i}{h_i \times f_i(V_{t-1} + \xi(V_t - V_{t-1}))}.$$

On the other hand if $i = I_t$ then

$$|\varphi'(\xi)| \leq \frac{c}{f_i(V_{t-1})} \frac{m_i}{h_i}.$$

To finish we only have to prove that $f_{I_t}(V_{t-1} + \xi(V_t - V_{t-1})) \leq a f_{I_t}(V_{t-1})$. Since ψ is increasing it is enough to prove that $f_{I_t}(V_t) \leq a f_{I_t}(V_{t-1})$ which is equivalent to

$$\psi(V_{I_t,t-1} + v_{I_t,t} - C_t) \leq a\psi(V_{I_t,t-1} - C_{t-1}).$$

Since $0 \leq v_{i,t} \leq \frac{c}{p_{i,t}} \mathbb{I}_{i=I_t}$ and C is an increasing function in each of its argument it is enough to prove

$$\psi\left(V_{I_t,t-1} - C_{t-1} + \frac{c}{\psi(V_{I_t,t-1} - C_{t-1})}\right) \leq a\psi(V_{I_t,t-1} - C_{t-1})$$

which is true by hypothesis on ψ. ■

Appendix B. Lower Bounds

In this section we propose a simple unified proof to derive lower bounds on the pseudo-regret in the four problems that we consider.

Theorem 30 *Let $m \geq K$. Let* sup *represents the supremum taken over all oblivious adversaries and* inf *the infimum taken over all forecasters, then the following holds true in the label efficient game:*[4]

$$\inf \sup \overline{R}_n \geq 0.03 n \sqrt{\frac{\log(K)}{m}}.$$

and in the label efficient bandit game we have:

$$\inf \sup \overline{R}_n \geq 0.04 n \sqrt{\frac{K}{m}}.$$

Proof *First step: Definitions.*

We consider a set of K oblivious adversaries. The i^{th} adversary selects its gain vectors as follows: For any $t \in \{1, \ldots, n\}, g_{i,t} \sim Ber\left(\frac{1+\varepsilon}{2}\right)$ and for $j \neq i, g_{j,t} \sim Ber\left(\frac{1-\varepsilon}{2}\right)$. We note $\mathbb{E}_i$ when we integrate with respect to the reward generation process of the i^{th} adversary. We focus on the label efficient versions of the full information and bandits games since by taking $m = n$ we recover the traditional games.

Until the fifth step we consider a deterministic forecaster, that is he does not have access to an external randomization. Let $q_n = (q_{1,n}, \ldots, q_{K,n})$ be the empirical distribution of plays over the arms defined by:

$$q_{i,n} = \frac{\sum_{t=1}^n \mathbb{1}_{I_t = i}}{n}.$$

Let J_n be drawn according to q_n. We note $\mathbb{P}_i$ the law of J_n when the forecaster plays against the i^{th} adversary. Remark that we have $\mathbb{P}_i(J_n = j) = \mathbb{E}_i \frac{1}{n} \sum_{t=1}^n \mathbb{1}_{I_t = j}$, hence, against the i^{th} adversary we have:

$$\overline{R}_n = \mathbb{E}_i \sum_{t=1}^n (g_{i,t} - g_{I_t,t}) = \varepsilon n \sum_{j \neq i} \mathbb{P}_i(J_n = j) = \varepsilon n (1 - \mathbb{P}_i(J_n = i)),$$

which implies (since a maximum is larger than a mean)

$$\sup \overline{R}_n \geq \varepsilon n \left(1 - \frac{1}{K} \sum_{i=1}^K \mathbb{P}_i(J_n = i)\right). \tag{26}$$

Second step: Information inequality.

Let $\mathbb{P}_0$ (respectively $\mathbb{P}_{K+1}$) be the law of J_n against the adversary drawing all its losses from the Bernoulli of parameter $\frac{1-\varepsilon}{2}$ (respectively $\frac{1-\varepsilon}{2} + \frac{\varepsilon}{K}$), we call it the 0^{th} adversary (respectively the $(K+1)^{th}$ adversary). Now we use either Pinsker's inequality which gives:

$$\mathbb{P}_i(J_n = i) \leq \mathbb{P}_0(J_n = i) + \sqrt{\frac{1}{2} \mathrm{KL}(\mathbb{P}_0, \mathbb{P}_i)},$$

4. Slightly better numerical constants can be obtained with a more careful optimization in step four of the proof.

and thus (thanks to the concavity of the square root)

$$\frac{1}{K}\sum_{i=1}^{K}\mathbb{P}_i(J_n=i)\leq\frac{1}{K}+\sqrt{\frac{1}{2K}\sum_{i=1}^{K}\mathrm{KL}(\mathbb{P}_0,\mathbb{P}_i)}; \tag{27}$$

or Fano's lemma:

$$\frac{1}{K}\sum_{i=1}^{K}\mathbb{P}_i(J_n=i)\leq\frac{\log 2+\frac{1}{K}\sum_{i=1}^{K}\mathrm{KL}(\mathbb{P}_i,\mathbb{P}_{K+1})}{\log(K-1)}. \tag{28}$$

We will use (28) for the full information games when $K>3$ and (27) the bandits games and the full information games with $K\in\{2,3\}$.

Third step: Computation of $\mathrm{KL}(\mathbb{P}_0,\mathbb{P}_i)$ *and* $\mathrm{KL}(\mathbb{P}_i,\mathbb{P}_{K+1})$ *with the chain rule for Kullback-Leibler divergence*.

Remark that since the forecaster is deterministic, the sequence of observed rewards (up to time n) W_n ($W_n\in\{0,1\}^{mK}$ for the full information label efficient game and $W_n\in\{0,1\}^m$ for the label efficient bandit game) uniquely determines the empirical distribution of plays q_n, and in particular the law of J_n conditionally to W_n is the same for any adversary. Thus, if for $i\in\{0,\dots,K+1\}$ we note $\mathbb{P}_i^n$ the law of W_n when the forecaster plays against the i^{th} adversary, then one can easily prove that

$$\mathrm{KL}(\mathbb{P}_0,\mathbb{P}_i)\leq\mathrm{KL}(\mathbb{P}_0^n,\mathbb{P}_i^n),\ \text{ and }\ \mathrm{KL}(\mathbb{P}_i,\mathbb{P}_{K+1})\leq\mathrm{KL}(\mathbb{P}_i^n,\mathbb{P}_{K+1}^n).$$

Now we use the Chain rule for Kullback-Leibler divergence iteratively to introduce the laws $\mathbb{P}_i^t$ of the observed rewards W_t up to time t. We also note $Z_t=1$ if some rewards are revealed at the end of round t and $Z_t=0$ otherwise. With these notations we have in the full information games, for $K>3$,

$$\begin{aligned}
&\mathrm{KL}(\mathbb{P}_i^n,\mathbb{P}_{K+1}^n)\\
&\quad=\ \mathrm{KL}(\mathbb{P}_i^1,\mathbb{P}_{K+1}^1)+\sum_{t=2}^{n}\sum_{w_{t-1}}\mathbb{P}_i^{t-1}(w_{t-1})\mathrm{KL}(\mathbb{P}_i^t(.|w_{t-1}),\mathbb{P}_{K+1}^t(.|w_{t-1}))\\
&\quad=\ \mathrm{KL}(\mathbb{P}_i^1,\mathbb{P}_{K+1}^1)\\
&\qquad+\sum_{t=2}^{n}\left\{\sum_{w_{t-1}:Z_t=1}\mathbb{P}_i^{t-1}(w_{t-1})\left[\mathrm{KL}\left(\frac{1+\varepsilon}{2},\frac{1-\varepsilon}{2}+\frac{\varepsilon}{K}\right)+(K-1)\mathrm{KL}\left(\frac{1-\varepsilon}{2},\frac{1-\varepsilon}{2}+\frac{\varepsilon}{K}\right)\right]\right\}\\
&\quad=\ \left[\mathrm{KL}\left(\frac{1+\varepsilon}{2},\frac{1-\varepsilon}{2}+\frac{\varepsilon}{K}\right)+(K-1)\mathrm{KL}\left(\frac{1-\varepsilon}{2},\frac{1-\varepsilon}{2}+\frac{\varepsilon}{K}\right)\right]\mathbb{E}_i\sum_{t=1}^{n}Z_t\\
&\quad\leq\ m\left[\mathrm{KL}\left(\frac{1+\varepsilon}{2},\frac{1-\varepsilon}{2}+\frac{\varepsilon}{K}\right)+(K-1)\mathrm{KL}\left(\frac{1-\varepsilon}{2},\frac{1-\varepsilon}{2}+\frac{\varepsilon}{K}\right)\right].
\end{aligned}$$

Summing and plugging this into (28) we obtain for the full information games:

$$\frac{1}{K}\sum_{i=1}^{K}\mathbb{P}_i(J_n=i)\leq\frac{\log 2+m\mathrm{KL}\left(\frac{1+\varepsilon}{2},\frac{1-\varepsilon}{2}+\frac{\varepsilon}{K}\right)+m(K-1)\mathrm{KL}\left(\frac{1-\varepsilon}{2},\frac{1-\varepsilon}{2}+\frac{\varepsilon}{K}\right)}{\log(K-1)}. \tag{29}$$

In the bandits games we have:

$$\begin{aligned}
&\mathrm{KL}(\mathbb{P}_0^n, \mathbb{P}_i^n) \\
&= \mathrm{KL}(\mathbb{P}_0^1, \mathbb{P}_i^1) + \sum_{t=2}^{n} \sum_{w_{t-1}} \mathbb{P}_0^{t-1}(w_{t-1}) \mathrm{KL}(\mathbb{P}_0^t(.|w_{t-1}), \mathbb{P}_i^t(.|w_{t-1})) \\
&= \mathrm{KL}(\mathbb{P}_0^1, \mathbb{P}_i^1) + \sum_{t=2}^{n} \sum_{w_{t-1}: Z_t=1, I_t=i} \mathbb{P}_0^{t-1}(w_{t-1}) \mathrm{KL}\left(\frac{1-\varepsilon}{2}, \frac{1+\varepsilon}{2}\right) \\
&= \mathrm{KL}\left(\frac{1-\varepsilon}{2}, \frac{1+\varepsilon}{2}\right) \mathbb{E}_0 \sum_{t=1}^{n} \mathbb{1}_{Z_t=1, I_t=i}.
\end{aligned}$$

Summing and plugging this into (27) we obtain for the bandits games:

$$\frac{1}{K} \sum_{i=1}^{K} \mathbb{P}_i(J_n = i) \leq \frac{1}{K} + \sqrt{\frac{m}{2K} \mathrm{KL}\left(\frac{1-\varepsilon}{2}, \frac{1+\varepsilon}{2}\right)}. \tag{30}$$

Note that with the same reasoning we obtain for the full information games:

$$\frac{1}{K} \sum_{i=1}^{K} \mathbb{P}_i(J_n = i) \leq \frac{1}{K} + \sqrt{\frac{m}{2} \mathrm{KL}\left(\frac{1-\varepsilon}{2}, \frac{1+\varepsilon}{2}\right)}. \tag{31}$$

Fourth step: Conclusion for deterministic forecasters.

To conclude the proof for deterministic forecaster one needs to plug in (29) (for the full information games with $K > 3$) or (31) (for the full information games with $K \in \{2, 3\}$) or (30) (for the bandits games) in (26) along with straightforward computations and the following simple formula:

$$\mathrm{KL}(p, q) \leq \frac{(p-q)^2}{q(1-q)}.$$

Fifth step: Fubini's theorem to handle non-deterministic forecasters.

Now let us consider a randomized forecaster. Denote by $\mathbb{E}_{reward,i}$ the expectation with respect to the reward generation process of the i^{th} adversary, $\mathbb{E}_{rand}$ the expectation with respect to the randomization of the forecaster and $\mathbb{E}_i$ the expectation with respect to both processes. Then one has (thanks to Fubini's Theorem),

$$\frac{1}{K} \sum_{i=1}^{K} \mathbb{E}_i \sum_{t=1}^{n} (g_{i,t} - g_{I_t,t}) = \mathbb{E}_{rand} \frac{1}{K} \sum_{i=1}^{K} \mathbb{E}_{reward,i} \sum_{t=1}^{n} (g_{i,t} - g_{I_t,t}).$$

Now remark that if we fix the realization of the forecaster's randomization then the results of the previous steps apply and in particular we can lower bound $\frac{1}{K} \sum_{i=1}^{K} \mathbb{E}_{reward,i} \sum_{t=1}^{n} (g_{i,t} - g_{I_t,t})$ as before. ■

Appendix C. Proofs

This section gathers the proofs that have not been provided so far.

C.1 Proof of Theorem 2 (page 2793)

The proof relies on combining Theorem 27 (page 2807) with Lemma 28 (page 2810) for $\gamma = 0$, and with Lemma 29 (page 2811) for $\gamma > 0$.

We make use of Theorem 27 and start with straightforward computations to bound the first sum in (25). We have $\psi^{-1}(x) = -\eta(x-\gamma/K)^{-1/q}$ which admits as a primitive $\int \psi^{-1}(u)du = \frac{-\eta}{1-1/q}(u-\gamma/K)^{1-1/q}$. Thus one immediately gets

$$\int_{p_{i,n+1}}^{1/K} (-\psi^{-1})(u)du \leq \frac{\eta}{1-1/q}\frac{1}{K^{1-1/q}} - \eta(p_{i,n+1}-\gamma/K)^{1-1/q}$$

and

$$p_{i,n+1}(-\psi^{-1})(p_{i,n+1}) = -\frac{\gamma}{K}\psi^{-1}(p_{i,n+1}) + \eta(p_{i,n+1}-\gamma/K)^{1-1/q}.$$

Summing over i proves that

$$-\sum_{i=1}^{K}\left(p_{i,n+1}\psi^{-1}(p_{i,n+1}) + \int_{p_{i,n+1}}^{1/K}\psi^{-1}(u)du\right) \leq \frac{q}{q-1}\eta K^{1/q} - \frac{\gamma}{K}\sum_{i=1}^{K}\psi^{-1}(p_{i,n+1}).$$

With the notations of Theorem 27, we need now to bound ρ and A_t. First we deal with the case $\gamma = 0$. Lemma 28 (page 2810) implies $\rho \leq \exp(B(q+1)/\eta)$ since we have $\frac{\psi''}{\psi'}(x) = \frac{q+1}{-x} = \frac{q+1}{\eta}\psi(x)^{1/q}$. The proof of (6) is concluded by $\psi' = \frac{q}{\eta}\psi^{(q+1)/q}$, and

$$A_t \leq B_t^2\sum_{i=1}^{K}\psi'\circ\psi^{-1}(p_{i,t}) = B_t^2\sum_{i=1}^{K}\frac{q}{\eta}p_{i,t}^{(q+1)/q} \leq \frac{q}{\eta}B_t^2.$$

For (7), the term A_t is controlled differently:

$$A_t \leq (1+\rho^2)\sum_{i=1}^{K}\psi'\circ\psi^{-1}(p_{i,t})v_{i,t}^2 = \frac{q}{\eta}(1+\rho^2)\sum_{i=1}^{K}p_{i,t}^{(q+1)/q}v_{i,t}^2 \leq \frac{qB}{\eta}(1+\rho^2)\sum_{i=1}^{K}p_{i,t}v_{i,t}.$$

Now we have already seen that $\rho \leq \exp(B(q+1)/\eta)$, hence $\rho^2(1+\rho^2) \leq 2\exp(8Bq/\eta)$, which leads to (7).

The case $\gamma > 0$ is more intricate. This is why we restrict ourselves to a specific form for the estimates $v_{i,t}$, see the assumption in Theorem 2. We start by using Lemma 29 (page 2811) to prove that $\rho \leq \mu$. First we have $\frac{\psi''}{\psi'} = \frac{q+1}{\eta}(\psi-\gamma/K)^{1/q} \leq \frac{q+1}{\eta}\psi^{1/q}$. Besides, for any $a \geq b \geq d$ we have $\frac{a}{b} \leq \frac{a-d}{b-d}$ and thus for any $x < 0$, we have

$$\frac{\psi\left(x+\frac{c}{\psi(x)}\right)}{\psi(x)} \leq \frac{\psi\left(x+\frac{c}{\psi(x)}\right)-\frac{\gamma}{K}}{\psi(x)-\frac{\gamma}{K}} = \left(1-\frac{c}{-x\psi(x)}\right)^{-q} \leq \left(1-\frac{c}{q\eta}\left(\frac{(q-1)K}{\gamma}\right)^{(q-1)/q}\right)^{-q}.$$

Thus Lemma 29 gives us

$$\rho^2 \leq \exp\left\{\frac{2(q+1)c}{\eta}\left(\frac{K}{\gamma}\right)^{(q-1)/q}\left(1-\frac{c}{q\eta}\left(\frac{(q-1)K}{\gamma}\right)^{(q-1)/q}\right)^{-q}\right\} = \mu.$$

Next we use $\psi' = \frac{q}{\eta}(\psi - \gamma/K)^{(q+1)/q}$ and the form of $v_{i,t}$ to get

$$A_t \leq (1+\rho^2)\sum_{i=1}^{K} \psi' \circ \psi^{-1}(p_{i,t}) v_{i,t}^2 \leq \frac{q(1+\mu)}{\eta} \sum_{i=1}^{K} p_{i,t}^{(q+1)/q} v_{i,t}^2 = \frac{q(1+\mu)}{\eta} p_{I_t,t}^{(1-q)/q} c_t^2.$$

Let $\zeta' = \frac{qc\mu(1+\mu)}{2\eta}$. From Theorem 27, we get

$$\begin{aligned}
C_n - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t} &\leq \frac{q}{q-1}\eta K^{1/q} + \gamma C_n + \frac{\rho^2}{2}\sum_{t=1}^{n} A_t - \frac{\gamma}{K}\sum_{t=1}^{n}\sum_{i=1}^{K} v_{i,t} \\
&\leq \frac{q}{q-1}\eta K^{1/q} + \gamma C_n + \sum_{t=1}^{n} c_t \left(\zeta' p_{I_t,t}^{(1-q)/q} - \frac{\gamma}{K p_{I_t,t}} \right) \\
&\leq \frac{q}{q-1}\eta K^{1/q} + \gamma C_n + \max_{u>0} \left(\zeta' u^{(1-q)/q} - \frac{\gamma}{Ku} \right) \sum_{t=1}^{n} c_t \\
&= \frac{q}{q-1}\eta K^{1/q} + \gamma C_n + \frac{\gamma}{(q-1)K} \left(\frac{(q-1)\zeta' K}{q\gamma} \right)^q \sum_{t=1}^{n} c_t \\
&= \frac{q}{q-1}\eta K^{1/q} + \gamma C_n + \gamma\zeta \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t}.
\end{aligned}$$

The proof of (8) is concluded by using Inequality (2).

C.2 Proof of Theorem 3 (page 2794)

We have

$$\begin{aligned}
\sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t} &= \sum_{t=1}^{n} \mathbb{E}_{k\sim p_t} v_{k,t} \\
&= \frac{1-\gamma}{\eta} \sum_{t=1}^{n} \left(\log \mathbb{E}_{i\sim q_t} \exp(\eta v_{i,t}) - \log \left[\exp\left(-\frac{\eta}{1-\gamma} \mathbb{E}_{k\sim p_t} v_{k,t} \right) \mathbb{E}_{i\sim q_t} \exp(\eta v_{i,t}) \right] \right) \\
&= \frac{1-\gamma}{\eta} \left(S - \sum_{t=1}^{n} \log(D_t) \right),
\end{aligned}$$

where

$$\begin{aligned}
S &= \sum_{t=1}^{n} \log \mathbb{E}_{i\sim q_t} \exp(\eta v_{i,t}) \\
&= \sum_{t=1}^{n} \log \left(\frac{\sum_{i=1}^{K} \exp(\eta V_{i,t})}{\sum_{i=1}^{K} \exp(\eta V_{i,t-1})} \right) = \log \left(\frac{\sum_{i=1}^{K} \exp(\eta V_{i,n})}{K} \right) \geq \eta \max_{1\leq i\leq K} V_{i,n} - \log K
\end{aligned}$$

and

$$D_t = \exp\left(-\frac{\eta}{1-\gamma} \mathbb{E}_{k\sim p_t} v_{k,t} \right) \mathbb{E}_{i\sim q_t} \exp(\eta v_{i,t})$$

When $\gamma = 0$, since $0 \leq v_{i,t} \leq B_t$, by applying Hoeffding's inequality, we get $\log(D_t) \leq \frac{\eta^2 B_t^2}{8}$, hence Inequality (9). For $\gamma = 0$, we can also use Lemma 35 and obtain $\log(D_t) \leq \eta^2 B \Theta(\eta B) \mathbb{E}_{i\sim p_t} v_{i,t}$,

hence Inequality (10). For γ satisfying (11), we have

$$\begin{aligned} D_t &\leq \exp\left(-\frac{\eta}{1-\gamma}\mathbb{E}_{k\sim p_t} v_{k,t}\right)\mathbb{E}_{i\sim q_t}\left(1+\eta v_{i,t}+\Theta(\eta B)\eta^2 v_{i,t}^2\right) \qquad (32)\\ &= \exp\left(-\frac{\eta}{1-\gamma}\mathbb{E}_{k\sim p_t} v_{k,t}\right)\left(1+\frac{\eta}{1-\gamma}\mathbb{E}_{i\sim p_t} v_{i,t}-\eta\frac{\gamma\sum_{i=1}^K v_{i,t}}{K(1-\gamma)}+\Theta(\eta B)\eta^2\mathbb{E}_{i\sim q_t} v_{i,t}^2\right)\\ &\leq \exp\left(-\frac{\eta}{1-\gamma}\mathbb{E}_{k\sim p_t} v_{k,t}\right)\left(1+\frac{\eta}{1-\gamma}\mathbb{E}_{i\sim p_t} v_{i,t}\right) \qquad (33)\\ &\leq 1. \end{aligned}$$

To get (32), we used that Θ is an increasing function and that $\eta v_{i,t}\leq \eta B$. To get (33), we noticed that it is trivial when $\max_{i,t} p_{i,t}v_{i,t}=0$, and that otherwise, we have

$$\frac{\gamma\sum_{i=1}^K v_{i,t}}{K(1-\gamma)}\geq\frac{\gamma\sum_{i=1}^K p_{i,t}v_{i,t}^2}{K(1-\gamma)\max_{i,t} p_{i,t}v_{i,t}}\geq\frac{\gamma}{K\max_{i,t} p_{i,t}v_{i,t}}\mathbb{E}_{i\sim q_t} v_{i,t}^2\geq\eta\Theta(\eta B)\mathbb{E}_{i\sim q_t} v_{i,t}^2,$$

where the last inequality uses (11). We have thus proved

$$\sum_{t=1}^n\sum_{i=1}^K p_{i,t}v_{i,t}\geq\frac{1-\gamma}{\eta}\log\mathbb{E}_{i\sim p_1}\exp(\eta V_{i,n})\geq(1-\gamma)\left(\max_{1\leq i\leq K} V_{i,n}-\frac{\log K}{\eta}\right),$$

hence the announced result.

C.3 Recovering Theorem 3 from Theorem 27

We start with straightforward computations to bound the first sum in (25). We have $\psi^{-1}(x)=\frac{1}{\eta}\log(x-\gamma/K)$ which admits as a primitive $\int\psi^{-1}(u)du=\frac{1}{\eta}\left[(u-\gamma/K)\log(u-\gamma/K)-u\right]$. Thus one immediately gets

$$\begin{aligned} &-\int_{p_{i,n+1}}^{1/K}\psi^{-1}(u)du-p_{i,n+1}\psi^{-1}(p_{i,n+1})\\ &\qquad=\frac{1}{\eta}\left(\frac{1}{K}-\frac{1-\gamma}{K}\log\left(\frac{1-\gamma}{K}\right)-p_{i,n+1}-\frac{\gamma}{K}\log\left(p_{i,n+1}-\frac{\gamma}{K}\right)\right). \end{aligned}$$

Summing over i proves that

$$-\sum_{i=1}^K\left(p_{i,n+1}\psi^{-1}(p_{i,n+1})+\int_{p_{i,n+1}}^{1/K}\psi^{-1}(u)du\right)=\frac{1-\gamma}{\eta}\log\left(\frac{K}{1-\gamma}\right)-\frac{\gamma}{K}\sum_{i=1}^K\psi^{-1}(p_{i,n+1}).$$

With the notations of Theorem 27, we need now to bound ρ and A_t. For the former, we use Lemma 28 (page 2810) which directly shows $\rho\leq\exp(\eta B)$. For the latter we distinguish two cases. If $\gamma=0$ we use

$$A_t\leq B_t^2\sum_{i=1}^K\psi'\circ\psi^{-1}(p_{i,t})=\eta B_t^2,$$

which concludes the proof of the weakened version of (9) with $\frac{\eta}{8}$ replaced by $\frac{\eta}{2}\exp(2\eta B)$. On the other hand if $\gamma>0$ we use

$$A_t\leq(1+\rho^2)\sum_{i=1}^K\psi'\circ\psi^{-1}(p_{i,t})v_{i,t}^2\leq(1+\rho^2)\eta\sum_{i=1}^K p_{i,t}v_{i,t}^2.$$

From Theorem 27, when the weakened version of (11) holds, that is when

$$\gamma \geq K \frac{\eta \exp(2B\eta)\,[1+\exp(2B\eta)]}{2} \max_{i,t} p_{i,t} v_{i,t},$$

we have

$$\begin{aligned}
&C_n - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t} \\
&\leq \frac{1-\gamma}{\eta}\log\left(\frac{K}{1-\gamma}\right) - \frac{\gamma}{K}\sum_{t=1}^{K}\left(\sum_{t=1}^{n} v_{i,t} - C_n\right) + \frac{\eta\exp(2B\eta)\,[1+\exp(2B\eta)]}{2}\sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t}^2 \\
&\leq \frac{1-\gamma}{\eta}\log\left(\frac{K}{1-\gamma}\right) + \gamma C_n,
\end{aligned}$$

hence

$$(1-\gamma)\left(C_n + \frac{\log(1-\gamma)}{\eta}\right) - \sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t} v_{i,t} \leq (1-\gamma)\frac{\log K}{\eta}.$$

This gives the desired result since we have

$$C_n + \frac{\log(1-\gamma)}{\eta} = \frac{1}{\eta}\log\left(\sum_{j=1}^{K}\exp(\eta V_{i,n})\right) \geq \max_{1\leq i\leq K} V_{i,n}.$$

C.4 Proof of Theorem 8 (page 2797)

We will use the following version of Bernstein's inequality for martingales.

Theorem 31 *Let $\mathcal{F}_1 \subset \cdots \subset \mathcal{F}_n$ be a filtration, and $X_1, \ldots, X_n$ random variables such that $|X_t| \leq b$ for some $b > 0$, X_t is $\mathcal{F}_t$-measurable, $\mathbb{E}(X_t|\mathcal{F}_{t-1}) = 0$ and $\mathbb{E}(X_t^2|\mathcal{F}_{t-1}) \leq v$ for some $v > 0$. Then, for any $t > 0$, we have*

$$\mathbb{P}\Big(\sum_{t=1}^{n} X_t \geq t\Big) \leq \exp\left(-\frac{t^2}{2nv + 2bt/3}\right), \tag{34}$$

and for any $\delta > 0$, with probability at least $1-\delta$, we have

$$\sum_{t=1}^{n} X_t \leq \sqrt{2nv\log(\delta^{-1})} + \frac{b\log(\delta^{-1})}{3}.$$

Proof of Theorem 31 Both inequalities come from Result (1.6) of Freedman (1975). The first inequality then uses $(1+x)\log(1+x) - x \geq \frac{x^2}{2+2x/3}$, while the other uses Inequality (45) of Audibert et al. (2009). This last inequality allows to remove the $\sqrt{2}$ factor appearing in Lemma A.8 of Cesa-Bianchi and Lugosi (2006). ■

We start the proof of Theorem 8 by noting that, since $R_n \leq n$, the result is trivial for $\delta \leq 2K\exp(-m/27)$ so that we assume hereafter that $\delta \geq 2K\exp(-m/27)$, or equivalently $\frac{\log(2K\delta^{-1})}{m} \leq \frac{1}{27}$. We consider the event $\mathcal{E}$ on which we simultaneously have

$$\sum_{t=1}^{n} Z_t \leq m, \tag{35}$$

$$-\sum_{t=1}^{n} g_{I_t,t} \leq -\sum_{t=1}^{n}\sum_{k=1}^{K} p_{k,t} g_{k,t} + \sqrt{\frac{n\log(4\delta^{-1})}{2}}, \tag{36}$$

and

$$\max_{1\leq i\leq K} \sum_{t=1}^{n} \left(g_{i,t} - \frac{\eta}{8\varepsilon} - \sum_{k=1}^{K} p_{k,t} g_{k,t}\right)\left(1 - \frac{Z_t}{\varepsilon}\right) \leq 2\sqrt{\frac{n\log(2K\delta^{-1})}{\varepsilon}} + \frac{\log(2K\delta^{-1})}{2\varepsilon}. \tag{37}$$

Let us first prove that this event holds with probability at least $1-\delta$. From (34), we have

$$\mathbb{P}\left(\sum_{t=1}^{n} Z_t > m\right) \leq \exp\left(-\frac{m^2/16}{3m/2+m/6}\right) \leq \exp\left(-\frac{m}{27}\right) \leq \frac{\delta}{4}$$

So (35) holds with probability at least $1-\delta/4$. From the concentration of martingales with bounded differences (Hoeffding, 1963; Azuma, 1967), (36) holds with probability at least $1-\delta/4$. For $\eta/(8\varepsilon) \leq \sqrt{2}-1$ (which is true for our particular η), we can apply Theorem 31 with $b = \sqrt{2}/\varepsilon$ and $v = 2/\varepsilon$ to the random variables $\left(g_{i,t} - \frac{\eta}{8\varepsilon} - \sum_{k=1}^{K} p_{k,t} g_{k,t}\right)\left(1 - \frac{Z_t}{\varepsilon}\right)$. We get that for a fixed $i \in \{1,\dots,K\}$, with probability at least $1-\delta/(2K)$, we have

$$\sum_{t=1}^{n} \left(g_{i,t} - \frac{\eta}{8\varepsilon} - \sum_{k=1}^{K} p_{k,t} g_{k,t}\right)\left(1 - \frac{Z_t}{\varepsilon}\right) \leq 2\sqrt{\frac{n\log(2K\delta^{-1})}{\varepsilon}} + \frac{\log(2K\delta^{-1})}{2\varepsilon}.$$

From a union bound, we get that (37) holds with probability at least $1-\delta/2$. Using again a union bound, we thus have proved that the event $\mathcal{E}$ holds with probability at least $1-\delta$.

Now, on the event $\mathcal{E}$, by combining (36) and (37), we obtain

$$\begin{aligned}
R_n = \max_{1\leq i\leq K} \sum_{t=1}^{n} g_{i,t} - \sum_{t=1}^{n} g_{I_t,t} &\leq \sqrt{\frac{n\log(4\delta^{-1})}{2}} + \max_{1\leq i\leq K} \sum_{t=1}^{n} g_{i,t} - \sum_{t=1}^{n}\sum_{k=1}^{K} p_{k,t} g_{k,t} \\
&\leq \sqrt{\frac{n\log(4\delta^{-1})}{2}} + \max_{1\leq i\leq K} \sum_{t=1}^{n} g_{i,t}\frac{Z_t}{\varepsilon} - \sum_{t=1}^{n}\sum_{k=1}^{K} p_{k,t} g_{k,t}\frac{Z_t}{\varepsilon} \\
&\quad + \sum_{t=1}^{n} \frac{\eta}{8\varepsilon}\left(1 - \frac{Z_t}{\varepsilon}\right) + 2\sqrt{\frac{n\log(2K\delta^{-1})}{\varepsilon}} + \frac{\log(2K\delta^{-1})}{2\varepsilon}
\end{aligned}$$

Since we have $\sum_{t=1}^{n} Z_t \leq m$, the rewards received by the forecaster are equal to the rewards which would receive the forecaster that uses Z_t to decide whether he asks for the gains or not, whatever $\sum_{s=1}^{t-1} Z_s$ is. This enables us to use (9) (which holds with probability one). We obtain

$$\begin{aligned}
R_n &\leq \sqrt{\frac{n\log(4\delta^{-1})}{2}} + \frac{\log K}{\eta} + \frac{n\eta}{8\varepsilon} + 2\sqrt{\frac{n\log(2K\delta^{-1})}{\varepsilon}} + \frac{\log(2K\delta^{-1})}{2\varepsilon} \\
&\leq \sqrt{\frac{n\log(4\delta^{-1})}{2}} + \frac{\log K}{\eta} + \frac{n^2\eta}{6m} + 4n\sqrt{\frac{\log(2K\delta^{-1})}{3m}} + \frac{2n\log(2K\delta^{-1})}{3m}.
\end{aligned}$$

From the inequalities $m \leq n$, $K \geq 2$ and $\frac{\log(2K\delta^{-1})}{m} \leq \frac{1}{27}$, this implies

$$R_n \leq \frac{10n}{3}\sqrt{\frac{\log(2K\delta^{-1})}{m}} + \frac{\log K}{\eta} + \frac{\eta n^2}{6m}.$$

The first inequality of the theorem is then obtained by plugging $\eta = \frac{\sqrt{m\log K}}{n}$. The second inequality is derived by integrating the deviations using the standard formula $\mathbb{E}W \leq \int_0^1 \frac{1}{\delta}\mathbb{P}(W > \log(\delta^{-1}))d\delta$.

C.5 Proof of Theorem 9 (page 2797)

The proof goes exactly like for Theorem 8. We just use (6) instead of (9).

C.6 Proof of Theorem 12 (page 2799)

The bound is trivial for $9K\log(3K) \geq n$. So we consider hereafter that $\gamma = 2\sqrt{\frac{K\log(3K)}{n}} < \frac{2}{3}$. The result is then a direct consequence of Theorem 21 with $G_0 = n$. The inequality on $\mathbb{E}R_n$ comes by integrating the deviations.

C.7 Proof of Theorem 13 (page 2800)

First note that (16) holds for $9\sqrt{nK} \geq n$ since we trivially have $R_n \leq n$. For $9\sqrt{nK} < n$, we apply (18) with $G_0 = n > 81K$, and obtain $R_n \leq 8.5\sqrt{nK} + \sqrt{2nK}\log(\delta^{-1})$. This implies (16) and also (17) by using Proposition 33.

For the last assertions, we proceed similarly. They trivially hold for $9\sqrt{nK\log(3K)} \geq n$. For $n > 9\sqrt{nK\log(3K)}$, we apply Theorem 20 with $G_0 = n$, and obtain

$$R_n \leq \frac{9}{2}\sqrt{nK\log(3K)} + 4\sqrt{\frac{nK}{\log(3K)}} + \sqrt{\frac{2nK}{\log(3K)}}\log(K\delta^{-1}).$$

By using $\frac{1}{\sqrt{\log(3K)}} \leq \frac{1}{\log(6)}\sqrt{\log(3K)}$, this independently implies

$$R_n \leq 9\sqrt{nK\log(3K)} + \sqrt{\frac{2nK}{\log(3K)}}\log(\delta^{-1}),$$

and by integration,

$$\mathbb{E}R_n \leq 9\sqrt{nK\log(3K)},$$

hence the desired inequalities.

C.8 Proof of Theorem 17 (page 2802)

The proof follows the scheme described in Section 5.1.2. In particular let

$$\nu = \frac{\gamma\varepsilon}{\beta K} + \frac{1}{\log\left(1 - \frac{\beta K}{\gamma\varepsilon}\right)}.$$

Then we have

$$\begin{aligned}
-\sum_{i=1}^{K} p_{i,t} v_{i,t} &= Z_t \frac{p_{I_t,t}}{\beta}\log\left(1 - \frac{\beta g_{I_t,t}}{\varepsilon p_{I_t,t}}\right) \\
&\geq Z_t\left(-\frac{g_{I_t,t}}{\varepsilon} + \frac{\nu g_{I_t,t}}{\varepsilon}\log\left(1 - \frac{\beta g_{I_t,t}}{\varepsilon p_{I_t,t}}\right)\right) \\
&\geq -g_{I_t,t}\frac{Z_t}{\varepsilon} - \frac{\nu\beta}{\varepsilon}\sum_{i=1}^{K} v_{i,t}.
\end{aligned}$$

Moreover with a simple application of Theorem 31 we have that with probability at least $1-\delta$,

$$-\sum_{t=1}^{n} g_{I_t,t} \leq -\sum_{t=1}^{n} g_{I_t,t}\frac{Z_t}{\varepsilon} + \sqrt{\frac{2n\log\delta^{-1}}{\varepsilon}} + \frac{\log\delta^{-1}}{3\varepsilon}.$$

Now note that the sequence $W_t = \exp\big(\beta G_{i,t} - \beta V_{i,t}\big)$, $t = 1,\dots,n$, is a supermartingale over the filtration generated by $(g_t, I_t, Z_t), t = 1,\dots,n$. Indeed, we have for any $t \in \{1,\dots,n\}$,

$$\mathbb{E}_{I_t\sim p_t, Z_t} \exp(-\beta v_{i,t}) = 1-\varepsilon+\varepsilon\left(1-\frac{\beta g_{i,t}}{\varepsilon}\right) = 1-\beta g_{i,t} \leq \exp(-\beta g_{i,t}).$$

Thus, with probability at least $1-\delta$, we have against deterministic adversaries

$$\max_{1\leq i\leq K} V_{i,n} \geq G_{\max} - \frac{\log\delta^{-1}}{\beta},$$

and against general adversaries

$$\max_{1\leq i\leq K} V_{i,n} \geq G_{\max} - \frac{\log(K\delta^{-1})}{\beta}.$$

Now we apply (8) of Theorem 2. Let $c = -\frac{\gamma}{\beta K}\log\big(1-\frac{\beta K}{\gamma\varepsilon}\big)$. If $c < q\eta\big(\frac{\gamma}{(q-1)K}\big)^{(q-1)/q}$ then we have

$$(1-\gamma)\left(\max_{1\leq i\leq K} V_{i,n}\right) - (1+\gamma\zeta)\sum_{t=1}^{n}\sum_{i=1}^{K} p_{i,t}v_{i,t} \leq \frac{q}{q-1}\eta K^{\frac{1}{q}},$$

where

$$\zeta = \frac{1}{(q-1)K}\Big(\frac{(q-1)cK\mu(1+\mu)}{2\gamma\eta}\Big)^q,$$

with

$$\mu = \exp\left\{\frac{2(q+1)c}{\eta}\left(\frac{K}{\gamma}\right)^{(q-1)/q}\left(1-\frac{c}{q\eta}\left(\frac{(q-1)K}{\gamma}\right)^{(q-1)/q}\right)^{-q}\right\}.$$

Thus, in the case of a deterministic adversaries, we obtain

$$\begin{aligned}
&G_{\max} - \sum_{t=1}^{n} g_{I_t,t} \\
&\leq \big(\gamma(1+\zeta) + \frac{\nu\beta K}{\varepsilon}\big)n + \frac{q}{q-1}\eta K^{\frac{1}{q}} + \frac{\log(2\delta^{-1})}{\beta} + n\sqrt{\frac{2\log(2\delta^{-1})}{m}} + n\frac{\log(2\delta^{-1})}{3m} \\
&= \frac{n}{m}\left(\big(\gamma(1+\zeta)+\nu\beta' K\big)m + \frac{q}{q-1}\eta' K^{\frac{1}{q}} + \frac{\log(2\delta^{-1})}{\beta'}\right) + n\sqrt{\frac{2\log(2\delta^{-1})}{m}} + n\frac{\log(2\delta^{-1})}{3m}, \quad (38)
\end{aligned}$$

where $\beta' = \beta/\varepsilon$ and $\eta' = \eta\varepsilon$. One can see that the term into parenthesis in (38) is exactly the same than the right hand side of (43), up to the relabelling of β and η into β' and η'. This allows us to use the same numerical application as in Section C.9 (up to the additional terms outside of the parenthesis in (43)). One can apply the same technique in the case of a general adversary.

C.9 Proof of Theorem 18, Corollary 19 and Theorem 20 (page 2803)

Consider parameters $q > 1$, $0 < \gamma < 1$, $\eta > 0$ and $\beta > 0$ such that $\beta K < \gamma$ and such that the real number $c = -\frac{\gamma}{\beta K}\log\left(1 - \frac{\beta K}{\gamma}\right)$ satisfies $c < q\eta\left(\frac{\gamma}{(q-1)K}\right)^{(q-1)/q}$. From (8) of Theorem 2, since we have $v_{i,t} = \frac{c_t}{p_{i,t}}\mathbb{I}_{I_t=i}$ with $c_t = -\frac{p_{i,t}}{\beta}\log\left(1 - \frac{\beta g_{i,t}}{p_{i,t}}\right) \le -\frac{\gamma}{\beta K}\log\left(1 - \frac{\beta K}{\gamma}\right) = c$, we have

$$(1-\gamma)\left(\max_{1\le i\le K} V_{i,n}\right) + \frac{1+\gamma\zeta}{\beta}\sum_{t=1}^{n} p_{I_t,t}\log\left(1 - \frac{\beta g_{I_t,t}}{p_{I_t,t}}\right) \le \frac{q}{q-1}\eta K^{\frac{1}{q}}, \tag{39}$$

where

$$\zeta = \frac{1}{(q-1)K}\left(\frac{(q-1)cK\mu(1+\mu)}{2\gamma\eta}\right)^{q},$$

with

$$\mu = \exp\left\{\frac{2(q+1)c}{\eta}\left(\frac{K}{\gamma}\right)^{(q-1)/q}\left(1 - \frac{c}{q\eta}\left(\frac{(q-1)K}{\gamma}\right)^{(q-1)/q}\right)^{-q}\right\}.$$

Let

$$\nu = \frac{\gamma}{\beta K} + \frac{1}{\log(1-\beta K/\gamma)}.$$

The function $x \mapsto \frac{1}{x} + \frac{1}{\log(1-x)}$ is increasing on $(0, +\infty)$. So we have

$$\frac{1}{\log(1 - \beta g_{I_t,t}/p_{I_t,t})} + \frac{p_{I_t,t}}{\beta g_{I_t,t}} \le \nu,$$

hence

$$\frac{p_{I_t,t}}{\beta}\log\left(1 - \frac{\beta g_{I_t,t}}{p_{I_t,t}}\right) \ge -g_{I_t,t} + \nu g_{I_t,t}\log\left(1 - \frac{\beta g_{I_t,t}}{p_{I_t,t}}\right) \ge -g_{I_t,t} - \nu\beta\sum_{i=1}^{K} v_{i,t}. \tag{40}$$

Inequality (39) thus implies

$$(1-\gamma)\left(\max_{1\le i\le K} V_{i,n}\right) - (1+\gamma\zeta)\sum_{t=1}^{n} g_{I_t,t} - (1+\gamma\zeta)\nu\beta\sum_{i=1}^{K} V_{i,n} \le \frac{q}{q-1}\eta K^{\frac{1}{q}},$$

which leads to

$$\left(1 - \gamma - (1+\gamma\zeta)\nu\beta K\right)\left(\max_{1\le i\le K} V_{i,n}\right) - (1+\gamma\zeta)\sum_{t=1}^{n} g_{I_t,t} \le \frac{q}{q-1}\eta K^{\frac{1}{q}}, \tag{41}$$

We now provide a high probability lower bound of the left-hand side. The technical tool (essentially deviation inequalities for supermartingales) comes from Section 6.8 of Cesa-Bianchi and Lugosi (2006).

For any $t \in \{1, \dots, n\}$, we have

$$\mathbb{E}_{I_t\sim p_t}\exp(-\beta v_{i,t}) = \mathbb{E}_{I_t\sim p_t}\exp\left\{\log\left(1 - \frac{\beta g_{i,t}}{p_{i,t}}\right)\mathbb{I}_{I_t=i}\right\} = 1 - \beta g_{i,t} \le \exp(-\beta g_{i,t}).$$

This implies that the sequence $W_t = \exp\left(\beta G_{i,t} - \beta V_{i,t}\right)$, $t = 1, \dots, n$, forms a supermartingale over the filtration generated by (g_t, I_t), $t = 1, \dots, n$. Indeed, we have

$$\mathbb{E}\left(\exp(W_t)|(g_s, I_s), s = 1, \dots, t-1\right) = \mathbb{E}_{g_t|(g_s,I_s),s=1,\dots,t-1}\mathbb{E}_{I_t\sim p_t}\exp(W_t) \le \exp(W_{t-1}).$$

So, we have $\mathbb{E}\exp(W_n) \leq \mathbb{E}\exp(W_1) \leq 1$, which implies that with probability at least $1-\delta$, $V_{i,n} \geq G_{i,n} - \frac{\log(\delta^{-1})}{\beta}$ with probability at least $1-\delta$. So, for any fixed $k \in \{1,\dots,K\}$, we have

$$\max_{1\leq i\leq K} V_{i,n} \geq G_{k,n} - \frac{\log(\delta^{-1})}{\beta}. \tag{42}$$

Combining (41) and (42), we obtain that for any $\delta > 0$ and any fixed $k \in \{1,\dots,K\}$, with probability at least $1-\delta$, we have

$$\big(1-\gamma-(1+\gamma\zeta)\nu\beta K\big)G_{k,n} - (1+\gamma\zeta)\sum_{t=1}^{n} g_{I_t,t} \leq \frac{q}{q-1}\eta K^{\frac{1}{q}} + \frac{\log(\delta^{-1})}{\beta},$$

hence

$$G_{k,n} - \sum_{t=1}^{n} g_{I_t,t} \leq \big(\gamma(1+\zeta)+\nu\beta K\big)G_{k,n} + \frac{q}{q-1}\eta K^{\frac{1}{q}} + \frac{\log(\delta^{-1})}{\beta}. \tag{43}$$

Now, for $G_0 \geq 81K$, let us take

$$q = 2, \quad \gamma = 3\sqrt{\frac{K}{G_0}}, \quad \beta = \frac{1}{\sqrt{2KG_0}}, \quad \text{and} \quad \eta = 2\sqrt{G_0}.$$

Then we have $c \approx 1.14$, $\nu \approx 0.522$, $\mu \leq 2.09$, $\zeta \leq 0.377$, and

$$G_{k,n} - \sum_{t=1}^{n} g_{I_t,t} \leq 4.5\sqrt{K\frac{G_{\max}^2}{G_0}} + 4\sqrt{KG_0} + \sqrt{2KG_0}\log(\delta^{-1}). \tag{44}$$

For deterministic adversaries, the arm achieving a cumulative reward equal to $G_{\max}$ is deterministic (it does not depend on the randomization of the forecaster). So, we may take k equal to this fixed arm, and obtain (18).

To prove the inequality for a fully oblivious adversary, let us take $k \in \operatorname{argmax}_{i\in\{1,\dots,K\}} \mathbb{E}G_{i,n}$. From (44) which holds with probability at least $1-\delta$, it suffices to prove that with probability at least $1-\delta$, we have $G_{k,n} \geq G_{\max} - \sqrt{8\log(K\delta^{-1})G_{\max}}$. Let $\lambda > 0$. Since the reward vectors $g_1,\dots,g_n$ are independent, and from the inequality $\exp(\lambda x) \leq 1 + [\exp(\lambda)-1]x$ for any $x \in [0,1]$ (by convexity of the exponential function), for any $j \neq k$, from Lemma 35, we have

$$\mathbb{E}\exp(\lambda G_{j,n}) = \prod_{t=1}^{n}\mathbb{E}\exp(\lambda g_{j,t}) \leq \prod_{t=1}^{n}\exp\big[\big(\exp(\lambda)-1\big)\mathbb{E}g_{j,t}\big] = \exp\big[\big(\exp(\lambda)-1\big)\mathbb{E}G_{j,n}\big],$$

and

$$\begin{aligned}
\mathbb{E}\exp(-\lambda G_{k,n}) &= \prod_{t=1}^{n}\mathbb{E}\exp(-\lambda g_{k,t}) \\
&\leq \prod_{t=1}^{n}\mathbb{E}\left(1-\lambda g_{k,t}+\frac{1}{2}\lambda^2 g_{k,t}^2\right) \\
&\leq \prod_{t=1}^{n}\left(1-\lambda\Big(1-\frac{\lambda}{2}\Big)\mathbb{E}g_{k,t}\right) \\
&\leq \prod_{t=1}^{n}\exp\left[-\lambda\Big(1-\frac{\lambda}{2}\Big)\mathbb{E}g_{k,t}\right] = \exp\left[-\lambda\Big(1-\frac{\lambda}{2}\Big)\mathbb{E}G_{k,n}\right].
\end{aligned}$$

This implies respectively that for any $j \neq k$, with probability at least $1-\delta$,

$$G_{j,n} \leq \mathbb{E}G_{j,n} + \lambda\Theta(\lambda)\mathbb{E}G_{j,n} + \frac{\log(\delta^{-1})}{\lambda},$$

and with probability at least $1-\delta$,

$$\mathbb{E}G_{k,n} \leq G_{k,n} + \frac{\lambda}{2}\mathbb{E}G_{k,n} + \frac{\log(\delta^{-1})}{\lambda}.$$

By optimizing the free parameter λ (using Lemma 32 below), and from a union bound, with probability at least $1-\delta$, we simultaneously have

$$G_{j,n} \leq \mathbb{E}G_{j,n} + \sqrt{2\mathbb{E}G_{j,n}\log(K\delta^{-1})} + \frac{\log(K\delta^{-1})}{3},$$

and

$$\mathbb{E}G_{k,n} \leq G_{k,n} + \sqrt{2\mathbb{E}G_{k,n}\log(K\delta^{-1})}.$$

Since we have $\mathbb{E}G_{k,n} \geq \mathbb{E}G_{j,n}$, we get consecutively $G_{k,n} \geq \mathbb{E}G_{j,n} - \sqrt{2\mathbb{E}G_{j,n}\log(K\delta^{-1})}$, and after computations, $G_{k,n} \geq G_{j,n} - \sqrt{8G_{j,n}\log(K\delta^{-1})}$ for any $j \neq k$. With probability at least $1-\delta$, we thus have $G_{k,n} \geq G_{\max} - \sqrt{8\log(K\delta^{-1})G_{\max}}$, which concludes the proof of (19).

To prove Corollary 19, first note that (20) holds for $9\sqrt{KG_{\max}} \geq G_{\max}$ since we trivially have $R_n \leq G_{\max}$. For $9\sqrt{KG_{\max}} < G_{\max}$, we may apply Theorem 18 with $G_0 = G_{\max}$ since $G_{\max} > 81K$, and obtain $R_n \leq 8.5\sqrt{KG_{\max}} + \sqrt{2KG_{\max}}\log(\delta^{-1})$. This implies (20) and (21).

Lemma 32 *Let* $\Theta(\lambda) = \frac{\exp(\lambda)-1-\lambda}{\lambda^2}$. *For any* $A > 0$, $\inf_{\lambda>0}\left\{\lambda\Theta(\lambda) + \frac{A^2}{2\lambda}\right\} \leq A + A^2/6$.

Proof Considering $\lambda = \log(1+A)$, we have $\inf_{\lambda>0}\left\{\lambda\Theta(\lambda) + \frac{A^2}{2\lambda}\right\} \leq \log(1+A)\Theta[\log(1+A)] + \frac{A^2}{2\log(1+A)} = A + \frac{A^2}{6} - \frac{1+A+\frac{A^2}{6}}{\log(1+A)}\Phi(A)$ where $\Phi(A) \triangleq \log(1+A) - \frac{A+\frac{A^2}{2}}{1+A+\frac{A^2}{6}}$. Since $\Phi(0) = 0$ and $\Phi'(A) = \frac{A^4}{36(1+A)(1+A+A^2/6)^2} \geq 0$, we get $\Phi(A) \geq 0$, hence the result. ■

To prove Theorem 20, we replace (42), which holds with probability at least $1-\delta$, by

$$\max_{1\leq i\leq K} V_{i,n} \geq G_{\max} - \frac{\log(\delta^{-1})}{\beta},$$

which, by a union bound, holds with probability at least $1-K\delta$. (It is this union bound that makes the $\log K$ factor appears in the bound.) This leads to the following modified version of (43): with probability $1-K\delta$,

$$G_{\max} - \sum_{t=1}^{n} g_{I_t,t} \leq \big(\gamma(1+\zeta) + \nu\beta K\big)G_{\max} + \frac{q}{q-1}\eta K^{\frac{1}{q}} + \frac{\log(\delta^{-1})}{\beta}.$$

Now, for $G_0 \geq 81K\log(3K)$, let us take $q = 2$,

$$\gamma = 3\sqrt{\frac{K\log(3K)}{G_0}}, \quad \beta = \sqrt{\frac{\log(3K)}{2KG_0}}, \quad \text{and} \quad \eta = 2\sqrt{\frac{G_0}{\log(3K)}}.$$

Then we have $c \approx 1.14, \nu \approx 0.522, \mu \leq 2.09, \zeta \leq 0.377$, and

$$G_{\max} - \sum_{t=1}^{n} g_{I_t,t} \leq 4.5\sqrt{\frac{G_{\max}^2}{G_0} K \log(3K)} + 4\sqrt{\frac{KG_0}{\log(3K)}} + \sqrt{\frac{2KG_0}{\log(3K)}} \log(\delta^{-1}).$$

This inequality holds with probability at least $1 - K\delta$. This implies the result of Theorem 20.

C.10 Proof of Theorem 21 (page 2803)

Consider parameters $q > 1, 0 < \gamma < 1, \eta > 0$ and $\beta > 0$ such that $\beta K < \gamma$. Introduce $c = -\frac{\gamma}{\beta K} \log\left(1 - \frac{\beta K}{\gamma}\right)$. We have $\max_{i,t} p_{i,t} v_{i,t} \leq c$. So (11) holds as soon as

$$\gamma \geq K\eta c \Theta\left(-\frac{\eta}{\beta} \log\left(1 - \frac{\beta K}{\gamma}\right)\right). \tag{45}$$

From (12) and as in the proof of Theorem 13, by using (40) with $\nu = \frac{\gamma}{\beta K} + \frac{1}{\log(1-\beta K/\gamma)}$, we obtain

$$(1-\gamma)\left(\max_{1 \leq i \leq K} V_{i,n}\right) - \sum_{t=1}^{n} g_{I_t,t} - \nu\beta \sum_{i=1}^{K} V_{i,n} \leq (1-\gamma)\frac{\log K}{\eta},$$

hence

$$(1 - \gamma - \nu\beta K)\left(\max_{1 \leq i \leq K} V_{i,t}\right) - \sum_{t=1}^{n} g_{I_t,t} \leq (1-\gamma)\frac{\log K}{\eta}.$$

From the same argument as in the proof of Theorem 18, for any $i \in \{1, \ldots, K\}$, we have $\mathbb{E}\exp\left(\beta G_{i,n} - \beta V_{i,n}\right) \leq 1$, and for any $\delta > 0$, $V_{i,n} \geq G_{i,n} - \frac{\log(\delta^{-1})}{\beta}$ holds with probability at least $1 - \delta$. By a union bound, we get that with probability at least $1 - K\delta$,

$$\max_{1 \leq i \leq K} V_{i,n} \geq G_{\max} - \frac{\log(\delta^{-1})}{\beta}.$$

With probability at least $1 - \delta$, we thus have

$$G_{\max} - \sum_{t=1}^{n} g_{I_t,t} \leq (\gamma + \nu\beta K) G_{\max} + \frac{\log(K\delta^{-1})}{\beta} + \frac{\log K}{\eta}.$$

This inequality holds for any parameters $q > 1, 0 < \gamma < 1, \eta > 0$ and $\beta > 0$ such that the inequality $\beta K < \gamma$ and (45) hold. We choose

$$\gamma = 2\sqrt{\frac{K\log(3K)}{G_0}}, \quad \beta = \sqrt{\frac{\log(3K)}{2KG_0}}, \quad \text{and} \quad \eta = 2\sqrt{\frac{\log(3K)}{KG_0}},$$

which gives $c \approx 1.23, \nu \approx 0.536$, and

$$G_{\max} - \sum_{t=1}^{n} g_{I_t,t} \leq \frac{5}{2}\sqrt{\frac{G_{\max}^2}{G_0} K \log(3K)} + \sqrt{\frac{2KG_0}{\log(3K)}} \log(K\delta^{-1}) + \frac{1}{2}\sqrt{KG_0 \log(3K)}.$$

C.11 Proof of Theorem 22 (page 2804)

Consider parameters $0 < \gamma < 1$, $\eta > 0$ and $\beta > 0$. We have $\max_{i,t} p_{i,t} v_{i,t} \leq 1 + \frac{\beta K}{\gamma}$ and $\max_{i,t} v_{i,t} \leq (1+\beta)\frac{K}{\gamma}$. So (11) holds as soon as

$$\gamma \geq K\eta\Big(1 + \frac{\beta K}{\gamma}\Big)\Theta\bigg(\frac{\eta(1+\beta)K}{\gamma}\bigg). \tag{46}$$

Then, from (12), we have

$$(1-\gamma)\bigg(\max_{1\leq i\leq K} V_{i,n}\bigg) - \sum_{t=1}^{n} g_{I_t,t} - \beta nK \leq (1-\gamma)\frac{\log K}{\eta}.$$

Let $\xi_t = \max_{1\leq i\leq K} V_{i,t} - \min_{1\leq j\leq K} V_{j,t}$ and $\xi = \max_{1\leq t\leq n} \xi_t$. Consider a fixed switching strategy $(i_1,\ldots,i_n) \in \{1,\ldots,K\}^n$, and let $V_{(i_1,\ldots,i_n)} = \sum_{t=1}^{n} v_{i_t,t}$. One can easily check that $\max\limits_{1\leq i\leq K} V_{i,n} \geq V_{(i_1,\ldots,i_n)} - \xi\mathcal{S}(i_1,\ldots,i_n)$, and consequently

$$\max_{1\leq i\leq K} V_{i,n} \geq \max_{(i_1,\ldots,i_n):\mathcal{S}(i_1,\ldots,i_n)\leq S} V_{(i_1,\ldots,i_n)} - \xi S.$$

Since $\exp(-x) \leq 1 - x + x^2/2$ for $x \leq 0$, we have for any $t \in \{1,\ldots,n\}$ and any $i \in \{1,\ldots,K\}$

$$\begin{aligned}
\mathbb{E}_{I_t\sim p_t} \exp\bigg(-2\beta g_{i,t}\frac{\mathbb{I}_{I_t=i}}{p_{i,t}}\bigg) &\leq \mathbb{E}_{I_t\sim p_t}\bigg(1 - 2\beta g_{i,t}\frac{\mathbb{I}_{I_t=i}}{p_{i,t}} + 2\beta^2 g_{i,t}^2\frac{\mathbb{I}_{I_t=i}}{p_{i,t}^2}\bigg) \\
&= 1 - 2\beta g_{i,t} + 2\beta^2\frac{g_{i,t}^2}{p_{i,t}} \\
&\leq 1 - 2\beta\Big(g_{i,t} - \frac{\beta}{p_{i,t}}\Big) \\
&\leq \exp\bigg(-2\beta\Big(g_{i,t} - \frac{\beta}{p_{i,t}}\Big)\bigg),
\end{aligned}$$

hence

$$\mathbb{E}_{I_t\sim p_t} \exp\big(2\beta(g_{i,t} - v_{i,t})\big) \leq 1.$$

For a fixed $(i_1,\ldots,i_n)$, by using this inequality n times corresponding to the n time steps and their associated actions, this implies $\mathbb{E}\exp\big(2\beta(G_{(i_1,\ldots,i_n)} - V_{(i_1,\ldots,i_n)})\big) \leq 1$, hence with probability at least $1-\delta$,

$$G_{(i_1,\ldots,i_n)} - V_{(i_1,\ldots,i_n)} \leq \frac{\log(\delta^{-1})}{2\beta}.$$

Let $M = \sum_{j=0}^{S}\binom{n-1}{j}K(K-1)^j$ be the number of switching strategies of size not larger than S. By a union bound, we get that with probability at least $1-\delta$,

$$\max_{(i_1,\ldots,i_n):\mathcal{S}(i_1,\ldots,i_n)\leq S} V_{(i_1,\ldots,i_n)} \geq \max_{(i_1,\ldots,i_n):\mathcal{S}(i_1,\ldots,i_n)\leq S} G_{(i_1,\ldots,i_n)} - \frac{\log(M\delta^{-1})}{2\beta}.$$

By putting the previous inequalities together, we obtain that with probability at least $1-\delta$,

$$(1-\gamma)\max_{(i_1,\dots,i_n):\mathcal{S}(i_1,\dots,i_n)\leq S} G_{(i_1,\dots,i_n)} - \sum_{t=1}^{n} g_{I_t,t} \leq \beta nK + (1-\gamma)\frac{\log K}{\eta} + \xi S + \frac{\log(M\delta^{-1})}{2\beta},$$

hence

$$R_n^S = \max_{(i_1,\dots,i_n):\mathcal{S}(i_1,\dots,i_n)\leq S} G_{(i_1,\dots,i_n)} - \sum_{t=1}^{n} g_{I_t,t} \leq (\gamma+\beta K)n + \frac{\log K}{\eta} + \xi S + \frac{\log(M\delta^{-1})}{2\beta}.$$

We now upper bound M and ξ. We have

$$M = \sum_{j=0}^{S}\binom{n-1}{j}K(K-1)^j \leq K^{S+1}\sum_{j=0}^{S}\binom{n-1}{j} \leq K^{S+1}\left(\frac{en}{S}\right)^S = \frac{\exp(s)}{2},$$

where the second inequality comes from Sauer's lemma. Let

$$\tilde{\rho} = \exp\left((1+\beta)\frac{K\eta}{\gamma}\right)\frac{1+K\beta}{1-\gamma}.$$

By contradiction, we now prove

$$\xi \leq \tilde{\rho} - \frac{1}{\eta}\log\left(\frac{\beta}{\tilde{\rho}} - \frac{\gamma}{K}\right). \tag{47}$$

To this end, we start by bounding $C_t - C_{t-1}$. By the mean value theorem, with the notations of the third step of the proof of Theorem 27, there exists $W \in [V_{t-1}, V_t]$ such that

$$\begin{aligned}
C_t - C_{t-1} &= C(V_t) - C(V_{t-1}) \\
&= \sum_{i=1}^{K}\frac{\partial C}{\partial x_i}(W)(V_{i,t} - V_{i,t-1}) \\
&= \sum_{i=1}^{K}\frac{h_i(W)}{\sum_{j=1}^{K}h_j(W)}\frac{g_{i,t}\mathbb{I}_{I_t=i}+\beta}{f_i(V_{i,t-1})} \\
&= \frac{1}{\sum_{j=1}^{K}\eta(f_j(W)-\gamma/K)}\sum_{i=1}^{K}\eta h_i(W)\frac{g_{i,t}\mathbb{I}_{I_t=i}+\beta}{h_i(V_{i,t-1})+\eta\gamma/K} \\
&\leq \frac{1}{1-\gamma}\sum_{i=1}^{K}h_i(W)\frac{\mathbb{I}_{I_t=i}+\beta}{h_i(V_{t-1})} \leq \frac{\rho}{1-\gamma}\sum_{i=1}^{K}(\mathbb{I}_{I_t=i}+\beta) = \rho\frac{1+K\beta}{1-\gamma}.
\end{aligned}$$

From Lemma 28 (page 2810), we have $\rho \leq \exp\left((1+\beta)\frac{K\eta}{\gamma}\right)$, hence $C_t - C_{t-1} \leq \exp\left((1+\beta)\frac{K\eta}{\gamma}\right)\frac{1+K\beta}{1-\gamma} = \tilde{\rho}$. If (47) does not hold, then from Lemma 1, we have

$$\max_{1\leq t\leq n}\left(C_t - \min_{1\leq j\leq K}V_{j,t}\right) > \tilde{\rho} - \psi^{-1}(\beta/\tilde{\rho}).$$

Besides we have $C_0 - \min_{1\leq j\leq K}V_{j,0} = -\psi^{-1}(1/K) \leq \tilde{\rho} - \psi^{-1}(\beta/\tilde{\rho})$, since $K\beta \leq \tilde{\rho}$. So there exist $T \in \{1,\dots,n\}$ and $\ell \in \{1,\dots,K\}$ such that $C_{T-1} - V_{\ell,T-1} \leq \tilde{\rho} - \psi^{-1}(\beta/\tilde{\rho})$ and $C_T - V_{\ell,T} > \tilde{\rho} - \psi^{-1}(\beta/\tilde{\rho})$. In particular, we have $\psi(V_{\ell,T} - C_T + \tilde{\rho}) < \frac{\beta}{\tilde{\rho}}$, hence

$$V_{\ell,T} - V_{\ell,T-1} \geq \frac{\beta}{p_{\ell,T}} = \frac{\beta}{\psi(V_{\ell,T-1} - C_{T-1})} \geq \frac{\beta}{\psi(V_{\ell,T} - C_T + \tilde{\rho})} \geq \tilde{\rho} \geq C_T - C_{T-1},$$

which contradicts the inequality $C_{T-1} - V_{\ell,T-1} < C_T - V_{\ell,T}$. This ends the proof of (47). We have thus proved that for any $0 < \gamma < 1$, $\eta > 0$ and $\beta > 0$ such that (46) holds, we have

$$R_n^S \leq (\gamma + \beta K)n + \frac{\log K}{\eta} + S\left\{\tilde{\rho} - \frac{1}{\eta}\log\left(\frac{\beta}{\tilde{\rho}} - \frac{\gamma}{K}\right)\right\} + \frac{\log(K\delta^{-1})}{2\beta} + \frac{S\log(Ken/S)}{2\beta},$$

with $\tilde{\rho} = \frac{1+K\beta}{1-\gamma}\exp\left((1+\beta)\frac{K\eta}{\gamma}\right)$. For the numerical application, we first notice that the bound trivially holds for $7\sqrt{Ks} \geq \sqrt{n}$. For $7\sqrt{Ks} < \sqrt{n}$, with $s = S\log\left(\frac{enK}{S}\right) + 2\log K$, we choose

$$\gamma = \sqrt{\frac{Ks}{2n}}, \quad \beta = 3\sqrt{\frac{s}{nK}}, \quad \text{and} \quad \eta = \frac{1}{5}\sqrt{\frac{s}{nK}}.$$

We then use $\gamma \leq \frac{1}{7\sqrt{2}}$, $\beta K \leq \frac{3}{7}$, $\beta \leq \frac{3}{14}$ to deduce $\tilde{\rho} \leq 2.25$, and $\tilde{\rho}S \leq 0.05\sqrt{nKs}$. We check (46) by the upper bound $\frac{K\eta}{\gamma}\left(1 + \frac{\beta K}{\gamma}\right)\Theta\left(\frac{\eta(1+\beta)K}{\gamma}\right) \leq 0.84 < 1$. We also use $-\log\left(\frac{\beta}{\tilde{\rho}} - \frac{\gamma}{K}\right) \leq \frac{1}{2}\log\left(3nK/s\right) \leq \frac{1}{2}\log\left(3nK/S\right)$. We thus have

$$R_n^S \leq \left(3 + \frac{1}{\sqrt{2}} + 0.05 + \frac{5}{2} + \frac{1}{6}\right)\sqrt{nKs} + \frac{\log(\delta^{-1})}{2\beta} \leq 6.5\sqrt{nKs} + \frac{\log(\delta^{-1})}{6}\sqrt{\frac{nK}{s}}$$

The last inequality follows by integrating the deviations.

C.12 Proof of Theorem 24 (page 2806)

This proof requires some new arguments compared to the one for UCB1. First, we need to decouple the arm, while not being too loose. This is achieved by introducing appropriate stopping times. The decoupled upper bound on the pseudo-regret is (51). Secondly, we use peeling arguments to tightly control the terms in the right-hand side of (51).

We may assume $\mu_1 \geq \ldots \geq \mu_K$. Using the trivial equality $\sum_{i=1}^K \mathbb{E}T_i(n) = n$, we have

$$\begin{aligned}
\overline{R}_n &= \max_{1\leq i\leq K} \mathbb{E}\sum_{t=1}^n \left(g_{i,t} - g_{I_t,t}\right) \\
&= n\Big(\max_{1\leq i\leq K} \mathbb{E}g_{i,t}\Big) - \sum_{t=1}^n \mathbb{E}g_{I_t,t} \\
&= n\Big(\max_{1\leq i\leq K} \mu_i\Big) - \sum_{t=1}^n \mathbb{E}\mu_{I_t} \\
&= n\Big(\max_{1\leq i\leq K} \mu_i\Big) - \mathbb{E}\sum_{t=1}^n \mu_{I_t} \\
&= \left(\sum_{i=1}^K \mathbb{E}T_i(n)\right)\Big(\max_{1\leq i\leq K} \mu_i\Big) - \mathbb{E}\sum_{i=1}^K \mu_i T_i(n) = \sum_{i=1}^K \Delta_i \mathbb{E}T_i(n).
\end{aligned}$$

First step: Decoupling the arms

For an arm k_0, we trivially have $\sum_{k=1}^K \Delta_k T_k(n) \leq n\Delta_{k_0} + \sum_{k=k_0+1}^K \Delta_k T_k(n)$. Let $\Delta_{K+1} = +\infty$, $z_k = \mu_1 - \frac{\Delta_k}{2}$ for $k_0 < k \leq K+1$ and $z_{k_0} = +\infty$. Let $Z = \min_{1\leq s\leq n} B_{1,s}$ and $W_{j,k} = \mathbb{1}_{Z\in[z_{j+1},z_j)}(\Delta_k -$

$\Delta_{k_0})T_k(n)$. By using $\mathbb{E}\sum_{k=1}^{k_0} T_k(n) = n - \mathbb{E}\sum_{k=k_0+1}^{K} T_k(n)$, we get

$$\overline{R}_n = \mathbb{E}\sum_{k=1}^{K} \Delta_k T_k(n) \leq n\Delta_{k_0} + \mathbb{E}\sum_{k=k_0+1}^{K} (\Delta_k - \Delta_{k_0})T_k(n).$$

We have

$$\sum_{k=k_0+1}^{K} (\Delta_k - \Delta_{k_0})T_k(n) = \sum_{k=k_0+1}^{K}\sum_{j=k_0}^{K} W_{j,k} = \sum_{j=k_0}^{K}\sum_{k=k_0+1}^{j} W_{j,k} + \sum_{j=k_0}^{K}\sum_{k=j+1}^{K} W_{j,k}. \tag{48}$$

An Abel transformation takes care of the first sum of (48):

$$\sum_{j=k_0}^{K}\sum_{k=k_0+1}^{j} W_{j,k} \leq \sum_{j=k_0}^{K} \mathbb{1}_{Z\in[z_{j+1},z_j)} n(\Delta_j - \Delta_{k_0}) = n\sum_{j=k_0+1}^{K} \mathbb{1}_{Z<z_j}(\Delta_j - \Delta_{j-1}). \tag{49}$$

To bound the second sum of (48), we introduce the stopping times $\tau_k = \min\{t : B_{k,t} < z_k\}$ and remark that, by definition of MOSS, we have $\{Z \geq z_k\} \subset \{T_k(n) \leq \tau_k\}$, since once we have pulled τ_k times arm k its index will always be lower than the index of arm 1. This implies

$$\sum_{j=k_0}^{K}\sum_{k=j+1}^{K} W_{j,k} = \sum_{k=k_0+1}^{K}\sum_{j=k_0}^{k-1} W_{j,k} = \sum_{k=k_0+1}^{K} \mathbb{1}_{Z\geq z_k}\Delta_k T_k(n) \leq \sum_{k=k_0+1}^{K} \tau_k\Delta_k. \tag{50}$$

Combining (48), (49) and (50) and taking the expectation, we get

$$\overline{R}_n \leq n\Delta_{k_0} + \sum_{k=k_0+1}^{K} \Delta_k\mathbb{E}\tau_k + n\sum_{k=k_0+1}^{K} \mathbb{P}(Z < z_k)(\Delta_k - \Delta_{k-1}). \tag{51}$$

Let $\delta_0 = \sqrt{\frac{75K}{n}}$ and set k_0 such that $\Delta_{k_0} \leq \delta_0 < \Delta_{k_0+1}$. If $k_0 = K$, we trivially have $\overline{R}_n \leq n\delta_0 \leq \sqrt{75nK}$ so that (22) holds trivially. In the following, we thus consider $k_0 < K$.

Second step: Bounding $\mathbb{E}\tau_k$ for $k_0 + 1 \leq k \leq K$.

Let $\log_+(x) = \max(\log(x), 0)$. For $\ell_0 \in \mathbb{N}$, we have

$$\begin{aligned}
\mathbb{E}\tau_k - \ell_0 &= \sum_{\ell=0}^{+\infty} \mathbb{P}(\tau_k > \ell) - \ell_0 \\
&\leq \sum_{\ell=\ell_0}^{+\infty} \mathbb{P}(\tau_k > \ell) = \sum_{\ell=\ell_0}^{+\infty} \mathbb{P}(\forall t \leq \ell, B_{k,t} > z_k) \\
&\leq \sum_{\ell=\ell_0}^{+\infty} \mathbb{P}\left(\widehat{\mu}_{k,\ell} - \mu_k \geq \frac{\Delta_k}{2} - \sqrt{\frac{\log_+(n/K\ell)}{\ell}}\right).
\end{aligned} \tag{52}$$

Now let us take $\ell_0 = \lceil 7\log\left(\frac{n}{K}\Delta_k^2\right)/\Delta_k^2 \rceil$ with $\lceil x \rceil$ the smallest integer larger than x. For $\ell \geq \ell_0$, since $k > k_0$, we have

$$\log_+\left(\frac{n}{K\ell}\right) \leq \log_+\left(\frac{n}{K\ell_0}\right) \leq \log_+\left(\frac{n\Delta_k^2}{7K}\right) \leq \frac{\ell_0\Delta_k^2}{7} \leq \frac{\ell\Delta_k^2}{7},$$

hence $\frac{\Delta_k}{2} - \sqrt{\frac{\log_+(n/(K\ell))}{\ell}} \geq c\Delta_k$, with $c = \frac{1}{2} - \frac{1}{\sqrt{7}}$. Therefore, by using Hoeffding's inequality and (52), we get

$$\begin{aligned}\mathbb{E}\tau_k - \ell_0 &\leq \sum_{\ell=\ell_0}^{+\infty} \mathbb{P}\left(\widehat{\mu}_{k,\ell} - \mu_k \geq c\Delta_k\right) \\ &\leq \sum_{\ell=\ell_0}^{+\infty} \exp\left(-2\ell(c\Delta_k)^2\right) = \frac{\exp\left(-2\ell_0(c\Delta_k)^2\right)}{1-\exp\left(-2(c\Delta_k)^2\right)} \leq \frac{\exp(-14c^2\log(75))}{1-\exp\left(-2c^2\Delta_k^2\right)},\end{aligned}$$

where the last inequality uses $\ell_0\Delta_k^2 \geq 7\log(75)$. Plugging the value of ℓ_0, we obtain

$$\begin{aligned}\Delta_k\mathbb{E}\tau_k &\leq \Delta_k\left(1 + \frac{7\log\left(\frac{n}{K}\Delta_k^2\right)}{\Delta_k^2}\right) + \frac{\Delta_k\exp(-14c^2\log(75))}{1-\exp\left(-2c^2\Delta_k^2\right)} \\ &\leq 1 + 7\frac{\log\left(\frac{n}{K}\Delta_k^2\right)}{\Delta_k} + \frac{\exp(-14c^2\log(75))}{2c^2(1-c^2)\Delta_k},\end{aligned}$$

where the last step uses that, since $1-\exp(-x) \geq x - x^2/2$ for any $x \geq 0$, we have

$$\frac{1}{1-\exp\left(-2c^2\Delta_k^2\right)} \leq \frac{1}{2c^2\Delta_k^2 - 2c^4\Delta_k^4} \leq \frac{1}{2c^2\Delta_k^2(1-c^2)}$$

Third step: Bounding $n\sum_{k=k_0+1}^{K}\mathbb{P}(Z < z_k)(\Delta_k - \Delta_{k-1})$.

Let X_t denote the reward obtained by arm 1 when it is drawn for the t-th time. The random variables $X_1, X_2, \ldots$ are i.i.d. so that we have the maximal inequality (Hoeffding, 1963, Inequality (2.17)): for any $x > 0$ and $m \geq 1$,

$$\mathbb{P}\left(\exists s \in \{1,\ldots,m\}, \sum_{t=1}^{s}(\mu_1 - X_t) > x\right) \leq \exp\left(-\frac{2x^2}{m}\right).$$

Since $z_k = \mu_1 - \Delta_k/2$ and since $u \mapsto \mathbb{P}\left(Z < \mu_1 - u/2\right)$ is a nonincreasing function, we have

$$\sum_{k=k_0+1}^{K}\mathbb{P}(Z < z_k)(\Delta_k - \Delta_{k-1}) \leq \Delta_{k_0+1}\mathbb{P}(Z < z_{k_0+1}) + \int_{\Delta_{k_0+1}}^{1}\mathbb{P}\left(Z < \mu_1 - \frac{u}{2}\right)du. \tag{53}$$

We will now concentrate on upper bounding $\mathbb{P}\left(Z < \mu_1 - \frac{u}{2}\right)$ for a fixed $u \in [\delta_0, 1]$. Let $f(u) = 8\log\left(\sqrt{\frac{n}{K}}u\right)/u^2$. We have

$$\begin{aligned}\mathbb{P}\left(Z < \mu_1 - \frac{1}{2}u\right) &= \mathbb{P}\left(\exists 1 \leq s \leq n : \sum_{t=1}^{s}(\mu_1 - X_t) > \sqrt{s\log_+\left(\frac{n}{Ks}\right)} + \frac{su}{2}\right) \\ &\leq \mathbb{P}\left(\exists 1 \leq s \leq f(u) : \sum_{t=1}^{s}(\mu_1 - X_t) > \sqrt{s\log_+\left(\frac{n}{Ks}\right)}\right) \\ &\quad + \mathbb{P}\left(\exists f(u) < s \leq n : \sum_{t=1}^{s}(\mu_1 - X_t) > \frac{su}{2}\right).\end{aligned}$$

For the first term, we use a peeling argument with a geometric grid of the form $\frac{1}{2^{\ell+1}} f(u) \le s \le \frac{1}{2^\ell} f(u)$. The numerical constant in δ_0 ensures that $f(u) \le n/K$, which implies that for any $s \le f(u)$, $\log_+\left(\frac{n}{Ks}\right) = \log\left(\frac{n}{Ks}\right)$. We have

$$\begin{aligned}
&\mathbb{P}\left(\exists 1 \le s \le f(u) : \sum_{t=1}^{s} (\mu_1 - X_t) > \sqrt{s \log\left(\frac{n}{Ks}\right)}\right) \\
&\quad \le \sum_{\ell=0}^{+\infty} \mathbb{P}\left(\exists \frac{1}{2^{\ell+1}} f(u) \le s \le \frac{1}{2^\ell} f(u) : \sum_{t=1}^{s} (\mu_1 - X_t) > \sqrt{\frac{f(u)}{2^{\ell+1}} \log\left(\frac{n 2^\ell}{K f(u)}\right)}\right) \\
&\quad \le \sum_{\ell=0}^{+\infty} \exp\left(-2 \frac{f(u)\frac{1}{2^{\ell+1}} \log\left(\frac{n2^\ell}{Kf(u)}\right)}{f(u)\frac{1}{2^\ell}}\right) = \sum_{\ell=0}^{+\infty} \frac{Kf(u)}{n} \frac{1}{2^\ell} = \frac{16K}{nu^2} \log\left(\sqrt{\frac{n}{K}} u\right).
\end{aligned}$$

For the second term we also use a peeling argument but with a geometric grid of the form $2^\ell f(u) \le s \le 2^{\ell+1} f(u)$:

$$\begin{aligned}
&\mathbb{P}\left(\exists s \in \lceil f(u) \rceil, \dots, n\} : \sum_{t=1}^{s} (\mu_1 - X_t) > \frac{su}{2}\right) \\
&\qquad \le \sum_{\ell=0}^{+\infty} \mathbb{P}\left(\exists 2^\ell f(u) \le s \le 2^{\ell+1} f(u) : \sum_{t=1}^{s} (\mu_1 - X_t) > 2^{\ell-1} f(u) u\right) \\
&\qquad \le \sum_{\ell=0}^{+\infty} \exp\left(-2 \frac{\left(2^{\ell-1} f(u) u\right)^2}{f(u) 2^{\ell+1}}\right) \\
&\qquad = \sum_{\ell=0}^{+\infty} \exp\left(-2^\ell f(u) u^2/4\right) \\
&\qquad \le \sum_{\ell=0}^{+\infty} \exp\left(-(\ell+1) f(u) u^2/4\right) = \frac{1}{\exp\left(f(u)u^2/4\right) - 1} = \frac{1}{nu^2/K - 1}.
\end{aligned}$$

Putting together the last three computations, we obtain

$$\mathbb{P}\left(Z < \mu_1 - \frac{1}{2}u\right) \le \frac{16K}{nu^2} \log\left(\sqrt{\frac{n}{K}} u\right) + \frac{1}{nu^2/K - 1}.$$

Plugging this into (53) gives

$$\begin{aligned}
&\sum_{k=k_0+1}^{K} \mathbb{P}(Z < z_k)(\Delta_k - \Delta_{k-1}) \\
&\quad \leq \frac{16K}{n\Delta_{k_0+1}} \log\left(\sqrt{\frac{n}{K}}\Delta_{k_0+1}\right) + \frac{\Delta_{k_0+1}}{n\Delta_{k_0+1}^2/K - 1} \\
&\qquad + \left[-\frac{16K}{nu}\log\left(e\sqrt{\frac{n}{K}}u\right) + \sqrt{\frac{K}{4n}}\log\left(\frac{\sqrt{\frac{n}{K}}u-1}{\sqrt{\frac{n}{K}}u+1}\right)\right]_{\Delta_{k_0+1}}^{1} \\
&\quad \leq \frac{16K}{n\Delta_{k_0+1}} \log\left(\frac{en\Delta_{k_0+1}^2}{K}\right) + \frac{\Delta_{k_0+1}}{n\Delta_{k_0+1}^2/K - 1} + \sqrt{\frac{K}{4n}}\log\left(\frac{\sqrt{\frac{n}{K}}\Delta_{k_0+1}+1}{\sqrt{\frac{n}{K}}\Delta_{k_0+1}-1}\right) \\
&\quad \leq \frac{16K}{n\Delta_{k_0+1}} \log\left(\frac{en\Delta_{k_0+1}^2}{K}\right) + \left(\frac{75}{74} + \frac{\sqrt{75}}{\sqrt{75}-1}\right)\frac{K}{n\Delta_{k_0+1}}
\end{aligned}$$

where the penultimate inequality uses $\Delta_{k_0+1} \geq \sqrt{\frac{75K}{n}}$ and $\log(1+x) \leq x$ for any $x \geq 0$.

Gathering the results of the three steps, we get

$$\begin{aligned}
\overline{R}_n &\leq n\Delta_{k_0} + \sum_{k=k_0+1}^{K}\left(1 + 7\frac{\log\left(\frac{n}{K}\Delta_k^2\right)}{\Delta_k} + \frac{\exp(-14c^2\log(75))}{2c^2(1-c^2)\Delta_k}\right) \\
&\qquad + \frac{16K}{\Delta_{k_0+1}}\log\left(\frac{en\Delta_{k_0+1}^2}{K}\right) + \left(\frac{75}{74} + \frac{\sqrt{75}}{\sqrt{75}-1}\right)\frac{K}{\Delta_{k_0+1}} \\
&\leq n\Delta_{k_0} + K + (16+7)K\frac{\log\left(\frac{n}{K}\Delta_{k_0+1}^2\right)}{\Delta_{k_0+1}} + (16+16)\frac{K}{\Delta_{k_0+1}} \\
&\leq n\delta_0 \mathbb{I}_{\Delta \leq \delta_0} + 23K\frac{\log\left(\frac{n}{K}\Delta_{k_0+1}^2\right)}{\Delta_{k_0+1}} + \frac{33K}{\Delta_{k_0+1}} \\
&\leq 23K\frac{\log\left(\frac{n}{K}\max(\Delta,\delta_0)^2\right)}{\max(\Delta,\delta_0)} + \frac{108K}{\max(\Delta,\delta_0)} \\
&\leq 23K\frac{\log\left(\frac{110n}{K}\max(\Delta,\delta_0)^2\right)}{\max(\Delta,\delta_0)},
\end{aligned}$$

which implies (22) and also $\overline{R}_n \leq 24\sqrt{nK}$. Since Proposition 34 implies $\mathbb{E}R_n - \overline{R}_n \leq \sqrt{nK}$, we have proved (23). For (24), Proposition 36 implies

$$\mathbb{E}R_n - \overline{R}_n \leq \min\left(\frac{K}{\Delta}, \frac{\sqrt{nK}}{2}\right) \leq \frac{K\sqrt{75}}{2\max(\Delta,\delta_0)},$$

which implies

$$\mathbb{E}R_n \leq 23K\frac{\log\left(\frac{133n}{K}\max(\Delta,\delta_0)^2\right)}{\max(\Delta,\delta_0)}.$$

Appendix D. Pseudo-regret vs Expected Regret

The first two propositions hold for the four prediction games considered in this work and defined in Figure 1.

Proposition 33 *For deterministic adversaries, we have* $\mathbb{E}R_n = \overline{R}_n$. *For oblivious adversaries, we have*

$$\mathbb{E}R_n \leq \sup_{\textit{deterministic adversaries}} \overline{R}_n.$$

In particular, this means that the worst oblivious adversary for a forecaster cannot lead to a larger regret than the worst deterministic adversary.

Proof The first assertion is trivial. For the second one, let $\mathbb{E}_{\text{adv}}$ be the expectation with respect to the eventual randomization of the adversary and $\mathbb{E}_{\text{for}}$ be the expectation with respect to the randomization of the forecaster. For oblivious adversaries, we have $\mathbb{E}R_n = \mathbb{E}_{\text{adv}}\mathbb{E}_{\text{for}}R_n$, hence

$$\mathbb{E}R_n \leq \sup_{\text{deterministic adversaries}} \mathbb{E}_{\text{for}}R_n = \sup_{\text{deterministic adversaries}} \overline{R}_n.$$

■

While the previous proposition is useful for upper bounding the regret of a forecaster against the worst oblivious adversary, it does not say anything about the difference between the expected regret and the pseudo-regret for a given adversary. The next proposition gives an upper bound on this difference for fully oblivious adversaries, which are (oblivious) adversaries generating independently the reward vectors.

Proposition 34 *For fully oblivious adversaries, we have*

$$\mathbb{E}R_n - \overline{R}_n \leq \sqrt{\frac{n\log K}{2}},$$

and

$$\mathbb{E}R_n - \overline{R}_n \leq \sqrt{2\log(K)\max_i \mathbb{E}\sum_{t=1}^{n} g_{i,t}} + \frac{\log K}{3}.$$

Proof The proof is similar to the one of the upper bound on the expected supremum of a finite number of subgaussian random variables. We use the following lemma.

Lemma 35 *Let* $\lambda > 0$ *and* W *a random variable taking its values in* $[0,1]$. *We have*

$$\mathbb{E}\exp(\lambda W) \leq \exp\left[\big(\exp(\lambda) - 1\big)\mathbb{E}W\right].$$

Proof By convexity of the exponential function, we have $\exp(\lambda x) \leq 1 + \big(\exp(\lambda) - 1\big)x$ for any $x \in [0,1]$. So we have $\mathbb{E}\exp(\lambda W) \leq 1 + \big(\exp(\lambda) - 1\big)\mathbb{E}W$, hence Lemma 35. ■

Let $\lambda > 0$, then by Jensen's inequality and Lemma 35, we have

$$\begin{aligned}
\mathbb{E}\max_i \sum_{t=1}^n g_{i,t} &\leq \mathbb{E}\frac{1}{\lambda}\log\sum_{i=1}^K \exp\left(\lambda\sum_{t=1}^n g_{i,t}\right) \\
&\leq \frac{1}{\lambda}\log\sum_{i=1}^K \mathbb{E}\prod_{t=1}^n \exp(\lambda g_{i,t}) \\
&= \frac{1}{\lambda}\log\sum_{i=1}^K \prod_{t=1}^n \mathbb{E}\exp(\lambda g_{i,t}) \\
&\leq \frac{1}{\lambda}\log\sum_{i=1}^K \prod_{t=1}^n \exp\left([\exp(\lambda)-1]\mathbb{E}g_{i,t}\right) \\
&\leq \frac{\log K}{\lambda} + \frac{\exp(\lambda)-1}{\lambda}\max_i \mathbb{E}\sum_{t=1}^n g_{i,t}.
\end{aligned}$$

This implies

$$\mathbb{E}R_n - \overline{R}_n \leq \inf_{\lambda>0}\left(\frac{\log K}{\lambda} + \lambda\Theta(\lambda)\max_i \mathbb{E}\sum_{t=1}^n g_{i,t}\right),$$

where $\Theta(\lambda) = \frac{\exp(\lambda)-1-\lambda}{\lambda^2}$. By using Lemma 32, one obtains the second inequality of the theorem. Instead of using a variant of Bernstein's argument to control $\mathbb{E}\exp(\lambda g_{i,t})$, one can use Hoeffding's inequality. This leads to the first inequality by taking $\lambda = \sqrt{\frac{2\log K}{n}}$. ■

We can strengthen the previous result on the difference between the expected regret and the pseudo-regret when we consider the stochastic bandit game, in which the rewards coming from a given arm form an i.i.d. sequence. In particular, when there is a unique optimal arm, the following theorem states that the difference is exponentially small with n (instead of being of order $\sqrt{n}$).

Proposition 36 *For a given $\delta \geq 0$, let $I = \left\{i \in \{1,\ldots,K\} : \Delta_i \leq \delta\right\}$ be the set of arms "δ-close" to the optimal ones, and $J = \{1,\ldots,K\} \setminus I$ the remaining set of arms. In the stochastic bandit game, we have*

$$\mathbb{E}R_n - \overline{R}_n \leq \sqrt{\frac{n\log|I|}{2}} + \sum_{i\in J}\frac{1}{\Delta_i}\exp\left(-\frac{n\Delta_i^2}{2}\right),$$

and also

$$\begin{aligned}
\mathbb{E}R_n - \overline{R}_n \leq \sqrt{\frac{n\log|I|}{2}} + \sum_{i\in J}\Bigg\{ &\frac{8\sigma_i^2 + 4\Delta_i/3}{\Delta_i}\exp\left(-\frac{n\Delta_i^2}{8\sigma_i^2+4\Delta_i/3}\right) \\
&+ \frac{8\sigma_{i^*}^2 + 4\Delta_i/3}{\Delta_i}\exp\left(-\frac{n\Delta_i^2}{8\sigma_{i^*}^2+4\Delta_i/3}\right)\Bigg\},
\end{aligned}$$

where for any $j \in \{1,\ldots,K\}$, σ_j^2 denotes the variance of the reward distribution of arm j.

In particular when there exists a unique arm i^* such that $\Delta_{i^*} = 0$, we have

$$\mathbb{E}R_n - \overline{R}_n \leq \sum_{i\neq i^*}\frac{1}{\Delta_i}\exp\left(-\frac{n\Delta_i^2}{2}\right).$$

Note that the assumption on the uniqueness of the optimal arm in the last statement is necessary as we already discussed in Remark 25.

Proof Let $W_n^{(1)} = \max_{i\in I}\sum_{t=1}^n g_{i,t} - \sum_{t=1}^n g_{i^*,t}$ and $W_n^{(2)} = \max_{j\in\{1,\dots,K\}}\sum_{t=1}^n g_{j,t} - \max_{i\in I}\sum_{t=1}^n g_{i,t}$. We have $\mathbb{E}R_n - \overline{R}_n = \mathbb{E}W_n^{(1)} + \mathbb{E}W_n^{(2)}$. From the same argument as in the proof of Proposition 34, we have

$$\mathbb{E}W_n^{(1)} \le \sqrt{\frac{n\log|I|}{2}}.$$

Besides, we have

$$\begin{aligned}
\mathbb{E}W_n^{(2)} &= \int_0^{+\infty} \mathbb{P}(W_n^{(2)} > u)du \\
&\le \sum_{j\in J}\int_0^{+\infty} \mathbb{P}\left(\sum_{t=1}^n g_{j,t} - \max_{i\in I}\sum_{t=1}^n g_{i,t} > u\right)du \\
&\le \sum_{j\in J}\int_0^{+\infty} \mathbb{P}\left(G_{j,n} - G_{i^*,n} > u\right)du \\
&= \sum_{i\in J}\int_0^{+\infty} \mathbb{P}\left(G_{i,n} - \mathbb{E}G_{i,n} + \mathbb{E}G_{i^*,n} - G_{i^*,n} > u + n\Delta_i\right)du \\
&\le \sum_{i\in J}\int_0^{+\infty} \left\{\mathbb{P}\left(G_{i,n} - \mathbb{E}G_{i,n} > \frac{u+n\Delta_i}{2}\right) + \mathbb{P}\left(\mathbb{E}G_{i^*,n} - G_{i^*,n} > \frac{u+n\Delta_i}{2}\right)\right\}du.
\end{aligned}$$

This last integrand is upper bounded by $2\exp\left(-\frac{(u+n\Delta_i)^2}{2n}\right)$ from Hoeffding's inequality, and by $\exp\left(-\frac{(u+n\Delta_i)^2}{8n\sigma_i^2+4(u+n\Delta_i)/3}\right) + \exp\left(-\frac{(u+n\Delta_i)^2}{8n\sigma_{i^*}^2+4(u+n\Delta_i)/3}\right)$ from Bernstein's inequality. To control the two corresponding integrals, we note that for a nondecreasing convex function χ going to infinity at $+\infty$, we have

$$\int_x^{+\infty}\exp(-\chi(u))du \le \int_x^{+\infty}\frac{\chi'(u)}{\chi'(x)}\exp(-\chi(u))du = \frac{\exp(-\chi(x))}{\chi'(x)}.$$

We apply this inequality to the functions $r\mapsto\frac{r^2}{2n}$ and $r\mapsto\frac{r^2}{8n\sigma_i^2+4r/3}$ to obtain respectively

$$\mathbb{E}W_n^{(2)} \le 2\sum_{i\in J}\int_{n\Delta_i}^{+\infty}\exp\left(-\frac{u^2}{2n}\right)du \le \sum_{i\in J}\frac{1}{\Delta_i}\exp\left(-\frac{n\Delta_i^2}{2}\right),$$

and

$$\begin{aligned}
\int_{n\Delta_i}^{+\infty}\exp\left(-\frac{u^2}{8n\sigma_i^2+4u/3}\right)du &\le \frac{(8\sigma_i^2+4\Delta_i/3)^2}{\Delta_i(16\sigma_i^2+4\Delta_i/3)}\exp\left(-\frac{n\Delta_i^2}{8\sigma_i^2+4\Delta_i/3}\right) \\
&\le \frac{8\sigma_i^2+4\Delta_i/3}{\Delta_i}\exp\left(-\frac{n\Delta_i^2}{8\sigma_i^2+4\Delta_i/3}\right),
\end{aligned}$$

hence

$$\mathbb{E}W_n^{(2)} \le \sum_{i\in J}\left\{\frac{8\sigma_i^2+\frac{4\Delta_i}{3}}{\Delta_i}\exp\left(-\frac{n\Delta_i^2}{8\sigma_i^2+4\Delta_i/3}\right) + \frac{8\sigma_{i^*}^2+\frac{4\Delta_i}{3}}{\Delta_i}\exp\left(-\frac{n\Delta_i^2}{8\sigma_{i^*}^2+4\Delta_i/3}\right)\right\}.$$

Abstract

Information theoretic measures form a fundamental class of measures for comparing clusterings, and have recently received increasing interest. Nevertheless, a number of questions concerning their properties and inter-relationships remain unresolved. In this paper, we perform an organized study of information theoretic measures for clustering comparison, including several existing popular measures in the literature, as well as some newly proposed ones. We discuss and prove their important properties, such as the metric property and the normalization property. We then highlight to the clustering community the importance of correcting information theoretic measures for chance, especially when the data size is small compared to the number of clusters present therein. Of the available information theoretic based measures, we advocate the normalized information distance (NID) as a general measure of choice, for it possesses concurrently several important properties, such as being both a metric and a normalized measure, admitting an exact analytical adjusted-for-chance form, and using the nominal $[0,1]$ range better than other normalized variants.

Keywords: clustering comparison, information theory, adjustment for chance, normalized information distance

1. Introduction

Clustering comparison measures play an important role in cluster analysis. Most often, such measures are used for external validation, that is, assessing the goodness of clustering solutions according to a "ground truth" clustering. Recent advances in cluster analysis have driven new algorithms, in which the clustering comparison measures are used actively in searching for good clustering solutions. One such example occurs in the context of ensemble (consensus) clustering, whose aim is to unify a set of clusterings, already obtained by some algorithms, into a single high quality one (Singh et al., 2009; Strehl and Ghosh, 2002; Charikar et al., 2003). A possible approach is to choose the clustering which shares the most information with all the other clusterings, such as in Strehl and Ghosh (2002). A measure is therefore needed to quantify the amount of information shared between clusterings, more specifically in this case, between the "centroid" clustering and all the

†. Also in the Victoria Research Laboratory, National ICT Australia (NICTA).

other clusterings. Another example is in model selection by stability assessment (Ben-David et al., 2006; Shamir and Tishby, 2008). A possible realization of this scheme is to measure the average pairwise distances between all the clusterings obtained under some sort of perturbations (Vinh and Epps, 2009), hence requiring a clustering comparison measure.

Numerous measures for comparing clusterings have been proposed. Besides the class of *pair-counting based* and *set-matching based* measures, *information theoretic* measures form another fundamental class. In the clustering literature, such measures have been employed because of their strong mathematical foundation, and ability to detect non-linear similarities. For the particular purpose of clustering comparison, this class of measures has been popularized through the works of Strehl and Ghosh (2002) and Meilă (2005), and since then has been employed in various subsequent research (Fern and Brodley, 2003; He et al., 2008; Asur et al., 2007; Tumer and Agogino, 2008). In this context, the pioneering works of Meilă (2003, 2005, 2007) have shown a number of desirable theoretical properties of one of these measures—the *variation of information* (VI)—such as its metric property and its alignment with the lattice of partitions. Although having received considerable interest, in our opinion, the application of information theoretic measures for comparing clustering has been somewhat scattered. Apart from the VI which possesses a fairly comprehensive characterization, less is known about the *mutual information* and various forms of the so-called *normalized mutual information* (Strehl and Ghosh, 2002). The main technical contributions of this paper can be summarized as being three-fold:

1. We first review and make a coherent categorization of information theoretic similarity and distance measures for clustering comparison. We then discuss and prove their two important properties, namely the normalization and the metric properties. We show that among the prospective measures, the *normalized information distance* (NID) and the *normalized variation of information* (NVI) satisfy both these desirable properties.

2. We draw the attention of the clustering community towards the necessity of correcting information theoretic measures for chance in certain situations, derive analytical forms for the proposed adjusted-for-chance measures, and investigate their properties. Preliminary results regarding correcting information theoretic measures for chance have previously appeared in Vinh, Epps, and Bailey (2009). In this paper, we further analyze the large sample properties of the adjusted measures, and give a recommendation as to when adjustment is mostly needed.

3. Of the available information theoretic measures, we advocate the normalized information distance (NID) as a general purpose measure for comparing clusterings, which has the advantage of being both a metric and a normalized measure, admitting an exact analytical adjusted-for-chance form, and using better the nominal $[0,1]$ range. For ease of reading, we present the proofs of all results herein in the Appendix.

2. A Brief Review of Measures for Comparing Clusterings

Let S be a set of N data items, then a (partitional) clustering $\mathbf{U}$ on S is a way of partitioning S into non-overlap subsets $\{U_1, U_2, \ldots, U_R\}$, where $\cup_{i=1}^{R} U_i = S$ and $U_i \cap U_j = \emptyset$ for $i \neq j$. The information on the overlap between two clusterings $\mathbf{U} = \{U_1, U_2, \ldots, U_R\}$ and $\mathbf{V} = \{V_1, V_2, \ldots, V_C\}$ can be summarized in form of a $R \times C$ *contingency table* $M = [n_{ij}]_{j=1\ldots C}^{i=1\ldots R}$ as illustrated in Table 1, where n_{ij} denotes the number of objects that are common to clusters U_i and V_j.

Pair counting based measures are built upon counting pairs of items on which two clusterings agree or disagree. Specifically, the $\binom{N}{2}$ item pairs in S can be classified into one of the 4 types—N_{11}:

$\mathbf{U}\backslash\mathbf{V}$	V_1	V_2	$\dots$	V_C	Sums
U_1	n_{11}	n_{12}	$\dots$	n_{1C}	a_1
U_2	n_{21}	n_{22}	$\dots$	n_{2C}	a_2
$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$	$\vdots$
U_R	n_{R1}	n_{R2}	$\dots$	n_{RC}	a_R
Sums	b_1	b_2	$\dots$	b_C	$\sum_{ij} n_{ij} = N$

Table 1: The Contingency Table, $n_{ij} = |U_i \cap V_j|$

the number of pairs that are in the same cluster in both $\mathbf{U}$ and $\mathbf{V}$; N_{00}: the number of pairs that are in different clusters in both $\mathbf{U}$ and $\mathbf{V}$; N_{01}: the number of pairs that are in the same cluster in $\mathbf{U}$ but in different clusters in $\mathbf{V}$; and N_{10}: the number of pairs that are in different clusters in $\mathbf{U}$ but in the same cluster in $\mathbf{V}$—that can be calculated using the n_{ij}'s (Hubert and Arabie, 1985). Intuitively, N_{11} and N_{00} can be used as indicators of agreement between $\mathbf{U}$ and $\mathbf{V}$, while N_{01} and N_{10} can be used as disagreement indicators. A well known index of this class is the Rand index (RI, Rand 1971), defined straightforwardly as $\mathrm{RI}(\mathbf{U},\mathbf{V}) = (N_{00}+N_{11})/\binom{N}{2}$, which lies in the nominal range of [0,1]. In practice however, the RI often lies within the narrower range of [0.5,1]. Also, its baseline value can be high and does not take on a constant value. For these reasons, the RI has been mostly used in it adjusted form, known as the adjusted Rand index (ARI, Hubert and Arabie 1985):

$$\mathrm{ARI}(\mathbf{U},\mathbf{V}) = \frac{2(N_{00}N_{11} - N_{01}N_{10})}{(N_{00}+N_{01})(N_{01}+N_{11}) + (N_{00}+N_{10})(N_{10}+N_{11})}.$$

The ARI is bounded above by 1, and equals 0 when the RI equals its expected value (under the generalized hypergeometric distribution assumption for randomness). Besides the ARI, there are many other, possibly less popular, measures in this class. Albatineh et al. (2006) made a comprehensive list of 22 different indices of this type, a number which is large enough to make the task of choosing an appropriate measure difficult and confusing. Their work, and subsequent extension of Warrens (2008), showed that after correction for chance, some of these measures become equivalent. Despite the existence of numerous measures, the ARI remains the most well-known and widely used (Steinley, 2004). Therefore, in this work, we take it as the representative of this class for comparison with other measures. Although the ARI has been mainly used in its similarity form, it can be easily shown that its distance version, that is, $1-\mathrm{ARI}$, is not a proper metric.

Set matching based measures, as their name suggests, are based on finding matches between clusters in the two clusterings. A popular measure is the classification error rate which is often employed in supervised learning. Several other indices are discussed in Meilă (2007), all suffering from two major problems which have long been known in the clustering comparing literature (Dom, 2001; Steinley, 2004; Meilă, 2007) namely: (i) the number of clusters in the two clusterings may be different, making this approach problematic, since there are some clusters which are put outside consideration; and (ii) even when the numbers of clusters are the same, the unmatched part of each matched cluster pair is still put outside consideration. Due to the problems with this class of indices, we shall not consider them further in this paper.

Information theoretic based measures are built upon fundamental concepts from information theory (Cover and Thomas, 1991). Given two clusterings $\mathbf{U}$ and $\mathbf{V}$, their entropies, joint entropy,

conditional entropies and mutual information (MI) are defined naturally via the marginal and joint distributions of data items in $\mathbf{U}$ and $\mathbf{V}$ respectively as:

$$\begin{aligned} H(\mathbf{U}) &= -\sum_{i=1}^{R} \frac{a_i}{N} \log \frac{a_i}{N}, \\ H(\mathbf{U},\mathbf{V}) &= -\sum_{i=1}^{R}\sum_{j=1}^{C} \frac{n_{ij}}{N} \log \frac{n_{ij}}{N}, \\ H(\mathbf{U}|\mathbf{V}) &= -\sum_{i=1}^{R}\sum_{j=1}^{C} \frac{n_{ij}}{N} \log \frac{n_{ij}/N}{b_j/N}, \\ I(\mathbf{U},\mathbf{V}) &= \sum_{i=1}^{R}\sum_{j=1}^{C} \frac{n_{ij}}{N} \log \frac{n_{ij}/N}{a_i b_j/N^2}. \end{aligned}$$

The MI measures the information that $\mathbf{U}$ and $\mathbf{V}$ share: it tells us how much knowing one of these clusterings reduces our uncertainty about the other. From a communication theory point of view, the above-defined quantities can be interpreted as follows. Suppose we need to transmit all the cluster labels in $\mathbf{U}$ on a communication channel, then $H(\mathbf{U})$ can be interpreted as the average amount of information, for example, in bits, needed to encode the cluster label of each data point according to $\mathbf{U}$. Now suppose that $\mathbf{V}$ is made available to the receiver, then $H(\mathbf{U}|\mathbf{V})$ denotes the average number of bits needed to transmit each label in $\mathbf{U}$ if $\mathbf{V}$ is already known. We are interested in how seeing how much $H(\mathbf{U}|\mathbf{V})$ is smaller than $H(\mathbf{U})$, that is, how much the knowledge of $\mathbf{V}$ helps us to reduce the number of bits needed to encode $\mathbf{U}$. This can be quantified in terms of the mutual information $H(\mathbf{U}) - H(\mathbf{U}|\mathbf{V}) = I(\mathbf{U},\mathbf{V})$. The knowledge of $\mathbf{V}$ thus helps us to reduce the number of bits needed to encode each cluster label in $\mathbf{U}$ by an amount of $I(\mathbf{U},\mathbf{V})$ bits. In the reverse direction we also have $I(\mathbf{U},\mathbf{V}) = H(\mathbf{V}) - H(\mathbf{V}|\mathbf{U})$. Clearly, the higher the MI, the more useful the information in $\mathbf{V}$ helps us to predict the cluster labels in $\mathbf{U}$ and vice-versa.

Before closing this section, we list several generally desirable properties of a clustering comparison measure. This list is not meant to be exhaustive, and particular applications might require other specific properties.

- *Metric property*: the metric property requires that a distance measure satisfy the properties of a true metric, namely positive definiteness, symmetry and triangle inequality. As the most basic benefit, the metric property conforms to our intuition of distance (Meilă, 2007). Furthermore, it is important if one would like to study, either the structure of, or design algorithms for the complex space of clusterings, as many nice theoretical results already exist for metric spaces.

- *Normalization*: the normalization property requires that the range of a similarity or distance measure lies within a fixed range, for example, [-1,1] or [0,1]. Normalization facilitates interpretation and comparison across different conditions (Strehl and Ghosh, 2002; Luo et al., 2009), where unbounded measures might have different ranges. Also, normalization has been shown to improve the sensitiveness of certain measures, such as the MI, with respect to the difference in cluster distribution in the two clusterings (Wu et al., 2009). The fact that all of the 22 different pair counting based measures discussed in Albatineh et al. (2006) are normalized, further stresses the particular interest of the clustering community in this property.

- *Constant baseline property*: for a similarity measure, its expected value between pairs of independent clusterings, for example, clusterings sampled independently at random, should be a constant. Ideally this baseline value should be zero, indicating no similarity. The Rand index is an example of a similarity index which does not satisfy this rather intuitive property, the reason why it has been mainly used in its adjusted form.

*These measures are normalized in a stochastic sense, being equal to 1 if the (unadjusted) measures equal their value as expected by chance agreement. †Our proposed measures.

Table 2: Information theoretic-based similarity measures

Similarity measures: the mutual information (MI), a non-negative quantity, can be employed as the most basic similarity measure. Based on the observation that the MI is upper-bounded by the following quantities:

$$I(\mathbf{U},\mathbf{V}) \leq \min\{H(\mathbf{U}),H(\mathbf{V})\} \leq \sqrt{H(\mathbf{U})H(\mathbf{V})} \leq \frac{1}{2}(H(\mathbf{U})+H(\mathbf{V})) \leq \max\{H(\mathbf{U}),H(\mathbf{V})\} \leq H(\mathbf{U},\mathbf{V}), \quad (1)$$

we can derive several normalized versions of the mutual information (NMI) as listed in Table 2. All the normalized variants are bounded in [0,1], equaling 1 when the two clusterings are identical, and 0 when they are independent, that is, sharing no information about each other. In the latter case, the contingency table takes the form of the so-called "independence table" where $n_{ij} = |U_i||V_j|/N$ for all i, j. The MI and some of its normalized versions have been used in the clustering literature as similarity measures between objects in general (see, for example, Yao, 2003 and references therein). For the particular purpose of clustering comparison, Banerjee et al. (2005) employed the unnormalized MI. Strehl and Ghosh (2002) on the other hand made use of the NMI_{sqrt} normalized version, which has also been used in several follow-up works in the context of ensemble clustering (Fern and Brodley, 2003; He et al., 2008; Asur et al., 2007; Tumer and Agogino, 2008).

Table 3: Information theoretic-based distance measures

Distance measures: based on the five upper bounds for $I(\mathbf{U},\mathbf{V})$ given in (1), we can define five distance measures, namely $D_{joint}, D_{max}, D_{sum}, D_{sqrt}$ and D_{min}, as detailed in Table 3. However, it can be seen that $D_{joint} = 2D_{sum}$,[1] and these two measures have been known in the clustering literature as the variation of information—VI (Meilă, 2005). The fact that D_{joint} (and hence D_{sum}) is a true metric is a well known result (Meilă, 2005). In addition, we also present the following new results (see Appendix for proof):

Theorem 1 *D_{max} is a metric.*

Theorem 2 *D_{min} and D_{sqrt} are **not** metrics.*

The negative result given in Theorem 2 is indeed helpful in narrowing our search scope for a reasonable distance measure. So far, D_{max} and D_{joint} (D_{sum}) are potential candidates. These distance measures do not have a fixed upper bound however, and we are therefore seeking some normalized variants. By dividing each distance measure by its corresponding upper bound we can define five normalized variants as detailed in Table 3, which are actually the unit-complements of the corresponding NMI variants, for example, $d_{joint} = 1 - \mathrm{NMI}_{joint}$. We now state the following properties of the normalized distance measures:

Theorem 3 *The normalized variation of information, d_{joint}, is a metric*

Theorem 4 *The normalized information distance, d_{max}, is a metric*

1. $2D_{sum}(\mathbf{U},\mathbf{V}) = H(\mathbf{U})+H(\mathbf{V})-2I(\mathbf{U},\mathbf{V}) = [H(\mathbf{U})+H(\mathbf{V})-I(\mathbf{U},\mathbf{V})] - I(\mathbf{U},\mathbf{V}) = H(\mathbf{U},\mathbf{V}) - I(\mathbf{U},\mathbf{V}) = D_{joint}(\mathbf{U},\mathbf{V})$.

Theorem 5 *The normalized distance measures d_{min}, d_{sum} and d_{sqrt}, are* ***not*** *metrics.*

The proofs for Theorem 3 and 4 was presented in an unofficially extended version of Kraskov et al. (2005).[2] Unfortunately, their proof for Theorem 4 was erroneous.[3] Since these are two interesting results, we give our shortened proof for Theorem 3 and a corrected proof for Theorem 4 in the Appendix. The negative results in Theorem 5 are again useful in narrowing our scope looking for a good candidate. From our discussion so far, we can now identify two promising candidates: d_{joint} and d_{max}. Since the variation of information—D_{joint}—is the unnormalized version of d_{joint}, we shall name d_{joint} the normalized variation of information (NVI). d_{max} has not been named in the literature, therefore we name it after its well known analogue in Kolmogorov complexity theory (Li et al., 2004), the normalized information distance (NID). Both the NVI and NID have the remarkable property of being both a metric and a normalized measure. We note that Meilă (2007) proposed normalized variants for the VI, such as: $V(\mathbf{U},\mathbf{V}) = \frac{1}{\log N}\mathrm{VI}(\mathbf{U},\mathbf{V})$ or: $V_{K^*}(\mathbf{U},\mathbf{V}) = \frac{1}{2\log K^*}\mathrm{VI}(\mathbf{U},\mathbf{V})$ when the number of clusters in both $\mathbf{U}$ and $\mathbf{V}$ is bounded by the same constant $K^* < \sqrt{N}$. The bounds of $\log N$ and $2\log K^*$ are not as strict as $H(\mathbf{U},\mathbf{V})$ however,[4] thus the useful range of these normalized VI variants is narrower than that of d_{joint}. The joint entropy $H(\mathbf{U},\mathbf{V})$ provides a stricter upper bound, enabling d_{joint} to better exploit the [0,1] range, while still retaining the metric property. It is noted that since $\max\{H(\mathbf{U}),H(\mathbf{V})\}$ is yet a tighter upper bound for $\mathrm{MI}(\mathbf{U},\mathbf{V})$ than $H(\mathbf{U},\mathbf{V})$, d_{max} is generally more preferable to d_{joint} since it can even better use the nominal range of $[0,1]$. A subtle point regarding normalization by quantities such as $\max\{H(\mathbf{U}),H(\mathbf{V})\}$ and $H(\mathbf{U},\mathbf{V})$, as has been brought to our attention by the Editor, is their potential side effects on the normalization process. For validation purpose for example, if $\mathbf{U}$ is the ground-truth, and $\mathbf{V}$ is the clustering obtained by some algorithm, then the normalization also depends on $\mathbf{V}$. Thus, while random quantities such as $\max\{H(\mathbf{U}),H(\mathbf{V})\}$ and $H(\mathbf{U},\mathbf{V})$ provide tighter bounds, their effect on the normalization process is not as clear as looser, fixed bounds such as $\log N$ and $2\log K^*$.

4. Adjustment for Chance

In this section we inspect the proposed information theoretic measures with respect to the third desirable property, that is, the *constant baseline property*. We shall first point out that, just like the well-known Rand index, the baseline value of information theoretic measures does not take on a constant value, and thus adjustment for chance will be needed in certain situations. Let us consider the following two motivating examples:

1) Example 1 - Distance to a "true" clustering: given a ground-truth clustering $\mathbf{U}$ with K_{true} clusters, we need to assess the goodness of two clusterings $\mathbf{V}$ with C clusters, and $\mathbf{V}'$ with C' clusters. If $C = C'$ then the situation would be quite simple. Since the setting is the same for both $\mathbf{V}$ and $\mathbf{V}'$, we expect the comparison to be "fair" under any particular measure. However if $C \neq C'$, the situation becomes more complicated. We set up an experiment as follows: consider a set of N data points, let the number of clusters K vary from 2 to K_{max} and suppose that the true clustering has $K_{true} = [K_{max}/2]$ clusters. Now for each value of K, generate 10,000 random clusterings and calculate the average MI, NMI_{max}, VI, RI and ARI between those clusterings to a fixed, random

2. Available online at `http://arxiv.org/abs/q-bio/0311039v2`.
3. In their case 1, $D'(Z,Y)$ is in fact not equal to $H(Z|Y)/H(Y)$.
4. If $N \leq RC$ then $H(\mathbf{U},\mathbf{V}) \leq \log N$, with the equality attained only when cells of the contingency table contain only either 1 or 0. If $N > RC$ then $H(\mathbf{U},\mathbf{V}) \leq \log(RC) \leq \log(K^*K^*) = 2\log K^*$.

clustering chosen as the "true" clustering. The results for two combinations of (N, K_{true}) are given in Fig. 1(a,b). It can be observed that the unadjusted measures such as the RI, MI and NMI (VI) monotonically increase (decreases) as K increases. Thus even by selecting totally at random, a 7-cluster solution would have a greater chance to outperform a 3-cluster solution, although there isn't any difference in the clustering generation methodology. A corrected-for-chance measure, such as the ARI, on the other hand, has a baseline value always close to zero, and appears not to be biased in favor of any particular value of K. The same issue is observed with all other variants of the NMI (data not shown). Thus for this example, an adjusted-for-chance version of the MI is desirable.

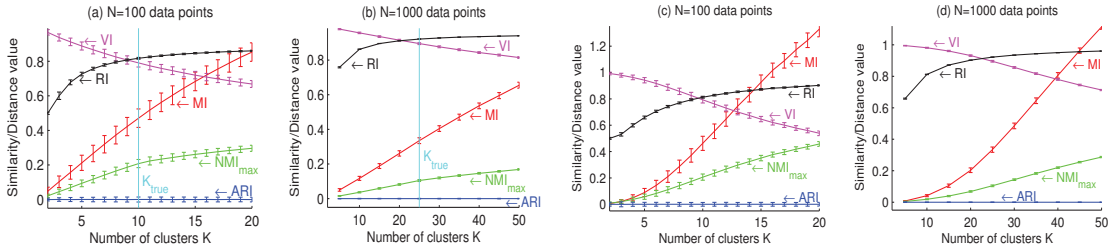

Figure 1: (a,b) Average distance between sets of random clusterings to a "true" clustering (c,d) Average pairwise distance in a set of random clusterings. Error bars denote standard deviation.

2) Example 2 - Determining the number of clusters via consensus (ensemble) clustering: in an era where a huge number of clustering algorithms exist, the consensus clustering idea (Monti et al., 2003; Strehl and Ghosh, 2002; Yu et al., 2007) has recently received increasing interest. Consensus clustering is not just another clustering algorithm: it rather provides a framework for unifying the knowledge obtained from other algorithms. Given a data set, consensus clustering employs one or several clustering algorithms to generate a set of clustering solutions on either the original data set or its perturbed versions. From these clustering solutions, consensus clustering aims to choose a robust and high quality representative clustering. Although the main objective of consensus clustering is to discover a high quality cluster structure, closer inspection of the set of clusterings obtained can often give valuable information about the appropriate number of clusters present. More specifically, we have empirically observed the following: in regard to the set of clusterings obtained, when the specified number of clusters coincides with the true number of clusters, this set has a tendency to be less diverse. This is an indication of the robustness of the obtained cluster structure. To quantify this diversity we have recently developed a novel index (Vinh and Epps, 2009), namely the *consensus index* (CI), which is built upon a suitable clustering similarity measure. Given a value of K, suppose we have generated a set of B clustering solutions $\mathcal{U}_K = \{\mathbf{U}_1, \mathbf{U}_2, \ldots, \mathbf{U}_B\}$, each with K clusters. We define the consensus index of $\mathcal{U}_K$ as:

$$\mathrm{CI}(\mathcal{U}_K) = \frac{\sum_{i<j} \mathrm{AM}(\mathbf{U}_i, \mathbf{U}_j)}{B(B-1)/2}$$

where the agreement measure AM is a suitable clustering similarity index. Thus, the CI quantifies the average pairwise agreement in $\mathcal{U}_K$. The optimal number of clusters K^* is chosen as which that maximizes CI, that is, $K^* = \arg\max_{K=2\ldots K_{max}} \mathrm{CI}(\mathcal{U}_K)$. In this setting, a normalized measure is preferable for its equalized range at different values of K. We performed an experiment as follows:

given N data points, randomly assign each data point into one of the K clusters with equal probability and check to ensure that the final clustering contains exactly K clusters. For each K, repeat this 200 times to create 200 random clusterings, then calculate the average values of the MI, VI, NMI_{max}, RI and ARI between all 19,900 clustering pairs. Typical experimental results are presented in Fig. 1(c,d). It can be observed that for a given data set, the average MI, NMI and RI (VI) values between random clusterings tend to increase (decrease) as the number of clusters increases, while the average value of the ARI is always close to zero. When the ratio of N/K is large, the average value for NMI is reasonably close to zero, but grows as N/K becomes smaller. This is clearly an unwanted effect, since a consensus index built upon the MI, NMI and VI would be biased in favour of a larger number of clusters. Thus in this situation, an adjusted-for-chance version of the MI is again important.

4.1 The Proposed Adjusted Measures

To correct the measures for randomness it is necessary to specify a model according to which random partitions are generated. Such a common model is the "permutation model" (Lancaster, 1969, p. 214), in which clusterings are generated randomly subject to having a fixed number of clusters and points in each clusters. Using this model, which was also adopted by Hubert and Arabie (1985) for the ARI, we have previously shown (Vinh et al., 2009) that the expected mutual information between two clusterings $\mathbf{U}$ and $\mathbf{V}$ is:

$$\mathbf{E}\{I(\mathbf{U},\mathbf{V})\} = \sum_{i=1}^{R}\sum_{j=1}^{C}\sum_{n_{ij}=\max(a_i+b_j-N,0)}^{\min(a_i,b_j)} \frac{n_{ij}}{N}\log\left(\frac{N.n_{ij}}{a_i b_j}\right)\frac{a_i!b_j!(N-a_i)!(N-b_j)!}{N!n_{ij}!(a_i-n_{ij})!(b_j-n_{ij})!(N-a_i-b_j+n_{ij})!}. \quad (2)$$

As suggested by Hubert and Arabie (1985), the general form of a similarity index corrected for chance is given by:

$$\text{Adjusted\_Index} = \frac{\text{Index} - \text{Expected\_Index}}{\text{Max\_Index} - \text{Expected\_Index}}, \quad (3)$$

which is upper-bounded by 1 and equals 0 when the index equals its expected value. Having calculated the expectation of the MI, we propose the adjusted form, which we call the *adjusted mutual information* (AMI), for the normalized mutual information according to (3). For example, taking the NMI_{max} we have:

$$\text{AMI}_{max}(\mathbf{U},\mathbf{V}) = \frac{\text{NMI}_{max}(\mathbf{U},\mathbf{V}) - \mathbf{E}\{\text{NMI}_{max}(\mathbf{U},\mathbf{V})\}}{1 - \mathbf{E}\{\text{NMI}_{max}(\mathbf{U},\mathbf{V})\}} = \frac{I(\mathbf{U},\mathbf{V}) - \mathbf{E}\{I(\mathbf{U},\mathbf{V})\}}{\max\{H(\mathbf{U}),H(\mathbf{V})\} - \mathbf{E}\{I(\mathbf{U},\mathbf{V})\}}.$$

Similarly, other adjusted *similarity* measures are listed in Table 2. It can be seen that the adjusted-for-chance forms of the MI are all normalized in a stochastic sense. Specifically, the AMI equals 1 when the two clusterings are identical, and 0 when the MI between the two clusterings equals its expected value. The adjusted forms for the *distance* measures, listed in Table 2, are again the unit-complements of the corresponding adjusted *similarity* measures, for example, $Ad_{max} = 1 - \text{AMI}_{max}$, and are also normalized in a stochastic sense. Following the naming scheme that we have adopted throughout in this paper, we name Ad_{max} the adjusted information distance. It is noted that at this stage, we have not been able to derive an analytical solution for the adjusted form for the normalized variation of information (d_{joint}) measure. The derivation of the expected value for this measure appears to be more involved observing that $I(\mathbf{U},\mathbf{V})$ is present in both the numerator and denominator ($H(\mathbf{U},\mathbf{V}) = H(\mathbf{U}) + H(\mathbf{V}) - I(\mathbf{U},\mathbf{V})$). We repeat the experiments described in examples 1 and 2, this time with the adjusted version of the NMI_{max}. Now it can be seen from Fig. 2 that just like the ARI, the AMI_{max} baseline values are close to zero. It is noted that in these experiments, we did not

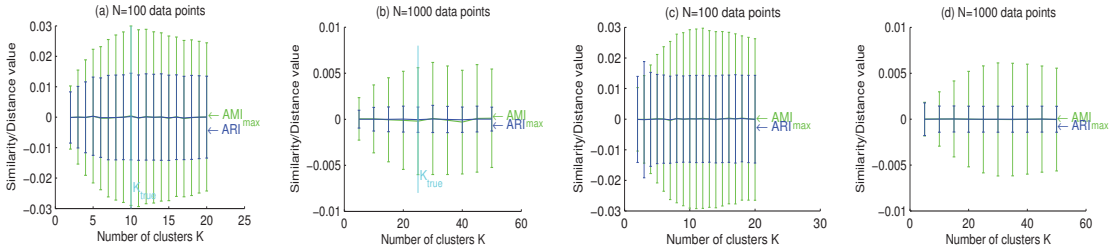

Figure 2: (a,b) Average distance between sets of random clusterings to a "true" clustering (c,d) Average pairwise distance in a set of random clusterings. Error bars denote standard deviation.

require the marginals of the contingency table to be fixed as per the assumption of the generalized hypergeometric model of randomness. Nevertheless, the adjusted measures still exhibit the desired behavior.

4.2 Properties of the Adjusted Measures

While admitting a constant baseline, the proposed adjusted-for-chance measures are, unfortunately, not proper metrics:

Theorem 6 *The adjusted measures $Ad_{max}, Ad_{sum}, Ad_{sqrt}$ and Ad_{min} are **not** metrics.*

There is thus a trade-off between the metric property and correction for chance, and the user should decide which property is of higher priority. Fortunately, during our experiments with the AMI, we have observed that when the data contain a fairly large number of items as compared to the number of clusters, for example, $N/K \geq 100$, then the expected mutual information is fairly close to zero, as can be seen in Fig. 1, suggesting scenarios where adjustment for chance is not of utmost necessity. The following results formalize this observation:

Theorem 7 *Some upper bounds for the expected mutual information between two random clusterings $\boldsymbol{U}$ and $\boldsymbol{V}$ (on a data set of N data items, with R and C clusters respectively), under the hypergeometric distribution model of randomness are given by the followings:*

$$\boldsymbol{E}\{I(\boldsymbol{U},\boldsymbol{V})\} \leq \sum_{i=1}^{R}\sum_{j=1}^{C}\frac{a_i b_j}{N^2}\log\left(\frac{N(a_i-1)(b_j-1)}{(N-1)a_i b_j}+\frac{N}{a_i b_j}\right) \leq \log\left(\frac{N+RC-R-C}{N-1}\right). \quad (4)$$

These bounds shed light on the large sample property of the adjusted measures. The following result trivially follows:

Corollary 1 *Given R and C fixed, $\lim_{N\to\infty}\boldsymbol{E}\{I(\boldsymbol{U},\boldsymbol{V})\} = 0$, and thus the adjusted measures tend toward the normalized measures.*

Also, these bounds give useful information on whether adjustment for chance is needed. For example, on a data set of 100 data items and two clusterings $\mathbf{U}$ and $\mathbf{V}$, each having 10 clusters with sizes of $[10,10,10,10,10,10,10,10,10,10]$ and $[2,4,6,8,10,10,12,14,16,18]$ respectively, the expected MI and its upper bounds according to (2) and (4) are $\mathbf{E}\{I(\mathbf{U},\mathbf{V})\} = 0.4618 < 0.5584 <$

0.5978. As the maximum MI value is only $\log(10) = 2.3$, correction for chance is needed since the baseline is high. However, if the data size increases ten-fold to 1000 items, keeping the same number of clusters and cluster distribution, the two upper bounds are 0.0764 and 0.0780 respectively, which can be considered small enough for many applications, therefore adjustment for chance might be omitted.

4.3 An Example Application

As per our analysis, adjustment for chance for information theoretic measures is mostly needed when the number of data items is relatively small compared to the number of clusters. One such prominent example is in microarray data analysis, where biological samples are clustered using gene expression data. Due to the high cost of preparing and collecting microarray data, each class, for example, of tumor, might contain only as few as several samples. In this section we demonstrate the use of the consensus index to estimate the number of clusters in microarray data. Eight synthetic and real microarray data sets are drawn from Monti et al. (2003), as detailed in Table 4 (see the original publication for preprocessing issues). A quick check upon the (higher) upper bound of the expected MI on these data sets suggests that correction for chance will be needed, for example, on the Leukemia data set, as $K(= R = C)$ grows from 2 to 10, this upper bound grows from 0.03 to 1.16.

Simulated Data	#Classes	#Samples	#Genes	Real data	#Classes	#Samples	#Genes
Gaussian3	3	60	600	Leukemia	3	38	999
Gaussian5	5	500	2	Novartis	4	103	1000

Simulated6	6-7	60	600	Normal tissues	13	90	1277

Table 4: Microarray data sets summary, source: Monti et al. (2003)

In Vinh and Epps (2009) we have shown that the CI, coupled with sub-sampling as the perturbation method, gives useful information on the appropriate number of clusters in microarray data. Herein, we experimented with random projection as the perturbation scheme. More specifically, the original data set was projected on a random set of 80% of the genes, and the K-means clustering algorithm was run with random initialization on the projected data set. For each value of K, 100 of such clustering solutions were created and the CI's for 6 measures, namely RI, ARI, MI, VI, NMI_{max} and AMI_{max} were calculated. Ideally we expect to see a strong global peak at the true number of cluster K_{true}. From Fig. 3(a) it can be observed that the unadjusted MI has a strong bias with respect to the number of clusters, increasing monotonically as K increases. Similar behavior was observed with all other data sets and therefore MI is not an appropriate measure for this purpose. For ease of presentation, we have excluded the MI from Fig. 3(b-h). The effect of adjustment for chance can be clearly observed in Fig. 3(c,d,e,h). Agreement by chance inflates the CI score of the unadjusted measures (RI, NMI, VI) in such cases, and can lead to incorrect estimation. The CI of the adjusted measures (ARI, AMI) correctly estimates the number of clusters in all synthetic data sets with high confidence, whereas on real data sets it gives correct estimations on the Leukemia and Normal tissues data set. The CI suggests only 3 clusters on the Novartis while the assumed number of clusters is 4. The Lung cancer data set is an example where human experts are not yet confident on the true number of clusters present (4+ clusters), while the CI gives a local peak at 6 clusters. These results are concordant with our previous finding (Vinh and Epps, 2009). The fact that the CI

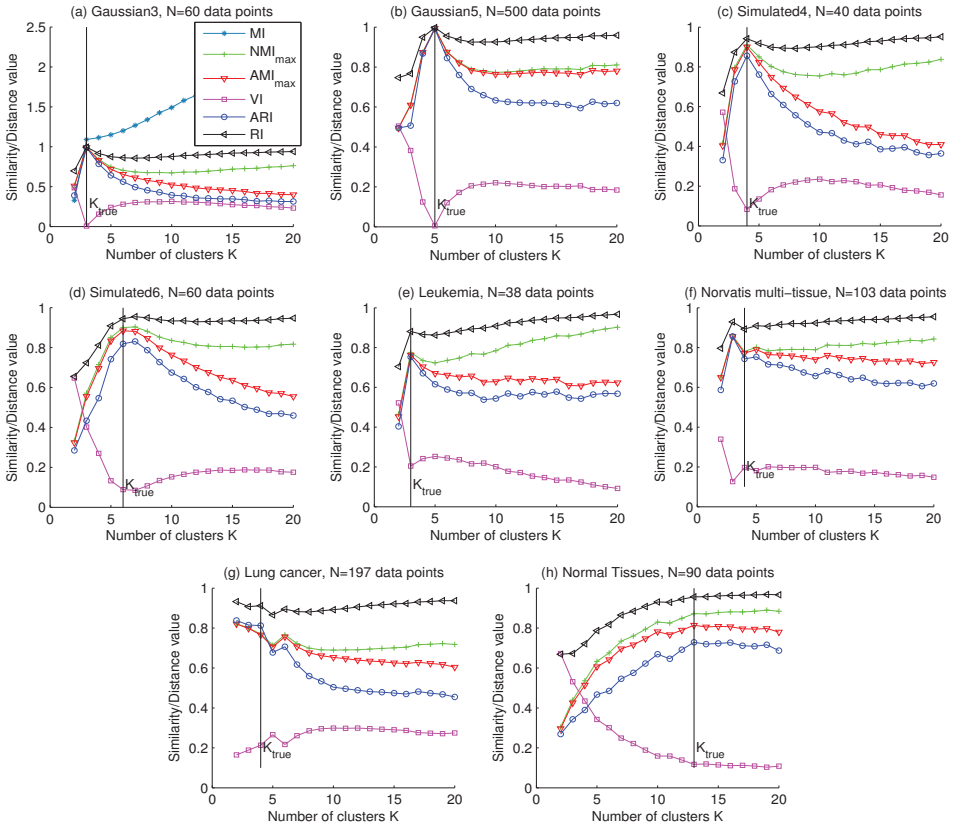

Figure 3: Consensus Index on microarray data sets.

showing global or local peaks at or near the presumably true number of clusters as attributed by the respective authors calls for further investigation on both the biological side (re-verifying the number of clusters), and the CI side (the behaviour of the index with respect to the structure of the data set, for example, the data set might contain a hierarchy of clusters and thus the CI may exhibit local peaks corresponding to such structures).

5. Related Work

Meilă (2005) considered clustering comparison measures with respect to their alignment with the lattice of partitions. In addition to the metric property, she considered three more properties namely *additivity with respect to refinement*, *additivity with respect to the join* and *convex additivity*, and showed that the VI satisfies all these properties. Unfortunately, none of the normalized or adjusted variants of the MI is fully aligned with the lattice of partitions in the above sense. Beside enhancing intuitiveness, these properties could possibly improve the efficiency of algorithms, for example, search algorithms, in the space of clusterings, though there seems not to be yet an experimental study to support such claim, calling for interesting further investigation. Nevertheless, we note that for a particular application, not always every desired property is concurrently needed at once. For example, when performing search in the space of clusterings, normalization might not be necessary, and the VI, which aligns better with the lattice of partitions, might be a more appropriate choice.

Wu et al. (2009) considered clustering comparison measures with respect to their sensitivity with class distribution. They showed that real life data can possess highly skewed class distributions, whereas some algorithms, such as K-means, tend to create balanced clusters. A good measure should therefore be sensitive to the difference in class distribution. To demonstrate this property, they used the example in Table 5, with a ground-truth clustering $\mathbf{U}$ having class sizes of [30, 2, 6, 10, 2], and two clustering solutions: $\mathbf{V}$ having cluster sizes of [10, 10, 10, 10, 10]; and $\mathbf{V}'$ having cluster sizes of [29, 2, 6, 11, 2]. It is easily seen that $\mathbf{V}'$ closely reflects the class structure in $\mathbf{U}$, and thus should be judged closer to $\mathbf{U}$ than $\mathbf{V}$. The authors showed that the unnormalized MI is a "defective measure", in that it judges $\mathrm{MI}(\mathbf{U},\mathbf{V}) > \mathrm{MI}(\mathbf{U},\mathbf{V}')$, and suggested using the "normalized VI" (d_{sum}). It can be shown that among the normalized and adjusted variants of the MI considered in this paper, only the $\mathrm{NMI}_{min}, D_{min}, d_{min}$ and Ad_{min} are defective measures in the above sense.

6. Conclusion

This paper has presented an organized study of information theoretic measures for clustering comparison. We have shown that the normalized information distance (NID) and normalized variation of information (NVI) satisfy both the normalization and the metric properties. Between the two, the NID is preferable since the tighter upper bound of the MI used for normalization allows it to better use the [0,1] range. We highlighted the importance of correcting these measures for chance agreement, especially when the number of data points is relatively small compared with the number of clusters, for example, in the case of microarray data analysis. One of the theoretical advantages of the NID over the popular adjusted Rand index is that it can be used in the non-adjusted form (when N/K is large), thus enjoying the property of being a true metric in the space of clusterings. We therefore advocate the NID as a "general purpose" measure for clustering validation, comparison and algorithm design, for it possesses concurrently several useful and important properties. Nevertheless, we note that for a particular application scenario, not always every desired property is needed concurrently, and therefore the user should prioritize the most important property. Our research systematically organizes and complements the current literature to help readers make more informed decisions.

Appendix A. Proofs

Proof (Theorem 1) We only prove the triangle inequality as other parts are trivial. We first show that

$$H(X|Y) \leq H(X|Z) + H(Z|Y) \tag{5}$$

holds true, since $H(X|Y) \leq H(X,Z|Y) = H(X|Z,Y) + H(Z|Y) \leq H(X|Z) + H(Z|Y)$ (the last inequality holds since conditioning always decreases entropy). We now prove the main theorem. Without loss of generality, assume that $H(Y) \leq H(X)$, and therefore $H(X|Y) \geq H(Y|X)$. The proof uses (5):

- Case 1: $H(Z) \leq H(Y)$

  $$D_{max}(X,Y) = H(X|Y) \leq H(X|Z) + H(Z|Y) \leq H(X|Z) + H(Y|Z) = D_{max}(X,Z) + D_{max}(Y,Z)$$

- Case 2: $H(Y) < H(Z) \leq H(X)$

  $$D_{max}(X,Y) = H(X|Y) \leq H(X|Z) + H(Z|Y) = D_{max}(X,Z) + D_{max}(Y,Z)$$

- Case 3: $H(X) < H(Z)$

  $$D_{max}(X,Y) = H(X|Y) \leq H(X|Z) + H(Z|Y) \leq H(Z|X) + H(Z|Y) = D_{max}(X,Z) + D_{max}(Y,Z)$$

■

Proof (Theorem 3) We prove the triangle inequality. Without loss of generality, assume that $H(X) \geq H(Y)$, therefore $H(X|Y) \geq H(Y|X)$ and $NID(X,Y) = H(X|Y)/H(X)$. The proof uses inequality (5) and simple algebra manipulations:

- Case 1: $H(Z) \leq H(Y) \leq H(X)$

  $$NID(X,Y) = \frac{H(X|Y)}{H(X)} \leq \frac{H(X|Z) + H(Z|Y)}{H(X)} \leq \frac{H(X|Z) + H(Y|Z)}{H(X)} \leq \frac{H(X|Z)}{H(X)} + \frac{H(Y|Z)}{H(Y)}$$

- Case 2: $H(Y) \leq H(Z) \leq H(X)$

  $$NID(X,Y) = \frac{H(X|Y)}{H(X)} \leq \frac{H(X|Z)}{H(X)} + \frac{H(Z|Y)}{H(X)} \leq \frac{H(X|Z)}{H(X)} + \frac{H(Z|Y)}{H(Z)} = NID(X,Z) + NID(Z,Y)$$

- Case 3: $H(Z) > H(X)$

  $$NID(X,Y) = \frac{H(X|Y)}{H(X)} < \frac{H(X|Z) + H(Z|Y)}{H(X)}$$

  If the *r.h.s* ≤ 1 then adding $H(Z) - H(X) > 0$ to both its nominator and denominator will increase it:

  $$r.h.s \leq \frac{H(X|Z) + H(Z|Y) + H(Z) - H(X)}{H(X) + H(Z) - H(X)} = \frac{H(Z|X)}{H(Z)} + \frac{H(Z|Y)}{H(Z)} = NID(X,Z) + NID(Z,Y),$$

therefore the triangle inequality holds. Otherwise if the *r.h.s* > 1 then adding $H(Z)-H(X) > 0$ to both its nominator and denominator as above will decrease it, but it will still be larger than 1. Therefore we also have:

$$NID(X,Y) \leq 1 < \frac{H(X|Z)+H(Z|Y)+H(Z)-H(X)}{H(X)+H(Z)-H(X)} = NID(X,Z)+NID(Z,Y).$$

■

Proof (Theorem 4) Again only the triangle inequality proof is of interest. It is sufficient to prove the following inequality:

$$\frac{H(X|Y)}{H(X,Y)} \leq \frac{H(X|Z)}{H(X,Z)} + \frac{H(Z|Y)}{H(Z,Y)},$$

then swap X and Y to obtain another analogous inequality and add them together we have the triangle inequality. The proof uses inequality (5) and simple algebra manipulations:

$$\frac{H(X|Y)}{H(X,Y)} = \frac{H(X|Y)}{H(Y)+H(X|Y)} \leq \frac{H(X|Z)+H(Z|Y)}{H(Y)+H(X|Z)+H(Z|Y)} = \frac{H(X|Z)+H(Z|Y)}{H(X|Z)+H(Y,Z)} = \dots$$
$$= \frac{H(X|Z)}{H(X|Z)+H(Y,Z)} + \frac{H(Z|Y)}{H(X|Z)+H(Y,Z)} \leq \frac{H(X|Z)}{H(X|Z)+H(Z)} + \frac{H(Z|Y)}{H(Y,Z)} = \frac{H(X|Z)}{H(X,Z)} + \frac{H(Z|Y)}{H(Z,Y)}.$$

■

Proof (Theorems 2 and 5) It is sufficient to point out a single counter example where the triangle inequality is violated. Let X and Y be two *independent* random binary variables with probability $P(X=1)=P(X=0)=P(Y=1)=P(Y=0)=1/2$, then $Z=[X;Y]$ is also a random variable with four discrete values. It is straightforward to verify that the triangle inequality is violated for all the mentioned distance measures, for example, $D_{min}(X,Y)=1 < D_{min}(X,Z)+D_{min}(Y,Z)=0$. ■

Proof (Theorem 6) For $N=5$, a counter example for the triangle inequality is the following three clusterings: $\mathbf{U}=\{U_3U_1U_1U_1U_2\}, \mathbf{V}=\{V_2V_2V_3V_1V_2\}, \mathbf{X}=\{X_2X_1X_1X_1X_2\}$.

Similarly, for $N=5+d$ $(d \in \mathbb{N}^+)$, a counter example for the triangle inequality is the following three clusterings: $\mathbf{U}=\{U_3U_1U_1U_1U_2U_6U_7\dots U_{5+d}\}$, $\mathbf{V}=\{V_2V_2V_3V_1V_2V_6V_7\dots V_{5+d}\}$, $\mathbf{X}=\{X_2X_1X_1X_1X_2X_6X_7\dots X_{5+d}\}$. ■

Proof (Theorem 7) The following facts from the generalized hypergeometric distribution will be useful:

$$\mathbf{E}(n_{ij}) = \sum_{n_{ij}} n_{ij}\mathcal{P}(M|n_{ij},a,b) = \frac{a_i,b_j}{N}, \tag{6}$$
$$\mathbf{E}(n_{ij}^2) = \sum_{n_{ij}} n_{ij}^2\mathcal{P}(M|n_{ij},a,b) = \frac{a_i(a_i-1)b_j(b_j-1)}{N(N-1)} + \frac{a_ib_j}{N},$$

where $\mathcal{P}\{M|n_{ij},a,b\} = \frac{\binom{N}{n_{ij}}\binom{N-n_{ij}}{a_i-n_{ij}}\binom{N-a_i}{b_j-n_{ij}}}{\binom{N}{a_i}\binom{N}{b_j}}$ is the probability of encountering a contingency table M having fixed marginals a,b and the $(i,j)-th$ entry being n_{ij} under the generalized hypergeometric

model of randomness. Note that for the sake of notational simplicity we have dropped the lower and upper values of n_{ij} which runs from $\max((a_i+b_j-N),0)$ to $\min(a_i,b_j)$ in the sums. From (6) we have:

$$\mathbf{E}(n_{ij}) = \sum_{n_{ij}} n_{ij}\mathcal{P}(M|n_{ij},a,b) = \frac{a_i b_j}{N}\sum_{n_{ij}} \frac{n_{ij}N}{a_i b_j}\mathcal{P}(M|n_{ij},a,b) = \frac{a_i b_j}{N},$$

therefore: $\sum_{n_{ij}} \frac{n_{ij}N}{a_i b_j}\mathcal{P}(M|n_{ij},a,b) = 1$. Let $Q(n_{ij}) = \frac{n_{ij}N}{a_i b_j}\mathcal{P}(M|n_{ij},a,b)$, then we can think of $Q(n_{ij})$ as a discrete probability distribution on n_{ij}. Applying Jensen's inequality ($\mathbf{E}(f(x)) \leq f(\mathbf{E}(x))$ for f concave) to the concave logarithm function yields:

$$\sum_{n_{ij}} \frac{n_{ij}}{N}\log(\frac{N.n_{ij}}{a_i b_j})\mathcal{P}(M|n_{ij},a,b) = \sum_{n_{ij}} \frac{a_i b_j}{N^2}\log(\frac{N.n_{ij}}{a_i b_j})Q(n_{ij}) \leq \frac{a_i b_j}{N^2}\log\left(\mathbf{E}_Q(\frac{N.n_{ij}}{a_i b_j})\right). \quad (7)$$

Now, let us calculate $\mathbf{E}_Q(\frac{N.n_{ij}}{a_i b_j})$:

$$\begin{aligned}\mathbf{E}_Q(\frac{N.n_{ij}}{a_i b_j}) &= \sum_{n_{ij}} \frac{N.n_{ij}}{a_i b_j}Q(n_{ij}) = \sum_{n_{ij}} \frac{N.n_{ij}}{a_i b_j}\frac{n_{ij}N}{a_i b_j}\mathcal{P}(M|n_{ij},a,b) = \frac{N^2}{a_i^2 b_j^2}\sum_{n_{ij}} n_{ij}^2\mathcal{P}(M|n_{ij},a,b) \\ &= \frac{N^2}{a_i^2 b_j^2}\left(\frac{a_i(a_i-1)b_j(b_j-1)}{N(N-1)} + \frac{a_i b_j}{N}\right) = \frac{N(a_i-1)(b_j-1)}{(N-1)a_i b_j} + \frac{N}{a_i b_j}.\end{aligned}$$

Substituting this expression into (7) yields:

$$\sum_{n_{ij}} \frac{n_{ij}}{N}\log(\frac{N.n_{ij}}{a_i b_j})\mathcal{P}(M|n_{ij},a,b) \leq \frac{a_i b_j}{N^2}\log\left(\frac{N(a_i-1)(b_j-1)}{(N-1)a_i b_j} + \frac{N}{a_i b_j}\right).$$

Finally:

$$\mathbf{E}\{I(\mathbf{U},\mathbf{V})\} = \sum_{i=1}^{R}\sum_{j=1}^{C}\sum_{n_{ij}} \frac{n_{ij}}{N}\log(\frac{N.n_{ij}}{a_i b_j})P(M|n_{ij},a,b) \leq \sum_{i=1}^{R}\sum_{j=1}^{C} \frac{a_i b_j}{N^2}\log\left(\frac{N(a_i-1)(b_j-1)}{(N-1)a_i b_j} + \frac{N}{a_i b_j}\right). \quad (8)$$

Note that $\sum_{ij} a_i b_j/N^2 = 1$, continue applying Jensen's inequality on (8) yields:

$$\mathbf{E}\{I(\mathbf{U},\mathbf{V})\} \leq \log\left(\sum_{i=1}^{R}\sum_{j=1}^{C} \frac{a_i b_j}{N^2}(\frac{N(a_i-1)(b_j-1)}{(N-1)a_i b_j} + \frac{N}{a_i b_j})\right) = \log\left(\frac{N+RC-R-C}{N-1}\right)$$

Abstract

We show how a preselection of hidden variables can be used to efficiently train generative models with binary hidden variables. The approach is based on Expectation Maximization (EM) and uses an efficiently computable approximation to the sufficient statistics of a given model. The computational cost to compute the sufficient statistics is strongly reduced by selecting, for each data point, the relevant hidden causes. The approximation is applicable to a wide range of generative models and provides an interpretation of the benefits of preselection in terms of a variational EM approximation. To empirically show that the method maximizes the data likelihood, it is applied to different types of generative models including: a version of non-negative matrix factorization (NMF), a model for non-linear component extraction (MCA), and a linear generative model similar to sparse coding. The derived algorithms are applied to both artificial and realistic data, and are compared to other models in the literature. We find that the training scheme can reduce computational costs by orders of magnitude and allows for a reliable extraction of hidden causes.

Keywords: maximum likelihood, deterministic approximations, variational EM, generative models, component extraction, multiple-cause models

1. Introduction

In many applications of artificial and biological systems, data interpretation is challenging because of noise, the complexity of the input and because of its ambiguity. Optimal inference based on probabilistic generative models is in general intractable in such situations because it involves the evaluation of all potential interpretations of the input. To approximate optimal inference, a fast initial stage of processing has therefore long since been suggested. In applications to visual data, a first processing stage can select candidate objects or components that are potential causes of the given input (see, e.g., Yuille and Kersten, 2006). Based on these candidates the meaning of a data point is subsequently inferred in a second recurrent stage. The strategy of candidate preselection has indeed been suggested and applied in different contexts (e.g., Körner et al., 1999; Lee and

Mumford, 2003; Yuille and Kersten, 2006; Westphal and Würtz, 2009) and prominent systems of feed-forward processing (such as Riesenhuber and Poggio, 1999, and van Rullen and Thorpe, 2001) are sometimes interpreted as sophisticated preprocessing stages for a subsequent recurrent stage. The general idea of candidate preselection followed by recurrent recognition will in this paper be formulated in terms of a variational approximation that allows for an efficient training of probabilistic generative models.

In Section 2 the approximation scheme will be introduced as an approximation to Expectation Maximization (EM). In Section 3 we systematically derive it as a variational EM approach. In Section 4 the training scheme is applied to a number of different generative models and a number of different data types. Section 5 discusses the features of the novel approach and the obtained results.

2. Expectation Maximization and Expectation Truncation

Our approach is based on Expectation Maximization (EM; Dempster et al., 1977) which is used to maximize the data likelihood under a given generative model:

$$\Theta^* \;=\; \text{argmax}_\Theta\{L(\Theta)\} \quad \text{with} \quad L(\Theta) = \log\left(p(\vec{y}^{\,(1)},\ldots,\vec{y}^{\,(N)}\,|\,\Theta)\right), \tag{1}$$

where Θ are the parameters of a given generative model and where the N data points, $\{\vec{y}^{\,(n)}\}_{n=1,\ldots,N}$, will be taken to be generated independently from a stationary process.

To find the parameters Θ^* at least approximately, we use the EM approach as it was formalized, for example, by Neal and Hinton (1998) and introduce the free-energy function $\mathcal{F}(q,\Theta)$ which is a function of Θ and an unknown distribution $q(\vec{s}^{\,(1)},\ldots,\vec{s}^{\,(N)})$ over the hidden variables. $\mathcal{F}(q,\Theta)$ can be shown to be a lower bound of the likelihood evaluated at the same parameter values. For our purposes we assume independently generated data vectors $\vec{y}^{\,(n)}$ and use (without loss of generality) a distribution q which is factored over the data points, $q(\vec{s}^{\,(1)},\ldots,\vec{s}^{\,(N)}) = \prod_n q^{(n)}(\vec{s}^{\,(n)};\Theta^{\text{old}})$. Note that we take q to be parameterized by Θ^{old}. The free-energy can thus be written as:

$$\mathcal{F}(q,\Theta) = \sum_{n=1}^{N}\left[\sum_{\vec{s}} q^{(n)}(\vec{s};\Theta^{\text{old}})\;\left[\log\left(p(\vec{y}^{\,(n)}\,|\,\vec{s},\Theta)\right) + \log\left(p(\vec{s}|\,\Theta)\right)\right]\right] + H(q)\,, \tag{2}$$

where $H(q) = -\sum_n \sum_{\vec{s}} q^{(n)}(\vec{s};\Theta^{\text{old}})\log(q^{(n)}(\vec{s};\Theta^{\text{old}}))$ is a function (the Shannon entropy) that is independent of Θ. The sum over all states of $\vec{s}$ becomes an integral if the values of $\vec{s}$ are continuous. In the EM scheme $\mathcal{F}(q,\Theta)$ is maximized alternately with respect to q in the E-step (while Θ is kept fixed) and with respect to Θ in the M-step (while q is kept fixed). It can be shown that the EM iterations increase the likelihood or keep it constant. In practical applications EM is found to increase the likelihood to (at least local) likelihood maxima.

The free-energy function (2) can be used to derive update rules for the parameters Θ of a given model. Such a derivation can in some cases be challenging but one usually arrives at expressions in which the new set of parameters Θ is a function of the old set Θ^{old} and the data $\{\vec{y}^{\,(n)}\}_{n=1,\ldots,N}$. The update rules derived contain what is often referred to as the *sufficient statistics* of the model, that is, they contain expressions of the form

$$\langle g(\vec{s})\rangle_{q^{(n)}} = \sum_{\vec{s}} q^{(n)}(\vec{s};\Theta^{\text{old}})\, g(\vec{s})\,, \tag{3}$$

where $g(\vec{s})$ is a function of the hidden variables. The functions $g(\vec{s})$ are often relatively simple, for example, $g(\vec{s}) = s_i$ or $g(\vec{s}) = s_i s_j$, but can for some models be more elaborate and may also include

parameter dependencies. For an exact E-step in the EM scheme the functions $q^{(n)}(\vec{s};\Theta^{\text{old}})$ are given by

$$q^{(n)}(\vec{s};\Theta^{\text{old}}) = p(\vec{s}|\vec{y}^{(n)},\Theta^{\text{old}}) = \frac{p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^{\text{old}})}{\sum_{\vec{s}'} p(\vec{s}',\vec{y}^{(n)}\,|\,\Theta^{\text{old}})}, \tag{4}$$

where $p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^{\text{old}}) = p(\vec{s}|\,\Theta^{\text{old}})\,p(\vec{y}^{(n)}\,|\,\vec{s},\Theta^{\text{old}})$ with the latter distributions being defined by the used generative model. To train models with multiple causes, the computation of the exact sufficient statistics is usually avoided because it involves summing or integrating over a large space of hidden states in (3) and (4). To reduce computational costs, training schemes therefore use approximations to these intractable sums (or integrals) or approximations to the exact posterior $p(\vec{s}|\vec{y}^{(n)},\Theta^{\text{old}})$. The approximation method discussed in this paper will be introduced as an approximation to the sufficient statistics.

Let us consider the sufficient statistics of a function g given by the combination of (3) and (4):

$$\langle g(\vec{s})\rangle_{q^{(n)}} = \frac{\sum_{\vec{s}} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^{\text{old}})\; g(\vec{s})}{\sum_{\vec{s}'} p(\vec{s}',\vec{y}^{(n)}\,|\,\Theta^{\text{old}})}. \tag{5}$$

Again, we have to sum over a very large space of hidden states. Let us for instance assume that we have already found the optimal or approximately optimal parameters $\Theta^{\text{old}} \approx \Theta^{*}$, that is, let us assume that any given input vector is well represented by a distribution over hidden states. A given $\vec{y}^{(n)}$ is in this case usually well represented by a distribution over just a small set of hidden vectors. For the sums in (5) this means that just some summands contribute significantly while the others are negligible. Thus, if we could find the right summands for a given $\vec{y}^{(n)}$, we could expect a good approximation of $\langle g(\vec{s})\rangle_{q^{(n)}}$ in (5) without having to sum over the entire state space of $\vec{s}$.

More formally, if $\mathcal{K}_n$ denotes the set of all states that contain significant contributions to the sums in (5), it applies:

$$\langle g(\vec{s})\rangle_{q^{(n)}} \approx \frac{\sum_{\vec{s}\in\mathcal{K}_n} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^{\text{old}})\; g(\vec{s})}{\sum_{\vec{s}'\in\mathcal{K}_n} p(\vec{s}',\vec{y}^{(n)}\,|\,\Theta^{\text{old}})}. \tag{6}$$

A potential subset containing the relevant summands could be found by exploiting specific data properties. If the data was generated by few hidden units on average, for instance, most data points are well approximated by only considering combinations of few active causes. A subset for the approximation in (6) for binary causes s_j could thus be given by $\mathcal{K} = \{\vec{s}\;|\;\sum_j s_j \leq \gamma\}$, where γ is the maximal number of active causes. Such a choice can significantly reduce the number of states that have to be evaluated. Depending on γ the combinatorics can still be considerable, however, and still, just a few of the summands might contribute.

To further constrain the state space, let us suppose that we can in some way find functions $\mathcal{S}_h : \mathbb{R}^D \to \mathbb{R}$ that give estimates of how likely it is for the hidden causes $h = 1,\ldots,H$ to have contributed to the generation of a specific input $\vec{y}^{(n)}$. If we had such functions, we could approximate the sufficient statistics (5) by neglecting all causes that are unlikely to have contributed. In other words, we could just sum over a subset $\mathcal{K}_n \subseteq \mathcal{K}$ that contains the combinations of all hidden variables that are likely to have caused the input $\vec{y}^{(n)}$. To define such a set $\mathcal{K}_n$ more formally,

consider the $h = 1,\ldots,H$ values $\mathcal{S}_h(\vec{y}^{(n)})$ for a given data point $\vec{y}^{(n)}$. To select H' candidates, we define the index set I to contain those latent indices h with the H' largest values $\mathcal{S}_h(\vec{y}^{(n)})$. The set $\mathcal{K}_n$ is then given by:

$$\mathcal{K}_n = \{\vec{s} \mid \textstyle\sum_j s_j \leq \gamma \text{ and } (\forall i \notin I : s_i = 0)\}. \tag{7}$$

Equation 6 represents a good approximation if the contributions of the states not in $\mathcal{K}_n$ are indeed negligible compared to the contributions of the states in $\mathcal{K}_n$. Much depends, of course, on the functions $\mathcal{S}_h$. From these functions, which we will term *selection functions*, we demand the following properties: (A) they have to be efficiently computable and (B) they have to give high values for hidden variables that actually are responsible for a given $\vec{y}^{(n)}$. Note that for the selection functions it is merely important to select candidates that can *potentially* explain the input. Neither are their exact values used in (6) nor is it disadvantageous for the accuracy of the approximation if some candidates are selected that turn out to contribute very little. We will see examples of such selection functions for different generative models in Section 4. Before let us summarize the approximation discussed above in the form of the pseudo-code given in Algorithm 1. As the approximation scheme resides on a truncation of the sums in the expectation value computations in (5), we will refer to it as *Expectation Truncation* (ET).

Algorithm 1: Expectation Truncation - Pseudo Code

```
Choose approximation parameters H' and γ (γ ≤ H' ≤ H) and randomly initialize the
parameters of the generative model.
while parameters have not converged do
    for all data points n = 1,...,N do
        Compute the selection function value S_h for each h = 1,...,H and determine the
        index set I of the H' hidden variables with the H' highest values for S_h.
        Compute the set of binary vectors K_n = {s | Σ_j s_j ≤ γ and (∀ i ∉ I : s_i = 0)}
        Compute the approximate sufficient statistics (6).
    Update the parameters in the M-step using the approximate sufficient statistics.
```

The two parameters H' and γ control the size of $\mathcal{K}_n$. H' determines how many candidates are selected and γ fixes the maximal number of non-zero hidden units s_h. For instance, if we choose $H' = 4$ and $\gamma = 2$, the summation over $\vec{s}$ considers four candidates of which either none, one, or two are simultaneously active (compare Figure 2). The size of $\mathcal{K}_n$ is thus given by $\sum_{\gamma'=0}^{\gamma} \binom{H'}{\gamma'}$. The approximation's accuracy increases with increasing values of H' and γ but its computational demand increases as well. For the highest possible values, $H' = \gamma = H$, we drop, for any selection function $\mathcal{S}_h$, back to the case of the exact sufficient statistics (5).

Note that while the approximation scheme presumably results in good approximations for many data points it can be expected to give poor results for data points generated by more than γ hidden causes (i.e., for data points not in $\mathcal{K}$). To avoid learning from such data points with inappropriately estimated sufficient statistics let us again assume that we have already found close to optimal parameters Θ^*. In such a situation and for any data point $\vec{y}^{(n)}$ generated by less or equal γ hidden

causes we get:

$$p(\vec{y}^{(n)}\,|\,\Theta^*) = \sum_{\vec{s}} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^*) \approx \sum_{\vec{s}\in\mathcal{K}_n} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^*)\,, \tag{8}$$

where we have assumed appropriate selection functions and relatively low noise levels. In the same situation but for data points $\vec{y}^{(n)}$ which were generated by more than γ hidden causes we obtain:

$$p(\vec{y}^{(n)}\,|\,\Theta^*) = \sum_{\vec{s}} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^*) \approx \sum_{\vec{s}\notin\mathcal{K}_n} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^*) \;\;\Rightarrow\;\; \sum_{\vec{s}\in\mathcal{K}_n} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^*) \approx 0\,. \tag{9}$$

The values of the sums $\sum_{\vec{s}\in\mathcal{K}_n} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^*)$ for the different data points can thus serve as indicators for finding data points that were presumably generated by less than γ causes. For learning we aim to include only those data points that are approximated well. We therefore define a set $\mathcal{M}$ of the $N^{\text{cut}} \leq N$ data points with largest sums. In the beginning of learning, the estimation of such data points is too imprecise, however. We therefore start by taking all data points into account $N^{\text{cut}} = N$ and decrease N^{cut} to values close to $N^{\leq\gamma}$ within the last third of the iterations. $N^{\leq\gamma}$ is hereby the expected number of data points generated by less or equal γ causes. For a given generative model, this number can usually be computed tractably. The number of data points generated by $\leq\gamma$ causes can, for a given data set, be smaller than $N^{\leq\gamma}$ because of finitely many data points. It can therefore be beneficial to finally use an N^{cut} slightly smaller than $N^{\leq\gamma}$. This potentially avoids the consideration of data points that are not well approximated. In numerical experiments in Section 4 we will therefore use final values of $N^{\text{cut}} = 0.9\,N^{\leq\gamma}$ although $N^{\text{cut}} = N^{\leq\gamma}$ gives similar results especially for large N.

Considering Algorithm 1 what is still left to specify are concrete expressions for the selection functions $\mathcal{S}_h$ and expressions for parameter update rules (M-step equations). These equations do, however, depend on the particular generative model the method is applied to. We will therefore discuss selection functions and update rules individually for the different generative models we investigate in Section 4. Given selection functions and update rules, Algorithm 1 describes an approximation scheme applicable to generative models with binary hidden variables. The scheme has been introduced and defined as an approximation to the sufficient statistics (5). In the next section it will be systematically derived as a variational EM approach. The assumptions used for the approximation will thus become explicit, allowing a generalization of the scheme and a specification of its potential limitations. The computational complexity of the method will be discussed in Appendix C.

3. Expectation Truncation and Variational EM

In this section we will show that Expectation Truncation corresponds to a variational EM approximation. The approximation, as introduced in Section 2, consists of two parts: (A) an approximation to the sufficient statistics in Equation 6, and (B) a selection of data points that are well approximated by Equation 6. Both of these parts can be formulated as variational EM steps. For the derivation we will start with (B), that is, with the selection of data points. The selection will take the form of a classification of data points into two classes: one class that contains the data points that can be well approximated, and another class that contains the remaining points. The corresponding variational step will be referred to as the first variational step (Section 3.1). The step (A) corresponding to approximation (6) will only be the second variational step (Section 3.2). Both steps combine to form the approximation scheme of Expectation Truncation. The scheme is compactly summarized in Section 3.3, and the basic procedural steps are listed in Algorithm 2 which represents a generalization of Algorithm 1.

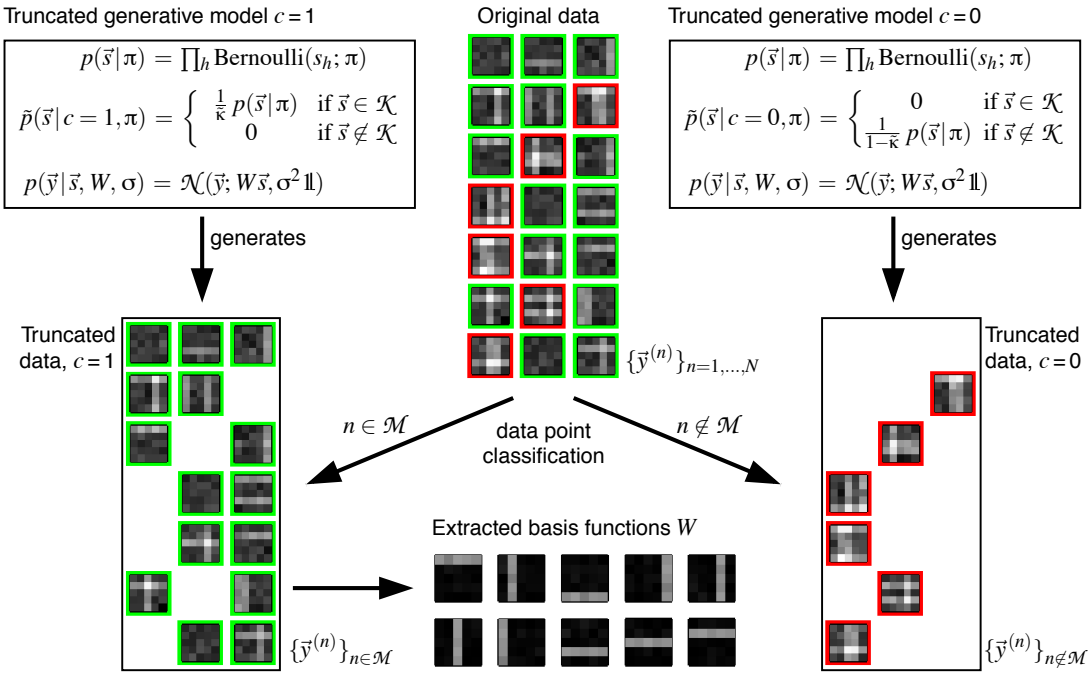

Figure 1: First variational approximation: data classification. The figure shows Expectation Truncation (without preselection) for a concrete generative model. In this example, the generative model generates data by linearly superimposing basis functions in the form of horizontal and vertical bars. Data generated by the original model contains up to ten bars chosen with a Bernoulli prior (example data points are shown in the center). Data generated by the truncated generative model with $c = 1$ contains up to two bars (we set $\mathcal{K} = \{\vec{s} \mid \sum_j s_j \leq \gamma\}$ with $\gamma = 2$). Data generated by the truncated generative model with $c = 0$ contains at least three bars. If we train the truncated generative model with $c = 1$ on data from which data points with $\sum_j s_j > \gamma$ were removed, we can expect to approximately recover the true generating basis functions W of the original model.

3.1 First Variational Approximation: Data Classification

As in Section 2, let us consider a generative model with a set of hidden variables denoted by $\vec{s}$, a set of observed variables denoted by $\vec{y}$, and a set of parameters denoted by Θ. Let us denote the prior distribution of the model by the (not further specified) function $p(\vec{s}|\Theta)$, and the noise distribution by the (not further specified) function $p(\vec{y}|\vec{s},\Theta)$. To distinguish this generative model from models introduced later, it will from now on be referred to as the *original* generative model.

We will formalize the classification of data points by introducing two new generative models defined based on the original model. The two models will correspond to two classes of data points: one class of those points that can be well approximated, and one class of points that can not. Let $\mathcal{K}$ be a subset of the space of all possible values of $\vec{s}$. Given such a set, we define the two generative

models by introducing two new prior distributions that are based on the original prior:

$$p(\vec{s}\,|\,c=1,\Theta) = \begin{cases} \frac{1}{\tilde{\kappa}}\,p(\vec{s}\,|\,\Theta) & \text{if } \vec{s}\in\mathcal{K} \\ 0 & \text{if } \vec{s}\notin\mathcal{K} \end{cases} \text{ and } p(\vec{s}\,|\,c=0,\Theta) = \begin{cases} 0 & \text{if } \vec{s}\in\mathcal{K} \\ \frac{1}{1-\tilde{\kappa}}\,p(\vec{s}\,|\,\Theta) & \text{if } \vec{s}\notin\mathcal{K} \end{cases} \tag{10}$$

where $\tilde{\kappa} = \sum_{\vec{s}\in\mathcal{K}} p(\vec{s}\,|\,\Theta)$. We take the noise distribution $p(\vec{y}\,|\,\vec{s},\Theta)$ of the new models to be identical to the original noise distribution. We will refer to the new generative models as *truncated* models because their prior distributions are truncated to be zero outside of specific subsets. Note that the generation of data according to the truncated model with $c=1$ corresponds to generating data according to the original model while only accepting data points generated by $\vec{s}\in\mathcal{K}$. Analogously, generating data according to the truncated model with $c=0$ is equivalent to generating data according to the original model while accepting only data points generated by $\vec{s}\notin\mathcal{K}$. Figure 1 shows the truncated generative models and data they generate for a concrete example (a model that linearly combines bar-like generative fields; compare Section 4.1). For the example, $\mathcal{K}$ is the set of binary states $\vec{s}$ with less or equal γ non-zero entries. In general, $\mathcal{K}$ can be any subset, however.

Let us now mix the two truncated models in Equation 10 by introducing $c\in\{0,1\}$ as additional hidden variable and by drawing $c=1$ with probability κ. The prior distribution of this mixed model is thus given by:

$$p(c\,|\,\kappa) \;=\; \kappa^{c}\,(1-\kappa)^{1-c}\,, \tag{11}$$

$$p(\vec{s}\,|\,c,\Theta) \;=\; \Big(\frac{c}{\tilde{\kappa}}\;\delta(\vec{s}\in\mathcal{K}) + \frac{1-c}{1-\tilde{\kappa}}\;\delta(\vec{s}\notin\mathcal{K})\Big)\,p(\vec{s}\,|\,\Theta)\,. \tag{12}$$

where we have introduced $\delta(\vec{s}\in\mathcal{K})=1$ if $\vec{s}\in\mathcal{K}$ and zero otherwise, and $\delta(\vec{s}\notin\mathcal{K})=1$ if $\vec{s}\notin\mathcal{K}$ and zero otherwise. We will refer to this model as the *mixed* generative model. Note that the mixed model is identical to the original generative model if we choose $\kappa=\tilde{\kappa}=\sum_{\vec{s}\in\mathcal{K}} p(\vec{s}\,|\,\Theta)$ as mixing proportion. The mixed model thus contains the original model as a special case.

Now, consider a set of N data points $\{\vec{y}^{\,(n)}\}_{n=1,\ldots,N}$ generated according to the original generative model. Let us maximize the likelihood of the data under the mixed model (11) and (12). If we use EM for optimization (compare Section 2), we obtain the free-energy

$$\begin{aligned}\tilde{\mathcal{F}}\,(q,\Theta,\kappa) \;\;=\;\; & \sum_{n}\sum_{c} q^{(n)}(c\,;\Theta^{\text{old}})\,\log\big(p(\vec{y}^{\,(n)}\,|\,c,\Theta)\big) \\ & +\log(\kappa)\sum_{n} q^{(n)}(c=1;\Theta^{\text{old}}) + \log(1-\kappa)\sum_{n} q^{(n)}(c=0;\Theta^{\text{old}}) + H(q)\,,\end{aligned} \tag{13}$$

where $H(q)$ is the entropy w.r.t. $q^{(n)}(c;\Theta^{\text{old}})$ (summed over all n and c). The free-energy (13) can be optimized iteratively by maximizing q in the E-step and (Θ,κ) in the M-step. For the E-step, choosing the exact posterior, $q^{(n)}(c\,;\,\Theta^{\text{old}}) = p(c\,|\,\vec{y}^{\,(n)},\Theta^{\text{old}})$, represents the optimal choice. Unfortunately, it is computationally intractable in general because

$$p(c=1\,|\,\vec{y}^{\,(n)},\Theta^{\text{old}}) = \frac{\sum_{\vec{s}\in\mathcal{K}} p(\vec{y}^{\,(n)},\vec{s}\,|\,\Theta)}{\sum_{\vec{s}} p(\vec{y}^{\,(n)},\vec{s}\,|\,\Theta)} \tag{14}$$

requires a summation over the entire state space of $\vec{s}$ (similarly for $c=0$). We thus choose a variational approximation to the true posterior by setting $q^{(n)}(c\,;\Theta^{\text{old}})$ to zero or one. This approximation

reduces the free-energy (13) to:

$$\tilde{\mathcal{F}}(q,\Theta) \;=\; \overbrace{\sum_{n\in\mathcal{M}} \log\left(p(\vec{y}^{\,(n)}\,|\,c=1,\Theta)\right)}^{\approx L_1(\Theta)} + \overbrace{\sum_{n\notin\mathcal{M}} \log\left(p(\vec{y}^{\,(n)}\,|\,c=0,\Theta)\right)}^{\approx L_0(\Theta)} \\ +\log(\kappa)|\mathcal{M}| + \log(1-\kappa)(N-|\mathcal{M}|) + H(q)\,. \tag{15}$$

where $\mathcal{M} = \{n\,|\,q^{(n)}(c=1\,;\Theta^{\rm old})=1\}$. Note that κ can be optimized independently of Θ because the first two summands in (15) only depend on Θ. As we also know its final optimal value ($\kappa=\tilde{\kappa}$), we will treat the mixing proportion as implicitly known. κ can thus be omitted as a parameter of the free-energy (15) and will not play a role for our further considerations.

For the data set $\mathcal{M}$ note that the best choice for $q^{(n)}(c\,;\Theta^{\rm old})$ under the constraint $q^{(n)}(c\,;\Theta^{\rm old})\in\{0,1\}$ is given by the assignment $q^{(n)}(c=1\,;\Theta^{\rm old})=1$ if $\vec{y}^{\,(n)}$ was generated by class $c=1$ (and zero otherwise). This would amount to setting $\mathcal{M}$ to

$$\mathcal{M}^{\rm opt} = \{n\,|\,\vec{y}^{\,(n)} \text{ generated by class } c=1\}\,. \tag{16}$$

In general this best choice can not be computed exactly. We can, however, derive tractable approximations to $\mathcal{M}^{\rm opt}$. Choosing a set $\mathcal{M}$ is equivalent to choosing a distribution $q^{(n)}(c\,;\Theta^{\rm old})$ with binary values (as an approximation to Equation 14). Any choice of $\mathcal{M}$ thus represents a variational approximation. In Appendix A.2 it is shown that one such approximation is obtained via sorting according to the denominator values in Equation 6. The selection of $N^{\rm cut}$ data points obtained in this way is thus equivalent to a variational E-step.

An interesting aspect of Equation 15 is that the first two summands take the form of two log-likelihoods. The first summand is the likelihood $L_1(\Theta)$ of the truncated generative model with $c=1$, and the second is the likelihood $L_0(\Theta)$ of the model with $c=0$. If $\mathcal{M}=\mathcal{M}^{\rm opt}$, both likelihoods are evaluated on the set of data points they can generate (see Figure 1). Considering these properties of Equation 15 the question arises how the maximum of $\tilde{\mathcal{F}}(q,\Theta)$ and the maxima of $L_1(\Theta)$ and $L_0(\Theta)$ are related. It could, for instance, be asked if all three functions have a maximum for the same parameter values. From the structure of the equation this can not be concluded, and, indeed, the question must be answered negatively because it can be shown that in general the maxima do not coincide. However, under assumptions that are usually fulfilled at least approximately, we can show that any global maximum of $\tilde{\mathcal{F}}(q,\Theta)$ is an approximate global maximum of $L_1(\Theta)$ and of $L_0(\Theta)$. A necessary condition for an approximate global maximum of $L(\Theta)$ (the likelihood of the original model) is thus a global likelihood maximum of $L_1(\Theta)$ (or of $L_0(\Theta)$). The technical derivation of this observation is given in Appendix A.1.

Note that, intuitively, it makes sense that the maximization of the likelihood $L_1(\Theta)$ results in parameters that can approximately maximize $L(\Theta)$. To see this consider the example of Figure 1. If the truncated generative model with $c=1$ is optimized on the truncated data class $c=1$, the displayed generative fields W are learned. These parameter values can be expected to also result in close to maximum likelihood values for the generative model with $c=0$ on data class $c=0$, and also correspond to approximately optimal likelihood values of the original generative model on the original data. The approximation improves with increasingly many data points. For this example, all parameters to approximately maximize $L(\Theta)$ can be recovered based on the necessary condition of maximizing $L_1(\Theta)$. The example of Figure 1 also demonstrates that the first variational step already significantly reduces computational costs. The truncated model with $c=1$ only requires the evaluation of 56 states per data point instead of $2^{10}=1024$ evaluations for the original model.

3.2 Second Variational Approximation: Preselection

Starting point for the second variational approximation will be the likelihood $L_1(\Theta)$ of the truncated generative model $c = 1$. We have seen in the previous section (and Appendix A.1) that a global maximum in $L_1(\Theta)$ is a necessary condition for an approximate global maximum of the likelihood $L(\Theta)$ of the original model. To find the maximum of $L_1(\Theta)$ we optimize the lower bound $\mathcal{F}_1(q,\Theta)$ given by:

$$\mathcal{F}_1(q,\Theta) \;=\; \overbrace{\sum_{n\in\mathcal{M}}\sum_{\vec{s}\in\mathcal{K}} q^{(n)}(\vec{s};\Theta^{\text{old}})\,\log\left(p(\vec{y}^{\,(n)}\,|\,\vec{s},\Theta)\,\frac{1}{\tilde{\kappa}}\,p(\vec{s}\,|\,\Theta)\right)}^{Q_1(q,\Theta)} + H(q)\,, \tag{17}$$

with $\sum_{\vec{s}\in\mathcal{K}} q^{(n)}(\vec{s};\Theta^{\text{old}}) = 1$. $\mathcal{F}_1(q,\Theta)$ is derived by a variational approximation, this time w.r.t. the hidden variables $\vec{s}$. The free-energy equals the likelihood $L_1(\Theta)$ after each E-step if the distributions $q^{(n)}(\vec{s};\Theta^{\text{old}})$ are given by:

$$q^{(n)}(\vec{s};\Theta^{\text{old}}) \;=\; p(\vec{s}\,|\,\vec{y}^{\,(n)},c=1,\Theta^{\text{old}}) \;=\; \frac{p(\vec{s}\,|\,\vec{y}^{\,(n)},\Theta^{\text{old}})}{\sum_{\vec{s}'\in\mathcal{K}} p(\vec{s}\,'\,|\,\vec{y}^{\,(n)},\Theta^{\text{old}})}\delta(\vec{s}\in\mathcal{K}). \tag{18}$$

M-step rules can be derived by setting the derivatives of $\mathcal{F}_1(q,\Theta)$ w.r.t. all parameters to zero. As the entropy term in (17) is independent of Θ if q is held fixed, we obtain

$$\frac{d}{d\Theta}\mathcal{F}_1(q,\Theta) = \frac{d}{d\Theta}Q_1(q,\Theta) = 0 \tag{19}$$

as necessary condition. The derivative $\frac{d}{d\Theta}$ hereby stands for derivatives w.r.t. all the individual parameters.

Based on condition (19) we can now introduce candidate preselection as a variational approximation. As described in Section 2, preselection amounts to selecting, for a given $\vec{y}^{\,(n)}$, a subset $\mathcal{K}_n$ of the state space. Section 2 gives an example of how to define the set $\mathcal{K}$ and how to construct subsets $\mathcal{K}_n$ using selection functions. Figure 2 shows a concrete example of how a set $\mathcal{K}_n$ is constructed using selection function values $\mathcal{S}_h(\vec{y}^{\,(n)})$. In Section 4 and Appendix B different instances of selection functions can be found. More generally, we here require from the sets $\mathcal{K}_n$ that for all data points generated by $\vec{s}\in\mathcal{K}$, they finally contain most of the posterior mass in $\mathcal{K}$. If this applies, we obtain an approximation to the posterior $q^{(n)}$ in (18) given by:

$$\tilde{q}^{(n)}(\vec{s};\Theta^{\text{old}}) \;=\; \frac{p(\vec{s}\,|\,\vec{y}^{\,(n)},\Theta^{\text{old}})}{\sum_{\vec{s}'\in\mathcal{K}_n} p(\vec{s}\,'\,|\,\vec{y}^{\,(n)},\Theta^{\text{old}})}\;\delta(\vec{s}\in\mathcal{K}_n) \;=\; \frac{p(\vec{s},\vec{y}^{\,(n)}\,|\,\Theta^{\text{old}})}{\sum_{\vec{s}'\in\mathcal{K}_n} p(\vec{s}\,',\vec{y}^{\,(n)}\,|\,\Theta^{\text{old}})}\;\delta(\vec{s}\in\mathcal{K}_n). \tag{20}$$

Note that $\tilde{q}^{(n)}(\vec{s};\Theta^{\text{old}})$ sums to one in $\mathcal{K}$ as $\mathcal{K}_n\subseteq\mathcal{K}$. It thus fulfils the condition on $q^{(n)}$ required for (17). If preselection finds, at least finally, appropriate sets $\mathcal{K}_n$, we obtain with (20) the necessary condition: $\frac{d}{d\Theta}Q_1(\tilde{q},\Theta)\approx\frac{d}{d\Theta}Q_1(q,\Theta)=0$. Parameter update rules derived from $\frac{d}{d\Theta}Q_1(\tilde{q},\Theta)=0$ can therefore be expected to (at least approximately) optimize the free-energy (15) and thus $L_1(\Theta)$. The update rules derived will contain expectation values (the sufficient statistics) of the form $\langle g(\vec{s})\rangle_{\tilde{q}^{(n)}}$. If we use (20) for these expectations we obtain:

$$\langle g(\vec{s})\rangle_{\tilde{q}^{(n)}} \;=\; \sum_{\vec{s}}\tilde{q}^{(n)}(\vec{s};\Theta^{\text{old}})\,g(\vec{s}) \;=\; \frac{\sum\limits_{\vec{s}\in\mathcal{K}_n} p(\vec{s},\vec{y}^{\,(n)}\,|\,\Theta^{\text{old}})\;g(\vec{s})}{\sum\limits_{\vec{s}'\in\mathcal{K}_n} p(\vec{s}\,',\vec{y}^{\,(n)}\,|\,\Theta^{\text{old}})}\,,$$

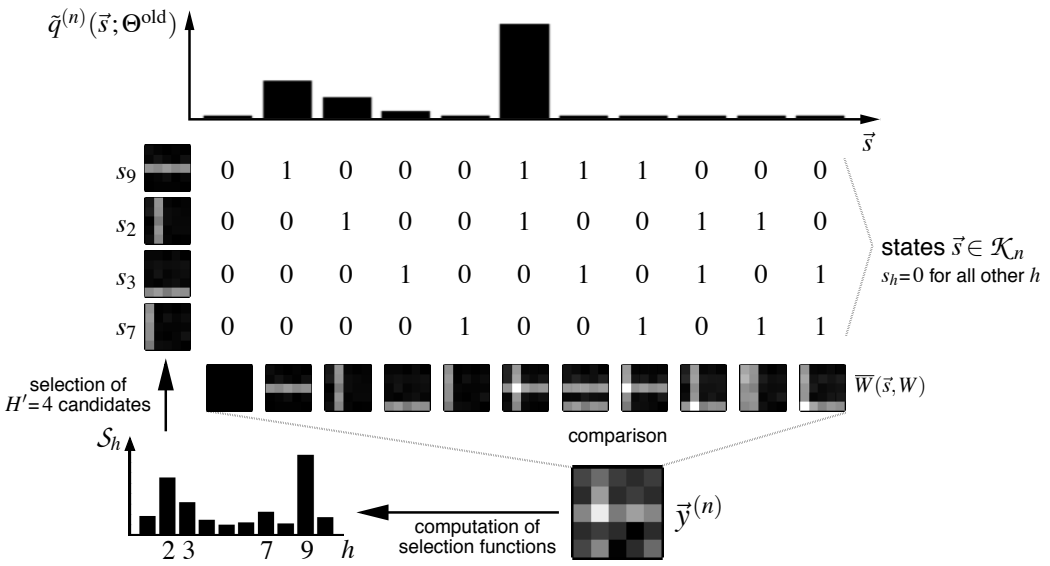

Figure 2: Second variational approximation: preselection. The figure illustrates how the variational approximation $\tilde{q}^{(n)}(\vec{s};\Theta^{\text{old}})$ in Equation 20 is computed. The selection of hidden states $\vec{s} \in \mathcal{K}_n$ and the computation of $\tilde{q}^{(n)}(\vec{s};\Theta^{\text{old}})$ are shown for the example of Figure 1 close to the optimal parameters W. Given the data point $\vec{y}^{(n)}$ a selection function value $\mathcal{S}_h$ for each hidden variable h is computed. The H' largest values are selected ($H' = 4$ for this example). The approximation $\tilde{q}^{(n)}(\vec{s};\Theta^{\text{old}})$ is then computed based on the combinatorics of these H' candidates (with $\sum_j s_j \leq \gamma = 2$). For the displayed data point and parameters all values of $\tilde{q}^{(n)}(\vec{s};\Theta^{\text{old}})$ except for one lie close to zero. For visualization purposes these values have been increase in the figure.

that is, precisely expression (6) in Section 2. Expectation Truncation, introduced as an approximation to Equation 5, can thus been derived as a variational approximation. Importantly, this approximation is tractable if $\mathcal{K}_n$ is small. The computational gain of preselection compared to an approximation without preselection is reflected by the reduced size of $\mathcal{K}_n$ compared to $\mathcal{K}$ (see Figure 2 for an example and Appendix C for a detailed complexity analysis).

3.3 Summary and Numerical Controls

We have seen that the approximation procedure introduced in Section 2 can be derived as a variational EM approach. This approach consists of two variational approximation steps: First, an approximation that assigns the data points to two classes (Section 3.1). Second, a variational step that approximates the posterior (18) by an approximate posterior (20) defined through preselection (Section 3.2). Although the derivation of ET as a variational approach requires in parts rather technical steps, the final result is intuitive (see Figure 1 and Figure 2) and can be stated very compactly. Algorithm 2 summarizes all required steps of the approximation scheme.

Note that also with preselection, the ET approximation still requires a summation over $\mathcal{K}$, namely $\sum_{\vec{s}\in\mathcal{K}} p(\vec{s}|\,\Theta)$. This sum has to be computed to determine N^{cut}, $N^{\text{cut}} = N\sum_{\vec{s}\in\mathcal{K}} p(\vec{s}|\,\Theta)$,

Algorithm 2: Expectation Truncation

Preselection:	select a state space volume $\mathcal{K}_n$ for each data point $\vec{y}^{(n)}$
Data classification:	find a data set $\mathcal{M}$ that approximates $\mathcal{M}^{\text{opt}}$ in Equation 16
E-step:	compute $\tilde{q}^{(n)}(\vec{s};\Theta^{\text{old}}) = \dfrac{p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^{\text{old}})}{\sum_{\vec{s}\in\mathcal{K}_n} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta^{\text{old}})}$ for all $\vec{y}^{(n)}$ and $\vec{s}\in\mathcal{K}_n$
M-step:	find parameters Θ such that $\dfrac{d}{d\Theta}\sum_{n\in\mathcal{M}}\sum_{\vec{s}\in\mathcal{K}_n}\tilde{q}^{(n)}(\vec{s};\Theta^{\text{old}})\,\log\left(p(\vec{y}^{(n)}\,|\,\vec{s},\Theta)\,\dfrac{p(\vec{s}\,|\,\Theta)}{\sum_{\vec{s}'\in\mathcal{K}}p(\vec{s}'\,|\,\Theta)}\right)=0$

and it appears in the M-step equation (Algorithm 2). Because of symmetries in the usual priors for generative models, this sum can, however, be computed without summing over all $\vec{s}$ explicitly (an example is given in the next section). Even if symmetries can not be exploited, note that the sum over $\vec{s}\in\mathcal{K}$ has to be computed at most once per EM iteration and not once per data point and per EM iteration (as it is the case for the sums over $\mathcal{K}_n$).

Algorithm 2 summarizes ET as a variational approximation and represents a generalization of Algorithm 1. Algorithm 1 in Section 2 contains, for example, one specific way of how to select an appropriate set $\mathcal{K}$ and appropriate sets $\mathcal{K}_n$: we defined $\mathcal{K}$ based on sparseness and selected $\mathcal{K}_n$ using selection functions $\mathcal{S}_h$. In the variational derivation of ET we, however, only specified the properties required from $\mathcal{K}$ and $\mathcal{K}_n$. In general, $\mathcal{K}$ does not have to be defined based on a sparseness assumption and there are potentially alternative ways to define the sets $\mathcal{K}_n$. Importantly, the variational derivation of ET allows for a comparison with other variational approaches. We can thus observe that ET is qualitatively different from the standard variational approach. Concrete instances of variational EM usually approximate the exact posteriors by fully or partly factored distributions over the hidden variables (compare Jordan et al., 1999; Jaakkola, 2000; MacKay, 2003; Bishop, 2006). Such approximations become the more severe the stronger dependencies between the hidden variables in the posterior are. In the derivation of the ET approximation, no independence assumption for the posterior has been used. Strong dependencies are therefore not expected to negatively affect the approximation quality of ET. On the other hand, the ET approximations can get more severe if the approximate classification of data points becomes imprecise (first variational step), if the preselection step does not include the relevant candidates (second variational step), or if too few data points are used.

ET has in common with all variational EM approaches that there is no guarantee for the likelihood to finally increase to values close to the global optimum. This can in general be due to the approximations being too severe or due to many local optima in the likelihood landscape. Variational approximations therefore have to be verified numerically. In the following section, ET will be evaluated based on different generative models and different data sets. During likelihood maximization we will monitor different values relevant for the approximation. We will thus control if the likelihood is indeed increased during learning and, given ground-truth, if it approaches values close to the global likelihood maximum. Ground-truth data will also allow us to quantify how well the generating parameters are recovered by the derived algorithm. Furthermore, we will monitor values that give evidence about the quality of the specific approximations used by ET. We will thus

monitor the quality of the data point classification (first variational approximation) and the quality of the approximation by preselection (second variational approximation). For the first approximation we compare the obtained classification with ground-truth of all data points. For the second approximation, we will monitor the differences between the exact posterior $p(\vec{s}\,|\,\vec{y}^{(n)},\Theta)$ and the approximate posterior $\tilde{q}^{(n)}(\vec{s};\Theta)$ in (20). If we evaluate the differences between these distributions using the Kullback-Leibler divergence, we obtain:

$$D_{KL}(\tilde{q}^{(n)},p) = -\log(Q^{(n)}) \quad \text{with} \quad Q^{(n)} = \frac{\sum_{\vec{s}\in\mathcal{K}_n} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta)}{\sum_{\vec{s}'} p(\vec{s}',\vec{y}^{(n)}\,|\,\Theta)}\,. \tag{21}$$

The preselection approximation has a high quality if for the data points in $\mathcal{M}$ the values $D_{KL}(\tilde{q}^{(n)},p)$ are close to zero. For data points not in $\mathcal{M}$ the differences between the distributions should be large. For practical reasons, we have introduced the quality values $Q^{(n)}$ in (21). The values $Q^{(n)}$ measure the percentage of the posterior probability mass concentrated in $\mathcal{K}_n$. In terms of these values the approximation quality is high if $Q^{(n)}$ is close to one for data points in $\mathcal{M}$, and close to zero for data points not in $\mathcal{M}$.

4. Training Generative Models

The approximation scheme defined and discussed in the previous sections is so far independent of the specific choice of a generative model except for the assumption of binary hidden variables. To demonstrate the applicability of the method and to investigate its properties, in this section we will apply it to a number of different generative models. The investigated models are all multiple-cause models that require tractable approximations. The three major classes investigated here are non-negative matrix factorization (NMF; Section 4.1), maximal causes analysis (MCA; Section 4.2), and a sparse-coding-like model termed LinCA (Section 4.3). For all these models we will assume independent hidden variables distributed according to a Bernoulli prior:

$$p(\vec{s}\,|\,\pi) = \prod_{h=1}^{H} p(s_h\,|\,\pi), \quad p(s_h\,|\,\pi) = \pi^{s_h}\,(1-\pi)^{1-s_h}\,, \tag{22}$$

where $\pi \in [0,1]$ parameterizes the sparseness of the distribution. For binary hidden variables the Bernoulli prior represents the most straightforward choice (compare, e.g., Berkes et al., 2009; Lücke and Sahani, 2008). Given the prior (22) the expected number of data points generated by less or equal γ causes is given by:

$$N^{\leq\gamma} = N \sum_{\vec{s},\,|\vec{s}|\leq\gamma} p(\vec{s}\,|\,\pi) = N \sum_{\gamma'=0}^{\gamma} \left(\begin{array}{c} H \\ \gamma' \end{array}\right) \pi^{\gamma'}\,(1-\pi)^{H-\gamma'}\,. \tag{23}$$

$N^{\leq\gamma}$ is required to find the set of N^{cut} data points $\mathcal{M}$ considered for a parameter update, and Equation 23 shows that this number is tractably computable. For all generative models we will use ET as described in Section 2 and Algorithm 1. That is, we will use a set $\mathcal{K}$ that constrains the number of simultaneously active causes, and use selection functions $\mathcal{S}_h$ to obtain sets $\mathcal{K}_n$.

4.1 Non-negative Matrix Factorization (NMF)

The first generative model considered uses prior (22) and combines the generative fields $\vec{W}_h = (W_{1h},\ldots,W_{Dh})^T$ of all latents with $s_h = 1$ linearly. We use a Gaussian noise model such

that the probability of a data vector $\vec{y}$ given $\vec{s}$ is defined by:

$$p(\vec{y}\,|\,\vec{s},\Theta) = \prod_{d=1}^{D} p(y_d\,|\,\overline{W}_d(\vec{s},W),\sigma), \quad p(y_d\,|\,w,\sigma) = \mathcal{N}(y_d;w,\sigma^2) \tag{24}$$

$$\text{with} \quad \overline{W}_d(\vec{s},W) = \sum_h W_{dh} s_h\,, \tag{25}$$

with $W \in \mathbb{R}^{D\times H}$. $\mathcal{N}(y_d;w,\sigma^2)$ is a scalar Gaussian density function with mean w and variance σ^2. The introduction of $\overline{W}$ will turn out to be convenient for the analytical treatment below. Note that we otherwise could have written $p(\vec{y}\,|\,\vec{s},\Theta) = \mathcal{N}(\vec{y};W\vec{s},\sigma^2\mathbb{1})$.

We then use (24) to compute the update equation (the M-step) for the weight matrix W as described in Section 2. The update equation is gained from the necessary condition for an optimum of the free-energy in (2). The W-update is consequently a function of the sufficient statistics $\langle\vec{s}\rangle^T_{q^{(n)}}$ and $\left\langle\vec{s}\vec{s}^{\,T}\right\rangle_{q^{(n)}}$. Following Section 2, these expectation values are approximated by using (6) instead of the exact sufficient statistics (5), that is, we use a subset of cause combinations as selected by the truncation approach. Furthermore, we sum only over the N^{cut} data points in $\mathcal{M}$ as explained at the end of Section 2. The update equation is then given by:

$$W \;=\; \left(\sum_{n\in\mathcal{M}} \vec{y}^{\,(n)}\,\langle\vec{s}\rangle^T_{q^{(n)}}\right)\left(\sum_{n'\in\mathcal{M}} \left\langle\vec{s}\vec{s}^{\,T}\right\rangle_{q^{(n')}}\right)^{-1}. \tag{26}$$

Note that the equation can consistently be gained from the necessary condition for a free-energy optimum in Equation 19 (see M-step of Algorithm 2).

Equations 24 to 26 are valid irrespective of the sign of the entries of the generative fields and the input data. Generative models corresponding to the class of non-negative Matrix Factorization (NMF) methods are based on a linear combination of generative fields but rely on non-negative data points and generative fields. In Equation 26, non-negativity can be ensured for the generative fields by clamping small appearing weights at zero.

A more direct way to ensure non-negativity for the parameters of the model defined by (22) and (24) is to rely on convergence proofs similar to those used for classical NMF (Lee and Seung, 2001), that is, to ensure non-negativity by deriving a multiplicative update rule for the generative fields. For the EM algorithm used as a basis for ET, it can be shown that the parameter-free update rule

$$\vec{W}_h \leftarrow \vec{W}_h \odot \frac{\langle\vec{y}\,s_h\rangle_{\text{ET}}}{\sum_{h'}\vec{W}_{h'}\,\langle s_{h'}\,s_h\rangle_{\text{ET}}} \tag{27}$$

provides monotonic convergence towards the M-step solution of the generative fields, where we have introduced the ET-averaging

$$\langle f(\vec{y},s_h)\rangle_{\text{ET}} := \sum_{n\in\mathcal{M}}\sum_{\vec{s}\in\mathcal{K}_n} p(\vec{s}|\vec{y}^{\,(n)},W)\,f(\vec{y}^{\,(n)},s_h) = \sum_{n\in\mathcal{M}}\left\langle f(\vec{y}^{\,(n)},s_h)\right\rangle_{q^{(n)}}.$$

Equation 27 corresponds to a partial M-step of ET-NMF ('Expectation-Truncation-NMF'). In simulations, it is therefore applied iteratively with 20 partial M-steps after each E-step.

For the introduced generative model, Equation 27 converges towards the M-step solutions of the EM algorithm under non-negativity constraints. The update rule can be understood as a diagonally rescaled gradient descent derived from the EM algorithm, with a rescaling factor that is "optimally

chosen to ensure convergence" (Lee and Seung, 2001). A thorough derivation of the update Equation 27 and its relation to the classical NMF algorithm known from the literature can be found in Appendix D.

The E-step of ET-NMF is based on the truncated expectation values (6) to calculate the averaged quantities in the W update equations according to

$$\langle \vec{y}\, s_h \rangle_{\mathrm{ET}} = \sum_{n\in\mathcal{M}} \vec{y}^{(n)} \langle s_h \rangle_{q^{(n)}} \qquad \text{and} \qquad \langle s_{h'}\, s_h \rangle_{\mathrm{ET}} = \sum_{n\in\mathcal{M}} \langle s_{h'}\, s_h \rangle_{q^{(n)}}$$

so that the sufficient statistics of the ET-NMF model that have to be computed for the M-step will be given by the first and second order moments $\langle s_h \rangle_{q^{(n)}}$ and $\langle s_{h'}\, s_h \rangle_{q^{(n)}}$ of the (approximate) posterior.

For our generatively formulated version of NMF with M-step equations (26) or (27) we can now apply ET as described in Section 2. We ran the ET-NMF algorithm with both M-step versions (26) and (27) and observed, at least for the data used, a qualitatively and quantitatively comparable behavior. Note that the probability density $p(\vec{y}\,|\,\Theta)$ of the model is invariant under the exchange of any two generative fields (or basis functions), $\vec{W}_h \rightarrow \vec{W}_{h'}$, because of symmetric priors. By the definition of the truncated generative models (Section 3), it can instantly be seen that their probability densities $p(\vec{y}\,|\,c=1,\Theta)$ and $p(\vec{y}\,|\,c=0,\Theta)$ are also invariant under these transformations (the same will apply for the other models considered).

As indicated, the sufficient statistics for ET-NMF are given by the first and second order moments, $\langle s_h \rangle_{q^{(n)}}$ and $\langle s_{h'}\, s_h \rangle_{q^{(n)}}$, of the exact posterior; to find approximations to these intractable expectation values we first have to find appropriate selection functions $\mathcal{S}_h$. A natural starting point for finding such functions is to consider the joint probability $p(s_h=1,\vec{y}^{(n)}\,|\,\Theta) = \sum_{\vec{s}\,(s_h=1)} p(\vec{s},\vec{y}^{(n)}\,|\,\Theta)$. If we knew that the joint probability was small for a given h, we would know that the sum over all $\vec{s}$ in (6) which contains $\vec{s}$ with $s_h = 1$ is small as well. Furthermore, note that for a given data point the joint represents the part of $p(s_h=1\,|\,\vec{y}^{(n)},\Theta)$ which depends on h, $p(s_h=1\,|\,\vec{y}^{(n)},\Theta) = \frac{p(s_h=1,\vec{y}^{(n)}\,|\,\Theta)}{p(\vec{y}^{(n)}\,|\,\Theta)}$. $p(s_h=1\,|\,\vec{y}^{(n)},\Theta)$, on the other hand, directly reports the probability of unit h to have contributed to the data point. It could thus be regarded as the optimal selection function. Unfortunately, neither $p(s_h=1,\vec{y}^{(n)}\,|\,\Theta)$ nor $p(s_h=1\,|\,\vec{y}^{(n)},\Theta)$ are computationally tractable and, thus, neither function fulfils one of the properties demanded from a selection function. Therefore, we will compute an upper bound of $p(s_h=1,\vec{y}^{(n)}\,|\,\Theta)$ which is tractable and still serves well in selecting a subset of hidden units that can explain a given $\vec{y}^{(n)}$. Let us for this purpose consider the data point dependent weight matrix defined by: $W^{\mathrm{ub}}_{dh} := W^{\mathrm{ub}}_{dh}(\vec{y}^{(n)},W) = \max\{y^{(n)}_d, W_{dh}\}$ and $\vec{W}^{\mathrm{ub}}_h := \left(W^{\mathrm{ub}}_{1h},\ldots,W^{\mathrm{ub}}_{Dh}\right)^T$, where 'ub' refers to 'upper bound'. This formal definition of W^{ub} allows for a compact notation of an upper bound of $p(s_h=1,\vec{y}^{(n)}\,|\,\Theta)$. Because of the non-negativity of the entries in W and the mono-modality of the Gaussian distribution w.r.t. the mean, we can show (see Appendix B for details):

$$p(s_h=1,\vec{y}^{(n)}\,|\,\Theta) = \sum_{\vec{s}\,(s_h=1)} p(\vec{y}^{(n)}\,|\,\overline{W}_d(\vec{s},W),\sigma)\, p(\vec{s}\,|\,\pi) \;\leq\; \pi\, p(\vec{y}^{(n)}\,|\,\vec{W}^{\mathrm{ub}}_h,\sigma) =: \mathcal{S}_h(\vec{y}^{(n)})\,. \tag{28}$$

The upper bound $\mathcal{S}_h$ is tractable (also compare Appendix C) because we have removed the summation over the $\vec{s}$. The price we pay is that the selection function $\mathcal{S}_h$ can be a relatively coarse estimate in some cases. Importantly, however, we know that if $\mathcal{S}_h$ is sufficiently small, then the contribution of all joint probabilities $p(\vec{s},\vec{y}^{(n)}\,|\,\Theta)$ with $s_h = 1$ can be neglected. The E-step given by the approximation of the sufficient statistics in Section 2 with (28) as selection function together with

the M-step in (27) or (26) represents the learning algorithm for the NMF generative model defined by (22), (24) and (25) with non-negativity constraint.

In addition we add after each M-step a small parameter noise to the basis vectors W (iid Gaussian, standard deviation 0.05) and we use a standard relaxation scheme in order to avoid local optima of the potentially multi-modal likelihood landscape. Annealing (see, e.g., Ueda and Nakano, 1998; Sahani, 1999) amounts to the replacements: $(1/\sigma^2) \to (\beta/\sigma^2)$, $\pi \to \pi^\beta$ and $(1-\pi) \to (1-\pi)^\beta$. The constant β is an inverse 'temperature', $\beta = 1/T$, where T is decreased from a high value T^{init} to a value T^{final} equal or close to one.

4.1.1 EXPERIMENTS - ARTIFICIAL DATA

Let us consider data as displayed in Figure 3A. That is, we consider hidden causes in the form of horizontal and vertical bars (five pixels each) on a 5×5 grid. Each bar appears with probability $\frac{2}{10}$ such that there are on average two bars per data point. We use $N = 500$ data points. The grey-value of a bar is taken to be 10, background pixels are zero. The bars superimpose linearly (pixel values in regions of overlap are 20) and are subject to Gaussian noise with standard deviation $\sigma = 2.0$. Data as in Figure 3A are well-suited to study the functioning of the approximation scheme because we know the underlying generating process and have ground-truth for each data point. We will later use this knowledge to illustrate the influence of each data point on the update of the model parameters. For this reason data points such as displayed in Figure 3A or versions without noise are frequently used in the recent literature (see, e.g., Hinton et al., 1995; Hoyer, 2002; Spratling, 2006).

The model which is applied to the data uses $H = 10$ hidden units and $D = 25$ observed units. The entries of W are initialized by drawing iid from a Gaussian distribution with a mean of 4 and a standard deviation of $\frac{4}{3}$. The standard deviation of the generative model is set to $\sigma = 2.0$ and the value of π is set to $\frac{2}{10}$. Small deviations from these values did not have significantly negative effects on the algorithms performance in extracting data components. Figure 4B shows the cooling schedule for annealing. We linearly decrease T from $T^{\text{init}} = 13$ to $T^{\text{final}} = 1$ during 100 EM-iterations (including ten initial iterations at T^{init} and twenty final iterations at T^{final}). Figure 3B shows a typical time-course of the parameters W if trained as described above. As approximation parameters we used $H' = 5$ and $\gamma = 3$. Although approximate EM schemes do in general not guarantee the increase of the data likelihood, we find that the learning algorithm increases the likelihood to values close to the one for the generating parameters (dashed horizontal line in Figure 4A). This behavior is reflected by the convergence of the model parameters to values close to the generating ones (compare Figure 3). In most trials the parameters converged to approximately optimal values relatively early but in some trials they converged relatively late during learning (compare likelihood values in Figure 4A). We ran 50 trials with 50 different sets of data points generated as described above. The algorithm extracted all bars in all of the trials (see Appendix E for measurement details). To quantify the quality of parameter reconstruction we computed, for each trial, the mean absolute error (MAE) between the obtained generative fields, $\vec{W}_h$, and the corresponding generating causes: $\text{MAE} = \frac{1}{HD}\sum_{hd}|W_{dh} - W^{\text{gen}}_{dh'}|$ where $W^{\text{gen}}_{dh'}$ denotes the cause represented by $\vec{W}_h$ (compare Appendix E). For all trials the MAE was smaller than 0.24 with a mean of 0.20 (note that pixels of bars were set to 10.0 and background to zero).

In a second series of measurements we used the model with the same parameters and the same data as above except that the generating noise variance was set to zero. In 50 trials on this non-noisy data the algorithm extracted all bars in 46 of the trials (92% reliability) and extracted nine of the ten

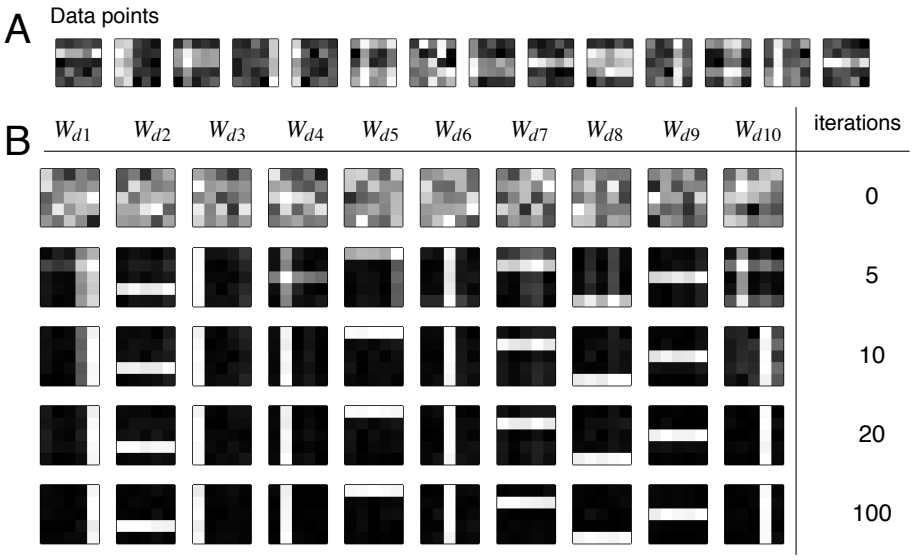

Figure 3: **A** 14 data points of the linear bars test with Gaussian noise. **B** Time course of the generative fields W of the NMF-like generative model if Expectation Truncation is used for learning.

single bars in the four remaining cases. All successful trials had a MAE of below 0.20 with a mean MAE of 0.05. Parameter recovery was more precise than in the previous trial series because of the non-noisy data. A higher initial temperature or a longer cooling increased reliability to values close to 100% for this data. E.g., when we used $T^{\text{init}} = 15$ and stretched the cooling schedule in Figure 4B to 200 iterations, the algorithm found all bars in all of 50 trials. Likewise, increasing the number of data points increased reliability ($> 94\%$ reliability for $N > 1000$ data points with $T = 13$ and 100 iterations cooling).

High reliability (i.e., a high probability to extract all causes) in this linear bars test has also been observed for other learning algorithms (see, e.g., algorithms investigated in Spratling, 2006). Note, however, that the standard bars benchmark test (Földiák, 1990) uses non-linearly overlapping bars (we will come to the standard version of the bars test in the next section). For the presented NMF algorithms we have (as is usual in the literature) only inferred the parameters W. In our generative setting it is in principle also possible to learn the model parameters σ and π (compare Lücke and Sahani, 2008). However, for comparison with other approaches and for brevity, we focused on W.

To investigate the quality of the ET approximation more directly, the values $Q^{(n)}$ (Equation 21) were computed for 40 data points during learning. Figure 4C shows time courses of $Q^{(n)}$ during a trial on the noisy linear bars test using the parameters given above. The data points were randomly selected but it was made sure that twenty of them were generated by less or equal γ causes (bright green lines) and the other twenty by more than γ causes (dark red lines). As can be observed, the approximation quality of the twenty data points generated by $\leq \gamma$ causes quickly increases whereas the approximation for the other twenty data points approaches zero. From the used approximation this could have been expected as we have restricted the summation in (6) to hidden states with less

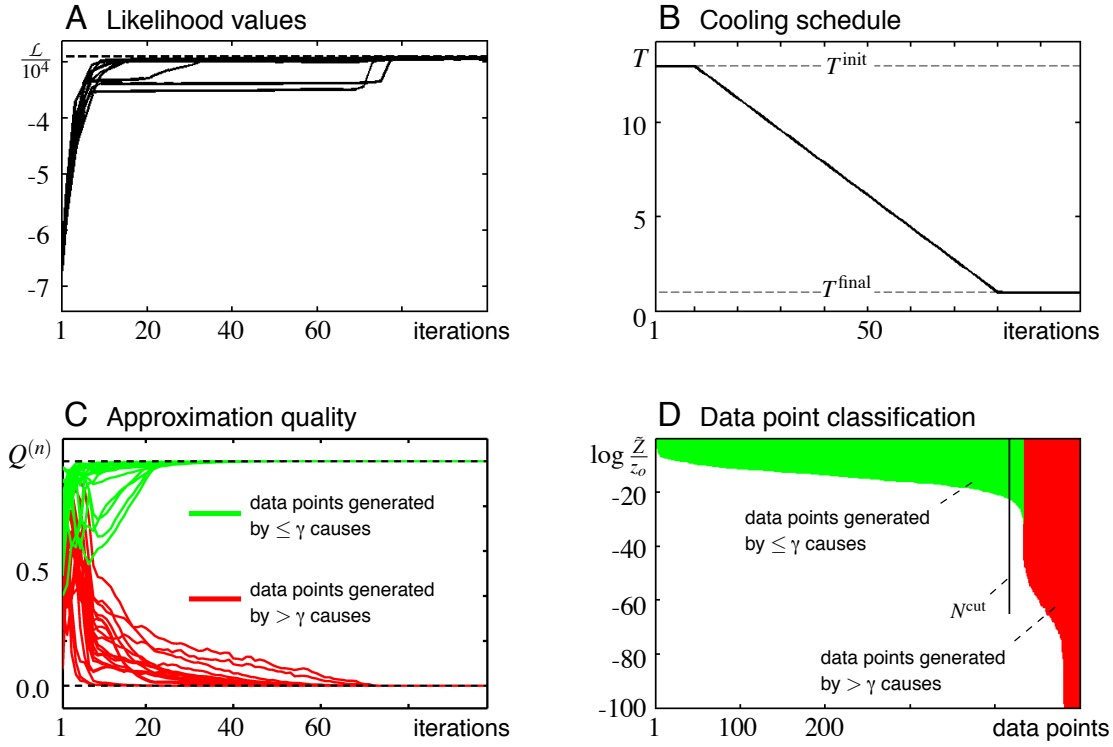

Figure 4: **A** Data likelihood during ten trials using the same set of $N = 500$ data points but different random initializations. The likelihood value that results from using the generating parameters is marked by the dashed horizontal line. **B** Cooling schedule during learning. **C** Approximation qualities $Q^{(n)}$ of 40 data points during learning. Twenty of the data points were generated by $\leq \gamma$ causes (bright green lines) and the other twenty by more than γ causes (dark red lines). **D** Sorted values of the sums $\tilde{Z} = \sum_{\vec{s} \in \mathcal{K}_n} p(\vec{s}, \vec{y}^{(n)} \,|\, \Theta)$ at the end of learning. Bright green bars were used to mark the data points generated by $\leq \gamma$ causes, dark red bars to mark data points generated by more than γ causes. The N^{cut} data points left of the black vertical line were used in the final M-steps.

or equal $\gamma = 3$ active causes. For other trials, the values $Q^{(n)}$ show the same qualitative behavior. However, the exact time-courses can differ quantitatively from trial to trial.

Note that the poorly approximated data points do finally not negatively affect the parameter updates because they are not taken into account for the M-step. This is illustrated in Figure 4D which shows the logarithms of the sum $\tilde{Z} = \sum_{\vec{s} \in \mathcal{K}_n} p(\vec{s}, \vec{y}^{(n)} \,|\, \Theta)$ at the end of learning and for each of the $N = 500$ data points used (divided by a common factor z_o). Bright green bars display the values of all data points generated by less or equal γ causes, dark red bars display the values of all other data points. The data points are ordered descendingly. According to the approximation used (see Section 2 resp. Equation 23), we only consider the N^{cut} data points left of the black bar, that is, we finally only use data points with quality values $Q^{(n)}$ close to one. The relation of the quality values to the KL-divergence in (21) directly shows that the ET approximation for these data points is virtually optimal in this case.

4.1.2 EXPERIMENTS - MORE REALISTIC DATA

As a second example, we applied the learning algorithm to gray-valued images of the postal digits database MNIST (http://yann.lecun.com/exdb/mnist/). This data is frequently used in the NMF literature, which makes it well suited as a means for comparison of our algorithm to standard NMF approaches. Note that we do not have ground-truth about the hidden components in this case.

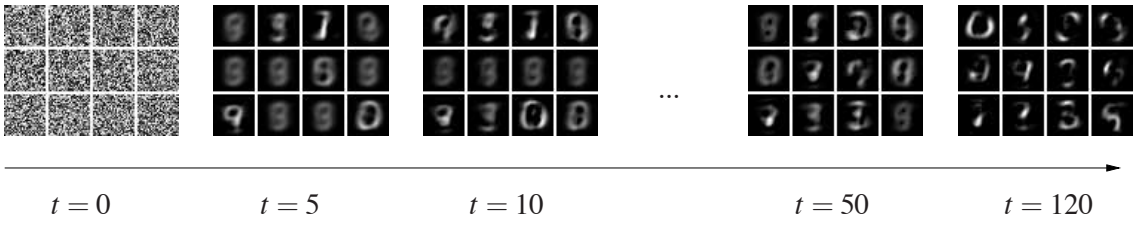

Figure 5: Resulting basis vectors $\vec{W}_h$ for the MNIST database. The probabilistic version of NMF trained with ET converges to a parts-based decomposition.

Figure 5 shows the application of the algorithm using $H = 12$ hidden variables and approximation parameters for ET set to $H' = 10$ and $\gamma = 5$. The prior parameter was set to $\pi = 0.3$ such that three to four of the 12 latent variables do explain a data point on average. The noise parameter σ in (24) was set to $\sigma = 0.73$ after screening through values between zero and one. The dimensionality of each data point is $D = 28 \times 28$ and we used a subset of $N = 1000$ data points, some of which are shown in Figure 6A. We linearly decreased the temperature as in Figure 4B but used a slightly longer learning time (120 iterations) to provide more time for convergence. In Figure 5 the time course of W displayed as basis vector sets is shown. As can be observed, the parameters W converge to basis vectors that represent digit parts.

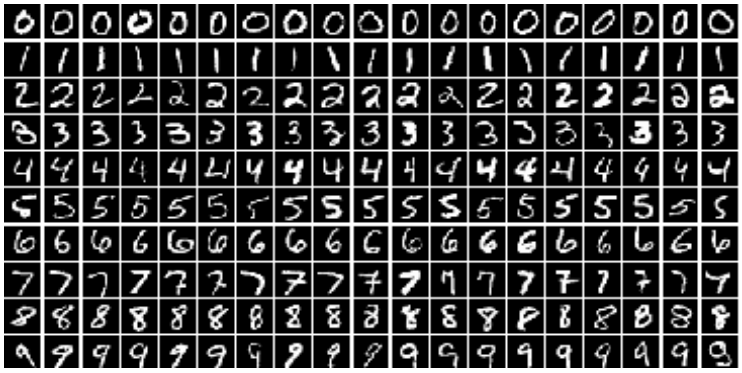
To assess the quality of the basis vectors and for comparison with standard NMF, we show average reconstructions of probabilistic NMF and standard NMF in Figure 6. In Figure 6B it can be observed that already for the small subset of 12 basis vectors in Figure 5 the reconstructions match the inputs in Figure 6A relatively well. Despite the constraint to binary hidden variables in our generative version of NMF, the resulting reconstructions are very similar to those of standard NMF as shown in Figure 6C. For these data, the overall average reconstruction error, $\frac{1}{ND}\sum_n ||\vec{y}^{(n)} - \sum_h \vec{W}_h \langle s_h \rangle_{q^{(n)}}||^2$, of the generative version is less than 5% larger than the reconstruction error of standard NMF.

4.2 Maximal Causes Analysis (MCA)

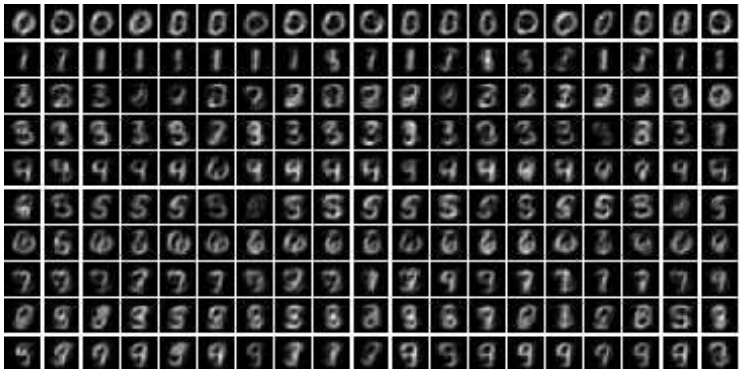
The second generative model we consider was suggested to extract the hidden causes from data whose components combine non-linearly. It uses a maximum rule in the place where NMF, sparse coding (Olshausen and Field, 1996), independent component analysis (ICA; Comon, 1994) and many other methods assume a linear superposition of hidden components:

$$p(\vec{y}\,|\,\vec{s},W) = \prod_{d=1}^{D} p(y_d\,|\,\overline{W}_d(\vec{s},W),\sigma), \quad p(y_d\,|\,w) = \mathcal{N}(y_d; w, \sigma^2) \tag{29}$$
$$\text{with} \quad \overline{W}_d(\vec{s},W) = \max_h\{s_h W_{dh}\},$$

A Digit data used for testing the ET-version of NMF



B ET-NMF average reconstruction



C Standard NMF reconstruction

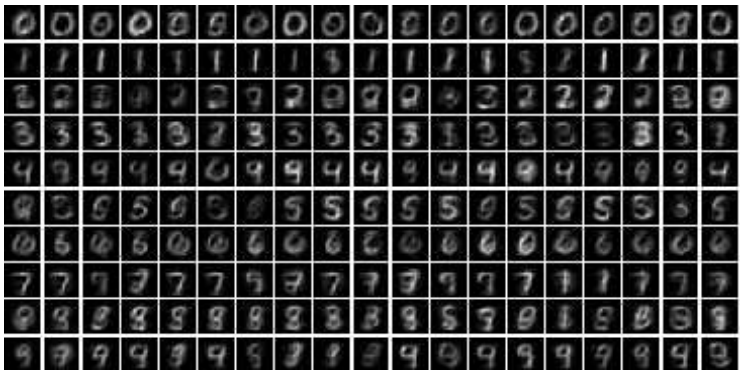


Figure 6: Reconstruction of data points representing hand-written digits. **A** Subset of the $N = 1000$ data points used for the application of probabilistic and standard NMF to the MNIST data base. **B** Average reconstruction of the digit data in **A** on the basis of the basis vectors in Figure 5. **C** Reconstruction of the digit data in **A** using standard NMF with the same number of basis vectors.

where we have used a Gaussian noise model with w as a place-hoder for $\overline{W}_d(\vec{s},W)$ (note the difference to Poisson noise used by Lücke and Sahani, 2008). For the activities of the binary hidden variables s_h we use the same prior as for the NMF model in Section 4.1 (see Equation 22). As in the previous model, the weight matrix $W \in \mathbb{R}^{D\times H}$ parameterizes the influence of the hidden causes on the distribution of $\vec{y}$. The function $\overline{W}_d(\vec{s},W)$ in (29) gives the *effective weight* on y_d, resulting from a particular instance of the state vector $\vec{s}$. An update rule for the weight matrix W of this model was derived in Lücke and Sahani (2008) and is given by:

$$W_{dh} = \frac{\sum\limits_{n\in\mathcal{M}} \left\langle \mathcal{A}^{\rho}_{dh}(\vec{s},W)\right\rangle_{q^{(n)}} y^{(n)}_d}{\sum\limits_{n\in\mathcal{M}} \left\langle \mathcal{A}^{\rho}_{dh}(\vec{s},W)\right\rangle_{q^{(n)}}}, \quad \text{where} \qquad \begin{aligned} \mathcal{A}^{\rho}_{dh}(\vec{s},W) &= \left(\frac{\partial}{\partial W_{dh}}\overline{W}^{\rho}_d(\vec{s},W)\right) && (30)\\ \overline{W}^{\rho}_d(\vec{s},W) &= \left(\sum_{h=1}^{H}(s_h W_{dh})^{\rho}\right)^{\frac{1}{\rho}}. && (31)\end{aligned}$$

The parameter ρ controls the nonlinearity and is increased to large values during learning. Again, the entries in W are non-negative. To derive a selection function we can therefore apply the same arguments as for NMF and thus arrive at the very same functions $\mathcal{S}_h$ as given in Equation 28. The selection function (28), M-step equations (30) and (31), and the E-step approximation described in Section 2 represent a full learning algorithm for the extraction of non-linearly combining components, which will be referred to as MCA_{ET}.

4.2.1 EXPERIMENTS - ARTIFICIAL DATA

To study the properties of MCA_{ET} let us first apply it to data with ground-truth. A well-suited type of data for the algorithm is the so-called bars test introduced by Földiák (1990). The bars test has become a standard benchmark for component extraction algorithms (see, e.g., Saund, 1995; Dayan and Zemel, 1995; Hochreiter and Schmidhuber, 1999; Charles et al., 2002; Lücke and von der Malsburg, 2004; Spratling, 2006; Butko and Triesch, 2007; Lücke and Sahani, 2008) and thus allows for quantitative comparison with other systems. To generate data according to the bars test we use the same parameter settings as for the artificial data in Figure 3A, that is, $D = 5\times 5$, bars pixel value 10 and other pixels zero, Gaussian generating noise with standard deviation 2.0, and the probability for each bar to occur is $\frac{2}{10}$. In contrast to the data used in the experiment of Figure 3, however, the standard form of the bars test uses a non-linear superposition of the causes (overlapping bar regions have pixel values 10 instead of 20 for NMF). Figure 7A shows a random selection of 12 of the $N = 500$ data points used.

We apply MCA_{ET} to the data using the same model parameters and the same approximation parameters ($H' = 5$ and $\gamma = 3$) as for the linear bars test in Section 4.1.1. Annealing for MCA_{ET} amounts to the same replacements as for NMF: $(1/\sigma^2) \to (\beta/\sigma^2)$, $\pi \to \pi^{\beta}$ and $(1-\pi) \to (1-\pi)^{\beta}$. Additionally, ρ in (30) and (31) is increased from a relatively small value at T^{init} to a large value at T^{final} by making ρ temperature dependent: $\rho = \frac{1}{1-\beta} = \frac{T}{T-1}$. As cooling schedule we use the same one as in Section 4.1.1 (see Figure 4B) but with $T^{\text{final}} = 1.05$ to avoid a singularity for ρ. For MCA we found it beneficial to add to the set $\mathcal{K}_n$ (Equation 7), the set of all vectors with just one non-zero entry: $\overline{\mathcal{K}}_n = \mathcal{K}_n \cup \{\vec{s} \mid \sum_i s_i = 1\}$. Making $\mathcal{K}_n$ larger can in general only increase the accuracy of the approximation. At the same time, using $\overline{\mathcal{K}}_n$ instead of $\mathcal{K}_n$ does not change the scaling behavior with H of the algorithm (see Appendix C for a discussion).

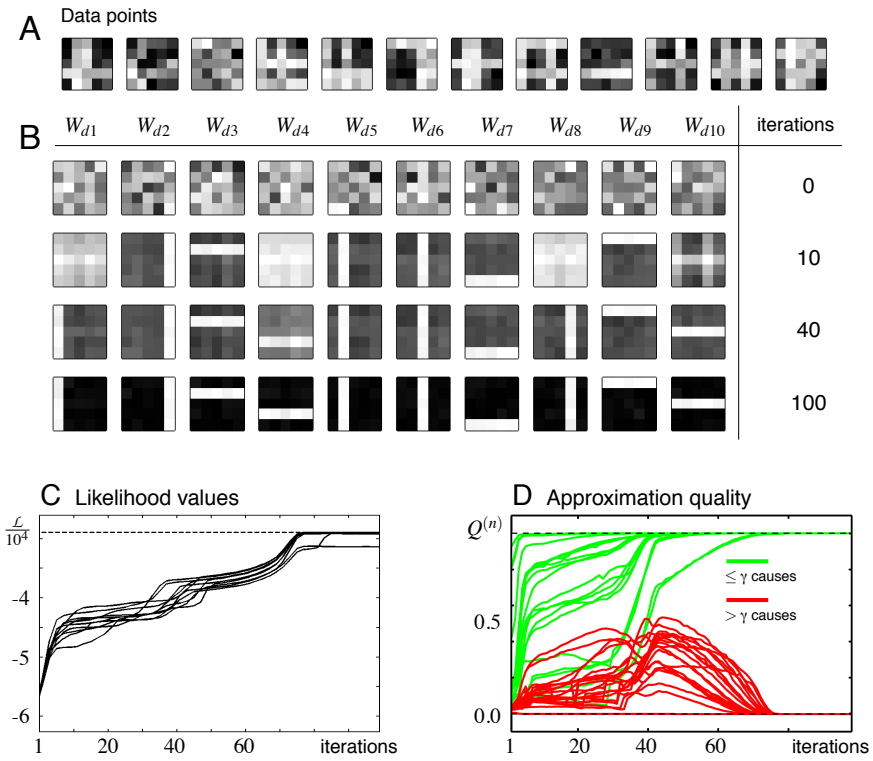

Figure 7: **A** Example data of a bars test with $D = 5 \times 5$ and additive Gaussian noise. **B** Time course of W for the MCA model trained with ET. **C** Likelihood values for ten trials with the same set of training patterns and different initial conditions for each trial. **D** Time course of the quality values of 40 data points during one trial. Values are plotted for twenty randomly selected data points generated by less or equal γ causes (bright green lines) and twenty randomly selected data points generated by greater than γ causes (dark red lines).

Figure 7B shows a typical time course of W during learning. Figure 7C shows time courses of the data likelihood for ten different runs using the same data set. The behavior of the likelihood values results from the specific form of annealing which includes the annealed nonlinearity in Equation 31. In Figure 7D typical time courses for the quality values $Q^{(n)}$ (Equation 21) for 40 data points are shown. For the 20 data points which were generated by $\leq \gamma$ causes (bright green lines) the quality values increased to one. For the data points generated by $> \gamma$ causes (dark red lines) the quality values finally decreased to zero. As for NMF, only the data points which were well approximated were finally taken into account for learning.

To probe the reliability of MCA_{ET}, we ran 50 trials of the bars test with the bars test parameters as given above. In each trial we used a new set of $N = 500$ data points. In 46 of the 50 trials MCA_{ET} extracted all bars (92% reliability), and in four of the trials 9 of 10 bars were extracted. Reconstruction of the generating parameters was high with a maximal MAE of 0.35 and a mean

MAE of 0.29 (bars had value 10). We observed that the convergence to local optima in 8% of the trials was mainly due to effects of finite sample size. When we ran 100 trials using the same parameters but $N = 2000$ data points instead of $N = 500$, the algorithm extracted all bars in all trials.

For comparison with other methods, we ran additional trials using the same parameters for bars generation but with Gaussian noise for data pixels set to variance zero. This version of the bars test is presumably the one most commonly used in the literature (e.g., Saund, 1995; Dayan and Zemel, 1995; Hochreiter and Schmidhuber, 1999; Lücke and Sahani, 2008). In 41 of the 50 trials MCA_{ET} extracted all bars (82% reliability) and found 9 of 10 bars in the other nine trials. Again, reconstruction of the generating parameters in the successful trials was high with a maximal MAE of 0.14 and a mean MAE of 0.05. Also for the non-noisy bars test, reliability of the algorithm increased when we increased the sample size. For instance, we obtained reliabilities of more than 90% for N larger than about 2000. With $N = 10\,000$ and slower cooling (same cooling schedule as in Figure 4B but stretched to 200 iterations), the algorithm found all bars in all of the 50 trials. Achieving close to 100% reliability is thus more difficult for non-noisy bars.[1]

In earlier work, generative modelling approaches to the bars test merely achieved relatively low reliability values. For instance, the model of Saund (1995) achieved 27% reliability, and the model of Dayan and Zemel (1995) (although trained without overlapping bars) achieved 69%. Approaches such as PCA or ICA that assume linear superposition have been reported to fail in this task (see Hochreiter and Schmidhuber, 1999). Other objective function approaches and different types of neural network approaches (e.g., Charles et al., 2002; Lücke and von der Malsburg, 2004; Spratling, 2006, and references therein) have been more successful in terms of reliability. They do, however, often use hidden assumptions and constraints which make an objective comparison difficult (see, e.g., Spratling, 2006, or Lücke and Sahani, 2008, for discussions). The more recently suggested approach of MCA (Lücke and Sahani, 2008) represents a fully generatively interpretable approach which achieves high reliability values. The unrestricted version of MCA_3 extracts all bars in 90% of the trials with noisy bars (with Poisson noise) and in 81% of the cases for the noiseless bars. MCA_{ET} slightly improves on these results with 92% vs. 90% for noisy bars and 82% vs. 81% in the non-noisy case (experiments with $N = 500$). If more data points are used, MCA_{ET} shows close to 100% reliability (50 of 50 trials successful, see above).

Other than the standard bars test, there has recently been an increasing interest in bars with more pronounced overlap. We therefore used a version of the bars test as suggested by Lücke (2004). For this data, bars of the same orientation can overlap (two neighboring vertical bars are not disjoint but overlap). For the test we adopted the same parameter setting for such input as used by Spratling (2006) and Lücke and Sahani (2008), that is, $N = 400$ example patterns, 16 bars, $D = 9 \times 9$, bars appear with probability $\frac{2}{16}$, and number of hidden units is $H = 32$. Bars are two pixels wide such that parallel neighboring bars have a one pixel wide region of overlap. Figure 8A shows some examples of the data points used. We applied MCA_{ET} to the data using the same parameters as for the standard bars test except of a higher initial temperature ($T = 23$) and longer cooling time (the cooling schedule in Figure 4B was stretched by a factor four to 400 iterations). In 21 of the 25 trials the system extracted all bars (see Figure 8B). In four trials 15 of the 16 bars were represented. The average number of extracted bars was thus 15.84. In all the successful trials, reconstruction of the generating parameters was high with a maximal MAE of 0.05 and a mean MAE of 0.04 (bars have

1. Note that alternatively to using $N = 10\,000$ and 200 iterations, we could, for non-noisy data, simply add Gaussian pixel noise. This would take us back to the noisy-bars test and we would obtain close to 100% reliability with $N = 1000$ data points.

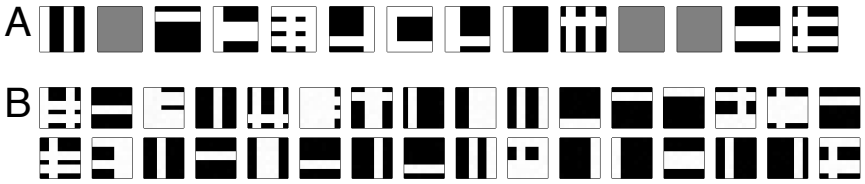

Figure 8: **A** Selection of 14 data points of a bars test with increased overlap. **B** Typical parameters W after learning if twice as many hidden units as bars are used. The supernumerous units are used to represent composite patterns.

value 10). As for the standard bars test we found that convergence to local optima was caused by effects of the finite sample size. When we repeated the experiment with the same generating and model parameters but with $N = 800$ instead of $N = 400$ data points, the algorithm extracted all bars in all of 50 trials (mean number of bars extracted equal to 16.0). In work by Spratling (2006) state-of-the-art systems were quantitatively compared using the mean number of extracted bars. From the evaluated systems only few achieved values close or equal to the optimal value of 16 for $N = 400$. From the systems with high values, many required additional constraints on the parameters (e.g., constrained forms of NMF) that had to be set by hand (see Spratling, 2006; Lücke and Sahani, 2008, for discussions).

In general, the component extraction performance of MCA_{ET} on the different bars test tasks is similar to the performance of MCA_3 suggested by Lücke and Sahani, 2008. In terms of computational cost, MCA_{ET} represents a substantial improvement, however (even compared to R-MCA_2, a constrained form of MCA; see Lücke and Sahani, 2008). This allows for applications with large H as demonstrated, for example, in the following section.

4.2.2 EXPERIMENTS - MORE REALISTIC DATA

As an example for an application to more realistic data, we applied MCA_{ET} to visual data in the form of image patches. We used the same image, Figure 9A, as in work by Lücke and Sahani (2008) to allow for a comparison. We randomly selected $N = 40\,000$ patches of 10×10 pixels as data points (see Figure 9D for ten examples). The data points were globally scaled to lie in the interval $[0, 10]$. However, just very few pixels had values close to 10 after scaling. The mean pixel value was 1.6 and thus smaller than for the bars test. We therefore used a smaller assumed Gaussian noise for the model (standard deviation $\sigma = 1.0$ instead of $\sigma = 2.0$) and started cooling at a lower temperature of $T^{\text{init}} = 4.0$. Also the small noise term on the model parameters was scaled down (0.01 instead of 0.05). During learning, we cooled for 400 iterations (cooling schedule of Figure 4B stretched by a factor four) and allowed for additional 400 iterations at T^{final} to guarantee full convergence (although changes after iteration 400 were small).

Figures 9B and 9C show the resulting parameters W after applying MCA_{ET} with $H = 50$ and $H = 100$ hidden units, respectively. For the approximations we again used $H' = 5$ and $\gamma = 3$. As can be observed, the extracted generative fields represent typical components of the training patches (compare Figure 9B-D). Data generated according to the MCA generative model using the

The image is taken from the van Hateren database of natural images (brightened for visualization). **B** Parameters $\vec{W}_h = (W_{h1}, \ldots, W_{hD})^T$ of the MCA generative model with $H = 50$ trained by ET with $H' = 5$ and $\gamma = 3$. **C** Parameters $\vec{W}_h$ of MCA with $H = 100$ ($H' = 5$ and $\gamma = 3$). **D** A selection of 10 typical training patches. **E** Ten examples of patches generated according to the MCA generative model using the generative fields in **C**. To reduce the apparent noise level, the patches were generated with a smaller σ than for training.

extracted generative fields thus resemble the structure of the training patches (Figure 9E). Note that the components of the data (e.g., images of grass blades and stems) superimpose non-linearly which motivated the application of MCA.

Due to impractically long computation times, no previous version of MCA could be applied to numbers of hidden units much larger than 50. The maximum achievable so far, was the application of the constrained MCA version (R-MCA$_2$) with $H = 50$ to $N = 5000$ patches of 10×10 pixels. As shown in the examples of Figure 9, Expectation Truncation allows for larger scale applications of unconstrained MCA with $H = 100$ and beyond. Compared to MCA$_3$ the number of states that

have to be evaluated by MCA_{ET} for $H = 100$ is reduced by more than three orders of magnitude (see Section 5.2 and Appendix C for discussions).

4.3 Linear Components Analysis (LinCA)

As third and final example let us discuss a generative model whose components can be negative as well as positive. Consider, therefore, the model given by (22), (24) and (25) without the restriction to non-negative weights. For small π in (22) such a generative model is reminiscent of sparse coding (SC; Olshausen and Field, 1996): its hidden variables are sparsely active, its basis functions are combined linearly, and its observed variables are, given the latents, independently drawn from standard Gaussian distributions. Instead of defining explicit prior and noise distributions, SC-like models are often, more informally, written in the form:

$$\vec{y} = \sum_{h=1}^{H} s_h \vec{W}_h + \sigma\vec{\eta} = W\vec{s} + \sigma\vec{\eta}, \tag{32}$$

where the entries of $\vec{\eta}$ are independently and identically drawn from a Gaussian distribution with zero mean and unit variance.

The model (32) with binary factors s_h distributed according to the Bernoulli prior (22) can be trained with Expectation Truncation. As M-step we can directly use Equation 26. However, in contrast to the previous generative models, we can not use Equation 28 as a selection function because it was derived assuming non-negative entries W_{dh}. To find appropriate selection functions, let us first consider a special case: let us assume the number of observed and hidden variables to be identical, $H = D$, and let us assume zero observation noise ($\sigma = 0$ in Equation 32; also compare Teh et al., 2003). For continuous factors s_h with non-Gaussian priors this special case represents the standard version of ICA (see, e.g., Comon, 1994; Hyvärinen et al., 2009). ICA is deterministic in the sense that for any given data point $\vec{y}^{(n)}$ the generating hidden vector $\vec{s}^{(n)}$ is known exactly. If W is invertible, the generating hidden vector is given by $\vec{s}^{(n)} = W^{-1}\vec{y}^{(n)}$ (as can directly be deduced from Equation 32 with $\sigma = 0$). ICA is most frequently applied to (PCA-)whitened data (compare, e.g., Bishop, 2006; Hyvärinen et al., 2009), in which case W is an orthogonal matrix ($W^{-1} = W^T$). For ICA on whitened data, the generating hidden units of a data point $\vec{y}^{(n)}$ are thus given by $\vec{s}^{(n)} = W^T\vec{y}^{(n)}$. In other words, the conditional distribution $p(\vec{y}\,|\,\vec{s},\Theta)$ and thus the posterior $p(\vec{s}\,|\,\vec{y}^{(n)},\Theta)$ become equal to the delta function $\delta(\vec{s} - W^T\vec{y}^{(n)})$. For $\sigma > 0$ in Equation 32, the conditional distribution $p(\vec{y}\,|\,\vec{s},\Theta)$ is, in hidden space, a Gaussian function with mean $W^T\vec{y}^{(n)}$, and the posterior is proportional to the product of this function with the prior. A multiplication with a sparse prior has the effect of moving the Gaussian function closer to those axes h with large values $\vec{W}_h^T\vec{y}^{(n)}$. The scalar products $\vec{W}_h^T\vec{y}^{(n)}$ can thus serve to select those hidden dimensions which span the space most posterior mass lies near to.

Knowing where most posterior mass is concentrated is the crucial prerequisite for finding selection functions for ET. In the binary case of model (32) with Bernoulli prior (22), selecting the hidden dimensions corresponds to selecting the hidden variables which are most likely to have non-zero entries. In analogy to the ICA case, we thus use the scalar product to define selection functions:

$$\mathcal{S}_h(\vec{y}^{(n)}) = \frac{\vec{W}_h^{\mathrm{T}}\vec{y}^{(n)}}{|\vec{W}_h|\,|\vec{y}^{(n)}|}, \quad \text{with } |\vec{v}| = \sqrt{\textstyle\sum_{i=1}^{D}(v_i)^2} \quad \text{and} \quad \vec{W}_h^T = (W_{1h},\ldots,W_{Dh}). \tag{33}$$

We use normalized scalar products because we are not constrained to an orthogonal matrix W and want to prevent the lengths of $|\vec{W}_h|$ from having a strong influence on the selections. Note, however,

that if the matrix W is orthogonal, the selection is equivalent to one based on non-normalized scalar products. The normalization by $|\vec{y}^{(n)}|$ does not affect the selection because $\vec{y}^{(n)}$ is independent of h.

Selection functions (33), M-step equation (26), and the ET approximation of the E-step represent a learning algorithm that will be referred to as Linear Components Analysis (LinCA).

4.3.1 EXPERIMENTS - ARTIFICIAL DATA

To study the LinCA learning algorithm it is first applied to artificial bars data. We use the same linear bars test setup as for the noisy bars test in Section 4.1.1 (compare Figure 3A) but invert five of the ten bars to negative values. Figure 10A shows 12 examples of the $N = 500$ data points used. The observed variables (or 'pixels') of positive bars have value 10.0, observed variables of negative bars have value -10.0, and all other observed variables have value zero. Consequently, we initialize the parameters W with positive and negative values by drawing iid from a Gaussian with zero mean and standard deviation 2.0. All other parameters (for initialization, approximation, annealing, and data generation) are chosen as in Section 4.1.1 for the NMF model. Figure 10B shows a typical time course of the parameters W for noisy data points. As can be observed, the parameters converge to the true generating causes relatively early. Figure 10C shows the likelihood values of ten trials with the same set of $N = 500$ data points. In most trials, likelihoods converged quickly to values close to the likelihood values of the generating parameters (dashed horizontal line). In some trials convergence took longer, however. Figure 10D shows the quality values $Q^{(n)}$ (Equation 21) during a typical trial. After an initially relatively low approximation quality, the quality values of the data points generated by less or equal γ causes (bright green lines) quickly increase. As previously, only these data points are finally used for learning. Data points generated by greater than γ causes (dark red lines) are finally discarded.

To measure the reliability of the system, we ran 50 trials with 50 different data sets of $N = 500$ data points. In all trials all bars were extracted. Parameter reconstruction in all the trials was high with all MAE smaller than 0.28 and a mean MAE of 0.21. For bars without noise we extract all bars in 49 trials (98%) and nine of ten bars in one trial. Due to the non-noisy data, parameter reconstruction was higher than for noisy data. The MAE of all successful trials was smaller than 0.09 and the mean MAE was 0.04. The reliability for non-noisy data increased to still higher reliability values when we cooled longer. If the cooling schedule in Figure 4B was stretched to 200 iterations, all bars were found in all of 100 trials. Alternatively, reliability increased when we increased the sample size: all bars were found in 100 of 100 trials if $N = 1000$ data points were used.

4.3.2 EXPERIMENTS - MORE REALISTIC DATA

As an example of more realistic data, we applied LinCA to sound waveforms. Sound waves have positive and negative parts and their components superimpose linearly, which is consistent with the assumptions of the LinCA model. As data we used short sound intervals obtained from recordings of ten different male voices uttering the sentence: "Don't ask me to carry an oily rag like that". Data was taken from the TIMIT database with voices sampled at 16kHz. To only learn from the spoken text, we cut off the silent initial part and the silent final part of each recorded sentence. Furthermore, we multiplied each voice recording by a different factor such that each recording filled the interval $[-5,5]$ (maximal absolute amplitude of each recording 5.0). This compensated for different sound levels of the different speakers and made the data range comparable to those of

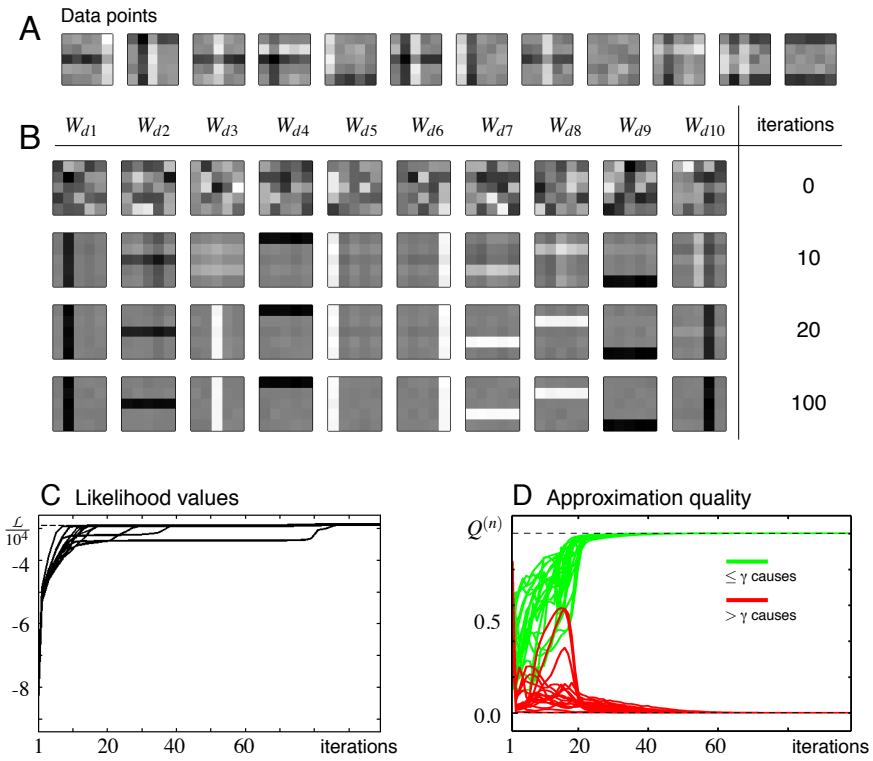

Figure 10: **A** Example data of a bars test with components of positive and negative values, $D = 5 \times 5$, and additive Gaussian noise. **B** Time course of W for the LinCA model trained with ET. **C** Likelihood values for ten trials with the same set of training patterns and different initial conditions for each trial. **D** Time course of the quality values of 40 data points during one trial. Values are plotted for twenty randomly selected data points generated by less or equal γ causes (bright green lines) and twenty randomly selected data points generated by greater than γ causes (dark red lines).

previous experiments. After the multiplication only few data values lay close to -5 or 5. As in Section 4.2.2 we therefore assumed a lower data noise than for the bars data ($\sigma = 0.5$ in this case). As data points we used all possible segments of 12.5ms length. This amounts to $N = 389\,510$ data points with $D = 200$ observed variables.

We applied LinCA with $H = 200$ hidden units to the data and used a prior parameter of $\pi = 0.01$ (on average $\pi H = 2.0$ causes per data point as in previous experiments). The approximation parameters for ET we set to $\gamma = 4$ and $H' = 10$ (as in Section 4.2, we found it beneficial to use $\overline{\mathcal{K}}_n$, which increases robustness of learning without changing the complexity; compare Appendix C). During training we annealed according to the cooling schedule in Figure 4B stretched by a factor two to 200 iterations. The initial temperature was set to $T^{\text{init}} = 5.0$ and the final temperature to $T^{\text{final}} = 1.0$. An additional 200 iterations at $T^{\text{final}} = 1$ were used to guarantee full parameter convergence (although

changes after 200 iterations were small; compare Section 4.2.2). Figure 11 shows the learnt parameters W after a typical run. Many of the generative fields (or basis functions) $\vec{W}_h$ are localized in time and frequency space (e.g., field **a**). Others are only localized in frequency space (e.g., field **b**). Still others resemble amplitude modulated waveforms (e.g., field **c**) or represent combinations of low and very high frequencies. We thus recover generative field properties similar to those obtained by other approaches (compare Teh et al., 2003, or Köster and Hyvärinen, 2007). Note, however, that we applied the algorithm to the data without preprocessing such as whitening. As for the previous experiments, no preprocessing except for data scaling was used. This is unlike SC or ICA approaches that usually require specifically preprocessed data. We also ran LinCA on a subset of the $N = 389\,510$ data points. Results with, for example, $N = 100\,000$ showed no significant differences. Similarly, a run of LinCA with $H = 400$ and $\pi H = 2.0$ showed comparable results (although we observed a tendency towards more generative fields with low absolute amplitudes in this case).

The experiments on acoustic data show that LinCA can be trained with ET also for large-scale applications. As the number of preselected candidates H' can be much smaller than the total number of hidden units, ET scales very favorably with H (see discussion in Section 5.2 and Appendix C). For the experiment of Figure 11, ET evaluates just a couple of hundreds of hidden states per data point instead of 2^{200} required for an exact E-step. Without preselection (i.e., $H' = H$) and same γ, the number of hidden states per data point is still larger than 200×10^6 (compare Appendix C), which would by far exceed currently available computational resources.

5. Discussion

We have studied an approximation to EM to train multiple-cause generative models with binary hidden variables. Training in the scheme is based on a candidate preselection to reduce the computational cost of intractable exact EM learning.

5.1 Properties of Expectation Truncation

The approximation scheme introduced in Section 2 and systematically derived in Section 3 is an example of a deterministic approximation to EM. In contrast to exact EM, there is no guarantee that the data likelihood under a given generative model is always increased or remains unchanged. In numerical experiments on a number of different generative models, we recovered, however, very close to optimal parameters for different types of data. This reflects the property of the approximation to become increasingly optimal the more it approaches the likelihood optimum. To quantify the approximation quality, we have, in different applications, monitored quality values, $Q^{(n)}$, for a selection of data points (see Section 4.1.1, Section 4.2.1, and Section 4.3.1). The quality values are themselves measures for the KL-divergence between the exact posterior (given a data point n) and its approximation (compare Section 3). The values for $Q^{(n)}$ as monitored during the experiments show that the KL-divergence for those data points, which are finally taken into account for learning, becomes virtually zero. Further away from the optimum, the approximation of ET is usually poorer than close to the optimum. However, when measured, also the initial iteration steps did increase the data likelihood in numerical experiments.

5.2 Applicability and Complexity

For the ET approximation to work, different requirements for the generative model and the data have to be fulfilled. These requirements have been made explicit in Section 3. For practical reasons, hidden variables with a small number of discrete values are the most salient requirement. In our formulation and in the experiments, we have used binary values, but ET can be applied without modifications to hidden variables with more than two discrete states. For hidden variables with continuous values the E-step can, however, not be evaluated directly (compare Equation 6 or Algorithm 2). Thus, generative models with latents of continuous values cannot be trained by the presented method. By combining ET with other approximation schemes, it could, however, be generalized to latents with continuous values. For this note that the derivation of ET in Section 3 in large parts does not rely on the assumption of discrete latents. Indeed, the derivations would still hold when all sums over $\vec{s}$ in Section 3 were replaced by integrals over the corresponding states. We are then, however, left with integrals over $\vec{s}$ (see Algorithm 2) that have to be evaluated. By applying approximation methods to these integrals over relatively small state spaces, learning algorithms for generative models with latents of continuous values could be derived.

As shown in Section 4, ET can be applied directly to data that can be generated well by combinations of binary causes. In numerical experiments we have seen examples of its application to NMF, to non-linear component superpositions (MCA), and to a form of sparse coding (LinCA). But also the applicability of ET to generative models with binary hidden variables is not without limits. From the inspection of the methods' functioning (compare Section 3) it becomes clear that it is based on the following assumption: for a sufficiently large number of data points the posterior probability mass has to be concentrated in a relatively small subset of the latents' state space. In other words, a large number of data points must be well-explicable by considering few configurations of the potential latent states. If this assumption is not fulfilled, good approximations can only be achieved by considering sums over large sets of states. We could still apply ET but the required approximation parameters would result in computational costs comparable to the ones for exact EM. Models with large numbers of hidden variables would thus not be computationally tractable in such cases. Even if the probability mass of most posteriors is finally concentrated within small regions of the state space, the applicability of ET may still be limited as it additionally requires a mechanism to locate these regions. For the generative models discussed in Section 4, the tractable selection functions (28) and (33) perform well in this respect, and successfully maximize the likelihood and recover close to optimal parameter values. However, for more complicated models the definition of tractable selection functions (or more generally of sets $\mathcal{K}_n$) may be challenging and can limit the applicability of ET. Again, the summation over more states would reduce the problem. For instance, by choosing $\mathcal{K}_n = \mathcal{K}$ (no second variational step) ET could be applied without a preselection process. However, without this crucial reduction of states, the application scale would be much more limited. In summary, applicability of ET for models with binary latents is thus not a question of principal nature but a question about the trade-off between computational cost and approximation quality.

Note that the space of models ET can be applied to is much larger than the space of models with sparsely active binary latents. ET only requires that, on average, few states can represent a data point well. These states do not have to be sparse nor do the hidden variables have to be independent. Examples are, for instance, the generative models discussed in Section 4 but with priors that fix the number of active causes (e.g., always five causes active). The requirements for ET

can still be satisfied in such situations. In preliminary numerical experiments using such non-sparse and dependent priors, ET still efficiently increased the likelihood to approximately optimal values.

In general, a reduction of the computational cost using ET is paid for by a reduction of the approximation's quality. Hereby, ET benefits from the fact that the reduction in quality is very limited compared to a vast reduction in required computations (compare Section 4). For the data considered, the computational cost can be reduced by many orders of magnitude with only minimal losses for the approximation's accuracy. For a given set of data, a good approximation setting for ET usually arises naturally. The Bernoulli prior (22), for instance, results in many data points requiring the consideration of at most πH components for good approximations. The overall computational complexity of ET thus depends on the complexity of the data and the generative model used. More specifically, it depends on how the subsets $\mathcal{K}_n$ in (6) are selected. For the generative models and data considered in this paper, a detailed discussion of ET's computational complexity can be found in Appendix C. The crucial advantage of preselection is that the computational cost is split up into essentially two parts (see Equation 38). Importantly, only the preselection part depends hereby on the total number of hidden variables H. The second and computationally more intensive part becomes independent of the total number of latents, depending only on the number of selected candidates. The preselection part is computationally much less costly: for the examples considered here, its complexity scales just linearly with H (also compare Figure 13). ET thus becomes especially efficient for large numbers of hidden variables. An example is the application of MCA_{ET} to the data of Section 4.2.2. Another example is the application of LinCA to the data of Section 4.3.2. In the latter case ET computes approximations by evaluating less than 1000 states for $H = 200$ instead of 2^{200} required for an exact E-step.

5.3 Relations to Other Approximation Schemes

A central role for optimal learning and inference in probabilistic models is played by the posterior probability $p(\vec{s}\,|\,\vec{y}^{(n)},\Theta)$. Computing expectation values w.r.t. to the posterior or computing the posterior directly is usually intractable for multiple-cause models. Approximation schemes find computationally tractable approximations to expectation values w.r.t. $p(\vec{s}\,|\,\vec{y}^{(n)},\Theta)$ or they approximate the posterior directly. Many examples of such approximations can be found in the literature, and they usually fall into two major classes: sampling methods and deterministic approaches.

Sampling methods are in a sense more general because they usually rely on fewer assumptions than deterministic approaches. Furthermore, there are no principled limits to most of them. In general, the approximations obtained recover the exact solutions in the limit of infinite computational resources. However, sampling methods can be computationally very demanding and may limit applications to relatively small scale problems. In contrast to sampling, deterministic approaches are based on analytical approximations to the posterior or its expectations computed w.r.t. it. By definition, they do in general not find the exact solutions and often rely on particular assumptions about the model they are applied to. However, if these assumptions are fulfilled, they are often computationally much less demanding. For these reasons, deterministic and sampling approaches are often regarded as complementary (see, e.g., MacKay, 2003, or Bishop, 2006, for discussions).

Major and frequently applied examples of deterministic approaches are *variational EM* approaches (e.g., Jordan et al., 1999; Jaakkola, 2000; MacKay, 2003; Bishop, 2006) and *expectation propagation* (EP) approaches (e.g., Minka, 2001; Bishop, 2006). The method of Expectation Truncation discussed in this paper is an example of a variational EM approach. Although introduced

as an approximation to expectation values (see Equation 6), we have shown in Section 3 that ET can be derived from variational approximations to exact posterior distributions. Thus, much of the typical properties of variational approaches and their differences to other approximation methods (discussed, e.g., by MacKay, 2003; Bishop, 2006) such as expectation propagation carry over to ET. A crucial difference between ET and standard variational EM is that ET does not use factorizing distributions to approximate the exact posterior. Instead ET uses two variational steps: one that takes the form of a data point selection, and a second that is based on a preselection of hidden variables (see Section 3 for more details). A consequence, for example, for the data discussed in this paper, was that we finally only learned from data points whose KL-divergence between exact and approximated posterior was virtually zero. In numerical simulations this resulted in a virtually optimal parameter recovery. At the same time, the preselection of relevant hidden variables per data point allowed a massive reduction of the computational cost.

Expectation Truncation was motivated by earlier approaches which were developed in the context of non-linear component extraction models (Lücke and Sahani, 2008; Lücke et al., 2009). For efficient learning truncated sums were used to optimize the model parameters (also see Lücke and Sahani, 2007). Optimization was partly performed under additional constraints to correct for imprecise approximations. Furthermore, the approach was developed for specific non-linear generative models and no explicit data point selection was used. As a consequence no clean relation to variational EM could be derived (but see discussion in Lücke and Sahani, 2008). Most significantly, however, no candidate preselection was used. This could result in impractically long computation times already for relatively small numbers of hidden variables. With the ET framework developed in this paper we can interpret the earlier approaches as approximations to special cases of ET. The approximations for MCA_3 (Lücke and Sahani, 2008) can thus be regarded as ET approximation without the second variational step, that is, without selecting subsets $\mathcal{K}_n$ of $\mathcal{K}$ (no preselection). Without preselection, the computational cost of learning algorithms can scale unfavorably with the number of hidden units H (cubically in the case of MCA_3; compare cases $H' = H$ in Appendix C). Data point selection in MCA_3 can be seen as implicitly accomplished by an E-step that considers more terms in the denominator than in the numerator. Likewise, the approximation for occlusive components analysis (OCA; Lücke et al., 2009) can be seen as ET without preselection (instead of implicit data point selection more terms of the truncated sums were used here). Note that instead of omitting the second variational approximation, another special case of ET is obtained if the first variational step is omitted (no data point classification). This amounts to setting $\mathcal{K}$ equal to the whole state space (the sums over $\mathcal{K}$ in Algorithm 2 equal one in this case). Efficient approximations can still be obtained if proper subsets $\mathcal{K}_n$ are selected. On different generative models preliminary experiments showed results similar to the ones reported in Section 4. Depending on the model, the approximations can be much less efficient or much less accurate, however.

An extreme case for selecting subsets $\mathcal{K}_n$ is to select them to contain just one element, $\mathcal{K}_n = \{\vec{s}^{(n)}\}$. In this case the approximated expectation value of a function g in (6) becomes equal to the functions value at $\vec{s}^{(n)}$: $\langle g(\vec{s})\rangle_{q^{(n)}} = g(\vec{s}^{(n)})$. This choice relates ET to energy models (compare, e.g., Teh et al., 2003, or Hyvärinen et al., 2009) and maximum a posteriori (MAP) approximations as, for example, used in the original sparse coding model (Olshausen and Field, 1996). Indeed, if we set $\mathcal{K}$ to be the entire state space and choose $\mathcal{K}_n = \{\vec{s}^{(n)}\}$ with $\vec{s}^{(n)}$ being the MAP estimate of the posterior, we obtain an update rule for basis functions W proportional to $\sum_n \vec{y}^{(n)} (\vec{s}^{(n)})^T$ (compare Equation 26). That is, a learning rule for W as used in sparse coding can be obtained (compare Olshausen and Field, 1996, or Olshausen, 2002). If instead of a MAP estimate the scalar

product $\vec{s}^{(n)} = \vec{W}_h^T \vec{y}^{(n)}$ is used to select $\vec{s}^{(n)}$, ET for linear generative models can be related to ICA approaches (also compare Section 4.3). Note that MAP estimate and scalar product play the role of the selection functions $\mathcal{S}_h$ in the case of SC and ICA, respectively.

More generally, MAP estimates or scalar products can be starting points to derive less basic selection functions for a generative model. Regarding a MAP estimate, it is likely that a significant amount of posterior mass is located in the vicinity of the MAP state. If the posterior is additionally known to be monomodal, $\mathcal{K}_n$ can be chosen as a region around the MAP estimate. For multi-modal posteriors, generalizations of MAP estimates could be used (see, e.g., Fromer and Globerson, 2009, and references therein). Alternatively, selection functions can be derived by considering the limit of no observation noise for a given model. For data with relatively low amounts of noise, most of the posterior mass will be located close to the estimated state for zero noise (compare the ICA case).

In numerical experiments we have compared the tractable selection functions (28) and (33) with the respective optimal selection function given by $\mathcal{S}_h^{\text{opt}}(\vec{y}^{(n)}) = p(s_h = 1 \,|\, \vec{y}^{(n)}, \Theta)$ (see Section 4.1). For low numbers of hidden variables, $p(s_h = 1 \,|\, \vec{y}^{(n)}, \Theta)$ can still be computed. Numerical experiments using the tractable selection functions, experiments using the optimal selection function, and experiments using exact EM hereby resulted in virtually identical final parameter values close to the optimum. We observed some differences in the convergence behavior. However, these differences were small compared, for example, to differences in using different annealing schemes or annealing parameters.

5.4 Results on Different Data Sets

In numerical experiments we have applied ET to three types of generative models: NMF, MCA, and LinCA. The experiments were aimed at demonstrating the method itself. However, as a by-product, we obtained some results that are closely related to recent developments in component extraction algorithms: The application of the probabilistic NMF algorithm to the MNIST data base showed that, for this data, potentially only very little is gained by considering continuous hidden units instead of binary ones. As could be observed by comparing reconstruction errors obtained for standard vs. probabilistic NMF, continuous hidden variables improved reconstructions by less than 5%. Regarding MCA, we showed that the algorithm derived with ET is competitive to the best performing systems in standard benchmarks. We applied the algorithm to the standard bars test with 10 bars and to a more recent benchmark with 16 bars and larger overlap. In both cases the algorithm extracted all causes with close to 100% reliability (50 successful trials out of 50) provided that we used sufficiently many data points. For fewer data points the algorithm was still competitive but reliability was lower. Applications of the algorithm to image patches and acoustic data showed robust applicability to large scale problems.

For all experiments in the paper we have used deterministic annealing (e.g., Ueda and Nakano, 1998; Sahani, 1999) to avoid the convergence to local optima (compare Section 4). The initial temperature for annealing can be chosen by observing that for a given model and application a critical temperature exists above which all generative fields converge to the same average field (no differentiation to different components). The initial temperature is then chosen to lie below this critical temperature. Note that for Gaussian noise, the annealing temperature changes the standard deviation σ. It is thus closely connected to the noise parameter. For many types of data, component extraction is robust to different values of σ. For instance, for the noiseless bars tests in Section 4.1,

Section 4.2, or Section 4.3, $\sigma = 2.0$ was used while the ground-truth would be $\sigma = 0.0$. For some data/model combinations the dependency on σ can be more sensitive, however.

In addition to the data and models discussed in Section 4 we also ran experiments on models with Poisson instead of Gaussian noise, used other types of data including, for example, sound spectrograms instead of sound waveforms, and used data and models in different combinations with different priors. The obtained results were all comparable to the ones reported for the other experiments: the likelihood (when computationally tractable) usually increased to close to optimal values, the generating parameters in successful trials were well recovered, and the reliability to recover the generating causes was high.

In general, the derivation of new learning algorithms based on ET is straightforward. If the data is well-explicable by combinations of binary hidden causes, a generative model should be chosen that appropriately reflects the data generation process. Once the parameter update rules for such a model are derived, the E-step can be computed with ET. This involves the definition of selection functions, the choice of an appropriate constraint for $\mathcal{K}_n$ (compare Equation 7), and the choice of approximation parameters. Depending on the data, a preselection function can take the form of an upper-bound on the joint probability as shown, for example, for NMF in Section 4.1, or it can take the form of a scalar product as for LinCA in Section 4.3. More generally, any discriminative method represents a potential choice for a selection function.

5.5 Conclusion

Motivated by earlier work that discusses the benefits of a candidate preselection (e.g., Körner et al., 1999; Lee and Mumford, 2003; Yuille and Kersten, 2006), we have defined and studied a novel approximation scheme for probabilistic generative models. This scheme is formulated as a deterministic variational EM approximation to maximize the data likelihood under a given generative model. The formulation in terms of a grounded probabilistic approach allowed us to quantify the gain in efficiency that is achievable by preselection. To study the approximation scheme empirically, it has been applied to different types of generative models with different combination rules. In standard benchmarks on artificial data we found that the derived algorithms increased the likelihood to values very close to the optimum, extracted hidden causes with high reliability, and reduced the computational cost potentially by orders of magnitude. We reported quantitative results on data with ground-truth and, where standard benchmarks were available, showed that the derived learning algorithms are competitive with the best performing systems so far. Applications to more realistic data demonstrated robustness and applicability to larger scale problems.

In conclusion, the contribution of the novel method is thus two-fold: (1) it relates the intuitive and frequently discussed benefits of preselection to the grounded framework of an EM-based approximation, and (2) it defines an approximation scheme that allows to efficiently train standard and novel types of generative models.

Acknowledgments. We would like to thank Marc Henniges for his help with the experiment of Figure 11 and Christian Keck for his help in generating animations (Online Appendix). Furthermore, we gratefully acknowledge funding by the German Research Foundation (DFG) in the project LU 1196/4-1, by the Honda Research Institute in Europe (HRI Europe), and by the German Federal Ministry of Education and Research (BMBF) in the project 01GQ0840 (BFNT Frankfurt). Finally, we would like to acknowledge support by the Frankfurt Center for Scientific Computing (CSC Frankfurt).

Appendix A. ET as Variational EM: Detailed Derivations

In Appendix A.1 we discuss the consistency of maximum likelihood parameters of original and truncated generative models. Appendix A.2 discusses details about the classification of data points.

A.1 Necessary Conditions for Global Likelihood Maxima

In Section 3.1 we have seen that $\tilde{F}(q,\Theta)$ in (15) is a lower bound of the likelihood $L(\Theta)$ in (1). If the used variational distributions $q^{(n)}(c;\Theta)$ are good approximations to the exact posteriors $p(c\,|\,\vec{y}^{\,(n)},\Theta)$ in (14), then $L(\Theta)\approx\tilde{F}(q,\Theta)$ after each E-step. Because of the variational approximation in Section 3.1 the equality $\tilde{F}(q,\Theta)=L(\Theta)$ holds if $\mathcal{M}$ is equal to $\mathcal{M}^{\text{opt}}$ (16) and if the true posterior values in (14) are equal to zero or one for all n. Although the latter condition is fulfilled only in boundary cases, we will, in this section, assume the equality to hold (while keeping in mind that it is almost always an approximation). If the equality holds, $\tilde{F}(q,\Theta)$ in (15) is in its global maximum equal to the likelihood $L(\Theta)$.

Let us, further, assume that there exist parameters Θ^* such that the original generative model reproduces the underlying distribution of the data points, $p(\vec{y})=p(\vec{y}\,|\,\Theta^*)$. From Section 3.1 we then know that the mixed model with prior (11) and (12) and $\kappa=\tilde{\kappa}$ also reproduces the original distribution for these parameters. Using the mixed model, the data points $\{\vec{y}^{\,(n)}\}_{n=1,\ldots,N}$ can thus be taken to have been generated by the truncated generative models. That is, the data set can be subdivided into the two disjoint sets $\{\vec{y}^{\,(n)}\}_{n\in\mathcal{M}^{\text{opt}}}$ and $\{\vec{y}^{\,(n)}\}_{n\notin\mathcal{M}^{\text{opt}}}$. If $p(\vec{y}\,|\,\Theta^*)$ is the underlying distribution of the whole data set, then $p(\vec{y}\,|\,c=1,\Theta^*)$ and $p(\vec{y}\,|\,c=0,\Theta^*)$ are the underlying distributions of the two disjoint parts (compare Figure 1).

We can approximately recover the distribution $p(\vec{y}\,|\,\Theta^*)$ by (globally) maximizing the data likelihood under the mixed generative model on $\{\vec{y}^{\,(n)}\}_{n=1,\ldots,N}$. Furthermore, we can recover the distributions $p(\vec{y}\,|\,c=1,\Theta^*)$ and $p(\vec{y}\,|\,c=0,\Theta^*)$ by (globally) maximizing the data likelihoods of the truncated generative models on $\{\vec{y}^{\,(n)}\}_{n\in\mathcal{M}^{\text{opt}}}$ and $\{\vec{y}^{\,(n)}\}_{n\notin\mathcal{M}^{\text{opt}}}$, respectively. Let us denote the pa-

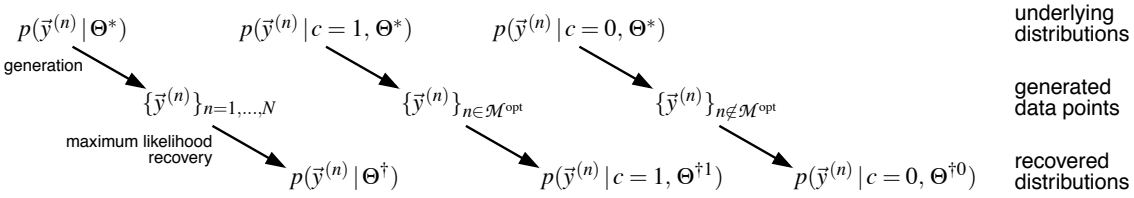

Figure 12: Recovery of the generating distributions through the original and the truncated generative models. The original distributions can be recovered from the data sets if the corresponding likelihoods are maximized.

rameters recovered by maximizing $L(\Theta)$ by $\Theta^\dagger$, and the parameters recovered by maximizing $L_1(\Theta)$ and $L_0(\Theta)$ by $\Theta^{\dagger 1}$ and $\Theta^{\dagger 0}$, respectively (compare Figure 12). In general, $\Theta^\dagger$, $\Theta^{\dagger 1}$, and $\Theta^{\dagger 0}$ are different. If the variational approximation $\mathcal{M}=\mathcal{M}^{\text{opt}}$ is exact, we know, however, that in the limit of infinitely many data points (and by still assuming $p(\vec{y})=p(\vec{y}\,|\,\Theta^*)$) applies:

$$p(\vec{y}\,|\,\Theta^*)=p(\vec{y}\,|\,\Theta^\dagger),\; p(\vec{y}\,|\,c{=}1,\Theta^*)=p(\vec{y}\,|\,c{=}1,\Theta^{\dagger 1}),\;\text{ and }\; p(\vec{y}\,|\,c{=}0,\Theta^*)=p(\vec{y}\,|\,c{=}0,\Theta^{\dagger 0}). \quad (34)$$

The equalities hold because for $N\to\infty$ and $p(\vec{y})=p(\vec{y}\,|\,\Theta^*)$ it follows from $L(\Theta^*)=L(\Theta^\dagger)$ that $D_{KL}(p(\vec{y}\,|\,\Theta^*),p(\vec{y}\,|\,\Theta^\dagger))=0$. As the Kullback-Leibler divergence between two distributions q and

p is zero if and only if the distributions are identical, (34) has to hold. Note, however, that the recovered parameters can still be different from Θ^*. For instance, if there exist transformations $\mathcal{T}$ of Θ^* that do not change the distribution, then any Θ obtained from Θ^* through such a transformation, $\Theta = \mathcal{T}(\Theta^*)$, is a likelihood maximum as well. Such multiple global maxima are the norm rather than the exception. Global maxima of models such as sparse coding (Olshausen and Field, 1996) or independent component analysis (e.g., Comon, 1994) remain global maxima under the exchange of any two basis functions or the negation of any of them.

Let all transformations $\mathcal{T}$ that map the global maxima of $L(\Theta)$ onto itself define a set that we will refer to as the *transformation set*. We say that the set of global maxima is *invariant* under the transformation set. For any two global maxima Θ^* and $\Theta^\dagger$ of $L(\Theta)$, there now exists a member $\mathcal{T}$ of the transformation set such that $\Theta^* = \mathcal{T}(\Theta^\dagger)$. Let us now demand that all global maxima of $L_1(\Theta)$ and $L_0(\Theta)$ are also invariant under the transformation set. Although this will usually be the case, for example, for the exchange of any two basis functions, it is important to state this requirement explicitly as it is not fulfilled in general. If this property is fulfilled, however, we can infer:

$$
\begin{aligned}
&\Theta^\dagger \text{ is maximum likelihood solution on } L(\Theta)\\
\Rightarrow\ &\text{There exists } \mathcal{T} \text{ such that } \Theta^\dagger = \mathcal{T}(\Theta^*) \text{ with } \Theta^* \text{ being the generating parameters.}\\
\Rightarrow\ &p(\vec{y}\,|\,c=1,\Theta^*) \text{ is the actual generating distribution of } \{\vec{y}^{(n)}\}_{n\in\mathcal{M}^{\mathrm{opt}}}\\
\Rightarrow\ &\Theta^* \text{ is maximum likelihood solution of } L_1(\Theta)\\
\Rightarrow\ &p(\vec{y}\,|\,c=1,\Theta^*) = p(\vec{y}\,|\,c=1,\mathcal{T}(\Theta^*)) = p(\vec{y}\,|\,c=1,\Theta^\dagger)\\
\Rightarrow\ &\Theta^\dagger \text{ is maximum likelihood solution of } L_1(\Theta).
\end{aligned}
$$

Analogously, $\Theta^\dagger$ is also a maximum likelihood solution of $L_0(\Theta)$ if it is a maximum likelihood solution of $L(\Theta)$. For the free-energy (15) this means that at a global maximum of $L(\Theta)$ both $L_1(\Theta)$ and $L_0(\Theta)$ also have a global maximum (under the stated assumptions). A global maximum, for example, in $L_1(\Theta)$ is thus a *necessary* condition for a global maximum in $L(\Theta)$. We have *not* shown that a maximum in $L_1(\Theta)$ is a sufficient condition for a maximum in $L(\Theta)$. Theoretically, $L_1(\Theta)$ might, for instance, not depend on all parameters, or it might have additional global maxima. Finally, note again that the necessary condition only holds under the introduced assumptions. While, for example, the assumption on invariance under transformations $\mathcal{T}$ can exactly be fulfilled (depending on the generative model), the assumptions that the true data distribution can exactly be matched or that the variational approximation in Section 3.1 is exact are in practice almost never fulfilled. The same applies for the assumption of infinitely many data points. All these assumptions can, however, be fulfilled approximately. By (globally) maximizing $L_1(\Theta)$ we can thus expect to recover parameters that maximize $L(\Theta)$ approximately.

A.2 Details of Data Classification

Starting point for choosing $\mathcal{M}$ is the set $\mathcal{M}^{\mathrm{opt}}$ in Equation 16. Setting $\mathcal{M}$=$\mathcal{M}^{\mathrm{opt}}$ would represent the best choice but without ground-truth information, $\mathcal{M}^{\mathrm{opt}}$ can not be computed exactly. We can, however, try to approximate $\mathcal{M}^{\mathrm{opt}}$. To do so, first note that we can compute an expectation value for the size of $\mathcal{M}^{\mathrm{opt}}$. It is given by $N(\mathcal{K}) = N\sum_{\vec{s}\in\mathcal{K}} p(\vec{s}\,|\,\Theta)$. We can now find an approximation to $\mathcal{M}^{\mathrm{opt}}$ by computing the values $q^{(n)}(c=1\,;\Theta^{\mathrm{old}})$ for all data points, sort them, and take the data points with the $N(\mathcal{K})$ highest values. This would represent a good approximation to $\mathcal{M}^{\mathrm{opt}}$ but it seems that we have gained very little, since we still have to compute the intractable posteriors

$q^{(n)}(c=1\,;\Theta^{\text{old}}) = p(c=1\,|\,\vec{y}^{\,(n)},\Theta^{\text{old}})$ for all n data points. Note, however, that with this procedure, the absolute values of $q^{(n)}(c=1\,;\Theta^{\text{old}})$ are not used for the approximation anymore. All that is required is a pairwise comparison of the data points based on their values $q^{(n)}(c=1\,;\Theta^{\text{old}})$.

To derive a tractable approximation of the pairwise comparison, consider two data points, $\vec{y}^{\,(n)}$ and $\vec{y}^{\,(n')}$, that are neighbors after a sorting according to $q^{(n)}(c=1\,;\Theta^{\text{old}})$. For arbitrarily many data points and for non-zero noise, the differences between the two data points become arbitrarily small. In particular, it applies for neighboring data points that the difference between the denominators of $q^{(n)}(c=1\,;\Theta^{\text{old}})$ become arbitrarily small: $\sum_{\vec{s}} p(\vec{y}^{\,(n)},\vec{s}\,|\,\Theta) \approx \sum_{\vec{s}} p(\vec{y}^{\,(n')},\vec{s}\,|\,\Theta)$. The same applies for differences between the numerators. However, as the numerators contain just small sums over $\vec{s}$, their values for neighboring data points can be expected to vary more strongly than those of the denominators. We can thus replace the comparison between $q^{(n)}(c=1\,;\Theta^{\text{old}})$ by a comparison of their numerators $\sum_{\vec{s}\in\mathcal{K}} p(\vec{y}^{\,(n)},\vec{s}\,|\,\Theta)$. This is an approximation to the pairwise comparison required for exact sorting. In the limit of infinitely many data points this procedure can be expected to result in sets $\mathcal{M}$ that represent good approximations to $\mathcal{M}^{\text{opt}}$.

If we now take preselection into account (compare Section 3.2), the comparison for sorting can be reduced further. For this note that the posterior in (14) is approximated by $q^{(n)}(c=1\,;\Theta^{\text{old}}) \approx \frac{\sum_{\vec{s}\in\mathcal{K}_n} p(\vec{y}^{\,(n)},\vec{s}\,|\,\Theta)}{\sum_{\vec{s}} p(\vec{y}^{\,(n)},\vec{s}\,|\,\Theta)}$. Following the same arguments as above, an approximation of the sorting by comparing the values $q^{(n)}(c=1\,;\Theta^{\text{old}})$ is given by sorting based on the values $\sum_{\vec{s}\in\mathcal{K}_n} p(\vec{y}^{\,(n)},\vec{s}\,|\,\Theta)$ for all n. This shows that the selection of N^{cut} data points as introduced in Section 2 (Equations 8 and 9) corresponds to defining a set $\mathcal{M}$ as an approximation to $\mathcal{M}^{\text{opt}}$.

Appendix B. Selection Function for NMF and MCA

We show that $p(s_h=1,\vec{y}^{\,(n)}\,|\,\Theta)$ is bounded by $\mathcal{S}_h(\vec{y}^{\,(n)})$ in (28) from above. This implies that $p(s_h=1\,|\,\vec{y}^{\,(n)},\Theta)$ is bounded by $\frac{\mathcal{S}_h(\vec{y}^{\,(n)})}{p(\vec{y}^{\,(n)}\,|\,\Theta)}$ from above. As $p(\vec{y}^{\,(n)}\,|\,\Theta)$ is independent of h, candidate selection based on the one bound is equivalent to selection based on the other bound. Now, consider the set $\delta_h := \{d\in\{1,\ldots,D\}\,|\,y^{(n)}_d < W_{dh}\}$ and note that if $y^{(n)}_d < W_{dh}$ and $s_h=1$ then $p(y^{(n)}_d\,|\,W_{dh},\sigma) < p(y^{(n)}_d\,|\,\overline{W}_d(\vec{s},W),\sigma)$. This is because $\overline{W}_d(\vec{s},W)$ can only be larger than W_{dh} for non-negative W and therefore the mono-modal Gaussian distribution $p(y^{(n)}_d\,|\,\overline{W}_d(\vec{s},W),\sigma)$ is further away from the maximum value. $p(y^{(n)}_d\,|\,w,\sigma)$ with $w=y^{(n)}_d$ is on the other hand larger or equal to

$p(y_d^{(n)} \,|\, w', \sigma)$ for any other value w'. It follows:

$$\begin{aligned}
p(s_h = 1, \vec{y}^{(n)} \,|\, \Theta) &= \sum_{\substack{\vec{s} \\ s_h = 1}} p(\vec{y}^{(n)} \,|\, \vec{s}, \Theta)\; p(\vec{s}\,|\,\pi) \\
&= \sum_{\substack{\vec{s} \\ s_h = 1}} \left(\prod_{d=1}^{D} p(y_d^{(n)} \,|\, \overline{W}_d(\vec{s}, W), \sigma) \right) p(\vec{s}\,|\,\pi) \\
&= \sum_{\substack{\vec{s} \\ s_h = 1}} \left(\prod_{d \in \delta_h} p(y_d^{(n)} \,|\, \overline{W}_d(\vec{s}, W), \sigma) \right) \left(\prod_{d \notin \delta_h} p(y_d^{(n)} \,|\, \overline{W}_d(\vec{s}, W), \sigma) \right) p(\vec{s}\,|\,\pi) \\
&\leq \left(\prod_{d \in \delta_h} p(y_d^{(n)} \,|\, W_{dh}, \sigma) \right) \left(\prod_{d \notin \delta_h} p(y_d^{(n)} \,|\, y_d^{(n)}, \sigma) \right) \sum_{\substack{\vec{s} \\ s_h = 1}} p(\vec{s}\,|\,\pi) \\
&= \left(\prod_{d \in \delta_h} p(y_d^{(n)} \,|\, W_{dh}^{\mathrm{ub}}, \sigma) \right) \left(\prod_{d \notin \delta_h} p(y_d^{(n)} \,|\, W_{dh}^{\mathrm{ub}}, \sigma) \right) \pi \\
&= \pi\, p(\vec{y}^{(n)} \,|\, \vec{W}_h^{\mathrm{ub}}, \sigma) \;=:\; \mathcal{S}_h(\vec{y}^{(n)}),
\end{aligned}$$

where $W_{dh}^{\mathrm{ub}} = \max\{y_d^{(n)}, W_{dh}\}$ as in Equation 28.

Appendix C. Computational Complexity

The computational cost of an E-step in the ET approximation scheme results from the computation of the selection functions $\mathcal{S}_h$ (Section 2 and Section 4) and the computation of the approximate sufficient statistics (6). For the sufficient statistics we have to compute the joint probabilities $p(\vec{s}, \vec{y}^{(n)} \,|\, \Theta)$ for different arguments. For the generative models of NMF, MCA and LinCA (Section 4.1, Section 4.2, and Section 4.3, respectively) the joint probabilities take the form:

$$p(\vec{s}, \vec{y}^{(n)} \,|\, \Theta) \;=\; \left(\prod_{d=1}^{D} p(y_d^{(n)} \,|\, \overline{W}_d(\vec{s}, W), \sigma) \right) \left(\prod_{h=1}^{H} p(s_h \,|\, \pi) \right). \tag{35}$$

For the first factor we have to compute D terms. Each term involves the computation of $\overline{W}_d(\vec{s}, W)$ which is equal to $\sum_h W_{dh} s_h$ in the cases of NMF and LinCA, and equal to $\max_h\{W_{dh} s_h\}$ in the case of MCA. In either case $\overline{W}_d(\vec{s}, W)$ can be computed with a cost proportional to the number of non-zero entries in a given vector $\vec{s}$, $\gamma' = |\vec{s}|$. The first factor in (35) is thus computable in times proportional to $D\gamma'$. The computational cost of the second factor can be neglected because just two terms (occurring γ' and $(H - \gamma')$ times) have to be computed.

The complexity of the selection functions, $\mathcal{S}_h$, used for NMF and MCA results from computing D times the conditional probabilities $p\big(y_d^{(n)} \,|\, W_{dh}^{\mathrm{ub}}, \sigma\big)$. The functions $\mathcal{S}_h$ have to be computed H times, which amounts to a computational cost proportional to DH (per data point). The selection functions used for the LinCA generative model (33) have the same computational cost. After preselection, the selection function values are used to determine the H' hidden units with the largest values, a computation that can be executed in times proportional to $\big(H + H' \log(H)\big)$ (see, e.g., Lam and Ting, 2000, for references).

In the approximate sufficient statistics (6) we sum over $|\mathcal{K}_n|$ different state vectors $\vec{s}$. If $\mathcal{K}_n$ is given as in Equation 7, it contains $\sum_{\gamma'=0}^{\gamma} \binom{H'}{\gamma'}$ different states with $\binom{H'}{\gamma'}$ counting the states with γ' non-zero entries. The denominator in (6) can therefore be computed in times proportional to $D\,\mathcal{C}(H',\gamma)$, where

$$\mathcal{C}(H',\gamma) := \sum_{\gamma'=0}^{\gamma} \binom{H'}{\gamma'} \gamma' .$$

For NMF, MCA, and LinCA the numerator can in both cases also be computed in times proportional to $D\,\mathcal{C}(H',\gamma)$ due to the special forms of the sufficient statistics. For NMF and LinCA the sufficient statistics $\langle s_i \rangle_{q^{(n)}}$ and $\langle s_i s_j \rangle_{q^{(n)}}$ do not require the computation of additional terms. For MCA the terms $\mathcal{A}^{\rho}_{di}(\vec{s},W)$ (see Equation 30) are of the form:

$$\mathcal{A}^{\rho}_{di}(\vec{s},W) = (s_i W_{di})^{\rho-1} \Big(\sum_h (s_h W_{dh})^{\rho} \Big)^{\frac{1-\rho}{\rho}} . \tag{36}$$

The last term in (36) can be computed together with $\overline{W}_d(\vec{s},W)$. Further, the computation of the D terms $p(\vec{s},\vec{y}^{(n)}\,|\,\Theta)\,\mathcal{A}_{di}(\vec{s},W)$ in the denominator is required just γ' times for a given $\vec{s}$. The numerator, like the denominator, is thus computable in times proportional to $D\gamma'$.

Selection functions and sufficient statistics have to be computed for each data point (see Algorithm 1), which results in a computational time proportional to:

$$\alpha_1 NDH \;+\; \alpha_2 N(H + H'\log(H)) \;+\; \alpha_3 ND\,\mathcal{C}(H',\gamma)\,, \tag{37}$$

where α_1, α_2, and α_3 are constants that describe potentially different weightings of the three terms. Note that if the size of $\mathcal{K}_n$ is increased by adding unit vectors, $\overline{\mathcal{K}}_n = \mathcal{K}_n \cup \{\vec{s}\,|\,\sum_i s_i = 1\}$ (as was done for MCA and LinCA) the scaling behavior (37) remains unchanged (also note that $\overline{\mathcal{K}}_n$ remains a subset of $\mathcal{K}$ as defined in Section 3.2). The usage of $\overline{\mathcal{K}}_n$ instead of $\mathcal{K}_n$ adds another $(H-H') \leq H$ terms to $\mathcal{C}(H',\gamma)$ and consequently a cost of $\alpha_4 ND(H-H') \leq \alpha_4 NDH$ to the whole expression. With a change of factor α_1, the additional cost thus gets absorbed into the first term in (37).

Considering expression (37) note that in our applications, D is always much larger than $\log(H)$. We can therefore neglect the second term such that the computational cost is approximately:[2]

$$C_{ET(H',\gamma)}(N,D,H) := \alpha_1 NDH \;+\; \alpha_3 ND\,\mathcal{C}(H',\gamma)\,. \tag{38}$$

The constants α_1 and α_3 depend on the generative model and the specific implementation of the algorithm. The principle scaling behavior remains the same, however. In Figure 13 we have plotted the scaling behavior for ET with $\alpha_1 = \alpha_3 = \frac{1}{2}$. The different graphs show the H dependence of $C_{ET(H',\gamma)}(N,D,H)$ for different values of H' and γ, $D = 100$ and $N = 1000$. Note that different choices of D and N would just globally shift the curves in the double-log plot. The steepest curve in Figure 13 is the one for ET(H,H), that is, if we choose $H' = H$ and $\gamma' = H$. In this case we drop back to the exact sufficient statistics with exponential computational cost. Note that for this

2. Note that ET also involves partial sorting of the data points once after each E-step. In a typical experiment (and in all of the experiments discussed in the paper), $\log(N)$ is much smaller than DH. The computational cost of discarding data points can therefore be neglected.

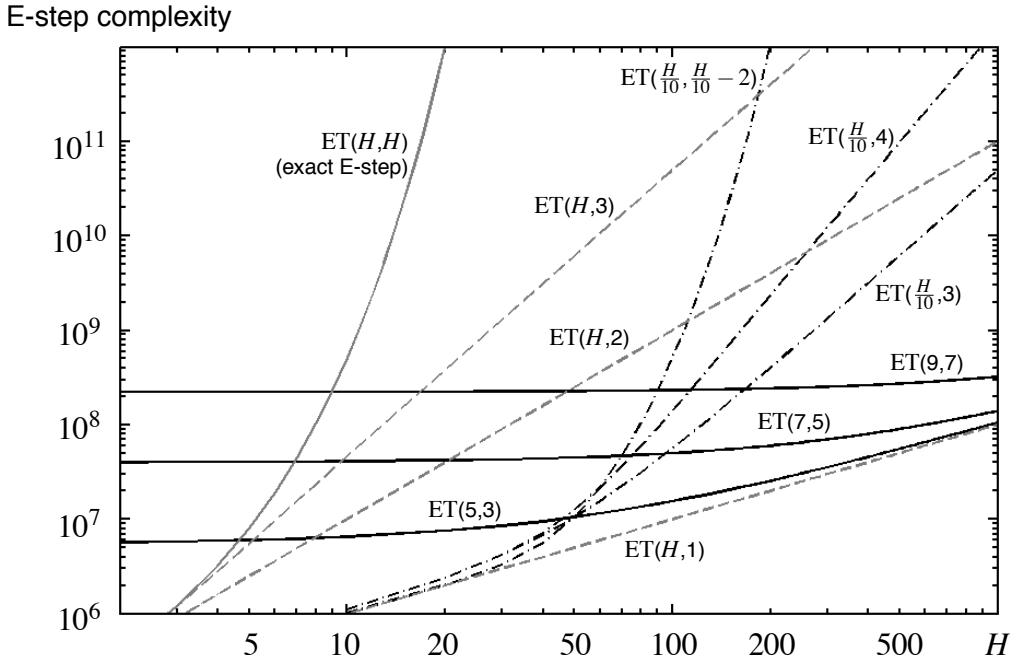

Figure 13: Scaling behavior of ET with (7) for different settings of the parameters H' and γ. The plots show the function (38) and its dependence on H.

and for all other plots with $H' = H$, we set the first term in (38) to zero because no preselection is required. The three dashed grey lines describe the computational costs of ET$(H,1)$, ET$(H,2)$, and ET$(H,3)$. They resemble straight lines because for large H their scaling is proportional to H, H^2, and H^3, respectively. Note that these three approximations are further examples for ET without preselection ($H' = H$). Their scaling behavior relative to the scaling with other parameters can therefore serve as a comparison for the computational gain of candidate preselection. The three solid black lines describe the computational time required for the parameter settings ET$(5,3)$, ET$(7,5)$, and ET$(9,7)$. These curves are flat initially because the first term in (13) (the preselection term) is small compared to the second term which is independent of H. For large H, the preselection term becomes increasingly dominant, however. The three black dashed lines describe the scaling with H for ET$(\frac{H}{10},3)$, ET$(\frac{H}{10},4)$, and ET$(\frac{H}{10},\frac{H}{10}-2)$. The computational cost of ET$(\frac{H}{10},3)$ is orders of magnitude smaller than the cost for ET$(H,3)$ but finally scales with the same slope. ET$(\frac{H}{10},4)$ is computational less expensive than ET$(H,3)$ for $H \leq 1000$ but will finally become computationally more intensive. If the parameters H' and γ' are both scaled up with H as for ET$(\frac{H}{10},\frac{H}{10}-2)$, we finally get a scaling behavior similar to that of an exact E-step. Note, however, that even in this case the computational cost remains smaller than that of ET$(H,3)$ for values of H smaller that about $H = 180$.

As discussed earlier, the computational gain achievable by ET depends on the data and the generative model used. If the data contains sufficiently many data points that are well represented by few active causes, the computational gain is potentially very substantial. For instance for the data used in this paper it was sufficient to use small values for H' and γ. Compared to systems without

preselection or an exact E-step, the gain amounts to several orders of magnitude (as, e.g., discussed for $H = 100$ in Section 4.2.2, or for $H = 200$ in Section 4.3.2).

Note that there are usually secondary effects that make learning slower if H increases. E.g., a large numbers of hidden variables usually requires large sets of data points to avoid overfitting. We also observed that longer cooling times are often beneficial for large values of D and/or H. However, ET scales essentially linearly with the number of data points, and the cooling schedule usually has to be increased merely by a factor of $2-8$. The secondary effects do, therefore, only play a role because ET has reduced the potentially exponential cost to a scaling which is close to linear in H.

Appendix D. Classical NMF vs. ET-NMF

The classical NMF belongs to the class of non-negative matrix factorization (NMF) methods, which makes use of non-negative data points, generative fields and sources. In this appendix, we first summarize the classical NMF and then derive the probabilistic version (ET-NMF) using Expectation Truncation.

D.1 Classical NMF

The standard NMF was proposed originally in Lee and Seung (1999) as a parameter-free method for the factorization of data into non-negative generative fields (or 'basis vectors') and source activities. Starting with generative fields $\vec{W}_h = (W_{1h}, \ldots, W_{Dh})^T$ for each source (or cause) s_h contained in the rows of a matrix $W \in \mathbb{R}^{D\times H}$, N data points $\vec{y}^{(n)}$ contained in the columns of a matrix $Y \in \mathbb{R}^{D\times N}$, and the corresponding source activity vectors $\vec{s}^{(n)}$ for each data point contained in the columns of a matrix $S \in \mathbb{R}^{H\times N}$, the NMF factorization tries to find an approximation

$$Y \approx WS \qquad \text{resp., in vector form} \qquad \vec{y}^{(n)} \approx W\vec{s}^{(n)} \tag{39}$$

with non-negative entries for Y, W and S, meaning that the generative fields $\vec{W}_h$ are combined linearly using the source activations $s_h^{(n)}$ to approximate the data vectors $\vec{y}^{(n)}$.

Different cost functions $E(W,S)$ have been proposed for this factorization; here we will consider an Euclidean cost function which we will compare in the next section to a Gaussian-based generative version of NMF used for Expectation Truncation (ET-NMF). To factorize (39), we therefore minimize

$$E(W,S) = ||Y - WS||^2 \tag{40}$$

with respect to W and S. Introducing

$$\langle f(\vec{y}, s_h)\rangle := \frac{1}{N}\sum_{n=1}^{N} f(\vec{y}^{(n)}, s_h^{(n)})$$

for a more compact notation and using the vectorial form of (40), the task is to minimize

$$E(W,S) = \left\langle ||\vec{y} - W\vec{s}||^2 \right\rangle , \tag{41}$$

that is, the average Euclidean reconstruction error over all data points $\vec{y}^{(n)}$.

In Lee and Seung (2001), it could be shown that the following parameter-free multiplicative update rules converge to local minima of the cost function (41),

$$s_h^{(n)} \leftarrow s_h^{(n)} \frac{(\vec{W}_h)^T \vec{y}^{(n)}}{(\vec{W}_h)^T (\sum_{h'} \vec{W}_{h'} s_{h'}^{(n)})} \quad \text{and} \quad \vec{W}_h \leftarrow \vec{W}_h \odot \frac{\langle \vec{y}\, s_h\rangle}{\sum_{h'} \vec{W}_{h'} \langle s_{h'}\, s_h\rangle}, \tag{42}$$

(the multiplication $\odot$ and division in the second equation of (42) are applied component-wise on vectors). At start, the generative fields and the source activities are initialized randomly with positive values, and then the two equations (42) are applied in alternation until convergence.

The update rules (42) conserve non-negativity and, interestingly, provide a good compromise between speed and ease of implementation. This can be seen by considering directly the gradient descent update equations derived for $\vec{W}_h$ from the minimization of Equation 41,

$$\vec{W}_h \leftarrow \vec{W}_h + \vec{\alpha} \odot \left(\langle \vec{y}\, s_h \rangle - \sum_{h'} \vec{W}_{h'} \langle s_{h'}\, s_h \rangle \right) , \tag{43}$$

with a stepsize vector $\vec{\alpha}$, and modifying an argument from Lee and Seung (2001), diagonally rescaling the variables using a stepsize

$$\vec{\alpha} = \frac{\vec{W}_h}{\sum_{h'} \vec{W}_{h'} \langle s_{h'}\, s_h \rangle} . \tag{44}$$

Inserting (44) into (43) yields the second, multiplicative update rule from (42), so that in conjunction with the convergence proof of the multiplicative NMF equations from Lee and Seung (2001) we can interprete NMF as a gradient-descent optimization of (41) with $\vec{\alpha}$ from (44) being a good choice of the gradient descent stepsize for the update of the generative fields $\vec{W}_h$.

D.2 ET-NMF

For the generative version of NMF, the choice of the source activities occurs according to the Bernoulli prior (22) from Section 4. As for the classical NMF, we combine the generative fields $\vec{W}_h$ linearly with the source activities s_h using $\overline{W}(\vec{s}, W) := W\vec{s}$, with the difference that the activities are now binary and constitute the hidden variables of the system (remark that now we write s_h instead of $s_h^{(n)}$). In addition, we use a Gaussian noise model such that the probability of a data vector $\vec{y}$ given $\vec{s}$ is defined by $p(\vec{y}\,|\,\vec{s}, \Theta)$ given by Equation 24 from Section 4.1.

At this point we apply the Expectation Maximization formalism introduced in Section 2. From the data likelihood of the generative model resp. the free energy (2) we then get for the W-relevant terms ('+...' denotes terms that do not depend on W) an expression similar to Equation 41,

$$E(W) = \left\langle ||\vec{y} - W\vec{s}||^2 \right\rangle_{\mathrm{ET}} + \ldots , \tag{45}$$

so that again the average Euclidean reconstruction error should be minimized. The difference is that now the averaging $\langle ... \rangle$ runs not only over all data points, but also over all possible source combinations $\vec{s}$ used to generate each data point. Here we wrote $\langle ... \rangle_{\mathrm{ET}}$, to express that in addition, we use the Expectation Truncation formalism for the computation of averages. That is, the averaging runs over the subset of data vectors $n \in \mathcal{M}$ and the set of source vectors $\vec{s} \in \mathcal{K}_n$ gained by the source preselection and sparseness assumptions:

$$\langle f(\vec{y}, s_h) \rangle_{\mathrm{ET}} := \sum_{n \in \mathcal{M}} \sum_{\vec{s} \in \mathcal{K}_n} p(\vec{s}|\vec{y}^{(n)}, \Theta)\, f(\vec{y}^{(n)}, s_h) = \sum_{n \in \mathcal{M}} \left\langle f(\vec{y}^{(n)}, s_h) \right\rangle_{q^{(n)}} . \tag{46}$$

From here on, all following steps can be considered in analogy to the classical NMF, by replacing $\langle ... \rangle \rightarrow \langle ... \rangle_{\mathrm{ET}}$. The task of ET-NMF is therefore to minimize (45) with respect to W, using the preselected causes and all possible source activation vectors $\vec{s}$ generated by those causes.

It can be easily seen now that the gradient-descent minimization of W and a diagonal rescaling of the stepsize according to

$$\vec{\alpha} = \frac{\vec{W}_h}{\sum_{h'} \vec{W}_{h'} \langle s_{h'} s_h \rangle_{\mathrm{ET}}}$$

can also be done in analogy to the classical NMF, leading to the multiplicative update equation for the generative fields of ET-NMF,

$$\vec{W}_h \leftarrow \vec{W}_h \odot \frac{\langle \vec{y}\, s_h \rangle_{\mathrm{ET}}}{\sum_{h'} \vec{W}_{h'} \langle s_{h'}\, s_h \rangle_{\mathrm{ET}}} \; . \tag{47}$$

The multiplicative, parameter-free equation 47 therefore leads to a near-to-optimal decrease of the ET-NMF model resp. the energy function (45) for positive data points, positive generative fields and Bernoulli-prior-distributed source activations. Since the convergence proof of the original NMF as presented by Lee and Seung (2001) considers convergence of W and S separately, it is straightforward to apply it to the ET-NMF by considering the selected source activations $\vec{s} \in \mathcal{K}_n$ in (46) as given, and applying the classical NMF to an expanded data set which incorporates the given activation vectors together with the data vectors and the probabilities as occurrence frequencies. For a fixed set of $\vec{s}$'s, (47) can then be applied until convergence.

The differences and similarities between the classical NMF and ET-NMF can then be shortly stated as follows. The classical NMF uses data points in fixed association with their corresponding continuous activation vectors and minimizes the Euclidean cost function (41) for both the source activations *and* the generative fields, the latter according to the multiplicative update rule (42). ET-NMF explores a subset of allowed binary source activations for each data point and minimizes in its M-step the Euclidean cost function (45) for the generative fields only, according to the multiplicative update rule (47). The E-step of ET-NMF is based on the truncated expectation values (6) to calculate the averaged quantities in the W update equations according to

$$\langle \vec{y}\, s_h \rangle_{\mathrm{ET}} = \sum_{n \in \mathcal{M}} \vec{y}^{\,(n)} \langle s_h \rangle_{q^{(n)}} \qquad \text{and} \qquad \langle s_{h'}\, s_h \rangle_{\mathrm{ET}} = \sum_{n \in \mathcal{M}} \langle s_{h'}\, s_h \rangle_{q^{(n)}} \tag{48}$$

so that the sufficient statistics of the ET-NMF model that have to be computed for the M-step will be given by the first and second order moments $\langle s_h \rangle_{q^{(n)}}$ and $\langle s_{h'}\, s_h \rangle_{q^{(n)}}$ of the approximate posterior. The full Expectation Truncation formalism then comprises the calculation of the expectation values $\langle s_h \rangle_{q^{(n)}}$ and $\langle s_{h'}\, s_h \rangle_{q^{(n)}}$ (needed for (48)), and afterwards the adjustment of the generative fields according to (47).

Appendix E. Details of Measurements

For the measurements in Section 4, we here give details about the procedure we used to determine if a cause is represented by the parameters of a hidden variable.

Let $\vec{y}^{\,\mathrm{cause}}_{h'}$ denote a data point showing cause h' without noise (e.g., one noiseless bar). Let further $\vec{s}_h$ denote a hidden state with just one non-zero entry at position h. To determine if cause h' is represented, we compute the approximate posterior probabilities $\tilde{p}(\vec{s}_h \,|\, \vec{y}^{\,\mathrm{cause}}_{h'}, \Theta)$ for each vector $\vec{s}_h$ using the approximation provided by ET. The hidden unit h with the highest posterior value $\tilde{p}(\vec{s}_h \,|\, \vec{y}^{\,\mathrm{cause}}_{h'}, \Theta)$ is taken as the unit representing cause h'. We only take all causes to be represented if the mapping from the causes to the representing latents is injective. Additionally, we demand

that the mean average error (MAE) between the generating cause parameters $\vec{y}_{h'}^{\,\text{cause}}$ and the model parameters $\vec{W}_h$ of the representing unit is smaller than 1.0 for each cause. For the data used in this paper, the threshold discounted any generative fields $\vec{W}_h$ with significant traces of more than one cause.

Abstract

We introduce new Perceptron-based algorithms for the online multitask binary classification problem. Under suitable regularity conditions, our algorithms are shown to improve on their baselines by a factor proportional to the number of tasks. We achieve these improvements using various types of regularization that bias our algorithms towards specific notions of task relatedness. More specifically, similarity among tasks is either measured in terms of the geometric closeness of the task reference vectors or as a function of the dimension of their spanned subspace. In addition to adapting to the online setting a mix of known techniques, such as the multitask kernels of Evgeniou *et al.*, our analysis also introduces a matrix-based multitask extension of the p-norm Perceptron, which is used to implement spectral co-regularization. Experiments on real-world data sets complement and support our theoretical findings.

Keywords: mistake bounds, perceptron algorithm, multitask learning, spectral regularization

1. Introduction

In this work we study online supervised learning algorithms that process multiple data streams at the same time. More specifically, we consider the *multitask* classification learning problem where observed data describe different learning tasks.

Incremental multitask learning systems, which simultaneously process data from multiple streams, are widespread. For instance, in financial applications a trading platform chooses investments and allocates assets using information coming from multiple market newsfeeds. When the learning tasks are unrelated, running different instances of the same underlying algorithm, one for each task, is a sound and reasonable policy. However, in many circumstances data sources share similar traits and are therefore related in some way. Unsurprisingly, this latter situation is quite common in real-world applications. In these cases the learning algorithm should be able to capitalize on data relatedness.

In multitask classification an online linear classifier (such as the Perceptron algorithm) learns from examples associated with $K > 1$ different binary classification tasks. Our goal is to design online interacting algorithms that perform better than independent learners whenever the tasks are related. We formalize task relatedness in different ways, and derive precise formalizations of the

advantage resulting from such interaction. Our investigation considers two variants of the online multitask protocol: (1) at each time step the learner acts on a single adversarially chosen task; (2) all tasks are simultaneously processed at each time step. Each setup allows for different approaches to the multitask problem and caters for different real-world scenarios. For instance, one of the advantages of the first approach is that, in most cases, the cost of running multitask algorithms has a mild dependence on the number K of tasks. The multitask classifiers we study here manage to improve, under certain assumptions, the cumulative regret achieved by a natural baseline algorithm through the information acquired and shared across different tasks.

Our analysis builds on ideas that have been developed in the context of statistical learning where the starting point is a regularized empirical loss functional or Tikhonov functional. In that framework the objective includes a co-regularization term in the form of a squared norm in some Hilbert space of functions that favors those solutions (i.e., predictive functions for the K tasks) that lie "close" to each other. In this respect, we study two main strategies. The first approach followed here is to learn K linear functions parameterized by $u^\top = (u_1^\top, \ldots, u_K^\top) \in \mathbb{R}^{Kd}$ through the minimization of an objective functional involving the sum of a loss term plus the regularization term $u^\top A u$, where A is a positive definite matrix enforcing certain relations among tasks. Following Evgeniou et al. (2005), the K different learning problems are reduced to a single problem by choosing a suitable embedding of the input instances into a common Reproducing Kernel Hilbert Space (RKHS). This reduction allows us to solve a multitask learning problem by running any kernel-based single-task learning algorithm with a "multitask kernel" that accounts for the co-regularization term in the corresponding objective functional. We build on this reduction to analyze the performance of the Perceptron algorithm and some of its variants when run with a multitask kernel.

As described above, we also consider a different learning setup that prescribes the whole set of K learning tasks to be worked on at the same time. Once again we adopt a regularization approach, this time by adding a bias towards those solutions that lie on the same low dimensional subspace. To devise an algorithm for this model, we leverage on the well-established theory of potential-based online learners. We first define a natural extension of the p-norm Perceptron algorithm to a certain class of matrix norms, and then provide a mistake bound analysis for the multitask learning problem depending on spectral relations among different tasks. Our analysis shows a factor K improvement over the algorithm that runs K independent Perceptrons and predicts using their combined margin (see Section 1.1). The above is possible as long as the the example vectors observed at each time step are unrelated, while the sequences of multitask data are well predicted by a set of highly related linear classifiers.

1.1 Main Contributions

The contribution of this paper to the current literature is twofold. First, we provide theoretical guarantees in the form of mistake bounds for various algorithms operating within the online multitask protocol. Second, we present various experiments showing that these algorithms perform well on real problems.

Our theoretical results span across the two previously mentioned settings. In the adversarially chosen task setting, we extend the ideas introduced by Evgeniou et al. (2005) to the online learning setup, and present upper bounds which depend on task relatedness. On one hand, we show that whenever the reference vectors associated with different tasks are related, we achieve an improvement of a factor up to K over the baseline approach where K online classifiers are run in parallel and

tasks are processed in isolation. On the other hand, when tasks are unrelated our bounds become not much worse than the one achieved by separately running K classifiers. In this context, the notion of relatedness among tasks follows from the specific choice of a matrix parameter that essentially defines the so-called multitask kernel. We also provide some new insight on the role played by this kernel when used as a plug-in black-box by the Perceptron or other Perceptron-like algorithms.

In the simultaneous task setting, we introduce and analyze a matrix-based multitask extension of the p-norm Perceptron algorithm (Grove et al., 2001; Gentile, 2003) which allows us to obtain a factor K improvement in a different learning setting, where the baseline, which is still the algorithm that maintains K independent classifiers, is supposed to output K predictions per trial.

On the experimental side, we give evidence that our multitask algorithms provide a significant advantage over common baselines. In particular, we show that on a text categorization problem, where each task requires detecting the topic of a newsitem, a large multitask performance increase is attainable whenever the target topics are related. Additional experiments on a spam data set confirm the potential advantage of the p-norm Perceptron algorithm in a real-world setting.

This work is organized as follows. In Section 2 we introduce notation and formally define the *adversarially chosen task* protocol. The multitask Perceptron algorithm is presented in Section 3 where we also discuss the role of the multitask feature map and show (Section 4) that it can be used to turn online classifiers into multitask classifiers. We detail the matrix-based approach to the simultaneous multitask learning framework in Section 5. Section 6 is devoted to the theoretical analysis of a general potential-based algorithm for this setup. We conclude the paper with a number of experiments establishing the empirical effectiveness of our algorithms (Section 7).

1.2 Related Work

The problem of learning from multiple tasks has been the subject of a number of recently published papers. In Evgeniou et al. (2005) a batch multitask learning problem is defined as a regularized optimization problem and the notion of multitask kernel is introduced. More specifically, they consider a regularized functional that encodes multitask relations over tasks, thus biasing the solution of the problem towards functions that lie close to each other. Argyriou et al. (2007, 2008) build on this formalization to simultaneously learn a multitask classifier and the underlying spectral dependencies among tasks. A similar model but under cluster-based assumptions is investigated in Jacob et al. (2009). A different approach is discussed in Ando and Zhang (2005) where a structural risk minimization method is presented and multitask relations are established by enforcing predictive functions for the different tasks to belong to the same hypothesis set. Complexity results for multitask learning under statistical assumptions are also given in Maurer (2006).

In the context of online learning, multitask problems have been studied in Abernethy et al. (2007) within the learning with expert advice model. In this model the forecaster has access to a fixed set of experts and is expected to make predictions for K different tasks. Regret bounds are given under the assumption that the set of best experts for the K tasks is small, as a way to formalize task similarity. Whereas these studies consider a multitask protocol in which a single task is acted upon at each time step (what we call in this paper the adversarially chosen task protocol), the work of Lugosi et al. (2009) investigates the problem where an action for each task must be chosen at every step. The relatedness among tasks is captured by imposing restrictions on the joint action chosen at each step.

Online linear multitask algorithms for the simultaneous task setting have been studied in Dekel et al. (2007), where the separate learning tasks are collectively dealt with through a common multitask loss. Their approach, however, is fundamentally different from the one considered here. In fact, using a common loss function has more the effect of prioritizing certain tasks over the others, whereas our regularized approach hopes to benefit from the information provided by each task to speed up the learning process for the other ones. Nonetheless, it is not difficult to extend our analysis to consider a more sophisticated notion of multitask loss (see Remark 12 in Section 6.2), thus effectively obtaining a shared loss regularized multitask algorithm.

Online matrix approaches to the multitask and the related multiview learning problems were considered in various works. Matrix versions of the EG algorithm and the Winnow algorithm (related to specific instances of the quasi-additive algorithms) have been proposed and analyzed in Tsuda et al. (2005), Warmuth (2007), and Warmuth and Kuzmin (2006). When dealing with the trace norm regularizer, their algorithms could be generalized to our simultaneous multitask framework to obtain mistake bounds comparable to ours. However, unlike those papers, we do not have learning rate tuning issues and, in addition, we directly handle general nonsquare task matrices.

Finally, Agarwal et al. (2008) consider multitask problems in the restricted expert setting, where task relatedness is enforced by a group norm regularization. Their results are essentially incomparable to ours.

2. The Adversarially Chosen Task Protocol: Preliminaries

The adversarially chosen task protocol works as follows. Let K be the number of binary classification tasks indexed by $1,\dots,K$. Learning takes place in a sequential fashion: At each time step $t = 1,2,\dots$ the learner receives a task index $i_t \in \{1,\dots,K\}$ and observes an instance vector $x_t \in \mathbb{R}^d$ which plays the role of side information for the task index i_t. Based on the pair $\big(x_t, i_t\big)$ it outputs a binary prediction $\widehat{y}_t \in \{-1,1\}$ and then receives the correct label $y_t \in \{-1,1\}$ for task index i_t. So, within this scheme, the learner works at each step on a single chosen task among the K tasks and operates under the assumption that instances from different tasks are vectors of the same dimension. No assumptions are made on the mechanism generating the sequences $\big(x_1,y_1\big), \big(x_2,y_2\big), \dots$ of task examples. Moreover, similarly to Abernethy et al. (2007), the sequence of task indices $i_1, i_2, \dots$ is also generated in an adversarial manner. To simplify notation we introduce a "compound" description for the pair $\big(x_t, i_t\big)$ and denote by $\phi_t \in \mathbb{R}^{dK}$ the vector

$$\phi_t^\top \stackrel{\text{def}}{=} \big(\underbrace{0,\dots,0}_{(i_t-1)d \text{ times}} \; x_t^\top \; \underbrace{0,\dots,0}_{(K-i_t)d \text{ times}} \big) \,. \tag{1}$$

Within this protocol (studied in Sections 3 and 4) we use ϕ_t or $\big(x_t, i_t\big)$ interchangeably when referring to a multitask instance. In the following we assume instance vectors are of (Euclidean) unit norm, that is, $\|x_t\| = 1$, so that $\|\phi_t\| = 1$.

We measure the learner's performance with respect to that of a (compound) reference predictor that is allowed to use a different linear classifier, chosen in hindsight, for each one of the K tasks. To remain consistent with the notation used for multitask instances, we introduce the "compound" reference task vector $u^\top = \big(u_1^\top, \dots, u_K^\top\big)$ and define the hinge loss for the compound vector u as

$$\ell_t(u) \stackrel{\text{def}}{=} \max\big\{0, 1 - y_t\, u^\top \phi_t\big\} = \max\big\{0, 1 - y_t\, u_{i_t}^\top x_t\big\}.$$

It is understood that the compound vectors are of dimension Kd. Our goal is then to compare the learner's mistakes count to the cumulative hinge loss

$$\sum_t \ell_t(u) \tag{2}$$

suffered by the compound reference task vector u. This of course amounts to summing over time steps t the losses incurred by reference task vectors u_{i_t} with respect to instance vectors x_{i_t}.

In this respect, we aim at designing algorithms that make fewer mistakes than K independent learners when the tasks are related, and do not perform much worse than those when the tasks are completely unrelated. For instance, if we use Euclidean distance to measure task relatedness, we say that the K tasks are related if there exist reference task vectors $u_1,\ldots,u_K \in \mathbb{R}^d$ having small pairwise distances $\|u_i - u_j\|$, and achieving a small cumulative hinge loss in the sense of (2). More general notions of relatedness are investigated in the next sections.

Finally, we find it convenient at this point to introduce some matrix notation. We use I_d to refer to the $d \times d$ identity matrix but drop the subscript whenever it is clear from context. Given a matrix $M \in \mathbb{R}^{m\times n}$ we denote by $M_{i,j}$ the entry that lies in the i-th row, j-th column. Moreover, given two matrices $M \in \mathbb{R}^{m\times n}$ and $N \in \mathbb{R}^{m\times r}$ we denote by $[M,N]$ the $m \times (n+r)$ matrix obtained by the horizontal concatenation of M and N. The Kronecker or direct product between two matrices $M \in \mathbb{R}^{m\times n}$ and $N \in \mathbb{R}^{q\times r}$ is the block matrix $M \otimes N$ of dimension $mq \times nr$ whose block on row i and column j is the $q \times r$ matrix $M_{i,j}N$.

3. The Multitask Perceptron Algorithm

We first introduce a simple multitask version of the Perceptron algorithm for the protocol described in the previous section. This algorithm keeps a weight vector for each task and updates all weight vectors at each mistake using the Perceptron rule with different learning rates. More precisely, let $w_{i,t}$ be the weight vector associated with task i at time t. If we are forced (by the adversary) to predict on task i_t, and our prediction happens to be wrong, we update $w_{i_t,t-1}$ through the standard additive rule $w_{i_t,t} = w_{i_t,t-1} + \eta y_t x_t$ (where $\eta > 0$ is a constant learning rate) but, at the same time, we perform a "half-update" on the remaining $K-1$ Perceptrons, that is, we set $w_{j,t} = w_{j,t-1} + \frac{\eta}{2} y_t x_t$ for each $j \neq i_t$. This rule is based on the simple observation that, in the presence of related tasks, any update step that is good for one Perceptron should also be good for the others. Clearly, this rule keeps the weight vectors $w_{j,t}$, $j = 1,\ldots,K$, always close to each other.

The above algorithm is a special case of the *multitask Perceptron algorithm* described below. This more general algorithm updates each weight vector $w_{j,t}$ through learning rates defined by a $K \times K$ *interaction matrix* A. It is A that encodes our beliefs about the learning tasks: different choices of the interaction matrix result in different geometrical assumptions on the tasks.

The pseudocode for the multitask Perceptron algorithm using a generic interaction matrix A is given in Figure 1. At the beginning of each time step, the counter s stores the mistakes made so far plus 1. The weights of the K Perceptrons are maintained in a compound vector $w_s^\top = \left(w_{1,s}^\top,\ldots,w_{K,s}^\top\right)$, with $w_{j,s} \in \mathbb{R}^d$ for all j. The algorithm predicts y_t through the sign $\widehat{y}_t$ of the i_t-th Perceptron's margin $w_{s-1}^\top \phi_t = w_{i_t,s-1}^\top x_t$. Then, if the prediction and the true label disagree, the compound vector update rule is $w_s = w_{s-1} + \left(A \otimes I_d\right)^{-1} \phi_t$. Since $\left(A \otimes I_d\right)^{-1} = A^{-1} \otimes I_d$, the above update is equivalent to the K task updates

$$w_{j,s} = w_{j,s-1} + y_t A^{-1}_{j,i_t} x_t \qquad j = 1,\ldots,K\,.$$

Parameters: Positive definite $K \times K$ interaction matrix A.
Initialization: $w_0 = 0 \in \mathbb{R}^{Kd}$, $s = 1$.
At each time $t = 1, 2, \ldots$ do the following:

1. Observe task number $i_t \in \{1, \ldots, K\}$ and the corresponding instance vector $x_t \in \mathbb{R}^d$: $||x_t|| = 1$;
2. Build the associated multitask instance $\phi_t \in \mathbb{R}^{Kd}$;
3. Predict label $y_t \in \{-1, +1\}$ with $\widehat{y}_t = \mathrm{SGN}\big(w_{s-1}^\top \phi_t\big)$;
4. Get label $y_t \in \{-1, +1\}$;
5. If $\widehat{y}_t \neq y_t$ then update:

$$w_s = w_{s-1} + y_t \big(A \otimes I_d\big)^{-1} \phi_t, \quad s \leftarrow s + 1 \ .$$

Figure 1: The multitask Perceptron algorithm.

The algorithm is mistake-driven, hence w_{s-1} is updated (and s is increased) only when $\widehat{y}_t \neq y_t$. In the following we use $A_\otimes$ as a shorthand for $A \otimes I_d$.

We now show that the algorithm in Figure 1 has the potential to make fewer mistakes than K independent learners when the tasks are related, and does not perform much worse than that when the tasks are completely unrelated. The bound dependence on the task relatedness is encoded as a quadratic form involving the compound reference task vector u and the interaction matrix A.

We specify the online multitask problem by the sequence $(\phi_1, y_1), (\phi_2, y_2), \ldots \in \mathbb{R}^{dK} \times \{-1, 1\}$ of multitask examples.

Theorem 1 *The number of mistakes m made by the multitask Perceptron algorithm in Figure 1, run with an interaction matrix A on any finite multitask sequence of examples $(\phi_1, y_1), (\phi_2, y_2), \ldots \in \mathbb{R}^{Kd} \times \{-1, 1\}$ satisfies, for all $u \in \mathbb{R}^{Kd}$,*

$$m \leq \sum_{t \in \mathcal{M}} \ell_t(u) + \max_{i=1,\ldots,K} (A^{-1})_{i,i} \big(u^\top A_\otimes u\big) + \sqrt{\max_{i=1,\ldots,K} (A^{-1})_{i,i} \big(u^\top A_\otimes u\big) \sum_{t \in \mathcal{M}} \ell_t(u)}$$

where $\mathcal{M}$ is the set of mistaken trial indices.

Theorem 1 is readily proven by using the fact that the multitask Perceptron is a specific instance of the kernel Perceptron algorithm, for example, Freund and Schapire (1999), using the so-called linear *multitask* kernel introduced in Evgeniou et al. (2005) (see also Herbster et al., 2005). This kernel is defined as follows: for any positive definite $K \times K$ interaction matrix A introduce the Kd-dimensional RKHS $\mathcal{H} = \mathbb{R}^{Kd}$ with the inner product $\langle u, v \rangle_{\mathcal{H}} = u^\top A_\otimes v$. Then define the kernel feature map $\psi : \mathbb{R}^d \times \{1, \ldots, K\} \to \mathcal{H}$ such that $\psi(x_t, i_t) = A_\otimes^{-1} \phi_t$. The kernel used by the multitask Perceptron is thus defined by

$$\mathcal{K}\big((x_s, i_s), (x_t, i_t)\big) = \big\langle \psi(x_s, i_s), \psi(x_t, i_t) \big\rangle_{\mathcal{H}} = \phi_s^\top A_\otimes^{-1} \phi_t \ . \tag{3}$$

Remark 2 *Although the multitask kernel is appealing because it makes the definition of the multitask Perceptron simple and intuitive, one easily sees that the RKHS formalism is not necessary here since the kernel is actually linear. In fact, by re-defining the feature mapping as* $\psi : \mathbb{R}^d \times \{1,\ldots,K\} \to \mathbb{R}^{Kd}$*, where* $\mathbb{R}^{Kd}$ *is now endowed with the usual Euclidean product, and by letting* $\psi(x_t,i_t) = A_\otimes^{-1/2}\phi_t$*, one gets an equivalent formulation of the multitask Perceptron based on* $A_\otimes^{-1/2}$ *rather than* $A_\otimes^{-1}$*. In the rest of the paper we occasionally adopt this alternative linear kernel formulation, in particular whenever it makes the definition of the algorithm and its analysis simpler.*

Proof [Theorem 1] We use the following version of the kernel Perceptron bound (see, e.g., Cesa-Bianchi et al., 2005),

$$m \le \sum_t \ell_t(h) + \|h\|_{\mathcal{H}}^2 \left(\max_t \|\psi(x_t,i_t)\|_{\mathcal{H}}^2\right) + \|h\|_{\mathcal{H}} \sqrt{\left(\max_t \|\psi(x_t,i_t)\|_{\mathcal{H}}^2\right) \sum_t \ell_t(h)}$$

where h is any function in the RKHS $\mathcal{H}$ induced by the kernel. The proof is readily concluded by observing that, for the kernel (3) we have

$$\|u\|_{\mathcal{H}}^2 = u^\top A_\otimes u \qquad \text{and} \qquad \|\psi(x_t,i_t)\|_{\mathcal{H}}^2 = \phi_t^\top A_\otimes^{-1}\phi_t = (A^{-1})_{i_t,i_t}$$

since ϕ_t singles out the i_t's block of matrix $A_\otimes^{-1}$. ■

In the next three subsections we investigate the role of the quadratic form $u^\top A_\otimes u$ and specialize Theorem 1 to different interaction matrices.

3.1 Pairwise Distance Interaction Matrix

The first choice of A we consider is the following simple update step (corresponding to the multitask Perceptron example we made at the beginning of this section).

$$w_{j,s} = w_{j,s-1} + \begin{cases} \frac{2}{K+1} y_t x_t & \text{if } j = i_t, \\ \frac{1}{K+1} y_t x_t & \text{otherwise.} \end{cases}$$

As it can be easily verified, this choice is given by

$$A = \begin{bmatrix} K & -1 & \ldots & -1 \\ -1 & K & \ldots & -1 \\ \ldots & \ldots & \ldots & \ldots \\ -1 & \ldots & \ldots & K \end{bmatrix} \tag{4}$$

with

$$A^{-1} = \frac{1}{K+1} \begin{bmatrix} 2 & 1 & \ldots & 1 \\ 1 & 2 & \ldots & 1 \\ \ldots & \ldots & \ldots & \ldots \\ 1 & \ldots & \ldots & 2 \end{bmatrix} .$$

We have the following result.

Corollary 3 *The number of mistakes m made by the multitask Perceptron algorithm in Figure 1, run with the interaction matrix (4) on any finite multitask sequence of examples* $(\phi_1, y_1), (\phi_2, y_2), \ldots \in \mathbb{R}^{Kd} \times \{-1, 1\}$ *satisfies, for all* $u \in \mathbb{R}^{Kd}$,

$$m \leq \sum_{t \in \mathcal{M}} \ell_t(u) + \frac{2\left(u^\top A_\otimes u\right)}{K+1} + \sqrt{\frac{2\left(u^\top A_\otimes u\right)}{K+1} \sum_{t \in \mathcal{M}} \ell_t(u)}$$

where

$$u^\top A_\otimes u = \sum_{i=1}^{K} \|u_i\|^2 + \sum_{1 \leq i < j \leq K} \left\|u_i - u_j\right\|^2 .$$

In other words, running the Perceptron algorithm of Figure 1 with the interaction matrix (4) amounts to using the Euclidean distance to measure task relatedness. Alternatively, we can say that the regularization term of the regularized target functional favors task vectors $u_1, \ldots, u_K \in \mathbb{R}^d$ having small pairwise distances $\left\|u_i - u_j\right\|$.

Note that when all tasks are equal, that is when $u_1 = \cdots = u_K$, the bound of Corollary 3 becomes the standard Perceptron mistake bound (see, e.g., Cesa-Bianchi et al., 2005). In the general case of distinct u_i we have

$$\frac{2\left(u^\top A_\otimes u\right)}{K+1} = \frac{2K}{K+1} \sum_{i=1}^{K} \|u_i\|^2 - \frac{4}{K+1} \sum_{1 \leq i < j \leq K} u_i^\top u_j .$$

The sum of squares $\sum_{i=1}^{K} \|u_i\|^2$ is the mistake bound one can prove when learning K independent Perceptrons (under linear separability assumptions). On the other hand, highly correlated reference task vectors (i.e., large inner products $u_i^\top u_j$) imply a large negative second term in the right-hand side of the above expression.

3.2 A More General Interaction Matrix

In this section we slightly generalize the analysis of the previous section and consider an update rule of the form

$$w_{j,s} = w_{j,s-1} + \begin{cases} \frac{b+K}{(1+b)K}\, y_t x_t & \text{if } j = i_t, \\ \frac{b}{(1+b)K}\, y_t x_t & \text{otherwise} \end{cases}$$

where b is a nonnegative parameter. The corresponding interaction matrix is given by

$$A = \frac{1}{K} \begin{bmatrix} a & -b & \ldots & -b \\ -b & a & \ldots & -b \\ \ldots & \ldots & \ldots & \ldots \\ -b & \ldots & \ldots & a \end{bmatrix} \tag{5}$$

with $a = K + b(K-1)$. It is immediate to see that the previous case (4) is recovered by choosing $b = K$. The inverse of (5) is

$$A^{-1} = \frac{1}{(1+b)K} \begin{bmatrix} b+K & b & \ldots & b \\ b & b+K & \ldots & b \\ \ldots & \ldots & \ldots & \ldots \\ b & \ldots & \ldots & b+K \end{bmatrix} .$$

When (5) is used in the multitask Perceptron algorithm, Theorem 1 can be specialized to the following result.

Corollary 4 *The number of mistakes m made by the multitask Perceptron algorithm in Figure 1, run with the interaction matrix (5) on any finite multitask sequence of examples $(\phi_1, y_1), (\phi_2, y_2), \ldots \in \mathbb{R}^{Kd} \times \{-1, 1\}$ satisfies, for all $u \in \mathbb{R}^{Kd}$,*

$$m \le \sum_{t \in \mathcal{M}} \ell_t(u) + \frac{(b+K)}{(1+b)K}\left(u^\top A_\otimes u\right) + \sqrt{\frac{(b+K)}{(1+b)K}\left(u^\top A_\otimes u\right) \sum_{t \in \mathcal{M}} \ell_t(u)}$$

where

$$u^\top A_\otimes u = \sum_{i=1}^{K} \|u_i\|^2 + bK \,\mathrm{VAR}[u]$$

being $\mathrm{VAR}[u] = \frac{1}{K}\sum_{i=1}^{K} \|u_i - \overline{u}\|^2$ *the "variance", of the task vectors, and* $\overline{u}$ *the centroid* $\frac{1}{K}\left(u_1 + \cdots + u_K\right)$.

It is interesting to investigate how the above bound depends on the trade-off parameter b. The optimal value of b (requiring prior knowledge about the distribution of $u_1, \ldots, u_K$) is

$$b = \max\left\{0, \sqrt{(K-1)\frac{\|\overline{u}\|^2}{\mathrm{VAR}[u]}} - 1\right\} .$$

Thus b grows large as the reference task vectors u_i get close to their centroid $\overline{u}$ (i.e., as all u_i get close to each other). Substituting this choice of b gives

$$\frac{(b+K)}{(1+b)K}\left(u^\top A_\otimes u\right) = \begin{cases} \|u_1\|^2 + \cdots + \|u_K\|^2 & \text{if } b = 0, \\ \left(\|\overline{u}\| + \sqrt{K-1}\sqrt{\mathrm{VAR}[u]}\right)^2 & \text{otherwise.} \end{cases}$$

When the variance $\mathrm{VAR}[u]$ is large (compared to the squared centroid norm $\|\overline{u}\|^2$), then the optimal tuning of b is zero and the interaction matrix becomes the identity matrix, which amounts to running K independent Perceptron algorithms. On the other hand, when the optimal tuning of b is nonzero we learn K reference vectors, achieving a mistake bound equal to that of learning a *single* vector whose length is $\|\overline{u}\|$ plus $\sqrt{K-1}$ times the standard deviation $\sqrt{\mathrm{VAR}[u]}$.

At the other extreme, if the variance $\mathrm{VAR}[u]$ is zero (namely, when all tasks coincide) then the optimal b grows unbounded, and the quadratic term $\frac{(b+K)}{(1+b)K}\left(u^\top A_\otimes u\right)$ tends to the average square norm $\frac{1}{K}\sum_{i=1}^{K} \|u_i\|^2$. In this case the multitask algorithm becomes essentially equivalent to an algorithm that, before learning starts, chooses one task at random and keeps referring all instance vectors x_t to that task (somehow implementing the fact that now the information conveyed by i_t can be disregarded).

3.3 Encoding Prior Knowledge

We could also pick the interaction matrix A so as to encode prior knowledge about tasks. For instance, suppose we know that only certain pairs of tasks are potentially related. We represent this knowledge in a standard way through an undirected graph $G = (V, E)$, where two vertices i and j

are connected by an edge if and only if we believe task i and task j are related. A natural choice for A is then $A = I + L$, where the $K \times K$ matrix L is the Laplacian of G, defined as

$$L_{i,j} = \begin{cases} d_i & \text{if } i = j, \\ -1 & \text{if } (i,j) \in E, \\ 0 & \text{otherwise.} \end{cases}$$

Here we denoted by d_i the degree (number of incoming edges) of node i. If we now follow the proof of Theorem 1, which holds for any positive definite matrix A, we obtain the following result.

Corollary 5 *The number of mistakes m made by the multitask Perceptron algorithm in Figure 1, run with the interaction matrix $I+L$ on any finite multitask sequence of examples $(\phi_1, y_1), (\phi_2, y_2), \ldots \in \mathbb{R}^{Kd} \times \{-1,1\}$ satisfies, for all $u \in \mathbb{R}^{Kd}$,*

$$m \le \sum_{t \in \mathcal{M}} \ell_t(u) + c_G\, u^\top \big(I+L\big)_\otimes u + \sqrt{c_G\, u^\top \big(I+L\big)_\otimes u \sum_{t \in \mathcal{M}} \ell_t(u)}$$

where

$$u^\top \big(I+L\big)_\otimes u = \sum_{i=1}^{K} \|u_i\|^2 + \sum_{(i,j) \in E} \big\|u_i - u_j\big\|^2 \tag{6}$$

and $c_G = \max_{i=1,\ldots,K} \sum_{j=1}^{K} \frac{v_{j,i}^2}{1+\lambda_j}$. Here $0 = \lambda_1 < \lambda_2 \le \cdots \le \lambda_K$ are the eigenvalues of the positive semidefinite matrix L, and $v_{j,i}$ denotes the i-th component[1] of the eigenvector v_j of L associated with eigenvalue λ_j.

Proof Following the proof of Theorem 1, we just need to bound

$$\max_{i=1,\ldots,K} A^{-1}_{i,i} = \max_{i=1,\ldots,K} (I+L)^{-1}_{i,i} \ .$$

If $v_1, \ldots, v_K$ are the eigenvectors of L, then

$$(I+L)^{-1} = \sum_{j=1}^{K} \frac{v_j v_j^\top}{1+\lambda_j}$$

which concludes the proof. ■

Ideally, we would like to have $c_G = O\big(\frac{1}{K}\big)$. Clearly enough, if G is the clique on K vertices we expect to exactly recover the bound of Theorem 1. In fact, we can easily verify that the eigenvector v_1 associated with the zero eigenvalue λ_1 is $\big(K^{-1/2}, \ldots, K^{-1/2}\big)$. Moreover, it is well known that all the remaining eigenvalues are equal to K—see, for example, Hogben (2006). Therefore $c_G = \frac{1}{K} + \big(1 - \frac{1}{K}\big)\frac{1}{K+1} = \frac{2}{K+1}$. In the case of more general graphs G, we can bound c_G in terms of the smallest nonzero eigenvalue λ_2,

$$c_G \le \frac{1}{K} + \left(1 - \frac{1}{K}\right) \frac{1}{1+\lambda_2} \ .$$

The value of λ_2, known as the algebraic connectivity of G, is 0 only when the graph is disconnected. λ_2 is known for certain families of graphs. For instance, if G is a complete bipartite graph (i.e., if

1. Note that the orthonormality of the eigenvectors implies $v_{1,i}^2 + \cdots + v_{K,i}^2 = 1$ for all i.

tasks can be divided in two disjoint subsets T_1 and T_2 such that every task in T_1 is related to every task in T_2 and for both $i = 1,2$ no two tasks in T_i are related), then it is known that $\lambda_2 = \min\{|T_1|, |T_2|\}$.

The advantage of using a graph G with significantly fewer edges than the clique is that the sum of pairwise distances in (6) will contain less than $\binom{K}{2}$ terms. On the other hand, this reduction has to be contrasted to a larger coefficient c_G in front of $u^\top (I+L)_\otimes u$. This coefficient, in general, is related to the total number of edges in the graph (observe that the trace of L is exactly twice this total number). The role of prior knowledge is thus to avoid the insertion in A of edges connecting tasks that are hardly related, thus preventing the presence of large terms in the sum $u^\top (I+L)_\otimes u$.

4. Turning Perceptron-like Algorithms Into Multitask Classifiers

We now show how to obtain multitask versions of well-known classifiers by using the multitask kernel mapping detailed in Section 3.

4.1 The Multitask p-norm Perceptron Algorithm

We first consider the p-norm Perceptron algorithm of Grove et al. (2001) and Gentile (2003). As before, when the tasks are all equal we want to recover the bound of the single-task algorithm, and when the task vectors are different we want the mistake bound to increase according to a function that penalizes task diversity according to their p-norm distance.

The algorithm resembles the Perceptron algorithm and maintains its state in the compound *primal* weight vector $v_s \in \mathbb{R}^{Kd}$ where s stores the mistakes made so for (plus one). What sets the *multitask p-norm Perceptron* aside from the algorithm of Section 3 is that the prediction at time t is computed, for an arbitrary positive definite interaction matrix A, as $\text{SGN}\left(w_{s-1}^\top A_\otimes^{-1} \phi_t\right)$ where the *dual* weight vector w_{s-1} is a (one-to-one) transformation of the weight vector v_{s-1}, specifically $w_{s-1} = \nabla \frac{1}{2} \|v_{s-1}\|_p^2$, with $p \geq 2$. If a mistake occurs at time t, $v_{s-1} \in \mathbb{R}^{Kd}$ is updated using the multitask Perceptron rule, $v_s = v_{s-1} + y_t A_\otimes^{-1} \phi_t$. We are now ready to state the mistake bound for the the multitask p-norm Perceptron algorithm. In this respect we focus on a specific choices of p and A.

Theorem 6 *The number of mistakes m made by the p-norm multitask Perceptron, run with the pairwise distance matrix (4) and $p = 2\ln\max\{K,d\}$, on any finite multitask sequence of examples $(\phi_1, y_1), (\phi_2, y_2), \ldots \in \mathbb{R}^{Kd} \times \{-1,1\}$ satisfies, for all $u \in \mathbb{R}^{Kd}$,*

$$m \leq \sum_{t \in \mathcal{M}} \ell_t(u) + H + \sqrt{2H \sum_{t \in \mathcal{M}} \ell_t(u)}$$

where

$$H = \frac{8e^2 \ln\max\{K,d\}}{(K+1)^2} X_\infty^2 \left(\sum_{i=1}^K \left\| u_i + \sum_{j \neq i} (u_i - u_j) \right\|_1 \right)^2$$

and $X_\infty = \max_{t \in \mathcal{M}} \|x_t\|_\infty$.

Proof Let v_m be the primal weight vector after any number m of mistakes. By Taylor-expanding $\frac{1}{2}\|v_s\|_p^2$ around v_{s-1} for each $s = 1, \ldots, m$, and using the fact $y_t\, w_{s-1}^\top A_\otimes^{-1} \phi_t \leq 0$ whenever a mistake occurs at step t, we get

$$\frac{1}{2}\|v_m\|_p^2 \leq \sum_{s=1}^m D\left(v_s \| v_{s-1}\right) \tag{7}$$

where $D(v_s\|v_{s-1}) = \frac{1}{2}\left(\|v_s\|_p^2 - \|v_{s-1}\|_p^2\right) - y_t\, w_{s-1}^\top A_\otimes^{-1}\phi_t$ is the so-called Bregman divergence, that is, the error term in the first-order Taylor expansion of $\frac{1}{2}\|\cdot\|_p^2$ around vector v_{s-1}, at vector v_s.

Fix any $u \in \mathbb{R}^{Kd}$. Using the convex inequality for norms $u^\top v \le \|u\|_q \|v\|_p$ where $q = p/(p-1)$ is the dual coefficient of p (so that $\|\cdot\|_q$ is the dual norm of $\|\cdot\|_p$), and the fact that

$$u^\top A_\otimes v_s = u^\top A_\otimes v_{s-1} + y_t u^\top \phi_t \ge u^\top A_\otimes v_{s-1} + 1 - \ell_t(u),$$

one then obtains

$$\|v_m\|_p \ge \frac{u^\top A_\otimes v_m}{\|A_\otimes u\|_q} \ge \frac{m - \sum_{t\in\mathcal{M}} \ell_t(u)}{\|A_\otimes u\|_q}\ . \tag{8}$$

Combining (7) with (8) and solving for m gives

$$m \le \sum_{t\in\mathcal{M}} \ell_t(u) + \|A_\otimes u\|_q \sqrt{2\sum_{s=1}^{m} D(v_s\|v_{s-1})}\ . \tag{9}$$

Following the analysis contained in, for example, Cesa-Bianchi and Lugosi (2006), one can show that the Bregman term can be bounded as follows, for $t_s = t$,

$$D(v_s\|v_{s-1}) \le \frac{p-1}{2}\left\|A_\otimes^{-1}\phi_t\right\|_p^2 = \frac{p-1}{2}\|x_t\|_p^2 \left\|A_{\downarrow i_t}^{-1}\right\|_p^2$$

where $A_{\downarrow i_t}^{-1}$ is the i_t-th column of A^{-1}.

We now focus our analysis on the choice $p = 2\ln\max\{K,d\}$ which gives mistake bounds in the dual norms $\|u\|_1$ and $\|x_t\|_\infty$, and on the pairwise distance matrix (4). It is well known that for $p = 2\ln d$ the mistake bound of the single-task p-norm Perceptron is essentially equivalent to the one of the zero-threshold Winnow algorithm of Littlestone (1989). We now see that this property is preserved in the multitask extension. We have $\|x_t\|_p^2 \le e\,\|x_t\|_\infty^2$ and

$$\left\|A_{\downarrow i_t}^{-1}\right\|_p^2 \le e\left\|A_{\downarrow i_t}^{-1}\right\|_\infty^2 = e\left(A_{i_t,i_t}^{-1}\right)^2 = \frac{4e}{(K+1)^2}\ .$$

As for the dual norm $\|A_\otimes u\|_q$, we get

$$\|A_\otimes u\|_q^2 \le \|A_\otimes u\|_1^2 = \left(\sum_{i=1}^{K}\left\|u_i + \sum_{j\ne i}(u_i - u_j)\right\|_1\right)^2\ .$$

Substituting into (9) gives the desired result. ■

The rightmost factor in the expression for H in the statement of Theorem 6 reveals the way similarity among tasks is quantified in this case. To gain some intuition, assume the task vectors u_i are all sparse (few nonzero coefficients). Then H is small when the task vectors u_i have a common pattern of sparsity; that is, when the nonzero coordinates tend to be the same for each task vector. In the extreme case when all task vectors are equal (and not necessarily sparse), H becomes

$$\left(\frac{K}{K+1}\right)^2 \left(8e^2 \ln\max\{K,d\}\right)\left(\max_{t=1,\ldots,n}\|x_t\|_\infty\right)^2 \|u_1\|_1^2\ . \tag{10}$$

If $K \le d$ this bound is equivalent (apart from constant factors) to the mistake bound for the single-task zero-threshold Winnow algorithm of Littlestone (1989).

Parameters: Positive definite $K \times K$ interaction matrix A.
Initialization: $S_0 = \emptyset,\ v_0 = 0 \in \mathbb{R}^{Kd},\ s = 1$.
At each time $t = 1, 2, \ldots$ do the following:

1. Observe task number $i_t \in \{1, \ldots, K\}$ and the corresponding instance vector $x_t \in \mathbb{R}^d\ :\ ||x_t|| = 1$;
2. Build the associated multitask instance $\phi_t \in \mathbb{R}^{Kd}$ and compute $\widetilde{\phi}_t = \left(A \otimes I_d\right)^{-1/2} \phi_t$;
3. Predict label $y_t \in \{-1, +1\}$ with $\widehat{y}_t = \mathrm{SGN}\left(w_{s-1}^\top \widetilde{\phi}_t\right)$, where $w_{s-1} = \left(I + S_{s-1} S_{s-1}^\top + \widetilde{\phi}_t \widetilde{\phi}_t^\top\right)^{-1} v_{s-1}$;
4. Get label $y_t \in \{-1, 1\}$;
5. If $\widehat{y}_t \neq y_t$ then update:

$$v_s = v_{s-1} + y_t \widetilde{\phi}_t\ , \quad S_s = \left[S_{s-1}, \widetilde{\phi}_t\right]\ , \quad s \leftarrow s + 1\ .$$

Figure 2: The second-order multitask Perceptron algorithm.

Remark 7 *Note that for $p = 2$ our p-norm variant of the multitask Perceptron algorithm does not reduce to the multitask Perceptron of Figure 1. In order to obtain the latter as a special case of the former, we could use the fact that the multitask Perceptron algorithm is equivalent to the standard 2-norm Perceptron run on "multitask instances" $A_\otimes^{-1/2} \phi_t$—see Remark 2. One then obtains a proper p-norm generalization of the multitask Perceptron algorithm by running the standard p-norm Perceptron on such multitask instances. Unfortunately, this alternative route apparently prevents us from obtaining a bound as good as the one proven in Theorem 6. For example, when p is chosen as in Theorem 6 and all task vectors are equal, then multitask instances of the form $A_\otimes^{-1/2} \phi_t$ yield a bound K times worse than (10), which is obtained with instances of the form $A_\otimes^{-1} \phi_t$.*

Finally, we should mention that an alternative definition of the p-norm Perceptron for a related problem of predicting a labelled graph has been recently proposed in Herbster and Lever (2009).

4.2 The Multitask Second-order Perceptron Algorithm

We now turn to the second-order kernel Perceptron algorithm of Cesa-Bianchi et al. (2005). The algorithm, described in Figure 2, maintains in its internal state a matrix S (initialized to the empty matrix $\emptyset$) and a multitask Perceptron weight vector v (initialized to the zero vector). Just like in Figure 1, we use the subscript s to denote the current number of mistakes plus one. The algorithm computes a tentative (inverse) matrix

$$\left(I + S_{s-1} S_{s-1}^\top + \widetilde{\phi}_t \widetilde{\phi}_t^\top\right)^{-1}\ .$$

Such a matrix is combined with the current Perceptron vector v_{s-1} to predict the label y_t. If the prediction $\widehat{y}_t$ and the label y_t disagree both v_{s-1} and S_{s-1} get updated (no update takes place otherwise). In particular, the new matrix S_s is augmented by padding with the current vector $\widetilde{\phi}_t$. Since supports are shared, the computational cost of an update is not significantly larger than that for learning a single-task (see Subsection 4.2.1).

Theorem 8 *The number of mistakes m made by the multitask Second Order Perceptron algorithm in Figure 2, run with an interaction matrix A on any finite multitask sequence of examples $(\phi_1,y_1),(\phi_2,y_2),\ldots \in \mathbb{R}^{Kd}\times\{-1,1\}$ satisfies, for all $u\in\mathbb{R}^{Kd}$,*

$$m \le \sum_{t\in\mathcal{M}} \ell_t(u) + \sqrt{\left(u^\top A_\otimes u + \sum_{t\in\mathcal{M}} \left(u_{i_t}^\top x_t\right)^2\right)\sum_{j=1}^{m}\ln(1+\lambda_j)}$$

where $\mathcal{M}$ is the sequence of mistaken trial indices and $\lambda_1,\ldots,\lambda_m$ are the eigenvalues of the matrix whose (s,t) entry is $x_s^\top A_{i_s,i_t}^{-1} x_t$, with $s,t\in\mathcal{M}$.

Proof From the mistake bound for the kernel second-order Perceptron algorithm (Cesa-Bianchi et al., 2005) we have, for all h in $\mathcal{H}$,

$$m \le \sum_{t\in\mathcal{M}} \ell_t(h) + \sqrt{\left(\|h\|_{\mathcal{H}}^2 + \sum_{t\in\mathcal{M}} h(\phi_t)^2\right)\sum_{i=1}^{m}\ln(1+\lambda_i)}$$

where $\lambda_1,\ldots,\lambda_m$ are the eigenvalues of the kernel Gram matrix including only time steps in $\mathcal{M}$. Making the role of $A_\otimes$ explicit in the previous expression yields

$$\|u\|_{\mathcal{H}}^2 = u^\top A_\otimes u$$

and

$$\left\langle u,\psi(x_t,i_t)\right\rangle_{\mathcal{H}}^2 = \left(u^\top A_\otimes A_\otimes^{-1}\phi_t\right)^2 = \left(u_{i_t}^\top x_t\right)^2.$$

Finally, the kernel Gram matrix has elements $\mathcal{K}\big(\psi(x_s,i_s),\psi(x_t,i_t)\big) = \phi_s^\top A_\otimes^{-1}\phi_t = x_s^\top A_{i_s,i_t}^{-1} x_t$, where $s,t\in\mathcal{M}$. This concludes the proof. ■

Again, this bound should be compared to the one obtained when learning K independent tasks. As in the Perceptron algorithm, we have the complexity term $u^\top A_\otimes u$. In this case, however, the interaction matrix A also plays a role in the scale of the eigenvalues of the resulting multitask Gram matrix. Roughly speaking, when the tasks are close and A is the pairwise distance matrix, we essentially gain a factor $\sqrt{K}$ from the fact that $u^\top A_\otimes u$ is close to K times the complexity of the single task (according to the arguments in Section 3). On the other hand, the trace of the multitask Gram matrix $\left[\phi_s^\top A_\otimes^{-1}\phi_t\right]_{s,t\in\mathcal{M}} = \left[x_s^\top A_{i_s,i_t}^{-1} x_t\right]_{s,t\in\mathcal{M}}$ is about the same as the trace of the single task matrix, since the K times larger dimension of the multitask matrix is offset by the factor $1/K$ delivered by $A_\otimes^{-1}$ in $\left[\phi_s^\top A_\otimes^{-1}\phi_t\right]_{s,t\in\mathcal{M}}$ when compared to the single task Gram matrix $\left[x_s^\top x_t\right]_{s,t\in\mathcal{M}}$. So, in a sense, the spectral quantity $\sum_{j=1}^m \ln(1+\lambda_j)$ is similar to the corresponding quantity for the single task case. Putting together, unlike the first-order Perceptron, the gain factor achieved by a multitask second-order perceptron over the K independent tasks bound is about $\sqrt{K}$.

4.2.1 IMPLEMENTING THE MULTITASK SECOND-ORDER PERCEPTRON IN DUAL FORM

It is easy to see that the second-order multitask Perceptron can be run in dual form by maintaining K classifiers that share the same set of support vectors. This allows an efficient implementation that does not impose any significant overhead with respect to the corresponding single-task version.

Specifically, given some interaction matrix A the margin at time t is computed as (see Cesa-Bianchi et al., 2005, Theorem 3.3)

$$\begin{aligned} w_{s-1}^\top \widetilde{\phi}_t &= v_{s-1}^\top \left(I + S_{s-1} S_{s-1}^\top + \widetilde{\phi}_t \widetilde{\phi}_t^\top \right)^{-1} \widetilde{\phi}_t \\ &= y_s^\top \left(I + S_s^\top S_s \right)^{-1} S_s^\top \widetilde{\phi}_t \end{aligned} \tag{11}$$

where y_s is the s-dimensional vector whose first $s-1$ components are the labels y_i where the algorithm has made a mistake up to time $t-1$, and the last component is 0.

Note that replacing $I + S_s^\top S_s$ with $I + S_{s-1}^\top S_{s-1}$ in (11) does not change the sign of the prediction. The margin at time t can then be computed by calculating the scalar product between $S_s^\top \widetilde{\phi}_t$ and $y_s^\top \left(I + S_{s-1}^\top S_{s-1} \right)^{-1}$. Now, each entry of the vector $S_s^\top \widetilde{\phi}_t$ is of the form $A_{j,i_t}^{-1} x_j^\top x_t$, and thus computing $S_s^\top \widetilde{\phi}_t$ requires $O(s)$ inner products so that, overall, the prediction step requires $O(s)$ scalar multiplications and $O(s)$ inner products (independent of the number of tasks K).

On the other hand, the update step involves the computation of the vector $y_s^\top \left(I + S_s^\top S_s \right)^{-1}$. For the matrix update we can write

$$I + S_s^\top S_s = \begin{bmatrix} I + S_{s-1}^\top S_{s-1} & S_{s-1}^\top \widetilde{\phi}_t \\ \widetilde{\phi}_t^\top S_{s-1} & 1 + \widetilde{\phi}_t^\top \widetilde{\phi}_t \end{bmatrix}.$$

Using standard facts about the inverse of partitioned matrices (see, e.g., Horn and Johnson, 1985, Ch. 0), one can see that the inverse of matrix $I + S_s^\top S_s$ can be computed from the inverse of $I + S_{s-1}^\top S_{s-1}$ with $O(s)$ extra inner products (again, independent of K) and $O(s^2)$ additional scalar multiplications.

5. The Simultaneous Multitask Protocol: Preliminaries

The multitask kernel-based regularization approach adopted in the previous sections is not the only way to design algorithms for the multiple tasks scenario. As a different strategy, we now aim at measuring tasks relatedness as a function of the dimension of the space spanned by the task reference vectors. In matrix terms, this may be rephrased by saying that we hope to speed up the learning process, or reduce the number of mistakes, whenever the matrix of reference vectors is spectrally sparse. For reasons that will be clear in a moment, and in order to make the above a valid and reasonable goal for a multitask algorithm, we now investigate the problem of *simultaneously* producing multiple predictions after observing the corresponding (multiple) instance vectors. We therefore extend the traditional online classification protocol to a fully simultaneous multitask environment where at each time step t the learner observes exactly K instance vectors $x_{i,t} \in \mathbb{R}^d$, $i = 1, \ldots, K$. The learner then outputs K predictions $\widehat{y}_{i,t} \in \{-1, +1\}$ and obtains the associated labels $y_{i,t} \in \{-1, +1\}$, $i = 1, \ldots, K$. We still assume that the K example sequences are adversarially generated and that $\|x_{i,t}\| = 1$. We call this setting the *simultaneous multitask setting*.

Once again the underlying rationale here is that one should be able to improve the performance over the baseline by leveraging the additional information conveyed through multiple instance vectors made available all at once, provided that the tasks to learn share common characteristics. Theoretically, this amounts to postulating the existence of K vectors $u_1,\ldots,u_K$ such that *each* u_i is a good linear classifier for the corresponding sequence $(x_{i,1},y_{i,1}),(x_{i,2},y_{i,2}),\ldots$ of examples. As before, the natural baseline is the algorithm that simultaneously run K independent Perceptron algorithms, each one observing its own sequence of examples and acting in a way that is oblivious to the instances given as input to and the labels observed by its peers. Of course, we now assume that this baseline outputs K predictions per trial. The expected performance of this algorithm is simply K times the one of a single Perceptron algorithm. An additional difference that sets the protocol and the algorithms discussed here apart from the ones considered in the previous sections is that the cumulative count of mistakes is not only over time but also over tasks; that is, at each time step more the one mistake might occur since $K > 1$ predictions are output.

In the next section we show that simultaneous multitask learning algorithms can be designed in such a way that the cumulative number of mistakes is, in certain relevant cases, provably better than the K independent Perceptron algorithm. The cases where our algorithms outperform the latter are exactly those when the overall information provided by the different example sequences are related, that is, when the reference vectors associated with different tasks are "similar", while the instance vectors received during each time step are unrelated (and thus overall more informative). These notions of similarity and unrelatedness among reference and instance vectors will be formally defined later on.

5.1 Notation and Definitions

We denote by $\langle M,N\rangle = \mathrm{TR}\big(M^\top N\big)$, for $M,N \in \mathbb{R}^{d\times K}$ the Frobenious matrix inner product. Let $r = \min\{d,K\}$ and define the function $\sigma : \mathbb{R}^{d\times K} \to \mathbb{R}^r$ such that $\sigma(M) = \big(\sigma_1(M),\ldots,\sigma_r(M)\big)$, where $\sigma_1(M) \geq \cdots \geq \sigma_r(M) \geq 0$ are the singular values of a matrix $M \in \mathbb{R}^{d\times K}$. In the following, we simply write σ_i instead of $\sigma_i(M)$ whenever the matrix argument is clear from the context.

Following Horn and Johnson (1991) we say that a function $f : \mathbb{R}^r \to \mathbb{R}$ is a *symmetric gauge function* if it is an absolute norm on $\mathbb{R}^r$ and is invariant under permutation of the components of its argument. We consider matrix norms of the form $\|\cdot\| : \mathbb{R}^{d\times K} \to \mathbb{R}$ such that $\|\cdot\| = f\circ\sigma$ where f is symmetric gauge function. A matrix norm is said unitarily (orthogonally, indeed, since we only consider matrices with real entries) invariant if $\|UAV\| = \|A\|$ for any matrix A and for any unitary (orthogonal) matrices U and V for which UAV is defined. It is well known that a matrix norm is unitarily invariant if and only if it is a symmetric gauge function of the singular values of its argument.

One important class of unitarily invariant norms is given by the Schatten p-norms, $\|U\|_{s_p} \stackrel{\text{def}}{=} \|\sigma(U)\|_p$, where the right-hand expression involves a vector norm. Note that the Schatten 2-norm is the Frobenius norm, while for $p = 1$ the Schatten p-norm becomes the trace norm $\|U\|_{s_1} = \|\sigma(U)\|_1$, which is a good proxy for the rank of U, $\|\sigma(U)\|_0$.

Let M be a matrix of size $d\times K$. We denote by $\mathrm{VEC}(M)$ the vector of size Kd obtained by stacking the columns of M one underneath the other. Important relationships can be established among the Kronecker product, the VEC operator and the trace operator. In particular, we have

$$\mathrm{VEC}(MNO) \quad = \quad (O^\top \otimes M)\mathrm{VEC}(N) \tag{12}$$

for any M,N,O for which MNO is defined, and

$$\textsc{vec}(M)^\top \textsc{vec}(N) \quad = \quad \textsc{tr}(M^\top N) \tag{13}$$

for any M,N of the same order. We denote by T_{K^2} the $K^2 \times K^2$ commutation matrix such that $T_{K^2}\textsc{vec}(M) = \textsc{vec}(M^\top)$. We recall that T_{K^2} also satisfies $T_{K^2}(M \otimes N) = (M \otimes N)T_{K^2}$ for any $M,N \in \mathbb{R}^{d\times K}$.

We rely on the notation introduced by Magnus and Neudecker (1999) to derive calculus rules for functions defined over matrices. Given a differentiable function $F : \mathbb{R}^{m\times p} \to \mathbb{R}^{n\times q}$, we define the Jacobian of F at M as the matrix $\nabla F(M) \in \mathbb{R}^{nq\times mp}$

$$\nabla F(X) = \frac{\partial \textsc{vec}\big(F(M)\big)}{\partial \textsc{vec}(M)^\top} \ . \tag{14}$$

It is easy to see that (14) generalizes the well-known definition of Jacobian for vector valued functions of vector variables. The following rules, which hold for any matrix $M \in R^{K\times K}$, can be seen as extensions of standard vector derivation formulas

$$\begin{aligned} \nabla \textsc{tr}(M^p) \quad &= \quad p\,\textsc{vec}(M^{p-1})^\top \qquad\qquad p = 1,2,\ldots & (15)\\ \nabla M^\top M \quad &= \quad (I_{K^2} + T_{K^2})(I_K \otimes M^\top) \ . & (16) \end{aligned}$$

6. The Potential-based Simultaneous Multitask Classifier

As discussed in Section 5, a reasonable way to quantify the similarity among reference vectors, as well as the unrelatedness among example vectors, is to arrange such vectors into matrices, and then deal with special properties of these matrices. In order to focus on this concept, we lay out vectors as columns of $d \times K$ matrices and extend the dual norm analysis of Subsection 4.1 to matrices. The idea is to design a classifier which is able to perform much better than the K independent Perceptron baseline discussed in Section 5 whenever the set of reference vectors $u_i \in \mathbb{R}^d$ (arranged into a $d \times K$ reference matrix U), have some matrix-specific, for example, *spectral*, properties.

Our potential-based matrix algorithm for classification shown in Figure 3 generalizes the classical potential-based algorithms operating on vectors to simultaneous multitask problems with matrix examples. This family of potential-based algorithms has been introduced in the learning literature by Kivinen and Warmuth (2001) and Grove et al. (2001), and by Nemirovski and Yudin (1978) and Beck and Teboulle (2003) in the context of nonsmooth optimization. The algorithm maintains a $d \times K$ matrix W. Initially, W_0 is the zero matrix. If $s-1$ updates have been made in the first $t-1$ time steps, then the K predictions at time t are $\textsc{sgn}\big(w_{i,s-1}^\top x_{i,t}\big)$, $i = 1,\ldots,K$, where the vector $w_{i,s-1} \in \mathbb{R}^d$ is the i-th column of the the $d \times K$ matrix W_s and $x_{i,t} \in \mathbb{R}^d$ is the instance vector associated with the i-th task at time t. An update is performed if at least one mistake occurs. When the s-th update occurs at time t then W_s is computed as

$$W_s = \nabla \frac{1}{2}\,\|V_s\|^2$$

where, in turn, the columns of the $d \times K$ matrix V_s are updated using the Perceptron rule,[2] $v_{i,s} = v_{i,s-1} + y_{i,t}\,x_{i,t}\,\mathbb{1}_{\{\widehat{y}_{i,t}\neq y_{i,t}\}}$ which, as in the basic Perceptron algorithm, is mistake driven. In other

2. Here and throughout this section, $\mathbb{1}_{\{\widehat{y}_{i,t}\neq y_{i,t}\}}$ denotes the indicator function which is 1 if the label associated with the i-th task is wrongly predicted at time t, and 0 otherwise.

Parameters: Unitarily invariant norm $\|\cdot\|$.
Initialization: $V_0 = [v_{0,0}, \ldots, v_{K,0}] = 0$, $W_0 = [w_{0,0}, \ldots, w_{K,0}] = \nabla \frac{1}{2} \|V_0\|^2$, $s = 1$.
At each time $t = 1, 2, \ldots$ do the following:

1. Get multitask instance vectors $x_{1,t}, \ldots, x_{K,t} \in \mathbb{R}^d$;
2. Predict labels $y_{i,t} \in \{-1, +1\}$ with $\widehat{y}_{i,t} = \text{SGN}(w_{i,s-1}^\top x_{i,t}), \qquad i = 1, \ldots, K$;
3. Get labels $y_{i,t} \in \{-1, 1\}, \qquad i = 1, \ldots, K$;
4. If $\widehat{y}_{i,t} \neq y_{i,t}$ for some i then update:

$$
\begin{aligned}
v_{i,s} &= v_{i,s-1} + y_{i,t} x_{i,t} \mathbb{1}_{\{\widehat{y}_{i,t} \neq y_{i,t}\}} \qquad i = 1, \ldots, K \\
W_s &= \nabla \frac{1}{2} \|V_s\|^2 \\
s &\leftarrow s + 1 \, .
\end{aligned}
$$

Figure 3: The potential-based matrix algorithm for the simultaneous multitask setting.

words, the i-th column in V_{s-1} is updated if and only if the label associated with the i-th task was wrongly predicted. We say that W_s is the dual matrix weight associated with the primal matrix weight V_s. So far we left the mapping from V_s to W_s partially unspecified since we did not say anything other than it is the gradient of some unitarily invariant (squared) norm.

6.1 Analysis of Potential-based Matrix Classifiers

We now develop a general analysis of potential-based matrix algorithms for (simultaneous) multitask classification. Then, in Section 6.2 we specialize it to Schatten p-norms. The analysis proceeds along the lines of the standard proof for potential-based algorithms. Before turning to the details, we introduce a few shorthands. Let $\mathbb{1}_{i,t} = \mathbb{1}_{\{\widehat{y}_{i,t} \neq y_{i,t}\}}$, and $\mathbb{1}_t$ be the K-dimensional vector whose i-th component is $\mathbb{1}_{i,t}$. Also, e_i denotes the i-th vector of the standard basis for $\mathbb{R}^K$. Finally, we define the matrix $M_t = \sum_{i=1}^K \mathbb{1}_{i,t} y_{i,t} x_{i,t} e_i^\top$ whose i-th column is the example vector $y_{i,t} x_{i,t}$ if the label $y_{i,t}$ was wrongly predicted at time t, or the null vector otherwise. It is easy to see that, by using this notation, the update of the primal weight matrix V can be written as $V_s = V_{s-1} + M_t$.

Let $\mathcal{M}$ be the set of trial indices where at least one mistake occurred over the K tasks, and set $m = |\mathcal{M}|$. We start by Taylor-expanding $\frac{1}{2} \|V_s\|^2$ around V_{s-1} for each $s = 1, \ldots, m$ and obtain

$$
\frac{1}{2} \|V_m\|^2 \leq \sum_{s=1}^m D(V_s \| V_{s-1}) \tag{17}
$$

where $D(V_s\|V_{s-1}) = \frac{1}{2}\big(\|V_s\|^2 - \|V_{s-1}\|^2\big) - \langle W_{s-1}, M_t\rangle$ is the matrix Bregman divergence associated with $\nabla\frac{1}{2}\|\cdot\|^2$. The upper bound in (17) follows from

$$\langle W_{s-1}, M_t\rangle = \mathrm{TR}(W_{s-1}^\top M_t) = \sum_{i=1}^{K} \mathbb{1}_{i,t}\, y_{i,t}\, w_{s-1}^\top x_{i,t} \le 0$$

the last inequality holding because $\mathbb{1}_{i,t}$ is 1 if only if a mistake in the prediction for the i-th task occurs at time t.

Fix any $d \times K$ comparison matrix U and denote by $\|\cdot\|_*$ the matrix dual norm. By the convex inequality for matrix norms we have $\|V_m\|\,\|U\|_* \ge \langle V_m, U\rangle$, where $\|U\|_* = f^*\big(\sigma(U)\big)$ and f^* is the Legendre dual of function f—see Lewis (1995, Theorem 2.4). From $\langle U, V_s\rangle = \langle U, V_{s-1}\rangle + \langle U, M_t\rangle$. we obtain

$$\|V_m\| \ge \frac{\langle U, V_m\rangle}{\|U\|_*} \ge \frac{\sum_{t\in\mathcal{M}} \|\mathbb{1}_t\|_1 - \sum_{t\in\mathcal{M}} \ell_t^{\mathbb{1}}(U)}{\|U\|_*}$$

where

$$\ell_t^{\mathbb{1}}(U) \stackrel{\text{def}}{=} \sum_{i=1}^{K} \mathbb{1}_{i,t}\big[1 - y_{i,t}\, u_i^\top x_{i,t}\big]_+ = \sum_{i=1}^{K} \mathbb{1}_{i,t}\, \ell_t(u_i)$$

and $\|\mathbb{1}_t\|_1$ counts the number of mistaken tasks at time t. Solving for $\mu = \sum_{t\in\mathcal{M}} \|\mathbb{1}_t\|_1$ gives

$$\mu \le \sum_{t\in\mathcal{M}} \ell_t^{\mathbb{1}}(U) + \|U\|_* \sqrt{2\sum_{s=1}^{m} D(V_s\|V_{s-1})}\,. \tag{18}$$

Equation (18) is our general starting point for analyzing potential-based matrix multitask algorithms. In particular, the analysis reduces to bounding from above the Bregman term for the specific matrix norm under consideration.

6.2 Specialization to Schatten p-norms

In this section we focus on Schatten p-norms, therefore measuring similarity (or dissimilarity) in terms of spectral properties. This amounts to saying that a set of reference vectors are similar if they span a low dimensional subspace. Along the same lines, we say that a set of K example vectors are dissimilar if their spanned subspace has dimension close to K. The rank of a matrix whose columns are either the reference vectors or the example vectors exactly provides this information. Here we use certain functions of the singular values of a matrix as proxies for its rank. It is easy to see that this leads to a kind of regularization that is precisely enforced through the use of unitarily-invariant norms. In fact, unitarily-invariant matrix norms control the distribution of the singular values of U, thus acting as spectral co-regularizers for the reference vectors—see, for example, Argyriou et al. (2008) for recent developments on this subject. In different terms, by relying only on the singular values (or on the magnitudes of principal components), unitarily invariant norms are a natural way to determine and measure the most informative directions for a given set of vectors.

For these reasons we now specialize the potential-based matrix classifier of Figure 3 to the Schatten $2p$-norm and set $\|V\| = \|V\|_{s_{2p}} = \|\sigma(V)\|_{2p}$, where V is a generic $d \times K$ matrix, and p is a positive *integer* (thus $2p$ is an even number ≥ 2). Note that, in general,

$$\|V\|_{s_{2p}}^2 = \mathrm{TR}\big((V^\top V)^p\big)^{1/p}.$$

We are now ready to state our main result of this section. The proof, along with surrounding comments, can be found in the appendix.

Theorem 9 *The overall number of mistakes μ made by the $2p$-norm matrix multitask Perceptron (with p positive integer) run on finite sequences of examples $(x_{i,1},y_{1,t}),(x_{i,2},,y_{i,2}),\cdots \in \mathbb{R}^{d\times K}\times\{-1,+1\}$, for $i=1,\ldots,K$, satisfies, for all $U\in\mathbb{R}^{d\times K}$,*

$$\mu \le \sum_{t\in\mathcal{M}} \ell_t^{\mathbb{1}}(U) + (2p-1)\left(\mathbf{M}_{s_{2p}}\|U\|_{s_{2q}}\right)^2 + \mathbf{M}_{s_{2p}}\|U\|_{s_{2q}}\sqrt{(2p-1)\sum_{t\in\mathcal{M}}\ell_t^{\mathbb{1}}(U)}$$

where

$$\mathbf{M}_{s_{2p}} = \max_{t\in\mathcal{M}} \frac{\|M_t\|_{s_{2p}}}{\sqrt{\|\mathbb{1}_t\|_1}}$$

and $\|U\|_{s_{2q}}$ is the Schatten $2q$-norm of U, with $2q=\frac{2p}{2p-1}$.

Remark 10 *In order to verify that in certain cases the bound of Theorem 9 provides a significant improvement over the K independent Perceptron baseline, we focus on the linearly separable case; that is, when the sequences $(x_{i,1},y_{i,1}),(x_{i,2},y_{i,2}),\ldots$ are such that there exists a matrix $U\in\mathbb{R}^{d\times K}$ whose columns u_i achieve a margin of at least 1 on each example: $y_{i,t}u_i^\top x_{i,t}\ge 1$ for all $t=1,2,\ldots$ and for all $i=1,\ldots,K$. In this case the bound of Theorem 9 reduces to*

$$\mu \le (2p-1)\left(\mathbf{M}_{s_{2p}}\|U\|_{s_{2q}}\right)^2 . \tag{19}$$

It is easy to see that for $p=q=1$ the $2p$-norm matrix multitask Perceptron decomposes into K independent Perceptrons, which is our baseline. On the other hand, similarly to the vector case, a trace norm/spectral norm bound can be established when the parameter p is properly chosen. Note first that for basic properties of norms $\|U\|_{s_{2q}}\le\|U\|_{s_1}$ and $\|M\|_{s_{2p}}\le r^{1/(2p)}\|M\|_{s_\infty}$, with $r=\min\{d,K\}$. It now suffices to set $p=\lceil\ln r\rceil$ in order to rewrite (19) as

$$\mu \le (2\ln r+1)e\left(\mathbf{M}_{s_\infty}\|U\|_{s_1}\right)^2$$

where U is now penalized with the trace norm and M_t is measured with the spectral norm $\|\cdot\|_{s_\infty}$. If the columns of U span a subspace of dimension $\ll K$, and the matrices of mistaken examples M_t tend to have K nonzero singular values of roughly the same magnitude, then $\|U\|_{s_1}\approx\|U\|_{s_2}$ while $\mathbf{M}_{s_\infty}^2\approx\mathbf{M}_{s_2}^2/K$. Hence this choice of p may lead to a factor K improvement over the bound achieved by the independent Perceptron baseline. See also Remark 11 below. Note that in Theorem 9 (and in the above argument) what matters the most is the quantification in terms of the spectral properties of U via $\|U\|_{s_{2q}}$. The fact that p has to be a positive integer is not a big limitation here, since $2q=\frac{2p}{2p-1}$ can be made arbitrarily close to 1 anyway.

Remark 11 *The bound of Theorem 9 is not in closed form, since the terms $\|\mathbb{1}_t\|_1$ occur in both the left-hand side (via μ) and in the right-hand side (via $\mathbf{M}_{s_{2p}}$). These terms play an essential role to assess the potential advantage of the $2p$-norm matrix multitask Perceptron. In order to illustrate the influence of $\|\mathbb{1}_t\|_1$ on the bound, let us consider the two extreme cases $\|\mathbb{1}_t\|_1=1$ for all $t\in\mathcal{M}$, and $\|\mathbb{1}_t\|_1=K$ for all $t\in\mathcal{M}$. In the former case, the right-hand side of (19) becomes $(2p-1)\|U\|_{s_{2q}}^2$*

(since $\mathbf{M}_{s_{2p}} = 1$*), which is* always *worse than the baseline case* $p = q = 1$*. In the latter case, the bound becomes*

$$(2p-1)\,\frac{\left(\max_{t\in\mathcal{M}} \|M_t\|_{s_{2p}}^2\right)\|U\|_{s_{2q}}^2}{K}$$

which, according to the discussion in the previous remark, opens up the possibility for the factor K *improvement. This is precisely the reason why the spectral regularization is not advantageous in the adversarially chosen task framework described in Section 2. Since the* K *instance-label pairs are the information obtained for each task at any given time step, it appears reasonable that a multitask approach has a chance to improve when such information is abundant, as is the case when* $\|\mathbb{1}_t\|_1 = K$*, and, at the same time, the tasks to be learned are sufficiently similar. For example, in the extreme case when the* K *tasks do actually coincide, it is as if we had to learn a single task, but received* K *independent pieces of information per time step, rather than just one.*

Remark 12 *The* $2p$*-norm matrix multitask Perceptron algorithm updates the primal vector associated with a given task whenever an example for that task is wrongly predicted. Specifically, at time* t *the mistake-driven update rule for the* i*-th task vector is defined as* $v_{i,s} = v_{i,s-1} + y_{i,t}\,x_{i,t}\,\mathbb{1}_{\{\widehat{y}_{i,t}\neq y_{i,t}\}}$*. It is now straightforward to generalize the above update mechanism to the shared loss framework of Dekel et al. (2007), where the sharing is performed via a norm applied to the vector of task losses. Let* $\ell_t(W)$ *be the vector whose entries are the hinge losses incurred by the* K *columns of* W *and pick any vector norm* $\|\cdot\|$*. The goal is to bound the cumulative shared loss* $\sum_t \|\ell_t(W)\|$*. To do so, introduce an additional parameter* $C > 0$ *and write the update as* $v_{i,s} = v_{i,s-1} + y_{i,t}\,x_{i,t}\,\tau_{i,t}$*, where the vector* $\boldsymbol{\tau}_t = [\tau_{1,t},\ldots,\tau_{K,t}]^\top$ *is such that* $\boldsymbol{\tau}_t = \arg\max_{\boldsymbol{\tau}:\|\boldsymbol{\tau}\|_*\le C} \boldsymbol{\tau}^\top \ell_t(W_{s-1})$ *and* $\|\cdot\|_*$ *is the dual of* $\|\cdot\|$*. Since each entry of* $\boldsymbol{\tau}_t$ *is dependent on all the* K *hinge losses suffered by the* $2p$*-norm matrix multitask Perceptron algorithm at time* t*, the update now acts so as to favor certain tasks over the others according to the shared loss induced by* $\|\cdot\|$*. By adapting our proof to the analysis given in Dekel et al. (2007), it is not hard to show that*

$$\sum_{t=1}^{T} \|\ell_t(W_{t-1})\| \le \sum_{t=1}^{T} \|\ell_t(U)\| + \frac{\|U\|_{S_{2q}}^2}{2C} + \frac{T\mathbf{M}_{s_{2p}}^2}{2}$$

where, in analogy with our previous definitions,

$$\mathbf{M}_{s_{2p}} = \max_{t=1,\ldots,T} \frac{\|M_t\|_{s_{2p}}}{\sqrt{\|\boldsymbol{\tau}_t\|_*}} \qquad \textit{and} \qquad M_t = \sum_{i=1}^{K} \tau_{i,t}\,y_{i,t}\,x_{i,t}\,e_i^\top\ .$$

Observe that $\mathbf{M}_{s_{2p}}$ *depends on* C *through* $\boldsymbol{\tau}_t$*, thus preventing an easy optimization over* C*. Moreover, since the upper bound depends on dual Schatten* $2p$*-norms, the discussions in Remark 10 and Remark 11 still apply, with the caveat that in order to have* $\mathbf{M}_{s_\infty}^2 \approx \mathbf{M}_{s_2}^2/K$ *it must be* $\tau_{1,t} \approx \cdots \approx \tau_{K,t}$*.*

6.2.1 IMPLEMENTATION IN DUAL FORM

As for the algorithms in previous sections, the $2p$-norm matrix multitask Perceptron algorithm can also be implemented in dual variables. Setting $X_t = [x_{1,t},\ldots,x_{K,t}]$, it suffices to observe that the predictions $\widehat{y}_{i,t} = \mathrm{SGN}\big(w_{i,s-1}^\top x_{i,t}\big)$ of the $2p$-norm matrix Perceptron reduces to computing the sign of the diagonal entries of the matrix $(V_{s-1}^\top V_{s-1})^{p-1} V_{s-1}^\top X_t$—recall the expression for ∇G calculated in the proof of Theorem 9. Since matrix V_s is updated additively, it is clear that both $V_{s-1}^\top V_{s-1}$

and $V_{s-1}^{\top} X_t$ do depend on instance vectors $x_{i,t}$ only through inner products. This allows us to turn our $2p$-norm matrix multitask Perceptron into a kernel-based algorithm, and repeat the analysis given here using a standard RKHS formalism—see Warmuth (2009) for a more general treatment of kernelizable matrix learning algorithms.

7. Experiments

We evaluated our multitask algorithms on several real-world data sets. Since we are more interested in the multitask kernel for sequential learning problems rather than the nature of the underlying classifiers, we restricted the experiments for the adversarially chosen task model to the multitask Perceptron algorithm of Section 3. In particular, we compare the performance of the multitask Perceptron algorithm with parameter $b > 0$ to that of the same algorithm run with $b = 0$, which is our multitask baseline. Recall from Subsection 3.2 that $b = 0$ amounts to running an independent standard Perceptron on each task. We also evaluated the $2p$-norm matrix multitask Perceptron algorithm under a similar experimental setting, reporting the achieved performance for different values of the parameter p. Finally, we provide experimental evidence of the effectiveness of the $2p$-norm matrix multitask Perceptron algorithm when applied to a learning problem which requires the simultaneous processing of a significant number of tasks.

In our initial experiments, we empirically evaluated the multitask kernel using a collection of data sets derived from the first 160,000 newswire stories in the Reuters Corpus Volume 1 (RCV1, for details see NIST, 2004). Since RCV1 is a hierarchical multiclass and multilabel data set, we could not use it right away. In fact, in order to evaluate the performance of our multitask algorithms in the presence of increasing levels of correlation among target tasks, we derived from RCV1 a collection of data sets where each example is associated with one task among a set of predefined tasks. We generated eight multitask data sets (D1 through D8) in such a way that tasks in different data sets have different levels of correlation, from almost uncorrelated (D1) to completely overlapped (D8). The number of tasks in each of the eight data sets was set to four.

Roughly speaking, we hand-crafted tasks by clustering categories from the original data set. We started from non intersecting sets of categories, which represent nonrelated tasks, and from there we progressively enlarged the intersection areas, thus obtaining tasks which get closer and closer. The whole process involved several steps. We first defined tasks as sets of RCV1 categories (RCV1 is a multilabel data set where labels are sets of hierarchically organized categories). In order to obtain the four tasks in D1, we first chose four subsets of categories from the initial set of all categories in the RCV1 taxonomy in such a way that each subset is both made up of hierarchically related categories and contains at least 15% of positive examples. More precisely, each of the four tasks in D1 is made up of second-level and third-level categories from one of the four main RCV1 sub-trees (CORPORATE/INDUSTRIAL, ECONOMICS, GOVERNMENT/SOCIAL, MARKETS). Since categories in different tasks belong to *different* sub-trees in the RCV1 taxonomy, and each task is composed by categories from the *same* sub-tree, the resulting four tasks in D1 describe very different but consistent topics. Tasks in D2-D8 are generated as follows. First, task one is kept the same in all the eight data sets. As for the other three tasks, we progressively added categories from the first task and dropped some from their own set of categories. We repeated this process seven times. During the first three times (corresponding to data sets D2, D3, and D4) we augmented task two to four with topics from task one; during the last four times (corresponding to data sets D5-D8) we progressively dropped their own initial categories. The whole process is illustrated in Figure 4. As a

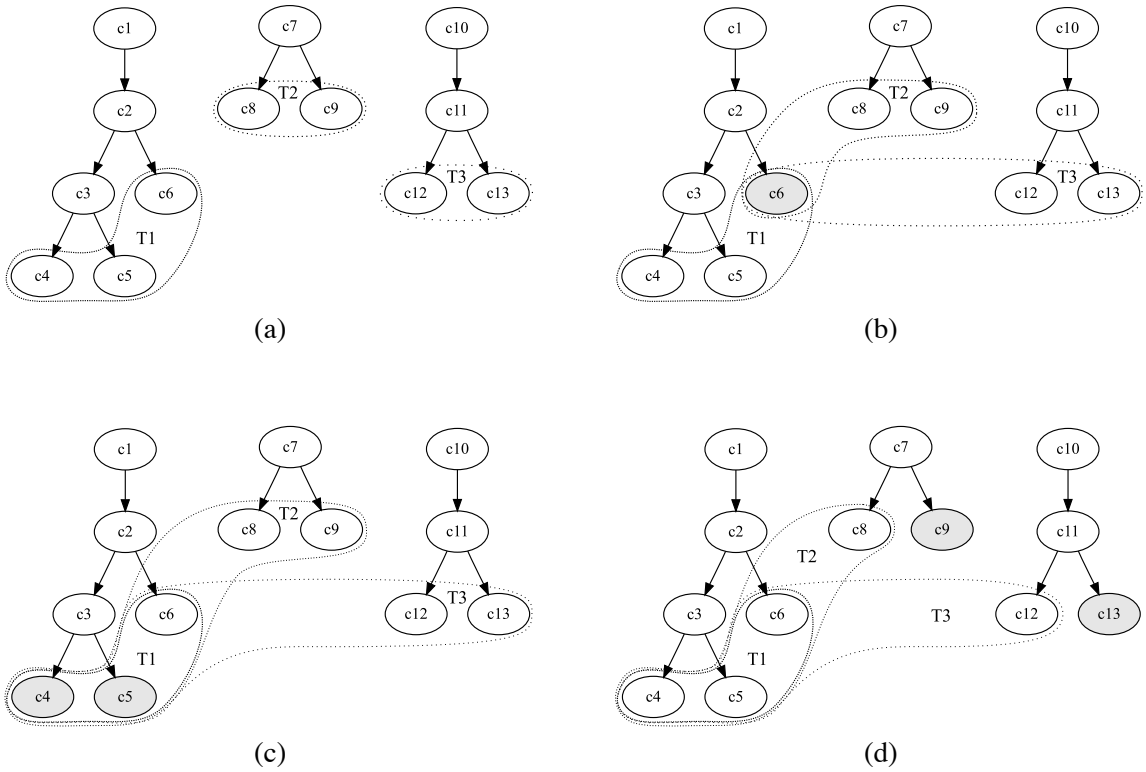

Figure 4: A sample of the task generation process given a taxonomy of 13 categories with three main sub-hierarchies. Tasks are marked as T1, T2 and T3. (a) Uncorrelated tasks are initially defined as sets of categories from different sub-hierarchies. (b and c) Partially overlapped tasks are obtained by first augmenting T2 and T3 with the addition of categories from T1 (category c6 first, then categories c4 and c5), then (d) by shrinking both T2 and T3 with the removal of their initial nodes (these are categories c9 and c13). The shrinking step is repeated until T1, T2 and T3 do coincide.

result of the above construction, as we go from D1 to D8, tasks two, three, and four get both closer to each other and to task one. The last set of four tasks (corresponding to data set D8) is made up of four occurrences of the first task, that is, tasks are completely overlapped in D8.

Once the eight sets of four tasks have been chosen, we generated labels for the corresponding multitask examples as follows. We went through the whole RCV1 data set (whose news example are sorted in chronological order), and gathered examples four by four, where the first example is associated with the first task, the second with the second task, and so on. A multitask example, defined as a set of four (instance, binary label) pairs, was then derived by replacing, for each of the four RCV1 examples, the original RCV1 categories with -1 if the intersection between the associated task and the categories was empty (i.e., if the example did not belong to any of the RCV1 categories which are part of that task), $+1$ otherwise. Since we used 160,000 multilabel and multiclass examples, this process ended up with eight multitask data sets of 40,000 (multitask) examples each.

Subsequences	D1	D2	D3	D4	D5	D6	D7	D8

Table 1: Online training error rates made by the baseline $b = 0$ on consecutive sequences of multitask examples after a single pass on the data sets D1-D8. The task i_t is chosen either randomly (top) or adversarially (bottom).

We note that the tasks considered here are not linearly separable and, as result of the above construction, different tasks in each data set may have different degrees of nonseparability. This explains why the baseline error rates for data sets D1-D8 are different—see Tables 1 and 2.

Figure 5 shows the fraction of wrongly predicted examples during the online training of the multitask Perceptron algorithm with interaction matrix (5), when the task i_t is chosen either randomly[3] (left) or in an adversarial manner (right). The latter means that i_t is selected so as the resulting signed margin is smallest over the four tasks. This implies that in the first case each task is invoked on average 10,000 times. Nothing can be said in hindsight about the task choices for the adversarial criterion, since this choice is heavily dependent on the online behavior of the classifiers and the noise in the tasks at hand. In both cases we show to what extent the incurred cumulative training error for different values of parameter b exceeds the one achieved by the multitask baseline $b = 0$, depicted here as a straight horizontal line (a negative value means that the chosen value of b achieves an error lower than $b = 0$). Recall that $b = 0$ amounts to running four independent Perceptron algorithms, while $b = 4$ corresponds to running the multitask Perceptron algorithm with the interaction matrix (4). The actual fractions of training error mistakes achieved by the baseline $b = 0$ are reported in Table 1. In order to illustrate how the generalization capabilities of our algorithms progress over time, four pairs of plots are reported, each one showing, from top to bottom, the fraction of mistakes occurred in the example subsequences 1-10,000, 10,001-20,000, 20,001-30,000, and 30,001-40,000, respectively.

Figure 5 confirms that multitask algorithms get more and more competitive as tasks get closer (since tasks are uncorrelated in D1 and totally overlapped in D8). Unsurprisingly, this advantage is higher as we increase the value of b. In fact, Figure 5 clearly shows that the delta errors from $b = 0$ decrease faster, when going from D1 to D8, as we increase b. This amounts to saying that the more we bias our algorithm towards a possible correlation the more we benefit from an actual correlation among tasks. Moreover, it is worth observing that the (rather conservative) choice $b = 1$ obtains an

3. In this case the results are averaged over 3 runs. The observed results were within a 0.002 interval of the plotted values in all 3 runs.

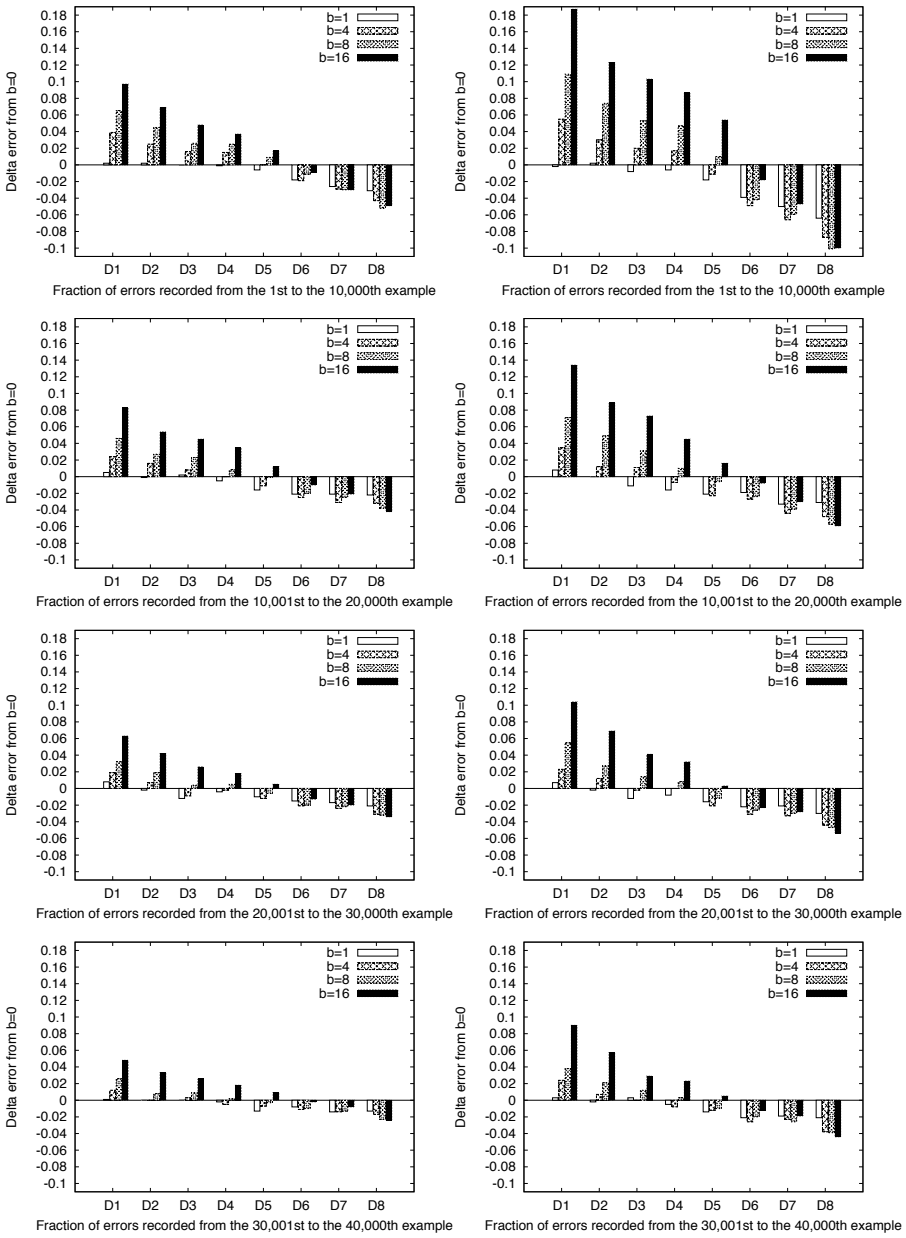

Figure 5: Online behavior of the multitask Perceptron algorithm. We report the extent to which during a single pass over the entire data set the fraction of training mistakes made by the multitask Perceptron algorithm (with $b = 1, 4, 8, 16$) exceeds the one achieved by the baseline $b = 0$, represented here as an horizontal line. On the x-axis are the multitask data sets whose tasks have different levels of correlations, from low (D1) to high (D8). Task indices are randomly chosen in the left plots and adversarially selected in the right ones. The pair of plots on top reports the online training behavior on the first $10,000$ (multitask) examples, the second from top refers to the second $10,000$ examples, and so on.

Subsequences	D1	D2	D3	D4	D5	D6	D7	D8
1-10,000	0.154	0.198	0.207	0.206	0.202	0.196	0.185	0.166
10,001-20,000	0.104	0.141	0.159	0.157	0.152	0.149	0.135	0.120

30,001-40,000	0.085	0.125	0.132	0.135	0.132	0.124	0.117	0.101

Table 2: Fractions of training errors made by the baseline $p = 1$ on consecutive sequences of multitask examples after a single pass on the data sets D1-D8.

Parameters	Training Error	Test Error	StdDev
P=1	19.0%	13.4%	1.7%
P=2	16.7%	10.9%	1.3%
P=3	16.4%	10.6%	1.6%
P=4	16.6%	9.7%	1.5%
P=5	17.1%	10.2%	1.9%

Table 3: Training errors recorded after a single pass over the spam data set, along with the corresponding test errors. The values are averaged over 40 repetitions of a 10-fold cross-validation scheme. The standard deviation for the test error is reported in parentheses. The standard deviation for the training error is negligible and is therefore omitted.

overall better performance than the multitask baseline $b = 0$, with a higher cumulative error only on the first data set.

We then evaluated the $2p$-norm matrix multitask Perceptron algorithm on the same data set. In this case, we dropped the task choice mechanism since the algorithm is designed to receive all the four instance vectors and to output four predicted labels at each time step. We limited our experiments to the first 10,000 multitask examples. This allows us to make the results achieved by the $2p$-norm matrix multitask Perceptron algorithm somehow comparable (i.t.o. total number of binary labels received) with the ones achieved by the multitask Perceptron algorithm under the random task selection model (the four plots on the left in Figure 5). In Figure 6 we report the (differential) fractions of online training mistakes made by the algorithm on the subsequences 1-2,500, 2,501-5,000, 5,001-7,500 and 7,501-10,000, of multitask examples. The actual fractions of online training error mistakes achieved by the baseline $p = 1$ are showed in Table 2. As expected, the more the tasks get closer to each other the less is the number of wrongly predicted labels output by the $2p$-norm matrix multitask Perceptron algorithm and the larger is the gap from the baseline. In particular, it can be observed that even in D1 the performance of the $2p$-norm matrix multitask Perceptron algorithm is no worse than the one achieved by the baseline. In fact, while our construction tends to guarantee that tasks get closer as we move from D1 to D8 (recall how the tasks are defined in terms of subsets of RCV1 categories), we do not really know in advance how dissimilar the tasks in D1 are, and the performance of the $2p$-norm matrix multitask Perceptron algorithm reveals that they are indeed not so dissimilar.

As a further assessment, we evaluated the empirical performance of the p-norm matrix multitask algorithm on the ECML/PKDD 2006 Discovery Challenge spam data set (for details, see

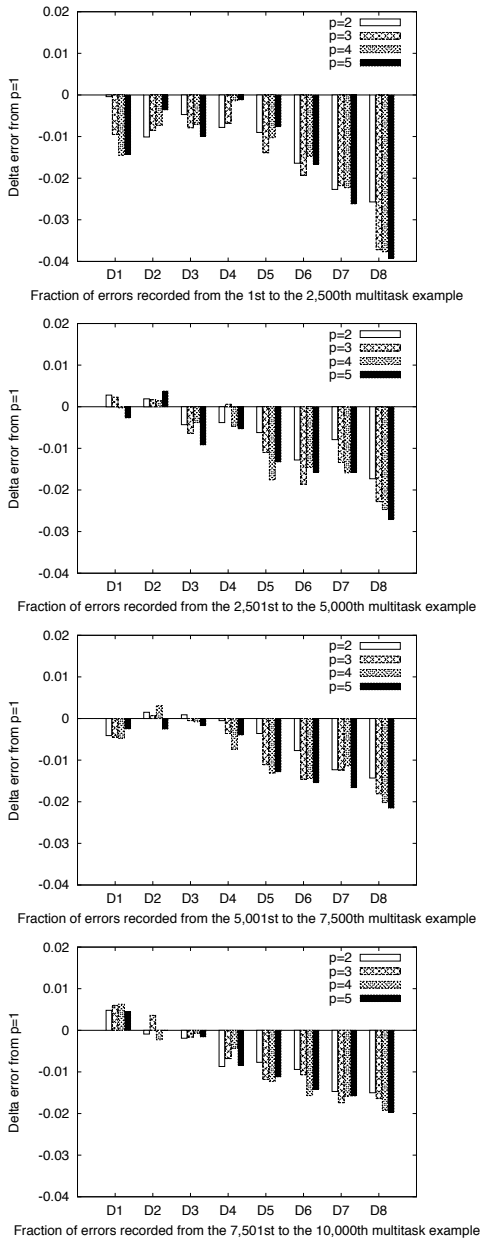

Figure 6: Online behavior of the $2p$-norm matrix multitask Perceptron algorithm. Again, we report the extent to which during a single pass over the entire data set the fraction training mistakes made by the $2p$-norm matrix multitask Perceptron algorithm (with $p = 2,3,4,5$) exceeds the one achieved by the baseline $p = 1$, represented here as an horizontal line. On the x-axis are the multitask data sets whose tasks have different levels of correlations, from low (D1) to high (D8). The top plot reports the online training behavior on the first $2,500$ (multitask) examples, the second from top refers to the second $2,500$ examples, and so on.

ECML/PKDD, 2006). The data set includes 15 sub-data sets, each one containing 400 spam/ham emails for 15 different users. Email messages are encoded by a standard bag-of-words vector representation. Naturally enough, we associated each user with a different task. The experiments were run using a 10-fold cross-validation scheme. Each run consists of a single training epoch followed by a test phase. Since these data are not ordered chronologically as those in RCV1, we repeated the 10-fold cross-validation process 40 times, preceding each repetition with independent shuffles of the 15 data sets. Table 3 shows that the $2p$-norm matrix multitask algorithm exploits underlying latent relations and manages to achieve a significant decrease in both the training and test errors. In particular, the best performance is achieved when p is set to 4, which results in a test error of 9.7%, an improvement of more than 25% relative to the baseline $p = 1$, or nearly a 4.0% decrease in absolute terms. Whereas these are average values, the advantage of the $2p$-norm matrix multitask algorithm is still significant even when the standard deviation is factored in. Moreover, in most runs, the deviation from the average tended to be the on the same side for both $p = 1$ and $p > 1$. In other words, if on a given fold the p-norm matrix multitask Perceptron algorithm with $p > 1$ made a larger number of mistakes than its average, the same held true for the baseline. We stress that the theoretical improvement of a factor K (in this case $K = 15$), is within reach only if the tasks are linearly separable and overlapped. In practice we should and could not expect these conditions to be generally met to their full extent. In particular, while we cannot state how exactly the different spam classification tasks are spectrally related (since the task are not synthetically generated), it is apparent that such relations do actually hold to a certain extent. In fact, by considering the specifics of the learning problem, it is intuitively reasonable that the target spam/ham discriminant functions, though changing from user to user, still share a significant number of common traits.

8. Conclusions and Open Problems

We have studied the problem of sequential multitask learning using two different approaches to formalize the notion of task relatedness: via the Euclidean distance between task vectors, or via a unitarily invariant norm applied to the matrix of task vectors. These two approaches naturally correspond to two different online multitask protocols: one where a single task is selected at each time step, and one where the learner operates simultaneously on all tasks at each time step. We believe that both these protocols have their own merits, each one having its array of possible practical applications. Moreover, while the Schatten-p norm regularization assumption does not make sense in the adversarially chosen task protocol, it is not difficult to adapt the multitask kernel-based algorithm of Section 3 to the fully simultaneous protocol and derive a mistake bound analysis in the lines of the one given in Section 6.

In our worst-case sequential prediction scenario, the best we can hope for i.t.o. prediction performance is a factor K improvement over the baseline running K independent classification algorithms, this is what we essentially achieved in our analysis. We have complemented our theoretical findings with experiments on real-world data sets showing that our algorithms are efficient and can effectively take advantage of latent task relatedness.

We conclude by mentioning a few directions along which our results could be extended.

1. In Section 3.2 it might be interesting to devise methods for dynamically adapting the b parameter as new data are revealed.

2. In Section 3.3 we have shown a simple adaptation to the case when the graph of tasks (i.e., interaction matrix A) is known ahead of time. Is it possible to achieve meaningful bounds when the graph is hidden, and can only be progressively inferred through the choices of i_t?

3. Our multitask regularization techniques rely on the fact that different tasks need to be embedded, either naturally or through some sensible preprocessing, in the same d-dimensional space. It would be interesting to devise a multitask algorithm that does not impose such a constraint.

4. Finally, we believe it would also be interesting to prove *lower* bounds on the number of mistakes as a function of task relatedness.

Appendix A.

The following trace inequality, which can be seen as a kind of Holder's inequality applied to non-square matrices, is our main technical tool in the proof of Theorem 9.

Lemma 13 *Let A, B be positive semidefinite matrices, of size $d \times d$ and $K \times K$ respectively, with the same nonzero eigenvalues. Let X be an arbitrary real matrix of size $d \times K$. Then, for any pair on nonnegative exponents $l, g \geq 0$, we have*

$$\mathrm{TR}(X^\top A^l X B^g) \leq \left(\mathrm{TR}(X^\top X)^p\right)^{1/p} \left(\mathrm{TR}\, A^{(l+g)q}\right)^{1/q}$$

where $1/p + 1/q = 1$, $p \geq 1$.

Proof We first consider the case $l \leq g$. By the Cauchy-Schwartz and Holder's inequalities applied to traces (Magnus and Neudecker, 1999, Chapter 11) we have

$$\begin{aligned} \mathrm{TR}(X^\top A^l X B^g) &= \mathrm{TR}\left(B^{(g-l)/2} X^\top A^l X B^{(g+l)/2}\right) \\ &\leq \mathrm{TR}\left(X^\top A^{2l} X B^{g-l}\right)^{1/2} \mathrm{TR}\left(X^\top X B^{g+l}\right)^{1/2} \\ &\leq \mathrm{TR}\left(X^\top A^{2l} X B^{g-l}\right)^{1/2} T_p\left(X^\top X\right)^{1/2} T_q\left(B^{g+l}\right)^{1/2} \end{aligned} \tag{20}$$

where we used the shorthand $T_r(Z) = (\mathrm{TR} Z^r)^{1/r}$. In the case when $l > g$ we can simply swap the matrices $X^\top A^l$ and $X B^g$ and reduce to the previous case.

We now recursively apply the above argument to the left-hand side of (20). Recalling that $T_q(A) = T_q(B)$ and $T_p(X^\top X) = T_p(X X^\top)$, after n steps we obtain

$$\mathrm{TR}\left(X^\top A^l X B^g\right) \leq \left(\mathrm{TR}(X^\top A^{l'} X B^{g'})\right)^{1/2^n} T_p\left(X^\top X\right)^{\sum_{i=1}^n (1/2)^i} T_q\left(B^{g+l}\right)^{\sum_{i=1}^n (1/2)^i}$$

for some pair of exponents $l', g' \geq 0$ such that $l' + g' = l + g$. Since for any such pair l', g', we have $\mathrm{TR}(X^\top A^{l'} X A^{g'}) < \infty$, we can take the limit as $n \to \infty$. Recalling that $\sum_{i=1}^{\infty} (1/2)^i = 1$ completes the proof. ■

We are now ready to prove Theorem 9.

Proof [Theorem 9] We set

$$G(V) = \frac{1}{2} \|V\|_{s_{2p}}^2 = \frac{1}{2} \mathrm{TR}\big((V^\top V)^p\big)^{1/p}.$$

Since $G(V)$ is twice[4] continuously differentiable, by the mean-value theorem we can write

$$D(V_s \| V_{s-1}) = \frac{1}{2} (\mathrm{VEC} M_t)^\top H_G(\xi) \mathrm{VEC}(M_t) \tag{21}$$

where H_G denotes the Hessian matrix of (matrix) function G and ξ is some matrix on the line connecting V_{s-1} to V_s. We start by computing the first derivative,

$$\nabla G(V) = \frac{1}{2} \nabla \mathrm{TR}\big((V^\top V)^p\big)^{1/p} = \frac{1}{2p} \mathrm{TR}\big((V^\top V)^p\big)^{1/p-1} \nabla \mathrm{TR}\big((V^\top V)^p\big) \,. \tag{22}$$

Then, by applying the chain rule to $\nabla\big(\mathrm{TR}(V^\top V)^p\big)$ and using (15) and (16) we obtain

$$\begin{aligned}
\nabla \mathrm{TR}\big((V^\top V)^p\big) &= p \mathrm{VEC}\big((V^\top V)^{p-1}\big)^\top (I_{K^2} + T_{K^2})(I_K \otimes V^\top) \\
&= p \mathrm{VEC}\big((V^\top V)^{p-1}\big)^\top (I_K \otimes V^\top) \\
&\quad + p \Big(T_{K^2} \mathrm{VEC}\big((V^\top V)^{p-1}\big) \Big)^\top (I_K \otimes V^\top) \\
&\quad \text{(since } V^\top V \text{ and } T_{K^2} \text{ are symmetric)} \\
&= 2p \big((I_K \otimes V) \mathrm{VEC}(V^\top V)^{p-1} \big)^\top \\
&= 2p \mathrm{VEC}\big(V (V^\top V)^{p-1} \big)^\top
\end{aligned} \tag{23}$$

the last equation following from (12). We now substitute (23) back into (22) and obtain

$$\nabla G(V) = c(V) \mathrm{VEC}(D)^\top$$

where we set for brevity $D = V B^{p-1}$ and $c(V) = \mathrm{TR}(B^p)^{1/p-1}$ with $B = V^\top V$. Taking the second derivative $H_G = \nabla^2 G$ gives

$$H_G(V) = \mathrm{VEC}(D) \nabla c(V) + c(V) \nabla D \,.$$

Recalling the definition of $c(V)$ and using (15) it is easy to see that $\mathrm{VEC}(D) \nabla c(V)$ is the $Kd \times Kd$ matrix

$$(1-p) \mathrm{TR}\big(B^p\big)^{1/p-2} \mathrm{VEC}(D) \mathrm{VEC}(D)^\top. \tag{24}$$

Since $p \geq 1$ this matrix is negative semidefinite, and we can disregard it when bounding from the above the quadratic form (21). Thus we continue by considering only the second term $c(V) \nabla(D)$ of the Hessian matrix. We have

$$\nabla D = \big(B^{p-1} \otimes I_d\big) + (I_K \otimes V) \nabla B^{p-1}$$

4. In fact G is C^∞ everywhere but (possibly) in zero, since $\mathrm{TR}\big((V^\top V)^p\big)$ is just a polynomial function of the entries of V. Moreover $\mathrm{TR}\big((V^\top V)^p\big) = 0$ if and only if V is the zero matrix.

where

$$\nabla(B^{p-1}) = \left(\sum_{\ell=0}^{p-2} B^\ell \otimes B^{p-2-\ell}\right)(I_{K^2} + T_{K^2})\left(I_K \otimes V^\top\right).$$

Putting together

$$\begin{aligned}(21) \quad \leq \quad & \frac{c(V)}{2}\,\mathrm{VEC}(M_t)^\top (B^{p-1}\otimes I_d)\,\mathrm{VEC}(M_t) \\ & + \frac{c(V)}{2}\mathrm{VEC}(M_t)^\top (I_K \otimes V)\Sigma \times \\ & \times (I_{K^2} + T_{K^2})\left(I_K \otimes V^\top\right)\mathrm{VEC}(M_t) \end{aligned} \tag{25}$$

where we used the shorthand $\Sigma = \sum_{\ell=0}^{p-2} B^\ell \otimes B^{p-2-\ell}$. We now bound the two terms in the right-hand side of (25). Using again (12) combined with (13) we can write

$$\frac{c(V)}{2}\,\mathrm{VEC}(M_t)^\top (B^{p-1}\otimes I_d)\,\mathrm{VEC}(M_t) = \frac{c(V)}{2}\,\mathrm{TR}(M_t^\top X_t B^{p-1}) \leq \frac{1}{2}\,\mathrm{TR}\big((M_t^\top M_t)^p\big)^{1/p}$$

independent of V. The majorization follows from Holder's inequality applied to the positive semidefinite matrices $M_t^\top M_t$ and B^{p-1} (Magnus and Neudecker, 1999, Chapter 11). Moreover, it is easy to see that the symmetric matrices Σ and T_{K^2} commute, thereby sharing the same eigenspace, in fact

$$T_{K^2}\Sigma = \sum_{\ell=0}^{p-2} T_{K^2}\big(B^\ell \otimes B^{p-2-\ell}\big) = \sum_{\ell=0}^{p-2}\big(B^{p-2-\ell}\otimes B^\ell\big)T_{K^2} = \Sigma\, T_{K^2}\ .$$

Hence, $\Sigma\,(I_{K^2} + T_{K^2}) \preccurlyeq 2\Sigma$, and we can bound from above the second term in (25) by

$$c(V)\mathrm{VEC}(M_t)^\top \sum_{\ell=0}^{p-2} B^\ell \otimes A^{p-1-\ell}\mathrm{VEC}(M_t) \tag{26}$$

where we set $A = VV^\top$. Again, (12) and (13) allow us to rewrite this quadratic form as the sum of traces

$$c(V)\sum_{\ell=0}^{p-2}\mathrm{TR}(M_t^\top A^{p-1-\ell} M_t B^\ell)\ .$$

Since A and B have the same nonzero eigenvalues, we can apply Lemma 13 to each term and put together as in (25). After simplifying we get

$$(21) \leq \frac{1}{2}\,(2p-1)\mathrm{TR}\big((M_t^\top M_t)^p\big)^{1/p} = \frac{1}{2}\,(2p-1)||M_t||^2_{s_{2p}}.$$

Substituting back into (18), and recalling that $\|U\|_* = \|U\|_{s_{2q}}$ in the case of Schatten norms, yields

$$\begin{aligned}\mu \quad \leq \quad & \sum_{t\in\mathcal{M}} \ell_t^{\mathbb{1}}(U) + \|U\|_{s_{2q}} \sqrt{(2p-1)\sum_{t\in\mathcal{M}} \|M_t\|^2_{s_{2p}}} \\ \leq \quad & \sum_{t\in\mathcal{M}} \ell_t^{\mathbb{1}}(U) + \|U\|_{s_{2q}} \sqrt{(2p-1)\max_{t\in\mathcal{M}} \frac{\|M_t\|^2_{s_{2p}}}{\|\mathbb{1}_t\|_1}\,\mu}\ .\end{aligned}$$

Solving the inequality for μ, and overapproximating via $\sqrt{a+b} \leq \sqrt{a} + \sqrt{b}$ we now obtain

$$\mu \leq \sum_{t \in \mathcal{M}} \ell_t^{\mathbb{1}}(U) + (2p-1)\left(\mathbf{M}_{s_{2p}} \|U\|_{s_{2q}}\right)^2 + \mathbf{M}_{s_{2p}} \|U\|_{s_{2q}} \sqrt{(2p-1)\sum_{t \in \mathcal{M}} \ell_t^{\mathbb{1}}(U)}$$

thereby concluding the proof. ■

The core of the above analysis is an upper bound on the second-order term of the Taylor expansion of the Schatten p-norm around V_{s-1}. Our proof of this bound is based on a direct matrix analysis. A more general bound has independently been derived in Juditsky and Nemirovski (2009, Proposition 3.1) and used in Kakade et al. (2009), where the unitarily invariant norms of our analysis are replaced by general convex functions.

Abstract

To handle problems created by large data sets, we propose a method that uses a decision tree to decompose a given data space and train SVMs on the decomposed regions. Although there are other means of decomposing a data space, we show that the decision tree has several merits for large-scale SVM training. First, it can classify some data points by its own means, thereby reducing the cost of SVM training for the remaining data points. Second, it is efficient in determining the parameter values that maximize the validation accuracy, which helps maintain good test accuracy. Third, the tree decomposition method can derive a generalization error bound for the classifier. For data sets whose size can be handled by current non-linear, or kernel-based, SVM training techniques, the proposed method can speed up the training by a factor of thousands, and still achieve comparable test accuracy.

Keywords: binary tree, generalization error ïbound, margin-based theory, pattern classification, tree decomposition, support vector machine, VC theory

1. Introduction

Support vector machines (SVMs) have proven very effective for solving pattern classification problems (Cortes and Vapnik, 1995; Vapnik, 1995). Because of the growing trend to apply them to various domains of interest, including bioinformatics, computer vision, data mining and knowledge discovery, the size of training data sets continues to grow at a rapid rate. At the same time, there is an ongoing effort to speed up the SVM training. One approach, called the *numerical technique* in this paper, seeks efficient solutions to SVM optimization problems.

Well-known numerical methods for solving dual optimization problems include sequential minimal optimization (SMO) (Platt, 1998) and SVM$^{\text{light}}$ (Joachims, 1998). Both methods break a large problem into a series of small problems in order to reduce the amount of memory required for computation. SMO, in particular, has proven superior to similar methods, such as the projected conjugated gradient "chunking" algorithm (Burges, 1998) and Osuna's algorithm (Osuna et al., 1997). For solving dual problems, there are now many new and faster methods, including LASVM (Bordes et al., 2005), maximum-gain working set selection (Glasmachers and Igle, 2006), SVM$^{\text{perf}}$ (Joachims, 2006), LaRank (Bordes et al., 2007), Pegasos (Shalev-Shwartz et al., 2007), bundle methods (Smola et al., 2007), and LIBLINEAR (Fan et al., 2008).

A new direction that has attracted increasing interest in recent years uses the stochastic gradient descent (SGD) technique to solve large-scale SVM problems. The advantage of SGD is that it implements an online learning process that converges to an optimal solution in one examination of the training samples. The above-mentioned LASVM, LaRank and Pegasos algorithms apply SGD to dual optimization problems. There are also algorithms that apply SGD to primal optimization problems, for example, NORMA (Kivinen et al., 2004) and SGD-QN (Bordes et al., 2009).

In addition to the methods for solving dual or primal problems, a number of approaches for solving large SVMs have been proposed, including core vector machines (Tsang et al., 2005) and OCAS (Franc and Sonnenburg, 2008). Readers may refer to a useful paper by Menon (2009) for more details of the numerical methods.

Another type of approach, called *data-reduction* in this paper, reduces a large training data set to one or several small data sets. If only one reduced set is obtained, we call the method *single-set reduction* (SSR); and if multiple reduced sets are obtained, we call the method *multiple-set reduction* (MSR). In the latter case, SVM training is conducted on each of the reduced sets and all the SVMs are combined into a final classifier.

We review MSR methods first. Perhaps the simplest MSR method is bagging (Breiman, 1996). It employs a number of down-sampled data sets to train SVMs, which jointly classify a test object based on majority vote. The boosting method (Schapire, 1990; Schapire and Singer, 2000) trains SVMs in a sequential manner, and the training of a particular SVM is dependent on the training and performance of previously trained SVMs. The divide-and-combine strategy (Rida et al., 1999) decomposes an input space into possibly overlapping regions, assigns each region a local predictor, and combines the local predictors to derive a global solution to the prediction problem. The Bayesian committee machine (Tresp, 2000) partitions a large data set into smaller ones, and the SVMs trained on the reduced sets jointly define the posteriori probabilities of the classes into which test objects are categorized. The method proposed by Collobert et al. (2002) divides a set of input samples into smaller subsets, assigns each subset a local expert, and forms a loop to re-assign samples to local experts according to how well the experts perform. The cascade SVM method (Graf et al., 2004) also splits a large data set into smaller sets and extracts support vectors (SVs) from each of them. The resulting SVs are combined and filtered in a cascade of SVMs. A few passes through the cascade ensures that the optimal solution is found.

On the SSR side of the data-reduction approach, the squashing method (Pavlov et al., 2000) uses a likelihood-based squashing technique to obtain a reduced data set, and then trains linear SVMs on that set. The sparse greedy approximation method (Smola and Schölkopf, 2000) constructs a compressed representation of the design matrix involved in the QP problem; while information vector machines (Lawrence et al., 2003) use a sparse Gaussian process to select training samples using criteria based on information-theoretic principles. Clustering-based SVM (Yu et al., 2003) applies a hierarchical clustering algorithm to obtain a reduced data set, which is used to train SVMs. The concept boundary detection (CBD) method (Panda et al., 2006) prepares nearest-neighbor lists as training samples, and uses a special down-sampling technique to extract the data points that lie close to class boundaries. This method can find a single set of near-boundary points for all class pairs. In contrast, many other methods that use SVMs to analyze training samples have to find different reduced sets for different class pairs, since SVMs can only work on one class pair at a time. For more details of data-reduction methods proposed up to 2001, readers may refer to Tresp (2001).

Finally, we remark that the numerical and data reduction approaches, instead of competing, can actually complement each other's functions. The data reduction approach must train SVMs on reduced data sets, so having an efficient numerical method to perform the task would certainly be useful. The numerical approach, on the other hand, could benefit by using an efficient data reduction method to reduce its computational burden.

In this paper, we propose a method that decomposes a large data set into a number of smaller ones and trains SVMs on each of them. This approach can reduce the total training time because the time complexity of training an SVM is in the order of n^2, where n is the number of training samples (Platt, 1998; Joachims, 1998) . If each smaller problem deals with σ samples, then the complexity of solving all the problems is in the order of $(n/\sigma) \times \sigma^2 = n\sigma$, which is much smaller than n^2 if n is significantly higher than σ. Decomposing a large problem into smaller problems has the added benefit of reducing the number of SVs in each of the resultant SVMs. Since a test sample is classified by only one of these SVMs, the decomposition strategy reduces the time required for the testing process in which the number of SVs dominates the complexity of the computation. One additional benefit of the decomposition approach is the ease of using multi-core/parallel/distributed computing for further speedup, since the SVM problems associated with the decomposed regions can be parallelized idealistically.

The proposed method can be categorized as an MSR method. However, it differs from other MSR methods in that it uses a *decision tree* to obtain multiple reduced data sets, whereas other methods use non-supervised clustering (Rida et al., 1999), random sampling (Breiman, 1996), or random partition (Tresp, 2000; Collobert et al., 2002; Graf et al., 2004). We thus call our method a *decision-tree support vector machine* (DTSVM) and the resultant classifier a DTSVM classifier.

A decision tree decomposes a data space recursively into smaller regions. In terms of the ways the regions are formed, a decision tree can be classified into three types: axis-parallel, oblique and Voronoi types. In the axis-parallel type, the regions are bounded by hyperplanes represented as $x_i = c$, where x_i is a feature and c is a real number (Breiman et al., 1984; Quinlan, 1986). In the oblique type, the regions are bounded by hyperplanes represented as $\sum \alpha_i x_i = c$, where α_i are real numbers (Murthy et al., 1994; Bennett and Blue, 1998; Wu et al., 1999; Bennett et al., 2000). In the Voronoi type, the regions are formed as Voronoi cells by way of various clustering techniques (for a survey, see Dattatreya and Kanal, 1985).

In this paper, we take an axis-parallel decision tree as our decomposition scheme because of its speed in both the training and testing phases. The other two types of decision trees can certainly be used as decomposition schemes, but their computational cost is significantly higher than that of the axis-parallel type. Without conducting a tradeoff study, it is rather difficult to determine whether the additional cost would yield a noteworthy benefit; therefore, we have decided not to adopt them at this stage.

A number of studies have attempted to combine decision trees and SVMs. Some of the methods were designed to improve the classification accuracy (e.g., Bennett and Blue, 1998; Wu et al., 1999; Bennett et al., 2000; Ramaswamy, 2006; Tibshirani and Hastie, 2007); while others were designed to speed up the SVM testing process (e.g., Platt et al., 2000; Sahbi and Geman, 2006; Sun et al., 2007). To the best of our knowledge, using a decision tree to speed up the training of multiclass SVMs has not been proposed previously.

Using a decision tree as a decomposition scheme can yield following benefits when dealing with large-scale SVM problems. First, the decision tree may decompose the data space so that certain decomposed regions become homogeneous; that is, they contain samples of the same labels. Then,

in the testing phase, when a data point flows to a homogeneous region, we simply classify it in terms of the common label of that region. This alleviates the burden of SVM training, which is only conducted in heterogeneous regions. In fact, our experiments revealed that, for certain data sets, more than 90% of the training samples reside in homogeneous regions; thus, the decision tree method saves an enormous amount of time when training SVMs. Random partition, on the other hand, cannot produce such an effect, since random pooling of a set of samples can hardly create a homogeneous data set due to the independent sampling operation.

Another benefit of using the decision tree is the convenience it provides when searching for all the relevant parameter values to maximize the solution's validation accuracy, which in turn helps maintain good test accuracy rates. The goal of the DTSVM method is to attain comparable validation accuracy while consuming less time than training SVMs on full data sets. To achieve our objective, we found that it is important to control the size σ of the tree-decomposed regions as well as the SVM-parameter values. For some data sets, σ could be set at 1,500; but for other data sets, it had to be set at a larger value. Thus, in the DTSVM method, σ is an additional parameter to the usual SVM-parameters. Other MSR methods do not attempt to search for the optimal size of decomposed regions. Such searches are particularly easy under the DTSVM method because a decision tree is constructed in a recursive manner; hence, obtaining a tree with a larger size of σ does not require the reconstruction of a decision tree corresponding to that size of σ.

Using a decision tree also reduces the cost of searching for the optimal values of SVM-parameters. Searching for these values is important, but it takes a tremendous amount of time, especially when training non-linear SVMs. To the best of our knowledge, no data-reduction method has attempted to reduce the cost of this operation. Our strategy involves training SVMs with all combinations of SVM-parameter values, but *only* for decomposed regions with an initial σ-level. The optimal values of the SVM-parameters obtained at this level are not necessarily the same as those obtained at higher levels. However, we observe that the best values for a higher level are usually among the top-ranked values for the initial level. Therefore, when we want to train SVMs for a higher σ-level, we only train them with the top-ranked values obtained for the initial level. Given the n^2-complexity of SVM training, restricting the full search of SVM-parameter values to regions with the initial σ-level certainly reduces the SVM training time. In fact, our experiments showed that such savings were possible even when the optimal σ-level was higher than that of the full size data set.

Although the decision tree method may not be the only way to achieve the above benefits for large-scale SVM problems, its effect can be understood in theory and a generalization error bound can be derived for the DTSVM classifier. The bound is the sum of two terms: the first term dominates in magnitude and is associated with SVM training; and the second term is associated with tree training. Our experimental results show that the numerical value of the dominant term is as small as, or of the same order of magnitude as, its counterpart in the generalization error bound for SVM training conducted on the whole data set. This finding constitutes indirect evidence of the efficacy of tree decomposition for large-scale SVM problems.

Finally, we remark that it is possible to have multiple decompositions of the same data space with multiple trees. These trees can be obtained by using a randomized, rather than the optimal, split point at each tree node (Dietterich, 2000). By so doing, we train SVMs on all the decomposed regions and classify the test data based on a majority vote strategy. We have actually studied the effect of such multiple decompositions. In terms of test accuracy, multiple decompositions are not as effective as searching for the optimal σ-level of decomposed regions in a single decision tree. In fact, under the latter search scheme, introducing multiple decompositions does not lead to

any significant improvement. Therefore, to avoid unnecessary complications, we only consider the decomposition of a data space by a single tree in this paper.

In the experimental study, we divided each data set into training, validation and test components. We then used the training component to build DTSVM classifiers, the validation component to determine the optimal parameters, and the test component to measure the test accuracy. We adopted two types of SVM training: one-against-one (1A1) (Knerr et al., 1990) and one-against-others (1AO) (Bottou et al., 1994) . Furthermore, we built non-linear SVMs on the data sets. When evaluating the DTSVM method, we found it could train DTSVM classifiers that achieved comparable test accuracy rates to those of SVM classifiers. For seven medium-size data sets, in which the largest number of sample was 494K and the largest number of feature was 62K, DTSVM achieved speedup factors between 4 and 3,691 for 1A1 training, and between 29 and 5,775 for 1AO training. Moreover, DTSVM achieved much higher speedup factors than several data reduction methods and numerical methods. To demonstrate that DTSVM can train classifiers efficiently for larger data sets, we applied it to four large-size data sets in which the largest number of samples was 4.9M and the largest number of features was 16.6M. For all the data sets, DTSVM could complete 1A1 training and 1AO training within 18.25 hours. Note that the training time included the time required to build a decision tree, the time to train SVMs on all the leaves, and the time to search for the optimal parameters.

The remainder of this paper is organized as follows. In Section 2, we describe the DTSVM method. Section 3 details the experimental results. In Section 4, we provide theoretical results for the DTSVM method. Section 5 contains some concluding remarks.

2. The DTSVM Method

In this section, we describe the decision tree that we use as the decomposition scheme, and discuss the training process for the DTSVM method. An implementation of the DTSVM method is available at

http://ocrwks11.iis.sinica.edu.tw/dar/Download/WebPages/DTSVM.htm

2.1 The Decision Tree

For the decomposition scheme, we adopt CART (Breiman et al., 1984) or a binary C4.5 scheme (Quinlan, 1986) that allows two child nodes to grow from each node that is not a leaf. Using a C4.5 scheme that allows multiple child nodes is feasible; however, we do not consider it in this paper, since a binary C4.5 performs the job rather well for us.

To grow a binary tree, we follow a recursive process, whereby each training sample flowing to a node is sent to its left-hand or right-hand child node. At a given node E, a certain feature f_E of the training samples flowing to E is compared with a certain value v_E so that all samples with $f_E < v_E$ are sent to the left-hand child node, and the remaining samples are sent to the right-hand child node. The values of f_E and v_E are determined as follows. First, the *split point* v_f of each feature f is calculated by

$$v_f = \arg\max_v IR(f, v),$$

where

$$IR(f,v) = I(S) - \frac{|S_{f<v}|}{|S|} I(S_{f<v}) - \frac{|S_{f\geq v}|}{|S|} I(S_{f\geq v}),$$

S is the set of all samples flowing to E; $S_{f<v}$ consists of the elements of S with $f < v$; $S_{f\geq v} = S \backslash S_{f<v}$; $|X|$ is the size of any data set X; and $I(X)$ is the impurity of X. The impurity function used in our experiments is the entropy measure, defined as

$$I(\mathrm{S}) = -\sum_{y} p(S_y) \log p(S_y),$$

where $p(S_y)$ is the proportion of S's samples whose label is y. Then,

$$f_E = \arg\max_{f} IR(f, v_f),$$

and v_E is taken as the split point of f_E.

We stop splitting a node E when one of the following conditions is satisfied: (i) the number of samples that flow to E is smaller than a *ceiling size* σ; or (ii) when $IR(f,v) = 0$ for all f and v at E. The value of σ in the first condition is determined in a data-driven fashion, which we describe in Section 2.2. The second condition occurs mainly in the following cases. (a) All the samples that flow to E are homogeneous; or (b) a subset of them is homogeneous and the remaining samples, although carrying different labels, are identical to some members of the homogeneous subset. There are other possible cases for the second condition, but their occurrence is extremely rare. If we want to split E in these cases, we can choose the following split point to minimize the difference between $|S_{f<v}|$ and $|S_{f\geq v}|$, that is,

$$v_f = \arg\min_{v} \left| |S_{f<v}| - |S_{f\geq v}| \right|.$$

After growing a tree, we train an SVM on each of its leaves, using samples that flow to each leaf as training data (Figure 1). The values of the SVM parameters are also determined in a data-driven fashion. A tree and all SVMs associated with its leaves constitute a DTSVM classifier, as shown in Figure 1. In the training phase, all the SVMs in a DTSVM classifier are trained with the same parameter values. We explain how the optimal values are obtained in Section 2.2. In the validation/testing process, we first input a given validation/test object $\mathbf{x}$ to the tree. If $\mathbf{x}$ reaches a leaf that contains homogeneous samples, we classify $\mathbf{x}$ as the label of those samples; otherwise, we classify it with the SVM associated with that leaf.

2.2 The DTSVM Training Process

Given a training and validation component, we build a DTSVM classifier on the training component and determine its optimal parameter values with the help of the validation component. The parameters associated with a DTSVM classifier are: (i) σ, the ceiling size of the decision tree; and (ii) the SVM parameters. Their optimal values are determined in the following manner.

We begin by training a binary tree with an initial ceiling size σ_0, and then train SVMs on the leaves with SVM-parameters $\theta \in \Theta$, where Θ is the set of all possible SVM-parameter values whose effects we want to evaluate. Note that we express θ in boldface to indicate that it may consist of more than one parameter. Let $v(\sigma_0, \theta)$ be the validation accuracy of the resultant DTSVM classifier.

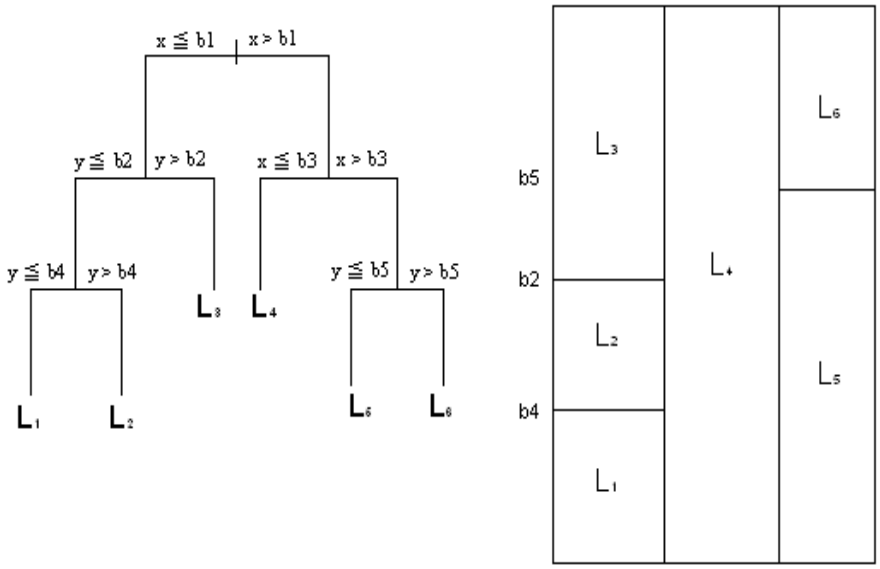

Figure 1: The architecture of a DTSVM classifier: a tree and all its leaves (L1 to L6) are produced and SVMs are trained on the leaves.

Next, we want to construct DTSVM classifiers with larger ceiling sizes, but we only train their associated SVMs with k top-ranked θ. To do this, we rank θ in descending order of $v(\sigma_0, \theta)$. Let Θ_k be the set that consists of k top-ranked θ.

More specifically, we implement the following sub-process, denoted as $SubProcess(\theta)$, for each $\theta \in \Theta_k$.

1. Set $t = 0$ and get the binary tree with the ceiling size σ_0.

2. Increase t by 1 and set $\sigma_t = 4 \times \sigma_{t-1}$. Modify the tree with ceiling size σ_{t-1} to obtain a tree with ceiling size σ_t. This is done by moving from the root towards the leaves and retaining each node whose parent's size is greater than σ_t. Then, train SVMs on the leaves with SVM-parameters θ. Let $v(\sigma_t, \theta)$ be the validation accuracy of the resultant DTSVM classifier.

3. If $v(\sigma_t, \theta) - v(\sigma_{t-1}, \theta) \geq 0.5\%$ and σ_t is less than the size of the training component, proceed to step 2.

4. Let $\sigma(\theta) = \sigma_{t-1}$ if $v(\sigma_t, \theta) - v(\sigma_{t-1}, \theta) < 0.5\%$ or $\sigma(\theta) = \sigma_t$ if σ_t is greater than or equal to the size of the training component.

When we have completed $SubProcess(\theta)$ for all $\theta \in \Theta_k$, we define

$$\theta_{opt} = \arg\max_{\theta \in \Theta_k} v(\sigma(\theta), \theta) \text{ and } \sigma_{opt} = \sigma(\theta_{opt}).$$

We then output the DTSVM classifier with the SVM-parameter θ_{opt} and the ceiling size σ_{opt}.

Figure 2: The test accuracy rates obtained by DTSVM on the seven data sets when σ_0 = 1,500 and k = 1, 3, 5, 7 and 9.

Note that, in each *SubProcess*(θ), we set σ_t as quadruple the size (rather than double the size) of σ_{t-1} for two reasons. First, quadrupling the size produces more significant differences between $v(\sigma_t, \theta)$ and $v(\sigma_{t-1}, \theta)$, especially when t is small. This means that if a *SubProcess* terminates at a small t, there is less risk of a low validation accuracy rate. Second, quadrupling the size enables the training process to progress at a faster pace. This means that if a *SubProcess* terminates at a large t, it moves more rapidly towards that end of the process.

The initial ceiling size σ_0 (=1,500) and the number k (=5) of the top-ranked parameters are set heuristically. To observe how these settings impact the test accuracy, we first fix σ_0 at 1,500 and vary k from 1 to 9 at a step size of 2; we then plot the test accuracy rates obtained by DTSVM on the seven data sets whose details are shown in Table 1. Figure 2 shows that any value of k is good for all the data sets except "Letter", while k = 5 or 7 is particularly good for "Letter". Moreover, setting the right value of k improves the test accuracy of "Letter" significantly. Next, we fix k at 5 and vary σ_0 from 500 to 3,000 with a step size of 500. As shown in Figure 3, varying the value of σ_0 does *not* affect the test accuracy of any data set significantly.

3. Experimental Results

In this section, we describe the data sets used in the experiments and the methods that we compared. We then present and discuss the experimental results.

3.1 The Data Sets

In the experiments, we divided the data sets into two groups. The first group was used to evaluate the efficiency of DTSVM and some alternative methods in terms of speeding up SVM training. The second group was used to verify that the DTSVM method could handle much larger data sets, for which most of the alternative methods required an excessive amount of time to complete the training process. The first group comprised seven medium-size data sets, ranging from 10K to 494K in size, as shown in Table 1. Most of the data sets have less than 50 features, but the "News20" has 62,060 features. The second group comprised four large-size data sets, ranging from 240K to 4,898K in size, as shown in the Table 2. The "Webspam" data set is not very large in terms of the number of samples (240K), but the number of features is more than 16M; thus, we consider it a large-size data set. All the data sets were obtained from UPI repository (Newman et al., 1998), with the following two exceptions: "PPI", which was used in a protein-protein interaction study (Tseng et al., 2010), and "Webspam", which was obtained from

http://www.cc.gatech.edu/projects/doi/WebbSpamCorpus.html

Note that the actual "Poker" data set in the repository contains 1 million samples; however, we only used its training component in our experiments.

We randomly divided each data set into six parts of approximately equal size, and used four parts as the training component, one part as the validation component, and the remaining part as the test component. The DTSVM classifiers were trained on the training and validation components, as described in Section 2.2. On completion of the training process, we applied the output DTSVM classifier to the corresponding test data set to obtain the test accuracy rate. All the data sets, divided into training, validation and test components, are available on the following website.

Table 2: The large-size data sets used in our experiments.

http://ocrwks11.iis.sinica.edu.tw/dar/Download/DataSets/DTSVM/datasets.htm

In each data set, we normalized all the feature values to a real number between 0 and 1. We did this by transforming each value v of feature f into $(v - f_{min})/(f_{max} - f_{min})$, where f_{max} and f_{min} are the maximum and minimum values of f respectively.

We only studied non-linear SVMs in our experiments. Moreover, we used the RBF kernel function to measure the similarity between vectors. As a result, we had two SVM parameters: the penalty factor C, whose values were taken from $\Phi = \{10^a : a = -1, 0, \ldots, 5\}$; and the γ parameter in the RBF function, whose values were taken from $\Psi = \{10^b : b = -4, -3, \ldots, 4\}$. Thus, the set of all SVM parameter values was $\Theta = \Phi \times \Psi$, which comprised 63 pairs of values for (C, γ).

SVM training is implemented under the 1A1 and 1AO approaches. When the 1A1 approach is used, there are $n(n-1)/2$ classifiers, where n is the number of labels. Each classifier assigns one of two possible labels to a given validation/test sample. We use all the classifiers to classify a given validation/test sample $\mathbf{x}$, based on a majority vote. Note that a more efficient technique (Platt et al., 2000) that only requires n classifiers can be used in the validation/testing procedure. However, we adopt Knerr et al.'s (1990) technique, which requires $n(n-1)/2$ classifiers, because we are only interested in the relative, rather than the absolute, performance of the methods compared in our experiments. When the 1AO approach is used, there are n decision functions, each of which is associated with a label. We assign $\mathbf{x}$ the label associated with the decision function that yields the highest functional value.

3.2 Methods Compared

The following methods are compared in our experiments.

CART. CART (Breiman et al., 1984) is similar to the decomposition scheme used in DTSVM, but it differs in terms of the stop and classification criteria. In the training phase, CART stops splitting a node when $IR(f,v) = 0$ for all features f and their values v. In the testing phase, it classifies a test sample $\mathbf{x}$ by the label shared by the majority of samples residing at the leaf to which $\mathbf{x}$ flows. Although CART is not designed for speeding up SVMs, it serves here as a benchmark for DTSVM. If CART performs as well as DTSVM in every respect, then there is no need for DTSVM, since CART runs much faster than DTSVM in both the training and testing phases.

RDSVM. RDSVM (randomized SVM) is an alternative to DTSVM that differs from DTSVM in the way it decomposes a data space. In the training phase, when a size σ is given, DTSVM randomly assigns a training sample to one of d subsets, where d is the smallest integer that is greater than or equal to n/σ and n is the number of training samples. RDSVM uses the same procedure as DTSVM to search for the optimal parameters. In the testing phase, RDSVM randomly assigns a test sample to a subset and classifies it according to the SVM associated with that subset.

Bagging. When implementing bagging (Breiman, 1996), we created a number of SVMs for each $\theta \in \Theta$. Each SVM was trained on 1,500 training samples chosen at random. For each θ, the training was conducted sequentially. We stopped at the first m so that the validation accuracy rate of m SVMs did not exceed that of $m-1$ SVMs by more than 0.5%.

CBD. The training process of CBD (Panda et al., 2006) comprises two steps: finding a reduced set, and training an SVM on that set for each $\theta \in \Theta$. The first part involves finding the k-nearest neighbors of each training sample and deriving the reduced data set via a down-sampling technique. Following Panda et al. (2006), we set k at 100. When searching for the 100 nearest neighbors of each training sample $\mathbf{x}$, we keep the current list of 100 nearest neighbors of $\mathbf{x}$. For another training sample $\mathbf{z}$, let $d(\mathbf{x},\mathbf{z})$ be the distance between $\mathbf{x}$ and $\mathbf{z}$. We need to compare this distance with $d(\mathbf{x},\mathbf{w})$, where $\mathbf{w}$ is on the current list and has the largest distance with $\mathbf{x}$. Since the squared distance is the sum of the squared feature differences, we can speed up the comparison by computing the partial sum of $d^2(\mathbf{x},\mathbf{z})$. When this partial sum exceeds $d^2(\mathbf{x},\mathbf{w})$, we stop the comparison and exclude $\mathbf{z}$ from the current list of $\mathbf{x}$.

LIBSVM. LIBSVM (Fan et al., 2005) is now the most widely used software for training and testing SVMs. We take it as the baseline in our experiments; thus, the speedup factor is 1 by assumption. If a compared method is faster in training than LIBSVM, it has a speedup factor above 1.

LASVM. LASVM (Bordes et al., 2005) is a method that solves a dual optimization problem by way of a stochastic gradient descent method that converges to an optimal solution in one examination of the training samples.

LIBLINEAR. LIBLINEAR (Fan et al., 2008) is a fast version of training and testing *linear* SVMs. Its training speed is comparable to, or even faster than, that of Pegasos (Shalev-Shwartz et al., 2007) and SVM$^{\text{perf}}$ (Joachims, 2006). Since LIBLINEAR is *not* a method for speeding up non-linear SVMs, we only include it in our experiments for large-size data sets, for which bagging, CBD, LIBSVM and LASVM take too long to complete the training process. When we train linear SVMs, the values of the penalty factor C are taken from $\Phi = \{10^a : a = -1, 0, \ldots, 5\}$, which comprises 7 real numbers. Furthermore, we require the discriminant function of the classifier to include a bias term.

Among the above methods, DTSVM, RTSVM, bagging and CBD are data reduction methods, while LIBSVM, LASVM and LIBLIEAR are numerical methods.

3.3 Results on Medium-Size Data Sets

The results of applying seven methods, CART, DTSVM, RDSVM, bagging, CBD, LIBSVM and LASVM, to the seven medium-size data sets are shown in Figures 4-8 for 1A1 training, and in Figures 9-13 for 1AO training. In all SVM training sessions, except for LASVM, we used the LIBSVM software (Fan et al., 2005). We adopted all default options of the software, except the parameter values, which we specified in Section 3.1.

Figure 4 and Figure 9 show the training times of the seven methods. The training time of each method comprises the time required to obtain reduced data sets if it is a data reduction method, the time to train all SVMs and the time to search for optimal parameters; however, the time required to input or output data is *not* included. The computation for all the medium-size data sets was performed on an Intel Xeon CPU 3.2 GHz with a 2GB RAM, while that for all the large-size data sets was performed on a Quad-Core Intel Xeon X5365 3.0GHz CPU and 32GB RAM.

Figure 5 and Figure 10 show the *speedup factors* of all the methods except LIBSVM, where the speedup factor of a method $\mathcal{M}$ is computed as LIBSVM's training time divided by $\mathcal{M}$'s training time.

Figure 6 and Figure 11 show the test accuracy rates of the four compared methods. Note that the DTSVM test accuracy is that of the DTSVM classifier with the ceiling size σ_{opt} and SVM-parameters θ_{opt}. When classifying a test sample with SVMs, the most time-consuming part is computing a decision function, whose complexity can be measured in terms of how many SVs are encountered in the classification. Therefore, we use the "*number of encountered support vectors*" (NESV) as a measure of the time-complexity of the test process. NESV is defined as the number of SVs contained in the decision function used to classify a test sample. When a DTSVM or an RDSVM classifier is used, the NESV is associated with the leaf that the test sample flows to. Thus, in the two cases, NESV is the *average* number of SVs encountered by a test sample.

Figure 7 and Figure 12 list the NESVs of the four methods; while Figure 8 and Figure 13 show the *NESV ratios* of all the methods except LIBSVM and CART, where the NESV ratio of a method $\mathcal{M}$ is computed as LIBSVM's NESV divided by $\mathcal{M}$'s NESV.

We now summarize the results shown in Figures 4 to 13.

1. There is no doubt that CART was extremely fast in training, but its test accuracy was poor, except on the "Shuttle" and "KDD-10%" data sets, where its accuracy matched the best of all the other methods.

2. In terms of training time, DTSVM outperformed all the other methods, except CART; and in terms of test accuracy and NESV, DSTVM outperformed or performed comparably to all the other methods. It also achieved very large speedup factors and NESV ratios on "Shuttle", "Poker", "CI" and "KDD-10%".

3. RDSVM, being an alternative approach to DTSVM, achieved comparable test accuracy to DTSVM. However, it performed worse in terms of training time on "Shuttle", "Poker" and "KDD-10%". It also performed worse in terms of NESV on "Shuttle", "Poker", "CI" and "KDD-10%".

4. CBD achieved speedup factors above 1 and NESV ratios above 1 on most data sets; however, its scores were overall not as high as those of DTSVM. In addition CBD lagged behind DTSVM in terms of test accuracy on "Letter" and "News20".

Table 3: The total number of SVs produced by DTSVM and LIBSVM on medium-size data sets. The two methods produced about the same numbers of SVs, even though DTSVM has much smaller NESVs than LIBSVM.

5. Bagging achieved speedup factors below 1 and NESV ratios below 1 on several data sets. It also lagged behind DTSVM in terms of test accuracy on "Letter" and "News20".

6. LASVM, being an alternative numerical method to LIBSVM, achieved speedup factors slightly above 1 on most data sets, but its scores were much lower than those of DTSVM. LASVM also achieved NESV ratios above 1 on most data sets, although they were generally not as high as those of DTSVM. An unexpected result occurred in the 1AO training on "KDD-10%", where LASVM obtained very high NESVs compared to LIBSVM, resulting in a low NESV ratio (0.1). We double checked the process to confirm that the above result was correct.

Finally, we provide some additional information about DTSVM. In Table 3, we show the *total number of support vectors* (TNSV) produced by DTSVM and LIBSVM on all medium-size data sets. TNSV expresses the space-complexity of a training process, whereas NESV expresses the time-complexity of a test process. For DTSVM, the NESV is smaller than the TNSV in most cases, because a test sample usually encounters only some, rather than all, SVs. For LIBSVM, NESV is always the same as TNSV. Note that DTSVM achieved much smaller NESVs on many data sets, but it produced about the same TNSV on all the data sets.

Table 4 shows the DTSVM testing times, as well as the LIBSVM and CART testing times for comparison. As expected from the NESV results, DTSVM's testing time is shorter than that of LIBSVM on all the data sets. We further divide DTSVM's testing time into the time spent on the decision-tree component (DTC) and that spent on local SVMs (lSVMs). In Table 4, the times are separated by a semi-colon. Clearly, the DTC testing time takes an extremely small proportion of DTSVM's testing time. In fact, it is so small that it cannot be measured accurately by the timing mechanism. CART's testing time, on the other hand, is higher than that of the DTC because CART-trees usually grow to deeper levels than DTC-trees.

3.4 Results on Large-Size Data Sets

The results of applying four methods, CART, DTSVM, RDSVM and LIBLINEAR, to the four large-size data sets are shown in Figures 14-16 for 1A1 training, and in Figures 17-19 for 1AO training. Once again, we used the LIBSVM software for all SVM training sessions of DTSVM and RDSVM.

We summarize the results on large-size data sets as follows.

1. Even though DTSVM was not as fast as CART and LIBLINEAR in training, it achieved consistently high test accuracy rates on all the four data sets. It outperformed LIBLINEAR

		PHW	Letter	Shuttle	Poker	CI	News20	KDD-10%
CART		0.063	0.125	0.360	0.157	0.204	0.093	2.187
1A1	DTSVM	0.047	3.844	0.000	0.406	0.219	38.141	0.063
		0; 0.047	0; 3.844	0; 0.000	0; 0.406	0; 0.219	0; 38.141	0; 0.063
	LIBSVM	0.265	4.078	0.187	7.406	8.453	39.062	7.344
1AO	DTSVM	0.062	7.344	0.000	1.125	0.219	126	0.063
		0; 0.062	0; 7.344	0; 0.000	0; 1.125	0; 0.219	0; 126	0; 0.063
	LIBSVM	0.328	7.328	0.250	17.313	8.453	138.000	19.875

Table 4: The testing time required by CART, DTSVM and LIBSVM on medium-size data sets. The time required by DTSVM is lower than that required by LIBSVM. The DTC testing time takes a very small proportion of DTSVM's testing time. CART's testing time is higher than that of DTC.

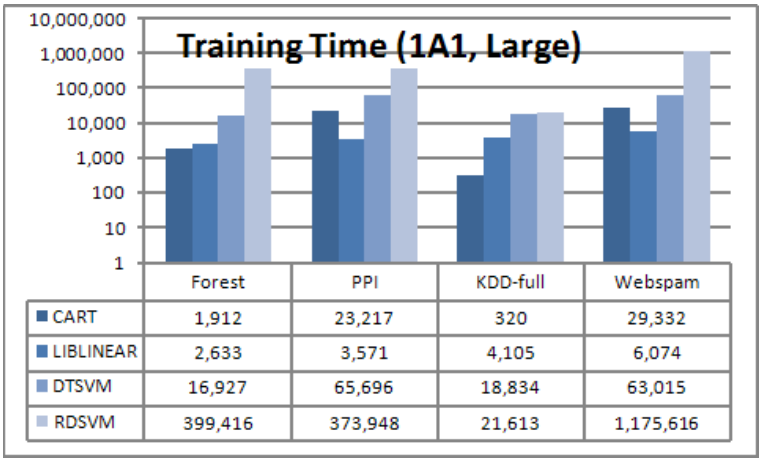

Figure 14: Training times of the four methods, expressed in *seconds*. Training type = 1A1. CART and LIBLINEAR outperformed the other methods.

and RDSVM on "Forest" and "PPI", and surpassed CART on "PPI" by a significant margin. Moreover, DTSVM achieved much lower NESVs than RDSVM on all the data sets.

2. Recall that RDSVM achieved equally good test accuracy rates on all the medium-size data sets. However, on the large-size data sets, it achieved much lower accuracy rates on "Forest" and "PPI", and it yielded much higher NESVs on all the data sets. The results show that RDSVM is *not* a good substitute for DTSVM in solving large-scale SVM problems.

3. The results also show that, despite their efficiency in training, CART and LIBLINEAR are *not* good substitutes for DTSVM in solving large-scale problems. LIBLINEAR achieved the best test accuracy rate on "Webspam", presumably because a linear model fits this data set

	Forest	PPI	KDD-full	Webspam
CART	93.31%	88.11%	99.99%	98.44%
LIBLINEAR	72.79%	87.42%	99.87%	99.53%
DTSVM	94.61%	92.29%	99.99%	99.03%
RDSVM	77.46%	87.43%	99.72%	99.45%

Figure 15: Test Accuracy of the four methods. Training type = 1A1. DTSVM outperformed, or performed comparably to, the other methods. CART performed rather well compared to LIBLINEAR.

	Forest	PPI	KDD-full	Webspam
DTSVM	350.0	662.9	4.7	33.7
RDSVM	259,768.5	1,498.4	91.1	3,878.4

Figure 16: The NESVs of DTSVM and RDSVM. Training type = 1A1. DTSVM achieved much lower NESVs than RDSVM.

rather well. However, to verify this assumption, we need to compare the test accuracy rates of linear and non-linear models. DTSVM offers us an opportunity to make such a comparison.

We also show the total number of SVs produced by DTSVM in Table 5, while the testing times required by DTSVM and CART are shown in Table 6. DTSVM's testing time is further divided into the amount of time required by the DTC and that required by lSVMs. Once again, it is clear that DTC's testing time only takes a very small proportion of DTSVM's testing time. CART's testing time is higher than that of DTC because CART-trees usually grow to deeper levels than DTC-trees.

3.5 Further Discussion

To gain insight into why DTSVM is so effective, we show in Table 7 the σ_{opt} derived by DTSVM on medium-size data sets, along with the proportion of training samples that flow to homogeneous leaves. Note that a single table suffices to show all the results because 1A1 training and 1AO training employ the same decision trees and DTSVM yields the same σ_{opt} value for both approaches.

First, we observe that DTSVM required a low ceiling size of 1,500 on all the data sets, except "Letter" and "News20." This explains why DTSVM generally achieved good speedup factors and NESV ratios. Furthermore, the proportion of training samples that flowed to homogeneous leaves under DTSVM was very high in "Shuttle" and "KDD-10%". Since no SVM classifier is involved

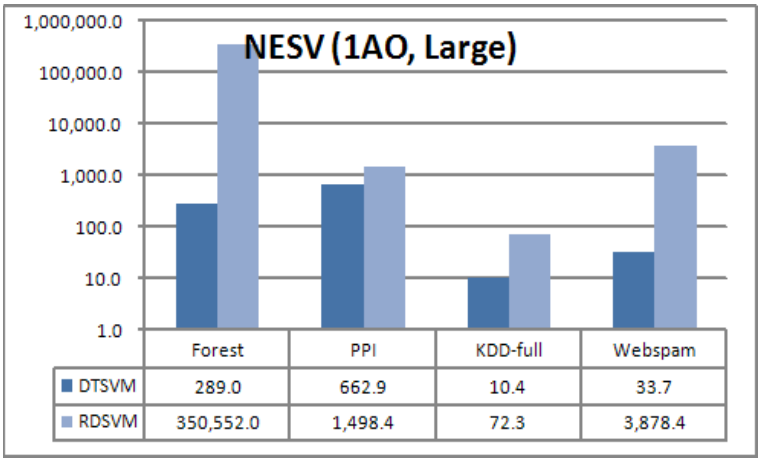

Figure 19: The NESVs of DTSVM and RDSVM. Training type = 1AO. DTSVM achieved much lower NESVs than RDSVM.

	1AO	95.71%	96.91%	97.66%
News20	1A1	67.02%	76.92%	83.22%
	1AO	70.82%	79.06%	84.34%

Table 10: The DTSVM test accuracy rates that correspond to different ceiling sizes.

in any homogeneous leaves, DTSVM achieved very high speedup factors and NESV ratios on these two data sets. The same fact also explains why DTSVM achieved such low NESVs, which even fell below 1 on "Shuttle". Note that this phenomenon occurs because decision trees group neighboring samples into the same leaf. RDSVM, on the other hand, does not produce the same effect because the probability that all samples will carry the same label in the same randomly decomposed region is extremely small.

The lack of homogeneous leaves is not the only reason for RDSVM's poor performance in training. Table 8 shows the σ_{opt} values derived by DTSVM and RDSVM. The results explain why RDSVM achieved much smaller speedup factors and NESV ratios on "CI" and "Poker".

Next, we examine the DTSVM results for the "Letter" and "News20" data sets in which the optimal sizes The σ_{opt} exceeded the size of the training component. Thus, the output DTSVM classifier was trained on the full training component. Even so, DTSVM still achieved speedup factors above 1 because it only trained lSVMs for all the parameter values on leaves with a ceiling size of 1,500, which took much less time than training them on the full training component. The amount of time spent on higher ceiling sizes did not increase at a faster rate, because DTSVM only trained a small number of lSVMs. Moreover, the lSVMs were trained with top-ranked parameters, which tended to require less time than those trained with bottom-ranked parameters.

	Forest	PPI	KDD-full	Webspam
σ_{opt}	1,500	1,500	1,500	1,500
Proportion	5.55%	1.64%	42.05%	80.63%

Table 11: The σ_{opt} values obtained by DTSVM on the large-size data sets and the proportion of training samples that flowed to homogeneous leaves.

		Forest	PPI	KDD-full	Webspam
1A1	DTSVM	1,500	1,500	1,500	1,500
	RDSVM	96,000	1,500	1,500	96,000
1AO	DTSVM	1,500	1,500	1,500	1,500
	RDSVM	1,536,000	1,500	1,500	96,000

Table 12: The σ_{opt} values obtained by DTSVM and RDSVM on the large-size data sets.

Table 9 shows the training times required for different ceiling sizes. We observe that DTSVM spent most of its time on the leaves with the lowest ceiling size. In addition, Table 10 shows the test accuracy rates corresponding to different ceiling sizes, assuming that the training was terminated at those sizes. The results demonstrate the benefit of searching for the σ_{opt} because, if we terminated the training at ceiling size 1,500 or 6,000, we would obtain significantly lower test accuracy rates.

Thus far, we have only discussed the DTSVM results for medium-size data sets. For completeness, Table 11 shows the σ_{opt} values obtained by DTSVM on the large-size data sets, along with the proportion of training samples that flowed to homogeneous leaves. In Table 12, we show the σ_{opt} values obtained by DTSVM and RDSVM. The results explain why RDSVM required much longer training times and more NESVs for "Forest", "PPI" and "Webspam".

Since DTSVM's $\sigma_{opt} = 1,500$ for all four data sets, we do not have any tables for the large-size data sets correspond to Tables 9 and 10 for the medium-size data sets.

4. Generalization Error Bounds for the DTSVM Classifier

To provide a generalization error bound of DTSVM, we start with the following framework. Let $\mathbf{R}^d$ be the d-dimensional Euclidean space. We assume that a set of training examples $X_n = \{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_n, y_n)\}$ is given, where $(\mathbf{x}_k, y_k) \in \mathbf{R}^d \times \{-1, 1\}$ for $k = 1, \ldots, n$. The DTSVM method produces a classifier $h(\mathbf{x}, \pi, \mathbf{f})$, in which π is a binary tree comprised of L leaves, $\mathbf{f} = (f_1, \ldots, f_L)$, and f_i is related to the lSVM trained on leaf i of π for $i = 1, \ldots, L$. The binary tree π produces a partition function that maps an input in $\mathbf{R}^d$ to $\{1, \ldots, L\}$, and let $\pi(\mathbf{x})$ be the leaf that $\mathbf{x}$ flows to. On the other hand, the lSVM trained on leave i, $i = 1, \ldots, L$ is expressed as $f_i \circ \Phi$, where Φ maps an input in $\mathbf{R}^d$ to a Hilbert space $\mathbf{H}$, and f_i is a *linear* function from $\mathbf{H}$ to $\mathbf{R}$. Note that for a linear function $g : \mathbf{H} \to \mathbf{R}$, there exists some $w \in \mathbf{H}$ such that

$$g(z) = \langle w, z \rangle$$

for all $z \in \mathbf{H}$, and we define $\|g\| = \langle w, w \rangle^{1/2}$.

Note that if $\pi(\mathbf{x}) = i$, then $h(\mathbf{x},\pi,\mathbf{f}) = sign(f_i(\Phi(\mathbf{x}))$. Let us define the function $\mathbf{f}^\pi : \mathbf{R}^d \to \{-1,1\}$ by

$$f^\pi(\mathbf{x}) = f_{\pi(\mathbf{x})}(\Phi(\mathbf{x})).$$

It follows that $h(\mathbf{x},\pi,\mathbf{f}) = sign(\mathbf{f}^\pi(\mathbf{x}))$.

Sometimes, Φ is only defined implicitly. That is, instead of specifying the functional form of Φ, only the inner product of $\Phi(\mathbf{u})$ and $\Phi(\mathbf{v})$ is specified as

$$\langle \Phi(\mathbf{u}), \Phi(\mathbf{v}) \rangle = k(\mathbf{u},\mathbf{v}),$$

where $\mathbf{u},\mathbf{v} \in \mathbf{R}^d$, and $k(\cdot,\cdot)$ is a kernel function. In the remainder of this section, we assume that the function Φ is given and fixed.

Next, we define several notations used in this section. $\mathbf{N}$ is the set of natural numbers; $\mathbf{R}^+$ is the set of positive real numbers; $\mathcal{P}_L(\mathbf{R}^d)$ is the class of all functions from $\mathbf{R}^d$ to $\{1,\ldots,L\}$; $\mathcal{R}(\mathbf{H})$ is the class of all functions from $\mathbf{H}$ to $\mathbf{R}$; and $\mathcal{L}(\mathbf{H})$ is the class of all *linear* functions from $\mathbf{H}$ to $\mathbf{R}$. Moreover, if T is a set, we define $T^L = \{(t_1,\ldots,t_L) : t_i \in T \text{ for } i = 1,\ldots,L\}$; that is, T^L comprises all the L-tuples of T's elements.

To provide a bound for the generalization error of $h(\mathbf{x},\pi,\mathbf{f})$, we need the standard notions of shatter coefficients, margins and covering numbers, which are defined below. Further details can be found in Vapnik (1995) and Cristianini and Shawe-Taylor (2000). First, we define the notion of the shatter coefficient, which we use to measure the complexity of the partition functions corresponding to binary decision trees. Informally, the n^{th} shatter coefficient of a class $\mathcal{G} \subseteq \mathcal{P}_L(\mathbf{R}^d)$ is the maximum number of ways in which n points can be partitioned into L parts by functions in $\mathcal{G}$. Formally, we have the following definition.

Definition 1 *Let $\mathcal{G} \subseteq \mathcal{P}_L(\mathbf{R}^d)$. For any $n \in \mathbf{N}$, the n^{th} shatter coefficient of $\mathcal{G}$ is*

$$V(\mathcal{G},n) = \max_{S \subseteq R^d, |S|=n} |\{\pi_S : \pi \in \mathcal{G}\}|,$$

where π_S is the function obtained by restricting π to the domain S.

Next, we extend the standard notion of the margin to a collection of margins, one for each part of a partition, in the following way.

Definition 2 *Let $\mathbf{f} = (f_1,\ldots,f_L) \in (\mathcal{R}(\mathbf{H}))^L$, $\pi \in \mathcal{P}_L(\mathbf{R}^d)$, $X_n \subseteq \mathbf{R}^d \times \{-1,1\}$, and $\gamma = (\gamma_1,\ldots,\gamma_L) \in (\mathbf{R}^+)^L$. We say that $\mathbf{f}^\pi$ has margin γ on X_n, or $mg(\mathbf{f}^\pi, X_n) \geq \gamma$, if*

$$y \cdot \mathbf{f}^\pi(\mathbf{x}) \equiv y \cdot f_i(\Phi(\mathbf{x})) \geq \gamma_i$$

for any $i \in \{1,\ldots,L\}$ and any $(\mathbf{x},y) \in X_n$ with $\pi(\mathbf{x}) = i$.

In addition, we adopt the following notion of a covering number proposed by Alon et al. (1997). We use it to measure the complexity of the classifiers corresponding to lSVMs. Informally, a covering of a class $\mathcal{F} \subseteq \mathcal{R}(\mathbf{H})$ of functions with respect to a set D of n inputs is a collection of functions in $\mathcal{R}(\mathbf{H})$ such that any function $f \in \mathcal{F}$ is covered by some function g in the collection, in the sense that their values are within some distance η on all the inputs in D. The goal is to find the smallest such collection for any set D of n inputs in some domain E. Formally, we define the covering number as follows.

Definition 3 *Let $\eta \in \mathbf{R}^+$ and $\mathcal{F} \subseteq \mathcal{R}(\mathbf{H})$. For a subset $D \subseteq \mathbf{H}$, let $\mathcal{C}(\mathcal{F}, D, \eta)$ be the smallest collection of functions from D to $\mathbf{R}$ such that, for each $f \in \mathcal{F}$, we have $g \in \mathcal{C}(\mathcal{F}, D, \eta)$ with $|f(z) - g(z)| \leq \eta$ for each $z \in D$. For $E \subseteq \mathbf{H}$ and $n \in \mathbf{N}$, we define the covering number of $\mathcal{F}$ with respect to E, n and η as*

$$N(\mathcal{F}, E, n, \eta) = \max_{D \subseteq E, |D|=n} |\mathcal{C}(\mathcal{F}, D, \eta)|.$$

4.1 Hard Margin Bounds

We have a set X_n of n training examples drawn independently and at random according to the distribution $\mathcal{D}$. Moreover, we have a learned classifier $sign(\mathbf{f}^\pi)$, with $\pi \in \mathcal{P}_L(\mathbf{R}^d)$ and $\mathbf{f} \in (\mathcal{R}(\mathbf{H}))^L$, which classifies all the training examples correctly with a large margin. Our objective is to bound the *generalization error* of the classifier $sign(\mathbf{f}^\pi)$, which is defined as the probability that $sign(\mathbf{f}^\pi(\mathbf{x})) \neq y$, with $(\mathbf{x}, y)$ sampled according to $\mathcal{D}$. The following lemma gives such a bound, which generalizes a known result for SVMs (cf. Cristianini and Shawe-Taylor, 2000).

Lemma 4 *Let $\mathcal{G} \subseteq \mathcal{P}_L(\mathbf{R}^d)$, $\gamma = (\gamma_1, \ldots, \gamma_L) \in (\mathbf{R}^+)^L$, and $\mathcal{F} = \mathcal{F}_1 \times \cdots \times \mathcal{F}_L$, where $\mathcal{F}_i \subseteq \mathcal{R}(\mathbf{H})$ for $1 \leq i \leq L$. In addition, let $\mathcal{D}$ be a probability distribution on $\mathbf{R}^d \times \{-1, 1\}$, and let n be a large enough integer. Suppose a set of n samples X_n are drawn independently and at random according to $\mathcal{D}$, and consider any classifier $sign(\mathbf{f}^\pi)$, with $\pi \in \mathcal{G}$ and $\mathbf{f} \in \mathcal{F}$, such that $mg(\mathbf{f}^\pi, X_n) \geq \gamma$. Then, with probability $1 - \delta$, the generalization error of $mg(\mathbf{f}^\pi)$ will be at most*

$$\frac{2}{n}\left[\sum_{i=1}^{L} \log N(\mathcal{F}_i, E, 2n, \gamma_i/2) + \log V(\mathcal{G}, 2n) + \log(2/\delta)\right],$$

where $E = \{\Phi(\mathbf{x}) : (\mathbf{x}, y) \in supp(\mathcal{D})\}$ and $supp(\mathcal{D})$ is the support of $\mathcal{D}$.

We provide the proof in Appendix A, as it is rather lengthy and closely follows the standard approach and that of Cristianini and Shawe-Taylor (2000). The idea is to show that the functions $\mathbf{f}^\pi$, with $\pi \in \mathcal{G}$ and $\mathbf{f} \in \mathcal{F}$, can be "well covered" by a small number of functions, so that a union bound can be applied to provide an upper bound on the probability that our classifier has a large generalization error.

Before proceeding further, we explain the meaning of Lemma 4. Suppose for some $\mathcal{G}$ and $\mathcal{F} = \mathcal{F}_1 \times \cdots \times \mathcal{F}_L$, we can build a classifier $sign(\mathbf{f}^\pi)$ with $\pi \in \mathcal{G}$ and $\mathbf{f} \in \mathcal{F}$ that has a large margin and zero training error. Then, Lemma 4 gives us an upper bound on the generalization error of $sign(\mathbf{f}^\pi)$ in terms of the complexity of $\mathcal{G}$ and $\mathcal{F}_i$, where we measure the complexity of $\mathcal{G}$ by its shatter coefficient $V(\mathcal{G}, 2n)$ and the complexity of each $\mathcal{F}_i$ by its covering number $N(\mathcal{F}_i, E, 2n, \gamma_i/2)$. To obtain a small generalization error, we need to have a $\mathcal{G}$ with a small $V(\mathcal{G}, 2n)$ and an $\mathcal{F}_i$ with a small $N(\mathcal{F}_i, E, 2n, \gamma_i/2)$. However, this does not suggest that we can simply choose any $\mathcal{G}$ and $\mathcal{F}_i$ with small $V(\mathcal{G}, 2n)$ and $N(\mathcal{F}_i, E, 2n, \gamma_i/2)$ for any classification task. This is because we may not be able to build a classifier from $\mathcal{G}$ and $\mathcal{F}_i$ to classify every training example correctly with a large margin. For example, if we do not choose $\mathcal{G}$ properly (say, by using a random partition), the training examples in some parts of the partition may not be separated by SVMs with a large margin. Our main contribution is the discovery that decision trees are good partition functions when combined with SVMs, since they allow a large margin and only require a short training time for lSVMs.

Lemma 4 states a general result for any $\mathcal{G}$ and any $\mathcal{F}_i$ for $1 \leq i \leq L$. We now consider our choice of $\mathcal{G}$ and $\mathcal{F}_i$, which correspond to decision trees and SVMs respectively. For $\beta \in \mathbf{R}^+$, we define

$\mathcal{L}(\mathbf{H},\beta)$ as the class of all linear functions $f \in \mathcal{L}(\mathbf{H})$ with $\|f\| \leq \beta$. A bound can be obtained for the covering number of $\mathcal{L}(\mathbf{H},\beta)$ with respect to E, n and η, provided that E is a bounded subset of $\mathbf{H}$ (see, for example, Bartlett and Shawe-Taylor, 1998). This shows that, although there is an infinite number of functions in $\mathcal{L}(\mathbf{H},\beta)$, they can be covered by a small number of functions in $\mathcal{R}(\mathbf{H})$ with respect to any set of n points in E. As a result, the complexity of the class $\mathcal{L}(\mathbf{H},\beta)$ is low when measured by its covering number.

Lemma 5 *Let $\alpha,\beta,\eta \in \mathbf{R}^+$ and let $n \in \mathbf{N}$. Consider any $E \subseteq \mathbf{H}$ with $\|z\| \leq \rho$ for every $z \in E$. Then, there is a constant c such that*

$$\log N(\mathcal{L}(\mathbf{H},\beta),E,n,\eta) \leq c\frac{\rho^2\beta^2}{\eta^2}\log^2 n.$$

We also define $\mathcal{B}_L(\mathbf{R}^d)$ as the class of partition functions associated with binary trees containing L leaves that partition the space $\mathbf{R}^d$ into L axis-aligned parts, as described in Section 2. Clearly, $\mathcal{B}_L(\mathbf{R}^d) \subseteq \mathcal{P}_L(\mathbf{R}^d)$. The following lemma provides a bound on the n^{th} shatter coefficient of $\mathcal{B}_L(\mathbf{R}^d)$.

Lemma 6 *Let $d,n,L \in \mathbf{N}$. Then*

$$V(\mathcal{B}_L(\mathbf{R}^d),n) \leq L\log(dnL^2).$$

Proof Consider any n-element subset $S \subseteq \mathbf{R}^d$. We need to cut S into L parts. Initially, there is only one part in S. We perform the cut operation iteratively in the following way. Each time, we choose one part from at most $L-1$ existing parts of S and cut it into two parts. To do this, we pick one of the d dimensions and at most one of the $n-1$ cutting hyperplanes on that dimension. Thus, there are at most $(L-1)d(n-1) \leq dnL$ ways to perform one cut operation. To obtain L parts, we repeat the cut operation L-1 times; hence, the number of possible partitions is at most $(dnL)^{L-1} \leq (dnL)^L$. Finally, there are $L!$ ways to order the L parts of each partition, yielding the following result:

$$V(\mathcal{B}_L(\mathbf{R}^d),n) \leq (dnL)^L \cdot (L!) \leq (dnL^2)^L.$$

■

From the above three lemmas, we immediately derive the following theorem.

Theorem 7 *Let $\rho \in \mathbf{R}^+$, $\beta_i \in \mathbf{R}^+$ for $1 \leq i \leq L$, $\gamma = (\gamma_1,\ldots,\gamma_L) \in (\mathbf{R}^+)^L$, and $\mathcal{F} = \mathcal{L}(\mathbf{H},\beta_1) \times \cdots \times \mathcal{L}(\mathbf{H},\beta_L)$. In addition, let $\mathcal{D}$ be a probability distribution on $\mathbf{R}^d \times \{-1,1\}$ such that $\|\Phi(\mathbf{x})\| \leq \rho$ for every $(\mathbf{x},y) \in supp(\mathcal{D})$, and let n be a large enough integer. Suppose a set X_n of n samples are drawn independently and at random according to $\mathcal{D}$, and consider any classifier $sign(\mathbf{f}^\pi)$, with $\pi \in \mathcal{B}_L(\mathbf{R}^d)$ and $\mathbf{f} \in \mathcal{F}$, such that $mg(\mathbf{f}^\pi,X_n) \geq \gamma$. Then, with probability $1-\delta$, the generalization error of $sign(\mathbf{f}^\pi)$ will be at most*

$$\frac{c}{n}\left(\sum_{i=1}^{L}\frac{\rho^2\beta_i^2}{\gamma_i^2}\log^2 n + L\log(dnL^2) + \log(1/\delta)\right),$$

for some constant c.

From Theorem 7, we conclude that if a classifier partitions the training data set into a small number of parts (i.e., L is sufficiently small), and it classifies each training sample with a large margin (i.e., γ_i is large for each i), then the classifier is likely to have a small generalization error. However, this theorem does not indicate how to find a good value for L because, in general, it is hard to know how L affects the margins and the generalization error bound. Instead of being led by any analytical result, the DTSVM learning algorithm takes a data driven approach to find a good L.

Note that the bound in Theorem 7 has a similar form to the generalization error bound of the perceptron decision trees proposed by Bennett et al. (2000). The main difference is that in their bound, γ_i is the margin at the i^{th} internal node and the sum is over all the internal nodes. We remark that it is hard to tell which one of these two bounds is better because, in general, we do not know their actual values for different learning tasks.

4.2 Soft Margin Bounds

Note that Theorem 7 works in the case where the training data X_n can be separated with a margin vector γ. If the data is non-separable or noisy, we need to consider the notion of a soft margin (Cristianini and Shawe-Taylor, 2000). Suppose we have $\pi \in \mathcal{P}_L(\mathbf{R}^d)$, which partitions X_n into L parts: $X_n^1, \ldots, X_n^{(L)}$, where $X_n^{(i)} \equiv \{(\mathbf{x}, y) \in X_n : \pi(\mathbf{x}) = i\}$, and let us denote $X_n^{(i)} = \{(\mathbf{x}_{i,1}, y_{i,1}), \ldots, (\mathbf{x}_{i,n_i}, y_{i,n_i})\}$ for some $n_i \in \mathbf{N}$, for $1 \le i \le L$. In addition, suppose we have $\mathbf{f} = (f_1, \ldots, f_L) \in \mathcal{L}(\mathbf{H}, \beta_1) \times \cdots \times \mathcal{L}(\mathbf{H}, \beta_L)$, where $\beta_i \in \mathbf{R}^+$ for $1 \le i \le L$. Then, we can define the margin slack vector of f_i as follows.

Definition 8 *Let $\gamma = (\gamma_1, \ldots, \gamma_L) \in (\mathbf{R}^+)^L$. For $1 \le i \le L$ and $1 \le j \le n_i$, let*

$$\xi_{i,j} = \max(0, \gamma_i - y_{i,j} \cdot f_i(\Phi(\mathbf{x}_{i,j}))).$$

The definition reflects how far the elements of $X_n^{(i)}$ are from having a margin γ_i. Therefore, for $1 \le i \le L$, we call the vector $\xi_i = (\xi_{i,1}, \ldots, \xi_{i,n_i})$ the margin slack vector of f_i with respect to π and γ_i over X_n.

To find a bound for the generalization error of $sign(\mathbf{f}^{\pi})$ in the case of such a soft margin, we follow the approach of Shawe-Taylor and Cristianini (1999, 2002), which works for the case of $L = 1$. The idea is to map points of $\mathbf{H}$ to a higher dimensional space $\hat{\mathbf{H}}$ so that, for each i, the image of $X_n^{(i)}$ can be separated by some function $\hat{f}_i$ with the desired margin. Theorem 7 can then be applied. To find each $\hat{f}_i$, we present the following lemma, which is a simple extension of Shawe-Taylor & Cristianini's approach. For completeness, we provide the proof in Appendix B.

Lemma 9 *Suppose that $\|\Phi(\mathbf{x})\| \le \rho$ for any $(\mathbf{x}, y) \in supp(\mathcal{D})$. Then, there exists a space $\hat{\mathbf{H}}$, a mapping $\tau_\rho : \mathbf{H} \to \hat{\mathbf{H}}$, and a sequence $\hat{\mathbf{f}} = (\hat{f}_1, \ldots, \hat{f}_L)$ of L functions such that the following four facts hold.*

1. *For any $(\mathbf{x}, y) \in supp(\mathcal{D})$, $\|\tau_\rho(\Phi(x))\| \le \sqrt{2}\rho$.*
2. *For $1 \le i \le L$, $\hat{f}_i \in \mathcal{L}(\hat{\mathbf{H}}, \hat{\beta}_i)$ with $\hat{\beta}_i \le \sqrt{\beta_i^2 + \|\xi_i\|^2/\rho^2}$.*
3. *For $1 \le i \le L$, any $(\mathbf{x}_{i,j}, y_{i,j}) \in X_n^{(i)}$ will be classified correctly with a margin*

$$y_{i,j} \cdot \hat{f}_i(\tau_\rho(\Phi(\mathbf{x}_{i,j}))) \ge \gamma_i.$$

4. For $1 \le i \le L$ *and for any* $(\mathbf{x}, y) \notin X_n$, $\hat{f}_i(\tau_\rho(\Phi(\mathbf{x}))) = f_i(\Phi(\mathbf{x}))$.

According to this lemma, we define

$$\Psi = \tau_\rho \circ \Phi, \text{ and}$$

$$\hat{\mathbf{f}}^\pi(\mathbf{x}) = \hat{f}_{\pi(\mathbf{x})}(\Psi(\mathbf{x})).$$

Then, we know that $\hat{\mathbf{f}}^\pi$ has a margin $(\gamma_1, \ldots, \gamma_L)$ on X_n. Moreover, for $(\mathbf{x}, y) \in \mathit{supp}(\mathcal{D})$, we have

$$\|\Psi(\mathbf{x})\| \le \|\tau_\rho(\Phi(\mathbf{x}))\| \le \sqrt{2}\rho.$$

Now we can apply Theorem 7, with the space $\mathbf{H}$ replaced by $\hat{\mathbf{H}}$ and the mapping Φ replaced by Ψ, to obtain a bound on the generalization error of $\mathit{sign}(\hat{\mathbf{f}}^\pi)$, but with the quantity $\rho^2\beta^2/\gamma^2$ replaced by

$$\frac{2\rho^2(\beta_i^2 + \|\xi_i\|^2/\rho^2)}{\gamma_i^2} = \frac{2(\rho^2\beta_i^2 + \|\xi_i\|^2)}{\gamma_i^2}.$$

Finally, to bound the generalization error of $\mathit{sign}(\mathbf{f}^\pi)$, by Lemma 9, we know that for any $(\mathbf{x}, y) \notin X_n$, $\mathit{sign}(\mathbf{f}^\pi(\mathbf{x})) = \mathit{sign}(\hat{\mathbf{f}}^\pi(\mathbf{x}))$; therefore, $\mathit{sign}(\mathbf{f}^\pi)$ and $\mathit{sign}(\hat{\mathbf{f}}^\pi)$ have the same generalization error for inputs that do not fall within X_n. However, it is possible that the elements of X_n misclassified by $\mathit{sign}(\mathbf{f}^\pi)$ take a nontrivial measure in D, which results in $\mathit{sign}(\mathbf{f}^\pi)$ having a larger generalization error over $\mathcal{D}$ than $\mathit{sign}(\hat{\mathbf{f}}^\pi)$. As suggested by Shawe-Taylor and Cristianini (2002), this can be handled by modifying $\mathit{sign}(\mathbf{f}^\pi)$ on the misclassified elements in X_n. We call this new function the X_n-filtered version of $\mathit{sign}(\mathbf{f}^\pi)$. Then, we have the following theorem.

Theorem 10 *Let* $\rho \in \mathbf{R}^+$, $\beta_i \in \mathbf{R}^+$ *for* $1 \le i \le L$, $\gamma = (\gamma_1, \ldots, \gamma_L) \in (\mathbf{R}^+)^L$, *and* $\mathcal{F} = \mathcal{L}(\mathbf{H}, \beta_1) \times \cdots \times \mathcal{L}(\mathbf{H}, \beta_L)$. *In addition, let* $\mathcal{D}$ *be a probability distribution on* $\mathbf{R}^d \times \{-1, 1\}$ *such that* $\|\Phi(\mathbf{x})\| \le \rho$ *for every* $(\mathbf{x}, y) \in \mathit{supp}(\mathcal{D})$, *and let* n *be a large enough integer. Suppose a set of* n *samples,* X_n, *are drawn independently and at random according to* $\mathcal{D}$; *and consider any* $\pi \in \mathcal{B}(\mathbf{R}^d)$ *and* $\mathbf{f} = (f_1, \ldots, f_L) \in \mathcal{F}$, *such that for* $i \le i \le L$, f_i *has a margin slack vector* ξ_i *with respect to* π *and* γ_i *over* X_n. *Then, with probability* $1 - \delta$, *the generalization error of the* X_n*-filtered version of* $\mathit{sign}(\mathbf{f}^\pi)$ *will be at most*

$$\frac{c}{n}\left(\sum_{i=1}^{L}\left(\frac{\rho^2\beta_i^2 + \|\xi_i\|^2}{\gamma_i^2}\right)\log^2 n + L\log(dnL^2) + \log(1/\delta)\right),$$

for some constant c.

Theorem 10 shows that if we can build a classifier with a small L and a small $\|\xi_i\|$ for every i, then the first two terms inside the parentheses of the bound will be small, and the classifier is likely to have a small generalization error. As with Theorem 7, this does not suggest a way to choose the number L. Instead, the learning algorithm in Section 2 finds a good L in a data-driven manner. To facilitate a better understanding of the bound, we provide numerical values for the two terms derived by DTSVM classifiers. We also compare the numerical values with related quantities derived by global SVM (gSVM) classifiers, that is, SVM classifiers built on the full training data set.

4.3 A Numerical Investigation

Note that in Theorem 10, β_i and γ_i are interdependent quantities for $1 \le i \le L$, so we can fix one of them and try to optimize the other. In the formulation of the SVM optimization problem, the objective is to minimize β_i under the constraint that $\gamma_i = 1$ for $1 \le i \le L$. Under this convention, the bound in Theorem 10 becomes

$$\frac{c}{n}\left(\sum_{i=1}^{L}\left(\rho^2\beta_i^2 + \|\xi_i\|^2\right)\log^2 n + L\log(dnL^2) + \log(1/\delta)\right). \tag{1}$$

Recall that a DTSVM classifier is associated with a tree with L leaves and each leaf is associated with an lSVM. If the tree has only one leaf (i.e., $L = 1$), then the DTSVM classifier will be reduced to a gSVM classifier, which has the following generalization error bound

$$\frac{c}{n}\left(\left(\rho^2\beta^2 + \|\xi\|^2\right)\log^2 n + \log(1/\delta)\right) \tag{2}$$

(cf. Cristianini and Shawe-Taylor, 2000).

Let us compare the terms that appear in parentheses in (1) and (2). The second term $L\log(dnL^2)$ in (1) is the shatter coefficient of the partition function π associated with a binary tree. We claim that the value of (1) achieved by DTSVM is dominated by the first term, which is the sum of L quantities associated with L leaves of a binary tree, as opposed to the single quantity in (2). Moreover, the first term in (1) achieved by DTSVM is comparable to the corresponding quantity in (2) achieved by gSVM. The following results confirm the above two claims.

To validate the first claim, we compare the two leading terms in parentheses in (1). The first term is $T_1 = \sum_{i=1}^{L}(\rho^2\beta_i^2 + \|\xi_i\|^2)\log^2 n$ and the second term is $T_2 = L\log(dnL^2)$. The results, shown in Table 13, confirm the claim that T_1 far exceeds T_2 and (1) is dominated by T_1. Note that we compute T_1 under the following assumptions. (i) When the data set contains more than two labels, T_1 is taken as the average of the quantities over all classifiers. (ii) The value of ρ is always 1 when RBF kernels are involved. (iii) The value of $\|\xi_i\|^2$ is obtained from the solution to the quadratic programming optimization problem. Further details can be found in Cristianini and Shawe-Taylor (2000), Section 6.1.2.

To validate the second claim, we compare $R = \sum_{i=1}^{L}(\rho^2\beta_i^2 + \|\xi_i\|^2)$ and $S = \rho^2\beta^2 + \|\xi\|^2$, which are derived, respectively, from the first terms in the generalization error bounds for DTSVM and

gSVM classifiers (i.e., in (1) and (2)) with the common factor $\log^2 n$ removed from them. To ensure a meaningful comparison between R and S, both classifiers have to take the same (C,γ) values, which we specify as the optimal values for gSVM. As a result, we had to train new DTSVM classifiers for some data sets, using the same decomposition schemes (i.e., the same binary trees and same ceiling sizes) as the old classifiers, but different (C,γ) values.

Table 14 shows the values of S, R and R/L, derived from five data sets. The "Letter" and "News20" data sets are not included in the table because the DTSVM classifier using the designated values of (C,γ) would be the same as the gSVM on those data sets. It is clear that the values of R are as small as (less than 150), or of the same order of magnitude as, those of the corresponding S. In fact, S can be viewed as the slack-to-margin ratio and R as the sum of such ratios. The results show that each lSVM generates smaller slack-to-margin ratios than the corresponding gSVM, while the sum of lSVM ratios is comparable to the corresponding gSVM ratio. This explains why the test accuracy rates of DTSVM classifiers are comparable to those of gSVM classifiers.

5. Conclusion

We have proposed a method that uses a binary tree to decompose a given data space and trains an lSVM on each of the decomposed regions. The resultant DTSVM classifier can be constructed in a much shorter time than the gSVM classifier, and still achieve comparable accuracy rates to the latter. We also provide a generalization error bound for the DTSVM classifier. Using some data sets to compute the theoretical bounds for gSVM and DTSVM classifiers, we find that DTSVM classifiers generate comparable error bounds to those generated by gSVM classifiers. This finding explains why DTSVM classifiers can achieve more or less the same accuracy rates as gSVM classifiers.

Appendix A. Proof of Lemma 4

Let $\mathcal{G} \subseteq \mathcal{P}_L(\mathbf{R}^d)$, $\gamma = (\gamma_1,\ldots,\gamma_L) \in (\mathbf{R}^+)^L$, and $\mathcal{F}_i \subseteq \mathcal{R}(\mathbf{H})$ for $i = 1,\ldots,L$. The samples in X_n are drawn independently and at random according to the distribution $\mathcal{D}$.

Our goal is to find an upper bound for the probability of the following event.

- A_1: there exist $\pi \in \mathcal{G}$ and $\mathbf{f} = (f_1, \ldots, f_L) \in \mathcal{F}_1 \times \cdots \times \mathcal{F}_L$ such that $mg(\mathbf{f}^\pi, X_n) \geq \gamma$ and $err(\mathbf{f}^\pi, \mathcal{D}) > \varepsilon$, where $err(\mathbf{f}^\pi, \mathcal{D})$ is the probability that $sign(\mathbf{f}^\pi(\mathbf{x})) \neq y$ with $(\mathbf{x}, y)$ being sampled according to $\mathcal{D}$.

Note that $err(\mathbf{f}^\pi, \mathcal{D})$ is the generalization error of $sign(\mathbf{f}^\pi(\mathbf{x}))$. We relate event A_1 to another event A_2 in which an additional set of n independent samples, $\hat{X}_n$, are drawn at random according to $\mathcal{D}$ and the empirical error of $sign(\mathbf{f}^\pi(\mathbf{x}))$ over $\hat{X}_n$ is considered.

- A_2: there exist $\pi \in \mathcal{G}$ and $\mathbf{f} = (f_1, \ldots, f_L) \in \mathcal{F}_1 \times \cdots \times \mathcal{F}_L$ such that $mg(\mathbf{f}^\pi, X_n) \geq \gamma$ and $err(\mathbf{f}^\pi, \hat{X}_n) > \varepsilon/2$, where $err(\mathbf{f}^\pi, \hat{X}_n) = |\{(x, y) \in \hat{X}_n : sign(\mathbf{f}^\pi(\mathbf{x})) \neq y\}|/n$.

Following a standard argument (Vapnik, 1995), one can relate the probability of A_1 with that of A_2. More precisely, we have

$$\Pr_{X_n, \hat{X}_n}[A_2] \geq \Pr_{X_n, \hat{X}_n}[A_2 \wedge A_1] = \Pr_{X_n}[A_1] \cdot \Pr_{X_n, \hat{X}_n}[A_2 | A_1],$$

and by Chebyshev's inequality, one can show that

$$\Pr_{X_n, \hat{X}_n}[A_2 | A_1] = 1 - \Pr_{X_n, \hat{X}_n}[\neg A_2 | A_1] \geq 1 - 1/(n\varepsilon^2) \geq 1/2,$$

for a large enough n. Consequently, we have

$$\Pr_{X_n}[A_1] \leq \left(1 / \Pr_{X_n, \hat{X}_n}[A_2 | A_1]\right) \cdot \Pr_{X_n, \hat{X}_n}[A_2] \leq 2 \cdot \Pr_{X_n, \hat{X}_n}[A_2].$$

To find a bound for $\Pr_{X_n, \hat{X}_n}[A_2]$, let us consider the following event, A_3, where a set of $2n$ samples, X_{2n}, are drawn independently and at random according to $\mathcal{D}$, and X_{2n} is further divided randomly into two disjoint parts of equal size: W_1 and W_2.

- A_3: there exist $\pi \in \mathcal{G}$ and $\mathbf{f} = (f_1, \ldots, f_L) \in \mathcal{F}_1 \times \cdots \times \mathcal{F}_L$ such that $mg(\mathbf{f}^\pi, W_1) \geq \gamma$ and $err(\mathbf{f}^\pi, W_2) > \varepsilon/2$.

We observe that the distribution of $(X_n, \hat{X}_n)$ is identical to that of (W_1, W_2) over random X_{2n}; consequently we have

$$\Pr_{X_{2n}, W_1, W_2}[A_3] = \Pr_{X_n, \hat{X}_n}[A_2].$$

The next step is to find a bound for $\Pr_{X_{2n}, W_1, W_2}[A_3]$.

Let $\mathcal{G}(X_{2n})$ be the family of functions of $\mathcal{G}$ restricted to the domain $\{\mathbf{x} : (\mathbf{x}, y) \in X_{2n}\}$; and for $\pi \in \mathcal{G}(X_{2n})$, let

$$B^\pi_{\gamma/2}(X_{2n}) = \mathcal{C}\left(\mathcal{F}_1, \Phi(X^{(1)}_{2n}), \gamma_1/2\right) \times \cdots \times \mathcal{C}\left(\mathcal{F}_L, \Phi(X^{(L)}_{2n}), \gamma_L/2\right),$$

where $\Phi(X^{(i)}_{2n}) = \{\Phi(\mathbf{x}) : (\mathbf{x}, y) \in X_{2n}, \pi(\mathbf{x}) = i\}$. For $\mathbf{g} = (g_1, \ldots, g_L) \in B^\pi_{\gamma/2}(X_{2n})$, let $g^\pi(\mathbf{x}) = g_i(\mathbf{x})$ for $\mathbf{x} \in \Phi(X^{(i)}_{2n})$ for $1 \leq i \leq L$. Then, for $\pi \in \mathcal{G}(X_{2n})$ and $\mathbf{f} = (f_1, \ldots, f_n) \in \mathcal{F}_1 \times \cdots \times \mathcal{F}_L$, there exists $\mathbf{g} = (g_1, \ldots, g_L) \in B^\pi_{\gamma/2}(X_{2n})$ such that for any $(\mathbf{x}, y) \in X_n$, if $\pi(\mathbf{x}) = i$, then

$$|f_i(\Phi(\mathbf{x})) - g_i(\Phi(\mathbf{x}))| \leq \gamma_i/2.$$

For such $\mathbf{f}^\pi$ and $\mathbf{g}^\pi$, $mg(\mathbf{f}^\pi, W_1) \geq \gamma$ implies that $mg(\mathbf{g}^\pi, W_1) \geq \gamma/2$; and $err(\mathbf{f}^\pi, W_2) \geq \varepsilon/2$ implies that $err_{\gamma/2}(\mathbf{g}^\pi, W_2) \geq \varepsilon/2$, where $err_{\gamma/2}(\mathbf{g}^\pi, W_2)$ is the proportion of $(\mathbf{x}, y)$ in W_2 for which $g_i(\mathbf{x}) < \gamma_i/2$ if $\pi(\mathbf{x}) = i$. Therefore, the probability of the event A_3 cannot exceed that of the following event A_4.

- A_4: there exist $\pi \in \mathcal{G}(X_{2n})$ and $\mathbf{g} \in B^\pi_{\gamma/2}(X_{2n})$ such that $mg(\mathbf{g}^\pi, W_1) \geq \gamma/2$ and $err_{\gamma/2}(\mathbf{g}^\pi, W_2) \geq \varepsilon/2$.

To bound the probability of A_4, let us first consider any fixed X_{2n}, π, and $\mathbf{g}$, and consider an event, denoted as $A_4(X_{2n}, \pi, \mathbf{g})$, over the random division of X_{2n} into W_1 and W_2, such that $mg(\mathbf{g}^\pi, W_1) \geq \gamma/2$ and $err_{\gamma/2}(\mathbf{g}^\pi, W_2) \geq \varepsilon/2$. Note that for the event $A_4(X_{2n}, \pi, \mathbf{g})$ to occur, there are at most $2n - (\varepsilon/2)n$ elements of X_{2n} which can be separated by $\mathbf{g}^\pi$ with margin $\gamma/2$, and these elements must contain all the n elements of W_1. This implies that

$$\Pr_{W_1, W_2}[A_4(X_{2n}, \pi, \mathbf{g})] \leq \frac{\binom{2n-(\varepsilon/2)n}{n}}{\binom{2n}{n}} \leq \left(\frac{n}{2n}\right)^{(\varepsilon/2)n} = 2^{-\varepsilon n/2}.$$

Next, let us fix any X_{2n} and consider an event, denoted as $A_4(X_{2n})$, over the random division of X_{2n} into W_1 and W_2, such that the event $A_4(X_{2n}, \pi, \mathbf{g})$ occurs for some $\pi \in \mathcal{G}(X_{2n})$ and $\mathbf{g} \in B^\pi_{\gamma/2}(X_{2n})$. By a simple union bound, we have

$$\Pr_{W_1, W_2}[A_4(X_{2n})] \leq \sum_{\pi \in \mathcal{G}(X_{2n})} \sum_{g \in B^\pi_{\gamma/2}(X_{2n})} 2^{-\varepsilon n/2} = |\mathcal{G}(X_{2n})| \cdot |B^\pi_{\gamma/2}(X_{2n})| \cdot 2^{-\varepsilon n/2}.$$

Since $|X_{2n}| = 2n$, we have $|\mathcal{G}(X_{2n})| \leq V(\mathcal{G}, 2n)$. Moreover,

$$\begin{aligned}
\left|B^\pi_{\gamma/2}(X_{2n})\right| &= \prod_{1 \leq i \leq L} \left|C\left(\mathcal{F}_i, X^{(i)}_{2n}, \gamma_i/2\right)\right| \\
&\leq \prod_{1 \leq i \leq L} N\left(\mathcal{F}_i, E, |X^{(i)}_{2n}|, \gamma_i/2\right) \\
&\leq \prod_{1 \leq i \leq L} N(\mathcal{F}_i, E, 2n, \gamma_i/2),
\end{aligned}$$

where $E = \{\Phi(\mathbf{x}) : (\mathbf{x}, y) \in supp(\mathcal{D})\}$. Therefore, we have

$$\Pr_{W_1, W_2}[A_4(X_{2n})] \leq V(\mathcal{G}, 2n) \cdot \left(\prod_{1 \leq i \leq L} N(\mathcal{F}_i, E, 2n, \gamma_i/2)\right) \cdot 2^{-\varepsilon n/2}.$$

Note that by randomizing the selection of X_{2n}, the expected value of $\Pr_{W_1, W_2}[A_4(X_{2n})]$ is just the probability of A_4, over the random selection of X_{2n} and its random division into W_1 and W_2, from a simple probability fact.[1] As a result, we have

$$\begin{aligned}
\Pr_{X_{2n}, W_1, W_2}[A_4] &= \mathop{\mathrm{E}}_{X_{2n}}\left[\Pr_{W_1, W_2}[A_4(X_{2n})]\right] \\
&\leq V(\mathcal{G}, 2n) \cdot \left(\prod_{1 \leq i \leq L} N(\mathcal{F}_i, E, 2n, \gamma_i/2)\right) \cdot 2^{-\varepsilon n/2}.
\end{aligned}$$

1. Suppose A is an event over a joint distribution $(\mathbf{X}, \mathbf{W})$. Let $A(X)$ denote the event A conditioned on $\mathbf{X} = X$. Then, $\Pr_{(X,W) \in (\mathbf{X}, \mathbf{W})}[A] = \sum_Z \Pr_{X \in \mathbf{X}}[X = Z] \cdot \Pr_{W \in \mathbf{W}}[A(Z)] = \mathrm{E}_{X \in \mathbf{X}}[\Pr_{W \in \mathbf{W}}[A(X)]]$.

Finally, by combining all the bounds derived so far, we obtain

$$\Pr_{X_n}[A_1] \leq 2 \cdot \Pr_{X_{2n},W_1,W_2}[A_4] \leq 2 \cdot V(\mathcal{G},2n) \cdot \left(\prod_{1 \leq i \leq L} N(\mathcal{F}_i, E, 2n, \gamma_i/2) \right) \cdot 2^{-\varepsilon n/2},$$

which is at most d if

$$\varepsilon = \frac{2}{n} \left(\log V(\mathcal{G},2n) + \sum_{1 \leq i \leq L} \log N(\mathcal{F}_i, E, 2n, \gamma_i/2) + \log(2/\delta) \right).$$

This proves the lemma.

Appendix B. Proof of Lemma 9

We begin by describing the space $\hat{\mathbf{H}}$ and the mapping $\tau_\rho : \mathbf{H} \to \hat{\mathbf{H}}$. Consider the inner product space

$$I(\mathbf{H}) = \{ f \in \mathcal{R}(\mathbf{H}) : f(\mathbf{x}) \neq 0 \text{ for a finite number of } \mathbf{x} \in \mathbf{H} \},$$

where the inner product of f and g in $I(\mathbf{H})$ is defined as $\langle f, g \rangle = \sum_z f(z)g(z)$. Let

$$\hat{\mathbf{H}} = \mathbf{H} \times I(\mathbf{H}).$$

Define the function $\tau_\rho : \mathbf{H} \to \hat{\mathbf{H}}$ by

$$\tau_\rho(z) = (z, \rho \cdot \delta_z),$$

where δ_z is the function defined by

$$\delta_z(z') = \begin{cases} 1 & \text{if } z = z', \\ 0 & \text{otherwise.} \end{cases}$$

Then, the first item of the lemma holds, since for $(\mathbf{x}, y) \in supp(\mathcal{D})$, $\|\Phi(\mathbf{x})\| \leq \rho$; thus,

$$\|\tau_\rho(\Phi(x))\|^2 = \|\Phi(x)\|^2 + \|\rho \delta_{\Phi(x)}\|^2 \leq 2\rho^2.$$

Next, we prove the existence of $\hat{\mathbf{f}} = (\hat{f}_1, \ldots, \hat{f}_L)$. Since $I(\mathbf{H})$ is an inner product space, each of its elements defines a linear function on $I(\mathbf{H})$. Hence, for $(f,g) \in \mathcal{L}(\mathbf{H}) \times I(\mathbf{H})$, the function $(f,g) : \hat{\mathbf{H}} \to \mathbf{R}$, defined by

$$(f,g)(z,h) = f(z) + \langle g, h \rangle,$$

for $(z,h) \in \hat{\mathbf{H}}$, is a linear function. Now, for $1 \leq i \leq L$, we can define $\hat{f}_i : \hat{\mathbf{H}} \to \mathbf{R}$ by

$$\hat{f}_i = (f_i, g_i/\rho),$$

where $g_i \in I(\mathbf{H})$ is defined by

$$g_i = \sum_{j=1}^{n_i} \xi_{i,j} \cdot y_{i,j} \cdot \delta_{\Phi(\mathbf{x}_{i,j})}.$$

Since $f_i \in \mathcal{L}(\mathbf{H}, \beta_i)$, there exists $w_i \in \mathbf{H}$ with $\|w_i\| \leq \beta_i$ such that $f_i(z) = \langle w_i, z \rangle$. It follows that for $\hat{z} \in \hat{\mathbf{H}}$,

$$\hat{f}_i(\hat{z}) = \langle \hat{w}_i, \hat{z} \rangle,$$

where $\hat{w}_i = (w_i, g_i/\rho)$, and

$$\|\hat{w}_i\|^2 = \|w_i\|^2 + \sum_{j=1}^{n_i} |\xi_{i,j}|^2/\rho^2 \leq \beta_i^2 + \|\xi_i\|^2/\rho^2.$$

Therefore, $\hat{f}_i \in \mathcal{L}(\hat{\mathbf{H}}, \hat{\beta}_i)$, where $\hat{\beta}_i = \sqrt{\beta_i^2 + \|\xi_i\|^2/\rho^2}$, and the second item of the lemma holds.

Furthermore, for any $(\mathbf{x}_{i,j}, y_{i,j}) \in X_n^{(i)}$, we have

$$\begin{aligned} y_{i,j} \cdot \hat{f}_i(\tau_\rho(\Phi(\mathbf{x}_{i,j}))) &= y_{i,j} \cdot f_i(\Phi(\mathbf{x}_{i,j})) + y_{i,j} \cdot (\xi_{i,j} \cdot y_{i,j}) \\ &= y_{i,j} \cdot f_i(\Phi(\mathbf{x}_{i,j})) + \xi_{i,j} \\ &\geq \gamma_i, \end{aligned}$$

by the definition of $\xi_{i,j}$. Thus, the third item of the lemma also holds.

Finally, for $1 \leq i \leq L$ and for any $(\mathbf{x}, y) \notin X_n$, we have

$$\hat{f}_i(\tau_\rho(\Phi(\mathbf{x}))) = f_i(\Phi(\mathbf{x})) + \sum_{j=1}^{n_i} \xi_{i,j} \cdot y_{i,j} \cdot \delta_{\Phi(\mathbf{x}_{i,j})}(\Phi(\mathbf{x})) = f_i(\Phi(\mathbf{x})).$$

Thus, the fourth item of the lemma holds as well. This concludes the proof of Lemma 9.

Abstract

A common setting for novelty detection assumes that labeled examples from the nominal class are available, but that labeled examples of novelties are unavailable. The standard (inductive) approach is to declare novelties where the nominal density is low, which reduces the problem to density level set estimation. In this paper, we consider the setting where an unlabeled and possibly contaminated sample is also available at learning time. We argue that novelty detection in this semi-supervised setting is naturally solved by a general reduction to a binary classification problem. In particular, a detector with a desired false positive rate can be achieved through a reduction to Neyman-Pearson classification. Unlike the inductive approach, semi-supervised novelty detection (SSND) yields detectors that are optimal (e.g., statistically consistent) regardless of the distribution on novelties. Therefore, in novelty detection, unlabeled data have a substantial impact on the theoretical properties of the decision rule. We validate the practical utility of SSND with an extensive experimental study.

We also show that SSND provides distribution-free, learning-theoretic solutions to two well known problems in hypothesis testing. First, our results provide a general solution to the general two-sample problem, that is, the problem of determining whether two random samples arise from the same distribution. Second, a specialization of SSND coincides with the standard p-value approach to multiple testing under the so-called random effects model. Unlike standard rejection regions based on thresholded p-values, the general SSND framework allows for adaptation to arbitrary alternative distributions in multiple dimensions.

Keywords: semi-supervised learning, novelty detection, Neyman-Pearson classification, learning reduction, two-sample problem, multiple testing

1. Introduction

Several recent works in the machine learning literature have addressed the issue of novelty detection. The basic task is to build a decision rule that distinguishes *nominal* from *novel* patterns. The learner is given a random sample $x_1, \ldots, x_m \in \mathcal{X}$ of nominal patterns, obtained, for example, from a

*. A preliminary version of this work appeared at AISTATS (Scott and Blanchard, 2009).

controlled experiment or an expert. Labeled examples of novelties, however, are not available. The standard approach has been to estimate a level set of the nominal density (Schölkopf et al., 2001; Steinwart et al., 2005; Scott and Nowak, 2006; Vert and Vert, 2006; El-Yaniv and Nisenson, 2007; Hero, 2007), and to declare test points outside the estimated level set to be novelties. We refer to this approach as *inductive* novelty detection.

In this paper we incorporate unlabeled data into novelty detection, and argue that this framework offers substantial advantages over the inductive approach. In particular, we assume that in addition to the nominal data, we also have access to an *unlabeled* sample $x_{m+1},\ldots,x_{m+n}$ consisting potentially of both nominal and novel data. We assume that each x_i, $i = m+1,\ldots,m+n$ is paired with an unobserved label $y_i \in \{0,1\}$ indicating its status as nominal ($y_i = 0$) or novel ($y_i = 1$), and that $(x_{m+1},y_{m+1}),\ldots,(x_{m+n},y_{m+n})$ are realizations of the random pair (X,Y) with joint distribution P_{XY}. The marginal distribution of an unlabeled pattern X is the contamination model

$$X \sim P_X = (1-\pi)P_0 + \pi P_1,$$

where P_y, $y = 0,1$, is the conditional distribution of $X|Y = y$, and $\pi = P_{XY}(Y = 1)$ is the a priori probability of a novelty. Similarly, we assume $x_1,\ldots,x_m$ are realizations of P_0. We assume no knowledge of P_X, P_0, P_1, or π, although in Section 6 (where we want to estimate the proportion π) we do impose a natural condition on P_1 that ensures identifiability of π.

We take as our objective to build a decision rule with a small false negative rate subject to a fixed constraint α on the false positive rate. Our emphasis here is on *semi-supervised* novelty detection (SSND), where the goal is to construct a general detector that could classify an arbitrary test point. This general detector can of course be applied in the *transductive* setting, where the goal is to predict the labels $y_{m+1},\ldots,y_{m+n}$ associated with the unlabeled data. Our results extend in a natural way to this setting.

Our basic contribution is to develop a general solution to SSND by a surrogate problem related to Neyman-Pearson (NP) classification, which is the problem of binary classification subject to a user-specified constraint α on the false positive rate. In particular, we argue that SSND can be addressed by applying a NP classification algorithm, treating the nominal and unlabeled samples as the two classes. Even though a sample from P_1 is not available, we argue that our approach can effectively adapt to any novelty distribution P_1, in contrast to the inductive approach which is only optimal in certain extremely unlikely scenarios. That is, by solving the surrogate problem, we obtain a classifier f such that, up to a tolerance that shrinks as sample sizes increase, $P_1(f(X) = 0)$ is minimal, while $P_0(f(X) = 1) \leq \alpha$.

Our learning reduction allows us to import existing statistical performance guarantees for Neyman-Pearson classification (Cannon et al., 2002; Scott and Nowak, 2005) and thereby deduce generalization error bounds, consistency, and rates of convergence for novelty detection. In addition to these theoretical properties, the reduction to NP classification has practical advantages, in that it allows essentially any algorithm for NP classification to be applied to SSND.

SSND is particularly suited to situations where the novelties occupy regions where the nominal density is high. If a single novelty lies in a region of high nominal density, it will appear nominal. However, if many such novelties are present, the unlabeled data will be more concentrated than one would expect from just the nominal component, and the presence of novelties can be detected. SSND may also be thought of as semi-supervised classification in the setting where labels from one class are difficult to obtain (see discussion of LPUE below). We emphasize that we do not assume

that novelties are rare, that is, that π is very small, as in anomaly detection. However, SSND is applicable to anomaly detection provided n is sufficiently large.

We also discuss estimation of π and the special case of $\pi = 0$, which is not treated in our initial analysis. We present a hybrid approach that automatically reverts to the inductive approach when $\pi = 0$, while preserving the benefits of the NP reduction when $\pi > 0$. In addition, we describe a distribution-free one-sided confidence interval for π, consistent estimation of π, and testing for $\pi = 0$, which amounts to a general version of the two-sample problem in statistics. We also discuss connections to multiple testing, where we show that SSND generalizes a standard approach to multiple testing, based on thresholding p-values, under the common "random effects" model. Whereas the p-value approach is optimal only under strong assumptions on the alternative distribution, SSND can optimally adapt to arbitrary alternatives.

The paper is structured as follows. After reviewing related work in the next section, we present the general learning reduction to NP classification in Section 3, and apply this reduction in Section 4 to deduce statistical performance guarantees for SSND. Section 5 presents our hybrid approach, while Section 6 applies learning-theoretic principles to inference on π. Connections to multiple testing are developed in Section 7. Experiments are presented in Section 8, while conclusions are discussed in the final section. Shorter proofs are presented in the main text, and longer proofs appear in the first appendix.

2. Related Work

Inductive novelty detection: Described in the introduction, this problem is also known as one-class classification (Schölkopf et al., 2001) or learning from only positive (or only negative) examples. The standard approach has been to assume that novelties are outliers with respect to the nominal distribution, and to build a novelty detector by estimating a level set of the nominal density (Scott and Nowak, 2006; Vert and Vert, 2006; El-Yaniv and Nisenson, 2007; Hero, 2007). As we discuss below, density level set estimation is equivalent to assuming that novelties are uniformly distributed on the support of P_0. Therefore these methods can perform arbitrarily poorly (when P_1 is far from uniform, and still has significant overlap with P_0). In Steinwart et al. (2005), inductive novelty detection is reduced to classification of P_0 against P_1 , wherein P_1 can be arbitrary. However an i.i.d. sample from P_1 is assumed to be available in addition to the nominal data. In contrast, the semi-supervised approach optimally adapts to P_1, where only an unlabeled contaminated sample is available besides the nominal data. In addition, we address estimation and testing of the proportion of novelties.

Classification with unlabeled data: In transductive and semi-supervised classification, labeled training data $\{(x_i, y_i)\}_{i=1}^m$ from *both* classes are given. The setting proposed here is a special case where training data from only one class are available. In two-class problems, unlabeled data typically have at best a slight effect on constants, finite sample bounds, and rates (Rigollet, 2007; Lafferty and Wasserman, 2008; Ben-David et al., 2008; Singh et al., 2009), and are not needed for consistency. In contrast, we argue that for novelty detection, unlabeled data are essential for these desirable theoretical properties to hold.

Learning from positive and unlabeled examples: Classification of an unlabeled sample given data from one class has been addressed previously, but with certain key differences from our work. This body of work is often termed learning from "positive" and unlabeled examples (LPUE), al-

though in our context we tend to think of nominal examples as negative. Terminology aside, a number of algorithms have been developed, which we now relate to the present work.

One class of algorithms proceeds roughly as follows: First, identify unlabeled points for which it seems highly likely that $y_i = 1$. Second, learn a classifier from the known positive examples and the supposed negative examples. Use it on the unlabeled data to update the group of candidates for the negative class and repeat until a stable labeling is reached. Several such algorithms are reviewed in Zhang and Lee (2005) and Zhang and Zuo (2008), but they tend to be heuristic in nature and sensitive to the initial choice of negative examples.

A theoretical analysis of LPUE is provided by Denis (1998); Denis et al. (2005) from the viewpoint of probably approximately correct (PAC) learnable classes. In PAC learnability, the objective is to find specific classes of classifiers such that the optimal classifier in that class can be approximated arbitrarily well, and where the number of samples required is polynomial in the inverse of the error tolerance. While some ideas are common with the present work (such as classifying the nominal sample against the contaminated sample as a proxy for the ultimate goal), our point of view is relatively different and based on statistical learning theory. In particular, our input space can be non-discrete and we assume the distributions P_0 and P_1 can overlap, which leads us to use the NP classification setting and study universal consistency properties.

Several other approaches have been developed which, either explicitly or implicitly, rely on a reduction to a classification problem. Steinberg and Cardell (1992) and Ward et al. (2009) propose frameworks based on logistic regression, but both assume that π is known. Elkan and Noto (2008) assume a particular sampling scheme where m and n are related in such a way that π can be readily estimated. Unfortunately, this sampling assumption is not valid in many applications of interest. All three of these works derive their algorithms by a consideration of posterior probabilities, and consequently they require that π is known or can be estimated. In contrast, our approach adopts the (non-Bayesian) Neyman-Pearson criterion and in no way depends on the ability to know or estimate π.

The idea of reducing LPUE to a binary classification problem has also been treated by Zhang and Lee (2005), Liu et al. (2002), Lee and Liu (2003) and Liu et al. (2003). Most notably, Liu et al. (2002) provide sample complexity bounds for VC classes for the learning rule that minimizes the number of false negatives while controlling the proportion of false positives at a certain level. Our approach extends theirs in several respects. First, Liu et al. (2002) does not consider approximation error or consistency, nor do the bounds established there imply consistency. In contrast, we present a general reduction that is not specific to any particular learning algorithm, and can be used to deduce consistency or rates of convergence. Our work also makes several contributions not addressed previously in the LPUE literature, including our results relating to the case $\pi = 0$, to the estimation of π, and to multiple testing.

We also note recent work by Smola et al. (2009) described as *relative novelty detection*. This work is presented as an extension of standard one-class classification to a setting where a reference measure (indicating regions where novelties are more likely) is known through a sample. In practice, the authors take this sample to be a contaminated sample consisting of both nominal and novel measurements, so the setting is the same as ours. The emphasis in this work is primarily on a new kernel method, whereas our work features a general learning reduction and learning theoretic analysis.

Multiple testing: The multiple testing problem is also concerned with the simultaneous detection of many potentially abnormal measurements (viewed as rejected null hypotheses). In Section 7, we

discuss in detail the relation of our contamination model to the *random effects model*, a standard model in multiple testing. We show how SSND is, in several respects, a generalization of that model, and includes several different extensions proposed in the recent multiple testing literature. The SSND model, and the results presented in this paper, are thus relevant to multiple testing as well, and suggest an interesting point of view to this domain. In particular, through a reduction to classification, we introduce broad connections to statistical learning theory.

3. The Fundamental Reduction

To begin, we first consider the population version of the problem, where the distributions are known completely. Recall that $P_X = (1-\pi)P_0 + \pi P_1$ is the distribution of unlabeled test points. Adopting a hypothesis testing perspective, we argue that the optimal tests for $H_0 : X \sim P_0$ vs. $H_1 : X \sim P_1$ are identical to the optimal tests for $H_0 : X \sim P_0$ vs. $H_X : X \sim P_X$. The former are the tests we would like to have, and the latter are tests we can estimate by treating the nominal and unlabeled samples as labeled training data for a binary classification problem.

To offer some intuition, we first assume that P_y has density h_y, $y = 0, 1$. According to the Neyman-Pearson Lemma (Lehmann, 1986), the optimal test with size (false positive rate) α for $H_0 : X \sim P_0$ vs. $H_1 : X \sim P_1$ is given by thresholding the likelihood ratio $h_1(x)/h_0(x)$ at an appropriate value. Similarly, letting $h_X = (1-\pi)h_0 + \pi h_1$ denote the density of P_X, the optimal tests for $H_0 : X \sim P_0$ vs. $H_X : X \sim P_X$ are given by thresholding $h_X(x)/h_0(x)$. Now notice

$$\frac{h_X(x)}{h_0(x)} = (1-\pi) + \pi \frac{h_1(x)}{h_0(x)}.$$

Thus, the likelihood ratios are related by a simple monotone transformation, provided $\pi > 0$. Furthermore, the two problems have the same null hypothesis. Therefore, by the theory of uniformly most powerful tests (Lehmann, 1986), the optimal test of size α for one problem is also optimal, *with the same size* α, for the other problem. In other words, we can discriminate P_0 from P_1 by discriminating between the nominal and unlabeled distributions. Note the above argument does not require knowledge of π other than $\pi > 0$.

The hypothesis testing perspective also sheds light on the inductive approach. In particular, estimating the nominal level set $\{x : h_0(x) \geq \lambda\}$ is equivalent to thresholding $1/h_0(x)$ at $1/\lambda$. Thus, the density level set is an optimal decision rule provided h_1 is constant on the support of h_0. This assumption that P_1 is uniform on the support of P_0 is therefore implicitly adopted by a majority of works on novelty detection.

We now drop the requirement that P_0 and P_1 have densities. Let $f : \mathbb{R}^d \to \{0, 1\}$ denote a classifier. For $y = 0, 1$, let

$$R_y(f) := P_y(f(X) \neq y)$$

denote the false positive rate (FPR) and false negative rate (FNR) of f, respectively. For greater generality, suppose we restrict our attention to some fixed set of classifiers $\mathcal{F}$ (possibly the set of all classifiers). The optimal FNR for a classifier of the class $\mathcal{F}$ with FPR $\leq \alpha, 0 \leq \alpha \leq 1$, is

$$\begin{aligned} R^*_{1,\alpha}(\mathcal{F}) \quad := \quad & \inf_{f \in \mathcal{F}} R_1(f) \\ & \text{s.t. } R_0(f) \leq \alpha. \end{aligned} \tag{1}$$

Similarly, introduce

$$\begin{aligned} R_X(f) &:= P_X(f(X)=0) \\ &= \pi R_1(f) + (1-\pi)(1-R_0(f)) \end{aligned}$$

and let

$$\begin{aligned} R^*_{X,\alpha}(\mathcal{F}) &:= \inf_{f\in\mathcal{F}} R_X(f) \\ &\quad \text{s.t. } R_0(f) \le \alpha. \end{aligned} \tag{2}$$

In this paper we will always assume the following property (involving $\mathcal{F}, P_0$ and P_1) holds:

(A) For any $\alpha \in (0,1)$, there exists $f^* \in \mathcal{F}$ such that $R_0(f^*) = \alpha$ and $R_1(f^*) = R^*_{1,\alpha}(\mathcal{F})$.

Remark. *This assumption is in particular satisfied if the class $\mathcal{F}$ is such that for any $f \in \mathcal{F}$ with $R_0(f) < \alpha$, we can find another classifier $f' \in \mathcal{F}$ with $R_0(f') = \alpha$ and $f' \ge f$ (so that $R_1(f') \le R_1(f)$). When P_0 is absolutely continuous with respect to Lebesque measure, this property can be easily verified for many common classifier sets, for example linear classifiers, decision trees or radial basis function classifiers.*

Even without any assumptions on the distribution, it is possible to ensure that **(A)** *is satisfied provided one extends the class $\mathcal{F}$ to a larger class containing randomized classifiers obtained by convex combination of classifiers of the original class. This construction is standard in the receiver operating characteristic (ROC) literature. Some basic results on this topic are recalled in Appendix B in relation to the above assumption.*

By the following result, the optimal classifiers for problems (1) and (2) are the same. Furthermore, one direction of this equivalence also holds in an approximate sense. In particular, approximate solutions to $X \sim P_0$ vs. $X \sim P_X$ translate to approximate solutions for $X \sim P_0$ vs. $X \sim P_1$. The following theorem constitutes our main *learning reduction* in the sense of Beygelzimer et al. (2005):

Theorem 1 *Assume property* **(A)** *is satisfied. Consider any α, $0 \le \alpha \le 1$, and assume $\pi > 0$. Then for any $f \in \mathcal{F}$ the two following statements are equivalent:*

(i) $R_X(f) = R^*_{X,\alpha}(\mathcal{F})$ and $R_0(f) \le \alpha$.

(ii) $R_1(f) = R^*_{1,\alpha}(\mathcal{F})$ and $R_0(f) = \alpha$.

More generally, let $L_{1,\alpha}(f,\mathcal{F}) = R_1(f) - R^*_{1,\alpha}(\mathcal{F})$ and $L_{X,\alpha}(f,\mathcal{F}) = R_X(f) - R^*_{X,\alpha}(\mathcal{F})$ denote the excess losses (regrets) for the two problems, and assume $\pi > 0$. If $R_0(f) \le \alpha + \varepsilon$ for $\varepsilon \ge 0$, then

$$L_{1,\alpha}(f,\mathcal{F}) \le \pi^{-1}(L_{X,\alpha}(f,\mathcal{F}) + (1-\pi)\varepsilon).$$

Proof . For any classifier f, we have the relation $R_X(f) = (1-\pi)(1-R_0(f)) + \pi R_1(f)$. We start with proving $(ii) \Rightarrow (i)$. Consider $f \in \mathcal{F}$ such that $R_1(f) = R^*_{1,\alpha}(\mathcal{F})$ and $R_0(f) = \alpha$, but assume $R_X(f) > R^*_X(\mathcal{F})$. Let $f' \in \mathcal{F}$ such that $R_X(f') < R_X(f)$ and $R_0(f') \le \alpha$. Then since $\pi > 0$,

$$\begin{aligned} R_1(f') &= \pi^{-1}\left(R_X(f') - (1-\pi)(1-R_0(f'))\right) \\ &< \pi^{-1}\left(R_X(f) - (1-\pi)(1-\alpha)\right) \\ &= R_1(f), \end{aligned}$$

contradicting minimality of $R_1(f)$.

To establish the converse implication, consider $f \in \mathcal{F}$ such that $R_X(f) = R^*_{X,\alpha}(\mathcal{F})$ and $R_0(f) \leq \alpha$, but assume $R_1(f) > R^*_{1,\alpha}(\mathcal{F})$ or $R_0(f) < \alpha$. Let f' be such that $R_0(f') = \alpha$ and $R_1(f') = R^*_1(\mathcal{F})$, whose existence is ensured by assumption **(A)**. Then

$$\begin{aligned} R_X(f') &= (1-\pi)(1-\alpha) + \pi R_1(f') \\ &< (1-\pi)(1-R_0(f)) + \pi R_1(f) \\ &= R_X(f), \end{aligned}$$

contradicting minimality of $R_X(f)$. To prove the final statement, first note that we established $R^*_{X,\alpha}(\mathcal{F}) = \pi R^*_{1,\alpha}(\mathcal{F}) + (1-\pi)(1-\alpha)$, by the first part of the theorem. By subtraction we have

$$\begin{aligned} L_{1,\alpha}(f,\mathcal{F}) &= \pi^{-1}(L_{X,\alpha}(f,\mathcal{F}) + (1-\pi)(R_0(f)-\alpha)) \\ &\leq \pi^{-1}(L_{X,\alpha}(f,\mathcal{F}) + (1-\pi)\varepsilon). \end{aligned}$$

■

Theorem 1 suggests that we may estimate the solution to (1) by solving a surrogate binary classification problem, treating $x_1, \ldots, x_m$ as one class and $x_{m+1}, \ldots, x_{m+n}$ as the other.

In the rest of the paper, we explore the consequences of this reduction from a theoretical as well as practical perspective. In the next section, we illustrate on the theoretical side, in the case of an empirical risk minimization (ERM) type algorithm, how a finite sample bound for NP classification translates to a finite sample bound for SSND and leads to desirable properties such as consistency. On the other hand, algorithms we can analyze (such as ERM) often do not have the best performance on actual data, and may be computationally infeasible (a situation that is not specific to SSND). Thus in the experimental Section 8 we implement a different method, namely simple but effective schemes based on kernel density estimates. It is important to observe that Theorem 1 still applies to these methods since it just compares two objective functions and is agnostic to the method used.

4. Statistical Performance Guarantees

We now illustrate how Theorem 1 leads to performance guarantees for SSND. We consider the case of a fixed set of classifiers $\mathcal{F}$ having finite VC-dimension (Vapnik, 1998), and the NP classification algorithm

$$\begin{aligned} \widehat{f}_\tau = \arg\min_{f \in \mathcal{F}} & \widehat{R}_X(f) \\ \text{s.t. } & \widehat{R}_0(f) \leq \alpha + \tau, \end{aligned}$$

based on (constrained) empirical risk minimization, where

$$\widehat{R}_X(f) = \frac{1}{n} \sum_{i=m+1}^{m+n} \mathbf{1}_{\{f(x_i) \neq 1\}}, \quad \widehat{R}_0(f) = \frac{1}{m} \sum_{i=1}^{m} \mathbf{1}_{\{f(x_i) \neq 0\}}.$$

This rule was analyzed in Cannon et al. (2002) and Scott and Nowak (2005). Define the precision of a classifier f for class i as $Q_i(f) = P_{XY}(Y = i | f(X) = i)$ (the higher the precision, the better the

performance). Then we have the following result bounding the difference of the quantities R_i and Q_i to their optimal values over $\mathcal{F}$:

Theorem 2 *Assume $x_1,\ldots,x_m$ and $x_{m+1},\ldots,x_{m+n}$ are i.i.d. realizations of P_0 and P_X, respectively, and that the two samples are independent of each other. Assume $\pi > 0$. Let $\mathcal{F}$ be a set of classifiers of VC-dimension V. Assume property* **(A)** *is satisfied and denote by f^* an optimal classifier in $\mathcal{F}$ with respect to the criterion in* (1)*. Fixing $\delta > 0$, define $\varepsilon_k = \sqrt{\frac{V\log k - \log\delta}{k}}$. There exist absolute constants c, c' such that, if we choose $\tau = c\varepsilon_n$, the following bounds hold with probability $1-\delta$:*

$$R_0(\widehat{f}_\tau) - \alpha \leq c'\varepsilon_n\,; \tag{3}$$

$$R_1(\widehat{f}_\tau) - R_1(f^*) \leq c'\pi^{-1}(\varepsilon_n + \varepsilon_m)\,; \tag{4}$$

$$Q_i(f^*) - Q_i(\widehat{f}_\tau) \leq \frac{c'}{P(f^*(X)=i)}(\varepsilon_n+\varepsilon_m),\ i=0,1\,. \tag{5}$$

The proof is given in Appendix A. The primary technical ingredients in the proof are Theorem 3 of Scott and Nowak (2005) and the learning reduction of Theorem 1 above. The above theorem shows that the procedure is consistent inside the class $\mathcal{F}$ for all criteria considered, that is, these quantities decrease (resp. increase) asymptotically to their value at f^*. This is in contrast to the statistical learning bounds previously obtained (Liu et al., 2002, Thm. 2), which do not imply consistency.

Following Scott and Nowak (2005), by extending suitably the argument and the method in the spirit of structural risk minimization over a sequence of classes $\mathcal{F}_k$ having the universal approximation property, we can conclude that this method is universally consistent (that is, relevant quantities converge to their value at f^*, where f^* is the solution of (1) over the set of all possible classifiers). Therefore, although technically simple, the reduction result of Theorem 1 allows us to deduce stronger results than the existing ones concerning this problem. This can be paralleled with the result that inductive novelty detection can be reduced to classification against uniform data (Steinwart et al., 2005), which made the statistical learning study of that problem significantly simpler.

It is interesting to note that the multiplicative constant in front of the rate of convergence of the precision criteria is $P_X(f^*(X)=i)^{-1}$ rather than π^{-1} for R_1. In particular $P_X(f^*(X)=0) \geq (1-\pi)(1-\alpha)$, so that the convergence rate for class 0 precision is not significantly affected as $\pi \to 0$. Similarly $P_X(f^*(X)=1) \geq (1-\pi)\alpha$, so the convergence rate for class 1 precision depends more crucially on the (known) α than on π.

For completeness, we briefly discuss the optimality of $Q_i(f^*)$ in (5) in the sense of the criterion Q_i itself. Under an additional minor condition, it is possible to show (the details are given at the end of Appendix B) that under the constraint $R_0(f) \leq \alpha$, the best attainable precision for class 0 in the set $\mathcal{F}$ is attained by $f = f^*$. Therefore, in (5) ($i=0$), we are really comparing the precision of $\widehat{f}_\tau$ against the best possible class 0 precision given the FPR constraint. On the other hand, it does not make sense to consider the best attainable class 1 precision under an upper constraint on R_0, since we can have both $R_0 \to 0$ and $Q_1 \to 1$ by only rejecting a vanishingly small proportion of very sure novelties. But it can easily be seen that f^* realizes the best attainable class 1 precision under the *equality* constraint $R_0(f) = \alpha$.

We emphasize that the above result is but one of many possible theorems that could be deduced from the learning reduction; other results from Neyman-Pearson classification could also be applied. We also remark that, although the previous theorem corresponds to the semi-supervised setting, an

analogous transductive result is easily obtained by incorporating an additional uniform deviation bound relating the empirical error rates on the unlabeled data to the true error rates.

5. The Case $\pi = 0$ and a Hybrid Method

The preceding reduction of SSND to NP classification is only justified when $\pi > 0$. Aside from the analysis breaking down, this can be seen as follows. The unlabeled sample is a draw from $P_X = (1-\pi)P_0 + \pi P_1$. When $\pi = 0$, the unlabeled sample is a draw from P_0. Therefore it contains no information about P_1. Were we to solve the surrogate NP problem, we would be attempting to classify between two identical distributions, and the best we could do would be random guessing. This is confirmed in Table 2 (case $\pi = 0$) where the AUC values for SSND are near one half. Our goal in this section is to develop a learning reduction, and a parallel result to Theorem 1 in Section 3, but which handles the case $\pi = 0$ more sensibly.

When $\pi = 0$, we have no information about P_1 in either sample. Therefore, the only way to get any traction on the problem is to make some assumption about P_1. The inductive method makes such an assumption (as noted previously in the paper), namely, that P_1 is uniform on the support of P_0. Since uniformity is the standard assumption without any additional prior knowledge, we aim to develop a method that performs at least as well as the inductive method when $\pi = 0$.

Therefore we ask the following question: Can we devise a method which, having no knowledge of π, shares the properties of the learning reduction of Section 3 when $\pi > 0$, and the inductive approach otherwise? Our answer to the question is "yes" under fairly general conditions.

The intuition behind our approach is the following. The inductive approach to novelty detection performs density level set estimation. Furthermore, as we saw in Section 3, density level sets are optimal decision regions for testing the nominal distribution against a uniform distribution. Therefore, level set estimation can be achieved by generating an artificial uniform sample and performing weighted binary classification against the nominal data (this idea has been developed in more detail by Steinwart et al., 2005). Our approach is to sprinkle a vanishingly small proportion of uniformly distributed data among the unlabeled data, and then implement SSND using NP classification on this modified data. When $\pi = 0$, the uniform points will influence the final decision rule to perform level set estimation. When $\pi > 0$, the uniform points will be swamped by the actual novelties, and the optimal detector will be estimated.

To formalize this approach, let $0 < p_n < 1$ be a sequence tending to zero. Assume that S is a compact set which is known to contain the support of P_0 (obtained, e.g., through support estimation or through a priori information on the problem), and let P_2 be the uniform distribution on S. Consider the following procedure: Let $k \sim \text{binom}(n, p_n)$. Draw k independent realizations from P_2, and redefine $x_{m+1}, \ldots, x_{m+k}$ to be these values. (In practice, the uniform data would simply be appended to the unlabeled data, so that information is not erased. The present procedure, however, is slightly simpler to analyze.)

The idea now is to apply the SSND learning reduction from before to this modified unlabeled data. Toward this end, we introduce the following notations. For simplicity, we do not explicitly indicate the underlying class $\mathcal{F}$. We refer to any data point that was drawn from either P_1 or P_2 as an *operative* novelty. The proportion of operative novelties in the modified unlabeled sample is $\tilde{\pi} := \pi(1-p_n) + p_n$. The distribution of operative novelties is $\tilde{P}_1 := \frac{\pi(1-p_n)}{\tilde{\pi}} P_1 + \frac{p_n}{\tilde{\pi}} P_2$, and the overall distribution of the modified unlabeled data is $\tilde{P}_X := \tilde{\pi}\tilde{P}_1 + (1-\tilde{\pi})P_0$. Let $R_2, R^*_{2,\alpha}, \tilde{R}_1, \tilde{R}^*_{1,\alpha}, \tilde{R}_X$, and

$\tilde{R}^*_{X,\alpha}$ be defined in terms of $P_2, \tilde{P}_1$, and $\tilde{P}_X$, respectively, in analogy to the definitions in Section 3. Also denote $L_{2,\alpha}(f) = R_2(f) - R^*_{2,\alpha}$, $\tilde{L}_{1,\alpha}(f) = \tilde{R}_1(f) - \tilde{R}^*_{1,\alpha}$, and $\tilde{L}_{X,\alpha} = \tilde{R}_X(f) - \tilde{R}^*_{X,\alpha}$.

By applying Theorem 1 to the modified data, we immediately conclude that if $R_0(f) \leq \alpha + \varepsilon$, then

$$\tilde{L}_{1,\alpha}(f) \leq \frac{1}{\tilde{\pi}}(\tilde{L}_{X,\alpha}(f) + (1-\tilde{\pi})\varepsilon) = \frac{1}{\tilde{\pi}}(\tilde{L}_{X,\alpha}(f) + (1-\pi)(1-p_n)\varepsilon). \tag{6}$$

By previously cited results on Neyman-Pearson classification, the quantities on the right-hand side can be made arbitrarily small as m and n grow. The following result translates this bound to the kind of guarantee we are seeking.

Theorem 3 *Assume* **(A)** *holds. Let f be a classifier with $R_0(f) \leq \alpha + \varepsilon$. If $\pi = 0$, then*

$$L_{2,\alpha}(f) \leq p_n^{-1}(\tilde{L}_{X,\alpha}(f) + (1-p_n)\varepsilon).$$

If $\pi > 0$, then

$$L_{1,\alpha}(f) \leq \frac{1}{\pi(1-p_n)}(\tilde{L}_{X,\alpha}(f) + (1-\pi)(1-p_n)\varepsilon + p_n).$$

To interpret the first statement, note that $L_{2,\alpha}(f)$ is the inductive regret. The bound implies that $L_{2,\alpha}(f) \to 0$ as long as both $\varepsilon = R_0(f) - \alpha$ and $\tilde{L}_{X,\alpha}(f)$ tend to zero *faster than* p_n. This suggests taking p_n to be a sequence tending to zero slowly. The second statement is similar to the earlier result in Theorem 1, but with additional factors of p_n. These factors suggest choosing p_n tending to zero rapidly, in contrast to the first statement, so in practice some balance should be struck.

Proof If $\pi = 0$, then $\tilde{L}_{1,\alpha} = L_{2,\alpha}$ and the first statement follows trivially from (6). To prove the second statement, denote $\beta_n := \frac{\pi(1-p_n)}{\tilde{\pi}}$, and observe that

$$\begin{aligned}
\tilde{R}^*_{1,\alpha} &= \inf_{R_0(f)\leq\alpha} \tilde{R}_1(f) \\
&= \inf_{R_0(f)\leq\alpha} [\beta_n R_1(f) + (1-\beta_n)R_2(f)] \\
&\leq \beta_n R^*_{1,\alpha} + (1-\beta_n).
\end{aligned}$$

Therefore

$$\begin{aligned}
\tilde{L}_{1,\alpha}(f) &= \tilde{R}_1(f) - \tilde{R}^*_{1,\alpha} \\
&\geq \beta_n R_1(f) + (1-\beta_n)R_2(f) - \beta_n R^*_{1,\alpha} - (1-\beta_n) \\
&\geq \beta_n(R_1(f) - R^*_{1,\alpha}) - (1-\beta_n) \\
&= \beta_n L_{1,\alpha}(f) - (1-\beta_n)
\end{aligned}$$

and we conclude, still using (6),

$$\begin{aligned}
L_{1,\alpha}(f) &\leq \frac{1}{\beta_n}\tilde{L}_{1,\alpha} + \frac{1-\beta_n}{\beta_n} \\
&\leq \frac{1}{\pi(1-p_n)}(\tilde{L}_{X,\alpha}(f) + (1-\pi)(1-p_n)\varepsilon + p_n).
\end{aligned}$$

■

Like Theorem 1, Theorem 3 is quite general, and has both theoretical and practical implications. Theoretically, it could be combined with specific, analyzable algorithms for Neyman-Pearson classification to yield novelty detectors with performance guarantees, as was illustrated in Section 4. We do not develop this theoretical direction here. Practically, any algorithm for Neyman-Pearson classification that generally works well in practice can be applied in the hybrid framework to produce novelty detectors that perform well for values of π that are zero or very near zero. We implement this idea in the experimental section below.

We also remark that this hybrid procedure could be applied with any prior distribution on novelties besides uniform. In addition, the hybrid approach could also be practically useful when n is small, assuming the artificial points are appended to the unlabeled sample.

6. Estimating π and Testing for $\pi = 0$

In the previous sections, our main goal was to find a good classifier function for the purpose of novelty detection. Besides the detector itself, it is often relevant to the user to have an estimate or bound on the proportion π of novelties in the contaminated distribution P_X. Estimation of π allows for estimating and optimizing the misclassification rate on the unlabeled data, which is often of interest in the LPUE literature (see Sec. 2). Estimation of π is also useful for estimating the precision (as defined in Section 4); this topic will be revisited in the next section in the context of multiple testing.

It may also be useful to test whether there are novelties at all; in other words, since the learnt detector $\widehat{f}$ is allowed a certain proportion of false positives, it is important to assess whether the reported novelties are a statistically significant indication of the presence of true novelties, or if they are likely to be all false positives. We focus on these issues in the present section.

It should first be noted that without additional assumptions, π is not an identifiable parameter in our model. To see this, consider the idealized case where we have an infinite amount of nominal and contaminated data, so that we have perfect knowledge of P_0 and P_X. Assuming the decomposition $P_X = (1-\pi)P_0 + \pi P_1$ holds, note that any alternate decomposition of the form $P_X = (1-\pi-\gamma)P_0 + (\pi+\gamma)P_1'$, with $P_1' = (\pi+\gamma)^{-1}(\pi P_1 + \gamma P_0)$, and $\gamma \in [0, 1-\pi]$, is equally valid. Because the most important feature of the model is that we have no direct knowledge of P_1, we cannot decide which representation is the "correct" one; we could not even exclude *a priori* the case where $\pi = 1$ and $P_1 = P_X$ (while producing the exact same observed data). The previous results established in Theorems 1-3 are valid for whatever underlying representation is assumed to be correct. For the estimation of the proportion of novelties, however, it makes sense to define π as the *minimal* proportion of novelties that can explain the difference between P_0 and P_X. First we introduce the following definition:

Definition 4 *Assume P_0, P_1 are probability distributions on the measure space $(\mathcal{X}, \mathfrak{S})$. We call P_1 a* proper novelty distribution *with respect to P_0 if there exists no decomposition of the form $P_1 = (1-\gamma)Q + \gamma P_0$ where Q is some probability distribution and $0 < \gamma \leq 1$.*

This defines a proper novelty distribution P_1 as one that cannot be confounded with P_0; it cannot be represented as a (nontrivial) mixture of P_0 with another distribution.

The next result establishes a canonical decomposition of the contaminated distribution into a mixture of nominal data and proper novelties. As a consequence the proportion π^* of proper novelties, and therefore the proper novelty distribution P_1 itself, are well-defined (that is, identifiable)

given the knowledge of the nominal and contaminated distributions (except for the special case $P_0 = P_X$, where of course the novelty distribution is not defined).

Proposition 5 *Assume P_0 , P_X are probability distributions on the measure space $(\mathcal{X}, \mathfrak{S})$. If $P_X \neq P_0$, there is a unique $\pi^* \in (0,1]$ and P_1 such that the decomposition $P_X = (1-\pi^*)P_0 + \pi^* P_1$ holds, and such that P_1 is a proper novelty distribution with respect to P_0 . If we additionally define $\pi^* = 0$ when $P_X = P_0$, then in all cases,*

$$\pi^* := \min\{\alpha \in [0,1] : \exists Q \text{ probability distribution: } P_X = (1-\alpha)P_0 + \alpha Q\} . \tag{7}$$

The proof is given in Appendix A. For the rest of this section we assume for simplicity of notation that π and P_1 are the proportion and distribution of proper novelties of P_X with respect to P_0 . The results to come are also informative for improper novelty distributions, in the following sense: if P_1 is not a proper novelty distribution and the decomposition $P_X = (1-\pi)P_0 + \pi P_1$ holds, then (7) entails that $\pi > \pi^*$. It follows that a lower bound on π^* (either deterministic or valid with a certain confidence), as will be derived in the coming sections, is always also a valid lower confidence bound on π when non-proper novelties are considered. A lower bound is effectively the best we can hope for π if P_1 is not assumed to be proper.

6.1 Population Case

We now want to relate the estimation of π to quantities previously introduced and problem (1). We first treat the population case and optimal novelty detection over the set of all possible classifiers.

Theorem 6 *For any classifier f, we have the inequality*

$$\pi \geq 1 - \frac{R_X(f)}{1 - R_0(f)} .$$

Optimizing this bound over a set of classifiers $\mathcal{F}$ under the FPR constraint $R_0(f) \leq \alpha$ yields for any $0 \leq \alpha < 1$:

$$\pi \geq 1 - \frac{R^*_{X,\alpha}(\mathcal{F})}{1-\alpha} . \tag{8}$$

Furthermore, if $\mathcal{F}$ is the set of all deterministic classifiers,

$$\pi = 1 - \inf_{\alpha \in [0,1)} \frac{R^*_{X,\alpha}(\mathcal{F})}{1-\alpha} . \tag{9}$$

Proof . For the first part, just write for any classifier f

$$\begin{aligned} 1 - R_X(f) &= P_X(f(X) = 1) \\ &= (1-\pi)P_0(f(X) = 1) + \pi P_1(f(X) = 1) \\ &\leq (1-\pi)R_0(f) + \pi , \end{aligned}$$

resulting in the first inequality in the theorem. Under the constraint $R_0(f) \leq \alpha$, this inequality then yields

$$\pi \geq 1 - \frac{R_X(f)}{1 - R_0(f)} \geq 1 - \frac{R_X(f)}{1-\alpha} ;$$

optimizing the bound under the constraint yields the second inequality.

We establish in Lemma 13 in Appendix A that for any $\varepsilon > 0$ there exists a classifier f_ε such that $R_0(f_\varepsilon) < 1$ and $R_1(f_\varepsilon)/(1-R_0(f_\varepsilon)) \leq \varepsilon$. Put $\alpha_\varepsilon = R_0(f_\varepsilon)$; we then have

$$R^*_{X,\alpha_\varepsilon}(\mathcal{F}) \leq R_X(f_\varepsilon) = (1-\pi)(1-\alpha_\varepsilon) + \pi R_1(f_\varepsilon)\,,$$

implying

$$\pi \geq 1 - \inf_{\alpha\in[0,1)} \frac{R^*_{X,\alpha}(\mathcal{F})}{1-\alpha} \geq 1 - \frac{R^*_{X,\alpha_\varepsilon}(\mathcal{F})}{1-\alpha_\varepsilon} \geq \pi\left(1 - \frac{R_1(f_\varepsilon)}{1-R_0(f_\varepsilon)}\right) \geq \pi(1-\varepsilon)\,,$$

which establishes the last claim of the theorem. ■

6.2 Distribution-free Lower Confidence Bounds on π

In the last part of Theorem 6, if we assume that the function $\alpha \mapsto R^*_{X,\alpha}(\mathcal{F})/(1-\alpha)$ is nonincreasing (a common regularity assumption; see Appendix B for a discussion of how this condition can always be ensured by considering possibly randomized classifiers), then $\alpha \mapsto R^*_{X,\alpha}(\mathcal{F})$ is left differentiable at $\alpha = 1$ and (8) is optimized by taking $\alpha \to 1$, that is,

$$\pi \geq 1 + \frac{dR^*_{X,\alpha}(\mathcal{F})}{d\alpha}\Big|_{\alpha=1^-}, \tag{10}$$

while (9) entails that the above inequality is an equality if $\mathcal{F}$ contains all deterministic classifiers. This suggests obtaining a lower bound on π by estimating the slope of $R^*_{X,\alpha}(\mathcal{F})$ at its right endpoint. The following result adopts this approach while accounting for the uncertainty inherent in empirical performance measures.

Theorem 7 *Consider a classifier set $\mathcal{F}$ for which we assume a uniform error bound of the following form is available: for any distribution Q on $\mathcal{X}$, with probability at least $1-\delta$ over the draw of an i.i.d. sample of size n according to Q , we have*

$$\forall f \in \mathcal{F} \quad \left|Q(f(X)=1) - \widehat{Q}(f(X)=1)\right| \leq \varepsilon_n(\mathcal{F},\delta)\,, \tag{11}$$

where $\widehat{Q}$ denotes the empirical distribution built on the sample.

Then the following quantity is a lower bound on π with probability at least $(1-\delta)^2 \geq 1-2\delta$ (over the draw of the nominal and unlabeled samples) :

$$\widehat{\pi}^-(\mathcal{F},\delta) := 1 - \inf_{f\in\mathcal{F}} \frac{\widehat{R}_X(f) + \varepsilon_n(\mathcal{F},\delta)}{(1-\widehat{R}_0(f) - \varepsilon_m(\mathcal{F},\delta))_+}\,, \tag{12}$$

where the ratio is formally defined to be 1 whenever the denominator is 0 .

Note that if we define $\widehat{f}_\alpha = \arg\min_{f\in\mathcal{F}} \widehat{R}_X(f)$ under the constraint $\widehat{R}_0(f) \leq \alpha$, this can be rewritten

$$\widehat{\pi}^-(\mathcal{F},\delta) = 1 - \inf_{\alpha\in[0,1]} \frac{\widehat{R}_X(\widehat{f}_\alpha) + \varepsilon_n(\mathcal{F},\delta)}{(1-\widehat{R}_0(\widehat{f}_\alpha) - \varepsilon_m(\mathcal{F},\delta))_+}\,.$$

There are two balancing forces at play here. From the population version (10) (valid under a mild regularity assumption), we know that we would like to have α as close as possible to 1 for estimating the derivative of $R^*_{X,\alpha}(\mathcal{F})$ at $\alpha = 1$. This is balanced by the estimation error which makes estimations close to $\alpha = 1$ unreliable because of the denominator. Taking the infimum along the curve takes in a sense the best available bias-estimation tradeoff.

Proof . To simplify notation we denote $\varepsilon_n(\mathcal{F}, \delta)$ simply by ε_n. As in the proof of the previous result, write for any classifier f:

$$P_X(f(X) = 1) \leq (1 - \pi) P_0(f(X) = 1) + \pi,$$

from which we deduce after applying the uniform bound

$$\begin{aligned} 1 - \widehat{R}_X(f) - \varepsilon_n &= \widehat{P}_X(f(X) = 1) - \varepsilon_n \\ &\leq (1 - \pi)(\widehat{R}_0(f) + \varepsilon_m) + \pi, \end{aligned}$$

which can be solved whenever $1 - \widehat{R}_0(f) - \varepsilon_m > 0$. ■

The following result shows that $\widehat{\pi}^-(\mathcal{F}, \delta)$, when suitably applied using a sequence of classifier sets $\mathcal{F}_1, \mathcal{F}_2, \ldots$ that have a universal approximation property, yields a strongly universally consistent estimate of the proportion π of proper novelties. The proof is given in Appendix A and relies on Theorem 7 in conjunction with the Borel-Cantelli lemma.

Theorem 8 *Consider a sequence $\mathcal{F}_1, \mathcal{F}_2, \ldots$ of classifier sets having the following universal approximation property: for any measurable function $f^* : \mathcal{X} \to \{0, 1\}$, and any distribution Q , we have*

$$\liminf_{k \to \infty} \inf_{f \in \mathcal{F}_k} Q(f(X) \neq f^*(X)) = 0 .$$

Suppose also that each class $\mathcal{F}_k$ has finite VC-dimension V_k, so that for each $\mathcal{F}_k$ we have a uniform confidence bound of the form (11) *for* $\varepsilon_n(\mathcal{F}_k, \delta) = 3\sqrt{\frac{V_k \log(n+1) - \log \delta/2}{n}}$ *. Define*

$$\widehat{\pi}^-(\delta) = \sup_k \widehat{\pi}^- \left(\mathcal{F}_k, \delta k^{-2}\right) .$$

If $\delta = (mn)^{-2}$, *then* $\widehat{\pi}^-$ *converges to* π *almost surely as* $\min(m, n) \to \infty$.

6.3 There are No Distribution-free Upper Bounds on π

The lower confidence bounds $\widehat{\pi}^-(\mathcal{F}, \delta)$ and $\widehat{\pi}^-(\delta)$ are distribution-free in the sense that they hold regardless of P_0, P_1 and π. We now argue that distribution-free upper confidence bounds do not generally exist.

We define a *distribution-free upper confidence bound* $\widehat{\pi}^+(\delta)$ to be a function of the observed data such that, for any P_0, any proper novelty distribution P_1, and any novelty proportion $\pi \leq 1$, we have $\widehat{\pi}^+(\delta) \geq \pi$ with probability $1 - \delta$ over the draw of the two samples.

We will show that such a universal upper bound does not exist unless it is trivial. The reason is that the novel distribution can be arbitrarily hard to distinguish from the nominal distribution. It is possible to detect with some certainty that there is a non-zero proportion of novelties in the contaminated data (see Corollary 11 below), but we can never be sure that there are no novelties.

This situation is similar to the philosophy of significance testing: one can never accept the null hypothesis, but only have insufficient evidence to reject it.

We will say that the nominal distribution P_0 is *weakly diffuse* if for any $\gamma > 0$ there exists a set A such that $0 < P_0(A) < \gamma$. We say an upper confidence bound $\widehat{\pi}^+(\delta)$ is *non-trivial* if there exists a weakly diffuse nominal distribution P_0, a proper novelty distribution P_1, a novelty proportion $\pi < 1$, and a constant $\delta > 0$ such that

$$P(\widehat{\pi}^+(\delta) < 1) > \delta,$$

where the probability is over the joint draw of nominal and contaminated samples. This assumption demands that there is at least a specific setting where the upper bound $\widehat{\pi}^+(\delta)$ is significantly different from the trivial bound 1, meaning that it is bounded away from 1 with larger probability than its allowed probability of error δ.

Theorem 9 *There exists no distribution-free, non-trivial upper confidence bound on* π.

The proof appears in Appendix A. The non-triviality assumption is quite weak and relatively intuitive. The only not directly intuitive assumption is that P_0 should be weakly diffuse, which is satisfied for all distributions having a continuous part. This assumption effectively excludes finite state spaces, which is an important condition: if $\mathcal{X}$ is finite, it is actually possible to obtain a non-trivial upper confidence bound on π.

The following corollary establishes that for any finite sample size, any estimator of π (and in particular the universally consistent estimator considered in the previous section) can have an average error bounded from below by a constant independent of the sample size.

Corollary 10 *Assume $\mathcal{X}$ is an infinite set and let m,n be fixed. For any estimator $\widehat{\pi}$ of π, based on a joint sample of size (m,n), and any fixed real $p > 0$:*

$$\sup_{P \in \mathcal{P}(m,n)} E\left[|\widehat{\pi} - \pi|^p\right] \geq c(p) > 0,$$

where $\mathcal{P}(m,n)$ denotes the set of all generating distributions of (m,n)-samples following the SSND model (that is, of the form $P = P_0^{\otimes m} \otimes P_X^{\otimes n}$ for arbitrary P_0, P_X), and $c(p)$ is a constant independent of (m,n).

This result essentially precludes the existence of universal convergence rates in the estimation of π. In other words, to achieve some prescribed rate of convergence, some assumptions on the generating distributions must be made. This parallels the estimation of the Bayes risk in classification (Devroye, 1982).

6.4 Testing for $\pi = 0$

The lower confidence bound on π can also be used as a test for $\pi = 0$, that is, a test for whether there are any novelties in the test data:

Corollary 11 *Let $\mathcal{F}$ be a set of classifiers. If $\widehat{\pi}^-(\mathcal{F}, \delta) > 0$, then we may conclude, with confidence $1 - \delta$, that the unlabeled sample contains novelties.*

It is worth noting that testing this hypothesis is equivalent to testing if P_0 and P_X are the same distribution, which is the classical two-sample problem in an arbitrary input space. This problem has recently generated attention in the machine learning community (Gretton et al., 2007), and the approach proposed here, using arbitrary classifiers, seems to be new. Our confidence bound could of course also be used to test the more general hypothesis $\pi \leq \pi_0$ for a prescribed $\pi_0, 0 \leq \pi_0 < 1$.

Note that, by definition of $\widehat{\pi}^-(\mathcal{F},\delta)$, testing the hypothesis $\pi = 0$ using the above lower confidence bound for π is equivalent to searching the classifier space $\mathcal{F}$ for a classifier f such that the proportions of predictions of 0 and 1 by f differ on the two samples in a statistically significant manner. Namely, for a classifier f belonging to a class $\mathcal{F}$ for which we have a uniform bound of the form (11), we have the lower bound $P_X(f(X)=1) \geq \widehat{P}_X(f(X)=1) - \varepsilon_n$ and the upper bound $P_0(f(X)=1) \leq \widehat{P}_0(f(X)=1) + \varepsilon_m$ (both bounds valid simultaneously with probability at least $1-\delta$). If the difference of the bounds is positive we conclude that we must have $P_X \neq P_0$, hence $\pi > 0$. This difference is precisely what appears in the numerator of $\widehat{\pi}^-(\mathcal{F},\delta)$ in (12) . Furthermore, if this numerator is positive then so is the denominator, since it is always larger. In the end, $\widehat{\pi}^-(\mathcal{F},\delta) > 0$ is equivalent to

$$\sup_{f\in\mathcal{F}} \Big((\widehat{P}_X(f(X)=1) - \varepsilon_n) - (\widehat{P}_0(f(X)=1) + \varepsilon_m) \Big) > 0 \,.$$

7. Relationship Between SSND and Multiple Testing

In this section, we show how SSND offers powerful generalizations of the standard p-value approach to multiple testing under the widely used "random effects" model, as considered for example by Efron et al. (2001).

7.1 Multiple Testing Under the Random Effects Model

In the multiple testing framework, a finite family $(H_1,\ldots,H_K)$ of null hypotheses to test is fixed; from the observation of some data X , a decision $D(H_i,X) \in \{0,1\}$ must be taken for each hypothesis, namely whether (given the data) hypothesis H_i is deemed to be false ($D(H_i,X)=1$, hypothesis rejected) or true ($D(H_i,X)=0$, hypothesis not rejected). A typical application domain is that of microarray data analysis, where each null hypothesis H_i corresponds to the absence of a difference in expression levels of gene i in a comparison between two experimental situations. A rejected null hypothesis then indicates such a differential expression for a specific gene, and is called a *discovery* (since differentially expressed genes are those of interest). However, the number of null hypotheses to test is very large, for example $K \simeq 4.10^4$ in the gene expression analysis, and the probability of rejecting by chance a null hypothesis must be strictly controlled.

In the standard setting for multiple testing, it is assumed that a testing statistic $Z_i(X) \in \mathbb{R}$ has been fixed for each null hypothesis H_i , and that its marginal distribution is known when H_i is true. This statistic can then be normalized (by suitable monotone transform) to take the form of a *p-value*. A p-value is a function $p_i(X)$ of the data such that, if the corresponding null hypothesis H_i is true, then $p_i(X)$ has a uniform marginal distribution on $[0,1]$. In this setting, it is expected that the rejection decisions $D(H_i,X)$ are taken based on the observed p-values $(p_1(X),\ldots,p_K(X))$ rather than on the raw data. In fact, in most cases it is assumed that the decisions take the form $D(H_i,X) = \mathbf{1}_{\{p_i(X)\leq \widehat{T}\}}$, where $\widehat{T}$ is a data-dependent threshold. Further, simplifying distributional assumptions on the family of p-values are often posited. A common distribution model called

random effects abstracts the p-values from the original data X and assumes that the veracity of hypothesis H_i is governed by an underlying latent variable h_i as follows:

- the variables $h_i \in \{0,1\}$, $1 \leq i \leq K$ are i.i.d. Bernoulli with parameter π
- the variables p_i are independent, and conditionally to $(h_1, \ldots, h_K)$ have distribution

$$p_i \sim \begin{cases} \text{Uniform}[0,1]\,, & \text{if } h_i = 0 \\ P_1\,, & \text{if } h_i = 1\,. \end{cases}$$

Under the random effects model, the p-values thus follow a mixture distribution $(1-\pi)U[0,1] + \pi P_1$ on the interval $[0,1]$ and can be seen as a contaminated sample, while the variables h_i play the role of the unknown labels. It should now be clear that the above model is in fact a *specification* of the SSND model, with the following additional assumptions:

1. The observation space is the interval $[0,1]$;
2. The nominal distribution P_0 is known to be exactly uniform on $[0,1]$ (equivalently, the nominal distribution is uniform and the nominal sample has infinite size);
3. The class of novelty detectors considered is the set of intervals of the form $[0,t], t \in [0,1]$.

Therefore, the results developed in this paper can apply to the more restricted setting of multiple testing under the random effects model as well. In particular, the estimator $\widehat{\pi}^-(\mathcal{F}, \delta)$ developed in Section 6, when specified under the above additional conditions, recovers the methodology of non-asymptotic estimation of $1-\pi$ which was developed by Genovese and Wasserman (2004), Section 3, and our notion of proper novelty distribution recovers their notion of *purity* in that setting (and has somewhat more generality, since they assumed P_1 to have a density).

There are several interesting benefits in considering for the purpose of multiple testing the more general SSND model developed here. First, it can be unrealistic in practice to assume that the distribution of the p-values is known exactly under each one of the null hypotheses. Instead, only assuming the knowledge of a reference sample under controlled experimental conditions as in the SSND model is often more realistic. This problem was recently motivated by problems in genomics (Ghosh and Chinnaiyan, 2009) and proteomics (Ghosh, 2009), where in the latter reference asymptotic analysis was also presented.

Secondly, the restriction to decision sets of the form $\{p_i \leq t\}$ can also be questionable. For a single test, decision regions of this form are optimal (in the Neyman-Pearson sense) only if the likelihood ratio of the alternative to the null is decreasing, which amounts to assuming that the alternative distribution P_1 has a decreasing density. This assumption has been criticized in some recent work. A simple example of a situation where this assumption fails is in the framework of z or t-tests, that is, the null distribution of the statistic (before rescaling into p-values) is a standard Gaussian or a Student t-distribution, and the corresponding p-value function is the usual one- or two-sided p-value. If the alternative distribution P_1 is a mixture of Gaussians (resp. of noncentral t distributions), optimal rejection regions for the original statistic are in general a finite union of disjoint intervals and do not correspond to level sets of the p-values. In order to counter this type of problem, Sun and Cai (2007) suggest to estimate from the data the alternate density and the proportion of true null hypotheses, and use these estimates directly in a plug-in likelihood ratio

based test. Chi (2007) develops a procedure based on growing rejection intervals around a finite number of fixed control points in $[0,1]$. In both cases, an asymptotic theory is developed. Both of these procedures are more flexible than using only rejection intervals of the form $[0,t]$ and aim at adaptivity with respect to the alternative distribution P_1.

Finally, the remaining restriction that effective observations (the p-values) belong to the unit interval was also put into question by Chi (2008), who considered a setting of multidimensional p-values belonging to $[0,1]^d$. The distribution was still assumed to be uniform under the corresponding null hypothesis, although this seems an even less realistic assumption than in dimension one. In this framework, the use of a reference "nominal" sample under the null distribution seems even more relevant.

The framework developed in the present paper allows to cover at once these different types of extensions rather naturally by just considering a richer class $\mathcal{F}$ of candidate classifiers (or equivalently in this setting, rejection regions), and provides a non-asymptotical analysis of their behavior using classical learning theoretical tools such as VC inequalities. Furthermore, such non-asymptotic inequalities can also give rise to adaptive and consistent model selection for the set of classifiers using the structural risk minimization principle, a topic that was not addressed previously for the extensions mentioned above.

7.2 SSND with Controlled FDR

One remaining important difference between the SSND setting studied here and that of multiple testing is that our main optimization problem (1) is under a false positive rate constraint $R_0(f) \leq \alpha$, while most recent work on multiple testing generally imposes a constraint on the false discovery rate (FDR) instead. If we denote

$$\mathrm{Pos}(f) = \widehat{P}_X(f(X)=1) = 1 - \widehat{R}_X(f) = \frac{1}{n}\sum_{i=1}^{n} \mathbf{1}_{\{f(x_{m+i})=1\}}$$

the proportion of reported novelties, and

$$\mathrm{FP}(f) = \widehat{P}_{XY}(f(X)=1, Y=0) = \frac{1}{n}\sum_{i=1}^{n} \mathbf{1}_{\{f(x_{m+i})=1, y_{m+i}=0\}}$$

the (unavailable to the user) proportion of false discoveries on the contaminated sample, then the false discovery proportion (FDP) is defined as $\mathrm{FDP}(f) = \mathrm{FP}(f)/\mathrm{Pos}(f)$ (taken to be zero if the denominator vanishes), and the FDR is defined as $\mathrm{FDR}(f) = E[\mathrm{FDP}(f)]$. Some classical variations of this quantity are the positive FDR, $\mathrm{pFDR}(f) = E[\mathrm{FDP}(f)|\mathrm{Pos}(f) > 0]$ and the marginal FDR, $\mathrm{mFDR}(f) = E[\mathrm{FP}(f)]/E[\mathrm{Pos}(f)]$. Under the mixture contamination model, it can be checked that $\mathrm{pFDR}(f) = \mathrm{mFDR}(f) = P_{XY}(Y=0|f(X)=1)$ (Storey, 2003), hence also equal to one minus the precision for class 1 (as defined earlier in Section 4). The following result states explicit empirical bounds on these quantities:

Proposition 12 *Consider a classifier set $\mathcal{F}$ for which we assume a uniform error bound of the following form is available: for any distribution Q on $\mathcal{X} \times \{0,1\}$, with probability at least $1-\delta$ over the draw of an i.i.d. sample of size n according to Q, both*

$$\forall f \in \mathcal{F} \quad \left| Q(f(X)=1) - \widehat{Q}(f(X)=1) \right| \leq \varepsilon_n(\mathcal{F}, \delta), \tag{13}$$

and

$$\forall f \in \mathcal{F} \quad \left| Q(f(X)=1, Y=0) - \widehat{Q}(f(X)=1, Y=0) \right| \leq \varepsilon_n(\mathcal{F}, \delta), \tag{14}$$

hold, where $\widehat{Q}$ denotes the empirical distribution built on the sample.

Then the following inequalities hold with probability at least $(1-\delta)^2 \geq 1-2\delta$ (over the draw of the nominal and unlabeled samples) :

$$\forall f \in \mathcal{F} \;\; \text{mFDR}(f) = P_X(Y=0|X=1) \leq \frac{(\widehat{R}_0(f)+\varepsilon_m)(1-\widehat{\pi}^-(\mathcal{F},\delta))}{(1-\widehat{R}_X(f)-\varepsilon_n)_+},$$

and

$$\forall f \in \mathcal{F} \;\; \text{FDP}(f) \leq \frac{(\widehat{R}_0(f)+\varepsilon_m)(1-\widehat{\pi}^-(\mathcal{F},\delta))+\varepsilon_n}{(1-\widehat{R}_X(f))},$$

where $\widehat{\pi}^-(\mathcal{F},\delta)$ is defined in (12).

Note that Equations (13) and (14) hold as before with $\varepsilon_n(\mathcal{F},\delta) = c\sqrt{\frac{V\log n - \log\delta}{n}}$ when $\mathcal{F}$ has VC dimension V. In the interest of simplicity, we use the same bound ε_n for both uniform error assumptions. Separate bounds could also be adopted, allowing (13) to be slightly tighter. We also remark that since FDP is an empirical quantity based on the contaminated sample, the second bound is in fact a *transductive* bound rather than semi-supervised.

Proof . The mFDR can be rewritten as $\text{mFDR}(f) = P_0(f(X)=1|Y=0)P_{XY}(Y=0)/P_X(f(X)=1) = R_0(f)(1-\pi)/(1-R_X(f))$. In this expression we can plug in the lower bound for π of Theorem 7 and uniform bounds for $R_0(f)$ and $R_X(f)$ coming from assumption (13). The FDP can be written as $\text{FDP}(f) = \widehat{P}_{XY}(f(X)=1, Y=0)/(1-\widehat{R}_X(f))$. Using assumption (14), the numerator can be upper bounded by $P_{XY}(f(X)=1,Y=0)+\varepsilon_n = R_0(f)(1-\pi)+\varepsilon_n$, and we can then use the same reasoning as for the first part. ■

Similarly to what was proposed in Section 4 under the false positive rate constraint, we can in this context consider to maximize $\widehat{R}_X(f)$ over $f \in \mathcal{F}$ subject to the constraint that the above empirical bound on the mFDR or FDP is less than α. This can then be suitably extended to a sequence of classes $\mathcal{F}_k$. While a full study of the resulting procedure is out of the scope of the present paper, we want to point out the important difference that the mFDR is necessarily lower bounded by $\inf_{x\in\mathcal{X}} P_{XY}(Y=0|X=x)$ which is generally strictly positive. Hence, the required constraint may not be realizable if α is smaller than this lower bound, in which case the empirical procedure should return a failure statement with probability one as $n \to \infty$.

8. Experiments

Despite previous work on learning with positive and unlabeled examples (LPUE), as discussed in Section 2, the efficacy of our proposed learning reduction, compared to the method of inductive novelty detection, has not been empirically demonstrated. In addition, we evaluate our proposed hybrid method. To assess the impact of unlabeled data on novelty detection, we applied our framework to some data sets which are common benchmarks for binary classification. The first 13 data sets (Müller et al., 2001) are from `http://www.fml.tuebingen.mpg.de/Members/`

Data Set	dim	N_{train}	N_{test}	π_{base}
banana	2	400	4900	0.45

Table 1: Description of data sets. dim is the number of features, and N_{train} and N_{test} are the numbers of training and test examples. π_{base} is the proportion of positive examples (novelties) in the combined training and test data. Thus, the average (across permutations) nominal sample size m is $(1-\pi_{\text{base}})N_{\text{train}}$.

`raetsch/benchmark` and the last five data sets (Chang and Lin, 2001) are from `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/`.

Each data set consists of both positive and negative examples. Furthermore, each data set is replicated 100 times (except for image and splice, which are replicated 20 times), with each copy corresponding to a different random partitioning into training and test examples. All numerical results for a data set were obtained by averaging across all partitions. The negative examples from the training set were taken to form the nominal sample, and the positive training examples were not used at all in the experiments. The data sets are summarized in Table 1. Here N_{train} and N_{test} are the sizes[1] of the training and test sets, respectively, while π_{base} is the proportion of positive examples in the combined training and test data. Thus, the average (across permutations) nominal sample size m is $(1-\pi_{\text{base}})N_{\text{train}}$.

We emphasize that in these experiments we do not implement the empirical risk minimization (ERM) algorithm from Sec. 4. The reduction to Neyman-Pearson classification is general and can by applied in conjunction with any NP classification algorithm, whether that algorithm has associated performance guarantees or not. We here elect to apply the reduction using a plug-in kernel density estimate (KDE) classifier. ERM is computationally infeasible, and the bounds tend

1. The web and adult data sets were subsampled owing to their large size.

to be too loose in practice to be effective. The KDE plug-in rule can be implemented efficiently, and there is a natural inductive counterpart for comparison, the thresholded KDE based on the nominal sample.

8.1 Experimental Setup

We evaluated our methodology in two learning paradigms, comparing five learning methods across several values of π. The two learning paradigms are semi-supervised and transductive. For semi-supervised learning, the test data were divided into two halves. The first half was used as the contaminated, unlabeled data. The second half was used as an independent sample of contaminated data, not used in the learning stage, but only for evaluation of classifiers returned by each method. In particular, the second half of the test data was used to estimate the area under the ROC (AUC) of each method. Here, the ROC is the one which views P_0 as the null distribution and P_1 as the alternative. For transductive learning, the entire test set was treated as the unlabeled data, and was also used for evaluating the AUC.

The learning methods are the inductive approach, our proposed learning reduction, and three versions of the hybrid approach. The three hybrids correspond to $p_n = 1.0, 0.5$, and 0.1, in which a uniform sample of size $100p_n\%$ of the unlabeled sample size is *appended* to the unlabeled data. We emphasize that each algorithm was implemented in the same way in the two learning paradigms; the only differences are the size of the contaminated sample, and how they are evaluated.

We implemented the inductive novelty detector using a thresholded kernel density estimate (KDE) with Gaussian kernel, and SSND using a plug-in KDE classifier. To alleviate concerns that our inductive implementation is inadequate, we also tested the one-class support vector machine (Schölkopf et al., 2001) in several experimental settings, and found its performance to be very similar. Letting k_σ denote a Gaussian kernel with bandwidth σ, the inductive novelty detector at density level λ is

$$f(x) = \begin{cases} 1 & \text{if } \frac{1}{m}\sum_{i=1}^{m} k_{\sigma_0}(x,x_i) > \lambda \\ 0 & \text{otherwise,} \end{cases}$$

and the SSND classifier at density ratio λ is

$$f(x) = \begin{cases} 1 & \text{if } (\frac{1}{n}\sum_{i=m+1}^{m+n} k_{\sigma_X}(x,x_i))/(\frac{1}{m}\sum_{i=1}^{m} k_{\sigma_0}(x,x_i)) > \lambda \\ 0 & \text{otherwise.} \end{cases}$$

The hybrid method is implemented similarly. The ROCs of these methods are obtained by varying the level/threshold λ.

For each class, a single kernel bandwidth parameter was employed, and optimized by maximizing a cross-validation estimate of the AUC. Note that this ROC is different from the one used to evaluate the methods (see above). In particular, it still views P_0 as the null distribution, but now the alternative distribution is taken to be the uniform distribution P_2 for the inductive detector (see Section 5; effectively we use a uniform random sample of size n in place of the unlabeled data), P_X for SSND, and the appropriate $\tilde{P}_X$ for the hybrid methods (see Section 5). Thus, the test label information was not used at any stage (prior to validation) by any of the methods.

We also compared the learning methods for several values of π. For semi-supervised learning, we examined $\pi = 0.5, \pi = 0.2, \pi = 0.1$, and $\pi = 0.0$. For transductive learning, we examined $\pi = 0.5, \pi = 0.2$, and $\pi = 0.1$. The case $\pi = 0.0$ cannot be evaluated in the transductive paradigm because there are no positive examples in the unlabeled data. For each value of π, we discarded

just enough examples (either negative or positive) so that the desired proportion was achieved in the contaminated data. Note that the number of positive examples (novelties) in the contaminated sample could be very small. For the smallest data sets, in the semi-supervised setting and when $\pi = 0.1$, this number is less than 10.

We remark that the AUC is only one possible performance measure to assess our algorithms. An alternative choice, and one that is more directly connected to our theory, would be to select several different values of α, and compare the false negative and false positive rates, for each value of α, across all different data sets and algorithms. It would be straightforward in our experimental setup to calibrate the thresholds, using cross-validation for example, to achieve the desired false positive rate. We have adopted the AUC as a more concise alternative that in a sense averages the performance for Neyman-Pearson classification across the complete range of α.

8.2 Statistical Summaries and Methodology

The complete results are summarized in Tables 2 through 5. Tables 2 and 3 show the average AUC for each data set and experimental setting, for the semi-supervised and transductive paradigms respectively. The inductive method is labeled Ind. Our learning reduction is labeled SSND or TND depending on the setting. The hybrid methods are labeled H(p_n) in Tables 2-3, and Hybrid(p_n) in Tables 4-5.

We followed the methodology of Demšar (2006) for comparing algorithms across multiple data sets. For each data set and each experimental setting, the algorithms were ranked 1 (best) through 5 (worst) based on AUC. The Friedman test was used to determine, for each experimental setting, whether there was a significant difference in the average ranks of the five algorithms across the data sets. The average ranks and p-values are reported in Tables 4 and 5. The results indicate that there is a significant difference among the algorithms at the 0.1 significance level for all settings, with the exception of the transductive setting when $\pi = 0.1$.

When the Friedman test resulted in significant differences, we then performed a post-hoc Nemenyi test to assess when there was a significant difference between individual algorithms. For a five algorithm experiment on 18 data sets, with a significance level of 0.1, the critical difference for the Nemenyi test is 1.30. That is, when the average ranks of two algorithms differ by more than 1.30, their performance is deemed to be significantly different.

8.3 Analysis of Results

From the results presented in Tables 2-5, we draw the following conclusions.

1. The average ranks in Tables 4-5 conform to our expectations in many respects. SSND/TND outrank the inductive approach when $\pi = 0.5$, and inductive outranks SSND when $\pi = 0.0$. At the intermediate values $\pi = 0.1$ and 0.2, hybrid methods achieve the best ranking.

2. The average ranks also reveal that the performance of the hybrid methods vary according to the value of π. As π increases, the best performing hybrid has a correspondingly smaller amount of auxiliary uniform data appended to the unlabeled sample. This also conforms to our expectations.

Table 4: The comparison of average ranks of the five algorithms in the semi-supervised setting, by the Friedman test. The critical difference of the post-hoc Nemenyi test is 1.30 at a significance level of 0.1.

π	Inductive	TND	Hybrid(1.0)	Hybrid(0.5)	Hybrid(0.1)	p-value
0.1	2.94	3.78	2.56	2.67	3.06	0.157
0.2	3.17	3.78	3.06	2.50	2.50	0.085
0.5	4.44	1.44	3.56	3.17	2.39	0.000

Table 5: The comparison of average ranks of the five algorithms in the transductive setting, by the Friedman test. The critical difference of the post-hoc Nemenyi test is 1.30 at a significance level of 0.1.

3. All tables indicate that the proposed methodology performs better in the transductive setting than the semi-supervised setting. A likely reason is that, in our experimental setup, TND sees twice as much unlabeled data as SSND.

4. When $\pi = 0.0$ in the semi-supervised experiments, SSND typically has an AUC around 0.5, which corresponds to random guessing. This makes sense, because it is essentially trying to classify between two realizations of the nominal distribution. From Tables 2 and 4 we see that the hybrid methods clearly improve upon SSND when $\pi = 0.0$.

5. For some data sets (splice, ionosphere, web), the inductive method does worse than random guessing, but our methods do not. In each case, our methods yield dramatic increases in AUC.

6. The benefits of unlabeled data increase with dimension. In particular, SSND and TND tend to perform much better relative to the inductive approach on data sets of dimension at least 18. This is especially evident in the second half of the data sets, which even show significant gains for $\pi = 0.1$. This trend suggests that as dimension increases, the assumption implicit in the inductive approach (that novelties are uniform where they overlap the support of the nominal distribution) breaks down.

Figure 1 depicts a sampling of results comparing the inductive and semi-supervised methods, and highlights the impact of dimension. The top graph shows ROCs for a two-dimensional data set where the two classes are fairly well separated, meaning the novelties lie in the tails of the nominal class, and $\pi = 0.5$. Not surprisingly, the inductive method is close to the semi-supervised method. The middle graph represents the 60-dimensional splice data set, where the inductive method does worse than random guessing, yet SSND does quite well. The bottom graph in Figure 1 shows the results for the 21-dimensional waveform data for $\pi = 0.1$. Here the assumptions of the inductive approach are also evidently violated to some degree.

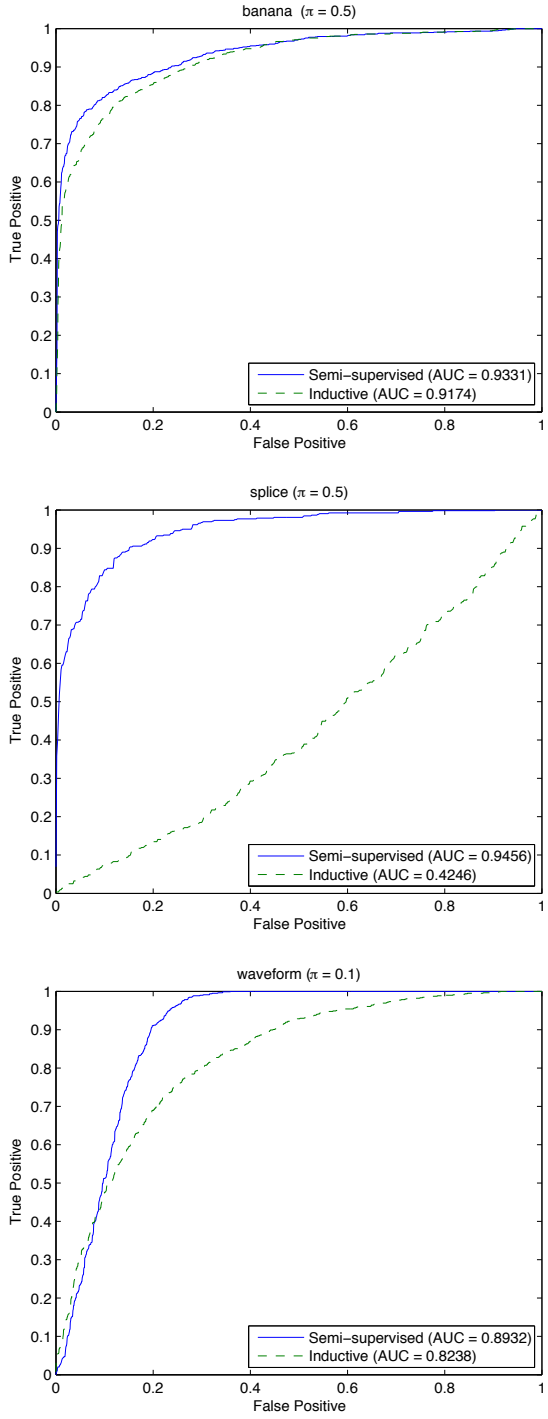

Figure 1: Illustrative results from the semi-supervised setting. Top: In the 2-dimensional banana data, the two classes are well separated, and the inductive approach fares well. Middle: In the 60-dimensional splice data, the inductive approach does worse than random guessing. Bottom: In the 21-dimensional waveform data, unlabeled data still offer gains when π is small (here 0.1).

9. Conclusions

We have shown that semi-supervised novelty detection reduces to Neyman-Pearson classification. This allows us to leverage known performance guarantees for NP classification algorithms, and to import practical algorithms. We have applied techniques from statistical learning theory, such as uniform deviation inequalities, to establish distribution free performance guarantees for SSND, as well as a distribution free lower bound and universally consistent estimator for π, and test for $\pi = 0$. Our approach optimally adapts to the unknown novelty distribution, unlike inductive approaches, which operate as if novelties are uniformly distributed. We also introduced a hybrid method that has the properties of SSND when $\pi > 0$, and effectively reverts to the inductive method when $\pi = 0$.

Our analysis strongly suggests that in novelty detection, unlike traditional binary classification, unlabeled data are essential for attaining optimal performance in terms of tight bounds, consistency, and rates of convergence. In an extensive experimental study, we found that the advantages of our approach are most pronounced for high dimensional data. Our analysis and experiments confirm some challenges that seem to be intrinsic to the SSND problem. In particular, SSND is more difficult for smaller π. Furthermore, estimating the novelty proportion π can become arbitrarily difficult as the nominal and novel distributions become increasingly similar.

Our methodology also provides general solutions to two well-studied problems in hypothesis testing. First, our lower bound on π translates immediately to a test for $\pi = 0$, which amounts to a distribution-free solution to the two-sample problem. Second, we also show that SSND provides a powerful generalization of standard multiple testing. Important problems for future work will include developing practical methodologies for these problems based on our theoretical framework.

Appendix A. Proofs

The remaining proofs are now presented.

A.1 Proof of Theorem 2

For the first two claims of the theorem, we directly apply Theorem 3 of Scott and Nowak (2005) to the problem of NP classification of P_0 versus P_X , and obtain that for a suitable choice of constants c, c' we have with probability at least $1-\delta$:

$$R_0(\widehat{f_\tau}) - \alpha \leq c'\varepsilon_n \; ; \; R_X(\widehat{f_\tau}) - R_X(f^*) \leq c'\varepsilon_m \, .$$

From this, we deduce (3)-(4) by application of Theorem 1.

For the second claim, by application of Bayes' rule we have for any classifier f :

$$Q_0(f) = \frac{(1-\pi)(1-R_0(f))}{P_X(f(X)=0)} = \frac{(1-\pi)(1-R_0(f))}{\pi R_1(f) + (1-\pi)(1-R_0(f))}$$

and

$$Q_1(f) = \frac{\pi(1-R_1(f))}{P_X(f(X)=1)} = \frac{\pi(1-R_1(f))}{(1-\pi)R_0(f)+\pi(1-R_1(f))}\,.$$

Observe that for $a,b>0$ the function $\zeta(x,y) = \frac{a(1-x)}{by+a(1-x)}$ is decreasing in $y \in \mathbb{R}_+$ for $x \in (-\infty,1]$, and decreasing in $x \in [0,1+by/a)$ for $y \in \mathbb{R}_+$. Hence, using (3)-(4) and the fact that $R_i(f) \in [0,1]$, we derive a lower bound on $Q_0(\widehat{f_\tau})$ as follows:

$$\begin{aligned}
Q_0(\widehat{f_\tau}) &= \frac{(1-\pi)(1-R_0(\widehat{f_\tau}))}{\pi R_1(\widehat{f_\tau})+(1-\pi)(1-R_0(\widehat{f_\tau}))} \\
&\geq \frac{(1-\pi)(1-\alpha-c'\varepsilon_n)}{\pi(R_1(f^*)+c'\pi^{-1}(\varepsilon_n+\varepsilon_m))+(1-\pi)(1-R_0(f^*)-c'\varepsilon_n)} \\
&= \frac{(1-\pi)(1-\alpha-c'\varepsilon_n)}{P_X(f^*(X)=0)+c'(\varepsilon_m+\pi\varepsilon_n)} \\
&\geq \frac{(1-\pi)(1-\alpha)}{P_X(f^*(X)=0)+c'(\varepsilon_m+\pi\varepsilon_n)} - \frac{c'(1-\pi)\varepsilon_n}{P_X(f^*(X)=0)} \\
&\geq \frac{(1-\pi)(1-\alpha)-c'(1-\pi)\varepsilon_n}{P_X(f^*(X)=0)} - \frac{(1-\pi)(1-\alpha)c'(\varepsilon_m+\pi\varepsilon_n)}{P_X(f^*(X)=0)^2} \\
&\geq Q_0(f^*) - \frac{c'(\varepsilon_n+\varepsilon_m)}{P_X(f^*(X)=0)}\,.
\end{aligned}$$

The first inequality comes from the monotonicity properties of $\zeta(x,y)$ (applied first with respect to y, then x). The second is elementary. In the third inequality we used the fact that the function $g:\delta \mapsto g(\delta) = \frac{A}{B+\delta}$ is convex for A,B,δ positive and has derivative $-A/B^2$ in zero, so that $g(\delta) \geq \frac{A}{B} - \delta\frac{A}{B^2}$, with $A=(1-\pi)(1-\alpha), B = P_X(f^*(X)=0), \delta = c'(\varepsilon_m+\pi\varepsilon_n)$. In the last inequality we used (with the same definition for A,B) that $\frac{A}{B} = Q_0(f^*) \leq 1$.

The treatment for Q_1 is similar. Suppose first that

$$c'(\varepsilon_n+\varepsilon_m) < P_X(f^*(X)=1). \tag{15}$$

We then have

$$\begin{aligned}
Q_1(\widehat{f_\tau}) &= \frac{\pi(1-R_1(\widehat{f_\tau}))}{(1-\pi)R_0(\widehat{f_\tau})+\pi(1-R_1(\widehat{f_\tau}))} \\
&\geq \frac{\pi(1-R_1(f^*)-c'\pi^{-1}(\varepsilon_n+\varepsilon_m))}{(1-\pi)(\alpha+c'\varepsilon_n)+\pi(1-R_1(f^*)-c'\pi^{-1}(\varepsilon_n+\varepsilon_m))} \\
&= \frac{\pi(1-R_1(f^*))-c'(\varepsilon_n+\varepsilon_m)}{P_X(f^*(X)=1)-c'(\pi\varepsilon_n+\varepsilon_m)} \\
&\geq Q_1(f^*) - \frac{c'(\varepsilon_n+\varepsilon_m)}{P_X(f^*(X)=1)-c'(\varepsilon_n+\varepsilon_m)},
\end{aligned}$$

where we used again the monotonicity properties of $\zeta(x,y)$. Note that assumption (15) ensures that all denominators in the above chain of inequalities are positive, which is required for these

inequalities to hold. Now, since $Q_1(\widehat{f_\tau}) \geq 0$ and $Q_1(f^*) \leq 1$, the above implies

$$\begin{aligned} Q_1(\widehat{f_\tau}) &\geq Q_1(f^*) - \min\left(1, \frac{c'(\varepsilon_n + \varepsilon_m)}{P_X(f^*(X)=1) - c'(\varepsilon_n+\varepsilon_m)}\right) \\ &\geq Q_1(f^*) - \frac{2c'(\varepsilon_n+\varepsilon_m)}{P_X(f^*(X)=1)}; \end{aligned}$$

in the last inequality we used the fact that $\min(1, x/(1-x)) \leq 2x$ for $x \in [0,1)$ (with $x = c'(\varepsilon_n + \varepsilon_m)/P_X(f^*(X)=1)$). If (15) is not satisfied, then the last display still trivially holds since its RHS is nonpositive. This establishes (5) for $i = 1$.

A.2 Proof of Proposition 5

Let π^* be defined as

$$\pi^* := \inf\{\alpha \in [0,1] : \exists Q \text{ probability distribution: } P_X = (1-\alpha)P_0 + \alpha Q\}.$$

We want to establish that π^* satisfies the claims of the theorem (and in particular that the above infimum is a minimum). In the case $P_0 = P_X$, obviously we have $\pi^* = 0$ and this is a minimum. We now assume for the remainder of the proof that $P_0 \neq P_X$. Consider the Lebesgue decomposition $P_X = P_X^0 + P_X^\perp$ with $P_X^0 \ll P_0$ (that is, P_X^0 is absolutely continuous with respect to P_0) and $P_X^\perp \perp P_X^0$ (that is, $P_X^\perp$ and P_0 are mutually singular). Let $f = dP_X^0/dP_0$ and a be the essential infimum of f wrt. P_0. We claim that $\pi^* = 1 - a$. Observe first that

$$a \leq E_{X\sim P_0}[f(X)] = P_X^0(\mathcal{X}) \leq P_X(\mathcal{X}) = 1.$$

In particular, $a = 1$ must imply that the above inequalities are equalities, hence that $E_{X\sim P_0}[f] = a$. The latter can only be valid if $f = a = 1$ P_0-a.s., implying that $P_0 = P_X^0$, and further $P_0 = P_X$, which we excluded before. Therefore it holds that $a < 1$. Certainly we then have the valid decomposition

$$P_X = aP_0 + (1-a)P_1, \qquad P_1 := \left((1-a)^{-1}\left((f-a)P_0 + P_X^\perp\right)\right),$$

so that $\pi^* \leq 1 - a$.

By definition of singular measures there exists a measurable set D such that $P_0(D) = 1$ and $P_X^\perp(D) = 0$. Fix $\varepsilon > 0$; by definition of the essential infimum there exists a measurable set C such that $P_0(C) > 0$ and $f \leq a + \varepsilon$ P_0-a.s. on C. Put $A = C \cap D$. Then $P_0(A) = P_0(C) > 0$. Furthermore

$$\frac{P_1(A)}{P_0(A)} = \frac{E_{X\sim P_0}\left[(1-a)^{-1}(f-a)\mathbf{1}_{\{X\in A\}}\right]}{P_0(A)} \leq \varepsilon/(1-a).$$

Existence of a decomposition of the form $P_1 = (1-\gamma)Q + \gamma P_0$ implies that for any measurable set A, $P_1(A) \geq \gamma P_0(A)$. Hence the above implies that $\gamma = 0$ for any such decomposition, that is, P_1 must be a proper novelty distribution wrt. P_0. It also implies that for any $\varepsilon > 0$ there exists a measurable set A with $P_0(A) > 0$ and $P_X(A)/P_0(A) \leq a + \varepsilon$. Hence for any decomposition $P_X = (1-\alpha)P_0 + \alpha Q$, it must hold that $(1-\alpha) \leq a$, so that $\pi^* \geq 1 - a$. We thus established $\pi^* = 1 - a$ and the existence of the decomposition. Concerning the unicity, the decomposition established above implies that for any $\alpha \geq \pi^*$, $P_X = (1-\alpha)P_0 + \alpha Q$ holds with $Q = (1 - \frac{\pi^*}{\alpha})P_0 + \frac{\pi^*}{\alpha}P_1$. Note that for any fixed α, existence of a decomposition $P_X = (1-\alpha)P_0 + \alpha Q$ uniquely determines Q. Hence for $\alpha > \pi^*$ the corresponding Q is not a proper novelty distribution, and the only valid decomposition of P_X into P_0 and a proper novelty distribution is the one established previously.

A.3 Lemma Used in Proof of Theorem 6

For the proof of Theorem 6 we made use of the following auxiliary result:

Lemma 13 *Assume P_1 is a proper novelty distribution wrt. P_0. Then for any $\varepsilon > 0$ there exists a (deterministic) classifier f such that $R_0(f) < 1$ and*

$$\frac{R_1(f)}{1-R_0(f)} \leq \varepsilon\,.$$

Proof . Since P_1 is a proper novelty distribution wrt. P_0, reiterating the reasoning in the proof of Proposition 5 shows that there exists a measurable set A with $P_0(A) > 0$ and $P_1(A)/P_0(A) \leq \varepsilon$. Put $\alpha = 1 - P_0(A) < 1$. Consider the classifier $f(x) = \mathbf{1}_{\{x \in A^c\}}$. Then $R_0(f) = P_0(f=1) = \alpha$, while

$$0 \leq R_1(f) = P_1(f=0) = P_1(A) \leq \varepsilon(1-\alpha)\,. \tag{16}$$

This leads to the desired conclusion.

■

A.4 Proof of Theorem 8

By application of Lemma 13, for any $\varepsilon > 0$ there exists a classifier f^* such that $\frac{R_1(f^*)}{1-R_0(f^*)} \leq \varepsilon$. Then we have as in the proof of Theorem 6:

$$1 - \frac{R_X(f^*)}{1-R_0(f^*)} = \pi\left(1 - \frac{R_1(f^*)}{1-R_0(f^*)}\right) \geq \pi(1-\varepsilon)\,.$$

Fix $\gamma > 0$ and define $\widetilde{P} = \frac{1}{2}(P_0 + P_1)$. Using the assumption of universal approximation, pick k such that there exists $f_k^* \in \mathcal{F}_k$ with $\widetilde{P}(f_k^*(X) \neq f^*(X)) \leq \gamma$. Since $\widetilde{P} \geq \frac{1}{2}P_0$ and $\widetilde{P} \geq \frac{1}{2}P_1$ this implies also $P_0(f_k^*(X) \neq f^*(X)) \leq 2\gamma$ as well as $P_X(f_k^*(X) \neq f^*(X)) \leq 2\gamma$.

From now we only work in the class $\mathcal{F}_k$ and so we omit the parameters in the notation $\varepsilon_i \equiv \varepsilon_i(\mathcal{F}_k, \delta k^{-2})$. By the union bound, the uniform control of the form (11) is valid simultaneously for all $\mathcal{F}_k$, with probability $1 - c\delta$ (with $c = \pi^2/6$). Hence with probability $1 - c\delta = 1 - c(mn)^{-2}$, we have

$$\widehat{R}_0(f_k^*) \leq R_0(f_k^*) + \varepsilon_m \leq R_0(f^*) + 2\gamma + \varepsilon_m\,,$$

and also

$$\widehat{R}_X(f_k^*) \leq R_X(f_k^*) + \varepsilon_n \leq R_X(f^*) + 2\gamma + \varepsilon_n\,.$$

From this we deduce that with probability $1 - c(mn)^{-2}$:

$$\widehat{\pi}^-(\delta) \geq \widehat{\pi}^-(\mathcal{F}_k, (mn)^{-2}k^{-2}) \geq 1 - \frac{R_X(f^*) + 2\gamma + 2\varepsilon_n}{1 - R_0(f^*) - 2\gamma - 2\varepsilon_m}\,.$$

Since $\varepsilon_n, \varepsilon_m$ go to zero as $\min(m,n)$ goes to infinity we deduce that a.s. (using the Borel-Cantelli lemma, and the fact that the error probabilities are summable over $(m,n) \in \mathbb{N}^2$)

$$\liminf_{\min(m,n)\to\infty} \widehat{\pi}^-(\delta) \geq 1 - \frac{R_X(f^*) + 2\gamma}{1 - R_0(f^*) - 2\gamma} \geq \pi(1-\varepsilon)\frac{1 - R_0(f^*)}{1 - R_0(f^*) - 2\gamma} - \frac{4\gamma}{1 - R_0(f^*) - 2\gamma}\,.$$

Taking the limit of the above as $\gamma \to 0$ (for fixed ε and f^*), then as $\varepsilon \to 0$, leads to the conclusion.

A.5 Proof of Theorem 9

The principle of the argument is relatively standard and can be sketched as follows. Assume there exists a non-trivial upper confidence bound $\widehat{\pi}^+(\delta)$ on the proportion of anomalies. From the non-triviality assumption, there exists a generating distribution P and a set of samples $\mathcal{B}$ such that $\widehat{\pi}^+(\delta) < 1$ for all samples in $\mathcal{B}$ while $P(\mathcal{B}) > \delta$. We will construct below an alternate generating distribution $\widetilde{P}$ and set of samples $\widetilde{\mathcal{B}} \subset \mathcal{B}$ which are very close to P and $\mathcal{B}$, in particular satisfying $\widetilde{P}(\widetilde{\mathcal{B}}) > \delta$; however the proportion of anomalies for $\widetilde{P}$ is 1, contradicting the universality of $\widehat{\pi}^+$ since $\widehat{\pi}^+(\delta) < 1$ for all samples in $\widetilde{\mathcal{B}}$.

Let P_0, P_1, δ, π be given by the non-triviality assumption and $P := P_0^{\otimes m} \otimes P_X^{\otimes n}$ denote correspondingly the joint distribution of nominal and contaminated data. Fix some $\gamma > 0$ and a set D such that $0 < P_0(D) < \gamma$ (such a set always exists by the assumption that P_0 is weakly diffuse). Put $A = D^c$, so that $1 - \gamma < P_0(A) < 1$. Consider the distribution P_0 conditional to belonging to A, given by $\frac{\mathbf{1}_{x \in A}}{P_0(A)} P_0$. Since it has its support strictly included in the support of P_0, it is a proper novelty distribution with respect to P_0. Therefore, since P_1 is also a proper novelty distribution with respect to P_0, so is $\widetilde{P}_1 := (1-\pi)\frac{\mathbf{1}_{x \in A}}{P_0(A)} P_0 + \pi P_1$.

Now consider the novelty detection problem with nominal distribution P_0, novelty distribution $\widetilde{P}_1$, and novelty proportion $\widetilde{\pi} = 1$, so that $\widetilde{P}_X = (1-\widetilde{\pi})P_0 + \widetilde{\pi}\widetilde{P}_1 = \widetilde{P}_1$. Finally, define the modified joint distribution on nominal and contaminated data $\widetilde{P} = P_0^{\otimes m} \otimes \widetilde{P}_X^{\otimes n}$.

By the non-triviality assumption, there exists a set $\mathcal{B}$ of (m,n) samples such that $\widehat{\pi}^+(\delta) < 1$ on the set $\mathcal{B}$ and $P(\mathcal{B}) = \delta_0 > \delta$. Denote $\mathcal{A} = \mathcal{X}^m \times A^n$. By assumption, $P(\mathcal{A}) \geq (1-\gamma)^n$; furthermore from the construction of $\widetilde{P}$ it can be verified straightforwardly that for any set $\mathcal{C} \subset \mathcal{A}$, $\widetilde{P}(\mathcal{C}) \geq P(\mathcal{C})$. Define now $\widetilde{\mathcal{B}} = \mathcal{B} \cap \mathcal{A}$; we have

$$\widetilde{P}(\widetilde{\mathcal{B}}) \geq P(\widetilde{\mathcal{B}}) \geq \delta_0 - (1 - (1-\gamma)^n).$$

Hence for γ small enough, we have $\widetilde{P}(\widetilde{\mathcal{B}}) > \delta$ which contradicts the fact that $\widehat{\pi}^+(\delta)$ is a $1-\delta$ confidence upper bound, since on $\widetilde{\mathcal{B}}$ we have $\widehat{\pi}^+(\delta) < 1 = \widetilde{\pi}$.

A.6 Proof of Corollary 10

Put

$$\gamma := \sup_{P \in \mathcal{P}(m,n)} E\left[\left|\widehat{\pi} - \pi\right|^p\right].$$

By Markov's inequality, it means that for any generating distribution P,

$$P\left(\pi > \widehat{\pi} + \left(\frac{\gamma}{\delta}\right)^{\frac{1}{p}}\right) \leq \delta.$$

Hence $\widehat{\pi}^+(\delta) = \widehat{\pi} + \left(\frac{\gamma}{\delta}\right)^{\frac{1}{p}}$ is a distribution-free upper confidence bound on π.

By theorem (9), this bound must be trivial. We investigate the consequences of this fact. Let us consider any generating distribution $P \in \mathcal{P}(m,n)$ for which $\pi = 0$, and the nominal distribution P_0 is weakly diffuse (it is possible to find such a P_0 since $\mathcal{X}$ is infinite). Assume $\delta < \frac{1}{2}$ and fix some $\delta_0 \in (\delta, 1-\delta)$. Markov's inequality again implies that for this distribution,

$$P\left(\widehat{\pi} \geq \left(\frac{\gamma}{\delta_0}\right)^{\frac{1}{p}}\right) \leq \delta_0,$$

so that

$$P\left(\widehat{\pi}^{+}(\delta) \geq 2\left(\frac{\gamma}{\delta}\right)^{\frac{1}{p}}\right) \leq \delta_0 \leq 1-\delta.$$

Choosing $\delta_0 = 1/2, \delta = 1/3$, the above implies that $\widehat{\pi}^{+}(\delta)$ would be non-trivial if $\gamma < 2^{-p}/3$. Thus we must conclude that $\gamma \geq c(p) := 2^{-p}/3$.

Appendix B. Randomized classifiers and ROCs

In this appendix we review some properties of ROCs that are relevant to our setting. These should be considered well-known (see for example the paper of Fawcett, 2006, and references therein, for an overview of ROC analysis over sets of classifiers). For the sake of completeness, we give here statements and short proofs that are tailored to correspond precisely to the context considered in the main body of the paper.

Let $\mathcal{F}$ be a fixed set of classifiers, and recall the Neyman-Pearson classification optimization problem (1), restated here for convenience:

$$\begin{aligned} R^*_{1,\alpha}(\mathcal{F}) := \inf_{f\in\mathcal{F}} \; & R_1(f) \\ \text{s.t. } & R_0(f) \leq \alpha\,. \end{aligned} \tag{1}$$

We call optimal ROC of P_1 versus P_0 for set $\mathcal{F}$ the function $\alpha \in [0,1] \mapsto 1 - R^*_{1,\alpha}(\mathcal{F}) \in [0,1]$.

For reference, first consider a very "regular" case where $\mathcal{F}$ is the set of all possible deterministic classifiers, and one assumes that both class probabilities P_0, P_1 have densities h_0, h_1 with respect to some reference measure, such that the likelihood ratio $F(x) = \frac{h_1(x)}{h_0(x)}$ is continuous with $\inf F = 0$ and $\sup F = +\infty$. Then the optimal solutions f^*_α of (1) are indicators of sets of the form

$$C_\lambda = \left\{ x \in \mathcal{X} : \frac{h_1(x)}{h_0(x)} \geq \lambda \right\},$$

with $\lambda(\alpha)$ such that $P_0(C_\lambda) = \alpha$. In this case $R^*_{1,\alpha}(\mathcal{F}) = P_1(C_{\lambda(\alpha)})$ and it can be shown that the ROC is continuous, nondecreasing and concave between the points $(0,0)$ and $(1,1)$. In particular in this case it holds that $R_0(f^*_\alpha) = \alpha$.

When some of the above assumptions are not satisfied, for example if we consider an arbitrary subset $\mathcal{F}$ of classifiers (which is of course necessary for adequate estimation error control), or the probability distributions P_0 and P_1 have atoms (which is the case in practice for empirical distributions), some of these properties may fail to hold. While it is clear that the optimal ROC is always a nondecreasing function, it might fail to be concave, and the optimal solution might have $R_0(f^*_\alpha) < \alpha$. This is for example obviously the case if $\mathcal{F}$ is a finite set of classifiers, in which case the ROC is a step function and $R_0(f)$ can only take finitely many values.

We are interested in the following regularity properties depending on $\mathcal{F}, P_0$ and P_1:

(A') For any $\alpha \in (0,1)$, there exists a sequence $f_n \in \mathcal{F}$ such that $R_0(f_n) = \alpha$ and $R_1(f_n) \to R^*_{1,\alpha}(\mathcal{F})$.

(B) The function $\alpha \mapsto R^*_{1,\alpha}(\mathcal{F})/(1-\alpha)$ is nondecreasing on $[0,1]$.

Note that for simplicity of exposition, in the main body of the paper we simplified property **(A')** into **(A)**, where the sequence f_n is replaced by its limit, assumed to belong to the considered set of classifiers. Our results still hold under **(A')** with straightforward modifications of the proofs.

Condition **(B)** states that the slope of the line joining the point of the optimal ROC at α and the point $(1,1)$ is nonincreasing in α; this assumption is weaker than concavity of the ROC. It is relevant for the discussion in the final paragraph below, related to our result on precision.

To ensure regularity properties of the ROC, a standard device is to extend the class $\mathcal{F}$ and consider *randomized* classifiers, whose output is not a deterministic function, but a Bernoulli variable with probability depending on the point x. Formally this amounts to allowing a classifier f to take real values in the interval $[0,1]$; now for a given x the final decision $D(f,x)$ is a Bernoulli variable (independent of everything else) taking value 1 with probability $f(x)$ and 0 with probability $1-f(x)$. In this setting the error probabilities become for $y=0,1$:

$$R_y(f) := P_y(D(f,X) \neq y) = E_y[|f(X)-y|],$$

where E_y is a shortcut for $E_{X\sim P_y}$. Although the function f itself remains strictly speaking deterministic, in view of the above interpretation we will call with some abuse f a deterministic classifier if it takes values in $\{0,1\}$ and randomized classifier if takes values in $[0,1]$.

We consider two types of extensions of a (usually deterministic) class $\mathcal{F}$, the first one is the convex hull of $\mathcal{F}$, or *full randomization*,

$$\overline{\mathcal{F}} = \left\{ g \middle| g = \sum_{i=1}^{N} \lambda_i f_i ; N \in \mathbb{N}, f_i \in \mathcal{F}, \lambda_i \geq 0 \text{ for } 1 \leq i \leq N, \sum_{i=1}^{N} \lambda_i = 1 \right\}.$$

The second is given by

$$\mathcal{F}^+ = \{ g | g = \lambda f + (1-\lambda), f \in \mathcal{F}, \lambda \in [0,1] \},$$

where the randomization is limited to convex interpolation between one classifier of the base class and the constant classifier equal to 1.

The following standard lemma summarizes the properties of the optimal ROC curve for these extended classes:

Lemma 14 *Let $\mathcal{F}$ be a set of deterministic classifiers containing the constant classifier equal to zero, and let P_0, P_1 be arbitrary distributions on $\mathcal{X}$. Then assumptions* **(A')** *and* **(B)** *are met when considering optimization problem* (1) *over either $\overline{\mathcal{F}}$ or $\mathcal{F}^+$. The optimal ROC for the set $\overline{\mathcal{F}}$ is concave.*

Proof . The fact that the constant zero classifier belongs to $\mathcal{F}$ ensures that the infimum in (1) (over either of the classes $\mathcal{F}$, $\mathcal{F}^+$ or $\overline{\mathcal{F}}$) is not taken over an empty set and exists. The definition of an infimum ensures that there exists a sequence g_n of elements of $\mathcal{F}^+$ such that $R_0(g_n) \leq \alpha$ and $R_1(g_n) \searrow R^*_{1,\alpha}(\mathcal{F}^+)$. Then putting $\lambda_n = (1-\alpha)/(1-R_0(g_n))$, the sequence $f_n = \lambda_n g_n + (1-\lambda_n)$ belongs to $\mathcal{F}^+$, and is such that

$$R_0(f_n) = E_0[f_n] = \frac{(1-\alpha)}{(1-R_0(g_n))} R_0(g_n) + \left(1 - \frac{(1-\alpha)}{(1-R_0(g_n))}\right) = \alpha$$

while

$$R^*_{1,\alpha}(\mathcal{F}^+) \leq R_1(f_n) = 1 - E_1[f_n] = \lambda_n R_1(g_n) \leq R_1(g_n) \searrow R^*_{1,\alpha}(\mathcal{F}^+),$$

and thus ensures **(A')**. The same reasoning applies to $\overline{\mathcal{F}}$.

For property **(B)**, consider a sequence (f_n) from property **(A')**, a number $\beta \in [\alpha, 1]$ and $h_n = (1-\zeta)f_n + \zeta$ where $\zeta = (1-\beta)/(1-\alpha) \in [0,1]$. Then $h_n \in \mathcal{F}^+$, $R_0(h_n) = \beta$ and $R_1(h_n) = (1-\zeta)R_1(f_n) + \zeta$. Letting n grow to infinity we obtain $R^*_{1,\beta}(\mathcal{F}^+) \leq (1-\zeta)R^*_{1,\alpha}(\mathcal{F}^+) + \zeta$ which in turn implies (**B**).

In the case of $\overline{\mathcal{F}}$, similarly consider sequences $f_{n,1}, f_{n,2}$ like above for $\alpha = \alpha_1$, resp. $\alpha = \alpha_2$ with $\alpha_2 \geq \alpha_1$; for any $\beta \in [\alpha_1, \alpha_2]$, write $\beta = \lambda\alpha_1 + (1-\lambda)\alpha_2$; correspondingly the sequence $\lambda f_{n,1} + (1-\lambda)f_{n,2}$ belongs to $\overline{\mathcal{F}}$ and ensures that $R^*_{1,\beta}(\overline{\mathcal{F}}) \leq \lambda R^*_{1,\alpha_1}(\overline{\mathcal{F}}) + (1-\lambda)R^*_{1,\alpha_2}(\overline{\mathcal{F}})$ that is, the optimal ROC for $\overline{\mathcal{F}}$ is concave. ■

Concerning estimation error control for the extended classes, a uniform control of the error on the base class is sufficient, since it carries over to the extended classes by convex combination. To be more specific, let us consider for example the estimation of $R_0(f)$ uniformly over $f \in \overline{\mathcal{F}}$. The empirical counterpart of $R_0(f)$ is given by

$$\widehat{R}_0(f) := \widehat{P}_0(D(f,X) \neq 0) = \widehat{E}_0[f(X)],$$

where $\widehat{E}_0$ denotes the empirical expectation on the nominal sample. By definition of $\overline{\mathcal{F}}$, f can be written $f = \sum_{i=1}^N \lambda_i f_i$ with $\sum_{i=1}^N \lambda_i = 1$ and $\lambda_i \geq 0, f_i \in \mathcal{F}$ for $1 \leq i \leq N$, and thus the estimation error is controlled as follows:

$$\begin{aligned}\left|R_0(f) - \widehat{R}_0(f)\right| = \left|E_0[f(X)] - \widehat{E}_0[f(X)]\right| &\leq \sum_{i=1}^N |\lambda_i| \left|P_0(f_i(X)=1) - \widehat{P}_0(f_i(X)=1)\right| \\ &\leq \sup_{f\in\mathcal{F}} \left|P_0(f(X)=1) - \widehat{P}_0(f(X)=1)\right|,\end{aligned}$$

Therefore, if an error control of the form (11) holds over the base class $\mathcal{F}$ (for example if it is a VC-class), then the same type of bound holds for quantities of interest over the extended classes $\mathcal{F}^+$ and $\overline{\mathcal{F}}$.

For practical purposes, it might be significantly more difficult to find the solution of the (empirical version of) (1) for randomized classes and in particular for the fully randomized extension $\overline{\mathcal{F}}$. An advantage of the more limited form of randomization is that optimization problem (1) over $\mathcal{F}^+$ can be rewritten equivalently as an optimization problem over the original class, namely as

$$\inf_{h\in\mathcal{F}} \frac{R_1(h)}{1-R_0(h)} \qquad \text{s.t. } R_0(h) \leq \alpha. \tag{17}$$

To see why, assume for simplicity of exposition that **(A)** rather than **(A')** is satisfied. Then the optimization problem (1) over $\mathcal{F}^+$ is attained for some randomized classifier f^*; by construction f^* is of the form $f^* = \lambda h^* + (1-\lambda)$ for some $\lambda \in [0,1]$ and $h^* \in \mathcal{F}$. By property **(A)** we can assume $R_0(f^*) = \alpha$, which entails $\lambda = (1-\alpha)/(1-R_0(h^*))$ and $R_1(f^*) = (1-\alpha)R_1(h^*)/(1-R_0(h^*))$, hence the equivalence with (17) (with the above relation between f^* and h^*).

Finally, in general we can interpret the optimization problem (17) as a maximization of the class 0 precision,

$$Q_0(f) = P_{XY}(Y=0|f(X)=0) = \frac{(1-\pi)(1-R_0(f))}{(1-\pi)(1-R_0(f)) + \pi R_1(f)} = \frac{(1-\pi)}{(1-\pi) + \pi\frac{R_1(f)}{1-R_0(f)}},$$

under the constraint $R_0(f) \leq \alpha$, since the above display shows that $Q_0(f)$ is a decreasing function of the ratio $R_1(f)/(1-R_0(f))$. In general if properties **(A)** and **(B)** are satisfied for the considered class, then it is easy to see that the solutions to (1) and (17) coincide, so that the same classifier f^* achieves the minimum FNR and class 0 precision under the constraint on the FPR.

Abstract

The GPML toolbox provides a wide range of functionality for Gaussian process (GP) inference and prediction. GPs are specified by mean and covariance functions; we offer a library of simple mean and covariance functions and mechanisms to compose more complex ones. Several likelihood functions are supported including Gaussian and heavy-tailed for regression as well as others suitable for classification. Finally, a range of inference methods is provided, including exact and variational inference, Expectation Propagation, and Laplace's method dealing with non-Gaussian likelihoods and FITC for dealing with large regression tasks.

Keywords: Gaussian processes, nonparametric Bayes, probabilistic regression and classification

Gaussian processes (GPs) (Rasmussen and Williams, 2006) have convenient properties for many modelling tasks in machine learning and statistics. They can be used to specify distributions over functions without having to commit to a specific functional form. Applications range from regression over classification to reinforcement learning, spatial models, survival and other time series[1] models. Predictions of GP models come with a natural confidence measure: predictive error-bars.

Although the implementation of the basic principles in the simplest case is straight forward, various complicating features are often desired in practice. For example, a GP is determined by a *mean function* and a *covariance function*, but these functions are mostly difficult to specify fully a priori, and typically they are given in terms of *hyperparameters*, that is, parameters which have to be inferred. Another source of difficulty is the *likelihood function*. For Gaussian likelihoods, inference is analytically tractable; however, in many tasks, Gaussian likelihoods are not appropriate, and approximate inference methods such as Expectation Propagation (EP) (Minka, 2001), Laplace's approximation (LA) (Williams and Barber, 1998) and variational bounds (VB) (Gibbs and MacKay, 2000) become necessary (Nickisch and Rasmussen, 2008). In case of large training data, approximations (Candela and Rasmussen, 2005) like FITC (Snelson and Ghahramani, 2006) are needed.

The GPML toolbox is designed to overcome these hurdles with its variety of mean, covariance and likelihood functions as well as inference methods, while being simple to use and easy to extend.

∗. Also at Max Planck Institute for Biological Cybernetics, Spemannstraße 38, 72076 Tübingen, Germany.

1. Note, that here we typically think of GPs with a more general index set than time.

1. Implementation

The GPML toolbox can be obtained from `http://gaussianprocess.org/gpml/code/matlab/` and also `http://mloss.org/software/view/263/` under the FreeBSD license. Based on simple interfaces for covariance, mean, likelihood functions as well as inference methods, we offer full compatibility to both Matlab 7.x[2] and GNU Octave 3.2.x.[3] Special attention has been given to properly disentangle covariance, likelihood and mean hyperparameters. Also, care has been taken to avoid numerical inaccuracies, for example, safe likelihood evaluations for extreme inputs and stable matrix operations. For example, the covariance matrix $\mathbf{K}$ can become numerically close to singular making its naive inversion numerically unsafe. We handle these situations in a principled way[4] such that Cholesky decompositions are computed of well-conditioned matrices only. As a result, our code shows a high level of robustness along the full spectrum of possible hyperparameters. The focus of the toolbox is on approximate inference using dense matrix algebra. We currently do not support covariance matrix approximation techniques to deal with large numbers of training examples n. Looking at the (growing) body of literature on sparse approximations, this knowledge is still somewhat in flux, and consensus on the best approaches has not yet been reached.

We provide stable and modular code checked by an exhaustive suite of test cases. A single function `gp.m` serves as main interface to the user—it can make inference and predictions and allows the mean, covariance and likelihood function as well as the inference methods to be specified freely.

Furthermore, `gp.m` enables convenient learning of the hyperparameters by maximising the log marginal likelihood $\ln Z$. One of the particularly appealing properties of GP models is that principled and practical approaches exist for learning the parameters of mean, covariance and likelihood functions. Good adaptation of such parameters can be essential to obtain both high quality predictions and insights into the properties of the data. The GPML toolbox is particularly flexible, including a large library of different covariance and mean functions, and flexible ways to combine these into more expressive, specialised functions. The user can choose between two gradient-based optimisers: one uses conjugate gradients (CG)[5] and the other one relies on a quasi-Newton scheme.[6] Computing the derivatives w.r.t. hyperparameters $\frac{\partial}{\partial \theta_i} \ln Z$ with `gp.m` does not need any extra programming effort; every inference method automatically collects the respective derivatives from the mean, covariance and likelihood functions and passes them to `gp.m`.

Our documentation comes in two pieces: a hypertext user documentation[7] `doc/index.html` with examples and code browsing and a technical documentation[8] `doc/manual.pdf` focusing on the interfaces and more technical issues. A casual user will use the hypertext document to quickly get his data analysed, however a power user will consult the pdf document once he wants to include his own mean, covariance, likelihood and inference routines or learn about implementation details.

2. The GPML Toolbox

We illustrate the modular structure of the GPML toolbox by means of a simple code example. GPs are used to formalise and update knowledge about distributions over functions. A GP prior distribution on an unknown latent function $f \sim \mathcal{GP}(m_\phi(\mathbf{x}), k_\psi(\mathbf{x},\mathbf{x}'))$, consists of a mean function $m(\mathbf{x}) = \mathbb{E}[f(\mathbf{x})]$, and a covariance function $k(\mathbf{x},\mathbf{x}) = \mathbb{E}[(f(\mathbf{x}) - m(\mathbf{x}))(f(\mathbf{x}') - m(\mathbf{x}'))]$, both of which typically contain hyperparameters ϕ and ψ, which we want to fit in the light of data. We generally assume independent observations, that is, input/output pairs $(\mathbf{x}_i, y_i)$ of f with joint likelihood $\mathbb{P}_\rho(\mathbf{y}|\mathbf{f}) = \prod_{i=1}^n \mathbb{P}_\rho(y_i|f(\mathbf{x}_i))$ factorising over cases. Finally, after specification of the prior and fitting of the hyperparameters $\theta = \{\phi, \psi, \rho\}$, we wish to compute predictive distributions for test cases.

```
   % 1) SET UP THE GP: COVARIANCE; MEAN, LIKELIHOOD, INFERENCE METHOD
1  mf = {'meanSum',{'meanLinear',@meanConst}};   a = 2; b = 1;    % m(x) = a*x+b
2  cf = {'covSEiso'}; sf = 1; ell = 0.7;  % squared exponential covariance funct
3  lf = 'likLaplace'; sn = 0.2;        % assume Laplace noise with variance sn^2
4  hyp0.mean = [a;b]; hyp0.cov = log([ell;sf]); hyp0.lik  = log(sn); % hypers
5  inf = 'infEP';          % specify expectation propagation as inference method
   % 2) MINIMISE NEGATIVE LOG MARGINAL LIKELIHOOD nlZ wrt. hyp;  do 50 CG steps
6  Ncg = 50; [hyp, nlZ] = minimize(hyp0, 'gp', -Ncg, inf, mf, cf, lf, X, y);
   % 3) PREDICT AT UNKNOWN TEST INPUTS
7  [ymu, ys2] = gp(hyp, inf, mf, cf, lf, X, y, Xs);              % test input Xs
```

In **line 1**, we specify the mean $m_\phi(\mathbf{x}) = \mathbf{a}^\top \mathbf{x} + b$ of the GP with hyperparameters $\phi = \{\mathbf{a}, b\}$. First, the functional form of the mean function is given and its parameters are initialised. The desired mean function, happens not to exist in the library of mean functions; instead we have to make a *composite* mean function from *simple* constituents. This is done using a nested cell array containing the algebraic expression for $m(\mathbf{x})$: As the sum of a linear (`mean/meanLinear.m`) and a constant mean function (`mean/meanConst.m`) it is an affine function. In addition to linear and constant mean functions, the toolbox offers $m(\mathbf{x}) = 0$ and $m(\mathbf{x}) = 1$. These *simple* mean functions can be combined by *composite* mean functions to obtain sums (`mean/meanSum.m`) $m(\mathbf{x}) = \sum_j m_j(\mathbf{x})$, products $m(\mathbf{x}) = \prod_j m_j(\mathbf{x})$, scaled versions $m(\mathbf{x}) = \alpha m_0(\mathbf{x})$ and powers $m(\mathbf{x}) = m_0(\mathbf{x})^d$. This flexible mechanism is used for convenient specification of an extensible algebra of mean functions. Note that functions are referred to either as name strings `'meanConst'` or alternatively function handles `@meanConst`. The order of components of the hyperparameters ϕ is the same as in the specification of the cell array. Every mean function implements its evaluation $\mathbf{m} = m_\phi(\mathbf{X})$ and first derivative computation $\mathbf{m}_i = \frac{\partial}{\partial \phi_i} m_\phi(\mathbf{X})$ on a data set $\mathbf{X}$.

In the same spirit, the squared exponential covariance $k_\psi(\mathbf{x},\mathbf{x}') = \sigma_f{}^2 \exp(-\|\mathbf{x}-\mathbf{x}'\|^2/2\ell^2)$ (`cov/covSEiso.m`) with hyperparameters $\psi = \{\ln \ell, \ln \sigma_f\}$ is set up in **line 2**. Note, that the hyperparameters are represented by the logarithms, as these parameters are naturally positive. Many other *simple* covariance functions are contained in the toolbox. Among others, we offer linear, constant, Matérn, rational quadratic, polynomial, periodic, neural network and finite support covariance functions. *Composite* covariance functions allow for sums $k(\mathbf{x},\mathbf{x}') = \sum_j k_j(\mathbf{x},\mathbf{x}')$, products $k(\mathbf{x},\mathbf{x}') = \prod_j k_j(\mathbf{x},\mathbf{x}')$, positive scaling $k(\mathbf{x},\mathbf{x}') = \sigma_f^2 k_0(\mathbf{x},\mathbf{x}')$ and masking of components $k(\mathbf{x},\mathbf{x}') = k_0(\mathbf{x}_I,\mathbf{x}'_I)$ with $I \subseteq [1,2,..,D]$, $\mathbf{x} \in \mathbb{R}^D$. Again, the interface is simple since only the evaluation of the covariance matrix $\mathbf{K} = k_\psi(\mathbf{X})$ and its derivatives $\partial_i \mathbf{K} = \frac{\partial}{\partial \psi_i} k_\psi(\mathbf{X})$ on a data set $\mathbf{X}$ are required. Furthermore, we need cross terms $\mathbf{k}_* = k_\psi(\mathbf{X},\mathbf{x}_*)$ and $k_{**} = k_\psi(\mathbf{x}_*,\mathbf{x}_*)$ for prediction. There are no restrictions on the composition of both mean and covariance functions—any combination is allowed including nested composition.

The Laplace (`lik/likLaplace.m`) likelihood $\mathbb{P}_{\boldsymbol{\rho}}(y|f) = \exp(-\sqrt{2}/\sigma_n|y-f|)/\sqrt{2}\sigma_n$ with hyperparameters $\boldsymbol{\rho} = \{\ln\sigma_n\}$ is specified in **line 3**. There are only *simple* likelihood functions: Gaussian, Sech-squared, Laplacian and Student's t for ordinary and sparse regression as well as the error and the logistic function for classification. Again, the same inference code is used for any likelihood function. Although the specification of likelihood functions is simple for the user, writing new likelihood functions is slightly more involved as different inference methods require access to different properties; for example, LA requires second derivatives and EP requires derivatives of moments.

All hyperparameters $\boldsymbol{\theta} = \{\phi, \psi, \boldsymbol{\rho}\}$ are stored in a struct `hyp.{mean,cov,lik}`, which is initialised in **line 4**; we select the approximate inference algorithm EP (`inf/infEP.m`) in **line 5**.

We optimise the hyperparameters $\boldsymbol{\theta} \equiv$ `hyp` by calling the CG optimiser (`util/minimize.m`) with initial value $\boldsymbol{\theta}_0 \equiv$ `hyp0` in **line 6** allowing at most $N = 50$ evaluations of the EP approximation to the marginal likelihood $Z_{EP}(\boldsymbol{\theta})$ as done by `gp.m`. Here, $\mathcal{D} = (\mathbf{X}, \mathbf{y}) \equiv$ `(X,y)` is the training data where $\mathbf{X} = \{\mathbf{x}_1, .., \mathbf{x}_n\}$ and $\mathbf{y} \in \mathbb{R}^n$. Under the hood, `gp.m` computes in every step a Gaussian posterior approximation and the derivatives $\frac{\partial}{\partial \boldsymbol{\theta}} \ln Z_{EP}(\boldsymbol{\theta})$ of the marginal likelihood by calling EP.

Predictions with optimised hyperparameters are done in **line 7**, where we call `gp.m` with the unseen test inputs $\mathbf{X}_* \equiv$ `Xs` as additional argument. As a result, we obtain the approximate marginal predictive mean $\mathbb{E}[\mathbb{P}(\mathbf{y}_*|\mathcal{D}, \mathbf{X}_*)] \equiv$ `ymu` and the predictive variance $\mathbb{V}[\mathbb{P}(\mathbf{y}_*|\mathcal{D}, \mathbf{X}_*)] \equiv$ `ys2`.

Likelihood \ Inference	Exact	FITC	EP	Laplace	VB	Type, Output Domain	Alternate Name
Gaussian	✓	✓	✓	✓	✓	regression, $\mathbb{R}$	
Sech-squared			✓	✓	✓	regression, $\mathbb{R}$	logistic distribution
Laplacian			✓		✓	regression, $\mathbb{R}$	double exponential
Student's t				✓	✓	regression, $\mathbb{R}$	
Error function			✓	✓	✓	classification, $\{\pm 1\}$	probit regression
Logistic function			✓	✓	✓	classification, $\{\pm 1\}$	logit regression

Table 1: Likelihood $\leftrightarrow$ inference compatibility in the GPML toolbox

Table 1 gives the legal likelihood/inference combinations. Exact inference and the FITC approximation support the Gaussian likelihood only. Variational Bayesian (VB) inference is applicable to all likelihoods. Expectation propagation (EP) for the Student's t likelihood is inherently unstable due to its non-log-concavity. The Laplace approximation (LA) for Laplace likelihoods is not sensible due to the non-differentiable peak of the Laplace likelihood. Special care has been taken for the non-convex optimisation problem imposed by the combination Student's t likelihood and LA.

If the number of training examples is larger than a few thousand, dense matrix computations become too slow. We provide the FITC approximation for regression with Gaussian likelihood where instead of the exact covariance matrix $\mathbf{K}$, a low-rank plus diagonal matrix $\tilde{\mathbf{K}} = \mathbf{Q} + \mathrm{diag}(\mathbf{K} - \mathbf{Q})$ where $\mathbf{Q} = \mathbf{K}_{\mathbf{u}}^{\top}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}}$ is used. The matrices $\mathbf{K}_{\mathbf{uu}}$ and $\mathbf{K}_{\mathbf{u}}$ contain covariances and cross-covariances of and between inducing inputs $\mathbf{u}^i$ and data points $\mathbf{x}^j$. Using `inf/infFITC.m` together with any covariance function wrapped into `cov/covFITC.m` makes the computations feasible for large n.

Acknowledgments

Thanks to Ed Snelson for assisting with the FITC approximation.

Abstract

Probabilistic grammars offer great flexibility in modeling discrete sequential data like natural language text. Their symbolic component is amenable to inspection by humans, while their probabilistic component helps resolve ambiguity. They also permit the use of well-understood, general-purpose learning algorithms. There has been an increased interest in using probabilistic grammars in the Bayesian setting. To date, most of the literature has focused on using a Dirichlet prior. The Dirichlet prior has several limitations, including that it cannot directly model covariance between the probabilistic grammar's parameters. Yet, various grammar parameters are expected to be correlated because the elements in language they represent share linguistic properties. In this paper, we suggest an alternative to the Dirichlet prior, a family of logistic normal distributions. We derive an inference algorithm for this family of distributions and experiment with the task of dependency grammar induction, demonstrating performance improvements with our priors on a set of six treebanks in different natural languages. Our covariance framework permits soft parameter tying within grammars and *across* grammars for text in different languages, and we show empirical gains in a novel learning setting using bilingual, non-parallel data.

Keywords: dependency grammar induction, variational inference, logistic normal distribution, Bayesian inference

1. Introduction

One of the motivating applications for grammar induction, or unsupervised grammatical structure discovery, is for the syntactic analysis of text data. Grammar induction, in that case, may lead to the automatic acquisition of linguistic knowledge and the automatic construction of linguistic analyzers for under-studied text domains and languages, without the costly construction of manually annotated corpora. Grammar induction may also shed light on the cognitive process of language acquisition in humans.

When it comes to the problem of grammar induction from natural language data, a fruitful research direction has built on the view of a grammar as a parameterized, generative process explaining the data (Pereira and Schabes, 1992; Carroll and Charniak, 1992; Chen, 1995; Klein and Manning, 2002, 2004, *inter alia*). If the grammar is a probability model, then learning a grammar means selecting a model from a prespecified model *family*. In much prior work, the family is defined as the set of probabilistic grammar for a fixed set of grammar rules, so that grammar learning amounts to *parameter estimation* from incomplete data: sentences in the language are yields of hid-

den derivations from the grammar. Baker (1979) and Lari and Young (1990) describe how dynamic programming (the "inside-outside" algorithm) can be used within an Expectation-Maximization algorithm (Dempster et al., 1977) to estimate the grammar's probabilities from a corpus of text, in the context-free case.

Probabilistic grammars are attractive for several reasons. Like symbolic grammars, they are amenable to inspection by humans, so that it is relatively easy to understand what tendencies the model has captured if the underlying rules are understandable. Unlike purely symbolic grammars, they model frequency and provide a mechanism for reasoning in the face of ambiguity, which is ubiquitous in natural language. Probabilistic grammars can be specialized (e.g., as hidden Markov models for sequential structures) and generalized (e.g., as lexicalized grammars, as synchronous models over tuples of strings, and as grammars in context-sensitive classes). Probabilistic grammars are widely used to build models in natural language processing from *annotated* data, thus allowing easy comparison between unsupervised and supervised techniques. NLP applications of probabilistic grammars and their generalizations include parsing (Collins, 2003; Klein and Manning, 2003; Charniak and Johnson, 2005), machine translation (Wu, 1997; Ding and Palmer, 2005; Chiang, 2005), and question answering (Wang et al., 2007). Probabilistic grammars are probabilistic models, so they permit the use of well-understood methods for learning.

Meanwhile, in machine learning, significant attention has recently been devoted to Bayesian models. The attraction of Bayesian models is that they manage uncertainty in the face of learning from incomplete data, while permitting the use of background knowledge, in the form of a *prior* over models. This prior can be used to inject bias into a model. Such bias can be especially important in cases where the sample size is not large or when the grammar is highly non-identifiable, two scenarios that hold with grammar induction (see Cohen and Smith, 2010, for a discussion of the size of sample required for estimation of probabilistic grammars).

Bayesian methods have been applied to probabilistic grammars in various ways: specifying priors over the parameters of a PCFG (Johnson et al., 2007; Headden et al., 2009) as well as over the *states* in a PCFG (Finkel et al., 2007; Liang et al., 2007), and even over grammatical derivation structures larger than context-free production rules (Johnson et al., 2006; Cohn et al., 2009). The challenge in Bayesian grammar learning is efficiently approximating probabilistic inference. Variational approximations (Johnson, 2007; Kurihara and Sato, 2006) and randomized sampling approximations (Johnson et al., 2006; Goldwater, 2006) are typically applied.

Much of the Bayesian literature and its application to probabilistic grammars has focused on *conjugate priors* in the form of Dirichlet distributions. Conjugate priors were introduced by Raiffa and Schaifer (1961), who gave a desiderata for prior families, including analytical tractability. We argue that the literature has focused on this desideratum only, ignoring expressive power and interpretability. We begin by motivating the modeling of *covariance* among the probabilities of grammar derivation events, and propose the use of logistic normal distributions (Aitchison, 1986; Blei and Lafferty, 2006) over multinomials to build priors over grammars (Section 3). Our motivation relies on the observation that various grammar parameters are expected to be correlated because of the elements in language they represent share linguistic properties. Noting that grammars are built out of a large collection of multinomials, we introduce *shared* logistic normal distributions to allow *arbitrary* covariance among any grammar probabilities. We then describe efficient inference techniques to support decoding and learning with (shared) logistic normal priors over grammars (Section 4), facing the challenge of non-conjugacy of the logistic normal prior to the multinomial family. We experiment with probabilistic dependency grammar induction from data in six lan-

guages, showing how the new approach performs compared to non-Bayesian alternatives as well as more traditional Dirichlet prior-based alternatives (Section 5.1 and Section 5.2). We then demonstrate that the approach can also be effective when learning from *multilingual*, non-parallel text, softly tying parameters across languages (Section 5.4).

The research results in this paper build on work previously reported by Cohen et al. (2008) and Cohen and Smith (2009). Here we provide a more extensive discussion of the techniques, connections to related work, a full derivation of the variational inference algorithms, and a larger set of experiments on more data sets.

2. Probabilistic Grammars

We begin by discussing the general family of probabilistic grammars to which our methods are applicable. A probabilistic grammar defines a probability distribution over a certain kind of structured object (a derivation of the underlying symbolic grammar) explained step-by-step as a stochastic process. HMMs, for example, can be understood as a random walk through a probabilistic finite-state network, with an output symbol sampled at each state. PCFGs generate phrase-structure trees by recursively rewriting nonterminal symbols as sequences of "child" symbols (each itself either a nonterminal symbol or a terminal symbol analogous to the emissions of an HMM). Our experiments will consider a particular family of PCFGs that represent dependency structure (see Section 2.2).

Each step or emission of an HMM and each rewriting operation of a PCFG is conditionally independent of the others given a single structural element (one HMM or PCFG state); this Markov property permits efficient inference over derivations given a string.

In general, a probabilistic grammar defines the joint probability of a string $\mathbf{x}$ and a grammatical derivation $\mathbf{y}$:[1]

$$p(\mathbf{x},\mathbf{y} \mid \theta) = \prod_{k=1}^{K} \prod_{i=1}^{N_k} \theta_{k,i}^{f_{k,i}(\mathbf{x},\mathbf{y})} = \exp \sum_{k=1}^{K} \sum_{i=1}^{N_k} f_{k,i}(\mathbf{x},\mathbf{y}) \log \theta_{k,i}, \tag{1}$$

where $f_{k,i}$ is a function that "counts" the number of times the kth distribution's ith event occurs in the derivation. The parameters θ are a collection of K multinomials $\langle \theta_1, \ldots, \theta_K \rangle$, the kth of which includes N_k competing events. Letting $\theta_k = \langle \theta_{k,1}, \ldots, \theta_{k,N_k} \rangle$, each $\theta_{k,i}$ is a probability, such that

$$\forall k, \forall i, \qquad \theta_{k,i} \geq 0, \tag{2}$$

$$\forall k, \qquad \sum_{i=1}^{N_k} \theta_{k,i} = 1. \tag{3}$$

As is often the case in probabilistic modeling, there are different ways to carve up the random variables. We can think of $\mathbf{x}$ and $\mathbf{y}$ as correlated structure variables (often $\mathbf{x}$ is known if $\mathbf{y}$ is known), or the derivation event counts $\mathbf{f}(\mathbf{x},\mathbf{y}) = \langle f_{k,i}(\mathbf{x},\mathbf{y}) \rangle_{1 \leq k \leq K, 1 \leq i \leq N_k}$ as an integer-vector random variable (useful for variational inference, in Section 4). In this paper, $\mathbf{x}$ is always observable and $\mathbf{y}$ is hidden until we use gold standard data for testing.

Note that there may be many derivations $\mathbf{y}$ for a given string $\mathbf{x}$—perhaps even infinitely many in some kinds of grammars. For HMMs, there are three kinds of multinomials: a starting state multinomial, a transition multinomial per state and an emission multinomial per state. In that case $K = 2s+1$, where s is the number of states. The value of N_k depends on whether the kth multinomial is the starting state multinomial (in which case $N_k = s$), transition multinomial ($N_k = s$) or

1. A table of notation can be found in Appendix A, Table 4, page 3042.

emission multinomial ($N_k = t$, with t being the number of symbols in the HMM). For PCFGs, each multinomial among the K multinomials correspond to a set of N_k context-free rules headed by the same nonterminal. $\theta_{k,i}$ is then the probability of the ith rule for the kth nonterminal.

The field of grammatical inference also includes algorithms and methods for learning the *structure* of a (formal) language generator or grammar (Angluin, 1988; de la Higuera, 2005; Clark and Thollard, 2004; Clark et al., 2008, *inter alia*). This paper is complementary, focusing on the estimation of the *weights* assigned to the grammar's rules. The choice of using a fixed model family corresponds to a choice to work in a statistical parametric setting; extensions to nonparametric settings are possible (Goldwater, 2006; Johnson et al., 2006; Cohen et al., 2010). We focus on grammars which generate dependency structures for derivations. Dependency syntax is a popular representation that has been found useful in a wide range of natural language applications, including machine translation (Lin, 2004; Gimpel and Smith, 2009), question answering (Wang et al., 2007), as well as deeper semantic processing tasks (Johansson and Nugues, 2007; Das et al., 2010). The grammars used in our experiments are extremely permissive, allowing every possible dependency structure for a sentence (see Section 2.2).

2.1 Simple Example: Class-Based Unigram Model

It is helpful to keep in mind a simple model with a relatively small number of parameters such as a class-based unigram model (Brown et al., 1990). Let the observed symbols in $\mathbf{x}$ range over words in some language's vocabulary Γ. Let each word token x_i have an associated word class from a finite set Λ, denoted y_i; the y_i are all hidden. The derivation in this model is the sequence $\langle y_1, \ldots, y_n \rangle$. The probabilistic model consists of two parts:

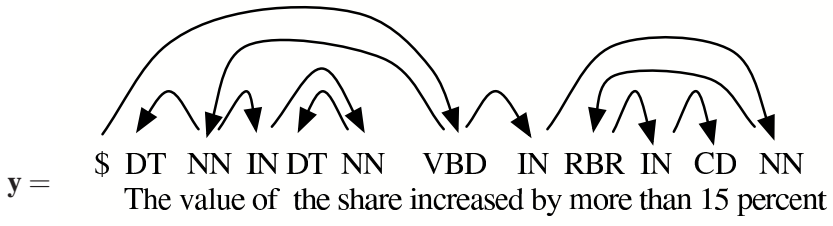
1. For all $y \in \Lambda \cup \{\text{stop}\}$, $\theta_c(y)$ is the probability that the next word will be generated by class y. $\theta_c(\text{stop})$ is the stopping probability.

2. For all $y \in \Lambda$ and all $x \in \Gamma$, $\theta_w(x \mid y)$ is the conditional probability that class y will generate word x.

In this simple model, $K = 1 + |\Lambda|$, $N_1 = |\Lambda|$, and for $k > 1$, $N_k = |\Gamma|$. This model can be thought of as a hidden Markov model with zero order, that is, it has no dependencies between the different hidden states. In addition, if we place a Dirichlet prior on the grammar parameters θ (Section 3.1) and treat θ as a latent variable sampled once per document, this model becomes equivalent to the latent Dirichlet allocation model (Blei et al., 2003). (Our θ_w is denoted β in their notation.) In this case, the derivation vector $\mathbf{y}$ corresponds to a set of topics selected for each word in the bag of words representing the document.

2.2 Dependency Model with Valence

Dependency grammar (Tesnière, 1959) refers to linguistic theories that posit graphical representations of sentences in which words are vertices and the syntax is a directed tree. Such grammars can be context-free or context-sensitive in power, and they can be made probabilistic (Gaifman, 1965). Dependency syntax is used in information extraction, machine translation, question answering, and other natural language processing applications. Our experiments perform unsupervised induction of probabilistic dependency grammars using a model known as "dependency model with valence" (Klein and Manning, 2004). The model is a probabilistic split head automaton grammar



$\mathbf{y} =$

$$\mathbf{x} = \langle \$\ \text{DT NN IN DT NN VBD IN RBR IN CD NN} \rangle$$

$$\begin{aligned}
p(\mathbf{x},\mathbf{y} \mid \theta) &= \theta_c(\text{VBD} \mid \$, \mathsf{r}) \times p(\mathbf{y}^{(1)} \mid \text{VBD}, \theta) \\
p(\mathbf{y}^{(1)} \mid \text{VBD}, \theta) &= \theta_s(\neg\text{stop} \mid \text{VBD}, \mathsf{l}, \mathsf{f}) \times \theta_c(\text{NN} \mid \text{VBD}, \mathsf{l}) \times p(\mathbf{y}^{(2)} \mid \text{NN}, \theta) \\
&\quad \times \theta_s(\text{stop} \mid \text{VBD}, \mathsf{l}, \mathsf{t}) \times \theta_s(\neg\text{stop} \mid \text{VBD}, \mathsf{r}, \mathsf{f}) \times \theta_c(\text{IN} \mid \text{VBD}, \mathsf{r}) \\
&\quad \times p(\mathbf{y}^{(4)} \mid \text{IN}, \theta) \times \theta_s(\text{stop} \mid \text{VBD}, \mathsf{r}, \mathsf{t}) \\
p(\mathbf{y}^{(2)} \mid \text{NN}, \theta) &= \theta_s(\neg\text{stop} \mid \text{NN}, \mathsf{l}, \mathsf{f}) \times \theta_c(\text{DT} \mid \text{NN}, \mathsf{l}) \times \theta_s(\text{stop} \mid \text{DT}, \mathsf{r}, \mathsf{f}) \\
&\quad \times \theta_s(\text{stop} \mid \text{DT}, \mathsf{l}, \mathsf{f}) \theta_c(\text{IN} \mid \text{NN}, \mathsf{r}) \times p(\mathbf{y}^{(3)} \mid \text{IN}, \theta) \\
&\quad \times \theta_s(\text{stop} \mid \text{IN}, \mathsf{l}, \mathsf{f}) \times \theta_s(\text{stop} \mid \text{NN}, \mathsf{l}, \mathsf{t}) \times \theta_s(\text{stop} \mid \text{NN}, \mathsf{r}, \mathsf{t}) \\
p(\mathbf{y}^{(3)} \mid \text{IN}, \theta) &= \theta_s(\neg\text{stop} \mid \text{IN}, \mathsf{r}, \mathsf{f}) \times \theta_c(\text{NN} \mid \text{IN}, \mathsf{r}) \times \theta_c(\text{DT} \mid \text{NN}, \mathsf{l}) \\
&\quad \times \theta_s(\text{stop} \mid \text{DT}, \mathsf{r}, \mathsf{f}) \times \theta_s(\text{stop} \mid \text{DT}, \mathsf{l}, \mathsf{f}) \\
&\quad \times \theta_s(\text{stop} \mid \text{NN}, \mathsf{r}, \mathsf{f}) \times \theta_s(\text{stop} \mid \text{NN}, \mathsf{l}, \mathsf{t}) \\
p(\mathbf{y}^{(4)} \mid \text{IN}, \theta) &= \theta_s(\text{stop} \mid \text{IN}, \mathsf{l}, \mathsf{f}) \times \theta_s(\neg\text{stop} \mid \text{IN}, \mathsf{r}, \mathsf{f}) \times \theta_c(\text{NN} \mid \text{IN}, \mathsf{r}) \\
&\quad \times \theta_s(\text{stop} \mid \text{NN}, \mathsf{r}, \mathsf{f}) \times \theta_s(\neg\text{stop} \mid \text{NN}, \mathsf{l}, \mathsf{f}) \times \theta_c(\text{RBR} \mid \text{NN}, \mathsf{r}) \\
&\quad \times \theta_s(\text{stop} \mid \text{RBR}, \mathsf{l}, \mathsf{f}) \times p(\mathbf{y}^{(5)} \mid \text{RBR}, \theta) \\
p(\mathbf{y}^{(5)} \mid \text{RBR}, \theta) &= \theta_s(\neg\text{stop} \mid \text{RBR}, \mathsf{r}, \mathsf{f}) \times \theta_c(\text{IN} \mid \text{RBR}, \mathsf{r}) \times \theta_c(\text{CD} \mid \text{IN}, \mathsf{r}) \\
&\quad \times \theta_s(\text{stop} \mid \text{IN}, \mathsf{l}, \mathsf{f}) \times \theta_s(\text{stop} \mid \text{IN}, \mathsf{r}, \mathsf{t}) \times \theta_s(\text{stop} \mid \text{CD}, \mathsf{r}, \mathsf{f}) \\
&\quad \times \theta_s(\text{stop} \mid \text{CD}, \mathsf{l}, \mathsf{f})
\end{aligned}$$

Figure 1: An example of a dependency tree (derivation $\mathbf{y}$). and its probability. The part-of-speech tags NN, VBD, DT, CD, RBR, and IN denote noun, past-tense verb, determiner, number, comparative adverb, and preposition, respectively, following Penn Treebank conventions. We break the probability of the tree down into recursive parts, one per head word, marked in blue (lighter). l, r, t, and f denote left, right, true, and false, respectively (see Equation 4).

(Alshawi and Buchsbaum, 1996) that renders inference cubic in the length of the sentence (Eisner, 1997). The language of the grammar is context-free, though our models are permissive and allow the derivation of any string in Γ^*. This is a major point of departure between theoretical work in grammatical inference and work on natural language text, particularly using probabilistic gram-

mars; our goal is to induce a distribution over derivations so that the most likely derivations under the model closely mimic those preferred by linguists (Smith and Eisner, 2005).

"Valence" here refers to the number of arguments controlled by the head of a phrase.[2] In the DMV, each word has a binomial distribution over whether it has at least one left child (similarly on the right), and a geometric distribution over the number of further children (for each side).

Let $\mathbf{x} = \langle x_1, x_2, ..., x_n \rangle$ be a sentence (here, as in prior work, represented as a sequence of part-of-speech tags). x_0 is a special "wall" symbol, \$, on the left of every sentence. A tree $\mathbf{y}$ is defined by a pair of functions $\mathbf{y}_{left}$ and $\mathbf{y}_{right}$ (both $\{0,1,2,...,n\} \rightarrow 2^{\{1,2,...,n\}}$) that map each word to its sets of left and right dependents, respectively. Here, the graph is constrained to be a *projective* tree rooted at $x_0 = \$$: each word except \$ has a single parent, and there are no cycles or crossing dependencies. $\mathbf{y}_{left}(0)$ is taken to be empty, and $\mathbf{y}_{right}(0)$ contains the sentence's single head. Let $\mathbf{y}^{(i)}$ denote the subtree rooted at position i (i.e., $\mathbf{y}^{(i)}$ is a tree consisting of all descendents of x_i in the tree $\mathbf{y}$). The probability $P(\mathbf{y}^{(i)} \mid x_i, \theta)$ of generating this subtree, given its head word x_i, is defined recursively:

$$p(\mathbf{y}^{(i)} \mid x_i, \theta) = \prod_{D \in \{left, right\}} \theta_s(\text{stop} \mid x_i, D, [\mathbf{y}_D(i) = \emptyset]) \times \prod_{j \in \mathbf{y}_D(i)} \theta_s(\neg\text{stop} \mid x_i, D, \text{first}_{\mathbf{y}}(j)) \times \theta_c(x_j \mid x_i, D) \times p(\mathbf{y}^{(j)} \mid x_j, \theta), \quad (4)$$

where $\text{first}_{\mathbf{y}}(j)$ is a predicate defined to be true iff x_j is the closest child (on either side) to its parent x_i. The probability of the entire tree is given by $p(\mathbf{x}, \mathbf{y} \mid \theta) = p(\mathbf{y}^{(0)} \mid \$, \theta)$. The parameters θ are the conditional multinomial distributions $\theta_s(\cdot \mid \cdot, \cdot, \cdot)$ and $\theta_c(\cdot \mid \cdot, \cdot)$. To follow the general setting of Equation 1, we index these distributions as $\theta_1, ..., \theta_K$. Figure 1 shows a dependency tree and its probability under this model (Equation 4).

Note that if all weights θ are greater than zero, the model permits *any* dependency tree over *any* sentence in Γ^*. Hence the goal of grammar induction is to model the *distribution* of derivations, not to separate grammatical strings or derivations from ungrammatical ones.

Klein and Manning's (2004) dependency model with valence is widely recognized as an effective probabilistic grammar for dependency grammar induction. Many recent studies on dependency grammar induction use it. For example, this model has been used to test estimation algorithms such as Viterbi EM (Spitkovsky et al., 2010b), contrastive estimation (Smith and Eisner, 2005), and algorithms which gradually introduce more data to the learning process (Spitkovsky et al., 2010a); it has been used to test the efficacy of multilingual learning through dependency grammar induction (Ganchev et al., 2009; Berg-Kirkpatrick and Klein, 2010); it has been used as a base model that has inspired more complex lexicalized models (Headden et al., 2009). The DMV has also been used as a base model within various estimation techniques with the goal of improving its performance by relying on other properties of language and text such as: dependencies between parameters in the model (Berg-Kirkpatrick et al., 2010), sparsity (Gillenwater et al., 2010), preference for short attachments (Smith and Eisner, 2006), and additional annotation offered by hypertext markup as found on the Web (Spitkovsky et al., 2010c). In addition, the DMV is related to the head-outward model used by Collins (2003) for supervised parsing; Collins' parser is one of the best performing parsers for English. In the rest of the paper, we assume we have a fixed grammar $\mathbf{G}$ for which we estimate the parameters.

2. Here, we refer to "head of a phrase" as in the linguistic sense—the word in a phrase that determines the syntactic category of this phrase.

2.3 Parameter Estimation by Maximum Likelihood

In the original framework, Klein and Manning (2004) treated the DMV as a model on its own, and also in combination with a model over bracketing structures called the "constituent-context model." Here we consider the DMV on its own as it is more capable of generalization and better exemplifies probabilistic grammars.

Klein and Manning learned the DMV using maximum likelihood estimation, carried out by the Expectation-Maximization (EM) algorithm. Because EM for probabilistic grammars has been well documented elsewhere (Lari and Young, 1990; Pereira and Schabes, 1992; Carroll and Charniak, 1992), we only briefly mention that it proceeds by alternating between two steps that update the model parameters. Let $\theta^{(t)}$ denote their values at time step t.

1. E-step: For each training example $\mathbf{x}$, infer the posterior distribution $p(\mathbf{y} \mid \mathbf{x}, \theta^{(t)}, \mathbf{G}) = p(\mathbf{x}, \mathbf{y} \mid \theta^{(t)}) / p(\mathbf{x} \mid \theta^{(t)}, \mathbf{G})$. This is accomplished by dynamic programming (for HMMs, the forward-backward algorithm; for PCFGs, the inside-outside algorithm; for the DMV, an algorithm due to Eisner, 1997), and the result is usually represented as a vector of derivation event expected frequencies, $\langle \mathbb{E}_{p(\cdot \mid \mathbf{x}, \theta^{(t)}, \mathbf{G})} f_{k,i}(\mathbf{x}, \cdot) \rangle_{k,i}$.

2. M-step: Estimate $\theta^{(t+1)}$ from the expected frequencies, as if they were observed frequencies. Since the model is built out of multinomials, there is a closed form solution obtained by normalizing the frequencies.

It is helpful to consider the problem EM iterations aim to solve in its declarative form, the problem of maximizing likelihood:

$$\max_{\theta} p(\mathbf{x} \mid \theta, \mathbf{G}) = \max_{\theta} \sum_{\mathbf{y}} p(\mathbf{x}, \mathbf{y} \mid \theta, \mathbf{G}).$$

(In fact, EM only locally maximizes this function.) In the above, we suppress the collection of sentences constituting the training data; to be precise, we should take a product of probabilities or a sum of log-probabilities for all training examples:

$$\max_{\theta} \prod_{m=1}^{M} \sum_{\mathbf{y}} p(\mathbf{x}_m, \mathbf{y} \mid \theta, \mathbf{G}).$$

In the Bayesian approach, we treat θ not as a set of parameters to be estimated, but rather as a random event. This contrasts with earlier research that aims to bias the grammar learner with prior information. Klein and Manning (2004), for example, biased the learner by initializing EM with a "harmonic" posterior over dependency attachments that preferred linking words that are closer together in the string to more distant words. Smith and Eisner (2006) more explicitly biased EM by manipulating the posterior calculated in the E-step with penalties for longer dependency attachments or, in an alternative model that permitted disconnected graphs, for contiguity.

3. Bayesian Models over Grammars

An attractive way to incorporate prior knowledge about grammars is through a prior distribution over the grammar's probabilities θ. Priors are often used to obtain *smooth* estimates; Smith (2006)

Model I:

For $m \in \{1, \ldots, M\}$:

1. Draw θ_m from the prior $p(\theta \mid \mathbf{G}, \ldots)$.
2. Draw $(\mathbf{x}_m, \mathbf{y}_m)$ from $p(\mathbf{x}_m, \mathbf{y}_m \mid \theta_m, \mathbf{G})$.

Model II:

1. Draw θ from the prior $p(\theta \mid \mathbf{G}, \ldots)$.
2. For $m \in \{1, \ldots, M\}$:
   Draw $(\mathbf{x}_m, \mathbf{y}_m)$ from $p(\mathbf{x}_m, \mathbf{y}_m \mid \theta, \mathbf{G})$.

Figure 2: Two variations on Bayesian modeling of probabilistic grammars.

explored symmetric Dirichlet priors in the DMV in a maximum *a posteriori* framework for learning that can still be accomplished by EM:

$$\max_{\theta} p(\theta \mid \alpha, \mathbf{G}) \prod_{m=1}^{M} \sum_{\mathbf{y}} p(\mathbf{x}_m, \mathbf{y} \mid \theta, \mathbf{G}), \tag{5}$$

where α denotes the parameters of the prior over grammars. EM is efficient when $p(\theta \mid \alpha, \mathbf{G})$ is a collection of Dirichlet distributions with each $\alpha \geq 1$ (discussed below). For the moment, we leave aside the form of the prior, though it is a major focus of this article.

In this paper, we go farther. We treat θ as a hidden variable, not unlike $\mathbf{y}$. It will therefore be integrated out in defining the probability of the data:

$$p(\mathbf{x}_1, \ldots, \mathbf{x}_M \mid \alpha, \mathbf{G}) = \int p(\theta \mid \alpha, \mathbf{G}) \prod_{m=1}^{M} \sum_{\mathbf{y}} p(\mathbf{x}_m, \mathbf{y} \mid \theta, \mathbf{G}) \, d\theta. \tag{6}$$

In this setting, it is α, the distribution over grammar parameters, that encodes knowledge about the grammar, and it will be α that we estimate when we perform learning.

We consider two alternative variations on the Bayesian idea, illustrated in Figure 2. In the first, called "model I," the grammar's probabilities θ are drawn randomly once per sentence for the whole corpus $\mathbf{x}_1, \ldots, \mathbf{x}_M$. In "model II," the grammar parameters are drawn *once* for all of the sentences in the corpus.

Conceptually, both options have advantages and disadvantages when modeling natural language. Drawing θ for each derivation permits more flexibility across derivations, perhaps allowing the learner to capture variation across the corpus (even if not systematically, as the grammars are drawn IID), arising from different authors, for example. Generating θ only once suggests we need to do inference in a smaller space: we only need to find the posterior over a single θ, perhaps leading to better generalization. We will consider both forms in our experiments (Section 5.1).

The question of the choice of a prior distribution still remains. In their pioneering work about conjugate priors,[3] Raiffa and Schaifer (1961) set desiderata for prior distributions in parametric models. These desiderata, which serve as the foundation for *conjugate priors*, include: (i) analytical tractability—the posterior using a certain prior family should stay in the prior family, while it is reasonably easy to identify the posterior from a sample and a prior; (ii) richness—there should be a member in the prior family that is able to express the modeler's beliefs and prior information; (iii)

3. A prior family is conjugate for a family of distributions if the posterior over the family, after observing some data, is also in the prior family. See Raiffa and Schaifer (1961).

interpretability—the prior should be easily interpreted so the modeler can verify that the choice of prior matches prior judgments.

Unfortunately, much of the Bayesian literature for probabilistic grammars and even in general has diverged considerably from these desiderata, and focused only on the first requirement of analytical tractability. As a result, most of the Bayesian language learning literature has focused on Bayesian models with a Dirichlet prior (Johnson et al., 2007; Goldwater and Griffiths, 2007; Toutanova and Johnson, 2007; Kurihara and Sato, 2006, *inter alia*), which is conjugate to the multinomial family. We argue that the last two requirements are actually more important than the first one, which is motivated by mere mathematical and computational convenience. We suggest replacing the first requirement with "computational tractability"—it should be easy to represent the posterior (or an approximation of it) computationally. In that case, the modeler can focus on choosing *rich* priors that can more properly model different structural elements of a grammar. To solve the problem of inference, we can now use approximate inference algorithms such as the one we give in Section 4 and Appendix B. Indeed, approximations are sometimes required even for the conjugate case, and are always required when the data are incomplete.

We next give an overview of the Dirichlet prior that provides analytical tractability for probabilistic grammars, and then demonstrate the alternative which focuses on the second and third requirements, the logistic normal distribution. The logistic normal, we suggest, improves over the Dirichlet from the perspective of desideratum (ii), though we must take further steps to achieve sufficient "richness" to account for arbitrary covariance and for multilingual text data.

3.1 Dirichlet Distributions

From the computational perspective, the Dirichlet distribution is indeed a natural choice for a prior over the parameters of the grammar because of its analytical tractability, which makes inference more elegant and less computationally intensive in both the maximum *a posteriori* (Equation 5) and Bayesian (Equation 6) settings. In addition, a Dirichlet prior can encourage sparse solutions (i.e., many $\theta_{k,i} = 0$), a property which is desirable in natural language learning (Johnson et al., 2007), as it corresponds to eliminating unnecessary grammar rules. (Indeed, learning to exclude rules by setting their probabilities to zero is one way of going about symbolic grammar induction.)

If we use a Dirichlet distribution with a probabilistic grammar, then the hyperparameters for the grammar consist of K vectors with positive elements, the kth of which has length N_k. We denote these hyperparameters by α, in which case the prior over the grammar parameters θ has the form:

$$p(\theta \mid \alpha) = \prod_{k=1}^{K} \left(\frac{\prod_{i=1}^{N_k} \Gamma(\alpha_{k,i})}{\Gamma\left(\sum_{i=1}^{N_k} \alpha_{k,i}\right)} \prod_{i=1}^{N_k} \theta_{k,i}^{\alpha_{k,i}-1} \right) = B(\theta) \times \prod_{k=1}^{K} \prod_{i=1}^{N_k} \theta_{k,i}^{\alpha_{k,i}-1},$$

where $\Gamma(\cdot)$ is the Gamma function and $B(\theta)$ is a constant term with respect to θ.

Consider again the simple model of Section 2.1. If we embed it inside model I (Figure 2) we arrive exactly at the latent Dirichlet allocation model of Blei et al. (2003), where each example is a document (not a sentence).

The Dirichlet distribution can also be derived as a normalized set of variables of exponentiated *independent* Gamma-distributed variables. More precisely, for each multinomial θ_k ($k \in \{1, \ldots, K\}$), we can draw N_k independent random samples $v_{k,1}, \ldots, v_{k,N_k}$ from Gamma distributions with shapes

$\alpha_{k,1},\ldots,\alpha_{k,N_k}$, respectively, and scale 1 and then let:

$$\theta_{k,i} = \frac{v_{k,i}}{\sum_{i'=1}^{N_k} v_{k,i'}}.$$

This alternative representation of the Dirichlet distribution points to a weakness: there is no explicit covariance structure present when θ are drawn from a Dirichlet. The only way θ_k covary is through the normalization that maps $v_{k,i}$ to the probability simplex. In fact, the correlation between $\theta_{k,i}$ and $\theta_{k,i'}$ is always negative and equals $-\frac{(\alpha_{k,i}\alpha_{k,i'})^{1/2}}{((\alpha_{k,0}-\alpha_{k,i})(\alpha_{k,0}-\alpha_{k,i'}))^{1/2}}$ where $\alpha_{k,0} = \sum_{i=1}^{N_k} \alpha_{k,i}$. This relates back to the desiderata of Raiffa and Schaifer: the covariance (and in fact, variance) structure that the Dirichlet distribution offers is not rich. This is especially true when modeling language, as we explain in the section below.

3.2 Modeling Covariance with Logistic Normal Distributions

When we consider probabilistic grammars for natural languages, especially those over words or word classes like parts of speech, we *do* expect to see covariance structure. Intuitively, the probability of a particular word or word class having singular nouns as arguments is likely tied to the probability of the same word having *plural* nouns as arguments. Words that tend to attach to one type of parent are expected to tend to attach to similar parents. This follows because words and word classes tend to follow patterns. This is a large part of the empirical motivation for syntactic theories that make use of part of speech and phrase categories.

A natural candidate for a distribution that models covariance is the multivariate normal distribution. However, values drawn from the multivariate normal distribution can be both positive and negative, and they also do not necessarily normalize to 1, both are requirements from θ (see Equations 2–3). Aitchison (1986) suggested a logistic transformation on a multivariate normal variable to get values which correspond to points on the probabilistic simplex. He called it the "logistic normal" distribution.

The logistic normal (LN) distribution maps a $(d-1)$-dimensional multivariate Gaussian to a distribution on the d-dimensional probability simplex, $\{\langle z_1,\ldots,z_d\rangle \in \mathbb{R}^d : z_i \geq 0, \sum_{i=1}^d z_i = 1\}$, as follows:

1. Draw $\eta = \langle \eta_1,\ldots,\eta_{d-1}\rangle$ from a multivariate Gaussian with mean μ and covariance matrix Σ.
2. Let $\eta_d = 0$.
3. For $i \in \{1,\ldots,d\}$, let:
$$z_i = \frac{\exp \eta_i}{\sum_{j=1}^d \exp \eta_j}.$$

Drawing from a $(d-1)$-dimensional Gaussian preserves identifiability; a d-dimensional Gaussian would have an extra degree of freedom, allowing more than one outcome of η to lead to the same $\mathbf{z}$.

For probabilistic grammars, we define one LN distribution per multinomial. This gives a prior over each θ_k that permits covariance among $\langle \theta_{k,1},\ldots,\theta_{k,N_k}\rangle$.

Blei and Lafferty (2006) and Ahmed and Xing (2007) successfully used the LN distribution for topic models, extending the latent Dirichlet allocation model (Blei et al., 2003). In Cohen et al.

\end{array}\right\} \text{softmax}
$$

Figure 3: An example of a shared logistic normal distribution, illustrating Def. 1. $N = 4$ experts are used to sample $K = 3$ multinomials; $L_1 = 3, L_2 = 2, L_3 = 2, L_4 = 1, \ell_1 = 9, \ell_2 = 6, \ell_3 = 7, \ell_4 = 2, N_1 = 2, N_2 = 4$, and $N_3 = 3$. From top to bottom: the partition structure $\mathcal{S}$ describes I_j which tell how segment a normal expert into parts which are matched to multinomials ("prt. struct. $\mathcal{S}$"). Each normal expert is sampled from a multivariate normal ("sample η"), and then matched and averaged according to the partition strcture ("combine η"). The final step is exponentiating and normalizing η to get θ ("softmax"). This figure is best viewed in color.

(2008), we demonstrated how the LN distribution is an effective alternative to the Dirichlet for probabilistic dependency grammar induction in the Bayesian setting.

We note that the family of logistic normal distributions and the family of Dirichlet distributions are very different from each another. One cannot find two distributions from each class which are arbitrary close to each other in any meaningful sense. However, it can be shown (Aitchison, 1986) that given a Dirichlet distribution with very large α, we can find a logistic normal distribution such that the KL-divergence between the Dirichlet distribution and logistic normal distribution is small.

3.3 Sharing Across Multinomials

The LN distribution has an inherent limitation when we consider probabilistic models made up of more than one multinomial distribution, such as probabilistic grammars. Each multinomial is drawn separately from an independent Gaussian, so that covariance can only be imposed among events competing within one multinomial, not across multinomials. With the DMV, for example, the probability of a past-tense verb (VBD) having a noun as a right child might correlate with the

probability that other kinds of verbs (VBZ, VBN, etc.) have a noun as a right child. This correlation cannot be captured by the LN distribution, because the VBZ and VBN as parents are represented using their own multinomials over children, unrelated to that of VBD as a parent.

One way to mend this limitation is to define a single Gaussian over $N \triangleq \sum_{k=1}^{K} N_k$ variables with one $N \times N$ covariance matrix. Then, instead of applying the logistic transformation to the whole vector as a single multinomial, we can apply it to subvectors to get disjoint multinomials. When learning, the large covariance matrix captures correlations between all pairs of events in all multinomials. The induced distribution is called the *partitioned* logistic normal (PLN) distribution. It is a generalization of the LN distribution (see Aitchison, 1986).

In practice, creating a covariance matrix of size $N \times N$ is likely to be too expensive. DMV, for example, has $O(t^2)$ weights for a part-of-speech vocabulary of size t, requiring a very large multivariate normal distribution with $O(t^4)$ covariance parameters.

To solve this problem, we suggest a refinement of the class of PLN distributions. Instead of using a single normal vector for all of the multinomials, we use several normal vectors, partition each one and then *recombine* parts which correspond to the same multinomial, as an average. Next, we apply the logistic transformation on the mixed vectors (each of which is normally distributed as well). Figure 3 gives an example of a non-trivial case of using a SLN distribution, where three multinomials are generated from four normal experts.

We now formalize this notion. For a natural number N, we denote by $1{:}N$ the set $\{1,\ldots,N\}$. For a vector in $v \in \mathbb{R}^N$ and a set $I \subseteq 1{:}N$, we denote by v_I the vector created from v by using the coordinates in I. Recall that K is the number of multinomials in the probabilistic grammar, and N_k is the number of events in the kth multinomial. We define a shared logistic normal distribution with N "experts" over a collection of K multinomial distributions:

Definition 1 *Let $\eta_n \sim \text{Normal}(\mu_n, \Sigma_n)$ be a set of multivariate normal variables for $n \in 1{:}N$, where the length of η_n is denoted ℓ_n. Let $I_n = \{I_{n,j}\}_{j=1}^{L_n}$ be a partition of $1{:}\ell_n$ into L_n sets, such that $\cup_{j=1}^{L_n} I_{n,j} = 1{:}\ell_n$ and $I_{n,j} \cap I_{n,j'} = \emptyset$ for $j \neq j'$. Let J_k for $k \in 1{:}K$ be a collection of (disjoint) subsets of $\{I_{n,j} \mid n \in 1{:}N, j \in 1{:}\ell_n, |I_{n,j}| = N_k\}$, such that all sets in J_k are of the same size, N_k. Let $\tilde{\eta}_k = \frac{1}{|J_k|} \sum_{I_{n,j} \in J_k} \eta_{n,I_{n,j}}$, and $\theta_{k,i} = \exp(\tilde{\eta}_{k,i}) \big/ \sum_{i'} \exp(\tilde{\eta}_{k,i'})$. We then say θ distributes according to the* shared logistic normal distribution *with* partition structure $\mathcal{S} = (\{I_n\}_{n=1}^{N}, \{J_k\}_{k=1}^{K})$ *and* normal experts $\{(\mu_n, \Sigma_n)\}_{n=1}^{N}$ *and denote it by* $\theta \sim \text{SLN}(\mu, \Sigma, \mathcal{S})$.

The partitioned LN distribution in Aitchison (1986) can be formulated as a shared LN distribution where $N = 1$. The LN collection presented in Section 3.2 is the special case where $N = K$, each $L_n = 1$, each $\ell_k = N_k$, and each $J_k = \{I_{k,1}\}$.

We note that there is an issue with identifiability that we need to resolve with SLN distributions, as with the LN distribution. It is required that for all multinomials, we set the first value of the samples from the normal expert to 0. For simplicity, we did not include it explicitly in Definition 1, because this can be achieved by setting the normal expert's mean and variance values to 0 in the first index of each normal expert ($\eta_{n,1} = 0$ for all n).

The covariance among arbitrary $\theta_{k,i}$ is not defined directly; it is implied by the definition of the normal experts $\eta_{n,I_{n,j}}$, for each $I_{n,j} \in J_k$. We note that a SLN can be represented as a PLN by relying on the distributivity of the covariance operator, and merging all the partition structure into one (perhaps sparse) covariance matrix. SLNs, in that case, represent a subset of PLNs with a factored structure on the covariance matrices.

It is convenient to think of each $\eta_{i,j}$ as a weight associated with a unique event's probability, a certain outcome of a certain multinomial in the probabilistic grammar. By letting different $\eta_{i,j}$ covary with each other, we strengthen the relationships among $\theta_{k,j}$ and permit learning of the one to affect the learning of the other. Definition 1 also implies that we multiply several multinomials together in a product-of-experts style (Hinton, 1999), because the exponential of an average of normals becomes a product of (unnormalized) probabilities.

We note that the partition structure is a hyperparameter. In our experiments, it encodes domain knowledge about the languages we experiment with (Section 5.3). We believe this is a key advantage of SLN in this setting: marrying the notions of prior knowledge and a Bayesian prior. The beliefs of the model about a language can be encoded into a distribution over the parameters. We leave for future work the discovery of partition structure during the learning process.

3.4 Local Log-Linear Models over Parameters

We give now another interpretation of the shared logistic normal prior using a feature representation, which is related to recent work by Berg-Kirkpatrick et al. (2010). A probabilistic grammar with a shared logistic normal prior can be thought of as a probabilistic grammar where the grammar's parameters are themselves modeled using a local log-linear model with a Gaussian prior over the weights of this log-linear model. Let θ_k be a multinomial in the collection of multinomials for a probabilistic grammar. Then, according to Definition 1 we have:

$$\theta_{k,i} = \frac{\exp\left(g_k(i) \cdot \eta\right)}{Z_k(\eta)},$$

where η is a vector of length $\sum_{n=1}^{N} \ell_n$, a concatenation of all normal experts, and $g_k(i)$ is a feature vector, again of length $\sum_{n=1}^{N} \ell_n$, which is divided into subvectors $g_{k,n}(i)$ each of length ℓ_n. $g_{k,n,j}(i) = 1/|J_k|$ if the ith event in the kth multinomial uses the jth coordinate of the nth normal expert—that is, there exists an $I_{n,r} \in I_n \cap J_k$ such that $j \in I_{n,r}$ (according to Definition 1)—and 0 otherwise. The term $Z_k(\eta)$ is a normalization constant of the form:

$$Z_k(\eta) = \sum_{i'} \exp\left(g_k(i') \cdot \eta\right).$$

Note that the features in the local log-linear model refer to the *hyperparameters* of the SLN, more specifically, the partition structure. They do not refer to the observed data or the latent structural elements in the probabilistic grammar. These features have a Gaussian prior over them, represented by the normal experts' mean values and covariance matrices (μ and Σ). In that case, the Gaussian prior which we optimize during inference using empirical Bayes (Section 4) can be thought of as a quadratic penalty on the local log-linear weights. We note that in most cases in the literature, Gaussian priors (or L_2 regularizers) are used with mean value 0 and a uniform diagonal covariance matrix, in order to push feature weights to values close to 0. This is not the case with our model.

Berg-Kirkpatrick et al. (2010) used the idea of local log-linear models for several natural language processing tasks, including dependency grammar induction and part-of-speech tagging. Instead of using features that are based on a Gaussian prior, they used a set of ordinary binary features, which describe relationships between different parameters in a similar way to the ones presented in Section 5.3.

4. Inference and Learning

Having defined a family of probability models over grammars, we now consider the problem of inferring posterior distributions under this model. We first consider inference over $\mathbf{y}$, then over θ, then learning the parameters of the distribution over grammars in an empirical Bayesian framework.

4.1 Decoding: Inferring y

Classical statistical approaches to language processing normally assume that inputs (here, sentences $\mathbf{x}$) are independently and identically distributed. Decoding is the problem of choosing an analysis (here, grammatical derivation $\mathbf{y}$) given the input. Most commonly this is accomplished by choosing the most probable analysis:

$$\mathbf{y}^* = \operatorname*{argmax}_{\mathbf{y}} p(\mathbf{y} \mid \mathbf{x}, \theta, \mathbf{G}) = \operatorname*{argmax}_{\mathbf{y}} p(\mathbf{x}, \mathbf{y} \mid \theta, \mathbf{G}). \tag{7}$$

This is commonly called "Viterbi" decoding, referring to the algorithm that accomplishes the maximization for hidden Markov models. An alternative is to choose the analysis that minimizes *risk*, or the expectation (under the model) of a cost function. Let $\text{cost}(\mathbf{y}, \mathbf{y}^*)$ denote the nonnegative cost of choosing analysis $\mathbf{y}$ when the correct analysis is $\mathbf{y}^*$.

$$\mathbf{y}^* = \operatorname*{argmax}_{\mathbf{y}} \mathbb{E}_{p(\cdot \mid \mathbf{x}, \theta, \mathbf{G})} \text{cost}(\mathbf{y}, \cdot) = \operatorname*{argmax}_{\mathbf{y}} \sum_{\mathbf{y}'} p(\mathbf{y}' \mid \mathbf{x}, \theta, \mathbf{G}) \ \text{cost}(\mathbf{y}, \mathbf{y}').$$

This is known as minimum Bayes risk (MBR) decoding.[4] For dependency parsing, the cost function counts the number of words attached to the wrong parent.

Decoding is a crucial step in evaluation of models of natural language. Typically for supervised and unsupervised models, decoding output is compared to expert human-annotated gold standard analyses, providing an objective measure of the quality of the learned model. Best practice measures quality on new test data unseen during training, to test the generalization ability of the learned model. This is an attractive approach to evaluating the quality of unsupervisedly induced grammars.

In the Bayesian setting, decoding might be accomplished using the posterior over derivations, marginalizing out the unknown grammar weights. For model I, Viterbi decoding would correspond to:

$$\mathbf{y}^* = \operatorname*{argmax}_{\mathbf{y}} p(\mathbf{y} \mid \alpha, \mathbf{G}) = \operatorname*{argmax}_{\mathbf{y}} \int p(\theta \mid \alpha, \mathbf{G}) p(\mathbf{x}, \mathbf{y} \mid \theta, \mathbf{G}) \, d\theta. \tag{8}$$

Unfortunately, there is no closed-form solution for the integral in Equation 8 and finding $\mathbf{y}^*$ is intractable. We therefore have to resort to approximate inference (Section 4.2). Model II creates dependence among the derivations of the different sentences in the training set, requiring a different inference procedure.

In this work, we consider three decoding techniques. The first takes a point estimate of θ and applies Viterbi decoding (Equation 7). The point estimate is derived using techniques discussed below. After estimating the μ (and the Σ), we use the logistic transformation on μ to obtain this point estimate for Viterbi decoding. Recall that for the DMV, decoding can be accomplished in cubic time using dynamic programming (Section 2.2).

4. In some cases, decoding selects only certain salient aspects of a derivation, such as the derived tree corresponding to a tree adjoining grammar's *derivation* tree. In such cases, Viterbi and/or MBR decoding may require approximations.

The second approach makes use of the same point estimate of θ, only with MBR decoding, as described above. The loss function we use is dependency attachment error, for the task of dependency grammar induction. MBR decoding in this case works as follows: using θ and the inside-outside algorithm, we compute the posterior probability of each dependency attachment (directed edge in the graph) being present in the grammatical derivation for the sentence. Then, we find the tree with the largest score, the score being the sum of the posterior probabilities of each edge present in the tree.

Neither Viterbi nor MBR decoding uses the entire distribution over grammar weights. In the LN case, for example, the covariance matrix Σ is ignored. We suggest "committee decoding," in which a set of randomly sampled grammar weights are drawn for each sentence to be parsed. The weights are drawn from the learned distribution over grammar weights, parameterized by μ and Σ in the LN case. Viterbi or MBR decoding can then be applied. Note that this decoding mechanism is randomized: we sample a grammar per sentence, and use it to decode. We apply this decoding mechanism ten times, and average performance. This decoding method is attractive because it has generalization error guarantees: in a PAC-Bayesian framework, it can be shown that the error of committee parsing on the sample given should be close to the expected error (see Seeger, 2002; McAllester, 2003; Banerjee, 2006).

4.2 Variational Inference with Logistic Normal Distributions

The lack of conjugacy of the logistic normal distribution to the multinomial family complicates the inference of distributions over θ and distributions over the hidden derivations $\mathbf{y}$ from the probabilistic grammar, given a sequence of observed sentences $x_1, \ldots, x_M$.

Mimno et al. (2008) explored inference with the logistic normal distribution using sampling with an auxiliary variable method. However, sampling is notoriously slow to converge, especially with complicated structures such as grammatical derivations. The algorithm Mimno et al. suggest is also rather complicated, while alternatives, such as mean-field variational inference (Wainwright and Jordan, 2008), offer faster convergence and a more intuitive solution to the problem of non-conjugacy of the logistic normal distribution.

Variational inference algorithms have been successfully applied to various grammar and syntax learning tasks (Kurihara and Sato, 2006; Liang et al., 2007; Headden et al., 2009; Boyd-Graber and Blei, 2010; Cohen et al., 2010, *inter alia*). We give the full technical details of mean-field variational inference for probabilistic grammars with logistic normal priors in Appendix B, and turn to give a brief overview of the main technical details next, under the simplifying assumption that we have a single observation $\mathbf{x}$.

Mean-field variational inference in the Bayesian setting relies on two principal approximations: the first approximation is done to the marginalized log-likelihood. Using Jensen's inequality and an auxiliary distribution $q(\theta, \mathbf{y})$, later to be used as our approximate posterior, we bound the log-likelihood, marginalizing out the parameters and the hidden derivations in the grammar:

$$\log \int \sum_{\mathbf{y}} p(\mathbf{x}, \mathbf{y}, \theta \mid \mu, \Sigma, \delta, \mathbf{G}) \, d\theta \geq \mathbb{E}_q[\log p(\mathbf{x}, \mathbf{y}, \theta \mid \mu, \Sigma, \delta, \mathbf{G})]. \tag{9}$$

The goal of the approximation in Equation 9 is to derive a bound which is optimized with respect to q, instead of optimizing the marginalized log-likelihood, which is intractable. q serves as our approximate posterior.

The bound in Equation 9 requires further approximation, the mean-field approximation, to be tractable. This mean-field approximation states that $q(\theta, \mathbf{y})$ is factorized and has the following form:

$$q(\theta, \mathbf{y}) = q(\theta)q(\mathbf{y}).$$

The variational distributions, $q(\theta)$ and $q(\mathbf{y})$ can take an arbitrary form, as long as the bound in Equation 9 can be efficiently maximized with respect to these variational distributions. For the case of logistic normal priors, an additional approximation will be necessary (a first-order Taylor approximation to the log of the normalization of the logistic normal distribution), because of the lack of conjugacy of the logistic normal priors to the multinomial family (see Appendix B). We show in Appendix B that even though $q(\mathbf{y})$ can have an arbitrary form, in order to maximize the variational bound it needs to have the form of a probabilistic grammar, dominated by the grammar's variational parameters. This makes inference applicable through the use of an inside-outside algorithm with a weighted grammar of the same form as the original model. The mean-field approximation yields an elegant algorithm, which looks similar to the Expectation-Maximization algorithm (Section 2.3), alternating between optimizing the bound in Equation 9 with respect to $q(\theta)$ and with respect to $q(\mathbf{y})$.

4.3 Variational EM

The variational inference algorithm in Section 4.2 assumes that the μ and Σ are fixed. We are interested in obtaining an *estimate* for μ and Σ, so that we can fit the data and then use the learned model as described in Section 4.1 to decode new data (e.g., the test set in our experiments). To achieve this, we will use the above variational method within an EM algorithm that estimates μ and Σ in empirical Bayes fashion. (For Viterbi and MBR decoding, we then estimate θ as μ, the mean of the learned prior; see Section 4.1.) In the E-step, we maximize the bound with respect to the variational parameters using coordinate ascent as in Section 4.2. We optimize each of these separately in turn, cycling through them, using appropriate optimization algorithms for each. In the M-step, we apply maximum likelihood estimation with respect to μ and Σ given sufficient statistics gathered from the variational parameters in the E-step. Appendix C describes the algorithm in full.

5. Experiments

We applied our modeling framework to unsupervised learning of the dependency model discussed in Section 2.2. We consider four scenarios:

1. (Section 5.1) Experiments with dependency grammar induction for English text using the logistic normal distribution.
2. (Section 5.2) Experiments with text in five additional languages: Chinese, Portuguese, Turkish, Czech, and Japanese.
3. (Section 5.3) Experiments with the shared logistic normal distribution for tying parameters which correspond to the same coarse part-of-speech tag (English, Portuguese, and Turkish).
4. (Section 5.4) Experiments with the shared logistic normal distribution in *bilingual* settings (English, Portuguese, and Turkish).

	attachment accuracy (%)								
	Viterbi decoding			MBR decoding			Committee decoding

Table 1: Attachment accuracy of different learning methods on unseen test data from the Penn Treebank of varying levels of difficulty imposed through a length filter. MLE is a reproduction of an earlier result using EM (Klein and Manning, 2004). LN-I and LN-II denote using the logistic normal with model I and model II (Figure 2), respectively. Committee decoding includes ten averaged runs. Numbers in small font denote variance. Results in bold denote best results in a column. Training is done on sentences of length ≤ 10, though testing is done on longer sentences as well.

5.1 English Text

We begin our experiments with the *Wall Street Journal* Penn treebank (Marcus et al., 1993). Following standard practice, sentences were stripped of words and punctuation, leaving part-of-speech tags for the unsupervised induction of dependency structure. We note that, in this setting, using gold standard part-of-speech tags as the input to the learning algorithm is common (Klein and Manning, 2004; Smith and Eisner, 2006; Spitkovsky et al., 2010b,a; Gillenwater et al., 2010, *inter alia*).

We train on §2–21, tune on §22 (without using annotations), and report final results on §23. Details of this data set (and others) are found in Table 2. Unsupervised training for these data sets can be costly, and requires iteratively running a cubic-time inside-outside dynamic programming algorithm, so we follow Klein and Manning (2004) in restricting the training set to sentences of ten or fewer words in length. Short sentences are also less structurally ambiguous and may therefore be easier to learn from.

To evaluate the performance of our models, we report the fraction of words whose predicted parent matches the gold standard annotation in the treebank.[5] This performance measure is known as *attachment accuracy*. We will report attachment accuracy on three subsets of the test corpus: sentences of length ≤ 10 (typically reported in prior work and most similar to the training data set), length ≤ 20, and the full test corpus. We considered the three decoding methods mentioned in Section 4.1. For MBR decoding, we use the number of dependency attachment errors as the loss function. This means that at decoding time, we minimize the expected number of attachment errors according to the prediction of the estimated model. Because committee decoding is a randomized algorithm, we run it ten times on the unseen data, and then average the dependency attachment accuracy.

5. The Penn Treebank's phrase-structure annotations were converted to dependencies using the head rules of Yamada and Matsumoto, which are very similar to the ones by Collins (1999). See `http://www.jaist.ac.jp/~h-yamada`.

Initialization is important for all conditions, because likelihood and our variational bound are non-concave functions. For the values of the multinomials (θ), we use the harmonic initializer from Klein and Manning (2004). It estimates θ using soft counts on the training data where, in an n-length sentence, (i) each word is counted as the sentence's head $\frac{1}{n}$ times, and (ii) each word x_i attaches to x_j proportional to $|i-j|^{-1}$, normalized to a single attachment per word. This initializer is used with MLE and Dirichlet-I ("I" stands for model I from Figure 2). In the case of LN-I and LN-II, it is used as an initializer both for μ and inside the E-step.

For learning with the logistic normal prior, we consider two initializations of the covariance matrices Σ_k. The first is the $N_k \times N_k$ identity matrix. We then tried to bias the solution by injecting prior knowledge about the part-of-speech tags. To do that, we manually mapped the tag set (34 tags) to twelve disjoint tag "families." These are simply coarser tags: adjective, adverb, conjunction, foreign, interjection, noun, number, particle, preposition, pronoun, proper, verb. The coarse tags were chosen to loosely account for the part-of-speech tag sets of seven treebanks in different languages. The mapping from fine-grained tags to coarser tags are based on the annotation guidelines of the relevant treebank. This mapping into families provides the basis for an initialization of the covariance matrices for the dependency distributions: 1 on the diagonal, 0.5 between probabilities of possible child tags that belong to the same family, and 0 elsewhere. These results are denoted "families" and are compared to the identity matrix as an initializer.

We compared several models, where learning is accomplished using (variational) EM: MLE, standard maximum-likelihood estimation using EM; Dirichlet-I, a common baseline in the literature which uses a Dirichlet prior together with variational EM; and LN-I (LN-II), a model with the logistic normal distribution using model I (model II). In all cases, we either run the (variational) EM algorithm until convergence of the log-likelihood (or its bound) or until the log-likelihood on an unannotated development set of sentences does not increase.

We note that on the full test set, attaching each word to the word on its right ("Attach-Right") achieves about 30% accuracy, and attaching each word to the word on its left ("Attach-Left") achieves about 20% accuracy.

Table 1 shows the experimental results. Note that there are two variants which consistently get lower performance than their counterparts: using model II (versus using model I) and using committee decoding instead of Viterbi or MBR decoding. This suggests that the covariance matrices play a useful role during the learning process, but are not informative when performing decoding, since they are not used by Viterbi and MBR decoding. Interestingly, Smith and Eisner (2006) report a similar result for *structurally biased* DMV—a model that includes a parameter to control the length of the decoded dependencies. Their bias parameter is useful only during the learning process, but never during decoding. In general, the logistic normal distribution with model I outperforms substantially the baselines. It is interesting to note that LN-I outperforms Dirichlet-I and MLE even when using identity covariance matrices for initialization. The reason could be the fact that the logistic normal distribution, even when permitting only just diagonal covariance matrices (the case with identity covariance matrix initialization is weaker—we only initialize with diagonal matrices) allows to model the variance directly in the parameters. This is not possible with the Dirichlet distribution.

When we tested model II and committee decoding on other languages, the performance decrease was consistent. For the rest of the experiments, we report only MBR (and possibly Viterbi) decoding results using model I. The reason for the underperformance of model II could be the small number

language	tag set	training		development		test		baselines	
		tokens	sent.	tokens	sent.	tokens	sent.	A-R	A-L
English	34	55340	7179	35021	1700	49363	2416	30.2	20.4
Chinese	34	27357	4775	5824	350	7007	348	32.9	9.7
Portuguese	21	15976	2477	14558	907	5009	288	25.9	31.1
Turkish	29	18873	4497	7812	500	6288	623	68.2	4.3
Czech	47	67756	10674	32647	2535	33147	2535	24.4	28.3
Japanese	74	39121	10300	14666	1700	13648	1700	66.4	13.4

Table 2: Information about the data sets used in this paper. "Tag set" stands for the size of the part-of-speech tag set. Train, development and test columns show the number of tokens and number of sentences in each data set. The training set consists of sentences of length ten or less, as described in the text. The development set and the test set do not have any length restriction. The development set includes unannotated set of sentences from the respective language. A-R (A-L) stands for Attach-Right (Attach-Left), which are attachment accuracy baselines on the test set for all sentences. See text for details.

of parameters which is defined by the model. This small set of parameters cannot capture well the nuances across sentences in the data.

5.2 Additional Languages

Following Section 5.1, we experiment with other languages: Chinese, Portuguese, Turkish, Czech and Japanese.

- For Chinese, we used the Chinese treebank (Xue et al., 2004). We train on §1–270, use §301–1151 for development and test on §271–300.
- For Portuguese, we used the Bosque treebank (Afonso et al., 2002) from the CoNLL shared task in 2006 (Buchholz and Marsi, 2006).
- For Turkish, we used the METU-Sabancı treebank (Atalay et al., 2003; Oflazer et al., 2003) from the CoNLL shared task in 2006.
- For Czech, we used the Prague treebank (Hajič et al., 2000) from the CoNLL shared task in 2007 (Nivre et al., 2007).
- For Japanese, we used the VERBMOBIL Treebank for Japanese (Kawata and Bartels, 2000) from the CoNLL shared task in 2006.

Whenever using CoNLL shared task data, we used the first 80% of the data distributed in the shared task for training, and the rest was divided equally for development and testing. Table 2 gives statistics about the data sets used with the performance of the Attach-Right and Attach-Left baselines given for the whole test data. As in the case for English, sentences were stripped of words and punctuation, leaving part-of-speech tags for the unsupervised induction of dependency structure. All learning algorithms were run on sentences of length ten words or less. Note that strong performance is achieved for Turkish and Japanese by the Attach-Right baseline.

Results of running the different learning algorithms are given in Figure 4. Note that for Portuguese, the difference is much smaller between the EM baselines and logistic normal variational EM when only short sentences are considered, but there is a wider gap for longer sentences; the LN models appear to generalize better to longer sentences. For Turkish, no method outperforms Attach-Right, but there is still a big gap between variational EM with the logistic normal and the other EM baselines. The case is similar for Japanese, though logistic normal does outperform the Attach-Right baselines for shorter sentences. For Czech, it seems like Dirichlet and EM do somewhat better than the logistic normal prior, but performance of all four methods is close. It is conceivable that the approximation inherent in a projective syntax representation for the Czech sentences (whose gold-standard analyses have a relatively large fraction of nonprojective dependencies) interacts with different models in different ways.[6]

In general, the covariance matrices learned when initializing with the identity covariance matrix are rather sparse, but there is a high degree of variability across the diagonal (for the variance values learned). For the DMV, when using an identity initializer, diagonal matrices are the local optimum that is reached by the variational EM algorithm. When initializing the covariance matrices with the tag families initializer, the learned matrices are still rather sparse, but they have a larger number of significant correlations (for Portuguese, for example, using a t-test for testing the significance of the correlation, we found that 0.3% of the values in the covariance matrices had significant correlation).[7]

5.3 SLN with Nouns, Verbs, and Adjectives

We now turn to experiments where the partition structure lets parameters across multinomials covary, making use of the expressive power of the shared logistic normal distribution. We use a few simple heuristics to decide which partition structure $\mathcal{S}$ to use. Our heuristics rely mainly on the centrality of content words: nouns, verbs, and adjectives. For example, in the English treebank, the most common attachment errors (with the LN prior) happen with a noun (25.9%) or a verb (16.9%) parent. The fact that the most common errors happen with these attachments results from nouns and verbs being the most common parents in most of the data sets we experimented with.

Following this observation, we compare four different settings in our experiments (all SLN settings include one normal expert for each multinomial on its own, equivalent to the regular LN setting):

- TIEV: We add normal experts that tie all probabilities corresponding to a verbal parent (*any* verbal parent, using the coarse tags of Cohen et al., 2008). Let V be the set of part-of-speech tags that belong to the verb category. For each direction D (left or right), the set of multinomials of the form $\theta_c(\cdot \mid v, D)$, for $v \in V$, all share a normal expert. For each direction D and each boolean value B of the predicate $\text{first}_\mathbf{y}(\cdot)$, the set of multinomials $\theta_s(\cdot \mid v, D, B)$ for $v \in V$ share a normal expert.
- TIEN: This is the same as TIEV, only for nominal parents.

6. We note that we also experimented with other languages, including Hebrew and Arabic. We do not include these results, because in these cases all methods, including MLE, Dirichlet-I and LN-I performed badly (though Dirichlet-I and MLE could do better than LN-I). We believe that for these languages, the DMV is probably not the appropriate model. Developing better grammatical models for these languages is beyond the scope of this paper.
7. However, it is interesting to note that most of the elements of the covariance matrices were not exactly zero. For example, 90% of the values in the covariance matrices were larger (in absolute value) than 2.3×10^{-6}.

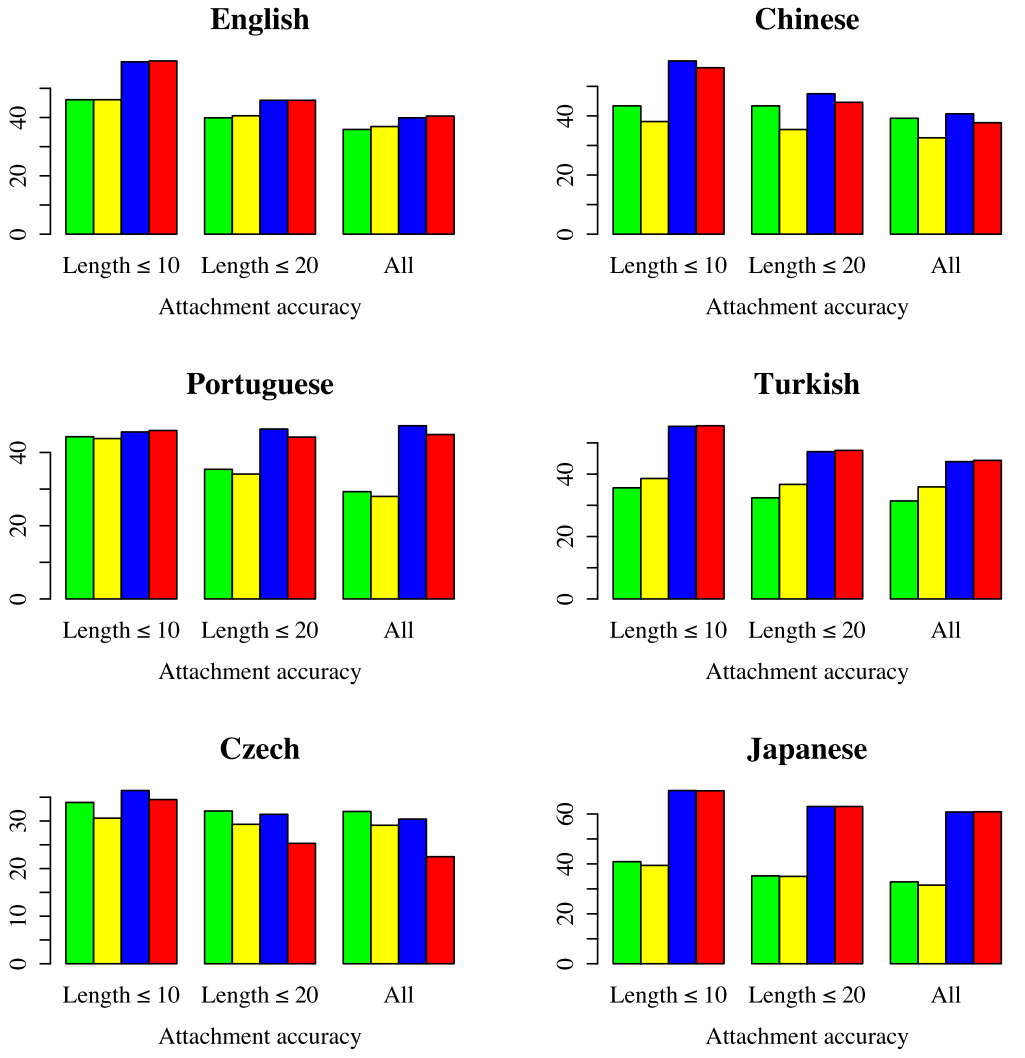

Figure 4: Attachment accuracy results for English (equivalent to Table 1), Chinese, Portuguese, Turkish, Czech and Japanese. The decoding mechanism used is MBR. Legend for the baselines: MLE (green, first column in each block); Dirichlet-I (yellow, second column); Legend for the methods in this paper: LN-I, $\Sigma_k^{(0)} = \mathbf{I}$ (blue, third column), and LN-I, families initializer (red, fourth column).

- TIEV&N: Tie both verbs and nouns (in separate partitions). This is equivalent to taking the union of the partition structures of the above two settings.

- TIEA: This is the same as TIEV, only for adjectival parents.

			English			Portuguese			Turkish

Table 3: Attachment accuracy of different monolingual tying models and bilingual tying models in varying levels of difficulty imposed through a length filter (Sections 5.3 and 5.4). Monolingual results (Section 5.3) are described when the languages in both the column and the row are identical (blocks on the diagonal). Results for MLE and Dirichlet-I are identical to Figure 4. Results for $\Sigma_k^{(0)} = \mathbf{I}$ and families are identical to Table 1 and Figure 4. Each block contains the results of tying one language with the other, specifying performance for the column language. Results in bold denote best results in a column, and † marks figures that are not significantly worse (binomial sign test, $p < 0.05$).

Since learning a model with parameter tying can be computationally intensive, we first run the inference algorithm without parameter tying, and then add parameter tying to the rest of the inference algorithm's execution until convergence.

For the covariance matrices, we follow the setting described in Section 5.1. For each treebank, we divide the tags into twelve disjoint tag families. The covariance matrices for all dependency distributions were initialized with 1 on the diagonal, 0.5 between tags which belong to the same family, and 0 otherwise.

The results are given in the blocks on the diagonal of Table 3, where the languages in the columns and rows are identical. MBR decoding was used. For English, there are small improvements when adding the expressive power of SLN. The best results are achieved when tying both nouns and verbs together. Portuguese shows small benefits compared on shorter sentences, and when compared to the families-initialized LN-I model, but not the stronger identity-initialized LN-I model. For Turkish, tying across multinomials hurts performance.

5.4 Bilingual Experiments

Leveraging linguistic information from one language for the task of disambiguating another language has received considerable attention (Dagan, 1991; Yarowsky et al., 2001; Hwa et al., 2005; Smith and Smith, 2004; Snyder and Barzilay, 2008; Burkett and Klein, 2008). Usually such a setting requires a parallel corpus or other annotated data that ties between those two languages. One notable exception is Haghighi et al. (2008), where bilingual lexicons were learned from non-parallel monolingual corpora.

Our bilingual experiments use the data for English, Portuguese, and Turkish (two at a time), which are not parallel corpora, to train parsers for two languages at a time, jointly. Sharing information between two models is accomplished by softly tying grammar weights in the two hidden grammars.

For each pair of languages, we first merge the models for these two languages by taking a union of the multinomial families of each and the corresponding prior parameters. We then add a normal expert that ties between the parts of speech in the respective partition structures for both grammars together. Parts of speech are matched through the single coarse tag set. For example, with TIEV, let $V = V_{\text{Eng}} \cup V_{\text{Por}}$ be the set of part-of-speech tags which belong to the verb category for either the English or Portuguese treebank (to take an example). Then, we tie parameters for all part-of-speech tags in V. We tested this joint model for each of TIEV, TIEN, TIEV&N, and TIEA. After running the inference algorithm which learns the two models jointly, we use unseen data to test each learned model separately.

We repeat the generative story specifically for the bilingual setting, using the example of TIEV. For each language, there are normal experts for all part-of-speech tags, for the basic DMV. In addition, there are normal experts, for each language, that combine together all part-of-speech tags that belong to the verb category. Finally, there are normal experts, for the two languages *together*, that combine together all part-of-speech tags that belong to the verb category in either language. For each sentence in the corpus, the following two steps are conducted as before (model I): the normal experts are sampled from the SLN distribution and combined into multinomials to parameterize the DMV; a grammar derivation is sampled from the resulting DMV.

Table 3 presents the results for these experiments (blocks not on the diagonal). English grammar induction shows moderate gains when tied with Portuguese and strong gains with Turkish. Cohen and Smith (2009) reported qualitatively similar results when English was tied with Chinese. For Portuguese, there is not much gain from tying it with other languages, though it improves the performance of the other two languages. In general, the table shows that with the proper selection of pair of languages and multinomials to tie together, we can usually get improvement over the LN baselines and the technique is not harmful (cf. Turkish grammar induction with SLN, on its own). We note that selection of the multinomials to tie encodes prior knowledge about the languages. This knowledge simply requires being able to map fine-grained, treebank-specific part-of-speech tags to coarse categories. In addition, bilingual learning with SLN does not require bitext parsing at any point, which is an expensive operation. The runtime of the variational E-step for a sentence $\mathbf{x}$ is still cubic in the length of $\mathbf{x}$, as in EM, so that the runtime of the variational E-step scales in the multilingual case the same as it would be if we added an equivalent amount of data in the monolingual case.

Since the experiments reported here were conducted, others, notably Gillenwater et al. (2010) and Spitkovsky et al. (2010b), have reported performance surpassing ours, for some of the languages

in our experiments. Differences in the experimental settings prevent direct comparisons. Some of the improvements in dependency grammar induction are achieved because of techniques which are orthogonal to ours, such as improvements in the underlying grammar (instead of DMV; Headden et al., 2009; Gillenwater et al., 2010), and those techniques could be incorporated into the Bayesian model we described. Others are somewhat different (e.g., Viterbi training).

6. Discussion

We have shown that modeling covariance among grammar weights within a probabilistic grammar's multinomial distributions, *across* its distributions, and *across* grammars in two languages can have benefits for learning dependency structure in an unsupervised empirical Bayesian framework. This approach addresses one of the desiderata of Raiffa and Schaifer (1961) for prior distributions, "richness." The empirical benefits of modeling covariance, we have shown, are compelling.

We believe, however, that more remains to be done to incorporate prior linguistic knowledge into unsupervised grammar induction. Covariance structure is, perhaps, not the most *interpretable* kind of prior knowledge about grammars that might be brought to bear on learning. The empirical Bayesian paradigm explored here, and the use of variational approximations for coping with non-conjugacy, will be important tools in future work that brings together prior knowledge and unannotated data for grammar induction.

For natural language data, a direction for future work is to capture deeper linguistic phenomena. Here, background knowledge abounds: the entire field of theoretical linguistics has contributed both descriptive facts about the structure of specific natural languages and general theories about the way that structure is constrained. Viewing the logistic normal prior as local log-linear models (Section 3.4) is a first step towards encoding such prior knowledge. Similar to Berg-Kirkpatrick et al. (2010), it permits the use of arbitrary features in the parameterization of the grammar.

We note that our inference algorithm, described in detail in Appendix B, can be easily adapted to scenarios which do not necessarily use the multivariate normal distribution as the base distribution in the prior. The "softmax" can be applied to any multivariate sample to get a point in the probability simplex—perhaps capturing other tendencies in the data than covariance. The convenience of performing such an extension depends on the ability to effectively compute the moment generating function of the distribution replacing the multivariate Gaussian, in which case we can develop Equation 13 and proceed with optimizing the variational bound using this distribution.

7. Conclusion

In this paper we demonstrated the effectiveness of estimating probabilistic grammars in a Bayesian setting. We used the Bayesian setting to model covariance between the different parameters of probabilistic grammars. To model the covariance, we used the logistic normal distribution as a prior over the grammar parameters. In addition, we extended the logistic normal distribution to a new family of distributions, in order to model covariance across the multinomial family in a probabilistic grammar.

We proposed a variational inference algorithm for estimating the parameters of the probabilistic grammar, providing a fast, parallelizable,[8] and deterministic alternative to MCMC methods to approximate the posterior over derivations and grammar parameters.

8. We used a cluster running MapReduce (Dean and Ghemawat, 2004) to perform inference when training our models.

We experimented with grammar induction on six different languages, demonstrating the usefulness of our approach. Our experiments include a novel promising setting, in which syntactic trees are inferred in a bilingual setting that uses multilingual, non-parallel corpora. Notably, our approach tends to generalize better to longer sentences, despite learning (as in previous research) on short sentences. The focus of the experiments was on dependency grammar induction with the dependency model with valence. Our choice of the DMV is motivated by the fact that it is a widespread grammar for dependency grammar induction (Section 2.2), enabling us to tease apart the problem of estimation of the grammar from the problem of deciding on the grammar structure. Our inference algorithm, though, could be applied to any probabilistic grammar that has an efficient procedure, such as the inside-outside algorithm, for computing sufficient statistics in the form of expected counts of rule firing in grammar derivations.

The authors would also like to thank Yahoo! for making computational resources available. This research was supported by NSF grants IIS-0713265, IIS-0836431 and IIS-0915187.

Appendix A. Notation

Table 4 gives a table of notation for symbols used throughout this paper.

Appendix B. Variational Inference with Logistic Normal Priors

We give a derivation of a variational inference algorithm for model I, with the shared logistic normal distribution as a prior. The derivation is based on the one given in Blei and Lafferty (2006). The derivation for model II can be followed similarly, as explained below. For model I, we seek to find an approximation posterior function $q(\eta_1, ..., \eta_M, \mathbf{y}_1, ..., \mathbf{y}_M)$ that maximizes a lower bound (the negated variational free energy) on the log-likelihood, a bound which is achieved using Jensen's inequality (the following probability quantities should be understood as if we always condition on the grammar $\mathbf{G}$):

$$\begin{aligned}
&\sum_{m=1}^{M} \sum_{\mathbf{y}} \log p(\mathbf{x}_m, \mathbf{y} \mid \mu, \Sigma, \mathcal{S}) \\
&\geq \sum_{m=1}^{M} \left(\sum_{i=1}^{N} \mathbb{E}_q \left[\log p(\eta_{m,i} \mid \mu_i, \Sigma_i) \right] + \mathbb{E}_q \left[\log p(\mathbf{x}_m, \mathbf{y}_m \mid \eta_m, \mathcal{S}) \right] \right) + H(q). \qquad (10)
\end{aligned}$$

$H(\cdot)$ denotes the Shannon entropy.

We make a mean-field assumption, and assume that the posterior has the following form:

$$q(\eta_1, ..., \eta_M, \mathbf{y}_1, ..., \mathbf{y}_M) = \prod_{m=1}^{M} q_m(\eta_m, \mathbf{y}_m), \qquad (11)$$

	symbol	description
grammars and data	$\mathbf{G}$	grammar (for example, context-free grammar rules)
	M	number of observed sentences
	$\mathbf{x}_m$	mth observed sentence in the available data
	$\mathbf{y}_m$	inferred derivation grammatical structure for $\mathbf{x}_m$
	θ	parameters of a probabilistic grammar
	K	number of multinomials in the probabilistic grammar
	N_k	size of the kth multinomial of the probabilistic grammar
	$f_{k,i}(\mathbf{x},\mathbf{y})$	number of times the ith event fires in the kth multinomial in the derivations $\mathbf{x}$ and $\mathbf{y}$
priors	α	hyperparameters for the Dirichlet prior of a probabilistic grammar
	Σ	covariance matrices for the (shared) logistic normal prior of a probabilistic grammar
	μ	mean values for the (shared) logistic normal prior of a probabilistic grammar
	η	values drawn from the Gaussians for (S)LN, before the logistic transformation is applied
	$\mathcal{S}$	partition structure for the shared logistic normal distribution
	N	number of normal experts for the SLN
	l_n	length of nth normal expert (SLN)
	I_n	partition of the nth normal expert into segments mapping to multinomials in $\mathbf{G}$ (SLN)
	J_k	collection of segments of normal experts mapping to kth multinomial in $\mathbf{G}$ (SLN)
variational EM	$q_m(\theta,\mathbf{y})$	variational distribution which is used as an approximation posterior for the mth datum
	$\tilde{\mu}_{m,k,i}$	variational parameter for mean value of the ith event in the kth for the mth datum
	$\tilde{\sigma}_{m,k,i}$	variational parameter for variance of the ith event in the kth for the mth datum
	$\tilde{f}_{m,k,i}$	expected count of the ith event in the kth for the mth datum
	$\tilde{\psi}_{m,k,i}$	intermediate quantity aggregating variational parameters
	$\tilde{\zeta}_{m,k}$	variational parameter for the first-order Taylor approximation of LN's denominator

Table 4: Table of notation symbols used in this paper.

where

$$q_m(\eta_m,\mathbf{y}_m) = \left(\prod_{k=1}^{N}\prod_{i=1}^{L_k} q_m(\eta_{m,k,i} \mid \tilde{\mu}_{m,k,i},\tilde{\sigma}^2_{m,k,i})\right) \times q_m(\mathbf{y}_m),$$

and $q_m(\eta_{m,k,i} \mid \tilde{\mu}_{m,k,i},\tilde{\sigma}^2_{m,k,i})$ is a Gaussian with mean $\tilde{\mu}_{m,k,i}$ and variance $\tilde{\sigma}^2_{m,k,i}$. Note that this means that the *variational* distributions have a diagonal matrix for their covariance structure. The model covariance matrices (the hyperparameters Σ) can still have covariance structure. This selection of variational distributions makes inference much easier. The factorized form of Equation 11 implies the following identities:

$$\mathbb{E}_q\left[\log p(\eta_{m,i} \mid \mu_i, \Sigma_i)\right] = \mathbb{E}_{q_m}\left[\log p(\eta_{m,i} \mid \mu_i, \Sigma_i)\right],$$
$$\mathbb{E}_q\left[\log p(\mathbf{x}_m, \mathbf{y}_m \mid \eta_m, \mathcal{S})\right] = \mathbb{E}_{q_m}\left[\log p(\mathbf{x}_m, \mathbf{y}_m \mid \eta_m, \mathcal{S})\right],$$
$$H(q) = \sum_{m=1}^{N} H(q_m).$$

Let $\eta^C_{k,i}$ be an intermediate variable, denoting the average of the normal experts which appear in the partition structure and determine the value of the ith event in the kth multinomial of the grammar. More formally, we define the vector η^C_k of length N_k to be:

$$\eta^C_k \triangleq \frac{1}{|J_k|} \sum_{I_{r,j} \in J_k} \eta_{r,I_{r,j}}.$$

Unfolding the expectation with respect to $q_m(\mathbf{y}_m)$ in the second term in Equation 10, while recalling that θ_m is a deterministic function of η_m that averages different subvectors from the collection of multinomials η_m according to the partition structure $\mathcal{S}$, we have that:

$$\begin{aligned}
&\mathbb{E}_{q_m}\left[\log p(\mathbf{x}_m, \mathbf{y}_m \mid \eta_m, \mathcal{S})\right] \\
&= \mathbb{E}_{q_m(\eta_m)}\left[\sum_{k=1}^{K} \sum_{i=1}^{N_k} \underbrace{\sum_{\mathbf{y}} q_m(\mathbf{y}_m) f_{k,i}(\mathbf{x}_m, \mathbf{y}_m)}_{\tilde{f}_{m,k,i}} \log \theta_{m,k,i}\right] \\
&= \mathbb{E}_{q_m(\eta_m)}\left[\sum_{k=1}^{K} \sum_{i=1}^{N_k} \tilde{f}_{m,k,i}\left(\eta^C_{m,k,i} - \log \sum_{i'=1}^{N_k} \exp \eta^C_{m,k,i'}\right)\right],
\end{aligned} \tag{12}$$

where $\tilde{f}_{m,k,i}$ is the expected number of occurrences of the ith event in distribution k, under $q_m(\mathbf{y}_m)$. With many kinds of probabilistic grammars, this quantity can be computed using a dynamic programming algorithm like the forward-backward or inside-outside algorithm.

The logarithm term in Equation 12 is problematic because of the expectation with respect to $q_m(\eta_m)$. We approximate it with a first-order Taylor expansion, introducing $M \times K$ more variational parameters $\tilde{\zeta}_{m,k}$ for $m \in \{1, ..., M\}$ and $K \in \{1, ..., K\}$:

$$\log\left(\sum_{i'=1}^{N_k} \exp \eta^C_{m,k,i'}\right) \leq \log \tilde{\zeta}_{m,k} - 1 + \frac{1}{\tilde{\zeta}_{m,k}} \sum_{i'=1}^{N_k} \exp \eta^C_{m,k,i'}. \tag{13}$$

We note that the value $\mathbb{E}_{q_m(\eta_m)}\left[\exp(\eta^C_{m,k,i'})\right]$ can be calculated by evaluating the moment-generating function of the normal distribution $g(t) = \mathbb{E}_{q_m(\eta_m)}\left[\exp(t\eta^C_{m,k,i'})\right]$ at $t = 1$. We now have:

Algorithm 1: Variational EM for probabilistic grammars with LN prior

Input: initial parameters $\mu^{(0)}, \Sigma^{(0)}$, training data $\mathbf{x}$, and development data $\mathbf{x}'$
Output: learned parameters μ, Σ
$t \leftarrow 1$;
repeat
  Call E-Step for each training example $m = 1, ..., M$ *(Algorithm 2)*
  Call M-Step (Algorithm 3)
  $t \leftarrow t + 1$;
until *likelihood of held-out data,* $p(\mathbf{x}' \mid E[\mu^{(t)}])$*, decreases* ;
return $\mu^{(t)}, \Sigma^{(t)}$

$$
\begin{aligned}
&\mathbb{E}_{q_m}[\log p(\mathbf{x}_m, \mathbf{y}_m \mid \eta_m, \mathcal{S})] \\
&\geq \mathbb{E}_{q_m(\eta_m)}\left[\sum_{k=1}^{K}\sum_{i=1}^{N_k} \tilde{f}_{m,k,i}\left(\eta_{m,k,i} - \log\tilde{\xi}_{m,k} + 1 - \frac{1}{\tilde{\xi}_{m,k}}\sum_{i'=1}^{N_k}\exp\eta_{m,k,i'}\right)\right] \\
&= \sum_{k=1}^{K}\sum_{i=1}^{N_k} \tilde{f}_{m,k,i}\underbrace{\left(\tilde{\mu}_{m,k,i} - \log\tilde{\xi}_{m,k} + 1 - \frac{1}{\tilde{\xi}_{m,k}}\sum_{i'=1}^{N_k}\exp\left(\tilde{\mu}^{C}_{m,k,i} + \frac{(\tilde{\sigma}^{C}_{m,k,i})^2}{2}\right)\right)}_{\tilde{\psi}_{m,k,i}} \\
&= \sum_{k=1}^{K}\sum_{i=1}^{N_k} \tilde{f}_{m,k,i}\tilde{\psi}_{m,k,i}
\end{aligned}
$$

where we use again the properties of the shared logistic normal distribution and rely on the partition structure $\mathcal{S}$ to define:

$$
\begin{aligned}
\tilde{\mu}^{C}_{m,k} &\triangleq \frac{1}{|J_k|}\sum_{I_{r,j}\in J_k}\tilde{\mu}_{m,r,I_{r,j}}, \\
(\tilde{\sigma}^{C}_{m,k})^2 &\triangleq \frac{1}{|J_k|^2}\sum_{I_{r,j}\in J_k}\tilde{\sigma}^{2}_{m,r,I_{r,j}}.
\end{aligned}
$$

Note the shorthand $\tilde{\psi}_{k,i}$ to denote an expression involving $\tilde{\mu}^{C}$, $\tilde{\sigma}^{C}$, and $\tilde{\xi}$.

The final form of our bound is:[9]

$$
\log p(\mathbf{x}, \mathbf{y} \mid \mu, \Sigma) \geq \left(\sum_{k=1}^{K}\mathbb{E}_q\left[\log p(\eta_k \mid \mu_k, \Sigma_k)\right]\right) + \left(\sum_{k=1}^{K}\sum_{i=1}^{N_k}\tilde{f}_{k,i}\tilde{\psi}_{k,i}\right) + H(q). \tag{14}
$$

Using an EM-style algorithm, we will alternate between finding the maximizing $q(\eta)$ and the maximizing $q(\mathbf{y})$. Maximization with respect to $q_m(\eta_m)$ is not hard, because $q(\eta)$ is parameterized. The following lemma shows that fortunately, finding the maximizing $q_m(\mathbf{y}_m)$, which we did not parameterize originally, is not hard either:

9. A tighter bound, based on a second-order approximation, was proposed in Ahmed and Xing (2007). We use a first-order approximation for simplicity, similar to Blei and Lafferty (2006).

Algorithm 2: E-Step (subroutine for Algorithm 1)

repeat

optimize for $\tilde{\mu}_{m,k}^{(t)}, k = 1, ..., K$: use conjugate gradient descent with

$$\frac{\partial B}{\partial \tilde{\mu}_{m,k,i}} = -\left((\Sigma_k^{(t-1)})^{-1})(\mu_k^{(t-1)} - \tilde{\mu}_{m,k})\right)_i - \tilde{f}_{m,k,i} + \sum_{i'=1}^{N_k} \left(\tilde{f}_{m,k,i'} / \tilde{\xi}_{m,k}\right) \exp\left(\frac{\tilde{\mu}_{k,i'} + \tilde{\sigma}_{k,i'}^2}{2}\right)$$

optimize $\tilde{\sigma}_{m,k}^{(t)}, k = 1, ..., K$: use Newton's method for each coordinate (with $\tilde{\sigma}_{m,k,i} > 0$) with

$$\frac{\partial B}{\partial \tilde{\sigma}_{m,k,i}^2} = -\frac{\Sigma_{k,ii}^{(t-1)}}{2} - \frac{\left(\sum_{i'=1}^{N_k} \tilde{f}_{m,k,i'}\right) \exp\left(\frac{\tilde{\mu}_{m,k,i} + \tilde{\sigma}_{m,k,i}^2}{2}\right)}{2\tilde{\xi}_{m,k}} + \frac{1}{2\tilde{\sigma}_{m,k,i}^2}$$

update $\tilde{\xi}_{m,k}^{(t)}, \forall k$:

$$\tilde{\xi}_{m,k}^{(t)} \leftarrow \sum_{i=1}^{N_k} \exp\left(\tilde{\mu}_{m,k,i}^{(t)} + \frac{(\tilde{\sigma}_{m,k,i}^{(t)})^2}{2}\right)$$

update $\tilde{\psi}_{m,k}^{(t)}, \forall k$:

$$\tilde{\psi}_{m,k,i}^{(t)} \leftarrow \tilde{\mu}_{m,k,i}^{(t)} - \log \tilde{\xi}_{m,k}^{(t)} + 1 - \frac{1}{\tilde{\xi}_{m,k}^{(t)}} \sum_{i'=1}^{N_k} \exp\left(\tilde{\mu}_{m,k,i}^{(t)} + \frac{(\tilde{\sigma}_{m,k,i}^{(t)})^2}{2}\right)$$

compute expected counts $\tilde{\mathbf{f}}_{m,k}^{(t)}, k = 1, ..., K$: use an inside-outside algorithm to re-estimate expected counts $\tilde{f}_{m,k,i}^{(t)}$ in weighted grammar $q(y)$ with weights $e^{\tilde{\psi}_m}$;

until *B does not change* ;

Lemma 2 *Let $r(\mathbf{y}_m \mid \mathbf{x}_m, e^{\tilde{\psi}_m})$ denote the conditional distribution over $\mathbf{y}_m$ given $\mathbf{x}_m$ defined as:*

$$r_m(\mathbf{y}_m \mid \mathbf{x}_m, e^{\tilde{\psi}}) = \frac{1}{Z_m(\tilde{\psi}_m)} \prod_{k=1}^{K} \prod_{i=1}^{N_k} \exp\left(\tilde{\psi}_{m,k,i} f_{m,k,i}(\mathbf{x}_m, \mathbf{y}_m)\right)$$

where $Z_m(\tilde{\psi}_m)$ is a normalization constant. Then $q_m(\mathbf{y}_m) = r_m(\mathbf{y}_m \mid \mathbf{x}_m, e^{\tilde{\psi}_m})$ maximizes the bound in Equation 14.

Proof First note that $H(q_m) = H(q_m(\eta_m \mid \tilde{\mu}_m, \tilde{\sigma}_m)) + H(q_m(\mathbf{y}_m))$. This means that the terms we are interested in maximizing from Equation 14 are the following, after plugging in $\tilde{f}_{m,k,i}$ explicitly:

$$L = \operatorname*{argmax}_{q_m(\mathbf{y}_m)} \sum_{\mathbf{y}_m} q_m(\mathbf{y}_m) \left(\sum_{k=1}^{K} \sum_{i=1}^{N_k} f_{m,k,i}(\mathbf{x}_m, \mathbf{y}_m) \tilde{\psi}_{m,k,i} \right) + H(q_m(\mathbf{y}_m)).$$

Algorithm 3: M-Step (subroutine for Algorithm 1)

Estimate $\mu^{(t)}$ and $\Sigma^{(t)}$ using the following maximum likelihood closed-form solution:

$$\mu_{k,i}^{(t)} \leftarrow \frac{1}{M}\sum_{m=1}^{M}\tilde{\mu}_{m,k,i}^{(t)}$$

$$\left[\Sigma_k^{(t)}\right]_{i,j} \leftarrow \frac{1}{M}\left(\sum_{m=1}^{M}\tilde{\mu}_{m,k,i}^{(t)}\tilde{\mu}_{m,k,j}^{(t)} + (\tilde{\sigma}^{(t)})_{m,k,i}^{2}\delta_{i,j} + M\mu_{k,i}^{(t)}\mu_{k,j}^{(t)} - \mu_{k,j}^{(t)}\sum_{m=1}^{M}\tilde{\mu}_{m,k,i}^{(t)} - \mu_{k,i}^{(t)}\sum_{m=1}^{M}\tilde{\mu}_{m,k,j}^{(t)}\right),$$

where $\delta_{i,j} = 1$ if $i = j$ and 0 otherwise.

Then, note that:

$$L = \operatorname*{argmin}_{q_m(\mathbf{y}_m)} D_{\mathrm{KL}}\left(q_m(\mathbf{y}_m) \;\middle\|\; r_m(\mathbf{y}_m \mid \mathbf{x}_m, e^{\tilde{\Psi}_m})\right), \tag{15}$$

where D_{KL} denotes the KL divergence. To see that, combine the definition of KL divergence with the fact that $\sum_{k=1}^{K}\sum_{i=1}^{N_k} f_{m,k,i}(\mathbf{x},\mathbf{y})\tilde{\Psi}_{m,k,i} - \log Z_m(\tilde{\Psi}_m) = \log r_m(\mathbf{y}_m \mid \mathbf{x}_m, e^{\tilde{\Psi}_m})$ where $\log Z_m(\tilde{\Psi})$ does not depend on $q_m(\mathbf{y}_m)$. Equation 15 is minimized when $q_m = r_m$. ■

The above lemma demonstrates that the minimizing $q_m(\mathbf{y}_m)$ has the same form as the probabilistic grammar $\mathbf{G}$, only without having sum-to-one constraints on the weights (leading to the required normalization constant $Z_m(\tilde{\Psi}_m)$). As in classic EM with probabilistic grammars, we never need to represent $q_m(\mathbf{y}_m)$ explicitly; we need only $\tilde{\mathbf{f}}_m$, which can be calculated as expected feature values under $r_m(\mathbf{y}_m \mid \mathbf{x}_m, e^{\tilde{\Psi}_m})$ using dynamic programming.

Variational inference for model II is done similarly to model I. The main difference is that instead of having variational parameters for each $q_m(\eta_m)$, we have a single distribution $q(\eta)$, and the sufficient statistics from the inside-outside algorithm are used altogether to update it during variational inference.

Appendix C. Variational EM for Logistic-Normal Probabilistic Grammars

The algorithm for variational inference with probabilistic grammars using logistic normal prior is defined in Algorithms 1–3.[10] Since the updates for $\tilde{\zeta}_k^{(t)}$ are fast, we perform them after each optimization routine in the E-step (suppressed for clarity). There are variational parameters for each training example, indexed by m. We denote by B the variational bound in Equation 14. Our stopping criterion relies on the likelihood of a held-out set (Section 5) using a point estimate of the model.

10. An implementation of the algorithm is available at `http://www.ark.cs.cmu.edu/DAGEEM`. For simplicity, we give the vanilla logistic normal version of the algorithm in this appendix. The full version requires a more careful indexing and can be derived using the equations from Appendix B.

Abstract

Inducing a grammar from text has proven to be a notoriously challenging learning task despite decades of research. The primary reason for its difficulty is that in order to induce plausible grammars, the underlying model must be capable of representing the intricacies of language while also ensuring that it can be readily learned from data. The majority of existing work on grammar induction has favoured model simplicity (and thus learnability) over representational capacity by using context free grammars and first order dependency grammars, which are not sufficiently expressive to model many common linguistic constructions. We propose a novel compromise by inferring a probabilistic *tree substitution grammar*, a formalism which allows for arbitrarily large tree fragments and thereby better represent complex linguistic structures. To limit the model's complexity we employ a Bayesian non-parametric prior which biases the model towards a sparse grammar with shallow productions. We demonstrate the model's efficacy on supervised phrase-structure parsing, where we induce a latent segmentation of the training treebank, and on unsupervised dependency grammar induction. In both cases the model uncovers interesting latent linguistic structures while producing competitive results.

Keywords: grammar induction, tree substitution grammar, Bayesian non-parametrics, Pitman-Yor process, Chinese restaurant process

1. Introduction

Inducing a grammar from a corpus of strings is one of the central challenges of computational linguistics, as well as one of its most difficult. Statistical approaches circumvent the theoretical problems with learnability that arise with non-statistical grammar learning (Gold, 1967), and performance has improved considerably since the early statistical work of Merialdo (1994) and Carroll and Charniak (1992), but the problem remains largely unsolved. Perhaps due to the difficulty of this unsupervised grammar induction problem, a more recent line of work has focused on a somewhat easier problem, where the input consists of a treebank corpus, usually in phrase-structure format,

and the task is to induce a grammar from the treebank that yields better parsing performance than the basic maximum-likelihood probabilistic context free grammar (PCFG). Examples of work on this kind of grammar induction, which we will refer to as *grammar refinement* because the learned grammars can be viewed as refinements of the treebank PCFG, include the symbol-splitting approach of Petrov and Klein (2007) and the tree-substitution grammars of Data-Oriented Parsing (Bod et al., 2003; Bod, 2003). Although the grammars induced by these systems are latent, the resulting parsers are supervised in the sense that the input to the learning system consists of strings and parses, and the goal is to learn how to parse new strings. Consequently, these systems do not remove the necessity of hand-annotating a large corpus, but they can potentially reduce the amount of engineering effort required to develop a successful statistical parser for a new language or domain, by obviating the need for complex hand-engineering of features, independence assumptions, and backoff schemes.

The desire for automatic grammar refinement methods highlights one possible reason why unsupervised grammar induction is so difficult. Simple models of syntactic structure such as hidden Markov models (HMMs) or PCFGs make strong independence assumptions that fail to capture the true complexity of language, so these models tend to learn something other than the desired structure when used in an unsupervised way. On the other hand, more complex models with, for example, head-lexicalized rules have too many free parameters to be learned successfully from unannotated data without the use of sophisticated backoff schemes. Thus, finding the right balance between learnability and complexity is critical to developing a successful model of grammar induction. We posit that this balance can be achieved by using a rich grammatical formalism coupled with a nonparametric Bayesian prior to limit the model's complexity. In this way the model can learn sufficiently complex structure to model the data, but will only do so when there is enough evidence to support such complexity; otherwise it will generalise to simpler structures. The model can therefore learn plausible structures from either small or large training samples.

We present here a model for automatically learning a *Probabilistic Tree Substitution Grammar* (PTSG) from either a treebank or strings. A PTSG is an extension to the PCFG in which nonterminals can rewrite as entire tree fragments (*elementary trees*), not just immediate children (Joshi, 2003; Bod et al., 2003). These large fragments can be used to encode non-local context, such as argument frames, gender agreement and idioms. A fundamental problem with PTSGs is that they are difficult to estimate, even in the supervised (grammar refinement) scenario where treebanked data is available. This is because treebanks are typically not annotated with their TSG derivations—how to decompose a tree into elementary tree fragments—instead the derivation needs to be inferred.

Probably the best-known previous work on inducing PTSGs is within the framework of Data-Oriented Parsing (DOP; Bod et al., 2003), which, like our model, has been applied in both supervised and unsupervised settings (Bod, 2003; Prescher et al., 2004; Zollmann and Sima'an, 2005; Zuidema, 2007; Bod, 2006).[1] DOP seeks to use as TSG productions all subtrees of the training corpus, an approach which makes parameter estimation difficult and led to serious problems with early estimation methods (Johnson, 2002), namely inconsistency for DOP1 (Bod, 2003) and overfitting of the maximum likelihood estimate (Prescher et al., 2004). More recent work on DOP estimation has tackled these problems, drawing from estimation theory to solve the consistency problem (Prescher et al., 2004; Zollmann and Sima'an, 2005), or using a grammar brevity heuristic to avoid the degeneracy of the MLE (Zuidema, 2007). Our work differs from DOP in that we use an ex-

1. Tree adjoining grammar induction (Chiang and Bikel, 2002; Xia, 2002) tackles a similar learning problem in the supervised case.

plicit generative model of TSG and a Bayesian prior for regularisation. The prior is nonparametric, which allows the model to learn a grammar of the appropriate complexity for the size of the training data. A further difference is that instead of seeking to use all subtrees from the training data in the induced TSG, our prior explicitly biases against such behaviour, such that the model learns a relatively compact grammar.[2] A final minor difference is that, because our model is generative, it assigns non-zero probability to all possible subtrees, even those that were not observed in the training data. In practice, unobserved subtrees will have very small probabilities.

We apply our model to the two grammar induction problems discussed above:

- **Inducing a TSG from a treebank.** This regime is analogous to the case of supervised DOP, where we induce a PTSG from a corpus of parsed sentences, and use this PTSG to parse new sentences. We present results using two different inference methods, training on either a subset of WSJ or on the full treebank. We report performance of 84.7% when training on the full treebank, far better than the 64.2% for a PCFG parser. These gains in accuracy are obtained with a grammar that is somewhat larger than the PCFG grammar, but still much smaller than the DOP all-subtrees grammar.

- **Inducing a TSG from strings.** As in other recent unsupervised parsing work, we adopt a dependency grammar (Mel′čuk, 1988) framework for the unsupervised regime. We use the split-head construction (Eisner, 2000; Johnson, 2007) to map between dependency and phrase-structure grammars, and apply our model to strings of POS tags. We report performance of 65.9% on the standard $\text{WSJ}_{\leq 10}$ data set, which is statistically tied with the best reported result on the task and considerably better than the EM baseline which obtains 46.1%. When evaluated on test data with no restriction on sentence length—a more realistic setting—our approach significantly improves the state-of-the-art.

Our work displays some similarities to previous work on both the grammar refinement and unsupervised grammar induction problems, but also differs in a number of ways. Aside from DOP, which we have already discussed, most approaches to grammar refinement can be viewed as symbol-splitting. That is, they allow each nonterminal to be split into a number of subcategories. The most notable examples of the symbol-splitting approach include Petrov et al. (2006), who use a likelihood-based splitting and merging algorithm, and Liang et al. (2007) and Finkel et al. (2007), who develop nonparametric Bayesian models. In theory, any PTSG can be recast as a PCFG with a sufficiently large number of subcategories (one for each unique subtree), so the grammar space of our model is a subspace of the symbol-splitting grammars. However, the number of nonterminals required to recreate our PTSG grammars in a PCFG would be exorbitant. Consequently, our model should be better able to learn specific lexical patterns, such as full noun phrases and verbs with their subcategorisation frames, while theirs are better suited to learning subcategories with larger membership, such as the days of the week or count versus mass nouns. The approaches are largely orthogonal, and therefore we expect that a PTSG with nonterminal refinement could capture both types of concept in a single model, thereby improving performance over either approach alone.

For the unsupervised grammar induction problem we adopt the Dependency Model with Valency (DMV; Klein and Manning, 2004) framework that is currently dominant for grammar induction (Cohen et al., 2009; Cohen and Smith, 2009; Headden III et al., 2009; Cohen et al., 2010;

2. The prior favours compact grammars by assigning the majority of probability mass to few productions, and very little (but non-zero) mass to other productions. In practice we use Markov Chain Monte Carlo sampling for inference which results in sparse counts with structural zeros, thus permitting efficient representation.

Spitkovsky et al., 2010). The first grammar induction models to surpass a trivial baseline concentrated on the task of inducing unlabelled bracketings for strings and were evaluated against treebank bracketing gold standard (Clark, 2001; Klein and Manning, 2002). Subsequently the DMV model has proved more attractive to researchers, partly because it defined a well founded generative stochastic grammar, and partly due to the popularity of dependency trees in many natural language processing (NLP) tasks. Recent work on improving the original DMV model has focused on three avenues: smoothing the head-child distributions (Cohen et al., 2009; Cohen and Smith, 2009; Headden III et al., 2009), initialisation (Headden III et al., 2009; Spitkovsky et al., 2010), and extending the conditioning distributions (Headden III et al., 2009). Our work falls into the final category: by extending the DMV CFG model to a TSG we increase the conditioning context of head-child decisions within the model, allowing the grammar to directly represent groups of linked dependencies.

Adaptor Grammars (Johnson et al., 2007b) are another recent nonparametric Bayesian model for learning hierarchical structure from strings. They instantiate a more restricted class of tree-substitution grammar in which each subtree expands completely, with only terminal symbols as leaves. Since our model permits nonterminals as subtree leaves, it is more general than Adaptor Grammars. Adaptor Grammars have been applied successfully to induce labeled bracketings from strings in the domains of morphology and word segmentation (Johnson, 2008a,b; Johnson and Goldwater, 2009) and very recently for dependency grammar induction (Cohen et al., 2010). The latter work also introduced a variational inference algorithm for Adaptor Grammar inference; we use a sampling method here.

The most similar work to that presented here is our own previous work (Cohn et al., 2009; Cohn and Blunsom, 2010), in which we introduced a version of the model described here, along with two other papers that independently introduced similar models (Post and Gildea, 2009; O'Donnell et al., 2009). Cohn et al. (2009) and Post and Gildea (2009) both present models based on a Dirichlet process prior and provide results only for the problem of grammar refinement, whereas in this article we develop a newer version of our model using a Pitman-Yor process prior, and also show how it can be used for unsupervised learning. These extensions are also reported in our recent work on dependency grammar induction (Blunsom and Cohn, 2010), although in this paper we present a more thorough exposition of the model and experimental evaluation. O'Donnell et al. (2009) also use a Pitman-Yor process prior (although their model is slightly different from ours) and present unsupervised results, but their focus is on cognitive modeling rather than natural language processing, so their results are mostly qualitative and include no evaluation of parsing performance on standard corpora.

To sum up, although previous work has included some aspects of what we present here, this article contains several novel contributions. Firstly we present a single generative model capable of both supervised and unsupervised learning, to induce tree substitution grammars from either trees or strings. We demonstrate that in both settings the model outperforms maximum likelihood baselines while also achieving results competitive with the best current systems. The second main contribution is to provide a thorough empirical evaluation in both settings, examining the effect of various conditions including data size, sampling method and parsing algorithm, and providing an analysis of the structures that were induced.

In the remainder of this article, we briefly review PTSGs in Section 2 before presenting our model, including versions for both constituency and dependency parsing, in Section 3. In Section 4 we introduce two different Markov Chain Monte Carlo (MCMC) methods for inference: a local Gibbs sampler and a blocked Metropolis-Hastings sampler. The local sampler is much simpler but

is only applicable in the supervised setting, where the trees are observed, whereas the Metropolis-Hastings sampler can be used in both supervised and unsupervised settings and for parsing. We discuss how to use the trained model for parsing in Section 5, presenting three different parsing algorithms. Experimental results for supervised parsing are provided in Section 6, where we compare the different training and parsing methods. Unsupervised dependency grammar induction experiments are described in Section 7, and we conclude in Section 8.

2. Tree-substitution grammars

A *Tree Substitution Grammar*[3] (TSG) is a 4-tuple, $G = (T, N, S, R)$, where T is a set of *terminal symbols*, N is a set of *nonterminal symbols*, $S \in N$ is the distinguished *root nonterminal* and R is a set of productions (rules). The productions take the form of *elementary trees*—tree fragments[4] of height ≥ 1—where each internal node is labelled with a nonterminal and each leaf is labelled with either a terminal or a nonterminal. Nonterminal leaves are called *frontier nonterminals* and form the substitution (recursion) sites in the generative process of creating trees with the grammar. For example, in Figure 1b the S $\rightarrow$ NP (VP (V hates) NP) production rewrites the S nonterminal as the fragment (S NP (VP (V hates) NP)).[5] This production has the two NPs as its frontier nonterminals.

A *derivation* creates a tree by starting with the root symbol and rewriting (substituting) it with an elementary tree, then continuing to rewrite frontier nonterminals with elementary trees until there are no remaining frontier nonterminals. We can represent derivations as sequences of elementary trees $\mathbf{e}$, where each elementary tree is substituted for the left-most frontier nonterminal of the tree being generated. Unlike Context Free Grammars (CFGs) a syntax tree may not uniquely specify the derivation, as illustrated in Figure 1 which shows two derivations using different elementary trees to produce the same tree.

A *Probabilistic Tree Substitution Grammar* (PTSG), like a PCFG, assigns a probability to each rule in the grammar, denoted $P(e|c)$ where the elementary tree e rewrites nonterminal c. The probability of a derivation $\mathbf{e}$ is the product of the probabilities of its component rules. Thus if we assume that each rewrite is conditionally independent of all others given its root nonterminal c (as in standard TSG models),[6] then we have

$$P(\mathbf{e}) = \prod_{c \rightarrow e \in \mathbf{e}} P(e|c)\,. \tag{1}$$

The probability of a tree, t, and string of words, $\mathbf{w}$, are given by

$$P(t) = \sum_{\mathbf{e}:\text{tree}(\mathbf{e})=t} P(\mathbf{e}) \quad \text{and}$$

$$P(\mathbf{w}) = \sum_{t:\text{yield}(t)=\mathbf{w}} P(t)\,,$$

3. A TSG is a *Tree Adjoining Grammar* (TAG; Joshi, 2003) without the adjunction operator, which allows insertions at internal nodes in the tree. This operation allows TAGs to describe the set of mildly context sensitive languages. A TSG in contrast can only describe the set of context free languages.
4. Elementary trees of height 1 correspond to productions in a context free grammar.
5. We use bracketed notation to represent tree structures as linear strings. The parenthesis indicate the hierarchical structure, with the first argument denoting the node label and the following arguments denoting child trees. The nonterminals used in our examples denote nouns, verbs, etc., and their respective phrasal types, using a simplified version of the Penn treebank tag set (Marcus et al., 1993).
6. Note that this conditional independence does not hold for our model because (as we will see in Section 3) we integrate out the model parameters.

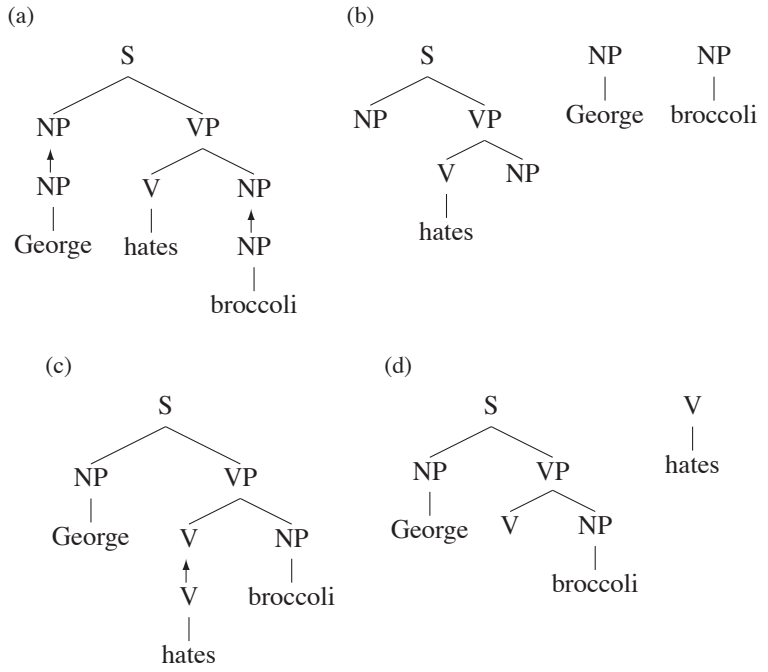

Figure 1: Example derivations for the same tree, where arrows indicate substitution sites. The left figures (a) and (c) show two different derivations and the right figures (b) and (d) show the elementary trees used in the respective derivation.

respectively, where tree($\mathbf{e}$) returns the tree for the derivation $\mathbf{e}$ and yield(t) returns the string of terminal symbols at the leaves of t.

Estimating a PTSG requires learning the sufficient statistics for $P(e|c)$ in (1) based on a training sample. Estimation has been done in previous work in a variety of ways, for example using heuristic frequency counts (Bod, 1993), a maximum likelihood estimate (Bod, 2000) and heldout estimation (Prescher et al., 2004). Parsing involves finding the most probable tree for a given string, that is, $\arg\max_t P(t|\mathbf{w})$. This is typically simplified to finding the most probable derivation, which can be done efficiently using the CYK algorithm. A number of improved algorithms for parsing have been reported, most notably a Monte-Carlo approach for finding the maximum probability tree (Bod, 1995) and a technique for maximising labelled recall using inside-outside inference in a PCFG reduction grammar (Goodman, 1998).

2.1 Dependency Grammars

Due to the wide availability of annotated treebanks, phrase structure grammars have become a popular formalism for building supervised parsers, and we will follow this tradition by using phrase structure trees from the Wall Street Journal corpus (Marcus et al., 1993) as the basis for our supervised grammar induction experiments (grammar refinement). However, the choice of formalism for unsupervised induction is a more nuanced one. The induction of phrase-structure grammars is notoriously difficult, since these grammars contain two kinds of ambiguity: the constituent structure and the constituent labels. In particular, constituent labels are highly ambiguous: firstly we don't know *a priori* how many there are, and secondly labels that appear high in a tree (e.g., an *S* category

Figure 2: An unlabelled dependency analysis for the example sentence *George hates broccoli*. The artificial ROOT node denotes the head of the sentence.

for a clause) rely on the correct inference of all the latent labels above and below them. Much of the recent work on unsupervised grammar induction has therefore taken a different approach, focusing on inducing dependency grammars (Mel′čuk, 1988). In applying our model to unsupervised grammar induction we follow this trend by inducing a dependency grammar. Dependency grammars represent the structure of language through directed links between words, which relate words (heads) with their syntactic dependents (arguments). An example dependency tree is shown in Figure 2, where directed arcs denote each word's arguments (e.g., hates has two arguments, 'George' and 'broccoli'). Dependency grammars are less ambiguous than phrase-structure grammars since the set of possible constituent labels (heads) is directly observed from the words in the sentence, leaving only the induction challenge of determining the tree structure. Most dependency grammar formalisms also include labels on the links between words, denoting, for example, subject, object, adjunct etc. In this work we focus on inducing unlabelled directed dependency links and assume that these links form a projective tree (there are no crossing links, which correspond to discontinuous constituents). We leave the problem of inducing labeled dependency grammars to further work.

Although we will be inducing dependency parses in our unsupervised experiments, we define our model in the following section using the formalism of a phrase-structure grammar. As detailed in Section 7, the model can be used for dependency grammar induction by using a specially designed phrase-structure grammar to represent dependency links.

3. Model

In defining our model, we focus on the unsupervised case, where we are given a corpus of text strings $\mathbf{w}$ and wish to learn a tree-substitution grammar G that we can use to infer the parses for our strings and to parse new data. (We will handle the supervised scenario, where we are given observed trees $\mathbf{t}$, in Section 4; we treat it as a special case of the unsupervised model using additional constraints during inference.) Rather than inferring a grammar directly, we go through an intermediate step of inferring a distribution over the derivations used to produce $\mathbf{w}$, that is, a distribution over sequences of elementary trees $\mathbf{e}$ that compose to form $\mathbf{w}$ as their yield. We will then essentially read the grammar off the elementary trees, as described in Section 5. Our problem therefore becomes one of identifying the posterior distribution of $\mathbf{e}$ given $\mathbf{w}$, which we can do using Bayes' Rule,

$$P(\mathbf{e}|\mathbf{w}) \propto P(\mathbf{w}|\mathbf{e})P(\mathbf{e})\,.$$

Note that any sequence of elementary trees uniquely specifies a corresponding sequence of words: those words that can be read off the leaves of the elementary trees in sequence. Therefore, given a sequence of elementary trees $\mathbf{e}$, $P(\mathbf{w}|\mathbf{e})$ either equals 1 (if $\mathbf{w}$ is consistent with $\mathbf{e}$) or 0 (otherwise). Thus, in our model, all the work is done by the prior distribution over elementary trees,

$$P(\mathbf{e}|\mathbf{w}) \propto P(\mathbf{e})\,\delta(w(\mathbf{e}),\mathbf{w})\,,$$

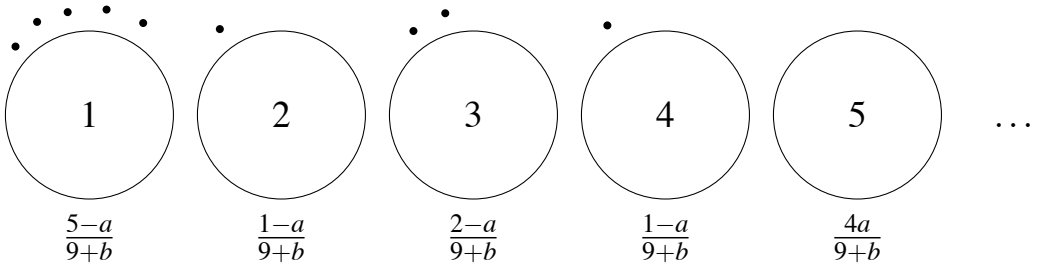

Figure 3: An example of the Pitman-Yor Chinese restaurant process with $\mathbf{z}_{-10} = (1,2,1,1,3,1,1,4,3)$. Black dots indicate the number of customers sitting at each table, and the value listed below table k is $P(z_{10} = k|\mathbf{z}_{-10})$.

where δ is the Kronecker delta and $w(\mathbf{e}) = \text{yield}(\text{tree}(\mathbf{e}))$ returns the string yield of the tree defined by the derivation $\mathbf{e}$.

Because we have no way to know ahead of time how many elementary trees might be needed to account for the data, we use a nonparametric Bayesian prior, specifically the Pitman-Yor process (PYP) (Pitman, 1995; Pitman and Yor, 1997; Ishwaran and James, 2003), which is a generalization of the more widely known Dirichlet process (Ferguson, 1973). Drawing a sample from a PYP (or DP) yields a probability distribution G with countably infinite support. The PYP has three parameters: a *discount parameter* a, a *strength parameter* b, and a *base distribution* P_{E}. Informally, the base distribution determines which items will be in the support of G (here, we will define P_{E} as a distribution over elementary trees, so that G is also a distribution over elementary trees), and the discount and strength parameters a and b determine the shape of G. The discount parameter a ranges from 0 to 1; when $a = 0$, the PYP reduces to a Dirichlet process, in which case the strength parameter b is known as the *concentration parameter* and is usually denoted with α. We discuss the roles of a and b further below.

Assuming an appropriate definition for P_{E} (we give a formal definition below), we can use the PYP to define a distribution over sequences of elementary trees $\mathbf{e} = e_1 \dots e_n$ as follows:

$$\begin{aligned} G|a,b,P_{\text{E}} &\sim \text{PYP}(a,b,P_{\text{E}}) \\ e_i|G \qquad &\sim G. \end{aligned} \tag{2}$$

In this formulation, G is an infinite distribution over elementary trees drawn from the PYP prior, and the e_i are drawn *iid* from G. However, since it is impossible to explicitly represent an infinite distribution, we integrate over possible values of G, which induces dependencies between the e_i. Perhaps the easiest way to understand the resulting distribution over $\mathbf{e}$ is through a variant of the Chinese restaurant process (CRP; Aldous, 1985; Pitman, 1995) that is often used to explain the Dirichlet process. Imagine a restaurant with an infinite number of tables, each with an infinite number of seats. Customers enter the restaurant one at a time and seat themselves at a table. If z_i is the index of the table chosen by the ith customer, then the Pitman-Yor Chinese Restaurant Process (PYCRP) defines the distribution

$$P(z_i = k|\mathbf{z}_{-i}) = \begin{cases} \frac{n_k^- - a}{i-1+b} & 1 \le k \le K^- \\ \frac{K^- a + b}{i-1+b} & k = K^- + 1 \end{cases},$$

where $\mathbf{z}_{-i}$ is the seating arrangement of the $i-1$ previous customers, n_k^- is the number of customers in $\mathbf{z}_{-i}$ who are seated at table k, $K^- = K(\mathbf{z}_{-i})$ is the total number of tables in $\mathbf{z}_{-i}$, and $z_1 = 1$ by definition. Figure 3 illustrates. When $a = 0$, this process reduces to the standard Chinese restaurant process. Like the CRP, the PYCRP is exchangeable and produces a power-law distribution on the number of customers at each table (Pitman, 2006). The hyperparameters a and b together control the manner of the clustering, although the difference between the two is rather subtle. A high value of b will bias towards more clusters irrespective of their individual sizes, only accounting for their aggregate size. In contrast a large $a \to 1$ will bias the clustering towards smaller individual clusters.

The PYCRP produces a sequence of integers $\mathbf{z}$ whose joint probability is

$$\begin{aligned} P(\mathbf{z}) &= \prod_{i=1}^{n} P(z_i|\mathbf{z}_{1\ldots i-1}) \\ &= 1 \cdot \prod_{i=2}^{n} P(z_i|\mathbf{z}_{1\ldots i-1}) \\ &= \left(\prod_{j=1}^{n-1} \frac{1}{j+b}\right)\left(\prod_{k=1}^{K(\mathbf{z})-1} (ka+b)\right)\left(\prod_{k=1}^{K(\mathbf{z})} \prod_{j=1}^{n_k^- - 1} (j-a)\right) \\ &= \frac{\Gamma(1+b)}{\Gamma(n+b)}\left(\prod_{k=1}^{K-1}(ka+b)\right)\left(\prod_{k=1}^{K} \frac{\Gamma(n_k^- - a)}{\Gamma(1-a)}\right), \end{aligned} \tag{3}$$

where K is the total number of tables in $\mathbf{z}$ and Γ is the gamma function. In order to produce a sequence of elementary trees $\mathbf{e}$ we need to introduce a second step in the process. We can do so by imagining that each table in the restaurant is labelled with an elementary tree, with $\ell(\mathbf{z}) = \ell_1 \ldots \ell_K$ being the trees labelling each table. Whenever a customer sits at a previously unoccupied table, a label is chosen for that table according to the base distribution P_{E}, and this label is used by all following customers at that table, as illustrated in Figure 4. We define e_i to be ℓ_{z_i}, the label of the table chosen by the ith customer. This yields the following conditional distribution on e_i:

$$\begin{aligned} P(e_i = e|\mathbf{z}_{-i}, \ell(\mathbf{z}_{-i})) &= \sum_{k=1}^{K(\mathbf{z}_{-i})} \delta(\ell_k, e)\frac{n_k^{(\mathbf{z}_{-i})} - a}{i-1+b} + \frac{K(\mathbf{z}_{-i})a+b}{i-1+b} P_{\text{E}}(e) \\ &= \frac{n_e^- - K_e(\mathbf{z}_{-i})a + (K(\mathbf{z}_{-i})a+b)P_{\text{E}}(e)}{i-1+b}, \end{aligned} \tag{4}$$

where K_e^- is the number of tables labelled with e in $\mathbf{z}_{-i}$, and δ is the Kronecker delta. The probability of an entire sequence of elementary trees is

$$P(\mathbf{e}) = \sum_{\mathbf{z},\ell} P(\mathbf{e}, \mathbf{z}, \ell),$$

where $P(\mathbf{e}, \mathbf{z}, \ell) = 0$ except when $\ell_{z_i} = e_i$ for all i, in which case

$$\begin{aligned} P(\mathbf{e}, \mathbf{z}, \ell) &= P(\mathbf{z}, \ell) = P(\mathbf{z})P(\ell|\mathbf{z}) \\ &= \frac{\Gamma(1+b)}{\Gamma(n+b)}\left(\prod_{k=1}^{K-1}(ka+b)\right)\left(\prod_{k=1}^{K} \frac{\Gamma(n_k^- - a)}{\Gamma(1-a)} P_{\text{E}}(\ell_k)\right), \end{aligned}$$

where K is the total number of tables in $\mathbf{z}$.

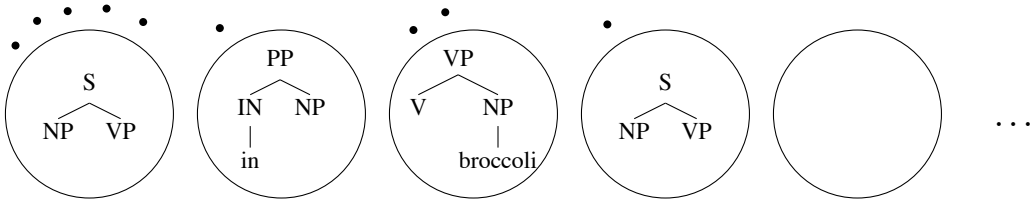

Figure 4: The Pitman-Yor process, illustrated as a labelled Chinese restaurant process. In this example, $\mathbf{z}_{-10} = (1,2,1,1,3,1,1,4,3)$ and each table k is labelled with an elementary tree ℓ_k. Black dots indicate the number of occurrences of each tree in $\mathbf{e} = (\ell_1,\ell_2,\ell_1,\ell_1,\ell_3,\ell_1,\ell_1,\ell_4,\ell_3)$. In this illustration, which corresponds to the model given in (2), a single Pitman-Yor process is used to generate all elementary trees, so the trees do not necessarily fit together properly. Our complete model, defined in (5), would have a separate Pitman-Yor restaurant for each root category.

Equation 4 shows that, like other PYP and DP models, this model can be viewed as a *cache model*, where e_i can be generated in one of two ways: by drawing from the base distribution or by drawing from a cache of previously generated elementary trees, where the probability of any particular elementary tree is proportional to the discounted frequency of that tree. This view makes it clear that the model embodies a "rich-get-richer" dynamic in which a few elementary trees will occur with high probability, but many will occur only once or twice, as is typical of natural language.

In the model just defined, a single PYP generates all of the elementary trees in $\mathbf{e}$. Notice, however, that these elementary trees might not tile together properly to create full syntax trees. For example, in Figure 4, e_1 = (S NP VP) and e_2 = (PP (IN in) NP), where the first substitution site in e_1 is an NP, but the root of e_2 is a PP, so e_2 cannot be used to expand e_1. To solve this problem, we modify the model so that there is a separate PYP for each non-terminal category c, with a base distribution conditioned on c. The distribution over elementary trees with root category c is defined as

$$\begin{aligned} G_c|a_c,b_c,P_{\text{E}} &\sim \text{PYP}(a_c,b_c,P_{\text{E}}(\cdot|c)) \\ e|c,G_c &\sim G_c\,, \end{aligned} \tag{5}$$

where $P_{\text{E}}(\cdot|c)$ is a distribution over the infinite space of elementary trees rooted with c, and a_c and b_c are the PYP hyper-parameters for non-terminal c. We elect not to tie together the values of these hyper-parameters as these control the tendency to infer larger or smaller sets of elementary trees from the observed data; we expect the distribution over productions to differ substantially between non-terminals. To generate $\mathbf{e}$, we now draw e_1 from G_S, giving us an elementary tree with frontier nodes $c_1 \ldots c_m$. We then draw $e_2 \ldots e_m$ in turn from $G_{c_1} \ldots G_{c_m}$. We continue in this fashion until a full tree is generated, at which point we can start again with a draw from G_S.

Integrating over G_c, we obtain the following distribution over e_i, now conditioned on its root category as well as the previously generated table labels and assignments:

$$P(e_i = e|c,\mathbf{z}_{-i},\ell(\mathbf{z}_{-i})) = \frac{n_e^- - K_e^- a_c + (K_c^- a_c + b_c)P_{\text{E}}(e|c)}{n_c^- + b_c}\,, \tag{6}$$

where $K_c^- = \sum_{e:\text{root}(e)=c} K_e^-$ is the total number of tables for nonterminal c, n_e^- is the number of times e has been used to rewrite c and $n_c^- = \sum_{e:\text{root}(e)=c} n_e^-$ is the total count of rules rewriting c. As

before, the $^-$ superscript denotes that the counts are calculated over the previous elementary trees, $\mathbf{e}_{-i}$, and their seating arrangements, $\mathbf{z}_{-i}$.

Finally, we turn to the definition of the base distribution over elementary trees, P_{E}. Recall that in an elementary tree, each internal node is labelled with a non-terminal category symbol and each frontier (leaf) node is labelled with either a non-terminal or a terminal symbol. Given a probabilistic context-free grammar R, we assume that elementary trees are generated (conditioned on the root non-terminal c) using the following generative process. First, choose a PCFG production $c \rightarrow \alpha$ for expanding c according to the distribution given by R. Next, for each non-terminal in α decide whether to stop expanding (creating a non-terminal frontier node, also known as a substitution site) or to continue expanding. If the choice is to continue expanding, a new PCFG production is chosen to expand the child, and the process continues recursively. The generative process completes when the frontier is composed entirely of substitution sites and terminal symbols.

Assuming a fixed distribution P_{C} over the rules in R, this generative process leads to the following distribution over elementary trees:

$$P_{\mathrm{E}}(e|c) = \prod_{i \in I(e)} (1 - s_{c_i}) \prod_{f \in F(e)} s_{c_f} \prod_{c' \rightarrow \alpha \in e} P_{\mathrm{C}}(\alpha|c') \,, \tag{7}$$

where $I(e)$ are the set of internal nodes in e excluding the root, $F(e)$ are the set of frontier non-terminal nodes, c_i is the non-terminal symbol for node i and s_c is the probability of stopping expanding a node labelled c. We treat s_c as a parameter which is estimated during training, as described in Section 4.3. In the supervised case it is reasonable to assume that P_{C} is fixed; we simply use the maximum-likelihood PCFG distribution estimated from the training corpus (i.e., $P_{\mathrm{C}}(\alpha|c')$ is simply the relative frequency of the rule $c' \rightarrow \alpha$). In the unsupervised case, we will infer P_{C}; this requires extending the model to assume that P_{C} is itself drawn from a PYP prior with a uniform base distribution. We describe this extension below, along with its associated changes to equation 14.

The net effect of our base distribution is to bias the model towards simple rules with a small number of internal nodes. The geometric increase in cost associated with the stopping decisions discourages the model from using larger rules; for these rules to be included they must occur very frequently in the corpus. Similarly, rules which use high-probability (frequent) CFG productions are favoured. It is unclear if these biases are ideal: we anticipate that other, more sophisticated distributions would improve the model's performance.

In the unsupervised setting we no longer have a training set of annotated trees and therefore do not have a PCFG readily available to use as the base distribution in Equation 7. For this reason we extend the previous model to a two level hierarchy of PYPs. As before, the topmost level is defined over the elementary tree fragments (G_c) with the base distribution (P_{E}) assigning probability to the infinite space of possible fragments. The model differs from the supervised one by defining P_C in (7) using a PYP prior over CFG rules. Accordingly the model can now infer a two level hierarchy consisting of a PCFG embedded within a TSG, compared to the supervised parsing model which only learnt the TSG level with a fixed PCFG. Formally, each CFG production is drawn from[7]

$$\begin{aligned} H_c|\, a'_c, b'_c &\sim \mathrm{PYP}(a'_c, b'_c, \mathrm{Uniform}(\cdot|c)) \\ \alpha|\, c, H_c &\sim H_c \,, \end{aligned} \tag{8}$$

7. As we are using a finite base distribution over CFG productions, we could use a Dirichlet instead of the PYP presented in (8). However we elect to use a PYP because it is more general, having additional expressive power from its discounting behaviour.

where a'_c and b'_c are the PYP hyper-parameters and Uniform$(\cdot|c)$ is a uniform distribution over the space of rewrites for non-terminal c.[8] As before, we integrate out the model parameters, H_c. Consequently draws from P_C are no longer *iid* but instead are tied in the prior, and the probability of the sequence of component CFG productions $\{c' \to \alpha \in e\}$ now follows a Pitman-Yor Chinese Restaurant Process.

The CFG level and TSG level PYCRPs are connected as follows: every time an elementary tree is assigned to a new table in the TSG level, each of its component CFG rules are drawn from the CFG level prior. Note that, just as elementary trees are divided into separate restaurants at the TSG level based on their root categories, CFG rules are divided into separate restaurants at the CFG level based on their left-hand sides. Formally, the probability of r_j, the j^{th} CFG rule in the sequence, is given by

$$P_C(r_j = r | c_j = c, \mathbf{z}'_{-j}, \ell'_{-j}) = \frac{n'^{-}_r - K'^{-}_r a'_c + (K'^{-}_c a'_c + b'_c)\frac{1}{|R_c|}}{K'^{-}_c + b'_c}, \tag{9}$$

where c_j is the left-hand side of r_j; $\mathbf{z}'_{-j}$ and ℓ'_{-j} are the table assignments and table labels in the CFG-level restaurants (we use prime symbols to indicate variables pertaining to the CFG level); n'^{-}_r is the number of times rule r is used in any table label in a TSG restaurant (equivalently, the number of customers at tables labelled r in the CFG restaurants); K'^{-}_r and $K'^{-}_c = \sum_{r:\text{root}(r)=c} K'^{-}_r$ are the CFG-level table counts for r and all rules rewriting c, respectively; and R_c is the set of CFG productions which can rewrite c. This formulation reflects that we now have multiple tied restaurants, and each time an elementary tree opens a new table in a top-level restaurant all its rules are considered to have entered their own respective P_C restaurants (according to their root c). Accordingly the CFG-level customer count, n'^{-}_r, is the number of occurrences of r in the elementary trees that label the tables in the TSG restaurants (excluding r_j). Thus, in the unsupervised case, the product of rule probabilities (the final factor) in Equation (7) is computed by multiplying together the conditional probability of each rule (9) given the previous ones.

4. Training

We present two alternative algorithms for training our model, both based on Markov chain Monte Carlo techniques, which produce samples from the posterior distribution of the model by iteratively resampling the values of the hidden variables (tree nodes). The first algorithm is a *local* sampler, which operates by making a local update to a single tree node in each sampling step. The second algorithm is a *blocked* sampler, which makes much larger moves by sampling analyses for full sentences, which should improve the mixing over the local sampler. Importantly the blocked sampler is more general, being directly applicable to both supervised and unsupervised settings (and for parsing test sentences, which is equivalent to an unsupervised setting) while the local sampler is only applicable for supervised learning, where the trees are observed. We now present the two sampling methods in further detail.

8. In our experiments on unsupervised dependency parsing the space of rewrites varied depending on c, and can be as large as the set of part-of-speech tags. See Section 7 for details.

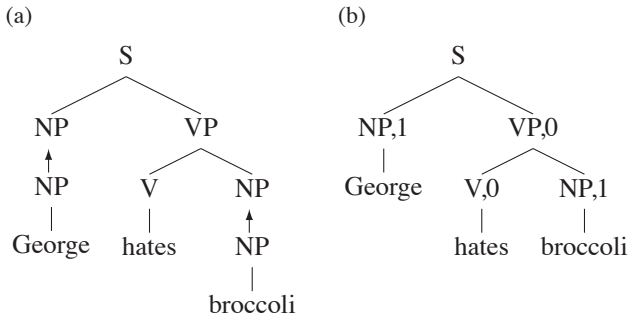

Figure 5: Gibbs sampler state (b) corresponding to the example derivation (a) (reproduced from Figure 1a). Each node is labelled with its substitution variable.

4.1 Local Sampler

The *local* sampler is designed specifically for the supervised scenario, and samples a TSG derivation for each tree by sampling local updates at each tree node. It uses Gibbs sampling (Geman and Geman, 1984), where random variables are repeatedly sampled conditioned on the current values of all other random variables in the model. The actual algorithm is analogous to the Gibbs sampler used for inference in the Bayesian model of word segmentation presented by Goldwater et al. (2006); indeed, the problem of inferring the derivations $\mathbf{e}$ from $\mathbf{t}$ can be viewed as a segmentation problem, where each full tree must be segmented into one or more elementary trees. To formulate the local sampler, we associate a binary variable $x_d \in \{0,1\}$ with each non-root internal node, d, of each tree in the training set, indicating whether that node is a substitution point ($x_d = 1$) or not ($x_d = 0$). Each substitution point forms the root of some elementary tree, as well as a frontier nonterminal of an ancestor node's elementary tree. Conversely, each non-substitution point forms an internal node inside an elementary tree. Collectively the training trees and substitution variables specify the sequence of elementary trees $\mathbf{e}$ that is the current state of the sampler. Figure 5 shows an example tree with its substitution variables and its corresponding TSG derivation.

Our Gibbs sampler works by sampling the value of the x_d variables, one at a time, in random order. If d is the node associated with x_d, the substitution variable under consideration, then the two possible values of x_d define two options for $\mathbf{e}$: one in which d is internal to some elementary tree e_M, and one in which d is the substitution site connecting two smaller trees, e_A and e_B. In the example in Figure 5, when sampling the VP node, $e_M =$ (S NP (VP (V hates) NP)), $e_A =$ (S NP VP), and $e_B =$ (VP (V hates) NP). To sample a value for x_d, we compute the probabilities of e_M and (e_A, e_B), conditioned on $\mathbf{e}^-$: all other elementary trees in the training set that share at most a root or frontier nonterminal with e_M, e_A, or e_B. These probabilities are easy to compute because the PYP is *exchangeable*, meaning that the probability of a set of outcomes does not depend on their ordering. Therefore we can treat the elementary trees under consideration as the last ones to be sampled, and apply Equation (6). We then sample one of the two outcomes (merging or splitting) according to the relative probabilities of these two events. More specifically, the probabilities of the two outcomes,

conditioned on the current analyses of the remainder of the corpus, are

$$P(e_M|c_M) = \frac{n^-_{e_M} - K^-_{e_M} a_{c_M} + (K^-_{c_M} a_{c_M} + b_{c_M}) P_{\mathrm{E}}(e_M|c_M)}{n^-_{c_M} + b_{c_M}} \quad \text{and}$$

$$\begin{aligned} P(e_A, e_B|c_A, c_B) &= \sum_{z_{e_A}} P(e_A, z_{e_A}|c_A) P(e_B|e_A, z_{e_A}, c_A, c_B) \\ &= \frac{n^-_{e_A} - K^-_{e_A} a_{c_A}}{n^-_{c_A} + b_{c_A}} \times \frac{n^-_{e_B} + \delta_e - K^-_{e_B} a_{c_B} + (K^-_{c_B} a_{c_B} + b_{c_B}) P_{\mathrm{E}}(e_B|c_B)}{n^-_{c_B} + \delta_c + b_{c_B}} \\ &\quad + \frac{(K^-_{c_A} a_{c_A} + b_{c_A}) P_{\mathrm{E}}(e_A|c_A)}{n^-_{c_A} + b_{c_A}} \\ &\quad \times \frac{n^-_{e_B} + \delta_e - (K^-_{e_B} + \delta_e) a_{c_B} + \left((K^-_{c_B} + \delta_c) a_{c_B} + b_{c_B}\right) P_{\mathrm{E}}(e_B|c_B)}{n^-_{c_B} + \delta_c + b_{c_B}}, \end{aligned} \tag{10}$$

where c_y is the root label of e_y, the counts n^- and K^- are derived from $\mathbf{z}_{-M}$ and $\ell(\mathbf{z}_{-M})$ (this dependency is omitted from the conditioning context for brevity), $\delta_e = \delta(e_A, e_B)$ is the Kronecker delta function which has value one when e_A and e_B are identical and zero otherwise, and similarly for $\delta_c = \delta(c_A, c_B)$ which compares their root nonterminals c_A and c_B. The δ terms reflect the changes to n^- that would occur after observing e_A, which forms part of the conditioning context for e_B. The two additive terms in (10) correspond to different values of z_{e_A}, the seating assignment for e_A. Specifically, the first term accounts for the case where e_A is assigned to an existing table, $z_{e_A} < K^-_{e_A}$, and the second term accounts for the case where e_A is seated at a new table, $z_{e_A} = K^-_{e_A}$. The seating affects the conditional probability of e_B by potentially increasing the number of tables $K^-_{e_A}$ or $K^-_{c_A}$ (relevant only when $e_A = e_B$ or $c_A = c_B$).

4.2 Blocked Sampler

The local sampler has the benefit of being extremely simple, however it may suffer from slow convergence (poor mixing) due to its very local updates. That is, it can get stuck because many locally improbable decisions are required to escape from a locally optimal solution. Moreover it is only applicable to the supervised setting: it cannot be used for unsupervised grammar induction or for parsing test strings. For these reasons we develop the *blocked* sampler, which updates blocks of variables at once, where each block consists of all the the nodes associated with a single sentence. This sampler can make larger moves than the local sampler and is more flexible, in that it can perform inference with both string (unsupervised) or tree (supervised) input.[9]

The blocked sampler updates the analysis for each sentence given the analyses for all other sentences in the training set. We base our approach on the algorithm developed by Johnson et al. (2007a) for sampling parse trees using a finite Bayesian PCFG model with Dirichlet priors over the multinomial rule probabilities. As in our model, they integrate out the parameters (in their case, the PCFG rule probabilities), leading to a similar caching effect due to interdependences between the latent variables (PCFG rules in the parse). Thus, standard dynamic programming algorithms cannot be used to sample directly from the desired posterior, $p(t|\mathbf{w}, \mathbf{t}^-)$, that is, the distribution of parse trees for the current sentence given the words in the corpus and the trees for all other sentences. To solve this problem, Johnson et al. (2007a) developed a Metropolis-Hastings (MH)

9. A recently-proposed alternative approach is to perform *type-level* updates, which samples updates to many similar tree fragments at once (Liang et al., 2010). This was shown to converge faster than the local Gibbs sampler.

sampler. The MH algorithm is an MCMC technique which allows for samples to be drawn from a probability distribution, $\pi(s)$, by first drawing samples from a *proposal distribution*, $Q(s'|s)$, and then correcting these to the true distribution using an acceptance/rejection step. Given a state s, we sample a next state $s' \sim Q(\cdot|s)$ from the proposal distribution; this new state is accepted with probability

$$A(s,s') = \min\left\{\frac{\pi(s')Q(s|s')}{\pi(s)Q(s'|s)}, 1\right\}$$

and is rejected otherwise, in which case s is retained as the current state. The Markov chain defined by this process is guaranteed to converge on the desired distribution, $\pi(s)$. Critically, the MH algorithm enables sampling from distributions from which we cannot sample directly, and moreover, we need not know the normalisation constant for $\pi(\cdot)$, since it cancels in $A(s,s')$.

In Johnson et al.'s (2007a) algorithm for sampling from a Bayesian PCFG, the proposal distribution is simply $Q(t'|t) = P(t'|\theta^{MAP})$, the posterior distribution over trees given fixed parameters θ^{MAP}, where θ^{MAP} is the MAP estimate based on the conditioning data, $\mathbf{t}^{-}$. Note that the proposal distribution is a close fit to the true posterior, differing only in that under the MAP the production probabilities in a derivation are *iid*, while for the true model the probabilities are tied by the prior (giving rise to the caching effect). The benefit of using the MAP is that its independences mean that inference can be solved using dynamic programming, namely the inside algorithm (Lari and Young, 1990). Given the inside chart, which stores the aggregate probability of all subtrees for each word span and rooted with a given nonterminal label, samples can be drawn using a simple top-down recursion (Johnson et al., 2007a).

Our model is similar to Johnson et al.'s, as we also use a Bayesian prior in a model of grammar induction and consequently face similar problems with directly sampling due to the caching effects of the prior. For this reason, we use the MH algorithm in a similar manner, except in our case we draw samples of derivations of elementary trees and their seating assignments, $p(\mathbf{z}_i, \ell_i|\mathbf{w}, \mathbf{z}_{-i}, \ell_{-i})$, and use a MAP estimate over $(\mathbf{z}_{-i}, \ell_{i-})$ as our proposal distribution.[10] However, we have an added complication: the MAP cannot be estimated directly. This is a consequence of the base distribution having infinite support, which means the MAP has an infinite rule set. For finite TSG models, such as those used in DOP, constructing a CFG equivalent grammar is straightforward (if unwieldy). This can be done by creating a rule for each elementary tree which rewrites its root nonterminal as its frontier. For example under this technique S $\rightarrow$ NP (VP (V hates) NP would be mapped to S $\rightarrow$ NP hates NP.[11] However, since our model has infinite support over productions, it cannot be mapped in the same way. For example, if our base distribution licences the CFG production NP $\rightarrow$ NP PP then our TSG grammar will contain the infinite set of elementary trees NP $\rightarrow$ NP PP, NP $\rightarrow$ (NP NP PP) PP, NP $\rightarrow$ (NP (NP NP PP) PP) PP, ..., each with decreasing but non-zero probability. These would all need to be mapped to CFG rules in order to perform inference under the grammar, which is clearly impossible.

Thankfully it is possible to transform the infinite MAP-TSG into a finite CFG, using a method inspired by Goodman (2003), who developed a grammar transform for efficient parsing with an

10. Calculating the proposal and acceptance probabilities requires sampling not just the elementary trees, but also their table assignments (for both levels in the hierarchical model). We elected to simplify the implementation by separately sampling the elementary trees and their table assignments.

11. Alternatively, interspersing a special nonterminal, for example, S $\rightarrow$ {S-NP-{VP-{V-hates}-NP} $\rightarrow$ NP hates NP, encodes the full structure of the elementary tree, thereby allowing the mapping to be reversed. We use a similar technique to encode non-zero count rules in our grammar transformation, described below.

all-subtrees DOP grammar. In the transformed grammar inside inference is tractable, allowing us to draw proposal samples efficiently and thus construct a Metropolis-Hastings sampler. The resultant grammar allows for efficient inference, both in unsupervised and supervised training and in parsing (see Section 5).

We represent the MAP using the grammar transformation in Table 1, which separates the count and base distribution terms in Equation 6 into two separate CFGs, denoted A and B. We reproduce Equation 6 below along with its decomposition:

$$\begin{aligned} P(e_i = e \,|\, c, \mathbf{z}_{-i}, \ell(\mathbf{z}_{-i})) &= \frac{n_e^- - K_e^- a_c + (K_c^- a_c + b_c) P_{\text{E}}(e|c)}{n_c^- + b_c} \\ &= \underbrace{\frac{n_e^- - K_e^- a_c}{n_c^- + b_c}}_{\text{count}} + \underbrace{\frac{K_c^- a_c + b_c}{n_c^- + b_c} P_{\text{E}}(e|c)}_{\text{base}} . \end{aligned} \tag{11}$$

Grammar A has productions for every elementary tree e with $n_e^- \geq 1$, which are assigned as their probability the count term in Equation 11.[12] The function $\text{sig}(e)$ returns a string signature for elementary trees, for which we use a form of bracketed notation. To signify the difference between these nonterminal symbols and trees, we use curly braces and hyphens in place of round parentheses and spaces, respectively, for example, the elementary tree (S NP (VP (V hates) NP)) is denoted by the nonterminal symbol {S-NP-{VP-{V-hates}-NP}}. Grammar B has productions for every CFG production licensed under P_{E}; its productions are denoted using primed (') nonterminals. The rule $c \to c'$ bridges from A to B, weighted by the base term in Equation 11 excluding the $P_{\text{E}}(e|c)$ factor. The contribution of the base distribution is computed recursively via child productions. The remaining rules in grammar B correspond to every CFG production in the underlying PCFG base distribution, coupled with the binary decision of whether or not nonterminal children should be substitution sites (frontier nonterminals). This choice affects the rule probability by including an s or $1-s$ factor, and child substitution sites also function as a bridge back from grammar B to A. There are often two equivalent paths to reach the same chart cell using the same elementary tree—via grammar A using observed TSG productions and via grammar B using P_{E} backoff—which are summed to yield the desired net probability. The transform is illustrated in the example in Figures 6 and 7.

Using the transformed grammar we can represent the MAP grammar efficiently and draw samples of TSG derivations using the inside algorithm. In an unsupervised setting, that is, given a yield string as input, the grammar transform above can be used directly with the inside algorithm for PCFGs (followed by the reverse transform to map the sampled derivation into TSG elementary trees). This has an asymptotic time complexity cubic in the length of the input.

For supervised training the trees are observed and thus we must ensure that the TSG analysis matches the given tree structure. This necessitates constraining the inside algorithm to only consider spans that are present in the given tree and with the given nonterminal. Nonterminals are said to match their primed and signed counterparts, for example, VP′ and {VP-{V-hates}-NP} both match VP. A sample from the constrained inside chart will specify the substitution variables for each node in the tree: For each node d if it has a non-primed category in the sample then it is a substitution

12. The transform assumes inside inference, where alternate analyses for the same span of words with the same nonterminal are summed together. In Viterbi inference the summation is replaced by maximisation, and therefore we need different expansion probabilities. This requires changing the weight for $c \to \text{sig}(e)$ to $P(e_i = e \,|\, c, \mathbf{z}_{-i}, \ell(\mathbf{z}_{-i}))$ in Table 1.

Grammar A	For every ET, e, rewriting c with non-zero count:	
	$c \to \text{sig}(e)$	$\frac{n_e^- - K_e^- a_c}{n_c^- + b_c}$
	For every internal node e_i in e with children $e_{i,1}, \ldots, e_{i,n}$	
	$\text{sig}(e_i) \to \text{sig}(e_{i,1}) \ldots \text{sig}(e_{i,n})$	1
A $\to$ B	For every nonterminal, c:	
	$c \to c'$	$\frac{K_c^- a_c + b_c}{n_c^- + b_c}$
Grammar B	For every pre-terminal CFG production, $c \to t$:	
	$c' \to t$	$P_{\text{C}}(c \to t)$
	For every unary CFG production, $c \to a$:	
	$c' \to a$	$P_{\text{C}}(c \to a) s_a$
	$c' \to a'$	$P_{\text{C}}(c \to a)(1 - s_a)$
	For every binary CFG production, $c \to ab$:	
	$c' \to ab$	$P_{\text{C}}(c \to ab) s_a s_b$
	$c' \to ab'$	$P_{\text{C}}(c \to ab) s_a (1 - s_b)$
	$c' \to a'b$	$P_{\text{C}}(c \to ab)(1 - s_a) s_b$
	$c' \to a'b'$	$P_{\text{C}}(c \to ab)(1 - s_a)(1 - s_b)$

Table 1: Grammar transformation rules to map an infinite MAP TSG into an equivalent CFG, separated into three groups for grammar A (top), the bridge between A $\to$ B (middle) and grammar B (bottom). Production probabilities are shown to the right of each rule. The $\text{sig}(e)$ function creates a unique string signature for an ET e (where the signature of a frontier node is itself) and s_c is the probability of c being a substitution variable, thus stopping the P_{E} recursion.

S $\to$ {NP-{VP-{V-hates}-NP}}	$\frac{n_e^- - K_e^- a_S}{n_S^- + b_S}$
{NP-{VP-{V-hates}-NP}} $\to$ NP {VP-{V-hates}-NP}	1
{VP-{V-hates}-NP} $\to$ {V-hates} NP	1
{V-hates} $\to$ hates	1
S $\to$ S'	$\frac{K_S^- a_S + b_S}{n_S^- + b_S}$
S' $\to$ NP VP'	$P_{\text{C}}(\text{S} \to \text{NP VP}) s_{NP} (1 - s_{VP})$
VP' $\to$ V' NP	$P_{\text{C}}(\text{VP} \to \text{V NP})(1 - s_V) s_{NP}$
V' $\to$ hates	$P_{\text{C}}(\text{V} \to \text{hates})$

Figure 6: Example showing the transformed grammar rules for the single elementary tree $e =$ (S NP (VP (V hates) NP)) and the scores for each rule. Only the rules which correspond to e and its substitution sites are displayed. Taking the product of the rule scores above the dashed line yields the *count* term in (11), and the product of the scores below the line yields the *base* term. When the two analyses are combined and their probabilities summed together, we get $P(e_i = e | c, \mathbf{z}_{-i}, \ell(\mathbf{z}_{-i}))$.

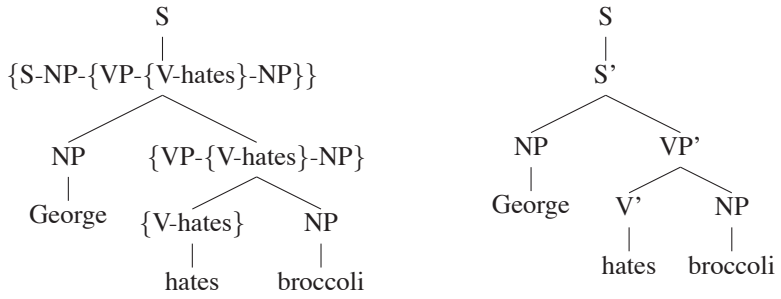

Figure 7: Example trees under the grammar transform, which both encode the same TSG derivation from Figure 1a. The left tree encodes that the S $\rightarrow$ NP (VP (V hates) NP elementary tree was drawn from the cache, while for the right tree this same elementary tree was drawn from the base distribution (the count and base terms in (11), respectively).

site, $x_d = 1$, otherwise it is an internal node, $x_d = 0$. For example, both trees in Figure 7 encode that both NP nodes are substitution sites and that the VP and V nodes are not substitution sites (the same configuration as Figure 5).

The time complexity of the constrained inside algorithm is linear in the size of the tree and the length of the sentence. The local sampler also has the same time complexity, however it is not immediately clear which technique will be faster in practise. It is likely that the blocked sampler will have a slower runtime due to its more complicated implementation, particularly in transforming the grammar and inside inference. Although the two samplers have equivalent asymptotic complexity, the constant factors may differ greatly. In Section 6 we compare the two training methods empirically to determine which converges more quickly.

4.3 Sampling Hyperparameters

In the previous discussion we assumed that we are given the model hyperparameters, $(\mathbf{a}, \mathbf{b}, \mathbf{s})$. While it might be possible to specify their values manually or fit them using a development set, both approaches are made difficult by the high dimensional parameter space. Instead we treat the hyperparameters as random variables in our model, by placing vague priors over them and infer their values during training. This is an elegant way to specify their values, although it does limit our ability to tune the model to optimise a performance metric on held-out data.

For the PYP discount parameters $\mathbf{a}$, we employ independent Beta priors, $a_c \sim \text{Beta}(1,1)$. The prior is uniform, encoding that we have no strong prior knowledge of what the value of each a_c should be. The conditional probability of a_c given the current derivations $\mathbf{z}, \ell$ is

$$P(a_c|\mathbf{z},\ell) \propto P(\mathbf{z},\ell|a_c) \times \text{Beta}(a_c|1,1)\,.$$

We cannot calculate the normaliser for this probability, however $P(\mathbf{z},\ell|a_c)$ can be calculated using Equation 3 and thus $P(a_c|\mathbf{z},\ell)$ can be calculated up to a constant. We use the range doubling slice sampling technique of Neal (2003) to draw a new sample of a_c' from its conditional distribution.[13]

We treat the concentration parameters, $\mathbf{b}$, as being generated by independent gamma priors, $b_c \sim \text{Gamma}(1,1)$. We use the same slice-sampling method for a_c to sample from the conditional

13. We used the slice sampler included in Mark Johnson's Adaptor Grammar implementation, available at `http://web.science.mq.edu.au/~mjohnson/Software.htm`.

over b_c,

$$P(b_c|\mathbf{z},\ell) \propto P(\mathbf{z},\ell|b_c) \times \text{Gamma}(b_c|1,1)\,.$$

This prior is not vague, that is, the probability density function decays exponentially for higher values of b_c, which serves to limits the influence of the P_{C} prior. In our experimentation we found that this bias had little effect on the generalisation accuracy of the supervised and unsupervised models, compared to a much vaguer Gamma prior with the same mean.

We use a vague Beta prior for the stopping probabilities in P_{E}, $s_c \sim \text{Beta}(1,1)$. The Beta distribution is conjugate to the binomial, and therefore the posterior is also a Beta distribution from which we can sample directly,

$$s_c \sim \text{Beta}\left(1+\sum_e K_e(\mathbf{z}) \sum_{n\in F(e)} \delta(n,c),\, 1+\sum_e K_e(\mathbf{z}) \sum_{n\in I(e)} \delta(n,c)\right),$$

where e ranges over all non-zero count elementary trees, $F(e)$ are the nonterminal frontier nodes in e, $I(e)$ are the non-root internal nodes and the δ terms count the number of nodes in e with nonterminal c. In other words, the first Beta argument is the number of tables in which a node with nonterminal c is a stopping node in the P_{E} expansion and the second argument is the number of tables in which c has been expanded (a non-stopping node).

All the hyper-parameters are resampled after every full sampling iteration over the training trees, except in the experiments in Section 7 where they are sampled every 10th iteration.

5. Parsing

We now turn to the problem of using the model to parse novel sentences. This requires finding the maximiser of

$$p(t|\omega,\mathbf{w}) = \int\int\int\int p(t|\omega,\mathbf{z},\ell,\mathbf{a},\mathbf{b},\mathbf{s})\, p(\mathbf{z},\ell,\mathbf{a},\mathbf{b},\mathbf{s}|\mathbf{w})\, d\mathbf{z}\, d\ell\, d\mathbf{a}\, d\mathbf{b}\, d\mathbf{s}\,, \tag{12}$$

where ω is the sequence of words being parsed, t is the resulting tree, $\mathbf{w}$ are the training sentences, $\mathbf{z}$ and ℓ represent their parses, elementary tree representation and table assignments and $(\mathbf{a},\mathbf{b},\mathbf{s})$ are the model's hyper-parameters. For the supervised case we use the training trees, $\mathbf{t}$, in place of $\mathbf{w}$ in Equation 12.

Unfortunately solving for the maximising parse tree in Equation 12 is intractable. However, it can be approximated using Monte Carlo techniques. Given a sample of $(\mathbf{z},\ell,\mathbf{a},\mathbf{b},\mathbf{s})$ we can reason over the space of possible TSG derivations, e, for sentence w using the same Metropolis-Hastings sampler presented in Section 4.2 for blocked inference in the unsupervised setting.[14] This gives us a set of samples from the posterior $p(\mathbf{e}|w,\mathbf{z},\ell,\mathbf{a},\mathbf{b},\mathbf{s})$. We then use a Monte Carlo integral to obtain a marginal distribution over trees (Bod, 2003),

$$\hat{p}^{MPT}(t) = \sum_{m=1}^{M} \delta(t, \text{tree}(\mathbf{e}_m))\,, \tag{13}$$

14. Using many samples in a Monte Carlo integral is a straight-forward extension to our parsing algorithm. We did not observe a significant improvement in parsing accuracy when using a multiple samples compared to a single sample, and therefore just present results for a single sample. However, using multiple models has been shown to improve the performance of other parsing models (Petrov, 2010).

where $\{\mathbf{e}_m\}_{m=1}^M$ are our sample of derivations for w. It is then straightforward to find the best parse, $t^* = \arg\max \hat{p}(t)$, which is simply the most frequent tree in the sample.

In addition to solving from the maximum probability tree (MPT) using Equation 13, we also present results for a number of alternative objectives. To test whether the derivational ambiguity is important, we also compute the maximum probability derivation (MPD),

$$\hat{p}^{MPD}(\mathbf{e}) = \sum_{m=1}^{M} \delta(\mathbf{e}, \mathbf{e}_m),$$

using a Monte-Carlo integral, from which we recover the tree, $t^* = \text{tree}(\arg\max_{\mathbf{e}} \hat{p}^{MPD}(\mathbf{e}))$. We also compare using the Viterbi algorithm directly with the MAP grammar, $t^* = \text{tree}(\arg\max_{\mathbf{e}} P_{MAP}(\mathbf{e}|w))$, which constitutes an approximation to the true model in which we can search exactly. This contrasts with the MPD which performs approximate search under the true model. We compare the different methods empirically in Section 6.

The MPD and MPT parsing algorithms require the computation of Monte-Carlo integrals over the large space of possible derivations or trees. Consequently, unless the distribution is extremely peaked the chance of sampling many identical structures is small, vanishingly so for long sentences (the space of trees grows exponentially with the sentence length). In other words, the sampling variance can be high which could negatively affect parsing performance. For this reason we present an alternative parsing method which compiles more local statistics for which we can obtain reliable estimates. The technique is based on Goodman's (2003) algorithm for maximising labelled recall in DOP parsing and subsequent work on parsing in state-splitting CFGs (Petrov and Klein, 2007). The first step is to acquire marginal distributions over the CFG productions within each sampled tree. Specifically, we collect counts for events of the form $(c \to \alpha, i, j, k)$, where $c \to \alpha$ is a CFG production spanning words $[i, j)$ and k is the split point between child constituents for binary productions, $i < k < j$ ($k = 0$ for unary productions). These counts are then marginalised by the number of trees sampled. Finally the Viterbi algorithm is used to find the tree with the maximum cumulative probability under these marginals, which we call the maximum expected rule (MER) parse. Note that this is a type of minimum Bayes risk decoding and was first presented in Petrov and Klein (2007) as the MAX-RULE-SUM method (using exact marginals, not Monte-Carlo estimates as is done here).

6. Supervised Parsing Experiments

In this section we present an empirical evaluation of the model on the task of supervised parsing. In this setting the model learns a segmentation of a training treebank, which defines a TSG. We present parsing results using the learned grammar, comparing the effects of the sampling strategy, initialisation conditions, parsing algorithm and the size of the training set. The unsupervised model is described in the following section, Section 7.

We trained the model on the WSJ part of Penn. treebank (Marcus et al., 1993) using the standard data splits, as shown in Table 2. As our model is parameter free (the $\mathbf{a}, \mathbf{b}, \mathbf{s}$ parameters are learnt in training), we do not use the development set for parameter tuning. We expect that fitting the hyperparameters to maximise performance on the development set would lead to a small increase in generalisation performance, but at a significant cost in runtime. We adopt Petrov et al.'s (2006) method for data preprocessing: right-binarizing the trees to limit the branching factor and replacing tokens with count ≤ 1 in the training sample with one of roughly 50 generic unknown word markers which convey the token's lexical features and position. The predicted trees are evaluated using

Partition	sections	sentences	tokens	types	types (unk)
training	2–21	33180	790237	40174	21387
development	22	1700	40117	6840	5473
testing	23	2416	56684	8421	6659
small training	2	1989	48134	8503	3728

Table 2: Corpus statistics for supervised parsing experiments using the Penn treebank, reporting for each partition its WSJ section/s, the number of sentences, word tokens and unique word types. The final column shows the number of word types after unknown word processing using the full training set, which replaces rare words with placeholder tokens. The number of types after preprocessing in the development and testing sets is roughly halved when using the the small training set.

EVALB[15] and we report the F1 score over labelled constituents and exact match accuracy over all sentences in the testing sets.

In our experiments, we initialised the sampler by setting all substitution variables to 0, thus treating every full tree in the training set as an elementary tree. Unless otherwise specified, the blocked sampler was used for training. We later evaluated the effect of different starting conditions on the quality of the configurations found by the sampler and on parsing accuracy. The sampler was trained for 5000 iterations and we use the final sample of $\mathbf{z}, \ell, \mathbf{a}, \mathbf{b}, \mathbf{s}$ for parsing. We ran all four different parsing algorithms and compare their results on the testing sets. For the parsing methods that require a Monte Carlo integral (MPD, MPT and MER), we sampled 1000 derivations from the MAP approximation grammar which were then input to the Metropolis-Hastings acceptance step before compiling the relevant statistics. The Metropolis-Hastings acceptance rate was around 99% for both training and parsing. Each experiment was replicated five times and the results averaged.

6.1 Small Data Sample

For our first treebank experiments we train on a small data sample by using only section 2 of the treebank (see Table 2 for corpus statistics.) Bayesian methods tend to do well with small data samples, while for larger samples the benefits diminish relative to point estimates. For this reason we present a series of exploratory experiments on the small data set before moving to the full treebank.

In our experiments we aim to answer the following questions: Firstly, in terms of parsing accuracy, does the Bayesian TSG model outperform a PCFG baseline, and how does it compare to existing high-quality parsers? We will also measure the effect of the parsing algorithm: Viterbi, MPD, MPT and MER. Secondly, which of the local and blocked sampling techniques is more efficient at mixing, and which is faster per iteration? Finally, what kind of structures does the model learn and do they match our expectations? The hyper-parameter values are also of interest, particularly to evaluate whether the increased generality of the PYP is justified over the DP. Our initial experiments aim to answer these questions on the small data set, after which we take the best model and apply it to the full set.

Table 3 presents the prediction results on the development set. The baseline is a maximum likelihood PCFG. The TSG models significantly outperform the baseline. This confirms our hypothesis that CFGs are not sufficiently powerful to model syntax, and that the increased context afforded to

15. See `http://nlp.cs.nyu.edu/evalb/`.

Model	Viterbi	MPD	MPP	MER	# rules
PCFG	60.20	60.20	60.20	-	3500
TSG PYP	74.90	76.68	77.17	78.59	25746
TSG DP	74.70	75.86	76.24	77.91	25339
Berkeley parser ($\tau = 2$)	71.93	71.93	-	74.32	16168
Berkeley parser ($\tau = 5$)	75.33	75.33	-	77.93	39758

Table 3: Development results for models trained on section 2 of the Penn treebank, showing labelled constituent F1 and the grammar size. For the TSG models the grammar size reported is the number of CFG productions in the transformed MAP PCFG approximation. Unknown word models are applied to words occurring less than two times (TSG models and Berkeley $\tau = 2$) or less than five times (Berkeley $\tau = 5$).

the TSG can make a large difference. Surprisingly, the MPP technique is only slightly better than the MPD approach, suggesting that derivational ambiguity is not as much of a problem as previously thought (Bod, 2003). Also surprising is the fact that exact Viterbi parsing under the MAP approximation is much worse than the MPD method which uses an approximate search technique under the true model. The MER technique is a clear winner, however, with considerably better F1 scores than either MPD or MPP, with a margin of 1–2 points. This method is less affected by sampling variance than the other MC algorithms due to its use of smaller tree fragments (CFG productions at each span).

We also consider the difference between using a Dirichlet process prior (DP) and a Pitman-Yor process prior (PYP). This amounts to whether the $\mathbf{a}$ hyper-parameters are set to 0 (DP) or are allowed to take on non-zero values (PYP), in which case we sample their values as described in Section 4.3. There is a small but consistent gain of around 0.5 F1 points across the different parsing methods from using the PYP, confirming our expectation that the increased flexibility of the PYP is useful for modelling linguistic data. Figure 8a shows the learned values of the PYP hyperparameters after training for each nonterminal category. It is interesting to see that the hyper-parameter values mostly separate the open-class categories, which denote constituents carrying semantic content, from the closed-class categories, which are largely structural. The open classes (noun-, verb-, adjective- and adverb-phrases: NP, VP, ADJP and ADVP, respectively) tend to have higher a and b values (towards the top right corner of the graph) and therefore can describe highly diverse sets of productions. In contrast, most of the closed classes (the root category, quantity phrases, wh-question noun phrases and sentential phrases: TOP, QP, WHNP and S, respectively) have low a and b (towards the bottom left corner of the graph), reflecting that encoding their largely formulaic rewrites does not necessitate diverse distributions.

The $\mathbf{s}$ hyper-parameter values are shown in Figure 8b, and are mostly in the mid-range (0.3–0.7). Prepositions (IN), adverbs (RB), determiners (DT) and some tenses of verbs (VBD and VBP) have very low s values, and therefore tend to be lexicalized into elementary trees. This is expected behaviour, as these categories select strongly for the words they modify and some (DT, verbs) must agree with their arguments in number and tense. Conversely particles (RP), modal verbs (MD) and possessive particles (PRP$) have high s values, and are therefore rarely lexicalized. This is reasonable for MD and PRP$, which tend to be exchangeable for one another without rendering the sentence ungrammatical (e.g., 'his' can be substituted for 'their' and 'should' for 'can'). However,

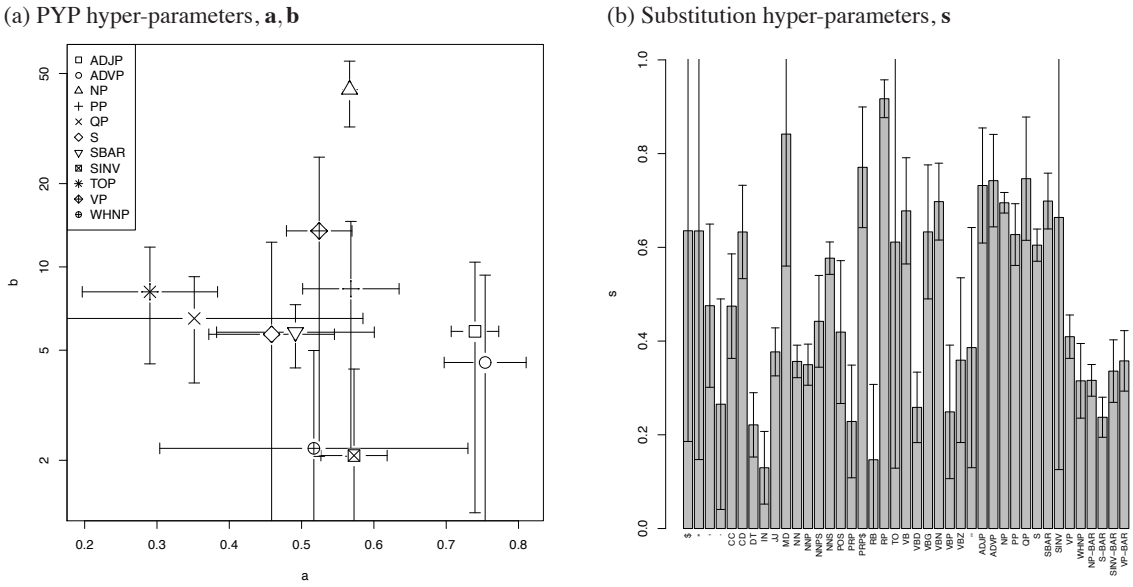

Figure 8: Inferred hyper-parameter values. Points (left) or bars (right) show the mean value with error bars indicating one standard deviation, computed over the final samples of five sampling runs. For legibility, a) has been limited to common phrasal nonterminals, while b) also shows preterminals and binarized nonterminals (those with the -BAR suffix). Note that in a) b is plotted on a log-scale.

particles are highly selective for the verbs they modify, and therefore should be lexicalized by the model (e.g., for 'tied in', we cannot substitute 'out' for 'in'). We postulate that the model does not learn to lexicalise verb-particle constructions because they are relatively uncommon, they often occur with different tenses of verb and often the particle is not adjacent to the verb, therefore requiring large elementary trees to cover both words. The phrasal types all have similar s values except for VP, which is much more likely to be lexicalized. This allows for elementary trees combining a verb with its subject noun-phrase, which is typically not part of the VP, but instead a descendent of its parent S node. Finally, the s values for the binarized nodes (denoted with the -BAR suffix) on the far right of Figure 8b are all quite low, encoding a preference for the model to reconstitute binarized productions into their original form. Some of the values have very high variance, for example, \$, which is due to their rewriting as a single string with probability 1 under P_C (or a small set of strings and a low entropy distribution), thus making the hyper-parameter value immaterial.

For comparison, we trained the Berkeley split-merge parser (Petrov et al., 2006) on the same data and decoded using the Viterbi algorithm (MPD) and expected rule count (MER, also known as MAX-RULE-SUM). We ran two iterations of split-merge training, after which the development F1 dropped substantially (in contrast, our model is not fit to the development data). The result (denoted $\tau = 2$) is an accuracy slightly below that of our model. To be fairer to their model, we adjusted the unknown word threshold to their default setting, that is, to apply to word types occurring fewer than five times (denoted $\tau = 5$).[16] Note that our model's performance degraded using the higher

16. The Berkeley parser has a number of further enhancements that we elected not to use, most notably, a more sophisticated means of handling unknown words. These enhancements produce further improvements in parse accuracy, but could also be implemented in our model to similar effect.

	≤ 40		all	
Parser	**F1**	**EX**	**F1**	**EX**
MLE PCFG	64.2	7.2	63.1	6.7
TSG PYP Viterbi	83.6	24.6	82.7	22.9
TSG PYP MPD	84.2	27.2	83.3	25.4
TSG PYP MPT	84.7	28.0	83.8	26.2
TSG PYP MER	85.4	27.2	84.7	25.8
DOP (Zuidema, 2007)			83.8	26.9
Berkeley parser (Petrov and Klein, 2007)	90.6		90.0	
Berkeley parser (restricted)	87.3	31.0	86.6	29.0
Reranking parser (Charniak and Johnson, 2005)	92.0		91.4	

Table 4: Full treebank testing results showing labelled F1 and exact match accuracy for sentences of up to 40 words, and for all sentences. The results of several treebank parsers are also shown (as reported in the literature, hence the missing values), representing a baseline (PCFG), systems similar to our own (DOP, Berkeley) and state-of-the-art (Berkeley, Reranking parser). Berkeley (restricted) uses simplified data preprocessing as compared to Berkeley; the simplified preprocessing is the same as used in our system, so provides a more fair comparison.

threshold, which impedes the model's ability to learn highly lexicalized fragments. The grammar sizes are not strictly comparable, because we are comparing different types of grammar. For our TSG models we report the number of CFG productions in the transformed MAP PCFG, in which non-zero count TSG rules typically rewrite as many CFG rules[17] and CFG rules from the base distribution are replicated up to four times. Nevertheless the trend is clear: our model produces similar results to a state-of-the-art parser, and does so using a similar sized grammar. With additional rounds of split-merge training the Berkeley grammar grows exponentially larger (200K rules after six iterations). Our TSG grammar is also far smaller than the full DOP grammar induced from this data set, which extracts every possible TSG rule from the training set with no size limit, and has approximately 700K rules.

6.2 Full Treebank

We now train the model on the full training partition of the Penn treebank, using sections 2–21 (see Table 2 for corpus statistics). We initialise the sampler using a converged model from the end of a sampling run on the small data set and run the blocked Metropolis Hastings sampler for 20,000 iterations. The MAP PCFG approximation had 156k productions and training took 1.2 million seconds in total or 61 seconds per iteration.[18] We repeated this three times and present the averaged results in Table 4.

17. The encoding of TSG rules could be made more compact by skipping the internal rewrite steps, instead directly rewriting the transformed root node as the rule's frontier. This would mean that each input TSG rule would produce only two rules in the transformed CFG. It would also affect the choice of parsing algorithm because the transformed grammar would no longer be binary.
18. Measured using a single core of an AMD Opteron 2.6GHz machine.

The TSG models far surpass the MAP PCFG baseline, while the relative orderings of the different parsing algorithms corroborate our earlier evaluation on the small training set. The model outperforms the most comparable DOP result, although the numbers are not strictly comparable as Zuidema (2007) used an enriched nonterminal set for testing. However, our results are still well below state-of-the art parsers, and even underperform the Berkeley parser when it is restricted to the same preprocessing steps for rare tokens and binarization as we used (results labelled *restricted* in Table 4). But we must bear in mind that these parsers have benefited from years of tuning to the Penn-treebank, where our model is much simpler and is largely untuned. We anticipate that careful data preparation, model tuning and improved inference algorithms would greatly improve our model's performance, bringing it closer to the state-of-the-art.

6.3 Sampling Strategy

Next we investigate which of the two sampling methods is more effective for training the model. Recall that in Section 4 we described a blocked sampler and a local sampler; these samplers differ in the number of variables that they update in every sampling step. We return to the small training sample for these experiments. Figure 9 shows how the log posterior over the training set varies with the sampling iteration and with time for the two different sampling algorithms. It is clear that the blocked MH sampler exhibits faster convergence in general than the local Gibbs sampler, despite being somewhat slower per iteration. The speed difference is fairly minor, amounting to roughly a 50% increase in time over the local sampler,[19] although on the full data set the time differential reduces to 19%. This difference is largely due to the cost of performing the grammar transformation, which could potentially be further optimised to reduce the gap.

Figure 9 shows the results for a number of different initialisations, using *minimal* elementary trees where every node is a substitution point (the CFG analysis), initialising the substitution variables uniformly at random (*even*), and using *maximal* elementary trees where no nodes are substitution points. The blocked sampler is more robust to starting point than the local sampler and converges faster in terms of iterations and total time in general. Interestingly, the blocked sampler converges faster with the maximal initialisation, which is due to the initialisation condition resulting in much smaller initial table counts, and therefore it is quite easy for the model to move away from that solution. However, with the minimal initialisation the counts begin with very high values, and therefore deviating from the initial solution will be much less likely. In contrast, the local sampler behaves in the opposite way with respect to initialisation, such that with the minimal initialisation it performs at or above the level of the blocked sampler. This is a surprising finding which contradicts our intuition about the mixing properties of the sampler and warrants further research.

In the above we have been comparing the log training posterior as a measure of the quality of the sampler, however it is not a given that a probable model is one with good parsing accuracy. Figure 10 shows that the posterior is highly correlated with generalisation F1, with a Pearson's correlation efficient of 0.95 on this data, and therefore improving the sampler convergence will have immediate positive effects on performance. This is corroborated in Table 5, which shows the F1 scores using the final sample for each initialisation condition. The blocked sampler out-performs the local sampler for all initialisation conditions and has lower lower variance. Moreover, the blocked sampler is less dependent on its initialisation, performing well independent of initialisation. In

19. To account for the speed differential, the local samplers were run for 15k iterations and the blocked samplers for 10k iterations to produce Figure 9 and Table 5.

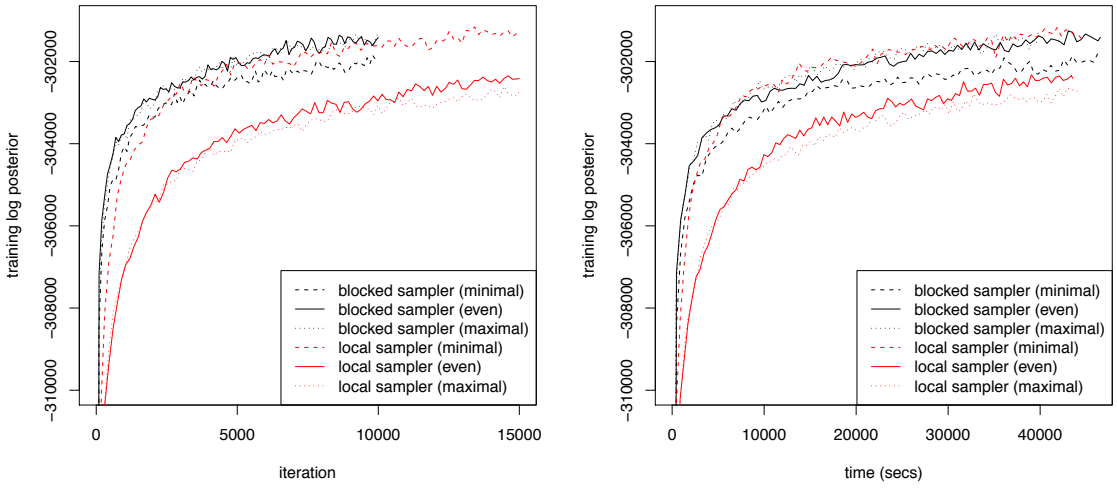

Figure 9: Training likelihood vs. iteration (left) or elapsed time (right). Both sampling methods were initialised in three different ways, *minimal* (all substitution variables set to 1, $\mathbf{x} = 1$), *even* ($x_d \sim \text{Uniform}(0,1)$) and *maximal* ($\mathbf{x} = 0$).

Sampling method	Initialisation	F1	σ_{F1}	Training time (s)
Local	minimal	78.2	0.50	44674
Local	even	78.3	0.31	43543
Local	maximal	78.5	0.51	44453
Block	minimal	78.5	0.18	46483
Block	even	78.6	0.35	46535
Block	maximal	78.6	0.38	39789

Table 5: Parsing performance and training time for the local versus blocked samplers with different initialisations. Results are shown on the development set using the MER parsing, reporting the mean F1 and standard deviation (σ_{F1}) from five independent runs. The blocked samplers were run for 10k iterations and the local sampler for 15k iterations iterations in order to allow all methods approximately the same running time.

contrast, the local sampler performs well only with the maximal initialisation, with which it roughly equals the blocked sampler in terms of F1 and log posterior (see Figure 9).

6.4 Discussion

The previous sections show that our model performs far better than a standard PCFG trained on the same corpus; it is natural to ask what kinds of rules it is learning that allow it to do so well. Figure 11 shows the grammar statistics for a TSG model trained on the full treebank training set. This model has a total of 72955 rules with an aggregate count of 733755. Of these, only 46% are

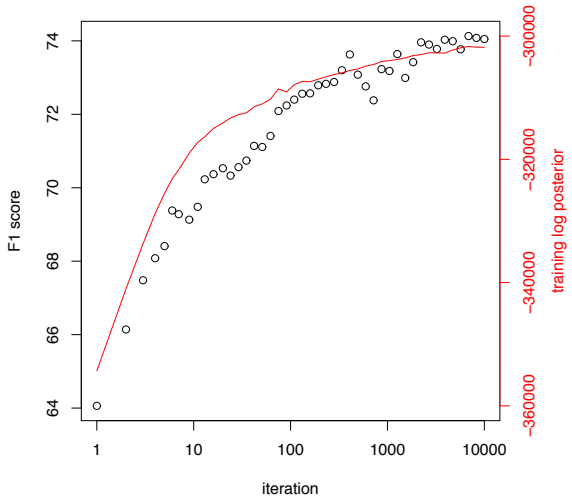

Figure 10: Likelihood and generalisation F1 are highly correlated. The black circles show the development F1 score (left axis) and the red line shows the training log-likelihood (right axis) during a Gibbs sampling run. The parsing results were obtained using Viterbi parsing with the MAP approximation grammar.

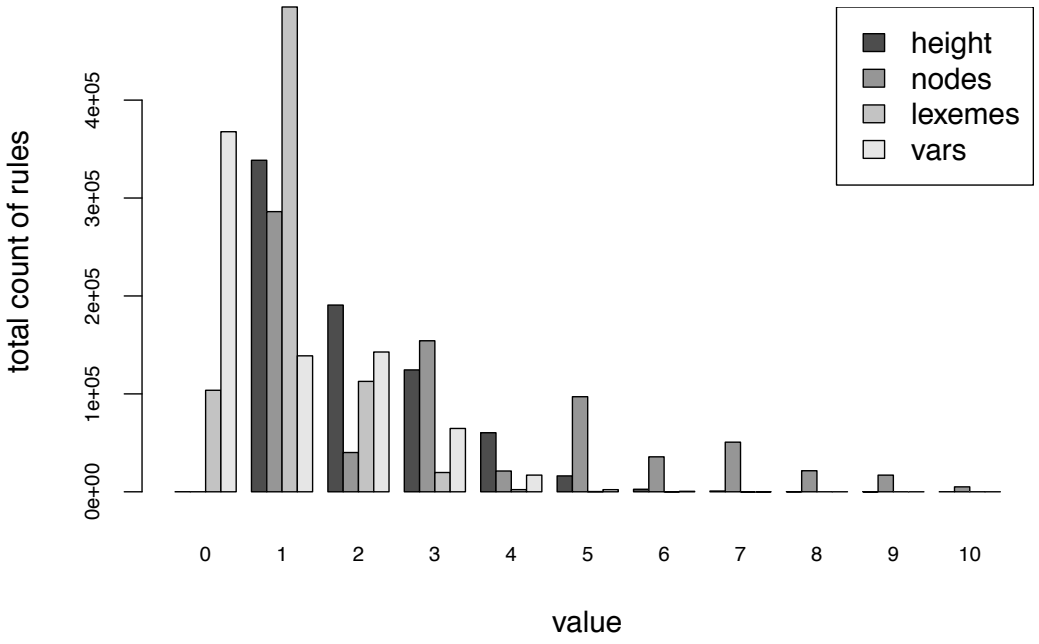

Figure 11: Grammar statistics for a TSG model trained on the full Penn treebank training set, showing the aggregate count for elementary trees of given height, number of nodes, terminals (lexemes) and frontier nonterminals (vars). An insignificant fraction of the rules had a height or number of nodes > 10; these have been truncated for display purposes.

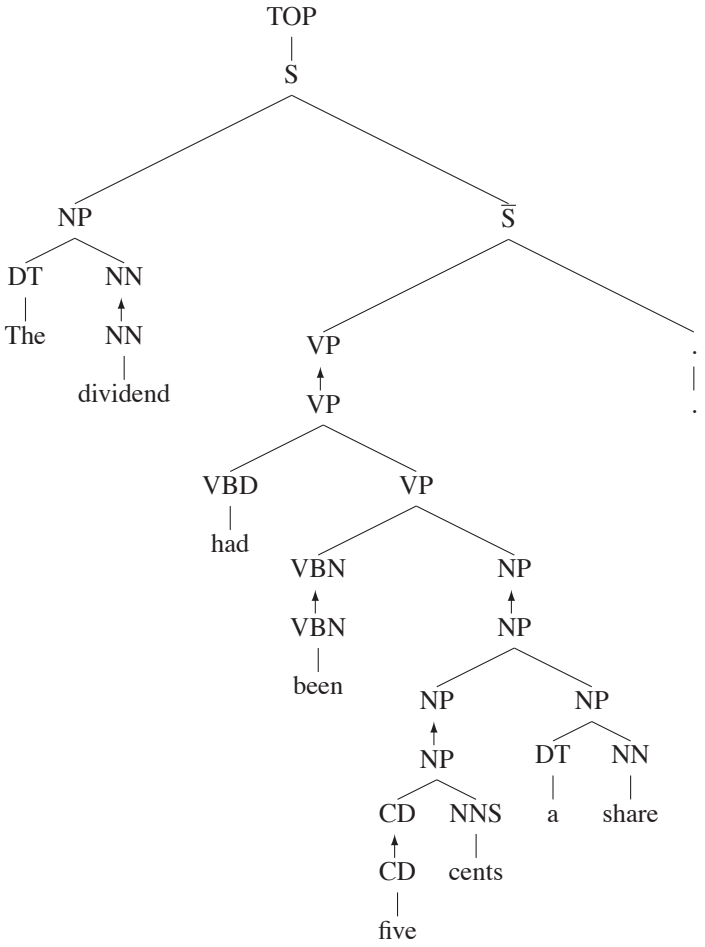

Figure 12: Inferred TSG structure for one of the training trees. Nonterminals shown with an overbar (e.g., $\overline{\text{S}}$) denote a binarized sub-span of the given phrase type.

CFG rules. The TSG rules vary in height from one to nineteen with the majority between one and four. Most rules combine a small amount of lexicalisation and a variable or two. This confirms that the model is learning local structures to encode, for example, multi-word units, subcategorisation frames and lexical agreement. The few very large rules specify full parses for sentences which were repeated in the training corpus. These complete trees are also evident in the long tail of node counts (up to 30; not shown in the figure) and counts for highly lexicalized rules (up to 11).

It is also instructive to inspect the inferred segmentations for individual trees in the training set. Figure 12 shows an example taken from the training set showing the learned derivation. Notice that the model has learned to use a large rule from the TOP node to capture the typical NP VP . sentence structure while lexicalizing the initial determiner, which is necessary to properly describe its capitalisation. It has also learnt a subcategorisation frame for `had` which specifies a VBN argument and an NP, and learnt the `<num> cents` and `NP a share` fragments, which are both common in the training corpus (Wall Street Journal articles).

To provide a better picture of the types of rules being learnt, Table 6 shows the top fifteen rules for three phrasal categories for the model trained on the full Penn treebank. We can see that many of these rules are larger than CFG rules, confirming that the CFG rules alone are inadequate to model the treebank. Two of the NP rules encode the prevalence of prepositional phrases headed by 'of' within a noun phrase, as opposed to other prepositions. Highly specific tokens are also incorporated into lexicalized rules.

The model also learns to use large rules to describe the majority of root node expansions (we add a distinguished TOP node to all trees). These rules mostly describe cases when the S category is used for a full sentence and includes punctuation such as the full stop and quotation marks. In contrast, the majority of expansions for the S category do not include any punctuation. The model has learnt to distinguish between the two different classes of S—full sentence versus internal clause—due to their different expansions.

Many of the verb phrase expansions have been lexicalized, encoding verb subcategorisation, as shown in Table 7. Notice that each verb here accepts only one or a small set of argument frames, indicating that by lexicalizing the verb in the VP expansion the model can find a less ambiguous and more parsimonious grammar. The lexicalized noun phrase expansions in Table 7 also show some interesting patterns, such as reconstituting binarized productions and lexicalizing prepositional phrase arguments. Of particular interest are the rules NP $\rightarrow$ CD (NN %) and NP $\rightarrow$ (NNP Mr.) NNP, in which the lexicalized item has a common tag but a very specific function. These rules are considerably more expressive than their CFG counterparts. Overall these results demonstrate that the model uses deep elementary trees to describe regular patterns in the data, thereby out-performing a simple PCFG. Despite having an infinite space of grammar productions, the induced grammars are compact, with the majority of probability mass on a small number of individually small productions.

7. Unsupervised Dependency Induction Experiments

Having considered the application of our non-parametric TSG model to supervised parsing, in this section we present an empirical evaluation for our model on the task of unsupervised parsing. Our approach to the unsupervised task differs from the supervised one in several ways. Two differences result from the fact that parse trees are not observed during training: first, we cannot use the local Gibbs sampler presented above, leaving the blocked sampler as our only option. Second, we cannot directly estimate P_C from the training data, so we must extend the model with an extra level of hierarchy (as described in Section 3) in order to induce P_C. A final difference in our unsupervised experiments is that we now focus on dependency grammar induction rather than phrase-structure induction; as outlined in Section 2.1, dependency grammars are a more feasible formalism for unsupervised grammar learning. Before presenting our experimental results, we first describe how to represent dependency grammars using our Bayesian TSG model.

To date, the most successful framework for unsupervised dependency induction is the Dependency Model with Valence (DMV, Klein and Manning, 2004). This approach induces a dependency grammar using a simple generative model in which the strings are said to be generated by a top-down process which recursively generates child dependents from each parent head word. This model has been adapted and extended by a number of authors (e.g., Cohen and Smith, 2009; Headden III et al., 2009); these approaches currently represent the state-of-the-art for dependency induction. In this section, we present a method for dependency grammar induction that incorporates the basic intuitions of the DMV, but is also capable of modelling larger units than just single parent-child

dependency relations. We approach the problem by representing dependency structures using the formalism of a CFG, and then applying our model (Section 3) to learn a TSG based on that CFG.

A dependency grammar can be represented in a CFG by labelling constituents with their head word, and encoding each dependency edge between a head and a child word in the grammar productions. This grammar has productions of the form $S \rightarrow H$ (word H heads the sentence), $H \rightarrow C\,H$ (C is a left child of H) and $H \rightarrow H\,C$ (C is a right child of H), where S is the start nonterminal and the H and C denote head and child nonterminals, respectively, which are both drawn from the same alphabet as the terminals (in our case part-of-speech tags). Unfortunately parsing with this representation is inefficient, having an asymptotic time complexity of $O(|\mathbf{w}|^5)$.[20] The complexity can be improved to $O(|\mathbf{w}|^3)$ by replicating (splitting) each terminal and processing all left and right dependents of each head word separately (Eisner, 2000). This is illustrated in Figure 13 where the leaves are all replicated with the l and r subscripts, while the spans defined by the tree structure denote the left and right dependents of each head word. Here we employ the *fold-unfold* representation (Johnson, 2007) that generalises Eisner's (2000) split-head parsing algorithm by defining an equivalent CFG under which standard inference methods can be used. Table 8 shows the CFG grammar for the DMV model (CFG-DMV), while Figure 13 shows the derivation in this grammar for the example sentence in Figure 2. The key insight to understanding the nonterminals in this grammar is that the subscripts encode the terminals at the boundaries of the span dominated by that nonterminal. For example the nonterminal L_H encodes that the right most terminal spanned by this constituent is H

20. This is a result of the usual CYK complexity of $O(G^2|\mathbf{w}|^3)$, and the grammar constant G being equal to the number of terminals $|\mathbf{w}|$ in the sentence.

(and the reverse for ${}_H\mathrm{R}$), while ${}_A\mathrm{M}_B$ encodes that A and B are the left and right terminals of the span. The superscripts * and ^{1} denote the valency of the head: both indicate that the head has at least one attached dependent in the specified direction, with ^{1} indicating that the head will continue to attach more children. The time complexity of inference in this grammar is only $O(|\mathbf{w}|^3)$ because each span in the parse chart bounded by terminals A and B can only contain nonterminal labels from the set $\{\mathrm{L}_B, \mathrm{L}^*_B, \mathrm{L}^1_B, {}_A\mathrm{R}, {}_A\mathrm{R}^*, {}_A\mathrm{R}^1, {}_A\mathrm{M}_{B^*}, {}_{A^*}\mathrm{M}_B, \mathrm{S}\}$. Consequently the grammar constant is fixed rather than quadratic in the sentence length.

We apply our TSG model to unsupervised dependency grammar induction using the CFG-DMV as the underlying grammar representation. Our model is capable of learning tree fragments which combine multiple adjacent CFG productions, affording considerable additional modelling power above that of a PCFG. Thereby the model can learn to condition dependency links on the valence. For example by combining $\mathrm{L}_{NN} \rightarrow \mathrm{L}^1_{NN}$ and $\mathrm{L}^1_{NN} \rightarrow \mathrm{L}_{DT\ DT}\mathrm{M}_{NN^*}$ rules into an elementary tree the model can describe that the leftmost child of a noun (NN) is a determiner (DT). Moreover, the model can learn groups of dependencies that occur together by conjoining multiple L^1_H or ${}_H\mathrm{R}^1$ nonterminals. This can represent, for example, the complete preferred argument frame of a verb.

7.1 Experiments

We perform inference for the TSG-DMV model by drawing 1000 samples using the blocked Metropolis-Hastings sampler described in Section 4.2 and evaluate the model using the final sample. Given that we do not observe parse trees in training, we cannot use the local Gibbs sampler as it only allows the sampling of the segmentation of a fixed tree, not the tree itself. In order to parse sentences in the test set we use the Viterbi algorithm to find the maximum probability parse under the MAP grammar (see Section 5). All hyperparameters, $\mathbf{a}, \mathbf{b}$ and $\mathbf{s}$, are sampled after every ten full samples over the training set.

A final and important consideration is the initialisation of the sampler. Klein and Manning (2004) emphasised the importance of the initialiser for achieving good performance with their model. We employ Klein and Manning's *harmonic* initialiser which defines a PCFG in which all words have the same valency distribution and probability of being the sentence head, while the probability of a head word attaching to a child word is inversely proportional to the average distance between these words in the training corpus. To obtain the initial derivations for the sampler we take the Viterbi derivations under this PCFG.

We follow the standard evaluation regime for DMV style models by performing experiments on the text of the WSJ section of the Penn. Treebank (Marcus et al., 1993). The corpus statistics are reported in Table 9. Like previous work we pre-process the training and test data to remove the words and punctuation, training our models on the gold-standard part-of-speech tags.

It is difficult for an unsupervised model to learn from long training sentences as their structure is highly ambiguous, and therefore the majority of DMV based approaches have been trained on sentences restricted in length to ≤ 10 tokens. This has the added benefit of decreasing the runtime for experiments. We present experiments with this training scenario, plus an additional experiment where we increase the length cutoff to ≤ 15. For the ≤ 15 experiment we start by sampling only sentences up to length 10, then gradually relax this length cutoff until we are sampling all sentences up to length 15 after 900 samples.[21] The training data is taken from sections 2-21, while section 23 is used for evaluation (see Table 9). An advantage of our sampling based approach over previous work

21. This training method is similar in spirit to the Baby Steps algorithm (Spitkovsky et al., 2010).

CFG Rule	DMV Distribution	Description
$S \rightarrow L_H\ {}_H R$	$p(root = H)$	The head of the sentence is H.
$L_H \rightarrow H_l$	$p(STOP \mid dir = L, head = H, val = 0)$	H has no left children.
$L_H \rightarrow L_H^1$	$p(CONT \mid dir = L, head = H, val = 0)$	H has at least one left child.
$L_H^* \rightarrow H_l$	$p(STOP \mid dir = L, head = H, val = 1)$	H has no more left children.
$L_H^* \rightarrow L_H^1$	$p(CONT \mid dir = L, head = H, val = 1)$	H has another left child.
${}_H R \rightarrow H_r$	$p(STOP \mid dir = R, head = H, val = 0)$	H has no right children.
${}_H R \rightarrow {}_H R^1$	$p(CONT \mid dir = R, head = H, val = 0)$	H has at least one right child.
${}_H R^* \rightarrow H_r$	$p(STOP \mid dir = R, head = H, val = 1)$	H has no more right children.
${}_H R^* \rightarrow {}_H R^1$	$p(CONT \mid dir = R, head = H, val = 1)$	H has another right child.
$L_H^1 \rightarrow L_C\ {}_C M_{H^*}$	$p(C \mid dir = L, head = H)$	C is a left child of H.
${}_H R^1 \rightarrow {}_{H^*} M_C\ {}_C R$	$p(C \mid dir = R, head = H)$	C is a right child of H.
${}_C M_{H^*} \rightarrow {}_C R\ L_H^*$	$p = 1$	Structural rule.
${}_{H^*} M_C \rightarrow {}_H R^*\ L_C$	$p = 1$	Structural rule.

Table 8: The CFG-DMV grammar schema. Note that the actual CFG is created by instantiating these templates with part-of-speech tags observed in the data for the variables H and C. Valency (*val*) can take the value 0 (no attachment in direction *dir*) and 1 (one or more attachment). L and R indicates child dependents left or right of the parent; superscripts encode the stopping and valency distributions, X^1 indicates that the head will continue to attach more children and X^* that it has already attached a child.

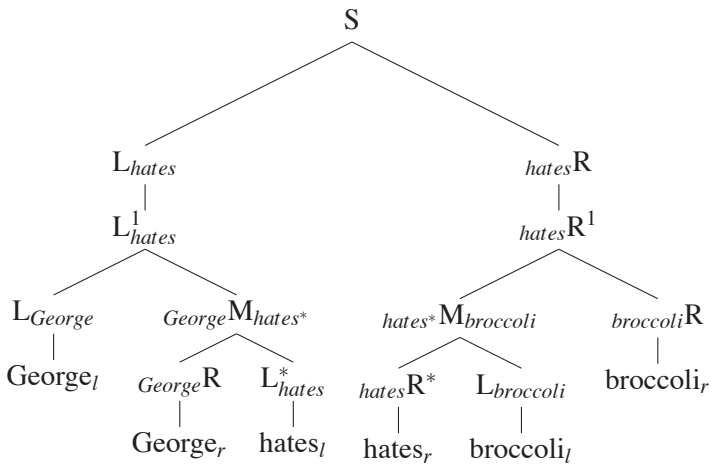

Figure 13: The CFG-DMV derivation for the example sentence *George hates broccoli*. The dependency parse for this sentence is given in Figure 2.

Partition	Sections	Words	Sentences
training$_{\leq 10}$	2–21	42505	6007

test$_{\leq 10}$	23	2649	398
test$_{\leq 15}$	23	16591	1286
test$_{\leq \infty}$	23	49368	2416

Table 9: Corpus statistics for the training and testing data for the TSG-DMV model. All models are trained on the gold standard part-of-speech tags after removing punctuation.

is that we infer all the hyperparameters; consequently there is no need to tune on the development set (section 22).

The models are evaluated in terms of head attachment accuracy (the percentage of correctly predicted head dependency links for each token in the test data), on three subsets of the testing data. Although unsupervised models are better learnt from a corpus of short rather than long sentences, they must still be able to parse long sentences. The most commonly employed test set mirrors the training data by only including sentences ≤ 10, however we also include results for sentences ≤ 20 and the whole test set with no length restriction. As we are using MCMC sampling the result of any single run is non-deterministic and will exhibit a degree of variance. Our reported results are the mean and standard deviation (σ) from 40 sampling runs.

7.2 Discussion

Table 10 shows the head attachment accuracy results for our TSG-DMV, along with those of several other competitive models. Our model performs very well in comparison to the others; in particular it achieves the highest reported accuracy on the full test set by a considerable margin. On the $|\mathbf{w}| \leq 10$ test set the TSG-DMV is second only to the L-EVG model of Headden III et al. (2009). The L-EVG model extends DMV by adding additional lexicalisation, valency conditioning, interpolated back-off smoothing and a random initialiser. In particular Headden III et al. show that the random initialiser is crucial for good performance, but their approach requires training 1000 models to select a single best model for evaluation and leads to considerable variance in test set performance. Our model exhibits considerably less variance than those induced using this random initialiser, suggesting that the combination of the harmonic initialiser and blocked MH sampling may be a more practical training regime. The recently-proposed Adaptor Grammar DMV model of Cohen et al. (2010) is similar in many ways to our TSG model, incorporating a Pitman Yor prior over units larger than CFG rules. As such it is surprising that our model performs significantly better than this model. We can identify a number of possible explanations for these results: the Adaptor Grammar model is trained using variational inference with the space of tree fragments truncated, while we employ a sampler which can nominally explore the full space of tree fragments; and the tree fragments in the Adaptor Grammar model must be complete subtrees (i.e., they don't contain variables), whereas our model can make use of arbitrary tree fragments. An interesting avenue for further research would be to extend the variational algorithm of Cohen et al. (2010) to our TSG

model, possibly improving inference time while also allowing for the implementation to be more easily parallelised.

To illustrate the kinds of structures the model induces and the types of errors it makes, Figure 14 presents a representative example tree for a sentence from Section 22 of the WSJ. Though many of the elementary trees in this example resist an obvious linguistic explanation, on the right side of the derivation (highlighted in green) we see that the model has learnt to encode that the verb takes a single noun phrase as its object, while on the left (highlighted in blue) is a rule specifying the DT JJ subject dependent of the VBZ. This derivation is typical of the analyses produced by the model as it contains a number of dependency links which are inconsistent with the treebank. However we can see that the model has learnt to analyse the noun, verb and preposition phrases in a manner which is quite plausible, despite not matching the reference tree. In particular there would seem to be little obvious reason to prefer the treebank's analysis of the conjunction phrase ('either apathy or civility') over that produced by the unsupervised model. This highlights the difficulty in evaluating the output of unsupervised grammar induction algorithms against a treebank reference; in this instance it is clear that the analysis found by the model, despite its low accuracy, could be very useful for a downstream NLP application reliant on a dependency analysis.

For further analysis Tables 11 and 12 show the accuracy of the model at predicting the head for each tag type and the accuracy for dependencies spanning a given number of tokens. Clearly the model is far more accurate when predicting short dependencies, a result that is also reflected in the per-tag results. We also note that the model accurately predicts the head of the sentence 84% of the time, indicating an ability to capture the high level sentence structure. As mentioned above, conjunctions pose a particular difficulty with unsupervised models as the correct modelling of these remains a contentious linguistic issue. Nevertheless on conjunctions the model does achieve a reasonable level of agreement with the treebank.

Table 13: The fifteen most frequent TSG-DMV rules in the training data.

Table 13 lists the most frequent TSG rules learnt by the model. The most frequent rule at the top of the table models noun phrases, encoding the fact that determiners have no children and attach as a left child to a phrase headed by a noun. It is interesting to see that our model has used a TSG rule to analyse noun phrases in a way consistent with the treebank, whereas the original DMV model preferred the opposite analysis of having DTs as the heads of noun phrases (Klein and Manning, 2004). Both results could be supported from a linguistic standpoint (Abney, 1987), but nevertheless it is a notable outcome that our more powerful model prefers to head noun phrases with nouns. Further down the table we see another interesting rule: $_{TO^*}\mathrm{M}_{VB} \rightarrow (_{TO^*}\mathrm{M}_{VB}\ (_{TO}\mathrm{R}^*\ \mathrm{TO}_r)\ \mathrm{L}_{VB})$. This rule specifies that a verb phrase headed by an infinitive attaches as the first child of the particle *to* on its left. Here the model has used the tree fragment to encode that the verb must be the first right child of the particle, an analysis both consistent with the treebank and expressing a bias against any form of split infinitive construction.

8. Conclusion

In this work we have presented a non-parametric Bayesian model for inducing tree substitution grammars in both supervised and unsupervised settings. By incorporating a structured prior over elementary rules our model is able to reason over the infinite space of all such rules, producing compact and simple grammars. In doing so, our model learns local structures for latent linguistic phenomena, such as verb subcategorisation and lexical agreement.

Our experimental results indicate that our model holds significant potential for a range of grammar induction tasks. In experiments using a treebank for training, we showed that the induced TSG grammars strongly out-perform standard PCFGs, and are comparable to a state-of-the-art parser on small data samples. While our results when training on the full treebank are well shy of the best available parsers, we have proposed a number of improvements to the model and the parsing algorithm that could lead to state-of-the-art performance in the future. Our second set of experiments removed the reliance on a treebank and showed that our TSG model achieves performance similar to the best recent models on sentences up to length 10, and outperforms all other models on longer sentences. This result is particularly promising, since it demonstrates the possibility of successfully learning complex hierarchical models, beyond just CFGs, without supervision. We hope that our work will open the door to further research into inducing linguistically rich grammars, such as tree adjoining and categorial grammars, that have so far been considered too difficult to learn from raw strings.

Abstract

Many structured information extraction tasks employ collective graphical models that capture inter-instance associativity by coupling them with various clique potentials. We propose tractable families of such potentials that are invariant under permutations of their arguments, and call them *symmetric clique potentials*. We present three families of symmetric potentials—MAX, SUM, and MAJORITY.

We propose cluster message passing for collective inference with symmetric clique potentials, and present message computation algorithms tailored to such potentials. Our first message computation algorithm, called α-pass, is sub-quadratic in the clique size, outputs exact messages for MAX, and computes $\frac{13}{15}$-approximate messages for Potts, a popular member of the SUM family. Empirically, it is upto two orders of magnitude faster than existing algorithms based on graph-cuts or belief propagation. Our second algorithm, based on Lagrangian relaxation, operates on MAJORITY potentials and provides close to exact solutions while being two orders of magnitude faster. We show that the cluster message passing framework is more principled, accurate and converges faster than competing approaches.

We extend our collective inference framework to exploit associativity of more general *intra-domain properties* of instance labelings, which opens up interesting applications in domain adaptation. Our approach leads to significant error reduction on unseen domains without incurring any overhead of model retraining.

Keywords: graphical models, collective inference, clique potentials, cluster graphs, message passing

1. Introduction

Markov Random Fields (MRFs) are the models of choice in various structured information extraction (IE) tasks such as part-of-speech tagging, NP-chunking, text segmentation, and named entity recognition. The goal of IE is to mark each token in a sentence with a label from a discrete set, like Person, Location, and Other. As illustrated in Figure 1(c), the basic MRF extraction model defines edge potentials between labels of adjacent words to capture first-order dependencies (Lafferty et al., 2001). The resulting chain model allows tractable exact inference that is, computing the maximum a-posteriori (MAP) labeling of the sentence is easy.

Apart from traditional settings, IE is now being increasingly used in many web scenarios, such as query-driven extraction (Gupta and Sarawagi, 2009; Carlson et al., 2010) and constructing on-the-fly relations from semi-structured web sources (Elmeleegy et al., 2009). However these setups are characterized by limited training data, which restricts the robustness of the resulting MRFs during deployment. One promising way to increase the robustness of MRFs during deployment is to strengthen the first-order dependencies of the model with extra long-range dependencies , resulting in more robust labelings. The goal of this paper is to exploit long-range dependencies in a principled manner.

There has been a lot of work on capturing long-range dependencies between labels of non-adjacent words. This typically includes dependencies of the form—if a token repeats in a document, then the labels of the repetitions should ideally be the same (Sutton and McCallum, 2004; Bunescu and Mooney, 2004; Krishnan and Manning, 2006; Finkel et al., 2005). In Figure 1(d), we show an example where the extra dotted edges join unigram recurrences. Such long-range dependencies are termed *associative* since they introduce positive couplings between labels of token pairs. Apart from textual tokens, associative dependencies have also been exploited while labeling documents (Lu and Getoor, 2003; Chakrabarti et al., 1998), image pixels (Taskar et al., 2004), and annotating Web documents (Kulkarni et al., 2009). Due to these couplings, MAP inference is done collectively across all sentences so as to maximize the sum of sentence-specific and long-range associative potentials. This joint MAP computation task is traditionally called **collective inference**.

Previous work on collective inference can be broadly classified into two categories. The first category defines a separate associative potential over every inter-instance edge (i.e., dotted edge in Figure 1(d)). Inference on such graphs is performed by viewing it as a graphical model with pairwise potentials. A variety of generic approximation algorithms have been used to solve this typically intractable inference task, including Loopy Belief propagation (Bunescu and Mooney, 2004; Sutton and McCallum, 2004), and Gibbs sampling (Finkel et al., 2005). The second category defines an associative potential for each clique that is created from all repetitions of a unigram and the potentials can take more general forms like the Majority function (Krishnan and Manning, 2006). Collective inference on this category of models is performed using local search algorithms such as Iterative Conditional Mode fitting (ICM) (Lu and Getoor, 2003; Chakrabarti et al., 1998) or two stage algorithms (Krishnan and Manning, 2006).

This paper unifies various collective extraction tasks with different forms of associative potentials under a single framework. We do this by employing a cluster graph representation of the collective model. Figure 1(e) illustrates the cluster graph for our toy example. The cluster graph comprises of one cluster per MRF-instance, and one cluster per clique with its corresponding associative potential. As in the traditional collective extraction models, we assume that a clique comprises of all the occurrences of a particular token. We emphasize that instead of clusters for chain models, the framework can also define clusters for any tractable component, such as a bipartite matching or an alignment, but since our interest is in IE tasks, we shall focus on chain models.

Collective inference in our model then simply corresponds to message passing in this cluster graph. This view of collective inference offers several advantages over earlier approaches. First, it allows us to plug in and study various clique potentials cleanly under the same cluster message passing umbrella. Second, it allows us to exploit special properties of the associative potentials to design combinatorial algorithms that are both more accurate and more efficient than existing algorithms. Specifically, we show that most associative potentials used in practice are **symmetric clique potentials**. Symmetric clique potentials are invariant under any permutation of their argu-

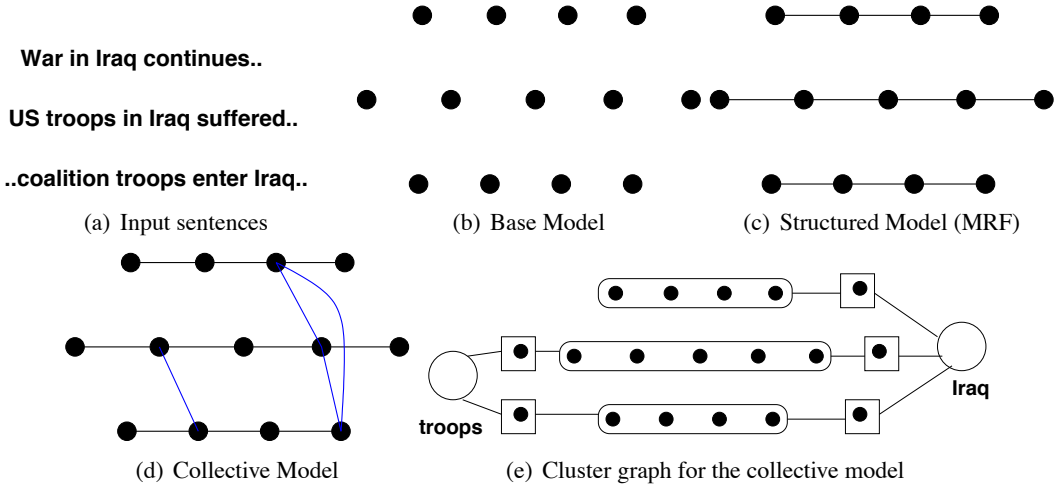
ments. So the value of a symmetric potential depends only on the counts of its distinct arguments, and not their position in the clique. For example in Figure 1(d), the clique potential on 'Iraq' would give a low score if its end vertices had different labels, regardless of which 'Iraq' vertex gets what label. We present three families of symmetric clique potentials that capture label associativity in different ways—MAX, SUM (which subsumes the popular Potts potential), and MAJORITY. The most crucial component of the collective inference problem is then to efficiently compute outgoing messages from clique clusters governed by symmetric potentials. We denote this sub-problem as **clique inference**.

1.1 Contributions

We show that the overall collective inference problem is intractable even for the case of two labels. We therefore concentrate on designing efficient and accurate message passing algorithms on our special cluster graph. We present a suite of efficient combinatorial algorithms tailored to specific symmetric clique potentials for the clique inference sub-problem. We devised a combinatorial algorithm called α-pass that computes exact outgoing messages for cliques with MAX potentials, and also for any arbitrary symmetric clique potential over two labels. We show that α-pass provides a $\frac{13}{15}$-approximation for clique inference with the well-known and NP-hard Potts potential with the SUM family. We show that this analysis is tight, and that the corresponding clique inference bound by alternative schemes like α-expansion, LP-rounding, TRW-S and ICM are either $\frac{1}{2}$. or at best locally optimal. Further, the runtime of α-pass is $O(mn\log n)$ where n is the clique size, and m is the number of labels. We also show that α-pass can be generalized to provide a better approximation of $\frac{8}{9}$, but with a runtime of $O(m^2 n\log n)$. Alternative clique inference approaches such as the graph-cut algorithm of Boykov et al. (2001) and the tree-reweighted message passing (TRWS) algorithm of Kolmogorov (2006) are quadratic in n. We present a new Lagrangian-relaxation based algorithm, called LR, for MAJORITY potentials. The LR algorithm is nearly exact in practice but is usually two orders of magnitude faster than an exact LP-based algorithm.

Our experiments show that computing a rich set of messages leads to significantly more accuracy gains over other collective inference approaches that do not compute such messages, for example, Krishnan and Manning (2006). We also show that decomposing the problem over the cluster graph and employing fast message computation algorithms helps our collective inference scheme converge one-order faster than alternatives like loopy belief propagation. In short, we show that it makes more sense to compute messages at a cluster level, and we provide fast and accurate algorithms to do so.

We then extend our collective inference framework to capture associativity of a more general kind than just labels of unigram repetitions. We encourage associativity of *properties* of labelings of records appearing as a group. We apply this framework to domain adaptation, where a model trained on one or more domains is deployed on a different but related domain. For example, a model trained for extracting fields of a bibliographic records is deployed on all records coming from the homepage of a single author. The bibliographic entries from the same author's publications homepage would predominantly have the same style, such as order of labels, say Title followed by Author(s) followed by Venue, or the HTML tag before a Title. While we do not know the property values across the records apriori, we do know that they will be largely unimodal across records within a given domain. We use this collective signal to couple together the labelings of intra-domain records, and show how our collective inference framework naturally extends to this scenario and provides significant reduction in error.



(a) Input sentences (b) Base Model (c) Structured Model (MRF)

(d) Collective Model (e) Cluster graph for the collective model

Figure 1: Various models for named-entity recognition illustrated on a small corpus. Figure 1(e) shows the cluster graph for the collective model of (d) with one cluster per sentence (shown as flat chains), and one cluster per associative clique (shown as big circles).

At this point, we note that our previous work (Gupta et al., 2007) focused primarily on the α-pass algorithm along with a sketch of some of its properties. This paper presents a detailed treatment of the algorithm and its generalized version, with rigorous proofs of their approximation bounds, including some new bounds for a variant of the clique inference objective with Potts potential. In addition, new material in this paper includes the LR algorithm for the MAJORITY potential, extension of our framework to include properties-based associativity, and empirical studies of various collective inference techniques.

We also note that subsequent to our work (Gupta et al., 2007), there has been an abundance of research on higher order clique potentials in last few years, primarily by the computer vision community. While their applications and basic graph structure are different (grids vs chains), many of their ideas are highly relevant—either in terms of special algorithms for clique/collective inference (Komodakis et al., 2007a; Komodakis and Paragios, 2009; Kumar and Torr, 2008a; Werner, 2008), reduction of clique potentials to pairwise potentials (Kohli et al., 2009; Ishikawa, 2009), and special families of clique potentials (Potetz and Lee, 2008; Rother et al., 2009; Tarlow et al., 2010). We will present theoretical and empirical comparisons and draw parallels with the relevant schemes later on in this paper.

1.2 Outline

In Section 2, we present the MRF model for extraction and define the collective inference problem in the traditional setup of unigrams. We show that even with this setup, collective inference remains NP-hard. In Section 3, we discuss the cluster message passing algorithm for collective inference, and introduce the *clique inference* sub-problem which formalizes the task of computing outbound messages from clique clusters. Then in Section 4, we describe the MAX, SUM, and MAJORITY families of symmetric potentials. In Section 5 we present the α-pass and LR clique inference algorithms,

and analyze their approximation quality. In Section 6, we extend our framework to capture more general associative properties. Section 7 contains experimental results of three types: (a) quality of the α-pass and LR algorithms; (b) effect of modeling more general associative properties in a domain adaptation task; and (c) collective inference via cluster message passing vs alternatives. Finally, Section 8 discusses prior art and Section 9 contains conclusions and a discussion of future work.

2. Collective Inference with MRFs

We now review the basic first-order MRF model for information extraction, and then formally define the collective inference problem over various coupled MRFs. We denote a sentence by bold $\mathbf{x}$, and its labeling vector by $\mathbf{y}$. Consequently, x_i and y_i denote the i^{th} token in $\mathbf{x}$ and its label respectively. The MRF defines a log-linear model parameterized by a weight vector $\mathbf{w}$, where the conditional probability of a labeling is given by:

$$\log P(\mathbf{y}|\mathbf{x},\mathbf{w}) = \sum_i \phi_i(y_i, y_{i-1}; \mathbf{x}, \mathbf{w}) - \log Z_{\mathbf{w}}.$$

Here $\phi_i(y_i, y_{i-1}; \mathbf{w})$ is the log of the potential on the edge between tokens i and $i-1$, These potentials are local, that is, they depend only on the labels of the edge and $\log Z_{\mathbf{w}}$ is the normalization factor. During inference, we compute the most probable labeling of $\mathbf{x}$:

$$\arg\max_{\mathbf{y}} \log P(\mathbf{y}|\mathbf{x},\mathbf{w}) = \arg\max_{\mathbf{y}} \sum_i \phi_i(y_i, y_{i-1}; \mathbf{x}, \mathbf{w}).$$

If there are m possible labels at each token, and n tokens in $\mathbf{x}$, then exact inference can be done using max-product message passing in $O(nm^2)$ time.

We now move to the collective model whose toy example is illustrated in Figure 1(d). Let there be N sentences $\{\mathbf{x}^1, \ldots, \mathbf{x}^N\}$. Correspondingly, we have N conditional distributions $P(\mathbf{y}^k|\mathbf{x}^k, \mathbf{w})$, $k = 1, \ldots, N$. We use the shorthand $\phi_i^k(y_i^k, y_{i-1}^k)$ to refer to $\phi_i^k(y_i^k, y_{i-1}^k; \mathbf{x}^k, \mathbf{w})$.

Let t denote a token that repeats across the sentences, and let $\mathcal{T}$ denote the set of all such tokens. For a repeating token t, let $D(t)$ be the set of all (sentence-id, token-id) locations where it occurs in the N sentences, that is, $D(t) = \{(k,i)|x_i^k = t\}$. We express the conformance in the label assigned to positions in $D(t)$ with a higher order clique potential $\mathrm{C}_t(\{y_i^k\}_{(k,i)\in D(t)})$. Our collective MRF model that couples sentences using unigrams is then given by (up to a normalization constant):

$$\begin{aligned} \log P(\{\mathbf{y}^k\}_{k=1}^N | \{\mathbf{x}^k\}_{k=1}^N, \mathbf{w}) &\approx \sum_{k=1}^N \log P(\mathbf{y}^k|\mathbf{x}^k,\mathbf{w}) + \sum_{t\in\mathcal{T}} \mathrm{C}_t(\{y_i^k\}_{(k,i)\in D(t)}) \qquad (1) \\ &\approx \left(\sum_{k=1}^N \sum_{i=1}^{|\mathbf{x}^k|} \phi_i^k(y_i^k, y_{i-1}^k) \right) + \sum_{t\in\mathcal{T}} \mathrm{C}_t(\{y_i^k\}_{(k,i)\in D(t)}). \end{aligned}$$

The clique potential C_t has two important properties: First, it is invariant under any permutation of its arguments—that is, it is a *symmetric* function of its input. Thus, if there are m possible labels, we can represent the arguments with an m-bin histogram. For example, if $m = 3$ and input is $\{1,2,1,1,2,3,2\}$, then $\mathrm{C}_t(S)$ depends on the 3-bin histogram with values $3,3,1$. Second, C_t is *associative*—that is, it favors agreement of labels in its argument set, and it maximized when all arguments have the same label.

All collective extraction methods proposed in the literature fit the above framework. The earliest and the most popular collective model used associative potentials over every pair of occurrences of t (Sutton and McCallum, 2004; Finkel et al., 2005). This pairwise potential was a Potts potential—1 if the pair had matching labels and 0 otherwise. Clearly, we can define an appropriate C_t that mimics this behavior while staying symmetric. Consider the clique potential:

$$C_t(\{y_i^k|(k,i) \in D(t)\}) = \sum_{(k,i),\ (l,j)\in D(t)} \delta(y_i^k = y_j^l).$$

This is equivalent to all the pairwise potentials for t. Also, using the histogram view, this can be re-written up to a constant as $\sum_{\alpha=1}^{m} n_\alpha^2$, where n_α is the bin count for label α in the histogram corresponding to $\{y_i^k|(k,i) \in D(t)\}$. Other known collective models like the ones proposed by Lu and Getoor (2003) and Krishnan and Manning (2006) can also be cast using the 'Majority' symmetric clique potential as we shall see in later sections.

Having defined our collective model, and shown that it subsumes popular collective models, we are ready to define the collective inference objective.

Definition 1 (Collective Inference) *Collective inference is the task of finding labelings* $\mathbf{y}^1, \ldots, \mathbf{y}^N$ *that jointly maximize the probability of the collective model (Equation 1):*

$$\arg\max_{\mathbf{y}^1,\ldots,\mathbf{y}^N} \left(\sum_{k=1}^{N} \sum_{i=1}^{|\mathbf{x}^k|} \phi_i^k(y_i^k, y_{i-1}^k) \right) + \sum_{t\in\mathcal{T}} C_t(\{y_i^k\}_{(k,i)\in D(t)}). \tag{2}$$

In general terms, collective inference corresponds to labeling the nodes of a generic cyclic graph. However, our graph has a special structure—it is composed of chains and cliques, and although the intra-chain edge potentials ϕ can be arbitrary, the clique potentials are associative and symmetric. However we next prove that even in this setup, collective inference is NP-hard.

Theorem 2 *The collective inference problem is NP-hard even with just two labels.*

Proof We reduce the well-known NP-hard problem of finding MAX-CUTs in an arbitrary graph G to our collective inference problem (called CI). For each node $u \in G$ define a 2-node chain $u_1\ u_2$ in CI where each node can take binary labels and with edge potential $\phi^u(y,y') = M\delta(y \neq y')$. M is a large positive number $> 2E$, where E is the number of edges in G. For an edge $(u,v) \in G$, we add three cliques: $(u_1,v_1),(u_1,v_2)$ and (u_2,v_1). All three clique potentials are $C_t(\{y,y'\}) = \delta(y = y')$.

The key observation is that G has a cut of size $\geq k$ iff CI has a map score of $\geq Mn+E+k$ where n is the number of nodes in G.

Suppose G has a cut (A,B) of size $\geq k$. Define a labeling in CI where all variables in $A' \triangleq \{v_1|v \in A\} \cup \{v_2|v \in B\}$ are labeled 0 and the rest B' are labeled 1. Then for every $u \in G$, (u_1,u_2) are labeled differently, thus the total contribution from the edge potentials within chains of CI is Mn. For an edge $(u,v) \in G$ that is part of the cut (A,B) with $u \in A, v \in B$, two cliques (u_1,v_2) and (u_2,v_1) have both their arguments labeled the same whereas for all other edges only one of the cliques (u_1,v_1) reaches such conformance. Thus, the total contribution from clique potentials is $E+k$. The converse holds the same way. Since M is sufficiently large, the edge (u_1,u_2) in CI will always have both ends labeled differently. So given a labeling in CI, we can define a cut in G by the subset of vertices v for which v_1 is labeled 0 in CI.

■

At this point we note that our collective inference objective is related to various bodies of work on joint inference, primarily in computer vision tasks. For the sake of continuity we defer our discussion of all related work to Section 8 and instead present our framework for maximizing the collective inference objective.

3. Cluster Graph based Collective Inference Framework

Having established that optimizing the objective in Equation 2 is NP-hard, one natural choice for approximating it is ordinary pairwise belief propagation on the collective graphical model. This involves passing messages along edges inside the chains, as well as along the clique edges. However this approach is not suitable due to many reasons. First, some symmetric potentials like the Majority potential cannot be decomposed along the clique edges, so we cannot compute the corresponding messages. Second, the approach does not exploit the special nature of the clusters and the symmetric potentials. Third, this approach is not tenable if we wish to extend the framework to capture associativities of more general properties of the kind discussed in Section 6.

Hence we adopt message passing on a special cluster graph where every chain and clique corresponds to a cluster. The clique cluster for a unigram is adjacent to all the chains that contain that unigram, as shown via singleton separator vertices in Figure 1(e). This setup of message passing on the cluster graph allows us to exploit potential-specific algorithms at the cliques, and at the same time work with any arbitrary symmetric clique potentials. Cluster graphs have been used effectively for message passing elsewhere as well (Yedidia et al., 2003; Duchi et al., 2007).

Let $m_{k\to t}$ and $m_{t\to k}$ denote message vectors from chain k to an incident clique t and vice-versa. A chain is said to be incident on a clique if there exists a position j in chain k which matches term t, that is, $(k, j) \in D(t)$. We assume that $D(t)$ is created such that from any chain only one position belongs to it. We next discuss how these messages are computed.

3.1 Message from an Instance to a Clique

The message $m_{k\to t}(y)$ for a $(k, j) \in D(t)$ is given by:

$$m_{k\to t}(y) = \max_{\mathbf{y}^k : y^k_j = y} \left(\sum_{i=1}^{|\mathbf{x}^k|} \phi^k(y^k_i, y^k_{i-1}) + \sum_{t' \neq t \in \mathcal{T}, (k,j') \in D(t')} m_{t'\to k}(y^k_{j'}) \right).$$

To compute $m_{k\to t}(y)$, we need to absorb the incoming messages from other incident cliques $t' \neq t$, and do the maximization while freezing the label of position j in chain k to y for a $(k, j) \in D(t)$. A clique t' is incident to chain k via only a singleton vertex so we can easily absorb the message $m_{t'\to k}$ by including it in the node potential of this vertex. After absorption, $m_{k\to t}$ can be computed using the same inference algorithm applicable to the chain.

3.2 Message from a Clique to an Instance

The more interesting message computation is that for $m_{t\to k}$ given a $(k,j) \in D(t)$. Let the clique t have n vertices. Then the message computation can be written as:

$$m_{t\to k}(y) = \max_{(y_1,\ldots,y_k=y,\ldots,y_n)} \sum_{(k',j')\in D(t)\ k'\neq k} m_{k'\to t}(y_{k'}) + \mathrm{C}_t(\{y_1,\ldots,y_n\}). \tag{3}$$

The maximization in Equation 3 can be re-written as

$$-m_{k\to t}(y) + \max_{(y_1,\ldots,y_k=y,\ldots,y_n)} \left(\sum_{(k',j')\in D(t)} m_{k'\to t}(y_{k'}) + \mathrm{C}_t(\{y_1,\ldots,y_n\}) \right). \tag{4}$$

The maximization term is an instance of the general *clique inference problem* defined as:

Definition 3 (Clique Inference) *Given a clique over n vertices, with a symmetric clique potential $C(y_1,\ldots,y_n)$, and vertex potentials ψ_{jy} for all $j \le n$ and labels y. Compute a labeling of the clique vertices that maximizes:*

$$\max_{y_1,\ldots,y_n} \sum_{j=1}^{n} \psi_{jy_j} + C(y_1,\ldots,y_n). \tag{5}$$

Thus the second term in Equation 4 can be seen as clique inference by defining $\psi_{jy} \triangleq m_{j\to t}(y)$ and $\mathrm{C} \triangleq \mathrm{C}_t$. To compute $m_{t\to k}(y)$, we can solve the clique inference problem with the easily enforceable constraint $y_k = y$. From now on, we refer to outbound message computation at the cliques as clique inference.

4. Symmetric Clique Potentials

Having established cluster message passing as our collective inference paradigm, and clique inference as our message computation tool, we turn our attention towards various families of symmetric clique potentials. As seen in Section 2, these associative clique potentials depend only on the histogram of label counts $\{n_y | y = 1,\ldots,m\}$ over the clique, n_y being the number of clique vertices labeled y. Thus for ease of notation, we will denote the arguments of a symmetric potential C_t by either the vertex labels $\mathbf{y}_t = (y_1,\ldots,y_n)$ or by its corresponding count histogram $\mathbf{n}(\mathbf{y}_t) = (n_1,\ldots,n_m)$. Here we clarify that $\mathbf{n}$ is used to denote the entire count histogram, n_y to denote the count for label y, while n denotes the clique size. An associative symmetric clique potential is thus maximized when $n_y = n$ for some y, that is, one label is given to all the clique vertices.

We consider specific families of clique potentials, many of which are currently used in real-life tasks. In Section 5 we will look at various potential-specific exact and approximate clique inference algorithms that exploit the specific structure of the potential at a clique.

In particular, we consider the three types of symmetric clique potentials listed in Table 1. They differ in the manner in which they reward skew in the count histogram $\mathbf{n}$.

4.1 MAX Clique Potentials

These clique potentials are of the form:

$$\mathrm{C}(n_1,\ldots,n_m) = \max_y f_y(n_y).$$

Name	Form	Remarks
MAX	$\max_y f_y(n_y)$	f_y is a non-decreasing function.
SUM	$\sum_y f_y(n_y)$	f_y non-decreasing. Includes Potts = $\lambda \sum_y n_y^2$.
MAJORITY	$f_a(\mathbf{n})$, where $a = \text{argmax}_y n_y$	A popular form is $f_a(\mathbf{n}) = \sum_y w_{ay} n_y$.

Table 1: Three kinds of symmetric clique potentials considered in this paper. $\mathbf{n} = (n_1, \ldots, n_m)$ denotes the counts of various labels among the clique vertices.

for arbitrary non-decreasing functions f_y. When $f_y(n_y) \triangleq n_y$, we get the *makespan* clique potential which has roots in the job-scheduling literature. This potential depends only on the biggest label count and ignores the other labels. Truncated version of this potential have been recently used in computer vision (Kohli et al., 2009).

In Section 5.1, we present the α-pass algorithm that computes messages for MAX clique potentials exactly in $O(mn \log n)$ time. MAX potentials are tractable and relatively simpler potentials, but most importantly, they provide key insights to deal with the more complex SUM potentials.

4.2 SUM Clique Potentials

SUM clique potentials are of the form:

$$\mathrm{C}(n_1, \ldots, n_m) = \sum_y f_y(n_y).$$

This family of potentials includes functions that aggregate the histogram skew over bins, for example, the entropy potential where $f_y(n_y) \propto n_y \log n_y$. One very interesting member is the case when the well-known Potts model is applied homogeneously on all edges of a clique. Let $\lambda > 0$ be the pairwise reward of assigning the same label to two nodes of an edge. The summation of these terms over a clique is equivalent (up to a constant) to the clique potential:

$$\mathrm{C}^{\text{Potts}}(n_1, \ldots, n_m) = \lambda \sum_y n_y^2.$$

This corresponds to the gini entropy of the histogram. We will show that the clique inference problem is NP-hard with the above potential and provide a $\frac{13}{15}$-approximation in Section 5.

We note that the traditional usage of Potts is in a minimization setting, that is, edges are penalized by some cost γ if their end vertices are labeled differently. The corresponding cost version of Potts is then $\mathrm{C}^{\min}(y_1, \ldots, y_n; \gamma) \triangleq \gamma \sum_{j>i} \delta(y_i \neq y_j)$. It is easy to see that these two versions are related by:

$$\mathrm{C}^{\text{Potts}}(y_1, \ldots, y_n; \lambda) = \lambda n^2 - \mathrm{C}^{\min}(y_1, \ldots, y_n; 2\lambda).$$

We show that our algorithm provides a $\frac{3}{2}$ approximation for the minimization version of the problem.

4.3 MAJORITY Clique Potentials

A MAJORITY potential is defined as:

$$\mathrm{C}(n_1, \ldots, n_m) = f_a(\mathbf{n}),\ a = \text{argmax}_y\ n_y. \tag{6}$$

An important special subclass is the linear majority potentials defined as:

$$\mathrm{C}^{\mathrm{Maj}} = \sum_y w_{ay} n_y,\ a = \mathrm{argmax}_y\ n_y.$$

This potential has been used for a variety of tasks such as link-based classification of web-pages (Lu and Getoor, 2003) and named-entity extraction (Krishnan and Manning, 2006). The role of the parameters w_{ay} is to capture the co-existence of some label pairs in the same clique. Co-existence allows us to downplay 'strict associativity' viz. it permits a few cliques vertices to have similar but not necessarily the same labels. For example, consider a clique made from occurrences of the unigram 'America'. However, some occurrences of America correspond to Location, while others might correspond to an Organization, say Bank of America. Also, it is rare for a location name to be shared with a person name. This can be captured by allowing a higher value of $w_{\alpha y}$ for the (Location, Organization) pair than for the (Location, Person) pair.

Unlike Potts potential, MAJORITY potential cannot be represented using edge potentials. We will present an exact polynomial time algorithm and several efficient approximations in Section 5.3.

5. Algorithms for Clique Inference

We will use $F(y_1,\ldots,y_n)$ to denote the clique inference objective in Equation 5. As short-hand, we will denote $F(y_1,\ldots,y_n)$ by $F(\mathbf{y}) = \psi(\mathbf{y}) + \mathrm{C}(\mathbf{y})$, where $\psi(\mathbf{y})$ is the vertex score (i.e., node potential) of the clique labeling $\mathbf{y}$ and the second term is the clique score (i.e., clique potential). Wlog assume that all the vertex terms ψ_{iy} are positive. Otherwise a constant can be added to all of them and that will not affect the maximization. The MAP clique labeling will be denoted by $\mathbf{y}^*$, and $\hat{\mathbf{y}}$ will denote a possibly sub-optimal labeling.

We show that the clique inference is easy for *any* $\mathrm{C}()$ with just two labels and in Section 5.1 we present an exact algorithm called α-pass for this case. We show that the same algorithm generalizes to give an exact solution for MAX potentials. We address the SUM and MAJORITY clique potentials respectively in Sections 5.2 and 5.3. Finally, in Section 5.4 we show how to extend the clique inference algorithms to efficiently batch the computation of multiple max-marginals.

5.1 α-pass Algorithm

We begin with MAX potentials. Recall that a MAX potential is of the form $\mathrm{C}(\mathbf{n}(\mathbf{y})) = \max_y f_y(n_y)$. We propose an exact inference procedure called α-pass (Algorithm 1) for such potentials.

The α-pass algorithm guesses that the dominant label in $\mathbf{y}^*$ is α, with a count of k. Of course we do not know α or k so all (α,k) combinations are tried out. For each (α,k) combination, α-pass computes the best k vertices to assign the label α. These k vertices are obtained by sorting all the vertices according to the criteria $\psi_{.\alpha} - \max_{\beta\neq\alpha}\psi_{.\beta}$, and picking the top-$k$ vertices. Every remaining vertex u is labeled with the best non-α label as per the vertex score, that is, with $\arg\max_\beta \psi_{u\beta}$. Let $\hat{\mathbf{y}}^{\alpha k}$ denote the clique labeling thus obtained in the $(\alpha,k)^{th}$ combination. Trying out all (α,k) combinations, α-pass returns the $\hat{\mathbf{y}}^{\alpha k}$ whose score $F(\hat{\mathbf{y}}^{\alpha k})$ is the highest.

It is straightforward to see that α-pass runs in $O(mn\log n)$ time by incrementally computing $F(\hat{\mathbf{y}}^{\alpha k})$ from $F(\hat{\mathbf{y}}^{\alpha(k-1)})$, that is, for each α, we can sort the vertices just once for all $k = 1,\ldots,n$. For clique potentials that are decomposable over the edges, as in Potts, this runtime is much better than ordinary belief propagation, which would cost $O(m^2n^2)$.

We now look at properties of α-pass.

Input: Vertex scores ψ, Clique Potential C
Output: Labeling $\hat{\mathbf{y}}$
Best = $-\infty$;
foreach *label* $\alpha \in \{1,\ldots,m\}$ **do**
  Sort the vertices in descending order according to the metric $\psi_{.\alpha} - \max_{\beta\neq\alpha}\psi_{.\beta}$;
  foreach $k \in \{1,\ldots,n\}$ **do**
    Assign the first k sorted vertices the label α;
    Assign the remaining vertices their individual best non-α label;
    s $\leftarrow$ score of this labeling under $F()$;
    if $s >$ *Best* **then**
      Best $\leftarrow$ s;
      $\hat{\mathbf{y}} \leftarrow$ current labeling;
    end
  end
end
return $\hat{\mathbf{y}}$;

Algorithm 1: The α-pass algorithm

Claim 5.1 *Assignment* $\hat{\mathbf{y}}^{\alpha k}$ *has the maximum vertex score over all* $\mathbf{y}$ *where* k *vertices are assigned label* α*, that is,* $\psi(\hat{\mathbf{y}}^{\alpha k}) = max_{\mathbf{y}:n_\alpha(\mathbf{y})=k}\psi(\mathbf{y})$.

Claim 5.2 *For* MAX *potentials,* $C(\hat{\mathbf{y}}^{\alpha k}) \geq f_\alpha(k)$.

Proof Label α has a count of k and the MAX potential considers the maximum over all label counts, which is at least k. ■

Theorem 4 *The* α*-pass algorithm solves the clique inference problem exactly for* MAX *clique potentials in* $O(mn\log n)$ *time.*

Proof Let $\mathbf{y}^*$ be the true MAP and let $\beta = \text{argmax}_y f_y(n_y(\mathbf{y}^*))$, $\ell = n_\beta(\mathbf{y}^*)$. Let $\hat{\mathbf{y}}$ be the labeling returned by α-pass. We have:

$$\begin{aligned}
F(\hat{\mathbf{y}}) &= \max_{1\leq\alpha\leq m, 1\leq k\leq n} F(\hat{\mathbf{y}}^{\alpha k}) \\
&\geq F(\hat{\mathbf{y}}^{\beta\ell}) \\
&= \psi(\hat{\mathbf{y}}^{\beta\ell}) + \mathrm{C}(\hat{\mathbf{y}}^{\beta\ell}) \\
&\geq \psi(\hat{\mathbf{y}}^{\beta\ell}) + f_\beta(\ell) \quad \text{(by Claim 5.2)} \\
&= \psi(\hat{\mathbf{y}}^{\beta\ell}) + \mathrm{C}(\mathbf{y}^*) \\
&\geq \psi(\mathbf{y}^*) + \mathrm{C}(\mathbf{y}^*) \quad \text{(by Claim 5.1)} \\
&= F(\mathbf{y}^*).
\end{aligned}$$

■

Although we had initially designed the α-pass algorithm for MAX potentials, a similar argument can be used to show that α-pass performs exact clique inference for *any* arbitrary symmetric potential when we have two labels.

Claim 5.3 α*-pass is exact for arbitrary symmetric potentials over two labels.*

Proof Let the MAP $\mathbf{y}^*$ have label counts n_1 and $n-n_1$, and a vertex score of $\psi(\mathbf{y}^*)$. Let $\hat{\mathbf{y}}$ be the labeling returned by α-pass. Then we get $F(\hat{\mathbf{y}}) \geq F(\hat{\mathbf{y}}^{1n_1}) = \psi(\hat{\mathbf{y}}^{1n_1}) + C(n_1, n-n_1) \geq \psi(\mathbf{y}^*) + C(n_1, n-n_1) = F(\mathbf{y}^*)$. Since C is arbitrary, the result follows. ■

We also note that in some real-life tasks the vertex terms tend to heavily dominate the clique term. In such a case too, α-pass will provide an exact solution. This follows immediately from Claim 5.1 and the observation that $F(\mathbf{y}) \approx \psi(\mathbf{y})$.

5.2 Clique Inference for SUM Potentials

We focus on the Potts potential, the most popular member of the SUM family. Potts potential is given by $C^{\text{Potts}}(\mathbf{y}) = \lambda \sum_y n_y^2$ and the clique inference objective is:

$$\max_{y_1,\ldots,y_n} \sum_{j=1}^{n} \psi_{jy_j} + \lambda \sum_y n_y^2. \tag{7}$$

In the above, $\lambda > 0$ since we are interested in the associative case which encourages agreement among labels. It is well known that inference with Potts potentials over general graphs, is NP-hard (Boykov et al., 2001) when number of labels is > 2 even with $\lambda > 0$. So we will first show that the task remains NP-hard even for cliques. Then, we will prove that α-pass achieves an approximation ratio of $\frac{4}{5}$, followed by a more complex proof for a better and tight approximation ratio of $\frac{13}{15}$. We will then generalize the α-pass algorithm, which will result in an improved ratio of $\frac{8}{9}$ at a cost of higher runtime. In contrast, the α-expansion algorithm of Boykov et al. (2001) will be shown to have a ratio of only $\frac{1}{2}$.

Theorem 5 *When $C(\mathbf{y}) = \lambda \sum_y n_y^2, \lambda > 0$, clique inference is NP-hard.*

Proof We prove hardness by reduction from the NP-complete *Exact Cover by 3-sets* problem (Papadimitriou and Steiglitz, 1982). In an instance of Exact Cover by 3-sets, we are given a universe U of elements, a set S of subsets of U where each subset has three elements, and the goal is to find $S' \subseteq S$ that covers U, while minimizing $|S'|$. We create an instance of clique inference as follows. We let elements of U correspond to vertices, and each set in S to a label. Assign $\psi_{iy} = 2n\lambda$ if element i belongs to set y, and zero otherwise (set $\lambda > 0$ arbitrarily). Consider the problem of deciding if exactly $\frac{n}{3}$ out of m subsets cover U. The MAP score in the constructed clique inference instance will be $(2n^2 + 3^2\frac{n}{3})\lambda$ iff we can find an exact cover. ■

The above proof establishes that there cannot be an algorithm that is polynomial in both n and m. But we have not ruled out algorithms with complexity that is polynomial in n but exponential in m, say of the form $O(2^m n^k)$ for a constant k.

We next analyze the approximation guarantees provided by the α-pass algorithm. We first present an easy proof for a weaker bound of $\frac{4}{5}$ and then move on to a more detailed proof for $\frac{13}{15}$. Recall that the optimal labeling is $\mathbf{y}^*$ and the labeling output by α-pass is $\hat{\mathbf{y}}$.

Theorem 6 $F(\hat{\mathbf{y}}) \geq \frac{4}{5} F(\mathbf{y}^*)$.

Proof Without loss of generality assume that the label counts of $\mathbf{y}^*$ are $n_1 \geq n_2 \geq \ldots \geq n_m$. Then $\mathrm{C}(\mathbf{y}^*) = \lambda \sum_y n_y^2 \leq \lambda n_1 \sum_y n_y = \lambda n n_1$.

$$\begin{aligned} F(\hat{\mathbf{y}}) &\geq F(\hat{\mathbf{y}}^{1n_1}) = \psi(\hat{\mathbf{y}}^{1n_1}) + \mathrm{C}(\hat{\mathbf{y}}^{1n_1}) \\ &\geq \psi(\mathbf{y}^*) + \mathrm{C}(\hat{\mathbf{y}}^{1n_1}) \quad \text{(from Claim 5.1)} \\ &\geq \psi(\mathbf{y}^*) + \lambda n_1^2 \quad \text{(since } \lambda > 0\text{)} \\ &\geq \psi(\mathbf{y}^*) + \mathrm{C}(\mathbf{y}^*) - \lambda n_1 n + \lambda n_1^2 \\ &\geq F(\mathbf{y}^*) - \lambda n^2/4. \end{aligned} \tag{8}$$

Now consider the two cases where $F(\mathbf{y}^*) \geq \frac{5}{4}\lambda n^2$ and $F(\mathbf{y}^*) < \frac{5}{4}\lambda n^2$. For the first case we get from above that $F(\hat{\mathbf{y}}) \geq F(\mathbf{y}^*) - \lambda n^2/4 \geq \frac{4}{5}F(\mathbf{y}^*)$. For the second case, we know that the score $F(\hat{\mathbf{y}}^{mn})$ where we assign all vertices the last label is at least λn^2 (because all vertex scores are assumed to be non-negative) and thus $F(\hat{\mathbf{y}}) \geq \frac{4}{5}F(\mathbf{y}^*)$. ■

We stress that non-negativity of the vertex scores is important for the multiplicative bound of $\frac{4}{5}$, else one can construct examples where $F(\mathbf{y}^*) = 0$. At the same time, Equation 8 provides a useful additive bound that holds for arbitrary vertex scores.

We now state the more involved proof for showing that α-pass actually provides a tight approximation bound of $\frac{13}{15}$ for clique inference with Potts when the vertex scores are non-negative.

Theorem 7 *$F(\hat{\mathbf{y}}) \geq \frac{13}{15}F(\mathbf{y}^*)$. Further, this ratio is tight.*

Proof See Appendix A. ■

We next present a generalization of the α-pass algorithm that provides provably better guarantees for Potts.

5.2.1 GENERALIZED α-PASS ALGORITHM

In α-pass, for each label α, we go over each count k and find the best vertex score with k vertices assigned label α. We generalize this to go over all label subsets of size no more than q, a parameter of the algorithm that is fixed based on the desired approximation guarantee.

For each label subset $A \subseteq \{1,\ldots,m\}$ of size no more than q, and for each count k, maximize vertex scores with exactly k vertices assigned a label from A. For this, we sort the vertices in decreasing order of $\max_{\alpha \in A} \psi_{i\alpha} - \max_{y \notin A} \psi_{iy}$, assign the top k vertices their best label in A and the remaining their best label not in A. The best solution over all combinations (A,k) with $|A| \leq q$ is returned as the final labeling $\hat{\mathbf{y}}$. It is easy to see that this algorithm reduces to α-pass when $q = 1$.

The complexity of this algorithm is $O(nm^q \log n)$ because there are $\binom{m}{q}$ choices for the set A. In practice, we can use heuristics to prune the number of label subsets. Further, we can make the following claims about the quality of its output.

Theorem 8 *Generalized α-pass enjoys an approximation bound of $\frac{8}{9}$, that is, $F(\hat{\mathbf{y}}) \geq \frac{8}{9}F(\mathbf{y}^*)$.*

Proof The bound is achieved with $q = 2$. We provide the details in Appendix A. ■

We *conjecture* that the bound for general q is $\frac{4q}{4q+1}$. This bound is not tight as for $q = 1$ we have already shown that the $\frac{4}{5}$ bound can be tightened to $\frac{13}{15}$. With $q = 2$ we get a bound of $\frac{8}{9}$ which is better than $\frac{13}{15}$.

5.2.2 α-EXPANSION ALGORITHM

In general graphs, a popular method that provides the approximation guarantee of 1/2 for the Potts model is the graph-cut based α-expansion algorithm (Boykov et al., 2001). We explore the behavior of this algorithm for clique inference with Potts potentials.

In this scheme, we start with any initial labeling—for example, all vertices are assigned the first label, as suggested in Boykov et al. (2001). Next, for each label α we perform an α-expansion phase where we switch the labeling of an optimal set of vertices from their current label to α. We repeat this in a round over the m labels, until no vertices switch their labeling in a complete round.

For graphs whose edge potentials form a metric, an optimal α-expansion move is based on the use of the mincut algorithm of Boykov et al. (2001) which for the case of cliques can be $O(n^3)$. We next show how to perform optimal α-expansion moves more efficiently (in $O(mn^2)$ time) for all kinds of SUM potentials.

An α-expansion move: Let $\tilde{\mathbf{y}}$ be the labeling at the start of this move. For each label $y \neq \alpha$ create a sorted list S_y of vertices assigned y in $\tilde{\mathbf{y}}$ in decreasing order of $\psi_{i\alpha} - \psi_{iy}$. If in an optimal move, we move k_y vertices from y to α, then it is clear that we need to pick the top k_y vertices from S_y. Let r_i be the rank of a vertex i in S_y. Our remaining task is to decide the optimal number k_y to take from each S_y. We find these using dynamic programming. Without loss of generality assume $\alpha = m$. Let $D_j(k)$ denote the best score when k vertices with current labels in $1 \ldots j$ switch to α. We compute

$$D_j(k) = \max_{l \leq k,\ l \leq n_j(\tilde{\mathbf{y}})} D_{j-1}(k-l) + f_j(n_j(\tilde{\mathbf{y}}) - l) + \sum_{i':r_{i'} \leq l} \psi_{i'\alpha} + \sum_{i':r_{i'} > l} \psi_{i'j},$$

where $n_j()$ is the usual cardinality of label j in the labeling. Now we can find the optimal number of vertices to switch to α as $\text{argmax}_{k \leq n - n_\alpha(\tilde{\mathbf{y}})} D_{m-1}(k) + f_\alpha(k + n_\alpha(\tilde{\mathbf{y}}))$.

5.2.3 COMPARISON WITH EXISTING APPROXIMATION BOUNDS

As mentioned earlier, the C^{Potts} clique potential is equivalent to the sum of Potts potentials over edges of a complete graph. For arbitrary graphs with homogeneous Potts potential on edges, the alpha expansion algorithm of Boykov et al. (2001) and the LP relaxation algorithm of Kleinberg and Tardos (2002) provide a factor of 2 approximation guarantee for a minimization version of the objective. For cliques with homogeneous edge potentials, their objective reduces to an energy-based formulation (using their notation):

$$\min_{\mathbf{y}} \sum_j \theta_j(y_j) + \gamma \sum_{i,j>i} \delta(y_j \neq y_i) \equiv \min_{\mathbf{y}} \sum_j \theta_j(y_j) + \frac{\gamma}{2}(n^2 - \sum_y n_y^2), \tag{9}$$

where $\theta_j(y_j)$ denotes node energy and is assumed to be positive and γ denotes the homogeneous Potts parameter.

First we show that α-expansion provides an approximation bound of 2 even for the special case of cliques. Symmetrically, we also show that the α-expansion algorithm provides a bound of $\frac{1}{2}$ for our original max-version of the clique inference problem. Next, we show that α-pass provides a bound of $\frac{3}{2}$ for even the minimization objective above. Thus, for both the minimization and maximization objectives, α-pass improves upon the guarantees obtained by existing algorithms.

Theorem 9 *The α-expansion algorithm provides no better approximation guarantee than 2 for the minimization objective (9).*

Proof An instance where this occurs is as follows. There are n nodes and $n+1$ labels $y_0, \ldots, y_n$. The vertex energy for (x_i, y_0) is $2n-2$ and for (x_i, y_i) it is 0. All other vertex energies are ∞, and $\gamma = 1$. Suppose initially all nodes are assigned label y_0. Then the clique energy is 0 and vertex energy is $n(2n-2)$. Now considering any other label $y_i, i >= 1$, the optimal set of nodes to switch is just x_i. But this reduces vertex energy by $2n-2$ but increases clique energy by the same amount, so no switching is done. However the optimal solution has x_i labeled with y_i, which has a total energy of $n^2 - n$. ■

Theorem 10 *The α-expansion algorithm provides no better approximation guarantee than 1/2 for the maximization objective (7).*

Proof Consider an instance where $m = \sqrt{n}+1$, and $\lambda = 1$. Let $\psi_{u1} = 2\sqrt{n}$ for all u. Divide the vertices into $\sqrt{n}$ groups of size $\sqrt{n}$ each, and let $\psi_{u,i+1} = 2n$ for every vertex u in the i^{th} group. All other vertex scores are zero. Consider the solution where every vertex is assigned label 1. This labeling is locally optimal wrt any α-expansion move, and its score is $n^2(1+2/\sqrt{n})$. However, the exact solution assigns every vertex group its label, with a score $n^2(2+1/\sqrt{n})$, thus giving a ratio of $1/2$ in the limit. ■

Theorem 11 *The α-pass algorithm achieves an approximation ratio of $\frac{3}{2}$ for the minimization objective 9.*

Proof Suppose $k = \max_y n_y$ is the highest count in the optimal labeling. Consider two cases, $k \geq n/2$ and $k < n/2$.

If $k \geq n/2$, the clique energy is at least $\gamma(n^2 - (k^2 + (n-k)^2)) = \gamma 2k(n-k)$. The clique energy in α-pass is at most $\gamma(2n^2 - k^2 - (n-k)) = \gamma(n-k)(n+k-1)$. The vertex energy in the optimal labeling cannot be smaller than that in α-pass. Since $k >= n/2, (n+k-1)/2k \leq 3/2$.

If $k \leq n/2$, then the clique energy in the optimal labeling is at least $\gamma(n^2 - nk) = \gamma n(n-k)$. Therefore the ratio is again at most $(n+k-1)/n \leq 3/2$. ■

As expected, generalized α-pass provides a superior approximation ratio for Objective 9.

Theorem 12 *The generalized α-pass algorithm with two labels ($q = 2$) achieves an approximation ratio of $\frac{1+\sqrt{2}}{2}$ for objective 9.*

Proof We omit the complete proof as it is quite detailed and give only a brief sketch. Wlog assume that 1 and 2 are the two most dominant labels in the optimal labeling OPT, with counts $n_1, n_2 \leq n_1$. Consider two solutions—one given by α-pass (i.e., $q = 1$) when label 1 has count n_1, and another given by generalized α-pass with $q = 2$ when counts of labels 1 and 2 are $n_1 + n_2$. The node energies of these two labelings cannot be worse than that of OPT (Claim 5.1). So the approximation bound depends only on the ratios of the clique energies. Therefore wlog assume that $\gamma = 2$ in Objective 9. The clique energies of the two solutions cannot exceed $(n^2 - n_1^2)$ and $(n^2 - \frac{(n_1+n_2)^2}{2})$ respectively. We can now work out the two cases whether $n_1^2 \leq (n_1+n_2)^2/2$ or not, and get the desired approximation bound through contradictions. The analysis also shows that the bound is tight, and is achieved when

$n_1 = n/\sqrt{2}$ and $n_2 = n - n/\sqrt{2}$. ■

5.2.4 ENTROPY POTENTIALS AND THE α-PASS ALGORITHM

As an aside, let us explore the behavior of α-pass on another family of additive potentials—entropy potentials. Entropy potentials are of the form:

$$C(\mathbf{n}(\mathbf{y})) = \lambda \sum_y n_y \log n_y, \text{ where } \lambda > 0.$$

The main reason α-pass provides a good bound for Potts potentials is that it guarantees a clique potential of at least n_1^2 where n_1 is the count of the most dominant label in the optimal solution $\mathbf{y}^*$. The quadratic term compensates for possible sub-optimality of counts of other labels. If we had a sub-quadratic term instead, say $n_1 \log n_1$ for the entropy potentials, the same bound would not have held. In fact the following theorem shows that for entropy potentials, even though α-pass guarantees a clique potential of at least $n_1 \log n_1$, that is not enough to provide a good approximation ratio.

Theorem 13 *α-pass does not provide a bound better than $\frac{1}{2}$ for entropy potentials.*

Proof Consider a counter example where there are $m = n + \log n$ labels. Divide the labels into two sets—A with $\log n$ labels and B with n labels. The vertex scores are as follows: the vertices are divided into $\log n$ chunks of size $n/\log n$ each. If the j^{th} vertex lies in the y^{th} chunk, then let it have a vertex score of $\log n$ with label y in A and a vertex score of $\log n + \varepsilon$ with the j^{th} label in B. Let all other vertex scores be zero. Also, let $\lambda = 1$.

Consider the labeling which assigns the y^{th} label in A to the y^{th} chunk. Its score is $2n \log n - n \log \log n$. Now consider α-pass, with $\alpha \in A$. Initially vertex y will be set to the y^{th} label in B. The best labeling found by α-pass will assign every vertex to α, for a total score of roughly $n + n \log n$. If $\alpha \in B$, then again the best labeling will assign everything to α for a total score of roughly $(n+1)\log n$.

Thus the bound is no better than $\frac{1}{2}$ as $n \to \infty$. ■

Thus, α-pass provides good approximations when the clique potential is heavily dominated by the most dominating label. We now look at MAJORITY potentials, which are linear in the counts $\{n_y\}_y$. Looking at Theorem 13, we expect that α-pass will not have decent approximation guarantees for MAJORITY. This is indeed the case. We will prove in Section 5.3 that neither α-pass nor a natural modification of α-pass enjoy good approximation guarantees.

5.3 Clique Inference for MAJORITY Potentials

Recall that MAJORITY potentials are of the form $C = f_a(\mathbf{n}),\ a = \text{argmax}_y\ n_y$. We consider linear majority potentials where $f_a(\mathbf{n}) = \sum_y w_{ay} n_y$. The matrix $W = \{w_{yy'}\}$ is not necessarily diagonally dominant or symmetric.

We show that exact MAP for linear majority potentials can be found in polynomial time. We also present a modification to the α-pass algorithm to serve as an efficient heuristic, but without approximation guarantees. Then we present a Lagrangian relaxation based approximation, whose runtime is competitive with α-pass, but which provides much more accurate solutions.

5.3.1 MODIFIED α-PASS ALGORITHM

Assume that we magically know the majority label α in advance. Then for linear majority potentials, we can incorporate the linear clique term $w_{\alpha y} n_y$ in the various vertex scores, and this leads to the following natural modifications to the α-pass algorithm: (a) While making iterations for the label α, sort the vertices according to the modified metric $\psi_{i\alpha} + w_{\alpha\alpha} - \max_{y \neq \alpha}(\psi_{iy} + w_{\alpha y})$, and (b) While sweeping the list for α with varying values of k, discard all candidate solutions whose majority label is not α.

However even after these modifications, α-pass does not provide the same approximation guarantee as for homogeneous Potts potentials, as we prove next.

Theorem 14 *The modified α-pass algorithm cannot have an approximation ratio better than $\frac{1}{2}$ on linear majority potentials with arbitrary W.*

Proof Consider the degenerate example where all vertex scores are zero. Let β and γ be two fixed labels and let the matrix W be defined as follows: $w_{\beta\gamma} = M + \varepsilon$, $w_{\beta y} = M \; \forall y \neq \beta, \gamma$ and all the other entries in W are zero.

In modified α-pass, when $\alpha \neq \beta$, the labeling returned will have a zero score. When $\alpha = \beta$, all vertices will prefer the label γ, so α-pass will have to assign exactly $n/2$ vertices to β to make it the majority label, thus returning a score of $\frac{(M+\varepsilon)n}{2}$. However, consider the labeling which assigns n/m vertices to each value, with a score of $(m-1)Mn/m$. Hence the approximation ratio cannot be better than $\frac{1}{2}$. ■

5.3.2 EXACT ALGORITHM

Since MAJORITY potentials are linear, we can pose the optimization problem in terms of Integer Programs (IPs). Assume that we know the majority label α. Then, the optimization problem corresponds to the IP:

$$\begin{aligned} \max_{\mathbf{z}} \sum_{i,y} (\psi_{iy} + w_{\alpha y}) z_{iy}, \\ \text{s.t. } \forall y: \; \sum_i z_{iy} \leq \sum_i z_{i\alpha}, \\ \forall i: \; \sum_y z_{iy} = 1, \; z_{iy} \in \{0,1\}. \end{aligned} \tag{10}$$

We can solve m such IPs by guessing various labels as the majority label, and reporting the best overall labeling as the output. However, Equation 10 cannot be tightly relaxed to a linear program. This can be easily shown using a counter example: Consider a 3-vertex, 3-label clique with a zero W matrix. Let the vertex score vectors be $\psi_0 = (1,4,0)$, $\psi_1 = (4,0,4)$, $\psi_2 = (3,4,0)$. While solving for $\alpha = 0$, the best IP labeling is $1,0,0$ with a score of 11. However the LP relaxation has the solution $\mathbf{z} = (0,1,0;1,0,0;1/2,1/2,0)$ with a score of 11.5.

This issue can be resolved by making the constraint matrix totally unimodular as follows. Guess the majority label α, its count $k = n_\alpha$, and solve the following IP:

$$\begin{aligned} \max_{\mathbf{z}} \sum_{i,y} (\psi_{iy} + w_{\alpha y}) z_{iy}, \\ \text{s.t. } \forall y \neq \alpha : \sum_i z_{iy} \leq k, \\ \sum_i z_{i\alpha} = k, \\ \forall i : \sum_y z_{iy} = 1,\ z_{iy} \in \{0,1\}. \end{aligned} \tag{11}$$

This IP solves the degree constrained bipartite matching problem, which can be solved exactly in polynomial time. Indeed, it can be shown that the constraint matrix of this IP is totally unimodular, so its LP relaxation will have an integral solution. We refer the reader to Gupta et al. (2009) for the details. Thus we solve $O(mn)$ such problems by varying α and k, and report the best solution. We believe that the above LP is concave in k, so the system for a fixed α should be efficiently solvable using golden section search.

5.3.3 LAGRANGIAN RELAXATION BASED ALGORITHM FOR MAJORITY POTENTIALS

Solving the linear system in Equation 11 is very expensive because we need to solve $O(mn)$ LPs, whereas the system in Equation 10 cannot be solved exactly using a linear relaxation. Here, we look at a Lagrangian Relaxation based approach (LR), where we solve the system in Equation 10 but bypass the troublesome constraint $\forall y \neq \alpha : \sum_i z_{iy} \leq \sum_i z_{i\alpha}$.

We use Lagrangian relaxation to move this constraint to the objective function. Any violation of this constraint is penalized by a positive penalty term. Consider the following modified program, also called the Lagrangian:

$$\begin{aligned} L(\gamma) = L(\gamma_1, \ldots, \gamma_m) = \max_{\mathbf{z}} \sum_{i,y} (\psi_{iy} + w_{\alpha y}) z_{iy} \quad + \quad \sum_y \gamma_y (\sum_i z_{i\alpha} - \sum_i z_{iy}), \\ \text{s.t. } \forall i : \sum_y z_{iy} = 1, \qquad z_{iy} \in \{0,1\}. \end{aligned} \tag{12}$$

For $\gamma \geq \mathbf{0}$, and feasible $\mathbf{z}$, $L(\gamma)$ is an upper bound for our objective in Equation 10. Thus, we compute the lowest such upper bound:

$$L^* = \min_{\gamma \geq \mathbf{0}} L(\gamma). \tag{13}$$

Further, the penalty term in Equation 12 is linear in $\mathbf{z}$, so we can merge it with the first term to get another set of modified vertex potentials:

$$\psi^\alpha_{iy} \triangleq \psi_{iy} + w_{\alpha y} - \gamma_y + \begin{cases} \sum_{y'} \gamma_{y'} & y = \alpha \\ 0 & y \neq \alpha \end{cases}.$$

Equation 12 can now be rewritten in terms of ψ^α, with the only constraint that $\mathbf{z}$ correspond to a valid labeling:

$$\begin{aligned} \max_{\mathbf{y}} \sum_{i,y} \psi^\alpha_{iy} z_{iy}, \\ \text{s.t. } \forall i : \sum_y z_{iy} = 1,\ \ z_{iy} \in \{0,1\}. \end{aligned}$$

Hence, $L(\gamma)$ can be computed by independently assigning each vertex i to its best label viz. $\text{argmax}_y \psi^{\alpha}_{iy}$.

We now focus on computing L^*. We use an iterative approach, beginning with $\gamma = \mathbf{0}$, and carefully choose a new γ at each step to get a non-increasing sequence of $L(\gamma)$'s. We describe the method of choosing a new γ later in this section, and instead outline sufficient conditions for termination and detection of optimality.

Theorem 15 *$\mathbf{z}^*$ and γ^* are optimum solutions to Equations 10 and 13 respectively if they satisfy the conditions:*

$$\forall y: \quad \sum_i z^*_{iy} \leq \sum_i z^*_{i\alpha}, \tag{14}$$

$$\forall y: \quad |\gamma^*_y(\sum_i z^*_{iy} - \sum_i z^*_{i\alpha})| = 0. \tag{15}$$

Theorem 15 holds only for fractional $\mathbf{z}^*$. To see how, consider an example with three vertices and two labels. Let $\psi_{i1} + w_{\alpha 1} > \psi_{i2} + w_{\alpha 2}$ for all i and α. During Lagrangian relaxation with $\alpha = 2$, initially $\gamma = \mathbf{1}$ will cause all vertices to be assigned label 1, violating Equation 14. Since the count difference $\sum_i z_{i1} - \sum_i z_{i2} \in \{\pm 1, \pm 2, \pm 3\}$, any non-zero γ_1 will violate Equation 15. Subsequent reduction of γ_1 to zero will again cause the original violation of Equation 14. Consequently, one of Equations 14 and 15 will never be satisfied and the algorithm will oscillate.

To tackle this, we relax Equation 15 to $|\gamma_y(\sum_i z^*_{iy} - \sum_i z^*_{i\alpha})| \leq \varepsilon$, where ε is a small fraction of an upper bound on γ_y. This helps in reporting labelings that respect the majority constraint in Equation 14 and are close to the optimal.

The outline of the algorithm is described in Figure 2.

We now discuss a somewhat conservative approach to select a new γ at every step. We initially attempted subgradient optimization and golden search to compute step direction and sizes for changing γ. However, we ran into various practical difficulties. Subgradient optimization required very careful tweaking of the step size across iterations, an issue exacerbated by the discrete nature of our problem. On the other hand, golden search was too aggressive in practice, leading to many avoidable label flips and consequently many more iterations. So instead we implemented a conservative approach which we describe next.

5.3.4 CONSERVATIVE COORDINATE DESCENT

We perform conservative coordinate descent which avoids large changes and thus too many label flips. Let y be the worst violating label in the current iteration. We will first consider the case when its count exceeds that of α, so that Equation 14 does not hold.

To decrease the count of y, we need to increase γ_y. Let i be a vertex currently assigned y and let $\beta(i)$ be its second most preferred label under the vertex potentials ψ^{α}_i. The vertex $j = \text{argmax}_{i:z_{iy}=1} \psi^{\alpha}_{i\beta(i)} - \psi^{\alpha}_{iy}$ is the easiest to flip. So we increase γ_y just enough to make this flip happen. The new value of γ_y is therefore given by:

$$\gamma_y = \min_{i:z_{iy}=1} \begin{cases} \Delta\psi(i,y,\beta(i)) + \gamma_{\beta(i)} & \beta(i) \neq \alpha \\ \frac{1}{2}(\Delta\psi(i,y,\alpha) - \sum_{y' \neq y} \gamma_{y'}) & \beta(i) = \alpha \end{cases}, \tag{16}$$

where $\Delta\psi(i,y,y')$ denotes $\psi_{iy} + w_{\alpha y} - \psi_{iy'} - w_{\alpha y'}$. It is possible that by flipping vertex j, $\beta(j)$ now violates Equation 14. Moreover, increasing γ_y also increases $\psi^{\alpha}_{i\alpha}$, so some other vertices that are not

assigned y may also move to α. However since the change is conservative, we expect this behavior to be limited. In our experiments, we found that this conservative scheme converges much faster than golden search over a variety of data.

We now look at the case when Equation 14 is satisfied by all labels but Equation 15 is violated by some label y. In this scenario, we need to decrease γ_y to decrease the magnitude of the violation. Here too, we conservatively decrease γ_y barely enough to flip one vertex to y. If i is any vertex not assigned label y and $\beta(i)$ is its current label, then the new value of γ_y is given by:

$$\gamma_y = \max_{i:z_{iy}\neq 1} \begin{cases} \Delta\psi(i,y,\beta(i)) + \gamma_{\beta(i)} & \beta(i) \neq \alpha \\ \frac{1}{2}(\Delta\psi(i,y,\alpha) - \sum_{y'\neq y}\gamma_{y'}) & \beta(i) = \alpha \end{cases} . \tag{17}$$

Note that the arguments of Equations 16 and 17 are the same. In this case too, in spite of a conservative move, more than one vertex marked α may flip to some other value, although at most one of them will be flipped to y. As before, the small magnitude of the change restricts this behavior in practice.

Input: ψ, W, α,maxIters,tolerance
Output: approximately best assignment $\hat{\mathbf{y}}$
$\gamma \leftarrow \mathbf{0}$;
iter $\leftarrow 0$;
$\hat{\mathbf{z}} \leftarrow$ Assignment with all vertices assigned α;
while *iter* $<$ *maxIters* **do**
  Compute $L(\gamma)$ (Equation 12), let $\mathbf{z}$ be the solution;
  if $F(\mathbf{z}) > F(\hat{\mathbf{z}})$ **then**
    $\hat{\mathbf{z}} \leftarrow \mathbf{z}$;
  end
  $(y, \Delta) \leftarrow$ Worst violator and violation (Equations 14 and 15);
  if $\Delta <$ *tolerance* **then**
    We are done, $L^* = L(\gamma)$;
    break;
  else
    Modify γ_y using conservative coordinate descent;
  end
  iter $\leftarrow$ iter+1;
end
Construct assignment $\hat{\mathbf{y}}$ from $\hat{\mathbf{z}}$;
return $\hat{\mathbf{y}}$

Algorithm 2: LR Algorithm for Majority potentials

5.4 Computing All Node Max-marginals

In this section, we discuss an important optimization that speeds up message-passing in a cluster graph. We show that for symmetric potentials we can compute max-marginals in $O(m^2)$ calls to the clique inference algorithm in practice, as opposed to the expected nm invocations. Cliques can be arbitrarily big, so removing the dependence on n is very helpful in practice.

Our basic strategy is as follows. For label pairs α, β, define a modified clique potential function $C_{\alpha\beta}$ that adds "1" to the count for label β and subtracts "1" from the count of label α:

$$C_{\alpha\beta}(\mathbf{y}) = C(n_1(\mathbf{y}), \ldots, n_\alpha(\mathbf{y}) - 1, \ldots, n_\beta(\mathbf{y}) + 1, \ldots n_m).$$

Find MAP labeling $\mathbf{y}^{\alpha\beta}$ using the modified scoring function $F_{\alpha\beta}(\mathbf{y}) = \psi(\mathbf{y}) + C_{\alpha\beta}(\mathbf{y})$. Let v be a vertex whose label in $\mathbf{y}^{\alpha\beta}$ is α, then the max marginal $M_{v\beta} \triangleq \max_{\mathbf{y}:y_v=\beta} F(\mathbf{y}) = F_{\alpha\beta}(\mathbf{y}^{\alpha\beta}) - \psi_{v\alpha} + \psi_{v\beta}$. The outgoing message $m_{t\to v}(\beta)$ is then simply $M_{v\beta} - m_{v\to t}(\beta)$ as per Equation 4. A proof of correctness of this optimization is as follows.

Theorem 16 $\max_{\mathbf{y}:y_v=\beta} F(\mathbf{y}) = F_{\alpha\beta}(\mathbf{y}^{\alpha\beta}) - \psi_{v\alpha} + \psi_{v\beta}$.

Proof

$$\begin{aligned}
\max_{\mathbf{y}} F_{\alpha\beta}(\mathbf{y}) &= \max_{\mathbf{y}:y_v=\alpha} F_{\alpha\beta}(\mathbf{y}) \text{ since } v \text{ is labeled } \alpha \text{ in } \mathbf{y}^{\alpha\beta} \\
&= \max_{\mathbf{y}:y_v=\alpha} \psi(\mathbf{y}) + C_{\alpha\beta}(\mathbf{y}) \\
&= \max_{\mathbf{y}:y_v=\beta} \psi(\mathbf{y}) - \psi_{v\beta} + \psi_{v\alpha} + C(\mathbf{y}) \\
&= \max_{\mathbf{y}:y_v=\beta} F(\mathbf{y}) - \psi_{v\beta} + \psi_{v\alpha}.
\end{aligned}$$

■

We invoke the above strategy for all label pairs α, β when some vertex in the original MAP gets label α. There is no guarantee that all *nm* messages would be generated by the above scheme. The ones that are not covered are computed using separate invocations of MAP.

This concludes the description of our various clique inference algorithms and their theoretical properties. The discussion until now had focused on the traditional unigram-clique collective inference model. We now switch tracks and describe an extension of the collective inference framework—one which captures richer kinds of associativity that is often present in the data. We will see that the same cluster message passing setup and collective inference algorithms can be used almost as is in this more general scenario.

6. Properties-based Collective Inference Framework

We broaden the notion of collective inference to encourage richer forms of associativity amongst the labelings of multiple records. This more general framework has applications in domain adaptation. We illustrate this via an example.

Example: Consider extracting bibliographic information from an author's publications homepage using a model trained on a different set of pages. The labels of interest are Title, Author, Venue, and Date. Typically, within each homepage (a domain) we expect consistency in the style of individual publication records. For example, we expect the following properties to be largely uni-valued *inside* a domain:

1. The ordering of labels in the labelings (e.g., Title $\to$ Author* $\to$ Venue).
2. The token preceding the Title, or 'Start' if Title occurs at the beginning.
3. The label appearing after the Venue, or 'End' if Venue occurs at the end.
4. Label of the token 'IEEE'.

Table 2: Two publications pages with different styles. Text in parentheses shows the values of three properties on the correct labelings: (i) Token before Title (ii) First non-Other label after Venue (iii) HTML tag containing Title. The properties are largely uni-modal inside a page, but the mode varies across pages.

Note that 'IEEE' will tend to recur across multiple records, so the last property corresponds to the unigram-based cliques that we modeled thus far. It is clear now that we can gain a lot more if we couple the records together according to 'richer' properties than just unigrams.

Of course the choice of properties is crucial. For all the properties illustrated above, we expect that the labelings inside the domain agree on the property value, without caring for what the value actually is (which varies from domain to domain). This allows us to use the same property on different domains, with varying formatting and authoring styles. Table 2 illustrates this for two publications pages with different styles. It shows three properties that take on largely similar values across records inside a domain, but the dominant value changes across domains. Thus we can reward associativity of these property values using the same symmetric potentials that we have used for unigram cliques.

Now assume that we have an array of such conformance-promoting properties, and a basic MRF trained on some labeled domains. An effective way of deploying this MRF on a previously unseen domain is by labeling the records in the new domain collectively while encouraging the individual labelings to agree on our set of properties. If the properties continue to remain associative in the unseen domain, then collective inference can be expected to correct a significant number of errors. This provides us with an inference-only approach, in contrast to many existing solutions for domain adaptation which require model re-training (Blei et al., 2002; Blitzer et al., 2006; Mann and McCallum, 2007).

We now give an intuitive description of how the introduction of properties causes only minor changes in our collective inference framework. The modified collective inference objective is now given by:

$$\arg\max_{\mathbf{y}^1,\ldots,\mathbf{y}^N} \left(\sum_{k=1}^{N} \sum_{i=1}^{|\mathbf{x}^k|} \phi_i^k(y_i^k, y_{i-1}^k) \right) + \sum_{\mathrm{g} \in \mathcal{G}} \mathrm{C_g}(\{\mathrm{g}(\mathbf{x}^k, \mathbf{y}^k)\}_k),$$

instead of Equation 2. Here $\mathcal{G}$ is the set of properties, each of which defines an associative clique. We reuse the cluster message passing setup in this collective inference scenario. We define one cluster per chain, one per property, while separators remain singleton—they correspond to the property value. The new messages are of the kind $m_{\mathrm{g}\to k}(v)$ and $m_{k\to \mathrm{g}}(v)$, where v is a possible value output by the property g(). The property-to-chain messages are computed as before using our potential-specific clique inference algorithms. However the chain-to-property messages $m_{k\to \mathrm{g}}$ cannot be com-

puted for arbitrary properties. To illustrate, say $g(\mathbf{x}^k, \mathbf{y}^k) =$ Number of tokens marked Author in $\mathbf{y}^k$. Computing chain messages for this property is quite expensive, if not hard. So for computational reasons we restrict ourselves to *Markovian properties*, that is, properties whose chain-to-property messages can be computed with a first-order algorithm like Viterbi or max-product. Examples of Markovian properties include—Token before Title, and Label after Author. A sample message for the second property would be, say, $m_{k\to g}(\text{Title})$, which can be computed by running Viterbi with the first-order constraint that Author be followed by Title. In general, values of Markovian properties depend only on the Markovian blanket of a part of the chain, which leads to tractability of message computation. We refer the reader to Gupta et al. (2009) for the formal technical details of chain-to-property message computation for Markovian properties.

We stress that such a support for Markovian properties is not possible in alternative collective inference approaches like TRW-S. This is because even with Potts potentials over properties, the inter-cluster separators still remain complete chain labelings instead of scalar property values, so the cluster model cannot be represented as a pairwise graphical model.

In Section 7.3 we will look at the effect of introducing associative properties in the context of domain adaptation on a citation extraction task.

7. Experiments

Our goal is to empirically demonstrate that cluster message passing is indeed a more accurate and efficient framework for doing collective inference. Once this is established, it would necessitate the design of fast and accurate message computation algorithms that work for symmetric clique potentials. This would justify our design and analysis of the various clique inference algorithms presented in this paper. After illustrating the effectiveness of cluster message passing, we will show that the extension of collective inference to capture richer associative properties leads to significant boosts in domain adaptation tasks. Keeping these goals in mind, we present results of three different experiments—clique inference, collective inference, and the extension to general Markovian properties.

First, in Section 7.1 we compare our clique inference algorithms against applicable alternatives in the literature. We compare the algorithms on computation speed and accuracy of the MAP assignments. For Potts potentials, we show that α-pass provides similar MAPs as the various alternatives but is up to two orders faster. For linear MAJORITY potentials (Equation 6), we compare our algorithms against the exact LP-based approach of Section 5.3.2 and the ICM algorithm. For other clique potentials that are not decomposable along the clique edges, we compare α-pass against the ICM algorithm.

Second, in Section 7.2 we show that message passing on the cluster graph is a more effective method for collective inference than its alternatives. For collective models with Potts potentials, we compare cluster message passing against belief propagation that decomposes Potts along the clique edges. In the case of linear MAJORITY potentials, we compare against the stacking based approach of Krishnan and Manning (2006).

Finally, in Section 7.3 we demonstrate the application of our generalized collective framework on domain adaptation. On a citation extraction task, we show that capturing the associativity of richer properties leads to significant reduction in test error.

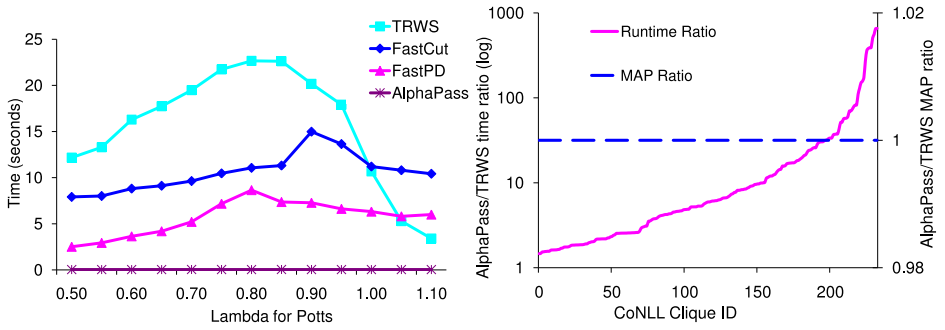
7.1 Clique Inference Experiments

For clique potentials decomposable over clique edges, we compare our clique inference algorithms against sequential tree re-weighted message passing (TRW-S), graph-cut based inference (α-exp), the ICM algorithm, and recent advancements including the faster graph-cut algorithm of Alahari et al. (2008) (FastCut), the fast primal-dual algorithm of Komodakis and Tziritas (2007) (FastPD), and the dual-decomposition scheme of Komodakis et al. (2007a) (DD). For non-decomposable potentials, we present comparisons against the ICM algorithm. We present comparison results on running time and quality of the MAP. Our experiments were performed on both synthetic and real data.



(a) POTTS: Runtime vs λ (b) CoNLL with Potts: α-pass vs TRW-S

Figure 2: Potts potential: (a) Runtime of α-pass vs TRW-S, Graph-cut and FastPD aggregated on 25 cliques as λ is varied in the synthetic data set POTTS (b) Comparing α-pass and TRW-S on MAP scores and runtimes for each CoNLL clique.

Synthetic Data Set: We generated cliques with 100 vertices and $m = 24$ labels by choosing vertex potentials at random from $[0,2]$ for all vertex-label pairs. A Potts version (POTTS) was created by gradually varying λ, and generating 25 cliques for every value of λ. We also created analogous ENTROPY, MAKESPAN and MAKESPAN2 versions of the data set by choosing entropy ($\lambda \sum_y n_y \log n_y$), linear makespan ($\lambda \max_y n_y$) and square makespan ($\lambda \max_y n_y^2$) clique potentials respectively.

For linear MAJORITY potentials we generated two kinds of data sets (parameterized by λ): (a) MAJ-DENSE obtained by generating a random symmetric W for each clique, where $W_{yy} = \lambda$ was the same for all y and $W_{yy'} \in [0, 2\lambda]$ $(y \neq y')$, and (b) MAJ-SPARSE from symmetric W with $W_{yy'} \in [0, 2\lambda]$ for all y, y', roughly 70% of whose entries were zeroed. This sparse data set is supposed to mirror the sparseness of W in real-life data sets.

CoNLL Data Set: The CoNLL 2003 data set[1] is a popular choice for demonstrating the benefit of collective labeling in named entity recognition tasks. We used the BIOU encoding of the entities, that resulted in 20 labels. We took a subset of 1460 records from the test set of CoNLL, and selected all 233 cliques of size 10 and above. The smaller cliques were ignored as the algorithms hardly differ in performance over them. The median and largest clique sizes were 16 and 259 respectively. The vertex potentials of the cliques were set by a sequential Conditional Random Field trained on a separate training set. We created a Potts version by setting $\lambda = 0.9/n$ using the development set, where n is the clique size. Such a λ allowed us to balance the vertex and clique potentials for each clique. A majority version was also created by learning W discriminatively in the training phase.

We developed Java implementations for all our algorithms—α-pass, generalized α-pass with $q = 2$, dynamic programming based α-expansion of Section 5.2.2 (denoted α-exp DP), modified α-pass, Lagrangian relaxation, and the Exact LP-based algorithm for Majority potentials. We used publicly available C++ implementations for TRW-S,[2] (Boykov et al., 2001; Szeliski et al., 2006; Kolmogorov and Zabih, 2004; Boykov and Kolmogorov, 2004), FastCut (Alahari et al., 2008), and FastPD (Komodakis and Tziritas, 2007; Komodakis et al., 2008). In addition, we implemented DD

1. This data set can be found at `http://cnts.uia.ac.be/conll2003/ner/`.
2. This code can be found at `http://www.adastral.ucl.ac.uk/~vladkolm/papers/TRW-S.html` and `http://vision.middlebury.edu/MRF/`.

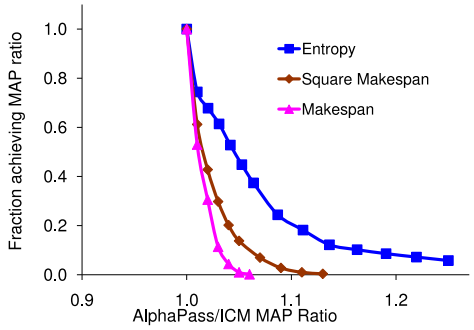


Figure 3: Comparing the MAP quality of α-pass vs ICM on non-decomposable potentials. Plotted point (r, f) denotes that for a fraction f of the cliques, α-pass returned a MAP score at least r times that of ICM.

in C++ and ICM in Java. All experiments were performed on a Pentium-IV 3.0 GHz machine with 8 GB of RAM.

7.1.1 EDGE DECOMPOSABLE POTENTIALS

Table 3 compares the various clique inference algorithms on the POTTS data set. We vary the Potts parameter λ uniformly in the range $[0.5, 1.1]$. This range is of special interest because it allows maximal contention between the clique and vertex potentials. For λ outside this range, the MAP is usually a trivial assignment, viz. one which either individually assigns each vertex to its best label (optimizing vertex potential), or assigns all vertices to a single label (optimizing clique potential). Each number in the upper half of Table 3 is the aggregate MAP score of 25 cliques for that particular λ, while the bottom half reports the aggregate clique inference time rounded to the nearest millisecond.

We observe that apart from ICM and DD, all the other algorithms return MAP scores in a small interval (0.5%) of each other. In particular α-pass performs almost identical to α-exp and FastPD in this regard. FastCut provides the best aggregate MAP scores, but α^2-pass and TRW-S are quite close as well. We note that the three expansion algorithms α-exp, α-exp DP, and FastCut return different MAP scores, primarily because they employ different bootstrapping steps. Further we observe that DD returns significantly low MAP scores, because even with suitable step-size selection heuristics such as the one proposed by Komodakis et al. (2007a), DD converges very slowly and invariably hits the maximum iteration limit of 30 with a sub-par MAP. ICM also returns lower MAP scores, as expected, due to its highly local updates.

In terms of runtime, Table 3 shows a clear separation of the algorithms. ICM and α-pass are the fastest, while α-exp, FastCut, FastPD, and TRW-S are 150-400 times slower. This is because in contrast to α-pass, the other algorithms perform multiple costly iterations (e.g., an iteration of TRW-S is $O(n^2)$). The cut-based algorithms and FastPD are faster than TRW-S, while DD is the slowest, at 3000 times α-pass. This is because DD has to deal with $O(n)$ spanning trees which is costly, and leads to slow convergence. Consequently DD hits the iteration limit every time. Our α^2-pass and dynamic programming based α-expansion (α-exp DP) algorithms are ten and three times slower than α-pass respectively, but still more than an order faster than the other algorithms. Finally we

see that while α-pass and α^2-pass take almost a constant time irrespectively of λ, the other schemes take up more time (as they iterate more) around the "maximal contention range" of $[0.7, 1.0]$ for λ. Figure 2(a) illustrates this behavior, where we vary λ and plot the runtimes of α-pass, FastPD, TRW-S, and FastCut. Note that α-pass lies very close to the x-axis, illustrating its small runtime.

Figure 2(b) presents the results on Potts cliques from the CoNLL data set. For simplicity we only compare α-pass with TRW-S as the other algorithms behave analogous to the synthetic scenario. For each clique, we plot (a) the ratio of the α-pass MAP score with that of TRW-S, and (b) ratio of TRW-S runtime vs α-pass runtime. While both the algorithms report the same MAP, α-pass is still more than 10 times faster on more than one-third of the cliques, and is never slower. This ratio is not as bad as for synthetic cliques mainly because the median clique size here is much smaller at 16.

7.1.2 NON-DECOMPOSABLE POTENTIALS

In this case, we cannot compare against the TRW-S or graph-cut based algorithms. Hence we compare with the ICM algorithm that has been popular in such scenarios (Lu and Getoor, 2003). The scheme of Potetz and Lee (2008) is another alternative, but we omit a comparison with it as it is bound to be quite expensive in m (see discussion in Section 8).

We varied λ with increments of 0.02 in $[0.7, 1.1)$ and generated 500 cliques each from MAJ-DENSE, MAJ-SPARSE, ENTROPY, MAKESPAN and MAKESPAN2. We measure the ratio of MAP score of α-pass with ICM and for each ratio r we plot the fraction of cliques where α-pass returns a MAP score at least r times that of ICM. Figure 3 shows the results on all the potentials except MAJORITY, which will be presented later. The curves for linear and square makespan lie totally to the right of $ratio = 1$, which is expected because α-pass will always return the true MAP for those potentials. In contrast ICM can only return a locally optimal solution. For entropy, α-pass was found to be significantly better than ICM in all the cases. The runtimes of ICM and α-pass were similar.

7.1.3 MAJORITY POTENTIALS

In Figures 4(a) and 4(b), we compare ICM, Lagrangian Relaxation (LR) and modified-α-pass (Section 5.3.1, denoted ModAlpha) against the LP-based exact method (LP) on synthetic data. Each curve plots, for each MAP ratio r, the fraction of cliques on which ICM (or LR or ModAlpha) returns a MAP score better than r times the optimal MAP score. An ideal algorithm's curve would just be a dot at $(1, 1)$ indicating that it retrieves the true MAP for all the cliques.

We observe that on MAJ-DENSE, both ModAlpha and ICM return a MAP score better than 0.85 of the true MAP, with ICM being slightly better. However, LR out-performs both of them, providing a MAP ratio always better than 0.97 and returning the true MAP in more than 70% of the cases. In MAJ-SPARSE too, LR dominates the other two algorithms, returning the true MAP in more than 80% of the cases, with a MAP ratio always better than 0.92. Further it can be derived that on average, LR returns a MAP score 1.15 times that of ICM. Thus, LR performs much better than its competitors across dense as well as sparse majority potentials.

The results on CoNLL data set, whose W matrix is 85% sparse, are displayed in Figure 4(c). ICM, ModAlpha, and LR return the true MAP in 87%, 95% and 99% of the cliques respectively, with the worst case MAP ratio of LR being 0.97 as opposed to 0.94 and 0.74 for ModAlpha and ICM respectively. Figure 4(d) displays runtime ratios on all CoNLL cliques for all three inexact algorithms vs LP. ICM and ModAlpha are roughly 100-10000 times faster than LP, while LR is

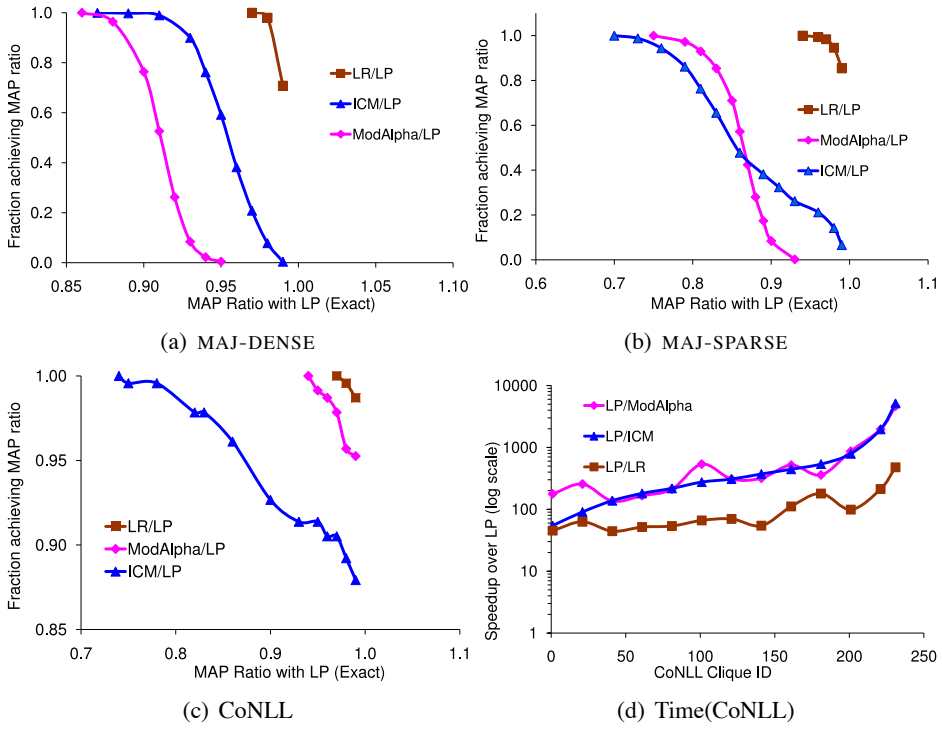

Figure 4: (a)-(c) MAP quality of modified α-pass, ICM, LR vs LP on MAJORITY potentials over MAJ-DENSE, MAJ-SPARSE, and CoNLL. To be interpreted in the same way as Figure 3. (d) Runtime ratios vs LP of these algorithms for each CoNLL clique.

only $3-5$ times more expensive than ICM and ModAlpha on average. Thus, for practical majority potentials, LR and ModAlpha quickly provide highly accurate solutions.

7.2 Collective Labeling of Repeated Words

We now establish that for collective inference setups like the one in Figure 1(d), message passing on the cluster graph (denoted CI) is a better option than the alternatives. This would justify the design of special clique inference algorithms such as α-pass and LR.

We consider information extraction over text records, and define cliques over repeated occurrences of words. We create two versions of the experiment—with Potts and MAJORITY potentials on the cliques respectively. Message computation at those cliques will be done using α-pass and LR respectively, as we have already established their efficiency and accuracy in Section 7.1.

For the edge-decomposable Potts version, we compare CI against TRW-S on the giant pairwise graph. Other algorithms such as FastPD, FastCut, and α-exp are not applicable as none of the chain edge potentials in the giant graph are semi-metric or submodular. For the MAJORITY version, we compare CI against the stacking approach of Krishnan and Manning (2006).

We report results on three data sets—the Address data set consisting of roughly 400 non-US postal addresses, the Cora data set (McCallum et al., 2000) containing 500 bibliographic records, and the CoNLL'03 data set. The training splits were 30%, 10% and 100% respectively for the three

data sets, and the parameter λ for Potts was set to 0.2,1 and 0.05 using cross-validation on a held out split. The MAJORITY parameter W was learnt generatively through label co-occurrence statistics in the cliques present in the training data. We report the token-F1 scores as a measure of accuracy of the various approaches.

Figure 5 reports the combined token-F1 over all labels except 'Other'. Unless specified otherwise, all the approaches post statistically significant gains over the base model. The accuracies show only modest improvements over the base model. This is because our cliques are of a highly limited form and so we cannot expect to correct too many errors using a collective model. We will look at more complex cliques in Section 7.3. Coming back to Figure 5, for MAJORITY potentials, CI is superior to the stacking based approach. The difference is statistically significant for Cora and CoNLL'03. For the Potts version, TRW-S and CI provide similar gains over Address and Cora. We could not run TRW-S on CoNLL'03, as the resulting graph was too big for the TRW-S code to handle.

We now compare the different approaches on running time. In Figure 6 we plot the accuracy of the two methods versus the number of iterations. CI achieves its best accuracy after just one round of message passing, whereas TRW-S takes around 20 iterations. In terms of clock time, an iteration of TRW-S costs $\sim$ 3.2s for CORA, and that of CI costs 3s, so CI is roughly an order of magnitude faster than TRW-S for the same accuracy levels. The comparison was similar for the Address data set.

Potential	**Model**	**Addr**	**Cora**	**CoNLL**
	Base	81.5	88.9	87.0
Potts	CI	81.9	89.7	88.8
	TRW-S	81.9	89.7	-
Majority	CI	82.2	89.6	88.8
	Stacking	81.7*	87.5$\downarrow$	87.8

Figure 5: Token-F1 of various collective inference schemes. F1 averaged over five splits for Address and Cora. '*' and $\downarrow$ denote statistically insignificant difference and significant loss over Base respectively.

7.3 Domain Adaptation

We move on to a generalization of our collective inference framework, and show that capturing associativity of a richer set of properties can help us in domain adaptation. We focus on a citation extraction task, where the aim is to adapt a sequential model across widely varying publications pages of authors. Our data set consists of 433 bibliographic entries from the web-pages of 31 authors, hand-labeled with 14 labels such as Title, Author, Venue, Location and Year. Bibliographic entries across different authors differ in many aspects like label-ordering, missing labels, punctuation, HTML formatting and bibliographic style.

A fraction of the 31 domains were used to train a baseline sequential model. The model was trained with the LARank algorithm of Bordes et al. (2007), using the BCE encoding for the labels.

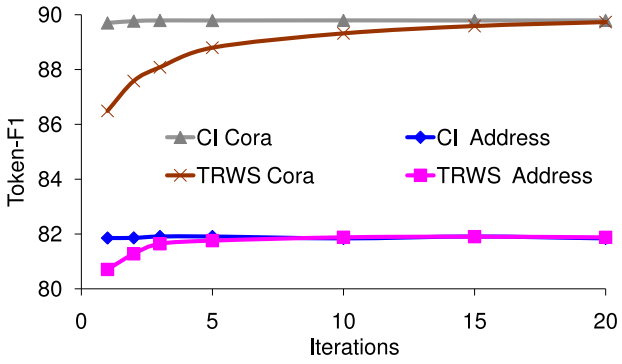

Figure 6: F1 vs iterations for CI vs TRW-S on Cora and Address.

We used standard extraction features in a window around each token, along with label transition features (Peng and McCallum, 2004).

For our collective framework, we used the following Markovian properties:

$$\begin{aligned} g_1(\mathbf{x},\mathbf{y}) &= \text{First non-Other label in } \mathbf{y} \\ g_2(\mathbf{x},\mathbf{y}) &= \text{Token before the Title segment in } \mathbf{y} \\ g_3(\mathbf{x},\mathbf{y}) &= \text{First non-Other label after Title in } \mathbf{y} \\ g_4(\mathbf{x},\mathbf{y}) &= \text{First non-Other label after Venue in } \mathbf{y} \end{aligned}$$

Inside a domain, any one of the above properties will predominantly favor one value, for example, g_3 might favor the value 'Author' in one domain, and 'Date' in another. Thus these properties encourage consistent labeling around the Title and Venue segments. We use Potts potential for each property, setting $\lambda = 1$ using cross-validation.

We reiterate that there are no alternative collective inference schemes for this property-based framework. This is primarily because other algorithms like TRW-S or ordinary belief propagation cannot deal with property-based separators (ref. Section 6).

The performance results of CI with the above properties versus the baseline model are presented in Figure 7. For the test domains, we report token-F1 of the important labels—Title, Author and Venue. The accuracies are averaged over five trials. CI leads to upto 25% reduction over the base test error for Venue and Title, labels for which we had defined related properties. The gain is statistically significant ($p < 0.05$). Though the improvement is more prominent when only a few domains are available for training, we continue to see an improvement even with more training domains as there invariably are new styles in the test data. Figure 8 shows the error reduction on individual test domains for one particular train-test split of five and 26 domains respectively. The errors are computed from the combined token F1 scores of Title, Venue and Author. For some domains the errors are reduced by more than 50%. Collective inference increases errors in only two domains. Such an increase happens when most of the records in the domain take on wrong property values, so collective inference ends up reinforcing those errors by wrongly biasing the remaining minority of the records that have correct property values.

Finally, we mention that for this task, applying the classical collective inference setup with cliques over word repetitions leads to very minor gains. This is because most of the word cliques

already agree on their vertex labels under the base model, so collective inference with word cliques does not add too much value. In this context, the generalized collective inference framework is indeed a much more accurate mechanism for joint labeling.

Train	**Title**		**Venue**		**Author**	
(%)	Base	CI	Base	CI	Base	CI
5	70.7	74.8	58.8	62.5	74.1	74.3
10	78.0	82.1	69.2	72.2	75.6	75.9

8. Related Work

We group the known approaches into various categories and compare them with our collective inference framework.

8.1 Generic Collective Inference Approaches

Collective graphical models have been used to capture associativity in many text mining tasks such as IE, entity labeling, and document classification (Sutton and McCallum, 2004; Finkel et al., 2005; Bunescu and Mooney, 2004; Krishnan and Manning, 2006; Kulkarni et al., 2009; Chakrabarti et al., 1998; Lu and Getoor, 2003; Taskar et al., 2004). However these models use generic algorithms like ordinary belief propagation (Sutton and McCallum, 2004; Bunescu and Mooney, 2004; Taskar et al., 2004), Gibbs sampling (Finkel et al., 2005), local search (Lu and Getoor, 2003) or multi-stage schemes (Krishnan and Manning, 2006). Our framework is general enough to support various clique potentials, yet exploits the structure of the potential to efficiently compute a full set of messages for collective inference.

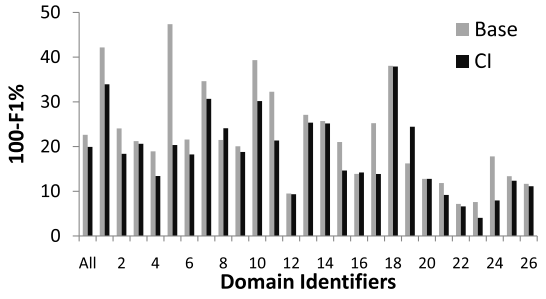

Figure 8: Per-domain F1-error

8.2 MAP Inference on Pairwise Models

We provide only a brief overview of the many recent advances in inference over pairwise graphs since our main interest lies in higher-order potentials. These approaches fall under two broad categories. The first category has message passing algorithms that solve the dual of an LP relaxation, including TRW-S (Kolmogorov, 2006), max-sum diffusion (Werner, 2009), and other convergent alternatives (Meltzer et al., 2009; Ravikumar et al., 2010). These LP relaxations, that only impose local pairwise constraints, have been tightened in various ways using cycle and higher order marginal constraints (Sontag et al., 2008; Werner, 2009; Komodakis and Paragios, 2008; Kumar et al., 2009). The second category includes combinatorial algorithms based on graph-cuts. For binary labels, two well known methods are the graph-cut method for submodular potentials (Boykov et al., 2001) and the Quadratic Pseudo-Boolean Optimization method (QPBO) for getting a partial solution for arbitrary potentials (Boros and Hammer, 2002; Kovtun, 2003; Kolmogorov and Rother, 2007). For multi-label models with metric edge potentials, the α-expansion algorithm of Boykov et al. (2001) provides a 1/2-approximation. α-expansion has subsequently been generalized, analyzed and optimized (Veksler, 2007; Kumar and Torr, 2008b; Lempitsky et al., 2007; Komodakis and Tziritas, 2005; Komodakis et al., 2007b; Alahari et al., 2008). In particular, the FastPD algorithm of Komodakis et al. (2007b) is a primal-dual generalization which works even with semi-metric edge potentials. However our chain edge potentials are not even semi-metric. Similarly the partial optimality guarantee of QPBO is of limited appeal, as our model has a large fraction of non-submodular edges.

8.3 Alternate Collective Inference Frameworks

Recently, two inference frameworks, the LP relaxation of Werner (2008) and the dual-decomposition framework of Komodakis and Paragios (2009) have been extended to handle higher-order potentials. In the LP relaxation framework, a max-sum diffusion algorithm is used to solve the dual and each step of the algorithm requires the computation of max-marginals from the higher-order cliques. In the dual-decomposition framework, the model is decomposed into tractable components and the component MAPs or marginals are used to construct a sub-gradient of the collective inference LP. Like cluster message passing, these frameworks also allow the plugging-in of arbitrary algorithms for computing max-marginals at each clique. Thus, our clique inference algorithms can be used unchanged in these two frameworks. However, while these alternative frameworks provide interesting new ways of looking at inference, they do not necessarily provide faster convergence guarantees. For example, as noted in Werner (2009), max-sum diffusion converges very slowly as compared to TRW-S even for binary potentials. We showed in Section 7.1 that dual decomposition is significantly slower than α-pass when used for clique inference.

8.4 Transforming Higher-Order Cliques to Pairwise Potentials

A lot of recent work on higher-order clique potentials in vision deals with reducing these potentials to pairwise and then applying α-expansion or QPBO as applicable (Ishikawa, 2009; Kohli et al., 2008; Ramalingam et al., 2008; Rother et al., 2009; Kohli and Kumar, 2010). These transformations add auxiliary nodes, which are few in number when the potentials are truncated and sparse (Rother et al., 2009). However our potentials are dense and not truncated. Consequently these techniques will introduce too many extra nodes, for example, exponential in n (Ishikawa, 2009), or $O(mn)$

(Kohli et al., 2008). Similarly, the method of Kohli and Kumar (2010) will expand the node set by a factor equal to the number of functions used to approximate our potential (and this can be quite large). Too many auxiliary nodes makes inference using α-expansion/QPBO quite expensive. In contrast we perform clique inference without any transformation, and our clique inference bounds are better than the alternatives.

We also note that there are transformations that extend α-expansion to metric potentials over triangles (Kolmogorov and Zabih, 2004), and truncated versions of Potts potentials over arbitrarily large cliques (Kohli et al., 2007, 2009). Our symmetric potentials are not truncated so the same transformations cannot be applied to our model.

8.5 Special Higher-Order Potentials

An orthogonal body of work deals with special higher-order potentials that allow efficient message computation, such as linear-constrained potentials (Potetz and Lee, 2008), convex and order-based potentials (Tarlow et al., 2010), and decomposable potentials (Chen et al., 2008). Although our cluster graph can seamlessly incorporate these potentials and their clique inference algorithms, it is fruitful to compare some of these potentials with ours. Linear-constrained potentials assume that the labels are numeric and the potential's value depends only on a linear combination of node labels. Such potentials allow $O(nm^2)$ message computation using clever variable substitution during belief propagation. When we have only two labels, our symmetric potentials can be encoded as linear-constrained potentials, thus leading to $O(n)$ clique inference as compared to $O(n \log n)$ using α-pass. However, this encoding does not have an inexpensive generalization to *discrete* multi-label cliques. Also, representing multi-label potentials using a collection of linear-constrained potentials can make clique inference exponential in m (Potetz and Lee, 2008). Chen et al. (2008) propose *decomposable potentials* that are sums of a few sub-potentials, each of which is a product of low-arity functions. This includes the *Voting Potential*, which combines associativity scores additively along edges unlike multiplicatively as in Potts.[3] For some decomposable potentials, including the Voting Potential, exact messages can be computed in closed form.

Symmetric potentials have been used in special ways in other inference tasks too. Jaimovich et al. (2007) proposed a framework for inference over relational data where symmetric potentials are used to collapse large instance-level factor graphs into template-level graphs. Similarly, Milch et al. (2008) proposes lifting techniques with counting potentials. In our framework we have a mix of symmetric potentials, individual node and non-symmetric edge potentials. We therefore cannot perform any kind of collapsing or lifted inference.

9. Conclusions and Future Work

We presented a general collective inference framework that exploits the associativity of a rich set of properties of instances and their labelings. We argued that cluster message passing, which exploits the special associative structure and computes a complete set of messages, is a more principled inference mechanism than other cluster-oblivious or message-oblivious approaches. We demonstrated the effectiveness of the framework on a real-life domain adaptation task.

3. Although Potts decomposes additively along the clique edges, the probability $P(\mathbf{y}|\mathbf{x})$ is exponential in the clique potential term, which makes it multiplicative.

We presented potential-specific combinatorial algorithms for message computation in associative cliques. We presented the α-pass algorithm which is sub-quadratic in the clique size and gives the exact MAP for all MAX clique potentials, and any symmetric potential with two labels, and a tight approximation guarantee of $\frac{13}{15}$ on the Potts potential. We showed that α-pass is significantly faster while providing the same or better accuracy than alternatives such as TRW-S, graph-cuts, and their recently proposed improved versions. We gave a Lagrangian relaxation method for generating messages from a clique with majority potential. This algorithm is at least two orders of magnitude faster than an exact algorithm and more accurate than other approximate approaches.

Our future work includes automated property induction to figure out rich associative properties in unlabeled domains. We are also interested in applying symmetric potentials to general dense subgraphs instead of cliques. We believe that this might help in semi-supervised learning tasks.

Appendix A. Proofs

Theorem 7 *$F(\hat{\mathbf{y}}) \geq \frac{13}{15} F(\mathbf{y}^*)$. Further, this ratio is tight.*

Proof The proof is by contradiction. Suppose there is an instance where $F(\hat{\mathbf{y}}) < \frac{13}{15} F(\mathbf{y}^*)$. Wlog assume that $\lambda = 1$ and $n_1 \geq n_2 \geq \ldots \geq n_k > 0,\ (2 \leq k \leq m)$ be the non-zero counts in the optimal solution and let ψ^* be its vertex score. Thus $F(\mathbf{y}^*) = \psi^* + n_1^2 + n_2^2 + \ldots + n_k^2$.

Now, $F(\hat{\mathbf{y}})$ is at least $\psi^* + n_1^2$ (ref. Claim 5.1). This implies $\frac{\psi^* + n_1^2}{\psi^* + n_1^2 + \ldots + n_k^2} \leq \frac{13}{15}$, that is, $2(\psi^* + n_1^2) < 13(n_2^2 + \ldots + n_k^2)$ or

$$\psi^* < \frac{13}{2}(n_2^2 + \ldots + n_k^2) - n_1^2. \tag{18}$$

Since k labels have non-zero counts, and the vertex score is ψ^*, at least ψ^*/k of the vertex score is assigned to one label. Considering a solution where all vertices are assigned to this label, we get $F(\hat{\mathbf{y}}) \geq \psi^*/k + n^2$.

Therefore $F(\mathbf{y}^*) > 15/13(n^2 + \psi^*/k)$.

Since $F(\mathbf{y}^*) = \psi^* + n_1^2 + \ldots + n_k^2$, we get:

$$\psi^* > \frac{15kn^2 - 13k(n_1^2 + \ldots + n_k^2)}{13k - 15}. \tag{19}$$

We show that Equations 18 and 19 contradict each other. It is sufficient to show that for all $n_1 \geq \ldots \geq n_k \geq 1$,

$$\frac{15kn^2 - 13k(n_1^2 + \ldots n_k^2)}{13k - 15} \geq \frac{13}{2}(n_2^2 + \ldots + n_k^2) - n_1^2.$$

Simplifying, this is equivalent to

$$kn^2 - \frac{13}{2}(k-1)(n_2^2 + \ldots + n_k^2) - n_1^2 \geq 0.$$

Consider a sequence $n_1, \ldots, n_k$ for which the expression on the left hand side is minimized. If $n_i > n_{i+1}$ then we must have $n_l = 1\ \forall l \geq i+2$. Otherwise, replace n_{i+1} by $n_{i+1} + 1$ and decrement n_j by 1, where j is the largest index for which $n_j > 1$. This gives a new sequence for which the value of the expression is smaller. Therefore the sequence must be of the form $n_i = n_1$ for $1 \leq i < l$ and $n_i = 1$ for $i > l$, for some $l \geq 2$. Further, considering the expression as a function of n_l, it is

quadratic with a negative second derivative. So the minimum occurs at one of the extreme values $n_l = 1$ or $n_l = n_1$. Therefore we only need to consider sequences of the form $n_1, \ldots, n_1, 1, \ldots, 1$ and show that the expression is non-negative for these.

In such sequences, differentiating with respect to n_1, the derivative is positive for $n_1 \geq 1$, which means that the expression is minimized for the sequence $1, \ldots, 1$. Now it is easy to verify that it is true for such sequences. The expression is zero only for the sequence $1, 1, 1$, which gives the worst case example.

We now illustrate the tightness of this ratio through a pathological instance where the solution of α-pass is exactly $\frac{13}{15}$ of the optimal. The clique is constructed as follows. Let $m = n + 3$ and $\lambda = 1$. For the first $n/3$ vertices let $\psi_{u1} = 4n/3$, for the next $n/3$ vertices let $\psi_{u2} = 4n/3$, and for the remaining $n/3$ let $\psi_{u3} = 4n/3$. Also for all vertices let $\psi_{u(u+3)} = 4n/3$. All other vertex scores are zero. The optimal solution is to assign the first three labels $n/3$ vertices each, yielding a score of $4n^2/3 + 3(\frac{n}{3})^2 = 5n^2/3$. The first α-pass with $\alpha = 1$, where initially a vertex u is assigned its vertex optimal label $u + 3$, will assign the first $n/3$ vertices label 1. This keeps the sum of total vertex scores unchanged at $4n^2/3$, the clique score increases to $n^2/9 + 2n/3$ and total score = $4n^2/3 + n^2/9 + 2n/3 = 13n^2/9 + 2n/3$. No subsequent combinations with any other label α can improve this score. Thus, the score of α-pass is $\frac{13}{15}$ of the optimal in the limit $n \to \infty$. ■

Theorem 8 *Generalized α-pass enjoys an approximation bound of $\frac{8}{9}$, that is, $F(\hat{\mathbf{y}}) \geq \frac{8}{9} F(\mathbf{y}^*)$.*

Proof This bound is achieved if we run the algorithm with $q = 2$. Let the optimal solution have counts $n_1 \geq n_2 \geq \ldots \geq n_m$ and let its vertex score be ψ^*. For simplicity let $a = n_1/n$, $b = n_2/n$ and $c = \psi^*/n^2$. Then $F(\mathbf{y}^*)/n^2 \leq c + a^2 + b(1-a)$, $F(\hat{\mathbf{y}})/n^2 \geq c + a^2$ and $F(\hat{\mathbf{y}})/n^2 \geq c + \frac{(a+b)^2}{2}$.
Case 1: $a^2 \geq \frac{(a+b)^2}{2}$. Then $F(\mathbf{y}^*) - F(\hat{\mathbf{y}}) \leq bn^2(1-a)$. For a given value of a, this is maximized when b is as large as possible. For Case 1 to hold, the largest possible value of b is given by $a^2 = \frac{(a+b)^2}{2}$, which gives $b = a(\sqrt{2}-1)$. Therefore $F(\mathbf{y}^*) - F(\hat{\mathbf{y}}) \leq \frac{n^2(\sqrt{2}-1)}{4} < \frac{n^2}{8} \leq \frac{F(\hat{\mathbf{y}})}{8}$, that is, $F(\hat{\mathbf{y}}) \geq \frac{8}{9} F(\mathbf{y}^*)$.
Case 2: $a^2 \leq \frac{(a+b)^2}{2}$. This holds if $b \geq (\sqrt{2}-1)a$. Since $a + b \leq 1$, this is possible only if $a \leq 1/\sqrt{2}$. Now $\frac{F(\mathbf{y}^*) - F(\hat{\mathbf{y}})}{n^2} \leq a^2 + b(1-a) - (a+b)^2/2 = \frac{a^2 - 4ab + 2b - b^2}{2}$.

For a given a, this expression is quadratic in b with a negative second derivative. This is maximized (by differentiating) for $b = 1 - 2a$. Since $b \leq a$, this value is possible only if $a \geq 1/3$. Similarly, for case 2 to hold with this value of b, we must have $a \leq \sqrt{2} - 1$. Substituting this value of b, the difference in scores is $\frac{5a^2 - 4a + 1}{2}$.

Since this is quadratic with a positive second derivative, it is maximized when a has either the minimum or maximum possible value. For $a = 1/3$ this value is $1/9$, while for $a = \sqrt{2} - 1$, it is $10 - 7\sqrt{2}$. In both cases, it is less than $1/8$.

If $a \leq 1/3$ the maximum is achieved when $b = a$. In this case, the score difference is at most $(a - 2a^2)$ which is maximized for $a = 1/4$, where the value is $1/8$. (This is the worst case).

For $\sqrt{2} - 1 < a \leq 1/\sqrt{2}$, the maximum will occur for $b = (\sqrt{2}-1)a$. Substituting this value for b, the score difference is $(\sqrt{2}-1)(a - a^2)$, which is maximized for $a = 1/2$, where its value is $(\sqrt{2}-1)/4 < 1/8$. ■

Abstract

With the goal to generate more scalable algorithms with higher efficiency and fewer open parameters, reinforcement learning (RL) has recently moved towards combining classical techniques from optimal control and dynamic programming with modern learning techniques from statistical estimation theory. In this vein, this paper suggests to use the framework of stochastic optimal control with path integrals to derive a novel approach to RL with parameterized policies. While solidly grounded in value function estimation and optimal control based on the stochastic Hamilton-Jacobi-Bellman (HJB) equations, policy improvements can be transformed into an approximation problem of a path integral which has no open algorithmic parameters other than the exploration noise. The resulting algorithm can be conceived of as model-based, semi-model-based, or even model free, depending on how the learning problem is structured. The update equations have no danger of numerical instabilities as neither matrix inversions nor gradient learning rates are required. Our new algorithm demonstrates interesting similarities with previous RL research in the framework of probability matching and provides intuition why the slightly heuristically motivated probability matching approach can actually perform well. Empirical evaluations demonstrate significant performance improvements over gradient-based policy learning and scalability to high-dimensional control problems. Finally, a learning experiment on a simulated 12 degree-of-freedom robot dog illustrates the functionality of our algorithm in a complex robot learning scenario. We believe that **P**olicy **I**mprovement with **P**ath **I**ntegrals (**PI**^{2}) offers currently one of the most efficient, numerically robust, and easy to implement algorithms for RL based on trajectory roll-outs.

Keywords: stochastic optimal control, reinforcement learning, parameterized policies

1. Introduction

While reinforcement learning (RL) is among the most general frameworks of learning control to create truly autonomous learning systems, its scalability to high-dimensional continuous state-action systems, for example, humanoid robots, remains problematic. Classical value-function based methods with function approximation offer one possible approach, but function approximation under the non-stationary iterative learning process of the value-function remains difficult when one exceeds about 5-10 dimensions. Alternatively, direct policy learning from trajectory roll-outs has recently made significant progress (Peters, 2007), but can still become numerically brittle and full of open

∗. Also at ATR Computational Neuroscience Laboratories, Kyoto 619-0288, Japan.

tuning parameters in complex learning problems. In new developments, RL researchers have started to combine the well-developed methods from statistical learning and empirical inference with classical RL approaches in order to minimize tuning parameters and numerical problems, such that ultimately more efficient algorithms can be developed that scale to significantly more complex learning system (Dayan and Hinton, 1997; Koeber and Peters, 2008; Peters and Schaal, 2008c; Toussaint and Storkey, 2006; Ghavamzadeh and Yaakov, 2007; Deisenroth et al., 2009; Vlassis et al., 2009; Jetchev and Toussaint, 2009).

In the spirit of these latter ideas, this paper addresses a new method of probabilistic reinforcement learning derived from the framework of stochastic optimal control and path integrals, based on the original work of Kappen (2007) and Broek et al. (2008). As will be detailed in the sections below, this approach makes an appealing theoretical connection between value function approximation using the stochastic HJB equations and direct policy learning by approximating a path integral, that is, by solving a statistical inference problem from sample roll-outs. The resulting algorithm, called **P**olicy **I**mprovement with **P**ath **I**ntegrals (**PI**^{2}), takes on a surprisingly simple form, has no open algorithmic tuning parameters besides the exploration noise, and it has numerically robust performance in high dimensional learning problems. It also makes an interesting connection to previous work on RL based on probability matching (Dayan and Hinton, 1997; Peters and Schaal, 2008c; Koeber and Peters, 2008) and motivates why probability matching algorithms can be successful.

This paper is structured into several major sections:

- Section 2 addresses the theoretical development of stochastic optimal control with path integrals. This is a fairly theoretical section. For a quick reading, we would recommend Section 2.1 for our basic notation, and Table 1 for the final results. Exposing the reader to a sketch of the details of the derivations opens the possibility to derive path integral optimal control solutions for other dynamical systems than the one we address in Section 2.1.

  The main steps of the theoretical development include:

  - Problem formulation of stochastic optimal control with the stochastic Hamilton-Jacobi-Bellman (HJB) equation
  - The transformation of the HJB into a linear PDE
  - The generalized path integral formulation for control systems with controlled and uncontrolled differential equations
  - General derivation of optimal controls for the path integral formalism
  - Path integral optimal control applied to special cases of control systems

- Section 3 relates path integral optimal control to reinforcement learning. Several main issues are addressed:

  - Reinforcement learning with parameterized policies
  - Dynamic Movement Primitives (DMP) as a special case of parameterized policies, which matches the problem formulation of path integral optimal control.
  - Derivation of **P**olicy **I**mprovement with **P**ath **I**ntegrals (**PI**^{2}), which is an application of path integral optimal control to DMPs.

- Section 4 discusses related work.

- Section 5 illustrates several applications of $\mathbf{PI}^2$ to control problems in robotics.
- Section 6 addresses several important issues and characteristics of RL with $\mathbf{PI}^2$.

2. Stochastic Optimal Control with Path Integrals

The goal in stochastic optimal control framework is to control a stochastic dynamical system while minimizing a performance criterion. Therefore, stochastic optimal control can be thought as a constrained optimization problem in which the constrains corresponds to stochastic dynamical systems. The analysis and derivations of stochastic optimal control and path integrals in the next sections rely on the Bellman Principle of optimality (Bellman and Kalaba, 1964) and the HJB equation.

2.1 Stochastic Optimal Control Definition and Notation

For our technical developments, we will use largely a control theoretic notation from trajectory-based optimal control, however, with an attempt to have as much overlap as possible with the standard RL notation (Sutton and Barto, 1998). Let us define a finite horizon cost function for a trajectory τ_i (which can also be a piece of a trajectory) starting at time t_i in state $\mathbf{x}_{t_i}$ and ending at time[1] t_N

$$R(\tau_i) = \phi_{t_N} + \int_{t_i}^{t_N} r_t \, dt, \tag{1}$$

with $\phi_{t_N} = \phi(x_{t_N})$ denoting a terminal reward at time t_N and r_t denoting the immediate cost at time t. In stochastic optimal control (Stengel, 1994), the goal is to find the controls $\mathbf{u}_t$ that minimize the value function:

$$V(\mathbf{x}_{t_i}) = V_{t_i} = \min_{\mathbf{u}_{t_i:t_N}} E_{\tau_i}\left[R(\tau_i)\right], \tag{2}$$

where the expectation $E_{\tau_i}[.]$ is taken over all trajectories starting at $\mathbf{x}_{t_i}$. We consider the rather general class of control systems:

$$\dot{\mathbf{x}}_t = \mathbf{f}(\mathbf{x}_t,t) + \mathbf{G}(\mathbf{x}_t)\left(\mathbf{u}_t + \varepsilon_t\right) = \mathbf{f}_t + \mathbf{G}_t\left(\mathbf{u}_t + \varepsilon_t\right), \tag{3}$$

with $\mathbf{x}_t \in \Re^{n\times 1}$ denoting the state of the system, $\mathbf{G}_t = \mathbf{G}(\mathbf{x}_t) \in \Re^{n\times p}$ the control matrix, $\mathbf{f}_t = \mathbf{f}(\mathbf{x}_t) \in \Re^{n\times 1}$ the passive dynamics, $\mathbf{u}_t \in \Re^{p\times 1}$ the control vector and $\varepsilon_t \in \Re^{p\times 1}$ Gaussian noise with variance Σ_ε. As immediate cost we consider

$$r_t = r(\mathbf{x}_t,\mathbf{u}_t,t) = q_t + \frac{1}{2}\mathbf{u}_t^T\mathbf{R}\mathbf{u}_t, \tag{4}$$

where $q_t = q(\mathbf{x}_t,t)$ is an arbitrary state-dependent cost function, and $\mathbf{R}$ is the positive semi-definite weight matrix of the quadratic control cost. The stochastic HJB equation (Stengel, 1994; Fleming and Soner, 2006) associated with this stochastic optimal control problem is expressed as follows:

$$-\partial_t V_t = \min_{\mathbf{u}}\left(r_t + (\nabla_{\mathbf{x}}V_t)^T\mathbf{F}_t + \frac{1}{2}trace\left((\nabla_{\mathbf{xx}}V_t)\mathbf{G}_t\Sigma_\varepsilon\mathbf{G}_t^T\right)\right), \tag{5}$$

1. If we need to emphasize a particular time, we denote it by t_i, which also simplifies a transition to discrete time notation later. We use t without subscript when no emphasis is needed when this "time slice" occurs, t_0 for the start of a trajectory, and t_N for the end of a trajectory.

where $\mathbf{F}_t$ is defined as $\mathbf{F}_t = \mathbf{f}(\mathbf{x}_t, t) + \mathbf{G}(\mathbf{x}_t)\mathbf{u}_t$. To find the minimum, the cost function (4) is inserted into (5) and the gradient of the expression inside the parenthesis is taken with respect to controls $\mathbf{u}$ and set to zero. The corresponding optimal control is given by the equation:

$$\mathbf{u}(\mathbf{x}_t) = \mathbf{u}_t = -\mathbf{R}^{-1}\mathbf{G}_t^T(\nabla_{x_t} V_t).$$

Substitution of the optimal control above, into the stochastic HJB (5), results in the following nonlinear and second order Partial Differential Equation (PDE):

$$-\partial_t V_t = q_t + (\nabla_{\mathbf{x}} V_t)^T \mathbf{f}_t - \frac{1}{2}(\nabla_{\mathbf{x}} V_t)^T \mathbf{G}_t \mathbf{R}^{-1} \mathbf{G}_t^T (\nabla_{\mathbf{x}} V_t) + \frac{1}{2} trace\left((\nabla_{\mathbf{xx}} V_t)\mathbf{G}_t \Sigma_{\varepsilon} \mathbf{G}_t^T\right).$$

The $\nabla_{\mathbf{x}}$ and $\nabla_{\mathbf{xx}}$ symbols refer to the Jacobian and Hessian, respectively, of the value function with respect to the state $\mathbf{x}$, while ∂_t is the partial derivative with respect to time. For notational compactness, we will mostly use subscripted symbols to denote time and state dependencies, as introduced in the equations above.

2.2 Transformation of HJB into a Linear PDE

In order to find a solution to the PDE above, we use a exponential transformation of the value function:

$$V_t = -\lambda \log \Psi_t.$$

Given this logarithmic transformation, the partial derivatives of the value function with respect to time and state are expressed as follows:

$$\partial_t V_t = -\lambda \frac{1}{\Psi_t} \partial_t \Psi_t,$$

$$\nabla_{\mathbf{x}} V_t = -\lambda \frac{1}{\Psi_t} \nabla_{\mathbf{x}} \Psi_t,$$

$$\nabla_{\mathbf{xx}} V_t = \lambda \frac{1}{\Psi_t^2} \nabla_{\mathbf{x}} \Psi_t \, \nabla_{\mathbf{x}} \Psi_t^T - \lambda \frac{1}{\Psi_t} \nabla_{\mathbf{xx}} \Psi_t.$$

Inserting the logarithmic transformation and the derivatives of the value function we obtain:

$$\frac{\lambda}{\Psi_t} \partial_t \Psi_t = q_t - \frac{\lambda}{\Psi_t} (\nabla_{\mathbf{x}} \Psi_t)^T \mathbf{f}_t - \underline{\frac{\lambda^2}{2\Psi_t^2} (\nabla_{\mathbf{x}} \Psi_t)^T \mathbf{G}_t \mathbf{R}^{-1} \mathbf{G}_t^T (\nabla_{\mathbf{x}} \Psi_t)} + \frac{1}{2} trace(\Gamma), \tag{6}$$

where the term Γ is expressed as:

$$\Gamma = \left(\lambda \frac{1}{\Psi_t^2} \nabla_{\mathbf{x}} \Psi_t \, \nabla_{\mathbf{x}} \Psi_t^T - \lambda \frac{1}{\Psi_t} \nabla_{\mathbf{xx}} \Psi_t \right) \mathbf{G}_t \Sigma_{\varepsilon} \mathbf{G}_t^T.$$

The trace of Γ is therefore:

$$trace(\Gamma) = \underline{\lambda \frac{1}{\Psi^2} trace\left(\nabla_{\mathbf{x}} \Psi_t^T \mathbf{G}_t \Sigma_{\varepsilon} \mathbf{G}_t \nabla_{\mathbf{x}} \Psi_t\right)} - \lambda \frac{1}{\Psi_t} trace\left(\nabla_{\mathbf{xx}} \Psi_t \mathbf{G}_t \Sigma_{\varepsilon} \mathbf{G}_t^T\right). \tag{7}$$

Comparing the underlined terms in (6) and (7), one can recognize that these terms will cancel under the assumption of $\lambda \mathbf{R}^{-1} = \Sigma_\varepsilon$, which implies the simplification:

$$\lambda \mathbf{G}_t \mathbf{R}^{-1} \mathbf{G}_t^T = \mathbf{G}_t \Sigma_\varepsilon \mathbf{G}_t^T = \Sigma(\mathbf{x}_t) = \Sigma_t. \tag{8}$$

The intuition behind this assumption (cf. also Kappen, 2007; Broek et al., 2008) is that, since the weight control matrix $\mathbf{R}$ is inverse proportional to the variance of the noise, a high variance control input implies cheap control cost, while small variance control inputs have high control cost. From a control theoretic stand point such a relationship makes sense due to the fact that under a large disturbance (= high variance) significant control authority is required to bring the system back to a desirable state. This control authority can be achieved with corresponding low control cost in $\mathbf{R}$.

With this simplification, (6) reduces to the following form

$$-\partial_t \Psi_t = -\frac{1}{\lambda} q_t \Psi_t + \mathbf{f}_t^T (\nabla_{\mathbf{x}} \Psi_t) + \frac{1}{2} trace \left((\nabla_{\mathbf{xx}} \Psi_t) \mathbf{G}_t \Sigma_\varepsilon \mathbf{G}_t^T \right), \tag{9}$$

with boundary condition: $\Psi_{t_N} = \exp\left(-\frac{1}{\lambda}\phi_{t_N}\right)$. The partial differential equation (PDE) in (9) corresponds to the so called Chapman Kolmogorov PDE, which is of second order and linear. Analytical solutions of (9) cannot be found in general for general nonlinear systems and cost functions. However, there is a connection between solutions of PDEs and their representation as stochastic differential equation (SDEs), that is mathematically expressed by the Feynman-Kac formula (Øksendal, 2003; Yong, 1997). The Feynman-Kac formula (see appendix B) can be used to find distributions of random processes which solve certain SDEs as well as to propose numerical methods for solving certain PDEs. Applying the Feynman-Kac theorem, the solution of (9) is:

$$\Psi_{t_i} = E_{\boldsymbol{\tau}_i} \left(\Psi_{t_N} e^{-\int_{t_i}^{t_N} \frac{1}{\lambda} q_t dt} \right) = E_{\boldsymbol{\tau}_i} \left[\exp\left(-\frac{1}{\lambda}\phi_{t_N} - \frac{1}{\lambda} \int_{t_i}^{t_N} q_t \, dt \right) \right]. \tag{10}$$

Thus, we have transformed our stochastic optimal control problem into the approximation problem of a path integral. With a view towards a discrete time approximation, which will be needed for numerical implementations, the solution (10) can be formulated as:

$$\Psi_{t_i} = \lim_{dt \to 0} \int p(\boldsymbol{\tau}_i | \mathbf{x}_i) \exp\left[-\frac{1}{\lambda} \left(\phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} dt \right) \right] d\boldsymbol{\tau}_i, \tag{11}$$

where $\boldsymbol{\tau}_i = (\mathbf{x}_{t_i}, ..., \mathbf{x}_{t_N})$ is a sample path (or trajectory piece) starting at state $\mathbf{x}_{t_i}$ and the term $p(\boldsymbol{\tau}_i | \mathbf{x}_i)$ is the probability of sample path $\boldsymbol{\tau}_i$ conditioned on the start state $\mathbf{x}_{t_i}$. Since Equation (11) provides the exponential cost to go Ψ_{t_i} in state $\mathbf{x}_{t_i}$, the integration above is taken with respect to sample paths $\boldsymbol{\tau}_i = (\mathbf{x}_{t_i}, \mathbf{x}_{t_{i+1}}, ..., \mathbf{x}_{t_N})$. The differential term $d\boldsymbol{\tau}_i$ is defined as $d\boldsymbol{\tau}_i = (d\mathbf{x}_{t_i}, ..., d\mathbf{x}_{t_N})$. Evaluation of the stochastic integral in (11) requires the specification of $p(\boldsymbol{\tau}_i | \mathbf{x}_i)$, which is the topic of our analysis in the next section.

2.3 Generalized Path Integral Formulation

To develop our algorithms, we will need to consider a more general development of the path integral approach to stochastic optimal control than presented in Kappen (2007) and Broek et al. (2008). In particular, we have to address that in many stochastic dynamical systems, the control transition matrix $\mathbf{G}_t$ is state dependent and its structure depends on the partition of the state in directly and

non-directly actuated parts. Since only some of the states are directly controlled, the state vector is partitioned into $\mathbf{x} = [\mathbf{x}^{(m)^T} \;\; \mathbf{x}^{(c)^T}]^T$ with $\mathbf{x}^{(m)} \in \Re^{k\times 1}$ the non-directly actuated part and $\mathbf{x}^{(c)} \in \Re^{l\times 1}$the directly actuated part. Subsequently, the passive dynamics term and the control transition matrix can be partitioned as $\mathbf{f}_t = [\mathbf{f}_t^{(m)^T} \;\; \mathbf{f}_t^{(c)^T}]^T$ with $\mathbf{f}_m \in \Re^{k\times 1}$, $\mathbf{f}_c \in \Re^{l\times 1}$ and $\mathbf{G}_t = [0_{k\times p} \;\; \mathbf{G}_t^{(c)^T}]^T$ with $\mathbf{G}_t^{(c)} \in \Re^{l\times p}$. The discretized state space representation of such systems is given as:

$$\mathbf{x}_{t_{i+1}} = \mathbf{x}_{t_i} + \mathbf{f}_{t_i} dt + \mathbf{G}_{t_i} \left(\mathbf{u}_{t_i} dt + \sqrt{dt}\varepsilon_{t_i} \right),$$

or, in partitioned vector form:

$$\begin{pmatrix} \mathbf{x}_{t_{i+1}}^{(m)} \\ \mathbf{x}_{t_{i+1}}^{(c)} \end{pmatrix} = \begin{pmatrix} \mathbf{x}_{t_i}^{(m)} \\ \mathbf{x}_{t_i}^{(c)} \end{pmatrix} + \begin{pmatrix} \mathbf{f}_{t_i}^{(m)} \\ \mathbf{f}_{t_i}^{(c)} \end{pmatrix} dt + \begin{pmatrix} 0_{k\times p} \\ \mathbf{G}_{t_i}^{(c)} \end{pmatrix} \left(\mathbf{u}_{t_i} dt + \sqrt{dt}\varepsilon_{t_i} \right). \tag{12}$$

Essentially the stochastic dynamics are partitioned into controlled equations in which the state $\mathbf{x}_{t_{i+1}}^{(c)}$ is directly actuated and the uncontrolled equations in which the state $\mathbf{x}_{t_{i+1}}^{(m)}$ is not directly actuated. Since stochasticity is only added in the directly actuated terms (c) of (12), we can develop $p(\tau_i|\mathbf{x}_i)$ as follows.

$$\begin{aligned} p(\tau_i|\mathbf{x}_{t_i}) &= p(\tau_{i+1}|\mathbf{x}_{t_i}) \\ &= p(\mathbf{x}_{t_N}, ..., \mathbf{x}_{t_{i+1}}|\mathbf{x}_{t_i}) \\ &= \Pi_{j=i}^{N-1} p\left(\mathbf{x}_{t_{j+1}}|\mathbf{x}_{t_j}\right), \end{aligned}$$

where we exploited the fact that the start state $\mathbf{x}_{t_i}$ of a trajectory is given and does not contribute to its probability. For systems where the control has lower dimensionality than the state (12), the transition probabilities $p\left(\mathbf{x}_{t_{j+1}}|\mathbf{x}_{t_j}\right)$ are factorized as follows:

$$\begin{aligned} p\left(\mathbf{x}_{t_{j+1}}|\mathbf{x}_{t_j}\right) &= p\left(\mathbf{x}_{t_{j+1}}^{(m)}|\mathbf{x}_{t_j}\right) \cdot p\left(\mathbf{x}_{t_{j+1}}^{(c)}|\mathbf{x}_{t_j}\right) \\ &= p\left(\mathbf{x}_{t_{j+1}}^{(m)}|\mathbf{x}_{t_j}^{(m)}, \mathbf{x}_{t_j}^{(c)}\right) \cdot p\left(\mathbf{x}_{t_{j+1}}^{(c)}|\mathbf{x}_{t_j}^{(m)}, \mathbf{x}_{t_j}^{(c)}\right) \\ &\propto p\left(\mathbf{x}_{t_{j+1}}^{(c)}|\mathbf{x}_{t_j}\right), \end{aligned} \tag{13}$$

where we have used the fact that $p\left(\mathbf{x}_{t_{i+1}}^{(m)}|\mathbf{x}_{t_i}^{(m)}, \mathbf{x}_{t_i}^{(c)}\right)$ is the Dirac delta function, since $\mathbf{x}_{t_{j+1}}^{(m)}$ can be computed deterministically from $\mathbf{x}_{t_j}^{(m)}, \mathbf{x}_{t_j}^{(c)}$. For all practical purposes,[2] the transition probability of the stochastic dynamics is reduced to the transition probability of the directly actuated part of the state:

$$p(\tau_i|\mathbf{x}_{t_i}) = \Pi_{j=i}^{N-1} p\left(\mathbf{x}_{t_{j+1}}|\mathbf{x}_{t_j}\right) \propto \Pi_{j=i}^{N-1} p\left(\mathbf{x}_{t_{j+1}}^{(c)}|\mathbf{x}_{t_j}\right). \tag{14}$$

Since we assume that the noise ε is zero mean Gaussian distributed with variance Σ_ε, where $\Sigma_\varepsilon \in \Re^{l\times l}$, the transition probability of the directly actuated part of the state is defined as:[3]

$$p\left(\mathbf{x}_{t_{j+1}}^{(c)}|\mathbf{x}_{t_j}\right) = \frac{1}{\left((2\pi)^l \cdot |\Sigma_{t_j}|\right)^{1/2}} \exp\left(-\frac{1}{2} \left\| \mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)} - \mathbf{f}_{t_j}^{(c)} dt \right\|_{\Sigma_{t_j}^{-1}}^2 \right), \tag{15}$$

2. The delta functions will all integrate to 1 in the path integral.

3. For notational simplicity, we write weighted square norms (or Mahalanobis distances) as $\mathbf{v}^T\mathbf{M}\mathbf{v} = \|\mathbf{v}\|_{\mathbf{M}}^2$.

where the covariance $\Sigma_{t_j} \in \Re^{l \times l}$ is expressed as $\Sigma_{t_j} = \mathbf{G}_{t_j}^{(c)} \Sigma_\varepsilon \mathbf{G}_{t_j}^{(c)^T} dt$. Combining (15) and (14) results in the probability of a path expressed as:

$$p(\tau_i|\mathbf{x}_{t_i}) \propto \frac{1}{\Pi_{j=i}^{N-1} \left((2\pi)^l |\Sigma_{t_j}|\right)^{1/2}} \exp\left(-\frac{1}{2}\sum_{j=1}^{N-1} \left\| \mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)} - \mathbf{f}_{t_j}^{(c)} dt \right\|_{\Sigma_{t_j}^{-1}}^2\right).$$

Finally, we incorporate the assumption (8) about the relation between the control cost and the variance of the noise, which needs to be adjusted to the controlled space as $\Sigma_{t_j} = \mathbf{G}_{t_j}^{(c)} \Sigma_\varepsilon \mathbf{G}_{t_j}^{(c)^T} dt = \lambda \mathbf{G}_{t_j}^{(c)} \mathbf{R}^{-1} \mathbf{G}_{t_j}^{(c)^T} dt = \lambda \mathbf{H}_{t_j} dt$ with $\mathbf{H}_{t_j} = \mathbf{G}_{t_j}^{(c)} \mathbf{R}^{-1} \mathbf{G}_{t_j}^{(c)^T}$. Thus, we obtain:

$$p(\tau_i|\mathbf{x}_{t_i}) \propto \frac{1}{\Pi_{j=i}^{N-1} \left((2\pi)^l |\Sigma_{t_j}|\right)^{1/2}} \exp\left(-\frac{1}{2\lambda}\sum_{j=i}^{N-1} \left\| \frac{\mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)}}{dt} - \mathbf{f}_{t_j}^{(c)} \right\|_{\mathbf{H}_{t_j}^{-1}}^2 dt\right).$$

With this formulation of the probability of a trajectory, we can rewrite the the path integral (11) as:

$$\begin{aligned}
\Psi_{t_i} &= \lim_{dt\to 0} \int \frac{\exp\left(-\frac{1}{\lambda}\left(\phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} dt + \frac{1}{2}\sum_{j=i}^{N-1} \left\| \frac{\mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)}}{dt} - \mathbf{f}_{t_j}^{(c)} \right\|_{\mathbf{H}_{t_j}^{-1}}^2 dt\right)\right)}{\Pi_{j=i}^{N-1} \left((2\pi)^{l/2} |\Sigma_{t_j}|^{1/2}\right)} d\tau_i^{(c)} \\
&= \lim_{dt\to 0} \int \frac{1}{D(\tau_i)} \exp\left(-\frac{1}{\lambda} S(\tau_i)\right) d\tau_i^{(c)}, \qquad (16)
\end{aligned}$$

where, we defined

$$S(\tau_i) = \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} dt + \frac{1}{2}\sum_{j=i}^{N-1} \left\| \frac{\mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)}}{dt} - \mathbf{f}_{t_j}^{(c)} \right\|_{\mathbf{H}_{t_j}^{-1}}^2 dt,$$

and

$$D(\tau_i) = \Pi_{j=i}^{N-1} \left((2\pi)^{l/2} |\Sigma_{t_j}|^{1/2}\right).$$

Note that the integration is over $d\tau_i^{(c)} = \left(d\mathbf{x}_{t_i}^{(c)}, ..., d\mathbf{x}_{t_N}^{(c)}\right)$, as the non-directly actuated states can be integrated out due to the fact that the state transition of the non-directly actuated states is deterministic, and just added Dirac delta functions in the integral (cf. Equation (13)). Equation (16) is written in a more compact form as:

$$\begin{aligned}
\Psi_{t_i} &= \lim_{dt\to 0} \int \exp\left(-\frac{1}{\lambda} S(\tau_i) - \log D(\tau_i)\right) d\tau_i^{(c)} \\
&= \lim_{dt\to 0} \int \exp\left(-\frac{1}{\lambda} Z(\tau_i)\right) d\tau_i^{(c)}, \qquad (17)
\end{aligned}$$

where $Z(\tau_i) = S(\tau_i) + \lambda \log D(\tau_i)$. It can be shown that this term is factorized in path dependent and path independent terms of the form:

$$Z(\tau_i) = \tilde{S}(\tau_i) + \frac{\lambda(N-i)l}{2}\log(2\pi dt\lambda),$$

where $\tilde{S}(\tau_i) = S(\tau_i) + \frac{\lambda}{2}\sum_{j=i}^{N-1}\log|\mathbf{H}_{t_j}|$. This formula is a required step for the derivation of optimal controls in the next section. The constant term $\frac{\lambda(N-i)l}{2}\log(2\pi dt\lambda)$ can be the source of numerical instabilities especially in cases where fine discretization dt of stochastic dynamics is required. However, in the next section, and in a great detail in Appendix A, lemma 1, we show how this term drops out of the equations.

2.4 Optimal Controls

For every moment of time, the optimal controls are given as $\mathbf{u}_{t_i} = -\mathbf{R}^{-1}\mathbf{G}_{t_i}^T(\nabla_{x_{t_i}}V_{t_i})$. Due to the exponential transformation of the value function, the equation of the optimal controls can be written as

$$\mathbf{u}_{t_i} = \lambda\mathbf{R}^{-1}\mathbf{G}_{t_i}\frac{\nabla_{\mathbf{x}_{t_i}}\Psi_{t_i}}{\Psi_{t_i}}.$$

After substituting Ψ_{t_i} with (17) and canceling the state independent terms of the cost we have:

$$\mathbf{u}_{t_i} = \lim_{dt\to 0}\left(\lambda\mathbf{R}^{-1}\mathbf{G}_{t_i}^T\frac{\nabla_{\mathbf{x}_{t_i}^{(c)}}\left(\int e^{-\frac{1}{\lambda}\tilde{S}(\tau_i)}d\tau_i^{(c)}\right)}{\int\ e^{-\frac{1}{\lambda}\tilde{S}(\tau_i)}d\tau_i^{(c)}}\right),$$

Further analysis of the equation above leads to a simplified version for the optimal controls as

$$\boxed{\mathbf{u}_{t_i} = \int P(\tau_i)\,\mathbf{u}_L(\tau_i)\,d\tau_i^{(c)}}, \tag{18}$$

with the probability $P(\tau_i)$ and local controls $\mathbf{u}_L(\tau_i)$ defined as

$$\boxed{P(\tau_i) = \frac{e^{-\frac{1}{\lambda}\tilde{S}(\tau_i)}}{\int e^{-\frac{1}{\lambda}\tilde{S}(\tau_i)}d\tau_i}} \tag{19}$$

$$\mathbf{u}_L(\tau_i) = -\mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\lim_{dt\to 0}\left(\nabla_{\mathbf{x}_{t_i}^{(c)}}\tilde{S}(\tau_i)\right).$$

The path cost $\tilde{S}(\tau_i)$ is a generalized version of the path cost in Kappen (2005a) and Kappen (2007), which only considered systems with state independent control transition[4] $\mathbf{G}_{t_i}$. To find the local controls $\mathbf{u}_L(\tau_i)$ we have to calculate the $\lim_{dt\to 0}\nabla_{\mathbf{x}_{t_i}^{(c)}}\tilde{S}(\tau_i)$. Appendix A and more precisely lemma 2 shows in detail the derivation of the final result:

$$\lim_{dt\to 0}\left(\nabla_{\mathbf{x}_{t_i}^{(c)}}\tilde{S}(\tau_i)\right) = -\mathbf{H}_{t_i}^{-1}\left(\mathbf{G}_{t_i}^{(c)}\varepsilon_{t_i} - \mathbf{b}_{t_i}\right),$$

where the new term $\mathbf{b}_{t_i}$ is expressed as $\mathbf{b}_{t_i} = \lambda\mathbf{H}_{t_i}\Phi_{t_i}$ and $\Phi_{t_i} \in \Re^{l\times 1}$ is a vector with the j^{th} element defined as:

$$(\Phi_{t_i})_j = \frac{1}{2}trace\left(\mathbf{H}_{t_i}^{-1}\left(\partial_{[\mathbf{x}_{t_i}^{(c)}]_j}\mathbf{H}_{t_i}\right)\right).$$

4. More precisely if $\mathbf{G}_{t_i}^{(c)} = \mathbf{G}^{(c)}$ then the term $\frac{\lambda}{2}\sum_{j=i}^{N-1}\log|\mathbf{H}_{t_j}|$ disappears since it is state independent and it appears in both nominator and denominator in (19). In this case, the path cost is reduced to $\tilde{S}(\tau_i) = S(\tau_i)$.

The local control can now be expressed as:

$$\mathbf{u}_L(\tau_i) = \mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\mathbf{H}_{t_i}^{-1}\left(\mathbf{G}_{t_i}^{(c)}\varepsilon_{t_i} - \mathbf{b}_{t_i}\right),$$

By substituting $\mathbf{H}_{t_i} = \mathbf{G}_{t_i}^{(c)}\mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}$ in the equation above, we get our main result for the local controls of the sampled path for the generalized path integral formulation:

$$\boxed{\mathbf{u}_L(\tau_i) = \mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\left(\mathbf{G}_{t_i}^{(c)}\mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\right)^{-1}\left(\mathbf{G}_{t_i}^{(c)}\varepsilon_{t_i} - \mathbf{b}_{t_i}\right)}. \tag{20}$$

The equations in boxes (18), (19) and (20) form the solution for the generalized path integral stochastic optimal control problem. Given that this result is of general value and constitutes the foundation to derive our reinforcement learning algorithm in the next section, but also since many other special cases can be derived from it, we summarized all relevant equations in Table 1.

The **Given** components of Table 1 include a model of the system dynamics, the cost function, knowledge of the system's noise process, and a mechanism to generate trajectories τ_i. It is important to realize that this is a *model-based* approach, as the computations of the optimal controls requires knowledge of ε_i. ε_i can be obtained in two ways. First, the trajectories τ_i can be generated purely in simulation, where the noise is generated from a random number generator. Second, trajectories could be generated by a real system, and the noise ε_i would be computed from the difference between the actual and the predicted system behavior, that is, $\mathbf{G}_{t_i}^{(c)}\varepsilon_i = \dot{\mathbf{x}}_{t_i} - \hat{\dot{\mathbf{x}}}_{t_i} = \dot{\mathbf{x}}_{t_i} - (\mathbf{f}_{t_i} + \mathbf{G}_{t_i}\mathbf{u}_{t_i})$. Computing the prediction $\hat{\dot{\mathbf{x}}}_{t_i}$ also requires a model of the system dynamics.

Previous results in Kappen (2005a), Kappen (2007), Kappen (2005b) and Broek et al. (2008) are special cases of our generalized formulation. In the next section we show how our generalized formulation is specialized to different classes of stochastic dynamical systems and we provide the corresponding formula of local controls for each class.

2.5 Special Cases

The purpose of this section is twofold. First, it demonstrates how to apply the path integral approach to specialized forms of dynamical systems, and how the local controls in (20) simplify for these cases. Second, this section prepares the special case which we will need for our reinforcement learning algorithm in Section 3.

2.5.1 SYSTEMS WITH ONE DIMENSIONAL DIRECTLY ACTUATED STATE

The generalized formulation of stochastic optimal control with path integrals in Table 1 can be applied to a variety of stochastic dynamical systems with different types of control transition matrices. One case of particular interest is where the dimensionality of the directly actuated part of the state is 1D, while the dimensionality of the control vector is 1D or higher dimensional. As will be seen below, this situation arises when the controls are generated by a linearly parameterized function approximator. The control transition matrix thus becomes a row vector $\mathbf{G}_{t_i}^{(c)} = \mathbf{g}_{t_i}^{(c)T} \in \Re^{1\times p}$. According to (20), the local controls for such systems are expressed as follows:

$$\mathbf{u}_L(\tau_i) = \frac{\mathbf{R}^{-1}\mathbf{g}_{t_i}^{(c)}}{\mathbf{g}_{t_i}^{(c)T}\mathbf{R}^{-1}\mathbf{g}_{t_i}^{(c)}}\left(\mathbf{g}_{t_i}^{(c)T}\varepsilon_{t_i} - \mathbf{b}_{t_i}\right).$$

- **Given**:
  - The system dynamics $\dot{\mathbf{x}}_t = \mathbf{f}_t + \mathbf{G}_t\left(\mathbf{u}_t + \varepsilon_t\right)$ (cf. 3)
  - The immediate cost $r_t = q_t + \frac{1}{2}\mathbf{u}_t^T \mathbf{R}\mathbf{u}_t$ (cf. 4)
  - A terminal cost term ϕ_{t_N} (cf. 1)
  - The variance Σ_ε of the mean-zero noise ε_t
  - Trajectory starting at t_i and ending at t_N: $\tau_i = (\mathbf{x}_{t_i}, ..., \mathbf{x}_{t_N})$
  - A partitioning of the system dynamics into (c) controlled and (m) uncontrolled equations, where $n = c + m$ is the dimensionality of the state $\mathbf{x}_t$ (cf. Section 2.3)
- **Optimal Controls**:
  - Optimal controls at every time step t_i: $\mathbf{u}_{t_i} = \int P\left(\tau_i\right)\mathbf{u}\left(\tau_i\right) d\tau_i^{(c)}$
  - Probability of a trajectory: $P\left(\tau_i\right) = \frac{e^{-\frac{1}{\lambda}\tilde{S}(\tau_i)}}{\int e^{-\frac{1}{\lambda}\tilde{S}(\tau_i)} d\tau_i}$
  - Generalized trajectory cost: $\tilde{S}(\tau_i) = S(\tau_i) + \frac{\lambda}{2}\sum_{j=i}^{N-1} \log|\mathbf{H}_{t_j}|$ where
    - $S(\tau_i) = \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} dt + \frac{1}{2}\sum_{j=i}^{N-1} \left\| \frac{\mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)}}{dt} - \mathbf{f}_{t_j}^{(c)} \right\|_{\mathbf{H}_{t_j}^{-1}}^2 dt$
    - $\mathbf{H}_{t_j} = \mathbf{G}_{t_j}^{(c)} \mathbf{R}^{-1} \mathbf{G}_{t_j}^{(c)T}$
  - Local Controls: $\mathbf{u}_L(\tau_i) = \mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\left(\mathbf{G}_{t_i}^{(c)}\mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\right)^{-1}\left(\mathbf{G}_{t_i}^{(c)}\varepsilon_{t_i} - \mathbf{b}_{t_i}\right)$ where
    - $\mathbf{b}_{t_i} = \lambda \mathbf{H}_{t_i}\Phi_{t_i}$
    - $[\Phi_{t_i}]_j = \frac{1}{2} trace\left(\mathbf{H}_{t_i}^{-1}\left(\partial_{[\mathbf{x}_{t_i}^{(c)}]_j}\mathbf{H}_{t_i}\right)\right)$

Table 1: Summary of optimal control derived from the path integral formalizm.

Since the directly actuated part of the state is 1D, the vector $\mathbf{x}_{t_i}^{(c)}$ collapses into the scalar $x_{t_i}^{(c)}$ which appears in the partial differentiation above. In the case that $\mathbf{g}_{t_i}^{(c)}$ does not depend on $x_{t_i}^{(c)}$, the differentiation with respect to $x_{t_i}^{(c)}$ results to zero and the the local controls simplify to:

$$\mathbf{u}_L(\tau_i) = \frac{\mathbf{R}^{-1}\mathbf{g}_{t_i}^{(c)}\mathbf{g}_{t_i}^{(c)T}}{\mathbf{g}_{t_i}^{(c)T}\mathbf{R}^{-1}\mathbf{g}_{t_i}^{(c)}}\varepsilon_{t_i}.$$

2.5.2 SYSTEMS WITH PARTIALLY ACTUATED STATE

The generalized formula of the local controls (20) was derived for the case where the control transition matrix is state dependent and its dimensionality is $\mathbf{G}_t^{(c)} \in \Re^{l \times p}$ with $l < n$ and p the dimensionality of the control. There are many special cases of stochastic dynamical systems in optimal control

and robotic applications that belong into this general class. More precisely, for systems having a state dependent control transition matrix that is square ($\mathbf{G}_{t_i}^{(c)} \in \Re^{l \times l}$ with $l = p$) the local controls based on (20) are reformulated as:

$$\mathbf{u}_L(\tau_i) = \varepsilon_{t_i} - \mathbf{G}_{t_i}^{(c)^{-1}} \mathbf{b}_{t_i}. \tag{21}$$

Interestingly, a rather general class of mechanical systems such as rigid-body and multi-body dynamics falls into this category. When these mechanical systems are expressed in state space formulation, the control transition matrix is equal to rigid body inertia matrix $\mathbf{G}_{t_i}^{(c)} = \mathbf{M}(\theta_{t_i})$ (Sciavicco and Siciliano, 2000). Future work will address this special topic of path integral control for multi-body dynamics.

Another special case of systems with partially actuated state is when the control transition matrix is state independent and has dimensionality $\mathbf{G}_t^{(c)} = \mathbf{G}^{(c)} \in \Re^{l \times p}$. The local controls, according to (20), become:

$$\mathbf{u}_L(\tau_i) = \mathbf{R}^{-1}\mathbf{G}^{(c)^T}\left(\mathbf{G}^{(c)}\mathbf{R}^{-1}\mathbf{G}^{(c)^T}\right)^{-1}\mathbf{G}^{(c)}\varepsilon_{t_i}. \tag{22}$$

If $\mathbf{G}_{t_i}^{(c)}$ is square and state independent, $\mathbf{G}_{t_i}^{(c)} = \mathbf{G}^{(c)} \in \Re^{l \times l}$, we will have:

$$\mathbf{u}_L(\tau_i) = \varepsilon_{t_i}. \tag{23}$$

This special case was explored in Kappen (2005a), Kappen (2007), Kappen (2005b) and Broek et al. (2008). Our generalized formulation allows a broader application of path integral control in areas like robotics and other control systems, where the control transition matrix is typically partitioned into directly and non-directly actuated states, and typically also state dependent.

2.5.3 SYSTEMS WITH FULLY ACTUATED STATE SPACE

In this class of stochastic systems, the control transition matrix is not partitioned and, therefore, the control $\mathbf{u}$ directly affects all the states. The local controls for such systems are provided by simply substituting $\mathbf{G}_{t_i}^{(c)} \in \Re^{n \times p}$ in (20) with $\mathbf{G}_{t_i} \in \Re^{n \times n}$. Since $\mathbf{G}_{t_i}$ is a square matrix we obtain:

$$\mathbf{u}_L(\tau_i) = \varepsilon_{t_i} - \mathbf{G}_{t_i}^{-1}\mathbf{b}_{t_i},$$

with $\mathbf{b}_{t_i} = \lambda \mathbf{H}_{t_i}\Phi_{t_i}$ and

$$(\Phi_{t_i})_j = \frac{1}{2} trace\left(\mathbf{H}_{t_i}^{-1}\left(\partial_{(\mathbf{x}_{t_i})_j}\mathbf{H}_{t_i}\right)\right),$$

where the differentiation is not taken with respect to $(\mathbf{x}_{t_i}^{(c)})_j$ but with respect to the full state $(\mathbf{x}_{t_i})_j$. For this fully actuated state space, there are subclasses of dynamical systems with square and/or state independent control transition matrix. The local controls for these cases are found by just substituting $\mathbf{G}_{t_i}^{(c)}$ with $\mathbf{G}_{t_i}$ in (21), (22) and (23).

3. Reinforcement Learning with Parameterized Policies

Equipped with the theoretical framework of stochastic optimal control with path integrals, we can now turn to its application to reinforcement learning with parameterized policies. Since the beginning of actor-critic algorithms (Barto et al., 1983), one goal of reinforcement learning has been

to learn compact policy representations, for example, with neural networks as in the early days of machine learning (Miller et al., 1990), or with general parameterizations (Peters, 2007; Deisenroth et al., 2009). Parameterized policies have much fewer parameters than the classical time-indexed approach of optimal control, where every time step has it own set of parameters, that is, the optimal controls at this time step. Usually, function approximation techniques are used to represent the optimal controls and the open parameters of the function approximator become the policy parameters. Function approximators use a state representation as input and not an explicit time dependent representation. This representation allows generalization across states and promises to achieve better generalization of the control policy to a larger state space, such that policies become re-usable and do not have to be recomputed in every new situation.

The path integral approach from the previous sections also follows the classical time-based optimal control strategy, as can be seen from the time dependent solution for optimal controls in (33). However, a minor re-interpretation of the approach and some small mathematical adjustments allow us to carry it over to parameterized policies and reinforcement learning, which results in a new algorithm called **P**olicy **I**mprovement with **P**ath **I**ntegrals (**PI**^{2}).

3.1 Parameterized Policies

We are focusing on direct policy learning, where the parameters of the policy are adjusted by a learning rule directly, and not indirectly as in value function approaches of classical reinforcement learning (Sutton and Barto, 1998)—see Peters (2007) for a discussion of pros and cons of direct vs. indirect policy learning. Direct policy learning usually assumes a general cost function (Sutton et al., 2000; Peters, 2007) in the form of

$$J(\mathbf{x}_0) = \int p(\tau_0) R(\tau_0) d\tau_0, \tag{24}$$

which is optimized over states-action trajectories[5] $\tau_0 = (\mathbf{x}_{t_0}, \mathbf{a}_{t_0}, ..., \mathbf{x}_{t_N})$. Under the first order Markov property, the probability of a trajectory is

$$p(\tau_i) = p(\mathbf{x}_{t_i}) \Pi_{j=i}^{N-1} p(\mathbf{x}_{t_{j+1}} | \mathbf{x}_{t_j}, \mathbf{a}_{t_j}) p(\mathbf{a}_{t_j} | \mathbf{x}_{t_j}).$$

Both the state transition and the policy are assumed to be stochastic. The particular formulation of the stochastic policy is a design parameter, motivated by the application domain, analytical convenience, and the need to inject exploration during learning. For continuous state action domains, Gaussian distributions are most commonly chosen (Gullapalli, 1990; Williams, 1992; Peters, 2007). An interesting generalized stochastic policy was suggested in Rueckstiess et al. (2008) and applied in Koeber and Peters (2008), where the stochastic policy $p(\mathbf{a}_{t_i} | \mathbf{x}_{t_i})$ is linearly parameterized as:

$$\mathbf{a}_{t_i} = \mathbf{g}_{t_i}^T (\theta + \varepsilon_{t_i}), \tag{25}$$

with $\mathbf{g}_{t_i}$ denoting a vector of basis functions and θ the parameter vector. This policy has state dependent noise, which can contribute to faster learning as the signal-to-noise ratio becomes adaptive since it is a function of $\mathbf{g}_{t_i}$. It should be noted that a standard additive-noise policy can be expressed in this formulation, too, by choosing one basis function $(\mathbf{g}_{t_i})_j = 0$. For Gaussian noise ε the probability of an action is $p(\mathbf{a}_{t_i} | \mathbf{x}_{t_i}) = N\left(\theta^T \mathbf{g}_{t_i}, \Sigma_{t_i}\right)$ with $\Sigma_{t_i} = \mathbf{g}_{t_i}^T \Sigma_\varepsilon \mathbf{g}_{t_i}$. Comparing the policy formulation

5. We use $\mathbf{a}_t$ to denote actions here in order to avoid using the symbol $\mathbf{u}$ in a conflicting way in the equations below, and to emphasize that an action does not necessarily coincide with the control command to a physical system.

in (25) with the control term in (3), one recognizes that the control policy formulation (25) should fit into the framework of path integral optimal control.

3.2 Generalized Parameterized Policies

Before going into more detail of our proposed reinforcement learning algorithm, it is worthwhile contemplating what the action $\mathbf{a}_t$ actually represents. In many applications of stochastic optimal control there are three main problems to be considered: i) trajectory planning, ii) feedforward control, and iii) feedback control. The results of optimization could thus be an optimal kinematic trajectory, the corresponding feedforward commands to track the desired trajectory accurately in face of the system's nonlinearities, and/or time varying linear feedback gains (gain scheduling) for a negative feedback controller that compensates for perturbations from accurate trajectory tracking.

There are very few optimal control algorithms which compute all three issues simultaneously, such as Differential Dynamic Programming(DDP) (Jacobson and Mayne, 1970), or its simpler version the Iterative Linear Quadratic Regulator(iLQR) (Todorov, 2005). However, these are model based methods which require rather accurate knowledge of the dynamics and make restrictive assumptions concerning differentiability of the system dynamics and the cost function.

Path integral optimal control allows more flexibility than these related methods. The concept of an "action" can be viewed in a broader sense. Essentially, we consider any "input" to the control system as an action, not unlike the inputs to a transfer function in classical linear control theory. The input can be a motor command, but it can also be anything else, for instance, a desired state, that is subsequently converted to a motor command by some tracking controller, or a control gain (Buchli et al., 2010) . As an example, consider a robotic system with rigid body dynamics (RBD) equations (Sciavicco and Siciliano, 2000) using a parameterized policy:

$$\ddot{\mathbf{q}} = \mathbf{M}(\mathbf{q})^{-1}\left(-\mathbf{C}(\mathbf{q},\dot{\mathbf{q}})-\mathbf{v}(\mathbf{q})\right)+\mathbf{M}(\mathbf{q})^{-1}\mathbf{u}, \tag{26}$$

$$\mathbf{u} = \mathbf{G}(\mathbf{q})(\theta+\varepsilon_{t_i}), \tag{27}$$

where $\mathbf{M}$ is the RBD inertia matrix, $\mathbf{C}$ are Coriolis and centripetal forces, and $\mathbf{v}$ denotes gravity forces. The state of the robot is described by the joint angles $\mathbf{q}$ and joint velocities $\dot{\mathbf{q}}$. The policy (27) is linearly parameterized by θ, with basis function matrix $\mathbf{G}$—one would assume that the dimensionality of θ is significantly larger than that of $\mathbf{q}$ to assure sufficient expressive power of this parameterized policy. Inserting (27) into (26) results in a differential equation that is compatible with the system equations (3) for path integral optimal control:

$$\begin{aligned} \ddot{\mathbf{q}} &= \mathbf{f}(\mathbf{q},\dot{\mathbf{q}})+\tilde{\mathbf{G}}(\mathbf{q})(\theta+\varepsilon_{t_i}) \\ &\textit{where} \\ \mathbf{f}(\mathbf{q},\dot{\mathbf{q}}) &= \mathbf{M}(\mathbf{q})^{-1}\left(-\mathbf{C}(\mathbf{q},\dot{\mathbf{q}})-\mathbf{v}(\mathbf{q})\right), \\ \tilde{\mathbf{G}}(\mathbf{q}) &= \mathbf{M}(\mathbf{q})^{-1}\mathbf{G}(\mathbf{q}). \end{aligned} \tag{28}$$

This example is a typical example where the policy directly represents motor commands.

Alternatively, we could create another form of control structure for the RBD system:

$$\begin{aligned} \ddot{\mathbf{q}} &= \mathbf{M}(\mathbf{q})^{-1}\left(-\mathbf{C}(\mathbf{q},\dot{\mathbf{q}})-\mathbf{v}(\mathbf{q})\right)+\mathbf{M}(\mathbf{q})^{-1}\mathbf{u}, \\ \mathbf{u} &= \mathbf{K}_P(\mathbf{q}_d-\mathbf{q})+\mathbf{K}_D(\dot{\mathbf{q}}_d-\dot{\mathbf{q}}), \\ \ddot{\mathbf{q}}_d &= \mathbf{G}(\mathbf{q}_d,\dot{\mathbf{q}}_d)(\theta+\varepsilon_{t_i}). \end{aligned} \tag{29}$$

Here, a Proportional-Derivative (PD) controller with positive definite gain matrices $\mathbf{K}_P$ and $\mathbf{K}_D$ converts a desired trajectory $\mathbf{q}_d, \dot{\mathbf{q}}_d$ into a motor command $\mathbf{u}$. In contrast to the previous example, the parameterized policy generates the desired trajectory in (29), and the differential equation for the desired trajectory is compatible with the path integral formalism.

What we would like to emphasize is that the control system's structure is left to the creativity of its designer, and that path integral optimal control can be applied on various levels. Importantly, as developed in Section 2.3, only the *controlled* differential equations of the entire control system contribute to the path integral formalism, that is, (28) in the first example, or (29) in the second example. And *only these controlled differential equations* need to be known for applying path integral optimal control—none of the variables of the uncontrolled equations is ever used.

At this point, we make a very important transition from model-based to model-free learning. In the example of (28), the dynamics model of the control system needs to be known to apply path integral optimal control, as this is a *controlled* differential equation. In contrast, in (29), the system dynamics are in an *uncontrolled* differential equation, and are thus irrelevant for applying path integral optimal control. In this case, only knowledge of the desired trajectory dynamics is needed, which is usually created by the system designer. Thus, we obtained a model-free learning system.

3.3 Dynamic Movement Primitives as Generalized Policies

As we are interested in model-free learning, we follow the control structure of the 2^{nd} example of the previous section, that is, we optimize control policies which represent desired trajectories. We use Dynamic Movement Primitives (DMPs) (Ijspeert et al., 2003) as a special case of parameterized policies, which are expressed by the differential equations:

$$\begin{aligned} \frac{1}{\tau}\dot{z}_t &= f_t + \mathbf{g}_t^T(\theta+\varepsilon_t), \\ \frac{1}{\tau}\dot{y}_t &= z_t, \\ \frac{1}{\tau}\dot{x}_t &= -\alpha x_t, \\ f_t &= \alpha_z(\beta_z(g-y_t)-z_t). \end{aligned} \tag{30}$$

Essentially, these policies code a learnable point attractor for a movement from y_{t_0} to the goal g, where θ determines the shape of the attractor. $y_t, \dot{y}_t$ denote the position and velocity of the trajectory, while z_t, x_t are internal states. α_z, β_z, τ are time constants. The basis functions $\mathbf{g}_t \in \Re^{p\times 1}$are defined by a piecewise linear function approximator with Gaussian weighting kernels, as suggested in Schaal and Atkeson (1998):

$$\begin{aligned} [\mathbf{g}_t]_j &= \frac{w_j\, x_t}{\sum_{k=1}^{p} w_k}(g-y_0), \\ w_j &= \exp\left(-0.5h_j(x_t-c_j)^2\right), \end{aligned} \tag{31}$$

with bandwith h_j and center c_j of the Gaussian kernels—for more details see Ijspeert et al. (2003). The DMP representation is advantageous as it guarantees attractor properties towards the goal while remaining linear in the parameters θ of the function approximator. By varying the parameter θ the shape of the trajectory changes while the goal state g and initial state y_{t_0} remain fixed. These properties facilitate learning (Peters and Schaal, 2008a).

3.4 Policy Improvements with Path Integrals: The (PI^2) Algorithm

As can be easily recognized, the DMP equations are of the form of our control system (3), with only one controlled equation and a one dimensional actuated state. This case has been treated in Section 2.5.1. The motor commands are replaced with the parameters θ—the issue of time dependent vs. constant parameters will be addressed below. More precisely, the DMP equations can be written as:

$$\begin{pmatrix} \dot{x}_t \\ \dot{z}_t \\ \dot{y}_t \end{pmatrix} = \begin{pmatrix} -\alpha x_t \\ y_t \\ \alpha_z(\beta_z(g-y_t)-z_t) \end{pmatrix} + \begin{pmatrix} 0_{1\times p} \\ 0_{1\times p} \\ \mathbf{g}_t^{(c)T} \end{pmatrix} (\theta_t + \varepsilon_t).$$

The state of the DMP is partitioned into the controlled part $\mathbf{x}_t^{(c)} = y_t$ and uncontrolled part $\mathbf{x}_t^{(m)} = (x_t \; z_t)^T$. The control transition matrix depends on the state, however, it depends only on one of the state variables of the uncontrolled part of the state, that is, x_t. The path cost for the stochastic dynamics of the DMPs is given by:

$$\begin{aligned}
\tilde{S}(\tau_i) &= \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} dt + \frac{1}{2}\sum_{j=i}^{N-1} \left\| \frac{\mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)}}{dt} - \mathbf{f}_{t_j}^{(c)} \right\|^2_{\mathbf{H}_{t_j}^{-1}} dt + \frac{\lambda}{2}\sum_{j=i}^{N-1} \log|\mathbf{H}_{t_j}| \\
&\propto \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} + \frac{1}{2}\sum_{j=i}^{N-1} \left\| \mathbf{g}_{t_j}^{(c)T}(\theta_{t_j} + \varepsilon_{t_j}) \right\|^2_{\mathbf{H}_{t_j}^{-1}} \\
&= \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} + \frac{1}{2}\sum_{j=i}^{N-1} \frac{1}{2}(\theta_{t_j} + \varepsilon_{t_j})^T \mathbf{g}_{t_j}^{(c)} \mathbf{H}_{t_j}^{-1} \mathbf{g}_{t_j}^{(c)T}(\theta_{t_j} + \varepsilon_{t_j}) \\
&= \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} + \frac{1}{2}\sum_{j=i}^{N-1} \frac{1}{2}(\theta_{t_j} + \varepsilon_{t_j})^T \frac{\mathbf{g}_{t_j}^{(c)} \mathbf{g}_{t_j}^{(c)T}}{\mathbf{g}_t^{(c)T} \mathbf{R}^{-1} \mathbf{g}_t^{(c)}}(\theta_{t_j} + \varepsilon_{t_j}) \\
&= \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} + \frac{1}{2}\sum_{j=i}^{N-1} \frac{1}{2}(\theta_{t_j} + \varepsilon_{t_j})^T \mathbf{M}_{t_j}^T \mathbf{R} \mathbf{M}_{t_j}(\theta_{t_j} + \varepsilon_{t_j}).
\end{aligned} \tag{32}$$

with $\mathbf{M}_{t_j} = \frac{\mathbf{R}^{-1}\mathbf{g}_{t_j}\mathbf{g}_{t_j}^T}{\mathbf{g}_{t_j}^T \mathbf{R}^{-1} \mathbf{g}_{t_j}}$. $\mathbf{H}_t$ becomes a scalar given by $\mathbf{H}_t = \mathbf{g}_t^{(c)T} \mathbf{R}^{-1} \mathbf{g}_t^{(c)}$. Interestingly, the term $\frac{\lambda}{2}\sum_{j=i}^{N-1} \log|\mathbf{H}_{t_j}|$ for the case of DMPs depends only on x_t, which is a deterministic variable and therefore can be ignored since it is the same for all sampled paths. We also absorbed, without loss of generality, the time step dt in cost terms. Consequently, the fundamental result of the path integral stochastic optimal problem for the case of DMPs is expressed as:

$$\boxed{\mathbf{u}_{t_i} = \int P(\tau_i)\, \mathbf{u}_L(\tau_i)\, d\tau_i^{(c)}}, \tag{33}$$

where the probability $P(\tau_i)$ and local controls $\mathbf{u}(\tau_i)$ are defined as

$$P(\tau_i) = \frac{e^{-\frac{1}{\lambda}\tilde{S}(\tau_i)}}{\int e^{-\frac{1}{\lambda}\tilde{S}(\tau_i)} d\tau_i}, \quad \mathbf{u}_L(\tau_i) = \frac{\mathbf{R}^{-1}\mathbf{g}_{t_i}^{(c)} \mathbf{g}_{t_i}^{(c)T}}{\mathbf{g}_{t_i}^{(c)T} \mathbf{R}^{-1} \mathbf{g}_{t_i}^{(c)}} \varepsilon_{t_i},$$

and the path cost given as

$$\tilde{S}(\tau_i) = \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} + \frac{1}{2} \sum_{j=i}^{N-1} \varepsilon_{t_j}^T \mathbf{M}_{t_j}^T \mathbf{R} \mathbf{M}_{t_j} \varepsilon_{t_j}.$$

Note that $\theta = 0$ in these equations, that is, the parameters are initialized to zero. These equations correspond to the case where the stochastic optimal control problem is solved with one evaluation of the optimal controls (33) using dense sampling of the whole state space under the "passive dynamics" (i.e., $\theta = 0$), which requires a significant amount of exploration noise. Such an approach was pursued in the original work by Kappen (2007) and Broek et al. (2008), where a potentially large number of sample trajectories was needed to achieve good results. Extending this sampling approach to high dimensional spaces, however, is daunting, as with very high probability, we would sample primarily rather useless trajectories. Thus, biasing sampling towards good initial conditions seems to be mandatory for high dimensional applications.

Thus, we consider only local sampling and an iterative update procedure. Given a current guess of θ, we generate sample roll-outs using stochastic parameters $\theta + \varepsilon_t$ at every time step. To see how the generalized path integral formulation is modified for the case of iterative updating, we start with the equations of the update of the parameter vector θ, which can be written as:

$$\begin{aligned}
\theta_{t_i}^{(new)} &= \int P(\tau_i) \frac{\mathbf{R}^{-1} \mathbf{g}_{t_i} \mathbf{g}_{t_i}^T (\theta + \varepsilon_{t_i})}{\mathbf{g}_{t_i}^T \mathbf{R}^{-1} \mathbf{g}_{t_i}} d\tau_i \\
&= \int P(\tau_i) \frac{\mathbf{R}^{-1} \mathbf{g}_{t_i} \mathbf{g}_{t_i}^T \varepsilon_{t_i}}{\mathbf{g}_{t_i}^T \mathbf{R}^{-1} \mathbf{g}_{t_i}} d\tau_i + \frac{\mathbf{R}^{-1} \mathbf{g}_{t_i} \mathbf{g}_{t_i}^T \theta}{\mathbf{g}_{t_i}^T \mathbf{R}^{-1} \mathbf{g}_{t_i}} \\
&= \delta\theta_{t_i} + \frac{\mathbf{R}^{-1} \mathbf{g}_{t_i} \mathbf{g}_{t_i}^T}{trace(\mathbf{R}^{-1} \mathbf{g}_{t_i} \mathbf{g}_{t_i}^T)} \theta \\
&= \delta\theta_{t_i} + \mathbf{M}_{t_i} \theta. \qquad (34)
\end{aligned}$$

The correction parameter vector $\delta\theta_{t_i}$ is defined as $\delta\theta_{t_i} = \int P(\tau_i) \frac{\mathbf{R}^{-1} \mathbf{g}_{t_i} \mathbf{g}_{t_i}^T \varepsilon_{t_i}}{\mathbf{g}_{t_i}^T \mathbf{R}^{-1} \mathbf{g}_{t_i}} d\tau_i$. It is important to note that $\theta_{t_i}^{(new)}$ is now time dependent, that is, for every time step t_i, a different optimal parameter vector is computed. In order to return to one single time independent parameter vector $\theta^{(new)}$, the vectors $\theta_{t_i}^{(new)}$ need to be averaged over time t_i.

We start with a first tentative suggestion of averaging over time, and then explain why it is inappropriate, and what the correct way of time averaging has to look like. The tentative and most intuitive time average is:

$$\theta^{(new)} = \frac{1}{N} \sum_{i=0}^{N-1} \theta_{t_i}^{(new)} = \frac{1}{N} \sum_{i=0}^{N-1} \delta\theta_{t_i} + \frac{1}{N} \sum_{i=0}^{N-1} \mathbf{M}_{t_i} \theta.$$

Thus, we would update θ based on two terms. The first term is the average of $\delta\theta_{t_i}$, which is reasonable as it reflects the knowledge we gained from the exploration noise. However, there would be a second update term due to the average over projected mean parameters θ from every time step—it should be noted that $\mathbf{M}_{t_i}$ is a projection matrix onto the range space of $\mathbf{g}_{t_i}$ under the metric $\mathbf{R}^{-1}$, such that a multiplication with $\mathbf{M}_{t_i}$ can only shrink the norm of θ. From the viewpoint of having optimal parameters for *every time step*, this update component is reasonable as it trivially eliminates the part of the parameter vector that lies in the null space of $\mathbf{g}_{t_i}$ and which contributes to the command cost

of a trajectory in a useless way. From the view point of a parameter vector that is *constant and time independent* and that is updated *iteratively*, this second update is undesirable, as the multiplication of the parameter vector θ with $\mathbf{M}_{t_i}$ in (34) and the averaging operation over the time horizon reduces the L_2 norm of the parameters at every iteration, potentially in an uncontrolled way.[6] What we rather want is to achieve convergence when the average of $\delta\theta_{t_i}$ becomes zero, and we do not want to continue updating due to the second term.

The problem is avoided by eliminating the projection matrix in the second term of averaging, such that it become:

$$\theta^{(new)} = \frac{1}{N}\sum_{i=0}^{N-1}\delta\theta_{t_i} + \frac{1}{N}\sum_{i=0}^{N-1}\theta = \frac{1}{N}\sum_{i=0}^{N-1}\delta\theta_{t_i} + \theta.$$

The meaning of this reduced update is simply that we keep a component in θ that is irrelevant and contributes to our trajectory cost in a useless way. However, this irrelevant component will not prevent us from reaching the optimal effective solution, that is, the solution that lies in the range space of $\mathbf{g}_{t_i}$. Given this modified update, it is, however, also necessary to derive a compatible cost function. As mentioned before, in the unmodified scenario, the last term of (32) is:

$$\frac{1}{2}\sum_{j=i}^{N-1}(\theta+\varepsilon_{t_j})^T\mathbf{M}_{t_j}^T\mathbf{R}\mathbf{M}_{t_j}(\theta+\varepsilon_{t_j})$$

To avoid a projection of θ, we modify this cost term to be:

$$\frac{1}{2}\sum_{j=i}^{N-1}(\theta+\mathbf{M}_{t_j}\varepsilon_{t_j})^T\mathbf{R}(\theta+\mathbf{M}_{t_j}\varepsilon_{t_j}).$$

With this modified cost term, the path integral formalism results in the desired $\theta_{t_i}^{(new)}$ without the $\mathbf{M}_{t_i}$ projection of θ.

The main equations of the iterative version of the generalized path integral formulation, called **P**olicy **I**mprovement with **P**ath **I**ntegrals (**PI**^{2}), can be summarized as:

$$P(\tau_i) = \frac{e^{-\frac{1}{\lambda}S(\tau_i)}}{\int e^{-\frac{1}{\lambda}S(\tau_i)}d\tau_i}, \tag{35}$$

$$S(\tau_i) = \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j}dt + \frac{1}{2}\sum_{j=i}^{N-1}(\theta+\mathbf{M}_{t_j}\varepsilon_{t_j})^T\mathbf{R}(\theta+\mathbf{M}_{t_j}\varepsilon_{t_j})dt, \tag{36}$$

$$\delta\theta_{t_i} = \int P(\tau_i)\,\mathbf{M}_{t_i}\varepsilon_{t_i}d\tau_i, \tag{37}$$

$$[\delta\theta]_j = \frac{\sum_{i=0}^{N-1}(N-i)\;w_{j,t_i}\;[\delta\theta_{t_i}]_j}{\sum_{i=0}^{N-1}w_{j,t_i}(N-i)}, \tag{38}$$

$$\theta^{(new)} = \theta^{(old)} + \delta\theta.$$

Essentially, (35) computes a discrete probability at time t_i of each trajectory roll-out with the help of the cost (36). For every time step of the trajectory, a parameter update is computed in (37) based

6. To be precise, θ would be projected and continue shrinking until it lies in the intersection of all null spaces of the $\mathbf{g}_{t_i}$ basis function—this null space can easily be of measure zero.

on a probability weighted average over trajectories. The parameter updates at every time step are finally averaged in (38). Note that we chose a weighted average by giving every parameter update a weight[7] according to the time steps left in the trajectory and the activation of the kernel in (31). This average can be interpreted as using a function approximator with only a constant (offset) parameter vector to approximate the time dependent parameters. Giving early points in the trajectory a higher weight is useful since their parameters affect a large time horizon and thus higher trajectory costs. Other function approximation (or averaging) schemes could be used to arrive at a final parameter update—we preferred this simple approach as it gave very good learning results. The final parameter update is $\theta^{(new)} = \theta^{(old)} + \delta\theta$.

The parameter λ regulates the sensitivity of the exponentiated cost and can automatically be optimized for every time step i to maximally discriminate between the experienced trajectories. More precisely, a constant term can be subtracted from (36) as long as all $S(\tau_i)$ remain positive—this constant term[8] cancels in (35). Thus, for a given number of roll-outs, we compute the exponential term in (35) as

$$\exp\left(-\frac{1}{\lambda}S(\tau_i)\right) = \exp\left(-h\frac{S(\tau_i)-\min S(\tau_i)}{\max S(\tau_i)-\min S(\tau_i)}\right),$$

with h set to a constant, which we chose to be $h = 10$ in all our evaluations. The max and min operators are over all sample roll-outs. This procedure eliminates λ and leaves the variance of the exploration noise ε as the only open algorithmic parameter for **PI**^{2}. It should be noted that the equations for **PI**^{2} have no numerical pitfalls: no matrix inversions and no learning rates,[9] rendering **PI**^{2} to be very easy to use in practice.

The pseudocode for the final **PI**^{2} algorithm for a one dimensional control system with function approximation is given in Table 2. A tutorial Matlab example of applying **PI**^{2} can be found at http://www-clmc.usc.edu/software .

4. Related Work

In the next sections we discuss related work in the areas of stochastic optimal control and reinforcement learning and analyze the connections and differences with the **PI**^{2} algorithm and the generalized path integral control formulation.

4.1 Stochastic Optimal Control and Path Integrals

The path integral formalism for optimal control was introduced in Kappen (2005a,b). In this work, the role of noise in symmetry breaking phenomena was investigated in the context of stochastic optimal control. In Kappen et al. (2007), Wiegerinck et al. (2006), and Broek et al. (2008), the path integral formalism is extended for the stochastic optimal control of multi-agent systems.

Recent work on stochastic optimal control by Todorov (2008), Todorov (2007) and Todorov (2009b) shows that for a class of discrete stochastic optimal control problems, the Bellman equa-

7. The use of the kernel weights in the basis functions (31) for the purpose of time averaging has shown better performance with respect to other weighting approaches, across all of our experiments. Therefore this is the weighting that we suggest. Users may develop other weighting schemes as more suitable to their needs.

8. In fact, the term inside the exponent results by adding $\frac{h\min S(\tau_i)}{\max S(\tau_i)-\min S(\tau_i)}$, which cancels in (35), to the term $-\frac{hS(\tau_i)}{\max S(\tau_i)-\min S(\tau_i)}$ which is equal to $-\frac{1}{\lambda}S(\tau_i)$.

9. **R** is a user design parameter and usually chosen to be diagonal and invertible.

- **Given**:
  - An immediate cost function $r_t = q_t + \theta_t^T \mathbf{R} \theta_t$ (cf. 1)
  - A terminal cost term ϕ_{t_N} (cf. 1)
  - A stochastic parameterized policy $\mathbf{a}_t = \mathbf{g}_t^T (\theta + \varepsilon_t)$ (cf. 25)
  - The basis function $\mathbf{g}_{t_i}$ from the system dynamics (cf. 3 and Section 2.5.1)
  - The variance Σ_ε of the mean-zero noise ε_t
  - The initial parameter vector θ
- **Repeat** until convergence of the trajectory cost R:
  - Create K roll-outs of the system from the same start state $\mathbf{x}_0$ using stochstic parameters $\theta + \varepsilon_t$ at every time step
  - **For** $k = 1...K$, compute:
    - $P(\tau_{i,k}) = \frac{e^{-\frac{1}{\lambda} S(\tau_{i,k})}}{\sum_{k=1}^{K} [e^{-\frac{1}{\lambda} S(\tau_{i,k})}]}$
    - $S(\tau_{i,k}) = \phi_{t_N,k} + \sum_{j=i}^{N-1} q_{t_j,k} + \frac{1}{2} \sum_{j=i+1}^{N-1} (\theta + \mathbf{M}_{t_j,k} \varepsilon_{t_j,k})^T \mathbf{R} (\theta + \mathbf{M}_{t_j,k} \varepsilon_{t_j,k})$
    - $\mathbf{M}_{t_j,k} = \frac{\mathbf{R}^{-1} \mathbf{g}_{t_j,k} \mathbf{g}_{t_j,k}^T}{\mathbf{g}_{t_j,k}^T \mathbf{R}^{-1} \mathbf{g}_{t_j,k}}$
  - **For** $i = 1...(N-1)$, compute:
    - $\delta\theta_{t_i} = \sum_{k=1}^{K} [P(\tau_{i,k}) \mathbf{M}_{t_i,k} \varepsilon_{t_i,k}]$
  - Compute $[\delta\theta]_j = \frac{\sum_{i=0}^{N-1} (N-i) w_{j,t_i} [\delta\theta_{t_i}]_j}{\sum_{i=0}^{N-1} w_{j,t_i} (N-i)}$
  - Update $\theta \leftarrow \theta + \delta\theta$
  - Create one noiseless roll-out to check the trajectory cost $R = \phi_{t_N} + \sum_{i=0}^{N-1} r_{t_i}$. In case the noise cannot be turned off, that is, a stochastic system, multiple roll-outs need be averaged.

Table 2: Pseudocode of the **PI**^{2} algorithm for a 1D Parameterized Policy (Note that the discrete time step dt was absorbed as a constant multiplier in the cost terms).

tion can be written as the KL divergence between the probability distribution of the controlled and uncontrolled dynamics. Furthermore it is shown that the class of discrete KL divergence control problem is equivalent to the continuous stochastic optimal control formalism with quadratic cost control function and under the presence of Gaussian noise. In Kappen et al. (2009), the KL divergence control formalism is considered and it is transformed to a probabilistic inference problem. In all this aforementioned work, both in the path integral formalism as well as in KL divergence control, the class of stochastic dynamical systems under consideration is rather restrictive since the

control transition matrix is state independent. Moreover, the connection to direct policy learning in RL and model-free learning was not made in any of the previous projects.

Our **PI**^{2} algorithm differs with respect to the aforementioned work in the following points.

- In Todorov (2009b) the stochastic optimal control problem is investigated for discrete action - state spaces and therefore it is treated as Markov Decision Process (MDP). To apply our **PI**^{2} algorithm, we do not discretize the state space and we do not treat the problem as an MDP. Instead we work in continuous state - action spaces which are suitable for performing RL in high dimensional robotic systems. To the best of our knowledge, our results present RL in one of the most high dimensional continuous state action spaces.

- In our derivations, the probabilistic interpretation of control comes directly from the Feynman-Kac Lemma. Thus we do not have to impose any artificial "pseudo-probability" treatment of the cost as in Todorov (2009b). In addition, for the continuous state - action spaces we do not have to learn the value function as it is suggested in Todorov (2009b) via Z-learning. Instead we directly find the controls based on our generalization of optimal controls.

- In the previous work, the problem of how to sample trajectories is not addressed. Sampling is performed at once with the hope to cover the all state space. We follow a rather different approach that allows to attack robotic learning problems of the complexity and dimensionality of the little dog robot.

- The work in Todorov (2009a) considers stochastic dynamics with state dependent control matrix. However, the way of how the stochastic optimal control problem is solved is by imposing strong assumptions on the structure of the cost function and, therefore, restrictions of the proposed solution to special cases of optimal control problems. The use of this specific cost function allows transforming the stochastic optimal control problem to a deterministic optimal control problem. Under this transformation, the stochastic optimal control problem can be solved by using deterministic algorithms.

- With respect to the work in Broek et al. (2008), Wiegerinck et al. (2006) and Kappen et al. (2009) our **PI**^{2} algorithm has been derived for a rather general class of systems with control transition matrix that is state dependent. In this general class, Rigid body and multi-body dynamics as well as the DMPs are included. Furthermore we have shown how our results generalize previous work.

4.2 Reinforcement Learning of Parameterized Policies

There are two main classes of related algorithms: Policy Gradient algorithms and probabilistic algorithms.

Policy Gradient algorithms (Peters and Schaal, 2006a,b) compute the gradient of the cost function (24) at every iteration and the policy parameters are updated according to $\theta^{(new)} = \theta^{(old)} + \alpha\nabla_\theta J$. Some well-established algorithms, which we will also use for comparisons, are as follows (see also Peters and Schaal, 2006a,b).

4.2.1 REINFORCE

Williams (1992) introduced the episodic REINFORCE algorithm, which is derived from taking the derivative of (24) with respect to the policy parameters. This algorithm has rather slow convergence

due to a very noisy estimate of the policy gradient. It is also very sensitive to a reward baseline parameter b_k (see below). Recent work derived the optimal baseline for REINFORCE (cf. Peters and Schaal, 2008a), which improved the performance significantly. The episodic REINFORCE update equations are:

$$\begin{aligned} \nabla_{\theta_k} J &= E_{\boldsymbol{\tau}_0}\left[(R(\boldsymbol{\tau}_0) - b_k) \sum_{i=0}^{N-1} \nabla_{\theta_k} \ln p(\mathbf{a}_{t_i}|\mathbf{x}_{t_i}) \right], \\ b_k &= \frac{E_{\boldsymbol{\tau}_0}\left[\left(\sum_{i=0}^{N-1} \nabla_{\theta_k} \ln p(\mathbf{a}_{t_i}|\mathbf{x}_{t_i})\right)^2 R(\boldsymbol{\tau}_0) \right]}{E_{\boldsymbol{\tau}_0}\left[\left(\sum_{i=0}^{N-1} \nabla_{\theta_k} \ln p(\mathbf{a}_{t_i}|\mathbf{x}_{t_i})\right)^2 \right]}, \end{aligned}$$

where k denotes the k-th coefficient of the parameter vector and $R(\boldsymbol{\tau}_0) = \frac{1}{N}\sum_{i=0}^{N-1} r_{t_i}$.

4.2.2 GPOMDP AND THE POLICY GRADIENT THEOREM ALGORITHM

In their GPOMDP algorithm, Baxter and Bartlett (2001) introduced several improvements over REINFORCE that made the gradient estimates more efficient. GPOMDP can also be derived from the policy gradient theorem (Sutton et al., 2000; Peters and Schaal, 2008a), and an optimal reward baseline can be added (cf. Peters and Schaal, 2008a). In our context, the GPOMDP learning algorithm can be written as:

$$\begin{aligned} \nabla_{\theta_k} J &= E_{\boldsymbol{\tau}_0}\left[\sum_{j=0}^{N-1} (r_{tj} - b_{t_j}^{(k)}) \sum_{i=0}^{j} (\nabla_{\theta_k} \ln p(\mathbf{a}_{t_i}|\mathbf{x}_{t_i})) \right], \\ b_{t_i}^{(k)} &= \frac{E_{\boldsymbol{\tau}_0}\left[(\nabla_{\theta_k} \ln p(\mathbf{a}_{t_i}|\mathbf{x}_{t_i}))^2 r_{ti} \right]}{E_{\boldsymbol{\tau}_0}\left[(\nabla_{\theta_k} \ln p(\mathbf{a}_{t_i}|\mathbf{x}_{t_i}))^2 \right]}. \end{aligned}$$

4.2.3 THE EPISODIC NATURAL ACTOR CRITIC

One of the most efficient policy gradient algorithm was introduced in Peters and Schaal (2008b), called the Episodic Natural Actor Critic. In essence, the method uses the Fisher Information Matrix to project the REINFORCE gradient onto a more effective update direction, which is motivated by the theory of natural gradients by Amari (1999). The eNAC algorithm takes the form of:

$$\begin{aligned} \xi_{t_i,k} &= \begin{bmatrix} \nabla_{\theta_k} \ln p(\mathbf{a}_{t_i}|\mathbf{x}_{t_i}) \\ 1 \end{bmatrix}, \\ \begin{bmatrix} \nabla_\theta J \\ J_0 \end{bmatrix} &= E_{\boldsymbol{\tau}_0}\left[\sum_{i=0}^{N-1} \xi_{t_i,k} \xi_{t_i,k}^T \right]^{-1} E_{\boldsymbol{\tau}_0}\left[R(\boldsymbol{\tau}_0) \sum_{i=0}^{N-1} \xi_{t_i,k} \right], \end{aligned}$$

where J_0 is a constant offset term.

4.2.4 POWER

The PoWER algorithm (Koeber and Peters, 2008) is a probabilistic policy improvement method, not a gradient algorithm. It is derived from an Expectation-Maximization framework using probability

matching (Dayan and Hinton, 1997; Peters and Schaal, 2008c). Using the notation of this paper, the parameter update of PoWER becomes:

$$\delta\theta = E_{\tau_0}\left[\sum_{t=0}^{N-1} R_{t_i}\frac{\mathbf{g}_{t_i}\mathbf{g}_{t_i}^T}{\mathbf{g}_{t_i}^T\mathbf{g}_{t_i}}\right]^{-1} E_{\tau_0}\left[\sum_{t_i=t_o}^{t_N} R_{t_i}\frac{\mathbf{g}_{t_i}\mathbf{g}_{t_i}^T\varepsilon_t}{\mathbf{g}_{t_i}^T\mathbf{g}_{t_i}}\right],$$

where $R_{t_i} = \sum_{j=i}^{N-1} r_{t_j}$. If we set $\mathbf{R}^{-1} = c\ \mathbf{I}$ in the update (37) of $\mathbf{PI}^2$, and set $\frac{\mathbf{g}_{t_i}\mathbf{g}_{t_i}^T}{\mathbf{g}_{t_i}^T\mathbf{g}_{t_i}} = \mathbf{I}$ in the matrix inversion term of (39), the two algorithms look essentially identical. But it should be noted that the rewards r_{t_i} in PoWER need to behave like an improper probability, that is, be strictly positive and integrate to a constant number—this property can make the design of suitable cost functions more complicated. $\mathbf{PI}^2$, in contrast, uses exponentiated sum of reward terms, where the immediate reward can be arbitrary, and only the cost on the motor commands needs be quadratic. Our empirical evaluations revealed that, for cost functions that share the same optimum in the PoWER pseudo-probability formulation and the $\mathbf{PI}^2$ notation, both algorithms perform essentially identical, indicating that the matrix inversion term in PoWER may be unimportant for many systems. It should be noted that in Vlassis et al. (2009), PoWER was extended to the discounted infinite horizon case, where PoWER is the special case of a non-discounted finite horizon problem.

5. Evaluations

We evaluated $\mathbf{PI}^2$ in several synthetic examples in comparison with REINFORCE, GPOMDP, eNAC, and, when possible, PoWER. Except for PoWER, all algorithms are suitable for optimizing immediate reward functions of the kind $r_t = q_t + \mathbf{u}_t\mathbf{R}\mathbf{u}_t$. As mentioned above, PoWER requires that the immediate reward behaves like an improper probability. This property is incompatible with $r_t = q_t + \mathbf{u}_t\mathbf{R}\mathbf{u}_t$ and requires some special nonlinear transformations, which usually change the nature of the optimization problem, such that PoWER optimizes a different cost function. Thus, only one of the examples below has a compatible a cost function for all algorithms, including PoWER. In all examples below, exploration noise and, when applicable, learning rates, were tuned for every individual algorithms to achieve the best possible numerically stable performance. Exploration noise was only added to the maximally activated basis function in a motor primitive,[10] and the noise was kept constant for the entire time that this basis function had the highest activation—empirically, this tick helped improves the learning speed of all algorithms.

5.1 Learning Optimal Performance of a 1 DOF Reaching Task

The first evaluation considers learning optimal parameters for a 1 DOF DMP (cf. Equation 30). The immediate cost and terminal cost are, respectively:

$$r_t = 0.5 f_t^2 + 5000\ \theta^T\theta, \qquad \phi_{t_N} = 10000(\dot{y}_{t_N}^2 + 10(g - y_{t_N})^2)$$

with $y_{t_0} = 0$ and $g = 1$—we use *radians* as units motivated by our interest in robotics application, but we could also avoid units entirely. The interpretation of this cost is that we would like to reach the goal g with high accuracy while minimizing the acceleration of the movement and while keeping the parameter vector short. Each algorithm was run for 15 trials to compute a parameter update, and

10. That is, the noise vector in (25) has only one non-zero component.

a total of 1000 updates were performed. Note that 15 trials per update were chosen as the DMP had 10 basis functions, and the eNAC requires at least 11 trials to perform a numerically stable update due to its matrix inversion. The motor primitives were initialized to approximate a 5-th order polynomial as point-to-point movement (cf. Figure 1a,b), called a minimum-jerk trajectory in the motor control literature; the movement duration was 0.5 seconds, which is similar to normal human reaching movements. Gaussian noise of $N(0,0.1)$ was added to the initial parameters of the movement primitives in order to have different initial conditions for every run of the algorithms. The results are given in Figure 1. Figure 1a,b show the initial (before learning) trajectory generated by the DMP together with the learning results of the four different algorithms after learning—essentially, all algorithms achieve the same result such that all trajectories lie on top of each other. In Figure 1c, however, it can be seen that **PI**^{2} outperforms the gradient algorithms by an order of magnitude. Figure 1d illustrates learning curves for the same task as in Figure 1c, just that parameter updates are computed already after two roll-outs—the eNAC was excluded from this evaluation as it would be too heuristic to stabilize its ill-conditioned matrix inversion that results from such few roll-outs. **PI**^{2} continues to converge much faster than the other algorithms even in this special scenario. However, there are some noticeable fluctuation after convergence. This noise around the convergence baseline is caused by using only two noisy roll-outs to continue updating the parameters, which causes continuous parameter fluctuations around the optimal parameters. Annealing the exploration noise, or just adding the optimal trajectory from the previous parameter update as one of the roll-outs for the next parameter update can alleviate this issue—we do not illustrate such little "tricks" in this paper as they really only affect fine tuning of the algorithm.

5.2 Learning Optimal Performance of a 1 DOF Via-Point Task

The second evaluation was identical to the first evaluation, just that the cost function now forced the movement to pass through an intermediate via-point at $t = 300ms$. This evaluation is an abstract approximation of hitting a target, for example, as in playing tennis, and requires a significant change in how the movement is performed relative to the initial trajectory (Figure 2a). The cost function was

$$r_{300ms} = 100000000(G - y_{t_{300ms}})^2, \qquad \phi_{t_N} = 0$$

with $G = 0.25$. Only this single reward was given. For this cost function, the PoWER algorithm can be applied, too, with cost function $\tilde{r}_{300ms} = \exp(-1/\lambda \quad r_{300ms})$ and $\tilde{r}_{t_i} = 0$ otherwise. This transformed cost function has the same optimum as r_{300ms}. The resulting learning curves are given in Figure 2 and resemble the previous evaluation: **PI**^{2} outperforms the gradient algorithms by roughly an order of magnitude, while all the gradient algorithms have almost identical learning curves. As was expected from the similarity of the update equations, PoWER and **PI**^{2} have in this special case the same performance and are hardly distinguishable in Figure 2. Figure 2a demonstrates that all algorithms pass through the desired target G, but that there are remaining differences between the algorithms in how they approach the target G—these difference have a small numerical effect in the final cost (where **PI**^{2} and PoWER have the lowest cost), but these difference are hardly task relevant.

5.3 Learning Optimal Performance of a Multi-DOF Via-Point Task

A third evaluation examined the scalability of our algorithms to a high-dimensional and highly redundant learning problem. Again, the learning task was to pass through an intermediate target G,

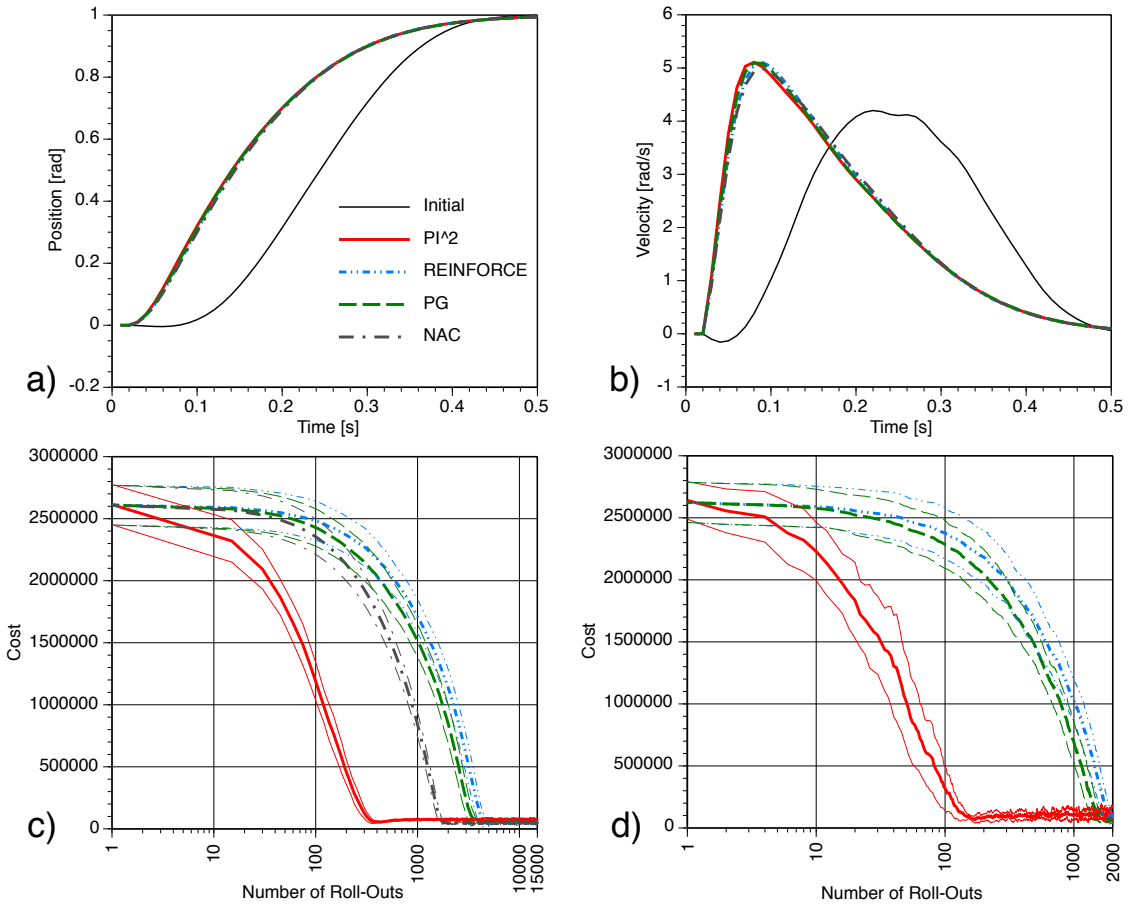

Figure 1: Comparison of reinforcement learning of an optimized movement with motor primitives. a) Position trajectories of the initial trajectory (before learning) and the results of all algorithms after learning—the different algorithms are essentially indistighuishable. b) The same as a), just using the velocity trajectories. c) Average learning curves for the different algorithms with 1 std error bars from averaging 10 runs for each of the algorithms. d) Learning curves for the different algorithms when only two roll-outs are used per update (note that the eNAC cannot work in this case and is omitted).

just that a $d = 2, 10$, or 50 dimensional motor primitive was employed. We assume that the multi-DOF systems model planar robot arms, where d links of equal length $l = 1/d$ are connected in an open chain with revolute joints. Essentially, these robots look like a multi-segment snake in a plane, where the tail of the snake is fixed at the origin of the 2D coordinate system, and the head of the snake can be moved in the 2D plane by changing the joint angles between all the links. Figure 3b,d,f illustrate the movement over time of these robots: the initial position of the robots is when all joint angles are zero and the robot arm completely coincides with the x-axis of the coordinate frame. The goal states of the motor primitives command each DOF to move to a joint angle, such that the entire robot configuration afterwards looks like a semi-circle where the most distal link of the robot

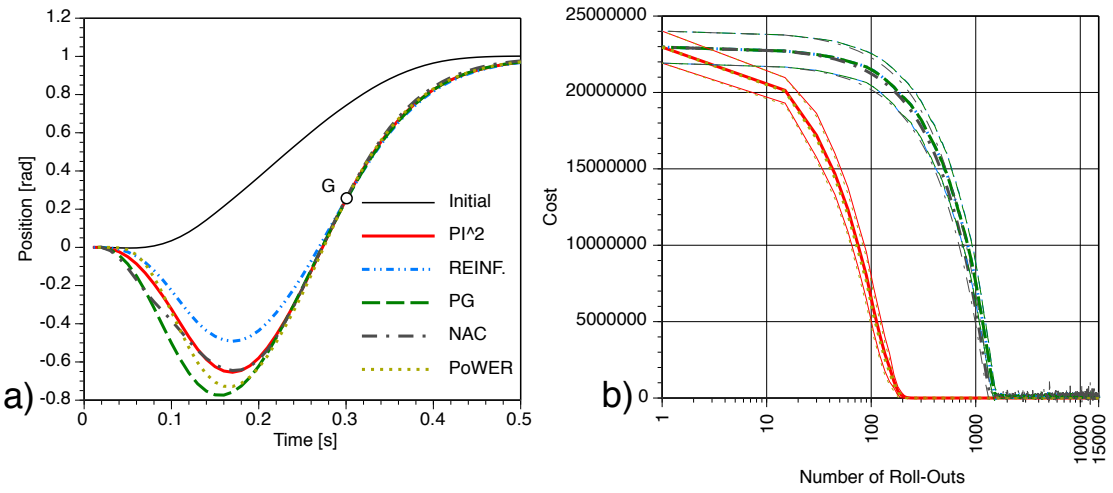

Figure 2: Comparison of reinforcement learning of an optimized movement with motor primitives for passing through an intermediate target G. a) Position trajectories of the initial trajectory (before learning) and the results of all algorithms after learning. b) Average learning curves for the different algorithms with 1 std error bars from averaging 10 runs for each of the algorithms.

(the end-effector) touches the y-axis. The higher priority task, however, is to move the end-effector through a via-point $G = (0.5, 0.5)$. To formalize this task as a reinforcement learning problem, we denote the joint angles of the robots as ξ_i, with $i = 1, 2, ..., d$, such that the first line of (30) reads now as $\ddot{\xi}_{i,t} = f_{i,t} + \mathbf{g}_{i,t}^T(\theta_i + \varepsilon_{i,t})$—this small change of notation is to avoid a clash of variables with the (x, y) task space of the robot. The end-effector position is computed as:

$$x_t = \frac{1}{d}\sum_{i=1}^{d} cos(\sum_{j=1}^{i} \xi_{j,t}), \quad y_t = \frac{1}{d}\sum_{i=1}^{d} sin(\sum_{j=1}^{i} \xi_{j,t}).$$

The immediate reward function for this problem is defined as

$$\begin{aligned} r_t &= \frac{\sum_{i=1}^{d}(d+1-i)\left(0.1 f_{i,t}^2 + 0.5\, \theta_i^T \theta_i\right)}{\sum_{i=1}^{d}(d+1-i)}, \\ \Delta r_{300ms} &= 100000000\left((0.5 - x_{t_{300ms}})^2 + (0.5 - y_{t_{300ms}})^2\right), \\ \phi_{t_N} &= 0, \end{aligned} \tag{39}$$

where Δr_{300ms} is added to r_t at time $t = 300ms$, that is, we would like to pass through the via-point at this time. The individual DOFs of the motor primitive were initialized as in the 1 DOF examples above. The cost term in (39) penalizes each DOF for using high accelerations and large parameter vectors, which is a critical component to achieve a good resolution of redundancy in the arm. Equation (39) also has a weighting term $d + 1 - i$ that penalizes DOFs proximal to the orgin more than those that are distal to the origin—intuitively, applied to human arm movements, this would mean that wrist movements are cheaper than shoulder movements, which is motivated by the

fact that the wrist has much lower mass and inertia and is thus energetically more efficient to move.

The results of this experiment are summarized in Figure 3. The learning curves in the left column demonstrate again that **PI**^{2} has an order of magnitude faster learning performance than the other algorithms, irrespective of the dimensionality. **PI**^{2} also converges to the lowest cost in all examples:

Algorithm	2-DOFs	10-DOFs	50-DOFs
PI^2	98000 ± 5000	15700 ± 1300	2800 ± 150
REINFORCE	125000 ± 2000	22000 ± 700	19500 ± 24000
PG	128000 ± 2000	28000 ± 23000	27000 ± 40000
NAC	113000 ± 10000	48000 ± 8000	22000 ± 2000

Figure 3 also illustrates the path taken by the end-effector before and after learning. All algorithms manage to pass through the via-point G appropriately, although the path particularly before reaching the via-point can be quite different across the algorithms. Given that **PI**^{2} reached the lowest cost with low variance in all examples, it appears to have found the best solution. We also added a "stroboscopic" sketch of the robot arm for the **PI**^{2} solution, which proceeds from the very right to the left as a function of time. It should be emphasized that there were absolutely no parameter tuning needed to achieve the **PI**^{2} results, while all gradient algorithms required readjusting of learning rates for every example to achieve best performance.

5.4 Application to Robot Learning

Figure 4 illustrates our application to a robot learning problem. The robot dog is to jump across as gap. The jump should make forward progress as much as possible, as it is a maneuver in a legged locomotion competition which scores the speed of the robot—note that we only used a physical simulator of the robot for this experiment, as the actual robot was not available. The robot has three DOFs per leg, and thus a total of $d = 12$ DOFs. Each DOF was represented as a DMP with 50 basis functions. An initial seed behavior (Figure 5-top) was taught by learning from demonstration, which allowed the robot barely to reach the other side of the gap without falling into the gap—the demonstration was generated from a manual adjustment of spline nodes in a spline-based trajectory plan for each leg.

PI^2 learning used primarily the forward progress as a reward, and slightly penalized the squared acceleration of each DOF, and the length of the parameter vector. Additionally, a penalty was incurred if the yaw or the roll exceeded a threshold value—these penalties encouraged the robot to

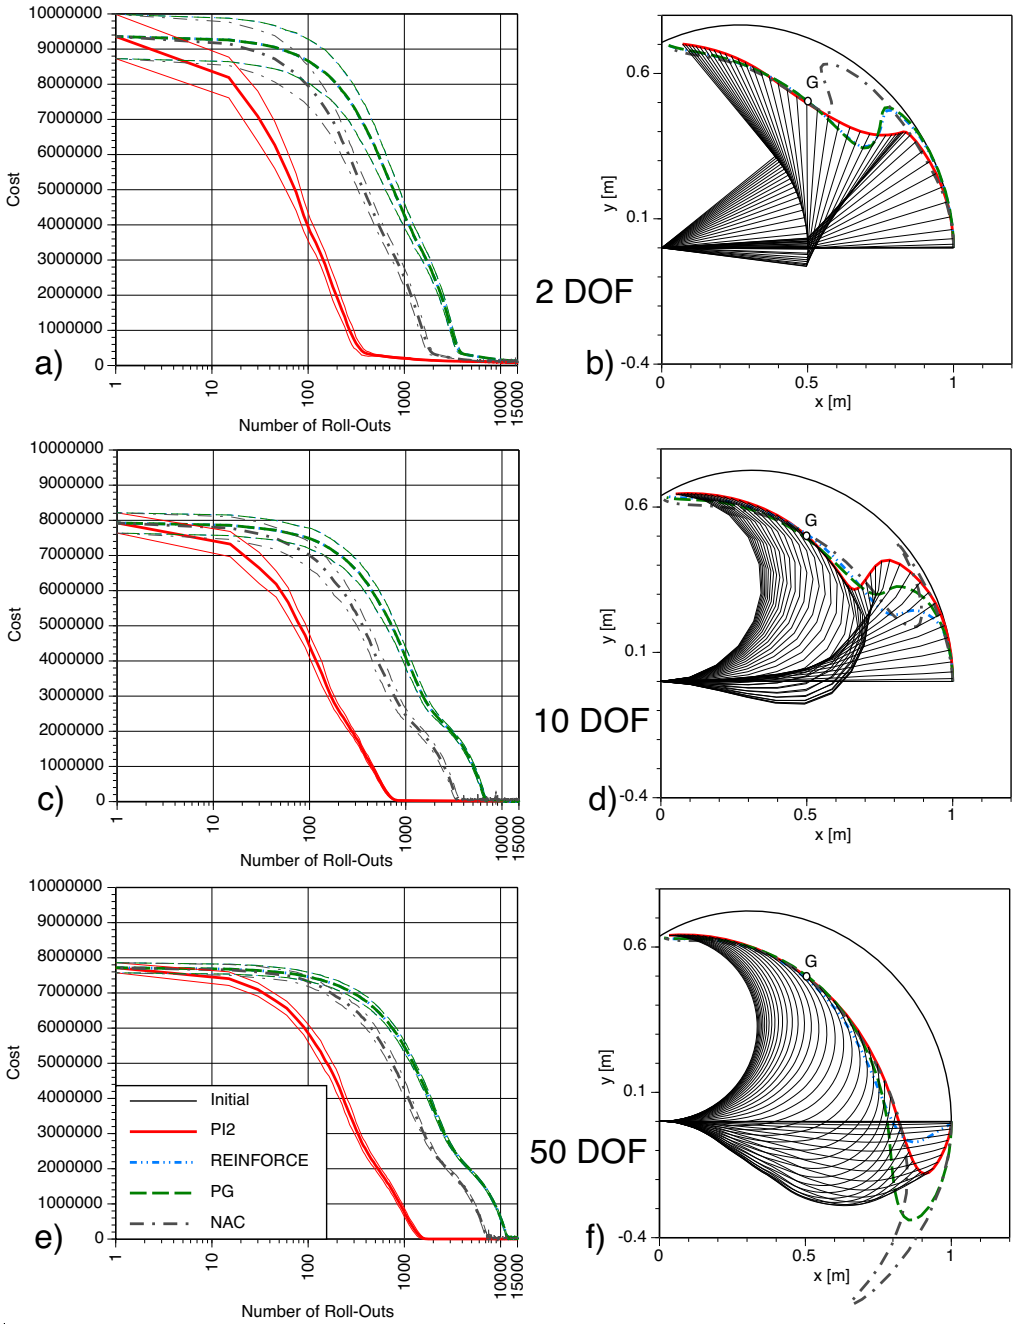

Figure 3: Comparison of learning multi-DOF movements (2,10, and 50 DOFs) with planar robot arms passing through a via-point G. a,c,e) illustrate the learning curves for different RL algorithms, while b,d,f) illustrate the end-effector movement after learning for all algorithms. Additionally, b,d,f) also show the initial end-effector movement, before learning to pass through G, and a "stroboscopic" visualization of the arm movement for the final result of $\mathbf{PI}^2$ (the movements proceed in time starting at the very right and ending by (almost) touching the y axis).

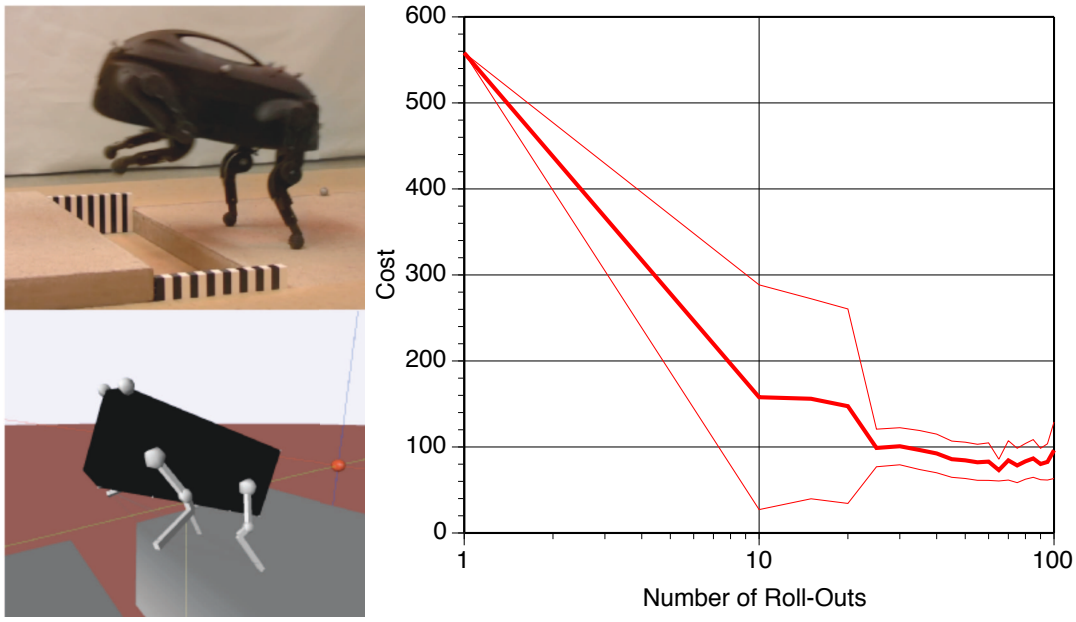

(a) Real & Simulated Robot Dog

(b) Learning curve for Dog Jump with $\mathbf{PI}^2$ $\pm 1 std$

Figure 4: Reinforcement learning of optimizing to jump over a gap with a robot dog. The improvement in cost corresponds to about 15 cm improvement in jump distance, which changed the robot's behavior from an initial barely successful jump to jump that completely traversed the gap with entire body. This learned behavior allowed the robot to traverse a gap at much higher speed in a competition on learning locomotion. The experiments for this paper were conducted only on the robot simulator.

jump straight forward and not to the side, and not to fall over. The exact cost function is:

$$
\begin{aligned}
r_t &= r_{roll} + r_{yaw} + \sum_{i=1}^{d} \left(a_1 f_{i,t}^2 + 0.5 a_2\, \theta_i^T \theta\right) (a_1 = 1.e-6, a_2 = 1.e-8), \\
r_{roll} &= \begin{cases} 100 * (|roll_t| - 0.3)^2, & \text{if } (|roll_t| > 0.3) \\ 0, & otherwise, \end{cases} \\
r_{yaw} &= \begin{cases} 100 * (|yaw_t| - 0.1)^2, & \text{if } (|yaw_t| > 0.1) \\ 0, & otherwise, \end{cases} \\
\phi_{t_N} &= 50000 (goal - x_{nose})^2,
\end{aligned}
$$

where $roll, yaw$ are the roll and yaw angles of the robot's body, and x_{nose} is the position of the front tip (the "nose") of the robot in the forward direction, which is the direction towards the $goal$. The multipliers for each reward component were tuned to have a balanced influence of all terms. Ten learning trials were performed initially for the first parameter update. The best 5 trials were kept, and five additional new trials were performed for the second and all subsequent updates. Essentially, this method performs importance sampling, as the rewards for the 5 trials in memory were re-computed

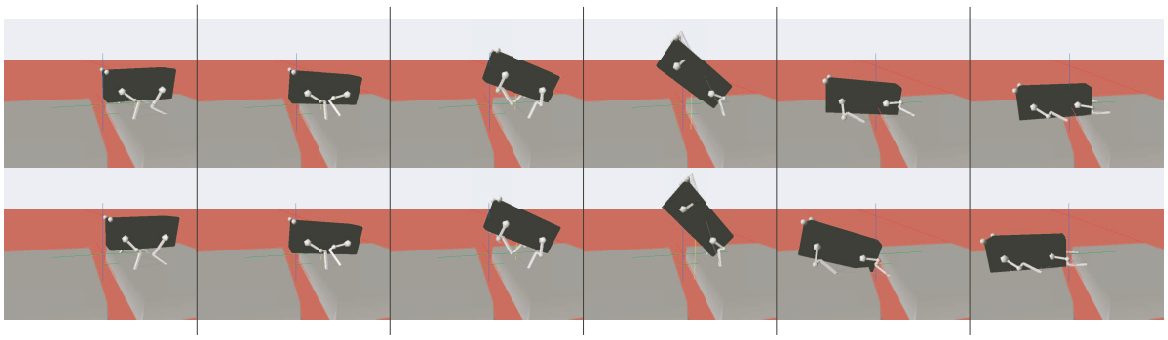

Figure 5: Sequence of images from the simulated robot dog jumping over a 14cm gap. Top: before learning. Bottom: After learning. While the two sequences look quite similar at the first glance, it is apparent that in the 4th frame, the robot's body is significantly higher in the air, such that after landing, the body of the dog made about 15cm more forward progress as before. In particular, the entire robot's body comes to rest on the other side of the gap, which allows for an easy transition to walking. In contrast, before learning, the robot's body (and its hind legs) are still on the right side of the gap, which does not allow for a successful continuation of walking.

with the latest parameter vectors. A total of 100 trials was performed per run, and ten runs were collected for computing mean and standard deviations of learning curves.

Figure 4 illustrates that after about 30 trials (i.e., 5 updates), the performance of the robot was converged and significantly improved, such that after the jump, almost the entire body was lying on the other side of the gap. Figure 4 captures the temporal performance in a sequence of snapshots of the robot. It should be noted that applying $\mathbf{PI}^2$ was algorithmically very simple, and manual tuning only focused on generated a good cost function, which is a different research topic beyond the scope of this paper.

6. Discussion

This paper derived a more general version of stochastic optimal control with path integrals, based on the original work by Kappen (2007) and Broek et al. (2008). The key results were presented in Table 1 and Section 2.5, which considered how to compute the optimal controls for a general class of stochastic control systems with state-dependent control transition matrix. One important class of these systems can be interpreted in the framework of reinforcement learning with parameterized policies. For this class, we derived Policy Improvement with Path Integrals ($\mathbf{PI}^2$) as a novel algorithm for learning a parameterized policy. $\mathbf{PI}^2$ inherits its sound foundation in first order principles of stochastic optimal control from the path integral formalism. It is a probabilistic learning method without open algorithmic tuning parameters, except for the exploration noise. In our evaluations, $\mathbf{PI}^2$ outperformed gradient algorithms significantly. It is also numerically simpler and has easier cost function design than previous probabilistic RL methods that require that immediate rewards are pseudo-probabilities. The similarity of $\mathbf{PI}^2$ with algorithms based on probability matching indicates that the principle of probability matching seems to approximate a stochastic optimal control framework. Our evaluations demonstrated that $\mathbf{PI}^2$ can scale to high dimensional control systems, unlike many other reinforcement learning systems.

Some issues, however, deserve more detailed discussions in the following paragraphs.

6.1 The Simplification $\lambda \mathbf{R}^{-1} = \Sigma_\varepsilon$

In order to obtain linear 2^{nd} order differential equations for the exponentially transformed HJB equations, the simplification $\lambda \mathbf{R}^{-1} = \Sigma_\varepsilon$ was applied. Essentially, this assumption couples the control cost to the stochasticity of the system dynamics, that is, a control with high variance will have relatively small cost, while a control with low variance will have relatively high cost. This assumption makes intuitively sense as it would be mostly unreasonable to attribute a lot of cost to an unreliable control component. Algorithmically, this assumption transforms the Gaussian probability for state transitions into a quadratic command cost, which is exactly what our immediate reward function postulated. Future work may allow removing this simplification by applying generalized versions of the Feynman-Kac Lemma.

6.2 Model-based, Hybrid, and Model-free Learning

Stochastic optimal control with path integrals makes a strong link to the dynamic system to be optimized—indeed, originally, it was derived solely as model-based method. As this paper demonstrated, however, this view can be relaxed. The roll-outs, needed for computing the optimal controls, can be generated either from simulating a model, or by gathering experience from an actual system. In the latter case, only the control transition matrix of the model needs be known, such that we obtain a hybrid model-based/model-free method. In this paper, we even went further and interpreted the stochastic dynamic system as a parameterized control policy, such that no knowledge of the model of the control system was needed anymore—that is, we entered a model-free learning domain. It seems that there is a rich variety of ways how the path integral formalism can be used in different applications.

6.3 Rules of Cost Function Design

The cost functions allowed in our formulations can have arbitrary state cost, but need quadratic command cost. This is somewhat restrictive, although the user can be flexible in what is defined as a command. For instance, the dynamic movement primitives (30) used in this paper can be written in two alternative ways:

$$\begin{aligned} \frac{1}{\tau}\dot{z}_t &= f_t + \mathbf{g}_t^T(\theta + \varepsilon_t), \\ &\text{or} \\ \frac{1}{\tau}\dot{z}_t &= \left[\mathbf{g}_t^T f_t\right]\left(\begin{bmatrix} \theta \\ 1 \end{bmatrix} + \tilde{\varepsilon}_t\right), \end{aligned}$$

where the new noise vector $\tilde{\varepsilon}_t$ has one additional coefficient. The second equation treats f_t as another basis function whose parameter is constant and is thus simply not updated. Thus, we added f_t to the command cost instead of treating it as a state cost.

We also numerically experimented with violations of the clean distinction between state and command cost. Equation (36) could be replaced by a cost term, which is an arbitrary function of state and command. In the end, this cost term is just used to differentiate the different roll-outs in a reward weighted average, similarly as in Peters and Schaal (2008c) and Koeber and Peters (2008). We noticed in several instances that $\mathbf{PI}^2$ continued to work just fine with this improper cost formulation.

Again, it appears that the path integral formalism and the **PI**^{2} algorithm allow the user to exploit creativity in designing cost functions, without absolute need to adhere perfectly to the theoretical framework.

6.4 Dealing with Hidden State

Finally, it is interesting to consider in how far **PI**^{2} would be affected by hidden state. Hidden state can either be of stochastic or deterministic nature, and we consider hidden state as adding additional equations to the system dynamics (3). Section 2.3 already derived that deterministic hidden states drop out of the **PI**^{2} update equations—these states of the system dynamics were termed as " non-directly actuated" states.

More interesting are hidden state variables that have stochastic differential equations, that is, these equations are uncontrolled but do have a noise term and a non-zero corresponding coefficient in $\mathbf{G}_t$ in Equation (3), and these equations are coupled to the other equations through their passive dynamics. The noise term of these equations would, in theory, contribute terms in Equation (36), but given that neither the noise nor the state of these equations are observable, we will not have the knowledge to add these terms. However, as long as the magnitude of these terms is small relative to the other terms in Equation (36), **PI**^{2} will continue to work fine, just a bit sub-optimally. This issue would affect other reinforcement learning methods for parameterized policies in the same way, and is not specific to **PI**^{2}.

6.5 Arbitrary States in the Cost Function

As a last point, we would like to consider which variables can actually enter the cost functions for **PI**^{2}. The path integral approach prescribes that the cost function needs to be a function of the state and command variables of the system equations (3). It should be emphasized that the state cost q_t can be any deterministic function of the state, that is, anything that is predictable from knowing the state, even if we do not know the predictive function. There is a lot of flexibility in this formulation, but it is also more restrictive than other approaches, for example, like policy gradients or the PoWER algorithm, where arbitrary variables can be used in the cost, no matter whether they are states or not.

We can think of any variable that we would like to use in the cost as having a corresponding differential equation in the system dynamics (3), that is, we simply add these variables as state variables, just that we do not know the analytical form of these equations. As in the previous section, it is useful to distinguish whether these states have deterministic or stochastic differential equations.

If the differential equation is deterministic, we can cover the case with the derivations from Section 2.3, that is, we consider such an equation as uncontrolled deterministic differential equation in the system dynamics, and we already know that we can use its state in the cost without any problems as it does not contribute to the probability of a roll-out.

If the differential equation is stochastic, the same argument as in the previous section applies, that is, the (unknown) contribution of the noise term of this equation to the exponentiated cost (36) needs to be small enough for **PI**^{2} to work effectively. Future work and empirical evaluations will have to demonstrate when these issues really matter—so far, we have not encountered problems in this regard.

7. Conclusions

The path integral formalism for stochastic optimal control has a very interesting potential to discover new learning algorithms for reinforcement learning. The $\mathbf{PI}^2$ algorithm derived in this paper for learning with parameterized policies demonstrated a surprisingly good performance, literally without any need for manual tuning of the parameters of the algorithm. We also demonstrated that the algorithm scales well into very high dimensional domains that were previously hardly approachable for reinforcement learning. Future work will thus allow us to focus much more on machine learning algorithms for cost function design, as the algorithmic components of the learning algorithm seem to be able to move towards a "black box" character.

Appendix A.

Appendix **A** contains the lemmas **A1** and **A2** and one theorem. The theorem provides the main result of the generalized path integral control formalism expressed by (18), (19), (20). Its proof is based on results proven in the lemmas **A1** and **A2**. In appendix **B** we provide the Feynman-Kac formula and we sketch the corresponding proof.

Lemma 1 *: The optimal control solution to the stochastic optimal control problem expressed by (1),(2),(3) and (4) is formulated as:*

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left[-\mathbf{R}^{-1} \mathbf{G}_{t_i}^{(c)T} \int \tilde{p}(\boldsymbol{\tau}_i) \nabla_{\mathbf{x}_{t_i}^{(c)}} \tilde{S}(\boldsymbol{\tau}_i) d\boldsymbol{\tau}_i \right]$$

where $\tilde{p}(\boldsymbol{\tau}_i) = \frac{\exp\left(-\frac{1}{\lambda}\tilde{S}(\boldsymbol{\tau}_i)\right)}{\int \exp\left(-\frac{1}{\lambda}\tilde{S}(\boldsymbol{\tau}_i)\right) d\boldsymbol{\tau}_i}$ *is a path dependent probability distribution. The term* $\tilde{S}(\boldsymbol{\tau}_i)$ *is a path function defined as* $\tilde{S}(\boldsymbol{\tau}_i) = S(\boldsymbol{\tau}_i) + \frac{\lambda}{2} \sum_{j=i}^{N-1} \log |\mathbf{H}_{t_j}|$ *that satisfies the following condition* $\lim_{dt \to 0} \int \exp\left(-\frac{1}{\lambda}\tilde{S}(\boldsymbol{\tau}_i)\right) d\boldsymbol{\tau}_i \in \mathcal{C}^{(1)}$ *for any sampled trajectory starting from state* $\mathbf{x}_{t_i}$*. Moreover the term* $\mathbf{H}_{t_j}$ *is given by* $\mathbf{H}_{t_j} = \mathbf{G}_{t_j}^{(c)} \mathbf{R}^{-1} \mathbf{G}_{t_j}^{(c)T}$ *while the term* $S(\boldsymbol{\tau}_i)$ *is defined according to*

$$S(\boldsymbol{\tau}_i) = \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} dt + \frac{1}{2} \sum_{j=i}^{N-1} \| \frac{\mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)}}{dt} - \mathbf{f}_{t_j}^{(c)} \|_{\mathbf{H}_{t_j}}^2 dt.$$

Proof The optimal controls at the state $\mathbf{x}_{t_i}$ is expressed by the equation $\mathbf{u}_{t_i} = -\mathbf{R}^{-1} \mathbf{G}_{t_i} \nabla_{\mathbf{x}_{t_i}} V_{t_i}$. Due to the exponential transformation of the value function $\Psi_{t_i} = -\lambda \log V_{t_i}$ the equation of the optimal controls is written as:

$$\mathbf{u}_{t_i} = \lambda \mathbf{R}^{-1} \mathbf{G}_{t_i} \frac{\nabla_{\mathbf{x}_{t_i}} \Psi_{t_i}}{\Psi_{t_i}}.$$

In discrete time the optimal control is expressed as follows:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left(\lambda \mathbf{R}^{-1} \mathbf{G}_{t_i}^T \frac{\nabla_{\mathbf{x}_{t_i}} \Psi_{t_i}^{(dt)}}{\Psi_{t_i}^{(dt)}} \right).$$

By using equation (17) and substituting $\Psi^{(dt)}(\mathbf{x}_{t_i}, t)$ we have:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left(\lambda \mathbf{R}^{-1} \mathbf{G}_{t_i}^T \frac{\nabla_{\mathbf{x}_{t_i}} \int \exp\left(-\frac{1}{\lambda} Z(\tau_i)\right) d\tau_i}{\int \exp\left(-\frac{1}{\lambda} Z(\tau_i)\right) d\tau_i} \right).$$

Substitution of the term $Z(\tau_i)$ results in the equation:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left(\lambda \mathbf{R}^{-1} \mathbf{G}_{t_i}^T \frac{\nabla_{\mathbf{x}_{t_i}} \int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i) - \frac{\lambda(N-i)l}{2} \log\left(2\pi dt \lambda\right)\right) d\tau_i}{\int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i) - \frac{\lambda(N-i)l}{2} \log\left(2\pi dt \lambda\right)\right) d\tau_i} \right).$$

Next we are using standard properties of the exponential function that lead to:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left(\lambda \mathbf{R}^{-1} \mathbf{G}_{t_i}^T \frac{\nabla_{\mathbf{x}_{t_i}} \left[\int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) \exp\left(-\frac{\lambda(N-i)l}{2} \log\left(2\pi dt \lambda\right)\right) d\tau_i \right]}{\int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) \exp\left(-\frac{\lambda(N-i)l}{2} \log\left(2\pi dt \lambda\right)\right) d\tau_i} \right).$$

The term $\exp\left(-\frac{\lambda N l}{2} \log\left(2\pi dt \lambda\right)\right)$ does not depend on the trajectory τ_i, therefore it can be taken outside the integral as well as outside the gradient. Thus we will have that:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left(\lambda \mathbf{R}^{-1} \mathbf{G}_{t_i}^T \frac{\exp\left(-\frac{\lambda(N-i)l}{2} \log\left(2\pi dt \lambda\right)\right) \nabla_{\mathbf{x}_{t_i}} \left[\int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) d\tau_i \right]}{\exp\left(-\frac{\lambda(N-i)l}{2} \log\left(2\pi dt \lambda\right)\right) \int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) d\tau_i} \right).$$

The constant term drops from the nominator and denominator and thus we can write:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left(\lambda \mathbf{R}^{-1} \mathbf{G}_{t_i}^T \left[\frac{\nabla_{\mathbf{x}_{t_i}} \int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) d\tau_i}{\int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) d\tau_i} \right] \right).$$

Under the assumption that term $\exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) d\tau_i$ is continuously differentiable in $\mathbf{x}_{t_i}$ and dt we can change order of the integral with the differentiation operations. In general for $\nabla_x \int f(x,y) dy = \int \nabla_x f(x,y) dy$ to be true, $f(x,t)$ should be continuous in y and differentiable in x. Under this assumption, the optimal controls can be further formulated as:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left[\lambda \mathbf{R}^{-1} \mathbf{G}_{t_i}^T \frac{\int \nabla_{\mathbf{x}_{t_i}} \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) d\tau_i}{\int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) d\tau_i} \right].$$

Application of the differentiation rule of the exponent results in:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left[\lambda \mathbf{R}^{-1} \mathbf{G}_{t_i}^T \frac{\int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) \nabla_{\mathbf{x}_{t_i}} \left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) d\tau_i}{\int \exp\left(-\frac{1}{\lambda} \tilde{S}(\tau_i)\right) d\tau_i} \right].$$

The denominator is a function of $\mathbf{x}_{t_i}$ the current state and thus it can be pushed inside the integral of the nominator:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left[\lambda \mathbf{R}^{-1} \mathbf{G}_{t_i}^T \int \frac{\exp\left(-\frac{1}{\lambda}\tilde{S}(\boldsymbol{\tau}_i)\right)}{\int \exp\left(-\frac{1}{\lambda}\tilde{S}(\boldsymbol{\tau}_i)\right) d\boldsymbol{\tau}_i} \nabla_{\mathbf{x}_{t_i}} \left(-\frac{1}{\lambda}\tilde{S}(\boldsymbol{\tau}_i) \right) d\boldsymbol{\tau}_i \right].$$

By defining the probability $\tilde{p}(\boldsymbol{\tau}_i) = \frac{\exp\left(-\frac{1}{\lambda}\tilde{S}(\boldsymbol{\tau}_i)\right)}{\int \exp\left(-\frac{1}{\lambda}\tilde{S}(\boldsymbol{\tau}_i)\right) d\boldsymbol{\tau}_i}$ the expression above can be written as:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left[\lambda \mathbf{R}^{-1} \mathbf{G}_{t_i}^T \int \tilde{p}(\boldsymbol{\tau}_i) \nabla_{\mathbf{x}_{t_i}} \left(-\frac{1}{\lambda}\tilde{S}(\boldsymbol{\tau}_i) \right) d\boldsymbol{\tau}_i \right].$$

Further simplification will result in:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left[-\mathbf{R}^{-1} \mathbf{G}_{t_i}^T \int \tilde{p}(\boldsymbol{\tau}_i) \nabla_{\mathbf{x}_{t_i}} \tilde{S}(\boldsymbol{\tau}_i) d\boldsymbol{\tau}_i \right].$$

We know that the control transition matrix has the form $\mathbf{G}(\mathbf{x}_{t_i})^T = [0^T \quad \mathbf{G}_c(\mathbf{x}_{x_{t_i}})^T]$. In addition the partial derivative $\nabla_{\mathbf{x}_{t_i}} \tilde{S}(\boldsymbol{\tau}_i)$ can be written as $\nabla_{\mathbf{x}_{t_i}} \tilde{S}(\boldsymbol{\tau}_i)^T = [\nabla_{\mathbf{x}_{t_i}^{(m)}} \tilde{S}(\boldsymbol{\tau}_i)^T \quad \nabla_{\mathbf{x}_{t_i}^{(c)}} \tilde{S}(\boldsymbol{\tau}_i)^T]$. By using these equations we will have that:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left(-\mathbf{R}^{-1} [0^T \quad \mathbf{G}_{t_i}^{(c)T}] \int \tilde{p}(\boldsymbol{\tau}_o) \begin{bmatrix} \nabla_{\mathbf{x}_{t_i}^{(m)}} \tilde{S}(\boldsymbol{\tau}_i) \\ \nabla_{\mathbf{x}_{t_i}^{(c)}} \tilde{S}(\boldsymbol{\tau}_i) \end{bmatrix} d\boldsymbol{\tau}_i \right).$$

The equation above can be written in the form:

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left(-[0^T \quad \mathbf{R}^{-1} \mathbf{G}_{t_i}^{(c)T}] \int \tilde{p}(\boldsymbol{\tau}_i) \begin{bmatrix} \nabla_{\mathbf{x}_{t_i}^{(m)}} \tilde{S}(\boldsymbol{\tau}_i) \\ \nabla_{\mathbf{x}_{t_i}^{(c)}} \tilde{S}(\boldsymbol{\tau}_i) \end{bmatrix} d\boldsymbol{\tau}_i \right).$$

or

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left(-[0^T \quad \mathbf{R}^{-1} \mathbf{G}_{t_i}^{(c)T}] \begin{bmatrix} \int \tilde{p}(\boldsymbol{\tau}_i) \cdot \nabla_{\mathbf{x}_{t_i}^{(m)}} \tilde{S}(\boldsymbol{\tau}_i) d\boldsymbol{\tau}_i \\ \int \tilde{p}(\boldsymbol{\tau}_i) \cdot \nabla_{\mathbf{x}_{t_i}^{(c)}} \tilde{S}(\boldsymbol{\tau}_i) d\boldsymbol{\tau}_i \end{bmatrix} \right).$$

Therefore we will have the result

$$\mathbf{u}_{t_i} = \lim_{dt \to 0} \left[-\mathbf{R}^{-1} \mathbf{G}_{t_i}^{(c)T} \int \tilde{p}(\boldsymbol{\tau}_i) \nabla_{\mathbf{x}_{t_i}^{(c)}} \tilde{S}(\boldsymbol{\tau}_i) d\boldsymbol{\tau}_i \right].$$

■

Lemma 2 *: Given the stochastic dynamics and the cost in (1),(2),(3) and(4) the gradient of the path function $\tilde{S}(\boldsymbol{\tau}_i)$ with respect to the directly actuated part of the state $\mathbf{x}_{t_i}^{(c)}$ is formulated as:*

$$\lim_{dt \to 0} \left(\nabla_{\mathbf{x}_{t_i}^{(c)}} \tilde{S}(\boldsymbol{\tau}_i) \right) = -\mathbf{H}_{t_i}^{-1} \left(\mathbf{G}_{t_i}^{(c)} \boldsymbol{\varepsilon}_{t_i} - \mathbf{b}_{t_i} \right)$$

where the function $b(\mathbf{x}_{t_i})$ *defined as* $\lambda \mathbf{H}(\mathbf{x}_{t_i})\Phi_{t_i}$ *with* $\mathbf{H}_{t_i} = \mathbf{G}_{t_i}^{(c)} \mathbf{R}^{-1} \mathbf{G}_{t_i}^{(c)^T}$ *and the quantity* $\Phi_{t_i} \in \Re^{l \times 1}$ *is expressed as:*

$$\Phi_{t_i} = \frac{1}{2} \begin{bmatrix} trace\left(\mathbf{H}_{t_i}^{-1} \ \partial_{\mathbf{x}_{t_i}^{(c1)}} \mathbf{H}_{t_i}\right) \\ trace\left(\mathbf{H}_{t_i}^{-1} \ \partial_{\mathbf{x}_{t_i}^{(c2)}} \mathbf{H}_{t_i}\right) \\ \cdot \\ \cdot \\ \cdot \\ trace\left(\mathbf{H}_{t_i}^{-1} \ \partial_{\mathbf{x}_{t_i}^{(cl)}} \mathbf{H}_{t_i}\right) \end{bmatrix}.$$

Proof

We are calculating the term $\nabla_{\mathbf{x}_{t_o}^{(c)}} \tilde{S}(\tau_o)$. More precisely we have shown that

$$\tilde{S}(\tau_i) = \phi_{t_N} + \sum_{j=i}^{N-1} q_{t_j} dt + \frac{1}{2} \sum_{j=i}^{N-1} \| \frac{\mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)}}{dt} - \mathbf{f}_{t_j}^{(c)} \|_{\mathbf{H}_{t_j}}^2 dt + \frac{\lambda}{2} \sum_{j=i}^{N-1} \log |\mathbf{H}_{t_j}|.$$

To limit the length of our derivation we introduce the notation $\gamma_{t_j} = \alpha_{t_j}^T \ \mathbf{h}_{t_j}^{-1} \ \alpha_{t_j}$ and $\alpha_{t_j} = \left(\mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)} - \mathbf{f}_{t_j}^{(c)} dt\right)$ and it is easy to show that $\| \frac{\mathbf{x}_{t_{j+1}}^{(c)} - \mathbf{x}_{t_j}^{(c)}}{dt} - \mathbf{f}_{t_j}^{(c)} \|_{\mathbf{H}_{t_j}}^2 dt = \frac{1}{dt} \gamma_{t_j}$ and therefore we will have:

$$\tilde{S}(\tau_i) = \phi_{t_N} + \frac{1}{2dt} \sum_{j=i}^{N-1} \gamma_{t_j} + \sum_{t_o}^{t_N} Q_{t_j} dt + \frac{\lambda}{2} \sum_{j=i}^{N-1} \log |\mathbf{H}_{t_j}|.$$

■

In the analysis that follows we provide the derivative of the 1th, 2th and 4th term of the cost function. We assume that the cost of the state during the time horizon $Q_{t_i} = 0$. In cases that this is not true then the derivative $\nabla_{\mathbf{x}_{t_i}^{(c)}} \sum_{t_i}^{t_N} Q_{t_i} dt$ needs to be found as well. By calculating the term $\nabla_{\mathbf{x}_{t_o}^{(c)}} \tilde{S}(\tau_o)$ we can find the local controls $\mathbf{u}(\tau_i)$. It is important to mention that the derivative of the path cost $S(\tau_i)$ is taken only with respect to the current state $\mathbf{x}_{t_o}$.

The first term is:

$$\nabla_{\mathbf{x}_{t_i}^{(c)}} (\phi_{t_N}) = 0.$$

DERIVATIVE OF THE 2TH TERM $\nabla_{\mathbf{x}_{t_i}^{(c)}} \left[\frac{1}{2dt} \sum_{i=1}^{N-1} \gamma_{t_i}\right]$ OF THE COST $S(\tau_i)$.

The second term can be found as follows:

$$\nabla_{\mathbf{x}_{t_i}^{(c)}} \left[\frac{1}{2dt} \sum_{j=i}^{N-1} \gamma_{t_j}\right].$$

The operator $\nabla_{\mathbf{x}_{t_o}^{(c)}}$ is linear and it can massaged inside the sum:

$$\frac{1}{2dt}\sum_{j=i}^{N-1}\nabla_{\mathbf{x}_{t_j}^{(c)}}\left(\gamma_{t_j}\right).$$

Terms that do not depend on $\mathbf{x}_{t_i}^{(c)}$ drop and thus we will have:

$$\frac{1}{2dt}\nabla_{\mathbf{x}_{t_i}^{(c)}}\gamma_{t_i}.$$

Substitution of the parameter $\gamma_{t_i}=\alpha_{t_i}^T\ \mathbf{H}_{t_i}^{-1}\ \alpha_{t_i}$ will result in:

$$\frac{1}{2dt}\nabla_{\mathbf{x}_{t_i}^{(c)}}\left[\alpha_{t_i}^T\ \mathbf{H}_{t_i}^{-1}\ \alpha_{t_i}\right].$$

By making the substitution $\beta_{t_i}=\mathbf{H}_{t_i}^{-1}\ \alpha_{t_i}$ and applying the rule $\nabla\left(\mathbf{u}(\mathbf{x})^T\mathbf{v}(\mathbf{x})\right)=\nabla\left(\mathbf{u}(\mathbf{x})\right)\mathbf{v}(\mathbf{x})+\nabla\left(\mathbf{v}(\mathbf{x})\right)\mathbf{u}(\mathbf{x})$ we will have that:

$$\frac{1}{2dt}\left[\nabla_{\mathbf{x}_{t_i}^{(c)}}\alpha_{t_i}\ \beta_{t_i}+\nabla_{\mathbf{x}_{t_i}^{(c)}}\beta_{t_i}\ \alpha_{t_i}\right]. \tag{40}$$

Next we find the derivative of α_{t_o}:

$$\nabla_{\mathbf{x}_{t_i}^{(c)}}\alpha_{t_i}=\nabla_{\mathbf{x}_{t_i}^{(c)}}\left[\mathbf{x}_{t_{i+1}}^{(c)}-\mathbf{x}_{t_i}^{(c)}-\mathbf{f}_c(\mathbf{x}_{t_i})dt\right].$$

and the result is

$$\nabla_{\mathbf{x}_{t_i}^{(c)}}\alpha_{t_i}=-I_{l\times l}-\nabla_{\mathbf{x}_{t_i}^{(c)}}\mathbf{f}_{t_i}^{(c)}dt.$$

We substitute back to (40) and we will have:

$$\frac{1}{2dt}\left[-\left(I_{l\times l}+\nabla_{\mathbf{x}_{t_i}^{(c)}}\mathbf{f}_{t_i}^{(c)}dt\right)\ \beta_{t_i}+\nabla_{\mathbf{x}_{t_i}^{(c)}}\beta_{t_i}\ \alpha_{t_i}\right].$$

$$-\frac{1}{2dt}\left(I_{l\times l}+\nabla_{\mathbf{x}_{t_i}^{(c)}}\mathbf{f}_{t_i}^{(c)}dt\right)\ \beta_{t_i}+\frac{1}{2dt}\ \nabla_{\mathbf{x}_{t_i}^{(c)}}\beta_{t_i}\ \alpha_{t_i}.$$

After some algebra the result of $\nabla_{\mathbf{x}_{t_i}^{(c)}}\left(\frac{1}{2dt}\sum_{i=1}^{N-1}\gamma_{t_i}\right)$ is expressed as:

$$-\frac{1}{2dt}\ \beta_{t_i}-\frac{1}{2}\nabla_{\mathbf{x}_{t_i}^{(c)}}\mathbf{f}_{t_i}^{(c)}\ \beta_{t_i}+\frac{1}{2dt}\ \nabla_{\mathbf{x}_{t_i}^{(c)}}\beta_{t_i}\ \alpha_{t_i}.$$

The next step now is to find the limit of the expression above as $dt\to 0$. More precisely we will have that:

$$\lim_{dt\to 0}\left[-\frac{1}{2dt}\ \beta_{t_i}-\frac{1}{2}\nabla_{\mathbf{x}_{t_i}^{(c)}}\mathbf{f}_{t_i}^{(c)}\ \beta_{t_i}+\frac{1}{2dt}\ \nabla_{\mathbf{x}_{t_i}^{(c)}}\beta_{t_i}\ \alpha_{t_i}\right].$$

LIMIT OF THE FIRST SUBTERM: $-\frac{1}{2dt}\ \beta_{t_i}$

We will continue our analysis by finding the limit for each one of the 3 terms above. The limit of the first term is calculated as follows:

$$\begin{aligned}\lim_{dt\to 0}\left(-\frac{1}{2dt}\ \ \beta_{t_i}\right) &= -\lim_{dt\to 0}\left(\frac{1}{2dt}\ \ \mathbf{H}_{t_i}^{-1}\ \ \alpha_{t_i}\right)\\ &= -\frac{1}{2}\ \ \mathbf{H}_{t_i}^{-1}\ \ \lim_{dt\to 0}\alpha_{t_i}\\ &= -\frac{1}{2}\ \ \mathbf{H}_{t_i}^{-1}\ \ \lim_{dt\to 0}\left((\mathbf{x}_{t_{i+1}}^{(c)}-\mathbf{x}_{t_i}^{(c)})\frac{1}{dt}-\mathbf{f}_{t_i}^{(c)}\right).\end{aligned}$$

LIMIT OF THE SECOND SUBTERM: $-\frac{1}{2}\nabla_{\mathbf{x}_{t_i}^{(c)}}\mathbf{f}_{t_i}^{(c)}\ \ \beta_{t_i}$

The limit of the second term is calculated as follows:

$$\begin{aligned}-\lim_{dt\to 0}\left(\frac{1}{2}\nabla_{\mathbf{x}_{t_i}^{(c)}}\mathbf{f}_{t_i}^{(c)}\ \ \beta_{t_i}\right) &= -\frac{1}{2}\nabla_{\mathbf{x}_{t_i}^{(c)}}\mathbf{f}_c(\mathbf{x}_{t_i})\ \ \lim_{dt\to 0}\beta_{t_i}\\ &= -\frac{1}{2}\nabla_{\mathbf{x}_{t_i}^{(c)}}\mathbf{f}_{t_i}^{(c)}\ \ \lim_{dt\to 0}\left(\mathbf{H}_{t_i}^{-1}\ \ \alpha_{t_i}\right)\\ &= -\frac{1}{2}\nabla_{\mathbf{x}_{t_i}^{(c)}}\mathbf{f}_c(\mathbf{x}_{t_i})\ \ \mathbf{H}_{t_i}^{-1}\ \ \lim_{dt\to 0}\alpha_{t_i}\\ &= 0.\end{aligned}$$

The limit of the term $\lim_{dt\to 0}\alpha_{t_i}$ is derived as:

$$\lim_{dt\to 0}\left(\mathbf{x}_{t_{i+1}}^{(c)}-\mathbf{x}_{t_i}^{(c)}-\mathbf{f}_c(\mathbf{x}_{t_i})dt\right)=\lim_{dt\to 0}\left(\mathbf{x}_{t_i+dt}^{(c)}-\mathbf{x}_{t_i}^{(c)}\right)-\lim_{dt\to 0}\mathbf{f}_c(\mathbf{x}_{t_i})dt=0-0=0.$$

LIMIT OF THE THIRD SUBTERM: $\frac{1}{2dt}\ \ \nabla_{\mathbf{x}_{t_i}^{(c)}}\beta_{t_i}\ \ \alpha_{t_i}$

Finally the limit of the third term can be found as:

$$\begin{aligned}&\lim_{dt\to 0}\left(\frac{1}{2dt}\ \ \nabla_{\mathbf{x}_{t_i}^{(c)}}\beta_{t_i}\ \ \alpha_{t_i}\right)=\\ &=\lim_{dt\to 0}\nabla_{\mathbf{x}_{t_i}^{(c)}}\beta_{t_i}\ \ \lim_{dt\to 0}\left(\frac{1}{2dt}\ \ \alpha_{t_i}\right)=\\ &=\lim_{dt\to 0}\nabla_{\mathbf{x}_{t_i}^{(c)}}\beta_{t_i}\ \ \frac{1}{2}\lim_{dt\to 0}\left((\mathbf{x}_{t_{i+1}}^{(c)}-\mathbf{x}_{t_i}^{(c)})\frac{1}{dt}-\mathbf{f}_{t_i}^{(c)}\right).\end{aligned}$$

We substitute $\beta_{t_i}=\mathbf{H}_{t_i}^{-1}\ \ \alpha_{t_i}$ and write the matrix $\mathbf{H}_{t_i}^{-1}$ in row form:

$$= \lim_{dt\to 0} \nabla_{\mathbf{x}_{t_i}^{(c)}} \left(\mathbf{H}_{t_i}^{-1} \;\; \alpha_{t_i}\right) \;\; \frac{1}{2} \lim_{dt\to 0} \left((\mathbf{x}_{t_i}^{(c)} - \mathbf{x}_{t_i}^{(c)}) \frac{1}{dt} - \mathbf{f}_{t_i}^{(c)} \right) =$$

$$= \lim_{dt\to 0} \nabla_{\mathbf{x}_{t_i}^{(c)}} \left(\begin{bmatrix} \mathbf{H}_{t_i}^{(1)^{-T}} \\ \mathbf{H}_{t_i}^{(2)^{-T}} \\ \cdot \\ \cdot \\ \cdot \\ \mathbf{H}_{t_i}^{(l)^{-T}} \end{bmatrix} \;\; \alpha_{t_i} \right) \;\; \frac{1}{2} \lim_{dt\to 0} \left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)}) \frac{1}{dt} - \mathbf{f}_{t_i}^{(c)} \right)$$

$$= \lim_{dt\to 0} \nabla_{\mathbf{x}_{t_i}^{(c)}} \begin{bmatrix} \mathbf{H}_{t_i}^{(1)^{-T}} & \alpha_{t_i} \\ \mathbf{H}_{t_i}^{(2)^{-T}} & \alpha_{t_i} \\ \cdot & \\ \cdot & \\ \cdot & \\ \mathbf{H}_{t_i}^{(l)^{-T}} & \alpha_{t_i} \end{bmatrix} \frac{1}{2} \lim_{dt\to 0} \left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)}) \frac{1}{dt} - \mathbf{f}_{t_i}^{(c)} \right).$$

We can push the operator $\nabla_{\mathbf{x}_{t_i}^{(c)}}$ insight the matrix and apply it to each element.

$$= \lim_{dt\to 0} \begin{bmatrix} \nabla^T_{\mathbf{x}_{t_i}^{(c)}} \left(\mathbf{H}_{t_i}^{(1)^{-T}} \;\; \alpha_{t_i} \right) \\ \nabla^T_{\mathbf{x}_{t_i}^{(c)}} \left(\mathbf{H}_{t_i}^{(2)^{-T}} \;\; \alpha_{t_i} \right) \\ \cdot \\ \cdot \\ \cdot \\ \nabla^T_{\mathbf{x}_{t_i}^{(c)}} \left(\mathbf{H}_{t_i}^{(l)^{-T}} \;\; \alpha_{t_i} \right) \end{bmatrix} \frac{1}{2} \lim_{dt\to 0} \left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)}) \frac{1}{dt} - \mathbf{f}_{t_i}^{(c)} \right).$$

We again use the rule $\nabla \left(\mathbf{u}(\mathbf{x})^T \mathbf{v}(\mathbf{x}) \right) = \nabla \left(\mathbf{u}(\mathbf{x}) \right) \mathbf{v}(\mathbf{x}) + \nabla \left(\mathbf{v}(\mathbf{x}) \right) \mathbf{u}(\mathbf{x})$ and thus we will have:

$$= \lim_{dt\to 0} \begin{bmatrix} \left(\nabla_{\mathbf{x}_{t_i}^{(c)}} \mathbf{H}_{t_i}^{(1)^{-T}} \;\; \alpha_{t_i} + \nabla_{\mathbf{x}_{t_i}^{(c)}} \alpha_{t_i} \;\; \mathbf{H}_{t_i}^{(1)^{-T}} \right)^T \\ \left(\nabla_{\mathbf{x}_{t_i}^{(c)}} \mathbf{H}_{t_i}^{(2)^{-T}} \;\; \alpha_{t_i} + \nabla_{\mathbf{x}_{t_i}^{(c)}} \alpha_{t_i} \;\; \mathbf{H}_{t_i}^{(2)^{-T}} \right)^T \\ \cdot \\ \cdot \\ \cdot \\ \left(\nabla_{\mathbf{x}_{t_i}^{(c)}} \mathbf{H}_{t_i}^{(l)^{-T}} \;\; \alpha_{t_i} + \nabla_{\mathbf{x}_{t_i}^{(c)}} \alpha_{t_i} \;\; \mathbf{H}_{t_i}^{(l)^{-T}} \right)^T \end{bmatrix} \lim_{dt\to 0} \left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)}) \frac{1}{dt} - \mathbf{f}_{t_i}^{(c)} \right).$$

We can split the matrix above into two terms and then we pull out the terms α_{t_i} and $\nabla_{\mathbf{x}_{t_i}^{(c)}} \alpha_{t_i}$ respectively :

$$= \lim_{dt\to 0} \left(\alpha_{t_i}^T \begin{bmatrix} \nabla_{\mathbf{x}_{t_i}^{(c)}} \mathbf{H}_{t_i}^{(1)^{-T}} \\ \nabla_{\mathbf{x}_{t_i}^{(c)}} \mathbf{H}_{t_i}^{(2)^{-T}} \\ \cdot \\ \cdot \\ \cdot \\ \nabla_{\mathbf{x}_{t_i}^{(c)}} \mathbf{H}_{t_i}^{(l)^{-T}} \end{bmatrix} + \begin{bmatrix} \mathbf{H}_{t_i}^{(1)^{-T}} \\ \mathbf{H}_{t_i}^{(2)^{-T}} \\ \cdot \\ \cdot \\ \cdot \\ \mathbf{H}_{t_i}^{(l)^{-T}} \end{bmatrix} \nabla_{\mathbf{x}_{t_i}^{(c)}} \alpha_{t_i}^T \right) \frac{1}{2} \lim_{dt\to 0} \left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)}) \frac{1}{dt} - \mathbf{f}_{t_i}^{(c)} \right)$$

$$= \lim_{dt\to 0} \left(\alpha_{t_i}^T \;\; \nabla_{\mathbf{x}_{t_i}^{(c)}} \mathbf{H}_{t_i}^{-1} + \mathbf{H}_{t_i}^{-1} \;\; \nabla_{\mathbf{x}_{t_i}^{(c)}} \alpha_{t_i}^T \right) \frac{1}{2} \lim_{dt\to 0} \left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)}) \frac{1}{dt} - \mathbf{f}_{t_i}^{(c)} \right)$$

$$= \left(\lim_{dt\to 0} \left(\alpha_{t_i}^T \right) \;\; \nabla_{\mathbf{x}_{t_i}^{(c)}} \mathbf{H}_{t_i}^{-1} + \mathbf{H}_{t_i}^{-1} \;\; \lim_{dt\to 0} \left(\nabla_{\mathbf{x}_{t_i}^{(c)}} \alpha_{t_i}^T \right) \right) \frac{1}{2} \lim_{dt\to 0} \left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)}) \frac{1}{dt} - \mathbf{f}_{t_i}^{(c)} \right).$$

Since $\lim_{dt\to 0} \left(\alpha_{t_i}^T \right) = 0_{1\times l}$ and $\lim_{dt\to 0} \left(\nabla_{\mathbf{x}_{t_i}^{(c)}} \alpha_{t_i}^T \right) = -I_{l\times l}$ the final result is expressed as follows

$$\lim_{dt\to 0} \left(\frac{1}{2dt} \nabla_{\mathbf{x}_{t_i}^{(c)}} \beta_{t_i} \;\; \alpha_{t_i} \right) = -\mathbf{H}_{t_i}^{-1} \;\; \frac{1}{2} \lim_{dt\to 0} \left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)}) \frac{1}{dt} - \mathbf{f}_{t_o}^{(c)} \right).$$

After we have calculated the 3 sub-terms, the 2th term of the of the derivative of path cost $S(\tau_o)$ can be expressed in the following form:

$$\nabla_{\mathbf{x}_{t_i}^{(c)}} \left(\frac{1}{2\lambda dt} \sum_{j=i}^{N-1} \gamma_{t_j} \right) = -\mathbf{H}_{t_i}^{-1} \;\; \lim_{dt\to 0} \left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)}) \frac{1}{dt} - \mathbf{f}_{t_i}^{(c)}) \right).$$

DERIVATIVE OF THE FOURTH TERM $\nabla_{\mathbf{x}_{t_i}^{(c)}} \left(\frac{\lambda}{2} \sum_{j=i}^{N-1} \log |\mathbf{H}_{t_j}| \right)$ OF THE COST $S(\tau_i)$.

The analysis for the 4th term is given below:

$$\nabla_{\mathbf{x}_{t_i}^{(c)}} \left(\frac{\lambda}{2} \sum_{j=i}^{N-1} \log |\mathbf{H}_{t_j}| \right) = \frac{\lambda}{2} \nabla_{\mathbf{x}_{t_i}^{(c)}} \log |\mathbf{H}_{t_i}|.$$

If we assume that $\mathbf{x}_{t_o}^{(c)} = [x_{t_o}^{(c1)}, x_{t_o}^{(c2)} .... x_{t_o}^{(cl)}]$ and take the derivative with respect to each element we will have

$$\partial_{\mathbf{x}_{t_i}^{(ci)}} \left(\frac{\lambda}{2} \log |\mathbf{H}_{t_i}| \right) = \frac{\lambda}{2} \frac{1}{|\mathbf{H}_{t_i}|} \;\; \partial_{\mathbf{x}_{t_i}^{(ci)}} |\mathbf{H}_{t_i}|.$$

$$\partial_{\mathbf{x}_{t_i}^{(ci)}} \left(\frac{\lambda}{2} \log |\mathbf{H}_{t_i}| \right) = \frac{\lambda}{2} \frac{1}{|\mathbf{H}(\mathbf{x}_{t_i})|} \;\; |\mathbf{H}_{t_i}| \;\; trace \left(\mathbf{H}_{t_i}^{-1} \cdot \partial_{\mathbf{x}_{t_i}^{(ci)}} \mathbf{H}_{t_i} \right).$$

$$\partial_{\mathbf{x}_{t_i}^{(ci)}} \left(\frac{\lambda}{2} \log |\mathbf{H}_{t_i}| \right) = \frac{\lambda}{2} trace \left(\mathbf{H}_{t_i}^{-1} \;\; \partial_{\mathbf{x}_{t_i}^{(ci)}} \mathbf{H}_{t_i} \right).$$

Where we make used of the identity $\partial det(A) = det(A)Tr\left(A^{-1}\partial A\right)$. The result is expressed as:

$$\nabla_{\mathbf{x}_{t_i}^{(c)}}\left(\frac{\lambda}{2}\log|\mathbf{H}_{t_i}|\right) = \frac{\lambda}{2}\begin{bmatrix} trace\left(\mathbf{H}_{t_i}^{-1}\ \partial_{\mathbf{x}_{t_i}^{(c1)}}\mathbf{H}_{t_i}\right) \\ trace\left(\mathbf{H}_{t_i}^{-1}\ \partial_{\mathbf{x}_{t_i}^{(c2)}}\mathbf{H}_{t_i}\right) \\ \cdot \\ \cdot \\ \cdot \\ trace\left(\mathbf{H}_{t_i}^{-1}\ \partial_{\mathbf{x}_{t_i}^{(cl)}}\mathbf{H}_{t_i}\right) \end{bmatrix}.$$

or in a more compact form:

$$\nabla_{\mathbf{x}_{t_i}^{(c)}}\left(\frac{\lambda}{2}\log|\mathbf{H}_{t_i}|\right) = \mathbf{H}_{t_i}^{-1}\mathbf{b}_{t_i}.$$

where $\mathbf{b}(\mathbf{x}_{t_i}) = \lambda\mathbf{H}(\mathbf{x}_{t_i})\Phi_{t_i}$ and the quantity $\Phi_{t_i} \in \Re^{l\times 1}$ is defined as:

$$\Phi_{t_i} = \frac{1}{2}\begin{bmatrix} trace\left(\mathbf{H}_{t_i}^{-1}\ \partial_{\mathbf{x}_{t_i}^{(c1)}}\mathbf{H}_{t_i}\right) \\ trace\left(\mathbf{H}_{t_i}^{-1}\ \partial_{\mathbf{x}_{t_i}^{(c2)}}\mathbf{H}_{t_i}\right) \\ \cdot \\ \cdot \\ \cdot \\ trace\left(\mathbf{H}_{t_i}^{-1}\ \partial_{\mathbf{x}_{t_i}^{(cl)}}\mathbf{H}_{t_i}\right) \end{bmatrix}. \tag{41}$$

Since we computed all the terms of the derivative of the path cost $\tilde{S}(\tau_o)$ and after putting all the terms together we have the result expressed as follows:

$$\lim_{dt\to 0}\left(\nabla_{\mathbf{x}_{t_i}^{(c)}}\tilde{S}(\tau_i)\right) = -\mathbf{H}_{t_i}^{-1}\left(\lim_{dt\to 0}\left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)})\frac{1}{dt} - \mathbf{f}_{t_i}^{(c)}\right) - \mathbf{b}_{t_i}\right).$$

By taking into account the fact that $\lim_{dt\to 0}\left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)})\frac{1}{dt} - \mathbf{f}_{t_i}^{(c)}\right) = \mathbf{G}_{t_i}^{(c)}\varepsilon_{t_i}$ we get the following final expression:

$$\lim_{dt\to 0}\left(\nabla_{\mathbf{x}_{t_i}^{(c)}}\tilde{S}(\tau_i)\right) = -\mathbf{H}_{t_i}^{-1}\left(\mathbf{G}_{t_i}^{(c)}\varepsilon_{t_i} - \mathbf{b}_{t_i}\right).$$

Theorem 3 ***: The optimal control solution to the stochastic optimal control problem expressed by (1),(2),(3),(4) is formulated by the equation that follows:***

$$\mathbf{u}_{t_i} = \lim_{dt\to 0}\int \tilde{p}(\tau_i)\ \mathbf{u}_L(\tau_i)\ d\tau_i,$$

where $\tilde{p}(\tau_i) = \frac{\exp\left(-\frac{1}{\lambda}\tilde{S}(\tau_i)\right)}{\int \exp\left(-\frac{1}{\lambda}\tilde{S}(\tau_i)\right) d\tau_i}$ ***is a path depended probability distribution and the term*** $\mathbf{u}(\tau_i)$ ***defined as*** $\mathbf{u}_L(\tau_i) = \mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\left(\mathbf{G}_{t_i}^{(c)}\mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\right)^{-1}\left(\mathbf{G}_{t_i}^{(c)}\varepsilon_{t_i} - \mathbf{b}_{t_i}\right)$ ***are the local controls of each sampled trajectory starting from state*** $\mathbf{x}_{t_i}$***. The terms*** ε_{t_i} ***and*** $\mathbf{b}_{t_i}$ ***are defined as*** $\varepsilon_{t_i} = \left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)})\frac{1}{dt} - \mathbf{f}_{t_i}^{(o)}\right)$ ***and*** $\mathbf{b}(\mathbf{x}_{t_i}) = \lambda\mathbf{H}(\mathbf{x}_{t_i})\Phi_{t_i}$ ***with*** $\mathbf{H}_{t_i} = \mathbf{G}_{t_i}^{(c)}\mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)^T}$ ***and*** Φ_{t_i} ***given in (41).***

Proof

To prove the theorem we make use of the Lemma 2 and we substitute $\nabla_{\mathbf{x}_{t_i}^{(c)}}\tilde{S}(\tau_i)$ in the main result of Lemma 1. More precisely from lemma A1 we have that:

$$\mathbf{u}_{t_i} = \lim_{dt\to 0}\left(\mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\int \tilde{p}(\tau_i)\,\mathbf{H}_{t_i}^{-1}\left(\nabla_{\mathbf{x}_{t_i}^{(c)}}\tilde{S}(\tau_i)\right)d\tau_i\right).$$

The terms $\mathbf{R}^{-1}$ and $\mathbf{G}_{t_i}$ can be pushed insight the integral since they are independent of $\tau_i = (\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_N)$. Thus we have the expression:

$$\mathbf{u}_{t_i} = \lim_{dt\to 0}\left(\int \tilde{p}(\tau_i)\mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\mathbf{H}_{t_i}^{-1}\left(\nabla_{\mathbf{x}_{t_i}^{(c)}}\tilde{S}(\tau_i)\right)d\tau_i\right),$$

$$\mathbf{u}_{t_i} = \lim_{dt\to 0}\int \tilde{p}(\tau_i)\ \mathbf{u}_L^{(dt)}(\tau_i)\,d\tau_i,$$

where the local controls $\mathbf{u}_L^{(dt)}(\tau_i)$ are given as follows:

$$\mathbf{u}_L^{(dt)}(\tau_i) = \mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\mathbf{H}_{t_i}^{-1}\nabla_{\mathbf{x}_{t_i}^{(c)}}\tilde{S}(\tau_i).$$

After applying the limit, and making use of the result in Lemma 2 the equation above is expressed as:

$$\mathbf{u}_{t_i} = \int \tilde{p}(\tau_i)\,\mathbf{u}_L(\mathbf{x}_{t_{i+1}}, \mathbf{x}_{t_i})d\tau_i,$$

where the local controls $\mathbf{u}_L(\mathbf{x}_{t_{i+1}}, \mathbf{x}_{t_i})$ are given as follows:

$$\mathbf{u}_L(\tau_i) = \mathbf{u}_L(\mathbf{x}_{t_{i+1}}, \mathbf{x}_{t_i}) = \mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\mathbf{H}_{t_i}^{-1}\left(\lim_{dt\to 0}\left((\mathbf{x}_{t_{i+1}}^{(c)} - \mathbf{x}_{t_i}^{(c)})\frac{1}{dt} - \mathbf{f}_{t_i}^{(c)}\right) - \mathbf{b}_{t_i}\right),$$

or in a simpler form:

$$\mathbf{u}_L(\mathbf{x}_{t_{i+1}}, \mathbf{x}_{t_i}) = \mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\mathbf{H}_{t_i}^{-1}\left(\mathbf{G}_c\varepsilon_{t_i} - \mathbf{b}_{t_i}\right).$$

By substituting with $\mathbf{H}(\mathbf{x}_{t_i}) = \mathbf{G}_{t_i}^{(c)}\mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}$ we have the final result:

$$\mathbf{u}_L(\tau_i) = \mathbf{u}_L(\mathbf{x}_{t_{i+1}}, \mathbf{x}_{t_i}) = \mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\left(\mathbf{G}_{t_i}^{(c)}\mathbf{R}^{-1}\mathbf{G}_{t_i}^{(c)T}\right)^{-1}\left(\mathbf{G}_{t_i}^{(c)}\varepsilon_{t_i} - \mathbf{b}_{t_i}\right).$$

■

Appendix B.

Theorem 4 *: Let us assume that* $\mathbf{x}$ *satisfies the SDE* $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x},t) + \mathbf{G}(\mathbf{x})\varepsilon(t)$. *Then* $\Psi(\mathbf{x},t_o) = \Psi(\mathbf{x},t_o,t_N) = E\left(\Psi(\mathbf{x},t_N)\, e^{\int_{t_o}^{t_N} -\frac{1}{\lambda} q(\mathbf{x}) d\tau}\right)$ *if and only if* $\Psi(\mathbf{x},t)$ *satisfies the backward Kolmogorov PDE:*

$$-\partial_t \Psi_t = -\frac{1}{\lambda} q_t \Psi_t + \mathbf{f}_t^T (\nabla_{\mathbf{x}} \Psi_t) + \frac{1}{2} trace\left((\nabla_{\mathbf{xx}} \Psi_t) \mathbf{G}_t \Sigma_\varepsilon \mathbf{G}_t^T\right),$$

with boundary condition:

$$\Psi(\mathbf{x},t_N) = \exp\left(-\frac{1}{\lambda}\phi(\mathbf{x}(t_N))\right).$$

Proof Given that $\mathbf{x}$ satisfies the SDE $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x},t) + \mathbf{G}(\mathbf{x})\varepsilon(t)$ and $\Psi(\mathbf{x},t)$ satisfies the PDE above, application of Ito lemma (Øksendal, 2003) to function $Y(t) = \Psi(\mathbf{x}_t,t)\, e^{\int_{t_o}^{t} -\frac{1}{\lambda} q(\mathbf{x}) d\tau}$ leads to the final result $\Psi(\mathbf{x},t_o) = E\left(\Psi(\mathbf{x},t_N)\, e^{\int_{t_o}^{t_N} -\frac{1}{\lambda} q(\mathbf{x}) d\tau}\right)$. This result is the solution of the linear PDE. ■

Abstract

Large-scale linear classification is widely used in many areas. The L1-regularized form can be applied for feature selection; however, its non-differentiability causes more difficulties in training. Although various optimization methods have been proposed in recent years, these have not yet been compared suitably. In this paper, we first broadly review existing methods. Then, we discuss state-of-the-art software packages in detail and propose two efficient implementations. Extensive comparisons indicate that carefully implemented coordinate descent methods are very suitable for training large document data.

Keywords: L1 regularization, linear classification, optimization methods, logistic regression, support vector machines, document classification

1. Introduction

Recently, L1-regularized classifiers have attracted considerable attention because they can be used to obtain a sparse model. Given a set of instance-label pairs $(\mathbf{x}_i, y_i)$, $i = 1, \ldots, l$, $\mathbf{x}_i \in R^n$, $y_i \in \{-1, +1\}$, training an L1-regularized linear classifier involves the following unconstrained optimization problem:

$$\min_{\mathbf{w}} \quad f(\mathbf{w}) \equiv \|\mathbf{w}\|_1 + C \sum_{i=1}^{l} \xi(\mathbf{w}; \mathbf{x}_i, y_i), \tag{1}$$

where $\|\cdot\|_1$ denotes the 1-norm and $\xi(\mathbf{w}; \mathbf{x}_i, y_i)$ is a non-negative (convex) loss function. The regularization term $\|\mathbf{w}\|_1$ is used to avoid overfitting the training data. The user-defined parameter $C > 0$ is used to balance the regularization and loss terms.

If $\|\mathbf{w}\|_2$ is used in (1), we obtain an L2-regularized classifier. Although L2 regularization is used more commonly, an L1-regularized formula often produces a sparse $\mathbf{w}$. Nonzero elements help to select important features; in addition, the time required to produce predictions may be reduced. Considerable literature has been published on the advantages of using L1 regularization; see, for example, Zhao and Yu (2006). However, an L1-regularized form (1) is not differentiable regardless

of its loss function. This drawback leads to greater difficulty in solving the optimization problem. Therefore, certain considerations are required to handle the non-differentiability.

Many loss functions can be used for linear classification. A commonly used one is logistic loss:

$$\xi_{\log}(\mathbf{w};\mathbf{x},y) = \log(1+e^{-y\mathbf{w}^T\mathbf{x}}). \tag{2}$$

This loss function is twice differentiable. Note that minimizing logistic loss is equivalent to maximizing the likelihood, whereas minimizing the regularized loss in (1) is equivalent to maximizing the posterior with independent Laplace priors on the parameters. Two other frequently used functions are the L1- and the L2-loss functions:

$$\xi_{\mathrm{L1}}(\mathbf{w};\mathbf{x},y) = \max(1-y\mathbf{w}^T\mathbf{x},\ 0) \quad \text{and} \tag{3}$$

$$\xi_{\mathrm{L2}}(\mathbf{w};\mathbf{x},y) = \max(1-y\mathbf{w}^T\mathbf{x},\ 0)^2. \tag{4}$$

Because of the $\max(\cdot)$ operation, the L1-loss function is not differentiable. On the other hand, L2 loss is differentiable, but not twice differentiable (Mangasarian, 2002). We refer to (1) with logistic loss as L1-regularized logistic regression and (1) with L1/L2 loss as L1-regularized L1-/L2-loss support vector machines (SVMs).

In some applications, we require a bias term b (also called as an intercept) in the loss function; therefore, $\mathbf{w}^T\mathbf{x}$ in (2)–(4) is replaced with $\mathbf{w}^T\mathbf{x}+b$. For example, the logistic loss function becomes

$$\xi_{\log}(\mathbf{w},b;\mathbf{x},y) = \log\left(1+e^{-y(\mathbf{w}^T\mathbf{x}+b)}\right).$$

The optimization problem then involves variables $\mathbf{w}$ and b:

$$\min_{\mathbf{w},b} \quad \|\mathbf{w}\|_1 + C\sum_{i=1}^{l}\xi(\mathbf{w},b;\mathbf{x}_i,y_i). \tag{5}$$

Because b does not appear in the regularization term, most optimization methods used to solve (1) can solve (5) as well. In this paper, except whenever b is required, we mainly consider the formulation (1).

Many papers have proposed optimization methods for large-scale L1-regularized logistic regression (i.e., using $\xi_{\log}$ as the loss function). These studies did not consider L1- or L2-loss functions because logistic loss has a probability interpretation and is twice differentiable. These methods differ in various aspects such as the convergence speed, ease of implementation, and practical applicability. With so many available methods, it is important to conduct a comprehensive comparison. Schmidt et al. (2007, 2009) compared optimization methods for L1-regularized classifiers; however, they did not include some state-of-the-art solvers. Moreover, their comparison is based on the number of function evaluations instead of the actual running time. In this paper, we categorize and compare existing methods for logistic regression. We also extend some methods to solve L2-loss SVMs. We exclude L1 loss from the discussion because most methods for logistic regression or L2-loss SVMs assume the differentiability of the loss functions. Readers interested in using L1-loss SVMs can refer to Bradley and Mangasarian (1998), Zhu et al. (2004), Fung and Mangasarian (2004), Mangasarian (2006), and references therein.

1.1 Basic Properties of (1)

In this paper, we assume that the loss function $\xi(\mathbf{w};\mathbf{x}_i,y_i)$ is convex, differentiable, and nonnegative. The proof presented in Appendix A shows that (1) attains at least one global optimum. Unlike L2 regularization, which leads to a unique optimal solution, here, (1) may possess multiple optimal solutions. We use $\mathbf{w}^*$ to denote any optimal solution of (1). The convexity of $f(\mathbf{w})$ implies that all optimal solutions have the same function value, which is denoted as f^*. For more information about the set of optimal solutions, see, for example, Hale et al. (2008, Section 2).

From standard convex analysis, $\mathbf{w}^*$ is optimal for (1) if and only if $\mathbf{w}^*$ satisfies the following optimality conditions:

$$\begin{cases} \nabla_j L(\mathbf{w}^*) + 1 = 0 & \text{if } w_j^* > 0, \\ \nabla_j L(\mathbf{w}^*) - 1 = 0 & \text{if } w_j^* < 0, \\ -1 \le \nabla_j L(\mathbf{w}^*) \le 1 & \text{if } w_j^* = 0, \end{cases} \tag{6}$$

where $L(\mathbf{w})$ is the loss term in (1):

$$L(\mathbf{w}) \equiv C \sum_{i=1}^{l} \xi(\mathbf{w};\mathbf{x}_i,y_i). \tag{7}$$

1.2 Organization and Notation

The remainder of this paper is organized as follows. In Section 2, we briefly survey existing approaches. Section 3 lists state-of-the-art L1-regularized logistic regression packages compared in this study. Sections 4–6 discuss these packages in detail; two of these (Sections 4.1.2 and 5.1) are our proposed implementations. In Section 7, we extend several methods to train L2-loss SVMs. Section 8 describes the extensive experiments that were carried out. Comparison results indicate that decomposition methods (Section 4) are very suitable for large-scale document data. Finally, the discussions and conclusions are presented in Section 9. A supplementary file including additional details and descriptions of experiments is available at `http://www.csie.ntu.edu.tw/~cjlin/papers/l1/supplement.pdf`

In this study, we use consistent notation to describe several state-of-the-art methods that are considered. The following table lists some frequently used symbols:

l:	number of instances
n:	number of features
i:	index for a data instance
j:	index for a data feature
k:	iteration index for an optimization algorithm

We may represent training instances $(\mathbf{x}_i,y_i)$, $i=1,\ldots,l$ in the following form:

$$X = \begin{bmatrix} \mathbf{x}_1^T \\ \vdots \\ \mathbf{x}_l^T \end{bmatrix} \in R^{l\times n} \quad \text{and} \quad \mathbf{y} = \begin{bmatrix} y_1 \\ \vdots \\ y_l \end{bmatrix} \in \{-1,+1\}^l.$$

For any vector $\mathbf{v}$, we consider the following two representations for sub-vectors:

$$\mathbf{v}_{t:s} \equiv [v_t,\ldots,v_s]^T \quad \text{and} \quad \mathbf{v}_I \equiv [v_{i_1},\ldots,v_{i_{|I|}}]^T,$$

where $I = \{i_1, \ldots, i_{|I|}\}$ is an index set. Similarly,

$$X_{I,:} \equiv \begin{bmatrix} \mathbf{x}_{i_1}^T \\ \vdots \\ \mathbf{x}_{i_{|I|}}^T \end{bmatrix}. \tag{8}$$

The function $\tau(s)$ gives the first derivative of the logistic loss function $\log(1+e^s)$:

$$\tau(s) \equiv \frac{1}{1+e^{-s}}. \tag{9}$$

An indicator vector for the jth component is

$$\mathbf{e}_j \equiv [\underbrace{0, \ldots, 0}_{j-1}, 1, 0, \ldots, 0]^T. \tag{10}$$

We use $\|\cdot\|$ or $\|\cdot\|_2$ to denote the 2-norm and $\|\cdot\|_1$ to denote the 1-norm.

2. A Survey of Existing Methods

In this section, we survey existing methods for L1-regularized problems. In Sections 2.1–2.3, we focus on logistic regression and L2-loss SVMs for data classification. Section 2.5 briefly discusses works on regression problems using the least-square loss.

2.1 Decomposition Methods

Decomposition methods are a classical optimization approach. Because it is difficult to update all variables simultaneously, at each iteration, we can choose a subset of variables as the working set and fix all others. The resulting sub-problem contains fewer variables and is easier to solve. The various decomposition methods that have been applied to solve L1-regularized problems are categorized into two types according to the selection of the working set.

2.1.1 CYCLIC COORDINATE DESCENT METHODS

A simple coordinate descent method cyclically chooses one variable at a time and solves the following one-variable sub-problem:

$$\min_z \quad g_j(z) \equiv f(\mathbf{w} + z\mathbf{e}_j) - f(\mathbf{w}), \tag{11}$$

where $\mathbf{e}_j$ is defined in (10). This function $g_j(z)$ has only one non-differentiable point at $z = -w_j$. In optimization, the cyclic method for choosing working variables is often called the Gauss-Seidel rule (Tseng and Yun, 2007).

Several works have applied coordinate descent methods to solve (1) with logistic loss. Here, a difficulty arises in that sub-problem (11) does not have a closed-form solution. Goodman (2004) assumed nonnegative feature values (i.e., $x_{ij} \geq 0,\ \forall i, j$) and then approximated $g_j(z)$ by a function $A_j(z)$ at each iteration. $A_j(z)$ satisfies $A_j(z) \geq g_j(z), \forall z$, and $A_j(0) = g_j(0) = 0$; therefore, minimizing $A_j(z)$ may reduce the function value. Moreover, there is a closed-form solution for minimizing $A_j(z)$. Goodman (2004) actually studied a problem with additional constraints $w_j \geq 0$; however, his

approach can be extended to solve the original L1-regularized logistic regression by taking the sign of w_j into consideration.

Genkin et al. (2007) implemented a cyclic coordinate descent method called BBR to solve L1-regularized logistic regression. BBR approximately minimizes sub-problem (11) in a trust region and applies one-dimensional Newton steps. Balakrishnan and Madigan (2005) reported an extension of BBR for online settings.

In Section 4.1.2, we propose a coordinate descent method by extending Chang et al.'s (2008) approach for L2-regularized classifiers. Chang et al. (2008) approximately solved the sub-problem (11) by a one-dimensional Newton direction with line search. Experiments show that their approach outperforms a BBR variant for L2-regularized classification. Therefore, for L1 regularization, this approach might be faster than BBR. Hereafter, we refer to this efficient coordinate descent method as CDN (coordinate descent using one-dimensional Newton steps).

Tseng and Yun (2007) broadly discussed decomposition methods for L1-regularized problems. One of their approaches is a cyclic coordinate descent method. They considered a general cyclic setting so that several working variables are updated at each iteration. We show that CDN is a special case of their general algorithms.

If we randomly select the working variable, then the procedure becomes a stochastic coordinate descent method. Shalev-Shwartz and Tewari (2009, Algorithm 2) recently studied this issue. Duchi and Singer (2009) proposed a similar coordinate descent method for the maximum entropy model, which is a generalization of logistic regression.

2.1.2 VARIABLE SELECTION USING GRADIENT INFORMATION

Instead of cyclically updating one variable, we can choose working variables based on the gradient information.[1] This method for selecting variables is often referred to as the Gauss-Southwell rule (Tseng and Yun, 2007). Because of the use of gradient information, the number of iterations is fewer than those in cyclic coordinate descent methods. However, the cost per iteration is higher. Shevade and Keerthi (2003) proposed an early decomposition method with the Gauss-Southwell rule to solve (1). In their method, one variable is chosen at a time and one-dimensional Newton steps are applied; therefore, their method differs from the cyclic coordinate descent methods described in Section 2.1.1 mainly in terms of finding the working variables. Hsieh et al. (2008) showed that for L2-regularized linear classification, maintaining the gradient for selecting only one variable at a time is not cost-effective. Thus, for decomposition methods using the gradient information, a larger working set should be used at each iteration.

In the framework of decomposition methods proposed by Tseng and Yun (2007), one type of method selects a set of working variables based on the gradient information. The working set can be large, and therefore, they approximately solved the sub-problem. For the same method, Yun and Toh (2009) enhanced the theoretical results and carried out experiments with document classification data. We refer to their method as CGD-GS because the method described in Tseng and Yun (2007) is called "coordinate gradient descent" and a Gauss-Southwell rule is used.

2.1.3 ACTIVE SET METHODS

Active set methods are a popular optimization approach for linear-constrained problems. For problem (1), an active method becomes a special decomposition method because at each iteration, a

1. Because $f(\mathbf{w})$ is not differentiable, $\nabla_j L(\mathbf{w}) \pm 1$ is used according to the sign of w_j.

sub-problem over a working set of variables is solved. The main difference from decomposition methods described earlier is that the working set contains all non-zero variables. Therefore, an active set method iteratively predicts what a correct split of zero and non-zero elements in $\mathbf{w}$ is. If the split is correct, then solving the sub-problem gives the optimal values of non-zero elements.

Perkins et al. (2003) proposed an active set method for (1) with logistic loss. This implementation uses gradient information to predict $\mathbf{w}$'s zero and non-zero elements.

2.2 Methods by Solving Constrained Optimization Problems

This type of method transforms (1) to equivalent constrained optimization problems. We further classify them into two groups.

2.2.1 Optimization Problems with Smooth Constraints

We can replace $\mathbf{w}$ in (1) with $\mathbf{w}^+ - \mathbf{w}^-$, where $\mathbf{w}^+$ and $\mathbf{w}^-$ are both nonnegative vectors. Then, problem (1) becomes equivalent to the following bound-constrained optimization problem:

$$\begin{aligned} \min_{\mathbf{w}^+,\mathbf{w}^-} \quad & \sum_{j=1}^{n} w_j^+ + \sum_{j=1}^{n} w_j^- + C\sum_{i=1}^{l} \xi(\mathbf{w}^+ - \mathbf{w}^-; \mathbf{x}_i, y_i) \\ \text{subject to} \quad & w_j^+ \geq 0,\ w_j^- \geq 0, \quad j = 1,\ldots,n. \end{aligned} \tag{12}$$

The objective function and constraints of (12) are smooth, and therefore, the problem can be solved by standard bound-constrained optimization techniques. Schmidt et al. (2009) proposed ProjectionL1 to solve (12). This is an extension of the "two-metric projection" method (Gafni and Bertsekas, 1984). Limited-memory quasi Newton implementations, for example, LBFGS-B by Byrd et al. (1995) and BLMVM by Benson and Moré (2001), require function/gradient evaluations and use a limited amount of memory to approximate the Hessian matrix. Kazama and Tsujii (2003) presented an example of using BLMVM for (12). Lin and Moré's (1999) trust region Newton method (TRON) can also be applied to solve (12). In addition to function/gradient evaluations, TRON needs to calculate Hessian-vector products for faster convergence. Lin et al. (2008) applied TRON to solve L2-regularized logistic regression and showed that TRON outperforms LBFGS for document data. No previous work has applied TRON to solve L1-regularized problems, and therefore, we describe this in Section 5.1.

Koh et al. (2007) proposed an interior point method to solve L1-regularized logistic regression. They transformed (1) to the following constrained problem:

$$\begin{aligned} \min_{\mathbf{w},\mathbf{u}} \quad & \sum_{j=1}^{n} u_j + C\sum_{i=1}^{l} \xi(\mathbf{w}; \mathbf{x}_i, y_i) \\ \text{subject to} \quad & -u_j \leq w_j \leq u_j, \quad j = 1,\ldots,n. \end{aligned} \tag{13}$$

Equation (13) can be made equivalent to (12) by setting

$$w_j^+ = \frac{u_j + w_j}{2} \text{ and } w_j^- = \frac{u_j - w_j}{2}.$$

To ensure that $\mathbf{w}$ and $\mathbf{u}$ are in the interior of the feasible region set, Koh et al. (2007) added a log barrier to the objective function of (13) and applied a Newton method.

2.2.2 OPTIMIZATION PROBLEMS WITH NON-SMOOTH CONSTRAINTS

It is well-known that for any choice of C in (1), there exists a corresponding K such that (1) is equivalent to the following problem:

$$\begin{aligned} \min_{\mathbf{w}} \quad & \sum_{i=1}^{l} \xi(\mathbf{w}; \mathbf{x}_i, y_i) \\ \text{subject to} \quad & \|\mathbf{w}\|_1 \leq K. \end{aligned} \tag{14}$$

See the explanation in, for example, Donoho and Tsaig (2008, Section 1.2). Notice that in (14), the constraint is not smooth at $\{\mathbf{w} \mid w_j = 0 \text{ for some } j\}$. However, (14) contains fewer variables and constraints than (12). Lee et al. (2006) applied the LARS algorithm described in Efron et al. (2004) to find a Newton direction at each step and then used a backtracking line search to minimize the objective value. Kivinen and Warmuth's (1997) concept of exponentiated gradient (EG) can solve (14) with additional constraints $w_j \geq 0,\ \forall j$. In a manner similar to the technique for constructing (12), we can remove the nonnegative constraints by replacing $\mathbf{w}$ with $\mathbf{w}^+ - \mathbf{w}^-$. If k is the iteration index, EG updates $\mathbf{w}$ by the following rule:

$$w_j^{k+1} = \frac{w_j^k \exp\left(-\eta_k \nabla_j \left(\sum_{i=1}^{l} \xi(\mathbf{w}^k; \mathbf{x}_i, y_i)\right)\right)}{Z_k},$$

where Z_k is a normalization term for maintaining $\|\mathbf{w}^k\|_1 = K,\ \forall k$ and η_k is a user-defined learning rate. Duchi et al. (2008) applied a gradient projection method to solve (14). The update rule is

$$\mathbf{w}^{k+1} = \arg\min_{\mathbf{w}} \left\{ \left\| \left(\mathbf{w}^k - \eta_k \nabla\left(\sum_{i=1}^{l} \xi(\mathbf{w}^k; \mathbf{x}_i, y_i)\right)\right) - \mathbf{w} \right\| \;\middle|\; \|\mathbf{w}\|_1 \leq K \right\}. \tag{15}$$

They developed a fast algorithm to project a solution to the closest point satisfying the constraint. They also considered replacing the gradient in (15) with a stochastic sub-gradient. In a manner similar to (15), Liu et al. (2009) proposed a gradient projection method called Lassplore and carefully addressed the selection of the learning rate η_k. However, they evaluated their method only on data with no more than 2,000 instances.[2]

Kim and Kim (2004) discussed a coordinate descent method to solve (14). They used the gradient information to select an element w_j for update. However, because of the constraint $\|\mathbf{w}\|_1 \leq K$, the whole vector $\mathbf{w}$ is normalized at each step. Thus, the setting is very different from the unconstrained situations described in Section 2.1.1. Kim et al. (2008) made further improvements to realize faster convergence.

Active set methods have also been applied to solve (14). However, in contrast to the active set methods described in Section 2.1.3, here, the sub-problem at each iteration is a constrained optimization problem. Roth (2004) studied general loss functions including logistic loss.

2.3 Other Methods for L1-regularized Logistic Regression/L2-loss SVMs

We briefly review other methods in this section.

2. Although Table 1 in Liu et al. (2009) shows larger numbers, in Section 6 of the same paper, they stated that "we use a total of 2,000 samples in the following experiments."

2.3.1 EXPECTATION MAXIMIZATION

Many studies have considered Expectation Maximization (EM) frameworks to solve (1) with logistic loss (e.g., Figueiredo, 2003; Krishnapuram et al., 2004, 2005). These works find an upper-bound function $\hat{f}(\mathbf{w}) \geq f(\mathbf{w}), \forall \mathbf{w}$, and perform Newton steps to minimize $\hat{f}(\mathbf{w})$. However, as pointed out by Schmidt et al. (2009, Section 3.2), the upper-bound function $\hat{f}(\mathbf{w})$ may not be well-defined at some $w_i = 0$ and hence certain difficulties must be addressed.

2.3.2 STOCHASTIC GRADIENT DESCENT

Stochastic gradient descent methods have been successfully applied to solve (1). At each iteration, the solution is updated using a randomly selected instance. These types of methods are known to efficiently generate a reasonable model, although they suffer from slow local convergence. Under an online setting, Langford et al. (2009) solved L1-regularized problems by a stochastic gradient descent method. Shalev-Shwartz and Tewari (2009) combined Langford et al.'s (2009) method with other techniques to obtain a new stochastic gradient descent method for (1).

2.3.3 QUASI NEWTON METHODS

Andrew and Gao (2007) proposed an Orthant-Wise Limited-memory quasi Newton (OWL-QN) method. This method is extended from LBFGS (Liu and Nocedal, 1989), a limited memory quasi Newton approach for unconstrained smooth optimization. At each iteration, this method finds a sub-space without considering some dimensions with $w_j = 0$ and obtains a search direction similar to LBFGS. A constrained line search on the same sub-space is then conducted and the property $w_j^{k+1} w_j^k \geq 0$ is maintained. Yu et al. (2010) proposed a quasi Newton approach to solve non-smooth convex optimization problems. Their method can be used to improve the line search procedure in OWL-QN.

2.3.4 HYBRID METHODS

Shi et al. (2010) proposed a hybrid algorithm for (1) with logistic loss. They used a fixed-point method to identify the set $\{j \mid w_j^* = 0\}$, where $\mathbf{w}^*$ is an optimal solution, and then applied an interior point method to achieve fast local convergence.

2.3.5 QUADRATIC APPROXIMATION FOLLOWED BY COORDINATE DESCENT

Krishnapuram et al. (2005) and Friedman et al. (2010) replaced the loss term with a second-order approximation at the beginning of each iteration and then applied a cyclic coordinate descent method to minimize the quadratic function. We will show that an implementation in Friedman et al. (2010) is efficient.

2.3.6 CUTTING PLANE METHODS

Teo et al. (2010) implemented a bundle (cutting plane) method BMRM to handle non-smooth loss functions. It includes an extension for L1 regularization.

2.3.7 APPROXIMATING L1 REGULARIZATION BY L2 REGULARIZATION

Kujala et al. (2009) proposed the approximation of L1-regularized SVMs by iteratively reweighting training data and solving L2-regularized SVMs. That is, using the current w_j, they adjusted the jth feature of the training data and then trained an L2-regularized SVM in the next step.

2.3.8 SOLUTION PATH

Several works have attempted to find the "solution path" of (1). The optimal solution of (1) varies according to parameter C. It is occasionally useful to find all solutions as a function of C; see, for example, Rosset (2005), Zhao and Yu (2007), Park and Hastie (2007), and Keerthi and Shevade (2007). We do not provide details of these works because this paper focuses on the case in which a single C is used.

2.4 Strengths and Weaknesses of Existing Methods

Although this paper will compare state-of-the-art software, we discuss some known strengths and weaknesses of existing methods.

2.4.1 CONVERGENCE SPEED

Optimization methods using higher-order information (e.g., quasi Newton or Newton methods) usually enjoy fast local convergence. However, they involve an expensive iteration. For example, Newton methods such as TRON or IPM need to solve a large linear system related to the Hessian matrix. In contrast, methods using or partially using the gradient information (e.g., stochastic gradient descent) have slow local convergence although they can more quickly decrease the function value in the early stage.

2.4.2 IMPLEMENTATION EFFORTS

Methods using higher-order information are usually more complicated. Newton methods need to include a solver for linear systems. In contrast, methods such as coordinate descent or stochastic gradient descent methods are easy to implement. They involve only vector operations. Other methods such as expectation maximization are intermediate in this respect.

2.4.3 HANDLING LARGE-SCALE DATA

In some methods, the Newton step requires solving a linear system of n variables. Inverting an $n \times n$ matrix is difficult for large n. Thus, one should not use direct methods (e.g., Gaussian elimination) to solve the linear system. Instead, TRON and IPM employ conjugate gradient methods and Friedman et al. (2007) use coordinate descent methods. We observe that for existing EM implementations, many consider direct inversions, and therefore, they cannot handle large-scale data.

2.4.4 FEATURE CORRELATION

Methods that work on a block of variables at a time (e.g., decomposition methods) may be more efficient if features are almost independent; however, they may be less efficient if features are highly correlated.

2.4.5 DATA TYPE

No method is the most suitable for all data types. A method that is efficient for one application may be slow for another. This paper is focused on document classification, and a viable method must be able to easily handle large and sparse features.

2.5 Least-square Regression for Signal Processing and Image Applications

Recently, L1-regularized problems have attracted considerable attention for signal processing and image applications. However, they differ from (1) in several aspects. First, $y_i \in R$, and therefore, a regression instead of a classification problem is considered. Second, the least-square loss function is used:

$$\xi(\mathbf{w};\mathbf{x}_i,y_i) = (y_i - \mathbf{w}^T\mathbf{x}_i)^2. \tag{16}$$
