Abstract

We explore the framework of permutation-based p-values for assessing the performance of classifiers. In this paper we study two simple permutation tests. The first test assess whether the classifier has found a real class structure in the data; the corresponding null distribution is estimated by permuting the labels in the data. This test has been used extensively in classification problems in computational biology. The second test studies whether the classifier is exploiting the dependency between the features in classification; the corresponding null distribution is estimated by permuting the features within classes, inspired by restricted randomization techniques traditionally used in statistics. This new test can serve to identify descriptive features which can be valuable information in improving the classifier performance. We study the properties of these tests and present an extensive empirical evaluation on real and synthetic data. Our analysis shows that studying the classifier performance via permutation tests is effective. In particular, the restricted permutation test clearly reveals whether the classifier exploits the interdependency between the features in the data.

Keywords: classification, labeled data, permutation tests, restricted randomization, significance testing

1. Introduction

Building effective classification systems is a central task in data mining and machine learning. Usually, a classification algorithm builds a model from a given set of data records in which the labels are known, and later, the learned model is used to assign labels to new data points. Applications of such classification setting abound in many fields, for instance, in text categorization, fraud detection, optical character recognition, or medical diagnosis, to cite some.

For all these applications, a desired property of a good classifier is the power of generalization to new, unknown instances. The detection and characterization of statistically significant predictive patterns is crucial for obtaining a good classification accuracy that generalizes beyond the training data. Unfortunately, it is very often the case that the number of available data points with labels is not sufficient. Data from medical or biological applications, for example, are characterized by high

dimensionality (thousands of features) and small number of data points (tens of rows). An important question is whether we should believe in the classification accuracy obtained by such classifiers.

The most traditional approach to this problem is to estimate the error of the classifier by means of cross-validation or leave-one-out cross-validation, among others. This estimate, together with a variance-based bound, provides an interval for the expected error of the classifier. The error estimate itself is the best statistics when different classifiers are compared against each other (Hsing et al., 2003). However, it has been argued that evaluating a single classifier with an error measurement is ineffective for small amount of data samples (Braga-Neto and Dougherty, 2004; Golland et al., 2005; Isaksson et al., 2008). Also classical generalization bounds are not directly appropriate when the dimensionality of the data is too high; for these reasons, some recent approaches using filtering and regularization alleviate this problem (Rossi and Villa, 2006; Berlinet et al., 2008). Indeed, for many other general cases, it is useful to have other statistics associated to the error in order to understand better the behavior of the classifier. For example, even if a classification algorithm produces a classifier with low error, the data itself may have no structure. Thus the question is, how can we trust that the classifier has learned a significant predictive pattern in the data and that the chosen classifier is appropriate for the specific classification task?

For instance, consider the small toy example in Figure 1. There are two nominal data matrices D_1 and D_2 of sizes 16×8. Each row (data point) has two different values present, x and o. Both data sets have a clear separation into the two given classes, + and −. However, it seems at first sight that the structure within the classes for data set D_1 is much simpler than for data set D_2. If we train a 1-Nearest Neighbor classifier on the data sets of Figure 1, we have that the classification error (leave-one-out cross-validation) is 0.00 on both D_1 and D_2. However, is it true that the classifier is using a real dependency in the data? Or are the dependencies in D_1 or D_2 just a random artifact of

some simple structure? It turns out that the good classification result in D_1 is explained purely by the different value distributions inside the classes whereas in D_2 the interdependency between the features is important in classification. This example will be analyzed in detail later on in Section 3.3.

In recent years, a number of papers have suggested to use permutation-based p-values for assessing the competence of a classifier (Golland and Fischl, 2003; Golland et al., 2005; Hsing et al., 2003; Jensen, 1992; Molinaro et al., 2005). Essentially, the permutation test procedure measures how likely the observed accuracy would be obtained by chance. A p-value represents the fraction of random data sets under a certain null hypothesis where the classifier behaved as well as or better than in the original data.

Traditional permutation tests suggested in the recent literature study the null hypothesis that the features and the labels are independent, that is, that there is no difference between the classes. The null distribution under this null hypothesis is estimated by permuting the labels of the data set. This corresponds also to the most traditional statistical methods (Good, 2000), where the results on a control group are compared against the results on a treatment group. This simple test has been proven effective already for selecting relevant genes in small data samples (Maglietta et al., 2007) or for attribute selection in decision trees (Frank, 2000; Frank and Witten, 1998). However, the related literature has not performed extensive experimental studies for this traditional test in more general cases.

The goal of this paper is to study permutation tests for assessing the properties and performance of the classifiers. We first study the traditional permutation test for testing whether the classifier has found a real class structure, that is, a real connection between the data and the class labels. Our experimental studies suggest that this traditional null hypothesis leads to very low p-values, thus rendering the classifier significant most of the time even if the class structure is weak.

We then propose a test for studying whether the classifier is exploiting dependency between some features for improving the classification accuracy. This second test is inspired by restricted randomization techniques traditionally used in statistics (Good, 2000). We study its relation to the traditional method both analytically and empirically. This new test can serve as a method for obtaining descriptive properties for classifiers, namely whether the classifier is using the feature dependency in the classification or not. For example, many existing classification algorithms are like black boxes whose functionality is hard to interpret directly. In such cases, indirect methods are needed to get descriptive information for the obtained class structure in the data.

If the studied data set is known to contain useful feature dependencies that increase the class separation, this new test can be used to evaluate the classifier against this knowledge. For example, often the data is gathered by a domain expert having deeper knowledge of the inner structure of the data. If the classifier is not using a known useful dependency, the classifier performance could be improved. For example, with medical data, if we are predicting the blood pressure of a person based on the height and the weight of the individual, the dependency between these two features is important in the classification as large body mass index is known to be connected with high blood pressure. However, both weight and height convey information about the blood pressure but the dependency between them is the most important factor in describing the blood pressure. Of course, in this case we could introduce a new feature, the body mass index, but in general, this may not be practical; for example, introducing too many new features can make the classification ineffective or too time consuming.

If nothing is known previously from the structure of the data, Test 2 can give some descriptive information for the obtained class structure. This information can be useful as such for understanding

the properties of the classifier, or it can guide the search towards an optimal classifier. For example, if the classifier is not exploiting the feature dependency, there might be no reason to use the chosen classifier as either more complex classifiers (if the data contains useful feature dependencies) or simpler classifiers (if the data does not contain useful feature dependencies) could perform better. Note, however, that not all feature dependencies are useful in predicting the class labels. Therefore, in the same way that traditional permutation tests have already been proven useful for selecting relevant features in some contexts as mentioned above (Maglietta et al., 2007; Frank, 2000; Frank and Witten, 1998), the new test can serve for selecting combinations of relevant features to boost the classifier performance for specific applications.

The idea is to provide users with practical p-values for the analysis of the classifier. The permutation tests provide useful statistics about the underlying reasons for the obtained classification result. Indeed, no test is better than the other, but all provide us with information about the classifier performance. Each p-value is a statistic about the classifier performance; each p-value depends on the original data (whether it contains some real structure or not) and the classifier (whether it is able to use certain structure in the data or not).

The remaining of the paper is organized as follows. In Section 2, we give the background to classifiers and permutation-test p-values, and discuss connections with previous related work. In Section 3, we describe two simple permutation methods and study their behavior on the small toy example in Figure 1. In Section 4, we analyze in detail the properties of the different permutations and the effect of the tests for synthetic data on four different classifiers. In Section 5, we give experimental results on various real data sets. Finally, Section 6 concludes the paper.[1]

2. Background

Let X be an $n \times m$ data matrix. For example, in gene expression analysis the values of the matrix X are numerical expression measurements, each row is a tissue sample and each column represents a gene. We denote the i-th row vector of X by X_i and the j-th column vector of X by X^j. Rows are also called observations or data points, while columns are also called attributes or features. Observe that we do not restrict the data domain of X and therefore the scale of its attributes can be categorical or numerical.

Associated to the data points X_i we have a class label y_i. We assume a finite set of known class labels $\mathcal{Y}$, so $y_i \in \mathcal{Y}$. Let D be the set of labeled data $D = \{(X_i, y_i)\}_{i=1}^n$. For the gene expression example above, the class labels associated to each tissue sample could be, for example, "sick" or "healthy".

In a traditional classification task the aim is to predict the label of new data points by training a classifier from D. The function learned by the classification algorithm is denoted by $f : \mathcal{X} \to \mathcal{Y}$. A test statistic is typically computed to evaluate the classifier performance: this can be either the training error, cross-validation error or jackknife estimate, among others. Here we give as an example the leave-one-out cross-validation error,

$$e(f, D) = \frac{1}{n} \sum_{i=1}^{n} \mathrm{I}(f_{D \setminus D_i}(X_i) \neq y_i) \tag{1}$$

1. A shorter version of this paper appears in the proceedings of the IEEE International Conference on Data Mining (Ojala and Garriga, 2009). This is an improved version based on valuable comments by reviewers which includes: detailed discussions and examples, extended theoretical analysis of the tests including statistical power in special case scenarios, related work comparisons and a thorough experimental evaluation with large data sets.

where $f_{D\setminus D_i}$ is the function learned by the classification algorithm by removing the i-th observation from the data and $\mathrm{I}(\cdot)$ is the indicator function.

It has been recently argued that evaluating the classifier with an error measurement is ineffective for small amount of data samples (Braga-Neto and Dougherty, 2004; Golland et al., 2005; Hsing et al., 2003; Isaksson et al., 2008). Also classical generalization bounds are inappropriate when the dimensionality of the data is too high. Indeed, for many other general cases, it is useful to have other statistics associated to the error $e(f,D)$ in order to understand better the behavior of the classifier. For example, even if a consistent algorithm produces a classifier with low error, the data itself may have no structure.

Recently, a number of papers have suggested to use permutation-based p-values for assessing the competence of a classifier. Essentially, the permutation test procedure is used to obtain a p-value statistic from a null distribution of data samples, as described in Definition 1. In Section 3.1 we will introduce two different null hypotheses for the data.

Definition 1 (Permutation-based p-value) *Let $\widehat{D}$ be a set of k randomized versions D' of the original data D sampled from a given null distribution. The empirical p-value for the classifier f is calculated as follows (Good, 2000),*[2]

$$p = \frac{|\{D' \in \widehat{D} : e(f,D') \leq e(f,D)\}| + 1}{k+1}.$$

The empirical p-value of Definition 1 represents the fraction of randomized samples where the classifier behaved better in the random data than in the original data. Intuitively, it measures how likely the observed accuracy would be obtained by chance, only because the classifier identified in the training phase a pattern that happened to be random. Therefore, if the p-value is small enough—usually under a certain threshold, for example, $\alpha = 0.05$—we can say that the value of the error in the original data is indeed significantly small and in consequence, that the classifier is significant under the given null hypothesis, that is, the null hypothesis is rejected.

Ideally the entire set of randomizations of D should be used to calculate the corresponding permutation-based p-value. This is known as the *exact randomization test*; unfortunately, this is computationally infeasible in data that goes beyond toy examples. Instead, we will sample from the set of all permutations to approximate this p-value. It is known that the Monte Carlo approximation of the p-value has a standard deviation of $\sqrt{\frac{p(1-p)}{k}}$, see, for example, Efron and Tibshirani (1993) and Good (2000), where p is the underlying true p-value and k is the number of samples used. Since p is unknown in practice, the upper bound $\frac{1}{2\sqrt{k}}$ is typically used to determine the number of samples required to achieve the desired precision of the test, or the value of the standard deviation in the critical point of $p = \alpha$ where α is the significance level. Alternatively, a sequential probability ratio test can be used (Besag and Clifford, 1991; Wald, 1945; Fay et al., 2007), where we sample randomizations of D until it is possible to accept or reject the null hypothesis. With these tests, often already 30 samples are enough for statistical inference with significance level $\alpha = 0.05$.

2. Notice the addition of 1 in both the denominator and the numerator of the definition. This adjustment is an standard procedure to compute empirical p-values and it is justified by the fact that the original database D is as well a randomized version of itself.

We will specify with more details in the next section how the randomized versions of the original data D are obtained. Indeed, this is an important question as each randomization method entails a certain null distribution, that is, which properties of the original data are preserved in the randomization test, directly affecting the distribution of the error $e(f, D')$. In the following, we will assume that the number of samples k is determined by any of the standard procedures just described here.

2.1 Related Work

As mentioned in the introduction, using permutation tests for assessing the accuracy of a classifier is not new, see, for example, Golland and Fischl (2003), Golland et al. (2005), Hsing et al. (2003) and Molinaro et al. (2005). The null distribution in those works is estimated by permuting labels from the data. This corresponds also to the most traditional statistical methods (Good, 2000), where the results on a control group are compared against the results on a treatment group. This traditional null hypothesis is typically used to evaluate one single classifier at a time (that is, one single model) and we will call it as Test 1 in the next section where the permutation tests are presented.

This simple traditional test has already been proven effective for selecting relevant genes in small data samples (Maglietta et al., 2007) or for attribute selection in decision trees (Frank, 2000; Frank and Witten, 1998). Particularly, the contributions by Frank and Witten (1998) show that permuting the labels is useful for testing the significance of attributes at the leaves of the decision trees, since samples tend to be small. Actually, when discriminating attributes for a decision tree, this test is preferable to a test that assumes the chi-squared distribution.

In the context of building effective induction systems based on rules, permutation tests have been extensively used by Jensen (1992). The idea is to construct a classifier (in the form of a decision tree or a rule system) by searching in the space of several models generated in an iterative fashion. The current model is tested against other competitors that are obtained by local changes (such as adding or removing conditions in the current rules). This allows to find final classifiers with less over-fitting problems. The evaluation of the different models in this local search strategy is done via permutation tests, using the framework of multiple hypothesis testing (Benjamini and Hochberg, 1995; Holm, 1979). The first test used corresponds to permuting labels—that is, Test 1—while the second test is a conditional randomization test. Conditionally randomization tests permute the labels in the data while preserving the overall classification ability of the current classifier. When tested on data with a conditionally randomized labelling, the current model will achieve the same score as it does with the actual labelling, although it will misclassify different observations. This conditionally randomization test is effective when searching for models that are more adaptable to noise.

The different tests that we will contribute in this paper could be as well used in this process of building an effective induction system. However, in general our tests are not directly comparable to the conditional randomization tests of Jensen (1992) in the context of this paper. We evaluate the classifier performance on the different randomized samples, and therefore, creating data set samples that preserve such performance would only produce always p-values close to one.

The restricted randomization test that we will study in detail later, can be used for studying the importance of dependent features for the classification performance. Related to this, group variable selection is a method for finding similarities between the features (Bondell and Reich, 2008). In that approach, similar features are grouped together for decreasing the dimensionality and improving the classification accuracy. Such methods are good for clustering the features while

doing classification. However, our aim is to test whether the dependency between the features is essential in the classification and not to reduce the dimensionality and similarities, thus differing from the objective of group variable selection.

As part of the related work we should mention that there is a large amount of statistical literature about hypothesis testing (Casella and Berger, 2001). Our contribution is to use the framework of hypothesis testing for assessing the classifier performance by means of generating permutation-based p-values. How the different randomizations affect these p-values is the central question we would like to study. Also sub-sampling methods such as bootstrapping (Efron, 1979) use randomizations to study the properties of the underlying distribution, but this is not used for testing the data against some null model as we intend here.

3. Permutation Tests for Labeled Data

In this section we describe in detail two very simple permutation methods to estimate the null distribution of the error under two different null hypotheses. The questions for which the two statistical tests supply answers can be summarized as follows:

Test 1: Has the classifier found a significant class structure, that is, a real connection between the data and the class labels?

Test 2: Is the classifier exploiting a significant dependency between the features to increase the accuracy of the classification?

Note, that these tests study whether the classifier is using the described properties and not whether the plain data contain such properties. For studying the characteristics of a population represented by the data, standard statistical test could be used (Casella and Berger, 2001).

Let π be a permutation of n elements. We denote with $\pi(y)_i$ the i-th value of the vector label y induced by the permutation π. For the general case of a column vector X^j, we use $\pi(X^j)$ to represent the permutation of the vector X^j induced by π. Finally, we denote the concatenation of column vectors into a matrix by $X = [X^1, X^2, \ldots, X^m]$.

3.1 Two Simple Permutation Methods

The first permutation method is the standard permutation test used in statistics (Good, 2000). The null hypothesis assumes that the data X and the labels y are independent, that is, $p(X,y) = p(X)p(y)$. The distribution under this null hypothesis is estimated by permuting the labels in D.

Test 1 (Permute labels) *Let $D = \{(X_i, y_i)\}_{i=1}^n$ be the original data set and let π be a permutation of n elements. One randomized version D' of D is obtained by applying the permutation π on the labels, $D' = \{(X_i, \pi(y)_i)\}_{i=1}^n$. Compute the p-value as in Definition 1.*

A significant classifier for Test 1, that is, obtaining a small p-value, rejects the null hypothesis that the features and the labels are independent, meaning that there is no difference between the classes. Let us now study this by considering the following case analysis. If the original data contains a real (i.e., not a random effect) dependency between data points and labels, then: (1) a significant classifier f will use such information to achieve a good classification accuracy and this will result in a small p-value (because the randomized samples do not contain such dependency

by construction); (2) if the classifier f is not significant in the sense of Test 1 (that is, f was not able to use the existing dependency between data and labels in the original data), then the p-value would tend to be high because the error in the randomized data will be similar to the error obtained in the original data. Finally, if the original data did not contain any real dependency between data points and labels, that is, such dependency was similar to randomized data sets, then all classifiers tend to have a high p-value. However, as a nature of statistical tests, about α of the results will be incorrectly regarded as significant.

Applying randomizations on the original data is therefore a powerful way to understand how the different classifiers use the structure implicit in the data, if such structure exists. However, notice that a classifier might be using additionally some dependency structure in the data that is not checked by Test 1. Indeed, it is very often the case that the p-values obtained from Test 1 are very small on real data because a classifier is easily regarded as significant even if the class structure is weak. We will provide more evidence about this fact in the experiments.

An important point is in fact, that a good classifier can be using other types of dependency if this exists in the data, for example the dependency between the features. From this perspective, Test 1 does not generate the appropriate randomized data sets to test such hypotheses. Therefore, we propose a new test whose aim is to check for the dependency between the attributes and how classifiers use such information.

The second null hypothesis assumes that the columns in X are mutually independent inside a class, thus $p(X(c)) = p(X(c)^1) \cdots p(X(c)^m)$, where $X(c)$ represents the submatrix of X that contains all the rows having the class label $c \in \mathcal{Y}$. This can be stated also using conditional probabilities, that is, $p(X \mid y) = p(X^1 \mid y) \cdots p(X^m \mid y)$. Test 2 is inspired by the restricted randomizations from statistics (see, e.g., Good, 2000).

Test 2 (Permute data columns per class) *Let $D = \{(X_i, y_i)\}_{i=1}^n$ be the data. A randomized version D' of D is obtained by applying independent permutations to the columns of X within each class. That is:*

For each class label $c \in \mathcal{Y}$ do,

- *Let $X(c)$ be the submatrix of X in class label c, that is, $X(c) = \{X_i \mid y_i = c\}$ of size $l_c \times m$.*
- *Let $\pi_1, \ldots, \pi_m$ be m independent permutations of l_c elements.*
- *Let $X(c)'$ be a randomized version of $X(c)$ where each π_j is applied independently to the column $X(c)^j$. That is, $X(c)' = [\pi_1(X(c)^1), \ldots, \pi_m(X(c)^m)]$.*

Finally, let $X' = \{X(c)' \mid c \in Y\}$ and obtain one randomized version $D' = \{(X_i', y_i)\}_{i=1}^n$. Next, compute the p-value as in Definition 1.

Thus, a classification result can be regarded as nonsignificant with Test 2, if either the features are independent of each other inside the classes or if the classifier does not exploit the interdependency between the features. Notice that we are not testing the data but the classifier against the null hypothesis corresponding to Test 2. The classification result is significant with Test 2 only if the classifier exploits the interdependency between the features, if such interdependency exists. If the dependency is not used, there might be no reason to use a complicated classifier, as simpler and faster methods, such as Naive Bayes, could provide similar accuracy results for the same data. On

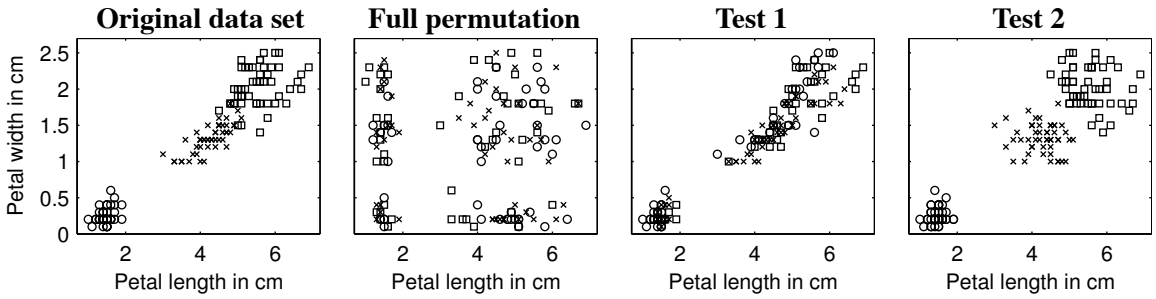

Figure 2: Scatter plots of original Iris data set and randomized versions for full permutation of the data and for Tests 1 and 2 (one sample for each test). The data points belong to three different classes denoted by different markers, and they are scattered against petal length and width in centimeters.

the other hand, this observation can lead us to find a classifier that can exploit the possibly existing dependency and thus improve the classification accuracy further, as discussed in the introduction.

There are three important properties of the permutation-based p-values and the two tests proposed here. The first one is that the number of missing values, that is, the number of entries in D that are empty because they do not have measured values, will be distributed equally across columns in the original data set D and the randomized data sets D'; this is necessary for a fair p-value computation. The second property is that the proposed permutations are always relevant regardless of the data domain, that is, values are permuted always within the same column, which does not change the domain of the randomized data sets. Finally, we have that unbalanced data sets, that is, data sets where the distribution of class labels is not uniform, remain equally unbalanced in the randomized samples.

In all, with permutation tests we obtain useful statistics about the classification result. No test is better than the other, but all provide us with information about the classifier. Each p-value is a statistic about the classifier performance; each p-value depends on the original data (whether it contains some real structure or not) and the classifier (whether it is able to use certain structure in the data or not).

In Figure 2, we give as an example one randomization for each test on the well-known Iris data set. We show here the projection of two features, before and after randomizations according to each one of the tests. For comparison, we include a test corresponding to full permutation of the data where each column is permuted separately, breaking the connection between the features and mixing the values between different classes. Note how well Test 2 has preserved the class structure compared to other tests. To provide more intuitions, in this case a very simple classifier, which predicts the class by means of one single of these two features would suffice in reaching a very good accuracy. In other words, the dependency between the two features is not significant as such, so that a more complex classifier making use of such dependency would end up having a high p-value with Test 2. We will discuss the Iris data more in the experiments.

3.2 Handling Instability of the Error

A related issue for all the above presented tests concerns the variability of the error estimate returned by a classifier. Indeed, applying the same classifier several times over the original data set D can

return different error estimates $e(f,D)$ if, for example, 10-fold cross-validation is used. So the question is, how can we ensure that the p-values given by the tests are stable to such variance?

The empirical p-value depends heavily on the correct estimation of the original classification accuracy, whereas the good estimation of the classification errors of the randomized data sets is not so important. However, exactly the same classification procedure has to be used for both the original and randomized data for the p-value to be valid. Therefore, we propose the following solution to alleviate the problem of having instable test statistic: We train the classifier on the original data r times, thus obtaining r different error estimates $E = \{e_1(f,D),\ldots,e_r(f,D)\}$ on D. Next, we obtain k randomized samples of D according to the desired null hypothesis and compute the p-value for each one of those original errors $e \in E$. We obtain therefore r different p-values by using the same k randomized data sets for each computation. We finally output the average of those r different p-values as the final empirical p-value.

Note that in total we will compute the error of the classifier $r+k$ times: r times on the original data and one time for each of the k randomized data sets. Of course, the larger the k and the larger the r, the more stable the final averaged p-value would be. A larger r decreases the variance in the final p-value due to the estimation of the classification error of the original data set whereas a larger k decreases the variance in the final p-value due to the random sampling from the null distribution. In practice, we have observed that a value of $r = 10$ and $k = 100$ produce sufficiently stable results.

This solution is closely related to calculating the statistic ρ, or calculating the test statistic U of the Wilcoxon-Mann-Whitney two-sample rank-sum test (Good, 2000). However, it is not valid to apply these approaches in our context as the r classification errors of the original data are not independent of each other. Nevertheless, the proposed solution has the same good properties as the ρ and U statistics as well as it generalizes the concept of empirical p-value to instable results.

A different solution would be to use a more accurate error estimate. For example, we could use leave-one-out cross-validation or cross-validation with 100 folds instead of 10-fold cross-validation. This will decrease the variability but increase the computation time dramatically as we need to perform the same slow classification procedure to all k randomized samples as well. However, it turns out that the stability issue is not vital for the final result; our solution produces sufficiently stable p-values in practice.

3.3 Example

We illustrate the concept of the tests by studying the small artificial example presented in the introduction in Figure 1. Consider the two data sets D_1 and D_2 given in Figure 1. The first data set D_1 was generated as follows: in the first eight rows corresponding to class +, each element is independently sampled to be x with probability 80% and o otherwise; in the last eight rows the probabilities are the other way around. Note that in the data set D_1 the features are independent given the class since, for example, knowing that $X_i^{j_1} =$ x inside class + does not increase the probability of $X_i^{j_2}$ being x. The data set D_2 was generated as follows: the first four rows contain x, the second four rows contain o, the third four rows contain x in the first four columns and o in the last four columns, and the last four rows contain o in the first four columns and x in the last four columns; finally, 10% of noise was added to the data set, that is, each x was flipped to o with probability of 10%, and vice versa.

Observe that both D_1 and D_2 have a clear separation into the two given classes, + and −. However, the structure inside the data set D_1 is much simpler than in the data set D_2. For illustration

1-Nearest Neighbor					
	Orig.	Test 1		Test 2	
Data Set	Err.	Err. (Std)	p-val.	Err. (Std)	p-val.
D_1	0.00	0.53 (0.14)	0.001	0.06 (0.06)	**0.358**
D_2	0.00	0.53 (0.14)	0.001	0.62 (0.14)	0.001

Table 1: Average error and p-value for Test 1 and Test 2 when using the 1-Nearest Neighbor classifier to data sets of Figure 1.

purposes, we analyze this with the 1-Nearest Neighbor classifier using the leave-one-out cross-validation given in Equation (1). Results for Test 1 and Test 2 are summarized in Table 1. The classification error obtained in the original data is 0.00 for both D_1 and D_2, which is expected since the data sets were generated to contain clear class structure.

First, we use the standard permutation test (i.e., permuting labels, Test 1) to understand the behavior under the null hypothesis where data points and labels are independent. We produce 1000 random permutations of the class labels for both the data sets D_1 and D_2, and perform the same leave-one-out cross-validation procedure to obtain a classification error for each randomized data set. On the randomized samples of data set D_1 we obtain an average classification error of 0.53, a standard deviation 0.14 and a minimum classification error of 0.13. For the randomized data from D_2 the corresponding values are 0.53, 0.14 and 0.19, respectively. These values result in two empirical p-values of both 0.001 on both the data sets D_1 and D_2. Thus, we can say that the classifiers are significant under the null hypothesis that data and labels are independent. That is, the connection between the data and the class labels is real in both data sets and the 1-Nearest Neighbor classifier is able to find that connection in both data sets, resulting into a good classification accuracy.

However, it is easy to argue that the results of Test 1 do not provide much information about the classifier performance. Actually the main problem of Test 1 is that p-values tend to be always very low as the null hypothesis is typically easy to reject. To get more information of the properties of the classifiers, we study next the performance of the classifiers by taking into account the inner structure of data sets D_1 and D_2 by applying Test 2. Again, we produce 1000 random samples of the data sets D_1 and D_2 by permuting each column separately inside each class. The same leave-one-out cross-validation procedure is performed for the randomized samples, obtaining for the data set D_1 the average classification error of 0.06, standard deviation of 0.06 and a minimum value of 0.00. For the data set D_2 the corresponding values are 0.62, 0.14 and 0.19, respectively. Therefore, under Test 2 the empirical p-values are 0.358 for the data set D_1 and 0.001 for the data set D_2.

We can say that, for Test 2, the 1-Nearest Neighbor classifier is significant for data set D_2 but not for data set D_1. Indeed, the data set D_1 was generated so that the features are independent inside the classes, and hence, the good classification accuracy of the algorithm on D_1 is simply due to different value distributions across the classes. Note, however, that none of the features in the data set D_1 is sufficient alone to correctly classify all the samples due to the noise in the data set. Thus using a combination of multiple features for classification is necessary for obtaining a good accuracy, even though the features are independent of each other. For data set D_2 we have that the dependency between the columns inside the classes is essential for the good classification result, and in this case, the 1-Nearest Neighbor classifier has been able to exploit that information.

4. Analysis

In this section we analyze the properties of the tests and demonstrate the behavior of the different p-values on simulated data. First, we state the relationships between the different sets of permutations.

4.1 Connection between Test 1 and Test 2

Remember that the random samples from Test 1 are obtained by permuting the class labels and the samples from Test 2 by permuting the features inside each class. To establish a connection between these randomizations, we study the randomization where each data column is permuted separately, regardless of the class label. This corresponds to the full permutation presented in Figure 2 in Section 3.1 for Iris data set. It breaks the connection between the features, and furthermore, between the data and the class labels. The following result states the relationship between Test 1, Test 2 and the full permutation method.

Proposition 2 *Let $\Pi_l(D)$, $\Pi_c(D)$, $\Pi_{cc}(D)$ be the sets of all possible randomized data sets obtained from D via permuting labels (Test 1), permuting data columns (full permutation), or permuting data columns inside class (Test 2), respectively. The following holds,*

(1) $\Pi_l(D) \subset \Pi_c(D)$

(2) $\Pi_{cc}(D) \subset \Pi_c(D)$

(3) $\Pi_l(D) \neq \Pi_{cc}(D)$

Note that $\Pi_l(D)$, $\Pi_c(D)$ and $\Pi_{cc}(D)$ refer to sets of data matrices. Therefore, we have that permuting the data columns is the randomization method producing the most diverse samples, while permuting labels (Test 1) and permuting data within class (Test 2) produce different randomized samples.

Actually, the relationship stated by Proposition 2 implies the following property: the p-value obtained by permuting the data columns is typically smaller than both the p-values obtained from Test 1 and Test 2. The reason is that all the randomized data sets obtained by Test 1 and Test 2 can also be obtained by permuting data columns and the additional randomized data sets obtained by permuting the columns are, in general, even more random. Theoretically, permuting the data columns is a combination of Test 1 and Test 2, and thus, it is not a useful test. In practice, we have observed that the p-value returned by permuting the data columns is very close to the p-value of Test 1, which tends to be much smaller than the p-value of Test 2.

Considering Proposition 2, it makes only sense to restrict the randomization to classes by using Test 2, whenever Test 1 has produced a small p-value. That is, it is only reasonable to study whether the classifier uses feature dependency in separating the classes if it has found a real class structure.

4.2 Behavior of the Tests

To understand better the behavior of the tests, we study generated data where correlation is used as the dependency between the features. Consider the following simulated data, inspired by the data used by Golland et al. (2005): 100 data points are generated from two-dimensional normal distribution with mean vector (1,0), unit variances and covariance $\rho \in [-1,1]$. Another 100 data points are generated from similar normal distribution with mean $(-1,0)$, unit variances and same

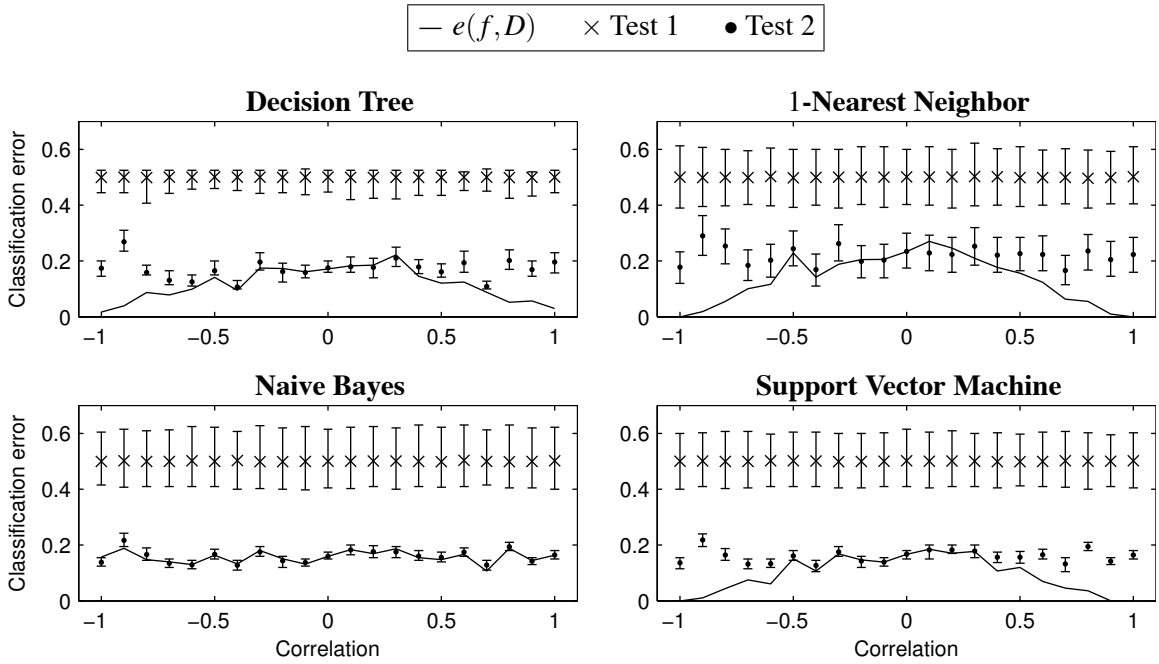

Figure 3: Average values of stratified 10-fold cross-validation error (y-axis) for varying values of correlation between the features per class (x-axis). The solid line shows the error on the original data, and symbols $\times$ and $\bullet$ represent the average of the error on 1000 randomized samples obtained from Test 1 and from Test 2, respectively. Each average of the error on the randomized samples $\times$ and $\bullet$ is depicted together with the $[1\%, 99\%]$-deviation bar. If the solid line falls below the bars the null hypothesis associated to the test is rejected; if the solid line crosses inside or above the bars the null hypothesis cannot be rejected with significance level $\alpha = 0.01$.

covariance ρ. The first 100 samples are assigned with class label $y = +1$ with probability $1-t$ and $y = -1$ with probability t. For the other 100 samples the probabilities are the opposite. The probability $t \in [0, 0.5]$ represents the noise level. When $t = 0.5$, there is no class structure at all. Note that the correlation between the features improves the class separation: if the correlation $\rho = 1$ and the noise $t = 0$, we have that the class $y = x_1 - x_2$ where x_1, x_2 are the values of the first and second features, respectively.

For these data sets (with varying parameters of noise and correlation) we use as an error estimate the stratified 10-fold cross-validation error. We study the behavior of four classifiers: 1-Nearest Neighbor, Decision Tree, Naive Bayes and Support Vector Machine. We use Weka 3.6 data mining software (Witten and Frank, 2005) with the default parameters of the implementations of those classification algorithms. The Decision Tree classifier is similar to C4.5 algorithm, and the default kernel used with Support Vector Machine is linear. Tuning the parameters of these algorithms is not in the scope of this paper; our objective is to show the behavior of the discussed p-values for some selected classifiers.

Figure 3 shows the behavior of the classifiers on data sets without class noise, $t = 0$, and with the correlation ρ between features inside classes varying from -1 (negative correlation) to 1 (positive correlation). The solid line corresponds to $e(f,D)$, that is, the error of the classifier in the original

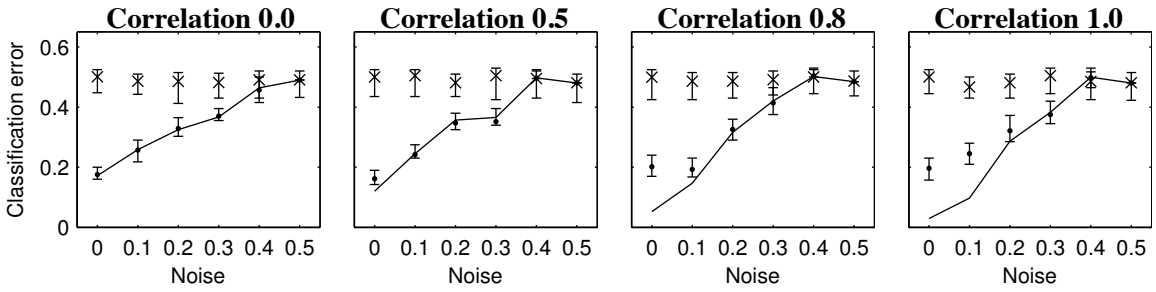

Figure 4: Average values of stratified 10-fold cross-validation error (y-axis) for the Decision Tree classifier when noise varies on the original data set (x-axis) with four fixed correlation values between the features inside the classes. The solid line shows the error on the original data, and symbols $\times$ and $\bullet$ show the average error on 1000 randomized samples from Test 1 and Test 2, respectively. Each average of the error on the randomized samples $\times$ and $\bullet$ is depicted together with the $[1\%, 99\%]$-deviation bar below which the associated null hypothesis is rejected with significance level $\alpha = 0.01$.

data. The symbols "$\times$" and "$\bullet$" represent the average error obtained by the classifier on 1000 randomized samples from Test 1 and Test 2, respectively. When the solid line of $e(f,D)$ falls below the $[1\%, 99\%]$-deviation bars, the corresponding associated null hypothesis is rejected with significance level $\alpha = 0.01$. Actually, the correspondence between the confidence intervals and hypotheses testing is only approximately true since the definition of empirical p-value contains the addition of 1 in both the numerator and denominator. However, the practical difference is negligible.

First, note that the Decision Tree, 1-Nearest Neighbor and Support Vector Machine classifiers have been able to exploit the dependency between the features, that is, the classification error goes to zero when there is either a high positive or negative correlation between the features. However, with Naive Bayes classifier the classification error seems to be independent of the correlation between the features.

For all classifiers we observe that the null hypothesis associated to Test 1 (i.e., labels and data are independent) is always rejected. Thus the data contains a clear class structure as expected since there exists no class noise in the data. All classifiers are therefore significant under Test 1.

Another expected observation is that the null hypothesis for Test 2 (i.e., features are independent within class) tends to be rejected as the magnitude of the correlation between features increases. That is, the correlation is useful in classifying the data. When the magnitude of the correlation is larger than approximately 0.4, the Decision Tree, Nearest Neighbor and Support Vector Machine classifiers reject the null hypothesis. Thus these classifiers produce significant results under Test 2 when the features are highly correlated.

Finally, observe the behavior of Naive Bayes classifier for Test 2: the null hypothesis can never be rejected. This is because Naive Bayes classifier explicitly assumes by default that the features are independent, thus it always performs similarly on the original data and the randomized data sets, which results in a very high p-value. Naive Bayes classifier is an example of such classifiers which are not able to use the dependency between the features at all. Thus applying Test 2 for Naive Bayes classifier will practically always produce a high p-value irrespective of the data.

Finally, Figure 4 shows the behavior of the Decision Tree classifier when the noise $t \in [0, 0.5]$ is increased on the x-axis. We also vary the correlation ρ between the features per class and show the results on four cases: zero correlation, 0.5, 0.8 and total correlation. We observe that as the noise increases the p-values tend to be larger. Therefore, it is more difficult to reject the null hypothesis on very noisy data sets, that is, when the class structure is weak. This is true for both Test 1 and Test 2. However, Test 1 rejects the null hypothesis even if there is 30% of noise. This supports the fact already observed in related literature (Golland et al., 2005), that even a weak class structure is easily regarded as significant with Test 1. Compared to this, Test 2 gives more conservative results.

4.3 Power Analysis of Test 2

The *power* of a statistical test is the probability that the test will reject the null hypothesis when the alternative hypothesis is true. The power of the test depends on how much or how clearly the null hypothesis is false. For example, in our case with Test 2, a classifier may rely solely on a strong dependency structure between some specific features in the classification, or it may use a weak feature dependency to slightly improve the classification accuracy. Rejecting the null hypothesis of Test 2 is much easier in the former than in the latter case. Note, however, that a strong dependency between the features is not always useful in separating the classes, as seen in Figure 2 with Iris data set. So, the question with Test 2 is whether the classifier is exploiting some of the dependency structure between the features in the data and how important such feature dependency is for the classification of the data.

In general, the power of the test can only be analyzed in special cases. Nevertheless, such analysis can give some general idea of the power the test. Next, we present a formal power analysis in the particular case where we vary the correlation between the features that is useful in separating the classes from each other. Note, however, that there exist also other types of dependency than correlation. The amount of correlation is just easy to measure, thus being suitable for formal power analysis.

We present the power analysis on similar data as studied in Section 4.2. The results in the previous subsection can be seen as informal power analysis. In summary, we observed that when the magnitude of the correlation in the data studied in Section 4.2 was larger than about 0.5 and the classifier was exploiting the feature dependency, that is, a classifier different from Naive Bayes, Test 2 was able to reject the null hypothesis. However, based on the data it is clear that even smaller correlations increased the class separation and were helpful in classifying the data but Test 2 could not regard such improvement as significant. The following analysis supports these observations.

Let the data set X consist of n points with two features belonging to two classes, $+1$ and -1. Let a point $x \in X$ be in class $y = +1$ with probability 0.5 and in class $y = -1$ with probability 0.5. Let the point $x \in X$ be sampled from two-dimensional normal distribution with mean $(0,0)$, unit variances and covariance $y\rho$ where $\rho \in [0,1]$ is a given parameter. Thus, in the first class, $y = +1$, the correlation between the two features is positive and in the second class, $y = -1$, it is negative. Compared to the data sets in Section 4.2, now the covariance changes between the classes, not the mean vector. An optimal classifier assigns a point $x \in X$ to class $y = +1$ if $x_1 x_2 > 0$ and to class $y = -1$ if $x_1 x_2 < 0$, where x_i is the i-th feature of the vector x.

The null hypothesis of Test 2 is that the classifier is not exploiting the dependency between the features in classification. To alleviate the power analysis, we assume that the classifier is able to find the optimal classification, that is, it assigns the point x to class $\text{sgn}(x_1 x_2)$ where $\text{sgn}(\cdot)$ is

the signum function. If the classifier is not optimal, it will just decrease the power of the test. The nonoptimality of the classifier could be taken into account by introducing a probability t for reporting a nonoptimal class label; this approach is used in the next subsection for power analysis of Test 1 but is left out here for simplicity in the analysis. Under this optimality scenario, the probability of correctly classifying a sample is

$$\begin{aligned}\Pr(\mathrm{sgn}(x_1x_2)=y) &= \frac{1}{2}\Pr(x_1x_2>0 \mid y=+1)+\frac{1}{2}\Pr(x_1x_2<0 \mid y=-1)\\ &= \Pr(x_1x_2>0 \mid y=+1) = 2\int_0^\infty\int_0^\infty \Pr(x_1,x_2)\,\mathrm{d}x_1\mathrm{d}x_2\\ &= 2\int_0^\infty\int_0^\infty \frac{1}{2\pi\sqrt{1-\rho^2}}\exp\left[-\frac{x_1^2-2\rho x_1x_2+x_2^2}{2(1-\rho^2)}\right]\mathrm{d}x_1\mathrm{d}x_2\\ &= \frac{1}{2}+\frac{1}{\pi}\arcsin\rho, \end{aligned} \tag{2}$$

where $\Pr(x_1,x_2)$ is just the standardized bivariate normal distribution. The null hypothesis corresponds to the case where the correlation parameter is zero, $\rho=0$, that is, no feature dependency exists. In that case, the probability of correctly classifying a sample is $1/2$.

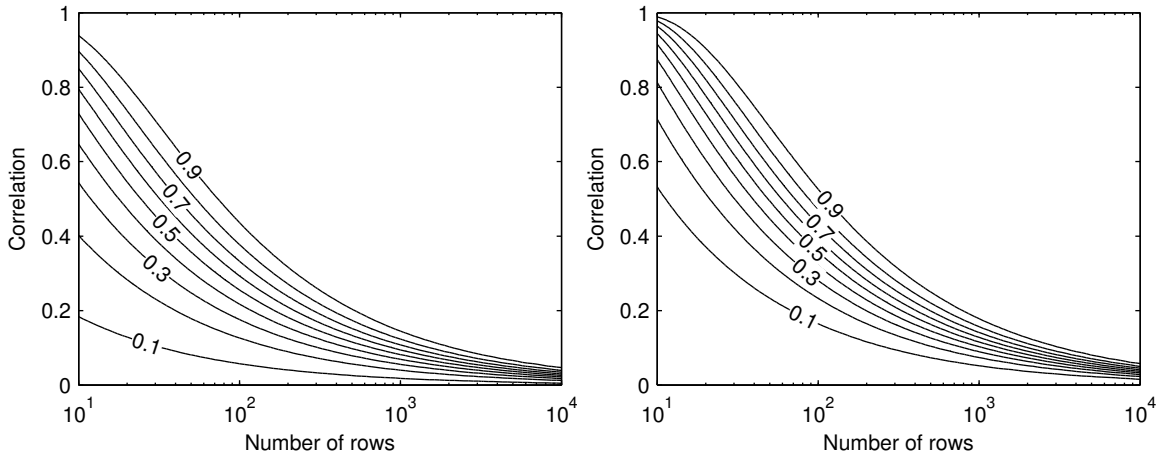
In our randomization approach, we are using classification error as the test statistic. Since we assume that the optimal classifier is given, we use all the n points of the data set X for testing the classifier and calculating the classification error. Under the null hypothesis H_0 and under the alternative hypothesis H_1 of Test 2, the classification errors $e(f \mid H_0)$ and $e(f \mid H_1)$ are distributed as follows:

$$\begin{aligned} n\cdot e(f \mid H_0) &\sim \mathrm{Bin}\left(n,\frac{1}{2}\right) \approx \mathcal{N}\left(\frac{n}{2},\frac{n}{4}\right),\\ n\cdot e(f \mid H_1) &\sim \mathrm{Bin}\left(n,\frac{1}{2}-\frac{1}{\pi}\arcsin\rho\right) \approx \mathcal{N}\left(\frac{n}{2}-\frac{n}{\pi}\arcsin\rho,\frac{n}{4}-\frac{n}{\pi^2}\arcsin^2\rho\right), \end{aligned}$$

where $\frac{1}{2}-\frac{1}{\pi}\arcsin\rho$ is the probability of incorrectly classifying a sample by Equation (2). The normal approximation $\mathcal{N}(np,np(1-p))$ of a binomial distribution $\mathrm{Bin}(n,p)$ holds with good accuracy when $np>5$ and $n(1-p)>5$. In our case, the approximation is valid if $n(\frac{1}{2}-\frac{1}{\pi}\arcsin\rho)>5$. This holds, for example, if $n\geq 20$ and $\rho\leq 0.7$.

Now the power of Test 2 for this generated data is the probability of rejecting the null hypothesis H_0 of $\rho=0$ with significance level α when the alternative hypothesis H_1 is that the correlation $\rho>0$. Note that we are implicitly assuming that the classifier is optimal, that is, we are excluding the classifier quality from the power analysis. Thus, the power is the probability that $e(f \mid H_1)$ is smaller than $1-\alpha$ of the errors $e(f \mid H_0)$ under the alternative hypothesis H_1:

$$\begin{aligned}\mathrm{Power} &= \Pr\left(e(f \mid H_1) < F^{-1}_{e(f|H_0)}(\alpha)\right)\\ &\approx \Pr\left(\frac{1}{2}-\frac{1}{\pi}\arcsin\rho+\sqrt{\frac{1}{4n}-\frac{1}{n\pi^2}\arcsin^2\rho}\cdot Z<\frac{1}{2}+\frac{1}{2\sqrt{n}}\Phi^{-1}(\alpha)\right)\\ &= \Phi\left(\frac{2\sqrt{n}\arcsin\rho+\pi\Phi^{-1}(\alpha)}{\sqrt{\pi^2-4\arcsin^2\rho}}\right), \end{aligned} \tag{3}$$



(a) $\alpha = 0.05$ (b) $\alpha = 0.01$

Figure 5: Contour plots of the statistical power of Test 2 as a function of the number of rows n in the generated data set and the correlation parameter ρ. Each solid line corresponds to a constant value of the power that is given on top of the contour. The power values are calculated by Equation (3) for two different values of significance level α.

where $F_{e(f|H_0)}$ is the cumulative distribution function of $e(f \mid H_0)$, Z is a random variable following standard normal distribution and Φ is the cumulative distribution function of the standard normal distribution. Note that we are using exact p-value instead of empirical p-value, effectively leaving out the influence of variance by using k randomized samples; see Fay et al. (2007) for analysis of resampling risk of using k samples. However, this has little effect to the power of the test. When the correlation $\rho = 0$, the power is α, that is, when the null hypothesis is true, it is rejected incorrectly about α of the times. Therefore, α is really the significance level of the tests.

In Figure 5 we present contour plots of the statistical power in Equation (3) for different values of the two varying parameters. As expected, the higher the correlation ρ and the number of rows n are, the higher the statistical power of Test 2 is. For example, if the data set contains about 1000 rows, we can infer with 90% probability that the classifier is exploiting the feature dependency of approximately a correlation of 0.2 in the data. The results are also in line with the results from Section 4.2 although the studied data sets are slightly different. When the significance level used is $\alpha = 0.01$ we can infer that the classifier is exploiting the feature dependency of correlation larger than 0.4 approximately 90% of the times when the data set has 200 rows.

Notice that if we had not considered an "optimal" classifier, that is, if we had introduced a probability t of assigning each observation to the incorrect label, then Equation (3) would depend on three parameters. In that case, the higher t, the smaller is the power of the test; however, for a fixed t we still would observe the same behaviour as in the contourplots above: the higher the correlation ρ and the larger the n, the higher is the statistical power of Test 2. The error parameter t is taken into account in the next section, where the power analysis of Test 1 does not depend on ρ between the features.

4.4 Power Analysis of Test 1

Let the data set X consist of n observations belonging to two different classes with equal probability. We assume that we have a classifier f whose error rate is $t \in [0,1]$, that is, the classifier assigns each observation to the correct class with probability $1-t$. Another way to see this is that the classifier f is optimal but the original class label of each point is erroneous with probability t. We perform power analysis of Test 1 for this general form of data.

Note that the results in Section 4.2 can be seen as informal power analysis of Test 1 on similar setting as studied here. The results in Figure 4 can be summarized as follows. When the error rate was smaller than $t < 0.4$, Test 1 was able to reject the null hypotheses. Note, however, that the error rate t used in this section is not directly comparable to the error rate used in Section 4.2.

The power analysis of Test 1 proceeds similarly as in the previous subsection for Test 2. Under the null hypothesis H_0 and under the alternative hypothesis H_1 of Test 1, the classification errors $e(f \mid H_0)$ and $e(f \mid H_1)$ are distributed as follows:

$$
\begin{aligned}
n \cdot e(f \mid H_0) &\sim \text{Bin}\left(n, \frac{1}{2}\right) \approx \mathcal{N}\left(\frac{n}{2}, \frac{n}{4}\right), \\
n \cdot e(f \mid H_1) &\sim \text{Bin}\,(n,t) \approx \mathcal{N}(nt, nt(1-t)).
\end{aligned}
$$

The null hypothesis H_0 assumes that there is no connection between the data and the class labels thus the probability of incorrect classification is $1/2$ as the classes are equally probable. Note that the null hypothesis corresponds to the case where the error rate of the classifier f is $t = 1/2$.

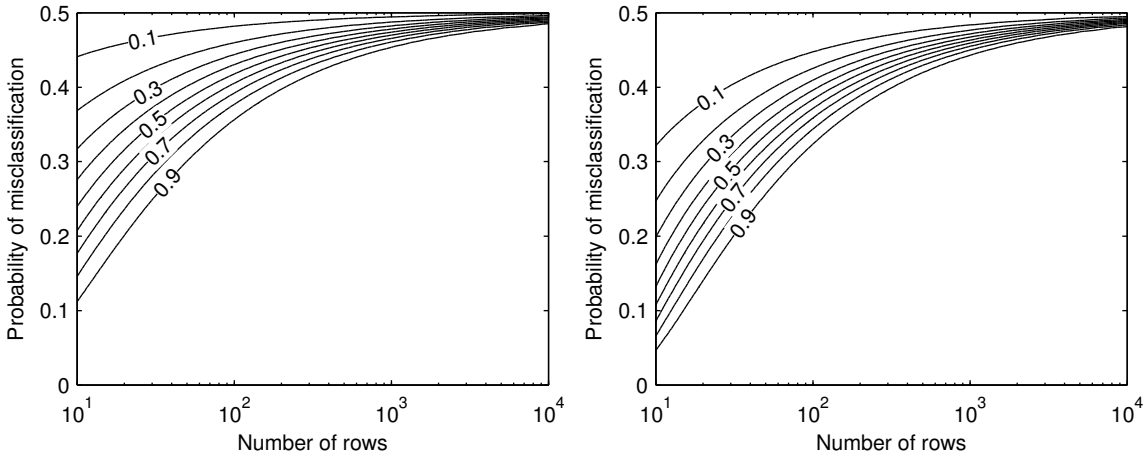
Now the power of Test 1 is the probability of rejecting the null hypothesis H_0 with significance level α when the alternative hypothesis H_1 is true, that is,

$$
\begin{aligned}
\text{Power} &= \Pr\left(e(f \mid H_1) < F^{-1}_{e(f|H_0)}(\alpha)\right) \\
&\approx \Pr\left(t + \sqrt{\frac{t(1-t)}{n}}\, Z < \frac{1}{2} + \frac{1}{2\sqrt{n}}\, \Phi^{-1}(\alpha)\right) \\
&= \Phi\left(\frac{(1-2t)\sqrt{n} + \Phi^{-1}(\alpha)}{2\sqrt{t(1-t)}}\right), \qquad (4)
\end{aligned}
$$

where the same notation as in the previous subsection is used. First, note that when the null hypothesis is true, that is, $t = 1/2$, the power of Test 1 calculated by Equation (4) equals the significance level α as it should.

In Figure 6 we present contour plots of the statistical power of Test 1 calculated by Equation (4) for different values of parameters. As expected, when the number of observations n increases or the error rate t decreases, the power increases. Furthermore, the larger the significance level α is, the larger the power of Test 1 is. When the parameter values are $\alpha = 0.01$, $n = 200$ and $t = 0.4$, the power of Test 1 is about 0.7 that is comparable to the results in Section 4.2.

In this section, we analyzed the behaviour and the power of the tests. Note that although we used correlation as the only type of dependency between features in this section, there exist also other forms of dependency that the classifier can exploit. As conclusions from the power analysis, the more rows the data set has, the easier we can infer that the classifier is using the feature dependency or some other properties in the data.



(a) $\alpha = 0.05$ (b) $\alpha = 0.01$

Figure 6: Contour plots of the statistical power of Test 1 as a function of the number of rows n in the generated data set and the probability of misclassification t. Each solid line corresponds to a constant value of the power that is given on top of the contour. The power values are calculated by Equation (4) for two different values of significance level α.

5. Empirical Results

In this section, we give extensive empirical results on 33 various real data sets from UCI machine learning repository (Asuncion and Newman, 2007). Basic characteristics of the data sets are described in Table 2. The data sets are divided into three categories based on their size: small, medium and large. Some data sets contain only nominal or numeric features whereas some data sets contain both kind of features (mixed). About one-third of the data sets contain also missing values. Notice that in most data sets the features are measured in different scales, thus it is not sensible to swap the values between different features. This justifies why it is only reasonable to consider column-wise permutations, and why some recent data mining randomization methods (Gionis et al., 2007; Ojala et al., 2009; Chen et al., 2005) are not generally applicable in assessing classification results.

In the experiments we use Weka 3.6 data mining software (Witten and Frank, 2005) that contains open source Java implementations of many classification algorithms. We use four different types of classification algorithms with the default parameters: Decision Tree, Naive Bayes, 1-Nearest Neighbor and Support Vector Machine classifier. The Decision Tree classifier is similar to C4.5 algorithm. The default kernel used with Support Vector Machine is linear. Missing values and the combination of nominal and numerical values are given as such as the input for the classifiers; the default approaches in Weka of the classifiers are used to handle these cases. Notice that tuning the parameters of these algorithms is not in the scope of this paper; our objective is to show the behavior of the discussed p-values for some selected classifiers on various data sets.

We use different classification procedures and the number of randomized data sets for each of the different size categories of the data sets (small, medium and large). For small data sets, we use stratified 10-fold cross-validation error as the statistic and 1000 randomized data sets for calculating the empirical p-values. For medium-sized data sets, we use the same stratified 10-fold cross-validation error and 100 randomized data sets. Finally, for large data sets, we divide the data

	Data Set	Rows	Features	Classes	Missing	Domain
Small	Audiology	226	70	24	2.0%	nominal
	Autos	205	25	6	1.2%	mixed
	Breast	286	9	2	0.3%	nominal
	Glass	214	9	6	No	numeric
	Hepatitis	155	19	2	5.7%	mixed
	Ionosphere	351	34	2	No	numeric
	Iris	150	4	3	No	numeric

Table 2: Summary of 33 selected data sets from UCI machine learning repository (Asuncion and Newman, 2007). The data sets are divided into three categories based on their size: small, medium and large.

set into training set with 10 000 random rows and to test set with the rest of the rows. We use 100 randomized data sets for calculating the empirical p-values with large data sets. The reason for the smaller number of randomized samples for medium and large data sets is mainly computation time. However, 100 samples is usually enough for statistical inference. Furthermore, as seen in Section 4 the power of the tests is greater when the data sets have more rows, that is, with large data sets it is easier to reject the null-hypotheses, supporting the need of fewer randomized samples in hypothesis testing.

Since the original classification error is not a stable result due to the randomness in training the classifier and dividing the data set into test and train data, we perform the same classification procedure ten times for the original data sets and calculate an empirical p-value for each of the ten results. This was described in Section 3.2. We give the average value of these empirical p-values as well as the average value and the standard deviation of the original classification errors.

As we are testing multiple hypotheses simultaneously, we need to correct for multiple comparisons. We apply the approach by Benjamini and Hochberg (1995) to control the false discovery rate (FDR), that is, the expected proportion of results incorrectly regarded as significant. In the experiments, we restrict the false discovery rate below $\alpha = 0.05$ separately for Test 1 and Test 2. In the Benjamini-Hochberg approach, if $p_1, \ldots, p_m$ are the original empirical p-values in increasing order, the results $p_1, \ldots, p_l$ are regarded as significant where l is the largest value such that $p_l \leq \frac{l}{m}\alpha$.

The significance testing results for the Decision Tree classifier are given in Table 3, for Naive Bayes in Table 4, for 1-Nearest Neighbor classifier in Table 5 and finally for Support Vector Machine classifier in Table 6. The mean and the standard deviation of the 10 original classification errors are given as well as the mean and standard deviation of the errors on the 1000 or 100 randomized samples with Test 1 and Test 2. The empirical p-values corresponding to nonsignificant results, when the false discovery rate is restricted below 0.05, are in boldface in the tables. With all classifiers, the largest significant empirical p-value was 0.01. The smallest non-significant p-values were 0.03 with Decision Tree and 1-Nearest Neighbor classifiers, 0.08 with Naive Bayes classifier and 0.19 with Support Vector Machine classifier.

The results for the traditional permutation method Test 1 show that the classification errors with most data sets are regarded as significant. These results show that the data sets contain clear class structure. However, they do not give any additional insight for understanding the class structure in the data sets.

There are two reasons why the simple permutation test, Test 1, regards the class structure of the data sets as significant. Firstly, most of the data sets that are publicly available, as all the data sets used in this paper, have already passed some quality checks, that is, someone has already found some interesting structure in them. Secondly, and as a more important reason, the traditional permutation tests easily regard the results as significant even if there is only a slight class structure present because in the corresponding permuted data sets there is no class structure, especially if the original data set is large.

Furthermore, the few results which were regarded as nonsignificant with Test 1 are with such classifiers that have not performed well on the data. That is, the other classifiers have produced smaller classification errors on the same data sets, and, in contrast, these results are regarded as significant.

Next, we consider the results for permuting the features inside each class, that is, Test 2. The results show that there are actually now almost equal amount of nonsignificant and significant results with respect to Test 2. This means that in many data sets the original structure inside the classes is

Table 3: Classification errors and empirical p-values obtained with Decision Tree classifier for Test 1 and Test 2. The empirical p-values are calculated over 1000 randomized samples for small data sets and over 100 randomized samples for medium and large data sets. Classification on the original data is repeated ten times. In the table, the average values and standard deviations of the classification errors are given. Bold p-values correspond to nonsignificant results when the false discovery rate is restricted below 0.05 with Benjamini and Hochberg (1995) approach.

Table 6: Classification errors and empirical p-values for the Support Vector Machine classifier for Test 1 and Test 2. The empirical p-values are calculated over 1000 randomized samples for small data sets and over 100 randomized samples for medium and large data sets. Classification on the original data is repeated ten times. In the table, the average values and standard deviations of the classification errors are given. Bold p-values correspond to nonsignificant results when the false discovery rate is restricted below 0.05 with Benjamini and Hochberg (1995) approach.

pretty simple, or it is not used by the classification algorithm. That is, the classes differ from each other, from the point of view of the classifiers, mainly due to their different value distributions of the features and not due to some dependency between the features. Thus, in many data sets the class structure is explained by considering the features independently of each other.

The results with Naive Bayes classifier are in line with the analysis in Section 4.2. That is, practically all of the results are nonsignificant with Naive Bayes with Test 2 as it explicitly assumes independence of the features. However, there are three data sets where the results are regarded as significant with Test 2: Balance, Car and Chess. These three data sets seem to contain a good balance between the features that makes the Naive Bayes classifier to perform better on the original data than on the randomized data sets. That is, each instance contains usually at least one feature which makes the classification easy whereas in the randomized data sets there are instances that do not have separating values in any of the features. Thus, applying Test 2 to Naive Bayes classifier does not tell whether the classifier uses the interdependency between the features but whether the data are such that usually at least one feature in each instance has a clear separating value.

Compared to the other three classifiers, Naive Bayes is having both better and worse performance with all kind of data sets. Surprisingly, however, Naive Bayes is performing better also in a few such cases where the other classifiers are exploiting the feature dependency. For example, with data sets Splice and Yeast the Naive Bayes classifier has the best accuracy although the Decision Tree and 1-Nearest Neighbor classifiers are significant with Test 2. Thus if a classifier is using the feature dependency in the classification, it does not directly imply that some other classifier could not do better without using the dependency. In such case, however, it is likely that neither of the classifiers are optimal and we could obtain even better performance by combining the good properties of both the classifiers.

In the rest of this section, we will consider only the three other classifiers, namely Decision Tree, 1-Nearest Neighbor and Support Vector Machine classifiers. There is a clear difference between the small and large data sets with these classifiers. The results with Test 2 for small data sets are almost all nonsignificant whereas the results for large data sets are almost all significant. Only the Adult data set from large data sets seems to contain simple class structure. Actually, the Decision Tree and Support Vector Machine classifiers are able to classify correctly all the test samples on the original Adult data set as well as on the randomized versions of the Adult data set of Test 2. The results with the studied small UCI data sets are understandable, as many of them are known to contain fairly simple structure.

The results with the three classifiers are close to each other with all tests. Surprisingly, however, 1-Nearest Neighbor classifier has been able to use the interdependency between the features the most, that is, it contains the most of small, significant p-values with Test 2. However, other more complex classifiers could be able to find more data sets where the dependency between the features is useful in classification.

Let us now study the results with Test 2 in more detail. Consider the well-known Iris data set that contains measurements of three different species of iris flowers from four features: the length and the width of sepal and petal. It turns out that the classes are almost linearly separable given the length of petal or given the width of petal. Although there is a high positive linear correlation between the length and width of petal, it is not important for the classification result as both features can explain the classes by themselves.

Actually, observe that for the Iris data set with Test 2, the classification error on the randomized samples is even smaller than in the original data set. This phenomenon is explained by the

positive linear correlation between the length and the width of petal, which disappears after the randomizations, as seen in Figure 2 in Section 3.1. Randomizations eliminate most of the rows containing extreme values for both of the features inside the classes. Thus, the classifiers do not use the dependency between these two features, as their correlation does not help in classifying the Iris data. When this positive correlation is eliminated per classes, the separation between the classes increases, and therefore, the classification accuracy is improved.

For most of the data sets where the empirical p-values are very high for the null hypothesis of Test 2, there are either outliers inside the classes or positive correlation between some features that is not used in the classification as it does not help in separating the classes. For example, the data set Votes contains congressional "yes" and "no" voting records from republicans and democrats. There are few voting cases where the opinion of the voter clearly reveals the political views. However, there are some outliers, that is, people who have behaved more like democrats although they are republicans, or vice versa, that vanish after randomization. Nevertheless, these reasons do not remove the fact that the features independently classify the voting records.

Finally, we discuss the results for the Balance data set. With all classifiers the classification results of the Balance data set are significant under the null hypothesis of Test 2, that is, the classifiers have exploited the dependency between the features. The structure of the data supports this: The data contains four features of a balance scale: left-weight, left-distance, right-weight and right-distance. The scale is in balance if left-weight times left-distance equals right-weight times right-distance. There are three classes: the scale tips to the left, to the right, or is in balance. It is clear that the dependency between the features is necessary for correct classification result.

Note however, that understanding the structure inside the data sets where the classification results are regarded as significant under the null hypothesis of Test 2 requires more study, that is, we just know that the features do not explain the class structure independently. Analyzing the dependency structure of the features is then a further task. But as seen, the null hypothesis of Test 2 explains about half of the good classification results in the 33 data sets.

We conclude the experiments with a summary about the running times of the methods. We used MATLAB for producing the randomized data sets and Weka for performing the classification on a 2.2 GHz Opteron with 4 GB of main memory. The running times of producing one randomization of each data set and the running times of calculating the classification errors on the original data sets and on the randomized data sets are given in Table 7. The running times of producing the randomized data sets are negligible compared to the running times of calculating the classification errors of the data sets, that is, training and testing the classifiers. There is, however, a small difference between the running times of obtaining the classification errors on the original and the randomized data sets. Usually, the classification is a little bit faster on the original data set than on the randomized data sets. Furthermore, the classification on randomized data sets of Test 2 is usually faster than on randomized data sets of Test 1. The reason is that it is harder to teach a classifier on a randomized data set which has usually a weaker class structure than the original data set. Among the two randomization tests, Test 2 generally preserves the original class structure the most because it preserves some connection between the data and the class labels.

6. Conclusions

We have considered the problem of assessing the classifier performance with permutation tests in the statistical framework of hypothesis testing. We have described two different null hypotheses and

Table 7: Average running times in seconds for obtaining one randomization version of each data set for Test 1 (T1) and Test 2 (T2), as well as running times for obtaining one classification error for the four studied classifiers on each original data set (Or.) and on each randomized version of each data set (T1, T2). The running times are the average values over all the samples produced. Note that the classification procedures for small, medium and large data sets differ from each other.

shown how samples can be produced from the corresponding null models by simple permutation methods. Each test provides an empirical p-value for the classifier performance; each p-value depends on the original data (whether it contains the type of structure tested) and the classifier (whether it is able to use the structure). The two null hypotheses can be summarized as follows: (1) the data and the class labels are independent; and (2) the features are mutually independent given the class label.

Each test evaluates whether a certain structure (label–class dependency or dependency between features inside a class) is present in the data, and whether the classifier can use such structure for obtaining good results. If the original data really contains the structure being tested, then a significant classifier should use such information and thus obtain a low p-value. If the classifier is not significant then it will not notice the structure from the original data and thus, get a high p-value. On the other hand, if the original data does not contain any structure at all, then all p-values should be very high.

We have performed extensive experiments both on synthetic and real data. Experiments showed that the traditional permutation test (i.e., data and class labels are independent) is not useful in studying real data sets as it produces a small p-value even if there is only a weak class structure present. Compared to this, the new test proposed, that is, permuting the features inside a class, was able to evaluate the underlying reasons for the classifier performance on the real data sets. Surprisingly, however, in about half of the studied real data sets the class structure looks fairly simple; the dependency between the features is not used in classifying the data with the four tested classifiers. In such cases, there might be no reason to use the chosen classifier. That is, either the same or even better performance could be obtained by using some simpler methods, or the classification performance could be improved further by taking some useful unused feature dependency into account by changing the classification algorithm.

Interpreting the descriptive information provided by Test 2 needs care. If the classifier is significant with Test 2, then the data really contains a feature dependency that the classifier is exploiting. However, if the classifier is not significant with Test 2, that is, we obtain a high p-value, there are three different possibilities: (1) there are no dependencies between the features in the data; (2) there are some dependencies between the features in the data but they do not increase the class separation; or (3) there are useful dependencies between the features in the data that increase the class separation but the chosen classifier is not able to exploit them. In the third case, we would like to find such a classifier that could use the feature dependency to improve the classification performance. However, in general, when a high p-value is obtained with Test 2, we cannot know which of these applies to the data and to the chosen classifier. Thus the best we can do is to continue the search for a better classifier by assuming that any of them could be true. That is, we try more complex classifiers that could use the possible existing feature dependency, as well as simpler classifiers that could perform better if no feature dependency exists. Nevertheless, the answer provided by Test 2 is definite, that is, it tells whether the chosen classifier uses feature dependency to improve the classification performance.

Future work should explore the use of Test 2 for selecting the best discriminant features for classifiers, in similar fashion as Test 1 has been used for decision trees and other biological applications (Frank, 2000; Frank and Witten, 1998; Maglietta et al., 2007). Also, it would be useful to extend the setting to unsupervised learning, such as clustering. In addition, more study is needed for exploiting the descriptive information provided by Test 2. Specifically, how should we proceed to improve and study the classification performance when a high p-value is obtained with Test 2?

Abstract

We present a new sparse Gaussian Process (GP) model for regression. The key novel idea is to sparsify the *spectral representation* of the GP. This leads to a simple, practical algorithm for regression tasks. We compare the achievable trade-offs between predictive accuracy and computational requirements, and show that these are typically superior to existing state-of-the-art sparse approximations. We discuss both the weight space and function space representations, and note that the new construction implies priors over functions which are always stationary, and can approximate any covariance function in this class.

Keywords: Gaussian process, probabilistic regression, sparse approximation, power spectrum, computational efficiency

1. Introduction

One of the main practical limitations of Gaussian processes (GPs) for machine learning (Rasmussen and Williams, 2006) is that in a direct implementation the computational and memory requirements scale as $O(n^2)$ and $O(n^3)$, respectively. In practice this limits the applicability of exact GP implementations to data sets where the number of training samples n does not exceed a few thousand.

A number of computationally efficient approximations to GPs have been proposed, which reduce storage requirements to $O(nm)$ and the number of computations to $O(nm^2)$, where m is much smaller than n. One family of approximations, reviewed in Quiñonero-Candela and Rasmussen (2005), is based on assumptions of conditional independence given a reduced set of *m inducing*

*. Also at Max Planck Institute for Biological Cybernetics, Spemannstr. 38, 72076 Tübingen, Germany .

inputs. Examples of such models are those proposed in Seeger et al. (2003), Smola and Bartlett (2001), Tresp (2000), Williams and Seeger (2001) and Csató and Opper (2002), as well as the Fully Independent Training Conditional (FITC) model, introduced as Sparse Pseudo-input GP (SPGP) by Snelson and Ghahramani (2006). Walder et al. (2008) introduced the Sparse Multiscale GP (SMGP), a modification of FITC that allows each basis function to have its own set of length-scales.[1] This additional flexibility typically yields some performance improvement over FITC, but it also requires learning twice as many parameters. SMGP can alternatively be derived within the unifying framework of Quiñonero-Candela and Rasmussen (2005) if we allow the inducing inputs to lie in a transformed domain, as shown in Lázaro-Gredilla and Figueiras-Vidal (2010).

Another family of approximations is based on approximate matrix-vector-multiplications (MVMs), where m is for example a reduced number of conjugate gradient steps to solve a system of linear equations. Some of these methods have been briefly reviewed in Quiñonero-Candela et al. (2007). Local mixtures of GP have been used by Urtasun and Darrell (2008) for efficient modelling of human poses.

In this paper we introduce a stationary trigonometric Bayesian model for regression that retains the computational efficiency of the aforementioned approaches, while improving performance. The model consists of a linear combination of trigonometric functions where both weights and phases are integrated out. All hyperparameters of the model (frequencies and amplitudes) are learned jointly by maximizing the marginal likelihood. This model is a stationary sparse GP that can approximate any desired stationary full GP. Sparse trigonometric expansions have been proposed in several contexts, for example, Lázaro-Gredilla et al. (2007) and Rahimi and Recht (2008), as discussed further in Section 4.3.

FITC, SMGP, and the model introduced in this paper focus on predictive accuracy at low computational cost, rather than on faithfully converging towards the full GP as the number of basis functions grows. Performance-wise, FITC and the more recent SMGP can be regarded as the current state-of-the-art sparse GP approximations, so we will use them as benchmarks in the performance comparisons.

In Section 2 we give a brief review of GP regression. In Section 3 we introduce the trigonometric Bayesian model, and in Section 4 we present the Sparse Spectrum Gaussian Process (SSGP) algorithm. Section 5 contains a comparative performance evaluation on several data sets.

2. Gaussian Process Regression

Regression is often formulated as the task of predicting the scalar output y_* associated to the D-dimensional input $\mathbf{x}_*$, given a training data set $\mathcal{D} \equiv \{\mathbf{x}_j, y_j | j = 1, \dots n\}$ of n input-output pairs. A common approach is to assume that the outputs have been generated by an unknown latent function $f(\mathbf{x})$ and independently corrupted by additive Gaussian noise of constant variance σ_n^2:

$$y_j \;=\; f(\mathbf{x}_j) + \varepsilon_j, \qquad \varepsilon_j \;\sim\; \mathcal{N}(0,\, \sigma_n^2)\,.$$

The regression task boils down to making inference about $f(\mathbf{x})$. Gaussian process (GP) regression is a probabilistic, non-parametric Bayesian approach. A Gaussian process prior distribution on $f(\mathbf{x})$ allows us to encode assumptions about the smoothness (or other properties) of the latent function

1. Note that SMGP only extends FITC in the specific case of the anisotropic squared exponential covariance function, whereas FITC can be applied to any covariance function.

(Rasmussen and Williams, 2006). For any set of inputs $\{\mathbf{x}_i\}_{i=1}^n$ the corresponding vector of function evaluations $\mathbf{f} = [f(\mathbf{x}_1), \ldots, f(\mathbf{x}_n)]^\top$ has a joint Gaussian distribution:

$$p(\mathbf{f}|\{\mathbf{x}_i\}_{i=1}^n) \;=\; \mathcal{N}(\mathbf{f}|\mathbf{0}, \mathbf{K_{ff}}).$$

This paper follows the common practice of setting the mean of the process to zero.[2] The properties of the GP prior over functions are governed by the covariance function

$$\left[\mathbf{K_{ff}}\right]_{ij} \;=\; k(\mathbf{x}_i, \mathbf{x}_j) \;=\; \mathbb{E}[f(\mathbf{x}_i) f(\mathbf{x}_j)], \tag{1}$$

which determines how the similarity between a pair of function values varies as a function of the corresponding pair of inputs. A covariance function is *stationary* if it only depends on the difference between its inputs

$$k(\mathbf{x}_i, \mathbf{x}_j) \;=\; k(\mathbf{x}_i - \mathbf{x}_j) \;=\; k(\boldsymbol{\tau}).$$

The elegance of the GP framework is that the properties of the function are conveniently expressed directly in terms of the covariance function, rather than implicitly via basis functions.

To obtain the predictive distribution $p(y_*|\mathbf{x}_*, \mathcal{D})$ it is useful to express the model in matrix notation by stacking the targets y_j in vector $\mathbf{y} = [y_1, \ldots, y_n]^\top$ and writing the joint distribution of training and test targets:

$$\begin{bmatrix} \mathbf{y} \\ y_* \end{bmatrix} \;\sim\; \mathcal{N}\left(\mathbf{0}, \begin{bmatrix} \mathbf{K_{ff}} + \sigma_n^2 \mathbf{I}_n & \mathbf{k_{f*}} \\ \mathbf{k_{f*}}^\top & k_{**} + \sigma_n^2 \end{bmatrix}\right),$$

where $\mathbf{k_{f*}}$ is the vector of covariances between $f(\mathbf{x}_*)$ and the training latent function values, and k_{**} is the prior variance of $f(\mathbf{x}_*)$. $\mathbf{I}_n$ is the $n \times n$ identity. The predictive distribution is obtained by conditioning on the observed training outputs:

$$p(y_*|\mathbf{x}_*, \mathcal{D}) \;=\; \mathcal{N}(\mu_*, \sigma_*^2), \;\; \text{where} \;\; \begin{cases} \mu_* = \mathbf{k}_{*\mathbf{f}}(\mathbf{K_{ff}} + \sigma_n^2 \mathbf{I}_n)^{-1}\mathbf{y} \\ \sigma_*^2 = \sigma_n^2 + k_{**} - \mathbf{k}_{*\mathbf{f}}(\mathbf{K_{ff}} + \sigma_n^2 \mathbf{I}_n)^{-1}\mathbf{k_{f*}}. \end{cases} \tag{2}$$

The covariance function is parameterized by *hyperparameters*. Consider for example the stationary anisotropic squared exponential covariance function

$$k_{\text{ARD}}(\boldsymbol{\tau}) \;=\; \sigma_0^2 \exp(-\tfrac{1}{2}\boldsymbol{\tau}^\top \Lambda^{-1} \boldsymbol{\tau}), \quad \text{where} \quad \Lambda \;=\; \text{diag}([\ell_1^2, \ell_2^2, \ \ldots \ \ell_D^2]). \tag{3}$$

The hyperparameters are the prior variance σ_0^2 and the lengthscales $\{\ell_d\}$ that determine how rapidly the covariance decays with the distance between inputs. This covariance function is also known as the ARD (Automatic Relevance Determination) squared exponential, because it can effectively prune input dimensions by growing the corresponding lengthscales.

It is convenient to denote all hyperparameters including the noise variance by θ. These can be learned by maximizing the evidence, or log marginal likelihood:

$$\log p(\mathbf{y}|\theta) \;=\; -\frac{n}{2}\log(2\pi) - \frac{1}{2}|\mathbf{K_{ff}} + \sigma_n^2 \mathbf{I}_n| - \frac{1}{2}\mathbf{y}^\top \left(\mathbf{K_{ff}} + \sigma_n^2 \mathbf{I}_n\right)^{-1} \mathbf{y}. \tag{4}$$

Provided there exist analytic forms for the gradients of the covariance function with respect to the hyperparameters, the evidence can be maximized by using a gradient-based search. Unfortunately, computing the evidence and the gradients requires the inversion of the covariance matrix $\mathbf{K_{ff}} + \sigma_n^2 \mathbf{I}_n$ at a cost of $O(n^3)$ operations, which is prohibitive for large data sets.

2. The extension to GPs with general mean functions is straightforward.

3. Trigonometric Bayesian Regression

In this section we present a Bayesian linear regression model with trigonometric basis functions, and related it to a full GP in the next section. Consider the model

$$f(\mathbf{x}) \;=\; \sum_{r=1}^{m} a_r \cos(2\pi \mathbf{s}_r^\top \mathbf{x}) + b_r \sin(2\pi \mathbf{s}_r^\top \mathbf{x}) \,, \tag{5}$$

where each of the m pairs of basis functions is parametrized by a D-dimensional vector $\mathbf{s}_r$ of spectral frequencies. Note that each *pair* of basis functions share frequencies, but each have independent amplitude parameters, a_r and b_r. We treat the frequencies as deterministic parameters and the amplitudes in a Bayesian way. The priors are independent Gaussian

$$a_r \;\sim\; \mathcal{N}\big(0, \frac{\sigma_0^2}{m}\big) \,, \quad b_r \;\sim\; \mathcal{N}\big(0, \frac{\sigma_0^2}{m}\big) \,,$$

where the variances are scaled down linearly by the number of basis functions. Under the prior, the distribution over functions from Equation (5) is Gaussian with mean function zero and covariance function (from Equation (1))

$$k(\mathbf{x}_i, \mathbf{x}_j) \;=\; \frac{\sigma_0^2}{m} \phi(\mathbf{x}_i)^\top \phi(\mathbf{x}_j) \;=\; \frac{\sigma_0^2}{m} \sum_{r=1}^{m} \cos\left(2\pi \mathbf{s}_r^\top (\mathbf{x}_i - \mathbf{x}_j)\right) \,, \tag{6}$$

where we define the column vector of length $2m$ containing the evaluation of the m pairs of trigonometric functions at $\mathbf{x}$

$$\phi(\mathbf{x}) \;=\; \big[\cos(2\pi \mathbf{s}_1^\top \mathbf{x}) \;\sin(2\pi \mathbf{s}_1^\top \mathbf{x}) \;\ldots\; \cos(2\pi \mathbf{s}_m^\top \mathbf{x}) \quad \sin(2\pi \mathbf{s}_m^\top \mathbf{x})\big]^\top .$$

Sparse linear models generally induce priors over functions whose variance depends on the input. In contrast, the covariance function in Equation (6) is stationary, that is, the prior variance is independent of the input and equal to σ_0^2. This is due to the particular nature of the trigonometric basis functions and implies that the predictive variances cannot be "healed", as proposed in Rasmussen and Quiñonero-Candela (2005) for the case of the Relevance Vector Machine.

The predictions and marginal likelihood can be evaluated using Equations (2) and (4), although direct evaluation is computationally inefficient when $2m < n$. For the predictive distribution we use the more efficient

$$\mathbb{E}[y_*] \;=\; \phi(\mathbf{x}_*)^\top \mathbf{A}^{-1} \mathbf{\Phi}_\mathbf{f} \mathbf{y}, \quad \mathbb{V}[y_*] \;=\; \sigma_n^2 + \sigma_n^2 \phi(\mathbf{x}_*)^\top \mathbf{A}^{-1} \phi(\mathbf{x}_*), \tag{7}$$

where we have defined the $2m$ by n design matrix $\mathbf{\Phi}_\mathbf{f} = [\phi(\mathbf{x}_1), \ldots, \phi(\mathbf{x}_n)]$ and $\mathbf{A} = \mathbf{\Phi}_\mathbf{f} \mathbf{\Phi}_\mathbf{f}^\top + \frac{m\sigma_n^2}{\sigma_0^2} \mathbf{I}_{2m}$. Similarly, for the log marginal likelihood

$$\log p(\mathbf{y}|\theta) \;=\; -\big[\mathbf{y}^\top \mathbf{y} - \mathbf{y}^\top \mathbf{\Phi}_\mathbf{f}^\top \mathbf{A}^{-1} \mathbf{\Phi}_\mathbf{f} \mathbf{y}\big]/(2\sigma_n^2) - \frac{1}{2} \log |\mathbf{A}| + m \log \frac{m\sigma_n^2}{\sigma_0^2} - \frac{n}{2} \log 2\pi\sigma_n^2 \,. \tag{8}$$

A stable and efficient implementation uses Cholesky decompositions, Appendix A. Both the predictive distribution and the marginal likelihood can be computed in $O(nm^2)$. The predictive mean and variance at an additional test point can be computed in $O(m)$ and $O(m^2)$ respectively. The storage costs are also reduced, since we no longer store the full covariance matrix (of size $n \times n$), but only the design matrix (of size $n \times 2m$).

3.1 Periodicity

One might be tempted to assume that this model would only be useful for modeling periodic functions, since strictly speaking a linear combination of periodic signals is itself periodic. However, if the individual frequencies are not all multiples of a common base frequency, then the period of the resulting signal will be very long, typically exceeding the range of the inputs by orders of magnitude. Thus, the model based on trigonometric basis functions has practical use for modeling non-periodic functions. The same principle is used (interchanging input and frequency domains) in uneven sampling to space apart frequency replicas an avoid aliasing, see for instance Bretthorst (2000). As our experimental results suggest, the model provides satisfactory predictive variances.

3.2 Representation

An alternative and equivalent representation of the model in Equation (5), which only uses half the number of trigonometric basis functions is possible, by writing the linear combination of a sine and a cosine as a cosine with an amplitude and a phase. Although these two representations are equivalent, *inference* based on them differs. Whereas we have been able to integrate out the amplitudes to arrive at the GP in Equation (6), this would not be possible analytically using the more parsimonious representation.

Optimization instead of marginalization of the phases has two important consequences. Firstly, we lose the property of stationarity of the prior over functions. Secondly we may expect that the model becomes more prone to overfitting. When considering the contribution from a basis function (pair) with a specific frequency, the optimization based scheme could fit arbitrarily the phase, whereas the integration based inference is constrained to use a flat prior over phases. In Section 5.3 we empirically verify that the computation vs accuracy tradeoff typically favors the less compact representation.

4. The Sparse Spectrum Gaussian Process

In the previous section we presented an explicit basis function regression model, but we did not discuss how to select the frequencies defining the basis functions. In this section, we present a sparse GP approximation view of this model, which shows how it can be understood as a computationally efficient approximation to any GP with stationary covariance function. In the next section we present experimental results showing that dramatic improvements over other state-of-the-art sparse GP regression algorithms are possible.

We will now take a generic GP with stationary covariance function and sparsify its power spectral density to obtain a sparse GP that approximates the full GP. The power spectral density (or power spectrum) $S(\mathbf{s})$ of a stationary random process expresses how the power is distributed over the frequency domain. For a stationary GP, the power is equal to the prior variance $k(\mathbf{x},\mathbf{x}) = k(\mathbf{0}) = \sigma_0^2$. The frequency vector $\mathbf{s}$ has the same length D as the input vector $\mathbf{x}$. The d-th element of $\mathbf{s}$ can be interpreted as the frequency associated to the d-th input dimension. The Wiener-Khintchine theorem (see for example Carlson, 1986, p. 162) states that the power spectrum and the autocorrelation of the random process constitute a Fourier pair. In our case, given that $f(\cdot)$ is drawn from a stationary Gaussian process, the autocorrelation function is equal to the stationary covariance function, and we have:

$$k(\boldsymbol{\tau}) = \int_{\mathbb{R}^D} e^{2\pi i \mathbf{s}^\top \boldsymbol{\tau}} S(\mathbf{s}) d\mathbf{s}, \qquad S(\mathbf{s}) = \int_{\mathbb{R}^D} e^{-2\pi i \mathbf{s}^\top \boldsymbol{\tau}} k(\boldsymbol{\tau}) d\boldsymbol{\tau}. \tag{9}$$

We thus see that there are two equivalent representations for a stationary Gaussian process: the traditional one in terms of the covariance function in the (input) space domain, and a perhaps less usual one as the power spectrum in the frequency domain.

Bochner's theorem (Stein, 1999, p. 24) states that any stationary covariance function $k(\boldsymbol{\tau})$ can be represented as the Fourier transform of a positive finite measure. This means that the power spectrum in (9) is a positive finite measure, and in particular that it is *proportional* to a probability measure, $S(\mathbf{s}) \propto p_S(\mathbf{s})$. The proportionality constant can be directly obtained by evaluating the covariance function in (9) at $\boldsymbol{\tau} = \mathbf{0}$. We obtain the relation:

$$S(\mathbf{s}) \;=\; k(\mathbf{0})\, p_S(\mathbf{s}) \;=\; \sigma_0^2\, p_S(\mathbf{s}). \tag{10}$$

We can use the fact that $S(\mathbf{s})$ is proportional to a multivariate probability density in $\mathbf{s}$ to rewrite the covariance function in (9) as an expectation:

$$\begin{aligned} k(\mathbf{x}_i, \mathbf{x}_j) \;&=\; k(\boldsymbol{\tau}) = \int_{\mathbb{R}^D} e^{2\pi i \mathbf{s}^\top (\mathbf{x}_i - \mathbf{x}_j)} S(\mathbf{s})\, \mathrm{d}\mathbf{s} \;=\; \sigma_0^2 \int_{\mathbb{R}^D} e^{2\pi i \mathbf{s}^\top \mathbf{x}_i} \left(e^{2\pi i \mathbf{s}^\top \mathbf{x}_j}\right)^* p_S(\mathbf{s}) d\mathbf{s} \\ &=\; \sigma_0^2 \mathbb{E}_{p_S}\left[e^{2\pi i \mathbf{s}^\top \mathbf{x}_i} \left(e^{2\pi i \mathbf{s}^\top \mathbf{x}_j}\right)^* \right], \end{aligned} \tag{11}$$

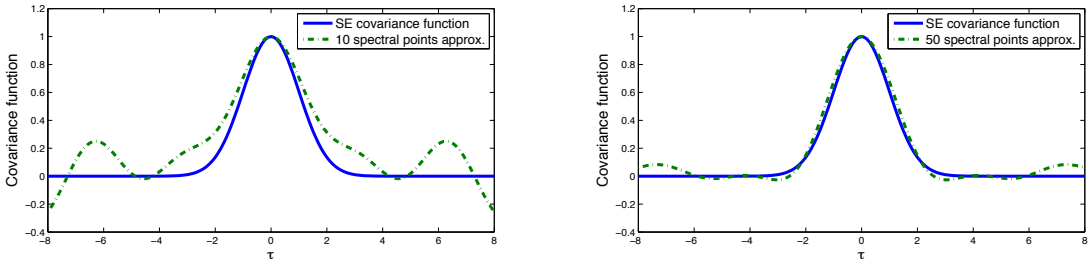
where $\mathbb{E}_{p_S}$ denotes expectation wrt. $p_S(\mathbf{s})$ and superscript asterisk[3] denotes complex conjugation. This last expression is an exact expansion of the covariance function as the expectation of a product of complex exponentials with respect to a particular distribution over their frequencies. This integral can be approximated by simple Monte Carlo by taking an average of a few samples corresponding to a finite set of frequencies, which we call *spectral points*.

Since the power spectrum is symmetric around zero, a valid Monte Carlo procedure is to sample frequencies always as a pair $\{\mathbf{s}_r, -\mathbf{s}_r\}$. This has the advantage of preserving the property of the exact expansion, Equation (11) that the imaginary terms cancel:

$$\begin{aligned} k(\mathbf{x}_i, \mathbf{x}_j) \;&\simeq\; \frac{\sigma_0^2}{2m} \sum_{r=1}^{m} \left[e^{2\pi i \mathbf{s}_r^\top \mathbf{x}_i} \left(e^{2\pi i \mathbf{s}_r^\top \mathbf{x}_j}\right)^* + \left(e^{2\pi i \mathbf{s}_r^\top \mathbf{x}_i}\right)^* e^{2\pi i \mathbf{s}_r^\top \mathbf{x}_j} \right] \\ &=\; \frac{\sigma_0^2}{m} \mathrm{Re}\Big[\sum_{r=1}^{m} e^{2\pi i \mathbf{s}_r^\top \mathbf{x}_i} \left(e^{2\pi i \mathbf{s}_r^\top \mathbf{x}_j}\right)^* \Big] \;=\; \frac{\sigma_0^2}{m} \sum_{r=1}^{m} \cos\left(2\pi \mathbf{s}_r^\top (\mathbf{x}_i - \mathbf{x}_j)\right), \end{aligned}$$

where $\mathbf{s}_r$ is drawn from $p_S(\mathbf{s})$ and $\mathrm{Re}[\cdot]$ denotes the real part of a complex number. Notice, that we have recovered exactly the expression for the covariance function induced by the trigonometric basis functions model, Equation (6). Further, we have given an interpretation of the frequencies as spectral Monte Carlo samples, approximating *any* stationary covariance function. This is a more general result than that of (MacKay, 2003, Ch. 45), which only applies to Gaussian covariances. The approximation is equivalent to replacing the original spectrum $S(\mathbf{s})$ by a set of Dirac deltas of amplitude σ_0^2 distributed according to $p_S(\mathbf{s})$. Thus, we "sparsify" the spectrum of the GP.

This convergence result can also be stated as follows: A stationary GP can be seen as a neural network with infinitely many hidden units and trigonometric activations if independent priors following Gaussian and $p_S(\mathbf{s})$ distributions are placed on the output and input weights, respectively. This is analogous to the result of Williams (1997) for the non-stationary multilayer perceptron covariance function.



(a) (b)

Figure 1: Squared exponential covariance function and its approximation with (a) 10 and (b) 50 random spectral points respectively.

4.1 Example: The Squared Exponential Covariance Function

The probability density associated to the squared exponential covariance function of Equation (3) can be obtained from the Fourier transform

$$p_S^{\mathrm{ARD}}(\mathbf{s}) = \frac{1}{k_{\mathrm{ARD}}(\mathbf{0})}\int_{\mathbb{R}^D} e^{-2\pi i \mathbf{s}^\top \boldsymbol{\tau}} k_{\mathrm{ARD}}(\boldsymbol{\tau})\, d\boldsymbol{\tau} = \sqrt{|2\pi\Lambda|}\exp(-2\pi^2 \mathbf{s}^\top \Lambda \mathbf{s}), \tag{12}$$

which also has the form of a multivariate Gaussian distribution. For illustration purposes, we compare the exact squared exponential covariance function with its spectral approximation in Figure 1, where the spectral points are sampled from Equation (12). As expected, the quality of the approximation improves with the number of samples.

4.2 The SSGP Algorithm

One of the main goals of sparse approximations is to reduce the computational burden while retaining as much predictive accuracy as possible. Sampling from the spectral density constitutes a way of building a sparse approximation. However, we may suspect that we can obtain much sparser models if the spectral frequencies are learned by optimizing the marginal likelihood, an idea which we pursue in the following.

The algorithm we propose uses conjugate gradients to optimize the marginal likelihood (8) with respect to the spectral points $\{\mathbf{s}_r\}$ and the hyperparameters σ_0^2, σ_n^2, and $\{\ell_1,\ \ell_2,\ \ldots\ \ell_D\}$. Optimizing with respect to the lengthscales in addition to the spectral points is effectively an overparametrization, but in our experience this redundancy proves helpful in avoiding undesired local minima. As is usual with this kind of optimization, the problem is non-convex and we cannot expect to find the global optimum. The goal of the optimization is to find a reasonable local optimum.

In detail, model selection for the SSGP algorithm consists in:

1. Initialize $\{\ell_d\}$, σ_0^2, and σ_n^2 to some sensible values. We use one half of the ranges of the input dimensions, the variance of $\{y_j\}$ and $\sigma_0^2/4$, respectively.

2. Initialize the $\{\mathbf{s}_r\}$ by sampling from (10).

3. The superscript asterisk denotes complex conjugate and the subscript asterisk indicates test quantity.

3. Jointly optimize the marginal likelihood wrt. spectral points and hyperparameters.

The computational cost of training the SSGP algorithm is $O(nm^2)$ per conjugate gradient step. At prediction time, the cost is $O(m)$ for the predictive mean and $O(m^2)$ for the predictive variance per test point. These computational costs are of the same order as those of the majority of the sparse GP approximations that have recently been proposed (see Quiñonero-Candela and Rasmussen, 2005, for a review).

Learning the spectral frequencies by optimization departs from the original motivation of approximating a full GP. The optimization stage poses a risk of overfitting, which we assess in the experimental section that follows. However, the additional flexibility can potentially improve performance since it allows learning a covariance function suitable to the problem at hand.

4.3 Related Algorithms

Finite decompositions in terms of harmonic basis functions, such as Fourier series, are a classic idea. In the context of kernel machines recent work include Lázaro-Gredilla et al. (2007) for GPs and Rahimi and Recht (2008) for Support Vector Machines (SVMs). As we show in the experimental section, the details of the implementation turn out to have a critical impact on the performance of the algorithms. The SVM based approach uses projections onto a random set of harmonic functions, whereas the approach used in this paper uses the evidence framework to carefully craft an optimized sparse harmonic representation. As is revealed in the experimental section, optimization of the frequencies, amplitudes and noise offers dramatic performance improvements for comparable sparseness.

5. Experiments

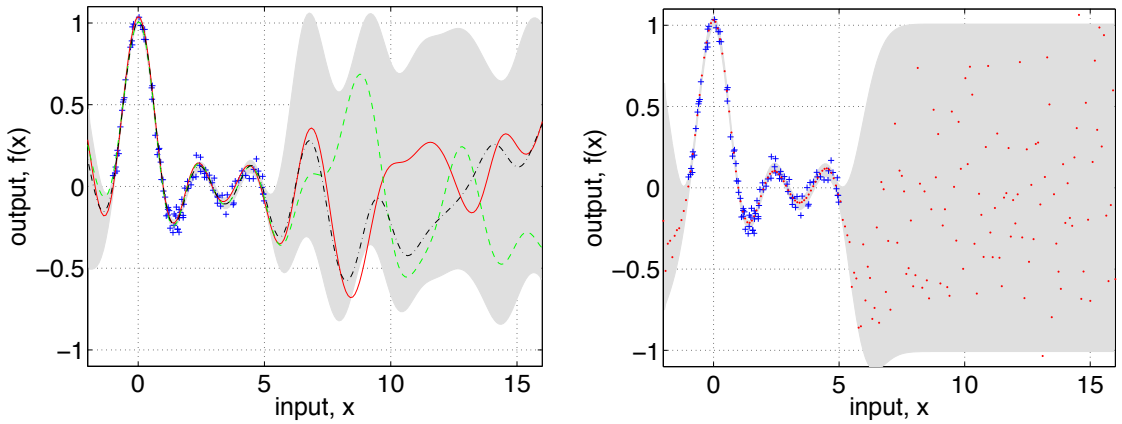
In this section we investigate properties of the SSGP algorithm, and evaluate the computational complexity vs. accuracy tradeoff. We first relate the FITC and SSGP approximations. We then present empirical comparisons on several data sets, using FITC and SMGP as benchmarks. Finally, we revisit the alternative more compact representation of SSGP using phases, and discuss a data set where SSGP performs badly.

Our implementation of SSGP in matlab is available from `http://www.tsc.uc3m.es/~miguel/simpletutorialssgp.php` together with a simple usage tutorial and the data sets from this section. An implementation of FITC is available from Snelson's web page at `http://www.gatsby.ucl.ac.uk/~snelson` .

5.1 Comparing Predictive Distributions for SSGP and FITC

Whereas SSGP relies on a sparse approximation to the spectrum, the FITC approximation is sparse in a spatial sense: A set of *pseudo-inputs* is used as an information bottleneck. The only evaluations of the covariance function allowed are those involving a function value at a pseudo-input. For a set of m pseudo-inputs the computational complexity of FITC is of the same order as that of SSGP with m spectral points.

The covariance function induced by FITC has a constant prior variance, but it is not stationary. The original covariance of the full GP is only approximated faithfully in the vicinity of the pseudo-inputs and the covariance between any two function values that are both far apart from any pseudo-



(a) (b)

Figure 2: Learning the sinc(x) function from 100 noisy observations (plusses) using 40 basis functions with shaded area showing 95% (noise free) posterior confidence area. In panel (a) the SSGP method with three functions drawn from the posterior is shown. In (b) the same data for the FITC method with samples (dots) drawn from the joint posterior.

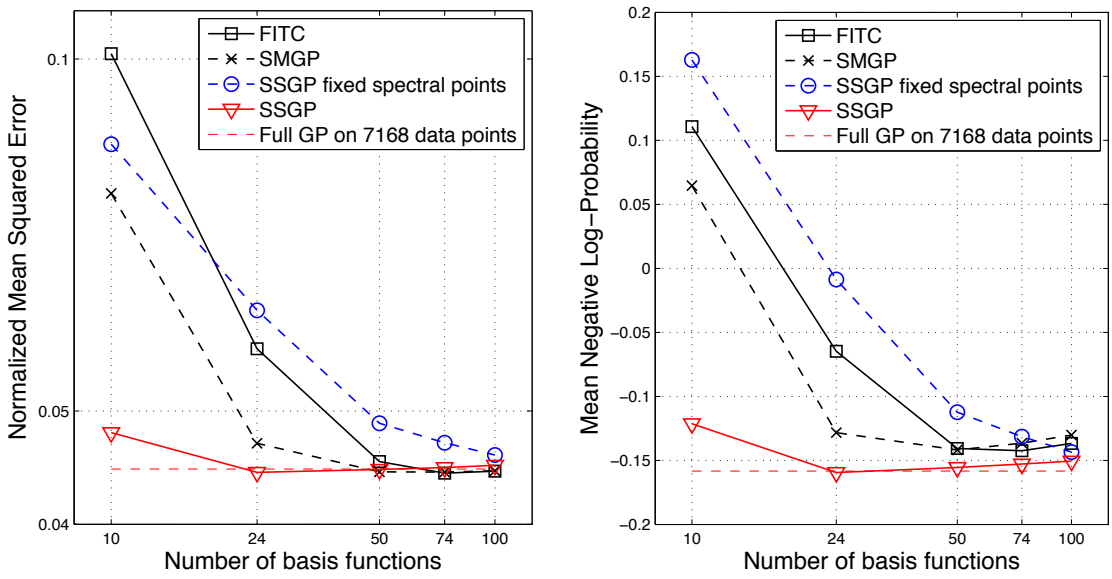
input decays to zero. As a result, functions sampled from the GP prior induced by FITC tend to white Gaussian noise away from the pseudo-inputs.



(a) (b)

Figure 4: *Pumadyn-32nm* data set. (a) NMSE and (b) MNLP as a function of the number of basis functions.

Figure 2 compares the predictive posterior distributions of SSGP and FITC for a simple synthetic data set. The training data is generated by evaluating the sinc function on 100 random inputs $x \in [-1,5]$ and adding white, zero-mean Gaussian noise of variance $\sigma_n^2 = 0.05^2$. SSGP is given 20 fixed spectral points sampled from the spectrum of a squared exponential covariance function, and FITC is given 40 fixed pseudo-inputs sampled uniformly from the range of the training inputs. The rest of the hyperparameters are optimized in both cases by maximizing the marginal likelihood. We plot the 95% confidence interval for both predictive distributions (mean $\pm$ two standard deviations), and draw three samples from the SSGP posterior and one sample from the FITC posterior.

Despite the different nature of the approximations, the figure shows that for an equal number of basis functions both predictive distributions are qualitatively very similar: the uncertainty grows away from the training data. In the following section, we verify empirically that the SSGP is a practical approximation for modelling non-periodic data.

5.2 Performance Evaluation

We will use two quantitative performance measures: the test Normalized Mean Square Error (NMSE) and the test Mean Negative Log Probability (MNLP) , defined as:

$$\text{NMSE} = \frac{\langle (y_{*j} - \mu_{*j})^2 \rangle}{\langle (y_{*j} - \bar{y})^2 \rangle} \quad \text{and} \quad \text{MNLP} = \frac{1}{2} \left\langle \left(\frac{y_{*j} - \mu_{*j}}{\sigma_{*j}} \right)^2 + \log \sigma_{*j}^2 + \log 2\pi \right\rangle , \tag{13}$$

where μ_{*j} and σ_{*j}^2 are, respectively, the predictive mean and variance for test sample j and y_{*j} is the actual test value for that sample. The average output value for training data is $\bar{y}$. We denote

the average over test cases by $\langle \cdot \rangle$. For all experiments the values reported are averages over ten repetitions.

For each data set we report the performance of five different methods: first, the SSGP algorithm as presented in Section 4.2; second, a version of SSGP where the spectral points are "fixed" to samples from the spectral density of a squared exponential covariance function whose lengthscales are learned (SSGP fixed spectral points);[4] third, the FITC approximation, learning the pseudo-inputs; fourth, SMGP, trained as described in Walder et al. (2008); and finally as a base line comparison we report the result of a full GP trained on the entire training set. We plot the performance as a function of the number of basis functions. For FITC this is equivalent to the number of pseudo-inputs, whereas for SSGP a spectral point corresponds to two basis functions. The number of basis functions is a good proxy for computational cost.

We consider four data sets of size moderate enough to be tractable by a full GP, but still large enough that there is a motivation for computationally efficient approximations.

The two first data sets are both artificially generated using a robot arm simulator and are highly non-linear and have very low noise. They were both used in Seeger et al. (2003) and Snelson and Ghahramani (2006), but note that their definition of the NMSE measure differs by a factor of 2 from our definition in (13). We follow precisely their preprocessing and use the original splits. The first data set is *Kin-40k* (8 dimensions, 10000 training and 30000 testing samples) and the results are displayed in Figure 3. For both error measures SSGP outperforms FITC and SMGP by a large margin, and even improves on the performance of the full GP. The SSGP with fixed spectral points is inferior, proving that a greater sparsity vs. accuracy tradeoff can be achieved by optimizing the spectral points.

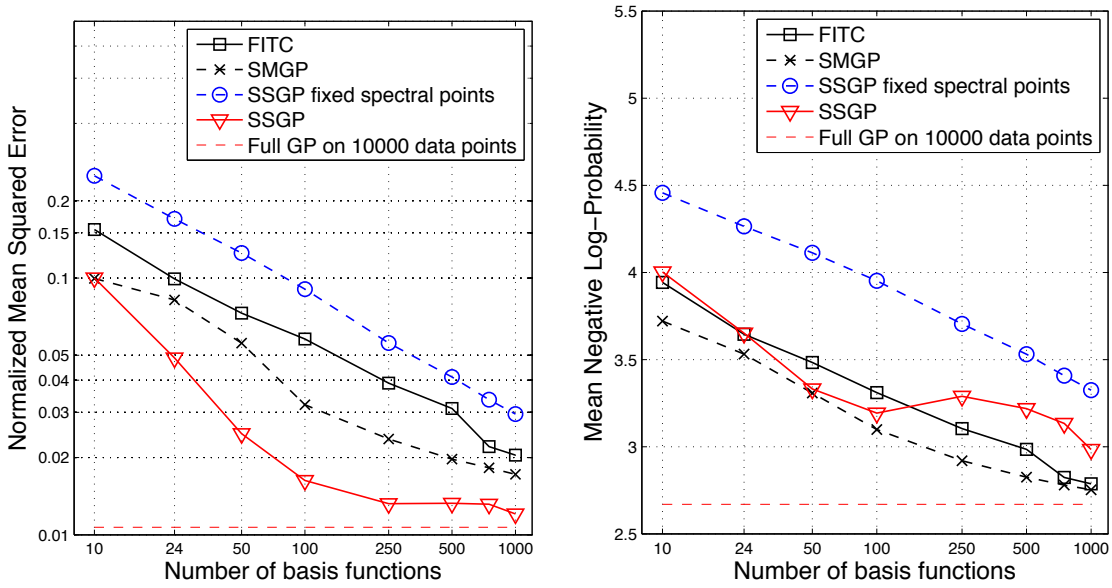
The *Pumadyn-32nm* problem (32 dimensions, 7168 training and 1024 testing samples) can be seen as a test of the ARD capabilities of a regression model, since only 4 out of the 32 input dimensions are relevant. Following Snelson and Ghahramani (2006), to avoid getting stuck at an undesirable bad local optimum, lengthscales are *initialized* from a full GP on a subset of 1024 training data points, for all compared methods. The results are shown in figure 4.

The conclusions are similar as for the *Kin-40k* data set. SSGP matches the full GP for a surprisingly small number of basis functions.

The *Pole Telecomm* and the *Elevators* data sets are taken from `http://www.liaad.up.pt/~ltorgo/Regression/DataSets.html` . In the *Pole Telecomm* data set we retain 26 dimensions, removing constants. We use the original split, 10000 data for training and 5000 for testing. Both the inputs and the outputs take a discrete set of values. In particular, the outputs take values between 0 and 100, in multiples of 10. We take into account the output quantization by lower bounding the value of σ_n^2 to the value of the quantization noise, $\text{bin}_{\text{spacing}}^2/12$. This lower bounding is applied to all the compared methods. The effect is to provide a better estimation for σ_n^2 and therefore, better MNLP measures, but we have observed that this modification has no noticeable effect on NMSE values. Resulting plots are in Figure 5.

SSGP is superior in terms of NMSE, getting very close to the full GP for more than 200 basis functions. In terms of MNLP, SSGP is between FITC and SMGP for small m, but slightly worse for more than 100 basis functions. This may be an indication that SSGP produces better predictive means than variances. We also see that SSGP with fixed spectral points is uniformly worse.

4. In practice the spectral points are sampled from the spectral density of a squared exponential covariance function, and scaled as the lengthscales adapt.



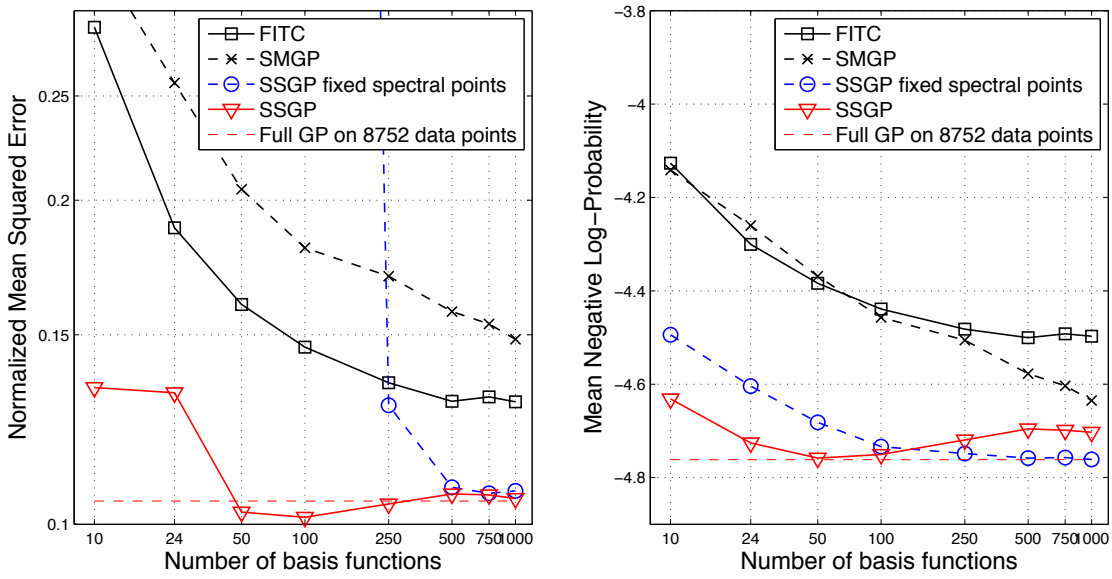
(a) (b)

Figure 5: *Pole Telecomm* data set. (a) NMSE and (b) MNLP as a function of the number of basis functions.

The fourth data set, *Elevators*, relates to controlling the elevators of an F16 aircraft. After removing some constant inputs the data is 17-dimensional. We use the original split with 8752 data for training and 7847 for testing. Results are displayed in Figure 6. SSGP consistently outperforms FITC and SMGP and gets very close to the full GP using a very low number of basis functions. The large NMSE average errors incurred by SSGP with fixed spectral points for small numbers of basis functions are due to outliers that are present in a small number (about 10 out of 7847) of the test inputs, in some of the 10 repeated runs. The predictive variances for these few points are also big, so their impact on the MNLP score is small. Such an effect has not been observed in any of the other data sets.

5.3 Explicit Phase Representation

In Section 3.2 we considered an alternative representation of the SSGP model using only half the basis functions, but explicitly representing the phases. Bayesian inference in this representation is intractable, but one can optimize the phases instead, at the possibly increased risk of overfitting. As an example, we evaluate the performance of the cosine only expansion with explicit phases on the *Pole-Telecomm* data set in Figure 7. Whereas the performance for the two variants are comparable for small numbers of basis functions, the cosine only representation becomes worse when the number of basis functions gets larger, confirming our suspicion that optimization of the phases increases the risk of overfitting.



(a) (b)

Figure 6: *Elevators* data set. (a) NMSE and (b) MNLP as a function of the number of basis functions.

5.4 The Pendulum Data Set

So far we have seen data sets where SSGP consistently outperforms FITC and SMGP, and often approaches the performance of a full GP for quite small numbers of basis functions. In this section we present a counter example, showing that SSGP may occasionally fail, although we suspect that this is the exception rather than the norm.

The small data set *Pendulum* (9 dimensions, 315 training and 315 testing samples) represents the problem of predicting the change in angular velocity of a simulated mechanical pendulum over a short time frame (50 ms) as a function of various parameters of the dynamical system. The target variable depends heavily on all inputs and the targets are almost noise free. Figure 8 shows the results of our experiments. Note that we use up to 800 basis functions for investigation, although for computational reasons it would make sense to use the full GP rather than an approximation with more than 315 basis functions. Although the SSGP NMSE performance is good, we see that especially for large number of basis functions, the MNLP performance is spectacularly bad. A closer inspection shows that the mean predictions are quite accurate, the predictive variances are excessively small. This SSGP model thus exhibits overfitting in the form of being overconfident. Note, that the SSGP with fixed spectral points seems to suffer much less from this effect, as would be expected. Interestingly, re-running the SSGP algorithm with different random initializations gives very different predictions, the predictive distributions from separate runs disagreeing wildly. One could perhaps diagnose the occurrence of the problem in this way. The bottom line is that any algorithm which optimizes the marginal likelihood over a large number of parameters, will risk

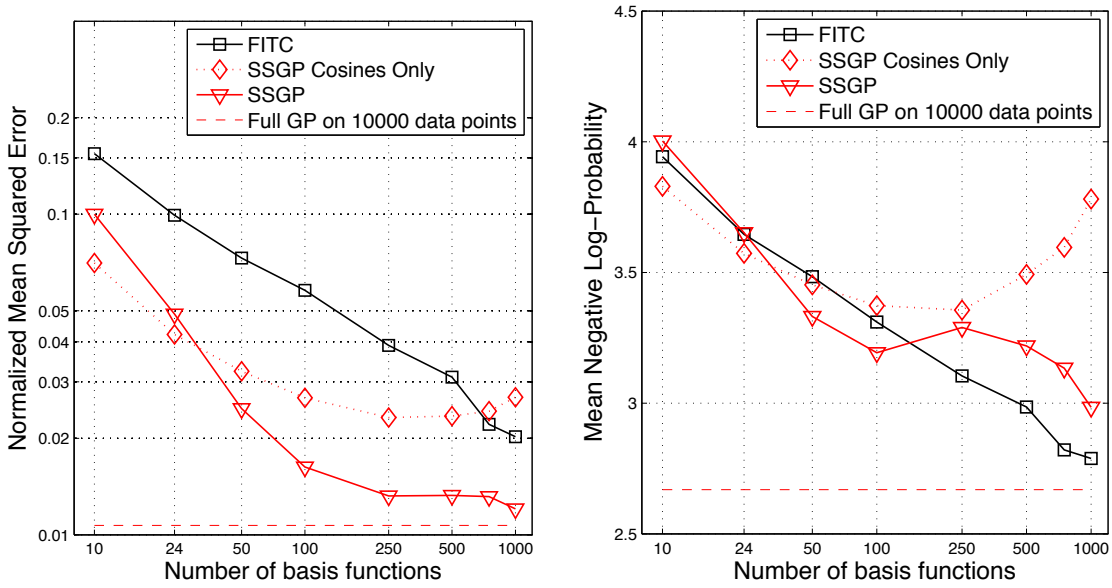


Figure 7: *Pole Telecomm* data set. (a) NMSE and (b) MNLP as a function of the number of basis functions, comparing SSGP with the version with cosines only and explicit phases.

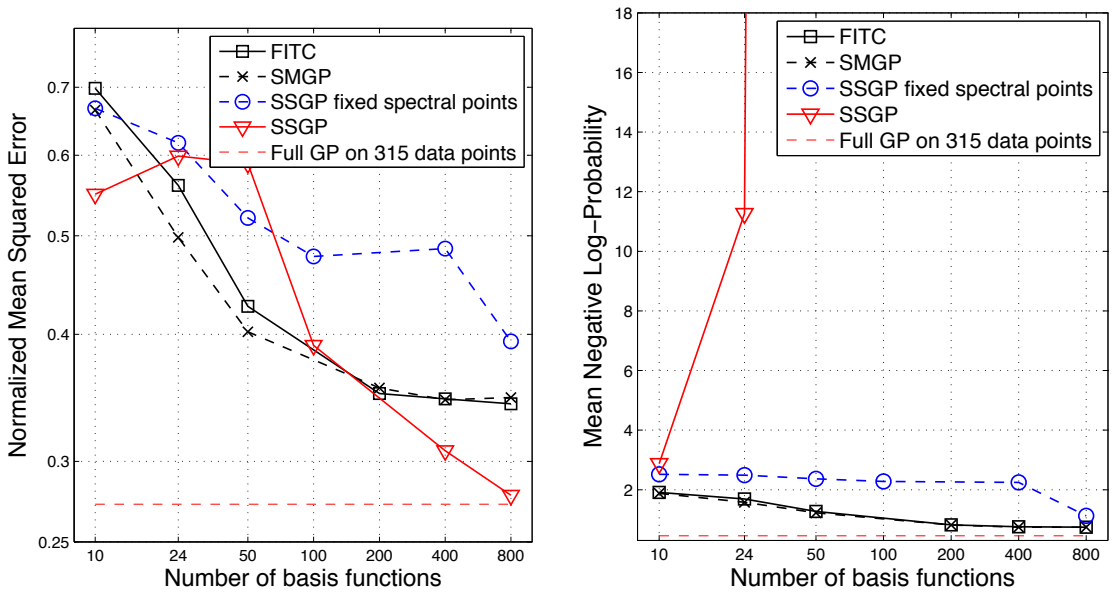
falling in the overfitting trap. We nevertheless think that the SSGP algorithm will often have very good performance, and will be a practically important algorithm, although one must use it with care.

6. Discussion

We have introduced the Sparse Spectrum Gaussian Process (SSGP) algorithm, a novel perspective on sparse GP approximations where rather than the usual sparsity approximation in the spatial domain, it is the spectrum of the covariance function that is subject to a sparse approximation by means of a discrete set of samples, the spectral points. We have provided a detailed comparison of the computational complexity vs. accuracy tradeoff of SSGP to that of the state of the art GP sparse approximation FITC and its extension SMGP. SSGP shows a dramatic improvement in four commonly used benchmark regression data sets, including the two data sets used for evaluation in the paper where FITC was originally proposed (Snelson and Ghahramani, 2006). However, we found a small data set where SSGP badly fails, with good predictive means but with overconfident predictive variances. This indicates that although SSGP is practically a very appealing algorithm, care must be taken to avoid the occasional risk of overfitting.

Other algorithms, such as the variational approach of Titsias (2009) which focus on approaching the full GP in the limit of large numbers of basis functions are to a large degree safeguarded from overfitting. However, algorithms derived from GPs whose focus is on achieving good predictive accuracy on a limited computational budget, such as FITC, SMGP and the currently proposed SSGP,



(a) (b)

Figure 8: *Pendulum* data set. (a) NMSE and (b) MNLP as a function of the number of basis functions.

typically achieve superior performance, see Figure 3 in Titsias (2009), with some risk of overfitting. Note, that these algorithms don't generally converge toward the full GP.

An equivalent view of SSGP is as a sparse Bayesian linear combination of pairs of trigonometric basis functions, a sine and a cosine for each spectral point. The weights are integrated out, and at the price of having two basis functions per frequency, the phases are effectively integrated out as well. We have shown that although a representation in terms of a single basis function per frequency and an explicit phase is possible, learning the phases poses an increased risk of overfitting. If the spectral points are sampled from the power spectrum of a stationary GP, then SSGP approximates its covariance function. However, much sparser solutions can be achieved by learning the spectral points, which effectively implies learning the covariance function. The SSGP model is to the best of our knowledge the only sparse GP approximation that induces a stationary covariance function.

SSGP has been presented here as a Gaussian process prior for regression with a tractable likelihood function from the assumption of Gaussian observation noise. Extending to other types of analytically intractable likelihood functions, such as sigmoid for classification or Laplace for robust regression is possible by using the same approximation techniques as for full GPs. An example is the use of Expectation Propagation in the derivation of generalized FITC (Naish-Guzman and Holden, 2008). Further modifications and extensions of SSGP are discussed in Lázaro-Gredilla (2010).

The main differences between SSGP and most previous approaches to sparse GP regression is the stationarity of the prior and the non-local nature of the basis functions. It will be interesting to

investigate more carefully in the future the exact conditions under which these spectacular sparsity vs. accuracy improvements can be expected.

Acknowledgments

Part of this work was developed while the first author was a visitor at the Computational and Biological Learning Lab, Department of Engineering, University of Cambridge.

Appendix A. Details of the Implementation

In practice, to improve numerical accuracy and speed, Equations (7) and (8) should be implemented using the Cholesky decomposition $\mathbf{R} = \text{chol}(\mathbf{A})$. Thus the predictive distribution is computed as

$$\mathbb{E}[y_*] \;=\; \phi(\mathbf{x}_*)^\top \mathbf{R}\backslash(\mathbf{R}^\top\backslash(\Phi_\mathbf{f}\mathbf{y})) \qquad \mathbb{V}[y_*] \;=\; \sigma_n^2 + \sigma_n^2||\mathbf{R}^\top\backslash\phi(\mathbf{x}_*)||^2,$$

and the log evidence as

$$\log p(\mathbf{y}|\theta) \;=\; -\frac{1}{2\sigma_n^2}\left[||\mathbf{y}||^2 - ||\mathbf{R}^\top\backslash(\Phi_\mathbf{f}\mathbf{y})||^2\right] - \frac{1}{2}\sum_i \log \mathbf{R}_{ii}^2 + m\log\frac{m\sigma_n^2}{\sigma_0^2} - \frac{n}{2}\log 2\pi\sigma_n^2\,,$$

where $\mathbf{R}_{ii}$ refers to the diagonal elements of $\mathbf{R}$.

Abstract

A computationally efficient approach to local learning with kernel methods is presented. The **Fa**st **L**ocal **K**ernel **S**upport **V**ector **M**achine (FaLK-SVM) trains a set of local SVMs on redundant neighbourhoods in the training set and an appropriate model for each query point is selected at testing time according to a proximity strategy. Supported by a recent result by Zakai and Ritov (2009) relating consistency and localizability, our approach achieves high classification accuracies by dividing the separation function in local optimisation problems that can be handled very efficiently from the computational viewpoint. The introduction of a fast local model selection further speeds-up the learning process. Learning and complexity bounds are derived for FaLK-SVM, and the empirical evaluation of the approach (with data sets up to 3 million points) showed that it is much faster and more accurate and scalable than state-of-the-art accurate and approximated SVM solvers at least for non high-dimensional data sets. More generally, we show that locality can be an important factor to sensibly speed-up learning approaches and kernel methods, differently from other recent techniques that tend to dismiss local information in order to improve scalability.

Keywords: locality, kernel methods, local learning algorithms, support vector machines, instance-based learning

1. Introduction

Efficiently processing large amount of data is one of the challenges of current research in kernel methods. Although most of the recently proposed techniques are based on different approaches, their common assumption is that scalability can be obtained by limiting or reducing the complexity of the decision function. In fact, very fast training algorithms have been developed for linear SVM (Keerthi and DeCoste, 2005; Collins et al., 2008; Chang et al., 2008; Bordes et al., 2009; Fan et al., 2008), and indeed they are effective when the linear separation is a good choice such as in high-dimensionality problems. Other approaches permit the non-linear feature space setting, but they limit the complexity by working with a reduced number of examples or a small set of support vectors (Lee and Mangasarian, 2001), using active and online example selection (Bordes et al., 2005; Bordes and Bottou, 2005) or bounding the number of basis functions (Keerthi et al., 2006; Joachims and Yu, 2009).

In the works referenced above, computational efficiency is sought bounding some aspects of the optimisation problem. The result is an *approximation* of the optimal separation and a *smoothing* of the decision function which is more influenced by the global distribution of the examples than by the local behaviour of the unknown target function in each specific sub-region. The emerging approach

is thus to trade locality for scalability permitting, with a potentially high level of under-fitting, to achieve a fast convergence to an approximated solution of the optimisation problem.

We show here that locality is not necessary related to computational inefficiency, but, instead, it can be the key factor to obtain very fast kernel methods without the need to smooth locally the global decision function. In our proposed approach, the model is formed by a set of accurate local models trained on fixed-cardinality sub-regions of the training set and the prediction module uses for each query point the more appropriate local model. In this setting, we are not approximating with some level of inaccuracy the original SVM optimisation problem, but we are separately considering different parts of the decision function with the potential advantage of better capturing the local separation. So, instead of locally under-fit the decision function by globally smoothing it like approximated SVM solvers do, we search for decision functions that are locally-calculated and they are very similar (or even better) in terms of accuracy to the global decision function in the proximity of each testing point. This approach is theoretically supported also by the recent result obtained by Zakai and Ritov (2009) that showed how, roughly speaking, "consistency implies local behaviour".

In this work we present **Fa**st **L**ocal **K**ernel **S**upport **V**ector **M**achine (FaLK-SVM), that pre-computes a set of local SVMs covering with adjustable redundancy the whole training set and uses for prediction a model which is the nearest (in terms of neighbourhood rank in feature space) to each testing point. FaLK-SVM is obtained introducing various strategies, detailed below, to speed-up the Local SVM approach (see Blanzieri and Melgani, 2006 and Section 3.3). Scalability is obtained approximating the Local SVM approach softening the assumption that the query point must be the central example of the neighbourhood on which the local SVM is trained; in this way we use the same local SVM model for more than one testing point and we can also pre-compute the local models during training. The locality of the approach is regulated by the neighbourhood size k and the method uses all the training points. Starting from the theory of local learning algorithms (Bottou and Vapnik, 1992; Vapnik and Bottou, 1993) we derive generalisation bounds for FaLK-SVM, and we analyse the computational complexity stating that, under reasonable assumptions, the training of our technique scales as $N \log N$ and the testing as $\log N$ where N is the training set size. We also introduce a procedure for local model selection in order to speed-up the selection of the parameters and better capturing local properties of the data. The empirical evaluation (with data sets with up to 3 million examples) shows that FaLK-SVM outperforms accurate and approximated SVM solvers both in term of generalisation accuracy and computational performances.

The effectiveness and efficiency of our approach is directly related to the role that locality plays in the learning problem. It is well known, for example, that for very high-dimensional problems such as text and document classification, the linear kernel performs better than non-linear kernels which are hard to tune and can be subject to the "curse of dimensionality" (Bengio et al., 2005). On the other hand, there are problems (Blackard and Dean, 1999; Uzilov et al., 2006) which inherently require non-linear approaches to be tackled. This is due to the combination of an intrinsic dimensionality which is low with respect to the training set size and of a decision function which is not simple to learn. In general, locality plays a more important role as the number of training examples increases because the ratio between training set cardinality and the dimensionality is more favourable and the local characteristics are more evident. Other signals for the need of a non-linear kernel are the detection of uneven distributions in the data sets (typical of real-world problems), the monotonic increasing of accuracy with respect to training size also for already large amount of data and the inclusion of a high fraction of training examples in the support vector set. A representative

of this class of problems is the Forest CoverType data set (Blackard and Dean, 1999) which is a large real data set (more than half a million examples) with bounded dimensionality (54 features) that needs as many examples as possible to increase accuracy. We already showed in a very preliminary study (Segata and Blanzieri, 2009c) that our approach on this data set is more accurate than SVM and much faster than both accurate and approximated SVM solvers.

The present contribution can be seen from multiple viewpoints. (i) FaLK-SVM modifies the Local SVM approach (Blanzieri and Melgani, 2006; Zhang et al., 2006) that showed excellent classification performances but had dramatic computational problems, leading to a scalable Local SVM classifier asymptotically much faster than SVM. (ii) The approach is also an enhancement of the local learning algorithms because the learning process is not delayed until the prediction phase (*lazy learning*) but the construction of the local models occurs during training (*eager learning*). (iii) From a practical viewpoint, FaLK-SVM is a novel kernel method which outperforms accurate and approximated SVM solvers for non high-dimensional data sets. (iv) For complex classification problems that require an high fraction of support vectors (SVs), we exploit locality to avoid the need of bounding the number of total SVs as existing approximated SVM solvers do for computational reasons. (v) More generally, our approach can also be seen as a framework for localising and make scalable any kernel method, classifier and regressor and in general every data analysis that can be applied on sub-regions of the entire data set. The proposed FaLK-SVM classifier and related tools are freely available with source code as part of the Fast Local Kernel Machine Library (Segata, 2009, FaLKM-lib).

In the next Section we analyse the work on local learning algorithms, Local SVM and fast large margin classifiers that are all related with our work. Section 3 formally introduces some machine learning tools that we need in order to introduce FaLK-SVM in Section 4 and analyse its learning bounds, complexity bounds, implementation, local model selection procedure and intuitive interpretation. Section 5 details the empirical evaluation with respect to accurate and approximated approaches.

2. Related Work

Locality is often a crucial component of machine learning systems, although we are not aware of approaches exploiting locality for improving the computational performances. We review in this section those areas that are more related with our approach: local learning algorithms, local support vector machines, approximated and scalable SVM solvers.

2.1 Local Learning Algorithms

Local learning algorithms (LLAs) are a class of learning approaches introduced by Bottou and Vapnik (1992). Instead of estimating a decision function which is optimal (with respect to some criteria) for all possible unseen testing examples, the idea underlying LLAs consists in estimating the optimal decision function for each single testing point. The value of the function is estimated in a small sub-region of the input space around the query point. For a local learning algorithm, the points in the proximity of the query point have an higher influence in the training of the local model. The approach is particularly effective for uneven distributed data sets, that is, data sets presenting regions in which the examples have different spatial resolutions. In fact, with LLAs, the characteristics of the learning process can be locally adjusted. A proper choice of the locality parameter can reduce the generalisation error with respect to a global classifier as formalised by the

Local Risk Minimization principle (Vapnik and Bottou, 1993; Vapnik, 2000). Notice that there are various ways of specifying the degree of locality for LLAs as discussed for instance by Atkeson et al. (1997). Examples of LLAs are the well-known k-Nearest Neighbours (kNN) classifier, the Radial Basis Function networks (Broomhead and Lowe, 1988), and the Local SVM classifier (Blanzieri and Melgani, 2006; Zhang et al., 2006) described in Section 2.2.

Despite their theoretical and practical appeal, LLAs seem not to have been studied in depth in the last few years. This is probably due to the fact that LLAs, as formulated by Bottou and Vapnik (1992), fall in the class of *lazy learning* (or *memory-based learning*) that have great overhead on the testing phase, as opposed to *eager learning* in which the function estimation is performed during training increasing the computational performances of the testing phase.

2.2 Local Support Vector Machines

The main idea of Local SVM, described in details in Section 3.3, is to build at prediction time an example-specific maximal marginal hyperplane based on the set of k-neighbours.

Local SVM is a LLA and was independently proposed by Blanzieri and Melgani (2006, 2008) and by Zhang et al. (2006) and applied respectively to remote sensing and visual recognition tasks. Other successful applications of the approach are detailed by Segata and Blanzieri (2009a) for general real data sets, by Blanzieri and Bryl (2007) for spam filtering and by Segata, Blanzieri, Delany, and Cunningham (2009b) for noise reduction. Similar approaches have been presented by Yang and Kecman (2008) and applied in the medical domain (Yang and Kecman, 2009) and for face recognition problems (Yang and Kecman, 2010).

However, Local SVM suffers from the high computational cost of the testing phase that comprises, for each example, (i) the selection of the k nearest neighbours and (ii) the computation of the maximal separating hyperplane on the k examples. An attempt to computationally improve the Local SVM approach of Zhang et al. (2006) has been proposed by Cheng et al. (2007) where the idea is to train multiple SVMs on clusters found by a variant of k-means, called MagKmeans, that introduces in the clustering criterion the requirement that the clusters cannot have unbalanced class cardinalities. However the method does not follow directly the idea of Local SVM, the main difference being that it can build only local linear models and the size of the clusters is not fixed (MagKmeans does not have constraints on the cardinalities and the balancing requirement can cause the detection of clusters with high cardinalities). The achieved computational performances are better than their formulation of Local SVM, but worse than global SVM.

2.3 Fast Large Margin Classifiers

The need for fast and scalable kernel-based classifiers led to the development of several methods in the last few years, although considerable attention seems to have been focused especially on linear SVM classifiers. Below, we initially consider the works applicable also to non-linear kernels, successively we review the works on the linear case.

One of the first large-scale maximal margin learning that can use non-linear kernel functions is represented by Core Vector Machines (Tsang et al., 2005, CVM); reformulating the SVM approach as a minimum enclosing ball problem, the authors proved that it is possible to obtain approximated optimal solution in competitive training times by using the core sets. Good results have been achieved using non-linear kernels although it has been pointed out that the choice of the stopping criteria is crucial for the trade-off between computational efficiency and generalisation accuracy.

Ball Vector Machines (Tsang et al., 2007, BVM) are a modification of CVM in which the minimality of the enclosing balls is not required, because the radius of the ball is fixed. The resulting classifier improves the computational performances. Another approach based on an online setting of the SVM optimisation problem has been proposed by Bordes et al. (2005, LASVM) and by Bordes and Bottou (2005) and it is an algorithm that converges to the SVM solution. It has been shown that competitive accuracies can be achieved also after a single pass over the training set. The approach can be seen as a SVM solver that includes a support vector removal step. In addition, several strategies for active training-points selection can further improve computational and generalisation performances. Formulating the optimisation problem in the primal, Keerthi et al. (2006, SpSVM) proposed a method that bounds the number of basis functions considered and thus the computational complexity. Increasing the cardinality of the basis function set allows the method to converge to the SVM solution. A greedy strategy guides the choice of the basis functions to be included in the working set. Collobert et al. (2006, USVM) showed that softening the convex setting of maximal margin classifiers using a non-convex loss function can bring computational advantage over the corresponding standard convex problem. The non-convex problem is solved using the *concave-convex procedure* (Yuille and Rangarajan, 2003). Recently, the Cutting-Plane Subspace Pursuit (Joachims and Yu, 2009, CPSP) based on cutting-plane training (Joachims et al., 2009) has been proposed; it permits to learn maximal-margin decision functions in the feature space using arbitrary basis vectors instead of the support vectors only. This can results in sparser solutions increasing the testing and training computational performances especially for high-dimensional data sets. Although not always considered a method for large-scale learning, LibSVM (Chang and Lin, 2001) demonstrated to be competitive with approximated approaches from the computational viewpoint. LibSVM is a SVM solver implementing a SMO-type decomposition method proposed by Fan et al. (2005) integrating it with caching and shrinking (Joachims, 1999).

Large margin classifiers can also achieve scalability using subsampling-based approaches that train the model on a relatively small subset of the whole training set. However, the accuracy of SVM with subsampling can decrease due to the loss of information contained in the discarded training points. The decreasing of accuracy with respect to SVM without subsampling is more dramatic when a complex decision function is needed. In these cases the accuracy problems can be mitigated or reduced by developing an ensemble of classifiers. Bootstrap aggregating (bagging) by Breiman (1996) is an effective strategy to perform accurate classification using an ensemble of classifiers trained on subsets of the training set (using uniform sampling with replacement) that can also overcome the accuracies of SVM. Bagging with SVM can thus be used for obtaining scalability as long as the advantage of training smaller SVM models on subsets of the training set (that can scale cubically) overcome the disadvantage of training multiple SVMs.

Recently a lot of work has been performed in order to develop very fast and scalable solvers applicable to *linear* SVM only. Keerthi and DeCoste (2005) modified the Finite Newton method of Mangasarian (2002) introducing robust conjugate gradient techniques and other heuristics. Joachims (2006) developed an alternative formulation of the SVM optimisation problem exploiting a different form of sparsity. Lin et al. (2007) used logistic regression with Trust Region Newton Methods. Variants of coordinate descent methods for linear SVM are developed by Chang et al. (2008) in the primal and by Hsieh et al. (2008) in the dual. A different gradient approach was developed by Smola et al. (2008). Other approaches are based on Stochastic Gradient Descent (SGD) like those developed by Shalev-Shwartz et al. (2007) and by Bordes et al. (2009) which work in the primal, whereas Collins et al. (2008) apply SGD in the dual. Although SGD methods can be theoretically

used for non-linear SVM the performances are analysed for the linear case only. LIBLINEAR (Fan et al., 2008) is a fast software package implementing some of the cited works. The common idea of all the proposed methods is that the advantage of having a method that uses a huge number of training points overcomes the disadvantage of approximating the decision function with a linear model. This is effective, as explicitly noticed in almost all the cited works, when the dimensionality is very large and thus the problem is very sparse. This is, for example, the typical situation of text document classification. However, when the needed decision function is highly non-linear and the intrinsic dimensionality of the space is relatively small, the linear SVM approach cannot compete with SVM using non-linear kernels in terms of generalisation accuracy. Apart from the generalisation ability also the computational performances can be compromised in these cases, because the algorithm cannot find a good decision function and so convergence problems can occur.

3. Preliminaries

In order to introduce our approach, we need to analyse the formulation of kNN, SVM, *k*NNSVM and cover trees.

Here and in the following of the paper, we consider a binary class classification with examples $(\mathbf{x}_i, y_i) \in \mathcal{H} \times \{-1,+1\}$ for $i = 1,\ldots,N$ and $\mathcal{X} = \{\mathbf{x}_i \,|\, i = 1,\ldots,N\}$, where $\mathcal{H}$ is an Hilbert space with inner product $\langle \cdot,\cdot \rangle$ and norm $\|\cdot\|$. Extensions to multi-class problems will be explicitly discussed.

3.1 The *k* Nearest Neighbour Algorithm

Given an example $\mathbf{x}' \in \mathcal{H}$, it is possible to order an entire set of points $\mathcal{X}$ with respect to $\mathbf{x}'$. This corresponds to define a function $r_{\mathbf{x}'} : \{1,\ldots,N\} \to \{1,\ldots,N\}$ that recursively reorders the indexes of the N points in $\mathcal{X}$:

$$\begin{cases} r_{\mathbf{x}'}(1) = \underset{i=1,\ldots,N}{\operatorname{argmin}} \|\mathbf{x}_i - \mathbf{x}'\| \\ r_{\mathbf{x}'}(j) = \underset{i=1,\ldots,N}{\operatorname{argmin}} \|\mathbf{x}_i - \mathbf{x}'\| \qquad i \neq r_{\mathbf{x}'}(1),\ldots,r_{\mathbf{x}'}(j-1) \quad \text{for} \quad j = 2,\ldots,N. \end{cases}$$

In this way, $\mathbf{x}_{r_{\mathbf{x}'}(j)}$ is the example in the j-th position in terms of distance from $\mathbf{x}'$, namely the j-th nearest neighbour, $\|\mathbf{x}_{r_{\mathbf{x}'}(j)} - \mathbf{x}'\|$ is its distance from $\mathbf{x}'$ and $y_{r_{\mathbf{x}'}(j)}$ is its class. In other terms:

$$j < k \Rightarrow \|\mathbf{x}_{r_{\mathbf{x}'}(j)} - \mathbf{x}'\| \leq \|\mathbf{x}_{r_{\mathbf{x}'}(k)} - \mathbf{x}'\|.$$

Given the above definition, the majority decision rule of kNN for binary classification problems is defined by

$$\text{kNN}(\mathbf{x}) = \text{sign}\left(\sum_{i=1}^{k} y_{r_{\mathbf{x}}(i)}\right).$$

For problems with more than two classes, the decision rule of kNN is the usual majority rule, namely the method selects the class with the highest number of representatives in the k-neighbourhood instead of taking the sign of the summation.

3.2 Support Vector Machines

SVMs (Cortes and Vapnik, 1995) are classifiers with sound foundations in statistical learning theory (Vapnik, 2000). The decision rule is

$$\mathrm{SVM}(\mathbf{x}) = \mathrm{sign}(\langle w, \Phi(\mathbf{x})\rangle_{\mathcal{F}} + b)$$

where $\Phi(\mathbf{x}) : \mathcal{H} \to \mathcal{F}$ is a mapping in a transformed Hilbert feature space, called $\mathcal{F}$, with inner product $\langle\cdot,\cdot\rangle_{\mathcal{F}}$. The parameters $w \in \mathcal{F}$ and $b \in \mathbb{R}$ are such that they minimise an upper bound on the expected risk while minimising the empirical risk. The minimisation of the complexity term is achieved by the minimisation of the quantity $\frac{1}{2}\cdot\|w\|^2$, which is equivalent to the maximisation of the margin between the classes. In the optimisation problem, the violation of the margin is prevented by the following set of constraints:

$$y_i\left(\langle w, \Phi(\mathbf{x}_i)\rangle_{\mathcal{F}} + b\right) \geq 1. \tag{1}$$

If a linear separation cannot be found in the input or feature space, the soft-margin variant of SVM permits the violation of the margin and the presence of misclassified training examples. This is possible introducing slack variables ξ_i (the empirical risk):

$$y_i\left(\langle w, \Phi(\mathbf{x}_i)\rangle_{\mathcal{F}} + b\right) \geq 1 - \xi_i \qquad \xi_i \geq 0, i = 1, \ldots, N. \tag{2}$$

For soft-margin SVM the optimisation problem with linear penalisation of ξ_i (L1-norm), becomes the minimisation of $\frac{1}{2}\cdot\|w\|^2 + C\sum_i \xi_i$ subject to (2). Reformulating such an optimisation problem with Lagrange multipliers α_i ($i = 1, \ldots, N$), and introducing a positive definite kernel (PD) function[1] $K(\cdot,\cdot)$ that substitutes the scalar product in the feature space $\langle\Phi(\mathbf{x}_i), \Phi(\mathbf{x})\rangle_{\mathcal{F}}$ the decision rule can be expressed as:

$$\mathrm{SVM}(\mathbf{x}) = \mathrm{sign}\left(\sum_{i=1}^{N} \alpha_i y_i K(\mathbf{x}_i, \mathbf{x}) + b\right).$$

Throughout this work, SVM denotes the soft-margin SVM.

The kernel trick avoids the explicit definition of the feature space $\mathcal{F}$ and of the mapping function Φ (Schölkopf and Smola, 2002). Popular kernels are the linear kernel, the radial basis function kernel, and the homogeneous and inhomogeneous polynomial kernels. Their definitions are:

$$\begin{aligned} K^{lin}(\mathbf{x},\mathbf{x}') &= \langle \mathbf{x}, \mathbf{x}'\rangle & K^{rbf}(\mathbf{x},\mathbf{x}') &= \exp\left(-\tfrac{\|\mathbf{x}-\mathbf{x}'\|^2}{\sigma}\right), \\ K^{hpol}(\mathbf{x},\mathbf{x}') &= \langle \mathbf{x}, \mathbf{x}'\rangle^d & K^{ipol}(\mathbf{x},\mathbf{x}') &= (\langle \mathbf{x}, \mathbf{x}'\rangle + 1)^d. \end{aligned}$$

The maximal separating hyperplane defined by SVM has been shown to have important generalisation properties and nice bounds on the VC dimension (Vapnik, 2000).

Multiple methods has been proposed in order to apply the maximal margin principle of SVM on multiple class problems. The more popular are the one-against-all method (Bottou et al., 1994) which builds a number of binary decision functions equal to the number of classes N_{cl}, the one-against-one method (Knerr et al., 1990; Kressel, 1999) which builds $N_{cl}\cdot(N_{cl}-1)/2$ binary decision functions using voting in the prediction phase, and the Directed Acyclic Graph SVM (Platt et al.,

1. For convention we refer to kernel functions with the capital letter K and to the number of nearest neighbours with the lower-case letter k.

2000, DAGSVM) which is a modification of the one-against-all method. Other general strategies for reducing the multi-class classification setting to a binary classification problem have been analysed and developed by Allwein et al. (2000). The study carried on by Hsu and Lin (2002) shows that, for SVM, the more effective strategies are the one-against-one and DAGSVM approaches.

3.3 Local SVM: The *k*NNSVM Classifier

We already introduced the idea of Local SVM in Section 2.2, here we detail *k*NNSVM which is the formulation of Local SVM proposed by Blanzieri and Melgani (2006, 2008). *k*NNSVM can be seen as a modification of the SVM approach in order to obtain a LLA able to locally adjust the capacity of the training systems.

In order to classify a given example $\mathbf{x}' \in \mathcal{H}$, we need first to retrieve its k-neighbourhood in the transformed feature space $\mathcal{F}$ and, then, to search for an optimal separating hyperplane only over this k-neighbourhood. In practice, this means that an SVM is built over the neighbourhood in $\mathcal{F}$ of each test example $\mathbf{x}'$. Accordingly, the constraints in (1) become:

$$y_{r_{\mathbf{x}'}(i)} \left(w \cdot \Phi(\mathbf{x}_{r_{\mathbf{x}'}(i)}) + b \right) \geq 1 - \xi_{r_{\mathbf{x}'}(i)}, \text{ with } i = 1, \ldots, k$$

where $r_{\mathbf{x}'} : \{1, \ldots, N\} \rightarrow \{1, \ldots, N\}$ is a function that reorders the indexes of the training examples defined as:

$$\begin{cases} r_{\mathbf{x}'}(1) = \underset{i=1,\ldots,N}{\operatorname{argmin}} \|\Phi(\mathbf{x}_i) - \Phi(\mathbf{x}')\|^2_{\mathcal{F}} \\ r_{\mathbf{x}'}(j) = \underset{i=1,\ldots,N}{\operatorname{argmin}} \|\Phi(\mathbf{x}_i) - \Phi(\mathbf{x}')\|^2_{\mathcal{F}} \qquad i \neq r_{\mathbf{x}'}(1), \ldots, r_{\mathbf{x}'}(j-1) \quad \text{for} \quad j = 2, \ldots, N. \end{cases} \tag{3}$$

In this way, $\mathbf{x}_{r_{\mathbf{x}'}(j)}$ is the example in the j-th position in terms of distance from $\mathbf{x}'$ and thus $j < k \Rightarrow \|\Phi(\mathbf{x}_{r_{\mathbf{x}'}(j)}) - \Phi(\mathbf{x}')\|_{\mathcal{F}} \leq \|\Phi(\mathbf{x}_{r_{\mathbf{x}'}(k)}) - \Phi(\mathbf{x}')\|_{\mathcal{F}}$ because of the monotonicity of the quadratic operator. The computation is expressed in terms of kernels as:

$$\begin{aligned} ||\Phi(\mathbf{x}) - \Phi(\mathbf{x}')||^2_{\mathcal{F}} &= \langle \Phi(\mathbf{x}), \Phi(\mathbf{x}) \rangle_{\mathcal{F}} + \langle \Phi(\mathbf{x}'), \Phi(\mathbf{x}') \rangle_{\mathcal{F}} - 2 \cdot \langle \Phi(\mathbf{x}), \Phi(\mathbf{x}') \rangle_{\mathcal{F}} = \\ &= K(\mathbf{x}, \mathbf{x}) + K(\mathbf{x}', \mathbf{x}') - 2 \cdot K(\mathbf{x}, \mathbf{x}'). \end{aligned}$$

If the kernel is the RBF kernel or any polynomial kernels with degree 1, the ordering function is equivalent to the one defined by the Euclidean metric. In general, for some non-linear kernels (other than the RBF kernel) the ordering function can be quite different to that produced using the Euclidean metric.

The decision rule associated with the method for an example $\mathbf{x}$ is:

$$k\text{NNSVM}(\mathbf{x}) = \text{sign} \left(\sum_{i=1}^{k} \alpha_{r_{\mathbf{x}}(i)} y_{r_{\mathbf{x}}(i)} K(\mathbf{x}_{r_{\mathbf{x}}(i)}, \mathbf{x}) + b \right).$$

For $k = N$, the *k*NNSVM method is the usual SVM whereas, for $k = 2$, the method implemented with the linear or Gaussian radial basis function kernel corresponds to the standard 1-NN classifier. Notice that in situations where the neighbourhood contains only one class the local SVM does not find any separation and so considers all the neighbourhood to belong to the predominant class similarly to the behaviour of the majority rule. Considering *k*NNSVM as a local SVM classifier

built in the feature space, the method has been shown to have a potentially favourable bound on the expectation of the probability of test error with respect to SVM (Blanzieri and Melgani, 2008).

The generalisation of *k*NNSVM for multi-class classification can occur locally, that is solving the local multi-class SVM problem, or globally, that is applying the binary *k*NNSVM classifier on multiple global binary problems. In Segata and Blanzieri (2009a) the adopted strategy for multi-class classification with *k*NNSVM is the one-against-one strategy applied on the local problems. The choice of the one-against-one approach gave good results in comparison with the same strategy on SVM, but no specific empirical studies have been performed yet to identify the most appropriate strategy for multi-class classification with Local SVM.

3.4 Cover Trees

A cover tree is a data structure introduced by Beygelzimer et al. (2006) for performing exact nearest-neighbour operations in a fast and efficient way. Cover trees can be applied in general metric spaces without any other assumption on their structure and thus also in Hilbert spaces calculating the distances by means of kernel functions using the kernel trick.

In more detail, a cover tree can be viewed as a sub-graph of a navigating net (Krauthgamer and Lee, 2004) and it is a levelled tree in which each level (indexed by a decreasing integer i) is a cover (i.e., is representative) for the level beneath it. Every node of a cover tree T is associated with a point of a data set S. Denoting with C_i the set of points associated with nodes in T at level i, with $b > 1$ a constant, and with $dist(\cdot,\cdot)$ the distance function defining the metric of the space, the invariants of a cover tree are:

Nesting $C_i \subset C_{i-1}$

Covering tree For every $\mathbf{p} \in C_{i-1}$ there exists a $\mathbf{q} \in C_i$ such that $dist(\mathbf{p},\mathbf{q}) < b^i$ and the node in level i associated with $\mathbf{q}$ is a parent of the node in level $i-1$ associated with $\mathbf{p}$.

Separation For all distinct $\mathbf{p},\mathbf{q} \in C_i$, $dist(\mathbf{p},\mathbf{q}) > b^i$.

Intuitively, the nesting invariant means that once a point appears in a level, it is present for every lower level. The covering tree invariant implies that every node has a parent in a higher level such that the distance between the respective points is less than b^i, while separation invariant assures that the distance between every pair of points associated to the nodes of a level i is higher than b^i. In addition, the root of the tree (called C_∞ and containing only one example) is a randomly chosen example.

Cover trees have state-of-the-art performance for exact nearest neighbour operations for general metrics in low-dimensional spaces both in terms of computational complexity and space requirements. As theoretically proved by Beygelzimer et al. (2006), the space required by the cover tree data-structure is linear in the data set size ($O(n)$), the computational time of single point insertions, deletions and exact nearest neighbour queries is logarithmic ($O(\log n)$) while the cover tree can be built in $O(n \log n)$.

4. FaLK-SVM: A Fast and Scalable Local Kernel Machine

In this section we introduce our novel technique. Initially we detail the way to pre-compute the local models during training (Section 4.1) and the strategies to reduce the number of local models

(Section 4.2). We then describe the prediction mechanism in Section 4.2.2 and our approach for fast local model selection in Section 4.3. Successively, we derive learning bounds for the approach in Section 4.4 before discussing the computational complexity in Section 4.5 and some details about the implementation (Section 4.6).

4.1 Pre-computing the Local Models during Training Phase

For the local approach we are proposing here, we need to generalise the decision rule of *k*NNSVM to the case in which the local model is trained on the *k*-neighbourhood of a point distinct, in the general case, from the query point. A modified decision function for a query point $\mathbf{q} \in \mathcal{H}$ and another (possibly different) point $\mathbf{t} \in \mathcal{H}$ is:

$$k\text{NNSVM}_{\mathbf{t}}(\mathbf{q}) = \text{sign}\left(\sum_{i=1}^{k} \alpha_{r_{\mathbf{t}}(i)} y_{r_{\mathbf{t}}(i)} K(\mathbf{x}_{r_{\mathbf{t}}(i)}, \mathbf{q}) + b\right) \tag{4}$$

where $r_{\mathbf{t}}(i)$ is the *k*NNSVM ordering function (see above Section 3.3) and $\alpha_{r_{\mathbf{t}}(i)}$ and b come from the training of an SVM on the *k*-neighbourhood of $\mathbf{t}$ in the feature space. In the following we will refer to $k\text{NNSVM}_{\mathbf{t}}(\mathbf{q})$ as being centred on $\mathbf{t}$, to $\mathbf{t}$ as the centre of the model, and, if $\mathbf{t} \in \mathcal{X}$, to $V_{\mathbf{t}}$ as the Voronoi cell induced by $\mathbf{t}$ in $\mathcal{X}$, formally:

$$V_{\mathbf{t}} = \{\mathbf{p} \in \mathcal{H} \text{ s.t. } \|\mathbf{p}-\mathbf{t}\| \leq \|\mathbf{p}-\mathbf{x}\|, \forall \mathbf{x} \in \mathcal{X} \text{ with } t \neq \mathbf{x}\}.$$

The original decision function of *k*NNSVM corresponds to the case in which $\mathbf{t} = \mathbf{q}$, and thus $k\text{NNSVM}_q(\mathbf{q}) = k\text{NNSVM}(\mathbf{q})$.

*k*NNSVM requires that the training of an SVM on the *k*-neighbourhood of the query point must be performed in the prediction step. This approach is computationally feasible only for problems with few points to test which is a condition that rarely holds in real-world classification problems. In general, we need to speed-up the prediction phase. The first modification of *k*NNSVM consists in predicting the label of a test point $\mathbf{q}$ using the local SVM model built on the *k*-neighbourhood of its nearest neighbour in $\mathcal{X}$. Formally, this can be written as:

$$k\text{NNSVM}_{\mathbf{t}}(\mathbf{q}) \text{ with } \mathbf{t} = \mathbf{x}_{r_{\mathbf{q}}(1)}. \tag{5}$$

Notice that in situations where the *k*-neighbourhood contains only one class the local model does not find any separation and so it can adopt the majority rule for improving the computational performances.

With this formulation the local learning can switch from the *lazy learning* (Aha, 1997) setting of the original formulation of *k*NNSVM to the *eager learning* setting with clear advantages in terms of prediction step complexity. This is possible computing a local SVM model for each $\mathbf{x} \in \mathcal{X}$ during the training phase obtaining the sets $\{(\mathbf{t}, k\text{NNSVM}_{\mathbf{t}}) \mid \mathbf{t} \in \mathcal{X}\}$ and applying the precomputed $k\text{NNSVM}_{\mathbf{t}}$ model such that $\mathbf{t} = \mathbf{x}_{r_{\mathbf{q}}(1)}$ for each query point $\mathbf{q}$ during the testing phase.

This approximation slightly modifies the approach of *k*NNSVM as a local learning algorithm. Instead of estimating the decision function for a *given* test example $\mathbf{q}$ and thus for a specific point in the input metric space, we estimate a decision function for *each* Voronoi cell $V_{\mathbf{x}}$ induced by the training set in the input metric space. In this way, the construction of the models in the training phase requires the estimation of N local decision functions. The prediction of a test point $\mathbf{q}$ is done using the model built for the Voronoi region in which $\mathbf{q}$ lies ($V_{\mathbf{h}}$ with $\mathbf{h} = \mathbf{x}_{r_{\mathbf{q}}(1)}$) that can be retrieved by searching for the nearest neighbour of $\mathbf{q}$ in $\mathcal{X}$.

4.2 Reducing the Number of Local Models that Need to Be Trained

The pre-computation of the local models during the training phase introduced above, increases the computational efficiency of the prediction step. However, a considerable overhead is added to the training phase. In fact, the training of an SVM for each training point can be slower than the training of a unique global SVM (especially for non small k values), so we introduce another modification of the method which aims to dramatically reduce the number of SVMs that need to be pre-computed. The idea is that we can relax the constraint that a query point $\mathbf{x}'$ is always evaluated using the model trained around its nearest training point. The decision function of this approach is

$$\mathsf{FastLSVM}(\mathbf{x}) = k\text{NNSVM}_{f(\mathbf{x})}(\mathbf{x}) \tag{6}$$

where $f : \mathcal{H} \mapsto \mathcal{C} \subseteq \mathcal{X}$ is a function mapping each unseen example $\mathbf{x}$ to a unique training example $f(\mathbf{x})$ which is, accordingly to Equation 4, the centre of the local model that is used to evaluate $\mathbf{x}$. The set $\mathcal{C}$ is the image of $f(\cdot)$, so $\mathcal{C} = f(\mathcal{H})$.

Notice that if $f(\cdot) = \mathbf{x}_{r_\cdot(1)}$, we have that $\mathcal{C} = \mathcal{X}$ and that $\mathsf{FastLSVM}(\mathbf{x})$ is equivalent to the kNNSVM formulation of Equation 5, and this can happen if we use *all* the examples in the training set as centres for local SVM models. In the general case, however, we select only a proper subset $\mathcal{C} \subset \mathcal{X}$ of points to be used as centres of kNNSVM models. In this case, if $\mathbf{x}_{r_\mathbf{x}(1)} \in \mathcal{C}$ then $f(\mathbf{x})$ can be defined as $f(\mathbf{x}) = \mathbf{x}_{r_\mathbf{x}(1)}$, but if $\mathbf{x}_{r_\mathbf{x}(1)} \notin \mathcal{C}$ then $f(x)$ must be defined in a way such that the principle of locality is preserved and the retrieval of the model is fast at prediction time.

Two aspects need to be addressed now: the strategy to select the subset $\mathcal{C}$ of $\mathcal{X}$, and the formulation of the function f associating each query example with an example in $\mathcal{C}$.

4.2.1 SELECTING THE CENTRES OF THE LOCAL MODELS

The approach we developed for selecting the set $\mathcal{C}$ of the centres of the local models is based on the idea that each training point must be in the k'-neighbourhood of at least one centre with k' being a fixed parameter and $k' \leq k$. From a slightly different viewpoint, we need to cover the entire training set with a set of hyper-spheres whose centres will be the examples in $\mathcal{C}$ and each hyper-sphere contains exactly k' points. We can formalise this idea with the concept of k'-neighbourhood covering set:

Definition 1 *Given $k' \in \mathbb{N}$, a k'-neighbourhood covering set of centres $\mathcal{C} \subseteq \mathcal{X}$ is a subset of the training set such that the following holds:*

$$\bigcup_{\mathbf{c} \in \mathcal{C}} \left\{ \mathbf{x}_{r_\mathbf{c}(i)} \mid i = 1, \ldots, k' \right\} = \mathcal{X}.$$

Definition 1 means that the union of the sets of the k'-nearest neighbours of $\mathcal{C}$ corresponds to the whole training set. Theoretically, for a fixed k', the minimisation of the number of local SVMs that we need to train can be obtained computing the SVMs centred on the points contained in the *minimal* k'-neighbourhood covering set of centres.

Definition 2 *The* Minimal k'-neighbourhood covering set of centres *is a k'-neighbourhood covering set $\mathcal{C} \subseteq \mathcal{X}$ which have the minimal cardinality.*

This problem is related to the *Set Cover Problem* (SC) (Garey and Johnson, 1979; Kearns and Vazirani, 1994; Marchand and Shawe-Taylor, 2003) and to the *Minimum Sphere Set Covering Problem* (MSSC) (Chen, 2005). However, in the SC and MSSC problems one specifies the radius of the spheres rather than their cardinality in terms of points they contain and it is not required that the centres of the hyperspheres correspond to points in the set. It is easy to show that MSSC is NP-hard but some efficient approximated results are available based on greedy approaches (Chvatal, 1979; Wang et al., 2006), integer and linear programming (Wei and Li, 2008).

In our case, however, we do not need the minimality of the constraints of the k'-neighbourhood covering set of centres to be strictly satisfied, because training some more local SVMs is acceptable instead of solving an NP-hard problem.

The heuristic procedure we developed can be seen as a modification of the greedy approach for the MSSC problem (Chvatal, 1979; Wang et al., 2006). The first k'-neighbourhood is selected randomly choosing its centre in $\mathcal{X}$, the following k'-neighbourhoods are retrieved selecting the centres that are still not members of other k'-neighbourhoods and are as far as possible from the already selected centres. The selection of the farthest example, still not included in the k'-neighbourhoods, as the centre of the next k'-neighbourhood, is the counterpart of the selection of the set of points having the minimum overlapping with the already covered set of points used by the greedy approach to the MSSC and SC problems.

For detailing the greedy approach we adopt, we need the concepts of minimum and maximum distance between the elements of a set of points A defined respectively as:

$$d(A) = \min \|\mathbf{x} - \mathbf{x}'\| \text{ with } \mathbf{x}, \mathbf{x}' \in A \text{ and } \mathbf{x} \neq \mathbf{x}'$$

and

$$D(A) = \max \|\mathbf{x} - \mathbf{x}'\| \text{ with } \mathbf{x}, \mathbf{x}' \in A.$$

In particular, the minimum distance between points in $\mathcal{X}$ is $m = d(\mathcal{X})$ and the maximum is $M = D(\mathcal{X})$. Our intention is to identify a system of subsets $S_i \subseteq \mathcal{X}$ with decreasing minimum distances $d(S_i)$; we can in this way define an ordering on the sets $\ldots \subset S_{i+1} \subset S_i \subset S_{i-1} \subset \ldots$ such that $\ldots > d(S_{i+1}) > d(S_i) > d(S_{i-1}) > \ldots$. With this strategy we can choose the centres of the local models first in the set S_{i+1}, then in the set S_i and so on, thus selecting first the centres that are assured to be distant at least $d(S_{i+1})$, then at least $d(S_i) < d(S_{i+1})$ and so on. More in detail, we require that in the ith set $S_i \subseteq \mathcal{X}$ the two nearest points are farther than b^i with $b > 1$, that is, they are subject to the constraint $d(S_i) > b^i$ with $b > 1$. The bound on the minimum distance $d(S_i)$ thus varies as powers of b depending on the set S_i.

Let us define precisely the system of sets $\{S_i\}$. The maximum i index of S_i is named top and the minimum is named bot, and they are univocally defined as those indexes satisfying $b^{top-1} \leq M < b^{top}$ and $b^{bot} < m \leq b^{bot+1}$. The S_i are recursively defined as:

$$\begin{cases} S_{top} &= \{\text{choose}(\mathcal{X})\} \\ S_i &= S_{i+1} \cup \underset{S \in \mathcal{X} \setminus S_{i+1}}{\text{argmax}} (|S| \text{ s.t. } d(S_{i+1} \cup S) > b^i) \quad \text{for } i = top-1, \ldots, bot \end{cases}, \tag{7}$$

where choose(A) is a function that selects only one element of the non-empty set A. An example of choose() for our case can be the following definition that selects the example with the minimum index:

$$\text{choose}(A) = \mathbf{x}_i \text{ with } i = min(z \in \mathbb{N} | \mathbf{x}_z \in A).$$

Notice that, since S_i contains S_{i+1} we have that

$$S_{top} = \{\text{choose}(\mathcal{X})\} \subseteq S_{top-1} \subseteq \ldots \subseteq S_{bot+1} \subseteq S_{bot} = \mathcal{X} \tag{8}$$

and, forcing for definition that $d(A) = \infty$ if $|A| = 1$,

$$d(S_{top}) = \infty > d(S_{top-1}) = M > d(S_{top-2}) > \ldots > d(S_{bot+1}) > d(S_{bot}) = m.$$

We can now formalise the selection of the centres from $\mathcal{X}$ using the S_i sets. The first centre $\mathbf{c}_1$ is simply the (only) example in S_{top}. The next centre $\mathbf{c}_2$ is chosen among the non-empty S_l sets obtained removing from S_i the first centre $\mathbf{c}_1$ and the points in its k'-neighbourhood; in particular $\mathbf{c}_2$ is chosen from the non-empty S_l with highest l. The general case for the $\mathbf{c}_j$ centre is similar, with the only difference being that we remove from the S_i sets all the centres $\mathbf{c}_t$ with $t < j$ and their k'-neighbourhood. More formally:

$$\begin{cases} \mathbf{c}_1 &= \text{choose}(S_{top}) \\ \mathbf{c}_j &= \text{choose}(S_l) \text{ with } l = \max(m \in \mathbb{N} | S_m \setminus \mathcal{X}_{\mathbf{c}_{j-1}} \neq \emptyset) \end{cases}, \tag{9}$$

where

$$\mathcal{X}_{\mathbf{c}_{j-1}} = \bigcup_{l=1}^{j} \left\{ \mathbf{x}_{r_{\mathbf{c}_l}(h)} \, | h = 1, \ldots, k' \right\}.$$

is the union of all the k'-neighbourhoods of the centres already included in $\mathcal{C}$.

We can briefly show that the $\mathcal{C}$ set found with Equation 9 is a k'-neighbourhood covering set of centres. In fact, the iterative procedure for selecting the centres in $\mathcal{C}$ terminates when the choose() function cannot select a point from S_l because all S_j with $j = bot, \ldots, top$ are empty. Since for the set S_{bot} we always have that $S_{bot} = \mathcal{X}$, this happens only when $\mathcal{X}_{\mathbf{c}_{i-1}} = \mathcal{X}$. Noticing that $\mathcal{X}_{\mathbf{c}_i}$ in this situation is equivalent to the constraint of Definition 1, we can conclude that $\mathcal{C}$ is a k'-neighbourhood covering set of centres.

Computationally, the selection of the centres from the S_j sets with Equation 9 can be performed efficiently once the S_j are identified. More problematic is the construction of the nested set of S_j sets. We can however notice that the S_j sets share some characteristics with the levels of cover trees. First, from Equation 7 we can easily see that for each S_j set with $j < top$ all the points in it are at least distant as b^j because $d(S_j) > b^j$; this is equivalent to the separation invariant of cover trees reported in Section 3.4. Second, always from Equation 7 we can conclude that each S_j is contained in every S_t set with $t < j$ as also explicated in Equation 8; this is equivalent to the nesting invariant of cover trees. The only constraint of our strategy to identify the S_j sets that is not respected by cover trees is the maximality of the set added to each S_j set to obtain S_{j+1}. However, the procedure to insert a new point in a cover tree is based on adding it to the highest possible level, and this is an efficient approximation of the maximality constraint we have in Equation 7. Taking all these facts into consideration, we chose to use the levels of cover tree as the S_j sets from which we select the centres as reported in Equation 9.

Consequently with the goal of reducing the number of local models, this approach no longer requires that a local SVM is trained for each training example, but we need to train only $|\mathcal{C}|$ SVMs centred on each $c \in \mathcal{C}$ obtaining the following models:

$$k\text{NNSVM}_{\mathbf{c}}(\mathbf{x}), \quad \forall \mathbf{c} \in \mathcal{C}.$$

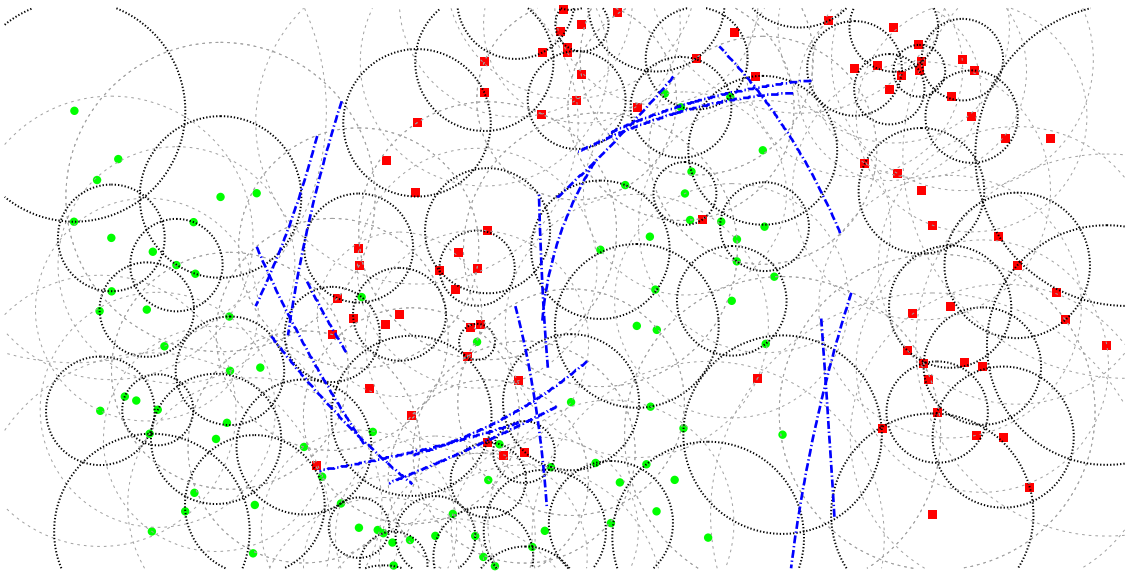

Figure 1: Graphical representation of the proposed approach using local models with $k' = 4$, $k = 15$, and local SVM with RBF kernel. The bold dotted circles highlights the k'-neighbourhoods covering all the training set (with some unavoidable redundancy), the thin dotted circles denotes the k-neighbourhoods on which the local models are trained. Some k-neighbourhoods do not produce an explicit decision function because entirely composed by points of the same class. The local SVM (with RBF kernel) decision functions are drawn in blue. Notice that, due both to the adoption of the k'-neighbourhood cover set and to the fact that only a fraction of the neighbourhoods need to be trained, we have only 17 local decision functions for 185 points.

Moreover if a neighbourhood contains only points belonging to one class the local model is the majority rule (specifically, unanimity) and the training of the SVM is avoided.

Figure 1 graphically shows the result of adopting the approach described above on a simple artificial data set with k and k' chosen for illustrative purposes. In fact, the example just aims to show the intuition behind the approach that is instead developed for large data sets and for non-extreme values of the neighbourhood parameters.

From Figure 1 we can also notice that the level of overlapping between k'-neighbourhoods and thus between k-neighbourhoods depends on the value of k'. If k' is low, a large number of k'-neighbourhoods are required to cover the entire training set, whereas if k' is large fewer k'-neighbourhoods are needed. The k' parameter thus tune the level of redundancy of the local models.

4.2.2 SELECTING THE LOCAL MODELS FOR TESTING POINTS

Once the set of centres $\mathcal{C}$ is defined and the corresponding local models are trained, we need to select the proper model to use for predicting the label of a test point. A simple strategy we can adopt consists in selecting the model whose centre $\mathbf{c} \in \mathcal{C}$ is the nearest centre with respect to the

testing example. Using the general definition of FastLSVM of Equation 6 with $f(x) = r^{\mathcal{C}}_{\mathbf{x}}(1)$ where $r^{\mathcal{C}}$ corresponds to the reordering function defined in Equation 3 performed on the $\mathcal{C}$ set instead of $\mathcal{X}$, the method, called FaLK-SVMc, is defined as:

$$\text{FaLK-SVMc}(\mathbf{x}) = k\text{NNSVM}_{\mathbf{c}}(\mathbf{x}) \text{ where } \mathbf{c} = \mathbf{x}_{r^{\mathcal{C}}_{\mathbf{x}}(1)}. \tag{10}$$

FaLK-SVMc is satisfactory from the computational viewpoint, for it performs the nearest neighbour search on $\mathcal{C}$ only. However, it does not assure that the testing point is evaluated with the model centred on the point for which the testing point itself is the nearest in terms of neighbour ranking. For example, a testing point $\mathbf{q}$ can be closer to $\mathbf{c}_1$ than $\mathbf{c}_2$ using the Euclidean distance, but at the same time we can have that $\mathbf{q}$ is the i-th nearest neighbour of $\mathbf{c}_1$ in $\mathcal{X}$ and the j-th nearest neighbour of $\mathbf{c}_2$ with $i > j$. This is a problem because using the model centred on $\mathbf{c}_2$ is better in terms of proximity. In order to overcome this issue of FaLK-SVMc we propose to use, for a testing point $\mathbf{q}$, the model centred on the training point which is the nearest in terms of the neighbourhood ranking to its training nearest neighbour. We can do this defining a function $cnt : \mathcal{X} \mapsto \mathcal{C}$ in the following way:

$$\begin{aligned} cnt(\mathbf{x}_i) &= \text{choose}(\left\{\mathbf{c}_z \in \mathcal{C} | \mathbf{x}_i = \mathbf{x}_{r_{\mathbf{c}_z}(h)}\right\}) \\ \text{where } h &= \min\left(t \in \{1,\ldots,k'\} \middle| \mathbf{x}_{r_{\mathbf{c}_j}(t)} = \mathbf{x}_i \text{ and } \mathbf{c}_j \in \mathcal{C}\right). \end{aligned} \tag{11}$$

The cnt function finds, for each example $\mathbf{x}$, the minimum value h such that $\mathbf{x}$ is in the h-neighbourhood of at least one centre $\mathbf{c} \in \mathcal{C}$; then, among the centres having $\mathbf{x}$ in their h-neighbourhoods, it selects the centre with the minimum index. The existence of h is guaranteed by the k'-neighbourhood covering strategy. In this way each training point is univocally assigned to a centre and so the decision function of this approximation of Local SVM derivable from FastLSVM of Equation 6 with $f(\mathbf{x}) = cnt(\mathbf{x})$, and called FaLK-SVM, is simply:

$$\text{FaLK-SVM}(\mathbf{x}) = k\text{NNSVM}_{cnt(\mathbf{t})}(\mathbf{x}) \text{ where } \mathbf{t} = \mathbf{x}_{r_{\mathbf{x}}(1)}. \tag{12}$$

The association between training points and centres defined by Equation 11 can be efficiently precomputed during the training phase, delaying to the testing phase only the retrieval of the nearest neighbour of the testing point and the evaluation of the local SVM model.

Figure 2 graphically shows the application of the FaLK-SVM($\mathbf{x}$) prediction strategy on a toy data set; the training phase for the same data set is illustrated in Figure 1.

FaLK-SVM can be generalised for multi-class problems in the same way of kNNSVM, but in this paper we focus on binary problems in order to better evaluate the approach.

4.3 FaLK-SVM with Internal Model Selection: FaLK-SVMI

For training a kernel machine, once a proper kernel is chosen, it is crucial to carefully tune the kernel parameters and, for SVM, to set the soft margin regularisation constant C. Model selection is very often performed estimating the empirical error with different parameter values and a popular method is the κ-fold cross-validation[2] with a grid search on parameter space. Given the following loss function for the two-class classification case

$$L(y, \text{SVM}(\mathbf{x})) = \begin{cases} 0 & \text{if } y = \text{SVM}(\mathbf{x}) \\ 1, & \text{if } y \neq \text{SVM}(\mathbf{x}) \end{cases},$$

2. Although κ can be confused with the neighbourhood size k or with the kernel function K, κ is always used for denoting κ-fold CV, so the context should be sufficient to avoid ambiguity.

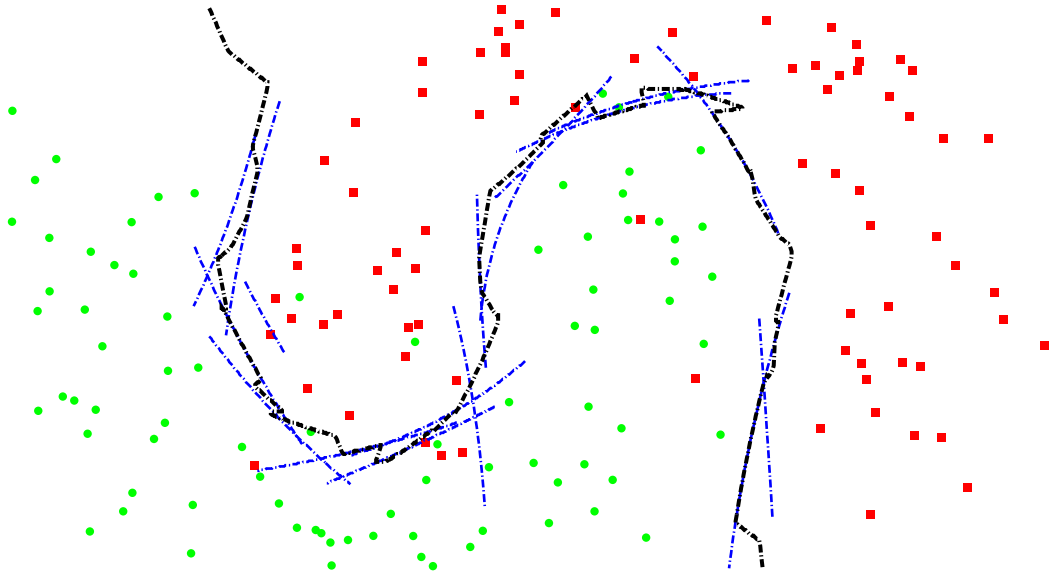

Figure 2: Graphical representation of the global decision function (black dotted line) obtained with the local decision functions (the same of Figure 1) using the described approach that uses for each query point the local decision function of the Voronoi region in which it lies.

and partitioning the training set $\mathcal{X}$ in κ subsets each with the same cardinality[3] (called folds), the κ-fold cross validation (CV) procedure consists in searching for the parameters that minimise the average of the losses on $\mathcal{X}_f$ of the classifier trained on $\mathcal{X} \setminus \mathcal{X}_f$ for $f = 1, \ldots, \kappa$. The effectiveness in terms of testing accuracies of κ-fold CV is high, but it adds a computational overhead to the training phase. In fact, the computational complexity of a κ-fold CV run on a single parameter choice is in the order of κ times the training time; if we have p parameters to set and c possible choices for each parameter, the κ-fold cross-validation with grid selection is $\kappa \cdot c^p$ times slower than a single training of the classifier.

The model selection for FaLK-SVM and FaLK-SVMc can be performed using κ-fold CV. The only difference with SVM is that our local kernel machines need to estimate an additional parameter which is the neighbourhood size k (which is however usually chosen in a small set of possible values). However, with the local setting of the classification problem we are discussing in this paper, it is also possible to efficiently tackle the complexity of the model selection phase. Basically, since FaLK-SVM trains a set of local models, we can perform the model selection in a grid-search setting on a subset of the neighbourhoods. In this way we can efficiently estimate the global parameters of FaLK-SVM without considering all the training points during model selection. The classifier implementing this approach to model selection is called FaLK-SVMl.

As a first step for defining the model selection approach of FaLK-SVMl, we define a different setting of model selection for kNNSVM.

3. Without loss of generality, we assume $|\mathcal{X}| \mod \kappa = 0$.

Definition 3 (Localised κ-fold CV model selection for *k*NNSVM) *The procedure applies the κ-fold CV model selection on the k-neighbourhood of the query point.*

However, since the local model is used by *k*NNSVM only for the central point, the model selection should be performed in order to make the local models predictive especially for the very internal points. The idea thus consists in selecting the κ validation sets exclusively from the k' most internal points, taking as each corresponding training fold the union of the remaining k'-neighbourhood points and of the $k-k'$ most external points of the k-neighbourhood.

Definition 4 (k'-internal κ-fold CV model selection for *k*NNSVM)
The procedure applies the localised κ-fold CV model selection on the k'-neighbourhood of the query point in the training set adding to each training fold the points in the k-neighbourhood that are not in the k'-neighbourhood with $k > k'$.

For FaLK-SVM we can apply the k'-internal κ-fold CV for *k*NNSVM model selection on a randomly chosen training example and use the resulting parameters for all the local models. In order to be robust the procedure is repeated on more than one k-neighbourhood choosing the parameters that minimise the average k'-internal κ-fold CV error among the k-neighbourhoods.

Definition 5 (k'-internal κ-fold CV model selection for FaLK-SVM)
The procedure applies the k'-internal κ-fold CV for kNNSVM model selection on the k-neighbourhoods of $1 \leq m \leq |\mathcal{C}|$ randomly chosen centres selecting the parameters that minimise the average error rate among the m applications.

The variant of FaLK-SVM that adopts the k'-internal κ-fold CV described in Definition 5 is named FaLK-SVMI. Since FaLK-SVMI selects the local model parameters using a small subset of the training set, the variance of the error may be higher than the standard cross-validation strategies. However, for huge data sets the standard model selection can be too slow to be applied and, in any case, one may use large values of m to decrease the risk of selecting non-optimal parameters.

4.3.1 A SPECIFIC STRATEGY FOR SETTING THE RBF KERNEL WIDTH

As already proposed by Tsang et al. (2005) and by Segata and Blanzieri (2009b), good choices for the RBF kernel width σ of SVM are based on the median (or other percentiles) of the distribution of distances. In FaLK-SVMI we can thus efficiently estimate σ for each local model simply calculating the median of the distances in the neighbourhood. This approach has some analogies with standard SVM using a variable RBF kernel width that have good potentialities for classification (Chang et al., 2005). Since other percentiles different from the median can give better accuracy performances, in FaLK-SVMI the percentile can be a value to set using the k'-internal κ-fold CV approach.

4.4 Generalisation Bounds for *k*NNSVM and FaLK-SVM

The class of LLAs introduced by Bottou and Vapnik (1992) includes *k*NNSVM, and can be theoretically analysed using the framework based on the local risk minimisation (Vapnik and Bottou, 1993; Vapnik, 2000). On the other hand, FaLK-SVM is not a LLA as intended by Bottou and Vapnik (1992). In fact, LLAs compute the local function for each specific testing point thus delaying the neighbourhood retrieval and model training until the testing point is available. However, we show here that generalisation bounds for FaLK-SVM can be derived starting from the LLA ones.

We need to recall the bound for the local risk minimisation, which is a generalisation of the global risk minimisation theory.

Theorem 6 (Vapnik (2000)) *For a testing point* $\mathbf{x}'$ *and with probability* $1-\eta$ *simultaneously for all bounded functions* $A \leq L(y, f(\mathbf{x},\alpha)) \leq B$, $\alpha \in \Lambda$ *(where* Λ *is a set of parameters), and all locality functions* $0 \leq T(\mathbf{x},\mathbf{x}_0,\beta) \leq 1$, $\beta \in (0,\infty)$, *the following inequality holds true:*

$$R^{LLA}(\alpha,\beta,\mathbf{x}') \leq \frac{\frac{1}{N}\sum_{i=1}^{N} L(y_i, f(\mathbf{x}_i,\alpha))T(\mathbf{x}_i,\mathbf{x}',\beta) + (B-A)\gamma(N,h^{\Sigma})}{|\frac{1}{N}\sum_{i=1}^{N} T(\mathbf{x}_i,\mathbf{x}',\beta) - \gamma(N,h^{\beta})|},$$

where

$$\gamma(N,h) = \sqrt{\frac{h\ln(2N/h+1) - \ln\eta/2}{N}},$$

and h^{Σ} *is the VC dimension of the set of functions* $L(y_i, f(\mathbf{x}_i,\alpha))T(\mathbf{x}_i,\mathbf{x}',\beta), \alpha \in \Lambda, \beta \in (0,\infty)$ *and* h^{β} *is the VC dimension of* $T(\mathbf{x}_i,\mathbf{x}',\beta)$

For kNNSVM, the loss function is simply

$$L(y_i, f(\mathbf{x}_i,\alpha)) = \begin{cases} 0 & \text{if } y_i = f(\mathbf{x}_i,\alpha) \\ 1 & \text{if } y_i \neq f(\mathbf{x}_i,\alpha) \end{cases}$$

and the locality function is

$$T(\mathbf{x}_i,\mathbf{x}',k) = \begin{cases} 1 & \text{if } \exists j \leq k \text{ s.t. } i = r_{\mathbf{x}'}(j) \\ 0 & \text{otherwise} \end{cases}.$$

It is straightforward to show that $\sum_{i=1}^{N} T(\mathbf{x}_i,\mathbf{x}',k) = k$. Moreover $T(\mathbf{x}_i,\mathbf{x}',k)$ has VC dimension equal to 2; it is, in fact, the class of functions corresponding to hyperspheres centred on $\mathbf{x}'$ with diameters equal to the distances of the points from $\mathbf{x}'$ and can thus shatter any set of two points with different classes, but cannot shatter three points with the nearest and furthest points having a class different from the third point.

We observe that, in our case,

$$\sum_{i=1}^{N} L(y_i, f(\mathbf{x}_i,\alpha))T(\mathbf{x}_i,\mathbf{x}',\beta) = \sum_{i=1}^{k} L(y_i, f(\mathbf{x}_i,\alpha))$$

and so we can obtain:

$$R^{k\text{NNSVM}}(\alpha,k,\mathbf{x}') \leq \frac{\frac{1}{N}k\cdot\nu_{\mathbf{x}'} + \gamma(N,h^{\Sigma})}{|\frac{1}{N}k - \gamma(N,2)|} \tag{13}$$

where $\nu_{\mathbf{x}'}$ is the ratio of misclassified training points in the k-neighbourhood of $\mathbf{x}'$.

The possibility of local approaches to obtain a lower bound on test misclassification probability acting with the locality parameter, as stated in Vapnik and Bottou (1993); Vapnik (2000) for LLA, it is even more evident for kNNSVM considering Equation 13. In fact, although choosing a $k < N$ is not sufficient to lower the bound, as the model training becomes more and more local k decreases and (very likely) the misclassification training rate $\nu_{\mathbf{x}'}$ decreases as well. Moreover, also the complexity of the classifier (and thus h^{Σ}) can decrease when the neighbourhood decreases, because simpler decision functions can be used when fewer points are considered. Taking this into

consideration, it is necessary to consider the trade-off between the degree of locality k, the function of the empirical error with respect to k and the complexity of the local classifier needed with respect to k, in order to find a minimum of the expected risk which is lower than the $k = N$ case. Multiple strategies can be used to tune this trade-off, especially if prior or high-level information are available for a specific problem; since in this work we aim to be as general as possible, the expected risk is estimated for the computational experiments using cross-validation based approaches.

FaLK-SVM pre-computes local models to be used for testing points lying in sub-regions (k-NN Voronoi cells) of the training set. The risk associated to FaLK-SVM considering a specific query point $\mathbf{x}'$ can be defined using the risk of kNNSVM, supposing that $\mathbf{x}' \in V_{\mathbf{x}_i}$ and so $\mathbf{x}_{r_{\mathbf{x}'}(1)} = \mathbf{x}_i$:

$$R^{\text{FaLK-SVM}}(\alpha, k, \mathbf{x}') = R^{k\text{NNSVM}}(\alpha, k, \mathbf{x}') + \lambda(\mathbf{x}', \mathbf{x}_{r_{\mathbf{x}'}(1)}) \leq R^{k\text{NNSVM}}(\alpha, k, \mathbf{x}') + \lambda_{r_{\mathbf{x}'}(1)} \tag{14}$$

where $\lambda(\mathbf{x}', \mathbf{x}_{r_{\mathbf{x}'}(1)})$ is due to the approximation introduced, for the prediction of the label of the query point $\mathbf{x}$', by the use of the k-neighbourhood of $r_{\mathbf{x}'}(1)$ instead of the k-neighbourhood of $\mathbf{x}'$ itself and

$$\lambda_{r_{\mathbf{x}'}(1)} = \max_{x'' \in V_{\mathbf{x}_i}} \lambda(\mathbf{x}'', \mathbf{x}_{r_{\mathbf{x}'}(1)}).$$

If we consider $k' = 1$, the approximation is due to the fact that $\{r_{\mathbf{c}}(i) | \, i = 1, \ldots, k\}$ and $\{r_{\mathbf{x}'}(i) | \, i = 1, \ldots, k\}$ can be slightly different; however, considering a non very low value for k, the differences between the two sets are possible only for the very peripheral points of the neighbourhoods which are those that influence less the shape of the decision function in the central region. We will empirically show that $\lambda_{r_{\mathbf{x}'}(1)}$ is, on average, a small penalising term that still permits to achieve lower risks than SVM using k' values higher than 1.

The risk of FaLK-SVM in its eager learning setting (i.e., without the explicit dependency on the query point) can thus be defined as:

$$\begin{aligned} R^{\text{FaLK-SVM}}(\alpha, k) &= \int_{\mathbf{x}'} R^{\text{FaLK-SVM}}(\alpha, k, \mathbf{x}') g(\mathbf{x}') d\mathbf{x}' \\ &\leq \int_{\mathbf{x}'} \left(R^{k\text{NNSVM}}(\alpha, k, \mathbf{x}_i) + \lambda_{r_{\mathbf{x}'}(1)} \right) g(\mathbf{x}') d\mathbf{x}' \\ &= \int_{\mathbf{x}'} R^{k\text{NNSVM}}(\alpha, k, \mathbf{x}_i) g(\mathbf{x}') d\mathbf{x}' + \int_{\mathbf{x}'} \lambda_{r_{\mathbf{x}'}(1)} g(\mathbf{x}') d\mathbf{x}' \\ &= \int_{\mathbf{x}'} R^{k\text{NNSVM}}(\alpha, k, \mathbf{x}_i) g(\mathbf{x}') d\mathbf{x}' + E[\lambda]. \end{aligned} \tag{15}$$

where $E[\lambda]$ is the expectation of the term due to the use of the kNNSVM risk for FaLK-SVM as discussed above.

4.5 Computational Complexity Analysis

We analyse here the computational performances of FaLK-SVM from the theoretical complexity viewpoint. The training phase of FaLK-SVM can be subdivided in four steps:

- the building of the cover tree that scales as $O(N \log N)$;
- the retrieval of the local models that scales as $O(|\mathcal{C}| \cdot k \log N)$;
- the assignment of each point to a k'-neighbourhood that scales as $O(N)$;

- the training of the local SVM models that scales as $O(|\mathcal{C}| \cdot k^3)$.

The overall training time, considering the worst case in which $k' = 1$ so $|\mathcal{C}| = N$, scales as:

$$O(N \log N + \mathcal{C} \cdot k \log N + N + \mathcal{C} \cdot k^3) = O(kN \cdot \max(\log N, k^2))$$

which is, considering a reasonably low and fixed value for k as happens in practice for large data sets, sub-quadratic, and in particular $O(N \log N)$, in the number of training points.

For the testing phase of FaLK-SVM we can distinguish two steps (for each testing point):

- the retrieval of the nearest training point that scales as $O(\log N)$;
- the prediction of the testing label using the selected local model that scales as $O(k)$.

The testing can thus be performed in $O(\max(\log N, k))$, so it is logarithmic in N. FaLK-SVMc is even faster because it scales as $O(\max(\log |\mathcal{C}|, k)) \leq O(\max(\log N, k))$.

FaLK-SVM is thus asymptotically faster than SVM (also considering the worst case in which SVM scales quadratically and $k' = 1$) and all the classifiers taking more than $O(N \log N)$ for training and $O(\log N)$ for testing. Moreover, FaLK-SVM can be very easily parallelised differently from SVM whose parallelisation, although possible (Zanni et al., 2006; Dong, 2005), is rather critical; for FaLK-SVM is sufficient that, every time the points for a model are retrieved, the training of the local SVM is performed on a different processor. In this way the time complexity of FaLK-SVM can be further lowered to $O(N \cdot \max(k \log N, k^3 / N_{proc}))$ where N_{proc} is the number of processors.

Another advantage of FaLK-SVM over SVM is space complexity. Since FaLK-SVM performs SVM training on small subregions (assuming a reasonable low k), there are no problems of fitting the kernel matrix into main memory. The overall required space is, in fact, $O(N + k^2)$, that is, linear in N, which is much lower than SVM space complexity of $O(N^2)$. For large data sets, FaLK-SVM can still maintain in memory the entire local kernel matrix (if k is not too large), whereas SVM must discard some kernel values thus increasing SVM time complexity due to the need of recomputing them. Analysing the space required to store the trained model in secondary storage devices (e.g., hard disks), we can notice that FaLK-SVM needs to save in the model file the entire set of local models; although we store the models with pointers to the training set points, we need to maintain the whole training set in the model file (or give as input for the testing module both the model file and the original training set). FaLK-SVM, in other words, needs to store the training set also in the model file, differently from SVM that needs to store only the support vectors (whose number however grows linearly with N).

4.5.1 CURSE OF DIMENSIONALITY

Although not explicitly considered here, cover trees have a constant in the complexity bounds depending on the so-called doubling constant (Clarkson, 1997; Krauthgamer and Lee, 2004) which is a robust estimation of the intrinsic dimensionality of the data. Notice that the intrinsic dimensionality of a data set can be much lower than the dimensionality intended simply as the number of features. Regardless of the doubling constant, FaLK-SVM maintains the derived complexity bounds[4] with respect to N, but the overhead introduced for building the cover tree and retrieving the k-neighbourhoods can be very high. This drawback, due to the well-known problem of the *curse of*

4. The high intrinsic dimensionality can cause the need for an high value of $|\mathcal{C}|$, but in the bound we already considered the worst case in which $k' = 1$ and thus $|\mathcal{C}| = N$.

Algorithm 1 FaLK-SVM-train (training set **x[]**, training size **n**, neighbourhood size **k**, assignment neighbourhood size **k'**)

```
models[] ⇐ null   // the set of models
modelPtrs[] ⇐ null   // the set of pointers to the models
c ⇐ 0   // the counter for the centres of the models
indexes[] ⇐ {1,...,N}   // the indexes for centres selection
Randomise indexes   // randomise the indexes
for i ⇐ 1 to N do
    index ⇐ indexes[i]   // get the i-th index
    if modelPtrs[index] = null then   // if the point has not been assigned to a model...
        localPoints[] ⇐ get ordered kNN of x[i]   // ...retrieve its k-neighbourhood ...
        models[c] ⇐ SVMtrain on localPoints[]   // ...train a local SVM...
        modelPtrs[index] ⇐ models[c]   // ...assign the centre to the trained model.
        for j = 1 to k' do   // Assign the model to the k'<k nearest neighbours of the centre
            ind ⇐ get index of localPoints[j]
            if modelPtrs[ind] = null then   // assign the points in the k'-neighbourhood ...
                modelPtrs[ind] ⇐ models[c]   // ...to the c-th model
            end if
        end for
        c ⇐ c+1
    end if
end for
return models, modelPtrs
```

Algorithm 2 FaLK-SVM-predict (training set **x[]**, points-to-model pointers **modelPtrs**, Local SVM models **models**, query point **q**)

```
Set p = get NN of q in x   // retrieve the nearest training point with respect to q...
Set nnIndex = get index of p   // ...retrieve its index ...
return label = SVMpredict q with modelPtrs[nnIndex]   // ...and use the corresponding model
for predict the label of the query point.
```

dimensionality that affects also SVM with local kernels (Bengio et al., 2005), is not however crucial here, as we are considering non-linear classification problems that are not high-dimensional. In fact, apart from computational problems, high-dimensional problems are typically tackled by approaches not related with the concept of locality (e.g., linear SVM instead of SVM with a RBF kernel).

4.6 Implementation and Availability

FaLK-SVM (and also FkNN and FkNNSVM that are the implementations of kNN and *k*NNSVM using cover trees) is available as part of the Fast Local Kernel Machine Library (Segata, 2009, FaLKM-lib). FaLK-SVM is written in *C*/*C*++ and it uses LibSVM v. 2.88 (Chang and Lin, 2001) for local SVM training and testing whereas we use our own implementation of the cover trees data-structure. The pseudo-code for the training phase is reported in Algorithm 1 and for the testing phase

method	brief description
FkNN	implementation of kNN (Section 3.1) with cover trees
FkNNSVM	implementation of *k*NNSVM (Section 3.3) with cover trees
FaLK-SVM	implementation of fast and scalable local kernel machines (see Equation 12)
FaLK-SVM-train	module for the training of FaLK-SVM (see Algorithm 1)
FaLK-SVM-predict	module for the testing of FaLK-SVM (see Algorithm 2)
FaLK-SVMc	faster prediction variant of FaLK-SVM (see Equation 10)
FaLK-SVMl	implementation of FaLK-SVM with local model selection (Section 4.3)
FkNNSVM-nr	implementation of *k*NNSVM for noise reduction (Segata et al., 2009b)
FaLKNR	impl. of noise reduction with FaLK-SVM (Segata et al., 2009a)

Table 1: Summary for the classifiers developed in the local kernel machine framework and implemented in FaLKM-lib.

in Algorithm 2 (use of cover trees and minimisation of t in Equation 11 are omitted for clearness). Table 1 summarizes the classifiers discussed in this paper and the modules of FaLKM-lib.

5. Empirical Analysis

The empirical analysis is organised into three experiments performed with different objectives and using different data sets. Experiment 1 (Section 5.1) has the objective of assessing the generalisation performances of FaLK-SVM with respect to SVM (using LibSVM) and to *k*NNSVM (using FkNNSVM) and thus assessing if FaLK-SVM is more accurate than SVM and if it is a good approximation of *k*NNSVM. For this experiment we use 25 non-large data sets. Experiment 2 (Section 5.2) focuses on comparing the classification accuracies and the computational performances of FaLK-SVM (and its variants FaLK-SVMc and FaLK-SVMl) with respect to SVM (using LibSVM) on large data sets. For this experiment we use 8 data sets with training set cardinalities ranging from about 50k examples to more than 1 million. Experiment 3 (Section 5.3) aims to understand (i) whether FaLK-SVM has better scalability and accuracy performances than LibSVM, a number of approximated SVM solvers (CVM, BVM, LASVM, CPSP and USVM) and SVM-bagging and (ii) which are the computational and accuracy differences between FaLK-SVM, FaLK-SVMc and FaLK-SVMl. For this last experiment we use 4 data sets with increasing training set size up to 3 million examples. The experiments, unless otherwise specified, are carried out on an AMD Athlon 64 X2 Dual Core Processor 5000+, 2600MHz, with 3.56Gb of RAM with Linux operating system.

5.1 Experiment 1: Comparison of FaLK-SVM with LibSVM and FkNNSVM

In this evaluation we compare SVM (using LibSVM), *k*NNSVM (using FkNNSVM) and FaLK-SVM on 25 non-large data sets, with the objective of studying the generalisation performances of *k*NNSVM with respect to SVM and the level of approximation introduced by FaLK-SVM to the FkNNSVM algorithm.

Table 2: The 25 binary-class data sets of Experiment 1.

5.1.1 EXPERIMENTAL PROTOCOL

The data sets are listed in Table 2; they are retrieved from the UCI (Asuncion and Newman, 2007) and STATLOG (Michie et al., 1994) repositories, with cardinality between 200 and 3100 points (some data sets have been randomly sub-sampled), dimensionality lower than 200, not very unbalanced, and they are all scaled in the $[0,1]$ interval. The comparison is carried out using three different kernel functions (linear, RBF and homogeneous polynomial), in a 10-fold CV experimental setting. Internal to each training fold the model selection is performed with a nested 10-fold CV choosing the parameters in the following ranges. The regularisation parameter C is chosen for all methods in the set $\{2^{-2}, 2^{-1}, \ldots, 2^{9}, 2^{10}\}$, the width parameter σ of the RBF kernel in $\{2^{-5}, 2^{-4}, \ldots, 2^{2}, 2^{3}\}$, the degree of the polynomial kernels in $\{1,2,3\}$. The neighbourhood parameter k for FkNNSVM and FaLK-SVM is selected by the cross-validation procedure in the set $\{2^1, 2^2, \ldots, 2^9, 2^{10}, |\mathcal{X}|\}$ where $|\mathcal{X}|$ is the cardinality of the training set,[5] while the k' parameter of FaLK-SVM is fixed to $k/2$ which is a value that privileges scalability over accuracy because we want to test a value that can permit good computational results for large and very large data sets.

5.1.2 RESULTS AND DISCUSSION

Table 3 reports the accuracy results of all tested methods and kernels. In addition to the mean ranks reported in the figure, we assessed the statistical significance of the differences between pairs of methods using the Wilcoxon Signed Rank Test (Wilcoxon, 1945; Demšar, 2006) with $\alpha = 0.05$. The test highlights that FkNNSVM is significantly better than LibSVM for the linear and polynomial kernels, whereas for the RBF kernel no significant differences are detected, although the mean rank of FkNNSVM with RBF kernel is lower than LibSVM with RBF kernel. Applied to FaLK-SVM, the Wilcoxon Signed Rank Test detects a significant difference with respect to LibSVM only for the linear kernel. If we perform the Friedman test (Friedman, 1940) ($\alpha = 0.05$), the null hypothesis is

5. For data set with less than 1024 points some k values are of course not tested.

violated, but, according to the Nemenyi post-hoc test (Nemenyi, 1963) ($\alpha = 0.05$) the only method that is statistically significantly different from the others is SVM with linear kernel.

The observation that FkNNSVM is significantly better than SVM if a non-local kernel is used, is a confirmation of what we already noticed (Segata and Blanzieri, 2009a). Using the RBF kernel, instead, no significant differences are detected, although the mean rank of FkNNSVM with RBF kernel is lower than LibSVM with RBF kernel. This is mainly due to the fact that SVM with RBF kernel is already very accurate and significant improvements over it are very difficult. We may also say that locality is already included in the RBF kernel and thus, at least for non-large data sets, the adoption of a local method is somehow equivalent. Regarding FaLK-SVM, significant differences with respect to LibSVM are detected only for the linear kernel. Although FaLK-SVM does not achieve the accuracy results of FkNNSVM, if we look to the mean ranks, we can conclude that the approximation on the *k*NNSVM approach introduced in FaLK-SVM still permits to achieve slightly

better results than SVM also on non-large data sets, confirming our preliminary analysis (Segata and Blanzieri, 2009c). These results also indicates that the $E[\lambda]$ term introduced in the risk of FaLK-SVM (Section 4.4), due to the approximations introduced to the kNNSVM approach, is small enough to assure higher generalisation accuracies with respect to SVM.

The overall outcome of this experiment is that FaLK-SVM is a good approximation of FkNNSVM that maintains a little advantage over SVM and it is particularly effective with the RBF kernel with respect to linear and polynomial kernels. Notice that the experiment is carried out using small data sets in which locality is very likely to play a marginal role differently from large data sets in which it can be crucial.

5.2 Experiment 2: FaLK-SVM, FaLK-SVMc and FaLK-SVMl vs. LibSVM and FkNN on Large Data Sets

In this experiment we apply FaLK-SVM, FaLK-SVMc, FaLK-SVMl, LibSVM on 8 large data sets comparing the computational and generalisation performances using the RBF kernel, because preliminary experiments showed that the linear or polynomial kernels have very low accuracy results on the considered problems. We also add to the comparison the kNN classifier (implemented with cover trees and called FkNN) using the Euclidean distance.

5.2.1 EXPERIMENTAL PROTOCOL

The data sets considered in this experiment are listed in Table 4 with the corresponding sources and are all scaled in the $[0,1]$ interval. They range from a training set cardinality of about 50k points to more than one million, whereas the dimensionality is not high (always under 60) with separated test sets. In order to select the parameters a 10-fold CV procedure is performed in the training set (apart from FaLK-SVMl) choosing the values in the following sets: $C \in \{2^{-2}, 2^{-1}, \ldots, 2^{9}, 2^{10}\}$, $\sigma \in \{2^{-15}, 2^{-14}, \ldots, 2^{4}, 2^{5}\}$, k for FaLK-SVM in $\{250, 500, 1000, 2000, 4000, 8000\}$ with $k' = k/2$, and k for FkNNSVM in $\{1, 3, 5, 9, 15, 21, 31, 51, 71, 101, 151\}$. FaLK-SVM does not necessarily test all values for k because if the maximum empirical accuracy is found for a specific value of k, for example $k = 500$, and for the following value, in this case $k = 1000$, the maximum is lower, the remaining higher values of k are not tested. Due to the computational resources necessary

for performing model selection, especially for LibSVM, we performed the cross-validation runs on a Linux-based TORQUE cluster with 20 nodes. For FaLK-SVMl the local model selection is performed on 10 local models, $C \in \{2^0, 2^2, 2^4, 2^6\}$, $k \in \{500, 1000, 2000, 4000\}$, σ locally estimated with the $1st$, $10th$, $50th$ or $90th$ percentile of the distribution of the distances.

5.2.2 RESULTS AND DISCUSSION

Table 5 reports the generalisation accuracies of the analysed classifiers. Looking at the mean ranks, we can see that FaLK-SVM is the most accurate (it achieves the best results in half of the data sets), followed by FaLK-SVMl. LibSVM and FaLK-SVMc seem to perform very similar but little worse than FaLK-SVM and FaLK-SVMl. Not surprisingly, FkNN performs poorly in almost all the data sets, except for the intr-det data set in which it achieves the best result. According to the Wilcoxon Signed Rank Test (Wilcoxon, 1945; Demšar, 2006) FaLK-SVM is significantly more accurate than LibSVM, whereas, excluding FkNN, no other significant differences are detected. Apart for the intr-det data set that has slightly different distribution in the training and testing sets (some types of network attacks are present in the test set only), the best empirical accuracies are always very similar to the generalisation accuracies meaning that all techniques avoid over-fitting.

Table 6 reports the training times together with the speed-ups of FaLK-SVM, FaLK-SVMc and FaLK-SVMl with respect to LibSVM. We can notice that the speed-ups achieved by FaLK-SVM and FaLK-SVMc are always greater than 4.7, and in the majority of the cases they are at least one order of magnitude bigger than LibSVM. Generally, FaLK-SVMc turns out to be faster than FaLK-SVM although the two classifiers implement the same training algorithm. This happens because the model selection chooses for FaLK-SVMc a lower value of k with respect to FaLK-SVM. In fact, FaLK-SVMc is less accurate than FaLK-SVM in choosing the nearest model for a testing point, and this causes an higher value of the $E[\lambda]$ constant that increases the risk of FaLK-SVMc with respect to FaLK-SVM (see Equation 14 and Equation 15). So using a lower k (and thus a lower k') tends to have more

models in the proximity of the testing point making the choice less problematic. FaLK-SVMl is sometimes slower than LibSVM, but we have to consider that FaLK-SVMl includes model selection, whereas for the other methods the time needed by model selection is not considered in the training time, so, practically speaking, FaLK-SVMl is the fastest method if the optimal parameters are not *a priori* known.

The testing times required by the analysed methods are reported in Table 7. As expected FaLK-SVMc is the fastest among all methods with speed-up over LibSVM ranging from more than 2 to almost 200. FaLK-SVM and FaLK-SVMl are also generally faster than LibSVM with only one case in which the testing time is about two times slower.

This experiment shows that for 8 non high-dimensional data sets, our approach outperforms a state-of-the-art accurate SVM solver both in terms of generalisation accuracies and computational

performances. Although we have an additional parameter to tune (k), FaLK-SVM and FaLK-SVMc are faster enough to maintain the performance advantages over LibSVM also for model selection (we choose k in a small set of values). Moreover, with FaLK-SVMl we addressed the problem of model selection with a specific approach to set the parameters; FaLK-SVMl outperforms LibSVM in generalisation accuracy, and the time it needs for both internal model selection and training is at least comparable (faster in 7 cases on a total of 8) with the time LibSVM needs for the training only.

5.3 Experiment 3: Comparison of Scalability Performances of FaLK-SVM, FaLK-SVMc, FaLK-SVMl, LibSVM and Approximated SVM Solvers

In this experiment we test the scalability performances of our techniques (FaLK-SVM, FaLK-SVMc, FaLK-SVMl) on training sets with increasing sizes using the RBF kernel against several other techniques. The techniques taken into account are LibSVM, the approximated SVM solvers called CVM, LASVM, USVM, BVM, CPSP (Section 2.3), SVM-bagging with fixed dimension of the sub-sampled training sets (SVM-B) and SVM-bagging with fixed proportion of the sub-sampled training sets with respect to the whole training set (SVM-Bs). Although we apply all the classifiers with the same protocol on the same data sets, we report, for clearness, the results in two parts: the comparison of FaLK-SVM with LibSVM and the approximated SVM solvers in Section 5.3.2, the comparison of FaLK-SVM with its variants FaLK-SVMc and FaLK-SVMl in Section 5.3.3.

5.3.1 EXPERIMENTAL PROTOCOL

We consider here the data sets of Table 4 for which we can further enlarge the training set size. The data sets for which we can add sets of new training examples are the cov-type data set (full training set of 500k points) and the three artificial data sets named 2-spirals, ndcc and checker-b (up to 3 million points). For cov-type the testing set is reduced to 50k examples (the other examples are added to the training set) so the accuracy results are not directly comparable to the previous experiment.

The model selection for all the classifiers (with the exception of FaLK-SVMl that performs internally a local model selection) is performed on the smallest training set only, using the chosen parameter for all the higher training set sizes. This is necessary, especially for LibSVM and approximated SVM solvers, for computational reasons. For LibSVM, BVM, CVM, USVM (with the convex concave procedure) and CPSP, we performed cross validation for C and σ using the same setting of the previous experiment. The default threshold value ε for the stopping criteria are maintained: 10^{-3} for LibSVM, FaLK-SVM, LASVM and 10^{-1} for CPSP while CVM and BVM automatically choose the value of ε based on the data at each application. We set the same size of the kernel cache (100M) for all the methods. The maximum number of core vectors for CVM and BVM is 50000 (the default value), the maximum number of basis vectors for CPSP is set to 1000. For SVM-B and SVM-Bs we need to set respectively the size and the proportion of the sub-sampled training sets and the parameters of the SVMs. For SVM-B the size of the sub-sampled training sets is equal to the 5% of the original training sets of each data set (namely 100000 for cov-type, 2-spirals and ndcc and 300000 for checker-b), whereas SVM-Bs maintains the same sampling rate (5%) for all the applications and so the cardinality of the sub-sampled training sets increases with the cardinality of the training set. Both SVM-B and SVM-Bs train 101 SVMs and the prediction is performed using the majority voting. The value of 101 is chosen because it is a sufficient high number for allowing good accuracies and it is an odd number preventing possible ties in the majority voting. The parameters of the

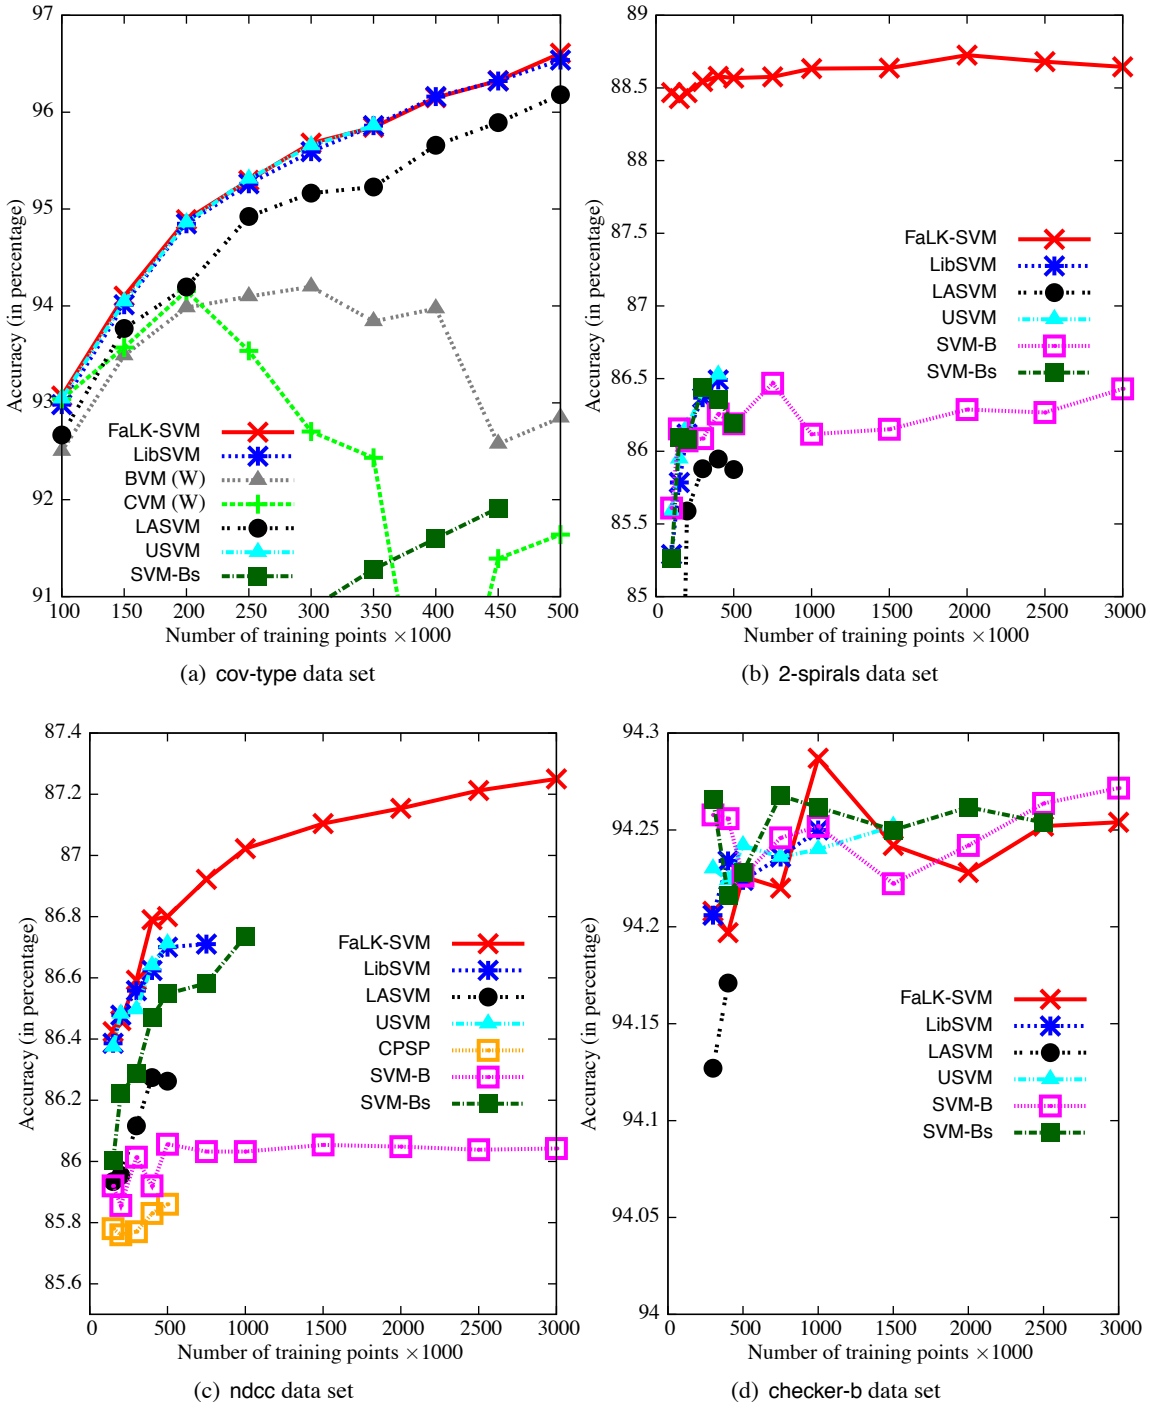
SVM for SVM-B and SVM-Bs (using LibSVM) are chosen using model selection with the same grids of parameters used for LibSVM. We also tested FaLK-SVMl using the same setting of the previous experiment. Each algorithm is tested for training set sizes requiring no more than 100000 seconds (more than 27 hours) for training.

Since the authors of BVM (Tsang et al., 2005) and CVM (Tsang et al., 2007) declared the Linux implementation of their techniques deprecated (see the authors reply to Loosli and Canu (2007) available on BVM webpage), we use the Windows executables on a Intel Pentium D Dual Core CPU 3.40GHz with 2Gb of RAM running Windows XP instead of the AMD Athlon 64 X2 Dual Core Processor 5000+, 2600MHz, with 3.56Gb of RAM with Linux operating system used for all the other classifiers. Because of the use of different operating systems and hardware for BVM and CVM, their running times should not be directly compared to the others. However, the comparison is justified by preliminary tests that showed that the Linux version of BVM on the AMD Athlon machine and the Windows version of BVM on the Intel Pentium machine have similar running times.

5.3.2 RESULTS AND DISCUSSION: FALK-SVM VS LIBSVM AND APPROXIMATED SVM SOLVERS

Figure 3 shows the generalisation accuracies of the methods at increasing training set sizes. Some methods do not appear in the figures due to low generalisation results or computational difficulties that cause abnormal terminations of the algorithms, and some accuracy results for large training set sizes are not present due to the excessive computational time required for training (more than 100000 seconds). We can observe that it is very important to use as many points as possible in order to increase the accuracies for the cov-type and ndcc data sets. The same consideration can be done for the 2-spirals data, although FaLK-SVM already starts from very high accuracies and the increment is limited, while for the checker-b data set the increment of the accuracies is negligible for almost all the methods. For the checker-b data set, the enlarging of the training set is not motivated from the accuracy viewpoint, but we still use it as a benchmark for the computational performances.

Comparing the generalisation accuracies of Figure 3 among the tested methods, we can see that FaLK-SVM is almost always on top for each of the four data sets. In this experiment as well as in the previous ones, we set $k' = k/2$; lower values for k' would probably allow FaLK-SVM to achieve higher accuracy results (although with worse computational performances). However, even if the choice of the k' parameter can be non-optimal, we decided to avoid the model selection for k' since the results are already satisfactory. The methods that seem to give results comparable with FaLK-SVM (apart from the 2-spirals data set) are LibSVM and USVM and they are able, in few cases, to slightly improve the FaLK-SVM results (LibSVM for 2 training set sizes for cov-type and checker-b, USVM for 2 training set sizes for cov-type and checker-b and 1 for ndcc). The bagging techniques give high accuracies only for the checker-b data set; this is not surprising because we already noticed that for the checker-b problem the use of large data sets is not required and thus subsampling-based methods like SVM-B and SVM-Bs are competitive. The results of the online and active learning approach of LASVM are slightly lower than FaLK-SVM, LibSVM and USVM. CPSP gives acceptable results in only one case, and for the 2-spirals and checker-b data sets it suffers from numerical problems possibly due to the scaling of the features in the $[0,1]$ interval. Enlarging the maximum number of basis functions for CPSP gives higher accuracies but the computational time needed to build the models is too high. The results we achieve here for LibSVM and LASVM on the



(a) cov-type data set

(b) 2-spirals data set

(c) ndcc data set

(d) checker-b data set

Figure 3: Generalisation accuracies of FaLK-SVM, LibSVM, BVM, CVM, LASVM, USVM, CPSP, SVM-B and SVM-Bs on the cov-type, 2-spirals, ndcc and checker-b data sets with increasing training set sizes (Experiment 3). Some accuracies are missing due to the excessive computational requirements (more than 100000 seconds for training) of the corresponding method for large training set sizes.

cov-type data sets are a little higher than the results in Bordes et al. (2005) (about 1% better both for 100k and 500k training set sizes), and we believe that this is due to the model selection approach we used here that is performed with an exhaustive cross-validation grid search for C and σ. As we can notice in Figure 3, we observed stability problems for CVM and BVM, even if we used the Windows binaries as suggested by the authors.

The training computational performances shown in Figure 4 highlight that FaLK-SVM is always much faster than the alternative techniques that are competitive from the accuracy viewpoint. In fact, although CVM, BVM and SVM-B show good scalability performances and in few cases they overcome the performances of FaLK-SVM, we noticed from Figure 3 that their generalisation abilities are poor. The scaling behaviours of LibSVM, LASVM and USVM are very similar (among the three methods LibSVM is the fastest for ndcc, LASVM is the fastest for 2-spirals and USVM is the fastest for checker-b) but substantially worse than FaLK-SVM one (FaLK-SVM is always at least one order of magnitude faster with speed-ups increasing with the training set sizes). SVM-Bs is slightly faster than LibSVM but the scalability behaviour is very similar. The methods that achieve acceptable accuracy results on the smallest training set size (i.e., LibSVM, LASVM, USVM) are not applicable when the number of training examples increases sensibly because of poor computational scalability performance; this is evident for the 2-spirals, ndcc and checker-b data sets in which the training times of LibSVM, LASVM, USVM exceed 100000 seconds as soon as the training set cardinality approaches one million (the only exception is USVM that is applicable on 1.5 training examples of the checker-b data set). On the contrary, FaLK-SVM processes data sets of 3 millions examples in the order of minutes or few hours. An experiment comparing LibSVM and LASVM on the cov-type data set with conclusions similar to ours is reported by Bordes et al. (2005) in which however LASVM is about a third faster than LibSVM whereas here LibSVM slightly overcomes LASVM; this is probably due to the fact that for LASVM the only available implementation is the original one by Bordes et al. (2005) whereas LibSVM is frequently updated and improved. Finally, CPSP performs slightly better than LibSVM, LASVM and USVM.

The computational performances of the prediction phase are reported in Figure 5. Also in this case the performance of FaLK-SVM is excellent: only CPSP and CVM are faster in 2 data sets than FaLK-SVM, but their corresponding generalisation accuracies are low. As expected, CPSP achieves very fast predictions because it limits the number of basis function to 1000 and thus for each testing points no more than 1000 kernel functions are computed. LibSVM, LASVM and USVM achieve similar results also in testing performances and, apart from small training sets for the ndcc data set, they are at least one order of magnitude slower than FaLK-SVM and the difference grows for large training set sizes. The slowest approach is SVM-Bs and this is due to the high number of models that need to be evaluated for each testing point and to the fact that the size of the models increases with the training set size. Also SVM-B has rather high prediction times but, since the size of the models is almost constant, also the performances at increasing training sizes are constant. It can be argued that the number of models used for bagging can be lowered to obtain faster prediction times; however, if we want to achieve the computational performances of FaLK-SVM we need to use no more than 20 models (in the worst case) and this seriously affects the prediction accuracies that are already much lower than FaLK-SVM ones.

The overall conclusion we can draw about the scalability of the proposed techniques is that, at least for these 4 non high-dimensional data sets, FaLK-SVM is substantially better than the state-of-the-art kernel methods for classification, and this is achieved without affecting the accuracy performances that showed to be always at least as good as the best alternative technique. Apart

Figure 5: Testing times of FaLK-SVM, LibSVM, BVM, CVM, LASVM, USVM, CPSP, SVM-B and SVM-Bs on the data sets of Experiment 3 with increasing training set sizes. The times (in seconds) are reported in logarithmic scale. Some testing times are missing due to the excessive computational requirements (more than 100000 seconds for training) of the corresponding method for large training set sizes.

for LibSVM (and consequently for SVM-B and SVM-Bs), we have to say that the available code of the other tested techniques has not been recently updated and for this reason it is possible to argue that higher performances with more optimised implementations of the tested approaches could be reached. It is also necessary to underline that in literature LASVM, USVM, CPSP, BVM and CVM have been prevalently tested on data sets with high dimensionality or, apart for cov-type, on data sets not requiring highly non-linear decision functions. The approximated non-linear SVM solvers and bagging approaches we tested could be indicated for data in which the linear kernel is not the optimal choice, but, at the same time, the decision function can be accurately reconstructed with a reduced amount of information (number of examples, support vectors or basis functions).

5.3.3 RESULTS AND DISCUSSION: COMPARISON BETWEEN FALK-SVM, FALK-SVMC AND FALK-SVML

Figure 6 reports the comparison of the generalisation accuracies of FaLK-SVM, FaLK-SVMc and FaLK-SVMl at increasing training set size. The computational performances for the training phase are reported in Figure 7, and for the testing phase in Figure 8.

From the accuracy viewpoint, we can notice that, as expected, FaLK-SVM is almost always slightly more accurate than FaLK-SVMc. FaLK-SVMl, apart from checker-b, is less accurate than FaLK-SVM for the smaller training set sizes, and this is due to the fact that FaLK-SVM performs a full grid search for model selection whereas FaLK-SVMl adopts the very fast local model selection approach. However, FaLK-SVMl rivals FaLK-SVM as the training set sizes increases. This is reasonable because FaLK-SVM uses for all the training set sizes the parameters found for the smaller training sets, and the best cross-validated parameters can differ for sub-sampled sets with different cardinality. For example, as the number of training points increases, the radius of the local neighbourhoods decreases if we maintain the same k and k' values, and the original value for the width parameter of the RBF kernel can no longer be the optimal one. For this reason, in the case of cov-type and ndcc data sets, FaLK-SVMl achieves higher accuracies than FaLK-SVM for the largest training sets. FaLK-SVMl shows a slightly higher accuracy variability then FaLK-SVM and FaLK-SVMc at different training set sizes; this is an empirical confirmation that the parameters selected by FaLK-SVMl can be less stable than the parameters selected with standard cross validation, but the phenomenon seems to be acceptable if not negligible.

The training computational performances of Figure 7 confirm (as already discussed in Section 5.2.2) that, although FaLK-SVM and FaLK-SVMc make use of the same training algorithm, the model selection procedure selects lower values of k for FaLK-SVMc, thus assuring faster training times than FaLK-SVM. The speed-ups of FaLK-SVMc with respect to FaLK-SVM are however never higher than one order of magnitude. For FaLK-SVMl we can notice a somehow irregular behaviour for increasing dimensions of the training set and this is due to the different values of the neighbourhood, kernel and regularisation parameters it chooses during the internal fast local model selection phase. In some cases FaLK-SVMl is significantly slower than FaLK-SVM. However, the training times for FaLK-SVMl include the model selection procedure whereas for FaLK-SVM we consider only the training with the optimal parameters, so we can conclude that FaLK-SVMl is a good choice for huge training sets on which traditional model selection becomes intractable.

The testing times reported in Figure 8 confirm that FaLK-SVMc is always faster than FaLK-SVM and FaLK-SVMl. In particular, we can notice that FaLK-SVMc at least halves the testing time of FaLK-SVM. FaLK-SVMl is computationally very similar to FaLK-SVM. This is not surprising because the

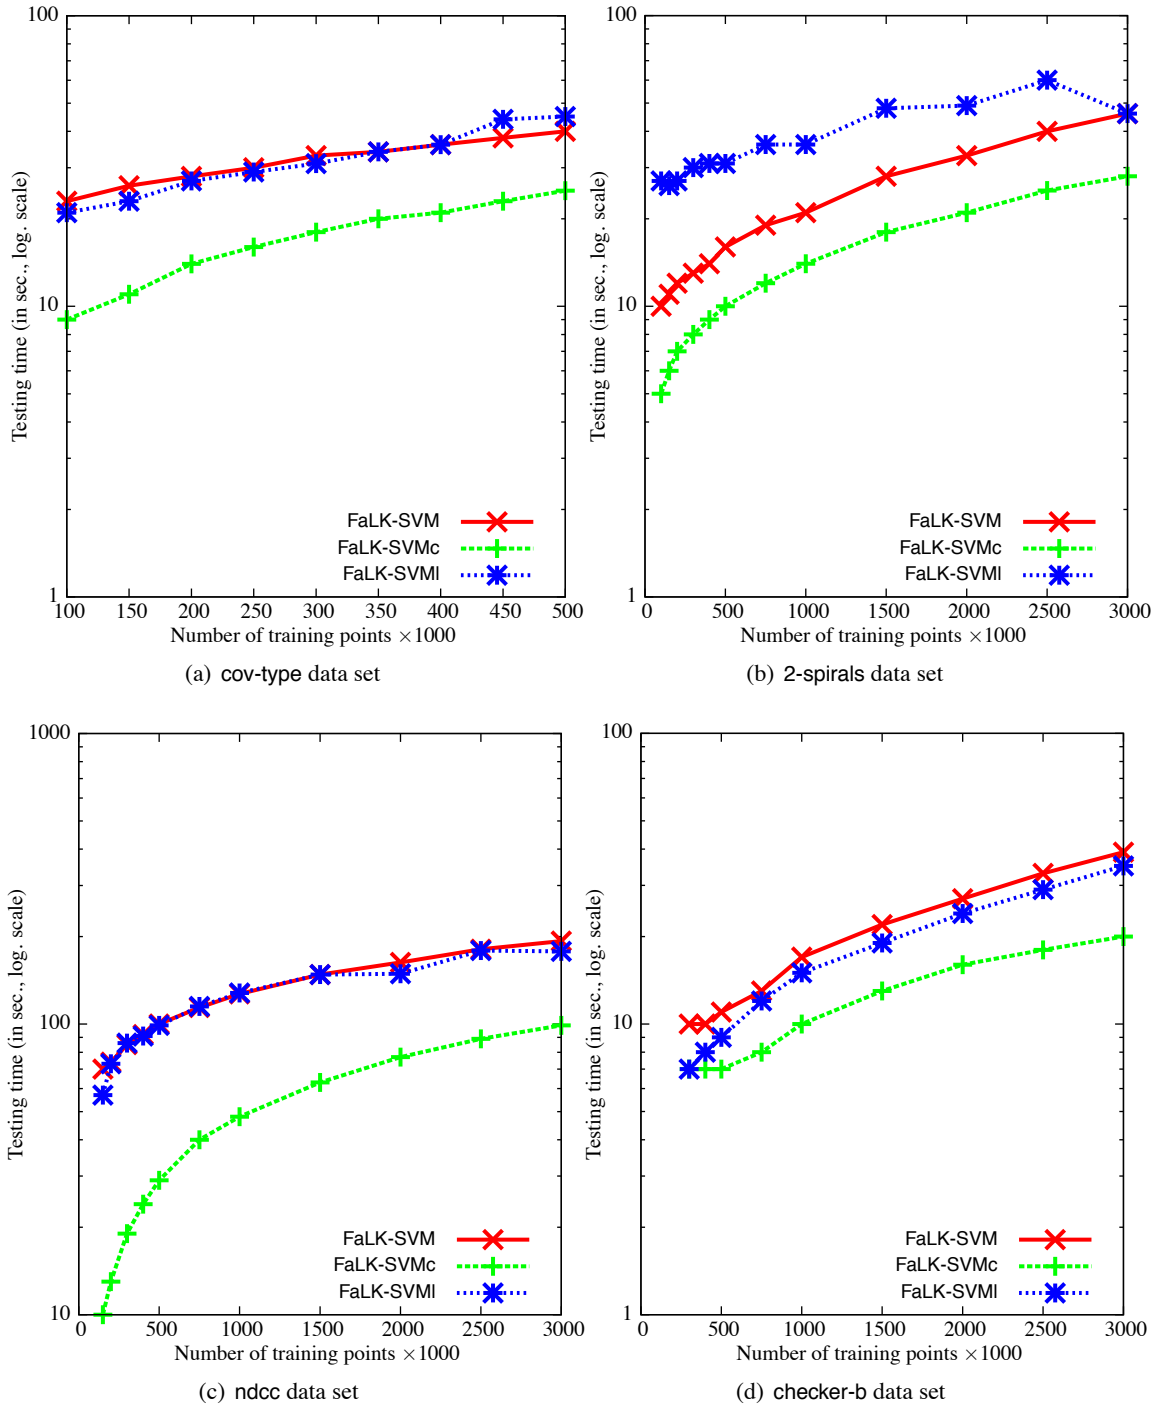

Figure 8: Testing times of FaLK-SVM, FaLK-SVMc, and FaLK-SVMl on the cov-type, 2-spirals, ndcc and checker-b data sets with increasing training set sizes (Experiment 3). The times (in seconds) are reported in logarithmic scale.

only difference between FaLK-SVM and FaLK-SVMl regards the model selection but both classifiers need, during testing, to perform a nearest neighbour search of the query points among all training examples, differently from FaLK-SVMc that performs the nearest neighbour search only among the centres of the local models.

The FaLK-SVMl results permit us to discuss the sensitivity of the local kernel machine approaches with respect to the neighbourhood parameter k. The local model selection of FaLK-SVMl selects different values of k at each application and the k selected by FaLK-SVMl is very often different from the value selected by FaLK-SVM with standard model selection. However, the accuracy results are not very dependent on this as we notice in Figure 6 in which the accuracy variations of FaLK-SVMl as the training sets increase are rather smooth and the accuracies are very similar to FaLK-SVM. So the sensitivity of the accuracies with respect to k for local kernel machines seems to be low at least for large data sets. From the computational viewpoint, instead, we know from the complexity analysis that the advantages of local kernel machines are effective as long as k is substantially lower then N. In our experiments the value of k selected by model selection is bounded to 8000; higher values, although not tested, may decrease the computational performances.

We can conclude that FaLK-SVM, FaLK-SVMc and FaLK-SVMl achieve similar accuracy and computational results. When the model selection for FaLK-SVM and FaLK-SVMc become computationally intractable, FaLK-SVMl is an option to efficiently perform model selection and thus obtain a lower overall training time. When very low testing times are required, FaLK-SVMc is preferable to FaLK-SVM at the price of a slightly lower generalisation accuracy.

6. Conclusions

In this work, we have introduced a new local kernel-based classifier, called FaLK-SVM, that is scalable for large non high-dimensional data. The approach is developed starting from the theory of local learning algorithms and in particular from the Local SVM classifier, called kNNSVM. Various strategies are introduced to overcome the computational problems of kNNSVM and to switch from a completely lazy-learning setting to a eager learning setting with efficient predictions. Learning and complexity bounds for FaLK-SVM are favourable if compared with the SVM ones. FaLK-SVM has, in fact, a training time complexity which is sub-quadratic in the training set size, and a prediction time complexity which is logarithmic. A novel approach for model selection, again based on locality, is introduced obtaining the FaLK-SVMl classifier which substantially unburdens the model selection strategies based on cross-validation. Another variant of the algorithm, calledFaLK-SVMc, permits to simplify the prediction phase. We thus showed that locality can be used to develop computationally efficient classifiers.

We carried out an extensive empirical evaluation of the introduced approaches showing that, for large classification problems requiring non linear decision functions our FaLK-SVM algorithm is much faster and accurate than traditional and approximated SVM solvers. In fact, (i) FaLK-SVM achieves very good accuracy results because it considers all the points without locally under-fitting the data and (ii) FaLK-SVM is very fast and scalable because the cardinality of the local problems can be maintained low. The variant called FaLK-SVMc further enhances testing speed at the price of a little accuracy loss, and the other variant, called FaLK-SVMl, decreases the overall training time.

In general, we have showed that locality can be the key not only for obtaining accurate classifiers, but also for effectively speeding-up kernel-based algorithms.

Further developments of the approach include a dimensionality reduction preprocessing step in order to attack also high-dimensional problems, the application of local classifiers different from SVM, and a distributed parallel version. Also the determination of the critical value of the intrinsic dimensionality (rather than the number of features) above which the local approaches are not effective is still an open question and the answer should be very data-dependent.

Abstract

PAC-Bayes bounds are among the most accurate generalization bounds for classifiers learned from independently and identically distributed (IID) data, and it is particularly so for margin classifiers: there have been recent contributions showing how practical these bounds can be either to perform model selection (Ambroladze et al., 2007) or even to directly guide the learning of linear classifiers (Germain et al., 2009). However, there are many practical situations where the training data show some dependencies and where the traditional IID assumption does not hold. Stating generalization bounds for such frameworks is therefore of the utmost interest, both from theoretical and practical standpoints. In this work, we propose the first—to the best of our knowledge—PAC-Bayes generalization bounds for classifiers trained on data exhibiting interdependencies. The approach undertaken to establish our results is based on the decomposition of a so-called dependency graph that encodes the dependencies within the data, in sets of independent data, thanks to graph *fractional covers*. Our bounds are very general, since being able to find an upper bound on the fractional chromatic number of the dependency graph is sufficient to get new PAC-Bayes bounds for specific settings. We show how our results can be used to derive bounds for ranking statistics (such as AUC) and classifiers trained on data distributed according to a stationary β-mixing process. In the way, we show how our approach seamlessly allows us to deal with U-processes. As a side note, we also provide a PAC-Bayes generalization bound for classifiers learned on data from stationary φ-mixing distributions.

Keywords: PAC-Bayes bounds, non IID data, ranking, U-statistics, mixing processes

1. Introduction

This introductory section first recalls a few PAC-Bayesian results that set the background of the present work. An overview of our contributions is then given, and results from the literature closely related to ours are described. Lastly, the structure of the paper is provided.

1.1 Background

Recently, there has been much progress in the field of generalization bounds for classifiers, the most noticeable of which are Rademacher-complexity-based bounds (Bartlett and Mendelson, 2002; Bartlett et al., 2005), stability-based bounds (Bousquet and Elisseeff, 2002) and PAC-Bayes bounds (McAllester, 1999). PAC-Bayes bounds, introduced by McAllester (1999), and refined in several occasions (Seeger, 2002a; Langford, 2005; Audibert and Bousquet, 2007), are some of the most appealing advances from the tightness and accuracy points of view (an excellent monograph on the PAC-Bayesian framework is that of Catoni (2007)). Among others, striking results have been obtained concerning PAC-Bayes bounds for linear classifiers: Ambroladze et al. (2007) showed that PAC-Bayes bounds are a viable route to do actual model selection; Germain et al. (2009) recently proposed to learn linear classifiers by directly minimizing the linear PAC-Bayes bound with conclusive results, while Langford and Shawe-taylor (2002) showed that under some margin assumption, the PAC-Bayes framework allows one to tightly bound not only the risk of the stochastic Gibbs classifier (see below) but also the risk of the Bayes classifier. The variety of (algorithmic, theoretical, practical) outcomes that can be expected from original contributions in the PAC-Bayesian setting explains and justifies the increasing interest it generates.

1.2 Contribution

To the best of our knowledge, PAC-Bayes bounds have essentially been derived for the setting where the training data are *independently and identically distributed* (IID). Yet, being able to learn from non-IID data while having strong theoretical guarantees on the generalization properties of the learned classifier is an actual problem in a number of real world applications such as, for instance, bipartite ranking (and more generally k-partite ranking) or classification from sequential data. Here, we propose the first PAC-Bayes bounds for classifiers trained on non-IID data; they constitute a generalization of the IID PAC-Bayes bound and they are generic enough to provide a principled way to establish generalization bounds for a number of non-IID settings. To establish these bounds, we make use of simple tools from probability theory, convexity properties of some functions, and we exploit the notion of *fractional covers* of graphs (Schreinerman and Ullman, 1997). One way to get a high level view of our contribution is the following: fractional covers allow us to cope with the dependencies within the set of random variables at hand by providing a strategy to make (large) subsets of independent random variables on which the usual IID PAC-Bayes bound is applied. Note that we essentially provide bounds for the case of *identically and non-independently* distributed data; the additional results that we give in the appendix generalizes to *non-identically and non-independently* distributed data.

1.3 Related Results

We would like to mention that the idea of dealing with sums of interdependent random variables by separating them into subsets of independent variables to establish concentration inequalities dates

back to the work of Hoeffding (1948, 1963) on U-statistics. Explicitly using the notion of (fractional) covers—or, equivalently, colorings—of graphs to derive such concentration inequalities has been proposed by Pemmaraju (2001) and Janson (2004) and later extended by Usunier et al. (2006) to deal with functions that are different from the sum. Just as Usunier et al. (2006), who used their concentration inequality to provide generalization bounds based on the *fractional Rademacher complexity*, we take the approach of decomposing a set of dependent random variables into subsets of dependent random variables a step beyond establishing concentration inequality to provide what we call *chromatic* PAC-Bayes generalization bounds.

The genericity of our bounds is illustrated in several ways. It allows us to derive generalization bounds on the ranking performance of scoring/ranking functions using two different performance measures, among which the *area under the* ROC *curve* (AUC) . These bounds are directly related to the work of Agarwal et al. (2005), Agarwal and Niyogi (2009), Clémençon et al. (2008) and Freund et al. (2003). Even if our bounds are obtained as simple specific instances of our generic PAC-Bayes bounds, they exhibit interesting peculiarities. Compared with the bound of Agarwal et al. (2005) and Freund et al. (2003), our AUC bound depends in a less stronger way on the *skew* (that is, the imbalance between positive and negative data) of the distribution; besides it does not rest on (rank-)shatter coefficients/VC dimension that may sometimes be hard to assess accurately; in addition, our bound directly applies to (kernel-based) linear classifiers. Agarwal and Niyogi (2009) base their analysis of ranking performances on algorithmic stability, and the qualitative comparison of their bounds and ours is not straightforward because stability arguments are somewhat different from the arguments used for PAC-Bayes bounds (and other uniform bounds). As already observed by Janson (2004), coloring provides a way to generalize large deviation results based on U-statistics; this observation carries over when generalization bounds are considered, which allows us to draw a connection between the results we obtain and that of Clémençon et al. (2008).

Another illustration of the genericity of our approach deals with mixing processes. In particular, we show how our chromatic bounds can be used to easily derive new generalization bounds for β-mixing processes. Rademacher complexity based bounds for such type of processes have recently been established by Mohri and Rostamizadeh (2009). To the best of our knowledge, it is the first time that such a bound is given in the PAC-Bayes framework. The striking feature is that it is done at a very low price: the independent block method proposed by Yu (1994) directly gives a dependency graph whose chromatic number is straightforward to compute. As we shall see, this suffices to instantiate our chromatic bounds, which, after simple calculations, leads to appropriate generalization bound. For sake of completeness, we also provide a PAC-Bayes bound for stationary φ-mixing processes; it is based on a different approach and its presentation is postponed to the appendix together with the tools that allows us to derive it.

1.4 Organization of the Paper

The paper is organized as follows. Section 2 recalls the standard IID PAC-Bayes bound. Section 3 introduces the notion of fractional covers and states the new chromatic PAC-Bayes bounds, which rely on the fractional chromatic number of the *dependency graph* of the data at hand. Section 4 provides specific versions of our bounds for the case of IID data, ranking and stationary β-mixing processes, giving rise to original generalization bounds. A PAC-Bayes bound for stationary φ-mixing based on arguments different from the chromatic PAC-Bayes bound is provided, in the appendix.

2. IID PAC-Bayes Bound

We introduce notation that will hold from here on. We mainly consider the problem of binary classification over the *input space* $\mathcal{X}$ and we denote the set of possible labels as $\mathcal{Y} = \{-1, +1\}$ (for the case of ranking described in Section 4, we we use $\mathcal{Y} = \mathcal{R}$); $\mathcal{Z}$ denotes the product space $\mathcal{X} \times \mathcal{Y}$. $\mathcal{H} \subseteq \mathcal{R}^{\mathcal{X}}$ is a family of real valued classifiers defined on $\mathcal{X}$: for $h \in \mathcal{H}$, the predicted output of $x \in \mathcal{X}$ is given by $\text{sign}(h(x))$, where $\text{sign}(x) = +1$ if $x \geq 0$ and -1 otherwise. D is a probability distribution defined over $\mathcal{Z}$ and $\mathbf{D}_m$ denotes the distribution of an m-sample; for instance, $\mathbf{D}_m = \otimes_{i=1}^m D = D^m$ is the distribution of an IID sample $\mathbf{Z} = \{Z_i\}_{i=1}^m$ of size m ($Z_i \sim D$, $i = 1 \ldots m$). P and Q are distributions over $\mathcal{H}$. For any positive integer m, $[m]$ stands for $\{1, \ldots, m\}$.

The IID PAC-Bayes bound, can be stated as follows (McAllester, 2003; Seeger, 2002a; Langford, 2005).

Theorem 1 (IID PAC-Bayes Bound) *$\forall D$, $\forall \mathcal{H}$, $\forall \delta \in (0,1]$, $\forall P$, with probability at least $1-\delta$ over the random draw of $\mathbf{Z} \sim \mathbf{D}_m = D^m$, the following holds:*

$$\forall Q,\ \text{kl}(\hat{e}_Q(\mathbf{Z}) || e_Q) \leq \frac{1}{m}\left[\text{KL}(Q||P) + \ln \frac{m+1}{\delta}\right]. \tag{1}$$

This theorem provides a generalization error bound for the *Gibbs classifier* g_Q: given a distribution Q, this stochastic classifier predicts a class for $\mathbf{x} \in \mathcal{X}$ by first drawing a hypothesis h according to Q and then outputting $\text{sign}(h(\mathbf{x}))$. Here, $\hat{e}_Q$ is the empirical error of g_Q on an IID sample $\mathbf{Z}$ of size m and e_Q is its true error:

$$\begin{aligned} \hat{e}_Q(\mathbf{Z}) &:= \mathbb{E}_{h\sim Q} \frac{1}{m}\sum_{i=1}^m r(h, Z_i) = \mathbb{E}_{h\sim Q}\hat{R}(h,\mathbf{Z}) \quad && \text{with } \hat{R}(h,\mathbf{Z}) := \tfrac{1}{m}\textstyle\sum_{i=1}^m r(h,Z_i), \\ e_Q &:= \mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m}\hat{e}_Q(\mathbf{Z}) = \mathbb{E}_{h\sim Q} R(h) && \text{with } R(h) := \mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m}\hat{R}(h,\mathbf{Z}), \end{aligned} \tag{2}$$

where, for $Z = (X, Y)$,

$$r(h, Z) := \mathbb{I}_{Yh(X)<0}.$$

Note that we will use this binary 0-1 risk function r throughout the paper and that a generalization of our results to bounded real-valued risk functions is given in appendix. Since $\mathbf{Z}$ is an (independently) identically distributed sample, we have

$$R(h) = \mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m}\hat{R}(h,\mathbf{Z}) = \mathbb{E}_{Z\sim D} r(h,Z). \tag{3}$$

For $p, q \in [0,1]$, $\text{kl}(q||p)$ is the Kullback-Leibler divergence between the Bernoulli distributions with probabilities of success q and p, and $\text{KL}(Q||P)$ is the Kullback-Leibler divergence between Q and P:

$$\begin{aligned} \text{kl}(q||p) &:= q \ln \frac{q}{p} + (1-q)\ln\frac{1-q}{1-p}, \\ \text{KL}(Q||P) &:= \mathbb{E}_{h\sim Q} \ln \frac{Q(h)}{P(h)}, \end{aligned}$$

where $\text{kl}(0||0) = \text{kl}(1||1) = 0$. All along, we assume that the posteriors are absolutely continuous with respect to their corresponding priors.

It is straightforward to see that the mapping $\mathrm{kl}_q : t \mapsto \mathrm{kl}(q||q+t)$ is strictly increasing for $t \in [0, 1-q)$ and therefore defines a bijection from $[0, 1-q)$ to $\mathcal{R}_+$: we denote by kl_q^{-1} its inverse. Then, as pointed out by Seeger (2002a), the function $\mathrm{kl}^{-1} : (q, \varepsilon) \mapsto \mathrm{kl}^{-1}(q, \varepsilon) = \mathrm{kl}_q^{-1}(\varepsilon)$ is well-defined over $[0,1) \times \mathcal{R}^+$, and, by definition:

$$t \geq \mathrm{kl}^{-1}(q, \varepsilon) \Leftrightarrow \mathrm{kl}(q||q+t) \geq \varepsilon.$$

This makes it possible to rewrite bound (1) in a more 'usual' form:

$$\forall Q,\ e_Q \leq \hat{e}_Q(\mathbf{Z}) + \mathrm{kl}^{-1}\left(\hat{e}_Q(\mathbf{Z}), \frac{1}{m}\left[\mathrm{KL}(Q||P) + \ln\frac{m+1}{\delta}\right]\right). \tag{4}$$

We observe that even if bounds (1) and (4) apply to the risk e_Q of the stochastic classifier g_Q, a straightforward argument gives that, if b_Q is the (deterministic) Bayes classifier such that $b_Q(x) = \mathrm{sign}(\mathbb{E}_{h\sim Q} h(x))$, then $R(b_Q) = \mathbb{E}_{Z\sim D} r(b_Q, Z) \leq 2e_Q$ (see for instance Herbrich and Graepel, 2001). Langford and Shawe-taylor (2002) show that under some margin assumption, $R(b_Q)$ can be bounded even more tightly.

3. Chromatic PAC-Bayes Bounds

The problem we focus on is that of generalizing Theorem 1 to the situation where there may exist probabilistic dependencies between the elements Z_i of $\mathbf{Z} = \{Z_i\}_{i=1}^m$ while the marginal distributions of the Z_i's are identical. As announced before, we provide PAC-Bayes bounds for classifiers trained on identically but not independently distributed data. These results rely on properties of a dependency graph that is built according to the dependencies within $\mathbf{Z}$. Before stating our new bounds, we thus introduce the concepts of graph theory that will play a role in their statements.

3.1 Dependency Graph, Fractional Covers

Definition 2 (Dependency Graph) *Let $\mathbf{Z} = \{Z_i\}_{i=1}^m$ be a set of m random variables taking values in some space $\mathcal{Z}$. The* dependency graph $\Gamma(\mathbf{Z}) = (V, E)$ *of $\mathbf{Z}$ is such that:*

- *the set of vertices V of $\Gamma(\mathbf{Z})$ is $V = [m]$;*
- *$(i, j) \notin E$ (there is no edge between i and j) $\Leftrightarrow$ Z_i and Z_j are independent.*

Definition 3 (Fractional Covers, Schreinerman and Ullman, 1997) *Let $\Gamma = (V, E)$ be an undirected graph, with $V = [m]$.*

- *$C \subseteq V$ is* independent *if the vertices in C are independent (no two vertices in C are connected).*
- *$\mathbf{C} = \{C_j\}_{j=1}^n$, with $C_j \subseteq V$, is a* proper cover *of V if each C_j is independent and $\bigcup_{j=1}^n C_j = V$. It is* exact *if $\mathbf{C}$ is a partition of V. The size of $\mathbf{C}$ is n.*
- *$\mathbf{C} = \{(C_j, \omega_j)\}_{j=1}^n$, with $C_j \subseteq V$ and $\omega_j \in [0,1]$, is a* proper exact fractional cover *of V if each C_j is independent and $\forall i \in V$, $\sum_{j=1}^n \omega_j \mathbb{I}_{i\in C_j} = 1$; $\omega(\mathbf{C}) = \sum_{j=1}^n \omega_i$ is the* chromatic weight *of $\mathbf{C}$.*
- *The (fractional) chromatic number $\chi(\Gamma)$ ($\chi^*(\Gamma)$) is the minimum size (chromatic weight) over all proper exact (fractional) covers of Γ*

A cover is a fractional cover such that all the weights ω_i are equal to 1 (and all the results we state for fractional covers apply to the case of covers). If n is the size of a cover, it means that the nodes of the graph at hand can be colored with n colors in a way such that no two adjacent nodes receive the same color.

The problem of computing the (fractional) chromatic number of a graph is NP-hard (Schreinerman and Ullman, 1997). However, for some particular graphs as those that come from the settings we study in Section 4, this number can be evaluated precisely. If it cannot be evaluated, it can be upper bounded using the following property.

Property 1 (Schreinerman and Ullman, 1997) *Let $\Gamma = (V,E)$ be a graph. Let $c(\Gamma)$ be the* clique number *of Γ, that is, the order of the largest clique in Γ. Let $\Delta(\Gamma)$ be the maximum degree of a vertex in Γ. We have the following inequalities:*

$$1 \leq c(\Gamma) \leq \chi^*(\Gamma) \leq \chi(\Gamma) \leq \Delta(\Gamma) + 1.$$

In addition, $1 = c(\Gamma) = \chi^*(\Gamma) = \chi(\Gamma) = \Delta(\Gamma) + 1$ if and only if Γ is totally disconnected.

If $\mathbf{Z} = \{Z_i\}_{i=1}^m$ is a set of random variables over $\mathcal{Z}$ then a (fractional) proper cover of $\Gamma(\mathbf{Z})$, splits $\mathbf{Z}$ into subsets of independent random variables. This is a crucial feature to establish our results. In addition, we can see $\chi^*(\Gamma(\mathbf{Z}))$ and $\chi(\Gamma(\mathbf{Z}))$ as measures of the amount of dependencies within $\mathbf{Z}$.

The following lemma (Lemma 3.1 in Janson, 2004) will be very useful in the following.

Lemma 4 *If $\mathbf{C} = \{(C_j, \omega_j)\}_{j=1}^n$ is an exact fractional cover of $\Gamma = (V,E)$, with $V = [m]$, then*

$$\forall \mathbf{t} \in \mathcal{R}^m, \ \sum_{i=1}^m t_i = \sum_{j=1}^n \omega_j \sum_{k \in C_j} t_k.$$

In particular, $m = \sum_{j=1}^n \omega_j |C_j|$.

3.2 Chromatic PAC-Bayes Bounds

We now provide new PAC-Bayes bounds for classifiers trained on samples $\mathbf{Z}$ drawn from distributions $\mathbf{D}_m$ where dependencies exist. We assume these dependencies are fully determined by $\mathbf{D}_m$ and we define the dependency graph $\Gamma(\mathbf{D}_m)$ of $\mathbf{D}_m$ to be $\Gamma(\mathbf{D}_m) = \Gamma(\mathbf{Z})$. As said before, the marginal distributions of $\mathbf{D}_m$ along each coordinate are the same and are equal to some distribution D.

We introduce additional notation. $\text{PEFC}(\mathbf{D}_m)$ is the set of proper exact fractional covers of $\Gamma(\mathbf{D}_m)$. Given a cover $\mathbf{C} = \{(C_j, \omega_j)\}_{j=1}^n \in \text{PEFC}(\mathbf{D}_m)$, we use the following notation:

- $\mathbf{Z}^{(j)} = \{Z_k\}_{k \in C_j}$;
- $\mathbf{D}_m^{(j)}$, the distribution of $\mathbf{Z}^{(j)}$: it is equal to $D^{|C_j|} = \otimes_{i=1}^{|C_j|} D$ (C_j is independent);
- $\alpha = (\alpha_j)_{1 \leq j \leq n}$ with $\alpha_j = \omega_j / \omega(\mathbf{C})$: we have $\alpha_j \geq 0$ and $\sum_j \alpha_j = 1$;
- $\pi = (\pi_j)_{1 \leq j \leq n}$, with $\pi_j = \omega_j |C_j| / m$: we have $\pi_j \geq 0$ and $\sum_j \pi_j = 1$ (cf. Lemma 4).

In addition, $\mathbf{P}_n$ and $\mathbf{Q}_n$ denote distributions over $\mathcal{H}^n$, P_n^j and Q_n^j are the marginal distributions of $\mathbf{P}_n$ and $\mathbf{Q}_n$ with respect to the jth coordinate, respectively.

We can now state our main results.

Theorem 5 (Chromatic PAC-Bayes Bound (I)) $\forall \mathbf{D}_m,\ \forall \mathcal{H},\ \forall \delta \in (0,1],\ \forall \mathbf{C} = \{(C_j, \omega_j)\}_{j=1}^n \in \text{PEFC}(\mathbf{D}_m),\ \forall \mathbf{P}_n$, *with probability at least* $1-\delta$ *over the random draw of* $\mathbf{Z} \sim \mathbf{D}_m$, *the following holds:*

$$\forall \mathbf{Q}_n,\ \text{kl}(\bar{e}_{\mathbf{Q}_n}(\mathbf{Z}) || e_{\mathbf{Q}_n}) \leq \frac{\omega}{m}\left[\sum_{j=1}^n \alpha_j \text{KL}(Q_n^j || P_n^j) + \ln \frac{m+\omega}{\delta\omega}\right], \tag{5}$$

where ω *stands for* $\omega(\mathbf{C})$, *and*

$$\bar{e}_{\mathbf{Q}_n}(\mathbf{Z}) := \sum_{j=1}^n \pi_j \mathbb{E}_{h\sim Q_n^j} \hat{R}(h, \mathbf{Z}^{(j)}),$$
$$e_{\mathbf{Q}_n} := \mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m} \bar{e}_{\mathbf{Q}_n}(\mathbf{Z}).$$

Proof Deferred to Section 3.4. ■

We would like to emphasize that the same type of result, using the same proof techniques, can be obtained if simple (that is, not exact nor proper) fractional covers are considered. However, as we shall see, the 'best' (in terms of tightness) bound is achieved for covers from the set of proper exact fractional covers, and this is the reason why we have stated Theorem 5 with a restriction to this particular set of covers.

The empirical quantity $\bar{e}_{\mathbf{Q}_n}(\mathbf{Z})$ is a weighted average of the empirical errors on $\mathbf{Z}^{(j)}$ of Gibbs classifiers with respective distributions Q_n^j. The following proposition characterizes $e_{\mathbf{Q}_n} = \mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m} \bar{e}_{\mathbf{Q}_n}(\mathbf{Z})$.

Proposition 6 $\forall \mathbf{D}_m, \forall \mathcal{H}, \forall \mathbf{C} = \{(C_j, \omega_j)\}_{j=1}^n \in \text{PEFC}(\mathbf{D}_m), \forall \mathbf{Q}_n$: $e_{\mathbf{Q}_n} = \mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m} \bar{e}_{\mathbf{Q}_n}(\mathbf{Z})$ *is the error of the Gibbs classifier based on the mixture of distributions* $Q^\pi = \sum_{j=1}^n \pi_j Q_n^j$.

Proof From the definition of π, $\pi_j \geq 0$ and $\sum_{j=1}^n \pi_j = 1$. Thus,

$$\begin{aligned}
\mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m} \bar{e}_{\mathbf{Q}_n}(\mathbf{Z}) &= \mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m} \sum_j \pi_j \mathbb{E}_{h\sim Q_n^j} \hat{R}(h, \mathbf{Z}^{(j)}) \\
&= \sum_j \pi_j \mathbb{E}_{h\sim Q_j} \mathbb{E}_{\mathbf{Z}^{(j)}\sim\mathbf{D}_m^{(j)}} \hat{R}(h, \mathbf{Z}^{(j)}) && \text{(marginalization)} \\
&= \sum_j \pi_j \mathbb{E}_{h\sim Q_n^j} R(h) && (\mathbb{E}_{\mathbf{Z}^{(j)}\sim\mathbf{D}_m^{(j)}} \hat{R}(h, \mathbf{Z}^{(j)}) = R(h), \forall j) \\
&= \mathbb{E}_{h\sim\pi_1 Q_n^1 + \ldots + \pi_j Q_n^j} R(h) = \mathbb{E}_{h\sim Q^\pi} R(h).
\end{aligned}$$

Where, in the third line, we have used the fact that the variables in $\mathbf{Z}^{(j)}$ are identically distributed (by assumption, they are IID). ■

Remark 7 *The prior* $\mathbf{P}_n$ *and the posterior* $\mathbf{Q}_n$ *enter into play in Proposition 6 and Theorem 5 through their marginals only. This advocates for the following learning scheme. Given a cover and a (possibly factorized) prior* $\mathbf{P}_n$, *look for a factorized posterior* $\mathbf{Q}_n = \otimes_{j=1}^n Q_j$ *such that each* Q_j *independently minimizes the usual* IID PAC*-Bayes bound given in Theorem 1 on each* $\mathbf{Z}^{(j)}$. *Then make predictions according to the Gibbs classifier defined with respect to* $Q^\pi = \sum_j \pi_j Q_j$.

The following theorem gives a result that readily applies without choosing a specific cover.

Theorem 8 (Chromatic PAC-Bayes Bound (II)) $\forall \mathbf{D}_m$, $\forall \mathcal{H}$, $\forall \delta \in (0,1]$, $\forall P$, *with probability at least* $1-\delta$ *over the random draw of* $\mathbf{Z} \sim \mathbf{D}_m$, *the following holds*

$$\forall Q,\ \mathrm{kl}(\hat{e}_Q(\mathbf{Z})||e_Q) \leq \frac{\chi^*}{m}\left[\mathrm{KL}(Q||P) + \ln\frac{m+\chi^*}{\delta\chi^*}\right], \tag{6}$$

where χ^* *is the fractional chromatic number of* $\Gamma(\mathbf{D}_m)$, *and where* $\hat{e}_Q(\mathbf{Z})$ *and* e_Q *are as in (2).*

Proof This theorem is just a particular case of Theorem 5. Assume that $\mathbf{C} = \{(C_j, \omega_j)\}_{j=1}^n \in \mathrm{PEFC}(\mathbf{D}_m)$ such that $\omega(C) = \chi^*(\Gamma(\mathbf{D}_m))$, $\mathbf{P}_n = \otimes_{j=1}^n P = P^n$ and $\mathbf{Q}_n = \otimes_{j=1}^n Q = Q^n$, for some P and Q.

For the right-hand side of (6), it directly comes that

$$\sum_j \alpha_j \mathrm{KL}(Q_n^j||P_n^j) = \sum_j \alpha_j \mathrm{KL}(Q||P) = \mathrm{KL}(Q||P).$$

It then suffices to show that $\bar{e}_{\mathbf{Q}_n}(\mathbf{Z}) = \hat{e}_Q(\mathbf{Z})$:

$$\begin{aligned}
\bar{e}_{\mathbf{Q}_n}(\mathbf{Z}) &= \sum_j \pi_j \mathbb{E}_{h\sim Q_n^j} \hat{R}(h, \mathbf{Z}^{(j)}) = \sum_j \pi_j \mathbb{E}_{h\sim Q} \hat{R}(h, \mathbf{Z}^{(j)}) \\
&= \frac{1}{m}\sum_j \omega_j |C_j| \mathbb{E}_{h\sim Q} \frac{1}{|C_j|}\sum_k r(h, Z_k) && (\pi_j = \tfrac{\omega_j|C_j|}{m}, \forall j) \\
&= \mathbb{E}_{h\sim Q} \frac{1}{m}\sum_j \omega_j \sum_k r(h, Z_k) \\
&= \mathbb{E}_{h\sim Q} \frac{1}{m}\sum_i r(h, Z_i) && \text{(cf. Lemma 4)} \\
&= \mathbb{E}_{h\sim Q} \hat{R}(h, \mathbf{Z}) = \hat{e}_Q(\mathbf{Z}).
\end{aligned}$$

■

A few comments are in order.

- A χ^* worsening. This theorem says that even in the case of non IID data, a PAC-Bayes bound very similar to the IID PAC-Bayes bound (1) can be stated, with a worsening (since $\chi^* \geq 1$) proportional to χ^*, that is, proportional to the amount of dependencies in the data. In addition, the new PAC-Bayes bounds is valid with any priors and posteriors, without the need for these distributions to depend on the chosen cover (as is the case with the more general Theorem 5).

- χ^*: the optimal constant. Among all elements of $\mathrm{PEFC}(\mathbf{D}_m)$, χ^* is the best constant achievable in terms of the tightness of the bound (6) on e_Q: getting an optimal coloring gives rise to an 'optimal' bound. Indeed, it suffices to observe that the right-hand side of (5) is decreasing with respect to ω when all Q_n^j are identical (we let the reader check that). As χ^* is the smallest chromatic weight, it gives the tightest bound.

- $\Gamma(\mathbf{D}_m)$ vs. induced subgraphs. If $\mathbf{s} \subseteq [m]$ and $\mathbf{Z}_\mathbf{s} = \{Z_s : s \in \mathbf{s}\}$, it is obvious that Theorem 8 holds for $|\mathbf{s}|$-samples drawn from the marginal distribution $\mathbf{D}_\mathbf{s}$ of $\mathbf{Z}_\mathbf{s}$. Considering only $\mathbf{Z}_\mathbf{s}$ amounts to working with the subgraph $\Gamma(\mathbf{D}_\mathbf{s})$ of $\Gamma(\mathbf{D}_m)$ induced by the vertices in $\mathbf{s}$: this

(a) $\Gamma_{\text{1-edge}}$ (b) Γ_u

Figure 1: Γ_u is the subgraph induced by $\Gamma_{\text{1-edge}}$ (which contains only one edge, between u and v) when u is removed: it might be preferable to consider the distribution corresponding to Γ_u in Theorem 8 instead of the distribution defined wrt $\Gamma_{\text{1-edge}}$, since $\chi^*(\Gamma_{\text{1-edge}}) = 2$ and $\chi^*(\Gamma_u) = 1$ (see text for detailed comments).

might provide a better bound in situations where $\chi^*(\mathbf{D}_\mathbf{s})/|\mathbf{s}|$ is smaller than $\chi^*(\mathbf{D}_m)/m$ (this is not guaranteed, however, because the empirical error $\hat{e}_Q(\mathbf{Z}_\mathbf{s})$ computed on $\mathbf{Z}_\mathbf{s}$ might be larger than $\hat{e}_Q(\mathbf{Z})$). To see this, consider a graph $\Gamma_{\text{1-edge}} = (V,E)$ of m vertices where $|E| = 1$, that is, there are only two nodes, say u and v, that are connected (see Figure 1). The fractional chromatic number $\chi^*_{\text{1-edge}}$ of $\Gamma_{\text{1-edge}}$ is 2 (u and v must use distinct colors) while the (fractional) chromatic number χ^*_u of the subgraph Γ_u of $\Gamma_{\text{1-edge}}$ obtained by removing u is 1: $\chi^*_{\text{1-edge}}$ is twice as big as χ^*_u while the number of nodes only differ by 1 and, for large m, this ratio roughly carries over for $\chi^*_{\text{1-edge}}/m$ and $\chi^*_u/(m-1)$.

This last comment outlines that considering a subset of $\mathbf{Z}$, or, equivalently, a subgraph of $\Gamma(\mathbf{D}_m)$, in (6), might provide a better generalization bound. However, it is assumed that the choice of the subgraph is done *before* computing the bound: the bound does only hold with probability $1-\delta$ for the chosen subgraph. To alleviate this and provide a bound that takes advantage of several induced subgraphs, we have the following proposition:

Proposition 9 *Let* $\{m\}^{\#k}$ *denote* $\{\mathbf{s} : \mathbf{s} \subseteq [m], |\mathbf{s}| = m-k\}$. $\forall \mathbf{D}_m, \forall \mathcal{H}, \forall k \in [m], \forall \delta \in (0,1], \forall P$, *with probability at least* $1-\delta$ *over the random draw of* $\mathbf{Z} \sim \mathbf{D}_m$: $\forall Q$,

$$e_Q \leq \min_{\mathbf{s} \in \{m\}^{\#k}} \left\{ \hat{e}_Q(\mathbf{Z}_\mathbf{s}) + \mathrm{kl}^{-1}\left(\hat{e}_Q(\mathbf{Z}_\mathbf{s}), \frac{\chi^*_\mathbf{s}}{|\mathbf{s}|}\left[\mathrm{KL}(Q||P) + \ln \frac{|\mathbf{s}| + \chi^*_\mathbf{s}}{\chi^*_\mathbf{s}} + \ln \binom{m}{k} + \ln \frac{1}{\delta} \right] \right) \right\}.$$

where $\chi^*_\mathbf{s}$ *is the fractional chromatic number of* $\Gamma(\mathbf{D}_\mathbf{s})$, *and where* $\hat{e}_Q(\mathbf{Z}_\mathbf{s})$ *is the empirical error of the Gibbs classifier* g_Q *on* $\mathbf{Z}_\mathbf{s}$, *that is:* $\hat{e}_Q(\mathbf{Z}_\mathbf{s}) = \mathbb{E}_{h\sim Q}\hat{R}(h, \mathbf{Z}_\mathbf{s})$.

Proof Simply apply the union bound to Equation (6) of Theorem 8: for fixed k, there are $\binom{m}{m-k} = \binom{m}{k}$ subgraphs and using $\delta/\binom{m}{k}$ makes the bound hold with probability $1-\delta$ for all possible $\binom{m}{k}$ subgraphs (simultaneously). Making use of the form (4) gives the result. ■

This bound is particularly useful when, for some small k, there exists a subset $\mathbf{s} \subseteq \{m\}^{\#k}$ such that the induced subgraph $\Gamma(\mathbf{D}_\mathbf{s})$, which has k fewer nodes than $\Gamma(\mathbf{D}_m)$, has a fractional chromatic number $\chi^*_\mathbf{s}$ that is smaller than $\chi^*(\mathbf{D}_m)$ (as is the case with the graph $\Gamma_{\text{1-edge}}$ of Figure 1, where $k = 1$). Obtaining a similar result that holds for subgraphs associated with sets $\mathbf{s}$ of sizes *larger or equal* to $m-k$ is possible by replacing $\ln\binom{m}{k}$ with $\ln\sum_{\kappa=0}^{k}\binom{m}{\kappa}$ in the bound (in that case, k should be kept small enough with respect to m—for example, $k = O_m(1)$—to ensure that the resulting bound still goes down to zero when $m \to \infty$).

3.3 On the Relevance of Fractional Covers

One may wonder whether using the fractional cover framework is the only way to establish a result similar to the one provided by Theorem 5. Of course, this is not the case and one may imagine other ways of deriving closely related results without mentioning the idea of fractional/cover coloring. (For instance, one may manipulate subsets of independent variables, assign weights to these subsets without referring to fractional covers, and arrive at results that are comparable to ours.)

However, if we assume that singling out independent sets of variables is the cornerstone of dealing with interdependent random variables, we find it enlightening to cast our approach within the rich and well-studied fractional cover/coloring framework. On the one hand, our objective of deriving tight bounds amounts to finding a decomposition of the set of random variables at hand into *few and large* independent subsets and taking the graph theory point of view, this obviously corresponds to a problem of graph coloring. Explicitly using the fractional cover/coloring argument allows us to directly benefit from the wealth of related results, such as Property 1 or, for instance, approaches as to how compute a cover or approximate the fractional chromatic number (for instance, linear programming). On the other hand, from a technical point of view, making use of the fractional cover argument allows us to preserve the simple structure of the proof of the classical IID PAC-Bayes bound to derive Theorem 5.

To summarize, the richness of the results on graph (fractional) coloring provides us with elegant tools to deal with a natural representation of the dependencies that may occur within a set of random variables. In addition, and as showed in this article, it is possible to seamlessly take advantage of these tools in the PAC-Bayesian framework (and probably in other bound-related frameworks).

3.4 Proof of Theorem 5

A proof in three steps, following the lines of the proofs given by Seeger (2002a) and Langford (2005) for the IID PAC-Bayes bound, can be provided.

Lemma 10 *$\forall \mathbf{D}_m$, $\forall \delta \in (0,1]$, $\forall \mathbf{C} = \{(C_j, \omega_j)\}_{j=1}^n$, $\forall \mathbf{P}_n$ distribution over $\mathcal{H}^n$, with probability at least $1-\delta$ over the random draw of $\mathbf{Z} \sim \mathbf{D}_m$, the following holds (here, ω stands for $\omega(\mathbf{C})$)*

$$\mathbb{E}_{\mathbf{h}\sim\mathbf{P}_n} \sum_{j=1}^{n} \alpha_j e^{|C_j|\,\mathrm{kl}(\hat{R}(h_j,\mathbf{Z}^{(j)})||R(h_j))} \leq \frac{m+\omega}{\delta\omega},$$

where $\mathbf{h} = (h_1, \ldots, h_n)$ is a random vector of hypotheses.

Proof We first observe the following:

$$\begin{aligned}
\mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m} \sum_j \alpha_j e^{|C_j|\,\mathrm{kl}(\hat{R}(h_j,\mathbf{Z}^{(j)})||R(h_j))} &= \sum_j \alpha_j \mathbb{E}_{\mathbf{Z}^{(j)}\sim\mathbf{D}_m^{(j)}} e^{|C_j|\,\mathrm{kl}(\hat{R}(h,\mathbf{Z}^{(j)})||R(h))} \\
&\leq \sum_j \alpha_j (|C_j|+1) && \text{(Lemma 20, Appendix)} \\
&= \frac{1}{\omega} \sum_j \omega_j (|C_j|+1) \\
&= \frac{m+\omega}{\omega}, && \text{(Lemma 4)}
\end{aligned}$$

where using Lemma 20 is made possible by the fact that $\mathbf{Z}^{(j)}$ is an IID sample. Therefore,

$$\mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m}\mathbb{E}_{\mathbf{h}\sim\mathbf{P}_n}\sum_{j=1}^{n}\alpha_j e^{|C_j|\,\mathrm{kl}(\hat{R}(h_j,\mathbf{Z}^{(j)})||R(h_j))} \leq \frac{m+\omega}{\omega}.$$

According to Markov's inequality (Theorem 22, Appendix),

$$\mathbb{P}_{\mathbf{Z}}\left(\mathbb{E}_{\mathbf{h}\sim\mathbf{P}_n}\sum_{j}\alpha_j e^{|C_j|\,\mathrm{kl}(\hat{R}(h_j,\mathbf{Z}^{(j)})||R(h_j))} \geq \frac{m+\omega}{\omega\delta}\right) \leq \delta.$$

■

Lemma 11 *$\forall\mathbf{D}_m$, $\forall\mathbf{C}=\{(C_j,\omega_j)\}_{j=1}^n$, $\forall\mathbf{P}_n$, $\forall\mathbf{Q}_n$, with probability at least $1-\delta$ over the random draw of $\mathbf{Z}\sim\mathbf{D}_m$, the following holds*

$$\frac{m}{\omega}\sum_{j=1}^{n}\pi_j\mathbb{E}_{h\sim Q_n^j}\mathrm{kl}(\hat{R}(h,\mathbf{Z}^{(j)})||R(h)) \leq \sum_{j=1}^{n}\alpha_j\,\mathrm{KL}(Q_n^j||P_n^j)+\ln\frac{m+\omega}{\delta\omega}.$$

Proof It suffices to use Jensen's inequality (Theorem 21, Appendix) with ln and the fact that $\mathbb{E}_{X\sim P}f(X)=\mathbb{E}_{X\sim Q}\frac{P(X)}{Q(X)}f(X)$, for all f,P,Q. Therefore, $\forall\mathbf{Q}_n$:

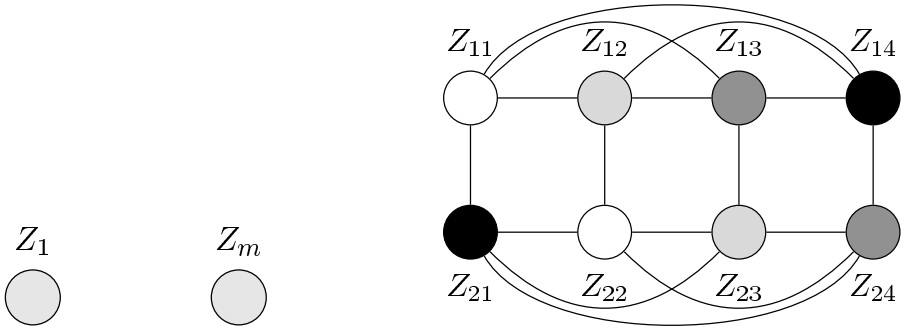
$$\begin{aligned}
\ln\mathbb{E}_{\mathbf{h}\sim\mathbf{P}_n}\sum_{j}\alpha_j e^{|C_j|\,\mathrm{kl}\left(\hat{R}(h_j,\mathbf{Z}^{(j)})||R(h_j)\right)} &= \ln\sum_{j}\alpha_j\mathbb{E}_{h\sim P_n^j}e^{|C_j|\,\mathrm{kl}\left(\hat{R}(h,\mathbf{Z}^{(j)})||R(h)\right)}\\
&= \ln\sum_{j}\alpha_j\mathbb{E}_{h\sim Q_n^j}\frac{P_n^j(h)}{Q_n^j(h)}e^{|C_j|\,\mathrm{kl}\left(\hat{R}(h,\mathbf{Z}^{(j)})||R(h)\right)}\\
&\geq \sum_{j}\alpha_j\mathbb{E}_{h\sim Q_n^j}\ln\left[\frac{P_n^j(h)}{Q_n^j(h)}e^{|C_j|\,\mathrm{kl}\left(\hat{R}(h,\mathbf{Z}^{(j)})||R(h)\right)}\right] \qquad \text{(Jensen's inequality)}\\
&= -\sum_{j}\alpha_j\,\mathrm{KL}(Q_n^j||P_n^j)+\sum_{j}\alpha_j|C_j|\mathbb{E}_{h\sim Q_n^j}\mathrm{kl}\left(\hat{R}(h,\mathbf{Z}^{(j)})||R(h)\right)\\
&= -\sum_{j}\alpha_j\,\mathrm{KL}(Q_n^j||P_n^j)+\frac{m}{\omega}\sum_{j}\pi_j\mathbb{E}_{h\sim Q_n^j}\mathrm{kl}\left(\hat{R}(h,\mathbf{Z}^{(j)})||R(h)\right).
\end{aligned}$$

Lemma 10 then gives the result. ■

Lemma 12 *$\forall\mathbf{D}_m$, $\forall\mathbf{C}=\{(C_j,\omega_j)\}_{j=1}^n$, $\forall\mathbf{Q}_n$,, the following holds*

$$\frac{m}{\omega}\sum_{j=1}^{n}\pi_j\mathbb{E}_{h\sim Q_n^j}\mathrm{kl}(\hat{R}(h,\mathbf{Z}^{(j)})||R(h)) \geq \mathrm{kl}(\bar{e}_Q||e_Q). \tag{7}$$

Proof This simply comes from the convexity of $\mathrm{kl}(x,y)$ in (x,y) (Lemma 23, Appendix). This, in combination with Lemma 11, closes the proof of Theorem 5. ■



(a) IID data (b) Bipartite ranking data

Figure 2: Dependency graphs for different settings described in Section 4. Nodes of the same color are part of the same cover element; hence, they are probabilistically independent. (a) When the data are IID, the dependency graph is disconnected and the fractional number is $\chi^* = 1$; (b) a dependency graph obtained for bipartite ranking from a sample of 4 positive and 2 negative instances: $\chi^* = 4$.

4. Applications

In this section, we provide instances of Theorem 8 for various settings; amazingly, they alllow us to easily derive PAC-Bayes generalization bounds for problems such as ranking and learning from stationary β-mixing processes. The theorems we provide here are all new PAC-Bayes bounds for different non-IID settings.

4.1 IID Case

The first case we are interested in is the IID setting. In this case, the training sample $\mathbf{Z} = \{(X_i, Y_i)\}_{i=1}^m$ is distributed according to $\mathbf{D}_m = D^m$ and the fractional chromatic number of $\Gamma(\mathbf{D}_m)$ is $\chi^* = 1$, since the dependency graph, depicted in Figure 2a is totally disconnected (see Property 1). Plugging in this value of χ^* in the bound of Theorem 8 gives the IID PAC-Bayes bound of Theorem 1. This emphasizes the fact that the standard PAC-Bayes bound is a special case of our more general results.

4.2 General Ranking and Connection to U-Statistics

Here, the learning problem of interest is the following. D is a distribution over $\mathcal{X} \times \mathcal{Y}$ with $\mathcal{Y} = \mathcal{R}$ and one looks for a ranking rule $h \in \mathcal{R}^{\mathcal{X}\times\mathcal{X}}$ that minimizes the *ranking risk* $R^{\text{rank}}(h)$ defined as:

$$R^{\text{rank}}(h) := \mathbb{P}_{\substack{(X,Y)\sim D \\ (X',Y')\sim D}} \left((Y - Y')h(X,X') < 0\right). \tag{8}$$

For a random pair (X,Y), Y can be thought of as a score that allows one to rank objects: given two pairs (X,Y) and (X',Y'), X has a higher rank (or is 'better') than X' if $Y > Y'$. The ranking rule h predicts X to be better than X' if $\text{sign}(h(X,X')) = 1$ and conversely. The objective of learning is to produce a rule h that makes as few misrankings as possible, as measured by (8). Given a finite IID (according to D) sample $\mathbf{S} = \{(X_i, Y_i)\}_{i=1}^{\ell}$ an unbiased estimate of $R^{\text{rank}}(h)$ is $\hat{R}^{\text{rank}}(h, \mathbf{S})$, with:

$$\hat{R}^{\text{rank}}(h, \mathbf{S}) := \frac{1}{\ell(\ell-1)} \sum_{i \neq j} \mathbb{I}_{(Y_i - Y_j)h(X_i,X_j)<0} = \frac{1}{\ell(\ell-1)} \sum_{i \neq j} \mathbb{I}_{Y_{ij}h(X_i,X_j)<0}, \tag{9}$$

where $Y_{ij} := (Y_i - Y_j)$. A natural question is to bound the ranking risk for any learning rule h given $\mathbf{S}$, where the difficulty is that (9) is a sum of identically but not independently random variables, namely the variables $\mathbb{I}_{Y_{ij}h(X_i,X_j)}$.

Let us define $X_{ij} := (X_i, X_j)$, $Z_{ij} := (X_{ij}, Y_{ij})$, and $\mathbf{Z} := \{Z_{ij}\}_{i \neq j}$. We note that the number ℓ of training data suffices to determine the structure of the dependency graph Γ_{rank} of $\mathbf{Z}$ and its distribution, which we denote $\mathbf{D}_{\ell(\ell-1)}$. Henceforth, we are clearly in the framework for the application of the chromatic PAC-Bayes bounds defined in the previous section. In particular, to instantiate Theorem 8 to the present ranking problem, we simply need to have at hand the value χ^*_{rank}, or an upper bound thereof, of the fractional chromatic number of Γ_{rank}. We claim that $\chi^*_{\text{rank}} \leq \ell(\ell-1)/\lfloor \ell/2 \rfloor$ where $\lfloor x \rfloor$ is the largest integer less than or equal to x. We provide the following new PAC-Bayes bound for the ranking risk:

Theorem 13 (Ranking PAC-Bayes bound) *$\forall D$ over $\mathcal{X} \times \mathcal{Y}$, $\forall \mathcal{H} \subseteq \mathcal{R}^{\mathcal{X} \times \mathcal{X}}$, $\forall \delta \in (0,1]$, $\forall P$, with probability at least $1-\delta$ over the random draw of $\mathbf{S} \sim D^\ell$, the following holds*

$$\forall Q,\ \mathrm{kl}(\hat{e}^{rank}_Q(\mathbf{S}) || e^{rank}_Q) \leq \frac{1}{\lfloor \ell/2 \rfloor} \left[\mathrm{KL}(Q||P) + \ln \frac{\lfloor \ell/2 \rfloor + 1}{\delta} \right],$$

where

$$\hat{e}^{rank}_Q(\mathbf{S}) := \mathbb{E}_{h \sim Q} \hat{R}^{rank}(h, \mathbf{S}),$$
$$e^{rank}_Q := \mathbb{E}_{\mathbf{S} \sim D^\ell} \hat{e}^{rank}_Q(\mathbf{S}).$$

Proof We essentially need to prove our claim on the bound on χ^*_{rank}. To do so, we consider a fractional cover of Γ_{rank} motivated by the theory of U-statistics (Hoeffding, 1948, 1963). $\hat{R}(h, \mathbf{S})$ is indeed a U-statistics of order 2 and it might be rewritten as a sum of IID blocks as follows

$$\hat{R}(h, \mathbf{S}) = \frac{1}{\ell(\ell-1)} \sum_{i \neq j} r(h, Z_{ij}) = \frac{1}{\ell!} \sum_{\sigma \in \Sigma_\ell} \frac{1}{\lfloor \ell/2 \rfloor} \sum_{i=1}^{\lfloor \ell/2 \rfloor} r\left(h, Z_{\sigma(i)\sigma(\lfloor \ell/2 \rfloor + i)}\right),$$

where Σ_ℓ is the set of permutations over $[\ell]$. The innermost sum is obviously a sum of IID random variables as no two summands share the same indices.

A proper exact fractional cover $\mathbf{C}_{\text{rank}}$ can be derived from this decomposition as[1]

$$\mathbf{C}_{\text{rank}} := \left\{ \left(C_\sigma := \left\{ Z_{\sigma(i)\sigma(\lfloor \ell/2 \rfloor + i)} \right\}_{i=1}^{\lfloor \ell/2 \rfloor}, \omega_\sigma := \frac{1}{(\ell-2)! \lfloor \ell/2 \rfloor} \right) \right\}_{\sigma \in \Sigma_\ell}.$$

Indeed, as remarked before, each C_σ is an independent set and each random variable Z_{pq} for $p \neq q$, appears in exactly $(\ell-2)! \times \lfloor \ell/2 \rfloor$ sets C_σ (for i fixed, the number of permutations σ such that $\sigma(i) = p$ and $\sigma(\lfloor \ell/2 \rfloor + i) = q$ is equal to $(\ell-2)!$, that is, the number of permutations on $\ell - 2$ elements; as i can take $\lfloor \ell/2 \rfloor$ values, this gives the result). Therefore, $\forall p, q, p \neq q$:

$$\sum_{\sigma \in \Sigma_\ell} \omega_\sigma \mathbb{I}_{Z_{pq} \in C_\sigma} = \frac{1}{(\ell-2)! \lfloor \ell/2 \rfloor} \sum_{\sigma \in \Sigma_\ell} \mathbb{I}_{Z_{pq} \in C_\sigma} = \frac{1}{(\ell-2)! \lfloor \ell/2 \rfloor} \times (\ell-2)! \lfloor \ell/2 \rfloor = 1,$$

1. Note that the cover defined here considers elements C_σ containing random variables themselves instead of their indices. This abuse of notation is made for sake of readability.

which proves that $\mathbf{C}_{\text{rank}}$ is a proper exact fractional cover. Its weight $\omega(\mathbf{C}_{\text{rank}})$ is

$$\omega(\mathbf{C}_{\text{rank}}) = \ell! \times \omega_\sigma = \frac{\ell(\ell-1))}{\lfloor \ell/2 \rfloor}.$$

Hence, from the definition of χ^*_{rank},

$$\chi^*_{\text{rank}} \leq \frac{\ell(\ell-1))}{\lfloor \ell/2 \rfloor}.$$

The theorem follows by an instantiation of Theorem 8 with $m := \ell(\ell-1)$ and the bound on χ^*_{rank} we have just proven. ■

To our knowledge, this is the first PAC-Bayes bound on the ranking risk, while a Rademacher-complexity based analysis was given by Clémençon et al. (2008). In the proof, we have used arguments from the analysis of U-processes, which allow us to easily derive a convenient fractional cover of the dependency graph of $\mathbf{Z}$. Note however that our framework still applies even if not all the Z_{ij}'s are known, as required if an analysis based on U-processes is undertaken. This is particularly handy in practical situations where one may only be given the values Y_{ij}—but *not* the values of Y_i and Y_j—for a limited number of (i, j) pairs (and not all the pairs).

An interesting question is to know how the so-called Hoeffding decomposition used by Clémençon et al. (2008) to establish fast rates of convergence for empirical ranking risk minimizers could be used to draw possibly tighter PAC-Bayes bounds. This would imply being able to appropriately take advantage of moments of order 2 in PAC-Bayes bounds, and a possible direction for that has been proposed by Lacasse et al. (2006). This is left for future work as it is not central to the present paper.

Of course, the ranking rule may be based on a scoring function $f \in \mathcal{R}^{\mathcal{X}}$ such that $h(X,X') = f(X) - f(X')$, in which case all the results that we state in terms of h can be stated similarly in terms of f. This is important to note from a practical point of view as it is probably more usual to learn functions defined over $\mathcal{X}$ rather than $\mathcal{X} \times \mathcal{X}$ (as is h).

Finally, we would like to stress that the bound on χ^*_{rank} that we have exhibited is actually rather tight. Indeed, it is straightforward to see that the clique number of Γ_{rank} is $2(\ell-1)$ (the cliques are made of variables $\{Z_{ip}\}_p \bigcup \{Z_{pi}\}_p$ for every i), and according to Property 1, $2(\ell-1)$ is therefore a lower bound on χ^*_{rank}. If ℓ is even, then our bound on χ^*_{rank} is equal to $2(\ell-1)$ and so is χ^*_{rank}; if ℓ is odd, then our bound is 2ℓ.

4.3 Bipartite Ranking and a Bound on the AUC

A particular ranking setting is that of bipartite ranking, where $\mathcal{Y} = \{-1, +1\}$. Let D be a distribution over $\mathcal{X} \times \mathcal{Y}$ and D_{+1} (D_{-1}) be the class conditional distribution $D_{X|Y=+1}$ ($D_{X|Y=-1}$) with respect to D. In this setting (see, for instance, Agarwal et al., 2005), one may be interested in controlling what we call the *bipartite misranking risk* $R^{\text{AUC}}(h)$ (the reason for the AUC superscript will become clear in the sequel), of a ranking rule $h \in \mathcal{R}^{\mathcal{X}\times\mathcal{X}}$ by

$$R^{\text{AUC}}(h) := \mathbb{P}_{\substack{X\sim D_{+1} \\ X'\sim D_{-1}}} (h(X,X') < 0). \tag{10}$$

Note that the relation between R^{AUC} and R^{rank} (cf. Equation 8) can be made clear whenever the hypotheses h under consideration are such that $h(x,x')$ and $h(x',x)$ have opposite signs. In this situation, it is straightforward to see that

$$R^{\text{rank}}(h) = 2\mathbb{P}(Y=+1)\mathbb{P}(Y=-1)R^{\text{AUC}}(h).$$

Let $\mathbf{S} = \{(X_i, Y_i)\}_{i=1}^{\ell}$ be an IID sample distributed according to $\mathbf{D}_\ell = D^\ell$. The empirical bipartite ranking risk $\hat{R}^{\text{AUC}}(h, \mathbf{S})$ of h on $\mathbf{S}$ defined as

$$\hat{R}^{\text{AUC}}(h, \mathbf{S}) := \frac{1}{\ell^+ \ell^-} \sum_{\substack{i:Y_i=+1 \\ j:Y_j=-1}} \mathbb{I}_{h(X_i,X_j)<0} \tag{11}$$

where ℓ^+ (ℓ^-) is the number of positive (negative) data in $\mathbf{S}$, estimates the fraction of pairs (X_i, X_j) that are incorrectly ranked incorrectly (given that $Y_i = +1$ and $Y_j = -1$) by h: it is an unbiased estimator of $R^{\text{AUC}}(h)$.

As before, h may be expressed in terms of a scoring function $f \in \mathcal{R}^{\mathcal{X}}$ such that $h(X, X') = f(X) - f(X')$, in which case (overloading notation):

$$R^{\text{AUC}}(f) = \mathbb{P}_{\substack{X \sim D_{+1} \\ X' \sim D_{-1}}} (f(X) < f(X')) \text{ and } \hat{R}^{\text{AUC}}(f, \mathbf{S}) = \frac{1}{\ell^+ \ell^-} \sum_{\substack{i:Y_i=+1 \\ j:Y_j=-1}} \mathbb{I}_{f(X_i)<f(X_j)},$$

where we recognize in $\hat{R}^{\text{AUC}}(f, \mathbf{S})$ one minus the Area under the ROC curve, or AUC, of f on $\mathbf{S}$ (Agarwal et al., 2005; Cortes and Mohri, 2004), hence the AUC superscript in the name of the risk. As a consequence, providing a PAC-Bayes bound on $R^{\text{AUC}}(h)$ (or $R^{\text{AUC}}(f)$) amounts to providing a generalization (lower) bound on the AUC, which is a widely used measure in practice to evaluate the performance of a scoring function.

Let us define $X_{ij} := (X_i, X_j)$, $Z_{ij} := (X_{ij}, 1)$ and $\mathbf{Z} := \{Z_{ij}\}_{ij:Y_i=+1, Y_j=-1}$, that is, $\mathbf{Z}$ is a sequence of pairs X_{ij} made of one positive example and one negative example. We then are once again in the framework defined earlier,[2] that is, the Z_{ij}'s share the same distribution but are dependent on each other, since Z_{ij} depends on $\{Z_{pq} : p = i \text{ or } q = j\}$ (see Figure 2). Note that in order to ease the reading of the present subsection, we make the implicit decomposition of training set $\mathbf{S}$ into $\mathbf{S} = \mathbf{S}^+ \cup \mathbf{S}^-$, where $\mathbf{S}^+$ (resp. $\mathbf{S}^-$) is made of the ℓ^+ (ℓ^-) positive (negative) data of $\mathbf{S}$; the size ℓ of $\mathbf{S}$ is therefore $\ell = \ell^+ + \ell^-$. This decomposition entails a separate reindexing of the positive (negative) data from 1 to ℓ^+ (from 1 to ℓ^-).

Building on Theorem 8, we have the following result:

Theorem 14 (AUC PAC-Bayes bound) *$\forall D$ over $\mathcal{X} \times \mathcal{Y}$, $\forall \mathcal{H} \subseteq \mathcal{R}^{\mathcal{X} \times \mathcal{X}}$, $\forall \delta \in (0, 1]$, $\forall P$, with probability at least $1 - \delta$ over the random draw of $\mathbf{S} \sim D^\ell$, the following holds*

$$\forall Q,\ \text{kl}(\hat{e}_Q^{\text{AUC}}(\mathbf{S}) || e_Q^{\text{AUC}}) \leq \frac{1}{\ell_{\min}} \left[\text{KL}(Q||P) + \ln \frac{\ell_{\min} + 1}{\delta} \right],$$

where $\ell_{\min} = \min(\ell^+, \ell^-)$, and

$$\hat{e}_Q^{\text{AUC}}(\mathbf{S}) := \mathbb{E}_{h \sim Q} \hat{R}^{\text{AUC}}(h, \mathbf{S}),$$
$$e_Q^{\text{AUC}} := \mathbb{E}_{\mathbf{S} \sim D^\ell} \hat{e}_Q^{\text{AUC}}(\mathbf{S}).$$

Proof The proof works in three steps and borrows ideas from Agarwal et al. (2005). The first two parts are necessary to deal with the fact that the dependency graph of $\mathbf{Z}$, as it depends on the random sample $\mathbf{S}$, does not have a deterministic structure.

2. The slight difference with what has been described above is that the dependency graph is now a random variable: it depends on the Y_i's. It is shown in the proof of Theorem 14 how this can be dealt with.

4.3.1 CONDITIONING ON $\mathbf{Y} = \mathbf{y}$

Let $\mathbf{y} \in \{-1,+1\}^\ell$ be a fixed vector and let $\ell^+_\mathbf{y}$ and $\ell^-_\mathbf{y}$ be the number of positive and negative labels in $\mathbf{y}$, respectively. We define the distribution $\mathbf{D}_\mathbf{y}$ as $\mathbf{D}_\mathbf{y} := \otimes_{i=1}^{\ell} D_{y_i}$; this is a distribution on $\mathcal{X}^\ell$. With a slight abuse of notation, $\mathbf{D}_\mathbf{y}$ will also be used to denote the distribution over $(\mathcal{X}\times\mathcal{Y})^\ell$ of samples $\mathbf{S} = \{(X_i,y_i)\}_{i=1}^{\ell}$ such that the sequence $\{X_i\}_{i=1}^{\ell}$ is distributed according to $\mathbf{D}_\mathbf{y}$. It is easy to check that $\forall h \in \mathcal{H}, \mathbb{E}_{\mathbf{S}\sim\mathbf{D}_\mathbf{y}} \hat{R}^{\text{rank}}(h,\mathbf{S}) = R^{\text{rank}}(h)$ (cf. Equations 10 and 11).

Given $\mathbf{S}$, if we define, as said earlier, $X_{ij} := (X_i, X_j)$, $Y_{ij} := 1$ and $Z_{ij} := (X_{ij}, Y_{ij})$, then $\mathbf{Z} := \{Z_{ij}\}_{i:y_i=1,j:y_j=-1}$ is a sample of identically distributed variables, each with distribution $D_{\pm 1} = D_{+1} \otimes D_{-1} \otimes \mathbf{1}$ over $\mathcal{X}\times\mathcal{X}\times\mathcal{Y}$, where $\mathcal{Y} = \{-1,+1\}$ and where $\mathbf{1}$ is the distribution that produces 1 with probability 1.

Letting $m = \ell^+_\mathbf{y}\ell^-_\mathbf{y}$ we denote by $\mathbf{D}_{\mathbf{y},m}$ the distribution of the training sample $\mathbf{Z}$, within which interdependencies exist, as illustrated in Figure 2. Theorem 8 can thus be directly applied to classifiers trained on $\mathbf{Z}$, the structure of $\Gamma(\mathbf{D}_{\mathbf{y},m})$ and its corresponding fractional chromatic number $\chi^*_\mathbf{y}$ being completely determined by $\mathbf{y}$. Hence, letting $\mathcal{H} \subseteq \mathcal{R}^{\mathcal{X}\times\mathcal{X}}$, we have: $\forall \delta \in (0,1], \forall P$ over $\mathcal{H}$, with probability at least $1-\delta$ over the random draw of $\mathbf{Z} \sim \mathbf{D}_{\mathbf{y},m}$,

$$\forall Q,\ \mathrm{kl}(\hat{e}_Q(\mathbf{Z})||e_Q) \leq \frac{\chi^*_\mathbf{y}}{m}\left[\mathrm{KL}(Q||P) + \ln\frac{m+\chi^*_\mathbf{y}}{\delta\chi^*_\mathbf{y}}\right],$$

where $\hat{e}_Q(\mathbf{Z}) = \mathbb{E}_{h\sim Q}\hat{R}(h,\mathbf{Z}) = \mathbb{E}_{h\sim Q}\sum_{ij}\mathbb{I}_{Y_{ij}h(Z_{ij})<0} = \mathbb{E}_{h\sim Q}\sum_{ij}\mathbb{I}_{h(Z_{ij})<0}$, which is exactly equal to $\hat{e}^{\text{AUC}}_Q(\mathbf{S})$ (cf. Equation 11); likewise, $e_Q = \mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_{\mathbf{y},m}}\hat{e}_Q(\mathbf{Z}) = \mathbb{E}_{\mathbf{S}\sim\mathbf{D}_\mathbf{y}}\hat{e}^{\text{AUC}}_Q(\mathbf{S}) = e^{\text{AUC}}_Q$. Hence, $\forall \delta \in (0,1], \forall P$, with probability at least $1-\delta$ over the random draw of $\mathbf{S} \sim \mathbf{D}_\mathbf{y}$,

$$\forall Q,\ \mathrm{kl}(\hat{e}^{\text{AUC}}_Q(\mathbf{S})||e^{\text{AUC}}_Q) \leq \frac{\chi^*_\mathbf{y}}{m}\left[\mathrm{KL}(Q||P) + \ln\frac{m+\chi^*_\mathbf{y}}{\delta\chi^*_\mathbf{y}}\right]. \tag{12}$$

4.3.2 UNCONDITIONING ON $\mathbf{Y}$

As proposed by Agarwal et al. (2005), let us call $\Phi(P,\mathbf{S},\delta)$ the event (12); we just stated that $\forall \mathbf{y} \in \{-1,+1\}^\ell, \forall P, \forall \delta \in (0,1], \mathbb{P}_{\mathbf{S}\sim\mathbf{D}_\mathbf{y}}(\Phi(P,\mathbf{S},\delta)) \geq 1-\delta$, or, equivalently

$$\mathbb{P}_{\mathbf{S}\sim\mathbf{D}_\ell}(\neg\Phi(P,\mathbf{S},\delta)|Y=\mathbf{y}) = \mathbb{P}_{\mathbf{S}\sim\mathbf{D}_\mathbf{y}}(\neg\Phi(P,\mathbf{S},\delta)) < \delta,$$

that is to say, the conditional (to $Y=\mathbf{y}$) probability of the event $\neg\Phi(P,\mathbf{S},\delta)$ is bounded by δ. This directly implies that the unconditional probability of $\neg\Phi(P,\mathbf{S},\delta)$ is bounded by δ as well:

$$\mathbb{P}_{\mathbf{S}\sim\mathbf{D}_\ell}(\neg\Phi(P,\mathbf{S},\delta)) \leq \mathbb{P}_{\mathbf{S}\sim\mathbf{D}_\ell}(\neg\Phi(P,\mathbf{S},\delta)|Y=\mathbf{y}) < \delta.$$

Hence, $\forall \delta \in (0,1], \forall P$, with probability at least $1-\delta$ over the random draw of $\mathbf{S} \sim \mathbf{D}_\ell$,

$$\forall Q,\ \mathrm{kl}(\hat{e}^{\text{AUC}}_Q||e^{\text{AUC}}_Q) \leq \frac{\chi^*_\mathbf{S}}{m_\mathbf{S}}\left[\mathrm{KL}(Q||P) + \ln\frac{m_\mathbf{S}+\chi^*_\mathbf{S}}{\delta\chi^*_\mathbf{S}}\right]. \tag{13}$$

where $\chi^*_\mathbf{S}$ is the fractional chromatic number of the graph $\Gamma(\mathbf{Z})$, with $\mathbf{Z}$ defined from $\mathbf{S}$ as in the first part of the proof, where the observed (random) labels are now taken into account; here $m_\mathbf{S} = \ell^+\ell^-$, where ℓ^+ (ℓ^-) is the number of positive (negative) data in $\mathbf{S}$.

4.3.3 COMPUTING THE FRACTIONAL CHROMATIC NUMBER

In order to finish the proof, it suffices to observe that, for $\mathbf{Z} = \{Z_{ij}\}_{ij}$, if $\ell_{\max} = \max(\ell^+, \ell^-)$, then the fractional chromatic number of $\Gamma(\mathbf{Z})$ is $\chi^* = \ell_{\max}$.

Indeed, the clique number of $\Gamma(\mathbf{Z})$ is $\ell_{\max}$ as for all $i = 1, \ldots, \ell^+$ ($j = 1, \ldots, \ell^-$), $\{Z_{ij} : j = 1, \ldots, \ell^-\}$ ($\{Z_{ij} : i = 1, \ldots, \ell^+\}$) defines a clique of order ℓ^- (ℓ^+) in $\Gamma(\mathbf{Z})$. Thus, from Property 1: $\chi \geq \chi^* \geq \ell_{\max}$.

A proper exact cover $\mathbf{C} = \{C_k\}_{k=1}^{\ell_{\max}}$ of $\Gamma(\mathbf{Z})$ can be constructed as follows. Suppose that $\ell_{\max} = \ell^+$, then $C_k = \{Z_{i\sigma_k(i)} : i = 1, \ldots, \ell^-\}$, with

$$\sigma_k(i) = (i + k - 2 \mod \ell^+) + 1,$$

is an independent set: no two variables Z_{ij} and Z_{pq} in C_k are such that $i = p$ or $j = q$. In addition, it is straightforward to check that $\mathbf{C}$ is indeed a cover of $\Gamma(\mathbf{Z})$. This cover is of size $\ell^+ = \ell_{\max}$, which means that it achieves the minimal possible weight over proper exact (fractional) covers since $\chi^* \geq \ell_{\max}$. Hence, $\chi^* = \chi = \ell_{\max} (= c(\Gamma))$. Plugging in this value of χ^* in (13), and noting that $m_{\mathbf{S}} = \ell_{\max}\ell_{\min}$ with $\ell_{\min} = \min(\ell^+, \ell^-)$, closes the proof. ■

We observe that in the theorem, the dependence on the skew of the sample is expressed in terms of $1/\min(\ell^+, \ell^-)$, whereas in the the works of Agarwal et al. (2005) and Usunier et al. (2005), the bound depends on the larger $1/\ell^+ + 1/\ell^-$.

The PAC-Bayes bound of Theorem 14 can be specialized to the case where $h(x, x') = f(x) - f(x')$ with $f \in \{x \mapsto w \cdot x : w \in \mathcal{X}\}$: f is therefore a linear scoring function and $h(x, x') = w \cdot (x - x')$. The ranking rule h is thus a linear classifier acting on the difference of its arguments (the next result we present therefore carries over to kernel classifiers). As proposed by Langford (2005), we may assume an isotropic Gaussian prior $P = \mathcal{N}(0, I)$ and a family of posteriors $Q_{w,\mu}$ parameterized by $w \in \overline{\mathcal{X}}$ and $\mu > 0$ such that $Q_{w,\mu}$ is $\mathcal{N}(\mu, 1)$ in the direction w and $\mathcal{N}(0, 1)$ in all perpendicular directions, we arrive at the following theorem:

Theorem 15 (AUC Linear PAC-Bayes bound) *$\forall \ell, \forall D$ over $\mathcal{X} \times \mathcal{Y}$, $\forall \delta \in (0, 1]$, the following holds with probability at least $1 - \delta$ over the draw of $\mathbf{S} \sim D^\ell$:*

$$\forall w, \mu > 0,\ \mathrm{kl}(\hat{e}^{\mathrm{AUC}}_{Q_{w,\mu}}(\mathbf{S}) || e^{\mathrm{AUC}}_{Q_{w,\mu}}) \leq \frac{1}{\ell_{\min}} \left[\frac{\mu^2}{2} + \ln \frac{\ell_{\min} + 1}{\delta} \right].$$

Proof Straightforward from the bound of Langford (2005) and Theorem 14. ■

Note that this specific parameterization of Q could have been done in Theorem 13 as well. We arbitrarily choose to provide it for this AUC based bound as learning linear ranking rule by AUC minimization is a common approach (Ataman et al., 2006; Brefeld and Scheffer, 2005; Rakotomamonjy, 2004), and the presented result may be of practical interest (for model selection purpose, for instance) for a larger audience.

The bounds given in Theorem 14 and Theorem 15 are very similar to what we would get if applying IID PAC-Bayes bound to one (independent) element C_j of a minimal cover (i.e., its weight equals the fractional chromatic number) $\mathbf{C} = \{C_j\}_{j=1}^n$ such as the one we used in the proof of Theorem 14. This would imply the empirical error $\hat{e}^{\mathrm{rank}}_{Q}$ to be computed on only one specific C_j and not all the C_j's simultaneously, as is the case for the new results. It turns out that, for proper exact fractional covers $\mathbf{C} = \{(C_j, \omega)\}_{j=1}^n$ with elements C_j having the same size, it is better, in terms of

absolute moments of the empirical error, to assess it on the whole data set, rather than on only one C_j. The following proposition formalizes this.

Proposition 16 $\forall \mathbf{D}_m, \forall \mathcal{H}, \forall \mathbf{C} = \{(C_j, \omega_j\}_{j=1}^n \in \text{PEFC}(\mathbf{D}_m), \forall Q, \forall r \in \mathcal{N}, r \geq 1$, *if* $|C_1| = \ldots = |C_n|$ *then*

$$\mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m}|\hat{e}_Q(\mathbf{Z}) - e_Q|^r \leq \mathbb{E}_{\mathbf{Z}^{(j)}\sim\mathbf{D}_m^{(j)}}|\hat{e}_Q(\mathbf{Z}^{(j)}) - e_Q|^r, \forall j \in \{1, \ldots n\}.$$

Proof Using the convexity of $|\cdot|^r$ for $r \geq 1$, the linearity of $\mathbb{E}$ and the notation of Section 3, for $\mathbf{Z} \sim \mathbf{D}_m$:

$$\begin{aligned}
|\hat{e}_Q(\mathbf{Z}) - e_Q|^r &= |\sum_j \pi_j (\mathbb{E}_{h\sim Q}\hat{R}(h, \mathbf{Z}^{(j)}) - R(h))|^r \\
&\leq \sum_j \pi_j |\mathbb{E}_{h\sim Q}(\hat{R}(h, \mathbf{Z}^{(j)}) - R(h))|^r \\
&= \sum_j \pi_j |\hat{e}_Q(\mathbf{Z}^{(j)}) - e_Q|^r.
\end{aligned}$$

Taking the expectation of both sides with respect to $\mathbf{Z}$ and noting that the random variables $|\hat{e}_Q(\mathbf{Z}^{(j)}) - e_Q|^r$, have the same distribution, gives the result. ■

This proposition upholds the idea of Pemmaraju (2001) to base the decomposition of a dependency graph on equitable coloring.

4.4 β-mixing Processes

Here, we provide a PAC-Bayes theorem for classifiers trained on data from a stationary β-mixing process, of which we recall some definitions, as formulated by Yu (1994) (see also, for example, Mohri and Rostamizadeh, 2009).

Definition 17 (Stationarity) *A sequence of random variables* $\mathbf{Z} = \{Z_t\}_{t=-\infty}^{+\infty}$ *is* stationary *if, for any t and nonnegative integer m and k, the random subsequences* $(Z_t, \ldots, Z_{t+m})$ *and* $(Z_{t+k}, \ldots, Z_{t+m+k})$ *are identically distributed.*

Definition 18 (β-mixing process) *Let* $\mathbf{Z} = \{Z_t\}_{t=-\infty}^{+\infty}$ *be a stationary sequence of random variables. For any* $i, j \in \mathcal{Z} \cup \{-\infty, +\infty\}$, *let* σ_i^j *denote the* σ*-algebra generated by the random variables* Z_k, $i \leq k \leq j$. *Then, for any positive integer k, the* β*-mixing coefficient* $\beta(k)$ *of the stochastic process* $\mathbf{Z}$ *is defined as*

$$\beta(k) = \sup_{n\geq 1} \mathbb{E} \sup \left\{ |\mathbb{P}(A|\sigma_1^n) - \mathbb{P}(A)| : A \in \sigma_{n+k}^{+\infty} \right\}.$$

$\mathbf{Z}$ *is said to be* β*-mixing if* $\beta(k) \to 0$ *when* $k \to \infty$.

(Note there is an equivalent definition of the β-mixing coefficient based on finite partitions; see Yu, 1994 for details.) Stationary β-mixing processes model a situation where the interdependence between the random variables at hand is temporal. When the process is mixing, it means that the strengh of dependence between variables weakens over times.

The bound that we propose is in the same vein as the one proposed by Mohri and Rostamizadeh (2009), with the difference that our bound is a PAC-Bayes bound and theirs a Rademacher-complexity-based bounds. In addition to being a new type of data-dependent bound for the case of stationary

β-mixing process, we may anticipate that, in practical situations, our bound inherits the tightness of the IID PAC-Bayes bound (whereas, to the best of our knowledge, there is no evidence of such practicality for Rademacher-complexity-based bounds).

Let us state our generalization bound for classifiers trained on samples $\mathbf{Z}$ drawn from stationary β-mixing distributions.

Theorem 19 (β-mixing process PAC-Bayes bound) *Let m be a positive integer. Let $\mathbf{D}^{\beta}$ be a stationary β-mixing distribution over $\mathcal{Z}$ and $\mathbf{D}_m^{\beta}$ be the distribution of m-samples according to $\mathbf{D}^{\beta}$. $\forall \mathcal{H} \subseteq \mathcal{R}^{\mathcal{X}}$, $\forall \mu, a \in \mathcal{N}$ such that $2\mu a = m$, $\forall \delta \in (2(\mu-1)\beta(a), 1]$, $\forall P$, with probability at least $1-\delta$ over the random draw of $\mathbf{Z} \sim \mathbf{D}_m^{\beta}$, the following holds*

$$\forall Q,\ \mathrm{kl}(\hat{e}_Q^{\beta}(\mathbf{Z}) || e_Q^{\beta}) \leq \frac{1}{\mu}\left[\mathrm{KL}(Q||P) + \ln \frac{2(\mu+1)}{\delta - 2(\mu-1)\beta(a)}\right],$$

where

$$\hat{e}_Q^{\beta}(\mathbf{Z}) := \mathbb{E}_{h\sim Q}\hat{R}(h,\mathbf{Z}) = \mathbb{E}_{h\sim Q}\sum_{t=1}^{m} \mathbb{I}_{Y_t h(X_t)<0},$$
$$e_Q^{\beta} := \mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m^{\beta}}\hat{e}_Q^{\beta}(\mathbf{Z}).$$

Proof The proof makes use of the independent block decomposition proposed by Yu (1994), our chromatic PAC-Bayes bound of Theorem 8, and Corollary 24 (Appendix).

4.4.1 THE CHROMATIC BOUND FOR INDEPENDENT BLOCKS

Let $\mathbf{Z} = \{Z_1, \ldots, Z_m\}$ be the random variables we have to deal with. If μ and a are two integers such that $2\mu a = m$ (we assume that m is even, if it is odd one may drop the last variable Z_m and work on a sample of size $m-1$). Then $\mathbf{Z}$ can be decomposed into two subsequences $\mathbf{Z}_0$ and $\mathbf{Z}_1$ as follows:

$$\mathbf{Z}_0 := \{\mathbf{Z}_0^s := (Z_{a(2s-2)+1}, \ldots, Z_{a(2s-2)+a}) : s \in [\mu]\},$$
$$\mathbf{Z}_1 := \{\mathbf{Z}_1^s := (Z_{a(2s-1)+1}, \ldots, Z_{a(2s-1)+a}) : s \in [\mu]\}.$$

Both $\mathbf{Z}_0$ and $\mathbf{Z}_1$ are made of μ blocks of a consecutive random variables. The blocks are interdependent as well as the variables within each block. $\mathbf{D}_0$ will denote the distribution of $\mathbf{Z}_0$.

We now define a sequence $\underline{\mathbf{Z}}$ of independent blocks as:

$$\underline{\mathbf{Z}} := \{\underline{\mathbf{Z}}^s := (Z_1^s, \ldots, Z_a^s) : s \in [\mu]\},$$

such that the blocks $\underline{\mathbf{Z}}^s$ are mutually independent and such that each block $\underline{\mathbf{Z}}^s$ has the same distribution as $\mathbf{Z}_0^s$, that is, from the stationarity assumption, the distribution of $\mathbf{Z}_0^1$ (the blocks $\underline{\mathbf{Z}}^s$ are IID).

The dependency graph $\underline{\Gamma}$ of $\underline{\mathbf{Z}}$ is such that all the variables in a block are all connected and such that there are no connections between blocks. Theorem 8 can readily be applied to the random sample $\underline{\mathbf{Z}}$, whose distribution we denote $\underline{\mathbf{D}}$: for all P and $\delta \in (0,1]$,

$$\mathbb{P}_{\underline{\mathbf{Z}}\sim\underline{\mathbf{D}}}\left(\Phi(P,\underline{\mathbf{Z}},\delta)\right) < \delta, \tag{14}$$

with $e_Q := \mathbb{E}_{\underline{\mathbf{Z}}\sim\underline{\mathbf{D}}}\hat{e}_Q(\underline{\mathbf{Z}})$ and $\Phi(P,\mathbf{Z},\delta)$ is the event defined as:

$$\Phi(P,\mathbf{Z},\delta) := \left\{ \exists Q,\ \mathrm{kl}(\hat{e}_Q(\mathbf{Z})||e_Q) > \frac{1}{\mu}\left[\mathrm{KL}(Q||P) + \ln\frac{\mu+1}{\delta}\right]\right\}.$$

To see why and how Theorem 8 can be used to get (14), observe that:

- the number of variables in $\underline{\mathbf{Z}}$ is μa;
- by stationarity, all variables Z_α^s, for $\alpha \in [a]$ and $s \in [\mu]$ share the same distribution: we therefore do actually work with dependent but identically distributed variables;
- the (fractional) chromatic number $\underline{\chi}^*$ of $\underline{\Gamma}$ is a, since
  1. the clique number is a (that is, the number of variables in each block),
  2. the cover $\underline{\mathbf{C}}$ of $\underline{\Gamma}$ with

$$\underline{\mathbf{C}} := \left\{ \left(C_\alpha := \{Z_\alpha^1,\ldots,Z_\alpha^\mu\}, 1\right)\right\}_{1\le\alpha\le a}$$

  is a proper exact cover of size a.

Noting that, consequently

$$\frac{\underline{\chi}^*}{\mu a} = \frac{a}{\mu a} = \frac{1}{\mu} \qquad \text{and} \qquad \frac{\mu a + \underline{\chi}^*}{\delta\underline{\chi}^*} = \frac{\mu a + a}{\delta a} = \frac{\mu+1}{\delta},$$

gives the expression of $\Phi(P,\mathbf{Z},\delta)$ and (14).

The last two steps of the proof are similar to those used by Mohri and Rostamizadeh (2009) to establish their bound.

4.4.2 A BOUND FOR $\mathbf{Z}_0$

To establish the bound for $\mathbf{Z}_0$, it suffices to use Corollary 24 (Appendix) with $c(\mathbf{z})$ being defined as:

$$c(\mathbf{z}) := \mathbb{I}_{\Phi(P,\mathbf{z},\delta)},$$

which is a bounded measurable function on the blocks $\mathbf{Z}_0^s$ (and thus on the blocks $\underline{\mathbf{Z}}_s$). We have:

$$|\mathbb{E}_{\mathbf{Z}_0\sim\mathbf{D}_0} c(\mathbf{Z}_0) - \mathbb{E}_{\underline{\mathbf{Z}}\sim\underline{\mathbf{D}}} c(\underline{\mathbf{Z}})| \le (\mu-1)\beta(a),$$

and therefore, since $\mathbb{P}_{\mathbf{Z}_0\sim\mathbf{D}_0}(\Phi(P,\mathbf{Z}_0,\delta)) = \mathbb{E}_{\mathbf{Z}_0\sim\mathbf{D}_0} c(\mathbf{Z}_0)$ and $\mathbb{P}_{\underline{\mathbf{Z}}\sim\underline{\mathbf{D}}}(\Phi(P,\underline{\mathbf{Z}},\delta)) = \mathbb{E}_{\underline{\mathbf{Z}}\sim\underline{\mathbf{D}}} c(\underline{\mathbf{Z}})$:

$$\begin{aligned}\mathbb{P}_{\mathbf{Z}_0\sim\mathbf{D}_0}(\Phi(P,\mathbf{Z}_0,\delta)) &\le \mathbb{P}_{\underline{\mathbf{Z}}\sim\underline{\mathbf{D}}}(\Phi(P,\underline{\mathbf{Z}},\delta)) + (\mu-1)\beta(a) && (15)\\ &< \delta + (\mu-1)\beta(a). && \text{(cf. Equation 14)}\end{aligned}$$

4.4.3 ESTABLISHING THE BOUND

Finally, observe that:

$$\begin{aligned}
\Phi(P,\mathbf{Z},\delta) &\Rightarrow \exists Q: \frac{1}{2}\mathrm{kl}(\hat{e}_Q(\mathbf{Z}_0)||e_Q)+\frac{1}{2}\mathrm{kl}(\hat{e}_Q(\mathbf{Z}_1)||e_Q) > \frac{1}{\mu}\left[\mathrm{KL}(Q||P)+\ln\frac{\mu+1}{\delta}\right] \\
&\Rightarrow \exists Q: \bigvee_{i\in\{0,1\}}\left\{\mathrm{kl}(\hat{e}_Q(\mathbf{Z}_i)||e_Q)) > \frac{1}{\mu}\left[\mathrm{KL}(Q||P)+\ln\frac{\mu+1}{\delta}\right]\right\} \\
&\Rightarrow \bigvee_{i\in\{0,1\}}\left\{\exists Q: \mathrm{kl}(\hat{e}_Q(\mathbf{Z}_i)||e_Q)) > \frac{1}{\mu}\left[\mathrm{KL}(Q||P)+\ln\frac{\mu+1}{\delta}\right]\right\} \\
&\Leftrightarrow \Phi(P,\mathbf{Z}_0,\delta)\vee\Phi(P,\mathbf{Z}_1,\delta),
\end{aligned}$$

where we used $\hat{e}_Q(\mathbf{Z}) = \hat{e}_Q(\mathbf{Z}_0)/2+\hat{e}_Q(\mathbf{Z}_1)/2$ and the convexity of kl in the first line.

This leads to:

$$\begin{aligned}
\mathbb{P}_{\mathbf{Z}\sim\mathbf{D}_m^\beta}(\Phi(P,\mathbf{Z},\delta)) &\leq \mathbb{P}_{\mathbf{Z}\sim\mathbf{D}_m^\beta}(\Phi(P,\mathbf{Z}_0,\delta)\vee\Phi(P,\mathbf{Z}_1,\delta)) \\
&\leq \mathbb{P}_{\mathbf{Z}\sim\mathbf{D}_m^\beta}(\Phi(P,\mathbf{Z}_0,\delta))+\mathbb{P}_{\mathbf{Z}\sim\mathbf{D}_m^\beta}(\Phi(P,\mathbf{Z}_1,\delta)) && \text{(union bound)} \\
&= 2\mathbb{P}_{\mathbf{Z}\sim\mathbf{D}_m^\beta}(\Phi(P,\mathbf{Z}_0,\delta)) && \text{(stationarity)} \\
&= 2\mathbb{P}_{\mathbf{Z}_0\sim\mathbf{D}_0}(\Phi(P,\mathbf{Z}_0,\delta)) && \text{(marginalization wrt } \mathbf{Z}_0) \\
&\leq 2\delta+2(\mu-1)\beta(a). && \text{(cf. Equation 15)}
\end{aligned}$$

Adjusting δ to $\delta/2-(\mu-1)\beta(a)$ ends the proof. ■

5. Conclusion

In this work, we propose the first PAC-Bayes bounds applying for classifiers trained on non-IID data. The derivation of these results rely on the use of fractional covers of graphs, convexity and standard tools from probability theory. The results that we provide are very general and can easily be instantiated for specific learning settings such as ranking and learning from from mixing distributions: amazingly, we obtain at a very low cost original PAC-Bayes bounds for these settings. Using a generalized PAC-Bayes bound, we provide in the appendix a chromatic PAC-Bayes bound that holds for non-independently and non-identically distributed data: it allows us to derive a PAC-Bayes bound for classifiers trained on data from a stationary φ-mixing distribution.

This work gives rise to many interesting questions. First, it seems that using a fractional cover to decompose the non-IID training data into sets of IID data and then tightening the bound through the use of the chromatic number is some form of variational relaxation as often encountered in the context of inference in graphical models, the graphical model under consideration in this work being one that encodes the dependencies in $\mathbf{D}_m$. It might be interesting to make this connection clearer to see if, for instance, tighter and still general bounds can be obtained with more appropriate variational relaxations than the one incurred by the use of fractional covers.

Besides, Theorem 5 advocates for the learning algorithm described in Remark 7. We would like to see how such a learning algorithm based on possibly multiple priors/multiple posteriors could perform empirically and how tight the proposed bound could be.

On another empirical side, it might be interesting to run simulations on bipartite ranking problems to see how accurate the bound of Theorem 15 can be: we expect the results to be of good quality, because of the resemblance of the bound of the theorem with the IID PAC-Bayes theorem for margin classifiers, which has proven to be rather accurate (Langford, 2005). The work of Germain et al. (2009) is also another contribution that tends to support that a practical use of our bounds should provide competitive results (note that Theorem 25 gives a sufficient condition for the general PAC-Bayes bound of Germain et al. (2009) to be non degenerate). Likewise, it would be interesting to see how the possibly more accurate PAC-Bayes bound for large margin classifiers proposed by Langford and Shawe-taylor (2002), which should translate to the case of bipartite ranking as well, performs empirically. The question also remains as to what kind of strategies to learn the prior(s) could be used to render the bound of Theorem 5 the tightest possible. This is one of the most stimulating question as performing such prior learning makes it possible to obtain very accurate generalization bound (Ambroladze et al., 2007).

The connection between our ranking bounds and the theory of U-statistics makes it possible to envision the use of higher order moments in establishing PAC-Bayes bounds, thanks to Hoeffding's decomposition. We plan to investigate further in this direction, for both the ranking measures we have studied (noting that the AUC is a two-sample U-statistics Hoeffding, 1963).

Finally, we have been working on a more general way to establish chromatic bounds from IID bounds (covering VC, Rademacher, PAC-Bayes and—possibly—binomial tail test set bounds), without the need to perform 'low-level' calculations such as the ones proposed in Section 3.4. The meta-bound that we have been developing is in the spirit of that proposed by Blanchard and Fleuret (2007), except that the randomization we propose is on the subsets constituting the fractional cover (and not the hypothesis set). In other terms, given a cover $\mathbf{C} = \{(C_j, \omega_j)\}_j$, the fact that an IID bound holds on one subset C_j of a cover is considered as a random event, the probability of a subset to be chosen being $\omega_j/\omega(\mathbf{C})$. A simple union bound gives our generic result, which translates into cover-independent (but fractional-chromatic-number-dependent) chromatic bounds such as (6) (Theorem 8) under very mild conditions on the shape of the base IID bound. Along with that work, we try to answer the question of establishing a principled way to handle situations where random variables show weak dependencies (as is the case for β-mixing processes), as for now, the framework described here applies when variables are either dependent or independent, disregarding the magnitude of the dependencies—our PAC-Bayes bound for β-mixing processes would then be a specific case of such general result.

Appendix A. Technical Lemmas

This appendix gathers useful (and well-known) results for the different proofs.

Lemma 20 *Let D be a distribution over $\mathcal{Z}$.*

$$\forall h \in \mathcal{H}, \mathbb{E}_{\mathbf{Z}\sim D^m} e^{m\,\mathrm{kl}\left(\hat{R}(h,\mathbf{Z})||R(h)\right)} \leq m+1.$$

Proof Let $h \in \mathcal{H}$. For $\mathbf{z} \in \mathcal{Z}^m$, we let $q(\mathbf{z}) = \hat{R}(h,\mathbf{z})$; we also let $p = R(h)$. Note that since $\mathbf{Z}$ is i.i.d, $mq(\mathbf{Z})$ is binomial with parameters m and p (recall that $r(h,Z)$ takes the values 0 and 1 upon correct and erroneous classification of Z by h, respectively).

$$\begin{aligned}
\mathbb{E}_{\mathbf{Z}\sim D^m} e^{m\,\mathrm{kl}(q(\mathbf{Z})||p)} &= \sum_{\mathbf{z}\in\mathcal{Z}^m} e^{m\,\mathrm{kl}(q(\mathbf{z})||p)} \mathbb{P}_{\mathbf{Z}\sim D^m}(\mathbf{Z}=\mathbf{z}) \\
&= \sum_{0\le k\le m} e^{m\,\mathrm{kl}\left(\frac{k}{m}||p\right)} \mathbb{P}_{\mathbf{Z}\sim D^m}(mq(\mathbf{Z})=k) \\
&= \sum_{0\le k\le m} \binom{m}{k} e^{m\,\mathrm{kl}\left(\frac{k}{m}||p\right)} p^k (1-p)^{m-k} \\
&= \sum_{0\le k\le m} \binom{m}{k} e^{m\left(\frac{k}{m}\ln\frac{k}{m} + (1-\frac{k}{m})\ln(1-\frac{k}{m})\right)} \\
&= \sum_{0\le k\le m} \binom{m}{k} \left(\frac{k}{m}\right)^k \left(1-\frac{k}{m}\right)^{m-k}.
\end{aligned}$$

However, it is obvious that, from the definition of the binomial distribution,

$$\forall m \in \mathcal{N}, \forall k \in [0,m], \forall t \in [0,1], \binom{m}{k} t^k (1-t)^{m-k} \le 1.$$

This is obviously the case for $t = \frac{k}{m}$, which gives

$$\sum_{0\le k\le m} \binom{m}{k} \left(\frac{k}{m}\right)^k \left(1-\frac{k}{m}\right)^{m-k} \le \sum_{0\le k\le m} 1 = m+1.$$

■

Theorem 21 (Jensen's inequality) *Let $f \in \mathcal{R}^{\mathcal{X}}$ be a convex function. For all probability distribution P on $\mathcal{X}$:*

$$f(\mathbb{E}_{X\sim P} X) \le \mathbb{E}_{X\sim P} f(X).$$

Theorem 22 (Markov's Inequality) *Let X be a positive random variable on $\mathcal{R}$, such that $\mathbb{E}X < \infty$.*

$$\forall t \in \mathcal{R}, \mathbb{P}_X\left\{X \ge \frac{\mathbb{E}X}{t}\right\} \le \frac{1}{t}.$$

Consequently: $\forall M \ge \mathbb{E}X, \forall t \in \mathcal{R}, \mathbb{P}_X\left\{X \ge \frac{M}{t}\right\} \le \frac{1}{t}$.

Lemma 23 (Convexity of kl) $\forall p,q,r,s \in [0,1], \forall \alpha \in [0,1]$,

$$\mathrm{kl}(\alpha p + (1-\alpha)q || \alpha r + (1-\alpha)s) \le \alpha\,\mathrm{kl}(p||r) + (1-\alpha)\,\mathrm{kl}(q||s).$$

Proof It suffices to see that $f \in \mathcal{R}^{[0,1]^2}, f(\mathbf{v} = [p\ q]) = \mathrm{kl}(q||p)$ is convex over $[0,1]^2$: the Hessian H of f is

$$H = \begin{bmatrix} \frac{q}{p^2} + \frac{1-q}{(1-p)^2} & -\frac{1}{p} - \frac{1}{1-p} \\ -\frac{1}{p} - \frac{1}{1-p} & \frac{1}{q} + \frac{1}{1-q} \end{bmatrix},$$

and, for $p,q \in [0,1]$, $\frac{q}{p^2} + \frac{1-q}{(1-p)^2} \geq 0$ and $\det H = \frac{(p-q)^2}{q(1-q)p^2(1-p)^2} \geq 0$: $H \succeq 0$ and f is indeed convex. ■

Finally, we have the following version by Mohri and Rostamizadeh (2009) of Corollary 2.7 in Yu (1994), which is based on the definition of the blocks $\mathbf{Z}_k^s$:

Corollary 24 *Let c be a measurable function defined with respect to the blocks $\mathbf{Z}_0^s$. If c has absolute value bounded by M, then*

$$|\mathbb{E}_{\mathbf{Z}_0 \sim \mathbf{D}_0} c(\mathbf{Z}) - \mathbb{E}_{\underline{\mathbf{Z}} \sim \underline{\mathbf{D}}} c(\underline{\mathbf{Z}})| \leq (\mu - 1) M \beta(a).$$

Appendix B. Applications of a Generic PAC-Bayes Theorem

Let us first recall the following generic PAC-Bayes result, which is a corollary/compound of results proposed by Seeger (2002b) and McAllester (2003). In particular, the γ function need not be differentiable with respect to its second argument and it applies to any 'risk' functional ψ for which a concentration inequality exists.

Corollary 25 (Generic PAC-Bayes Theorem) *Let $\mathcal{H} \subseteq \mathcal{R}^{\mathcal{X}}$ and $\psi : \mathcal{H} \times \bigcup_{m=1}^{\infty} \mathcal{Z}^m \to \mathcal{R}$. If there exist $\alpha \geq 1, \beta > 1$ and a nonnegative convex function $\Delta : \mathcal{R} \times \mathcal{R} \to \mathcal{R}_+$ that is strictly increasing with respect to its second argument such that*

$$\forall h \in \mathcal{H}, \forall \varepsilon > 0,\ \mathbb{P}_{\mathbf{Z} \sim \mathbf{D}_m} \left[\mathbb{E}\psi(h) - \psi(h, \mathbf{Z}) \geq \varepsilon \right] \leq \alpha \exp\left(-\beta \Delta(\mathbb{E}\psi(h), \varepsilon) \right), \tag{16}$$

where $\mathbb{E}\psi(h)$ stands for $\mathbb{E}_{\mathbf{Z} \sim \mathbf{D}_m} \psi(h, \mathbf{Z})$, then, $\forall P$, with probability at least $1 - \delta$ over the draw of $\mathbf{Z} \sim \mathbf{D}_m$:

$$\forall Q,\ \Delta(e_Q^{\psi}, e_Q^{\psi} - \hat{e}_Q^{\psi}(\mathbf{Z})) \leq \frac{1}{\beta - 1} \left[\mathrm{KL}(Q||P) + \ln \frac{\alpha\beta}{\delta} \right].$$

where

$$\hat{e}_Q^{\psi}(\mathbf{Z}) := \mathbb{E}_{h \sim Q} \psi(h, \mathbf{Z})$$
$$e_Q^{\psi} := \mathbb{E}_{\mathbf{Z}} \hat{e}_Q^{\psi}(\mathbf{Z}) = \mathbb{E}_{h \sim Q} \mathbb{E}_{\mathbf{Z}} \psi(h, \mathbf{Z})$$

Proof Along lines from Seeger (2002b) and McAllester (2003).

1. Observe that, thanks to Lemma 26 (below) with $\delta(\varepsilon) := \Delta(\mathbb{E}\psi(h), \varepsilon)$,

   $$\mathbb{E}_{\mathbf{Z}} e^{(\beta-1)\Delta(\mathbb{E}\psi(h), \mathbb{E}\psi(h) - \psi(h,\mathbf{Z}))} \leq \alpha\beta, \text{ and, } \mathbb{E}_{h \sim P} \mathbb{E}_{\mathbf{Z}} e^{(\beta-1)\Delta(\mathbb{E}\psi(h), \mathbb{E}\psi(h) - \psi(h,\mathbf{Z}))} \leq \alpha\beta$$

   Applying Markov's inequality then gives:

   $$\mathbb{P}_{\mathbf{Z}} \left[\mathbb{E}_{h \sim P} e^{(\beta-1)\Delta(\mathbb{E}\psi(h), \mathbb{E}\psi(h) - \psi(h,\mathbf{Z}))} \geq \frac{\alpha\beta}{\delta} \right] \leq \delta$$

2. Using the entropy extremal inequality $\ln \mathbb{E}_{X \sim P} f(X) \geq -\mathrm{KL}(Q||P)) + \mathbb{E}_{X \sim Q} \ln f(X)$, $\forall P, Q, X$ (see the proof of Lemma 11), and the fact that $x \mapsto \ln x$ is nondecreasing, the previous step leads to

   $$\mathbb{P}_{\mathbf{Z}} \left[\exists Q : -\mathrm{KL}(Q||P) + (\beta - 1) \mathbb{E}_{h \sim Q} \Delta(\mathbb{E}\psi(h), \mathbb{E}\psi(h) - \psi(h, \mathbf{Z})) \geq \ln \frac{\alpha\beta}{\delta} \right] \leq \delta.$$

3. Since Δ is convex, Jensen's inequality can be used to give (here, $h \sim Q$)

$$\mathbb{P}_{\mathbf{Z}}\left[\exists Q : -\mathrm{KL}(Q||P) + (\beta-1)\Delta(\mathbb{E}_{h,\mathbf{Z}}\psi(h,\mathbf{Z}), \mathbb{E}_{h,\mathbf{Z}}\psi(h,\mathbf{Z}) - \mathbb{E}_h\psi(h,\mathbf{Z})) \geq \ln\frac{\alpha\beta}{\delta}\right] \leq \delta.$$

■

Lemma 26 (McAllester, 2003) *Let X be a real-valued random variable on $\mathcal{X}$ and $\alpha \geq 1, \beta > 1$. Let $\delta : \mathcal{R} \to \mathcal{R}$ be a nonnegative and strictly increasing function. We have:*

$$\forall x \in \mathcal{R}, \mathbb{P}[X \geq x] \leq \alpha e^{-\beta\delta(x)} \Rightarrow \mathbb{E}\left[e^{(\beta-1)\delta(X)}\right] \leq \alpha\beta.$$

Proof See the proof of McAllester (2003). Here, we take α into account. As f is strictly increasing:

$$\mathbb{P}[X \geq x] = \mathbb{P}[\delta(X) \geq \delta(x)] = \mathbb{P}\left[e^{(\beta-1)\delta(X)} \geq e^{(\beta-1)\delta(x)}\right].$$

Hence: $\mathbb{P}\left[e^{(\beta-1)\delta(X)} \geq e^{(\beta-1)\delta(x)}\right] \leq \alpha e^{-\beta\delta(x)}$. Setting $\nu = e^{(\beta-1)\delta(x)}$, we get:

$$\mathbb{P}\left[e^{(\beta-1)\delta(X)} \geq \nu\right] \leq \min(1, \alpha\nu^{-\beta/(\beta-1)}).$$

Thus, as for a nonnegative random variable W, $\mathbb{E}[W] = \int_0^\infty \mathbb{P}[W \geq \nu]d\nu$:

$$\mathbb{E}\left[e^{(\beta-1)\delta(X)}\right] \leq 1 + \alpha\int_1^\infty \nu^{-\beta/(\beta-1)} = 1 + \alpha(\beta-1).$$

Since $\alpha > 1$, $1 + \alpha(\beta-1) \leq \alpha\beta$, which ends the proof. ■

We observe that:

- if $\psi(h,\mathbf{Z}) = \sum_{i=1}^m \mathbb{I}_{Y_i h(Xi)<0}$ then, by the one-sided Chernoff bound, $\alpha = 1, \beta = m$ and $\Delta(p,\varepsilon) = \mathrm{kl}(p-\varepsilon||p)$ make Equation (16) hold. The PAC-Bayes bound provided by Corollary 25 is that of Theorem 1 where m is replaced by $m-1$;

- if

$$\forall i \in [m], \sup_{z_1,\ldots,z_m,z_i' \in \mathcal{Z}} |\psi(z_1,\ldots,z_m) - \psi(z_1,\ldots,z_{i-1},z_i',z_{i+1},\ldots,z_m)| \leq c_i,$$

  then, thanks to McDiarmid inequality (McDiarmid, 1989), $\alpha = 1, \beta = 2/\sum_i c_i^2$ and $\Delta(p,\varepsilon) = \varepsilon^2$, make Equation (16) hold and a PAC-Bayes bound can be derived (we let the reader write the corresponding PAC-Bayes bound);

- it suffices to have an appropriate concentration inequality for the problem at hand to have an effective PAC-Bayes bound.

B.1 Generalized Chromatic PAC-Bayes Bound

To get a chromatic PAC-Bayes theorem for non-identically non-independently distributed data, we simply make use of the following concentration inequality of Janson (2004).

Theorem 27 (Janson, 2004) *Suppose that $\mathbf{Z} = \{Z_i\}_{i=1}^m$ is an m-sample of real-valued random variables distributed according to some distribution $\mathbf{D}_m$. Suppose that each Z_i has range $[a_i, b_i]$. If $S_\mathbf{Z} = \sum_{i=1}^m Z_i$, then,*

$$\forall \varepsilon > 0,\ \mathbb{P}_{S_\mathbf{Z}}\left[\mathbb{E}S_\mathbf{Z} - S_\mathbf{Z} \geq \varepsilon\right] \leq \exp\left[-\frac{2\varepsilon^2}{\chi^*(\mathbf{D}_m)\sum_{i=1}^m (b_i - a_i)^2}\right],$$

where $\chi^*(\mathbf{D}_m)$ is the fractional chromatic number of the dependency graph of $\mathbf{D}_m$.

Note that *no assumption* is made on the Z_i's being identically distributed.

This concentration inequality gives rise to the following generalized chromatic PAC-Bayes bound that applies to non independently, possibly non identically distributed data and allows us to use any bounded loss functions r.

Theorem 28 (Generalized Chromatic PAC-Bayes Bound) *$\forall \mathbf{D}_m$, $\forall \mathcal{H}$, $\forall \delta \in (0,1]$, $\forall P$, with probability at least $1-\delta$ over the random draw of $\mathbf{Z} \sim \mathbf{D}_m$, the following holds*

$$\forall Q,\ |\hat{e}_Q(\mathbf{Z}) - e_Q|^2 \leq \frac{\chi^* M^2}{2m - \chi^* M^2}\left[\mathrm{KL}(Q||P) + \ln\frac{2m}{\chi^* M^2} + \ln\frac{1}{\delta}\right],$$

where χ^* stands for $\chi^*(\mathbf{D}_m)$, r is a bounded function with range M and

$$\hat{e}_Q(\mathbf{Z}) := \mathbb{E}_{h\sim Q}\hat{R}(h,\mathbf{Z})$$
$$e_Q := \mathbb{E}_{h\sim Q}\hat{e}_Q(\mathbf{Z}) = \mathbb{E}_{h\sim Q}\mathbb{E}_{\mathbf{Z}\sim\mathbf{D}_m}\hat{R}(h,\mathbf{Z}),$$

with $\hat{R}(h,\mathbf{Z}) := \sum_i r(h,Z_i)/m$.

Proof It suffices to apply Corollary 25 with Theorem 27, $\alpha = 1$, $\Delta(p,\varepsilon) = \varepsilon^2$ and $\beta = 2m/\chi^* M$ (since, as r has range M, $\hat{R}$ has range M/m). ■

We notice the following.

- Here, as no assumption is done regarding the identical distribution of the Z_i's, the expected risk $R(h) = \mathbb{E}_\mathbf{Z}\hat{R}(h,\mathbf{Z})$ does not unfold as in (3).
- In the case of using identically distributed random variables and the 0-1 loss, there is no concentration inequality that allows us to retrieve the tighter PAC-Bayes bound given in Theorem 8.
- From a more general point of view, it is enticing to try to establish even more generic results resting on the principle of graph coloring with the aim of decoupling this approach to the PAC-Bayesian framework. This is the subject of ongoing work.

B.2 φ-mixing PAC-Bayes Bound

The definition of a φ-mixing process follows.

Definition 29 (φ-mixing process) *Let $\mathbf{Z} = \{Z_t\}_{t=-\infty}^{+\infty}$ be a stationary sequence of random variables. For any $i, j \in \mathbb{Z} \cup \{-\infty, +\infty\}$, let σ_i^j denote the σ-algebra generated by the random variables Z_k, $i \leq k \leq j$. Then, for any positive integer k, the φ-mixing coefficient $\varphi(k)$ of the stochastic process $\mathbf{Z}$ is defined as*

$$\varphi(k) = \sup_{n, A \in \sigma_{n+k}^{+\infty}, B \in \sigma_{-\infty}^{n}} \left| \mathbb{P}[A|B] - \mathbb{P}[A] \right|.$$

$\mathbf{Z}$ is said to be φ-mixing if $\varphi(k) \to 0$ as $k \to 0$.

In order to establish our new PAC-Bayes bounds for stationary φ-mixing distributions, it suffices to make use of the following concentration inequality by Kontorovich and Ramanan (2008).

Theorem 30 (Kontorovich and Ramanan, 2008) *Let $\psi : \mathcal{U}^m \to \mathcal{R}$ be a function defined over a countable space $\mathcal{U}$. If ψ is l-Lipschitz with respect to the Hamming metric for some $l > 0$, then the following holds for all $t > 0$:*

$$\mathbb{P}_{\mathbf{Z}}\left[|\psi(\mathbf{Z}) - \mathbb{E}_{\mathbf{Z}}[\psi(\mathbf{Z})]| > t \right] \leq 2 \exp\left[-\frac{t^2}{2ml^2 \|\Lambda_m\|_\infty^2} \right],$$

where $\|\Lambda_m\|_\infty \leq 1 + 2\sum_{k=1}^{m} \varphi(k)$.

Suppose that the loss function r is again such that it takes values in $[0, M]$. Then, for any $h \in \mathcal{H}$, the function $\psi(\mathbf{Z}) = \frac{1}{m}\sum_{i=1}^{m} r(h, Z_i) = \hat{R}(h, \mathbf{Z})$ is obviously M/m-Lipschitz. Therefore, for a sample $\mathbf{Z}$ drawn according to a φ-mixing process, we have the following concentration inequality on $\hat{R}(h, \mathbf{Z})$ that holds for any $h \in \mathcal{H}$:

$$\mathbb{P}_{\mathbf{Z} \sim \mathbf{D}_m}\left[\left| \hat{R}(h, \mathbf{Z}) - R(h) \right| > t \right] \leq 2 \exp\left[-\frac{mt^2}{2M^2 \|\Lambda_m\|_\infty^2} \right]. \tag{17}$$

We directly get the following PAC-Bayes bound for φ-mixing processes.

Theorem 31 (PAC-Bayes bound for stationary φ-mixing processes) *Let $\mathbf{D}^{\varphi}$ be a stationary φ-mixing distribution over $\mathcal{Z}$ and $\mathbf{D}_m^{\varphi}$ be the distribution of m-samples according to $\mathbf{D}^{\varphi}$. $\forall \mathcal{H} \subseteq \mathcal{R}^{\mathcal{X}}$, $\forall \delta \in (0, 1]$, $\forall P$, with probability at least $1 - \delta$ over the random draw of $\mathbf{Z} \sim \mathbf{D}_m^{\varphi}$, the following holds*

$$\forall Q,\ |\hat{e}_Q^{\varphi}(\mathbf{Z}) - e_Q^{\varphi}|^2 \leq \frac{2M^2 \|\Lambda_m\|_\infty^2}{m - 2M^2 \|\Lambda_m\|_\infty^2} \left[\mathrm{KL}(Q||P) + \ln \frac{m}{M^2 \|\Lambda_m\|_\infty^2} + \ln \frac{1}{\delta} \right],$$

where $\|\Lambda_m\|_\infty \leq 1 + 2\sum_{k=1}^{m} \varphi(k)$, $r(h, Z) = \mathbb{I}_{Yh(X)<0}$ and

$$\hat{e}_Q^{\varphi}(\mathbf{Z}) := \mathbb{E}_{h \sim Q} \hat{R}(h, \mathbf{Z}) = \mathbb{E}_{h \sim Q} \sum_{t=1}^{m} \mathbb{I}_{Y_t h(X_t)<0}$$

$$e_Q^{\varphi} := \mathbb{E}_{\mathbf{Z} \sim \mathbf{D}_m^{\varphi}} \hat{e}_Q^{\varphi}(\mathbf{Z}).$$

Proof Equation (17), and Corollary 25 with $\alpha = 2$, $\beta = m/(2M^2\|\Lambda\|_\infty^2)$, $\Delta(p, \varepsilon) = \varepsilon^2$. ■

Abstract

Principal component analysis (PCA) is a classical data analysis technique that finds linear transformations of data that retain the maximal amount of variance. We study a case where some of the data values are missing, and show that this problem has many features which are usually associated with nonlinear models, such as overfitting and bad locally optimal solutions. A probabilistic formulation of PCA provides a good foundation for handling missing values, and we provide formulas for doing that. In case of high dimensional and very sparse data, overfitting becomes a severe problem and traditional algorithms for PCA are very slow. We introduce a novel fast algorithm and extend it to variational Bayesian learning. Different versions of PCA are compared in artificial experiments, demonstrating the effects of regularization and modeling of posterior variance. The scalability of the proposed algorithm is demonstrated by applying it to the Netflix problem.

Keywords: principal component analysis, missing values, overfitting, regularization, variational Bayes

1. Introduction

Principal component analysis (PCA) is a data analysis technique that can be traced back to Pearson (1901). It can be used to compress data sets of high dimensional vectors into lower dimensional ones. This is useful, for instance, in visualization and feature extraction. PCA has been extensively covered in the literature (e.g., Jolliffe, 2002; Bishop, 2006; Diamantaras and Kung, 1996; Haykin, 1989; Cichocki and Amari, 2002). PCA can be derived from a number of starting points and optimization criteria. The most important of these are minimization of the mean-square error in data compression, finding mutually orthogonal directions in the data having maximal variances, and decorrelation of the data using orthogonal transformations.

In the data compression formulation, PCA finds a smaller-dimensional linear representation of data vectors such that the original data could be reconstructed from the compressed representation with the minimum square error. Assume that we have n $d \times 1$ data vectors $\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_n$ that are modeled as

$$\mathbf{y}_j \approx \mathbf{W}\mathbf{x}_j + \mathbf{m}, \tag{1}$$

where $\mathbf{W}$ is a $d \times c$ matrix, $\mathbf{x}_j$ are $c \times 1$ vectors of principal components, and $\mathbf{m}$ is a $d \times 1$ bias vector. We assume that $c \leq d \leq n$. Principal subspace methods (e.g., Cichocki and Amari, 2002;

Diamantaras and Kung, 1996) find $\mathbf{W}$, $\mathbf{x}_j$ and $\mathbf{m}$ such that the reconstruction error

$$C = \sum_{j=1}^{n} \|\mathbf{y}_j - \mathbf{W}\mathbf{x}_j - \mathbf{m}\|^2 \tag{2}$$

is minimized. In matrix notation, the data vectors and principal components can be compiled into $d \times n$ and $c \times n$ matrices $\mathbf{Y} = [\mathbf{y}_1\ \mathbf{y}_2\ \ldots\ \mathbf{y}_n]$ and $\mathbf{X} = [\mathbf{x}_1\ \mathbf{x}_2\ \ldots\ \mathbf{x}_n]$, and y_{ij}, w_{ik} and x_{kj} denote the elements of the matrices $\mathbf{Y}$, $\mathbf{W}$ and $\mathbf{X}$, respectively. The bias matrix $\mathbf{M}$ contains n copies of the bias vector $\mathbf{m}$ as its columns. Principal subspace methods find $\mathbf{W}$ and $\mathbf{X}$ such that $\mathbf{Y} \approx \mathbf{W}\mathbf{X} + \mathbf{M}$ and the minimized cost function is the sum of the squared elements (or Frobenius norm) of matrix $\mathbf{Y} - \mathbf{W}\mathbf{X} - \mathbf{M}$:

$$C = \|\mathbf{Y} - \mathbf{W}\mathbf{X} - \mathbf{M}\|_{\mathrm{F}}^2. \tag{3}$$

Without any further constraints, there exist infinitely many ways to perform a decomposition that minimizes (2) or equivalently (3). This can be seen by noting that any rotation or scaling of $\mathbf{W}$ can be compensated by rotating or scaling $\mathbf{X}$ accordingly, leaving the product $\mathbf{W}\mathbf{X}$ the same. However, the subspace spanned by the column vectors of the matrix $\mathbf{W}$, called the *principal subspace*, is unique.

PCA finds a specific representation of the principal subspace. It is traditionally defined using the requirement that the column vectors of $\mathbf{W}$ are mutually orthogonal, have unit length and, furthermore, for each $k = 1, \ldots, c$, the first k vectors form the k-dimensional principal subspace. This makes the solution practically unique (except for changing the sign, and in the special case of having equal eigenvalues, e.g., Diamantaras and Kung, 1996; Jolliffe, 2002; Haykin, 1989). In this article, we use the term PCA for methods which seek representations (1) by minimizing the error (2). Thus we assume that once the principal subspace is found, it can be transformed into the PCA solution. This is indeed true for the case of fully observed vectors $\mathbf{y}_j$ but can be more difficult in the case with missing values, as we discuss in Section 4.

Let us now consider the same problem when the data matrix $\mathbf{Y}$ has missing entries. In this paper, we make the typical assumption that values are *missing at random* (MAR) (Little and Rubin, 1987), that is, given the observed data, the missingness does not depend on the unobserved data or latent variables. An example where the assumption does not hold is when out-of-scale measurements are marked missing. In the following example, the data matrix contains $N = 9$ observed values and 6 missing values (marked with a sign $\times$):

$$\mathbf{Y} = \begin{bmatrix} y_{11} & y_{12} & y_{13} & y_{14} & \times \\ y_{21} & y_{22} & \times & \times & y_{25} \\ \times & \times & y_{33} & y_{34} & \times \end{bmatrix}.$$

A natural extension of PCA for the case with missing values would be to find a representation such that $\mathbf{Y} \approx \mathbf{W}\mathbf{X} + \mathbf{M}$ for the observed values. The rest of the matrix $\mathbf{W}\mathbf{X} + \mathbf{M}$ can be taken as the reconstruction of missing values.

Although the PCA problem in the presence of missing values seems to be as easy as classical PCA, there are some important distinctions: 1) There is no analytical solution available since even the estimation of the data covariance matrix is nontrivial. Therefore, iterative learning procedures must be exploited. 2) The optimized cost function typically has multiple local minima and thus finding the optimal solution is more difficult. 3) There is no analytical solution even for the bias

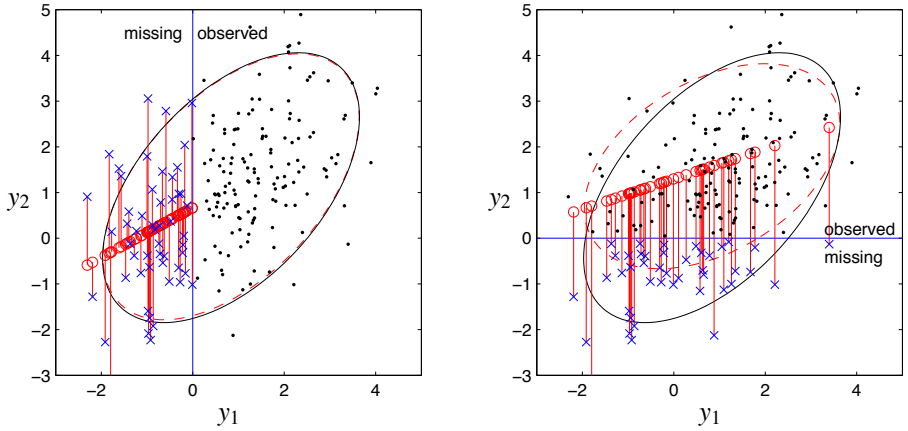

Figure 1: Two examples of PCA with missing values. In the left, the missing value mechanism is *missing at random (MAR)*, while on the right, it is *missing not at random (MNAR)*. The black dots represent fully observed samples, while the blue crosses represent observations where only the horizontal value has been observed. The red circles represent the reconstructions of the missing values produced by VBPCA. The dashed red ellipses represent the estimated data covariance. On the left, the estimated covariance is quite close to the data covariance (black ellipse).

term **m** in (1), which is not generally equal to the row-wise mean of the data matrix, as in classical PCA. 4) Standard PCA approaches can easily lead to overfitting, thus regularization is often required. 5) The algorithms may require heavy computations, especially for large-scale problems. 6) The concept of the PCA basis in the principal subspace is not easily generalized in the presence of missing values. 7) The choice of the dimensionality of the principal subspace is generally more difficult than in classical PCA. Thus, the PCA problem has many features which are usually associated with nonlinear models. This paper discusses some of these important issues providing illustrative examples and presenting ways to overcome possible difficulties.

All the methods studied in this work assume MAR, so they cannot be expected to work in the *missing not at random (MNAR)* case. Fig. 1 gives a first example of PCA with missing values. The data contain 200 samples generated from a Gaussian distribution represented by the black ellipse. In the first case (left subfigure), the vertical value is missing when the horizontal value is negative. This setting is MAR since the missingness depends only on the observed data. In the second case (right subfigure), the vertical value is missing when the vertical value itself is negative. Now the missingness depends on the missing data, and the missing value mechanism is thus MNAR. As expected, the variational Bayesian PCA (VBPCA, see Section 3.3) works well in the MAR case and gives reasonable reconstructions for the missing values. Also, the vertical part of the bias term **m** is estimated to be 1.13 which is much closer to the true value 1.10 than the row-wise mean 1.50 of the observed values in the data.

PCA in the presence of missing values can be relevant for many data sets which appear in practical applications. Sometimes, data sets contain relatively few missing observations and the

problem is to adjust standard PCA algorithms to handle partially observed instances. The choice of the algorithm is not very crucial in such a simple case, as most of the approaches would provide similar solutions. However, in other applications, the available observations can be very sparse and the modeling task is often to reconstruct the missing part from the observed data only. Examples include collaborative filtering problems which is the task of predicting preferences by using other people's preferences (e.g., Hofmann, 2004), and historical data reconstruction in climatic records (e.g., Kaplan et al., 1997).

Historically, the missing value problem in PCA was first studied by Dear (1959) who used only one component and just one imputation iteration (see below). It was based on the minimum mean-square error formulation of PCA introduced by Young (1941). Christoffersson (1970) also used a one-component model for reconstructing missing values. Wiberg (1976) first suggested to directly minimize the mean-square error of the observed part of the data. An algorithm by de Ligny et al. (1981) already worked with up to half of the values missing. The missing values problem using a multivariate normal distribution has been studied even earlier than using PCA, for instance, by Anderson (1957). More historical references can be found in the book by Jolliffe (2002).

More recently, PCA with missing values was studied by Grung and Manne (1998). They proposed using either the imputation or the faster alternating **W**–**X** algorithm (see below). They discussed the overfitting problem and suggested to delete troublesome rows or columns from data. Tipping and Bishop (1999) introduced the probabilistic formulation of PCA (PPCA). Although they mentioned shortly missing data, they did not provide the formulas to be used for incomplete data. Bishop (1999) introduced variational Bayesian PCA (VBPCA) for choosing the number of components in PCA. Raiko and Valpola (2001) reconstructed missing values with VBPCA to compare some nonlinear models to it. Oba et al. (2003) applied VBPCA for missing value estimation in gene expression profile data, and mentioned that it performs much better than the existing methods for missing value estimation.

The present article reviews possible approaches to the problem with the emphasis on probabilistic models and Bayesian methods. The rest of the article is organized as follows. In Section 2, we present classical algorithms for PCA based on minimizing the reconstruction error similar to (2) and the method based on estimation of the covariance matrix (imputation algorithm). We review how the algorithms are normally used for fully observed data and explain how they can be adapted to the case with missing values. We explain possible difficulties of the standard methods including bad locally optimal solutions, numerical problems and overfitting. Simple examples are given to illustrate these problems. In the same section, we discuss the properties of the imputation algorithm, such as implicit remedies against overfitting and overlearning and its expectation-maximization (EM) interpretation.

Section 3 presents probabilistic models for PCA which provide a good foundation for handling missing values. First, we introduce formulas for the probabilistic PCA model in the case with missing values. Then, we describe Bayesian regularization for handling problems that arise when data are sparse. We provide formulas for performing maximum a posteriori estimation and for variational Bayesian inference.

In Section 4, we propose an extension of the PCA-basis notion to the case of incomplete data. We also show how to find the PCA basis in a principal subspace estimated by different methods. Section 5 provides formulas for computing missing value reconstructions and the variance of the predicted values. We briefly discuss possible ways to select the right number of principal components to obtain reliable reconstructions.

Section 6 discusses large-scale problems and computational complexity. In case of high dimensional and very sparse data, overfitting becomes a severe problem and traditional algorithms for PCA are very slow. We introduce a novel fast optimization algorithm and show how to use it in Bayesian models.

In Section 7, different versions of PCA are compared in artificial experiments, demonstrating the effects of regularization and modeling of posterior variance. We demonstrate the importance of tricks such as fixing hyperparameters for the early learning in variational Bayesian methods. The scalability of the proposed algorithm is demonstrated by applying it to the Netflix problem. Finally, we conclude in Section 8.

1.1 Notation

The following notation is used throughout the article. Bold capital letters denote matrices, bold lower-case letters denote vectors, and normal lower-case letters denote scalars. The basic model equation is $\mathbf{y}_j \approx \mathbf{W}\mathbf{x}_j + \mathbf{m}$, where column vectors $\mathbf{y}_j$ are the data cases, $\mathbf{W}$ is the matrix that maps the principal components $\mathbf{x}_j$ to the data, and $\mathbf{m}$ is the bias vector. Indices $i = 1,\ldots,d$ and $j = 1,\ldots,n$ go over the rows and columns of $\mathbf{Y}$, respectively. The index of a principal component is denoted by $k = 1,\ldots,c$. Notation ij is used for the index of y_{ij}, the ij-th element of matrix $\mathbf{Y}$. O is the set of indices ij corresponding to *observed* values y_{ij}, O_i is the set of indices j (similarly O_j is the set of indices i) for which y_{ij} is observed. $|O_i|$ is the number of elements in O_i and $N = |O|$ is the number of observed data elements. Notation $\mathbf{A}_{i:}$ and $\mathbf{A}_{:j}$ is used for the i-th row and j-th column of a matrix $\mathbf{A}$, respectively. Both $\mathbf{A}_{i:}$ and $\mathbf{A}_{:j}$ are column vectors. The i-th row of $\mathbf{W}$ is denoted by $\mathbf{w}_i = \mathbf{W}_{i:}$, and the j-th column of $\mathbf{X}$ is $\mathbf{x}_j = \mathbf{X}_{:j}$. Table 1 lists the symbols used in the paper.

2. Least Squares Techniques

In this section, we present classical algorithms for PCA based on minimizing the reconstruction error similar to (2) and the method based on estimation of the covariance matrix.

2.1 The Cost Function

The minimum mean-square error compression of data is the formulation for PCA (Young, 1941) that can be generalized to the case with missing values in a very straightforward manner. The cost function (2) is adapted such that the sum is taken over only those indices i and j for which the data entry y_{ij} is observed (Wiberg, 1976):

$$C = \sum_{ij \in O} (y_{ij} - \hat{y}_{ij})^2 , \tag{4}$$

$$\hat{y}_{ij} = \mathbf{w}_i^{\mathrm{T}} \mathbf{x}_j + m_i = \sum_{k=1}^{c} w_{ik} x_{kj} + m_i . \tag{5}$$

In this section, we consider algorithms optimizing cost function (4), which we call the least squares (LS) approach to PCA of incomplete data.

The cost function (2) in the fully observed case has practically unique (up to an arbitrary rotation in the principal subspace) global minimum w.r.t. model parameters $\mathbf{W}, \mathbf{X}, \mathbf{m}$ provided that all eigenvalues of the sample covariance matrix are distinct. Srebro and Jaakkola (2003) showed that

d	dimensionality of the data vectors (indexed by i)
n	number of data vectors (indexed by j)
c	number of principal components (indexed by k)
$\mathbf{Y} = \{y_{ij}\}$	$d \times n$ data matrix
$\mathbf{y}_j$	d-dimensional data vector (j-th column of $\mathbf{Y}$)
$\hat{y}_{ij}$	reconstruction of the data element y_{ij}
$\mathbf{m} = \{m_i\}$	d-dimensional bias vector
$\mathbf{M}$	$= [\mathbf{m}\ \mathbf{m}\ \ldots\ \mathbf{m}]$, $d \times n$ bias matrix
$\overline{m}_i$	posterior mean of m_i (scalar)
$\widetilde{m}_i$	posterior variance of m_i (scalar)
$\mathbf{W} = \{w_{ik}\}$	$d \times c$ matrix for the mapping from principal components to the data
$\mathbf{W}_{:k}$	k-th column of matrix $\mathbf{W}$ (d-dimensional vector)
$\mathbf{w}_i$	i-th row of $\mathbf{W}$ (c-dimensional vector)
$\overline{\mathbf{w}}_i$	posterior mean of $\mathbf{w}_i$ (c-dimensional vector)
$\overline{\mathbf{W}}$	$= [\overline{\mathbf{w}}_1\ \overline{\mathbf{w}}_2\ \ldots\ \overline{\mathbf{w}}_d]^{\mathrm{T}}$, $d \times c$ matrix of posterior means of $\mathbf{w}_i$
$\mathbf{\Sigma}_{\mathbf{w}_i}$	posterior covariance of $\mathbf{w}_i$ ($c \times c$ matrix)
$\widetilde{w}_{ik}$	posterior variance of w_{ik} (scalar)
$\mathbf{X} = \{x_{kj}\}$	$c \times n$ matrix of principal components
$\mathbf{x}_j$	c-dimensional principal component vector (j-th column of $\mathbf{X}$)
$\overline{\mathbf{x}}_j$	posterior mean of $\mathbf{x}_j$ (c-dimensional vector)
$\overline{\mathbf{X}}$	$= [\overline{\mathbf{x}}_1\ \overline{\mathbf{x}}_2\ \ldots\ \overline{\mathbf{x}}_n]$, $c \times n$ matrix of posterior means of $\mathbf{x}_j$
$\mathbf{\Sigma}_{\mathbf{x}}$	posterior covariance of $\mathbf{x}_j$ (same $c \times c$ matrix for each j)
$\mathbf{\Sigma}_{\mathbf{x}_j}$	posterior covariance of $\mathbf{x}_j$ (separate $c \times c$ matrix for each j)
$\widetilde{x}_{kj}$	posterior variance of x_{kj} (scalar)
C	cost function to be minimized
O	set of indices i, j for which y_{ij} is observed
O_i	set of indices j for which y_{ij} is observed
O_j	set of indices i for which y_{ij} is observed
γ	learning rate (positive scalar)
ε_j	d-dimensional noise vector (j-th out of n vectors)
v_y	noise variance (scalar)
$\mathcal{N}(\mathbf{x}; \mu, \Sigma)$	Gaussian pdf over variable $\mathbf{x}$ with mean μ and covariance Σ
v_m	prior variance for the elements of $\mathbf{m}$ (scalar)
$v_{w,k}$	prior variance for the elements of $\mathbf{W}_{:k}$ (scalar for each k)
ξ	$= (v_y, v_{w,k}, v_m)$ hyperparameters
θ	parameters, typically $\theta = (\mathbf{W}, \mathbf{X}, \mathbf{m})$

Table 1: Symbols used in the paper. See also Section 1.1 about notation.

an extension to the weighted case, where each observation has a weight varying from 0 to 1, is a difficult non-convex problem where the cost function can have multiple local minima. We demonstrate this phenomenon for a simple data set with missing values, that is with weights either 0 (missing value) or 1 (observed value). In our example, model (1) with one principal component and fixed $\mathbf{m} = 0$ is fitted to the data

$$\mathbf{Y} = \begin{bmatrix} 0.8 & 0.8 \\ 1 & \times \\ \times & 1 \end{bmatrix} \approx \begin{bmatrix} w_1 \\ w_2 \\ w_3 \end{bmatrix} \begin{bmatrix} x_1 & x_2 \end{bmatrix}.$$

To discard the scaling ambiguity of the PCA solution, the column vector $\mathbf{W}$ can be restricted to have unit length. Thus, the minimized error can be represented as a function of two parameters which define a unit length vector in the three-dimensional space. The cost function in this simple example has three local minima, as shown in Fig. 2: The global minimum $\mathbf{W} = \pm[0.49\ 0.62\ 0.62]^{\mathrm{T}}$ corresponds to zero cost while the other two minima (close to $\pm[0\ 1\ 0]^{\mathrm{T}}$ and $\pm[0\ 0\ 1]^{\mathrm{T}}$) provide a non-zero error. Each of the two sub-optimal solutions reconstructs perfectly only three out of four observed values in $\mathbf{Y}$.

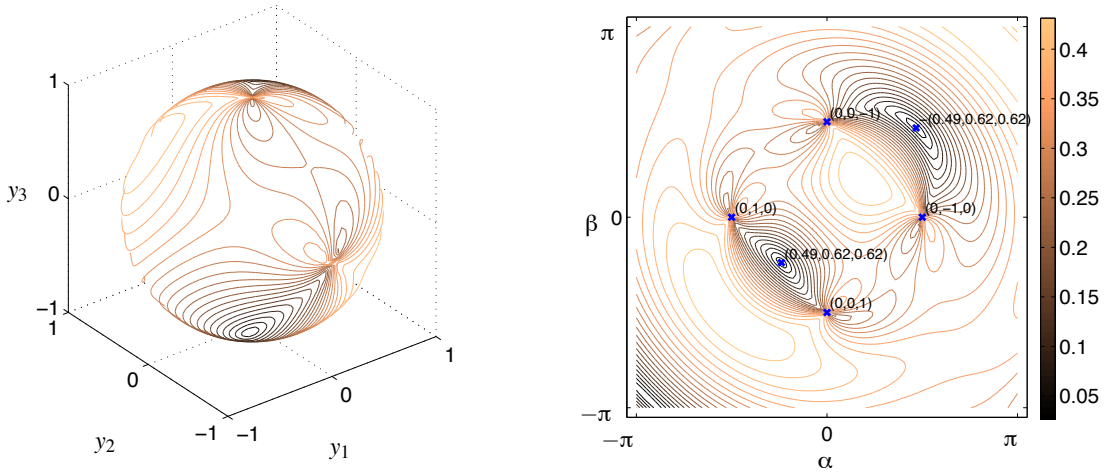

Figure 2: Example of local minima for the cost function (4). Data are three-dimensional ($d = 3$), the model has one principal component ($c = 1$) and therefore the PCA solution can be defined by a unit length vector $\mathbf{W}$. Left: The cost function plotted on a surface of unit length vectors. Right: The same plot using the Euler vector representation: The matrix $\mathbf{W}$ is constructed from α and β as $\mathbf{W} = e^{\mathbf{A}}[1\ 0\ 0]^{\mathrm{T}}$ with $\mathbf{A}$ a 3×3 matrix with four nonzero elements $a_{12} = -a_{21} = \alpha$ and $a_{13} = -a_{31} = \beta$. Coordinates in brackets correspond to coordinates in Euclidian space in the left hand side plot.

The cost function (4) can be minimized using any optimization procedure. Two possible approaches are presented in the following.

2.2 Alternating W–X Algorithm

Complete data. It is possible to optimize the cost function (3), and therefore to find the principal subspace, by updating $\mathbf{W}$ and $\mathbf{X}$ alternately. When either of these matrices is fixed, the other one

can be obtained from an ordinary least squares problem. We will further refer to this approach as the *alternating algorithm*.

The algorithm alternates between the updates

$$\mathbf{X} = (\mathbf{W}^{\mathrm{T}}\mathbf{W})^{-1}\mathbf{W}^{\mathrm{T}}\mathbf{Y}, \tag{6}$$

$$\mathbf{W} = \mathbf{Y}\mathbf{X}^{\mathrm{T}}(\mathbf{X}\mathbf{X}^{\mathrm{T}})^{-1}. \tag{7}$$

This iteration can be efficient when only a few principal components are needed, that is $c \ll d$ (Roweis, 1998). The bias vector $\mathbf{m}$ is the row-wise mean of the data and the above equations assume that it has been subtracted from the data as a preprocessing step.

Incomplete data. Grung and Manne (1998) studied the alternating algorithm in the case of missing values. In order to get the accurate least squares solution, we include the bias term into the estimation procedure, yielding the update rules

$$\mathbf{x}_j = \Big(\sum_{i\in O_j} \mathbf{w}_i\mathbf{w}_i^{\mathrm{T}}\Big)^{-1} \sum_{i\in O_j} \mathbf{w}_i(y_{ij} - m_i)\,, \quad j = 1,\ldots,n, \tag{8}$$

$$m_i = \frac{1}{|O_i|}\sum_{j\in O_i}\left[y_{ij} - \mathbf{w}_i^{\mathrm{T}}\mathbf{x}_j\right], \tag{9}$$

$$\mathbf{w}_i = \Big(\sum_{j\in O_i} \mathbf{x}_j\mathbf{x}_j^{\mathrm{T}}\Big)^{-1} \sum_{j\in O_i} \mathbf{x}_j(y_{ij} - m_i)\,, \quad i = 1,\ldots,d\,, \tag{10}$$

where m_i is the i-th element of $\mathbf{m}$.

2.3 Gradient Descent Algorithm

Complete data. The basis of neural network implementation of PCA learning rules is a gradient descent optimization procedure. Such algorithms work online, processing only one input vector $\mathbf{y}_j$ at once. The learning rules implement *stochastic* gradient descent and the algorithms will eventually converge to a basis in the principal subspace. Each data vector may have to be processed several times for convergence. The same can also be implemented in a batch procedure.

Using gradient descent for minimization of (4) w.r.t. $\mathbf{W}$ yields the update rule

$$\mathbf{W} \leftarrow \mathbf{W} + \gamma(\mathbf{Y} - \mathbf{W}\mathbf{X})\mathbf{X}^{\mathrm{T}}\,, \tag{11}$$

where $\gamma > 0$ is called the learning rate. Minimization w.r.t. matrix $\mathbf{X}$ can be performed using the least squares solution in (6). Some neural algorithms use learning rules which either explicitly orthogonalize $\mathbf{W}$ or which yield an orthogonal $\mathbf{W}$ at the convergence. Then the update of $\mathbf{X}$ can be simplified to $\mathbf{X} = \mathbf{W}^{\mathrm{T}}\mathbf{Y}$, which together with (11) is the batch version of the Oja learning algorithm (Oja, 1983; Diamantaras and Kung, 1996). The bias $\mathbf{m}$ is again removed from the data as a preprocessing step.

Incomplete data. In the presence of missing values, the gradient descent update rule for $\mathbf{W}$ is

$$\mathbf{W} \leftarrow \mathbf{W} - \gamma\frac{\partial C}{\partial \mathbf{W}}\,, \qquad \text{with} \qquad \frac{\partial C}{\partial w_{ik}} = -2\sum_{j\in O_i}(y_{ij} - \hat{y}_{ij})x_{kj}\,,$$

where $\hat{y}_{ij}$ is given in (5). Matrix $\mathbf{X}$ could be updated using (8) but a gradient-based update can also be used:

$$\mathbf{X} \leftarrow \mathbf{X} - \gamma \frac{\partial C}{\partial \mathbf{X}}, \qquad \text{with} \qquad \frac{\partial C}{\partial x_{kj}} = -2 \sum_{i \in O_j} (y_{ij} - \hat{y}_{ij}) w_{ik}.$$

The bias term $\mathbf{m}$ can be updated using (9). As we discuss in Section 6.1, gradient-based learning can be computationally more efficient than the alternating algorithm because there is no need to compute matrices $\left(\sum_{i \in O_j} \mathbf{w}_i \mathbf{w}_i^{\mathrm{T}}\right)^{-1}$ and $\left(\sum_{j \in O_i} \mathbf{x}_j \mathbf{x}_j^{\mathrm{T}}\right)^{-1}$ in (8) and (10).

2.4 Numerical Problems and Overfitting

Least squares PCA methods can work well for data sets with few missing values but they may not be applicable to sparse data sets because of severe problems with overfitting. Suppose that for some j the number $|O_j|$ of observed measurements y_{ij} is smaller than the number of principal components c. Then, the corresponding least square problem is ill posed: the matrix $\sum_{i \in O_j} \mathbf{w}_i \mathbf{w}_i^{\mathrm{T}}$ is rank deficient and Equation (8) cannot be used. Moreover, even if $|O_j|$ is greater than c, matrix $\sum_{i \in O_j} \mathbf{w}_i \mathbf{w}_i^{\mathrm{T}}$ may be badly conditioned and the corresponding $\mathbf{x}_j$ can become infinitely large. This means that the parameters would be overfitted to explain well a few observed values but the generalization ability of the model would be poor (e.g., reconstruction of missing data would be very inaccurate). This is exactly what happens in the vicinity of the two local minima in the example in Fig. 2.

The same problem can happen when the rows of $\mathbf{W}$ are estimated using, for example, (10): matrix $\sum_{j \in O_i} \mathbf{x}_j \mathbf{x}_j^{\mathrm{T}}$ can be rank deficient or badly conditioned. This is more probable when some rows of $\mathbf{Y}$ contain very few measurements. However, these problems can generally appear for any data set and for any algorithm optimizing the cost function (4).

Overfitting problems can be avoided by using proper regularization. A common way to prevent unbounded growth of model parameters is to add terms which penalize large parameter values into the cost function. The amount of regularization can be determined, for instance, by cross-validation. Another possibility is to use probabilistic methods (see Section 3) in which the extra penalty terms come naturally from a probabilistic model.

2.5 Method Using Singular Value Decomposition

Complete data. Perhaps the most popular approach to PCA is based on singular value decomposition (SVD) of the data matrix or (equivalently) eigen-decomposition of the sample covariance matrix. SVD of the data matrix is given by:

$$\mathbf{Y} = \mathbf{U} \Sigma \mathbf{V}^{\mathrm{T}},$$

where $\mathbf{U}$ is a $d \times d$ orthogonal matrix, $\mathbf{V}$ is an $n \times n$ orthogonal matrix and Σ is a $d \times n$ pseudo-diagonal matrix (diagonal if $d = n$) with the singular values on the main diagonal (e.g., Haykin, 1989). The PCA solution is obtained by selecting the c largest singular values from Σ, by forming $\mathbf{W}$ from the corresponding c columns of $\mathbf{U}$, and $\mathbf{X}$ from the corresponding c rows of $\Sigma \mathbf{V}^{\mathrm{T}}$ (Jolliffe, 2002). The bias $\mathbf{m}$ is again removed from the data as a preprocessing step.

PCA can equivalently be defined using the eigen-decomposition of the $d \times d$ covariance matrix $\mathbf{C}$ of the column vectors of the data matrix $\mathbf{Y}$:

$$\mathbf{C} = \frac{1}{n} \mathbf{Y} \mathbf{Y}^{\mathrm{T}} = \mathbf{U} \mathbf{D} \mathbf{U}^{\mathrm{T}}.$$

The diagonal matrix $\mathbf{D}$ contains the eigenvalues of $\mathbf{C}$, and the columns of the matrix $\mathbf{U}$ contain the unit-length eigenvectors of $\mathbf{C}$ in the same order (Cichocki and Amari, 2002; Diamantaras and Kung, 1996; Jolliffe, 2002; Haykin, 1989). Again, the columns of $\mathbf{U}$ corresponding to the largest eigenvalues are taken as $\mathbf{W}$, and $\mathbf{X}$ is computed as $\mathbf{W}^{\mathrm{T}}\mathbf{Y}$. This approach can be more efficient for cases where $d \ll n$, since it avoids the computation of the $n \times n$ matrix $\mathbf{V}$.

Incomplete data. The same approach cannot be directly used in the presence of missing values. Estimating the covariance matrix $\mathbf{C}$ becomes difficult. Let us consider a simple (but incorrect) estimate where we just leave out terms with missing values from the average for each element of $\mathbf{C}$. For the data matrix below, we get

$$\mathbf{Y} = \begin{bmatrix} -1 & +1 & 0 & 0 & \times \\ -1 & +1 & \times & \times & 0 \\ \times & \times & -1 & +1 & \times \end{bmatrix}, \quad \mathbf{C} = \frac{1}{n}\mathbf{Y}\mathbf{Y}^{\mathrm{T}} = \begin{bmatrix} 0.5 & 1 & 0 \\ 1 & 0.667 & \times \\ 0 & \times & 1 \end{bmatrix}.$$

There are at least two problems. First, the estimated covariance 1 between the first and second components is larger than their estimated variances 0.5 and 0.667. This clearly leads to the situation where the covariance matrix is not positive (semi)definite and some of its eigenvalues are negative. Secondly, the covariance between the second and the third component could not be estimated at all. For these reasons, this is a viable option only if the number of missing values is not significant. There are many algorithms for finding a proper estimate of the covariance matrix (e.g., Ghahramani and Jordan, 1994; Boscardin and Zhang, 2004) but they are computationally intensive iterative algorithms.

A simple alternative is an iterative procedure which performs PCA more directly. It alternates between imputing the missing values in $\mathbf{Y}$ and applying standard PCA to the infilled (complete) data matrix $\mathbf{Y}_c$ (e.g., Jolliffe, 2002). Initially, the missing values can be replaced, for example, by the row-wise means of $\mathbf{Y}$. The covariance matrix of the complete data $\mathbf{Y}_c$ can be estimated without the problems mentioned above, and $\mathbf{W}$ can be computed using its eigen-decomposition. The bias term $\mathbf{m}$ can be updated as the row-wise mean of $\mathbf{Y}_c$. Next, the principal components $\mathbf{X}$ are calculated:

$$\mathbf{X} = \mathbf{W}^{\mathrm{T}}(\mathbf{Y}_c - \mathbf{M}),$$

the reconstructions can be used as a better estimate for the missing values:

$$\mathbf{Y}_c = \begin{cases} \mathbf{Y} & \text{for observed values} \\ \mathbf{W}\mathbf{X} + \mathbf{M} & \text{for missing values} \end{cases}$$

and PCA can be applied again to the updated data matrix $\mathbf{Y}_c$. This process can be iterated until convergence. We will further refer to this approach as the *imputation algorithm*. In Appendix A, we show that the imputation algorithm also minimizes the cost function (4) and that it implements the EM steps for a simple probabilistic model. This approach requires the use of the complete data matrix, and therefore it is computationally very expensive for large-scale problems.

Although the imputation algorithm belongs to the class of least-squares PCA algorithms (i.e., it does not use explicit regularization), it still provides some remedy against overfitting. Performing SVD of a complete data matrix is equivalent to minimizing a cost function which is a sum of two terms: the reconstruction error for the observed values (which is the true minimized error) and the reconstruction error for the infilled missing data (which is a penalty term forcing the new reconstructions of missing data to be close to the infilled values). Initialization of the reconstructions

with the row-wise means of the data matrix introduces a bias in favor of the most "conservative" solutions. In practice, there can be infinitely many solutions that provide the same reconstruction error for the observed part but that have different reconstructions for the missing part. In such cases, the effect of the initialization can last even if the algorithm is iterated indefinitely.

Our experiments show that the imputation algorithm also has resistance against overlearning. By overlearning we mean situations when the training error decreases but the generalization ability of the model gets worse. Badly overfitted solutions correspond to regions in the parameter space where a small decrease of the training error can cause a large increase of the test error. However, the penalty term (which keeps the reconstructions of missing data close to the infilled values) makes the steps shorter and learning can practically stop once the algorithm enters regions where the training error changes very little. Thus, this regularization effect is due to early stopping.

3. Probabilistic Models for PCA

In this section, we presents probabilistic models for PCA which provide a good foundation for handling missing values.

3.1 Probabilistic PCA

The probabilistic formulation of PCA offers a number of benefits, including well-founded regularization, model comparison, interpretation of results, and extendability. *Probabilistic PCA* (Tipping and Bishop, 1999) explicitly includes the noise term in a generative model

$$\mathbf{y}_j = \mathbf{W}\mathbf{x}_j + \mathbf{m} + \varepsilon_j \,. \tag{12}$$

Both the principal components $\mathbf{x}_j$ and the noise ε_j are assumed normally distributed:

$$p(\mathbf{x}_j) = \mathcal{N}(\mathbf{x}_j; 0, \mathbf{I}) \,, \tag{13}$$

$$p(\varepsilon_j) = \mathcal{N}(\varepsilon_j; 0, v_y\mathbf{I}) \,, \tag{14}$$

where $\mathcal{N}(\mathbf{x}; \mu, \Sigma)$ denotes the normal probability density function (pdf) over variable $\mathbf{x}$ with mean μ and covariance Σ. The parameters of the model include $\mathbf{W}$, $\mathbf{m}$ and v_y. The model can be identified by finding the maximum likelihood (ML) estimate for the model parameters using the EM algorithm (Dempster et al., 1977).

Complete data. The E-step estimates the conditional distribution of the hidden variables $\mathbf{X}$ given the data and the current values of the model parameters:

$$p(\mathbf{X}|\mathbf{Y}, \mathbf{W}, v_y) = \prod_{j=1}^{n} \mathcal{N}\left(\mathbf{x}_j; \overline{\mathbf{x}}_j, \Sigma_{\mathbf{x}_j}\right) \,,$$

where the covariance matrix $\Sigma_{\mathbf{x}_j}$ is same for all $\mathbf{x}_j$:

$$\Sigma_{\mathbf{x}_j} = \Sigma_{\mathbf{x}} = v_y\left(v_y\mathbf{I} + \mathbf{W}^{\mathrm{T}}\mathbf{W}\right)^{-1}, \quad j = 1, \ldots n \,,$$

and the means $\overline{\mathbf{x}}_j$ can be summarized in the columns of matrix

$$\overline{\mathbf{X}} = \frac{1}{v_y}\Sigma_{\mathbf{x}}\mathbf{W}^{\mathrm{T}}\mathbf{Y} \,. \tag{15}$$

The M-step re-estimates the model parameters as

$$\mathbf{W} = \mathbf{Y}\overline{\mathbf{X}}^{\mathrm{T}}(\overline{\mathbf{X}\mathbf{X}}^{\mathrm{T}} + n\Sigma_{\mathbf{x}})^{-1}, \tag{16}$$
$$v_y = \frac{1}{nd}\sum_{i=1}^{d}\sum_{j=1}^{n}\left(y_{ij} - \mathbf{w}_i^{\mathrm{T}}\overline{\mathbf{x}}_j\right)^2 + \frac{1}{d}\,\mathrm{tr}(\mathbf{W}\Sigma_{\mathbf{x}}\mathbf{W}^{\mathrm{T}})\,.$$

Note that v_y is updated as the mean-square error plus the extra term which accounts for the uncertainty in $\mathbf{X}$.

Tipping and Bishop (1999) showed that $\mathbf{W}$ converges to the principal subspace. In the zero-noise limit, that is for $v_y \to 0$, the iterations (15)–(16) reduce to the least squares projections in (6)–(7) (Roweis, 1998). Note also that the ML estimator for $\mathbf{m}$ is given by the row-wise mean of the data (Tipping and Bishop, 1999). Therefore, it can be computed once and removed from the data in the preprocessing step.

Incomplete data. The generalization to the case with missing values happens as follows. First we write an element-wise version of the probabilistic model in (12)–(14):

$$\begin{aligned} y_{ij} &= \mathbf{w}_i^{\mathrm{T}}\mathbf{x}_j + m_i + \varepsilon_{ij}\,, \qquad \forall ij \in O,\\ p(\mathbf{x}_j) &= \mathcal{N}(\mathbf{x}_j; 0, \mathbf{I})\,,\\ p(\varepsilon_{ij}) &= \mathcal{N}(\varepsilon_{ij}; 0, v_y)\,. \end{aligned}$$

We treat $\mathbf{w}_i$, m_i, and v_y as model parameters and $\mathbf{x}_j$ as latent variables and apply the standard EM algorithm to arrive at the following update rules:

$$\Sigma_{\mathbf{x}_j} = v_y\Big(v_y\mathbf{I} + \sum_{i\in O_j}\mathbf{w}_i\mathbf{w}_i^{\mathrm{T}}\Big)^{-1}, \tag{17}$$
$$\overline{\mathbf{x}}_j = \frac{1}{v_y}\Sigma_{\mathbf{x}_j}\sum_{i\in O_j}\mathbf{w}_i(y_{ij} - m_i)\,, \qquad j = 1,\ldots,n,$$
$$m_i = \frac{1}{|O_i|}\sum_{j\in O_i}\left[y_{ij} - \mathbf{w}_i^{\mathrm{T}}\overline{\mathbf{x}}_j\right],$$
$$\mathbf{w}_i = \Big(\sum_{j\in O_i}\left[\overline{\mathbf{x}}_j\overline{\mathbf{x}}_j^{\mathrm{T}} + \Sigma_{\mathbf{x}_j}\right]\Big)^{-1}\sum_{j\in O_i}\overline{\mathbf{x}}_j(y_{ij} - m_i)\,, \qquad i = 1,\ldots,d, \tag{18}$$
$$v_y = \frac{1}{N}\sum_{ij\in O}\left[\left(y_{ij} - \mathbf{w}_i^{\mathrm{T}}\overline{\mathbf{x}}_j - m_i\right)^2 + \mathbf{w}_i^{\mathrm{T}}\Sigma_{\mathbf{x}_j}\mathbf{w}_i\right].$$

There are several distinctions compared to the fully observed data: 1) The optimal $\mathbf{m}$ depends on other parameters and therefore it has to be updated in the iterative procedure. 2) The covariance $\Sigma_{\mathbf{x}_j}$ is different for each $\mathbf{x}_j$. 3) Each row of $\mathbf{W}$ is recomputed based only on those columns of $\overline{\mathbf{X}}$ which contribute to the reconstruction of the *observed* values in the corresponding row of the data matrix. The same applies to the computation of the columns of $\overline{\mathbf{X}}$. Thus, the computations required for incomplete data are generally heavier.

3.2 Examples of Overfitting with Probabilistic PCA

PPCA provides some remedy against overfitting, in contrast to the least squares approach. First, a nonzero noise level v_y regularizes badly conditioned matrices $\sum_{i\in O_j}\mathbf{w}_i\mathbf{w}_i^{\mathrm{T}}$ in (17). Second, even

if the noise level is small, badly conditioned matrices $\sum_{i \in O_j} \mathbf{w}_i \mathbf{w}_i^{\mathrm{T}}$ result in large values both in the means $\overline{\mathbf{x}}_j$ and in the covariance matrices $\mathbf{\Sigma}_{\mathbf{x}_j}$. This diminishes the effect of large values in $\overline{\mathbf{x}}_j$ when $\mathbf{W}$ is re-estimated using (18).

However, PPCA can overfit, for example, if the estimated number of principal components is unreasonably large. In the example in Fig. 3, PPCA with one ($c = 1$) principal component is applied to two-dimensional ($d = 2$) data and each data vector is only partly observed (i.e., either y_{1j} or y_{2j} is known for all js). The observations are represented by triangles placed on the two axes in Fig. 3. The data points reconstructed with a trained PPCA model lie on a line, thus the model invents correlations that are not observed in the data. In fact, there are infinitely many PPCA models which are equally good and the final solution (and hence the reconstructions) depends on initialization. The situation would not change significantly if there were a few fully observed data vectors. Then, the trained model would be defined by those few samples and it would not generalize well for new data.

A similar overfitting example is presented in Fig. 4. There, three-dimensional data are described well by a model with $c = 1$ principal component. The first two rows of $\mathbf{Y}$ are fully observed while there are only two measurements in the third row (Fig. 4a). The reconstructions of the third row of $\mathbf{Y}$ are very inaccurate because the model relies only on the two available observations.

3.3 Variational Bayesian PCA (VBPCA)

A common way to cope with the overfitting problem is to penalize parameter values which correspond to more complex explanations of the data. A natural regularization in PCA is using penalization of large values in matrices $\mathbf{W}$ and $\mathbf{X}$. In the Bayesian formulation, this is equivalent to introducing a prior over the model parameters. For example, the PPCA model in (12)–(14) can be complemented with Gaussian priors over the elements of vector $\mathbf{m}$ and matrix $\mathbf{W}$:

$$p(\mathbf{m}) = \mathcal{N}(\mathbf{m}; 0, v_m \mathbf{I}), \tag{19}$$

$$p(\mathbf{W}) = \prod_{k=1}^{c} \mathcal{N}(\mathbf{W}_{:k}; 0, v_{w,k} \mathbf{I}). \tag{20}$$

Here, we use a zero mean prior for $\mathbf{m}$ for the sake of simplicity. Including a mean hyperparameter μ, that is $p(\mathbf{m}) = \prod_i \mathcal{N}(m_i; \mu, v_m)$, can be useful in practice.

The model (20) uses a shared prior for all elements in the same column of $\mathbf{W}$, parameterized with $v_{w,k}$. This is done to allow automatic selection of the right number of components needed for PCA. The hyperparameters v_m, $v_{w,k}$ can also be updated during learning (e.g., using the evidence framework or variational approximations). If the evidence of the relevance of the k-th principal component for reliable data modeling is weak, the corresponding $v_{w,k}$ should tend to zero. This is called *automatic relevance determination* (e.g., Bishop, 2006). The prior in (19)–(20) also introduces a bias towards the PCA basis within the principal subspace (Luttinen and Ilin, 2010).

Let us assume that we perform ML estimation of the hyperparameters $\xi = (v_y, v_{w,k}, v_m)$ in the probabilistic model defined in (12)–(14) and (19)–(20). This can be done using the EM-algorithm if one treats the model parameters $\theta = (\mathbf{W}, \mathbf{X}, \mathbf{m})$ as hidden random variables. Implementation of the EM algorithm would require the computation of the posterior of the hidden variables $p(\theta|\mathbf{Y}, \xi)$ on the E-step. Unfortunately, the true posterior $p(\theta|\mathbf{Y}, \xi)$ does not have an analytic form and one possible solution is to approximate it with a simpler pdf $q(\theta)$. This is justified by the variational view of the EM algorithm (Neal and Hinton, 1999).

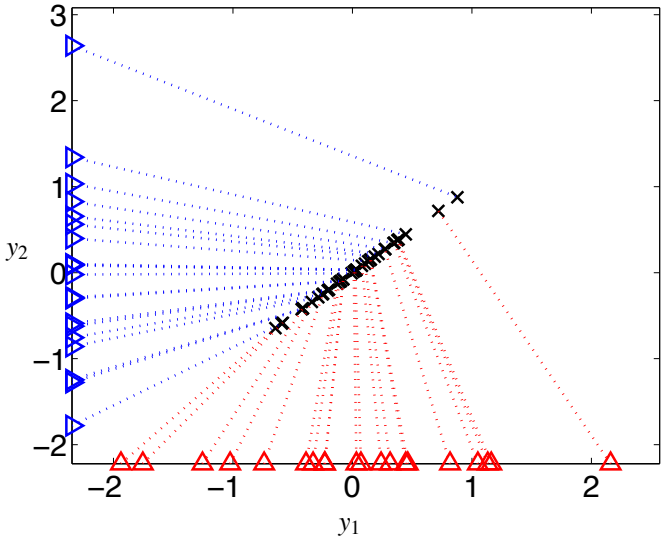

Figure 3: A simple example of overfitting with PPCA: data are two-dimensional and each sample contains only one observed value. The measurements are marked with blue and red triangles at the two axes. The reconstructions provided by a trained PPCA model are shown with crosses.

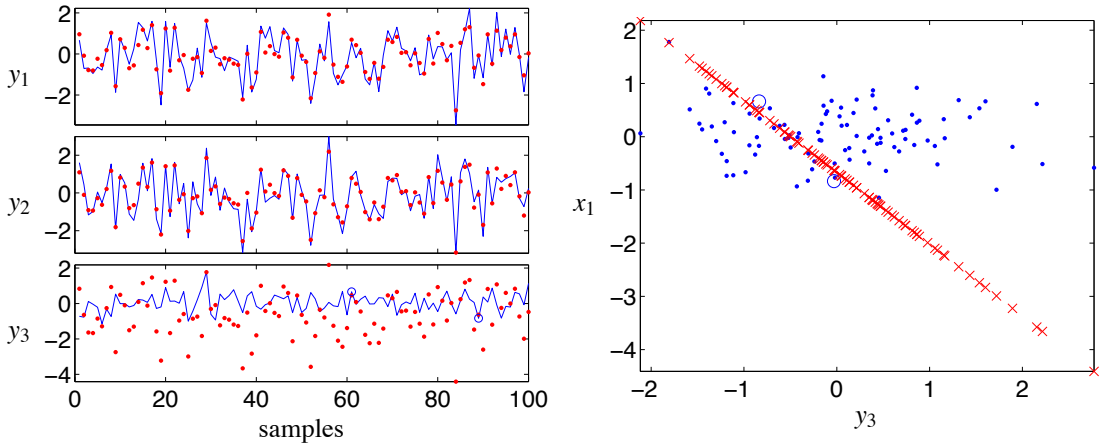

Figure 4: Example of inaccurate reconstruction with PPCA. Left: The "true" values in the three rows of $\mathbf{Y}$ are shown with blue lines. The first two rows are fully observed, the only two observations in the third row are marked with circles. The PPCA reconstruction is shown with red dots. Right: The blue dots is the scatter plot of the third row of $\mathbf{Y}$ (x-axis) against the principal component estimated by PPCA (y-axis). The dots corresponding to the two observations are marked with circles. The red crosses is the reconstruction of the third row (x-axis) against the estimated principal component (y-axis). The estimated correlation are due to the two fully observed data vectors.

Using the variational approach (Wallace, 1990; Hinton and van Camp, 1993), the E-step is modified to update the approximation $q(\theta)$ so as to minimize the cost function

$$C(q(\theta),\xi) = \int q(\theta)\log\frac{q(\theta)}{p(\mathbf{Y},\theta|\xi)}d\theta = \int q(\theta)\log\frac{q(\theta)}{p(\theta|\mathbf{Y},\xi)}d\theta - \log p(\mathbf{Y}|\xi)\,. \tag{21}$$

On the M-step, the approximation $q(\theta)$ is used as it was the actual posterior $p(\theta|\mathbf{Y},\xi)$ in order to increase likelihood $p(\mathbf{Y}|\xi)$. This can be seen as minimization of (21) w.r.t. ξ (Neal and Hinton, 1999).

The first term in (21) is the Kullback-Leibler divergence between the true posterior and its approximation. Since it is always non-negative, the cost function provides a lower bound of the log-likelihood:

$$\log p(\mathbf{Y}|\xi) \geq -C(q(\theta),\xi)\,. \tag{22}$$

This property can be used to compare solutions corresponding to different local minima of (21). More details on variational methods can be found, for example, in the book by Bishop (2006).

The variational Bayesian (VB) approach to PCA can be implemented by minimization of (21) w.r.t. the approximating pdf $q(\theta)$ and ξ.[1] The complexity of the cost function (21) depends on the form of the approximating pdf $q(\theta)$. A computationally convenient form for the PCA model is

$$q(\theta) = \prod_{i=1}^{d} q(m_i)\prod_{i=1}^{d} q(\mathbf{w}_i)\prod_{j=1}^{n} q(\mathbf{x}_j)\,. \tag{23}$$

Then, the cost function can be minimized alternately w.r.t. one factor $q(\theta_i)$ in (23) while keeping the other ones fixed. Because we use conjugate priors in (19)–(20), it is possible to find *optimal* pdfs $q(\theta_i)$ on each step: The optimal $q(m_i)$, $q(\mathbf{w}_i)$ and $q(\mathbf{x}_j)$ are Gaussian and their update boils down to re-estimation of the corresponding means and covariance matrices.

In Appendix C, we present the update rules for the resulting algorithm, which we call VBPCA. There, we assume incomplete data sets, the update rules for the fully observed data can be found in the paper by Bishop (1999). Note the resemblance of the learning rules to the EM algorithm applied to PPCA. The mean parameters $\overline{\mathbf{W}}$, $\overline{\mathbf{X}}$, $\overline{\mathbf{m}}$ of the approximating pdfs can be used as estimates of the corresponding model parameters. The covariance matrices $\Sigma_{\mathbf{w}_i}$, $\Sigma_{\mathbf{x}_j}$ and variances $\widetilde{m}_i$ reflect the uncertainty about the corresponding quantities.

The advantages of the VB approach can be summarized in the following.

- VB learning is sensitive to posterior probability mass rather than posterior probability density, which makes it more resistant against overfitting compared to point estimation (e.g., PPCA or MAPPCA presented in Section 6.4). Typically, overfitted solutions correspond to high peaks in the posterior density while robust solutions contain much of the posterior probability mass in their neighborhood.

- The method provides information about uncertainty for the unknown quantities (in the estimated posterior covariance matrices). This can be useful to detect unreliable results similar to the one presented in Fig. 4. For example, the uncertainty of the reconstructions of missing values can be estimated as we show in Section 5.

1. In the fully Bayesian treatment, the hyperparameters ξ are also assigned priors and they are treated equally to the rest of the parameters θ. We omit the effect of the prior for the hyperparameters to simplify the equations.

- The VB cost function can be used for comparison between different solutions based on (22): A smaller cost yields a greater lower bound of the solution evidence. This is a useful feature for PCA of incomplete data as, in this problem, even simpler models can provide cost functions with multiple local minima. A greater lower bound does not guarantee a better solution, but still it seems to be a reliable measure in practice, see Figure 11 for an example.

4. Rotation in the Principal Subspace to the PCA Basis

A useful property of classical PCA is that the principal components are ordered by the amount of data variance they explain, which allows an intuitive interpretation of the results. Such a representation is quite trivial for complete data sets but the extensions to the case of incomplete data is not straightforward. In this section, we show how to find such a basis in the principal subspace estimated by different algorithms for incomplete data. We refer to this basis as the PCA basis in the principal subspace.

One can define the PCA basis for *complete data* as the solution which minimizes (2) and which satisfies the following conditions: 1) the principal components (in the rows of $\mathbf{X}$) are zero mean, mutually uncorrelated and scaled to unit variance:

$$\frac{1}{n}\sum_{j=1}^{n}\mathbf{x}_j = 0, \tag{24}$$

$$\frac{1}{n}\sum_{j=1}^{n}\mathbf{x}_j\mathbf{x}_j^{\mathrm{T}} = \frac{1}{n}\mathbf{X}\mathbf{X}^{\mathrm{T}} = \mathbf{I} \tag{25}$$

and 2) matrix $\mathbf{W}$ has mutually orthogonal columns which are ordered according to their norms:

$$\mathbf{W}^{\mathrm{T}}\mathbf{W} = \mathrm{diag}(\mathbf{s}), \tag{26}$$

$$s_k \geq s_l\,, \quad k < l\,, \tag{27}$$

where $\mathrm{diag}(\mathbf{s})$ denotes a diagonal matrix with diagonal elements $s_k = \|\mathbf{W}_{:k}\|^2$. Note that the normalized columns of $\mathbf{W}$ and their squared norms s_k are the eigenvectors and eigenvalues of the data covariance matrix.

We propose to use the same conditions (24)–(27) to define the PCA basis in the principal subspace estimated for *incomplete data*. Note the important difference to the complete data case: The PCA basis for complete data is unique (assuming distinct eigenvalues of the data covariance matrix) and it does not depend on the dimensionality for the assumed principal subspace. This cannot be guaranteed for incomplete data case: The principal subspace estimated with the same algorithm using fewer components may differ from the leading directions of the PCA basis found in the subspace with more components.

In the following, we show how to transform a solution found with different algorithms to the PCA basis such that conditions (24)–(27) are satisfied.

4.1 Least Squares Approaches

The first step to transform a solution $\{\mathbf{W},\mathbf{m},\mathbf{X}\}$ found by a least squares algorithm (as presented in Sections 2.2-2.3) is to center the rows in $\mathbf{X}$ to zero mean:

$$\mathbf{x}_j \leftarrow \mathbf{x}_j - \mu, \tag{28}$$

$$\mathbf{m}_{\text{pca}} = \mathbf{m} + \mathbf{W}\mu, \tag{29}$$

with $\mu = \frac{1}{n}\sum_{j=1}^{n}\mathbf{x}_j$. This ensures (24). The next step is to transform linearly $\mathbf{W}$ and $\mathbf{X}$:

$$\mathbf{W}_{\text{pca}} = \mathbf{W}\mathbf{U}\mathbf{D}_x^{1/2}\mathbf{V}, \tag{30}$$

$$\mathbf{X}_{\text{pca}} = \mathbf{V}^{\mathrm{T}}\mathbf{D}_x^{-1/2}\mathbf{U}^{\mathrm{T}}\mathbf{X}, \tag{31}$$

where matrices $\mathbf{U}, \mathbf{D}_x$ are computed by eigen-decomposition

$$\frac{1}{n}\mathbf{X}\mathbf{X}^{\mathrm{T}} = \mathbf{U}\mathbf{D}_x\mathbf{U}^{\mathrm{T}} \tag{32}$$

and $\mathbf{V}$ is calculated by eigen-decomposition

$$\mathbf{D}_x^{1/2}\mathbf{U}^{\mathrm{T}}\mathbf{W}^{\mathrm{T}}\mathbf{W}\mathbf{U}\mathbf{D}_x^{1/2} = \mathbf{V}\mathbf{D}_w\mathbf{V}^{\mathrm{T}}. \tag{33}$$

It is easy to show that the transformed solution satisfies (25)–(26):

$$\begin{aligned}
\frac{1}{n}\mathbf{X}_{\text{pca}}\mathbf{X}_{\text{pca}}^{\mathrm{T}} &= \frac{1}{n}\mathbf{V}^{\mathrm{T}}\mathbf{D}_x^{-1/2}\mathbf{U}^{\mathrm{T}}\mathbf{X}\mathbf{X}^{\mathrm{T}}\mathbf{U}\mathbf{D}_x^{-1/2}\mathbf{V} \\
&= \mathbf{V}^{\mathrm{T}}\mathbf{D}_x^{-1/2}\mathbf{U}^{\mathrm{T}}\mathbf{U}\mathbf{D}_x\mathbf{U}^{\mathrm{T}}\mathbf{U}\mathbf{D}_x^{-1/2}\mathbf{V} = \mathbf{V}^{\mathrm{T}}\mathbf{D}_x^{-1/2}\mathbf{D}_x\mathbf{D}_x^{-1/2}\mathbf{V} = \mathbf{V}^{\mathrm{T}}\mathbf{V} = \mathbf{I}, \\
\mathbf{W}_{\text{pca}}^{\mathrm{T}}\mathbf{W}_{\text{pca}} &= \mathbf{V}^{\mathrm{T}}\mathbf{D}_x^{1/2}\mathbf{U}^{\mathrm{T}}\mathbf{W}^{\mathrm{T}}\mathbf{W}\mathbf{U}\mathbf{D}_x^{1/2}\mathbf{V} = \mathbf{V}^{\mathrm{T}}\mathbf{V}\mathbf{D}_w\mathbf{V}^{\mathrm{T}}\mathbf{V} = \mathbf{D}_w.
\end{aligned}$$

4.2 Probabilistic PCA

We show in Appendix B that the following conditions hold at the convergence of PPCA:

$$\frac{1}{n}\sum_{j=1}^{n}\overline{\mathbf{x}}_j = 0, \tag{34}$$

$$\Sigma_* = \frac{1}{n}\sum_{j=1}^{n}\left[\overline{\mathbf{x}}_j\overline{\mathbf{x}}_j^{\mathrm{T}} + \Sigma_{\mathbf{x}_j}\right] = \mathbf{I}, \tag{35}$$

which can be seen as the analogue of (24)–(25). Note that Σ_* becomes the sample covariance matrix of the principal components in the noiseless limit, when $v_y \to 0$. The extra requirements (26)–(27) can be used to define the (practically) unique PCA basis for a PPCA solution. They resolve the rotational ambiguity caused by the fact that any orthogonal transformation of the principal subspace does not change Σ_* in (35).

One can easily perform a transformation of a PPCA solution such that (34)–(35) and (26)–(27) hold. This is done by first normalizing $\overline{\mathbf{x}}_j$ to zero mean and updating the bias term similarly to (28)–(29). Then, a rotation of the subspace is performed similarly to (30)–(33) with the exception that

$\frac{1}{n}\mathbf{X}\mathbf{X}^{\mathrm{T}}$ is replaced with Σ_*. Finally, one can rotate the posterior covariance matrices of the estimated principal components:

$$\Sigma_{\mathbf{x}_j,\mathrm{pca}} = \mathbf{V}^{\mathrm{T}}\mathbf{D}_x^{-1/2}\mathbf{U}^{\mathrm{T}}\Sigma_{\mathbf{x}_j}\mathbf{U}\mathbf{D}_x^{-1/2}\mathbf{V}\,, \tag{36}$$

which follows from (31).

Although the optimal PPCA solution satisfy at least conditions (34)–(35), convergence of the learning algorithm to the optimal solution can be very slow. Therefore, performing the described transformations during learning can speed up learning. In the experiments, we use the transformations after each iteration.

4.3 VBPCA

It can be shown (Luttinen and Ilin, 2010) that VBPCA described in Section 3.3 converges to the solution which satisfies (34)–(35) and the condition analogous to (26):

$$\sum_{i=1}^{d}\left[\overline{\mathbf{w}_i}\overline{\mathbf{w}_i}^{\mathrm{T}} + \Sigma_{\mathbf{w}_i}\right] = \mathrm{diag}(\mathbf{s})\,, \tag{37}$$

where $\overline{\mathbf{w}_i}$, $\Sigma_{\mathbf{w}_i}$ are the posterior means and covariance matrices for the rows of matrix $\mathbf{W}$ (see Appendix C for notation details). Thus, one can simply use the ordering requirement (27) to define a meaningful basis for a VBPCA solution. Performing a transformation that ensures (34)–(35) and (37) during learning can speed up convergence (Luttinen and Ilin, 2010). The transformation can be performed similarly to (30)–(33) with the exception that $\mathbf{X}\mathbf{X}^{\mathrm{T}}$ is replaced with $\sum_{j=1}^{n}\left[\overline{\mathbf{x}}_j\overline{\mathbf{x}}_j^{\mathrm{T}} + \Sigma_{\mathbf{x}_j}\right]$ in (32) and $\mathbf{W}^{\mathrm{T}}\mathbf{W}$ is replaced with $\sum_{i=1}^{d}\left[\overline{\mathbf{w}_i}\overline{\mathbf{w}_i}^{\mathrm{T}} + \Sigma_{\mathbf{w}_i}\right]$ in (33). Finally, one can rotate the posterior covariance matrices using (36) and

$$\Sigma_{\mathbf{w}_i,\mathrm{pca}} = \mathbf{V}^{\mathrm{T}}\mathbf{D}_x^{1/2}\mathbf{U}^{\mathrm{T}}\Sigma_{\mathbf{w}_i}\mathbf{U}\mathbf{D}_x^{1/2}\mathbf{V}\,.$$

In the experiments, we use the transformations after each iteration.

5. Reconstruction of Missing Values and Selection of Model Rank

PCA is a popular approach to the problem of missing value reconstruction. The estimated principal components capture the correlations between different variables, which allows for reconstruction of missing values from the observed ones. The models discussed in this article compute reconstructions using (5), in which $\mathbf{w}_i, m_i, \mathbf{x}_j$ are replaced with the respective posterior means $\overline{\mathbf{w}}_i, \overline{m}_i, \overline{\mathbf{x}}_j$ when applicable. Additionally, one can estimate the uncertainty of the predictions for PPCA and VBPCA by computing its variance

$$\widetilde{y}_{ij} = \widetilde{m}_i + \overline{\mathbf{w}}_i^{\mathrm{T}}\Sigma_{\mathbf{x}_j}\overline{\mathbf{w}}_i + \overline{\mathbf{x}}_j^{\mathrm{T}}\Sigma_{\mathbf{w}_i}\overline{\mathbf{x}}_j + \mathrm{tr}(\Sigma_{\mathbf{x}_j}\Sigma_{\mathbf{w}_i})\,,$$

where $\widetilde{m}_i$, $\Sigma_{\mathbf{x}_j}$, $\Sigma_{\mathbf{w}_i}$ represent the posterior uncertainties of the respective parameters and $\Sigma_{\mathbf{w}_i}$ is zero for PPCA. This is a useful feature of the probabilistic methods compared to the least-squares approach.

The quality of reconstruction depends on the number of estimated principal components and therefore selection of the model rank is an important problem. In this section, we briefly outline possible solutions to this problem leaving out the detailed discussion.

The most straightforward way to define the rank of the model is to use cross-validation. The data set is divided into training and validation parts, models with different ranks are fitted to the training set and the the rank is selected based on the performance on the held-out validation set.

Another way is to use probabilistic methods for model selection. For example, Minka (2001) developed a means to detect the dimensionality of the principal subspace for *complete* data using Laplace's method and Bayesian information criterion (BIC) applied to the PPCA model. He also discussed other alternatives but his approach showed the best performance. However, the extension of Laplace's method to the case of *incomplete* data is not straightforward. An additional difficulty is the possibility that the posterior distribution over the model parameters has multiple modes corresponding to different principal subspaces. VBPCA can select the optimal number of components automatically by setting some columns of $\mathbf{W}$ to zero. However, the VB cost function may have many local minima which correspond to different model ranks and exploring different local solutions can be a tedious procedure. Hoff (2008) estimated the dimensionality of the principal subspace in the complete data using a sampling procedure.

6. Speeding Up Learning For Sparse High-Dimensional Data Sets

Obtaining a reasonably good solution in appropriate time is a very important issue for high-dimensional problems in which learning may take several days, as in the example considered in Section 7.4. The algorithms presented in the previous sections scale differently to problems with large dimensions and large degree of sparsity of observed values.

The computational complexities of different algorithms are summarized in Tables 2 and 3. For example, the alternating optimization algorithm for PPCA requires computation and inversion of matrices $\sum_{j\in O_i}\left[\mathbf{x}_j\mathbf{x}_j^{\mathrm{T}}+\boldsymbol{\Sigma}_{\mathbf{x}_j}\right]$ and $\left(v_y\mathbf{I}+\sum_{i\in O_j}\mathbf{w}_i\mathbf{w}_i^{\mathrm{T}}\right)$, which are generally unique for each row of $\mathbf{W}$ and each column of $\mathbf{X}$, respectively. The corresponding computational complexity is $O(Nc^2+nc^3)$ per iteration,[2] which is quite a bit heavier than $O(ndc)$ per iteration (Roweis, 1998) required for complete data.

The computational complexity $O(Nc+nc)$ of the gradient method is small compared to previously reported results. For instance, Srebro and Jaakkola (2003) reported the complexity $O(ndc^2)$ for a more general model which was a huge improvement over the complexity $O(n^3c^3)$ of the algorithms proposed even earlier. Using the numbers from the Netflix problem considered in Section 7.4 ($N\approx 10^8$, $n\approx 480189$, $d=17770$, $c=30$), we get rough estimates of the differences in practice: Imputation algorithm $nd^2\approx 10^{14}$, (Srebro and Jaakkola, 2003) $ndc^2\approx 10^{12}$, alternating $\mathbf{W}$–$\mathbf{X}$ $Nc^2+nc^3\approx 10^{11}$, and gradient $Nc+nc\approx 10^{9.5}$.

Once the model has been learned and fixed, doing inference on a new sample is fast. Using the alternating algorithm, it requires only one E-step with $O(N_0c^2+c^3)$, where $N_0\leq d$ is the number of observed values in the new sample, while imputation and gradient algorithms require a number of iterations with $O(dc)$ and $O(N_0c)$ each.

Efficient memory usage is an important issue for sparse data sets. It is preferable that the amount of used memory scales linearly with the number of observed values regardless of the data matrix dimensionalities. In Table 2, we provide the number of parameters estimated by different models, which gives the lower bound for the amount of the required memory. Only the imputation algorithm

2. The computational complexity of the alternating $\mathbf{W}$–$\mathbf{X}$ scheme can be reduced if the matrices requiring inversion are computed once for all rows (columns) of $\mathbf{Y}$ that have observed values at exactly the same columns (rows respectively).

	Section	Number of parameters	Imputation with SVD	Alternating **W**–**X**	Gradient descent

Table 3: Summary of computational complexities (per iteration) of different optimization methods, assuming naïve computation of products and inverses of matrices and ignoring the computation of SVD in the imputation algorithm.

requires memory for the complete data matrix, and even that requirement can be diminished at a cost of greater time complexity.

6.1 Gradient-Based Learning

The gradient-based optimization scheme, extending the Oja learning algorithm to regularized PCA models, can be very efficient for large-scale problems and sparse data sets. The computational complexity of one iteration scales very well with dimensionalities, which can lead to faster learning in practice. The gradient-based approach can also be advantageous compared to the alternating optimization scheme as the latter discards the joint effect of parameters $\mathbf{W}$ and $\mathbf{X}$ on the changes in the cost function. This results in slow convergence without proper speed-up procedures (e.g., Honkela et al., 2003).

We also propose to use a speed-up to the gradient descent algorithm. In Newton's method for optimization, the gradient is multiplied by the inverse of the Hessian matrix. Newton's method is known to be fast-converging, but using the full Hessian is computationally costly in high-dimensional problems ($d \gg 1$). We propose a simplified approach which uses only the diagonal part of the Hessian matrix and includes a control parameter α that allows the learning algorithm to vary from the standard gradient descent ($\alpha = 0$) to the diagonal Newton's method ($\alpha = 1$). The final learning rules then take the form

$$\theta_i \leftarrow \theta_i - \gamma \left(\frac{\partial^2 C}{\partial \theta_i^2} \right)^{-\alpha} \frac{\partial C}{\partial \theta_i}.$$

For example, the cost function (4) has the second-order derivatives

$$\frac{\partial^2 C}{\partial w_{ik}^2} = \sum_{j \in O_i} x_{kj}^2, \qquad \frac{\partial^2 C}{\partial x_{kj}^2} = \sum_{i \in O_j} w_{ik}^2,$$

which can be computed efficiently for sparse data. We showed the efficiency of the proposed optimization scheme in the application to large-scale PCA problems in our conference papers (Raiko et al., 2008, 2007a).

6.2 Online Learning

In cases where the number of data samples is very large, $n \gg d$, it is wasteful to go through the whole data set before updating $\mathbf{W}$ (and $\mathbf{m}$). Using online learning (Oja, 1983), one sample j is processed at a time as follows: The principal components $\mathbf{x}_j$ are inferred using (8) (or the E-step in general), and $\mathbf{W}$ is updated using the gradient approach. When sweeping through the data, updates concerning the latter samples benefit from using the $\mathbf{W}$ that has already been updated using the earlier ones. This reduces the required number of iterations. Downsides of this approach include that determining the step size, or using speed-ups such as the one in Section 6.1 or the conjugate gradient, becomes difficult. Also, for enabling parallel implementation, one should process at least a small batch of samples at a time before updating $\mathbf{W}$ (e.g., Salakhutdinov et al., 2007). Online learning was not considered in this paper.

6.3 Factorial Variational Approximations

The overfitting problem can be more severe for high-dimensional sparse data sets. The situations discussed in Sections 2.4 and 3.2 are more probable when data points are sparsely distributed in high dimensions. Thus, methods penalizing large values of model parameters and taking into account their posterior uncertainty are especially relevant here.

The PPCA and VBPCA approaches, which take into account the posterior uncertainty at least in $\mathbf{X}$, are hardly applicable to large-scale problems. First, the computational burden of one iteration of the alternating $\mathbf{W}$–$\mathbf{X}$ scheme is very large (see Table 3) and application of the gradient-based optimization is cumbersome because of the need to compute $c \times c$ covariance matrices. Second, the required memory is at least nc^2 elements for storing posterior correlations only in $\mathbf{X}$. This becomes infeasible for many large-scale problems even for a decent number of principal components.

A possible solution is to take into account only some posterior correlations and to use variational techniques for learning. For example, the posterior approximation $q(\theta)$ in VBPCA can be made fully factorial leading to

$$q(\theta) = \prod_{i=1}^{d} q(m_i) \prod_{i=1}^{d} \prod_{k=1}^{c} q(w_{ik}) \prod_{c=1}^{k} \prod_{j=1}^{n} q(x_{kj}). \tag{38}$$

instead of (23). Such posterior approximation was used, for example, by Raiko et al. (2007b) for PCA in the presence of missing values. The implementation proposed there was based on the imputation algorithm and thus not easily scalable to high-dimensional sparse problems.

The fully factorial approximation (38) reduces significantly the number of variational parameters. They now include the mean parameters $\overline{m}_i$, $\overline{w}_{ik}$ and $\overline{x}_{kj}$ and the variance parameters $\widetilde{m}_i$, $\widetilde{w}_{ik}$, $\widetilde{x}_{kj}$ in addition to hyperparameters v_y, $v_{w,k}$, v_m, which can be point-estimated. The corresponding

cost function is given in Appendix D. It can be minimized in different ways, for example, by using the gradient-based optimization scheme explained in Section 6.1. The complete algorithm works by alternating four update steps: $\{\widetilde{w}_{ik}, \forall i,k\}$, $\{\widetilde{x}_{kj}, \forall k,j\}$, $\{\overline{w}_{ik}, \overline{x}_{kj}, \forall i,k,j\}$, and $\{v_y, v_{w,k}, v_m, \forall k\}$. The required derivatives are reported in Appendix D. We will further refer to this algorithm as *VBPCAd*.

The idea of fully factorial approximation can also be used for reducing the complexity of PPCA. The posterior of the hidden states $p(\mathbf{X}|\mathbf{Y},\mathbf{W},\mathbf{m},v_y)$ can be approximated to be fully factorial on the E-step. The approximating pdf (38) can be fitted to the true posterior by minimizing the cost function

$$C_{\mathrm{PPCA}} = \int q(\mathbf{X}) \log \frac{q(\mathbf{X})}{p(\mathbf{Y},\mathbf{X}|\mathbf{W},\mathbf{m},v_y)} d\mathbf{X},$$

which is motivated by the variational view of the EM algorithm. The resulting update rules resemble the ones of VBPCAd with the exceptions outlined in Fig. 5. We refer to this approach as *PPCAd*.

Note that the approximation used in PPCAd does not restrict the generality of the PPCA model when it is applied to *complete* data. The variational approximation introduces a bias in favor of solutions for which the form of the posterior approximation agrees with the form of the true posterior (e.g., Ilin and Valpola, 2005). The posterior covariance matrix $\mathbf{\Sigma}_{\mathbf{x}_j}$, which is the same for each j in the fully observed case, is diagonal if and only if the columns of $\mathbf{W}$ are mutually orthogonal. Therefore, restricting the posterior covariance to be diagonal guarantees that (26) holds at convergence. Requirements (24)–(25) are fulfilled because of the assumed prior model for $\mathbf{X}$. Thus, PPCAd for complete data should converge to the PCA basis. PPCAd applied to *incomplete* data is biased in favor of solutions in which the true posterior covariance matrices are closer to being diagonal. Note also that the idea of speeding up learning by using transformations as described in Section 4.3 for VBPCA, cannot be used for VBPCAd, because the transformations would break up the diagonality of the posterior covariance matrices.

There is an interesting connection between the speed-up proposed in Section 6.1 and the fully diagonal posterior approximation. The second order derivatives needed for the speed-up coincide with the inverse of the posterior variance of each parameter, and thus their computation is practically free.

6.4 Ignoring Posterior Uncertainty (MAPPCA)

A further simplification is to use maximum a posteriori (MAP) estimation for the model parameters. The minimized cost function is then minus log-posterior of the parameters. Assuming uniform prior for hyperparameters v_y, $v_{w,k}$, v_m, it is proportional to

$$C_{\mathrm{MAP}} = \frac{1}{v_y} \sum_{ij \in O} (y_{ij} - \mathbf{w}_i^{\mathrm{T}} \mathbf{x}_j - m_i)^2 + N \log 2\pi v_y + \frac{1}{v_m} \sum_{i=1}^{d} m_i^2 + d \log 2\pi v_m \\ + \sum_{k=1}^{c} \left[\frac{1}{v_{w,k}} \sum_{i=1}^{d} w_{ik}^2 + d \log 2\pi v_{w,k} + \sum_{j=1}^{n} x_{kj}^2 + n \log 2\pi \right]. \quad (39)$$

and it should be minimized w.r.t. the unknown quantities $\mathbf{W}, \mathbf{X}, v_y, v_{w,k}, v_m$. We refer to this approach as MAPPCA.

Minimization of (39) can be done by any suitable optimization procedure. Derivatives required for gradient-based optimization are given in Appendix E. However, some difficulties should be

avoided. First, using an improper prior for hyperparameters leads to a situation where the posterior pdf is infinitely large when $v_{w,k} \to 0$, $\sum_{i=1}^{d} w_{ik}^2 \to 0$. This can be overcome by penalizing too small values of the variance hyperparameters. For example, a hyperparameter v_z, which is a variance parameter of the prior for a set of zero-mean variables $\{z_i, i = 1, \ldots, M\}$, can be updated as $v_z = \frac{2\beta + \sum_{i=1}^{M} \langle z_i^2 \rangle}{2\alpha + M}$, where $\langle z_i^2 \rangle$ denotes the expectation of z_i^2 over the posterior, and α and β are some small values (we used $\alpha = 10^{-3}$ and $\beta = 10^{-3}$). This update rule corresponds to broad priors restricting v_z to be positive and it guarantees that $v_z \geq \frac{\beta}{\alpha + M/2}$. The maximum likelihood (ML) estimate $v_z = \frac{1}{M} \sum_{i=1}^{M} \langle z_i^2 \rangle$ is achieved when $\alpha \to 0, \beta \to 0$.[3]

Another issue is the non-identifiability of scaling between $\mathbf{W}$ and $\mathbf{X}$. A practical way to avoid this problem is to fix the scale by normalizing the rows of $\mathbf{X}$ to zero mean and unit variance (after each update) and compensating by scaling the columns of $\mathbf{W}$ accordingly. This guarantees the fulfilment of (24)–(25), which are the conditions justified by the prior model.

6.5 Summary of the PCA Variants

The differences between the six described variants of the PCA models are summarized in Table 4 and Fig. 5. The approaches differ on the posterior models and on the use of prior for $\mathbf{W}$ and $\mathbf{m}$. All the variants can be derived as special cases of VBPCA by making simplifying assumptions, which is shown in Fig. 5.

7. Experiments

We study the properties of the discussed algorithms first using artificial data and then presenting a case study using the Netflix competition data (Netflix, 2007). In the experiments with artificial data, we generated data matrices $\mathbf{Y}$ according to model (12)–(14) with fixed dimensionalities d, c and n. The mixing matrix $\mathbf{W}$ was generated by taking a random orthogonal matrix and scaling its columns by $1, 2, \ldots, c$. The bias term $\mathbf{m}$ was selected randomly from a Gaussian distribution with variance 10. For one of the data sets (10-5-mlp), we nonlinearly transformed the resulting data. The observed values were selected randomly in $\mathbf{Y}$ and the rest of the data matrix was used to compute the test reconstruction error.

We used four types of data sets in the experiments:

- *Data Set 10-5-g*: The data set is for the case where $d \ll n$ and Gaussian components. We generated $n = 1000$ samples from a 10-dimensional Gaussian distribution with $c = 5$ principal directions. The standard deviation of the noise in (14) was $\sqrt{v_y} = 0.5$.

- *Data Set 10-5-mlp*: The data lie within a nonlinear manifold and $d \ll n$. The data were generated by a random nonlinear transformation of five-dimensional Gaussian data to the 10-dimensional space and adding relatively small Gaussian noise. The transformation was performed by randomly initialized multi-layer perceptron networks. The number of samples was $n = 1000$.

- *Data Set 10-4-mog*: The data set is a linear combination (12) of non-Gaussian $\mathbf{x}_j$ and $d \ll n$. We used $c = 4$ independently distributed non-Gaussian components (elements of $\mathbf{x}_j$). The

3. In the formulas reported in the article, we always present the ML update rules, although more robust update rules were used in practice.

	prior for $\mathbf{W}, \mathbf{m}$	posterior for $\mathbf{W}, \mathbf{m}$	posterior for $\mathbf{X}$
LS	uniform	point	point
PPCA	uniform	point	full
PPCAd	uniform	point	diagonal

VBPCAd	yes	diagonal	diagonal
MAPPCA	yes	point	point

Table 4: Variants of probabilistic approaches to PCA.

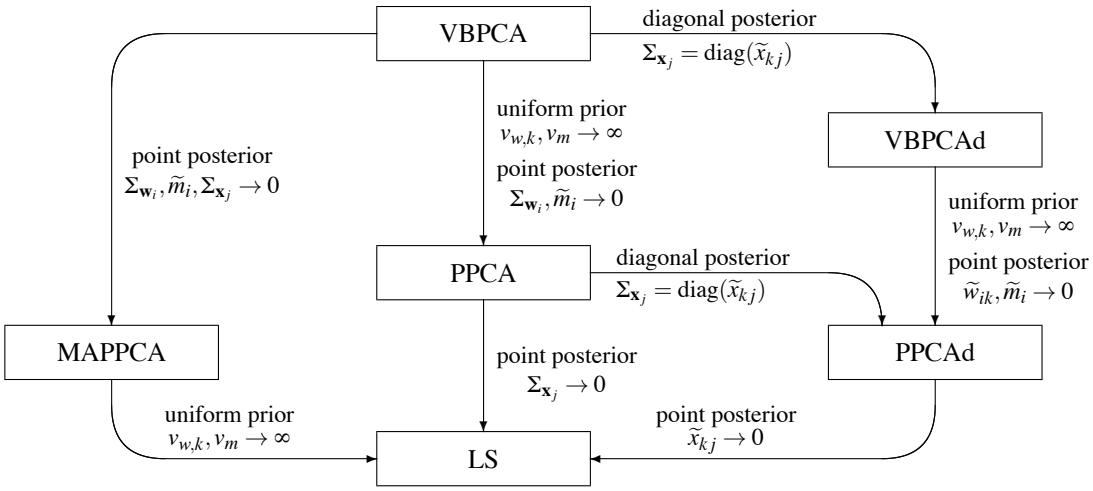

Figure 5: Relationships between the PCA variants are easily described by deriving each of them as a special case of VBPCA. The corresponding update rules can also be derived from the VBPCA update rules using the given restrictions.

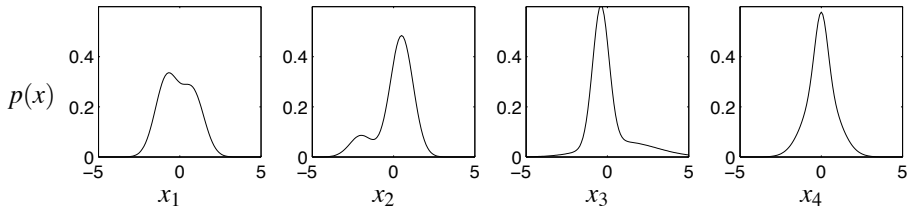

Figure 6: The distributions of the four components used to generate the 10-4-mog data set.

Data Set	d	n	c	Gaussianity	Square root of variances
10-5-g	10	1000	5	yes	[5 4 3 2 1 0.5 ... 0.5]
10-5-mlp	10	1000	5	no	varying by nonlinear transformation
10-4-mog	10	1000	4	no	[4 3 2 1 0.5 ... 0.5]
100-10-g	100	100	10	yes	[10 9 ... 1 0.1 ... 0.1]

Table 5: Characteristics of four types of data sets used in artificial experiments.

distributions of the four components are presented in Fig. 6. The standard deviation of the noise in (14) was $\sqrt{v_y} = 0.5$. The number of samples was $n = 1000$.

- *Data Set 100-10-g*: The data set is for the case where $d \approx n$ and small noise. The data were generated from a 100-dimensional Gaussian distribution with $c = 10$ principal directions. The standard deviation of the noise in (14) was $\sqrt{v_y} = 0.5$. The number of samples was $n = 100$.

The ratio of missing values was varied for all data sets. We used data sets with relatively small dimensionalities in order to test the performance of many alternative algorithms in a reasonable time. The summary of the data sets is shown in Table 5.

Different PCA algorithms considered in this article were used to estimate the same number c of principal components that was used for generating the data (see Table 5). The algorithms were initialized randomly except for the imputation algorithm which has a standard procedure of infilling missing values with the row-wise means of $\mathbf{Y}$.

The performance of the algorithms was assessed by the speed of their convergence and the accuracy in the task of missing value reconstruction. We computed three quantities: the average training root mean square (RMS) reconstruction error $\sqrt{\frac{1}{N}\sum_{ij\in O}(y_{ij} - \hat{y}_{ij})^2}$, the average test RMS reconstruction error and the average time to convergence. Averaging was done across 30 different data sets of the same type and the same ratio of missing values. The algorithms were run until the deviation of the training error was less than 0.0001 during 100 iterations. This stopping criterion was used to estimate the time to convergence.

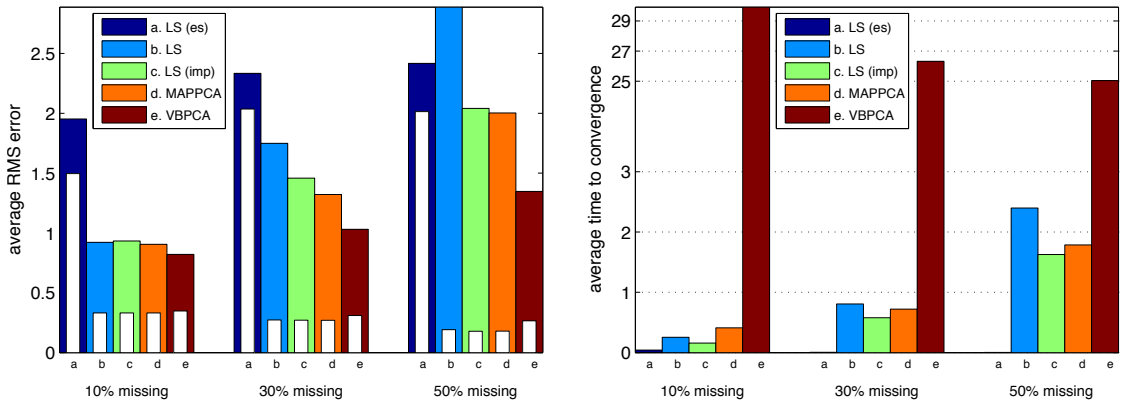
7.1 Performance of Least Squares Approaches and MAPPCA When $d \ll n$

In this section, we present the performance of three techniques:

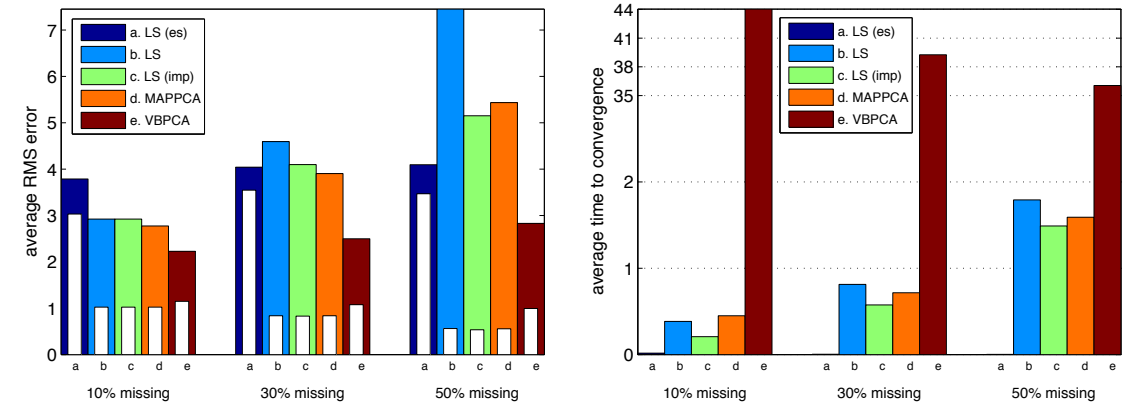
- LS: the least squares approach which optimizes the cost function (4) using the gradient-based procedure with the speed-up explained in Section 6.1
- LS (es): the same algorithm which also used early stopping: 20% of data was reserved as validation set and learning was stopped when the reconstruction error for the validation set started to increase
- LS (imp): the imputation algorithm presented in Section 2.5
- MAPPCA: method presented in Section 6.4. We used the gradient-based optimization procedure with the speed-up explained in Section 6.1.

The estimated performance of the four algorithms is presented in Fig. 7. There, we also show the results of VBPCA which turned out to be the most accurate method. We summarize the observed results in the following.

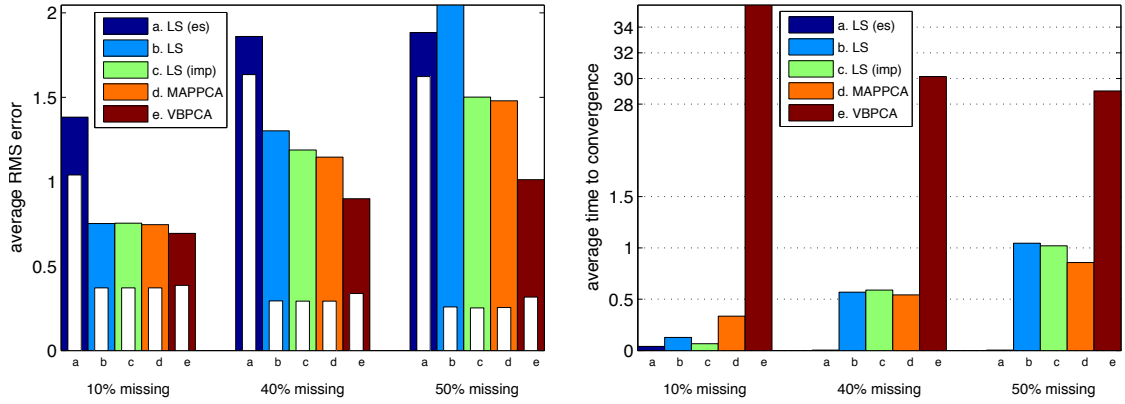
The gradient-based LS approach can be used for data sets with a relatively small amount of missing data. For such data sets, it provides reasonable accuracy, converges fast and scales well to high-dimensional data. However, its performance deteriorates fast with the increase of the ratio of missing values. The algorithm can get stuck at regions where learning proceeds very slowly and overfitting problems become very frequent. When overfitting happens, some parameter values can grow very large to explain perfectly only part of data. This results in very bad generalization and large test reconstruction errors (see discussion in Section 2.1). Thus, this method can badly overfit



(a) Data Set 10-5-g



(b) Data Set 10-5-mlp



(c) Data Set 10-4-mog

Figure 7: Left: Average test RMS errors (colored bars) and training RMS errors (white bars) obtained from 30 realizations of data sets of three types. Right: Average time to convergence, in seconds, estimated in the same way. Note the different scale on the r.h.s. plots for VBPCA.

even in relatively simple problems. We observed similar performance for the alternating optimization (see Section 2.2) of the sum-squared cost function: The alternating optimization procedure provided similar reconstruction errors but it seemed to get stuck in regions with slow convergence more often.

The simplest strategy of *early stopping* did not seem to improve the performance of the LS algorithms. On the contrary, the obtained accuracy was the worst among the considered approaches.

The imputation algorithm can also be a good choice for data sets with a relatively small amount of missing data. The algorithm converges fast, provides good accuracy and it has less problems with overfitting compared to explicit optimization of the sum-squared error. However, the complexity of the required computations grows fast with the increase of the dimensionalities, and therefore the algorithm is hardly applicable to large-scale data sets.

MAPPCA is a fast algorithm which provides reasonable accuracy for data sets with a relatively small amount of missing data. In many cases, it slightly outperforms the LS approaches in terms of the reconstruction accuracy. It is also less prone to serious overfitting problems compared to explicit optimization of (4). Again, similar performance was observed for MAPPCA optimized with the alternating optimization procedure explained in Section 2.2.

7.2 Performance of More Advanced Probabilistic Approaches When $d \ll n$

In this section, we present the performance of the more advanced probabilistic approaches:

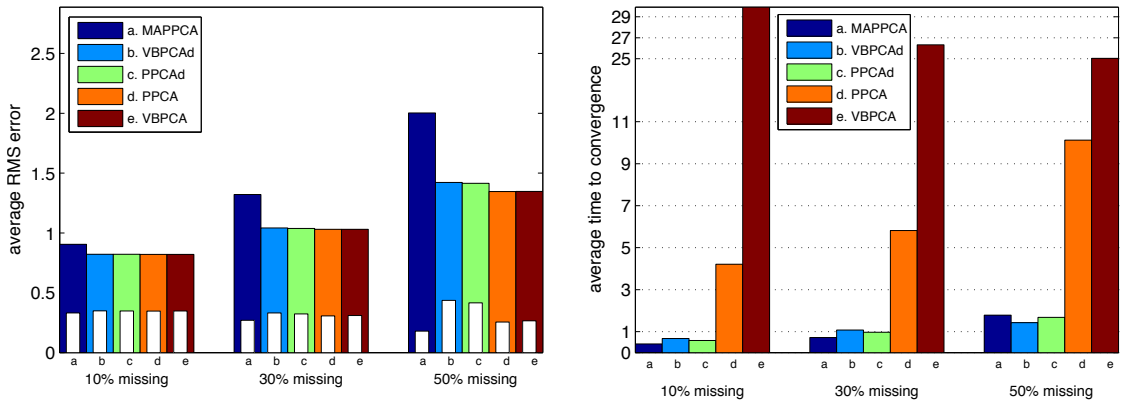
- PPCA presented in Section 3.1
- PPCAd which is PPCA with fully factorial variational approximation explained in Section 6.3
- VBPCA presented in Section 3.3
- VBPCAd which is VBPCA with fully factorial variational approximation explained in Section 6.3.

We used the gradient-based optimization procedure with the speed-up explained in Section 6.1 for training PPCAd and VBPCAd.

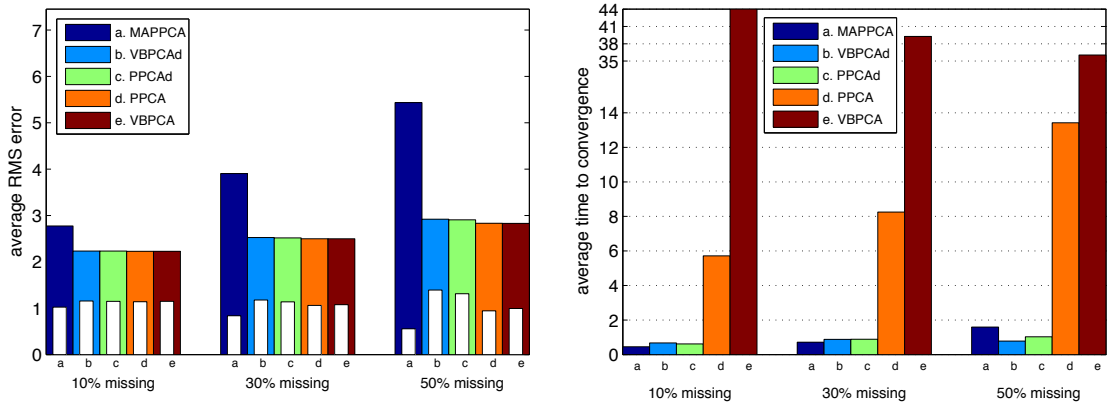
Fig. 8 presents the estimated performance of the algorithms for three data sets with $d \ll n$. We also show the results of MAPPCA for comparison. We summarize the results in the following.

Approaches using variational approximations, especially VBPCA and VBPCAd, may suffer from the underfitting problem. The algorithms may converge to a sub-optimal solution (corresponding to a local minimum of the VB cost function) in which some potentially useful principal components are not used. The algorithms seem to find such sub-optimal solutions more often for sparse data. Special care has to be taken to avoid such local minima. For example, in the presented experiments we fixed priors for $\mathbf{W}$ to be very broad at the beginning of learning and this helped improve the performance of VBPCA and VBPCAd significantly. See also the experiment showing the effect of the broad priors in Section 7.3.

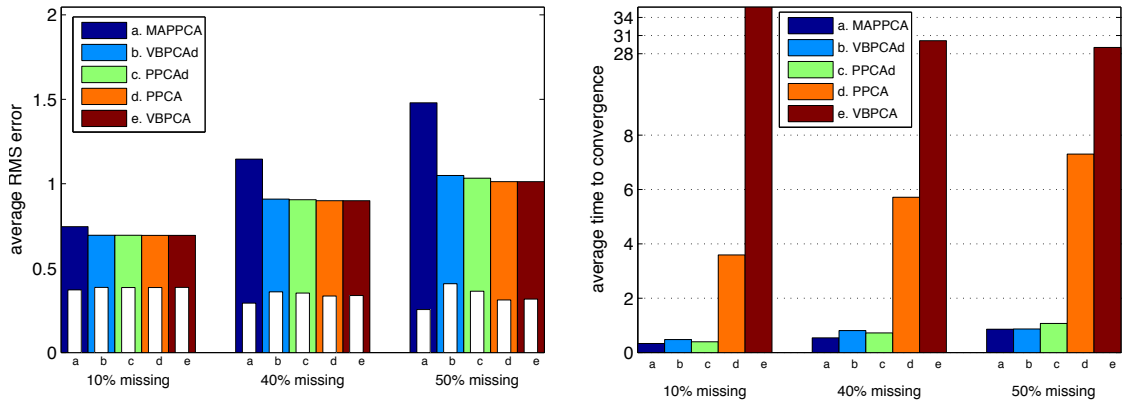
PPCAd is a very efficient algorithm for data sets with $d \ll n$. Its reconstruction accuracy is comparable to the best results (obtained with VBPCA) but the algorithm converges fast and scales well to high-dimensional problems. The difference of the accuracy of PPCAd compared to the best results of VBPCA becomes more noticeable when the ratio of missing values or the number of estimated principle components increase.



(a) Data Set 10-5-g



(b) Data Set 10-5-mlp



(c) Data Set 10-4-mog

Figure 8: Left: Average test RMS errors (colored bars) and training RMS errors (white bars) obtained from 30 realizations of data sets of three types. Right: Average time to convergence, in seconds, estimated in the same way. Note the different scale on the r.h.s. plots for VBPCA.

VBPCAd provides similar performance to PPCAd for data sets with $d \ll n$ but it is more prone to the underfitting problem mentioned earlier.

VBPCA and *PPCA* are the most accurate algorithms in these experiments. However, they are also very slow because of the required computations of the posterior covariance matrices. Thus, the methods are computationally very expensive to use in high-dimensional problems but if they are feasible, they are worth trying. The difference in the accuracy of VBPCA and PPCA is not noticeable in these experiments. This is likely due to the fact that the number n of samples was very large and the effect of priors was very small. VBPCA is also more prone to the underfitting problem compared to PPCA.

7.3 Performance in Difficult Sparse Problems

In this section, we test the performance of the considered algorithms on a more challenging data set 100-10-g. The data set is quite sparse (up to 75% of values are missing) and the number n of samples is very small compared to the data dimensionality d. Sparse data sets with $d \approx n$ can appear in some practical applications. For example, in collaborative filtering the number of users can be comparable to the number of ranked items and the number of missing values can be large. Here we used Gaussian data with $n = d = 100$, $c = 10$ principal directions and with relatively small noise.

Fig. 9 presents the performance of the considered algorithms for these data. The LS algorithms and MAPPCA do not provide good performance because of overfitting problems. The probabilistic approaches perform much better and the best results are obtained with VBPCA. The advantage of VBPCA becomes more significant for data sets with many missing values. The experiments also show a larger effect of using priors in VBPCA and VBPCAd (in comparison with PPCA and PPCAd) for data sets with a relatively small number of samples.

One of the reasons for the superior performance of the VB approach is its ability to select automatically the optimal rank of the model by cutting off useless principal components. Model selection is useful even in such artificial tests (when the number of principal components used for data generation is known) because the number of components which are useful for reliable reconstruction of missing data can turn out to be smaller than the model rank used for generating the data. Thus, the reported accuracy of the algorithms alternative to VBPCA and VBPCAd might be improved if model selection was explicitly performed for them (e.g., by cross-validation).

In Section 7.2, we pointed out that the downside of the VB model selection is the existence of multiple sub-optimal solutions corresponding to different local minima of the VB cost function. Solutions in which the effect of some components is set to zero are potentially attractive for the method. In order to avoid sub-optimal solutions, we fixed the priors for $\mathbf{W}$ to be very broad at the beginning of learning for VBPCA and VBPCAd in our experiments. We show the effect of the number of iterations with fixed broad priors on the resulting accuracy in Fig. 10.

A useful feature of the VB approach is that the value of the VB cost function at a local minimum can be used to estimate the accuracy of the corresponding model. This follows from the fact that the VB cost gives the lower bound of the likelihood, as shown in (22). In Fig. 11, we demonstrate the correlations between the accuracy of a trained VBPCA model and the corresponding value of the cost function. In that experiment, we initialized VBPCA in two different ways and applied it to 30 realizations of the 100-10-g data set with 80% of missing data. The negative result was that different initializations led to different VBPCA solutions for most of the 30 realizations. The positive result

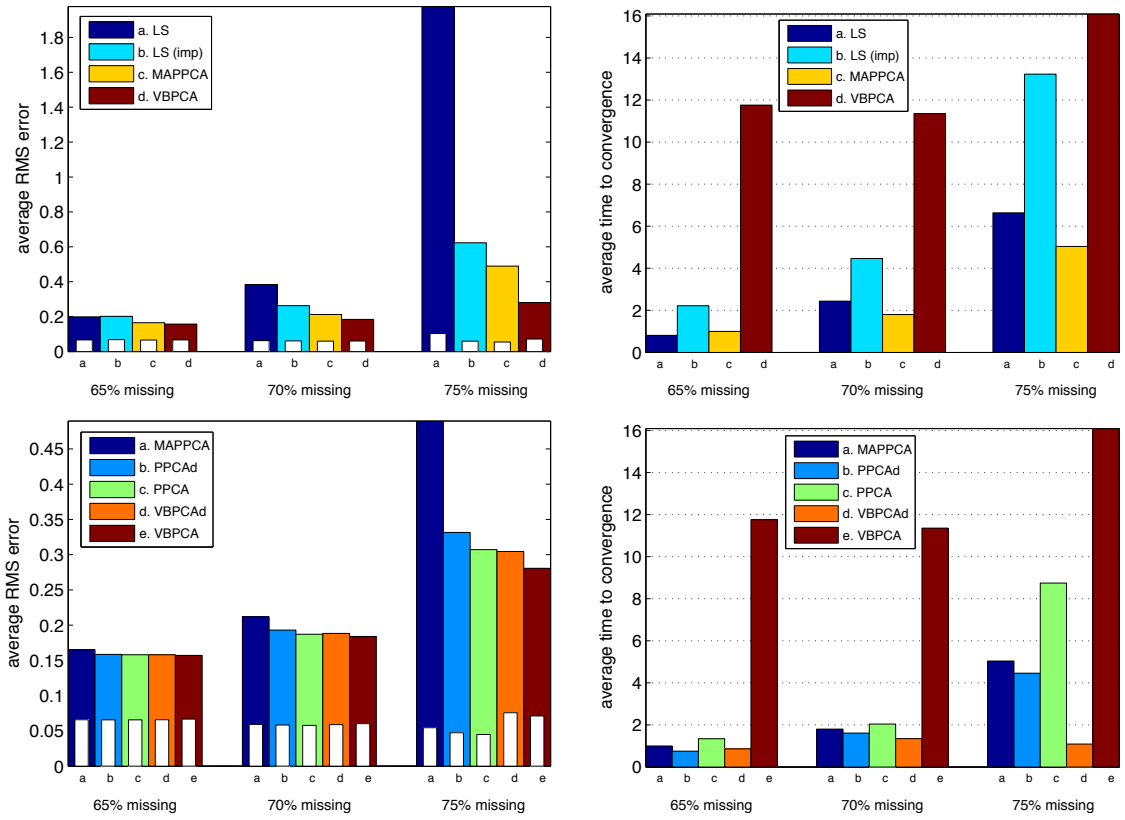


Figure 9: Left: Average test rms errors (colored bars) and training rms errors (white bars) obtained from 30 realizations of data set 100-10-g. Right: Average time to convergence, in seconds, estimated in the same way.

was that the solutions with the smaller cost function values generally provided better reconstruction accuracy. Similar results were obtained for VBPCAd (not shown here).

Thus, in order to find a *globally* good VB solution, one could, in practice, run the learning algorithm many times. The algorithm should be run until *full convergence*, otherwise the cost function values cannot be used for model comparison. Running VBPCA can be computationally heavy because it is the slowest algorithm among the considered ones. Therefore, VBPCAd is an attractive alternative for large-scale data sets.

7.4 Experiments with the Netflix Data

We have tested different PCA approaches in the task of collaborative filtering. The Netflix (2007) problem is a collaborative filtering task that has received a lot of attention recently. It consists of movie ratings given by $n = 480189$ customers to $d = 17770$ movies. There are $N = 100480507$ ratings from 1 to 5 given, and the task is to predict 2817131 other ratings among the same group of customers and movies. 1408395 of the ratings are reserved for validation (or probing). Note that 98.8% of the values are thus missing.

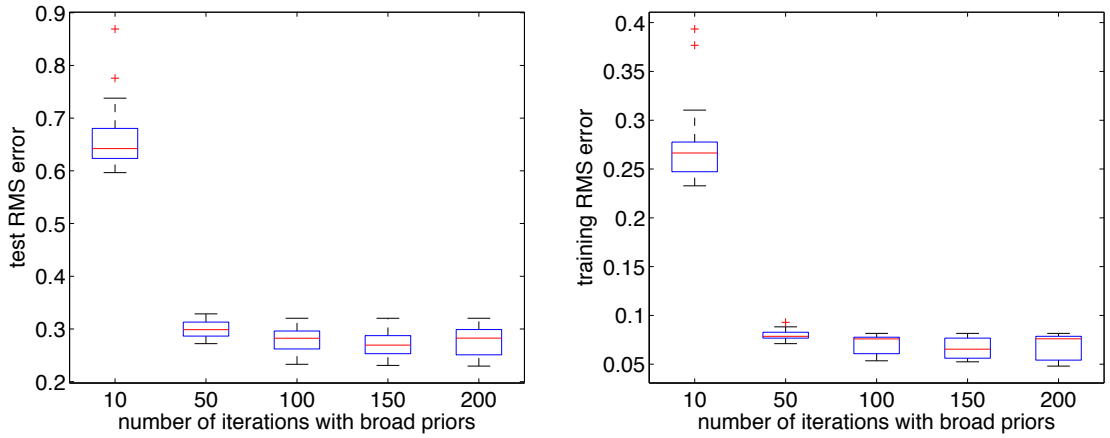

Figure 10: The underfitting effect for VBPCA when the priors are updated too early: Box plots of test (left) and training (right) RMS errors depending on the number of iterations with fixed broad priors for $\mathbf{W}$ (x-axes) at the beginning of learning. VBPCA was applied to 30 data sets of type 100-10-g with 75% of missing values.

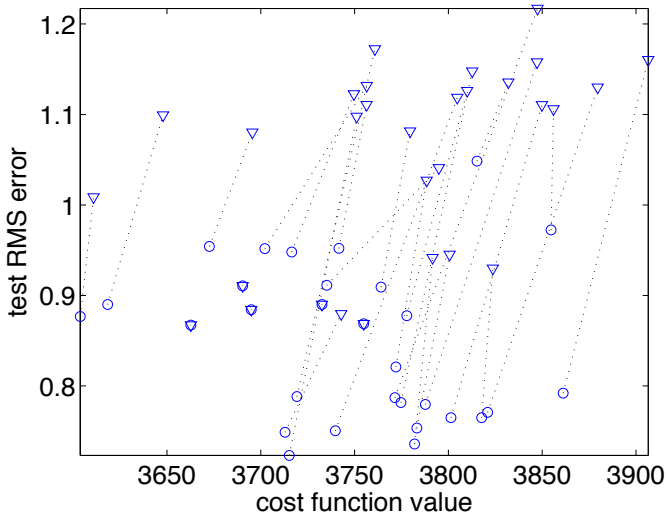

Figure 11: Test RMS error (y-axis) against cost function values (x-axis) obtained with VBPCA for 30 realizations of the data set 100-10-g with 80% of missing values. Two initializations were used for each realization: random (the corresponding local minima are shown with triangles) and with 100 iterations of PPCAd (the corresponding local minima are shown with circles). The dotted lines connect two solutions obtained for the same realization.

The PCA approach is one of the most popular techniques considered by the Netflix contestants (e.g., Funk, 2006; Bell et al., 2007; Salakhutdinov et al., 2007; Paterek, 2007; Lim and Teh, 2007). In our recent conference papers (Raiko et al., 2007a, 2008), we tried to estimate $c = 15$ principal components from the data using unregularized (LS) PCA, MAPPCA, and VBPCAd approaches. We reproduce the results for the LS approaches in Fig. 12. The results clearly show that overfitting is a serious problem for this sparse data set and the LS approach fails. It is also evident that the alternating optimization algorithm is very slow and it can hardly be used for such high-dimensional data. The imputation algorithm is also infeasible in this problem (Raiko et al., 2008). The proposed remedy is to use probabilistic approaches.

Fig. 13 presents the results obtained with MAPPCA and VBPCAd using a varying number of principal components. MAPPCA starts to overfit after about five hours of computation, that is, the RMS error on the test data (lower curves) starts to degrade even if the RMS error on the training data is still diminishing. This does not happen with VBPCAd as the validation error seems to decrease monotonically. The experiments also confirm that VBPCAd is computationally scalable to very large problems. We also tried to run VBPCA, but the straightforward Matlab implementation turned out to be too slow to produce meaningful results. The experiments were run on a dual cpu AMD Opteron SE 2220 using Matlab and the implementations did not use parallel computing.

Our best RMS error for the probing Netflix data was 0.9055 and it was achieved with VBPCAd with 50 components. The same model re-trained using both training and probing data provided an RMS error 0.8990 on the quiz set. The only pre/post-processing that we used was bounding the reconstructions $\hat{y}_{ij}$ such that $1 \leq \hat{y}_{ij} \leq 5$. This is a good result compared to conceptually similar models developed by other contestants. For example, Bell et al. (2007) reported an RMS error of 0.9135 with basic factor analysis with 40 components. Lim and Teh (2007) studied a model which basically implements VBPCA and they reported an RMS error of 0.9141 for a model with 30 components. Salakhutdinov and Mnih (2008b) reported the probing RMS error 0.9280 for an SVD method which essentially implements the LS approach. Their constrained probabilistic matrix factorization model provided a probing RMS error 0.9016 but it used extra informations and more sophisticated priors. The accuracy of our VBPCAd model is comparable to the accuracy of an MCMC approach applied to a similar generative model (Salakhutdinov and Mnih, 2008a). The RMS error achieved with a model with 60 components trained by MCMC was 0.8989 for the quiz set.

Besides reconstruction of missing values, probabilistic PCA methods provide extra information which can be useful in practice. For example, one can predict the uncertainty of the provided reconstructions, as discussed in Section 5. Fig. 14 shows good correlation between the probing RMS errors and the uncertainty of the reconstructions computed by VBPCAd. It is clear that the predicted uncertainty is underestimated, which is largely because of the approximations used in modeling the posterior distributions.

The estimated uncertainty can provide additional information when PCA is used as a preprocesing step for more sophisticated methods. For example, Bell and Koren (2007) used PCA results for constructing a user-oriented neighborhood model for collaborative filtering. Because each column of matrix $\mathbf{X}$ computed by PCA can be considered as a collection of some features associated with a particular user, the similarity between n users can be estimated based on the similarity between the columns of $\mathbf{X}$. The information about the uncertainty of the feature estimates could be used to build a robust similarity measure: Users who have rated few movies (and whose features

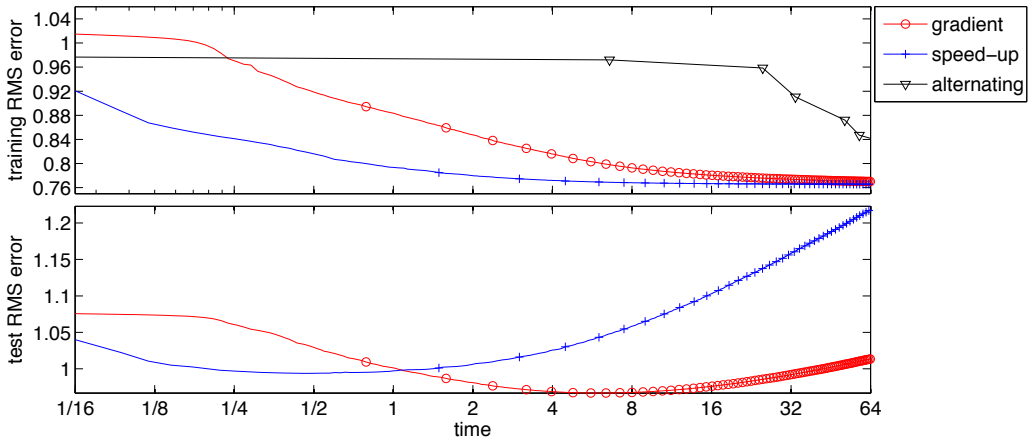

Figure 12: Learning curves for LS algorithms in the Netflix problem. The RMS error (y-axis) is plotted against the processor time in hours. The upper curves show the training error while the lower curves show the test error (for the probing data provided by Netflix). Note that the time scale is logarithmic. The probing error provided by the alternating algorithm is not shown because it is too large compared to the other two curves. The two gradient-based approaches were implemented using parallel computing (this implementation was about twice as fast as the implementation on a single CPU).

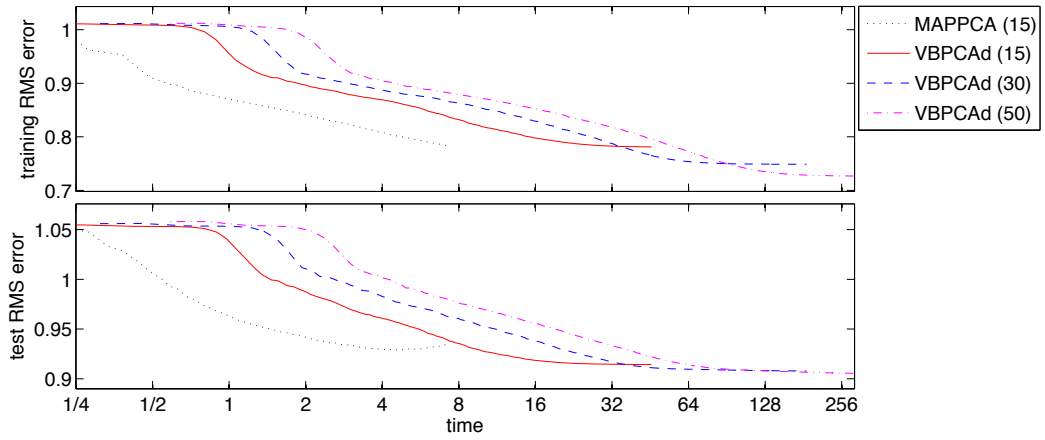

Figure 13: Learning curves for regularized methods in the Netflix problem. The RMS error (y-axis) is plotted against the processor time in hours. The upper curves show the training error while the lower curves show the test error (for the probing data provided by Netflix). Note that the time scale is logarithmic.

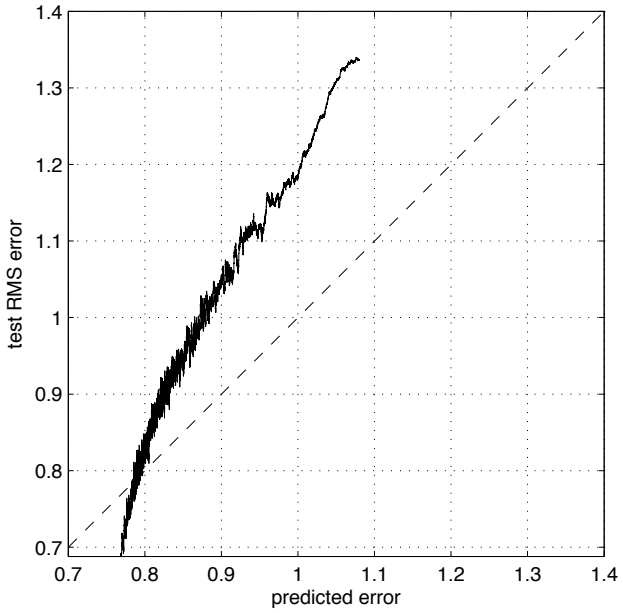

Figure 14: Uncertainty predicted by VBPCAd for the Netflix probing data. The RMS error for the probing data (y-axis) is plotted against the square root of the reconstruction variance estimated by VBPCAd with 50 components (x-axis). To show the dependency more clearly, the estimates of the probing RMS errors are obtained by averaging over a batch of ratings with similar predicted uncertainties.

are estimated with high uncertainty) should not affect the predictions of their neighbors as much as users who have rated many movies (and whose features are estimated more accurately).

Finally, we note that the accuracy achieved by the best teams in the Netflix competition is significantly better than the numbers reported here. However, that does not mean that PCA (and its implementations discussed in this paper) is of no use in collaborative filtering tasks. On the contrary, PCA or its close relatives were used by the leading teams (e.g., Bell et al., 2007) as an important element of the final blend of models. The key to success in that competition was in combining a vast collection of different models rather than in perfecting a single approach (e.g., The Ensemble, 2009).

8. Discussion

We have reviewed the problem of PCA learning in the presence of missing values and discussed various approaches to it. We demonstrated that the simplicity of PCA is lost when introducing missing values. Firstly, the estimation of the bias term and the covariance matrix of the data becomes difficult and thus the solution by eigen-decomposition cannot be used directly. Secondly, the convergence to a unique solution cannot be guaranteed even for the simplest PCA models.

Missing values also make the problem of overfitting more relevant to PCA, so there is a need for some form of regularization. In regularized solutions, reconstructions of data vectors are no longer

conditions	small-scale problems	large-scale problems
few missing values	imputation	gradient-based LS
$d \ll n$	PPCA	PPCAd
many missing values or $d \approx n$	VBPCA	VBPCAd

Table 6: Recommendations on the use of different PCA algorithms.

the projections of the data to the principal subspace. Regularization can be done elegantly using probabilistic models.

Inference and learning in the relevant probabilistic models are generally more complex compared to the complete data case. For example, the posterior covariance of principal components $\Sigma_{\mathbf{x}_j}$ is no longer same for each sample. Thus, a diagonal posterior covariance $\Sigma_{\mathbf{x}_j}$ is no longer sufficient for finding the optimal PCA solution. Regularized models typically have more local minima of the optimized cost function. In particular, there can be local minima corresponding to zero values of hyperparameters.

Another type of treatment for random variables is to use MCMC methods. Their benefits compared to VBPCA includes not having to assume posterior independence like in (23) and being able to vary the number of components (Hoff, 2008), but the downsides include worse interpretability, higher computational complexity, and the need to store samples in case the model is to be applied to new incoming data. Salakhutdinov and Mnih (2008a) used Gibbs sampling initialized with the MAPPCA method for the Netflix problem. The resulting accuracy was similar to ours with similar number of components (0.8989 with 60 components against our 0.8990 for VBPCAd with 50 components).

Large-scale PCA problems require fast converging learning algorithms which allow for efficient implementation. Additionally, sparse data sets require that the amount of computer memory would scale linearly with the number of observed values regardless of the data matrix dimensionalities. In this paper, efficient solutions are proposed based on fully factorial variational approximations and approximate Newton's iteration for the relevant optimization procedure. An alternative learning algorithm based on natural gradient was discussed in our conference paper (Raiko et al., 2008).

The choice of the right PCA algorithm depends on a particular data analysis problem. We gave some recommendations in Sections 7.1–7.3 and we summarize our recommendations in Table 6. The LS approaches can be applied to data sets with relatively few missing data: The *imputation* algorithm can be a good choice for smaller-scale problems and the gradient-based LS algorithms would be good for large data sets. When the number n of samples is relatively large and the data matrix is relatively densely populated, PPCA is a proper choice (or PPCAd for large-scale problems). VB algorithms can be most efficient when there are very few samples ($d \approx n$) or for very sparse data sets. Again, VBPCAd would be a better alternative for large-scale problems.

A Matlab toolbox which contains implementations of all the considered PCA techniques is available online at `http://www.cis.hut.fi/projects/bayes/`. Some of the implemented algorithms scale well to large-scale sparse data sets, which is achieved by low level implementation of core computations and by support of parallel computing. For example, the experiments with the Netflix data reported in Fig. 13 were obtained using the provided Matlab code.

Acknowledgments

The authors would like to thank Juha Karhunen, Erkki Oja, Alexey Kaplan, and Jaakko Luttinen for useful discussions. This work was supported by the Academy of Finland (projects 'Unsupervised machine learning in latent variable models', 'Novel machine learning techniques for studying climate variability and its impacts', 'Auditory approaches to automatic speech recognition' and 'Bayesian Machine Learning Algorithms for Discovering Relations with Latent Variable Models'), and by the IST Program of the European Community, under the PASCAL2 Network of Excellence. This publication only reflects the authors' views. We would like to thank Netflix (2007) for providing the data.

Appendix A. Notes on the Imputation Algorithm

The imputation algorithm can be seen as the application of the EM algorithm (Dempster et al., 1977) to the model

$$\mathbf{y}_j = \mathbf{W}\mathbf{x}_j + \mathbf{m} + \varepsilon_j$$

with isotropic Gaussian noise $p(\varepsilon_j) = \mathcal{N}(\varepsilon_j; 0, v_y\mathbf{I})$ and model parameters $\mathbf{W}$, $\mathbf{x}_j$, $\mathbf{m}$, v_y. Note that $\mathbf{x}_j$ belong to the model parameters and missing values in $\mathbf{y}_j$ are treated as *hidden variables*. This is contrary to the probabilistic PCA model (see Section 3.1) where $\mathbf{x}_j$ are treated as hidden variables. Note also that with this interpretation, there is no well defined inference procedure for a new data case outside of the training set.

Following the view of the EM algorithm presented by Neal and Hinton (1999), we can write down the cost function

$$\begin{aligned} C_{\text{imp}}(\theta, v_y, q(Y_{\text{mis}})) &= \int q(Y_{\text{mis}}) \log \frac{q(Y_{\text{mis}})}{p(\mathbf{Y}|\theta, v_y)} dY_{\text{mis}} \\ &= \int q(Y_{\text{mis}}) \log \frac{q(Y_{\text{mis}})}{p(Y_{\text{mis}}|\theta, v_y)} dY_{\text{mis}} - \log p(Y_{\text{obs}}|\theta, v_y)\,, \end{aligned} \tag{40}$$

which should be minimized w.r.t. model parameters $\theta = \{\mathbf{W}, \mathbf{m}, \mathbf{x}_j, \forall j\}$, v_y and the pdf over the missing data $q(Y_{\text{imp}})$. We denoted the missing data by $Y_{\text{mis}} = \{y_{ij}\,, ij \notin O\}$ and the observed data by $Y_{\text{obs}} = \{y_{ij}\,, ij \in O\}$.

Minimization of (40) w.r.t. $q(Y_{\text{mis}})$ for fixed θ and v_y yields that $q(Y_{\text{mis}}) = p(Y_{\text{mis}}|\theta, v_y)$ because the first term in (40) is simply the Kullback-Leibler divergence between the two pdfs. It is straightforward that

$$p(Y_{\text{mis}}|\theta, v_y) = \prod_{ij \in O} \mathcal{N}(y_{ij}; \hat{y}_{ij}(\theta), v_y)\,,$$

where $\hat{y}_{ij}(\theta)$ are the reconstructed missing values using (5) with the current estimates θ. Thus, infilling missing data with the reconstructions $\hat{y}_{ij}(\theta)$ is the step of the imputation algorithm which corresponds to the E-step of the EM-algorithm.

Collecting the terms in (40) which depend only on θ and v_y gives

$$\begin{aligned} &-\int q(Y_{\text{mis}}) \log p(Y_{\text{obs}}, Y_{\text{mis}}|\theta, v_y) dY_{\text{mis}} \\ &= -\frac{dn}{2}\log 2\pi v_y - \frac{1}{2v_y}\sum_{ij\in O}\left(y_{ij}-\hat{y}_{ij}(\theta)\right)^2 - \frac{1}{2v_y}\sum_{ij\notin O}\left[\left(\bar{y}_{ij}-\hat{y}_{ij}(\theta)\right)^2 + v_y\right] \\ &= -\frac{dn}{2}\log 2\pi v_y - \frac{1}{2v_y}\sum_{ij}\left(y_{ij}-\hat{y}_{ij}(\theta)\right)^2 - \frac{dn-N}{2}. \end{aligned} \tag{41}$$

It is easy to see that minimization of (41) w.r.t. θ is equivalent to minimizing the LS cost (2) for the infilled data matrix. This is done in the imputation algorithm by SVD of the complete data matrix. Thus, the M-step of the EM-algorithm corresponds to performing SVD in the imputation algorithm. Minimization of (41) w.r.t. v_y does not affect the steps of the imputation algorithm.

The imputation algorithm implicitly minimizes the cost function (4), thus it belongs to the class of LS PCA algorithms. It can be shown (Neal and Hinton, 1999) that the minimum of (40) coincides with the minimum of minus log-likelihood

$$-\log p(Y_{\text{obs}}|\theta, v_y) = \frac{N}{2}\log 2\pi v_y + \frac{1}{2v_y}\sum_{ij\in O}\left(y_{ij}-\hat{y}_{ij}(\theta)\right)^2. \tag{42}$$

Replacing v_y in (42) with its maximum likelihood estimate yields that the function being minimized is

$$\frac{N}{2}\left[\log\left(\frac{2\pi}{N}\sum_{ij\in O}\left(y_{ij}-\hat{y}_{ij}(\theta)\right)^2\right)+1\right],$$

from which it follows that the imputation algorithm implicitly optimizes the sum-squared error.

Appendix B. Conditions Fulfilled at the Convergence of Probabilistic PCA

The variational view of the EM algorithm allows for an interpretation of the PPCA learning algorithm in which the cost function

$$C = \int q(\mathbf{X}) \log \frac{q(\mathbf{X})}{p(\mathbf{X})} d\mathbf{X} - \int q(\mathbf{X}) \log p(\mathbf{Y}|\mathbf{W}, \mathbf{X}, \mathbf{m}, v_y) d\mathbf{X} \tag{43}$$

is minimized w.r.t. to the model parameters $\mathbf{W}$, $\mathbf{m}$, v_y and the pdf $q(\mathbf{X})$. The E-step fixes the model parameters and minimizes the cost function w.r.t. the distribution $q(\mathbf{X})$ while the M-step minimizes C w.r.t. $\mathbf{W}$, $\mathbf{m}$ and v_y assuming that $q(\mathbf{X})$ is fixed.

Let us consider simple transformations of $\{\mathbf{W}, \mathbf{m}, q(\mathbf{X})\}$ which do not change the second term in (43). For example, subtraction of a constant $\mathbf{b}$ from the columns of $\mathbf{X}$ can be compensated by changing the bias term $\mathbf{m}$ correspondingly:

$$q(\mathbf{X}) \leftarrow \prod_{j=1}^{n} \mathcal{N}\left(\mathbf{x}_j; \bar{\mathbf{x}}_j - \mu, \Sigma_{\mathbf{x}_j}\right), \tag{44}$$

$$\mathbf{m} \leftarrow \mathbf{m} + \mathbf{W}\mu. \tag{45}$$

because $\mathbf{y} = \mathbf{W}\mathbf{x} + \mathbf{m} = \mathbf{W}(\mathbf{x} - \mu) + (\mathbf{W}\mu + \mathbf{m})$. Similarly, rotation of the columns of $\mathbf{X}$ can be compensated by changing $\mathbf{W}$:

$$q(\mathbf{X}) \leftarrow \prod_{j=1}^{n} \mathcal{N}\left(\mathbf{x}_j; \mathbf{A}\overline{\mathbf{x}}_j, \mathbf{A}\Sigma_{\mathbf{x}_j}\mathbf{A}^{\mathrm{T}}\right), \tag{46}$$

$$\mathbf{W} \leftarrow \mathbf{W}\mathbf{A}^{-1} \tag{47}$$

because $\mathbf{y} = \mathbf{W}\mathbf{x} + \mathbf{m} = (\mathbf{W}\mathbf{A}^{-1})(\mathbf{A}\mathbf{x}) + \mathbf{m}$.

These transformations generally affect the first term in (43) which is the Kullback-Leibler divergence between $q(\mathbf{X})$ and $p(\mathbf{X})$:

$$D = \sum_{j=1}^{n} \int q(\mathbf{x}_j) \log \frac{q(\mathbf{x}_j)}{p(\mathbf{x}_j)} d\mathbf{x}_j = \frac{1}{2} \sum_{j=1}^{n} \left[\mathrm{tr}(\Sigma_{\mathbf{x}_j}) + \overline{\mathbf{x}}_j^{\mathrm{T}} \overline{\mathbf{x}}_j - \log\det \Sigma_{\mathbf{x}_j} \right]. \tag{48}$$

and at the convergence this term cannot be made smaller by transformations of the form (44)–(45) or (46)–(47).

Transformation (44)–(45) changes (48) to

$$D = \frac{1}{2} \sum_{j=1}^{n} \left[\mathrm{tr}(\Sigma_{\mathbf{x}_j}) + (\overline{\mathbf{x}}_j - \mu)^{\mathrm{T}} (\overline{\mathbf{x}}_j - \mu) - \log\det \Sigma_{\mathbf{x}_j} \right].$$

Now taking the derivative w.r.t. μ and equating it to zero gives the optimal $\mu = \frac{1}{n}\sum_{j=1}^{n} \overline{\mathbf{x}}_j$. At the convergence, the optimal μ should be zero and therefore (34) should hold.

Similarly, transformation (46)–(47) gives

$$\begin{aligned} D &= \frac{1}{2} \sum_{j=1}^{n} \left[\mathrm{tr}(\mathbf{A}\Sigma_{\mathbf{x}_j}\mathbf{A}^{\mathrm{T}}) + \overline{\mathbf{x}}_j^{\mathrm{T}} \mathbf{A}^{\mathrm{T}} \mathbf{A} \overline{\mathbf{x}}_j - \log\det(\mathbf{A}\Sigma_{\mathbf{x}_j}\mathbf{A}^{\mathrm{T}}) \right] \\ &= \frac{n}{2} \mathrm{tr}(\mathbf{A}\Sigma_* \mathbf{A}^{\mathrm{T}}) - \frac{1}{2} \sum_{j=1}^{n} \log\det(\mathbf{A}\Sigma_{\mathbf{x}_j}\mathbf{A}^{\mathrm{T}}), \end{aligned}$$

where $\Sigma_* = \frac{1}{n}\sum_{j=1}^{n} \left[\overline{\mathbf{x}}_j \overline{\mathbf{x}}_j^{\mathrm{T}} + \Sigma_{\mathbf{x}_j} \right]$. Taking the derivative w.r.t. $\mathbf{A}$ gives

$$\mathbf{A}\Sigma_* - (\mathbf{A}^{\mathrm{T}})^{-1} = 0$$

and therefore the optimal $\mathbf{A}$ satisfies $\mathbf{A}\Sigma_*\mathbf{A}^{\mathrm{T}} = \mathbf{I}$. Transformation (46)–(47) yields that $\Sigma_* \leftarrow \mathbf{A}\Sigma_*\mathbf{A}^{\mathrm{T}}$ and therefore at the convergence $\Sigma_* = \mathbf{I}$, which is condition (35).

Appendix C. Variational Bayesian PCA (VBPCA)

The following form of the posterior approximation is used:

$$q(\mathbf{W}, \mathbf{X}, \mathbf{m}) = \prod_{i=1}^{d} \mathcal{N}(m_i; \overline{m}_i, \widetilde{m}_i) \prod_{i=1}^{d} \mathcal{N}(\mathbf{w}_i; \overline{\mathbf{w}}_i, \Sigma_{\mathbf{w}_i}) \prod_{j=1}^{n} \mathcal{N}\left(\mathbf{x}_j; \overline{\mathbf{x}}_j, \Sigma_{\mathbf{x}_j}\right).$$

The update of the principal components:

$$\Sigma_{\mathbf{x}_j} = v_y\Big(v_y\mathbf{I} + \sum_{i\in O_j}\left[\overline{\mathbf{w}}_i\overline{\mathbf{w}}_i^{\mathrm{T}} + \Sigma_{\mathbf{w}_i}\right]\Big)^{-1},$$

$$\overline{\mathbf{x}}_j = \frac{1}{v_y}\Sigma_{\mathbf{x}_j}\sum_{i\in O_j}\overline{\mathbf{w}}_i(y_{ij}-\overline{m}_i), \qquad j = 1,\ldots,n.$$

The update of the bias term and matrix $\mathbf{W}$:

$$\overline{m}_i = \frac{v_m}{|O_i|(v_m + v_y/|O_i|)}\sum_{j\in O_i}[y_{ij} - \overline{\mathbf{w}}_i^{\mathrm{T}}\overline{\mathbf{x}}_j], \tag{49}$$

$$\widetilde{m}_i = \frac{v_y v_m}{|O_i|(v_m + v_y/|O_i|)}, \tag{50}$$

$$\Sigma_{\mathbf{w}_i} = v_y\Big(v_y\,\mathrm{diag}(v_{w,k}^{-1}) + \sum_{j\in O_i}\left[\overline{\mathbf{x}}_j\overline{\mathbf{x}}_j^{\mathrm{T}} + \Sigma_{\mathbf{x}_j}\right]\Big)^{-1},$$

$$\overline{\mathbf{w}}_i = \frac{1}{v_y}\Sigma_{\mathbf{w}_i}\sum_{j\in O_i}\overline{\mathbf{x}}_j(y_{ij}-\overline{m}_i), \qquad i = 1,\ldots,d$$

and the variance parameters:

$$v_y = \frac{1}{N}\sum_{ij\in O}\left[(y_{ij} - \overline{\mathbf{w}}_i^{\mathrm{T}}\overline{\mathbf{x}}_j - \overline{m}_i)^2 + \widetilde{m}_i + \overline{\mathbf{w}}_i^{\mathrm{T}}\Sigma_{\mathbf{x}_j}\overline{\mathbf{w}}_i + \overline{\mathbf{x}}_j^{\mathrm{T}}\Sigma_{\mathbf{w}_i}\overline{\mathbf{x}}_j + \mathrm{tr}(\Sigma_{\mathbf{x}_j}\Sigma_{\mathbf{w}_i})\right],$$

$$v_{w,k} = \frac{1}{d}\sum_{i=1}^{d}\left(\overline{w}_{ik}^2 + \widetilde{w}_{ik}\right), \qquad v_m = \frac{1}{d}\sum_{i=1}^{d}\left(\overline{m}_i^2 + \widetilde{m}_i\right), \tag{51}$$

where $\widetilde{w}_{ik}$ is the k-th element on the diagonal of $\Sigma_{\mathbf{w}_i}$.

Appendix D. VBPCA with Fully Factorial Approximation (VBPCAd)

VBPCAd uses the fully factorial posterior approximation

$$q(\mathbf{W},\mathbf{X},\mathbf{m}) = \prod_{i=1}^{d}\mathcal{N}(m_i;\overline{m}_i,\widetilde{m}_i)\prod_{i=1}^{d}\prod_{k=1}^{c}\mathcal{N}(w_{ik};\overline{w}_{ik},\widetilde{w}_{ik})\prod_{k=1}^{c}\prod_{j=1}^{n}\mathcal{N}\left(x_{kj};\overline{x}_{kj},\widetilde{x}_{kj}\right).$$

The VB cost function is then the sum of the following terms:

$$C_{\mathrm{vb}} = \sum_{ij\in O}C_{yij} + \sum_{i=1}^{d}C_{mi} + \sum_{i=1}^{d}\sum_{k=1}^{c}C_{wik} + \sum_{k=1}^{c}\sum_{j=1}^{n}C_{xkj},$$

where the individual terms are

$$C_{yij} = \frac{1}{2v_y}\left[(y_{ij} - \overline{\mathbf{w}}_i^{\mathrm{T}}\overline{\mathbf{x}}_j - \overline{m}_i)^2 + \widetilde{m}_i + \sum_{k=1}^{c}\left(\widetilde{w}_{ik}\overline{x}_{kj}^2 + \overline{w}_{ik}^2\widetilde{x}_{kj} + \widetilde{w}_{ik}\widetilde{x}_{kj}\right)\right] + \frac{1}{2}\log 2\pi v_y,$$

$$C_{mi} = \left\langle\log\frac{q(m_i)}{p(m_i)}\right\rangle = \frac{\overline{m}_i^2 + \widetilde{m}_i}{2v_m} - \frac{1}{2}\log\frac{\widetilde{m}_i}{v_m} - \frac{1}{2},$$

$$C_{wik} = \left\langle\log\frac{q(w_{ik})}{p(w_{ik})}\right\rangle = \frac{\overline{w}_{ik}^2 + \widetilde{w}_{ik}}{2v_{w,k}} - \frac{1}{2}\log\frac{\widetilde{w}_{ik}}{v_{w,k}} - \frac{1}{2},$$

$$C_{xkj} = \left\langle\log\frac{q(x_{kj})}{p(x_{kj})}\right\rangle = \frac{1}{2}(\overline{x}_{kj}^2 + \widetilde{x}_{kj}) - \frac{1}{2}\log\widetilde{x}_{kj} - \frac{1}{2}.$$

Variational parameters $\overline{m}_i$, $\widetilde{m}_i$, $v_{w,k}$ and v_m are updated to minimize the cost function using the update rules in (49)–(51). Parameters $\widetilde{w}, \widetilde{x}$ can be updated to minimize the cost function:

$$\widetilde{w}_{ik} = v_y \left[\frac{v_y}{v_{w,k}} + \sum_{j \in O_i} \left(\overline{x}_{kj}^2 + \widetilde{x}_{kj} \right) \right]^{-1}, \tag{52}$$

$$\widetilde{x}_{kj} = v_y \left[v_y + \sum_{i \in O_j} \left(\overline{w}_{ik}^2 + \widetilde{w}_{ik} \right) \right]^{-1}. \tag{53}$$

The update rule for v_y is

$$v_y = \frac{1}{N} \sum_{ij \in O} \left[(y_{ij} - \overline{\mathbf{w}}_i^{\mathrm{T}} \overline{\mathbf{x}}_j - \overline{m}_i)^2 + \widetilde{m}_i + \sum_{k=1}^{c} \left(\widetilde{w}_{ik} \overline{x}_{kj}^2 + \overline{w}_{ik}^2 \widetilde{x}_{kj} + \widetilde{w}_{ik} \widetilde{x}_{kj} \right) \right].$$

Minimizing the cost function w.r.t. each parameter $\overline{w}_{ij}$ keeping the others fixed would lead to a slow algorithm (e.g., Honkela et al., 2003). Instead, derivatives required for gradient-based optimization are:

$$\frac{\partial C_{\mathrm{vb}}}{\partial \overline{w}_{ik}} = \frac{\overline{w}_{ik}}{v_{w,k}} + \frac{1}{v_y} \sum_{j \in O_i} \left[-\left(y_{ij} - \overline{\mathbf{w}}_i^{\mathrm{T}} \overline{\mathbf{x}}_j - \overline{m}_i \right) \overline{x}_{kj} + \overline{w}_{ik} \widetilde{x}_{kj} \right],$$

$$\frac{\partial C_{\mathrm{vb}}}{\partial \overline{x}_{kj}} = \overline{x}_{kj} + \frac{1}{v_y} \sum_{i \in O_j} \left[-\left(y_{ij} - \overline{\mathbf{w}}_i^{\mathrm{T}} \overline{\mathbf{x}}_j - \overline{m}_i \right) \overline{w}_{ik} + \widetilde{w}_{ik} \overline{x}_{kj} \right].$$

The second-order derivatives which can be used to speed up learning, as explained in Section 6.1, coincide with the inverse of the updated variances given in (52)–(53): $\partial^2 C_{\mathrm{vb}} / \partial \overline{w}_{ik}^2 = \widetilde{w}_{ik}^{-1}$ and $\partial^2 C_{\mathrm{vb}} / \partial \overline{x}_{kj}^2 = \widetilde{x}_{kj}^{-1}$.

Appendix E. MAPPCA

The cost function C_{MAP} is given in (39). The alternating optimization procedure can be implemented as follows:

$$\mathbf{x}_j = \left(v_y \mathbf{I} + \sum_{i \in O_j} \mathbf{w}_i \mathbf{w}_i^{\mathrm{T}} \right)^{-1} \sum_{i \in O_j} \mathbf{w}_i (y_{ij} - m_i), \qquad j = 1, \ldots, n,$$

$$m_i = \frac{v_m}{|O_i|(v_m + v_y/|O_i|)} \sum_{j \in O_i} \left[y_{ij} - \mathbf{w}_i^{\mathrm{T}} \mathbf{x}_j \right],$$

$$\mathbf{w}_i = \left(v_y \, \mathrm{diag}(v_{w,k}^{-1}) + \sum_{j \in O_i} \mathbf{x}_j \mathbf{x}_j^{\mathrm{T}} \right)^{-1} \sum_{j \in O_i} \mathbf{x}_j (y_{ij} - m_i), \qquad i = 1, \ldots, d,$$

$$v_y = \frac{1}{N} \sum_{ij \in O} (y_{ij} - \mathbf{w}_i^{\mathrm{T}} \mathbf{x}_j - m_i)^2,$$

$$v_{w,k} = \frac{1}{d} \sum_{i=1}^{d} w_{ik}^2, \qquad v_m = \frac{1}{d} \sum_{i=1}^{d} m_i^2.$$

Gradient-based learning discussed in Section 6.1 requires the following derivatives:

$$\frac{\partial C_{\mathrm{MAP}}}{\partial w_{ik}} = \frac{w_{ik}}{v_{w,k}} + \frac{1}{v_y} \sum_{j \in O_i} \left[-\left(y_{ij} - \mathbf{w}_i^{\mathrm{T}} \mathbf{x}_j - m_i\right) x_{kj} \right],$$

$$\frac{\partial C_{\mathrm{MAP}}}{\partial x_{kj}} = x_{kj} + \frac{1}{v_y} \sum_{i \in O_j} \left[-\left(y_{ij} - \mathbf{w}_i^{\mathrm{T}} \mathbf{x}_j - m_i\right) w_{ik} \right],$$

$$\frac{\partial^2 C_{\mathrm{MAP}}}{\partial w_{ik}^2} = \frac{1}{v_{w,k}} + \frac{1}{v_y} \sum_{j \in O_i} x_{kj}^2,$$

$$\frac{\partial^2 C_{\mathrm{MAP}}}{\partial x_{kj}^2} = 1 + \frac{1}{v_y} \sum_{i \in O_j} w_{ik}^2 .$$

Abstract

We present posterior regularization, a probabilistic framework for structured, weakly supervised learning. Our framework efficiently incorporates indirect supervision via constraints on posterior distributions of probabilistic models with latent variables. Posterior regularization *separates* model complexity from the complexity of structural constraints it is desired to satisfy. By directly imposing decomposable regularization on the posterior moments of latent variables during learning, we retain the computational efficiency of the unconstrained model while ensuring desired constraints hold in expectation. We present an efficient algorithm for learning with posterior regularization and illustrate its versatility on a diverse set of structural constraints such as bijectivity, symmetry and group sparsity in several large scale experiments, including multi-view learning, cross-lingual dependency grammar induction, unsupervised part-of-speech induction, and bitext word alignment.[1]

Keywords: posterior regularization framework, unsupervised learning, latent variables models, prior knowledge, natural language processing

1. Introduction

In unsupervised problems where data has sequential, recursive, spatial, relational, and other kinds of structure, we often employ structured statistical models with latent variables to tease apart the underlying dependencies and induce meaningful semantic categories. Unsupervised part-of-speech and grammar induction, and word and phrase alignment for statistical machine translation in natural language processing are examples of such aims. Generative models (probabilistic grammars,

1. A preliminary version of the PR framework appeared in Graça et al. (2007). Various extensions and applications appeared in Ganchev et al. (2008a), Ganchev et al. (2008b), Ganchev et al. (2009), Graça et al. (2009a) and Graça et al. (2010).

graphical models, etc.) are usually estimated by maximizing the likelihood of the observed data by marginalizing over the hidden variables, typically via the Expectation Maximization (EM) algorithm. Because of computational and statistical concerns, generative models used in practice are very simplistic models of the underlying phenomena; for example, the syntactic structure of language or the language translation process. A pernicious problem with such models is that marginal likelihood may not guide the model towards the intended role for the latent variables, instead focusing on explaining irrelevant but common correlations in the data. Since we are mostly interested in the distribution of the latent variables in the hope that they capture *intended* regularities without direct supervision, controlling this latent distribution is critical. Less direct methods such as clever initialization, ad hoc procedural modifications, and complex data transformations are often used to affect the posteriors of latent variables in a desired manner.

A key challenge for structured, weakly supervised learning is developing a flexible, declarative framework for expressing structural constraints on latent variables arising from prior knowledge and indirect supervision. Structured models have the ability to capture a very rich array of possible relationships, but adding complexity to the model often leads to intractable inference. In this article, we present the posterior regularization (PR) framework (Graça et al., 2007), which *separates* model complexity from the complexity of structural constraints it is desired to satisfy. Unlike parametric regularization in a Bayesian framework, our approach incorporates data-dependent constraints that are easy to encode as information about model *posteriors* on the observed data, but may be difficult to encode as information about model parameters through Bayesian *priors*. In Sections 5-8 we describe a variety of such useful prior knowledge constraints in several application domains.

The contributions of this paper are:

- A flexible, declarative framework for structured, weakly supervised learning via posterior regularization.
- An efficient algorithm for model estimation with posterior regularization.
- An extensive evaluation of different types of constraints in several domains: multi-view learning, cross-lingual dependency grammar induction, unsupervised part-of-speech induction, and bitext word alignment.
- A detailed explanation of the connections between several other recent proposals for weak supervision, including structured constraint-driven learning (Chang et al., 2007), generalized expectation criteria (Mann and McCallum, 2008, 2007) and Bayesian measurements (Liang et al., 2009).

The rest of this paper is organized as follows. Section 2 describes the posterior regularization framework and Section 3 illustrates the range of different types of weak supervision constraints representable in our framework. Section 4 describes the relationship between posterior regularization and other related frameworks. Sections 5-8 describe applications of PR to several problems: word alignment (§5), multi-view learning (§6), cross-lingual projection (§7) and inducing sparsity structure (§8). Section 9 concludes the paper and presents areas for future work.

2. Posterior Regularization Framework

In this section we describe the posterior regularization framework, which incorporates side-information into parameter estimation in the form of linear constraints on posterior expectations. As we will

show, this allows tractable learning and inference even when the constraints would be intractable to encode directly in the model parameters. By defining a flexible language for specifying diverse types of problem-specific prior knowledge, we make the framework applicable to a wide variety of probabilistic models, both generative and discriminative. In Sections 2.1-2.7 we will focus on generative models, and describe the case of discriminative models in Section 2.8. We will use a problem from natural language processing as a running example in the exposition:

> **Running Example** *The task is part-of-speech (POS) tagging with limited or no training data. Suppose we know that each sentence should have at least one verb and at least one noun, and would like our model to capture this constraint on the unlabeled sentences. The model we will be using is a first-order hidden Markov model (HMM).*

We describe four other applications with empirical results in Sections 5-8, but it will be easier to illustrate key concepts using this simple example.

2.1 Preliminaries and Notation

We assume that there is a natural division of variables into "input" variables $\mathbf{x}$ and "target" variables $\mathbf{y}$ for each data instance, where $\mathbf{x}$'s are always observed. We denote the set of all instances of unlabeled data as $\mathbf{X}$. In case of semi-supervised learning, we have some labeled data as well, and we will use the notation $(\mathbf{X}_L, \mathbf{Y}_L)$ to denote all the labeled instances.

The starting point for using the PR framework is a probabilistic model. Let θ be the parameters of the model. For now we assume a generative model $p_\theta(\mathbf{x}, \mathbf{y})$, and we use $\mathcal{L}(\theta) = \log p_\theta(\mathbf{X}_L, \mathbf{Y}_L) + \log \sum_{\mathbf{Y}} p_\theta(\mathbf{X}, \mathbf{Y}) + \log p(\theta)$ to denote the parameter-regularized log-likelihood of the data.

> **Running Example** *In the POS tagging example from above, we would use* $\mathbf{x} = \{x_1, x_2, \ldots x_{|\mathbf{x}|}\}$ *to denote a sentence (i.e., a sequence of words* x_i*) and* $\mathbf{y} = \{y_1, y_2, \ldots y_{|\mathbf{x}|}\}$ *to denote a possible POS assignment. Using an HMM, it is defined in the normal way as:*
>
> $$p_\theta(\mathbf{x}, \mathbf{y}) = \prod_{i=1}^{|\mathbf{x}|} p_\theta(y_i|y_{i-1}) \; p_\theta(x_i|y_i),$$
>
> *with* θ *representing the multinomial distributions directly, and where* $p_\theta(y_1|y_0) = p_\theta(y_1)$ *represents a set of initial probabilities. Suppose we have a small labeled corpus and a larger unlabeled corpus. For a generative model such as an HMM, the log-likelihood (+ log-prior) is:*
>
> $$\mathcal{L}(\theta) = \log p_\theta(\mathbf{X}_L, \mathbf{Y}_L) + \log \sum_{\mathbf{Y}} p_\theta(\mathbf{X}, \mathbf{Y}) + \log p(\theta),$$
>
> *where corpus probabilities are products over instances:* $p_\theta(\mathbf{x}, \mathbf{y}) = \prod p_\theta(\mathbf{x}, \mathbf{y})$ *and analogously for* $\mathbf{X}_L, \mathbf{Y}_L$*; and where* $p(\theta)$ *is a prior distribution over the parameters* θ.

2.2 Regularization via Posterior Constraints

The goal of the posterior regularization framework is to restrict the space of the model posteriors on unlabeled data as a way to guide the model towards desired behavior. In this section we describe a version of PR specified with respect to a set of constraints. In this case, posterior information is

specified with sets $\mathcal{Q}$ of allowed distributions over the hidden variables $\mathbf{y}$. We will define $\mathcal{Q}$ in terms of *constraint* features $\phi(\mathbf{X}, \mathbf{Y})$ and their expectations.[2]

Running Example *Recall that in our running example, we want to bias learning so that each sentence is labeled to contain at least one verb. To encode this formally, we define a feature* $\phi(\mathbf{x}, \mathbf{y}) =$ *"number of verbs in* $\mathbf{y}$*", and require that this feature has expectation at least 1. For consistency with the rest of the exposition and standard optimization literature, we will use the equivalent* $\phi(\mathbf{x}, \mathbf{y}) =$ *"negative number of verbs in* $\mathbf{y}$*" and require this has expectation at most -1.*[3]

$$\mathcal{Q}_{\mathbf{x}} = \{q_{\mathbf{x}}(\mathbf{y}) \ : \ \mathbf{E}_q[\phi(\mathbf{x}, \mathbf{y})] \leq -1\}.$$

Note that we enforce the constraint only in expectation, so there might be a labeling with non-zero probability that does not contain a verb. To actually enforce this constraint in the model would break the first-order Markov property of the distribution.[4] *In order to also require at least one noun per sentence in expectation, we would add another constraint feature, so that* ϕ *would be a function from* $\mathbf{x}, \mathbf{y}$ *pairs to* $\mathbb{R}^2$.

We define $\mathcal{Q}$, the set of valid distributions, with respect to the *expectations* of constraint features, rather than their probabilities, so that our objective leads to an efficient algorithm. As we will see later in this section, we also require that the constraint features decompose as a sum in order to ensure an efficient algorithm. More generally than in the running example, we will define constraints over an entire corpus:

$$\textbf{Constrained Posterior Set}: \qquad \mathcal{Q} = \{q(\mathbf{Y}) : \mathbf{E}_q[\phi(\mathbf{X}, \mathbf{Y})] \leq \mathbf{b}\}.$$

In words, $\mathcal{Q}$ denotes the region where constraint feature expectations are bounded by $\mathbf{b}$. Additionally, it is often useful to allow small violations whose norm is bounded by $\varepsilon \geq 0$:

$$\textbf{Constrained Set (with slack)}: \quad \mathcal{Q} = \{q(\mathbf{Y}) : \exists \xi, \ \mathbf{E}_q[\phi(\mathbf{X}, \mathbf{Y})] - \mathbf{b} \leq \xi; \ ||\xi||_\beta \leq \varepsilon\}. \qquad (1)$$

Here ξ is a vector of slack variables and $||\cdot||_\beta$ denotes some norm. Note that the PR method we describe will only be useful if $\mathcal{Q}$ is non-empty:

Assumption 2.1 *$\mathcal{Q}$ is non-empty.*

We explore several types of constraints in Sections 5-8, including: constraints similar to the running example, where each hidden state is constrained to appear at most once in expectation; constraints that bias two models to agree on latent variables in expectation; constraints that enforce a particular group-sparsity of the posterior moments. The constraint set defined in Equation 1 is usually referred to as inequality constraints with slack, since setting $\varepsilon = 0$ enforces inequality constraints strictly. The derivations for equality constraints are very similar to the derivations for inequality so we leave them out in the interest of space. Note also that we can encode equality

2. Note: the constraint features do not appear anywhere in the model. If the model has a log-linear form, then it would be defined with respect to a different set of *model* features, not related to the *constraint* features we consider here.
3. Note that the distribution $q_{\mathbf{x}}$ and $\mathcal{Q}_{\mathbf{x}}$ depend on $\mathbf{x}$ because the features $\phi(\mathbf{x}, \mathbf{y})$ might depend on the particular example $\mathbf{x}$.
4. At every position in the sentence, we would need to know whether a verb was used at any other position.

Symbol	Meaning
$\mathbf{x}$	(observed) input variables for a particular example
$\mathbf{y}$	(usually hidden) output variables for a particular example
$\mathbf{X}, \mathbf{Y}$	$\mathbf{x}$ and $\mathbf{y}$ for the entire unlabeled portion of the corpus
$\mathbf{X}_L, \mathbf{Y}_L$	$\mathbf{x}$ and $\mathbf{y}$ for the entire labeled portion of the corpus (possibly empty)
$p_\theta(\mathbf{x}, \mathbf{y})$	a generative, joint model with parameters θ
$\mathcal{L}(\theta)$	data log-likelihood and parameter prior: $\log p_\theta(\mathbf{X}_L, \mathbf{Y}_L) + \log \sum_{\mathbf{Y}} p_\theta(\mathbf{X}, \mathbf{Y}) + \log p(\theta)$
$\mathcal{Q}_\mathbf{x}, \mathcal{Q}$	posterior regularization set: constrained set of desired data-conditional distributions
$\phi(\mathbf{x}, \mathbf{y})$	constraint features: used to encode posterior regularization
$\mathbf{b}$	bounds on the desired expected values of constraint features
ξ	slack variables used to allow small violations of constraints
$J_\mathcal{Q}(\theta)$	posterior regularized likelihood: $\mathcal{L}(\theta) - \mathbf{KL}(\mathcal{Q} \parallel p_\theta(\mathbf{Y}\|\mathbf{X}))$

Table 1: Summary of notation used.

constraints by adding two inequality constraints, although this will leave us with twice as many variables in the dual. The assumption of linearity of the constraints is computationally important, as we will show below. For now, we do not make any assumptions about the features $\phi(\mathbf{x}, \mathbf{y})$, but if they factor in the same way as the model, then we can use the same inference algorithms in PR training as we use for the original model (see Proposition 2.2). In PR, the log-likelihood of a model is penalized with the KL-divergence between the desired distribution space $\mathcal{Q}$ and the model posteriors,

$$\mathbf{KL}(\mathcal{Q} \parallel p_\theta(\mathbf{Y}|\mathbf{X})) = \min_{q \in \mathcal{Q}} \mathbf{KL}(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X})).$$

The posterior-regularized objective is:

$$\textbf{Posterior Regularized Likelihood}: \quad J_\mathcal{Q}(\theta) = \mathcal{L}(\theta) - \mathbf{KL}(\mathcal{Q} \parallel p_\theta(\mathbf{Y}|\mathbf{X})). \tag{2}$$

The objective trades off likelihood and distance to the desired posterior subspace (modulo getting stuck in local maxima) and provides an effective means of controlling the posteriors. In many cases, prior knowledge is easy to specify in terms of posteriors, and much more difficult to specify as priors on model parameters or by explicitly adding constraints to the model. A key advantage of using regularization on posteriors is that the learned model itself remains simple and tractable, while during learning it is driven to obey the constraints through setting appropriate parameters θ. The advantage of imposing the constraints via KL-divergence from the posteriors is that the objective above can be optimized using a simple EM scheme described in Section 2.6. It is also possible to use a similar algorithm to maximize $\mathcal{L}(\theta) - \alpha\mathbf{KL}(\mathcal{Q} \parallel p_\theta(\mathbf{Y} \mid \mathbf{X}))$, for $\alpha \in [0,1]$. See Appendix A for details. Note that the algorithm we will present in Section 2.6 will not allow us to optimize an objective with $\alpha > 1$, and this leads us to have both a KL-penalty term in Equation 2 and also to potentially have slack in the definition of the constraint set $\mathcal{Q}$. We do not need to allow slack in the objective, as long as we are sure that the constraint set $\mathcal{Q}$ is non-empty. At increased computational cost, it is also possible to eliminate the KL-penalty portion of the objective, instead directly constraining the model's posterior distribution to be inside the constraint set $p_\theta(\mathbf{Y}|\mathbf{X}) \in \mathcal{Q}$. See Section 4 for details. Figure 1 illustrates the objective in Equation 2. Normal maximum likelihood training is equivalent to minimizing the KL distance between the distribution concentrated on $\mathbf{X}$ and the set of distributions representable by the model. Any particular setting of the model parameters results in

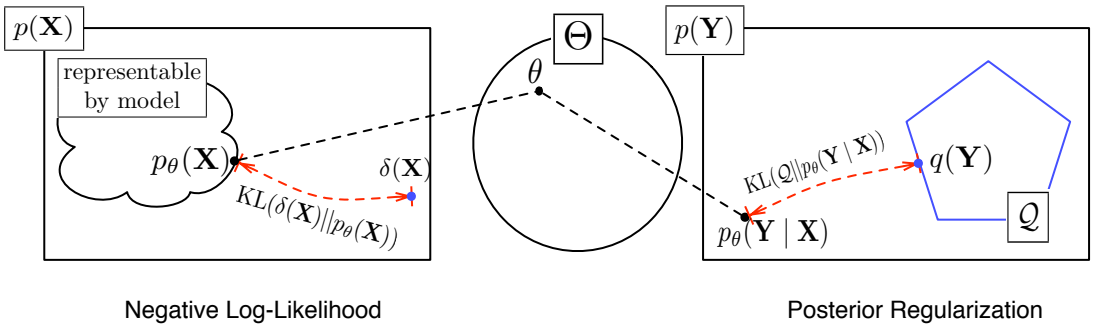

Figure 1: An illustration of the PR objective for generative models, as a sum of two KL terms. The symbol Θ represents the set of possible model parameters, $\delta(\mathbf{X})$ is a distribution that puts probability 1 on $\mathbf{X}$ and 0 on all other assignments. Consequently $\mathbf{KL}(\delta(\mathbf{X})||p_\theta(\mathbf{X})) = \mathcal{L}(\theta)$. (We ignore the parameter prior and additional labeled data in this figure for clarity.)

the posterior distribution $p_\theta(\mathbf{Y}|\mathbf{X})$. PR adds to the maximum likelihood objective a corresponding KL distance for this distribution. If Q has only one distribution, then we recover labeled maximum likelihood training. This is one of the justifications for the use and the particular direction of the KL distance in the penalty term.

> **Running Example** *In order to represent a corpus-wide constraint set Q for our POS problem, we stack the constraint features into a function from $\mathbf{X},\mathbf{Y}$ pairs (sentences, part-of-speech sequences) to $\mathbb{R}^{2|\mathbf{X}|}$, where $|\mathbf{X}|$ is the number of sentences in our unlabeled corpus. For the POS tagging example, the PR objective penalizes parameters that do not assign each sentence at least one verb and one noun in expectation.*

For PR to be successful, the model $p_\theta(\mathbf{Y}|\mathbf{X})$ has to be expressive enough to ensure that the learned model has posteriors $p_\theta(\mathbf{Y}|\mathbf{X})$ in or nearly in Q. Even if that is the case, the same parameters might not ensure that the constraints are satisfied on a test corpus, so we could also use $q(\mathbf{Y}) = \arg\min_{q' \in Q} \mathbf{KL}(q'(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X}))$ for prediction instead of $p_\theta(\mathbf{Y}|\mathbf{X})$. We will see in Sections 5 and 7 that this sometimes results in improved performance. Chang et al. (2007) report similar results for their constraint-driven learning framework.

2.3 Slack Constraints vs. Penalty

In order for our objective to be well defined, Q must be non-empty. When there are a large number of constraints, or when the constraint features ϕ are defined by some instance-specific process, it might not be easy to choose constraint values $\mathbf{b}$ and slack ε that lead to satisfiable constraints. It is sometimes easier to penalize slack variables instead of setting a bound ε on their norm. In these cases, we add a slack penalty to the regularized likelihood objective in Equation 2:

$$\begin{aligned} \mathcal{L}(\theta) \quad - \min_{q,\xi} \quad & \mathbf{KL}\left(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X})\right) + \sigma||\xi||_\beta \\ & \text{s.t.} \quad \mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b} \leq \xi. \end{aligned} \tag{3}$$

The slack-constrained and slack-penalized versions of the objectives are equivalent in the sense that they follow the same regularization path: for every ε there exists some σ that results in identical parameters θ. Note that while we have used a norm $||\cdot||_\beta$ to impose a cost on violations of the constraints, we could have used any arbitrary convex penalty function, for which the minimal q is easily computable.

2.4 Computing the Posterior Regularizer

In this subsection, we describe how to compute the objective we have introduced for fixed parameters θ. The regularization term is stated in Equations 2 and 3 in terms of an optimization problem. We assume that we have algorithms to do inference[5] in the statistical model of interest, p_θ. We describe the computation of the regularization term for the inequality constraints:

$$\min_{q,\xi} \quad \mathbf{KL}(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X})) \qquad \text{s.t.} \quad \mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b} \leq \xi; \quad ||\xi||_\beta \leq \varepsilon. \tag{4}$$

Proposition 2.1 *The regularization problems for PR with inequality constraints in Equation 4 can be solved efficiently in its dual form. The primal solution q^* is unique since KL divergence is strictly convex and is given in terms of the dual solution λ^* by:*

$$q^*(\mathbf{Y}) = \frac{p_\theta(\mathbf{Y}|\mathbf{X}) \exp\{-\lambda^* \cdot \phi(\mathbf{X},\mathbf{Y})\}}{Z(\lambda^*)} \tag{5}$$

where $Z(\lambda^*) = \sum_{\mathbf{Y}} p_\theta(\mathbf{Y}|\mathbf{X}) \exp\{-\lambda^* \cdot \phi(\mathbf{X},\mathbf{Y})\}$. Define $||\cdot||_{\beta^*}$ as the dual norm of $||\cdot||_\beta$. The dual of the problem in Equation 4 is:

$$\max_{\lambda \geq 0} \quad -\mathbf{b} \cdot \lambda - \log Z(\lambda) \; - \varepsilon \, ||\lambda||_{\beta^*}. \tag{6}$$

The proof is included in Appendix B using standard Lagrangian duality results and strict convexity of KL (e.g., Bertsekas, 1999). The dual form in Equation 6 is typically computationally more tractable than the primal form (Equation 4) because there is one dual variable per expectation constraint, while there is one primal variable per labeling $\mathbf{Y}$. For structured models, this is typically intractable. An analogous proposition can be proven for the objective with penalties (Equation 3), with almost identical proof. We omit this for brevity.

2.5 Factored $q(\mathbf{Y})$ for Factored Constraints

The form of the optimal q with respect to $p_\theta(\mathbf{Y}|\mathbf{X})$ and ϕ has important computational implications.

Proposition 2.2 *If $p_\theta(\mathbf{Y}|\mathbf{X})$ factors as a product of clique potentials over a set of cliques $\mathcal{C}$, and $\phi(\mathbf{X},\mathbf{Y})$ factors as a sum over some subset of those cliques, then the optimizer $q^*(\mathbf{Y})$ of Equation 5 will also factor as a product of potentials of cliques in $\mathcal{C}$.*

This is easy to show. Our assumptions are a factorization for p_θ:

$$\textbf{Factored Posteriors}: \quad p(\mathbf{Y} \mid \mathbf{X}) = \frac{1}{Z(\mathbf{X})} \prod_{c \in \mathcal{C}} \psi(\mathbf{X}, \mathbf{Y}_c)$$

5. Specifically, we need to be able to compute marginal distributions efficiently.

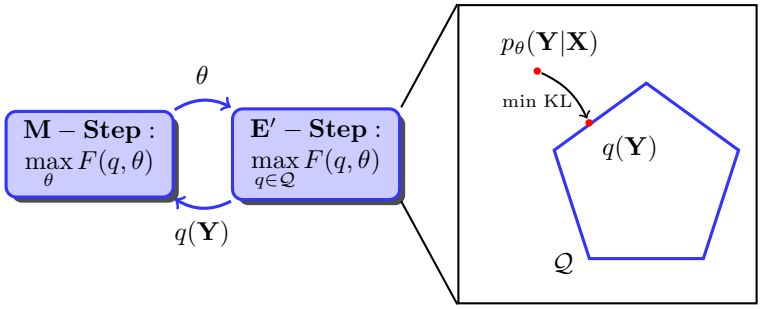

Figure 2: Modified EM for optimizing generative PR objective $\mathcal{L}(\theta) - \mathbf{KL}(Q \,\|\, p_\theta(\mathbf{Y}|\mathbf{X}))$.

and the same factorization for ϕ:

$$\textbf{Factored Features}: \quad \phi(\mathbf{X},\mathbf{Y}) = \sum_{c\in\mathcal{C}} \phi(\mathbf{X},\mathbf{Y}_c)$$

which imply that $q^*(\mathbf{Y})$ will also factor as a product over the cliques $\mathcal{C}$:

$$\begin{aligned} \textbf{Factored Solution}: \quad q^*(\mathbf{Y}) &= \frac{1}{Z(\mathbf{X})Z(\lambda)} \prod_{c\in\mathcal{C}} \psi(\mathbf{X},\mathbf{Y}_c)\, \exp\{-\lambda\cdot\phi(\mathbf{X},\mathbf{Y}_c)\} \\ &= \frac{1}{Z'(\mathbf{X})} \prod_{c\in\mathcal{C}} \psi'(\mathbf{X},\mathbf{Y}_c), \end{aligned}$$

where $\psi'(\mathbf{X},\mathbf{Y}_c) = \psi(\mathbf{X},\mathbf{Y}_c)\exp\{-\lambda\cdot\phi(\mathbf{X},\mathbf{Y}_c)\}$ and $Z'(\mathbf{X}) = Z(\mathbf{X})Z(\lambda)$.

2.6 Generative Posterior Regularization via Expectation Maximization

This section presents an optimization algorithm for the PR objective. The algorithm we present is a minorization-maximization algorithm akin to EM, and both slack-constrained and slack-penalized formulations can be optimized using it. To simplify the exposition, we focus first on slack-constrained version, and leave a treatment of optimization of the slack-penalized version to Section 2.7.

Recall the standard expectation maximization (EM) algorithm used to optimize marginal likelihood $\mathcal{L}(\theta) = \log \sum_{\mathbf{Y}} p_\theta(\mathbf{X},\mathbf{Y})$. Again, for clarity of exposition, we ignore $\log p(\theta)$, the prior on θ, as well as $\log p_\theta(\mathbf{X}_L,\mathbf{Y}_L)$, the labeled data term, as they are simple to incorporate, just as in regular EM. Neal and Hinton (1998) describe an interpretation of the EM algorithm as block coordinate ascent on a function that lower-bounds $\mathcal{L}(\theta)$, which we also use below. By Jensen's inequality, we define a lower-bound $F(q,\theta)$ as

$$\mathcal{L}(\theta) = \log \sum_{\mathbf{Y}} q(\mathbf{Y}) \frac{p_\theta(\mathbf{X},\mathbf{Y})}{q(\mathbf{Y})} \geq \sum_{\mathbf{Y}} q(\mathbf{Y}) \log \frac{p_\theta(\mathbf{X},\mathbf{Y})}{q(\mathbf{Y})} = F(q,\theta).$$

we can re-write $F(q,\theta)$ as

$$\begin{aligned} F(q,\theta) &= \sum_{\mathbf{Y}} q(\mathbf{Y}) \log(p_\theta(\mathbf{X}) p_\theta(\mathbf{Y}|\mathbf{X})) - \sum_{\mathbf{Y}} q(\mathbf{Y}) \log q(\mathbf{Y}) \\ &= \mathcal{L}(\theta) - \sum_{\mathbf{Y}} q(\mathbf{Y}) \log \frac{q(\mathbf{Y})}{p_\theta(\mathbf{Y}|\mathbf{X})} \\ &= \mathcal{L}(\theta) - \mathbf{KL}(q(\mathbf{Y}) || p_\theta(\mathbf{Y}|\mathbf{X})). \end{aligned}$$

Using this interpretation, we can view EM as performing coordinate ascent on $F(q,\theta)$. Starting from an initial parameter estimate θ^0, the algorithm iterates two block-coordinate ascent steps until a convergence criterion is reached:

$$\begin{aligned} \mathbf{E}: q^{t+1} &= \arg\max_q F(q,\theta^t) = \arg\min_q \mathbf{KL}(q(\mathbf{Y}) \parallel p_{\theta^t}(\mathbf{Y} \mid \mathbf{X})), \\ \mathbf{M}: \theta^{t+1} &= \arg\max_\theta F(q^{t+1},\theta) = \arg\max_\theta \mathbf{E}_{q^{t+1}}[\log p_\theta(\mathbf{X},\mathbf{Y})]. \end{aligned} \tag{7}$$

It is easy to see that the E-step sets $q^{t+1}(\mathbf{Y}) = p_{\theta^t}(\mathbf{Y}|\mathbf{X})$.

The PR objective (Equation 2) is

$$J_\mathcal{Q}(\theta) = \max_{q \in \mathcal{Q}} F(q,\theta) = \mathcal{L}(\theta) - \min_{q(\mathbf{Y}) \in \mathcal{Q}} \mathbf{KL}(q(\mathbf{Y}) || p_\theta(\mathbf{Y}|\mathbf{X})),$$

where $\mathcal{Q} = \{q(\mathbf{Y}) : \exists \xi,\ \mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b} \leq \xi;\ ||\xi||_\beta \leq \varepsilon\}$. In order to optimize this objective, it suffices to modify the E-step to include the constraints:

$$\mathbf{E}': q^{t+1} = \arg\max_{q \in \mathcal{Q}} F(q,\theta^t) = \arg\min_{q \in \mathcal{Q}} \mathbf{KL}(q(\mathbf{Y}) \parallel p_{\theta^t}(\mathbf{Y}|\mathbf{X})). \tag{8}$$

The projected posteriors $q^{t+1}(\mathbf{Y})$ are then used to compute sufficient statistics and update the model's parameters in the M-step, which remains unchanged, as in Equation 7. This scheme is illustrated in Figure 2.

Proposition 2.3 *The modified EM algorithm illustrated in Figure 2, which iterates the modified E-step (Equation 8) with the normal M-step (Equation 7), monotonically increases the PR objective:* $J_\mathcal{Q}(\theta^{t+1}) \geq J_\mathcal{Q}(\theta^t)$.

Proof: The proof is analogous to the proof of monotonic increase of the standard EM objective. Essentially,

$$J_\mathcal{Q}(\theta^{t+1}) = F(q^{t+2},\theta^{t+1}) \geq F(q^{t+1},\theta^{t+1}) \geq F(q^{t+1},\theta^t) = J_\mathcal{Q}(\theta^t).$$

The two inequalities are ensured by the $\mathbf{E}'$-step and M-step. $\mathbf{E}'$-step sets $q^{t+1} = \arg\max_{q \in \mathcal{Q}} F(q,\theta^t)$, hence $J_\mathcal{Q}(\theta^t) = F(q^{t+1},\theta^t)$. The M-step sets $\theta^{t+1} = \arg\max_\theta F(q^{t+1},\theta)$, hence $F(q^{t+1},\theta^{t+1}) \geq F(q^{t+1},\theta^t)$. Finally, $J_\mathcal{Q}(\theta^{t+1}) = \max_{q \in \mathcal{Q}} F(q,\theta^{t+1}) \geq F(q^{t+1},\theta^{t+1})$ ■

Note that the proposition is only meaningful when $\mathcal{Q}$ is non-empty and $J_\mathcal{Q}$ is well-defined. As for standard EM, to prove that coordinate ascent on $F(q,\theta)$ converges to stationary points of $J_\mathcal{Q}(\theta)$, we need to make additional assumptions on the regularity of the likelihood function and boundedness of the parameter space as in Tseng (2004). This analysis can be easily extended to our setting, but is beyond the scope of the current paper.

We can use the dual formulation of Proposition 2.1 to perform the projection. Proposition 2.2 implies that we can use the same algorithms to perform inference in our projected model q as we did in our original model p_θ. We illustrate this with the running example.

Running Example *For the POS tagging example with zero slack, the optimization problem we need to solve is:*

$$\arg\min_{q} \quad \mathbf{KL}(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X})) \qquad \text{s.t.} \quad \mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] \leq -\mathbf{1}$$

where $\mathbf{1}$ *is a vector of with 1 in each entry. The dual formulation is given by*

$$\arg\max_{\lambda \geq 0} \quad \mathbf{1}\cdot\lambda - \log Z(\lambda) \quad \textit{with} \quad q^*(\mathbf{Y}) = \frac{p_\theta(\mathbf{Y}|\mathbf{X})\exp\{-\lambda^*\cdot\phi(\mathbf{X},\mathbf{Y})\}}{Z(\lambda^*)}. \tag{9}$$

We can solve the dual optimization problem by projected gradient ascent. The HMM model can be factored as products over sentences, and each sentence as a product of emission probabilities and transition probabilities.

$$p_\theta(\mathbf{y} \mid \mathbf{x}) = \frac{\prod_{i=1}^{|\mathbf{x}|} p_\theta(y_i|y_{i-1})p_\theta(x_i|y_i)}{p_\theta(\mathbf{x})} \tag{10}$$

where $p_\theta(y_1|y_0) = p_\theta(y_1)$ *are the initial probabilities of our HMM. The constraint features* ϕ *can be represented as a sum over sentences and further as a sum over positions in the sentence:*

$$\phi(\mathbf{x},\mathbf{y}) \quad = \quad \sum_{i=1}^{|\mathbf{x}|}\phi_i(\mathbf{x},y_i) \quad = \quad \sum_{i=1}^{|\mathbf{x}|}\begin{cases}(-1,0)^\top & \textit{if } y_i \textit{ is a verb in sentence } \mathbf{x}\\ (0,-1)^\top & \textit{if } y_i \textit{ is a noun in sentence } \mathbf{x}\\ (0,0)^\top & \textit{otherwise}\end{cases} \tag{11}$$

combining the factored Equations 10 and 11 with the definition of $q(\mathbf{Y})$ *we see that* $q(\mathbf{Y})$ *must also factor as a first-order Markov model for each sentence:*

$$q^*(\mathbf{Y}) \propto \quad \prod_{\mathbf{x}\in\mathbf{X}}\prod_{i=1}^{|\mathbf{x}|} p_\theta(y_i|y_{i-1})p_\theta(x_i|y_i)e^{-\lambda^*\cdot\phi_i(\mathbf{x},y_i)}.$$

Hence $q^*(\mathbf{Y})$ *is just a first-order Markov model for each sentence, and we can compute the normalizer* $Z(\lambda^*)$ *and marginals* $q(y_i)$ *for each example using forward-backward. This allows computation of the dual objective in Equation 9 as well as its gradient efficiently. The gradient of the dual objective is* $1 - \mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})]$*. We can use projected gradient (Bertsekas, 1999) to perform the optimization, and the projection can be done sentence-by-sentence allowing for online optimization such as stochastic gradient. Optimization for non-zero slack case can be done using projected subgradient (since the norm is not smooth).*

Note that on *unseen* unlabeled data, the learned parameters θ might not satisfy the constraints on posteriors exactly, although typically they are fairly close if the model has enough capacity.

2.7 Penalized Slack via Expectation Maximization

If our objective is specified using slack-penalty such as in Equation 3, then we need a slightly different E-step. Instead of restricting $q \in Q$, the modified $\mathbf{E}'$-step adds a cost for violating the constraints

$$\begin{aligned}\mathbf{E}' : \min_{q,\xi} \quad & \mathbf{KL}\left(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X})\right) + \sigma||\xi||_\beta \\ \text{s.t.} \quad & \mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b} \leq \xi.\end{aligned} \tag{12}$$

An analogous monotonic improvement of modified EM can be shown for the slack-penalized objective. The dual of Equation 12 is

$$\max_{\lambda \geq 0} \; -\mathbf{b} \cdot \lambda - \log Z(\lambda) \qquad \text{s.t.} \quad ||\lambda||_{\beta^*} \leq \sigma.$$

2.8 PR for Discriminative Models

The PR framework can be used to guide learning in discriminative models as well as generative models. In the case of a discriminative model, we only have $p_\theta(\mathbf{y}|\mathbf{x})$, and the likelihood does not depend on unlabeled data. Specifically,

$$\mathcal{L}^D(\theta) = \log p_\theta(\mathbf{Y}_L|\mathbf{X}_L) + \log p(\theta),$$

where $(\mathbf{Y}_L, \mathbf{X}_L)$ are any available labeled data and $\log p(\theta)$ is a prior on the model parameters. With this definition of $\mathcal{L}(\theta)$ for discriminative models we will optimize the discriminative PR objective (zero-slack case):

$$\textbf{Discriminative PR Likelihood}: \quad J^D_Q(\theta) = \mathcal{L}^D(\theta) - \mathbf{KL}(Q \,\|\, p_\theta(\mathbf{Y}|\mathbf{X})). \tag{13}$$

In the absence of both labeled data and a prior on parameters $p(\theta)$, the objective in Equation 2 is optimized (equal to zero) for any $p_\theta(\mathbf{Y} \mid \mathbf{X}) \in Q$. If we employ a parametric prior on θ, then we will prefer parameters that come close to satisfying the constraints, where proximity is measured by KL-divergence.

> **Running Example** *For the POS tagging example, our discriminative model might be a first order conditional random field. In this case we model:*
>
> $$p_\theta(\mathbf{y}|\mathbf{x}) = \frac{\exp\{\theta \cdot \mathbf{f}(\mathbf{x}, \mathbf{y})\}}{Z_\theta(\mathbf{x})}$$
>
> *where* $Z_\theta(\mathbf{x}) = \sum_{\mathbf{y}} \exp\{\theta \cdot \mathbf{f}(\mathbf{x}, \mathbf{y})\}$ *is a normalization constant and* $\mathbf{f}(\mathbf{x}, \mathbf{y})$ *are the* model *features. We will use the same constraint features as in the generative case:* $\phi(\mathbf{x}, \mathbf{y}) =$ *"negative number of verbs in* $\mathbf{y}$*", and define* $Q_{\mathbf{x}}$ *and* $q_{\mathbf{x}}$ *also as before. Note that* $\mathbf{f}$ *are features used to define the model and do not appear anywhere in the constraints while* ϕ *are constraint features that do not appear anywhere in the model.*

Traditionally, the EM algorithm is used for learning generative models (the model can condition on a subset of observed variables, but it must define a distribution over some observed variables). The reason for this is that EM optimizes marginal log-likelihood ($\mathcal{L}$ in our notation) of the observed data $\mathbf{X}$ according to the model. In the case of a discriminative model, $p_\theta(\mathbf{Y}|\mathbf{X})$, we do not model the distribution of the observed data, the value of $\mathcal{L}^D$ as a function of θ depends only on the parametric prior $p(\theta)$ and the labeled data. By contrast, the PR objective uses the KL term and the corresponding constraints to bias the model parameters. These constraints depend on the observed data $\mathbf{X}$ and if they are sufficiently rich and informative, they can be used to train a discriminative model. In the extreme case, consider a constraint set Q that contains only a single distribution q, with $q(\mathbf{Y}^*) = 1$. So, q is concentrated on a particular labeling $\mathbf{Y}^*$. In this case, the PR objective in Equation 13 reduces to

$$J^D_Q(\theta) = \mathcal{L}^D(\theta) + \log p_\theta(\mathbf{Y}^*|\mathbf{X}) = \log p(\theta) + \log p_\theta(\mathbf{Y}_L|\mathbf{X}_L) + \log p_\theta(\mathbf{Y}^*|\mathbf{X}).$$

§#	Problem	Gen/Disc	p/q	Summary of Structural Constraints
§5	Word Alignment	G	q	Translation process is symmetric and bijective
§6	Multi-view learning	D	q	Multiple views should agree on label distribution
§7	Dependency Parsing	G+D	p	Noisy, partially observed labels encoded in ϕ and $\mathbf{b}$
§8	Part-of-speech induction	G	p	Sparsity structure independent of model parameters: each word should be generated by a small number of POS tags

Table 2: Summary of applications of Posterior Regularization described in this paper. Gen/Disc refers to generative or discriminative models. The p/q column shows whether we use the original model p or the projected distribution q at decode time.

Thus, if $\mathcal{Q}$ is informative enough to uniquely specify a labeling of the unlabeled data, the PR objective reduces to the supervised likelihood objective. When $\mathcal{Q}$ specifies a range of distributions, such as the one for multi view learning (Section 6), PR biases the discriminative model to have $p_\theta(\mathbf{Y}|\mathbf{X})$ close to $\mathcal{Q}$.

Equation 13 can also be optimized with a block-coordinate ascent, leading to an EM style algorithm very similar to the one presented in Section 2.6. We define a lower bounding function:

$$F'(q,\theta) = -\mathbf{KL}(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X})) = \sum_{\mathbf{Y}} q(\mathbf{Y}) \log \frac{p_\theta(\mathbf{Y}|\mathbf{X})}{q(\mathbf{Y})}.$$

Clearly, $\max_{q\in\mathcal{Q}} F'(q,\theta) = -\mathbf{KL}(\mathcal{Q} \parallel p_\theta(\mathbf{Y}|\mathbf{X}))$ so $F'(q,\theta) \leq -\mathbf{KL}(\mathcal{Q} \parallel p_\theta(\mathbf{Y}|\mathbf{X}))$ for $q \in \mathcal{Q}$.

The modified $\mathbf{E}'$ and $\mathbf{M}'$ steps are:[6]

$$\begin{aligned}
\mathbf{E}' : q^{t+1} &= \arg\max_{q\in\mathcal{Q}} F'(q,\theta^t) = \arg\min_{q\in\mathcal{Q}} \mathbf{KL}(q(\mathbf{Y}) \parallel p_{\theta^t}(\mathbf{Y}|\mathbf{X})), \\
\mathbf{M}' : \theta^{t+1} &= \arg\max_{\theta} F'(q^{t+1},\theta) = \arg\max_{\theta} \mathbf{E}_{q^{t+1}}\left[\log p_\theta(\mathbf{Y}|\mathbf{X})\right].
\end{aligned} \tag{14}$$

Here the difference between Equation 7 and Equation 14 is that now there is no generative component in the lower-bound $F'(q,\theta)$ and hence we have a discriminative update to the model parameters in Equation 14.

3. Summary of Applications

Because the PR framework allows very diverse prior information to be specified in a single formalism, the application Sections (§5-§8) are very diverse in nature. This section attempts to summarize their similarities and differences without getting into the details of the problem applications and intuition behind the constraints. Table 2 summarizes the applications and constraints described in the rest of the paper while Table 3 summarizes the meanings of the variables $\mathbf{x}$, $\mathbf{y}$ and $\phi(\mathbf{X},\mathbf{Y})$ as well as the optimization procedures used for the applications presented in the sequel.

In the statistical word alignment application described in Section 5, the goal is to identify pairs or sets of words that are direct translations of each other. The statistical models used suffer from what

6. As with the **M-step** in Equation 7 we have ignored the prior $p(\theta)$ on model parameters and the labeled data terms, which can be easily incorporated in the $\mathbf{M}'$ step.

Application	Symbol	Meaning
Word Alignment	$\mathbf{x}$	Pair of sentences that are translations of each other.
	$\mathbf{y}$	Set of alignment links between words in the sentences (exponentially many possibilities).
	$\phi(\mathbf{x},\mathbf{y})$	Bijective: number of times each source word is used in the alignment $\mathbf{y}$. Symmetric: expected difference in number of times each link is used by source$\rightarrow$target model and target $\rightarrow$source model.
	OPT	Bijective: projected gradient. Symmetric: L-BFGS.
Multi-view learning	$\mathbf{x}$	Varies by application.
	$\mathbf{y}$	Varies by application.
	$\phi(\mathbf{x},\mathbf{y})$	Indexed by label; ± 1 if only one model predicts the label, and 0 if both or none predict the label.
	OPT	Closed form.
Dependency Parsing	$\mathbf{x}$	Natural language sentence as a sequence of words.
	$\mathbf{y}$	Dependency parse tree (set of edges from one word to another, forming a tree).
	$\phi(\mathbf{x},\mathbf{y})$	Number of edges in $\mathbf{y}$ that are in the set of translated edges.
	OPT	Line search.
Part-of-speech induction	$\mathbf{x}$	Natural language sentence as a sequence of words.
	$\mathbf{y}$	Sequence of syntactic categories, one for each word.
	$\phi(\mathbf{X},\mathbf{Y})$	Indexed by w,i,s; 1 if the i^{th} occurrence of word w in the corpus is tagged with syntactic category s, and 0 otherwise.
	OPT	Projected gradient.

Table 3: Summary of input and output variable meanings as well as meanings of constraint features and optimization methods used (OPT) for the applications summarized in Table 2.

is known as a garbage collector effect: the likelihood function of the simplistic translation models used prefers to align sections that are not literal translations to rare words, rather than leaving them unaligned (Brown et al., 1993). This results in each rare word in a source language being aligned to 4 or 5 words in the target language. To alleviate this problem, we introduce constraint features that count how many target words are aligned to each source word, and use PR to encourage models where this number is small in expectation. Modifying the model itself to include such a preference would break independence and make it intractable.

The multi-view learning application described in Section 6 leverages two or more sources of input ("views") along with unlabeled data. The requirement is to train two models, one for each view, such that they usually agree on the labeling of the unlabeled data. We can do this using PR, and we recover the Bhattacharyya distance as a regularizer. The PR approach also extends naturally to structured problems, and cases where we only want partial agreement.

The grammar induction application of Section 7 takes advantage of an existing parser for a resource-rich language to train a comparable resource for a resource-poor language. Because the two languages have different syntactic structures, and errors in word alignment abound, using such out-of-language information requires the ability to train with missing and noisy labeling. This is

achieved using PR constraints that guide learning to prefer models that tend to agree with the noisy labeling wherever it is provided, while standard regularization guides learning to be self-consistent.

Finally, Section 8 describes an application of PR to ensure a particular sparsity structure, which can be independent of the structure of the model. Section 8 focuses on the problem of unsupervised part-of-speech induction, where we are given a sample of text and are required to specify a syntactic category for each token in the text. A well-known but difficult to capture piece of prior knowledge for this problem is that each word type should only occur with a small number of syntactic categories, even though there are some syntactic categories that occur with many different word types. By using an ℓ_1/ℓ_∞ norm on constraint features we are able to encourage the model to have precisely this kind of sparsity structure, and greatly increase agreement with human-generated syntactic categories.

Table 2 also shows for each application whether we use the distribution over hidden variables given by the model parameters $p_\theta(\mathbf{Y}|\mathbf{X})$ to decode, or whether we first project the distribution to the constraint set and use $q(\mathbf{Y})$ to decode. In general we found that when applying the constraints on the labeled data is sensible, performing the projection before decoding tends to improve performance. For the word alignment application and the multi-view learning application we found decoding with the projected distribution improved performance. By contrast, for dependency parsing, we do not have the English translations at test time and so we cannot perform a projection. For part-of-speech induction the constraints are over the entire corpus, and different regularization strengths might be needed for the training and test sets. Since we did not want to tune a second hyperparameter, we instead decoded with p.

4. Related Frameworks

The work related to learning with constraints on posterior distributions is described in chronological order in the following three subsections. An overall summary is most easily understood in reverse chronological order though, so we begin with a few sentences detailing the connections to it in that order. Liang et al. (2009) describe how we can view constraints on posterior distributions as measurements in a Bayesian setting, and note that inference using such information is intractable. By approximating this problem, we recover either the generalized expectation constraints framework of Mann and McCallum (2007), or with a further approximation we recover a special case of the posterior regularization framework presented in Section 2. Finally, a different approximation recovers the constraint driven learning framework of Chang et al. (2007). To the best of our knowledge, we are the first to describe all these connections.

4.1 Constraint Driven Learning

Chang et al. (2007, 2008) describe a framework called constraint driven learning (CODL) that can be viewed as an approximation to optimizing the slack-penalized version of the PR objective (Equation 3). Chang et al. (2007) are motivated by hard-EM, where the distribution q is approximated by a single sample at the mode of $\log p_\theta(\mathbf{Y}|\mathbf{X})$. Chang et al. (2007) propose to augment $\log p_\theta(\mathbf{Y}|\mathbf{X})$ by adding to it a penalty term based on some domain knowledge. When the penalty terms are well-behaved, we can view them as adding a cost for violating expectations of constraint features ϕ. In such a case, CODL can be viewed as a "hard" approximation to the PR objective:

$$\arg\max_\theta \ \mathcal{L}(\theta) \quad -\min_{q \in M} \Big(\mathbf{KL}(q(\mathbf{Y})||p_\theta(\mathbf{Y}|\mathbf{X})) \ + \ \sigma \big|\big|\mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b}\big|\big|_\beta \Big)$$

where M is the set of distributions concentrated on a single $\mathbf{Y}$. The modified E-Step becomes:

$$\text{CODL } \mathbf{E}'\text{-step} : \max_{\mathbf{Y}} \log p_\theta(\mathbf{Y}|\mathbf{X}) \; - \; \sigma||\phi(\mathbf{X},\mathbf{Y}) - \mathbf{b}||_\beta \, .$$

Because the constraints used by Chang et al. (2007) do not allow tractable inference, they use a beam search procedure to optimize the min-KL problem. Additionally they consider a K-best variant where instead of restricting themselves to a single point estimate for q, they use a uniform distribution over the top K samples.

Carlson et al. (2010) train several named entity and relation extractors concurrently in order to satisfy type constraints and mutual exclusion constraints. Their algorithm is related to CODL in that hard assignments are made in a way that guarantees the constraints are satisfied. However, their algorithm is motivated by adding these constraints to algorithms that learn pattern extractors: at each iteration, they make assignments only to the highest confidence entities, which are then used to extract high confidence patterns for use in subsequent iterations. By contrast hard EM and CODL would make assignments to every instance and change these assignments over time. Daumé III (2008) also use constraints to filter out examples for self-training and also do not change the labels.

4.2 Generalized Expectation Criteria

Generalized expectation criteria (GE) allow a user to specify preferences about model expectations in the form of linear constraints on some feature expectations (Mann and McCallum, 2007, 2008). As with PR, a set of constraint features ϕ are introduced, and a penalty term is added to the log-likelihood objective. The GE objective is

$$\max_{\theta} \; \mathcal{L}(\theta) - \sigma||\mathbf{E}_{p_\theta}[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b}||_\beta \, . \tag{15}$$

where $||\cdot||_\beta$ is typically the l_2 norm (Druck et al., 2009 use l_2^2) or a distance based on KL divergence (Mann and McCallum, 2008), and the model is a log-linear model such as maximum entropy or a CRF.

The idea leading to this objective is the following: Suppose that we only had enough resources to make a very small number of measurements when collecting statistics about the true distribution $p^*(\mathbf{y}|\mathbf{x})$. If we try to create a maximum entropy model using these statistics we will end up with a very impoverished model. It will only use a small number of features and consequently will fail to generalize to instances where these features cannot occur. In order to train a more feature-rich model, GE defines a wider set of *model* features $\mathbf{f}$ and uses the small number of estimates based on constraint features ϕ to guide learning. By using l_2 regularization on model parameters, we can ensure that a richer set of model features are used to explain the desired expectations.

Druck et al. (2009) use a gradient ascent method to optimize the objective. Unfortunately, because the second term in the GE objective (Equation 15) couples the constraint features ϕ and the model parameters θ, the gradient requires computing the covariance between model features $\mathbf{f}$ and the constraint features ϕ under p_θ:

$$\frac{\partial \mathbf{E}_{p_\theta}[\phi(\mathbf{X},\mathbf{Y})]}{\partial \theta} = \mathbf{E}_{p_\theta}[\mathbf{f}(\mathbf{X},\mathbf{Y})\phi(\mathbf{X},\mathbf{Y})] - \mathbf{E}_{p_\theta}[\phi(\mathbf{X},\mathbf{Y})]\mathbf{E}_{p_\theta}[\mathbf{f}(\mathbf{X},\mathbf{Y})].$$

Because of this coupling, the complexity of the dynamic program needed to compute the gradient is higher than the complexity of the dynamic program for the model. In the case of graphical models

where $\mathbf{f}$ and ϕ have the same Markov dependencies, computing this gradient usually squares the running time of the dynamic program. A more efficient dynamic program might be possible (Li and Eisner, 2009; Pauls et al., 2009), however current implementations are prohibitively slower than PR when there are many constraint features.

In order to avoid the costly optimization procedure described above, Bellare et al. (2009) propose a variational approximation. Recall that at a high level, the difficulty in optimizing Equation 15 is because the last term couples the constraint features ϕ with the model parameters θ. In order to separate out these quantities, Bellare et al. (2009) introduce an auxiliary distribution $q(\mathbf{Y}) \approx p_\theta(\mathbf{Y}|\mathbf{X})$, which is used to approximate the last term in Equation 15. The variational objective contains three terms instead of two:

$$\arg\max_{\theta} \ \mathcal{L}(\theta) \quad - \min_{q} \Big(\mathbf{KL}(q(\mathbf{Y})||p_\theta(\mathbf{Y}|\mathbf{X})) \ + \ \sigma \big|\big|\mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b}\big|\big|_\beta \Big). \tag{16}$$

This formulation is identical to the slack-penalized version of PR, and Bellare et al. (2009) use the same optimization procedure (described in Section 2). Because both the minorization and the maximization steps implement minimum Kullback-Leibler projections, Bellare et al. (2009) refer to this algorithm as alternating projections. Note that PR can also be trained in an online fashion, and Ganchev et al. (2009) use an online optimization for this objective to train a dependency parser. These experiments are described in Section 7.

Closely related to GE, is the work of Quadrianto et al. (2009). The authors describe a setting where the constraint values, $\mathbf{b}$, are chosen as the empirical estimates on some labeled data. They then train a model to have high likelihood on the labeled data, but also match the constraint features on unlabeled data. They show that for appropriately chosen constraint features, the estimated constraint values should be close to the true means, and show good experimental improvements on an image retrieval task.

4.3 Measurements in a Bayesian Framework

Liang et al. (2009) approach the problem of incorporating prior information about model posteriors from a Bayesian point of view. They motivate their approach using the following caricature. Suppose we have log-linear model $p_\theta(\mathbf{y}|\mathbf{x}) \propto \exp(\theta \cdot \mathbf{f}(\mathbf{y},\mathbf{x}))$. In addition to any labeled data $(\mathbf{X}_L, \mathbf{Y}_L)$, we also have performed some additional experiments.[7] In particular, we have observed the expected values of some constraint features $\phi(\mathbf{X},\mathbf{Y})$ on some unlabeled data $\mathbf{X}$. Because there is error in measurement, they observe $\mathbf{b} \approx \phi(\mathbf{X},\mathbf{Y})$. Figure 3 illustrates this setting. The leftmost nodes represent $(\mathbf{x},\mathbf{y})$ pairs from the labeled data $(\mathbf{X}_L, \mathbf{Y}_L)$. The nodes directly to the right of θ represent unlabeled $(\mathbf{x},\mathbf{y})$ pairs from the unlabeled data $\mathbf{X}$. All the data are tied together by the dependence on the model parameters θ. The constraint features take as input the unlabeled data set $\mathbf{X}$ as well as a full labeling $\mathbf{Y}$, and produce some value $\phi(\mathbf{X},\mathbf{Y})$, which is never observed directly. Instead, we observe some noisy version $\mathbf{b} \approx \phi(\mathbf{X},\mathbf{Y})$. The measured values $\mathbf{b}$ are distributed according to some noise model $p_N(\mathbf{b}|\phi(\mathbf{X},\mathbf{Y}))$. Liang et al. (2009) note that the optimization is convex for log-concave noise and use box noise in their experiments, giving $\mathbf{b}$ uniform probability in some range near $\phi(\mathbf{X},\mathbf{Y})$.

In the Bayesian setting, the model parameters θ as well as the observed measurement values $\mathbf{b}$ are random variables. Liang et al. (2009) use the mode of $p(\theta|\mathbf{X}_L,\mathbf{Y}_L,\mathbf{X},\mathbf{b})$ as a point estimate

7. In their exposition, Liang et al. (2009) incorporate labeled data by including the labels among experiments. We prefer to separate these types of observations because full label observations do not require approximations.

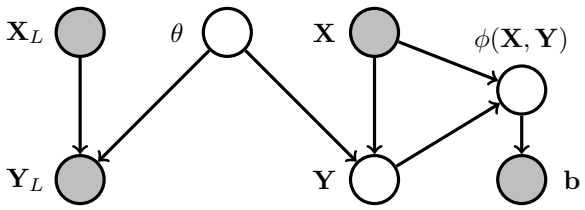

Figure 3: The model used by Liang et al. (2009), using our notation. We have separated treatment of the labeled data $(\mathbf{X}_L, \mathbf{Y}_L)$ from treatment of the unlabeled data $\mathbf{X}$.

for θ:

$$\arg\max_{\theta} \; p(\theta|\mathbf{X}_L, \mathbf{Y}_L, \mathbf{X}, \mathbf{b}) \quad = \quad \arg\max_{\theta} \; \sum_{\mathbf{Y}} p(\theta, \mathbf{Y}, \mathbf{b}|\mathbf{X}, \mathbf{X}_L, \mathbf{Y}_L),$$

with equality because $p(\theta|\mathbf{X}_L, \mathbf{Y}_L, \mathbf{X}, \mathbf{b}) \propto p(\theta, \mathbf{b}|\mathbf{X}_L, \mathbf{Y}_L, \mathbf{X}) = \sum_{\mathbf{Y}} p(\theta, \mathbf{Y}, \mathbf{b}|\mathbf{X}, \mathbf{X}_L, \mathbf{Y}_L)$. Liang et al. (2009) focus on computing $p(\theta, \mathbf{Y}, \mathbf{b}|\mathbf{X}, \mathbf{X}_L, \mathbf{Y}_L)$. They define their model for this quantity as follows:

$$p(\theta, \mathbf{Y}, \mathbf{b}|\mathbf{X}, \mathbf{X}_L, \mathbf{Y}_L) \quad = \quad p(\theta|\mathbf{X}_L, \mathbf{Y}_L) \;\; p_\theta(\mathbf{Y}|\mathbf{X}) \;\; p_N(\mathbf{b}|\phi(\mathbf{X}, \mathbf{Y})) \tag{17}$$

where the $\mathbf{Y}$ and $\mathbf{X}$ are particular instantiations of the random variables in the entire unlabeled corpus $\mathbf{X}$. Equation 17 is a product of three terms: a prior on θ, the model probability $p_\theta(\mathbf{Y}|\mathbf{X})$, and a noise model $p_N(\mathbf{b}|\phi)$. The noise model is the probability that we observe a value, $\mathbf{b}$, of the measurement features ϕ, given that its actual value was $\phi(\mathbf{X}, \mathbf{Y})$. The idea is that we model errors in the estimation of the posterior probabilities as noise in the measurement process. Liang et al. (2009) use a uniform distribution over $\phi(\mathbf{X}, \mathbf{Y}) \pm \varepsilon$, which they call "box noise". Under this model, observing $\mathbf{b}$ farther than ε from $\phi(\mathbf{X}, \mathbf{Y})$ has zero probability. In log space, the exact MAP objective, becomes:

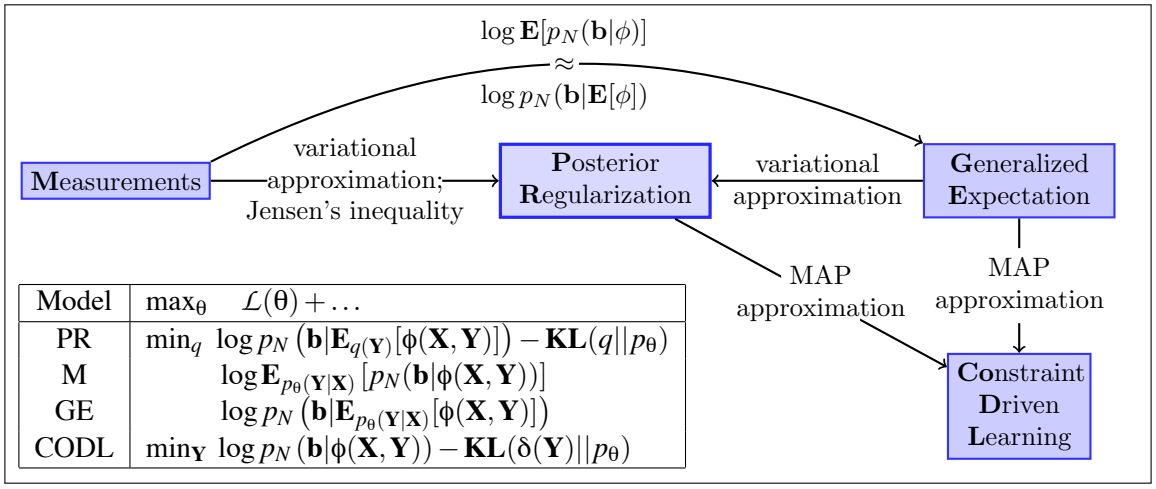
$$\max_{\theta} \quad \mathcal{L}(\theta) \quad + \log \mathbf{E}_{p_\theta(\mathbf{Y}|\mathbf{X})} \left[p_N(\mathbf{b}|\phi(\mathbf{X}, \mathbf{Y})) \right]. \tag{18}$$

Unfortunately with almost all noise models (including no noise), and box noise in particular, the second term in Equation 18 makes the optimization problem intractable.[8] Liang et al. (2009) use a variational approximation as well as a further approximation based on Jensen's inequality to reach the PR objective, which they ultimately optimize for their experiments. We also relate their framework to GE and CODL. If we approximate the last term in Equation 18 by moving the expectation inside the probability:

$$\mathbf{E}_{p_\theta(\mathbf{Y}|\mathbf{X})} \left[p_N(\mathbf{b} \mid \phi(\mathbf{X}, \mathbf{Y})) \right] \approx p_N \left(\mathbf{b} \mid \mathbf{E}_{p_\theta(\mathbf{Y}|\mathbf{X})} [\phi(\mathbf{X}, \mathbf{Y})] \right),$$

we end up with an objective equivalent to GE for appropriate noise models. In particular Gaussian noise corresponds to l_2^2 regularization in GE, since the log of a Gaussian is squared Euclidean distance (up to scaling). This approximation can be motivated by the case when $p_\theta(\mathbf{Y}|\mathbf{X})$ is concentrated on a particular labeling $\mathbf{Y}^*$: $p_\theta(\mathbf{Y}|\mathbf{X}) = \delta(\mathbf{Y}^*)$. In this special case the $\approx$ is an equality.

8. For very special noise, such as noise that completely obscures the signal, we can compute the second term in Equation 18.



Model	$\max_\theta \quad \mathcal{L}(\theta) + \ldots$
PR	$\min_q \ \log p_N\left(\mathbf{b}\middle\vert\mathbf{E}_{q(\mathbf{Y})}[\phi(\mathbf{X},\mathbf{Y})]\right) - \mathbf{KL}(q\vert\vert p_\theta)$
M	$\log \mathbf{E}_{p_\theta(\mathbf{Y}\vert\mathbf{X})}\left[p_N(\mathbf{b}\vert\phi(\mathbf{X},\mathbf{Y}))\right]$
GE	$\log p_N\left(\mathbf{b}\middle\vert\mathbf{E}_{p_\theta(\mathbf{Y}\vert\mathbf{X})}[\phi(\mathbf{X},\mathbf{Y})]\right)$
CODL	$\min_\mathbf{Y} \ \log p_N\left(\mathbf{b}\middle\vert\phi(\mathbf{X},\mathbf{Y})\right) - \mathbf{KL}(\delta(\mathbf{Y})\vert\vert p_\theta)$

Figure 4: A summary of the different models. We use $p_\theta(\mathbf{Y}|\mathbf{X})$ to denote the model probability, $q(\mathbf{Y})$ to denote a proposal distribution, and p_N for the noise model. The symbol $\delta(\mathbf{Y})$ denotes a distribution concentrated on $\mathbf{Y}$. The approximations are described in the text: M→GE near Equation 19, GE→PR near Equation 16, PR→CODL at the end of Section 4.3.

This approximation is also used in Liang et al. (2009). This provides an interpretation of GE as an approximation to the Bayesian framework proposed by Liang et al. (2009):

$$\max_\theta \quad \mathcal{L}(\theta) \quad + \log p_N\left(\mathbf{b}\middle|\mathbf{E}_{p_\theta(\mathbf{Y}|\mathbf{X})}[\phi(\mathbf{X},\mathbf{Y})]\right). \tag{19}$$

Note that the objective in Equation 19 is a reasonable objective in and of itself, essentially stating that the measured values $\mathbf{b}$ are not dependent on any particular instantiation of the hidden variables, but rather represent the integral over all their possible assignments. Liang et al. (2009) also use a variational approximation similar to the one of Bellare et al. (2009) so that the objective they optimize is exactly the PR objective, although their optimization algorithm is slightly different from the one presented in Section 2. Finally, if we restrict the set of allowable distributions further to be concentrated on a single labeling $\mathbf{Y}$, we recover the CODL algorithm. Figure 4 summarizes the relationships.

5. Statistical Word Alignments

Word alignments, introduced by Brown et al. (1994) as hidden variables in probabilistic models for statistical machine translation (IBM models 1-5), describe the correspondence between words in source and target sentences. We will denote each target sentence as $\mathbf{x}^t = (x_1^t, \ldots, x_i^t, \ldots, x_I^t)$ and each source sentence as $\mathbf{x}^s = (x_1^s, \ldots, x_j^s, \ldots, x_J^s)$. A word alignment will be represented as a matrix with entries y_{ij} indicating that target word i is a translation of source word j. Although the original IBM models are no longer competitive for machine translation, the resulting word alignments are still a valuable resource. Word alignments are used primarily for extracting minimal translation units for machine translation, for example, phrases in phrase-based translation systems (Koehn et al., 2003)

and rules in syntax-based machine translation (Galley et al., 2004; Chiang et al., 2005), as well as for MT system combination (Matusov et al., 2006). But their importance has grown far beyond machine translation: for instance, transferring annotations between languages by projecting POS taggers, NP chunkers and parsers through word alignment (Yarowsky and Ngai, 2001; Rogati et al., 2003; Hwa et al., 2005; Ganchev et al., 2009); discovery of paraphrases (Bannard and Callison-Burch, 2005; Callison-Burch, 2007, 2008); and joint unsupervised POS and parser induction across languages (Snyder and Barzilay, 2008; Snyder et al., 2009).

Here we describe two types of prior knowledge that when introduced as constraints in different word alignment models significantly boost their performance. The two constraints are: (i) bijectivity: "one word should not translate to many words"; and (ii) symmetry: "directional alignments of one model should agree with those of another model". A more extensive description of these constraints applied to the task of word alignments and the quality of the resulting alignments can be found in Graça et al. (2010).

5.1 Models

We consider two models below: IBM Model 1 proposed by Brown et al. (1994) and the HMM model proposed by Vogel et al. (1996). Both models can be expressed as:

$$p(\mathbf{x}^t, \mathbf{y} \mid \mathbf{x}^s) = \prod_j p_d(y_j \mid j, y_{j-1}) p_t(\mathbf{x}^t_j \mid \mathbf{x}^s_{y_j}),$$

where $\mathbf{y}$ is the alignment and y_j is the index of the hidden state (source language index) generating the target language word at index j. The models differ in their definition of the distortion probability $p_d(y_j \mid j, y_{j-1})$. Model 1 assumes that the target words are generated independently and assigns uniform distortion probability. The HMM model assumes that only the distance between the current and previous source word index is important $p_d(y_j \mid j, y_{j-1}) = p_d(y_j \mid y_j - y_{j-1})$. Both models are augmented by adding a special "null" word to the source sentence.

The likelihood of the corpus, marginalized over possible alignments, is concave for Model 1, but not for the HMM model (Brown et al., 1994; Vogel et al., 1996). For both models though, standard training using the Expectation Maximization algorithm (Dempster et al., 1977) seeks model parameters θ that maximize the log-likelihood of the parallel corpus.

On the positive side, both models are simple and complexity of inference is $O(I \times J)$ for IBM Model 1 and $O(I \times J^2)$ for the HMM. However there are several problems with the models that arise from their directionality.

- **Non-bijective:** Multiple target words can align to a single source word with no penalty.
- **Asymmetric:** Swapping the source and target languages can produce very different alignments, since only constraints and correlations between consecutive positions on one side are enforced by the models.

The top row of Figure 5 shows an example of the posterior distribution for the alignment between an English and a French sentence using the HMM model. The left figure shows the alignment in the English to French direction where the rows are source words and columns are target words, while the right figure shows the alignment posteriors of the opposite direction. The first observation we make is that the posteriors are concentrated around particular source words (rare words

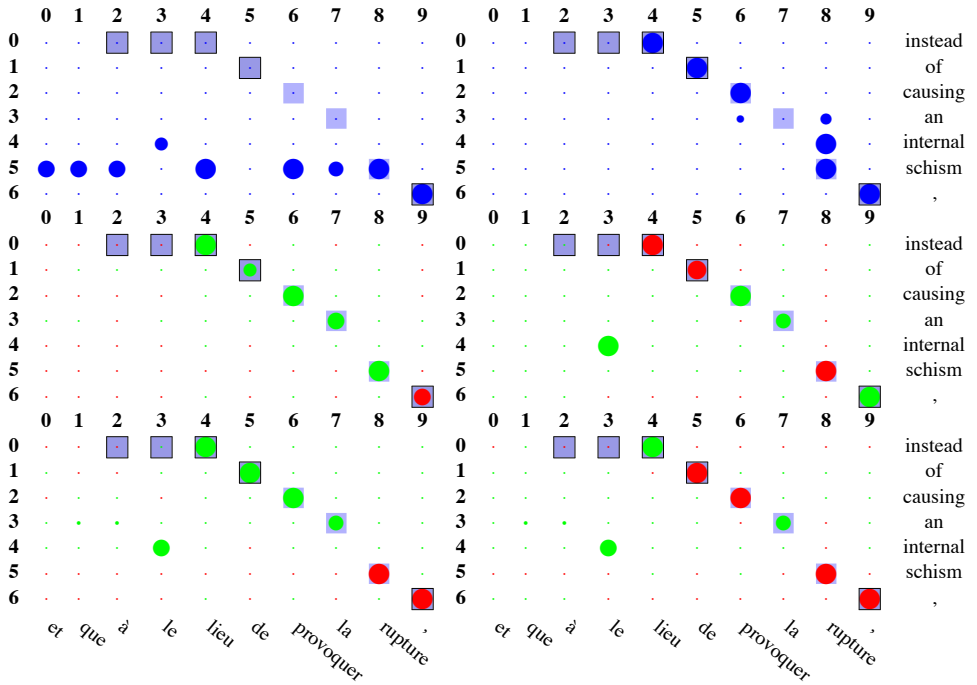


Figure 5: Posterior distributions on an English to French sentence using the HMM model. **Left:** EN→FR model. **Right:** FR→ EN model. **Top:** Regular EM posteriors. **Middle:** After applying bijective constraint. **Bottom:** After applying symmetric constraint. *Sure* alignments are squares with borders; *possible* alignments are squares without borders. Circle size indicates probability value. See Graça et al. (2010) for a description of the difference between sure and possible alignments. Circle color in the middle and bottom rows indicates difference in posterior from the top row. Green (light gray) - higher probability, red (dark gray) - lower probability.

occurring less than 5 times in the corpus) in both directions, instead of being spread across different words. This is a well known problem when training using EM, called the "garbage collector effect" (Brown et al., 1993). That is, rare words in the source language end up aligned to too many words in the target language because the generative model has to distribute translation probability for each source word among all candidate target words. Since the rare source word occurs in only a few sentences it needs to spread its probability mass over fewer competing target words. In this case, choosing to align the rare word to all of these target words leads to higher likelihood than correctly aligning them or aligning them to the special *null* word, since it increases the likelihood of this sentence without lowering the likelihood of many other sentences. Moreover, by correcting the garbage collector effect we increase the overall performance on the common words, since now these common words can be aligned to the correct words. For this particular corpus, 6.5% of the English tokens and 7.7% of the French tokens are rare.

5.2 Bijectivity Constraints

Bijectivity constraints are based on the observation that in most gold alignments, words are aligned one-to-one (98% for the sure alignments in the Hansard corpus). We would like to introduce this

trend into the model, but adding it directly requires large factors (breaking the Markov property). In fact, summing over one-to-one or near one-to-one weighted matchings is a classical #P-Complete problem (Valiant, 1979). However, introducing alignment degree constraints *in expectation* in the PR framework is easy and tractable. We simply add inequality constraints $\mathbf{E}[\phi(\mathbf{x},\mathbf{y})] \leq 1$ where we have one feature for each source word j that counts how many times it is aligned to a target word in the alignment $\mathbf{y}$:

$$\textbf{Bijective Features}: \quad \phi_j(\mathbf{x},\mathbf{y}) = \sum_i \mathbf{1}(y_i = j).$$

For example, in the alignment at the top right of Figure 5, the posteriors over the source word *schism* clearly sum to more than 1. The effect of applying PR constraints to the posteriors is shown in the second row. Enforcing the one to (at most) one constraint clearly alleviates the garbage collector effect. Moreover, when distributing the probability mass to the other words, most of the probability mass goes into the correct positions (as can be seen by comparison to the gold alignments). Note that the bijectivity constraints only hold approximately in practice and so we expect that having a KL-based penalty for them might be better than ensuring that the model satisfies them, since we can violate bijectivity in order to achieve higher likelihood. Another way to understand what is going on is to see how the parameters are affected by the bijectivity constraint. In particular the translation table becomes much cleaner, having a much lower entropy. The average entropy for the translation probability, averaged over all source language words for EM training is 2.0-2.6 bits, depending on the direction. When we train using PR with the bijectivity constraint, this entropy drops to 0.6 for both directions. We see that while the model does not have any particular parameter that can enforce bijectivity, in practice the model is expressive enough to learn a preference for bijectivity by appropriately setting the existing model parameters.

5.3 Symmetry Constraints

Word alignment should not depend on translation direction, but this principle is clearly violated by the directional models. In fact, each directional model makes different mistakes. The standard approach is to train two models independently and then intersect their predictions (Och and Ney, 2003).[9] However, we show that it is much better to train two directional models concurrently, coupling their posterior distributions over alignments with constraints that force them to approximately agree. The idea of training jointly has also been explored by Matusov et al. (2004) and Liang et al. (2006), although their formalization is quite different.

Let the directional models be defined as: $\overrightarrow{p}_\theta(\overrightarrow{\mathbf{y}})$ (forward) and $\overleftarrow{p}_\theta(\overleftarrow{\mathbf{y}})$ (backward). We suppress dependence on $\mathbf{x}^s$ and $\mathbf{x}^t$ for brevity. Define $\mathbf{y}$ to range over the union of all possible directional alignments $\overrightarrow{\mathbf{y}} \cup \overleftarrow{\mathbf{y}}$. We then define a mixture model $p_\theta(\mathbf{y}) = \frac{1}{2}\overrightarrow{p}_\theta(\mathbf{y}) + \frac{1}{2}\overleftarrow{p}_\theta(\mathbf{y})$ where $\overleftarrow{p}_\theta(\overrightarrow{\mathbf{y}}) = 0$ and vice-versa (i.e., the alignment of one directional model has probability zero according to the other model). We then define the following feature for each target-source position pair i, j:

$$\textbf{Symmetric Features}: \quad \phi_{ij}(\mathbf{x},\mathbf{y}) = \begin{cases} +1 & \mathbf{y} \in \overrightarrow{\mathbf{y}} \text{ and } \overrightarrow{y_i} = j \\ -1 & \mathbf{y} \in \overleftarrow{\mathbf{y}} \text{ and } \overleftarrow{y_j} = i \\ 0 & \text{otherwise.} \end{cases}$$

The feature takes the value zero in expectation if a word pair i, j is aligned with equal probability in both directions. So the constraint we want to impose is $\mathbf{E}_q[\phi_{ij}(\mathbf{x},\mathbf{y})] = 0$ (possibly with some small

9. Sometimes union or a heuristic is used instead of intersection.

violation). Note that this constraint is only feasible if the posteriors are bijective. Clearly these features are fully factored, so to compute expectations of these features under the model q we only need to be able to compute them under each directional model, as we show below. To see this, we have by the definition of q_λ and p_θ,

$$q_\lambda(\mathbf{y} \mid \mathbf{x}) = \frac{\overrightarrow{p}_\theta(\mathbf{y} \mid \mathbf{x}) + \overleftarrow{p}_\theta(\mathbf{y} \mid \mathbf{x})}{2} \frac{\exp\{-\lambda \cdot \phi(\mathbf{x}, \mathbf{y})\}}{Z} = \frac{\overrightarrow{q}(\mathbf{y} \mid \mathbf{x}) \frac{Z_{\overrightarrow{q}}}{\overrightarrow{p}_\theta(\mathbf{x})} + \overleftarrow{q}(\mathbf{y} \mid \mathbf{x}) \frac{Z_{\overleftarrow{q}}}{\overleftarrow{p}_\theta(\mathbf{x})}}{2Z},$$

where we have defined:

$$\begin{aligned}
\overrightarrow{q}(\mathbf{y} \mid \mathbf{x}) = &\quad \frac{1}{Z_{\overrightarrow{q}}} \overrightarrow{p}_\theta(\mathbf{y}, \mathbf{x}) \exp\{-\lambda \cdot \phi(\mathbf{x}, \mathbf{y})\} \quad \text{with} \quad Z_{\overrightarrow{q}} = \sum_{\mathbf{y}} \overrightarrow{p}_\theta(\mathbf{y}, \mathbf{x}) \exp\{-\lambda \cdot \phi(\mathbf{x}, \mathbf{y})\}, \\
\overleftarrow{q}(\mathbf{y} \mid \mathbf{x}) = &\quad \frac{1}{Z_{\overleftarrow{q}}} \overleftarrow{p}_\theta(\mathbf{y}, \mathbf{x}) \exp\{-\lambda \cdot \phi(\mathbf{x}, \mathbf{y})\} \quad \text{with} \quad Z_{\overleftarrow{q}} = \sum_{\mathbf{y}} \overleftarrow{p}_\theta(\mathbf{y}, \mathbf{x}) \exp\{-\lambda \cdot \phi(\mathbf{x}, \mathbf{y})\}, \\
Z = &\quad \frac{1}{2} \left(\frac{Z_{\overrightarrow{q}}}{\overrightarrow{p}_\theta(\mathbf{x})} + \frac{Z_{\overleftarrow{q}}}{\overleftarrow{p}_\theta(\mathbf{x})} \right).
\end{aligned}$$

All these quantities can be computed separately in each model.

The last row in Figure 5 shows both directional posteriors after imposing the symmetric constraint. Note that the projected posteriors are equal in the two models. Also, one can see that in most cases the probability mass was moved to the correct place with the exception of the word pair *internal*/*le*; this is because the word *internal* does not appear on the French side, but the model still has to spread around the probability mass for that word. In this case the model decided to accumulate it on the word *le* instead of moving it to the *null* word.

5.4 Algorithm for Projection

Because both the symmetric and bijective constraints decompose over sentences, and the model distribution $p(\mathbf{Y}|\mathbf{X})$ decomposes as a product distribution over instances, the projected distribution $q(\mathbf{Y})$ will also decompose as a product over instances. Furthermore, because the constraints for different instances do not interact, we can project the sentences one at a time and we do not need to store the posteriors for the whole corpus in memory at once. We compute $q(\mathbf{y})$ for each sentence pair $\mathbf{x}$ using projected gradient ascent for the bijective constraints and L-BFGS for the symmetric constraints.

5.5 Results

We evaluated the constraints using the Hansard corpus (Och and Ney, 2000) of English/French. Following prior work by Och and Ney (2003), we initialize the Model 1 translation table with uniform probabilities over word pairs that occur together in same sentence. The HMM is initialized with the translation probabilities from Model 1 and with uniform distortion probabilities. We train M1 for 5 iterations and train the HMM model until no further improvement on precision and recall is seen on standard (small) development set for this corpus. We note that when using regular EM training this requires around 4 iterations, while just 2 iterations suffices when using PR. This is likely due to the added information that the constraints provide. We use a 40 word maximum length cutoff for training sentences and train all models on 100,000 sentences, testing precision and recall on the standard test set.

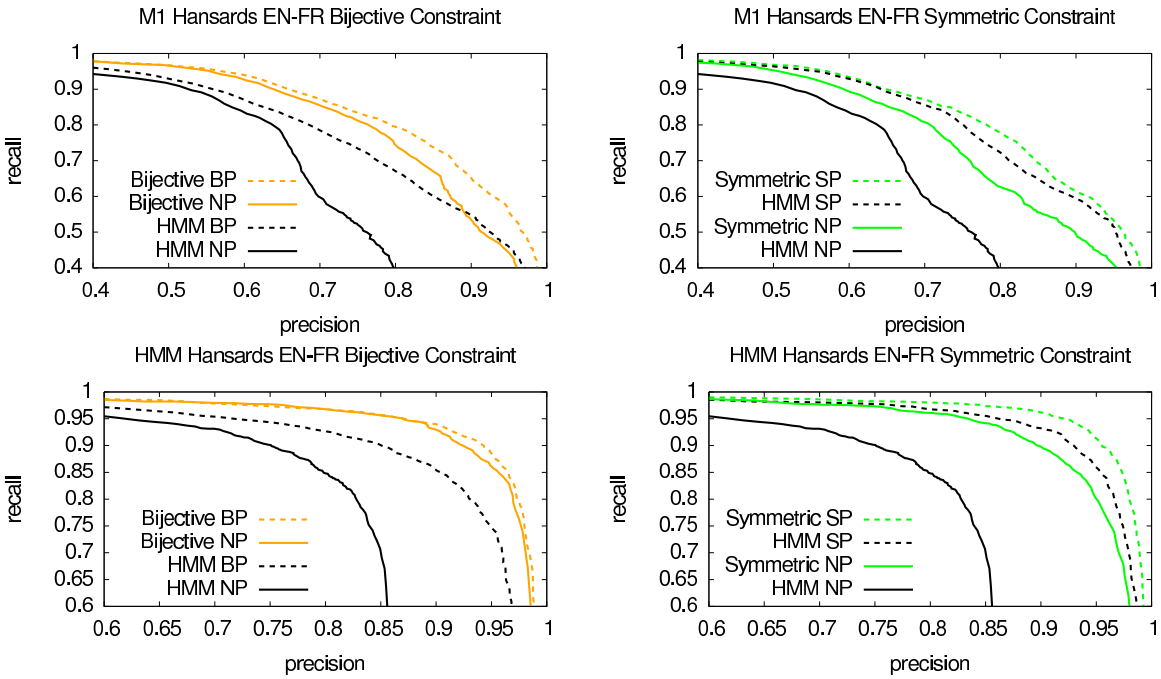

Figure 6: Precision vs Recall curves of both models using standard EM training (Regular) versus PR with bijective constraints (Bijective) and symmetry constraints (Symmetric) and different decoding types: decoding without any projection (NP), doing bijective projection before decoding (BP), and doing symmetric projection before decoding (SP). Data is 100k sentences of the Hansard corpus. Highest label in the legend corresponds to highest line in the graph, second highest label to second highest line, and so on.

Figure 6 shows the precision vs recall curves of both models (EN-FR, FR-EN independently) when training using standard EM versus PR with both constraints, and the results of additionally applying the constraints at decode time in order to tease apart the effect of the constraints during training vs. during testing. The first observation is that training with PR significantly boosts the performance of each model. Moreover using the projection at decode time always increases performance. Comparing both constraints, it seems that the bijective constraint is more useful at training time. Note that using this constraint at decode time with regular training yields worse results than just training with the same constraint using PR. On the other hand, the symmetric constraint is stronger at decode time.

A comprehensive comparison of the word alignment application is presented in Graça et al. (2010), where in six different languages the use of these constraints always significantly outperforms the simpler unconstrained HMM model. Moreover, in 9 out of 12 times using these constraints outperforms the more complex model IBM M4 (Brown et al., 1994). The alignments are also evaluated in the task of statistical machine translation where they are used as an initial step to extract parallel phrases used for translation. Using these constraints leads to better translation quality. Finally, the different alignments are tested on the task of transferring syntactic annotations, which

is described in the next section. The new alignments increase the number of correctly transferred edges.

6. Multi-view learning

Multi-view learning refers to a set of semi-supervised methods which exploit redundant views of the same input data (Blum and Mitchell, 1998; Collins and Singer, 1999; Brefeld et al., 2005; Sindhwani et al., 2005). These multiple views can come in the form of context and spelling features in the case of text processing and segmentation, hypertext link text and document contents for document classification, and multiple cameras or microphones in the case of speech and vision. Multi-view methods typically begin by assuming that each view alone can yield a good predictor. Under this assumption, we can regularize the models from each view by constraining the amount by which we permit them to disagree on unlabeled instances. This regularization can lead to better convergence by significantly decreasing the effective size of our hypothesis class (Balcan and Blum, 2005; Kakade and Foster, 2007; Rosenberg and Bartlett, 2007). This idea is related to the symmetry constraints described in Section 5.

In this section, we use PR to derive a multi-view learning algorithm. The idea is very simple: train a model for each view, and use constraints that the models should agree on the label distribution. Where our work is most similar to co-regularization schemes, a minimum Kullbeck-Leibler (KL) distance projection can be computed in closed form resulting in an algorithm that performs better than both CoBoosting and two view Perceptron on several natural language processing tasks. In this case, the resulting regularizer is identical to adding a penalty term based on the Bhattacharyya distance (Kailath, 1967) between models trained using different views.

In addition, this framework allows us to use different labeled training sets for the two classifiers, in the case where they have different label sets. That is, we don't require that our two views are both on the same labeled corpus. In that case, we can reduce the hypothesis space by preferring pairs of models that agree on *compatible* labeling of some additional unlabeled data rather than on *identical* labeling, while still minimizing KL in closed form. When the two views come from models that differ not only in the label set but also in the model structure of the output space, our framework can still encourage agreement, but the KL minimization cannot be computed in closed form. Finally, this method uses soft assignments to latent variables resulting in a more stable optimization procedure.

6.1 Stochastic Agreement

Note that the constraint in this section is similar to the one described in Section 5, but here we focus on discriminative learning and the formulation is slightly different. For notational convenience, we focus on two view learning in this exposition, however the generalization to more than two views is fairly straightforward. Also, we focus on two discriminative log-linear models and start by considering the setting of complete agreement. In this setting we have a common desired output for the two models and we believe that each of the two views is sufficiently rich to predict labels accurately. We can leverage this knowledge by restricting our search to model pairs p_1,p_2 that satisfy $p_1(\mathbf{y} \mid \mathbf{x}) \approx p_2(\mathbf{y} \mid \mathbf{x})$. Since p_1 and p_2 each define a distribution over labels, we will consider the product distribution $p_1(\mathbf{y}_1)p_2(\mathbf{y}_2)$ and define constraint features such that our proposal distribution $q(\mathbf{y}_1, \mathbf{y}_2)$ will have the same marginal for $\mathbf{y}_1$ and $\mathbf{y}_2$. In particular, we will have one constraint feature for each label $\mathbf{y}$:

$$\phi_{\mathbf{y}}(\mathbf{y}_1, \mathbf{y}_2) = \delta(\mathbf{y}_1 = \mathbf{y}) - \delta(\mathbf{y}_2 = \mathbf{y}).$$

Where $\delta(\cdot)$ is the 0-1 indicator function. The constraint set $Q = \{q : \mathbf{E}_q[\phi] = 0\}$ will require that the marginals over the two output variables are identical $q(\mathbf{y}_1) = q(\mathbf{y}_2)$. It will be useful in the sequel to define an agreement between two models agree(p_1, p_2) as

$$\text{agree}(p_1, p_2) = \arg\min_q \ \mathbf{KL}(q(\mathbf{y}_1, \mathbf{y}_2)||p_1(\mathbf{y}_1)p_2(\mathbf{y}_2)) \quad \text{s.t.} \quad \mathbf{E}_q[\phi] = 0. \tag{20}$$

Proposition 6.1 relates the Bhattacharyya regularization term to the value of the optimization problem in Equation 20. The Bhattacharyya distance is a very natural, symmetric measure of difference between distributions which has been used in many signal detection applications (Kailath, 1967). It is also related to the well-known Hellinger distance.

Proposition 6.1 *The Bhattacharyya distance* $-\log \sum_{\mathbf{y}} \sqrt{p_1(\mathbf{y})p_2(\mathbf{y})}$ *is equal to* $\frac{1}{2}$ *of the value of the convex optimization problem*

$$\begin{array}{ll} \min\limits_{q \in Q} & \mathbf{KL}(q(\mathbf{y}_1, \mathbf{y}_2)||p_1(\mathbf{y}_1)p_2(\mathbf{y}_2)) \\ \text{where} & Q = \left\{q : \mathbf{E}_q[\delta(\mathbf{y}_1 = \mathbf{y}) - \delta(\mathbf{y}_2 = \mathbf{y})] = 0 \ \forall y\right\}, \end{array} \tag{21}$$

and where $\delta(cond)$ *is* 1 *if cond is true and* 0 *otherwise. Furthermore, the minimizer decomposes as* $q(\mathbf{y}_1, \mathbf{y}_2) = q_1(\mathbf{y}_1)q_2(\mathbf{y}_2)$ *and is given by* $q_i(y) \propto \sqrt{p_1(\mathbf{y})p_2(\mathbf{y})}$.

Proof Taking the dual of the optimization problem in Equation 21 we get

$$\arg\max_{\lambda} -\log \sum_{\mathbf{y}_1, \mathbf{y}_2} p(\mathbf{y}_1, \mathbf{y}_2) \exp(\lambda \cdot \phi)$$

with $q(\mathbf{y}_1, \mathbf{y}_2) \propto p(\mathbf{y}_1, \mathbf{y}_2) \exp(\lambda \cdot \phi(\mathbf{y}_1, \mathbf{y}_2))$. Where $\phi(\mathbf{y}_1, \mathbf{y}_2)$ is a vector of features of the form $\delta(\mathbf{y}_1 = \mathbf{y}) - \delta(\mathbf{y}_2 = \mathbf{y})$ with one entry for each possible label $\mathbf{y}$. Noting that the features decompose into $\phi'(\mathbf{y}_1) - \phi'(\mathbf{y}_2)$, we know that $q(\mathbf{y}_1, \mathbf{y}_2)$ decomposes as $q_1(\mathbf{y}_1)q_2(\mathbf{y}_2)$. Furthermore, our constraints require that $q_1(\mathbf{y}) = q_2(\mathbf{y}) \forall \mathbf{y}$ so we have $q(\mathbf{y}_1)q(\mathbf{y}_2) \propto p_1(\mathbf{y}_1) \exp(\lambda \cdot \phi'(\mathbf{y}_1)) p_2(\mathbf{y}_2) \exp(-\lambda \cdot \phi'(\mathbf{y}_2))$. Letting $\mathbf{y}_1 = \mathbf{y}_2$ we have $q(\mathbf{y})^2 = p_1(\mathbf{y})p_2(\mathbf{y})$ which gives us a closed form computation of agree$(p_1, p_2) \propto \sqrt{p_1(\mathbf{y})p_2(\mathbf{y})}$. Substituting this solution into the problem of Proposition 6.1, and performing algebraic simplification yields the desired result. ■

Replacing the minimum KL term in Equation 2 with a Bhattacharyya regularization term yields the objective

$$\min_{\theta} \mathcal{L}_1(\theta_1) + \mathcal{L}_2(\theta_2) + c\mathbf{E}_U[B(p_1(\theta_1), p_2(\theta_2))]$$

where $\mathcal{L}_i = \mathbf{E}[-\log(p_i(\mathbf{y}_i|\mathbf{x}; \theta_i))] + \frac{1}{\sigma_i^2}||\theta_i||^2$ for $i = 1, 2$ are the standard regularized log likelihood losses of the models p_1 and p_2, $\mathbf{E}_U[B(p_1, p_2)]$ is the expected Bhattacharyya distance (Kailath, 1967) between the predictions of the two models on the unlabeled data, and c is a constant defining the relative weight of the unlabeled data relative to the labeled data.

Our regularizer extends to full agreement for undirected graphical models. In the case where p_1 and p_2 have the same structure, $q = \text{agree}(p_1, p_2)$ will share this structure and the projection can be computed in closed form.

Proposition 6.2 *Suppose $p_i(\mathbf{Y}|\mathbf{X}), i \in \{1,2\}$ factor as a set of clique potentials from a set of cliques $\mathcal{C}$:*

$$p_i(\mathbf{Y}|\mathbf{X}) = \frac{1}{Z_i(\mathbf{X})} \prod_{c \in \mathcal{C}} \psi_i(\mathbf{X}, \mathbf{Y}_c),$$

then $q_i(\mathbf{Y})$ also factors as a product over clique potentials in $\mathcal{C}$, and can be computed in closed form modulo normalization as $q(\mathbf{Y}_1, \mathbf{Y}_2) = q_1(\mathbf{Y}_1) q_2(\mathbf{Y}_2)$ with

$$q_i(\mathbf{Y}|\mathbf{X}) = \frac{1}{Z'(\mathbf{X})} \prod_{c \in \mathcal{C}} \sqrt{\psi_1(\mathbf{X}, \mathbf{Y}_c) \psi_2(\mathbf{X}, \mathbf{Y}_c)}.$$

Proof The proof is simple algebraic manipulation. We start with Equation 22, an application of Proposition 6.1.

$$\begin{aligned} q_i(\mathbf{Y})^2 &\propto p_1(\mathbf{Y}|\mathbf{X}) p_2(\mathbf{Y}|\mathbf{X}) \\ &= Z_1^{-1} Z_2^{-1} \prod_c \psi_1(\mathbf{X}, \mathbf{Y}_c) \psi_2(\mathbf{X}, \mathbf{Y}_c) \\ &= \left(\frac{1}{Z'(\mathbf{X})} \prod_c \sqrt{\psi_1(\mathbf{X}, \mathbf{Y}_c) \psi_2(\mathbf{X}, \mathbf{Y}_c)} \right)^2. \end{aligned} \tag{22}$$

■

Note that Proposition 6.2 is not a special case of Proposition 2.2 because we have defined one constraint feature $\phi_{\mathbf{y}}$ for each possible labeling $\mathbf{y}$, and these do not decompose according to $\mathcal{C}$. We could alternatively have proven that ensuring agreement on clique potentials is identical to ensuring agreement on labelings. In the case of log-linear Markov random fields, the clique potentials are stored in log space so computing q corresponds to averaging the values before computing normalization.

6.2 Partial Agreement and Hierarchical Labels

Our method extends naturally to partial-agreement scenarios. For example we can encourage two part-of-speech taggers with different tag sets to produce compatible parts of speech, such as noun in tag set one and singular-noun in tag set 2, as opposed to noun in tag set 1 and verb in tag set 2. In particular, suppose we have a mapping from both label sets into a common space where it makes sense to encourage agreement. For the part-of-speech tagging example, this could mean mapping all nouns from both tag sets into a single class, all verbs into another class and so on. In general suppose we have functions $g_1(\mathbf{y}_1)$ and $g_2(\mathbf{y}_2)$ that map variables for the two models onto the same space $\{\mathbf{z}\}$. Then, $p_i(\mathbf{y}_i)$ and g_i induce a distribution:

$$p_i(\mathbf{z}) = \sum_{\mathbf{y} \,:\, g_i(\mathbf{y}) = \mathbf{z}} p_i(\mathbf{y}) \quad \text{and} \quad p_i(\mathbf{y}_i|\mathbf{z}) = p_i(\mathbf{y}_i)/p_i(\mathbf{z}).$$

We can encourage $p_1(\mathbf{z}) \approx p_2(\mathbf{z})$ by adding a feature for each label in the joint space:

$$\phi_{\mathbf{z}}(\mathbf{y}_i) = \begin{cases} 1 & \text{if } i = 1 \text{ and } g_1(\mathbf{y}_1) = \mathbf{z} \\ -1 & \text{if } i = 2 \text{ and } g_2(\mathbf{y}_2) = \mathbf{z} \\ 0 & \text{otherwise.} \end{cases} \tag{23}$$

In this case our objective becomes:

$$\min_{\theta} \mathcal{L}_1(\theta_1) + \mathcal{L}_2(\theta_2) + c\mathbf{E}_U[B(p_1(\mathbf{z}), p_2(\mathbf{z}))] \ .$$

In the special case where some labels are identical for the two models and others are incompatible, we have $g_1(\mathbf{z}_1)$ mapping the incompatible labels into one bin and the others into their own special bins. Proposition 6.3 along with the optimization algorithm described in Section 2.6 allows us to optimize this objective.

Proposition 6.3 *The Bhattacharyya distance* $-\log \sum_{\mathbf{z}} \sqrt{p_1(\mathbf{z})p_2(\mathbf{z})}$ *is* $\frac{1}{2}$ *the value of the convex optimization problem*

$$\begin{aligned} \min_{q} \quad & \mathbf{KL}(q(\mathbf{Y}_1, \mathbf{Y}_2) || p_1(\mathbf{Y}_1)p_2(\mathbf{Y}_2)) \\ \text{s.t.} \quad & \mathbf{E}_q(\phi) = 0, \end{aligned}$$

where the constraint features ϕ *are defined as in Equation 23. Furthermore, the minimizer decomposes as* $q(\mathbf{Y}_1, \mathbf{Y}_2) = q_1(\mathbf{Y}_1|\mathbf{z}_1)q_1(\mathbf{z}_1)q_2(\mathbf{Y}_2|\mathbf{z}_2)q_2(\mathbf{z}_2)$*, where* $q_1(\mathbf{z}_1) = q_2(\mathbf{z}_2) \propto \sqrt{p_1(\mathbf{z}_1)p_2(\mathbf{z}_2)}$ *and* $q_i(\mathbf{Y}_i|\mathbf{z}_i) = p_i(\mathbf{Y}_i|\mathbf{z}_i)$ $i \in \{1,2\}$.

Note that the computation of agree(p_1, p_2) is still in closed form if our models are unstructured.

Unfortunately, if we collapse some labels for structured models, $p(\mathbf{Y})$ might not have the same Markov properties as $p(\mathbf{z})$. For example, consider the case where p is a distribution over three states (1,2,3) that assigns probability 1 to the sequence (1,2,3,1,2,3,...) and probability zero to other sequences. This is a first-order Markov chain. If the mapping is $1 \mapsto 1$ and $2,3 \mapsto 0$ then $p(\mathbf{y})$ assigns probability 1 to (1,0,0,1,0,0,...), which cannot be represented as a first-order Markov chain. Essentially, the original chain relied on being able to distinguish between the allowable transition (2,3) and the disallowed transition (3,2). When we collapse the states, both of these transitions map to (0,0) and cannot be distinguished. Consequently, the closed form solution given in Proposition 6.3 is not usable. Potentially, we could compute some approximation to $p(\mathbf{y})$ and from that compute an approximation to q. Instead, we re-formulate our constraints to require only that the marginals of each clique in p_1 and p_2 match each other rather than requiring the joint to have the same probability:

$$\phi_{c,\mathbf{z}_c}(\mathbf{Y}_1, \mathbf{Y}_2) = \begin{cases} 1 & \text{if } i = 1 \text{ and } g_1(\mathbf{y}_1)_c = \mathbf{z}_c \\ -1 & \text{if } i = 2 \text{ and } g_2(\mathbf{y}_2)_c = \mathbf{z}_c \\ 0 & \text{otherwise.} \end{cases} \tag{24}$$

By Proposition 2.2, the features in Equation 24 lead to a q that respects the Markov properties of the original models.

6.3 Relation to Other Multi-View Learning

To avoid a long detour from PR, we describe here only CoBoosting (Collins and Singer, 1999) and two view Perceptron (Brefeld et al., 2005), the frameworks with which we empirically compare our method in the next section. Since these methods are based on different objective functions from ours it is worth examining where each one works best. Altun et al. (2003) compare log-loss and exp-loss for sequential problems. They find that the loss function does not have as great an effect on performance as the feature choice. However, they also note that exp-loss is expected to

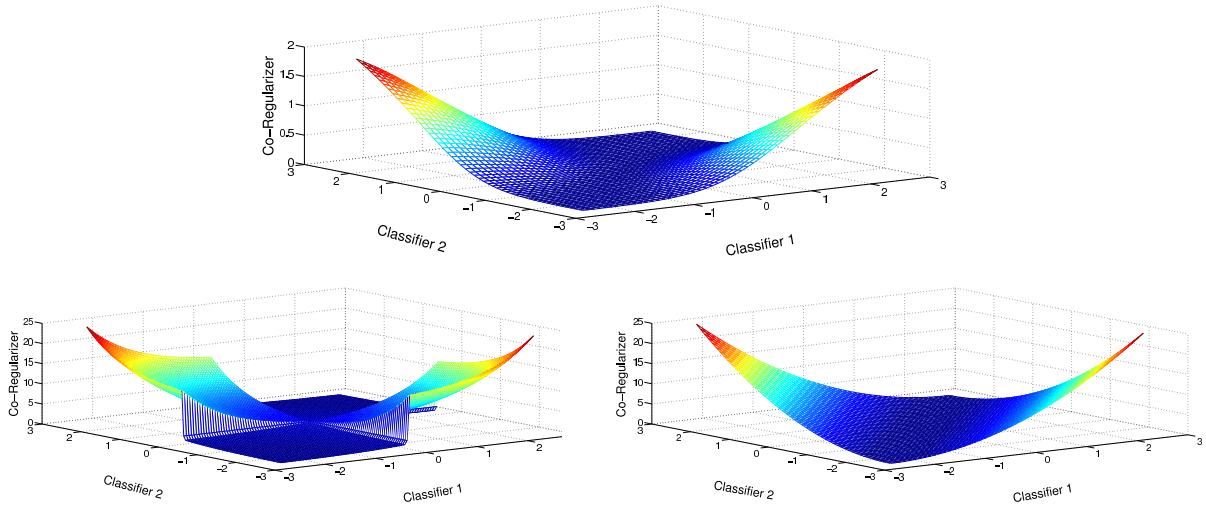

Figure 7: Different Loss Functions. **Top**: Bhattacharyya distance regularization. **Bottom left**: Exp-loss regularization. **Bottom right**: Least squares regularization.

perform better for clean data, while log-loss is expected to perform better when there is label noise. The intuition behind this is in the rate of growth of the loss functions. Exp-loss grows exponentially with misclassification margin while log-loss grows linearly. Consequently when there is label noise, AdaBoost focuses more on modeling the noise. Since CoBoosting optimizes a co-regularized exp-loss while our work optimizes a co-regularized log-loss we expect to do better on problems where the labels are noisy.

To get more intuition about this, Figure 7 shows the co-regularization loss functions for our method, CoBoosting, and co-regularized least squares (Sindhwani et al., 2005). For two underlying binary linear classifiers, $\hat{y}_1 = \text{sign}(w_1 \cdot x)$ and $\hat{y}_2 = \text{sign}(w_2 \cdot x)$, the horizontal axes represent the values $\hat{y}_1$ and $\hat{y}_2$, while the vertical axis is the loss. If we consider the plane parallel to the page, we see how the different co-regularizers penalize the classifiers when they disagree and are equally confident in their decision. Restricted to this plane, all three co-regularizers grow at the same asymptotic rate as the loss functions for the individual models: Linearly for our work, exponentially for CoBoosting and quadratically for co-RLS. If we look at the area where the two models agree (the flat part of the CoBoosting graph) we see what the penalty is when the classifiers agree but have different confidence. In this case co-RLS is harshest since it penalizes differences in the dot product equally regardless of the absolute value of the dot product. Intuitively, this is a problem. If one model predicts 1 with confidence 0.5 and the other predicts -1 with confidence 0.5 they are disagreeing while if they both predict 1 with confidence 1000 and 1001 respectively, they are agreeing on the label and are very close in their confidence estimates. At the other extreme, CoBoosting imposes almost no penalty whenever the two classifiers agree, regardless of their confidence. The Bhattacharyya distance co-regularizer lies between these extremes, penalizing differences in confidence near the origin but is more lenient when the classifiers are both very confident and agree.

Finally, if we have labeled data from one domain but want to apply it to another domain we can use any of the co-training frameworks mentioned earlier, including our own, to perform do-

Table 4: Performance of several methods on a sentiment classification transfer learning task. Reviews of objects of one type are used to train a classifier for reviews of objects of another type. The abbreviations in the column names are as follows. Boost: AdaBoost algorithm, Perc: Perceptron, mx-ent: maximum entropy, SCL: structural correspondence learning, CoBoost: CoBoosting, coPerc: two view Perceptron, PR: this work. The best accuracy is shown in bold for each task. The last two rows of the table show the average improvement over maximum entropy (the best performing supervised method), and also the standard deviation of the improvement.

main transfer. For sentiment classification we will see that our method performs comparably with Structural Correspondence Learning (Blitzer et al., 2006), which is based on Alternating Structure Optimization (Ando and Zhang, 2005).

6.4 Experiments

Our first set of experiments is for transfer learning for sentiment classification. We use the data from Blitzer et al. (2007). The two views are generated from a random split of the features. We compare our method to several supervised methods as well as CoBoosting (Collins and Singer, 1999), two view Perceptron (Brefeld et al., 2005) and structural correspondence learning (Blitzer et al., 2007). Results are in Table 4. The column labeled "SCL" contains the best results from Blitzer et al. (2007), and is not directly comparable with the other methods since it uses some extra knowledge about the transfer task to choose auxiliary problems. For all the two-view methods we weigh the total labeled data equally with the total unlabeled data. We regularize the maximum entropy classifiers with a unit variance Gaussian prior. Out of the 12 transfer learning tasks, our method performs best in 6 cases, SCL in 4, while CoBoosting performs best only once. Two view Perceptron never outperforms all other methods. One important reason for the success of our method is the relative strength of the maximum entropy classifier relative to the other supervised methods for this

particular task. We expect that CoBoosting will perform better than our method in situations where Boosting significantly out-performs maximum entropy.

The next set of our experiments are on named entity disambiguation. Given a set of already segmented named entities, we want to predict what type of named entity each one is. We use the training data from the 2003 CoNLL shared task (Sang and Meulder, 2003). The two views comprise content versus context features. The content features are words, POS tags and character n-grams of length 3 for all tokens in the named entity, while context features the same but for three words before and after the named entity. We used 2000 examples as test data and roughly 30,000 as unlabeled (train) data. Table 5 shows the results for different amounts of labeled train data. For this data, we choose the variance of the Gaussian prior as well as the relative weighting of the labeled and unlabeled data by cross validation on the train set. In order to test whether the advantage our method gets is from the joint objective or from the use of agree(p_1, p_2), which is an instance of logarithmic opinion pools, we also report the performance of using agree(p_1, p_2) when the two views p_1 and p_2 have been trained only on the labeled data. In the column labeled "agree$_0$" we see that for this data set the benefit of our method comes from the joint objective function rather than from the use of logarithmic opinion pools.

Data size	mx-ent	agree$_0$	PR	RRE
500	74.0	74.4	76.4	9.2%
1000	80.0	80.0	81.7	8.5%
2000	83.4	83.4	84.8	8.4%

Table 5: Named entity disambiguation. Prior variance and c chosen by cross validation. agree$_0$ refers to performance of two view model before first iteration of EM. RRE is reduction in error relative to error of MaxEnt model.

In order to investigate the applicability of our method to structured learning we apply it to the shallow parsing task of noun phrase chunking. We our experiments are on the English training portion of the CoNLL 2000 shared task (Sang and Buchholz, 2000). We select 500 sentences as test data and varying amounts of data for training; the remainder was used as unlabeled (train) data. We use content and context views, where the content view is the current word and POS tag while the context view is the previous and next words and POS tags. We regularize the CRFs with a variance 10 Gaussian prior and weigh the unlabeled data so that it has the same total weight as the labeled data. The variance value was chosen based on preliminary experiments with the data. Table 6 shows the F-1 scores of the different models. We compare our method to a monolithic CRF as well as averaged Perceptron the two view Perceptron of Brefeld et al. (2005) with averaging. The Perceptron models were trained for 20 iterations. Preliminary experiments show that performance on held out data does not change after 10 iterations so we believe the models have converged. Both two view semi-supervised methods show gains over the corresponding fully-supervised method for 10-100 sentences of training data, but do not improve further as the amount of labeled data increases. The method presented in this paper out-performs two view Perceptron when the amount of labeled data is very small, probably because regularized CRFs perform better than Perceptron for small amounts of data. As the number of training sentences increases, two view Perceptron performs as well as our method, but at this point it has little or no improvement over the fully-supervised Perceptron.

size	CRF	SAR(RRE)	Perc	coPerc
10	73.2	**78.2**(19%)	69.4	71.2
20	79.4	**84.2**(23%)	74.4	76.8
50	86.3	**86.9** (4%)	80.1	84.1

200	89.6	89.6 (0%)	89.3	**89.7**
500	**91.3**	90.6 (-8%)	90.8	90.9
1000	91.6	91.1 (-6%)	91.5	**91.8**

Table 6: F-1 scores for noun phrase chunking with context/content views. Test data comprises 500 sentences, with 8436 sentences divided among labeled and unlabeled train data. The best score is shown in bold for each train data size.

7. Cross Lingual Projection

For English and a handful of other languages, there are large, well-annotated corpora with a variety of linguistic information ranging from named entity to discourse structure. Unfortunately, for the vast majority of languages very few linguistic resources are available. This situation is likely to persist because of the expense of creating annotated corpora that require linguistic expertise (Abeillé, 2003). On the other hand, parallel corpora between many resource-poor languages and resource-rich languages are ample, motivating recent interest in transferring linguistic resources from one language to another via parallel text.

Dependency grammars are one such resource. They are useful for language modeling, textual entailment and machine translation (Haghighi et al., 2005; Chelba et al., 1997; Quirk et al., 2005; Shen et al., 2008), to name a few tasks. Dependency grammars are arguably more robust to transfer than constituent grammars, since syntactic relations between aligned words of parallel sentences are better conserved in translation than phrase structure (Fox, 2002; Hwa et al., 2005). The two main challenges to accurate training and evaluation from aligned bitext are: (1) errors in word alignments and source language parses, (2) unaligned words due to non-literal or distant translation.

Hwa et al. (2005) proposed to learn generative dependency grammars using Collins' parser (Collins, 1999) by constructing full target parses via projected dependencies. To address challenge (1), they introduced on the order of one to two dozen language-specific transformation rules. To address challenge (2), they used a set of tree-completion rules. We present here an alternative approach to dependency grammar transfer. Our approach uses a single, intuitive PR constraint to guide grammar learning. With this constraint, we avoid the need for complex tree completion rules and many language-specific rules, yet still achieve acceptable parsing accuracy.

It should be noted that while our source of supervision, a bitext, is the same as that of Hwa et al. (2005), our learning method is more closely related to that of Druck et al. (2009). They use the GE framework to train a dependency parser. Their source of supervision comes in the form of corpus-wide expected values of linguistic rules provided by a linguistic informant.

In what follows, X will indicate parallel part-of-speech tagged sentences in a bitext corpus, along with a dependency parse of the source language. Y will indicate the dependency parses for the target language sentences.

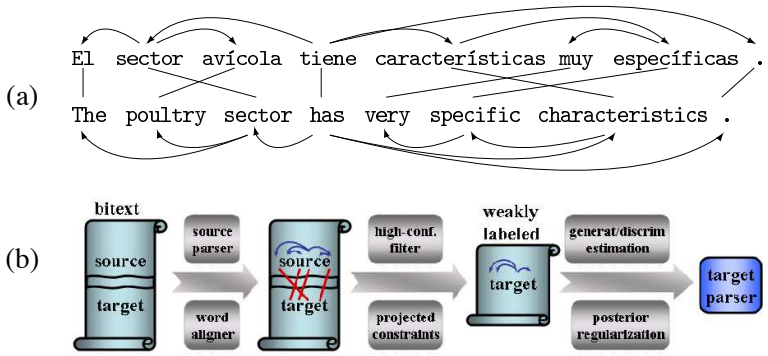

Figure 8: (a) An example word-aligned sentence pair with perfectly projected dependencies. (All dependency edges are conserved in this case.) (b) Overview of our grammar induction approach via bitext: the source (English) is parsed and word-aligned with target; after filtering, projected dependencies define constraints over target parse tree space, providing weak supervision for learning a target grammar.

7.1 Approach

Figure 8(a) shows an aligned sentence pair example where dependencies are perfectly "conserved" across the alignment. An edge from English parent p to child c is called conserved if word p aligns to word p' in the second language, c aligns to c' in the second language, and p' is the parent of c'. Note that we are not restricting ourselves to one-to-one alignments here; p, c, p', and c' can all also align to other words. Unfortunately the sentence in Figure 8(a) is highly unusual in its amount of dependency conservation, so we need to do more than directly transfer conserved edges to get good parsing accuracy.

The key to our approach is a single PR constraint, which ensures that the expected proportion of conserved edges in a sentence pair is at least η (the exact proportion we used was 0.9, which was determined using unlabeled data as described in the experiments section). Specifically, let $C_{\mathbf{x}}$ be the set of directed edges projected from English for a given sentence $\mathbf{x}$. Then given a parse $\mathbf{y}$, the proportion of conserved edges is $\phi(\mathbf{x},\mathbf{y}) = \frac{1}{|C_{\mathbf{x}}|}\sum_{y\in\mathbf{y}} \mathbf{1}(y \in C_{\mathbf{x}})$ and the expected proportion of conserved edges under distribution $p(\mathbf{y} \mid \mathbf{x})$ is

$$\mathbf{E}_p[\phi(\mathbf{x},\mathbf{y})] = \frac{1}{|C_{\mathbf{x}}|}\sum_{y\in C_{\mathbf{x}}} p(y \mid \mathbf{x}).$$

Consider how this constraint addresses errors in word alignment and source language parses, challenge (1) from above. First, note that we are constraining groups of edges rather than a single edge. For example, in some sentence pair we might find 10 edges that have both end points aligned and can be transferred. Rather than requiring our target language parse to contain each of the 10 edges, we require that the expected number of edges from this set is at least 10η. This gives the parser freedom to have some uncertainty about which edges to include, or alternatively to choose to exclude some of the transferred edges.

Our constraint does not address unaligned words due to non-literal or distant translation, challenge (2), as directly. Yet, we find that the constraint sufficiently limits the distribution over possible parses of unaligned words, such that the parser still makes reasonable choices for them. It is also

Table 7: Features used by the MSTParser. For each edge (i, j), x_i-word is the parent word and x_j-word is the child word, analogously for POS tags. The +1 and -1 denote preceeding and following tokens in the sentence, while b denotes tokens between x_i and x_j.

worth noting that if we wished to more directly address challenge (2), we could add additional constraint features to the PR framework. For example, it seems intuitive that unaligned words might tend to be leaves (e.g., articles that are dropped in some languages but not in others). Thus, one constraint we could enforce would be to restrict the number of children of unaligned words to fall below some threshold.

For both models, we compute the projection onto the constraint set using a simple line search. This is possible since there is only one constraint per sentence and the constraints do not interact.

At a high level our approach is illustrated in Figure 8(b). A parallel corpus is word-level aligned using the method described in Section 5, where we train an alignment model via PR using symmetry constraints. The source (English) is parsed using a dependency parser (McDonald et al., 2005). Then, the filtering stage eliminates low-confidence alignments such as noun-to-verb alignments, restricts the training set to exclude possible sentence fragments, and follows the method of Klein and Manning (2004) in stripping out punctuation. We then learn a probabilistic parsing model using PR. In our experiments we evaluate the learned models on dependency treebanks (Nivre et al., 2007).

7.2 Parsing Models

We explored two parsing models: a generative model used by several authors for unsupervised induction and a discriminative model previously used for fully supervised training.

The discriminative parser is based on the edge-factored model and features of the MSTParser (McDonald et al., 2005). The parsing model defines a conditional distribution $p_\theta(\mathbf{y} \mid \mathbf{x})$ over each projective parse tree $\mathbf{y}$ for a particular sentence $\mathbf{x}$, parameterized by a vector θ. The probability of any particular parse is

$$p_\theta(\mathbf{y} \mid \mathbf{x}) \propto \prod_{y \in \mathbf{y}} e^{\theta \cdot \mathbf{f}(y, \mathbf{x})},$$

where y is a directed edge contained in the parse tree $\mathbf{y}$ and $\mathbf{f}$ is a feature function. In the fully supervised experiments we run for comparison, parameter estimation is performed by stochastic gradient ascent on the conditional likelihood function, similar to maximum entropy models or conditional random fields. One needs to be able to compute expectations of the features $\mathbf{f}(y, \mathbf{x})$ under the distribution $p_\theta(y \mid \mathbf{x})$. A version of the inside-outside algorithm (Lee and Choi, 1997) performs this computation. Viterbi decoding is done using Eisner's algorithm (Eisner, 1996).

We also used a generative model based on dependency model with valence (Klein and Manning, 2004). Under this model, the probability of a particular parse $\mathbf{y}$ and a sentence with part-of-speech tags $\mathbf{x}$ is given by

$$p_\theta(\mathbf{y},\mathbf{x}) = p_{\text{root}}(r(\mathbf{x})) \cdot \Big(\prod_{y\in\mathbf{y}} p_{\neg\text{stop}}(y_p,y_d,v_y)\, p_{\text{child}}(y_p,y_d,y_c)\Big) \cdot \Big(\prod_{x\in\mathbf{x}} p_{\text{stop}}(x,\text{left},v_l)\, p_{\text{stop}}(x,\text{right},v_r)\Big)$$

where $r(\mathbf{x})$ is the part-of-speech tag of the root of the parse tree $\mathbf{y}$, y is an edge from parent y_p to child y_c in direction y_d, either left or right, and v_y indicates valency—false if y_p has no other children further from it in direction y_d than y_c, true otherwise. The valencies v_r/v_l are marked as true if x has any children on the left/right in $\mathbf{y}$, false otherwise.

We regularize the models by parameter prior $-\log p(\theta) = R(\theta)$, where $p(\theta)$ is Gaussian for the discriminative model and Dirichlet for the generative.

7.3 Experiments

We evaluate our approach by transferring from an English parser trained on the Penn treebank to Bulgarian and Spanish. We evaluate our results on the Bulgarian and Spanish corpora from the CoNLL X shared task. The Bulgarian experiments transfer a parser from English to Bulgarian, using the OpenSubtitles corpus (Tiedemann, 2007). The Spanish experiments transfer from English to Spanish using the Spanish portion of the Europarl corpus (Koehn, 2005). For both corpora, we performed word alignments with the open source PostCAT (Graça et al., 2009b) toolkit. We used the Tokyo tagger (Tsuruoka and Tsujii, 2005) to POS tag the English tokens, and generated parses using the first-order model of McDonald et al. (2005) with projective decoding, trained on sections 2-21 of the Penn treebank with dependencies extracted using the head rules of Yamada and Matsumoto (2003). For Bulgarian we trained the Stanford POS tagger (Toutanova et al., 2003) on the Bulgtreebank corpus from CoNLL X. The Spanish Europarl data was POS tagged with the FreeLing language analyzer (Atserias et al., 2006). The discriminative model used the same features as MSTParser, summarized in Table 7. Our model uses constraints of the form: the expected proportion of conserved edges in a sentence pair is at least $\eta = 90\%$.[10]

In order to better evaluate our method, we construct a baseline inspired by Hwa et al. (2005). The baseline creates a full parse tree from the incomplete and possibly conflicting transferred edges using a simple random process. We start with no edges and try to add edges one at a time verifying at each step that it is possible to complete the tree. We first try to add the transferred edges in random order, then for each orphan node we try all possible parents (both in random order). We then use this full labeling as supervision for a parser. Note that this baseline is very similar to the first iteration of our model, since for a large corpus the different random choices made in different sentences tend to smooth each other out. We also tried to create rules for the adoption of orphans, but the simple rules we tried added bias and performed worse than the baseline we report.

10. We chose η in the following way: We split the unlabeled parallel text into two portions. We trained models with different η on one portion and ran it on the other portion. We chose the model with the highest fraction of conserved constraints on the second portion.

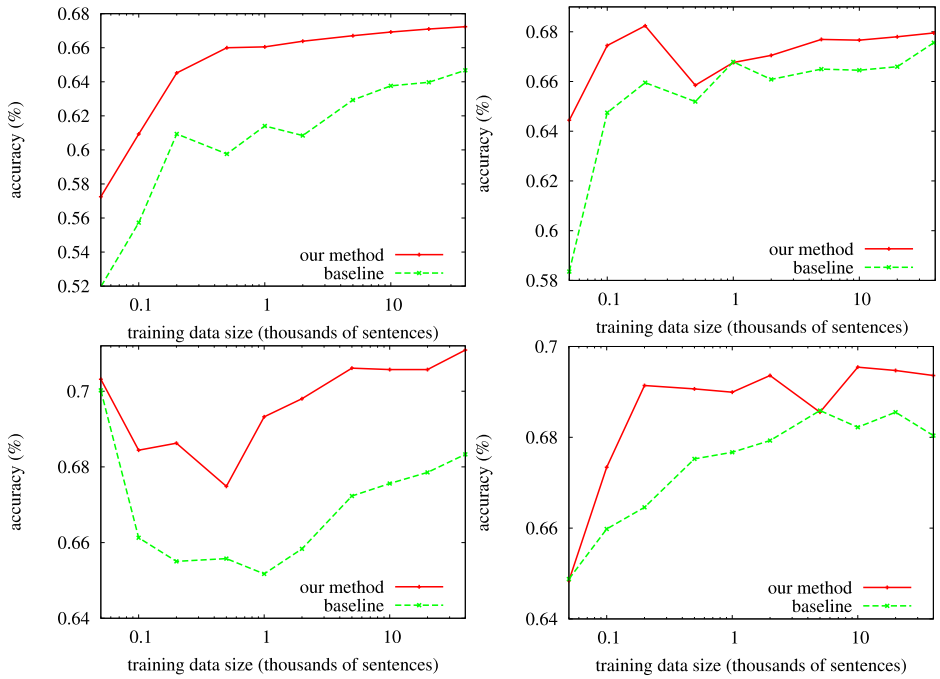

Figure 9: Learning curves. Each graph compares transferring a single tree of edges (baseline) and transferring all possible projected edges (our method). The models were trained on sentences of length up to 20 and tested on CoNLL train sentences of length up to 10. Punctuation was stripped at train time. **Top**: Bulgarian. **Bottom**: Spanish. **Left**: Discriminative model. **Right**: Generative model. The non-monotonicity of the (such as bottom left) is because each point is based on a single random sample of sentences. This random selection can greatly affect performance when the number of sentences is small.

7.3.1 RESULTS

Models are evaluated based on attachment accuracy—the fraction of words assigned the correct parent. Figure 9 shows that models generally improve with more transfer-type data. It also shows our method consistently outperforms the baseline. Note that each point in these graphs is based on a single random subsample of the data, which leads to some non-monotonicity in the left-half of some of the curves. The exact accuracy numbers for the 10k training sentences point of Figure 9 are given in Table 8. Link-left baselines for these corpora are much lower: 33.8% and 27.9% for Bulgarian and Spanish respectively.

7.3.2 GENERATIVE PARSER

The generative model we use is a state of the art model for unsupervised parsing. Before evaluating, we smooth the resulting models by adding e^{-10} to each learned parameter, merely to remove the chance of zero probabilities for unseen events. (We did not bother to tune this value at all as it makes very little difference for final parses.) Unfortunately, we found generative model performance was disappointing in the unsupervised setting. Using the initialization procedure from Klein and Man-

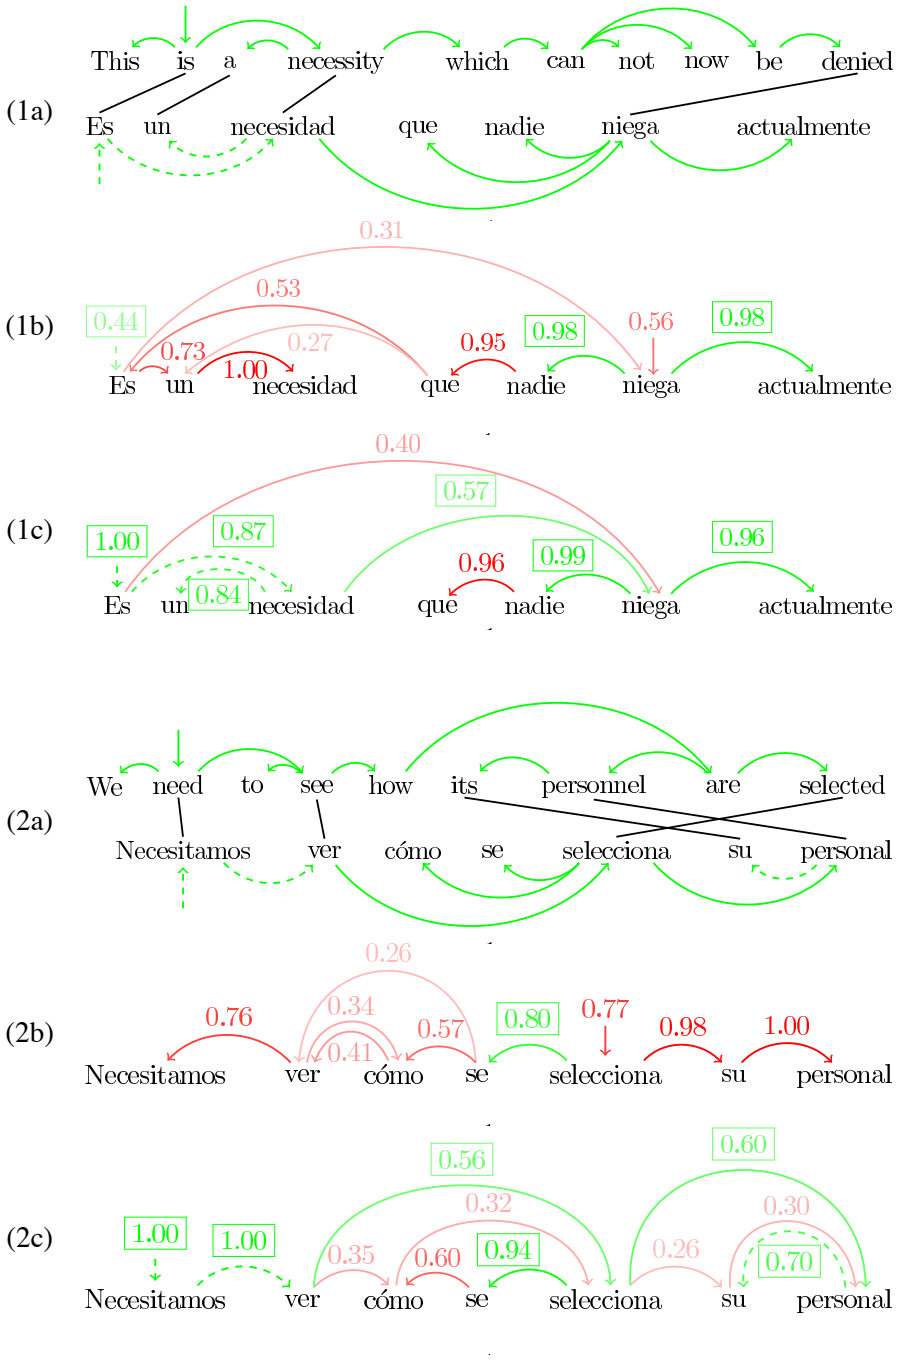

Figure 10: Posteriors of two Spanish sentences from Europarl. The number on each edge indicates the edge's posterior probability. Edges with probability less than 0.25 are not shown. Darker (more saturated) edges are higher probability. Green (with boxed number) indicates a correct edge, red (no box) an incorrect. Dotted edges are conserved. **(a)** The gold source and target parses and their alignment. **(b)** Unsupervised model initialized as per Klein and Manning (2004) and trained for 100 EM iterations. **(c)** PR projection applied to the posteriors of the middle figure, forcing $\mathbf{E}_p[C] \geq C * \eta = 3 * 0.9$, where C is the number of conserved edges.

	Discriminative		Generative	
	Bulgarian	Spanish	Bulgarian	Spanish
Baseline	63.8	67.6	66.5	68.2
Post.Reg.	**66.9**	**70.6**	**67.8**	**69.5**

Table 8: Accuracy values at the 10k training sentences point of Figure 9.

ning (2004), the maximum unsupervised accuracy it achieves is 55.4% for Bulgarian and 41.7% for Spanish, and these results are not stable. Changing the initialization parameters or training sample drastically affects the results, even for samples with several thousand sentences. But when we use the transferred information to constrain the learning, EM stabilizes and achieves much better performance, also beating the Hwa et al. (2005)-inspired baseline. With the transferred information, even setting all parameters equal at the outset does not prevent the model from learning the dependency structure of the aligned language. Figure 10 shows an example of how PR projection helps better estimate posteriors of two example sentences.

7.3.3 DISCRIMINATIVE PARSER

We trained our discriminative parser for 100 iterations of online EM with a Gaussian prior variance of 100. The transfer system performs better than the unsupervised generative model and the baseline model for both Bulgarian and Spanish. We observed another desirable property of the discriminative model: While the generative model can get confused and perform poorly when the training data contains very long sentences, the discriminative parser does not appear to have this drawback. In fact we observed that as the maximum training sentence length increased, the parsing performance also improved.

8. Enforcing Sparsity Structure

Many important NLP tasks (e.g., tagging, parsing, named-entity recognition) involve word classification. Often, we know a priori that a word type might belong to a small set of classes (where the class of a specific instance depends on its context) and should never belong to any of the many possible classes outside this small set. The part-of-speech tagging task, described in the running example, is one instance of this phenomenon. For example, consider the word type "run". It might belong to the verb class in some instances and the noun class in others, but it will never be an adjective, adverb, conjunction, determiner, etc. Learning algorithms typically assume that each word type can be associated with any existing tag, even though in reality each word type is only ever associated with a few tags.

Unsupervised induction of this latent structure is normally performed using the EM algorithm, but it has exhibited disappointing performance in previous work. One well-known reason for this is that EM tends to allow each word to be generated by most POS tags some of the time. In reality, we would like most words to have a small number of possible POS tags. Previous work has attempted to solve this problem by applying the Bayesian approach, using a prior to encourage sparsity in the model *parameters* (Gao and Johnson, 2008; Johnson, 2007; Goldwater and Griffiths, 2007). However, this approach has the drawback of enforcing sparsity in the wrong direction; sparsity at the parameter level encodes a preference that each POS tag should generate only a few words,

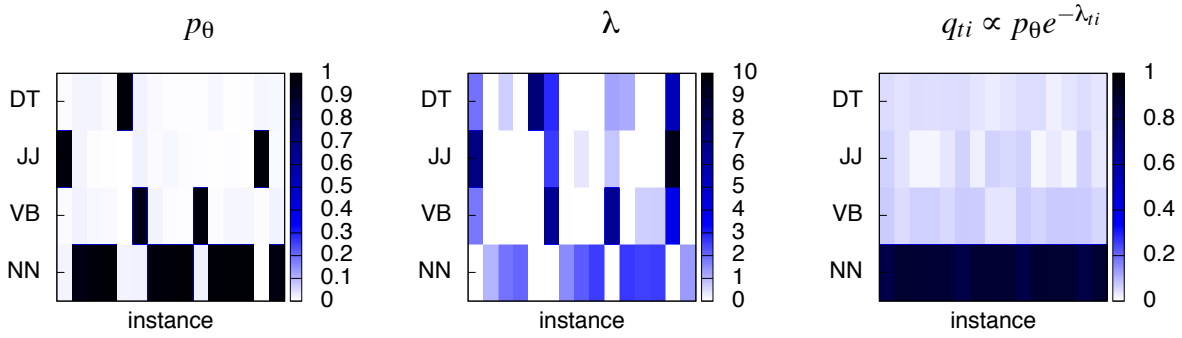

Figure 11: An illustration of ℓ_1/ℓ_∞ regularization. Left panel: initial tag distributions (columns) for 15 instances of a word. Middle panel: optimal regularization parameters λ, each row sums to $\sigma = 20$. Right panel: q concentrates the posteriors for all instances on the NN tag, reducing the ℓ_1/ℓ_∞ norm from just under 4 to a little over 1.

instead of encoding that each word should generate only a few POS tags. Here we explore the problem of biasing unsupervised models to favor the correct sparsity by encouraging the model to achieve *posterior* sparsity on unlabeled training data.

8.1 ℓ_1/ℓ_∞ Regularization

We focus on the slack-penalized formulation of Section 2.3 for this task. We choose the PR constraint to encourage each word to be associated with only a few parts of speech. Let the constraint feature $\phi_{wti}(\mathbf{X}, \mathbf{Y})$ have value 1 whenever the i^{th} occurrence of word w has part-of-speech tag t, and value 0 otherwise. For every word w, we would like there to be only a few POS tags t such that there are occurrences i where t has nonzero probability. This can be achieved if it "costs" a lot the first time an occurrence of a word takes a particular tag, but afterwards future occurrences of the word can receive that same tag for free. More precisely, for each word type w, we would like the sum (ℓ_1 norm), over tags t, of the maximum (ℓ_∞ norm), over all occurrences w_i of w, of $p(w_i \mid t)$, to be small; we want $\sum_{t,w} \max_i p(w_i \mid t)$ to be small. Note that in contrast to previous applications, these constraints are corpus-wide instead of instance-specific. For notational simplicity we will write $\phi_{wti}(\mathbf{X}, \mathbf{Y}) = \phi_{wti}(\mathbf{Y})$, since any dependence on $\mathbf{X}$ is captured in the subscripts of ϕ_{wti}.

Formally, this objective is an example of the slack-penalized formulation (as in Equation 3), but for simplicity we will use the notation:

$$\min_{q, c_{wt}} \ \mathbf{KL}(q||p_\theta) + \sigma \sum_{wt} c_{wt} \quad \text{s.t.} \quad \mathbf{E}_q[\phi_{wti}] \leq c_{wt}.$$

Mapping this notation to the original equation we have: $\mathbf{b} = 0$ and regularization strength σ. The constraints on the features ϕ_{wti} and the summation over c_{wt} together encode the ℓ_1/ℓ_∞ norm. The variables c_{wt} represent the ℓ_∞ norm of ϕ_{wti}, $c_{wt} = ||\phi_{wti}||_{\ell_\infty}$, while the summation is the ℓ_1 norm of c_{wt}. The dual of this objective has a very simple form:

$$\max_{\lambda \geq 0} \ -\log \left(\sum_y p_\theta(\mathbf{Y}) \exp(-\boldsymbol{\lambda} \cdot \phi(\mathbf{Y})) \right) \quad \text{s.t.} \quad \sum_t \lambda_{wti} \leq \sigma, \tag{25}$$

where $\mathbf{Y}$ ranges over assignments to the hidden tag variables for all of the occurrences in the training data, $\phi(\mathbf{Y})$ is the vector of ϕ_{wti} constraint feature values for assignment $\mathbf{Y}$, $\boldsymbol{\lambda}$ is the vector of dual parameters λ_{wti}, and the primal parameters are $q(\mathbf{Y}) \propto p_\theta(\mathbf{Y}) \exp(-\boldsymbol{\lambda} \cdot \phi(\mathbf{Y}))$.

An advantage of using slack penalties in this case is that ℓ_1/ℓ_∞ as a slack constraint in the primal would lead to a non-differentiable dual penalty term, which somewhat complicates optimization. Using a slack penalty makes sparsity regularization a primal penalty, yielding dual simplex constraints, solvable efficiently via projected gradient, as described by Bertsekas (1999). Note that the simplex constraints in Equation 25 can be interpreted as an ℓ_∞/ℓ_1 norm, which is the dual of the ℓ_1/ℓ_∞.

Figure 11 illustrates how the ℓ_1/ℓ_∞ norm operates on a toy example. For simplicity suppose we are only regularizing one word and our model p_θ is just a product distribution over 15 instances of the word. The left panel in Figure 11 shows the posteriors under p_θ. We would like to concentrate the posteriors on a small subset of rows. The center panel of the figure shows the $\boldsymbol{\lambda}$ values determined by Equation 25, and the right panel shows the projected distribution q, which concentrates most of the posterior on the bottom row. Note that we are not requiring the posteriors to be sparse, which would be equivalent to preferring that the distribution is peaked; rather, we want a word to concentrate its tag posterior on a few tags across all instances of the word. Indeed, most of the instances (columns) become less peaked than in the original posterior to allow posterior mass to be redistributed away from the outlier tags. Since they are more numerous than the outliers, they moved less. This also justifies only regularizing relatively frequent events in our model.

8.2 Results

In this section we present an empirical comparison of first-order HMMs trained with three different methods: classic EM (EM), ℓ_1/ℓ_∞ PR (Sparse), and Bayesian estimation using a variational approximation described in Johnson (2007) and Gao and Johnson (2008) (VEM). Models are trained and tested on three different corpora: the Wall Street Journal portion of the Penn treebank (Marcus et al., 1993) using a reduced set of 17 tags (Smith et al., 2005) (PTB17); the Bosque subset of the Portuguese Floresta Sinta(c)tica Treebank (Afonso et al., 2002)[11] used for the ConLL X shared task on dependency parsing (PT-CoNLL)[12]; and the Bulgarian BulTreeBank (Simov et al., 2002) (BulTree) with 12 coarse tags. All words that occurred only once were replaced by the token "unk". To measure model sparsity, we compute the average ℓ_1/ℓ_∞ norm over words occurring more than 10 times; the label 'L1LMax' denotes this measure in figures. Table 9 gives statistics for each corpus as well as the sparsity for a first-order HMM trained on the labeled data.

Following Gao and Johnson (2008), the parameters were initialized with a "pseudo E-step" as follows: we filled the expected count matrices with numbers $1 + X \times U(0,1)$, where $U(0,1)$ is a random number between 0 and 1 and X is a parameter. These matrices are then fed to the M-step; the resulting "random" transition and emission probabilities are used for the first real E step. For VEM X was set to 0.0001 (almost uniform) since this showed a significant improvement in performance. On the other hand EM showed less sensitivity to initialization, and we used $X = 1$ which resulted in the best results. The models were trained for 200 iterations as longer runs did not significantly change the results. For VEM we tested 4 different prior combinations based on the results of Johnson (2007); in later work Gao and Johnson (2008) considered a wider range of values

11. The subset can be found at `http://www.linguateca.pt/Floresta/`.
12. The task can be found at `http://nextens.uvt.nl/~conll/`.

	Types	Tokens	Unk	Tags	ℓ_1/ℓ_∞
PTB17	23768	950028	2%	17	1.23
PT-Conll	11293	206678	8.5%	22	1.14
BulTree	12177	174160	10%	12	1.04

Table 9: Corpus statistics. All words with only one occurrence where replaced by the 'unk' token. The third column shows the percentage of tokens replaced. ℓ_1/ℓ_∞ is the value of the sparsity for a fully supervised HMM trained in all available data.

but did not identify definitely better choices. Sparse was initialized with the parameters obtained by running EM for 30 iterations, followed by 170 iterations of the new training procedure. Predictions were obtained using posterior decoding since this consistently showed small improvements over Viterbi decoding.

We compare the models by measuring the mutual information between the distribution of hidden states and the distribution of the truth. Ideally, a perfect method would have mutual information equal to the entropy of both distributions. The farther the distribution that a method produces is from the truth the smaller the information gain is. We also evaluate the accuracy of the models using two established mappings between hidden states and POS tags: **(1-Many**) maps each hidden state to the tag with which it co-occurs the most; **1-1** (Haghighi and Klein, 2006) greedily picks a tag for each state under the constraint of never using the same tag twice. This results in an approximation of the optimal 1-1 mapping. If the numbers of hidden states and tags are not the same, some hidden states will be unassigned (and hence always wrong) or some tags not used. In all our experiments the number of hidden states is the same as the number of POS tags.

Figure 12 (Top Left) shows mutual information between the hidden state distribution of each method and the truth. The entropy of the true distribution are: BulTree 3.05, PT-CoNLL 3.49 and PTB17 3.22. Sparse is the method that achieves the biggest information gain across all corpora, and is not particularly sensitive to the strength of regularization used. Interestingly, VEM often has the smallest ℓ_1/ℓ_∞, even though mutual information is often worst than EM.

Figure 12 (Top Right) shows the different average values of the L1LMax statistics for each method across corpora. We see that both VEM and Sparse achieve values of ℓ_1/ℓ_∞ close to the gold standard, on the other hand EM as expected as bigger values which confirms the intuition that EM allows each word to be generated by most of the possible POS tags.

Figure 12 (Bottom Left) shows errors for all methods on the different corpora after 10 random initializations using the 1-Many mapping. For both VEM and Sparse we pick parameter settings resulting in the best average performance. A first conclusion is that using the ℓ_1/ℓ_∞ constraint consistently and significantly improves the results when compared with the other two methods.

Figure 12 (Bottom Right) shows the same errors for the 1-1 mapping. In this case Sparse still beats the EM but does not always outperform VEM. One reason for this behavior is that this metric is very sensitive to the number of word types associated with each hidden state. VEM tends to encourage some large hidden states with many word types, which is preferable using the 1-1 mapping for large word categories such as nouns. On the other hand Sparse tends to spread the nouns over 4 different hidden states. This difference is particularly pronounced for the condensed tag sets (PTB17, PT-CoNLL) where different kinds of nouns are joined into one large tag. Also this

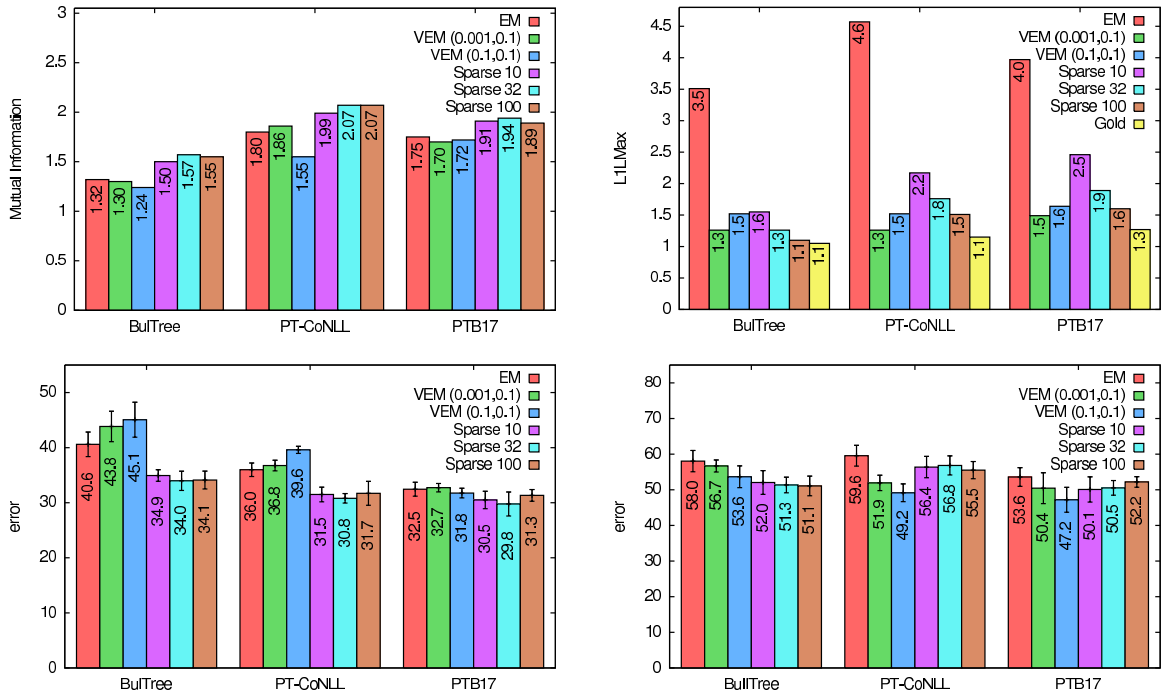

Figure 12: (Top Left) Mutual information in bits between gold tag distribution and hidden state distribution. The maximum is the entropy of the gold set (BulTree 3.05, PT-CoNLL 3.49 and PTB17 3.22), (Top Right) ℓ_1/ℓ_∞ value, and average (Bottom Left) 1-Many error, (Bottom Right) 1-1 error over 10 different runs (same seeds used for each model) for 200 iterations. Error bars are standard deviation for the 10 runs. All models are first order HMMs: EM trained using expectation maximization, VEM trained using variational EM using 0.1 state to state prior and (01,0.0001) observation prior; Sparse trained using PR with constraint strength $\sigma = 10, 32, 100$.

difference is bigger for VEM when the observation prior is set to bigger values (0.1), leading at the same time to worse results in 1-Many mapping.

9. Conclusion

In this paper we have presented posterior regularization (PR), a technique for regularizing models by encoding prior knowledge in constraints on model posteriors. On the algorithmic side, we have shown that PR can be solved efficiently in dual form, and that the regularization can be easily incorporated into a variant of the classical EM optimization method. In relating PR to similar frameworks, we have clarified its main advantages: faster optimization speed with respect to generalized expectation (Mann and McCallum, 2007, 2008), and greater distributional estimation accuracy with respect to constraint-driven learning (Chang et al., 2007). To the best of our knowledge, we are the first to link all these learning frameworks by explicitly stating a sense in which they all approximate the Bayesian perspective that motivates Liang et al. (2009). An interesting avenue for future work

includes an exploration of the tradeoff between computational complexity and accuracy of the different approximations presented in this and related work (Figure 4). For example, is there a large performance drop as we go from GE to PR and from PR to CODL, or are the variational and MAP approximations accurate in practice?

In addition to discussing PR's theoretical potential, we have demonstrated that it lives up to this potential in a wide variety realistic applications. The applications we focus on in this paper are word alignment, multi-view learning, dependency parsing, and part-of-speech tagging. Yet PR can express such a wide variety of prior knowledge that can be encoded by functions of model posteriors, and there remains a vast array of unexplored possible applications for this technique.

In addition to using PR in other applications, we would like to investigate alternative optimization methods. The main optimization bottleneck that PR implementations encounter is the extensive time required for projecting the posterior distribution into the constrained posterior space. Each evaluation of the objective or its gradient requires inference in the original model. One direction for exploration is the use of second order or approximate second-order optimization methods. Another potential direction is to use approximate inference in some parts of the optimization, for example fully factored variational inference. Finally, for applications where some constraints span multiple instances, but others do not not, it would be interesting to combine online and batch methods.

A last key extension to the current PR work is to explore the case where the constraint set Q is not easily specified using linear constraints on some constraint features ϕ. Thus far we have only developed theory and applications for linear constraints. It would be interesting to explore applications and derive efficient learning methods when the constraints are not linear, for example, applications with semi-definite or polynomial constraints.

Appendix A. Scaling the Strength of PR

This appendix describes how to optimize a version of our objective with scaled posterior regularization strength. In this case, we will use a modified EM algorithm that maximizes:

$$F'(q,\theta) = \mathcal{L}(\theta) - \alpha \mathbf{KL}(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y} \mid \mathbf{X})) \qquad \text{s.t.}\, q \in Q$$

where $\alpha \in [0,1]$. The optimization procedure closely follows the one in Section 2.6. When performing the M-step, we use a mixture of the projected posteriors q and the model posteriors $p_\theta(\mathbf{Y}|\mathbf{X})$ to

update the model parameters. The updated EM algorithm is:

$$\mathbf{E}' - \mathbf{step}: \max_q F'(q,\theta) = \min_{q \in Q} \mathbf{KL}(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X})),$$
$$\mathbf{M}' - \mathbf{step}: \max_\theta F'(q,\theta) = \max_\theta (1-\alpha)\mathbf{E}_{p_{\theta'}}[\log p_\theta(\mathbf{X},\mathbf{Y})] + \alpha \mathbf{E}_q[\log p_\theta(\mathbf{X},\mathbf{Y})].$$

Note that the $\mathbf{E}'$-step is identical to the one in Equation 8.

Appendix B. Proof of Proposition 2.1

The modified E-step involves a projection step that minimizes the Kullback-Leibler divergence:

$$\arg\min_{q,\xi} \quad \mathbf{KL}(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X})) \qquad \text{s.t.} \quad \mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b} \leq \xi; \quad ||\xi||_\beta \leq \varepsilon.$$

Assuming the set $Q = \{q(\mathbf{Y}) : \exists \xi : \mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b} \leq \xi; \quad ||\xi||_\beta \leq \varepsilon\}$ is non-empty, the corresponding Lagrangian is

$$\max_{\lambda \geq 0, \alpha \geq 0, \gamma} \min_{q(\mathbf{Y}), \xi} L(q(\mathbf{Y}), \xi, \lambda, \alpha, \gamma),$$

where

$$L(q,\xi,\lambda,\alpha,\gamma) = \mathbf{KL}(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X})) \quad + \lambda \cdot (\mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b} - \xi) \\ + \alpha(||\xi||_\beta - \varepsilon) \quad + \gamma \left(\sum_{\mathbf{Y}} q(\mathbf{Y}) - 1 \right).$$

In order to compute the dual of this Lagrangian, we first represent

$$\alpha ||\xi||_\beta = \max_\eta \xi \cdot \eta \quad \text{s.t.} \quad ||\eta||_{\beta^*} \leq \alpha.$$

This results in a variational Lagrangian

$$\max_{\lambda \geq 0, \alpha \geq 0, \gamma} \max_{||\eta||_{\beta^*} \leq \alpha} \min_{q(\mathbf{Y}), \xi} L(q(\mathbf{Y}), \xi, \lambda, \alpha, \gamma, \eta),$$

with $L(q(\mathbf{Y}), \xi, \lambda, \alpha, \gamma, \eta)$ defined as

$$L(q,\xi,\lambda,\alpha,\gamma,\eta) = \quad \mathbf{KL}(q(\mathbf{Y}) \parallel p_\theta(\mathbf{Y}|\mathbf{X})) \quad + \lambda \cdot (\mathbf{E}_q[\phi(\mathbf{X},\mathbf{Y})] - \mathbf{b} - \xi) \\ + \xi \cdot \eta - \alpha\varepsilon \quad + \gamma \left(\sum_{\mathbf{Y}} q(\mathbf{Y}) - 1 \right),$$

$$\frac{\partial L(q(\mathbf{Y}), \xi, \lambda, \alpha, \gamma, \eta)}{\partial q(\mathbf{Y})} = \quad \log q(\mathbf{Y}) + 1 - \log p_\theta(\mathbf{Y}|\mathbf{X}) + \lambda \cdot \phi(\mathbf{X},\mathbf{Y}) + \gamma = 0$$
$$\implies \quad q(\mathbf{Y}) = \frac{p_\theta(\mathbf{Y}|\mathbf{X}) \exp(-\lambda \cdot \phi(\mathbf{X},\mathbf{Y}))}{e \exp(\gamma)},$$

$$\frac{\partial L(q(\mathbf{Y}), \xi, \lambda, \alpha, \gamma, \eta)}{\partial \xi_i} = \quad \eta_i - \lambda_i = 0 \quad \implies \quad \eta = \lambda. \qquad (26)$$

Note that Equation 26 implies that we have the constraint $||\lambda||_{\beta^*} \leq \alpha$ and also the positive and negative $\lambda \cdot \xi$ cancel each other out. Plugging $q(\mathbf{Y})$, $\eta = \lambda$ in $L(q(\mathbf{Y}), \xi, \lambda, \alpha, \gamma, \eta)$ and taking the derivative with respect to γ

$$\frac{\partial L(\lambda, \alpha, \gamma)}{\partial \gamma} = \sum_{\mathbf{Y}} \frac{p_\theta(\mathbf{Y}|\mathbf{X}) \exp(-\lambda \cdot \phi(\mathbf{X}, \mathbf{Y}))}{e \exp(\gamma)} - 1 = 0$$
$$\implies \gamma = \log\left(\frac{\sum_{\mathbf{Y}} p_\theta(\mathbf{Y}|\mathbf{X}) \exp\left(-\lambda \cdot \phi(\mathbf{x}, \mathbf{z})\right)}{e}\right).$$

From there we can simplify $q(\mathbf{Y}) = \frac{p_\theta(\mathbf{Y}|\mathbf{X}) \exp(-\lambda \cdot \phi(\mathbf{X}, \mathbf{Y}))}{Z_\lambda}$ where $Z_\lambda = \sum_{\mathbf{Y}} p_\theta(\mathbf{Y}|\mathbf{X}) \exp(-\lambda \cdot \phi(\mathbf{X}, \mathbf{Y}))$ ensures that $q(\mathbf{Y})$ is properly normalized. Plugging γ into $L(\lambda, \alpha, \gamma)$

$$L(\lambda, \alpha) = -\log(Z_\lambda) - \mathbf{b} \cdot \lambda - \alpha\varepsilon.$$

Now our objective is:

$$\max_{\lambda \geq 0, \alpha \geq 0} \quad -\log(Z_\lambda) - \mathbf{b} \cdot \lambda - \alpha\varepsilon \quad \text{s.t.} \quad ||\lambda||_{\beta^*} \leq \alpha.$$

We can analytically see that the optimum of this objective with respect to α is $\alpha = ||\lambda||_{\beta^*}$ and placing this in $L(\lambda, \alpha)$ we get the dual objective:

$$\textbf{Dual } \mathbf{E}' : \quad \arg\max_{\lambda \geq 0} \quad -\mathbf{b} \cdot \lambda - \log(Z_\lambda) - \varepsilon ||\lambda||_{\beta^*}$$

as desired.

Abstract

An exceedingly large number of scientific and engineering fields are confronted with the need for computer simulations to study complex, real world phenomena or solve challenging design problems. However, due to the computational cost of these high fidelity simulations, the use of neural networks, kernel methods, and other surrogate modeling techniques have become indispensable. Surrogate models are compact and cheap to evaluate, and have proven very useful for tasks such as optimization, design space exploration, prototyping, and sensitivity analysis. Consequently, in many fields there is great interest in tools and techniques that facilitate the construction of such regression models, while minimizing the computational cost and maximizing model accuracy. This paper presents a mature, flexible, and adaptive machine learning toolkit for regression modeling and active learning to tackle these issues. The toolkit brings together algorithms for data fitting, model selection, sample selection (active learning), hyperparameter optimization, and distributed computing in order to empower a domain expert to efficiently generate an accurate model for the problem or data at hand.

Keywords: surrogate modeling, metamodeling, function approximation, model selection, adaptive sampling, active learning, distributed computing

1. Background and Motivation

In many science and engineering problems researchers make heavy use of computer simulation codes in order to replace expensive physical experiments and improve the quality and performance of engineered products and devices. Such simulation activities are collectively referred to as computational science/engineering. Unfortunately, while allowing scientists more flexibility to study phenomena under controlled conditions, computer simulations require a substantial investment of

computation time. One simulation may take many minutes, hours, days or even weeks, quickly rendering parameter studies impractical (Forrester et al., 2008; Simpson et al., 2008).

Of the different ways to deal with this problem, this paper is concerned with the construction of simpler approximation models to predict the system performance and develop a relationship between the system inputs and outputs. When properly constructed, these approximation models mimic the behavior of the simulation accurately while being computationally cheap(er) to evaluate. Different approximation methods exist, each with their relative merits. This work concentrates on the use of data-driven, global approximations using compact surrogate models (also known as metamodels, replacement models, or response surface models). Examples include: rational functions, Kriging models, Artificial Neural Networks (ANN), splines, and Support Vector Machines (SVM). Once such a global approximation is available it is of great use for gaining insight into the behavior of the underlying system. The surrogate may be easily queried, optimized, visualized, and seamlessly integrated into CAD/CAE software packages.

The challenge is thus how to generate an approximation model that is as accurate as possible over the *complete* domain of interest while minimizing the simulation cost. Solving this challenge involves multiple sub-problems that must be addressed: how to interface with the simulation code, how to run simulations (locally, or on a cluster or cloud), which model type to approximate the data with and how to set the model complexity (e.g., topology of a neural network), how to estimate the model quality and ensure the domain expert trusts the model, how to decide which simulations to run (data collection), etc. The data collection aspect is worth emphasizing. Since data is computationally expensive to obtain and the optimal data distribution is not known up front, data points should be selected iteratively, there where the information gain will be the greatest. A sampling function is needed that minimizes the number of sample points selected in each iteration, yet maximizes the information gain of each iteration step. This process is called adaptive sampling but is also known as active learning, or sequential design.

There is a complex dependency web between these different options and dealing with these dependencies is non-trivial, particularly for a domain expert for whom the surrogate model is just an intermediate step towards solving a larger, more important problem. Few domain experts will be experts in the intricacies of efficient sampling and modeling strategies. Their primary concern is obtaining an accurate replacement metamodel for their problem as fast as possible and with minimal overhead (Gorissen et al., 2009d). As a result these choices are often made in a pragmatic, sometimes even ad-hoc, manner.

This paper discusses an advanced, and integrated software framework that provides a flexible and rigorous means to tackle such problems. This work lies at the intersection of Machine Learning/AI, Modeling and Simulation, and Distributed Computing. The methods developed are applicable to any domain where a cheap, accurate, approximation is needed to replace some expensive reference model. Our experience has been that the availability of such a framework can facilitate the transfer of knowledge from surrogate modeling researchers and lower the barrier of entry for domain experts.

2. SUMO Toolbox

The platform in question is the Matlab SUrrogate MOdeling (SUMO) Toolbox, illustrated in Figure 1. Given a simulation engine (Fluent, Cadence, Abaqus, HFSS, etc.) or other data source (data

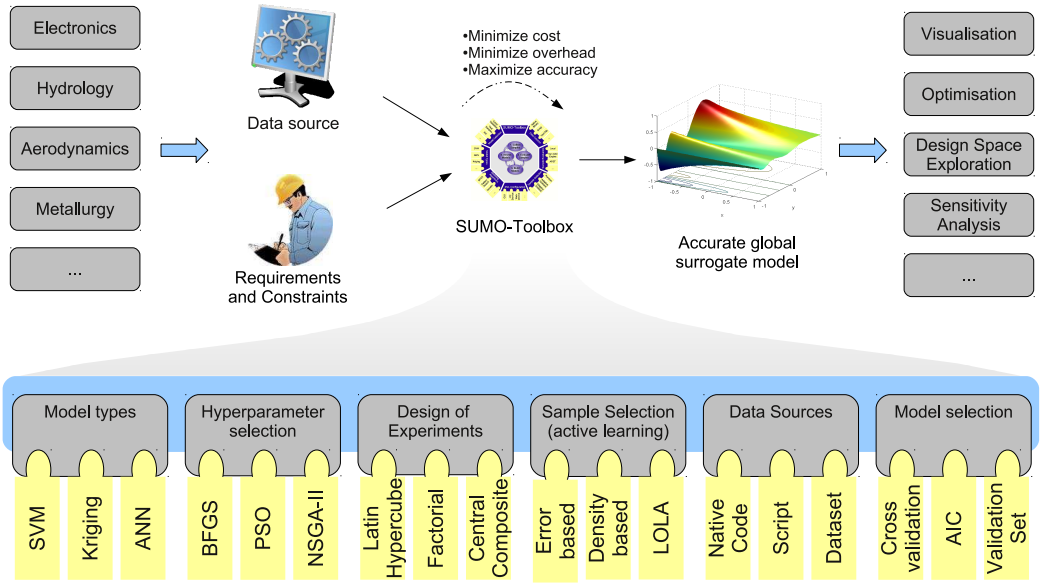

Figure 1: The SUMO Toolbox is a flexible framework for accurate global surrogate modeling and adaptive sampling (active learning). It features a rich set of plugins, is applicable to a wide range of domains, and can be applied in an autonomous, black-box fashion, or under full manual control. Written in Matlab and Java it is fully cross platform and comes with a large (60+) number of example problems.

set, Matlab script, Java class, etc.), the toolbox drives the data source to produce a surrogate model within the time and accuracy constraints set by the user.

The SUMO Toolbox adopts a microkernel design philosophy with many different plugins available for each of the different sub-problems:[1] model types (rational functions, Kriging, splines, SVM, ANN, etc.), hyperparameter optimization algorithms (Particle Swarm Optimization, Efficient Global Optimization, simulated annealing, Genetic Algorithm, etc.), model selection algorithms (cross validation, AIC, Leave-out set, etc.), sample selection (random, error based, density based, hybrid, etc.), Design of Experiments (Latin hypercube, Box-Bhenken, etc.), and sample evaluation methods (local, on a cluster or grid). The behavior of each software component is configurable through a central XML file and components can easily be added, removed or replaced by custom implementations. In addition the toolbox provides 'meta' plugins. For example to automatically select the best model type for a given problem (Gorissen et al., 2009d) or to use multiple model selection or sample selection criteria in concert (Gorissen et al., 2010).

Furthermore, there is built-in support for high performance computing. On the modeling side, the model generation process can take full advantage of multi-core CPUs and even of a complete cluster or grid. This can result in significant speedups for model types where the fitting process can be expensive (e.g., neural networks). Likewise, sample evaluation (simulation) can occur locally (with the option to take advantage of multi-core architectures) or on a separate compute cluster or grid (possibly accessed through a remote head-node). All interfacing with the grid middleware

1. The full list of plugins and features can be found at `http://www.sumowiki.intec.ugent.be`.

(submission, job monitoring, rescheduling of failed/lost simulation points, etc.) is handled transparently and automatically (see Gorissen et al., 2009c for more details). Also, the sample evaluation component runs in parallel with the other components (non-blocking) and not sequentially. This allows for an optimal use of computational resources.

In addition the SUMO Toolbox contains extensive logging and profiling capabilities so that the modeling process can easily be tracked and the modeling decisions understood. Once a final model has been generated, a GUI tool is available to visually explore the model (including derivatives and prediction uncertainty), assess its quality, and export it for use in other software tools.

3. Applications

The SUMO Toolbox has already been applied successfully to a very wide range of applications, including RF circuit block modeling (Gorissen et al., 2009b), hydrological modeling (Couckuyt et al., 2009), Electronic Packaging (Zhu and Franzon, 2009), aerodynamic modeling (Gorissen et al., 2009a), process engineering (Stephens et al., 2009), and automotive data modeling (Gorissen et al., 2010). Besides global modeling capabilities, the SUMO Toolbox also includes a powerful optimization framework based on the Efficient Global Optimization framework developed by Jones et al. (1998). As of version 6.1, the toolbox also contains an example of how the framework can also be applied to solve classification problems.

In sum, the goal of the toolbox is to fill the void in machine learning software when it comes to the challenging, costly, real-valued, problems faced in computational engineering. The toolbox is in use successfully at various institutions and we are continuously refining and extending the set of available plugins as the number of applications increase. Usage instructions, design documentation, and stable releases for all major platforms can be found at `http://www.sumo.intec.ugent.be`.

Abstract

Given a matrix M of low-rank, we consider the problem of reconstructing it from noisy observations of a small, random subset of its entries. The problem arises in a variety of applications, from collaborative filtering (the 'Netflix problem') to structure-from-motion and positioning. We study a low complexity algorithm introduced by Keshavan, Montanari, and Oh (2010), based on a combination of spectral techniques and manifold optimization, that we call here OPTSPACE. We prove performance guarantees that are order-optimal in a number of circumstances.

Keywords: matrix completion, low-rank matrices, spectral methods, manifold optimization

1. Introduction

Spectral techniques are an authentic workhorse in machine learning, statistics, numerical analysis, and signal processing. Given a matrix M, its largest singular values—and the associated singular vectors—'explain' the most significant correlations in the underlying data source. A low-rank approximation of M can further be used for low-complexity implementations of a number of linear algebra algorithms (Frieze et al., 2004).

In many practical circumstances we have access only to a sparse subset of the entries of an $m \times n$ matrix M. It has recently been discovered that, if the matrix M has rank r, and unless it is too 'structured', a small random subset of its entries allow to reconstruct it *exactly*. This result was first proved by Candès and Recht (2008) by analyzing a convex relaxation introduced by Fazel (2002). A tighter analysis of the same convex relaxation was carried out by Candès and Tao (2009). A number of iterative schemes to solve the convex optimization problem appeared soon thereafter (Cai et al., 2008; Ma et al., 2009; Toh and Yun, 2009).

In an alternative line of work, Keshavan, Montanari, and Oh (2010) attacked the same problem using a combination of spectral techniques and manifold optimization: We will refer to their algorithm as OPTSPACE. OPTSPACE is intrinsically of low complexity, the most complex operation being computing r singular values (and the corresponding singular vectors) of a sparse $m \times n$ matrix. The performance guarantees proved by Keshavan et al. (2010) are comparable with the information theoretic lower bound: roughly $nr \max\{r, \log n\}$ random entries are needed to reconstruct M exactly (here we assume m of order n). A related approach was also developed by Lee and Bresler (2009), although without performance guarantees for matrix completion.

*. Also in Department of Statistics.

The above results crucially rely on the assumption that M is *exactly* a rank r matrix. For many applications of interest, this assumption is unrealistic and it is therefore important to investigate their robustness. Can the above approaches be generalized when the underlying data is 'well approximated' by a rank r matrix? This question was addressed by Candès and Plan (2009) within the convex relaxation approach of Candès and Recht (2008). The present paper proves a similar robustness result for OPTSPACE. Remarkably the guarantees we obtain are order-optimal in a variety of circumstances, and improve over the analogous results of Candès and Plan (2009).

1.1 Model Definition

Let M be an $m \times n$ matrix of rank r, that is

$$M = U\Sigma V^T . \tag{1}$$

where U has dimensions $m \times r$, V has dimensions $n \times r$, and Σ is a diagonal $r \times r$ matrix. We assume that each entry of M is perturbed, thus producing an 'approximately' low-rank matrix N, with

$$N_{ij} = M_{ij} + Z_{ij} ,$$

where the matrix Z will be assumed to be 'small' in an appropriate sense.

Out of the $m \times n$ entries of N, a subset $E \subseteq [m] \times [n]$ is revealed. We let N^E be the $m \times n$ matrix that contains the revealed entries of N, and is filled with 0's in the other positions

$$N^E_{ij} = \begin{cases} N_{ij} & \text{if } (i,j) \in E , \\ 0 & \text{otherwise.} \end{cases}$$

Analogously, we let M^E and Z^E be the $m \times n$ matrices that contain the entries of M and Z, respectively, in the revealed positions and is filled with 0's in the other positions. The set E will be uniformly random given its size $|E|$.

1.2 Algorithm

For the reader's convenience, we recall the algorithm introduced by Keshavan et al. (2010), which we will analyze here. The basic idea is to minimize the cost function $F(X,Y)$, defined by

$$\begin{aligned} F(X,Y) &\equiv \min_{S \in \mathbb{R}^{r\times r}} \mathcal{F}(X,Y,S) , \\ \mathcal{F}(X,Y,S) &\equiv \frac{1}{2} \sum_{(i,j)\in E} (N_{ij} - (XSY^T)_{ij})^2 . \end{aligned} \tag{2}$$

Here $X \in \mathbb{R}^{n\times r}$, $Y \in \mathbb{R}^{m\times r}$ are orthogonal matrices, normalized by $X^TX = m\mathbf{I}$, $Y^TY = n\mathbf{I}$.

Minimizing $F(X,Y)$ is an *a priori* difficult task, since F is a non-convex function. The key insight is that the singular value decomposition (SVD) of N^E provides an excellent initial guess, and that the minimum can be found with high probability by standard gradient descent after this initialization. Two caveats must be added to this description: (1) In general the matrix N^E must be 'trimmed' to eliminate over-represented rows and columns; (2) For technical reasons, we consider a slightly modified cost function to be denoted by $\widetilde{F}(X,Y)$.

OPTSPACE(matrix N^E)

1: Trim N^E, and let $\widetilde{N}^E$ be the output;
2: Compute the rank-r projection of $\widetilde{N}^E$, $\mathsf{P}_r(\widetilde{N}^E) = X_0 S_0 Y_0^T$;
3: Minimize $\widetilde{F}(X,Y)$ through gradient descent, with initial condition (X_0, Y_0).

We may note here that the rank of the matrix M, if not known, can be reliably estimated from $\widetilde{N}^E$ (Keshavan and Oh, 2009).

The various steps of the above algorithm are defined as follows.

Trimming. We say that a row is 'over-represented' if it contains more than $2|E|/m$ revealed entries (i.e., more than twice the average number of revealed entries per row). Analogously, a column is over-represented if it contains more than $2|E|/n$ revealed entries. The trimmed matrix $\widetilde{N}^E$ is obtained from N^E by setting to 0 over-represented rows and columns.

Rank-r projection. Let

$$\widetilde{N}^E = \sum_{i=1}^{\min(m,n)} \sigma_i x_i y_i^T ,$$

be the singular value decomposition of $\widetilde{N}^E$, with singular values $\sigma_1 \geq \sigma_2 \geq \dots$. We then define

$$\mathsf{P}_r(\widetilde{N}^E) = \frac{mn}{|E|} \sum_{i=1}^{r} \sigma_i x_i y_i^T .$$

Apart from an overall normalization, $\mathsf{P}_r(\widetilde{N}^E)$ is the best rank-r approximation to $\widetilde{N}^E$ in Frobenius norm.

Minimization. The modified cost function $\widetilde{F}$ is defined as

$$\begin{aligned} \widetilde{F}(X,Y) &= F(X,Y) + \rho\, G(X,Y) \\ &\equiv F(X,Y) + \rho \sum_{i=1}^{m} G_1\left(\frac{\|X^{(i)}\|^2}{3\mu_0 r}\right) + \rho \sum_{j=1}^{n} G_1\left(\frac{\|Y^{(j)}\|^2}{3\mu_0 r}\right) , \end{aligned}$$

where $X^{(i)}$ denotes the i-th row of X, and $Y^{(j)}$ the j-th row of Y. The function $G_1 : \mathbb{R}^+ \to \mathbb{R}$ is such that $G_1(z) = 0$ if $z \leq 1$ and $G_1(z) = e^{(z-1)^2} - 1$ otherwise. Further, we can choose $\rho = \Theta(|E|)$.

Let us stress that the regularization term is mainly introduced for our proof technique to work (and a broad family of functions G_1 would work as well). In numerical experiments we did not find any performance loss in setting $\rho = 0$.

One important feature of OPTSPACE is that $F(X,Y)$ and $\widetilde{F}(X,Y)$ are regarded as functions of the r-dimensional subspaces of $\mathbb{R}^m$ and $\mathbb{R}^n$ generated (respectively) by the columns of X and Y. This interpretation is justified by the fact that $F(X,Y) = F(XA, YB)$ for any two orthogonal matrices $A, B \in \mathbb{R}^{r\times r}$ (the same property holds for $\widetilde{F}$). The set of r dimensional subspaces of $\mathbb{R}^m$ is a differentiable Riemannian manifold $\mathsf{G}(m,r)$ (the Grassmann manifold). The gradient descent algorithm is applied to the function $\widetilde{F} : \mathsf{M}(m,n) \equiv \mathsf{G}(m,r) \times \mathsf{G}(n,r) \to \mathbb{R}$. For further details on optimization by gradient descent on matrix manifolds we refer to Edelman et al. (1999) and Absil et al. (2008).

1.3 Some Notations

The matrix M to be reconstructed takes the form (1) where $U \in \mathbb{R}^{m\times r}$, $V \in \mathbb{R}^{n\times r}$. We write $U = [u_1, u_2, \dots, u_r]$ and $V = [v_1, v_2, \dots, v_r]$ for the columns of the two factors, with $\|u_i\| = \sqrt{m}$, $\|v_i\| = \sqrt{n}$, and $u_i^T u_j = 0$, $v_i^T v_j = 0$ for $i \neq j$ (there is no loss of generality in this, since normalizations can be absorbed by redefining Σ).

We shall write $\Sigma = \mathrm{diag}(\Sigma_1, \dots, \Sigma_r)$ with $\Sigma_1 \geq \Sigma_2 \geq \cdots \geq \Sigma_r > 0$. The maximum and minimum singular values will also be denoted by $\Sigma_{\max} = \Sigma_1$ and $\Sigma_{\min} = \Sigma_r$. Further, the maximum size of an entry of M is $M_{\max} \equiv \max_{ij} |M_{ij}|$.

Probability is taken with respect to the uniformly random subset $E \subseteq [m] \times [n]$ given $|E|$ and (eventually) the noise matrix Z. Define $\varepsilon \equiv |E|/\sqrt{mn}$. In the case when $m = n$, ε corresponds to the average number of revealed entries per row or column. Then it is convenient to work with a model in which each entry is revealed independently with probability $\varepsilon/\sqrt{mn}$. Since, with high probability $|E| \in [\varepsilon\sqrt{\alpha}n - A\sqrt{n\log n}, \varepsilon\sqrt{\alpha}n + A\sqrt{n\log n}]$, any guarantee on the algorithm performances that holds within one model, holds within the other model as well if we allow for a vanishing shift in ε. We will use C, C' etc. to denote universal numerical constants.

It is convenient to define the following projection operator $\mathcal{P}_E(\cdot)$ as the sampling operator, which maps an $m \times n$ matrix onto an $|E|$-dimensional subspace in $\mathbb{R}^{m\times n}$

$$\mathcal{P}_E(N)_{ij} = \begin{cases} N_{ij} & \text{if } (i,j) \in E\,, \\ 0 & \text{otherwise.} \end{cases}$$

Given a vector $x \in \mathbb{R}^n$, $\|x\|$ will denote its Euclidean norm. For a matrix $X \in \mathbb{R}^{n\times n'}$, $\|X\|_F$ is its Frobenius norm, and $\|X\|_2$ its operator norm (i.e., $\|X\|_2 = \sup_{u\neq 0} \|Xu\|/\|u\|$). The standard scalar product between vectors or matrices will sometimes be indicated by $\langle x, y\rangle$ or $\langle X, Y\rangle \equiv \mathrm{Tr}(X^T Y)$, respectively. Finally, we use the standard combinatorics notation $[n] = \{1, 2, \dots, n\}$ to denote the set of first n integers.

1.4 Main Results

Our main result is a performance guarantee for OPTSPACE under appropriate incoherence assumptions, and is presented in Section 1.4.2. Before presenting it, we state a theorem of independent interest that provides an error bound on the simple trimming-plus-SVD approach. The reader interested in the OPTSPACE guarantee can go directly to Section 1.4.2.

Throughout this paper, without loss of generality, we assume $\alpha \equiv m/n \geq 1$.

1.4.1 SIMPLE SVD

Our first result shows that, in great generality, the rank-r projection of $\widetilde{N}^E$ provides a reasonable approximation of M. We define $\widetilde{Z}^E$ to be an $m \times n$ matrix obtained from Z^E, after the trimming step of the pseudocode above, that is, by setting to zero the over-represented rows and columns.

Theorem 1.1 *Let $N = M + Z$, where M has rank r, and assume that the subset of revealed entries $E \subseteq [m] \times [n]$ is uniformly random with size $|E|$. Let $M_{\max} = \max_{(i,j)\in[m]\times[n]} |M_{ij}|$. Then there exists numerical constants C and C' such that*

$$\frac{1}{\sqrt{mn}} \|M - \mathsf{P}_r(\widetilde{N}^E)\|_F \leq C M_{\max} \left(\frac{nr\alpha^{3/2}}{|E|}\right)^{1/2} + C' \frac{n\sqrt{r\alpha}}{|E|} \|\widetilde{Z}^E\|_2\,,$$

with probability larger than $1-1/n^3$.

Projection onto rank-r matrices through SVD is a pretty standard tool, and is used as first analysis method for many practical problems. At a high-level, projection onto rank-r matrices can be interpreted as 'treat missing entries as zeros'. This theorem shows that this approach is reasonably robust if the number of observed entries is as large as the number of degrees of freedom (which is about $(m+n)r$) times a large constant. The error bound is the sum of two contributions: the first one can be interpreted as an undersampling effect (error induced by missing entries) and the second as a noise effect. Let us stress that trimming is crucial for achieving this guarantee.

1.4.2 OPTSPACE

Theorem 1.1 helps to set the stage for the key point of this paper: *a much better approximation is obtained by minimizing the cost* $\widetilde{F}(X,Y)$ *(step 3 in the pseudocode above), provided* M *satisfies an appropriate incoherence condition*. Let $M = U\Sigma V^T$ be a low rank matrix, and assume, without loss of generality, $U^TU = m\mathbf{I}$ and $V^TV = n\mathbf{I}$. We say that M is (μ_0,μ_1)-*incoherent* if the following conditions hold.

A1. For all $i \in [m]$, $j \in [n]$ we have, $\sum_{k=1}^r U_{ik}^2 \le \mu_0 r$, $\sum_{k=1}^r V_{ik}^2 \le \mu_0 r$.

A2. For all $i \in [m]$, $j \in [n]$ we have, $|\sum_{k=1}^r U_{ik}(\Sigma_k/\Sigma_1)V_{jk}| \le \mu_1 r^{1/2}$.

Theorem 1.2 *Let* $N = M + Z$, *where* M *is a* (μ_0,μ_1)-*incoherent matrix of rank* r, *and assume that the subset of revealed entries* $E \subseteq [m]\times[n]$ *is uniformly random with size* $|E|$. *Further, let* $\Sigma_{\min} = \Sigma_r \le \cdots \le \Sigma_1 = \Sigma_{\max}$ *with* $\Sigma_{\max}/\Sigma_{\min} \equiv \kappa$. *Let* $\widehat{M}$ *be the output of* OPTSPACE *on input* N^E. *Then there exists numerical constants* C *and* C' *such that if*

$$|E| \;\ge\; Cn\sqrt{\alpha}\kappa^2 \max\left\{\mu_0 r\sqrt{\alpha}\log n\,;\,\mu_0^2 r^2\alpha\kappa^4\,;\,\mu_1^2 r^2\alpha\kappa^4\right\}\,,$$

then, with probability at least $1-1/n^3$,

$$\frac{1}{\sqrt{mn}}\|\widehat{M}-M\|_F \le C'\kappa^2\frac{n\sqrt{r\alpha}}{|E|}\|Z^E\|_2\,. \tag{3}$$

provided that the right-hand side is smaller than $\Sigma_{\min}$.

As discussed in the next section, this theorem captures rather sharply the effect of important classes of noise on the performance of OPTSPACE.

1.5 Noise Models

In order to make sense of the above results, it is convenient to consider a couple of simple models for the noise matrix Z:

Independent entries model. We assume that Z's entries are i.i.d. random variables, with zero mean $\mathbb{E}\{Z_{ij}\} = 0$ and sub-Gaussian tails. The latter means that

$$\mathbb{P}\{|Z_{ij}| \ge x\} \le 2\,e^{-\frac{x^2}{2\sigma^2}}\,,$$

for some constant σ^2 uniformly bounded in n.

Worst case model. In this model Z is arbitrary, but we have an uniform bound on the size of its entries: $|Z_{ij}| \le Z_{\max}$.

The basic parameter entering our main results is the operator norm of $\widetilde{Z}^E$, which is bounded as follows in these two noise models.

Theorem 1.3 *If Z is a random matrix drawn according to the independent entries model, then for any sample size $|E|$ there is a constant C such that,*

$$\|\widetilde{Z}^E\|_2 \le C\sigma \left(\frac{|E|\log n}{n}\right)^{1/2}, \tag{4}$$

with probability at least $1-1/n^3$. Further there exists a constant C' such that, if the sample size is $|E| \ge n\log n$ (for $n \ge \alpha$), we have

$$\|\widetilde{Z}^E\|_2 \le C'\sigma \left(\frac{|E|}{n}\right)^{1/2}, \tag{5}$$

with probability at least $1-1/n^3$.

If Z is a matrix from the worst case model, then

$$\|\widetilde{Z}^E\|_2 \le \frac{2|E|}{n\sqrt{\alpha}} Z_{\max},$$

for any realization of E.

It is elementary to show that, if $|E| \ge 15\alpha n\log n$, no row or column is over-represented with high probability. It follows that in the regime of $|E|$ for which the conditions of Theorem 1.2 are satisfied, we have $Z^E = \widetilde{Z}^E$ and hence the bound (5) applies to $\|\widetilde{Z}^E\|_2$ as well. Then, among the other things, this result implies that for the independent entries model the right-hand side of our error estimate, Eq. (3), is with high probability smaller than $\Sigma_{\min}$, if $|E| \ge Cr\alpha n\kappa^4(\sigma/\Sigma_{\min})^2$. For the worst case model, the same statement is true if $Z_{\max} \le \Sigma_{\min}/C\sqrt{r}\kappa^2$.

1.6 Comparison with Other Approaches to Matrix Completion

Let us begin by mentioning that a statement analogous to our preliminary Theorem 1.1 was proved by Achlioptas and McSherry (2007). Our result however applies to any number of revealed entries, while the one of Achlioptas and McSherry (2007) requires $|E| \ge (8\log n)^4 n$ (which for $n \le 5\cdot 10^8$ is larger than n^2). We refer to Section 1.8 for further discussion of this point.

As for Theorem 1.2, we will mainly compare our algorithm with the convex relaxation approach recently analyzed by Candès and Plan (2009), and based on semidefinite programming. Our basic setting is indeed the same, while the algorithms are rather different.

Figures 1 and 2 compare the average root mean square error $\|\widehat{M}-M\|_F/\sqrt{mn}$ for the two algorithms as a function of $|E|$ and the rank-r respectively. Here M is a random rank r matrix of dimension $m = n = 600$, generated by letting $M = \widetilde{U}\widetilde{V}^T$ with $\widetilde{U}_{ij}, \widetilde{V}_{ij}$ i.i.d. $N(0, 20/\sqrt{n})$. The noise is distributed according to the independent noise model with $Z_{ij} \sim N(0,1)$. In the first suite of simulations, presented in Figure 1, the rank is fixed to $r = 2$. In the second one (Figure 2), the number of samples is fixed to $|E| = 72000$. These examples are taken from Candès and Plan (2009, Figure

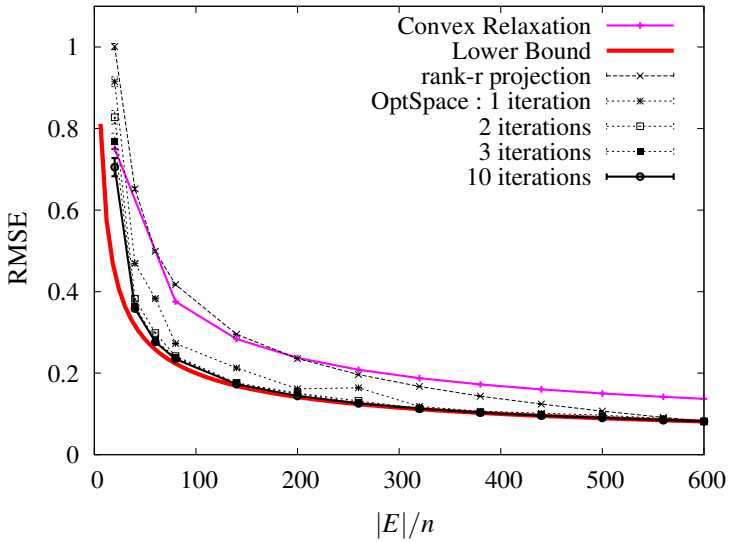

Figure 1: Numerical simulation with random rank-2 600×600 matrices. Root mean square error achieved by OPTSPACE is shown as a function of the number of observed entries $|E|$ and of the number of line minimizations. The performance of nuclear norm minimization and an information theoretic lower bound are also shown.

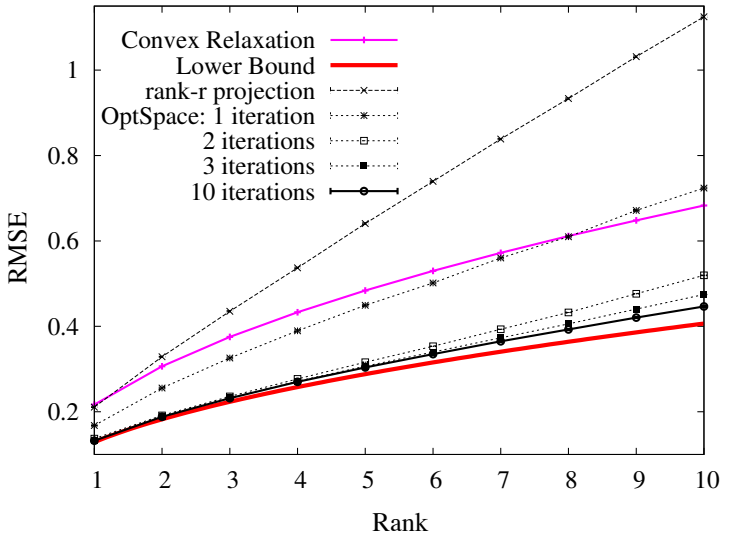

Figure 2: Numerical simulation with random rank-r 600×600 matrices and number of observed entries $|E|/n = 120$. Root mean square error achieved by OPTSPACE is shown as a function of the rank and of the number of line minimizations. The performance of nuclear norm minimization and an information theoretic lower bound are also shown.

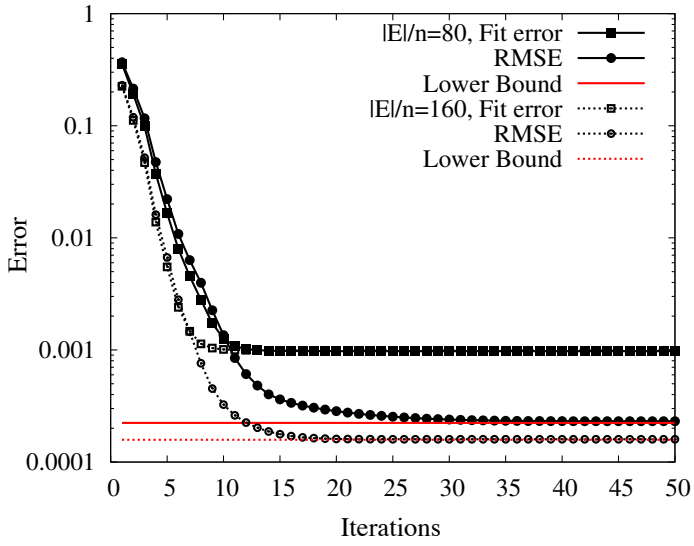

Figure 3: Numerical simulation with random rank-2 600×600 matrices and number of observed entries $|E|/n = 80$ and 160. The standard deviation of the i.i.d. Gaussian noise is 0.001. Fit error and root mean square error achieved by OPTSPACE are shown as functions of the number of line minimizations. Information theoretic lower bounds are also shown.

2), from which we took the data points for the convex relaxation approach, as well as the information theoretic lower bound described later in this section. After a few iterations, OPTSPACE has a smaller root mean square error than the one produced by convex relaxation. In about 10 iterations it becomes indistinguishable from the information theoretic lower bound for small ranks.

In Figure 3, we illustrate the rate of convergence of OPTSPACE. Two metrics, root mean squared error(RMSE) and fit error $\|\mathcal{P}_E(\widehat{M}-N)\|_F/\sqrt{|E|}$, are shown as functions of the number of iterations in the manifold optimization step. Note, that the fit error can be easily evaluated since $N^E = \mathcal{P}_E(N)$ is always available at the estimator. M is a random 600×600 rank-2 matrix generated as in the previous examples. The additive noise is distributed as $Z_{ij} \sim N(0, \sigma^2)$ with $\sigma = 0.001$ (A small noise level was used in order to trace the RMSE evolution over many iterations). Each point in the figure is the averaged over 20 random instances, and resulting errors for two different values of sample size $|E| = 80$ and $|E| = 160$ are shown. In both cases, we can see that the RMSE converges to the information theoretic lower bound described later in this section. The fit error decays exponentially with the number iterations and converges to the standard deviation of the noise which is 0.001. This is a lower bound on the fit error when $r \ll n$, since even if we have a perfect reconstruction of M, the average fit error is still 0.001.

For a more complete numerical comparison between various algorithms for matrix completion, including different noise models, real data sets and ill conditioned matrices, we refer to Keshavan and Oh (2009).

Next, let us compare our main result with the performance guarantee of Candès and Plan (2009, Theorem 7). Let us stress that we require the condition number κ to be bounded, while the analysis of Candès and Plan (2009) and Candès and Tao (2009) requires a stronger incoherence assumption

(compared to our **A1**). Therefore the assumptions are not directly comparable. As far as the error bound is concerned, Candès and Plan (2009) proved that the semidefinite programming approach returns an estimate $\widehat{M}$ which satisfies

$$\frac{1}{\sqrt{mn}}\|\widehat{M}_{\mathrm{SDP}}-M\|_F \le 7\sqrt{\frac{n}{|E|}}\|Z^E\|_F+\frac{2}{n\sqrt{\alpha}}\|Z^E\|_F\,. \tag{6}$$

(The constant in front of the first term is in fact slightly smaller than 7 in Candès and Plan (2009), but in any case larger than $4\sqrt{2}$. We choose to quote a result which is slightly less accurate but easier to parse.)

Theorem 1.2 improves over this result in several respects: (1) We do not have the second term on the right-hand side of (6), that actually increases with the number of observed entries; (2) Our error decreases as $n/|E|$ rather than $(n/|E|)^{1/2}$; (3) The noise enters Theorem 1.2 through the operator norm $\|Z^E\|_2$ instead of its Frobenius norm $\|Z^E\|_F \ge \|Z^E\|_2$. For E uniformly random, one expects $\|Z^E\|_F$ to be roughly of order $\|Z^E\|_2\sqrt{n}$. For instance, within the independent entries model with bounded variance σ, $\|Z^E\|_F=\Theta(\sqrt{|E|})$ while $\|Z^E\|_2$ is of order $\sqrt{|E|/n}$ (up to logarithmic terms).

Theorem 1.2 can also be compared to an information theoretic lower bound computed by Candès and Plan (2009). Suppose, for simplicity, $m=n$ and assume that an oracle provides us a linear subspace T where the correct rank r matrix $M=U\Sigma V^T$ lies. More precisely, we know that $M\in T$ where T is a linear space of dimension $2nr-r^2$ defined by

$$T=\{UY^T+XV^T \mid X\in\mathbb{R}^{n\times r}, Y\in\mathbb{R}^{n\times r}\}\,.$$

Notice that the rank constraint is therefore replaced by this simple linear constraint. The minimum mean square error estimator is computed by projecting the revealed entries onto the subspace T, which can be done by solving a least squares problem. Candès and Plan (2009) analyzed the root mean squared error of the resulting estimator $\widehat{M}$ and showed that

$$\frac{1}{\sqrt{mn}}\|\widehat{M}_{\mathrm{Oracle}}-M\|_F \approx \sqrt{\frac{1}{|E|}}\|Z^E\|_F\,.$$

Here $\approx$ indicates that the root mean squared error concentrates in probability around the right-hand side.

For the sake of comparison, suppose we have i.i.d. Gaussian noise with variance σ^2. In this case the oracle estimator yields (for $r=o(n)$)

$$\frac{1}{\sqrt{mn}}\|\widehat{M}_{\mathrm{Oracle}}-M\|_F \approx \sigma\sqrt{\frac{2nr}{|E|}}\,.$$

The bound (6) on the semidefinite programming approach yields

$$\frac{1}{\sqrt{mn}}\|\widehat{M}_{\mathrm{SDP}}-M\|_F \le \sigma\left(7\sqrt{n|E|}+\frac{2}{n}|E|\right).$$

Finally, using Theorems 1.2 and 1.3 we deduce that OPTSPACE achieves

$$\frac{1}{\sqrt{mn}}\|\widehat{M}_{\mathrm{OptSpace}}-M\|_F \le \sigma\sqrt{\frac{Cnr}{|E|}}\,.$$

Hence, when the noise is i.i.d. Gaussian with small enough σ, OPTSPACE is order-optimal.

1.7 Related Work on Gradient Descent

Local optimization techniques such as gradient descent of coordinate descent have been intensively studied in machine learning, with a number of applications. Here we will briefly review the recent literature on the use of such techniques within collaborative filtering applications.

Collaborative filtering was studied from a graphical models perspective in Salakhutdinov et al. (2007), which introduced an approach to prediction based on Restricted Boltzmann Machines (RBM). Exact learning of the model parameters is intractable for such models, but the authors studied the performances of a *contrastive divergence*, which computes an approximate gradient of the likelihood function, and uses it to optimize the likelihood locally. Based on empirical evidence, it was argued that RBM's have several advantages over spectral methods for collaborative filtering.

An objective function analogous to the one used in the present paper was considered early on in Srebro and Jaakkola (2003), which uses gradient descent in the factors to minimize a weighted sum of square residuals. Salakhutdinov and Mnih (2008) justified the use of such an objective function by deriving it as the (negative) log-posterior of an appropriate probabilistic model. This approach naturally lead to the use of quadratic regularization in the factors. Again, gradient descent in the factors was used to perform the optimization. Also, this paper introduced a logistic mapping between the low-rank matrix and the recorded ratings.

Recently, this line of work was pushed further in Salakhutdinov and Srebro (2010), which emphasize the advantage of using a non-uniform quadratic regularization in the factors. The basic objective function was again a sum of square residuals, and version of stochastic gradient descent was used to optimize it.

This rich and successful line of work emphasizes the importance of obtaining a rigorous understanding of methods based on local minimization of the sum of square residuals with respect to the factors. The present paper provides a first step in that direction. Hopefully the techniques developed here will be useful to analyze the many variants of this approach.

The relationship between the non-convex objective function and convex relaxation introduced by Fazel (2002) was further investigated by Srebro et al. (2005) and Recht et al. (2007). The basic relation is provided by the identity

$$\|M\|_* = \frac{1}{2} \min_{M=XY^T} \left\{ \|X\|_F^2 + \|Y\|_F^2 \right\}, \tag{7}$$

where $\|M\|_*$ denotes the nuclear norm of M (the sum of its singular values). In other words, adding a regularization term that is quadratic in the factors (as the one used in much of the literature reviewed above) is equivalent to weighting M by its nuclear norm, that can be regarded as a convex surrogate of its rank.

In view of the identity (7) it might be possible to use the results in this paper to prove stronger guarantees on the nuclear norm minimization approach. Unfortunately this implication is not immediate. Indeed in the present paper we assume the correct rank r is known, while on the other hand we do not use a quadratic regularization in the factors. (See Keshavan and Oh, 2009 for a procedure that estimates the rank from the data and is provably successful under the hypotheses of Theorem 1.2.) Trying to establish such an implication, and clarifying the relation between the two approaches is nevertheless a promising research direction.

1.8 On the Spectrum of Sparse Matrices and the Role of Trimming

The trimming step of the OPTSPACE algorithm is somewhat counter-intuitive in that we seem to be wasting information. In this section we want to clarify its role through a simple example. Before describing the example, let us stress once again two facts: (i) In the last step of our the algorithm, the trimmed entries are actually incorporated in the cost function and hence the full information is exploited; (ii) Trimming is not the only way to treat over-represented rows/columns in M^E, and probably not the optimal one. One might for instance rescale the entries of such rows/columns. We stick to trimming because we can prove it actually works.

Let us now turn to the example. Assume, for the sake of simplicity, that $m = n$, there is no noise in the revealed entries, and M is the rank one matrix with $M_{ij} = 1$ for all i and j. Within the independent sampling model, the matrix M^E has i.i.d. entries, with distribution Bernoulli(ε/n). The number of non-zero entries in a column is Binomial$(n, \varepsilon/n)$ and is independent for different columns. It is not hard to realize that the column with the largest number of entries has more than $C \log n/\log\log n$ entries, with positive probability (this probability can be made as large as we want by reducing C). Let i be the index of this column, and consider the test vector $\underline{e}^{(i)}$ that has the i-th entry equal to 1 and all the others equal to 0. By computing $\|M^E \underline{e}^{(i)}\|$, we conclude that the largest singular value of M^E is at least $\sqrt{C \log n/\log\log n}$. In particular, this is very different from the largest singular value of $\mathbb{E}\{M^E\} = (\varepsilon/n)M$ which is ε. This suggests that approximating M with the $\mathsf{P}_r(M^E)$ leads to a large error. Hence trimming is crucial in proving Theorem 1.1. Also, the phenomenon is more severe in real data sets than in the present model, where each entry is revealed independently.

Trimming is also crucial in proving Theorem 1.3. Using the above argument, it is possible to show that under the worst case model,

$$\|Z^E\|_2 \geq C'(\varepsilon)\, Z_{\max} \sqrt{\frac{\log n}{\log\log n}}\,.$$

This suggests that the largest singular value of the noise matrix Z^E is quite different from the largest singular value of $\mathbb{E}\{Z^E\}$ which is $\varepsilon Z_{\max}$.

To summarize, Theorems 1.1 and 1.3 (for the worst case model) simply do not hold without trimming or a similar procedure to normalize rows/columns of N^E. Trimming allows to overcome the above phenomenon by setting to 0 over-represented rows/columns.

2. Proof of Theorem 1.1

As explained in the introduction, the crucial idea is to consider the singular value decomposition of the trimmed matrix $\widetilde{N}^E$ instead of the original matrix N^E. Apart from a trivial rescaling, these singular values are close to the ones of the original matrix M.

Lemma 1 *There exists a numerical constant C such that, with probability greater than $1 - 1/n^3$,*

$$\left|\frac{\sigma_q}{\varepsilon} - \Sigma_q\right| \leq C M_{\max}\sqrt{\frac{\alpha}{\varepsilon}} + \frac{1}{\varepsilon}\|\widetilde{Z}^E\|_2\,,$$

where it is understood that $\Sigma_q = 0$ for $q > r$.

Proof For any matrix A, let $\sigma_q(A)$ denote the qth singular value of A. Then, $\sigma_q(A+B) \le \sigma_q(A) + \sigma_1(B)$, whence

$$\begin{aligned}\left|\frac{\sigma_q}{\varepsilon} - \Sigma_q\right| &\le \left|\frac{\sigma_q(\widetilde{M}^E)}{\varepsilon} - \Sigma_q\right| + \frac{\sigma_1(\widetilde{Z}^E)}{\varepsilon} \\ &\le CM_{\max}\sqrt{\frac{\alpha}{\varepsilon}} + \frac{1}{\varepsilon}\|\widetilde{Z}^E\|_2\,,\end{aligned}$$

where the second inequality follows from the next Lemma as shown by Keshavan et al. (2010).

Lemma 2 (Keshavan, Montanari, Oh, 2009) *There exists a numerical constant C such that, with probability larger than* $1 - 1/n^3$,

$$\frac{1}{\sqrt{mn}}\left|\left|M - \frac{\sqrt{mn}}{\varepsilon}\widetilde{M}^E\right|\right|_2 \le CM_{\max}\sqrt{\frac{\alpha}{\varepsilon}}\,.$$

■

We will now prove Theorem 1.1.

Proof (Theorem 1.1) For any matrix A of rank at most $2r$, $\|A\|_F \le \sqrt{2r}\|A\|_2$, whence

$$\begin{aligned}\frac{1}{\sqrt{mn}}\|M - \mathsf{P}_r(\widetilde{N}^E)\|_F &\le \frac{\sqrt{2r}}{\sqrt{mn}}\left|\left|M - \frac{\sqrt{mn}}{\varepsilon}\left(\widetilde{N}^E - \sum_{i\ge r+1}\sigma_i x_i y_i^T\right)\right|\right|_2 \\ &= \frac{\sqrt{2r}}{\sqrt{mn}}\left|\left|M - \frac{\sqrt{mn}}{\varepsilon}\left(\widetilde{M}^E + \widetilde{Z}^E - \sum_{i\ge r+1}\sigma_i x_i y_i^T\right)\right|\right|_2 \\ &= \frac{\sqrt{2r}}{\sqrt{mn}}\left|\left|\left(M - \frac{\sqrt{mn}}{\varepsilon}\widetilde{M}^E\right) + \frac{\sqrt{mn}}{\varepsilon}\left(\widetilde{Z}^E - \Big(\sum_{i\ge r+1}\sigma_i x_i y_i^T\Big)\right)\right|\right|_2 \\ &\le \frac{\sqrt{2r}}{\sqrt{mn}}\left(\left|\left|M - \frac{\sqrt{mn}}{\varepsilon}\widetilde{M}^E\right|\right|_2 + \frac{\sqrt{mn}}{\varepsilon}\|\widetilde{Z}^E\|_2 + \frac{\sqrt{mn}}{\varepsilon}\sigma_{r+1}\right) \\ &\le 2CM_{\max}\sqrt{\frac{2\alpha r}{\varepsilon}} + \frac{2\sqrt{2r}}{\varepsilon}\|\widetilde{Z}^E\|_2 \\ &\le C'M_{\max}\left(\frac{nr\alpha^{3/2}}{|E|}\right)^{1/2} + 2\sqrt{2}\left(\frac{n\sqrt{r\alpha}}{|E|}\right)\|\widetilde{Z}^E\|_2\,.\end{aligned}$$

where on the fourth line, we have used the fact that for any matrices A_i, $\|\sum_i A_i\|_2 \le \sum_i \|A_i\|_2$. This proves our claim. ■

3. Proof of Theorem 1.2

Recall that the cost function is defined over the Riemannian manifold $\mathsf{M}(m,n) \equiv \mathsf{G}(m,r) \times \mathsf{G}(n,r)$. The proof of Theorem 1.2 consists in controlling the behavior of F in a neighborhood of $\mathbf{u} = (U,V)$ (the point corresponding to the matrix M to be reconstructed). Throughout the proof we let $\mathcal{K}(\mu)$ be the set of matrix couples $(X,Y) \in \mathbb{R}^{m\times r} \times \mathbb{R}^{n\times r}$ such that $\|X^{(i)}\|^2 \le \mu r$, $\|Y^{(j)}\|^2 \le \mu r$ for all i, j.

3.1 Preliminary Remarks and Definitions

Given $\mathbf{x}_1 = (X_1, Y_1)$ and $\mathbf{x}_2 = (X_2, Y_2) \in \mathsf{M}(m,n)$, two points on this manifold, their distance is defined as $d(\mathbf{x}_1, \mathbf{x}_2) = \sqrt{d(X_1, X_2)^2 + d(Y_1, Y_2)^2}$, where, letting $(\cos\theta_1, \dots, \cos\theta_r)$ be the singular values of $X_1^T X_2/m$,

$$d(X_1, X_2) = \|\theta\|_2 .$$

The next remark bounds the distance between two points on the manifold. In particular, we will use this to bound the distance between the original matrix $M = U\Sigma V^T$ and the starting point of the manifold optimization $\widehat{M} = X_0 S_0 Y_0^T$.

Remark 3 (Keshavan, Montanari, Oh, 2009) *Let $U, X \in \mathbb{R}^{m\times r}$ with $U^T U = X^T X = m\mathbf{I}$, $V, Y \in \mathbb{R}^{n\times r}$ with $V^T V = Y^T Y = n\mathbf{I}$, and $M = U\Sigma V^T$, $\widehat{M} = XSY^T$ for $\Sigma = \mathrm{diag}(\Sigma_1, \dots, \Sigma_r)$ and $S \in \mathbb{R}^{r\times r}$. If $\Sigma_1, \dots, \Sigma_r \geq \Sigma_{\min}$, then*

$$d(U, X) \leq \frac{\pi}{\sqrt{2\alpha} n \Sigma_{\min}} \|M - \widehat{M}\|_F \quad , \quad d(V, Y) \leq \frac{\pi}{\sqrt{2\alpha} n \Sigma_{\min}} \|M - \widehat{M}\|_F$$

Given S achieving the minimum in Eq. (2), it is also convenient to introduce the notations

$$d_-(\mathbf{x}, \mathbf{u}) \equiv \sqrt{\Sigma_{\min}^2 d(\mathbf{x}, \mathbf{u})^2 + \|S - \Sigma\|_F^2} ,$$
$$d_+(\mathbf{x}, \mathbf{u}) \equiv \sqrt{\Sigma_{\max}^2 d(\mathbf{x}, \mathbf{u})^2 + \|S - \Sigma\|_F^2} .$$

3.2 Auxiliary Lemmas and Proof of Theorem 1.2

The proof is based on the following two lemmas that generalize and sharpen analogous bounds in Keshavan et al. (2010).

Lemma 4 *There exist numerical constants C_0, C_1, C_2 such that the following happens. Assume $\varepsilon \geq C_0 \mu_0 r \sqrt{\alpha} \max\{\log n ; \mu_0 r \sqrt{\alpha} (\Sigma_{\min}/\Sigma_{\max})^4\}$ and $\delta \leq \Sigma_{\min}/(C_0 \Sigma_{\max})$. Then,*

$$F(\mathbf{x}) - F(\mathbf{u}) \geq C_1 n \varepsilon \sqrt{\alpha}\, d_-(\mathbf{x}, \mathbf{u})^2 - C_1 n \sqrt{r\alpha} \|Z^E\|_2 d_+(\mathbf{x}, \mathbf{u}) , \quad (8)$$
$$F(\mathbf{x}) - F(\mathbf{u}) \leq C_2 n \varepsilon \sqrt{\alpha} \Sigma_{\max}^2 d(\mathbf{x}, \mathbf{u})^2 + C_2 n \sqrt{r\alpha} \|Z^E\|_2 d_+(\mathbf{x}, \mathbf{u}) , \quad (9)$$

for all $\mathbf{x} \in \mathsf{M}(m,n) \cap \mathcal{K}(4\mu_0)$ such that $d(\mathbf{x}, \mathbf{u}) \leq \delta$, with probability at least $1 - 1/n^4$. Here $S \in \mathbb{R}^{r\times r}$ is the matrix realizing the minimum in Eq. (2).

Corollary 3.1 *There exist a constant C such that, under the hypotheses of Lemma 4*

$$\|S - \Sigma\|_F \leq C \Sigma_{\max} d(\mathbf{x}, \mathbf{u}) + C \frac{\sqrt{r}}{\varepsilon} \|Z^E\|_2 .$$

Further, for an appropriate choice of the constants in Lemma 4, we have

$$\sigma_{\max}(S) \leq 2\Sigma_{\max} + C \frac{\sqrt{r}}{\varepsilon} \|Z^E\|_2 , \quad (10)$$
$$\sigma_{\min}(S) \geq \frac{1}{2} \Sigma_{\min} - C \frac{\sqrt{r}}{\varepsilon} \|Z^E\|_2 . \quad (11)$$

Lemma 5 *There exist numerical constants C_0, C_1, C_2 such that the following happens. Assume $\varepsilon \geq C_0 \mu_0 r \sqrt{\alpha}\, (\Sigma_{\max}/\Sigma_{\min})^2 \max\{\log n; \mu_0 r \sqrt{\alpha} (\Sigma_{\max}/\Sigma_{\min})^4\}$ and $\delta \leq \Sigma_{\min}/(C_0 \Sigma_{\max})$. Then,*

$$\|\mathrm{grad}\, \widetilde{F}(\mathbf{x})\|^2 \geq C_1\, n\varepsilon^2\, \Sigma_{\min}^4 \left[d(\mathbf{x},\mathbf{u}) - C_2 \frac{\sqrt{r}\Sigma_{\max}}{\varepsilon \Sigma_{\min}} \frac{\|Z^E\|_2}{\Sigma_{\min}} \right]_+^2 , \tag{12}$$

for all $\mathbf{x} \in \mathsf{M}(m,n) \cap \mathcal{K}(4\mu_0)$ such that $d(\mathbf{x},\mathbf{u}) \leq \delta$, with probability at least $1 - 1/n^4$. (Here $[a]_+ \equiv \max(a,0)$.)

We can now turn to the proof of our main theorem.

Proof (Theorem 1.2). Let $\delta = \Sigma_{\min}/C_0\Sigma_{\max}$ with C_0 large enough so that the hypotheses of Lemmas 4 and 5 are verified.

Call $\{\mathbf{x}_k\}_{k\geq 0}$ the sequence of pairs $(X_k, Y_k) \in \mathsf{M}(m,n)$ generated by gradient descent. By assumption the right-hand side of Eq. (3) is smaller than $\Sigma_{\min}$. The following is therefore true for some numerical constant C:

$$\|Z^E\|_2 \leq \frac{\varepsilon}{C\sqrt{r}} \left(\frac{\Sigma_{\min}}{\Sigma_{\max}} \right)^2 \Sigma_{\min} . \tag{13}$$

Notice that the constant appearing here can be made as large as we want by modifying the constant appearing in the statement of the theorem. Further, by using Corollary 3.1 in Eqs. (8) and (9) we get

$$F(\mathbf{x}) - F(\mathbf{u}) \geq C_1 n\varepsilon\sqrt{\alpha}\Sigma_{\min}^2 \left\{ d(\mathbf{x},\mathbf{u})^2 - \delta_{0,-}^2 \right\}, \tag{14}$$

$$F(\mathbf{x}) - F(\mathbf{u}) \leq C_2 n\varepsilon\sqrt{\alpha}\Sigma_{\max}^2 \left\{ d(\mathbf{x},\mathbf{u})^2 + \delta_{0,+}^2 \right\}, \tag{15}$$

with C_1 and C_2 different from those in Eqs. (8) and (9), where

$$\delta_{0,-} \equiv C \frac{\sqrt{r}\Sigma_{\max}}{\varepsilon \Sigma_{\min}} \frac{\|Z^E\|_2}{\Sigma_{\min}}, \qquad \delta_{0,+} \equiv C \frac{\sqrt{r}\Sigma_{\max}}{\varepsilon \Sigma_{\min}} \frac{\|Z^E\|_2}{\Sigma_{\max}} .$$

By Eq. (13), with large enough C, we can assume $\delta_{0,-} \leq \delta/20$ and $\delta_{0,+} \leq (\delta/20)(\Sigma_{\min}/\Sigma_{\max})$.

Next, we provide a bound on $d(\mathbf{u},\mathbf{x}_0)$. Using Remark 3, we have $d(\mathbf{u},\mathbf{x}_0) \leq (\pi/n\sqrt{\alpha}\Sigma_{\min})\|M - X_0 S_0 Y_0^T\|_F$. Together with Theorem 1.1 this implies

$$d(\mathbf{u},\mathbf{x}_0) \leq \frac{C M_{\max}}{\Sigma_{\min}} \left(\frac{r\alpha}{\varepsilon} \right)^{1/2} + \frac{C'\sqrt{r}}{\varepsilon \Sigma_{\min}} \|\widetilde{Z}^E\|_2 .$$

Since $\varepsilon \geq C'' \alpha \mu_1^2 r^2 (\Sigma_{\max}/\Sigma_{\min})^4$ as per our assumptions and $M_{\max} \leq \mu_1 \sqrt{r}\Sigma_{\max}$ for incoherent M, the first term in the above bound is upper bounded by $\Sigma_{\min}/20C_0\Sigma_{\max}$, for large enough C''. Using Eq. (13), with large enough constant C, the second term in the above bound is upper bounded by $\Sigma_{\min}/20C_0\Sigma_{\max}$. Hence we get

$$d(\mathbf{u},\mathbf{x}_0) \leq \frac{\delta}{10} .$$

We make the following claims :

1. $\mathbf{x}_k \in \mathcal{K}(4\mu_0)$ for all k.

   First we notice that we can assume $\mathbf{x}_0 \in \mathcal{K}(3\mu_0)$. Indeed, if this does not hold, we can 'rescale' those rows of X_0, Y_0 that violate the constraint. A proof that this rescaling is possible was given in Keshavan et al. (2010) (cf. Remark 6.2 there). We restate the result here for the reader's convenience in the next Remark.

   Remark 6 *Let $U, X \in \mathbb{R}^{n\times r}$ with $U^T U = X^T X = n\mathbf{I}$ and $U \in \mathcal{K}(\mu_0)$ and $d(X,U) \le \delta \le \frac{1}{16}$. Then there exists $X' \in \mathbb{R}^{n\times r}$ such that $X'^T X' = n\mathbf{I}$, $X' \in \mathcal{K}(3\mu_0)$ and $d(X',U) \le 4\delta$. Further, such an X' can be computed from X in a time of $O(nr^2)$.*

   Since $\mathbf{x}_0 \in \mathcal{K}(3\mu_0)$, $\widetilde{F}(\mathbf{x}_0) = F(\mathbf{x}_0) \le 4C_2 n\varepsilon\sqrt{\alpha}\Sigma_{\max}^2\delta^2/100$. On the other hand $\widetilde{F}(\mathbf{x}) \ge \rho(e^{1/9}-1)$ for $\mathbf{x} \notin \mathcal{K}(4\mu_0)$. Since $\widetilde{F}(\mathbf{x}_k)$ is a non-increasing sequence, the thesis follows provided we take $\rho \ge C_2 n\varepsilon\sqrt{\alpha}\Sigma_{\min}^2$.

2. $d(\mathbf{x}_k, \mathbf{u}) \le \delta/10$ for all k.

   Since $\varepsilon \ge C\alpha\mu_1^2 r^2(\Sigma_{\max}/\Sigma_{\min})^6$ as per our assumptions in Theorem 1.2, we have $d(\mathbf{x}_0,\mathbf{u})^2 \le (C_1\Sigma_{\min}^2/C_2\Sigma_{\max}^2)(\delta/20)^2$. Also assuming Eq. (13) with large enough C, we have $\delta_{0,-} \le \delta/20$ and $\delta_{0,+} \le (\delta/20)(\Sigma_{\min}/\Sigma_{\max})$. Then, by Eq. (15),

   $$F(\mathbf{x}_0) \le F(\mathbf{u}) + C_1 n\varepsilon\sqrt{\alpha}\Sigma_{\min}^2\frac{2\delta^2}{400}.$$

   Also, using Eq. (14), for all $\mathbf{x}_k$ such that $d(\mathbf{x}_k,\mathbf{u}) \in [\delta/10,\delta]$, we have

   $$F(\mathbf{x}) \ge F(\mathbf{u}) + C_1 n\varepsilon\sqrt{\alpha}\Sigma_{\min}^2\frac{3\delta^2}{400}.$$

   Hence, for all $\mathbf{x}_k$ such that $d(\mathbf{x}_k,\mathbf{u}) \in [\delta/10,\delta]$, we have $\widetilde{F}(\mathbf{x}) \ge F(\mathbf{x}) \ge F(\mathbf{x}_0)$. This contradicts the monotonicity of $\widetilde{F}(\mathbf{x})$, and thus proves the claim.

Since the cost function is twice differentiable, and because of the above two claims, the sequence $\{\mathbf{x}_k\}$ converges to

$$\Omega = \left\{\mathbf{x} \in \mathcal{K}(4\mu_0) \cap \mathsf{M}(m,n) : d(\mathbf{x},\mathbf{u}) \le \delta, \operatorname{grad}\widetilde{F}(\mathbf{x}) = 0\right\}.$$

By Lemma 5 for any $\mathbf{x} \in \Omega$,

$$d(\mathbf{x},\mathbf{u}) \le C\frac{\sqrt{r}\Sigma_{\max}}{\varepsilon\Sigma_{\min}}\frac{\|Z^E\|_2}{\Sigma_{\min}}. \tag{16}$$

Using Corollary 3.1, we have $d_+(\mathbf{x},\mathbf{u}) \le \Sigma_{\max} d(\mathbf{x},\mathbf{u}) + \|S-\Sigma\|_F \le C\Sigma_{\max} d(\mathbf{x},\mathbf{u}) + C(\sqrt{r}/\varepsilon)\|Z^E\|_2$. Together with Eqs. (18) and (16), this implies

$$\frac{1}{n\sqrt{\alpha}}\|M - XSY^T\|_F \le C\frac{\sqrt{r}\Sigma_{\max}^2\|Z^E\|_2}{\varepsilon\Sigma_{\min}^2},$$

which finishes the proof of Theorem 1.2. ■

3.3 Proof of Lemma 4 and Corollary 3.1

Proof (Lemma 4) The proof is based on the analogous bound in the noiseless case, that is, Lemma 5.3 in Keshavan et al. (2010). For readers' convenience, the result is reported in Appendix A, Lemma 7. For the proof of these lemmas, we refer to Keshavan et al. (2010).

In order to prove the lower bound, we start by noticing that

$$F(\mathbf{u}) \le \frac{1}{2}\|\mathcal{P}_E(Z)\|_F^2\,,$$

which is simply proved by using $S = \Sigma$ in Eq. (2). On the other hand, we have

$$\begin{aligned} F(\mathbf{x}) &= \frac{1}{2}\|\mathcal{P}_E(XSY^T - M - Z)\|_F^2 \\ &= \frac{1}{2}\|\mathcal{P}_E(Z)\|_F^2 + \frac{1}{2}\|\mathcal{P}_E(XSY^T - M)\|_F^2 - \langle \mathcal{P}_E(Z), (XSY^T - M)\rangle \qquad (17)\\ &\ge F(\mathbf{u}) + Cn\varepsilon\sqrt{\alpha}\, d_-(\mathbf{x},\mathbf{u})^2 - \sqrt{2r}\|Z^E\|_2\|XSY^T - M\|_F\,, \end{aligned}$$

where in the last step we used Lemma 7. Now by triangular inequality

$$\begin{aligned} \|XSY^T - M\|_F^2 &\le 3\|X(S-\Sigma)Y^T\|_F^2 + 3\|X\Sigma(Y-V)^T\|_F^2 + 3\|(X-U)\Sigma V^T\|_F^2 \\ &\le 3nm\|S-\Sigma\|_F^2 + 3n^2\alpha\Sigma_{\max}^2\Big(\frac{1}{m}\|X-U\|_F^2 + \frac{1}{n}\|Y-V\|_F^2\Big) \\ &\le Cn^2\alpha d_+(\mathbf{x},\mathbf{u})^2\,, \qquad (18) \end{aligned}$$

In order to prove the upper bound, we proceed as above to get

$$F(\mathbf{x}) \le \tfrac{1}{2}\|\mathcal{P}_E(Z)\|_F^2 + Cn\varepsilon\sqrt{\alpha}\Sigma_{\max}^2\, d(\mathbf{x},\mathbf{u})^2 + \sqrt{2r\alpha}\|Z^E\|_2 Cn d_+(\mathbf{x},\mathbf{u})\,.$$

Further, by replacing $\mathbf{x}$ with $\mathbf{u}$ in Eq. (17)

$$\begin{aligned} F(\mathbf{u}) &\ge \frac{1}{2}\|\mathcal{P}_E(Z)\|_F^2 - \langle \mathcal{P}_E(Z), (U(S-\Sigma)V^T)\rangle \\ &\ge \frac{1}{2}\|\mathcal{P}_E(Z)\|_F^2 - \sqrt{2r\alpha}\|Z^E\|_2 Cn d_+(\mathbf{x},\mathbf{u})\,. \end{aligned}$$

By taking the difference of these inequalities we get the desired upper bound. ■

Proof (Corollary 3.1) By putting together Eq. (8) and (9), and using the definitions of $d_+(\mathbf{x},\mathbf{u})$, $d_-(\mathbf{x},\mathbf{u})$, we get

$$\|S-\Sigma\|_F^2 \le \frac{C_1+C_2}{C_1}\Sigma_{\max}^2 d(\mathbf{x},\mathbf{u})^2 + \frac{(C_1+C_2)\sqrt{r}}{C_1\varepsilon}\|Z^E\|_2\sqrt{\Sigma_{\max}^2 d(\mathbf{x},\mathbf{u})^2 + \|S-\Sigma\|_F^2}\,.$$

Let $x \equiv \|S-\Sigma\|_F$, $a^2 \equiv \big((C_1+C_2)/C_1\big)\Sigma_{\max}^2 d(\mathbf{x},\mathbf{u})^2$, and $b \equiv \big((C_1+C_2)\sqrt{r}/C_1\varepsilon\big)\|Z^E\|_2$. The above inequality then takes the form

$$x^2 \le a^2 + b\sqrt{x^2+a^2} \le a^2 + ab + bx\,,$$

which implies our claim $x \le a+b$.

The singular value bounds (10) and (11) follow by triangular inequality. For instance

$$\sigma_{\min}(S) \geq \Sigma_{\min} - C\Sigma_{\max} d(\mathbf{x},\mathbf{u}) - C\frac{\sqrt{r}}{\varepsilon}\|Z^E\|_2 .$$

which implies the inequality (11) for $d(\mathbf{x},\mathbf{u}) \leq \delta = \Sigma_{\min}/C_0\Sigma_{\max}$ and C_0 large enough. An analogous argument proves Eq. (10). ■

3.4 Proof of Lemma 5

Without loss of generality we will assume $\delta \leq 1, C_2 \geq 1$ and

$$\frac{\sqrt{r}}{\varepsilon}\|Z^E\|_2 \leq \Sigma_{\min} , \tag{19}$$

because otherwise the lower bound (12) is trivial for all $d(\mathbf{x},\mathbf{u}) \leq \delta$.

Denote by $t \mapsto \mathbf{x}(t)$, $t \in [0,1]$, the geodesic on $\mathsf{M}(m,n)$ such that $\mathbf{x}(0) = \mathbf{u}$ and $\mathbf{x}(1) = \mathbf{x}$, parametrized proportionally to the arclength. Let $\widehat{\mathbf{w}} = \dot{\mathbf{x}}(1)$ be its final velocity, with $\widehat{\mathbf{w}} = (\widehat{W},\widehat{Q})$. Obviously $\widehat{\mathbf{w}} \in \mathsf{T}_{\mathbf{x}}$ (with $\mathsf{T}_{\mathbf{x}}$ the tangent space of $\mathsf{M}(m,n)$ at $\mathbf{x}$) and

$$\frac{1}{m}\|\widehat{W}\|^2 + \frac{1}{n}\|\widehat{Q}\|^2 = d(\mathbf{x},\mathbf{u})^2,$$

because $t \mapsto \mathbf{x}(t)$ is parametrized proportionally to the arclength.

Explicit expressions for $\widehat{\mathbf{w}}$ can be obtained in terms of $\mathbf{w} \equiv \dot{\mathbf{x}}(0) = (W,Q)$ (Keshavan et al., 2010). If we let $W = L\Theta R^T$ be the singular value decomposition of W, we obtain

$$\widehat{W} = -UR\Theta\sin\Theta R^T + L\Theta\cos\Theta R^T . \tag{20}$$

It was proved in Keshavan et al. (2010) that $\langle \operatorname{grad} G(\mathbf{x}), \widehat{\mathbf{w}}\rangle \geq 0$. It is therefore sufficient to lower bound the scalar product $\langle \operatorname{grad} F, \widehat{\mathbf{w}}\rangle$. By computing the gradient of F we get

$$\begin{aligned}
\langle \operatorname{grad} F(\mathbf{x}), \widehat{\mathbf{w}}\rangle &= \langle \mathcal{P}_E(XSY^T - N), (XS\widehat{Q}^T + \widehat{W}SY^T)\rangle \\
&= \langle \mathcal{P}_E(XSY^T - M), (XS\widehat{Q}^T + \widehat{W}SY^T)\rangle - \langle \mathcal{P}_E(Z), (XS\widehat{Q}^T + \widehat{W}SY^T)\rangle \\
&= \langle \operatorname{grad} F_0(\mathbf{x}), \widehat{\mathbf{w}}\rangle - \langle \mathcal{P}_E(Z), (XS\widehat{Q}^T + \widehat{W}SY^T)\rangle
\end{aligned} \tag{21}$$

where $F_0(\mathbf{x})$ is the cost function in absence of noise, namely

$$F_0(X,Y) = \min_{S\in\mathbb{R}^{r\times r}} \left\{ \frac{1}{2}\sum_{(i,j)\in E} \left((XSY^T)_{ij} - M_{ij}\right)^2 \right\} . \tag{22}$$

As proved in Keshavan et al. (2010),

$$\langle \operatorname{grad} F_0(\mathbf{x}), \widehat{\mathbf{w}}\rangle \geq Cn\varepsilon\sqrt{\alpha}\Sigma_{\min}^2 d(\mathbf{x},\mathbf{u})^2 \tag{23}$$

(see Lemma 9 in Appendix).

We are therefore left with the task of upper bounding $\langle \mathcal{P}_E(Z), (XS\widehat{Q}^T + \widehat{W}SY^T)\rangle$. Since $XS\widehat{Q}^T$ has rank at most r, we have

$$\langle \mathcal{P}_E(Z), XS\widehat{Q}^T\rangle \leq \sqrt{r}\,\|Z^E\|_2\,\|XS\widehat{Q}^T\|_F .$$

Since $X^T X = m\mathbf{I}$, we get

$$\begin{aligned} \|XS\widehat{Q}^T\|_F^2 &= m\mathrm{Tr}(S^T S\widehat{Q}^T\widehat{Q}) \le n\alpha\sigma_{\max}(S)^2\|\widehat{Q}\|_F^2 \\ &\le Cn^2\alpha\Big(\Sigma_{\max} + \frac{\sqrt{r}}{\varepsilon}\|Z^E\|_F\Big)^2 d(\mathbf{x},\mathbf{u})^2 \qquad (24) \\ &\le 4Cn^2\alpha\Sigma_{\max}^2\, d(\mathbf{x},\mathbf{u})^2\,, \end{aligned}$$

where, in inequality (24), we used Corollary 3.1 and in the last step, we used Eq. (19). Proceeding analogously for $\langle \mathcal{P}_E(Z), \widehat{W}SY^T\rangle$, we get

$$\langle \mathcal{P}_E(Z), (XS\widehat{Q}^T + \widehat{W}SY^T)\rangle \le C' n\Sigma_{\max}\sqrt{r\alpha}\,\|Z^E\|_2\, d(\mathbf{x},\mathbf{u})\,.$$

Together with Eq. (21) and (23) this implies

$$\langle \mathrm{grad}\, F(\mathbf{x}), \widehat{\mathbf{w}}\rangle \ge C_1 n\varepsilon\sqrt{\alpha}\Sigma_{\min}^2 d(\mathbf{x},\mathbf{u})\Big\{d(\mathbf{x},\mathbf{u}) - C_2\frac{\sqrt{r}\Sigma_{\max}}{\varepsilon\Sigma_{\min}}\frac{\|Z^E\|_2}{\Sigma_{\min}}\Big\}\,,$$

which implies Eq. (12) by Cauchy-Schwartz inequality.

4. Proof of Theorem 1.3

Proof (*Independent entries model*) We start with a claim that for any sampling set E, we have

$$\|\widetilde{Z}^E\|_2 \le \|Z^E\|_2\,.$$

To prove this claim, let x^* and y^* be m and n dimensional vectors, respectively, achieving the optimum in $\max_{\|x\|\le 1,\|y\|\le 1}\{x^T\widetilde{Z}^E y\}$, that is, such that $\|\widetilde{Z}^E\|_2 = x^{*T}\widetilde{Z}^E y^*$. Recall that, as a result of the trimming step, all the entries in trimmed rows and columns of $\widetilde{Z}^E$ are set to zero. Then, there is no gain in maximizing $x^T\widetilde{Z}^E y$ to have a non-zero entry x_i^* for i corresponding to the rows which are trimmed. Analogously, for j corresponding to the trimmed columns, we can assume without loss of generality that $y_j^* = 0$. From this observation, it follows that $x^{*T}\widetilde{Z}^E y^* = x^{*T}Z^E y^*$, since the trimmed matrix $\widetilde{Z}^E$ and the sample noise matrix Z^E only differ in the trimmed rows and columns. The claim follows from the fact that $x^{*T}Z^E y^* \le \|Z^E\|_2$, for any x^* and y^* with unit norm.

In what follows, we will first prove that $\|Z^E\|_2$ is bounded by the right-hand side of Eq. (4) for any range of $|E|$. Due to the above observation, this implies that $\|\widetilde{Z}^E\|_2$ is also bounded by $C\sigma\sqrt{\varepsilon\sqrt{\alpha}\log n}$, where $\varepsilon \equiv |E|/\sqrt{\alpha}n$. Further, we use the same analysis to prove a tighter bound in Eq. (5) when $|E| \ge n\log n$.

First, we want to show that $\|Z^E\|_2$ is bounded by $C\sigma\sqrt{\varepsilon\sqrt{\alpha}\log n}$, and Z_{ij}'s are i.i.d. random variables with zero mean and sub-Gaussian tail with parameter σ^2. The proof strategy is to show that $\mathbb{E}\big[\|Z^E\|_2\big]$ is bounded, using the result of Seginer (2000) on expected norm of random matrices, and use the fact that $\|\cdot\|_2$ is a Lipschitz continuous function of its arguments together with concentration inequality for Lipschitz functions on i.i.d. Gaussian random variables due to Talagrand (1996).

Note that $\|\cdot\|_2$ is a Lipschitz function with a Lipschitz constant 1. Indeed, for any M and M', $\big|\|M'\|_2 - \|M\|_2\big| \le \|M' - M\|_2 \le \|M' - M\|_F$, where the first inequality follows from triangular inequality and the second inequality follows from the fact that $\|\cdot\|_F^2$ is the sum of the squared singular values.

To bound the probability of large deviation, we use the result on concentration inequality for Lipschitz functions on i.i.d. sub-Gaussian random variables due to Talagrand (1996). For a 1-Lipschitz function $\|\cdot\|_2$ on $m \times n$ i.i.d. random variables Z^E_{ij} with zero mean, and sub-Gaussian tails with parameter σ^2,

$$\mathbb{P}\big(\|Z^E\|_2 - \mathbb{E}[\|Z^E\|_2] > t\big) \leq \exp\Big\{-\frac{t^2}{2\sigma^2}\Big\}. \tag{25}$$

Setting $t = \sqrt{8\sigma^2 \log n}$, this implies that $\|Z^E\|_2 \leq \mathbb{E}\big[\|Z\|_2\big] + \sqrt{8\sigma^2 \log n}$ with probability larger than $1 - 1/n^4$.

Now, we are left to bound the expectation $\mathbb{E}\big[\|Z^E\|_2\big]$. First, we symmetrize the possibly asymmetric random variables Z^E_{ij} to use the result of Seginer (2000) on expected norm of random matrices with symmetric random variables. Let Z'_{ij}'s be independent copies of Z_{ij}'s, and ξ_{ij}'s be independent Bernoulli random variables such that $\xi_{ij} = +1$ with probability $1/2$ and $\xi_{ij} = -1$ with probability $1/2$. Then, by convexity of $\mathbb{E}\big[\|Z^E - Z'^E\|_2 | Z'^E\big]$ and Jensen's inequality,

$$\mathbb{E}\big[\|Z^E\|_2\big] \leq \mathbb{E}\big[\|Z^E - Z'^E\|_2\big] = \mathbb{E}\big[\|(\xi_{ij}(Z^E_{ij} - Z'^E_{ij}))\|_2\big] \leq 2\mathbb{E}\big[\|(\xi_{ij} Z^E_{ij})\|_2\big],$$

where $(\xi_{ij} Z^E_{ij})$ denotes an $m \times n$ matrix with entry $\xi_{ij} Z^E_{ij}$ in position (i, j). Thus, it is enough to show that $\mathbb{E}\big[\|Z^E\|_2\big]$ is bounded by $C\sigma\sqrt{\varepsilon\sqrt{\alpha}\log n}$ in the case of symmetric random variables Z_{ij}'s.

To this end, we apply the following bound on expected norm of random matrices with i.i.d. symmetric random entries, proved by Seginer (2000, Theorem 1.1).

$$\mathbb{E}\big[\|Z^E\|_2\big] \leq C\Big(\mathbb{E}\big[\max_{i\in[m]} \|Z^E_{i\bullet}\|\big] + \mathbb{E}\big[\max_{j\in[n]} \|Z^E_{\bullet j}\|\big]\Big), \tag{26}$$

where $Z^E_{i\bullet}$ and $Z^E_{\bullet j}$ denote the ith row and jth column of A respectively. For any positive parameter β, which will be specified later, the following is true.

$$\mathbb{E}\big[\max_j \|Z^E_{\bullet j}\|^2\big] \leq \beta\sigma^2\varepsilon\sqrt{\alpha} + \int_0^\infty \mathbb{P}\big(\max_j \|Z^E_{\bullet j}\|^2 \geq \beta\sigma^2\varepsilon\sqrt{\alpha} + z\big)\,\mathrm{d}z. \tag{27}$$

To bound the second term, we can apply union bound on each of the n columns, and use the following bound on each column $\|Z^E_{\bullet j}\|^2$ resulting from concentration of measure inequality for the i.i.d. sub-Gaussian random matrix Z.

$$\mathbb{P}\Big(\sum_{k=1}^m (Z^E_{kj})^2 \geq \beta\sigma^2\varepsilon\sqrt{\alpha} + z\Big) \leq \exp\Big\{-\frac{3}{8}\Big((\beta-3)\varepsilon\sqrt{\alpha} + \frac{z}{\sigma^2}\Big)\Big\}. \tag{28}$$

To prove the above result, we apply Chernoff bound on the sum of independent random variables. Recall that $Z^E_{kj} = \tilde{\xi}_{kj} Z_{kj}$ where $\tilde{\xi}$'s are independent Bernoulli random variables such that $\tilde{\xi} = 1$ with probability $\varepsilon/\sqrt{mn}$ and zero with probability $1 - \varepsilon/\sqrt{mn}$. Then, for the choice of $\lambda = 3/8\sigma^2 < 1/2\sigma^2$,

$$\begin{aligned}
\mathbb{E}\Big[\exp\Big(\lambda \sum_{k=1}^m (\tilde{\xi}_{kj} Z_{kj})^2\Big)\Big] &= \Big(1 - \frac{\varepsilon}{\sqrt{mn}} + \frac{\varepsilon}{\sqrt{mn}}\mathbb{E}[e^{\lambda Z^2_{kj}}]\Big)^m \\
&\leq \Big(1 - \frac{\varepsilon}{\sqrt{mn}} + \frac{\varepsilon}{\sqrt{mn(1-2\sigma^2\lambda)}}\Big)^m \\
&= \exp\Big\{m\log\Big(1 + \frac{\varepsilon}{\sqrt{mn}}\Big)\Big\} \\
&\leq \exp\big\{\varepsilon\sqrt{\alpha}\big\},
\end{aligned}$$

where the first inequality follows from the definition of Z_{kj} as a zero mean random variable with sub-Gaussian tail, and the second inequality follows from $\log(1+x) \le x$. By applying Chernoff bound, Eq. (28) follows. Note that an analogous result holds for the Euclidean norm on the rows $\|Z^E_{i\bullet}\|^2$.

Substituting Eq. (28) and $\mathbb{P}\big(\max_j \|Z^E_{\bullet j}\|^2 \ge z\big) \le m\,\mathbb{P}\big(\|Z^E_{\bullet j}\|^2 \ge z\big)$ in Eq. (27), we get

$$\mathbb{E}\big[\max_j \|Z^E_{\bullet j}\|^2\big] \le \beta\sigma^2\varepsilon\sqrt{\alpha} + \frac{8\sigma^2 m}{3} e^{-\frac{3}{8}(\beta-3)\varepsilon\sqrt{\alpha}}\,. \tag{29}$$

The second term can be made arbitrarily small by taking $\beta = C\log n$ with large enough C. Since $\mathbb{E}\big[\max_j \|Z^E_{\bullet j}\|\big] \le \sqrt{\mathbb{E}\big[\max_j \|Z^E_{\bullet j}\|^2\big]}$, applying Eq. (29) with $\beta = C\log n$ in Eq. (26) gives

$$\mathbb{E}\big[\|Z^E\|_2\big] \le C\sigma\sqrt{\varepsilon\sqrt{\alpha}\log n}\,.$$

Together with Eq. (25), this proves the desired thesis for any sample size $|E|$.

In the case when $|E| \ge n\log n$, we can get a tighter bound by similar analysis. Since $\varepsilon \ge C'\log n$, for some constant C', the second term in Eq. (29) can be made arbitrarily small with a large constant β. Hence, applying Eq. (29) with $\beta = C$ in Eq. (26), we get

$$\mathbb{E}\big[\|Z^E\|_2\big] \le C\sigma\sqrt{\varepsilon\sqrt{\alpha}}\,.$$

Together with Eq. (25), this proves the desired thesis for $|E| \ge n\log n$.

■

Proof (*Worst Case Model*) Let D be the $m \times n$ all-ones matrix. Then for any matrix Z from the *worst case model*, we have $\|\widetilde{Z}^E\|_2 \le Z_{\max}\|\widetilde{D}^E\|_2$, since $x^T\widetilde{Z}^E y \le \sum_{i,j} Z_{\max}|x_i|\widetilde{D}^E_{ij}|y_j|$, which follows from the fact that Z_{ij}'s are uniformly bounded. Further, $\widetilde{D}^E$ is an adjacency matrix of a corresponding bipartite graph with bounded degrees. Then, for any choice of E the following is true for all positive integers k:

$$\|\widetilde{D}^E\|_2^{2k} \le \max_{x,\|x\|=1} \big|x^T((\widetilde{D}^E)^T\widetilde{D}^E)^k x\big| \le \mathrm{Tr}\big(((\widetilde{D}^E)^T\widetilde{D}^E)^k\big) \le n(2\varepsilon)^{2k}\,.$$

Now $\mathrm{Tr}\big(((\widetilde{D}^E)^T\widetilde{D}^E)^k\big)$ is the number of paths of length $2k$ on the bipartite graph with adjacency matrix $\widetilde{D}^E$, that begin and end at i for every $i \in [n]$. Since this graph has degree bounded by 2ε, we get

$$\|\widetilde{D}^E\|_2^{2k} \le n(2\varepsilon)^{2k}\,.$$

Taking k large, we get the desired thesis. ■

Appendix A. Three Lemmas on the Noiseless Problem

Lemma 7 *There exists numerical constants C_0, C_1, C_2 such that the following happens. Assume $\varepsilon \geq C_0 \mu_0 r \sqrt{\alpha} \max\{\log n; \mu_0 r \sqrt{\alpha} (\Sigma_{\min}/\Sigma_{\max})^4\}$ and $\delta \leq \Sigma_{\min}/(C_0 \Sigma_{\max})$. Then,*

$$C_1 \sqrt{\alpha} \Sigma_{\min}^2 d(\mathbf{x},\mathbf{u})^2 + C_1 \sqrt{\alpha} \|S_0 - \Sigma\|_F^2 \leq \frac{1}{n\varepsilon} F_0(\mathbf{x}) \leq C_2 \sqrt{\alpha} \Sigma_{\max}^2 d(\mathbf{x},\mathbf{u})^2 ,$$

for all $\mathbf{x} \in \mathsf{M}(m,n) \cap \mathcal{K}(4\mu_0)$ such that $d(\mathbf{x},\mathbf{u}) \leq \delta$, with probability at least $1 - 1/n^4$. Here $S_0 \in \mathbb{R}^{r \times r}$ is the matrix realizing the minimum in Eq. (22).

Lemma 8 *There exists numerical constants C_0 and C such that the following happens. Assume $\varepsilon \geq C_0 \mu_0 r \sqrt{\alpha} (\Sigma_{\max}/\Sigma_{\min})^2 \max\{\log n; \mu_0 r \sqrt{\alpha} (\Sigma_{\max}/\Sigma_{\min})^4\}$ and $\delta \leq \Sigma_{min}/(C_0 \Sigma_{\max})$. Then*

$$\|\operatorname{grad} \widetilde{F}_0(\mathbf{x})\|^2 \geq C n \varepsilon^2 \Sigma_{\min}^4 d(\mathbf{x},\mathbf{u})^2 ,$$

for all $\mathbf{x} \in \mathsf{M}(m,n) \cap \mathcal{K}(4\mu_0)$ such that $d(\mathbf{x},\mathbf{u}) \leq \delta$, with probability at least $1 - 1/n^4$.

Lemma 9 *Define $\widehat{\mathbf{w}}$ as in Eq. (20). Then there exists numerical constants C_0 and C such that the following happens. Under the hypothesis of Lemma 8*

$$\langle \operatorname{grad} F_0(\mathbf{x}), \widehat{\mathbf{w}} \rangle \geq C n \varepsilon \sqrt{\alpha} \Sigma_{\min}^2 d(\mathbf{x},\mathbf{u})^2 ,$$

for all $\mathbf{x} \in \mathsf{M}(m,n) \cap \mathcal{K}(4\mu_0)$ such that $d(\mathbf{x},\mathbf{u}) \leq \delta$, with probability at least $1 - 1/n^4$.

Abstract

Model selection strategies for machine learning algorithms typically involve the numerical optimisation of an appropriate model selection criterion, often based on an estimator of generalisation performance, such as k-fold cross-validation. The error of such an estimator can be broken down into bias and variance components. While unbiasedness is often cited as a beneficial quality of a model selection criterion, we demonstrate that a low variance is at least as important, as a non-negligible variance introduces the potential for over-fitting in model selection as well as in training the model. While this observation is in hindsight perhaps rather obvious, the degradation in performance due to over-fitting the model selection criterion can be surprisingly large, an observation that appears to have received little attention in the machine learning literature to date. In this paper, we show that the effects of this form of over-fitting are often of comparable magnitude to differences in performance between learning algorithms, and thus cannot be ignored in empirical evaluation. Furthermore, we show that some common performance evaluation practices are susceptible to a form of selection bias as a result of this form of over-fitting and hence are unreliable. We discuss methods to avoid over-fitting in model selection and subsequent selection bias in performance evaluation, which we hope will be incorporated into best practice. While this study concentrates on cross-validation based model selection, the findings are quite general and apply to any model selection practice involving the optimisation of a model selection criterion evaluated over a finite sample of data, including maximisation of the Bayesian evidence and optimisation of performance bounds.

Keywords: model selection, performance evaluation, bias-variance trade-off, selection bias, over-fitting

1. Introduction

This paper is concerned with two closely related topics that form core components of best practice in both the real world application of machine learning methods and the development of novel machine learning algorithms, namely model selection and performance evaluation. The majority of machine learning algorithms are based on some form of multi-level inference, where the model is defined by a set of model parameters and also a set of hyper-parameters (Guyon et al., 2009), for example in kernel learning methods the parameters correspond to the coefficients of the kernel expansion and the hyper-parameters include the regularisation parameter, the choice of kernel function and any associated kernel parameters. This division into parameters and hyper-parameters is typically

performed for computational convenience; for instance in the case of kernel machines, for fixed values of the hyper-parameters, the parameters are normally given by the solution of a convex optimisation problem for which efficient algorithms are available. Thus it makes sense to take advantage of this structure and fit the model iteratively using a pair of nested loops, with the hyper-parameters adjusted to optimise a model selection criterion in the outer loop (model selection) and the parameters set to optimise a training criterion in the inner loop (model fitting/training). In our previous study (Cawley and Talbot, 2007), we noted that the variance of the model selection criterion admitted the possibility of over-fitting during model selection as well as the more familiar form of over-fitting that occurs during training and demonstrated that this could be ameliorated to some extent by regularisation of the model selection criterion. The first part of this paper discusses the problem of over-fitting in model selection in more detail, providing illustrative examples, and describes how to avoid this form of over-fitting in order to gain the best attainable performance, desirable in practical applications, and required for fair comparison of machine learning algorithms.

Unbiased and robust[1] performance evaluation is undoubtedly the cornerstone of machine learning research; without a reliable indication of the relative performance of competing algorithms, across a wide range of learning tasks, we cannot have the clear picture of the strengths and weaknesses of current approaches required to set the direction for future research. This topic is considered in the second part of the paper, specifically focusing on the undesirable optimistic bias that can arise due to over-fitting in model selection. This phenomenon is essentially analogous to the selection bias observed by Ambroise and McLachlan (2002) in microarray classification, due to feature selection prior to performance evaluation, and shares a similar solution. We show that some, apparently quite benign, performance evaluation protocols in common use by the machine learning community are susceptible to this form of bias, and thus potentially give spurious results. In order to avoid this bias, model selection must be treated as an integral part of the model fitting process and performed afresh every time a model is fitted to a new sample of data. Furthermore, as the differences in performance due to model selection are shown to be often of comparable magnitude to the difference in performance between learning algorithms, it seems no longer meaningful to evaluate the performance of machine learning algorithms in isolation, and we should instead compare learning algorithm/model selection procedure combinations. However, this means that robust unbiased performance evaluation is likely to require more rigorous and computationally intensive protocols, such a nested cross-validation or "double cross" (Stone, 1974).

None of the methods or algorithms discussed in this paper are new; the novel contribution of this work is an empirical demonstration that over-fitting at the second level of inference (i.e., model selection) can have a very substantial deleterious effect on the generalisation performance of state-of-the-art machine learning algorithms. Furthermore the demonstration that this can lead to a misleading optimistic bias in performance evaluation using evaluation protocols in common use in the machine learning community is also novel. The paper is intended to be of some tutorial value in promoting best practice in model selection and performance evaluation, however we also hope that the observation that over-fitting in model selection is a significant problem will encourage much needed algorithmic and theoretical development in this area.

The remainder of the paper is structured as follows: Section 2 provides a brief overview of the kernel ridge regression classifier used as the base classifier for the majority of the experimental work

1. The term "robust" is used here to imply insensitivity to irrelevant experimental factors, such as the sampling and partitioning of the data to form training, validation and test sets; this is normally achieved by computationally expensive resampling schemes, for example, cross-validation (Stone, 1974) and the bootstrap (Efron and Tibshirani, 1994).

and Section 3 describes the data sets used. Section 4 demonstrates the importance of the variance of the model selection criterion, as it can lead to over-fitting in model selection, resulting in poor generalisation performance. A number of methods to avoid over-fitting in model selection are also discussed. Section 5 shows that over-fitting in model selection can result in biased performance evaluation if model selection is not viewed as an integral part of the modelling procedure. Two apparently benign and widely used performance evaluation protocols are shown to be affected by this problem. Finally, the work is summarised in Section 6.

2. Kernel Ridge Regression

In this section, we provide a brief overview of the Kernel Ridge Regression (KRR) classifier (Saunders et al., 1998), also known as the Least-Squares Support Vector Machine (Suykens et al., 2002), Regularised Least Squares (Rifkin and Lippert, 2007), Regularisation Network (Poggio and Girosi, 1990) etc., used as the base classifier in most of the empirical demonstrations in the sequel. Assume we are given labeled training data, $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{\ell}$, where $x_i \in \mathcal{X} \subset \mathbb{R}^d$ is a vector of input features describing the i^{th} example and $y_i \in \{-1, +1\}$ is an indicator variable such that $y_i = +1$ if the i^{th} example is drawn from the positive class, $\mathcal{C}^+$, and $y_i = -1$ if from the negative class, $\mathcal{C}^-$. Further let us assume there are ℓ^+ positive examples and $\ell^- = \ell - \ell^+$ negative examples. The Kernel Ridge Regression classifier aims to construct a linear model $f(x) = w \cdot \phi(x) + b$ in a fixed feature space, $\phi : \mathcal{X} \to \mathcal{F}$, that is able to distinguish between examples drawn from $\mathcal{C}^-$ and $\mathcal{C}^+$, such that

$$x \in \begin{cases} \mathcal{C}^+ & \text{if } f(x) \geq 0 \\ \mathcal{C}^- & \text{otherwise} \end{cases}.$$

However, rather than specifying the feature space, $\mathcal{F}$, directly, it is induced by a kernel function, $\mathcal{K} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$, giving the inner product between the images of vectors in the feature space, $\mathcal{F}$, that is, $\mathcal{K}(x, x') = \phi(x) \cdot \phi(x')$. A common kernel function, used throughout this study, is the Gaussian radial basis function (RBF) kernel

$$\mathcal{K}(x, x') = \exp\left\{-\eta \|x - x'\|^2\right\}, \tag{1}$$

where η is a kernel parameter controlling the sensitivity of the kernel function. However, the interpretation of the kernel function as evaluating the inner product between points in an implied feature space is valid for any kernel for which the kernel matrix $K = [k_{ij} = \mathcal{K}(x_i, x_j)]_{i,j=1}^{\ell}$ is positive definite (Mercer, 1909), such that

$$a^T K a > 0, \qquad \forall\, a \neq 0.$$

The model parameters (w, b) are given by the minimum of a regularised (Tikhonov and Arsenin, 1977) least-squares loss function,

$$\mathcal{L} = \frac{1}{2}\|w\|^2 + \frac{1}{2\lambda}\sum_{i=1}^{\ell}\left[y_i - w \cdot \phi(x_i) - b\right]^2, \tag{2}$$

where λ is a regularisation parameter controlling the bias-variance trade-off (Geman et al., 1992). The accuracy of the kernel machine on test data is critically dependent on the choice of good values for the *hyper-parameters*, in this case λ and η. The search for the optimal values for such hyper-parameters is a process known as *model selection*. The representer theorem (Kimeldorf and Wahba,

1971) states that the solution to this optimisation problem can be written as an expansion of the form

$$w = \sum_{i=1}^{\ell} \alpha_i \phi(x_i) \quad \Longrightarrow \quad f(x) = \sum_{i=1}^{\ell} \alpha_i \mathcal{K}(x_i, x) + b.$$

The dual parameters of the kernel machine, α, are then given by the solution of a system of linear equations,

$$\begin{bmatrix} K + \lambda I & 1 \\ 1^T & 0 \end{bmatrix} \begin{bmatrix} \alpha \\ b \end{bmatrix} = \begin{bmatrix} y \\ 0 \end{bmatrix}. \tag{3}$$

where $y = (y_1, y_2, \ldots, y_\ell)^T$, which can be solved efficiently via Cholesky factorisation of $K + \lambda I$, with a computational complexity of $O(\ell^3)$ operations (Suykens et al., 2002). The simplicity and efficiency of the kernel ridge regression classifier makes it an ideal candidate for relatively small-scale empirical investigations of practical issues, such as model selection.

2.1 Efficient Leave-One-Out Cross-Validation

Cross-validation (e.g., Stone, 1974) provides a simple and effective method for both model selection and performance evaluation, widely employed by the machine learning community. Under k-fold cross-validation the data are randomly partitioned to form k disjoint subsets of approximately equal size. In the i^{th} fold of the cross-validation procedure, the i^{th} subset is used to estimate the generalisation performance of a model trained on the remaining $k-1$ subsets. The average of the generalisation performance observed over all k folds provides an estimate (with a slightly pessimistic bias) of the generalisation performance of a model trained on the entire sample. The most extreme form of cross-validation, in which each subset contains only a single pattern is known as leave-one-out cross-validation (Lachenbruch and Mickey, 1968; Luntz and Brailovsky, 1969). An attractive feature of kernel ridge regression is that it is possible to perform leave-one-out cross-validation in closed form, with minimal cost as a by-product of the training algorithm (Cawley and Talbot, 2003). Let C represent the matrix on the left hand side of (3), then the residual error for the i^{th} training pattern in the i^{th} fold of the leave-one-out process is given by,

$$r_i^{(-i)} = y_i - \hat{y}_i^{(-i)} = \frac{\alpha_i}{C_{ii}^{-1}},$$

where $\hat{y}_i^{(-j)}$ is the output of the kernel ridge regression machine for the i^{th} observation in the j^{th} fold of the leave-one-out procedure and C_{ii}^{-1} is the i^{th} element of the principal diagonal of the inverse of the matrix C. Similar methods have been used in least-squares linear regression for many years, (e.g., Stone, 1974; Weisberg, 1985). While the optimal model parameters of the kernel machine are given by the solution of a simple system of linear equations, (3), some form of model selection is required to determine good values for the *hyper-parameters*, $\theta = (\lambda, \eta)$, in order to maximise generalisation performance. The analytic leave-one-out cross-validation procedure described here can easily be adapted to form the basis of an efficient model selection strategy (cf. Chapelle et al., 2002; Cawley and Talbot, 2003; Bo et al., 2006). In order to obtain a continuous model selection criterion, we adopt Allen's Predicted REsidual Sum-of-Squares (PRESS) statistic (Allen, 1974),

$$\text{PRESS}(\theta) = \sum_{i=1}^{\ell} \left[r_i^{(-i)} \right]^2.$$

The PRESS criterion can be optimised efficiently using scaled conjugate gradient descent (Williams, 1991) or Nelder-Mead simplex (Nelder and Mead, 1965) procedures. For full details of the training and model selection procedures for the kernel ridge regression classifier, see Cawley (2006). A public domain MATLAB implementation of the kernel ridge regression classifier, including automated model selection, is provided by the Generalised Kernel Machine (GKM) (Cawley et al., 2007) toolbox.[2]

3. Data Sets used in Empirical Demonstrations

In this section, we describe the benchmark data sets used in this study to illustrate the problem of over-fitting in model selection and to demonstrate the bias this can introduce into performance evaluation.

3.1 A Synthetic Benchmark

A synthetic benchmark, based on that introduced by Ripley (1996), is used widely in the next section to illustrate the nature of over-fitting in model selection. The data are drawn from four spherical bivariate Gaussian distributions, with equal probability. All four Gaussians have a common variance, $\sigma^2 = 0.04$. Patterns belonging to the positive classes are drawn from Gaussians centered on $[+0.4, +0.7]$ and $[-0.3, +0.7]$; the negative patterns are drawn from Gaussians centered on $[-0.7, +0.3]$ and $[+0.3, +0.3]$. Figure 1 shows a realisation of the synthetic benchmark, consisting of 256 patterns, showing the Bayes-optimal decision boundary and contours representing an a-posteriori probability of belonging to the positive class of 0.1 and 0.9. The Bayes error for this benchmark is approximately 12.38%. This benchmark is useful firstly as the Bayes optimal decision boundary is known, but also because it provides an inexhaustible supply of data, allowing the numerical approximation of various expectations.

3.2 A Suite of Benchmarks for Robust Performance Evaluation

In addition to illustrating the nature of over-fitting in model selection, we need to demonstrate that it is a serious concern in practical applications and show that it can result in biased performance evaluation if not taken into consideration. Table 1 gives the details of a suite of thirteen benchmark data sets, introduced by Rätsch et al. (2001). Each benchmark is based on a data set from the UCI machine learning repository, augmented by a set of 100 pre-defined partitions to form multiple realisations of the training and test sets (20 in the case of the larger `image` and `splice` data sets). The use of multiple benchmarks means that the evaluation is more robust as the selection of data sets that provide a good match to the inductive bias of a particular classifier becomes less likely. Likewise, the use of multiple partitions provides robustness against sensitivity to the sampling of data to form training and test sets. Results on this suite of benchmarks thus provides a reasonable indication of the magnitude of the effects of over-fitting in model selection that we might expect to see in practice.

Table 1: Details of data sets used in empirical comparison.

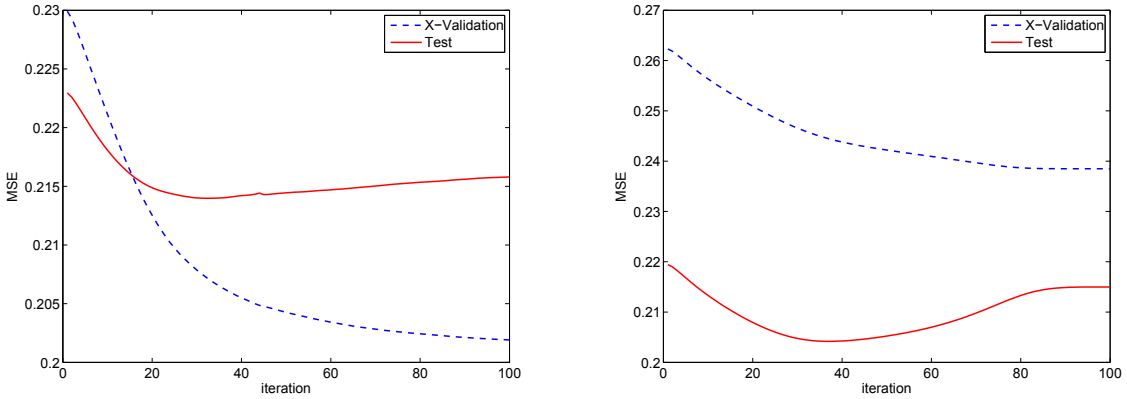
4. Over-fitting in Model Selection

We begin by demonstrating that it is possible to over-fit a model selection criterion based on a finite sample of data, using the synthetic benchmark problem, where ground truth is available. Here we use "over-fitting in model selection" to mean minimisation of the model selection criterion beyond the point at which generalisation performance ceases to improve and subsequently begins to decline.

Figure 1 (b) shows the output of a kernel ridge regression classifier for the synthetic problem, with the Automatic Relevance Determination (ARD) variant of the Gaussian radial basis function kernel,

$$\mathcal{K}(x,x') = \exp\left\{-\sum_{i=1}^{d} \eta_i (x_i - x_i')^2\right\},$$

which has a separate scaling parameter, η_i, for each feature. A much larger training set of 4096 samples was used, and the hyper-parameters were tuned to minimise the true test mean squared errors (MSE). The performance of this model achieved an error rate of 12.50%, which suggests that a model of this form is capable of approaching the Bayes error rate for this problem, at least in principle, and so there is little concern of model mis-specification.



(a) (b)

Figure 2: Evolution of the expected four-fold cross-validation and true test mean squared error as a function of the number of iterations (optimisation steps in the minimisation of the model selection criterion) of the model selection process, for a kernel ridge regression classifier trained on the `synthetic` benchmark data set (a) and (b) the evolution of those statistics for a particular realisation of the data set.

A further one thousand independent realisations of this benchmark were generated, each consisting of 64 samples. A kernel ridge regression classifier, based on the ARD kernel, was constructed for each realisation, with the hyper-parameters tuned so as to minimise a four-fold cross-validation estimate of the mean squared error. The true generalisation performance of each model was estimated numerically using the underlying generative model of the data set. Figure 2 (a) shows the expected true test and cross-validation estimates of the mean squared error averaged over all 1000 realisations of the benchmark. As would be expected, the cross-validation estimate of the mean squared error, forming the model selection criterion, is monotonically decreasing. However, the expected value of the true test MSE initially shows a decrease, as the hyper-parameters are modified in a manner that provides genuine improvements in generalisation, but after a relatively short time (approximately 30–40 iterations), the test error begins to climb slowly once more as the hyper-parameters are tuned in ways that exploit the meaningless statistical peculiarities of the sample. This produces a close analog of the classic plot used to illustrate the nature of over-fitting in training, for example, Figure

9.7 of the book by Bishop (1995). Figure 2 (b) shows the same statistics for one particular realisation of the data, demonstrating that the over-fitting can in some cases be quite substantial, clearly in this case some form of early-stopping in the model selection process would have resulted in improved generalisation. Having demonstrated that the classic signature of over-fitting during training is also apparent in the evolution of cross-validation and test errors during model selection, we discuss in the next section the origin of this form of over-fitting in terms of the *bias* and *variance* of the model selection criterion.

4.1 Bias and Variance in Model Selection

Model selection criteria are generally based on an estimator of generalisation performance evaluated over a finite sample of data, this includes resampling methods, such as split sample estimators, cross-validation (Stone, 1974) and bootstrap methods (Efron and Tibshirani, 1994), but also more loosely, the Bayesian evidence (MacKay, 1992; Rasmussen and Williams, 2006) and theoretical performance bounds such as the radius-margin bound (Vapnik, 1998). The error of an estimator can be decomposed into two components, *bias* and *variance*. Let $G(\theta)$ represent the true generalisation performance of a model with hyper-parameters θ, and $g(\theta;\mathcal{D})$ be an estimate of generalisation performance evaluated over a finite sample, $\mathcal{D}$, of n patterns. The expected squared error of the estimator can then be written in the form (Geman et al., 1992; Duda et al., 2001),

$$E_{\mathcal{D}}\left\{[g(\theta;\mathcal{D})-G(\theta)]^2\right\} = [E_{\mathcal{D}}\{g(\theta;\mathcal{D})-G(\theta)\}]^2 + E_{\mathcal{D}}\left\{\left[g(\theta;\mathcal{D})-E_{\mathcal{D}'}\left\{g(\theta;\mathcal{D}')\right\}\right]^2\right\},$$

where $E_{\mathcal{D}}\{\cdot\}$ represents an expectation evaluated over independent samples, $\mathcal{D}$, of size n. The first term, the squared *bias*, represents the difference between the expected value of the estimator and the unknown value of the true generalisation error. The second term, known as the *variance*, reflects the variability of the estimator around its expected value due to the sampling of the data $\mathcal{D}$ on which it is evaluated. Clearly if the expected squared error is low, we may reasonably expect $g(\cdot)$ to perform well as a model selection criterion. However, in practice, the expected squared error may be significant, in which case, it is interesting to ask whether the bias or the variance component is of greatest importance in reliably achieving optimal generalisation.

It is straightforward to demonstrate that leave-one-out cross-validation provides an almost unbiased estimate of the true generalisation performance (Luntz and Brailovsky, 1969), and this is often cited as being an advantageous property of the leave-one-out estimator in the setting of model selection (e.g., Vapnik, 1998; Chapelle et al., 2002). However, for the purpose of model selection, rather than performance evaluation, unbiasedness *per se* is relatively unimportant, instead the primary requirement is merely for the minimum of the model selection criterion to provide a reliable indication of the minimum of the true test error in hyper-parameter space. This point is illustrated in Figure 3, which shows a hypothetical example of a model selection criterion that is unbiased (by construction) (a) and another that is clearly biased (b). Unbiasedness provides the assurance that the minimum of the expected value of the model selection criterion, $E_{\mathcal{D}}\{g(\theta;\mathcal{D})\}$ coincides with the minimum of the test error, $G(\theta)$. However, in practice, we have only a finite sample of data, $\mathcal{D}_i$, over which to evaluate the model selection criterion, and so it is the minimum of $g(\theta;\mathcal{D}_i)$ that is of interest. In Figure 3 (a), it can be seen that while the estimator is unbiased, it has a high variance, and so there is a large spread in the values of θ at which the minimum occurs for different samples of data, and so $g(\theta;\mathcal{D}_i)$ is likely to provide a poor model selection criterion in practice. On the other hand, Figure 3 (b) shows a criterion with lower variance, and hence is the better model selection

criterion, despite being biased, as the minima of $g'(\theta;\mathcal{D}_i)$ for individual samples lie much closer to the minimum of the true test error. This demonstrates that while unbiasedness is reassuring, as it means that the form of the model selection criterion is correct *on average*, the variance of the criterion is also vitally important as it is this that ensures that the minimum of the selection criterion evaluated on a particular sample will provide good generalisation.

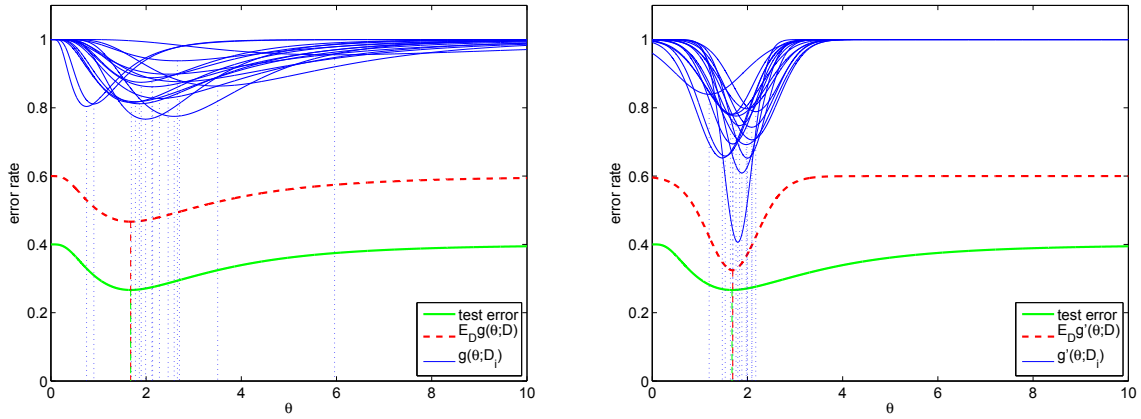


Figure 3: Hypothetical example of an unbiased (a) and a biased (b) model selection criterion. Note that the biased model selection criterion (b) is likely to provide the more effective model selection criterion as it has a lower variance, even though it is significantly biased. For clarity, the true error rate and the expected value of the model selection criteria are shown with vertical displacements of -0.6 and -0.4 respectively.

4.2 The Effects of Over-fitting in Model Selection

In this section, we investigate the effect of the variance of the model selection criterion using a more realistic example, again based on the `synthetic` benchmark, where the underlying generative model is known and so we are able to evaluate the true test error. It is demonstrated that over-fitting in model selection can cause both under-fitting and over-fitting of the training sample. A fixed training set of 256 patterns is generated and used to train a kernel ridge regression classifier, using the simple RBF kernel (1), with hyper-parameter settings defining a fine grid spanning reasonable values of the regularisation and kernel parameters, λ and η respectively. The smoothed error rate (Bo et al., 2006),

$$\mathrm{SER}(\theta) = \frac{1}{2n}\sum_{i=1}^{n}\left[1 - y_i \tanh\left\{\gamma f(x_i)\right\}\right]$$

is used as the statistic of interest, in order to improve the clarity of the figures, where γ is a parameter controlling the amount of smoothing applied ($\gamma = 8$ is used throughout, however the precise value is not critical). Figure 4 (a) shows the true test smoothed error rate as a function of the hyper-parameters. As these are both scale parameters, a logarithmic representation is used for both axes. The true test smoothed error rate is an approximately unimodal function of the hyper-parameters,

with a single distinct minimum, indicating the hyper-parameter settings giving optimal generalisation.

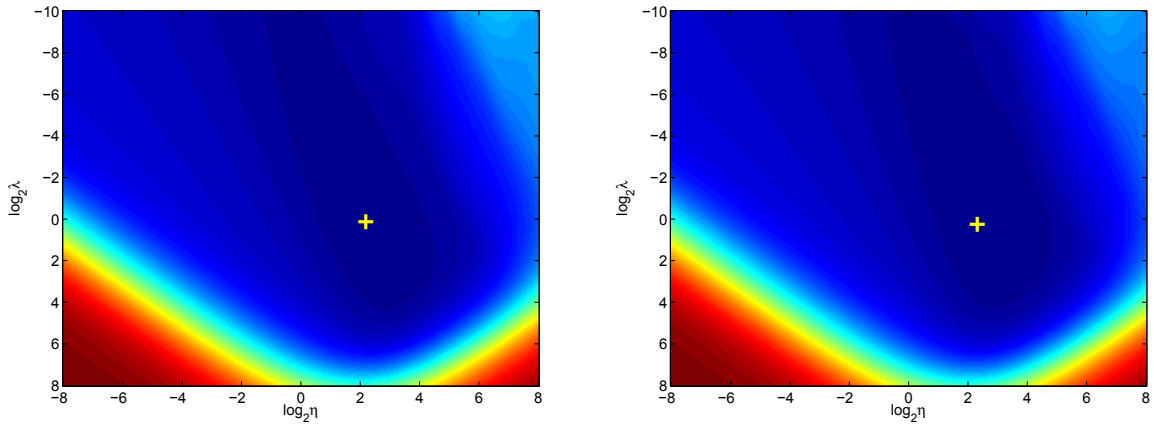

Figure 4: Plot of the true test smoothed error rate (a) and mean smoothed error rate over 100 random validation sets of 64 samples (b), for a kernel ridge regression classifier as a function of the hyper-parameters. In each case, the minimum is shown by a yellow cross, $+$.

In practical applications, however, the true test error is generally unknown, and so we must rely on an estimator of some sort. The simplest estimator for use in model selection is the error computed over an independent validation set, that is, the split-sample estimator. It seems entirely reasonable to expect the split-sample estimator to be unbiased. Figure 4 (b) shows a plot of the mean smoothed error rate using the split-sample estimator, over 100 random validation sets, each of which consists of 64 patterns. Note that the same fixed training set is used in each case. This plot is very similar to the true smoothed error, shown in Figure 4 (a), demonstrating that the split sample estimator is indeed approximately unbiased.

While the split-sample estimator is unbiased, it may have a high variance, especially as in this case the validation set is (intentionally) relatively small. Figure 5 shows plots of the split-sample estimate of the smoothed error rate for six selected realisations of a validation set of 64 patterns. Clearly, the split-sample error estimate is no longer as smooth, or indeed unimodal. More importantly, the hyper-parameter values selected by minimising the validation set error, and therefore the true generalisation performance, depends on the particular sample of data used to form the validation set. Figure 6 shows that the variance of the split-sample estimator can result in models ranging from severely under-fit (a) to severely over-fit (f), with variations in between these extremes.

Figure 7 (a) shows a scatter plot of the validation set and true error rates for kernel ridge regression classifiers for the synthetic benchmark, with split-sample based model selection using 100 random realisations of the validation set. Clearly, the split-sample based model selection procedure normally performs well. However, there is also significant variation in performance with different samples forming the validation set. We can also see that the validation set error is strongly biased, having been directly minimised during model selection, and (of course) should not be used for performance estimation.

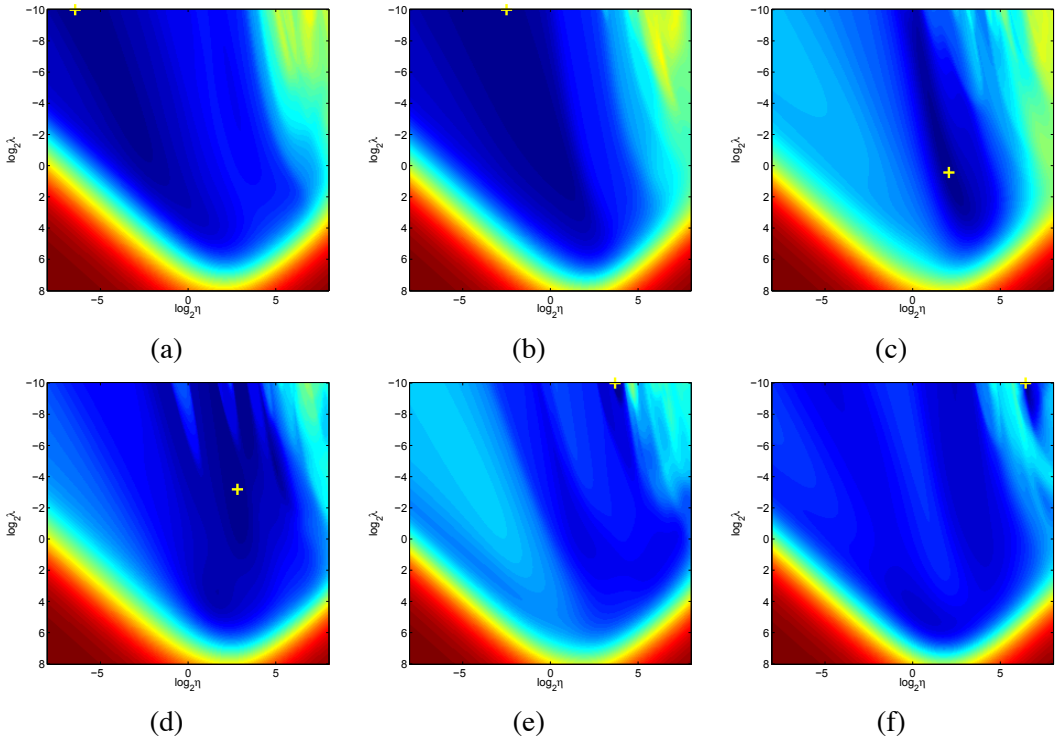

Figure 5: Contour plot of the split-sample estimate of the smoothed error rate for a kernel ridge regression machine as a function of the hyper-parameters, for six random realisations of the validation set. The minimum is shown by a cross, $+$.

Note that in this section we have deliberately employed a split-sample based model selection strategy with a relatively high variance, due to the limited size of the validation set. A straightforward way to reduce the variance of the model selection criterion is simply to increase the size of the validation sample over which it is evaluated. Figure 8 shows the optimal hyper-parameter settings obtained using 100 realisations of validation sets of 64 (a) and 256 (b) samples. It can be clearly seen that the use of a larger validation set has resulted in a tighter clustering of hyper-parameter values around the true optimum, note also that the hyper-parameters are concentrated along the bottom of a broad valley in hyper-parameter space, so even when the selected values are different from the optimal value, they still lie in positions giving good generalisation. This is further illustrated in Figure 7 (b), where the true smoothed error rates are much more tightly clustered, with fewer outliers, for the larger validation sets than obtained using smaller validation sets, shown in Figure 7 (a).

The variation in performance for different realisations of the benchmark suggests that evaluation of machine learning algorithms should always involve multiple partitions of the data to form training/validation and test sets, as the sampling of data for a single partition of the data might arbitrarily favour one classifier over another. This is illustrated in Figure 9, which shows the test error rates for Gaussian Process and Kernel Logistic Regression classifiers (GPC and KLR respectively), for 100

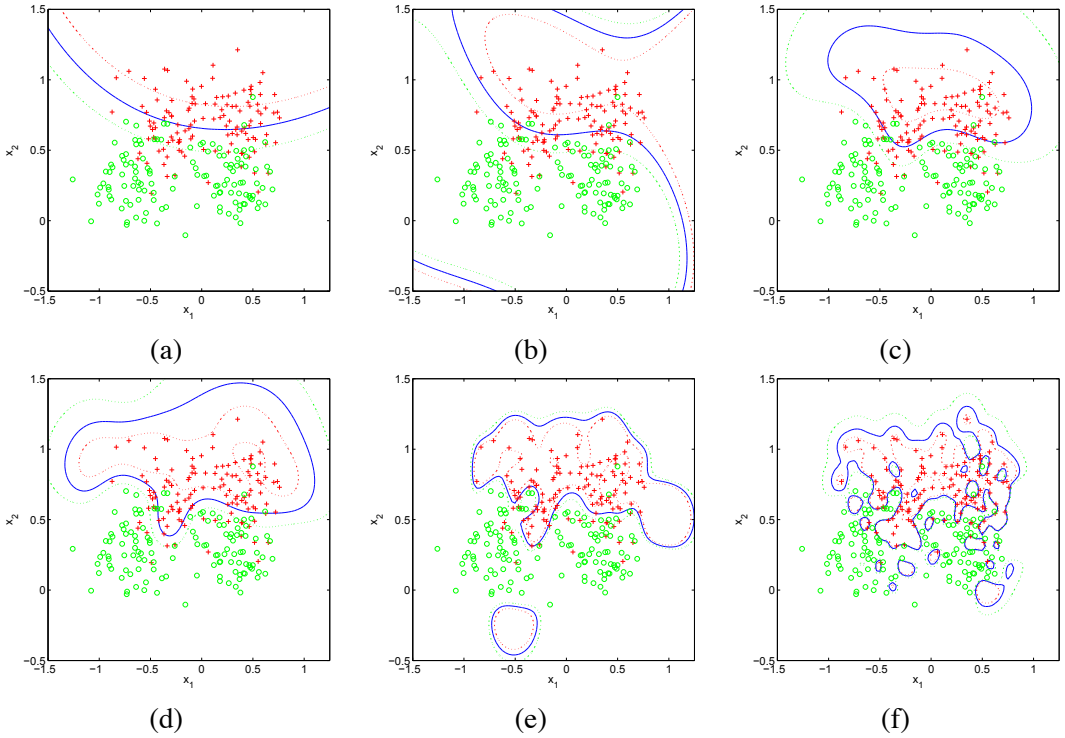

Figure 6: Kernel ridge regression models of the synthetic benchmark, using hyper-parameters selected according to the smoothed error rate over six random realisations of the validation set (shown in Figure 5). The variance of the model selection criterion can result in models ranging from under-fit, (a) and (b), through well-fitting, (c) and (d), to over-fit (e) and (f).

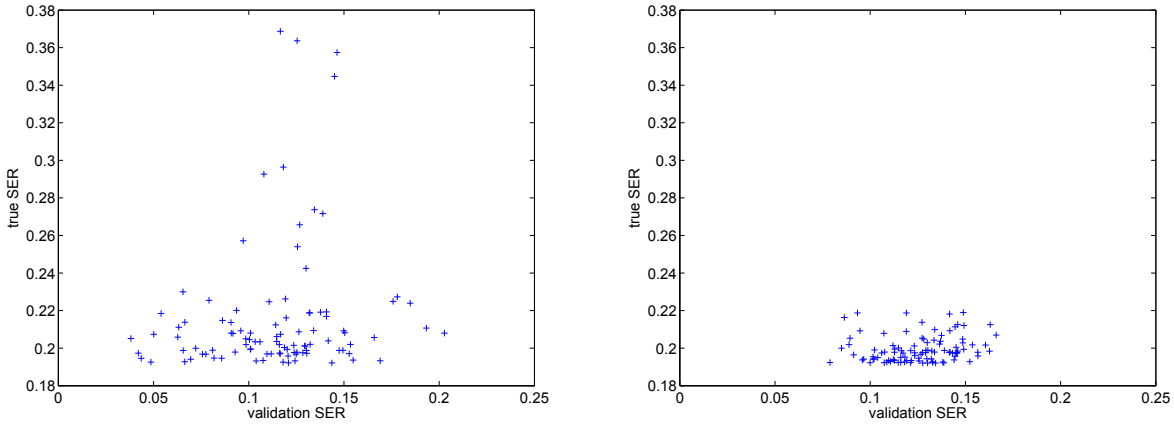
random realisations of the `banana` benchmark data set used in Rätsch et al. (2001) (see Section 5.1 for details). On 64 realisations of the data GPC out-performs KLR, but on 36 KLR out-performs GPC, even though the GPC is better on average (although the difference is not statistically significant in this case). If the classifiers had been evaluated on only one of the latter 36 realisations, it might incorrectly be concluded that the KLR classifier is superior to the GPC for that benchmark. However, it should also be noted that a difference in performance between two algorithms is unlikely to be of *practical* significance, even if it is *statistically* significant, if it is smaller than the variation in performance due to the random sampling of the data, as it is probable that a greater improvement in performance would be obtained by further data collection than by selection of the optimal classifier.

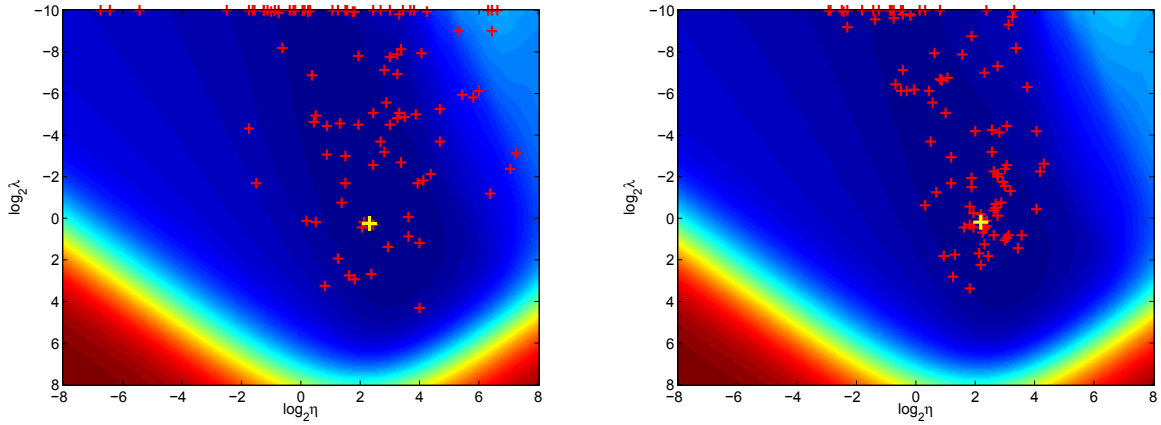
4.3 Is Over-fitting in Model Selection Really a Genuine Concern in Practice?

In the preceding part of this section we have demonstrated the deleterious effects of the variance of the model selection criterion using a synthetic benchmark data set, however this is not sufficient to establish that over-fitting in model selection is actually a genuine concern in practical applications or in the development of machine learning algorithms. Table 2 shows results obtained using



(a) (b)

Figure 7: Scatter plots of the true test smoothed error rate as a function of the validation set smoothed error rate for 100 randomly generated validation sets of (a) 64 and (b) 256 patterns.



(a) (b)

Figure 8: Contour plot of the mean validation set smoothed error rate over 100 randomly generated validation sets of (a) 64 and (b) 256 patterns. The minimum of the mean validation set error is marked by a large (yellow) cross, and the minimum for each realisation of the validation set marked by a small (red) cross.

kernel ridge regression (KRR) classifiers, with RBF and ARD kernel functions over the thirteen benchmarks described in Section 3.2. In each case, model selection was performed independently for each realisation of each benchmark by minimising the PRESS statistic using the Nelder-Mead simplex method (Nelder and Mead, 1965). For the majority of the benchmarks, a significantly lower

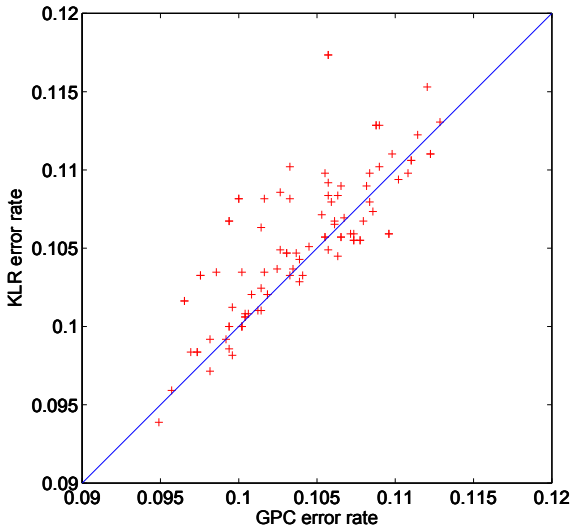


Figure 9: Scatter plots of the test set error for Gaussian process and Kernel Logistic regression classifiers (GPC and KLR respectively) for 100 realisations of the `banana` benchmark.

test error is achieved (according to the Wilcoxon signed ranks test) using the basic RBF kernel; the ARD kernel only achieves statistical superiority on one of the thirteen (`image`). This is perhaps a surprising result as the models are nested, the RBF kernel being a special case of the ARD kernel, so the optimal performance that can be achieved with the ARD kernel is guaranteed to be at least equal to the performance achievable using the RBF kernel. The reason for the poor performance of the ARD kernel in practice is because there are many more kernel parameters to be tuned in model selection and so many degrees of freedom available in optimising the model selection criterion. If the criterion used has a non-negligible variance, this includes optimisations exploiting the statistical peculiarities of the particular sample of data over which it is evaluated, and hence there will be more scope for over-fitting. Table 2 also shows the mean value of the PRESS statistic, following model selection, the fact that the majority of ARD models display a lower value for the PRESS statistic than the corresponding RBF model, while exhibiting a higher test error rate, is a strong indication of over-fitting the model selection criterion. This is a clear demonstration that over-fitting in model selection can be a significant problem in practical applications, especially where there are many hyper-parameters or where only a limited supply of data is available.

Table 3 shows the results of the same experiment performed using expectation-propagation based Gaussian process classifiers (EP-GPC) (Rasmussen and Williams, 2006), where the hyper-parameters are tuned independently for each realisation, for each benchmark individually by maximising the Bayesian evidence. While the leave-one-out cross-validation based PRESS criterion is known to exhibit a high variance, the variance of the evidence (which is also evaluated over a finite sample of data) is discussed less often. We find again here that the RBF covariance function often out-performs the more general ARD covariance function, and again the test error rate is often negatively correlated with the evidence for the models. This indicates that over-fitting the evidence is also a significant practical problem for the Gaussian process classifier.

Results shown in bold indicate an error rate that is statistically superior to that obtained with the same classifier using the other kernel function or evidence that is significantly higher.

4.4 Avoiding Over-fitting in Model Selection

It seems reasonable to suggest that over-fitting in model selection is possible whenever a model selection criterion evaluated over a finite sample of data is directly optimised. Like over-fitting in training, over-fitting in model selection is likely to be most severe when the sample of data is small and the number of hyper-parameters to be tuned is relatively large. Likewise, assuming additional data are unavailable, potential solutions to the problem of over-fitting the model selection criterion are likely to be similar to the tried and tested solutions to the problem of over-fitting the training criterion, namely regularisation (Cawley and Talbot, 2007), early stopping (Qi et al., 2004) and model or hyper-parameter averaging (Cawley, 2006; Hall and Robinson, 2009). Alternatively, one might minimise the number of hyper-parameters, for instance by treating kernel parameters as simply parameters and optimising them at the first level of inference and have a single regularisation hyper-parameter controlling the overall complexity of the model. For very small data sets, where the problem of over-fitting in both learning and model selection is greatest, the preferred approach would be to eliminate model selection altogether and opt for a fully Bayesian approach, where the hyper-parameters are integrated out rather than optimised (e.g., Williams and Barber, 1998). Another approach is simply to avoid model selection altogether using an ensemble approach, for example the Random Forest (RF) method (Breiman, 2001). However, while such methods often achieve state-of-the-art performance, it is often easier to build expert knowledge into hierarchical models, for example through the design of kernel or covariance functions, so unfortunately approaches such as the RF are not a panacea.

While the problem of over-fitting in model selection is of the same nature as that of over-fitting at the first level of inference, the lack of mathematical tractability appears to have limited the theoretical analysis of model selection via optimisation of a model selection criterion. For example, regarding leave-one-out cross-validation, Kulkarni et al. (1998) comment "In spite of the practical importance of this estimate, relatively little is known about its properties. *The available theory is especially poor when it comes to analysing parameter selection based on minimizing the deleted estimate*." (our emphasis). While some asymptotic results are available (Stone, 1977; Shao, 1993; Toussaint, 1974), these are not directly relevant to the situation considered here, where over-fitting occurs due to optimising the values of hyper-parameters using a model selection criterion evaluated over a finite, often quite limited, sample of data. Estimates of the variance of the cross-validation error are available for some models (Luntz and Brailovsky, 1969; Vapnik, 1982), however Bengio and Grandvalet (2004) have shown there is no unbiased estimate of the variance of (k-fold) cross-validation. More recently bounds on the error of leave-one-out cross-validation based on the idea of *stability* have been proposed (Kearns and Ron, 1999; Bousquet and Elisseeff, 2002; Zhang, 2003). In this section, we have demonstrated that over-fitting in model selection is a genuine problem in machine learning, and hence is likely to be an area that could greatly benefit from further theoretical analysis.

5. Bias in Performance Estimation

Avoiding potentially significant bias in performance evaluation, arising due to over-fitting in model selection, is conceptually straightforward. The key is to treat both training *and* model selection together, as integral parts of the model fitting procedure and ensure they are never performed separately at any point of the evaluation process. We present two examples of potentially biased evaluation protocols that do not adhere to this principle. The scale of the bias observed on some data sets

is much larger than the difference in performance between learning algorithms, and so one could easily draw incorrect inferences based on the results obtained. This highlights the importance of this issue in empirical studies. We also demonstrate that the magnitude of the bias depends on the learning and model selection algorithms involved in the comparison and that combinations that are more prone to over-fitting in model selection are favored by biased protocols. This means that studies based on potentially biased protocols are not internally consistent, even if it is acknowledged that a bias with respect to other studies may exist.

5.1 An Unbiased Performance Evaluation Methodology

We begin by describing an unbiased performance protocol, that correctly accounts for any over-fitting that may occur in model selection. Three classifiers are evaluated using an unbiased protocol, in which model selection is performed separately for each realisation of each data set. This is termed the "internal" protocol as the model selection process is performed independently within each fold of the resampling procedure. In this way, the performance estimate includes a component properly accounting for the error introduced by over-fitting the model selection criterion. The classifiers used were as follows: RBF-KRR—kernel ridge regression with a radial basis function kernel, with model selection based on minimisation of Allen's PRESS statistic, as described in Section 2. RBF-KLR—kernel logistic regression with a radial basis function kernel and model selection based on an approximate leave-one-out cross-validation estimate of the log-likelihood (Cawley and Talbot, 2008). EP-GPC—expectation-propagation based Gaussian process classifier, with an isotropic squared exponential covariance function, with model selection based on maximising the marginal likelihood (e.g., Rasmussen and Williams, 2006). The mean error rates obtained using these classifiers under an unbiased protocol are shown in Table 4. In this case, the mean ranks of all methods are only minimally different, and so there is little if any evidence for a statistically significant superiority of any of the classifiers over any other. Figure 10 shows a critical difference diagram (Demšar, 2006), providing a graphical illustration of this result. A critical difference diagram displays the mean rank of a set of classifiers over a suite of benchmark data sets, with cliques of classifiers with statistically similar performance connected by a bar. The critical difference in average ranks required for a statistical superiority of one classifier over another is also shown, labelled "CD".

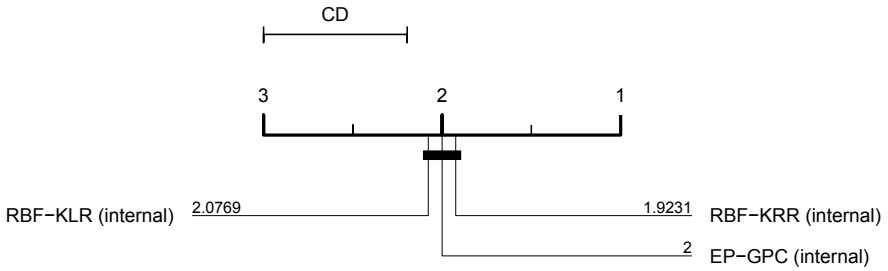

Figure 10: Critical difference diagram (Demšar, 2006) showing the average ranks of three classifiers with internal model selection protocol.

Data Set	GPC (internal)	KLR (internal)	KRR (internal)

waveform	10.100 ± 0.047	9.918 ± 0.043	9.792 ± 0.045

Table 4: Error rate estimates of three classifiers over a suite of thirteen benchmark data sets: The results for each method are presented in the form of the mean error rate over test data for 100 realisations of each data set (20 in the case of the `image` and `splice` data sets), along with the associated standard error.

It is not unduly surprising that there should be little evidence for any statistically significant superiority, as all three methods give rise to structurally similar models. The models though differ significantly in their model selection procedures, the EP-GPC is based on stronger statistical assumptions, and so can be expected to excel where these assumptions are justified, but poorly where the model is mis-specified (e.g., the ringnorm benchmark). The cross-validation based model selection procedures, on the other hand, are more pragmatic and being based on much weaker assumptions might be expected to provide a more consistent level of accuracy.

5.2 An Example of Biased Evaluation Methodology

The performance evaluation protocol most often used in conjunction with the suite of benchmark data sets, described in Section 3.2, seeks to perform model selection independently for only the first five realisations of each data set. The median values of the hyper-parameters over these five folds are then determined and subsequently used to evaluate the error rates for each realisation. This "median" performance evaluation protocol was introduced in the same paper that popularised this suite of benchmark data sets (Rätsch et al., 2001) and has been widely adopted (e.g., Mika et al., 1999; Weston, 1999; Billings and Lee, 2002; Chapelle et al., 2002; Chu et al., 2003; Stewart, 2003; Mika et al., 2003; Gold et al., 2005; Peña Centeno and D., 2006; Andelić et al., 2006; An et al., 2007; Chen et al., 2009). The original motivation for this protocol was that the internal model selection protocol was prohibitively expensive using workstations available (Rätsch et al., 2001), which was perfectly reasonable at the time, but is no longer true.[3] The use of the median, however, can be expected to introduce an optimistic bias into the performance estimates obtained using this "median" protocol. Firstly all of the training data comprising the first five realisations have been

3. All of the experimental results presented in this paper were obtained using a single modern Linux workstation.

Data Set	KRR (internal)	KRR (median)	Bias
banana	10.610 ± 0.051	10.384 ± 0.042	0.226 ± 0.034
breast cancer	26.727 ± 0.466	26.377 ± 0.441	0.351 ± 0.195

waveform	9.792 ± 0.045	9.821 ± 0.039	-0.029 ± 0.020

Table 5: Error rate estimates of three classifiers over a suite of thirteen benchmark data sets: The results for each method are presented in the form of the mean error rate over test data for 100 realisations of each data set (20 in the case of the image and splice data sets), along with the associated standard error.

used during the model selection process for the classifiers used in every fold of the re-sampling. This means that some of the test data for each fold is no longer statistically "pure" as it has been seen during model selection. Secondly, and more importantly, the median operation acts as a variance reduction step, so the median of the five sets of hyper-parameters is likely to be better on average than any of the five from which it is derived. Lastly, as the hyper-parameters are now fixed, there is no longer scope for over-fitting the model selection criterion due to peculiarities of the sampling of data for the training and test partitions in each realisation.

We begin by demonstrating that the results using the internal and median protocols are not commensurate, and so the results obtained using different methods are not directly comparable. Table 5 shows the error rate obtained using the RBF-KRR classifier with the internal and median performance evaluation protocols and the resulting bias, that is, the difference between the mean error rates obtained with the internal and median protocols. It is clearly seen that the median protocol introduces a positive bias on almost all benchmarks (`twonorm` and `waveform` being the exceptions) and that the bias can be quite substantial on some benchmarks. Indeed, for several benchmarks, `breast cancer`, `german`, `heart` and `thyroid` in particular, the bias is larger than the typical difference in performance between classifiers evaluated using an unbiased protocol. Demšar (2006) recommends the Wilcoxon signed ranks test for determination of the statistical significance of the superiority of one classifier over another over multiple data sets. Applying this test to the data shown for EP-GPC (internal), RBF-KLR (internal) and RBF-KRR (median), from Tables 4 and 5, reveals that the RBF-KRR (median) classifier is statistically superior to the remaining classifiers, at the 95% level of significance. A critical difference diagram summarising this result is shown in Figure 12. However, the difference in performance is entirely spurious as it is purely the result of reducing the effects of over-fitting in model selection and does not reflect the true operational performance of the combination of classifier and model selection method. It is clear then that results obtained using

the internal and median protocols are not directly comparable, and so reliable inferences cannot be drawn by comparison of results from different studies, using biased and unbiased protocols.

5.2.1 IS THE BIAS SOLELY DUE TO INADVERTENT RE-USE OF TEST SAMPLES?

One explanation for the observed bias of the median protocol is that some of the training samples for the first five realisations of the benchmark, which have been used in tuning the hyper-parameters, also appear in the test sets for other realisations of the benchmark used for performance analysis. In this section, we demonstrate that this inadvertent re-use of test samples is not the only cause of the bias. One hundred replications of the internal and median protocol were performed using the `synthetic` benchmark, for which an inexhaustible supply of i.i.d. data is available. However, in this case in each realisation, 100 training sets of 64 patterns and a large test set of 4096 samples were generated, all mutually disjoint. This means the only remaining source of bias is the amelioration of over-fitting in model selection by the reduction of variance by taking the median of the hyper-parameters over the first five folds (cf. Hall and Robinson, 2009). Figure 11 shows the mean test errors for the internal and median protocols over 100 replications, showing a very distinct optimistic bias in the median protocol (statistically highly significant according to the Wilcoxon signed ranks test, $p < 0.001$), even though there is absolutely no inadvertent re-use of test data.

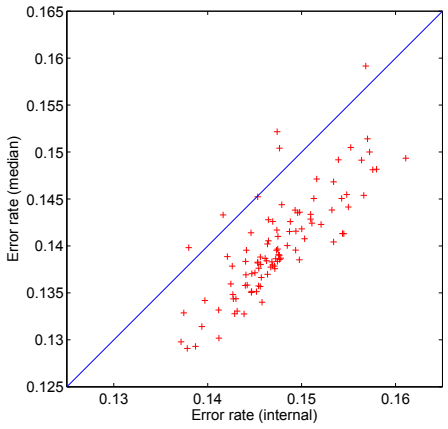

Figure 11: Mean error rates for the internal and median evaluation protocols for the `synthetic` benchmark, without inadvertent re-use of test data.

5.2.2 IS THE MEDIAN PROTOCOL INTERNALLY CONSISTENT?

Having established that the median protocol introduces an optimistic bias, and that the results obtained using the internal and median protocols do not give comparable results, we next turn our attention to whether the median protocol is internally consistent, that is, does the median protocol give the correct rank order of the classifiers? Table 6 shows the performance of three classifiers evaluated using the median protocol; the corresponding critical difference diagram is shown in Figure 13. In this case the difference in performance between classifiers is not statistically significant according to the Friedman test, however it can clearly be seen that the bias of the median protocol

Table 6: Error rate estimates of three classifiers over a suite of thirteen benchmark data sets: The results for each method are presented in the form of the mean error rate over test data for 100 realisations of each data set (20 in the case of the image and splice data sets), along with the associated standard error.

has favored one classifier, namely the RBF-KRR, much more strongly than the others. It seems feasible then that the bias of the median protocol may be sufficient in other cases to amplify a small difference in performance, due perhaps to an accidentally favorable choice of data sets, to the point where it spuriously appears to be statistically significant. This suggests that the median protocol may be unreliable and perhaps should be deprecated.

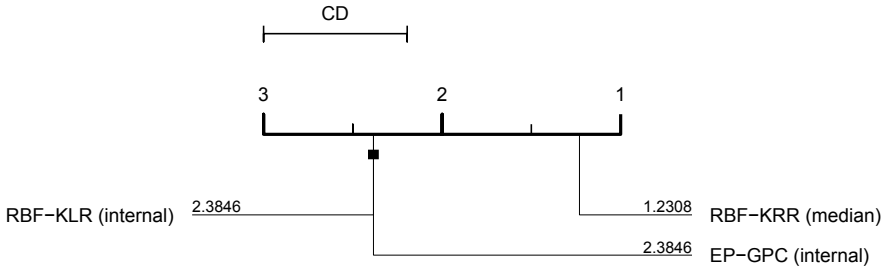

Figure 12: Critical difference diagram (Demšar, 2006) showing the average ranks of three classifiers, EP-GPC and RBF-KLR with internal model selection protocol and RBF-KLR using the optimistically biased median protocol (cf. Figure 10).

Next, we perform a statistical analysis to determine whether there is a statistically significant difference in the magnitude of the biases introduced by the median protocol for different classifiers,

Data Set	RBF-KRR bias	RBF-EP-GPC bias	Wilcoxon p-value
banana	0.226 ± 0.034	0.043 ± 0.012	< 0.05
breast cancer	0.351 ± 0.195	0.390 ± 0.186	0.934
diabetis	0.143 ± 0.074	-0.053 ± 0.051	< 0.05
flare solar	0.128 ± 0.082	0.050 ± 0.090	0.214
german	0.160 ± 0.067	0.203 ± 0.051	0.458
heart	1.010 ± 0.186	0.270 ± 0.120	< 0.05
image	0.188 ± 0.095	-0.035 ± 0.032	0.060
ringnorm	0.040 ± 0.010	0.006 ± 0.002	< 0.05
splice	0.014 ± 0.055	0.002 ± 0.014	0.860
thyroid	0.187 ± 0.100	0.067 ± 0.064	0.159
titanic	0.076 ± 0.077	0.147 ± 0.090	0.846
twonorm	-0.022 ± 0.014	-0.180 ± 0.032	< 0.05
waveform	-0.029 ± 0.020	-0.064 ± 0.022	0.244

Table 7: Results of a statistical analysis of the bias introduced by the median protocol into the test error rates for RBF-KRR and RBF-EP-GPC, using the Wilcoxon signed ranks test.

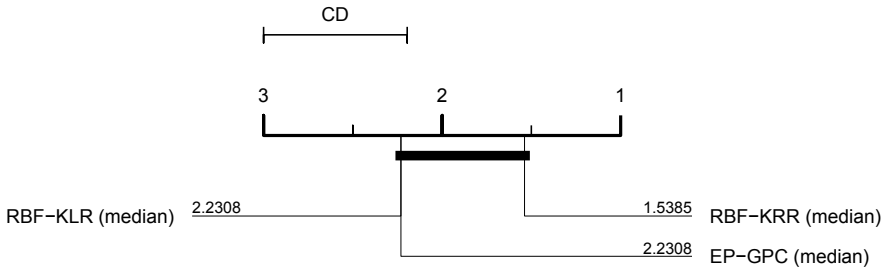

Figure 13: Critical difference diagram showing the average ranks of three classifiers with the median model selection protocol (cf. Figure 10).

for each benchmark data set.[4] First the bias introduced by the use of the median protocol was computed for the RBF KRR and RBF EP-GPC classifiers as the difference between the test set error estimated by the internal and median protocols. The Wilcoxon signed rank test was then used to determine whether there is a statistically significant difference in the bias, over the 100 realisations of the benchmark (20 in the case of the `image` and `splice` benchmarks) . The results obtained are shown in Table 7, the p-value is below 0.05 for five of the thirteen benchmarks, indicating that in each case the median protocol is significantly biased in favour of the RBF KRR classifier. Clearly, as the median protocol does not impose a commensurate bias on the estimated test error rates for different classifiers, it does not provide a reliable protocol for comparing the performance of machine learning algorithms.

4. We are grateful to an anonymous reviewer for suggesting this particular form of analysis.

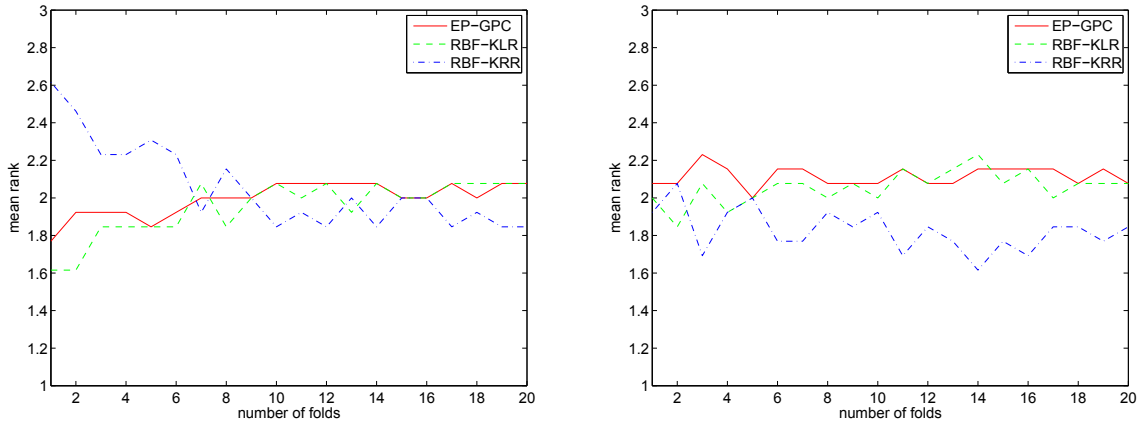

Figure 14: Mean ranks of three classifiers as a function of the number of folds used in the repeated split sample model selection procedure employed by the kernel ridge regression (RBF-KRR) machine, using (a) the unbiased *internal* protocol and (b) the biased *median* protocol.

In the final illustration of this section, we show that the magnitude of the bias introduced by the median protocol is greater for model selection criteria with a high variance. This means the median protocol favors most the least reliable model selection procedures and as a result does not provide a reliable indicator even of relative performance of classifier-model selection procedures combinations. Again the RBF-KRR model is used as the base classifier, however in this case a repeated split-sample model selection criterion is used, where the data are repeatedly split at random to form disjoint training and validation sets in proportions 9:1, and the hyper-parameters tuned to optimise the average mean-squared error over the validation sets. In this way, the variance of the model selection criterion can be controlled by varying the number of repetitions, with the variance decreasing as the number of folds becomes larger. Figure 14 (a) shows a plot of the average ranks of EP-GPC and RBF-KLR classifiers, with model selection performed as in previous experiments, and RBF-KRR with repeated split-sample model selection, as a function of the number of folds. In each case the unbiased internal evaluation protocol was used. Clearly if the number of folds is small (five or less), the RBF-KRR model performs poorly, due to over-fitting in model selection due to the high variance of the criterion used. However, as the number of folds increases, the variance of the model selection criterion falls, and the performances of all three algorithms are very similar. Figure 14 (b) shows the corresponding result using the biased median protocol. The averaging of hyper-parameters reduces the apparent variance of the model selection criterion, and this disguises the poor performance of the RBF-KRR model when the number of folds is small. This demonstrates that the bias introduced by the median protocol favors most the worst model selection criterion, which is a cause for some concern.

Data Set	External	Internal	Bias
banana	10.355 ± 0.146	10.495 ± 0.158	0.140 ± 0.035
breast cancer	26.280 ± 0.232	27.470 ± 0.250	1.190 ± 0.135
diabetis	22.891 ± 0.127	23.056 ± 0.134	0.165 ± 0.050

Table 8: Error rate estimates for kernel ridge regression over thirteen benchmark data sets, for model selection schemes that are internal and external to the cross-validation process. The results for each approach and the relative bias are presented in the form of the mean error rate over for 100 realisations of each data set (20 in the case of the image and splice data sets), along with the associated standard error.

5.3 Another Example of Biased Evaluation Methodology

In a biased evaluation protocol, occasionally observed in machine learning studies, an initial model selection step is performed using all of the available data, often interactively as part of a "preliminary study". The data are then repeatedly re-partitioned to form one or more pairs of random, disjoint design and test sets. These are then used for performance evaluation *using the same fixed set of hyper-parameter values*. This practice may seem at first glance to be fairly innocuous, however the test data are no longer statistically pure, as they have been "seen" by the models in tuning the hyper-parameters. This would not present a serious problem were it not for the danger of over-fitting in model selection, which means that in practice the hyper-parameters will inevitably be tuned to an extent in ways that take advantage of the statistical peculiarities of this particular set of data rather than only in ways that favor improved generalisation. As a result the hyper-parameter settings retain a partial "memory" of the data that now form the test partition. We should therefore expect to observe an optimistic bias in the performance estimates obtained in this manner.

Table 8 shows a comparison of 10-fold cross-validation estimates of the test error rate, for kernel ridge regression with a Gaussian radian basis function kernel, obtained using protocols where the model selection stage is either *external* or *internal* to the cross-validation procedure. In the external protocol, model selection is performed once using the entire design set, as described above. In the internal protocol, the model selection step is performed separately in each fold of the cross-validation. The internal cross-validation procedure therefore provides a more realistic estimate of the performance of the combination of model selection and learning algorithm that is actually used to construct the final model. The table also shows the relative bias (i.e., the mean difference between the internal and external cross-validation protocols). The external protocol clearly exhibits a consistently optimistic bias with respect to the more rigorous internal cross-validation protocol, over

all thirteen benchmarks. Furthermore, the bias is statistically significant (i.e., larger than twice the standard error of the estimate) for all benchmarks, apart from `splice` and `twonorm`. In many cases, the bias is of similar magnitude to the typical difference observed between competitive learning algorithms (cf. Table 4). In some cases, for example, `banana` and `thyroid` benchmarks, the bias is of a surprising magnitude, likely to be large enough to conceal even the true difference between even state-of-the-art and uncompetitive learning algorithms. This clearly shows that the external cross-validation protocol exhibits a consistent optimistic bias, potentially of a very substantial magnitude even when the number of hyper-parameters is small (in this case only two), and so should not be used in practice.

6. Conclusions

In this paper, we have discussed the importance of bias and variance in model selection and performance evaluation, and demonstrated that a high variance can lead to over-fitting in model selection, and hence poor performance, even when the number of hyper-parameters is relatively small. Furthermore, we have shown that a potentially severe form of selection bias can be introduced into performance evaluation by protocols that have been adopted in a number of existing empirical studies. Fortunately, it seems likely that over-fitting in model selection can be overcome using methods that have already been effective in preventing over-fitting during training, such as regularisation or early stopping. Little attention has so far been focused on over-fitting in model selection, however in this paper we have shown that it presents a genuine pitfall in the practical application of machine learning algorithms and in empirical comparisons. In order to overcome the bias in performance evaluation, model selection should be viewed as an integral part of the model fitting procedure, and should be conducted independently in each trial in order to prevent selection bias and because it reflects best practice in operational use. Rigorous performance evaluation therefore requires a substantial investment of processor time in order to evaluate performance over a wide range of data sets, using multiple randomised partitionings of the available data, with model selection performed separately in each trial. However, it is straightforward to fully automate these steps, and so requires little manual involvement. Performance evaluation according to these principles requires repeated training of models using different sets of hyper-parameter values on different samples of the available data, and so is also well-suited to parallel implementation. Given the recent trend in processor design towards multi-core designs, rather than faster processor speeds, rigorous performance evaluation is likely to become less and less time-consuming, and so there is little justification for the continued use of potentially biased protocols.

Acknowledgments

The authors would like to thank Gareth Janacek, Wenjia Wang and the anonymous reviewers for their helpful comments on earlier drafts of this paper, and the organisers and participants of the WCCI-2006 Performance Prediction Challenge and workshop that provided the inspiration for our work on model selection and performance prediction. Abstract

We describe version 2.0 of the R add-on package *mboost*. The package implements boosting for optimizing general risk functions using component-wise (penalized) least squares estimates or regression trees as base-learners for fitting generalized linear, additive and interaction models to potentially high-dimensional data.

Keywords: component-wise functional gradient descent, splines, decision trees

1. Overview

The R add-on package *mboost* (Hothorn et al., 2010) implements tools for fitting and evaluating a variety of regression and classification models that have been suggested in machine learning and statistics. Optimization within the empirical risk minimization framework is performed via a component-wise functional gradient descent algorithm. The algorithm originates from the statistical view on boosting algorithms (Friedman et al., 2000; Bühlmann and Yu, 2003). The theory and its implementation in *mboost* allow for fitting complex prediction models, taking potentially many interactions of features into account, as well as for fitting additive and linear models. The model class the package deals with is best described by so-called structured additive regression (STAR) models, where some characteristic ξ of the conditional distribution of a response variable Y given features X is modeled through a regression function f of the features $\xi(Y|X = x) = f(x)$. In order to facilitate parsimonious and interpretable models, the regression function f is structured, that is, restricted to additive functions $f(x) = \sum_{j=1}^{p} f_j(x)$. Each model component $f_j(x)$ might take only

a subset of the features into account. Special cases are linear models $f(x) = x^\top \beta$, additive models $f(x) = \sum_{j=1}^{p} f_j(x^{(j)})$, where f_j is a function of the jth feature $x^{(j)}$ only (smooth functions or stumps, for example) or a more complex function where $f(x)$ is implicitly defined as the sum of multiple decision trees including higher-order interactions. The latter case corresponds to boosting with trees. Combinations of these structures are also possible. The most important advantage of such a decomposition of the regression function is that each component of a fitted model can be looked at and interpreted separately for gaining a better understanding of the model at hand.

The characteristic ξ of the distribution depends on the measurement scale of the response Y and the scientific question to be answered. For binary or numeric variables, some function of the expectation may be appropriate, but also quantiles or expectiles may be interesting. The definition of ξ is determined by defining a loss function ρ whose empirical risk is to be minimized under some algorithmic constraints (i.e., limited number of boosting iterations). The model is then fitted using

$$(\hat{f}_1, \ldots, \hat{f}_p) = \operatorname*{argmin}_{(f_1,\ldots,f_p)} \sum_{i=1}^{n} w_i \rho \left(y_i, \sum_{j=1}^{p} f_j(x) \right).$$

Here $(y_i, x_i), i = 1, \ldots, n$, are n training samples with responses y_i and potentially high-dimensional feature vectors x_i, and w_i are some weights. The component-wise boosting algorithm starts with some offset for f and iteratively fits residuals defined by the negative gradient of the loss function evaluated at the current fit by updating only the best model component in each iteration. The details have been described by Bühlmann and Yu (2003). Early stopping via resampling approaches or AIC leads to sparse models in the sense that only a subset of important model components f_j defines the final model. A more thorough introduction to boosting with applications in statistics based on version 1.0 of *mboost* is given by Bühlmann and Hothorn (2007).

As of version 2.0, the package allows for fitting models to binary, numeric, ordered and censored responses, that is, regression of the mean, robust regression, classification (logistic and exponential loss), ordinal regression,[1] quantile[1] and expectile[1] regression, censored regression (including Cox, Weibull[1], log-logistic[1] or lognormal[1] models) as well as Poisson and negative binomial regression[1] for count data can be performed. Because the structure of the regression function $f(x)$ can be chosen independently from the loss function ρ, interesting new models can be fitted (e.g., in geoadditive regression, Kneib et al., 2009).

2. Design and Implementation

The package incorporates an infrastructure for representing loss functions (so-called 'families'), base-learners defining the structure of the regression function and thus the model components f_j, and a generic implementation of component-wise functional gradient descent. The main progress in version 2.0 is that only one implementation of the boosting algorithm is applied to all possible models (linear, additive, tree-based) and all families. Earlier versions were based on three implementations, one for linear models, one for additive models, and one for tree-based boosting. In comparison to the 1.0 series, the reduced code basis is easier to maintain, more robust and regression tests have been set-up in a more unified way. Specifically, the new code basis results in an enhanced and more user-friendly formula interface. In addition, convenience functions for hyper-parameter selection, faster computation of predictions and improved visual model diagnostics are available.

1. Model family is new in version 2.0 or was added after the release of *mboost* 1.0.

Currently implemented base-learners include component-wise linear models (where only one variable is updated in each iteration of the algorithm), additive models with quadratic penalties (e.g., for fitting smooth functions via penalized splines, varying coefficients or bi- and trivariate tensor product splines, Schmid and Hothorn, 2008), and trees.

As a major improvement over the 1.0 series, computations on larger data sets (both with respect to the number of observations and the number of variables) are now facilitated by memory efficient implementations of the base-learners, mostly by applying sparse matrix techniques (package *Matrix*, Bates and Mächler, 2009) and parallelization for a cross-validation-based choice of the number of boosting iterations (per default via package *multicore*, Urbanek, 2009). A more elaborate description of *mboost* 2.0 features is available from the `mboost` vignette.[2]

3. User Interface by Example

We illustrate the main components of the user-interface by a small example on human body fat composition: Garcia et al. (2005) used a linear model for predicting body fat content by means of common anthropometric measurements that were obtained for $n = 71$ healthy German women. In addition, the women's body composition was measured by Dual Energy X-Ray Absorptiometry (DXA). The aim is to describe the DXA measurements as a function of the anthropometric features. Here, we extend the linear model by i) an intrinsic variable selection via early stopping, ii) additional terms allowing for smooth deviations from linearity where necessary (by means of penalized splines orthogonalized to the linear effect, Kneib et al., 2009), iii) a possible interaction between two variables with known impact on body fat composition (hip and waist circumference) and iv) using a robust median regression approach instead of L_2 risk. For the data (available as data frame `bodyfat`), the model structure is specified via a formula involving the base-learners corresponding to the different model components (linear terms: `bols()`; smooth terms: `bbs()`; interactions: `btree()`). The loss function (here, the check function for the 0.5 quantile) along with its negative gradient function are defined by the `QuantReg(0.5)` family (Fenske et al., 2009). The model structure (specified using the formula `fm`), the data and the family are then passed to function `mboost()` for model fitting:[3]

```
R> library("mboost")                ### attach package 'mboost'
R> print(fm)                        ### model structure

DEXfat ~ bols(age) + bols(waistcirc) + bols(hipcirc) + bols(elbowbreadth) +
    bols(kneebreadth) + bols(anthro3a) + bols(anthro3b) + bols(anthro3c) +
    bols(anthro4) + bbs(age, center = TRUE, df = 1) + bbs(waistcirc,
    center = TRUE, df = 1) + bbs(hipcirc, center = TRUE, df = 1) +
    bbs(elbowbreadth, center = TRUE, df = 1) + bbs(kneebreadth,
    center = TRUE, df = 1) + bbs(anthro3a, center = TRUE, df = 1) +
    bbs(anthro3b, center = TRUE, df = 1) + bbs(anthro3c, center = TRUE,
    df = 1) + bbs(anthro4, center = TRUE, df = 1) + btree(hipcirc,
    waistcirc, tree_controls = ctree_control(maxdepth = 2, mincriterion = 0))

R> ### fit model for conditional median of DEXfat
R> model <- mboost(fm,                          ### model structure
```

2. Accessible via `vignette("mboost", package = "mboost")`.

3. The complete R code for reproducing this example is given in the accompanying file `mboost-MLOSS.R`.

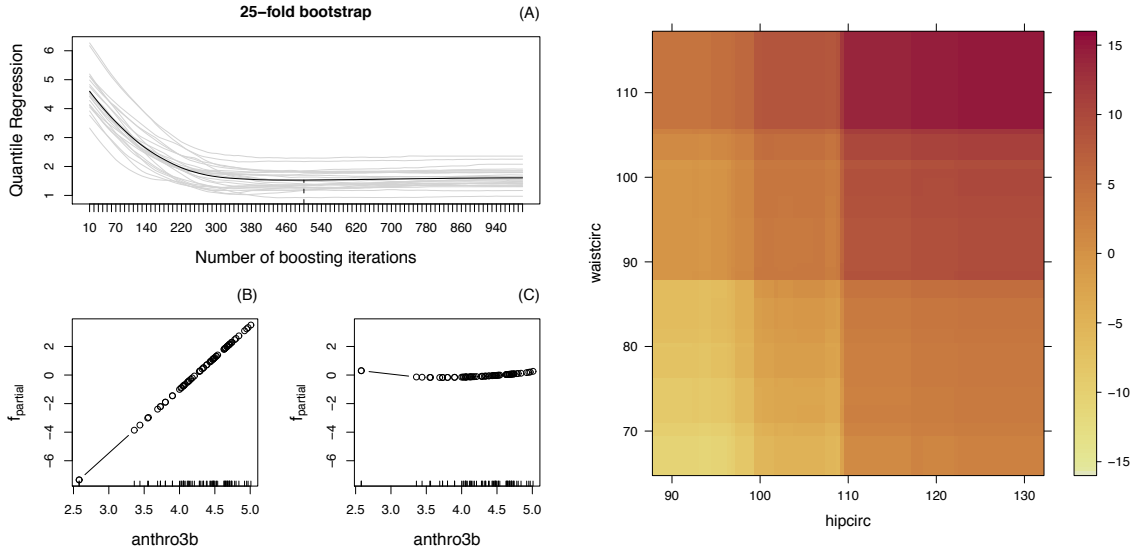

Figure 1: Out-of-bag empirical risk (A) indicating that 500 iterations are appropriate. Fitted model components for variable `anthro3b`, consisting of a linear (B) and smooth term (C). The right panel shows the interaction model component between hip and waist circumferences.

```
+                     data = bodyfat,                ### 71 observations
+                     family = QuantReg(tau = 0.5)) ### median regression
```

Once the model has been fitted it is important to assess the appropriate number of boosting iterations via the out-of-sample empirical risk. By default, 25 bootstrap samples from the training data are drawn and the out-of-bag empirical risk is computed (parallel computation if possible):

```
R> ### bootstrap for assessing the 'optimal' number
R> ### of boosting iterations
R> cvm <- cvrisk(model, grid = 1:100 * 10)
R> model[mstop(cvm)] ### restrict model to optimal mstop(cvm) iterations
```

Now, the final model is ready for a visual inspection:

```
R> plot(cvm)   ### depict out-of bag risk and
R> plot(model) ### selected components
```

The resulting plots are given in Figure 1. They indicate that a model based on three components, including a smooth function of `anthro3b` and a bivariate function of hip and waist circumference, provides the best characterization of the median body fat composition (given the model specification offered to the boosting algorithm). A hip circumference larger than 110 cm leads to increased body fat but only if the waist circumference is larger than 90 cm.

The sources of the *mboost* package are distributed at the Comprehensive R Archive Network under GPL-2, along with binaries for all major platforms as well as documentation and regression tests. Development versions are available from `http://R-forge.R-project.org`.

Abstract

A continuous time Bayesian network (CTBN) uses a structured representation to describe a dynamic system with a finite number of states which evolves in continuous time. Exact inference in a CTBN is often intractable as the state space of the dynamic system grows exponentially with the number of variables. In this paper, we first present an approximate inference algorithm based on importance sampling. We then extend it to continuous-time particle filtering and smoothing algorithms. These three algorithms can estimate the expectation of any function of a trajectory, conditioned on any evidence set constraining the values of subsets of the variables over subsets of the time line. We present experimental results on both synthetic networks and a network learned from a real data set on people's life history events. We show the accuracy as well as the time efficiency of our algorithms, and compare them to other approximate algorithms: expectation propagation and Gibbs sampling.

Keywords: continuous time Bayesian networks, importance sampling, approximate inference, filtering, smoothing

1. Introduction

Many real world applications involve highly complex dynamic systems. These systems usually contain a large number of stochastic variables, which evolve asynchronously in continuous time. Such dynamic systems include computer networks, sensor networks, social networks, mobile robots, and cellular metabolisms. Modeling, learning and reasoning about these complex dynamic systems is an important task and a great challenge.

1.1 Structured Process Representation

A central task of the above applications is to calculate probability distributions of the system over time. For instance, we may wish to know the distribution over when a variable will change next or the state of a current variable, given past (partial) evidence. However, as the number of the variables increases, the state space of the distribution grows exponentially. Such growth makes the inference task very difficult for large systems. One solution is to use structured representation to factorize the state space according to the dependencies of the variables. For dynamic systems, Dynamic Bayesian Networks (DBNs) (Dean and Kanazawa, 1989) are commonly used. A DBN describes the dynamic system as a time-sliced model by measuring the evolution of the system with a (usually fixed) time interval Δt . The transition probabilities from states at time t to states at time $t + \Delta t$ are represented by a Bayesian network. DBNs can work well for systems that are observed at regular time steps. However, for many applications, discretizing time has several limitations. First, we usually choose a fixed time interval, Δt. In many real world systems, variables evolve at different time granularities. Some variables may evolve very fast whereas some evolve very slowly. Choosing an appropriate time interval is a difficult task. Larger Δt may result in an inaccurate model while smaller Δt may cause inference in the model to be inefficient.

Second, the dependencies of the transition model are unstable with respect to Δt. That is, different choices of Δt may result in different network structures between t and $t + \Delta t$. The network structure represents independencies between variables at t and Δt. This is a function of Δt, both theoretically and empirically (Nodelman et al., 2003). If Δt is an inherent parameter of the process, this is not a problem. However, if it is chosen for estimation or computational reasons, this becomes an issue as its choice is not unique. Finally, DBNs (and discrete-time Markov processes in general) do not necessarily correspond to processes that are Markovian outside of the sampled instants of time. Consider that if T is the transition matrix for a process with time interval Δt, $T^{1/2}$ is the transition matrix for the same process with time interval $\frac{\Delta t}{2}$. However, such a square root may not exist in the space of real matrices. Therefore, there may not be any simple extension of a DBN to the times between the sampled instants.

An alternative and more natural approach to model dynamic systems is to use a continuous-time model. For systems with a finite number of states, one way is to consider the entire system as a continuous-time discrete-state Markov process. Like discrete-time processes, this method suffers from the fact that the state space of the process grows exponentially with the number of variables in the system. Recently, Nodelman et al. (2002) extended this framework to a *continuous time Bayesian network* (CTBN), which factorizes a system into local variables using a graphical representation, much as a DBN does for a discrete-time process. Parameter estimation in CTBNs with fully observed data and partially observed data were provided in Nodelman et al. (2003) and Nodelman et al. (2005b) respectively. Because CTBNs explicitly represent the temporal dynamics in continuous time and explore the dependencies among stochastic variables using a structured representation, they have been applied to various real world systems, including human-computer interactions (Nodelman and Horvitz, 2003), server farm failures (Herbrich et al., 2007), robot monitoring (Ng et al., 2005) and network intrusion detection (Xu and Shelton, 2008). Kan and Shelton (2008) used the CTBN representation in their solution of structured continuous-time Markov decision processes.

Queueing theory (Bolch et al., 1998) and Petri nets (Petri, 1962) provide an alternative continuous-time structured process models. However, they make different assumptions about the structure. They were designed to answer questions about steady-state distributions. Their algorithms are not suited to learning from partial data nor to answering many statistical questions. A singular and recent exception is the work of Sutton and Jordan (2008) which applied Gibbs sampling to queueing models.

1.2 Prior CTBN Inference Methods

In CTBNs, a trajectory (or sample) consists of the starting values for the system along with the (real-valued) times at which the variables change and their corresponding new values. Inference for a CTBN is the task of estimating the distribution over trajectories given a partial trajectory (in which some values or transitions are missing for some variables during some time intervals). Inference plays a central role as it not only helps us answer queries about distributions, but it is also involved in parameter estimation when the observation data is incomplete. Performing exact inference in a CTBN requires constructing a single rate matrix for the entire system and computing the exponential of the matrix, which is often intractable: the exponentiation must be performed separately for each period of constant evidence and (more problematic) even a sparse representation of the matrix may not fit in memory. Thus, many applications of CTBNs require an approximate inference method. A method based on expectation propagation (Minka, 2001) was presented in Nodelman et al. (2005a). Saria et al. (2007) extended it to full belief propagation and provided a method to adapt the approximation quality.

Other approximate inference methods are based on sampling. They have the advantage of being anytime algorithms. (We can stop at any time during the computation and obtain an answer.) Furthermore, in the limit of infinite samples (computation time), they converge to the true answer.

As we note below, because time is a continuous variable, any evidence containing a record of the change in a variable has a zero probability under the model. Therefore rejection sampling and straightforward likelihood weighting are generally not viable methods.

Ng et al. (2005) developed a continuous-time particle filtering algorithm. However, it only handles point evidence on binary and ternary discrete variables using rejection sampling and focuses primarily on the incor-

poration of evidence from a continuous-state part of the system (which we do not consider here). Recently, El-Hay et al. (2008) provided another sampling algorithm for CTBNs using Gibbs sampling. The algorithm starts from an arbitrary trajectory that is consistent with the evidence. Then, in each iteration, it randomly picks one variable X, and samples an entire trajectory for that variable by fixing the trajectory of all the other variables. Since only X is not fixed, the conditioned cumulative distribution that X stays in one state less than t and the state transition probabilities can be calculated exactly using standard forward and backward propagation within the Markov blanket of X. The Gibbs sampling algorithm can handle any type of evidence and it provides an approach to sample from the exact posterior distribution given the evidence. However, the posterior distribution can be any arbitrary function. To sample exactly from it, binary search has to be applied and $F(t)$ is repeatedly evaluated, which may affect the efficiency of the algorithm.

1.3 Outline of This Work

In this paper we explore a different sampling approach using importance sampling. Our algorithm generates weighted samples to approximate the expectation of a function of the trajectory. It differs from previous approaches in a number of key ways. There is no exact inference method involved in our approach. Thus, our algorithm does not depend on complex numeric computations. The transition times for variables are sampled from regular exponential distributions in our algorithm, which can be done in constant time. Our algorithm can be adapted to a population-based filter (a particle filter). It can handle both point and continuous evidence, is simple to implement, and can be easily extended to continuous time systems other than CTBNs. The formulation of this sampling procedure is not trivial due to the infinite extent of the trajectory space, both in the transition time continuum and the number of transitions. The algorithm was first presented in Fan and Shelton (2008). This paper extends that work by comparing the algorithm to the newly developed Gibbs sampling algorithm (El-Hay et al., 2008), evaluating its performance on parameter learning with partially observed data, and demonstrating its performance on real-world networks.

The remainder of the paper is structured as follows. In Section 2, we briefly describe the notation for CTBNs. In Section 3, we describe our importance sampling algorithm for CTBNs and extend the algorithm to particle filtering and particle smoothing algorithms. In Section 4, we describe our experiment results.

2. Continuous Time Bayesian Networks

We first briefly describe the definition, likelihood, and sufficient statistics of the CTBN model. We then review the exact inference and parameter estimation algorithms for CTBNs.

2.1 The CTBN Model

Continuous time Bayesian networks (Nodelman et al., 2002) are based on the framework of continuous time, finite state, homogeneous Markov processes (Norris, 1997). Let X be a continuous time, finite state, homogeneous Markov process with n states $\{x_1,\ldots,x_n\}$. The behavior of X is described by the initial distribution P_X^0 and the transition model which is often represented by the intensity matrix

$$\mathbf{Q}_X = \begin{bmatrix} -q_{x_1} & q_{x_1x_2} & \cdots & q_{x_1x_n} \\ q_{x_2x_1} & -q_{x_2} & \cdots & q_{x_2x_n} \\ \vdots & \vdots & \ddots & \vdots \\ q_{x_nx_1} & q_{x_nx_2} & \cdots & -q_{x_n} \end{bmatrix},$$

where $q_{x_ix_j}$ is the intensity with which X transitions from x_i to x_j and $q_{x_i} = \sum_{j\neq i} q_{x_ix_j}$. The intensity matrix $\mathbf{Q}_X$ is time invariant. Given $\mathbf{Q}_X$, the transient behavior of X can be described as the following: X stays in state x_i for an amount of time t and transitions to state x_j. t is exponentially distributed with parameter q_{x_i}. That is, the probability density function and the corresponding distribution function for X staying in state x_i

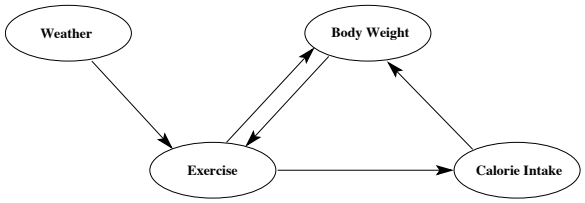

Figure 1: CTBN Example: Weight Control Effect

are

$$f(q_{x_i},t) = q_{x_i}\exp(-q_{x_i}t), \quad t \geq 0.$$
$$F(q_{x_i},t) = 1-\exp(-q_{x_i}t), \quad t \geq 0.$$

The expected time of transitioning is $1/q_{x_i}$. Upon transitioning, the probability X transitions from state x_i to x_j is $\theta_{x_i x_j} = q_{x_i x_j}/q_{x_i}$.The distribution over the state of X at time t can be calculated as

$$P_X(t) = P_X^0 \exp(\mathbf{Q}_X t)$$

where P_X^0 is the distribution over X at time 0 represented as a row vector, and exp is the matrix exponential.

To model a dynamic system containing several variables, we can consider the whole system as one variable, enumerate the entire state space, calculate the transition intensity of each pair of these states and put them into a single intensity matrix. However, the size of the state space grows exponentially with the number of variables in the system, which makes this method infeasible for large systems.

Nodelman et al. (2002) defined a *continuous time Bayesian network* (CTBN), which uses a graphical model to provide a compact factored representation of continuous time Markov process. A CTBN models each local variable X as an inhomogeneous Markov process, whose parametrization depends on some subset of other variables $\mathbf{U}$. The intensity matrix of X is called a conditional intensity matrix (*CIM*) $\mathbf{Q}_{X|\mathbf{U}}$, which is defined as a set of intensity matrices $\mathbf{Q}_{X|\mathbf{u}}$, one for each instantiation $\mathbf{u}$ of the variable set $\mathbf{U}$. The evolution of X depends instantaneously on the values of the variables in $\mathbf{U}$.

Let $\boldsymbol{X}$ be a dynamic system containing several variables X. A *continuous time Bayesian network* $\mathcal{N}$ over $\boldsymbol{X}$ consists of two components: an *initial distribution* $P_{\boldsymbol{X}}^0$, specified as a Bayesian network $\mathcal{B}$ over $\boldsymbol{X}$, and a *continuous transition model*, specified using a directed (possibly cyclic) graph $\mathcal{G}$ whose nodes are $X \in \boldsymbol{X}$. Let $\mathbf{U}_X$ denote the parents of X in $\mathcal{G}$. Each variable $X \in \boldsymbol{X}$ is associated with a conditional intensity matrix, $\mathbf{Q}_{X|\mathbf{U}_X}$.

Example 1 *Assume we want to model the behavior of a person controlling his body weight. When the person is overweight, he may exercise more to lose the excess weight. Increasing exercise intensity tends to increase his appetite, which will increase his daily calorie intake. Both exercise intensity and calorie intake contribute to his body weight. Furthermore, the exercise intensity also depends on the weather. Such a dynamic system contains four variables: body weight, exercise, calorie intake, and weather. Each variable changes in continuous time and its change rate depends on the current value of some other variables.*

We can use a CTBN to represent such behavior. The dependencies of these four variables are depicted using a graphical structure, as shown in Figure 1. The quantitative transient dynamics for each variable is represented using a conditional intensity matrix. Let us assume all the four variables are binary. Let $B(t)$ be the person's body weight ($Val(B(t)) = \{b_0 = normal, b_1 = overweight\}$), $E(t)$ be the exercise intensity ($Val(E(t) = \{e_0 = light, e_1 = heavy\}$), $C(t)$ be his daily calorie intake ($Val(C(t) = \{c_0 = low, c_1 = high\}$) and $W(t)$ be the weather ($Val(W(t) = \{w_0 = rainy, w_1 = sunny\}$). The conditional intensity matrices for the four variables can be specified as

$\mathbf{Q}_W$	$\mathbf{Q}_W$	$=$	$\begin{bmatrix} -0.5 & 0.5 \\ 0.5 & -0.5 \end{bmatrix}$,				
$\mathbf{Q}_{E\|W,B}$	$\mathbf{Q}_{E\|w_0,b_0}$	$=$	$\begin{bmatrix} -0.1 & 0.1 \\ 2 & -2 \end{bmatrix}$,	$\mathbf{Q}_{E\|w_1,b_0}$	$=$	$\begin{bmatrix} -0.3 & 0.3 \\ 1 & -1 \end{bmatrix}$,
	$\mathbf{Q}_{E\|w_0,b_1}$	$=$	$\begin{bmatrix} -0.5 & 0.5 \\ 0.5 & -0.5 \end{bmatrix}$,	$\mathbf{Q}_{E\|w_1,b_0}$	$=$	$\begin{bmatrix} -1 & 1 \\ 0.1 & -0.1 \end{bmatrix}$,
$\mathbf{Q}_{C\|E}$	$\mathbf{Q}_{C\|e_0}$	$=$	$\begin{bmatrix} -0.2 & 0.2 \\ 1 & -1 \end{bmatrix}$,	$\mathbf{Q}_{C\|e_1}$	$=$	$\begin{bmatrix} -1 & 1 \\ 0.2 & -0.2 \end{bmatrix}$,
$\mathbf{Q}_{B\|E,C}$	$\mathbf{Q}_{B\|e_0,c_0}$	$=$	$\begin{bmatrix} -0.2 & 0.2 \\ 0.8 & -0.8 \end{bmatrix}$,	$\mathbf{Q}_{B\|e_1,c_0}$	$=$	$\begin{bmatrix} -0.1 & 0.1 \\ 1 & -1 \end{bmatrix}$,
	$\mathbf{Q}_{B\|e_0,c_1}$	$=$	$\begin{bmatrix} -1 & 1 \\ 0.1 & -0.1 \end{bmatrix}$,	$\mathbf{Q}_{B\|e_1,c_1}$	$=$	$\begin{bmatrix} -0.2 & 0.2 \\ 0.6 & -0.6 \end{bmatrix}$.

Notice that unlike Bayesian networks, the CTBN model allows cycles. The transient behavior of each local variable is controlled by the current value of its parents. If the person is doing light exercise and his calorie intake is low, the dynamics of his body weight are determined by the intensity matrix $\mathbf{Q}_{B|e_0,c_0}$*. If the time unit is one month, we expect his weight will go back to normal in* $1/0.8 = 1.25$ *months if he is currently overweight and doing light exercise and controlling his daily calorie intake.*

We can also use a single continuous time Markov process to represent this network, which requires an intensity matrix of size 16×16*. To generate the single intensity matrix, we can follow the amalgamation algorithm in Nodelman et al. (2002). Basically, we enumerate the entire state space* (W,E,C,B)*, and assign intensity 0 to transitions that change two variables simultaneously. For any transition involving only one of the variables, simply use the entry from the appropriate intensity matrix above. The resulting matrix is*

$$

\end{array}
\end{bmatrix}.
$$

As we include more variables in this system, the size of the intensity matrix grows exponentially with the number of variables.

2.2 Likelihood and Sufficient Statistics

The probability density over trajectories σ of a set of variables $\boldsymbol{X}$ described by a CTBN belongs to the exponential family. Therefore, the distribution of a CTBN can be described in terms of the sufficient statistics

of σ (Nodelman et al., 2003). Let $T[x|\mathbf{u}]$ be the amount of time $X = x$ while $\mathbf{U}_X = \mathbf{u}$, and $M[x,x'|\mathbf{u}]$ be the number of transitions from x to x' while $\mathbf{U}_X = \mathbf{u}$. If we let $M[x|\mathbf{u}] = \sum_{x'} M[x,x'|\mathbf{u}]$, the probability density of trajectory σ (omitting the starting distribution) is

$$P_{\mathcal{N}}(\sigma) = \prod_{X \in \mathbf{X}} L_X(T[X|\mathbf{U}_X], M[X|\mathbf{U}_X]) \tag{1}$$

where

$$L_X(T[X|\mathbf{U}_X], M[X|\mathbf{U}_X]) = \prod_{\mathbf{u}} \prod_{x} \left(q_{x|\mathbf{u}}^{M[x|\mathbf{u}]} \exp(-q_{x|\mathbf{u}} T[x|\mathbf{u}]) \prod_{x' \neq x} \theta_{xx'|\mathbf{u}}^{M[x,x'|\mathbf{u}]} \right) \tag{2}$$

is the local likelihood for variable X. The likelihood also decomposes by time. That is, the likelihood of a trajectory on $[0,T)$ is equal to the likelihood based only on sufficient statistics from time 0 to time t multiplied by the likelihood based only on sufficient statistics from time t to time T.

2.3 Evidence and Queries

Given a CTBN model, we would like to use it to answer queries conditioned on observations. There are two common types of observations: point evidence and continuous evidence. Point evidence represents the observation of the value of some variables at a particular time instant. Continuous evidence provides the behavior of some variables throughout an interval $[t_1,t_2)$. For instance, $x = 1$ during the interval $[2,3.5)$, or $x = 1$ from $t = 2$ to $t = 3$ and then x transitions to $x = 0$ at $t = 3$ and stays in that state until $t = 5$. We define $x[t_1 : t_2)$ be the behavior of variable X on the interval $[t_1,t_2)$, $x[t_1 : t_2]$ be the behavior of X on the interval $[t_1,t_2]$ and $x(t_1 : t_2]$ be the behavior of X on the interval $(t_1,t_2]$.

Queries can ask about the marginal distribution of some variables at a particular time, such as the distribution of x and y at $t = 2$, or questions about the timing of a transition, such as the distribution over the time that y transitions from $y = 1$ to $y = 2$ for the first time in the interval $[1,4)$. In learning (especially when employing expectation-maximization), we might query the expected sufficient statistics of a CTBN, which include the total amount of time that a variable spends in a state, and the total number of times that a variable transitions from one state to another state under certain conditions. For example, we might want to know the total amount of time that $x = 0$ throughout the entire interval, or the number of times that x transitions from 1 to 2 during the time interval $[2,3)$ when $y = 0$. In this paper, we will concentrate on answering queries given the continuous evidence, but our method can be trivially extended to point evidence.

2.4 Exact Inference in CTBNs

A CTBN can be viewed as a homogeneous Markov process with a large joint intensity matrix amalgamated from the CIMs of the CTBN. Exact inference in a CTBN can be performed by generating a single joint intensity matrix over the entire state space of the CTBN and running the forward-backward algorithm on the joint intensity matrix of the homogeneous Markov process. We review this method here, but a more complete treatment can be found in Nodelman et al. (2002).

Assume that we have a partially observed trajectory σ of a CTBN $\mathcal{N}$ from 0 to T. We can divide the evidence σ into N intervals $[t_i,t_{i+1})$ $(i = 0,\ldots,N-1)$ according to the observed transition times. That is, each interval contains a constant observation of the CTBN, and t_i is the time that a variable begins to be observed, stops being observed, or is observed to transition. We set $t_0 = 0$ and $t_N = T$.

To perform exact inference, we first generate the intensity matrix $\mathbf{Q}$ for the joint homogeneous Markov process and incorporate the evidence into $\mathbf{Q}$. If each variable X_i in the CTBN $\mathcal{N}$ has n_i states, the number of states of the joint Markov process is $n = \prod n_i$ and $\mathbf{Q}$ is an $n \times n$ matrix. The value of the off-diagonal element q_{ij} in $\mathbf{Q}$ for which only one variable value is different between states i and j is the corresponding intensity in the CIM of that variable. All the other off-diagonal elements are zero since two variables can not transition at exactly the same time in a CTBN. The diagonal elements are computed to make each row sum to zero.

To incorporate the evidence, we reduce the joint intensity matrix $\mathbf{Q}$ to $\mathbf{Q}_i$ for each interval $[t_i,t_{i+1})$ by zeroing out the rows and columns of $\mathbf{Q}$ which represent states that are inconsistent with the evidence. Addi-

tionally, let $\mathbf{Q}_{i,j}$ be the matrix $\mathbf{Q}$ with all elements zeroed out except the off-diagonal elements that represent the intensities of transitioning from non-zero rows in $\mathbf{Q}_i$ to non-zero columns in $\mathbf{Q}_j$. If evidence blocks i and j differs only in which variables are observed (no transition is observed between them), then $\mathbf{Q}_{i,j}$ is the identity matrix instead.

$\exp(\mathbf{Q}_i(t_{i+1}-t_i))$ represents the transition matrix for interval $[t_i,t_{i+1})$ and $\mathbf{Q}_{i,i+1}$ corresponds to the transition probability density between two consecutive intervals at time t_{i+1}. We can use the forward-backward algorithm for Markov process to answer queries.

We define the forward and backward probability vectors $\boldsymbol{\alpha}_t$ and $\boldsymbol{\beta}_t$ as

$$\begin{aligned}\boldsymbol{\alpha}_t &= p(X_t, \sigma_{[0,t)}),\\ \boldsymbol{\beta}_t &= p(\sigma_{[t,T)}|X_t)\ .\end{aligned}$$

Let $\boldsymbol{\alpha}_0$ be the initial distribution P_X^0 over the state and $\boldsymbol{\beta}_T$ be a vector of ones. The forward and backward distribution vector for each interval can be calculated recursively:

$$\begin{aligned}\boldsymbol{\alpha}_{t_{i+1}} &= \boldsymbol{\alpha}_{t_i}\exp(\mathbf{Q}_i(t_{i+1}-t_i))\mathbf{Q}_{i,i+1},\\ \boldsymbol{\beta}_{t_i} &= \mathbf{Q}_{i-1,i}\exp(\mathbf{Q}_i(t_{i+1}-t_i))\boldsymbol{\beta}_{t_{i+1}}\ .\end{aligned}$$

The distribution over the state of the CTBN at time $t \in [t_i,t_{i+1})$ given the evidence $\sigma_{[0,T)}$ can be computed as

$$P(X_t = k, \sigma_{[0,T)}) = \boldsymbol{\alpha}_{t_i}\exp(\mathbf{Q}_i(t-t_i))\boldsymbol{\Delta}_{k,k}\exp(\mathbf{Q}_i(t_{i+1}-t))\boldsymbol{\beta}_{t_{i+1}} \tag{3}$$

where $\boldsymbol{\Delta}_{i,j}$ is an $n \times n$ matrix of zeros with a single one in position i,j. Other queries can be similarly computed.

2.5 CTBN Parameter Estimation

Given a set of trajectories $D = \{\sigma_1, \sigma_2, \ldots, \sigma_n\}$ and a fixed graphical structure, we would like to estimate the parameters (the conditional intensity matrix) of the CTBN model.

When the data set D is complete, where each trajectory σ_i is a complete set of state transitions and the times at which they occurred, the parameters can be learned by maximizing the log-likelihood of the data set (Nodelman et al., 2003). According to Equation 1 and Equation 2, the log-likelihood can be written as the sum of the log-likelihood for each local variable. By maximizing the log-likelihoods, the parameters can be derived as

$$\hat{q}_{x|\mathbf{u}} = \frac{M[x|\mathbf{u}]}{T[x|\mathbf{u}]}\ ; \quad \hat{\theta}_{xx'|\mathbf{u}} = \frac{M[x,x'|\mathbf{u}]}{M[x|\mathbf{u}]}\ . \tag{4}$$

When the data set is incomplete, the expectation maximization (EM) algorithm (Dempster et al., 1977) can be used to find the maximum likelihood parameters (Nodelman et al., 2005b). The EM algorithm begins with an arbitrary initial parameter assignment, and alternatively repeats the expectation step and maximization step until convergence. In expectation step, for each trajectory $\sigma_i \in D$, expected sufficient statistics $\bar{M}[x|\mathbf{u}]$, $\bar{M}[x,x'|\mathbf{u}]$ and $\bar{T}[x|\mathbf{u}]$ are computed using exact inference. In maximization step, new parameters are computed according to Equation 4 as if the expected sufficient statistics came from complete data.

3. Sampling-based Inference

As we described in the previous section, exact inference in a CTBN can be performed by generating a single joint intensity matrix over the entire state space. As the number of states is exponential in the number of the nodes in the network, this approach is infeasible when the network size is large. In this section we describe an algorithm for approximate CTBN inference based on importance sampling.

Procedure *CTBN-Sample*(t_{end})
1. $t \leftarrow 0, \sigma \leftarrow \emptyset$
2. For each variable $X \in \boldsymbol{X}$
   Choose state $x(0)$ according to $\boldsymbol{\theta}^{\mathcal{B}}_{X|\mathbf{pa}_{\mathcal{B}}(X)}$.

Loop:

3. For each variable X such that *Time*(X) is undefined:
   Choose Δt for next X transition from an exponential with parameter $q_{x(t)|\mathbf{u}_X(t)}$.
   Define *Time*(X) $\leftarrow t + \Delta t$
4. Let $X = \arg\min_{X \in \boldsymbol{X}} [\textit{Time}(X)]$
5. If *Time*(X) $\geq t_{end}$ **return** σ
6. Update $t \leftarrow$ *Time*(X)
7. Choose $x(t)$, the next value of X, from the multinomial with parameters $\boldsymbol{\theta}_{x(t)|\mathbf{u}_X(t)}$.
   Add $\langle X \leftarrow x(t), t \rangle$ to σ.
   Undefine *Time*(X), and *Time*(Y) for all variables Y for which $X \in \mathbf{U}_Y$.

Figure 2: Forward sampling semantics for a CTBN

3.1 Forward Sampling

Queries that are not conditioned on evidence can be answered by randomly sampling many trajectories and looking at the fraction that match the query. More formally, if we have a CTBN $\mathcal{N}$ we generate a set of particles $\mathcal{D} = \{\sigma[1], \ldots, \sigma[M]\}$ where each particle is a sampled trajectory. With $\mathcal{D}$ we can estimate the expectation of any function g by computing

$$\hat{\mathbf{E}}_{\mathcal{N}}[g] = \frac{1}{M} \sum_{m=1}^{M} g(\sigma[m]) \; . \tag{5}$$

For example, if we let $g = \mathbf{1}\{x(5) = x_1\}$ then we could use the above formula to estimate $P_{\mathcal{N}}(x(5) = x_1)$. Or the function $g(\sigma)$ might count the total number of times that X transitions from x_1 to x_2 while its parent U has value u_1, allowing us to estimate the expected sufficient statistic $M[x_1, x_2 | u_1]$. The algorithm for sampling a trajectory is shown in Figure 2. For each variable $X \in \boldsymbol{X}$, it maintains $x(t)$—the state of X at time t—and *Time*(X)—the next potential transition time for X. The algorithm adds transitions one at a time, advancing t to the next earliest variable transition. When a variable X (or one of its parents) undergoes a transition, *Time*(X) is resampled from the new exponential waiting time distribution. We use $\mathbf{u}_X(t)$ to represent the instantiation to parents of X at time t.

If we want to obtain a conditional probability of a query given evidence, the situation is more complicated. We might try to use *rejection sampling*: forward sample to generate possible trajectories, and then simply reject the ones that are inconsistent with our evidence. The remaining trajectories are sampled from the posterior distribution given the evidence, and can be used to estimate probabilities as in Equation 5. However, this approach is entirely impractical in our setting, as in any setting involving an observation of a continuous quantity—in our case, time. In particular, suppose we observe that X transitions from x_1 to x_2 at time t. The probability of sampling a trajectory in which that transition occurs at precisely that time is zero. Thus, if we have evidence about transitions, with probability 1, none of our sampled trajectories will be relevant.

3.2 Gibbs Sampling

Recently, El-Hay et al. (2008) provided a Markov Chain Monte Carlo (MCMC) procedure which used a Gibbs sampler to generate samples from the posterior distribution given the evidence.

Suppose we want to sample trajectories from a CTBN with n variables $(X_i, X_2, \ldots, X_n)$ given the evidence $\mathbf{e}$. The Gibbs sampler starts with an arbitrary trajectory that is consistent with the evidence. In each iteration, the sampler randomly picks one variable X_i and samples the entire trajectory of X_i by fixing the trajectories

of the other variables $Y = \{X_1, \ldots, X_{i-1}, X_{i+1}, \ldots, X_n\}$ as evidence. To generate the entire trajectory of X_i according to the evidence $\mathbf{e}$, the states and transitions of X_i need to be sampled in those intervals that X_i is not observed according to the evidence. The trajectory in each unobserved interval of X_i can be generated by alternatively sampling transition time Δt and new state x from the posterior distribution given $\mathbf{e}$ and the trajectories of the other variables Y.

Assume we are sampling the trajectory of X for the interval $[0,T]$, and $X_i(0) = x_0$, $X_i(T) = x_T$. The transition time Δt is sampled by inverse transform sampling: first draw ξ from the $[0,1]$ uniform distribution and set $\Delta t = F^{-1}(\xi)$, where $F^{-1}(\xi)$ is the inverse of the conditional cumulative distribution function $F(t)$ that X_i stays in state x_0 for a time less than t:

$$F(t) = 1 - Pr(X_i(0:t] = x_0 | x_0, x_T, Y[0:T]) .$$

$F(t)$ can be calculated by decomposing $Pr(X_i(0:t] = x_0|x_0, x_T, Y[0:T])$ using the Markov property of the process:

$$Pr(X_i(0:t] = x_0|x_0, x_T, Y[0:T]) = \frac{\tilde{\alpha}(t)\tilde{\beta}_{x_0}(t)}{\tilde{\beta}_{x_0}(0)}$$

where

$$\tilde{\alpha}(t) = Pr(X_i(0:t] = x_0, Y[0:t]|x_0, Y_0),$$
$$\tilde{\beta}_x(t) = Pr(x_T, Y(t:T]|X_i(t) = x, Y(t)) .$$

$\tilde{\alpha}(t)$ and $\tilde{\beta}_x(t)$ can be calculated using a slightly modified version of the standard forward-backward algorithm described in Section 2.4. Using the fact that X_i is independent of all the other components given the entire trajectory of its Markov blanket, the computation of $\tilde{\alpha}(t)$ and $\tilde{\beta}(t)$ can be limited to X_i and its Markov blanket (the parents of X_i, the children of X_i, and the children's parents).

Since the conditional cumulative distribution function $F(t)$ can be arbitrarily complex, the inverse function $F^{-1}(t)$ can not be solved analytically. Finding Δt that satisfies $F(\Delta t) = \xi$ is performed using a two-step searching method: first find the interval $[\tau_k, \tau_{k+1}]$ that satisfies $F(\tau_k) < \xi < F(\tau_{k+1})$, where τ_k are the transition points of the Markov blanket of X_i. Then Δt is found by performing an L step binary search on the interval $[\tau_k, \tau_{k+1}]$.

The transition probability that X_i transitions from $x^{(0)}$ to a new state x can be calculated similarly:

$$Pr(X_i(t^+) = x|X_i(0:t] = x^{(0)}, Y(0:T]) = \frac{q^{X_i|Y}_{x_0,x}\tilde{\beta}_x(t)}{\sum_{x' \neq x_0} q^{X_i|Y}_{x_0,x'}\tilde{\beta}_{x'}(t)} .$$

The Gibbs sampling algorithm can handle any type of evidence. The sampled trajectories are guaranteed to be consistent with the evidence. However, sampling the transition time Δt requires using a binary search algorithm and repeatedly computing the conditional cumulative distribution function $F(t)$, which may require long running time.

3.3 Importance Sampling

In this section, we introduce another approximate inference method using importance sampling, which does not require computing the exact posterior distribution. This method first appeared in Fan and Shelton (2008).

In importance sampling, we generate samples from a proposal distribution P' which guarantees that our sampled trajectories will conform to our evidence $\mathbf{e}$. We must weight our samples to correct for the fact that we are drawing them from P' instead of the target distribution $P_{\mathcal{N}}$ defined by the CTBN. In particular, if σ is a sample from P' we set its weight to be

$$w(\sigma) = \frac{P_{\mathcal{N}}(\sigma, \mathbf{e})}{P'(\sigma)} . \tag{6}$$

In normalized importance sampling, we draw a set of samples $\mathcal{D} = \{\sigma[1], \ldots, \sigma[M]\}$ i.i.d. from the proposal distribution, and estimate the conditional expectation of a function g given evidence $\mathbf{e}$ as

$$\hat{\mathbf{E}}_{\mathcal{N}}[g \mid \mathbf{e}] = \frac{1}{W} \sum_{m=1}^{M} g(\sigma[m]) w(\sigma[m])$$

where W is the sum of the weights.

This estimator is consistent if the support of P' is a superset of the support of $P_{\mathcal{N}}$. In general, $\hat{\mathbf{E}}_{\mathcal{N}}$ is biased and the bias decreases as $O(M^{-1})$. The variance of the estimator also decreases as $O(M^{-1})$. For more information on this and related sampling estimates, see Hesterberg (1995).

For our algorithm, we base the proposal distribution on the forward sampling algorithm. As we are sampling a trajectory, we occasionally depart from the regular forward sampling algorithm and "force" the behavior of one or more variables to ensure consistency with the evidence.

3.4 Simple Evidence

The simplest query involves evidence over some subset of variables $\boldsymbol{V} \subset \boldsymbol{X}$ for the total length of the trajectory. We force only the behavior of the variables $\boldsymbol{V}$ and there are no choices about how to do that. In particular, we use the following proposal distribution: forward sample the behavior of variables $X \in (\boldsymbol{X} \setminus \boldsymbol{V})$ inserting the known transitions at known times for variables in $\boldsymbol{V}$ as determined by the evidence. As there are no choices in our forcing, the likelihood of drawing σ from the proposal distribution is just the likelihood contribution of forward sampling the behavior of the variables $X \in (\boldsymbol{X} \setminus \boldsymbol{V})$, in the context of the total behavior of the system.

According to Section 2.2, $x[t_1 : t_2)$ can be summarized by the sufficient statistics over X on the interval $[t_1, t_2)$. Let $\tilde{L}_X(x[t_1 : t_2))$ be a partial likelihood contribution function, computed by plugging the sufficient statistics of $x[t_1 : t_2)$ into Equation 2. The partial contribution function can be defined over a collection of intervals I as $\tilde{L}_X(I) = \prod_{x[t_1 : t_2) \in I} \tilde{L}_X(x[t_1 : t_2))$. Returning to our simple evidence above, let $\tau_1 < \tau_2 \ldots, \tau_{n-1} < \tau_n$ be all the transition times in $\sigma_{[0,T)}$, $\tau_0 = 0$ and $\tau_{n+1} = T$. The likelihood of drawing σ from the target distribution $P_{\mathcal{N}}$ is

$$\tilde{L}_{\mathcal{N}}(\sigma) = \prod_{X \in \boldsymbol{X}} \prod_{i=0}^{n} \tilde{L}_X(x[\tau_i : \tau_{i+1}))$$

Let $\tilde{L}'_X(x[t_1 : t_2))$ be the corresponding probability density for our sampling procedure. Since we force the values and transitions of variables in $\boldsymbol{V}$ according to the evidence, the probability that we sample an interval $x[\tau_i : \tau_{i+1})$ for $X \in \boldsymbol{V}$ from proposal distribution P' is always 1. Therefore, the likelihood of drawing σ from the proposal distribution P' is

$$\begin{aligned}
\tilde{L}'_{\mathcal{N}}(\sigma) &= \prod_{X \in \boldsymbol{X}} \prod_{i=0}^{n} \tilde{L}'_X(x[\tau_i : \tau_{i+1})) \\
&= \prod_{X \in (\boldsymbol{X} \setminus \boldsymbol{V})} \prod_{i=0}^{n} \tilde{L}_X(x[\tau_i : \tau_{i+1})) \times \prod_{X \in \boldsymbol{V}} \prod_{i=0}^{n} 1.
\end{aligned}$$

To compute the proper weight $w(\sigma)$ we substitute in Equation 6, and get

$$\begin{aligned}
w(\sigma) = \frac{P_{\mathcal{N}}(\sigma, \mathbf{e})}{P'(\sigma)} &= \frac{\prod_{X \in \boldsymbol{X}} \prod_{i=0}^{n} \tilde{L}_X(x[\tau_i : \tau_{i+1}))}{\prod_{X \in (\boldsymbol{X} \setminus \boldsymbol{V})} \prod_{i=0}^{n} \tilde{L}_X(x[\tau_i : \tau_{i+1}))} \\
&= \prod_{X \in \boldsymbol{V}} \prod_{i=0}^{n} \tilde{L}_X(x[\tau_i : \tau_{i+1})).
\end{aligned}$$

Therefore, the weight $w(\sigma)$ is the likelihood contribution of all the variables in $\boldsymbol{V}$. This algorithm exactly corresponds to *likelihood weighting* in Bayesian networks (Shachter and Peot, 1989; Fung and Chang, 1989).

Intuitively, this makes sense because we can account for all the evidence by simply assigning the observed trajectories to the observed variables.

3.5 General Evidence

Now, consider a general evidence pattern $\mathbf{e}$, in which we have time instants where variables become observed or unobserved. How can we force our trajectory to be consistent with $\mathbf{e}$? Suppose there is a set of variables which has evidence beginning at t_e. We can not simply force a transition at time t_e to make the variables consistent with the evidence $\mathbf{e}$: if the set contains more than one variable, the sample would have multiple simultaneous transitions, an event whose likelihood is zero.

Instead, we look ahead for each variable we sample. If the current state of the variable does not agree with the upcoming evidence, we force the next sampled transition time to fall before the time of the conflicting evidence. To do this, we sample from a truncated exponential distribution instead of the full exponential distribution. In particular, if we are currently at time t and there is conflicting evidence for X at time $t_e > t$, we sample from an exponential distribution with the same q value as the normal sampling procedure, but where the sample for Δt (the time to the next transition) is required to be less than $t_e - t$. The probability density of sampling Δt from this truncated exponential is $\frac{q\exp(-q\Delta t)}{1-\exp(-q(t_e-t))}$ where q is the relevant intensity for the current state of X (the diagonal element of $\mathbf{Q}_{X|\mathbf{U}_X}$ corresponding to the current state of X).

The subsequent state is still sampled from the same (forward sampling) distribution. In Section 3.6 we explore a more intelligence option. Note that we cannot, in general, transition directly to the evidence state, as such a transition may not be possible (have 0 rate). Furthermore, if we are still "far away" from the upcoming evidence, such a transition may lead to a highly unlikely trajectory resulting in an inefficient algorithm.

To calculate the weight $w(\sigma)$, we partition σ into two pieces. Let σ_e be the collection for all variables $X \in \boldsymbol{X}$ of intervals $x[t_1 : t_2)$ where the behavior of X is set by the evidence. Let σ_s be the complement of σ_e containing the collection of intervals of unobserved behavior for all variables. By applying Equation 6, we have

$$\begin{aligned} w(\sigma) &= \frac{P_{\mathcal{N}}(\sigma, \mathbf{e})}{P'(\sigma)} \\ &= \prod_{x[\tau_i : \tau_{i+1}) \in \sigma_s} \frac{\tilde{L}_X(x[\tau_i : \tau_{i+1}))}{\tilde{L}'_X(x[\tau_i : \tau_{i+1}))} \times \prod_{x[\tau_i : \tau_{i+1}) \in \sigma_e} \frac{\tilde{L}_X(x[\tau_i : \tau_{i+1}))}{\tilde{L}'_X(x[\tau_i : \tau_{i+1}))} \\ &= \prod_{x[\tau_i : \tau_{i+1}) \in \sigma_s} \frac{\tilde{L}_X(x[\tau_i : \tau_{i+1}))}{\tilde{L}'_X(x[\tau_i : \tau_{i+1}))} \times \prod_{x[\tau_i : \tau_{i+1}) \in \sigma_e} \tilde{L}_X(x[\tau_i : \tau_{i+1})). \end{aligned} \tag{7}$$

Based on the distribution we sampled for transition time of the variable in each step, we can further partition σ_s into three pieces:

σ_{sn} be the collection for all variables $X \in \boldsymbol{X}$ of intervals $x[t_1 : t_2)$ where the transition time is sampled from an exponential distribution.

σ_{st} be the collection for all variables $X \in \boldsymbol{X}$ of intervals $x[t_1 : t_2)$ where the transition time is sampled from a truncated exponential distribution and the variable is involved in the next transition.

σ_{sf} be the collection for all variables $X \in \boldsymbol{X}$ of intervals $x[t_1 : t_2)$ where the transition time is sampled from a truncated exponential distribution and the variable is not involved in the next transition.

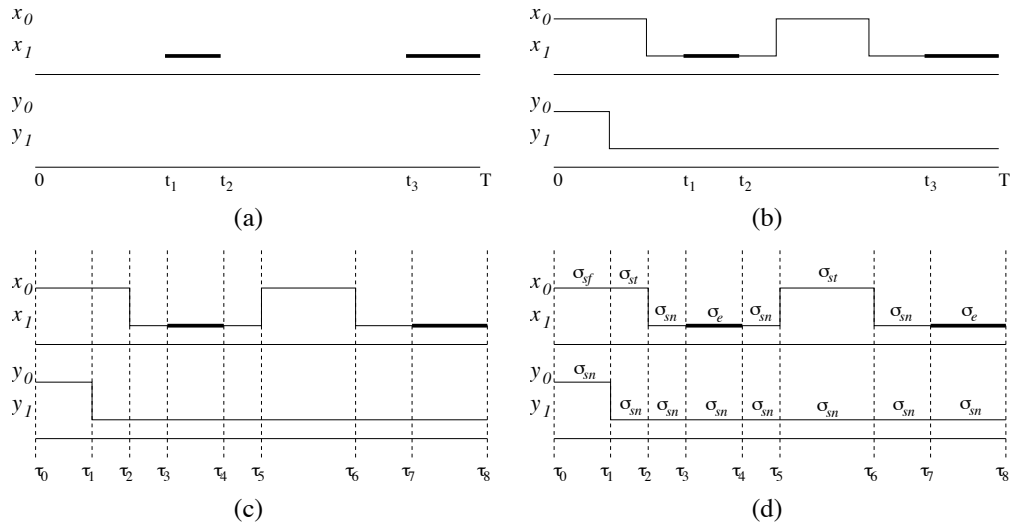

Figure 3: (a) Evidence of a CTBN. (b) A sampled trajectory agreeing with the evidence. (c). Partitioning of the trajectory according to the evidence and the transitions. σ_e equals $x[\tau_3 : \tau_4)$ and $x[\tau_7 : \tau_8)$ (d) Partitioning of the trajectory based on the different sampling situations.

Therefore, we can rewrite Equation 7 as

$$w(\sigma) = \prod_{x[\tau_i : \tau_{i+1}) \in \sigma_{sn}} \frac{\tilde{L}_X(x[\tau_i : \tau_{i+1}))}{\tilde{L}'_X(x[\tau_i : \tau_{i+1}))} \times \prod_{x[\tau_i : \tau_{i+1}) \in \sigma_{st}} \frac{\tilde{L}_X(x[\tau_i : \tau_{i+1}))}{\tilde{L}'_X(x[\tau_i : \tau_{i+1}))} \times \prod_{x[\tau_i : \tau_{i+1}) \in \sigma_{sf}} \frac{\tilde{L}_X(x[\tau_i : \tau_{i+1}))}{\tilde{L}'_X(x[\tau_i : \tau_{i+1}))} \times \prod_{x[\tau_i : \tau_{i+1}) \in \sigma_e} \tilde{L}_X(x[\tau_i : \tau_{i+1})). \quad (8)$$

Example 2 *Assume that we are given a CTBN with two binary variables X and Y. X has two states x_0 and x_1. Y has two states y_0 and y_1. We have such observation: X is x_1 in interval $[t_1, t_2)$ and $[t_3, T)$, as shown in Figure 3(a). To answer queries based on the evidence, we use the method above to sample trajectories. Figure 3(b) shows one of the sampled trajectories. To calculate the weight of the trajectory, we partition the trajectory into four categories (as shown in Figure 3(c) and Figure 3(d)), and apply Equation 8.*

According to Equation 8, each time we add a new transition to the trajectory, we advance time from t to $t + \Delta t$. For each variable x we must update the weight of trajectory to reflect the likelihood ratio for $x[t : t + \Delta t]$ based on the distribution we use to sample the "next time" and the transition variable we select. Each such variable can be considered separately as their times are sampled independently.

For any variable x whose value is given in the evidence during the interval $[t, t + \Delta t)$, as we discussed above, the contribution to the trajectory weight is just $\tilde{L}_{\mathcal{N}}(x[t : t + \Delta t))$. For any variable $x[t : t + \Delta t) \in \sigma_{ns}$, whose "next time" was sampled from an exponential distribution, $\tilde{L}_X(x[\tau_i : \tau_{i+1})) = \tilde{L}'_X(x[\tau_i : \tau_{i+1}))$ and the ratio is 1.

Now, we consider segments $x[t : t + \Delta t) \in \sigma_{st}$ and $x[t : t + \Delta t) \in \sigma_{sf}$. The behavior of the variables in these segments are forced due to upcoming evidence.

For variable X that $x[t : t + \Delta t) \in \sigma_{st}$, the variable's "next time" is sampled from a truncated exponential distribution and it is part of the next transition. The weight must be multiplied by the probability density of sampling the transition in $P_{\mathcal{N}}$ divided by the the probability density in the sampling algorithm. The former is

an exponential distribution and the latter is the same exponential distribution, truncated to be less than $t_e - t$. The ratio of these two probabilities is $1 - \exp(-q(t_e - t))$, where q is the relevant intensity.

Otherwise, $x[t : t + \Delta t) \in \sigma_{sf}$, the next time for the variable was sampled from a truncated exponential but was longer than Δt. In this case, the ratio of the probabilities of a sample being greater than Δt is $\frac{1-\exp(-q(t_e-t))}{1-\exp(-q(t_e-t-\Delta t))}$. Note that when Δt is small (relative to $t_e - t$, the time to the next evidence point for this variable), the ratio is almost 1. So, while the trajectory's weight is multiplied by this ratio for every transition for every variable that does not agree with the evidence, it does not overly reduce the weight of the entire trajectory.

The algorithm for CTBN importance sampling is shown in Figure 4. To more easily describe the evidence, we define a few helper functions:

$\mathbf{e}_X^{val}(t)$ is the value of X at time t according to the evidence, or undefined if X has no evidence at t.

$\mathbf{e}_X^{time}(t)$ is the first time after t when $\mathbf{e}_X^{val}(t)$ is defined.

$\mathbf{e}_X^{end}(t)$ is the first time after or equal to t when $\mathbf{e}_X^{val}(t)$ changes value or becomes undefined.

Note that $\mathbf{e}_X^{end}(t) = t$ when there is point evidence at t, when t is the end of an interval of evidence, and when there is a transition in the evidence at time t.

The line numbers follow those given in the forward sampling algorithm with new or changed lines marked with an asterisk. $Time(X)$ might be set to the end of an interval of evidence which is not a transition time but simply a time when we need to resample a next potential transition. This means that we will not update σ with a new transition every time through the loop. The algorithm differs from the forward sampling procedure as follows. Step 2 now accounts for evidence at the beginning of the trajectory (using standard likelihood weighting for Bayesian networks). In Step 3, we draw Δt from the truncated exponential if the current value disagrees with upcoming evidence. If the current evidence includes this variable, Δt is set to the duration of such evidence. Step 5 updates the weights using the procedure *Update-Weight*. Finally, Step 7 now deals with variables that are just leaving the evidence set.

3.6 Predictive Lookahead

The algorithm in Figure 4 draws the next state for a variable from the same distribution as the forward sampling algorithm. This may cause a variable to transition several times in a short interval before evidence as the variable "searches" to find a way to transition into the evidence. Thus, we may generate many unlikely samples, making the algorithm inefficient. We can help mitigate this problem by trying to force the variable into a state that will lead to the evidence.

When sampling the next state for variable X at time t, instead of sampling from the multinomial according to $\boldsymbol{\theta}_{x(t)|\mathbf{u}_X(t)}$, we would like to sample from the distribution of the next state conditioned on the upcoming evidence. Suppose X is in state x_i at time t, and the next evidence for X is state x_k at t_e. Assuming the parents of X do not change before t_e and ignoring evidence over the children of X, the distribution of the state of X at t given only the evidence can be calculated using Equation 3:

$$\tilde{P}(X_{t+\Delta t} = x_j | X[t : t + \Delta t) = x_i, X_{t_e} = x_k) = \frac{1}{Z}\mathbf{1}_j^\top \mathbf{Q}_X \exp(\mathbf{Q}_X(t_e - t))\mathbf{1}_k = p_{i,j}$$

where $\mathbf{1}_j$ is the vector of zeros, except for a one in position j. We can therefore select our new state according to the distribution of $\tilde{P}(X_{t+\Delta t} | X[t : t + \Delta t) = x_i, X_{t_e} = x_k)$ and, assuming state x_j is selected, multiply the weight by $\frac{\theta_{x_i x_j|\mathbf{u}_X(t)}}{p_{i,j}}$ to account for the difference between the target and sampling distributions.

3.7 Particle Filtering

The algorithm in Figure 4 allows us to generate a single trajectory and its weight, given the evidence. To apply this algorithm to the task of online inference in a dynamic system, we can generate multiple trajectories in parallel, advancing time forward as evidence is obtained.

Procedure *CTBN-Importance-Sample*$(t_{end}, \mathbf{e})$

1. $t \leftarrow 0, \sigma \leftarrow \emptyset, w \leftarrow 1$ *
2. For each variable $X \in \boldsymbol{X}$
   If $\mathbf{e}_X^{val}(0)$ defined,
   set $x(0) \leftarrow \mathbf{e}_X^{val}(0)$, *
   Set $w \leftarrow w \cdot \theta^{\mathcal{B}}_{x(0)|\mathbf{pa}_{\mathcal{B}}(0)}$ *
   Else
   choose state $x(0)$ according to $\boldsymbol{\theta}^{\mathcal{B}}_{X|\mathbf{pa}_{\mathcal{B}}(X)}$

Loop:

3. For each $X \in \boldsymbol{X}$ such that $Time(X)$ is undefined:
   If $\mathbf{e}_X^{val}(t)$ is defined, set $\Delta t \leftarrow \mathbf{e}_X^{end}(t) - t$ *
   Elseif $\mathbf{e}_X^{val}(t_e)$ is defined where $t_e = \mathbf{e}_X^{time}(t), x(t) \neq \mathbf{e}_X^{val}(t_e)$,
   choose Δt from an exponential distribution with
   parameter $q_{x(t)|\mathbf{u}_X(t)}$ given $\Delta t < (t_e - t)$. *
   Else choose Δt from an exponential w/ param. $q_{x(t)|\mathbf{u}_X(t)}$
   Define $Time(X) \leftarrow t + \Delta t$
4. Let $X = \arg\min_{X \in \boldsymbol{X}} [Time(X)]$
5. If $Time(X) \geq t_{end}$
   $w \leftarrow$ *Update-Weight*(X, w, t, t_{end}) *
   return (σ, w)
   Else *
   $w \leftarrow$ *Update-Weight*$(X, w, t, Time(X))$ *
6. Update $t \leftarrow Time(X)$
7. If $\mathbf{e}_X^{end}(t) \neq t$ or $\mathbf{e}_X^{val}(t)$ is defined *
   If $\mathbf{e}_X^{val}(t)$ is defined, set $x(t) \leftarrow \mathbf{e}_X^{val}(t)$ *
   Else choose $x(t)$, the next value of X, from a
   multinomial with parameter $\boldsymbol{\theta}_{x(t)|\mathbf{u}_X(t)}$
   Add $\langle X \leftarrow x(t), t \rangle$ to σ.
   Undefine $Time(X)$ and $Time(Y)$ for all variables Y
   for which $X \in \mathbf{U}_Y$
   Else *
   Undefine $Time(X)$. *

Procedure *Update-Weight*(Y, w, t_1, t_2)

1. For each $X \in \boldsymbol{X}$ such that $\mathbf{e}_X^{val}(t)$ is defined for $t \in [t_1, t_2)$:
   $w \leftarrow w \cdot \tilde{L}_X(x[t_1 : t_2))$
2. For each $X \in \boldsymbol{X}$ such that $\mathbf{e}_X^{val}(t_e)$ is defined,
   where $t_e = \mathbf{e}_X^{time}(t_1)$, and $x(t_1) \neq \mathbf{e}_X^{val}(t_e)$:
   If $X = Y$, $w \leftarrow w \cdot (1 - \exp(-q_{x(t_1)|\mathbf{u}_X(t_1)}(t_e - t_1)))$
   Else $w \leftarrow w \cdot \frac{1 - \exp(-q_{x(t_1)|\mathbf{u}_X(t_1)}(t_e - t_1))}{1 - \exp(-q_{x(t_1)|\mathbf{u}_X(t_1)}(t_e - t_2))}$
3. **return** w

Figure 4: Importance sampling for CTBNs. Changes from Figure 2 are noted with asterisks.

The resulting algorithm is an instance of sequential importance sampling, and therefore suffers from its characteristic flaw: As the trajectory length increases, the distribution of the importance weights gets increasingly skewed, with most importance weights converging to zero exponentially quickly. Thus, the number of "relevant" samples gets increasingly small, and the estimates provided by the set of samples quickly become meaningless. A family of methods, commonly known as sequential Monte Carlo or particle filtering (Doucet et al., 2001), have been proposed in the setting of discrete-time processes to address this flaw.

Procedure *CTBN-Particle-Filtering*$(\{X_0^i, w_0^i\}_{i=1\ldots N}, t_{end}, \mathbf{e})$
1. $k \leftarrow 0, W_t \leftarrow 1, N_r \leftarrow N$
2. For $i \leftarrow 1$ to N: $Pa_0^i \leftarrow i, w^i \leftarrow 1/N$

Loop:

3. For each i such that $t_k^i < t_{end}$:
   $(X_{k+1}^i, t_{k+1}^i, w_{k+1}^i) \leftarrow$
   *S*ample-Segment$(X_k^{Pa_k^i}, t_k^{Pa_k^i}, w^i, t_{end}, \mathbf{e})$
   If $t_{k+1}^i \geq t_{end}$
   $N_{remain} \leftarrow N_r - 1$,
   $W_t \leftarrow W_t - w_{k+1}^i$
4. $k \leftarrow k+1$
5. If $N_r = 0$
   return $\{X_{m_i}^i, t_{m_i}^i, w_{m_i}^i, Pa_{m_i}^i\}_{i=1\ldots N, m_i=1\ldots n_i}$,
   where n_i is the number of transitions of the i^{th} particle
6. Calculate $\widehat{N_{eff}}$ of all incomplete particles
7. If $\widehat{N_{eff}} < N_{thr}$
   Sample Pa_k^i according to w_k^i
   $w^i \leftarrow W_t \times 1/N_r$
   Else
   $w^i \leftarrow w_k^i, Pa_k^i \leftarrow Pa_{k-1}^i$

Figure 5: Particle Filtering for CTBNs

At a high level, these methods re-apportion our samples to focus more efforts on more relevant samples—those with higher weights.

The application of this idea to our setting introduces some subtleties because different samples are not generally synchronized. We could pick a time t and run the algorithm in Figure 4 with $t_{end} = t$ so that samples are synchronized at t. We would re-apportion the weights and continue each trajectory from its state at t, first setting $Time(X)$ to be undefined for all X. However, choosing the proper synchronization time t is a non-trivial problem which may depend on the evidence and the speed the system evolves.

Instead of synchronizing all the particles by the time, we can align particles by the number of transitions. If we let t_i be the i^{th} transition time and X_i be the value of X from t_{i-1} to t_i, the following recursion holds.

$$\begin{aligned} P(X[0:t_n)) &= P(X_{1:n}, t_{1:n}, e_{[0:t_n)}) \\ &= P(X_{1:n-1}, t_{1:n-1}, e_{[0:t_{n-1})}) P(X_n | X_{n-1}) P(X_{[t_{n-1},t_n)}, e_{[t_{n-1},t_n)} | X_{n-1}, e_{t_{n-1}}). \end{aligned}$$

The weighted approximation of this probability is given by

$$P(X[0:t_n)) \approx \sum_{i=1}^{N} w(X^i[0:t_n)) \delta(X[0:t_n), X^i[0:t_n))$$

where $X^i[0:t_n)$ is the i^{th} sample and $w(X^i[0:t_n))$ is the normalized weight of the i^{th}sample. According to Equation 8, the weight can be updated after every transition step. The weight update equation can be shown as

$$w(X^i[0:t_n)) \propto w(X^i[0:t_{n-1})) \frac{\tilde{L}_X(X^i[t_{n-1}:t_n))}{\tilde{L}'_X(X^i[t_{n-1}:t_n))}.$$

Thus, to sample multiple trajectories in parallel, we apply the CTBN importance sampling algorithm to each trajectory until a transition occurs. To avoid the degeneracy of the weights, we resample the particles when the estimated effective sample size $\widehat{N_{eff}} = \frac{1}{\sum_i (w_k^i)^2}$ is below a threshold N_{thr}. This procedure is similar to the regular particle filtering algorithm except that all particles are not synchronized by time but the number

Procedure *CTBN-Particle-Smoothing*$(\{X^i_{m_i}, t^i_{m_i}, w^i_{m_i}\}, t_{end}, \mathbf{e})$
$i = 1 \ldots N, m_i = 1 \ldots M_i$
1. $\sigma \leftarrow \emptyset$
2. Choose k with probability proportional to $w_i^{M_i}$
3. set $Y = X_{M_k^k}, s \leftarrow M_k, t \leftarrow t_s^k$
Loop:
4. $\sigma_{[t_{s-1},s)} \leftarrow Y$
5. If σ is complete
return σ
6. For $j \leftarrow 1$ to N
$w'_j \leftarrow$ *Check-Weight*$(Y, t, X^j_{s-1}, t^j_{s-1}, w^j_{s-1})$
7. Choose i with probability proportional to w'_i
8. $Y \leftarrow X_i^s, t \leftarrow t_s^j$ $s \leftarrow s-1$

Procedure *Check-Weight*(X, t, X_s, t_s, w_s)
1. If $t \leq t_s$ or $\mathbf{e}_{(ts,t)}$ contains a transition, or
the value of X and X_s do not differ by only one variable
return 0
2. $\sigma_{[t_s,t)} \leftarrow X_s, \sigma(t) \leftarrow X$
3. $w \leftarrow w_s \cdot \tilde{L}_X(\sigma_{[t_s,t_2]})$
4. **return** w

Figure 6: Particle Smoothing for CTBNs

of transitions. To answer queries in the time interval $[0, T)$, we propagate the particles until all of their last transitions are greater than T.

Figure 5 shows the algorithm for generating N trajectories from 0 to T in a CTBN. It assumes that the initial values and the weights have already been sampled. The procedure *Sample-Segment* loops from line 3 to 7 in Figure 4 until a transition occurs, returns the transition time and variables value, and updates the corresponding weight for that segment. Note that we are approximating the distribution $P(X_{1:n}, t_{1:n}, e_{[0:t_n)})$ for all possible n. Therefore, we only propagate and re-apportion weights for particles that have not yet reached time T. Particles that have been sampled past T are left untouched.

3.8 Particle Smoothing

Although the resampling step in the particle filtering algorithm reduces the skew of the weights, it leads to another problem: the diversity of the trajectories is also reduced since particles with higher weights are likely to be duplicated multiple times in the resampling step. Many trajectories share the same ancestor after the filtering procedure. A Monte Carlo smoothing algorithm using backward simulation addresses this problem (Godsill et al., 2004).

The smoothing algorithm for discrete-time systems generates trajectories using N weighted particles $\{x^i_t, w^i_t\}$ from the particle filtering algorithm. It starts with the particles at time T, moves backward one step each iteration and samples a particle according to the product of its weight and the probability of it transitioning to the previously sampled particle. Specifically, in the first step, it samples $\widetilde{x}_T$ from particles x^i_T at time T with probability w^i_T. In the backward smoothing steps it samples $\widetilde{x}_t$ according to $w^i_{t|t+1} = w^i_t f(\widetilde{x}_{t+1}|x^i_t)$, where $f(\widetilde{x}_{t+1}|x^i_t)$ is the probability that the particle transitions from state x^i_t to $\widetilde{x}_{t+1}$. The resulting trajectory set is an approximation of $P(x_{1:T}|y_{1:T})$ where $y_{1:T}$ is the observation.

This idea can be used in our setting with modification. Given the filtered particles $\{X^i_{m_i}, t^i_{m_i}, w^i_{m_i}\}$,we need to sample both variable values and transition times at each step when we move backward. There are two main differences from the algorithm in Godsill et al. (2004): There are fewer than N particles that can be

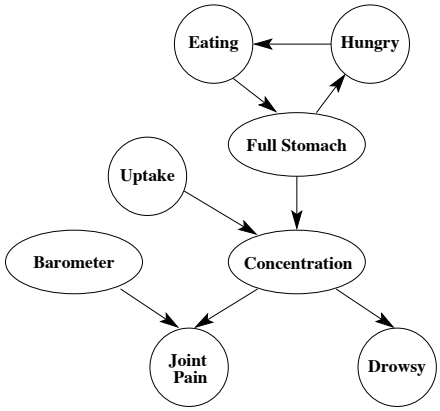

Figure 7: Drug Effect Network

used at the beginning steps of the backward smoothing since the trajectories do not have exactly the same number of transitions, and not all particles at step n can be considered as candidates to move backward. A particle $\{X_n^i, t_n^i, w_n^i\}$ is a valid candidate as the predecessor for $\{\widetilde{X}_{n+1}, \widetilde{t}_{n+1}\}$ only if (1) $t_n^i < \widetilde{t}_{n+1}$, (2) the values of X_n^i and $\widetilde{X}_{n+1}$ differ in only one variable (thus a single transition is possible), and (3) $\mathbf{e}_{(t_n^i, \widetilde{t}_{n+1})}$ contains no transitions.

Figure 6 shows the smoothing algorithm which generates a trajectory from the filtering particles. We apply the algorithm N times to sample N trajectories. These equally weighted trajectories can be used to approximate the smoothing distribution $P(X_{[0,T)}|\mathbf{e})$. Generating one trajectory with this smoothing process requires considering all the particles at each step. The running time of sampling N trajectories using particle smoothing is N times of that of particle filtering.

4. Experimental Results

In this section, we report on the performance of our algorithm on synthetic networks and a network built from a real data set of people's life histories. We tested our algorithm's accuracy for the task of inference and parameter estimation. We also compare our algorithms with other approximate inference algorithms for CTBNs: the method based on the expectation propagation in Saria et al. (2007) and the method based on Gibbs sampling in El-Hay et al. (2008).

All the algorithms we used in the experiments were implemented in the same code base to make fair comparisons. We tried our best to optimize all the code. The implementations are general so that they can be applied to any CTBN model. Our implementation of EP is adapted from that of Saria et al. (2007) who were kind enough to share their code. The code base is described in Shelton et al. (2010) and is available from the authors' website.

4.1 Networks

In our experiments, different types of network structures were used, including the drug effect network (Nodelman et al., 2002), a chain-structured network, and the BHPS network (Nodelman et al., 2005b). All the networks are at the upper size limit for the exact inference algorithm so that we can compare our result to the true value.

Drug Effect Network: The drug effect network is a toy model of the effect of a pain-relief medicine. It has 8 (5 binary and 3 ternary) variables. The structure of the network is shown in Figure 7. At $t = 0$ the person is not hungry, is not eating, has an empty stomach and is not drowsy. He has joint pain due to the falling barometric pressure and takes the drug to alleviate the pain.

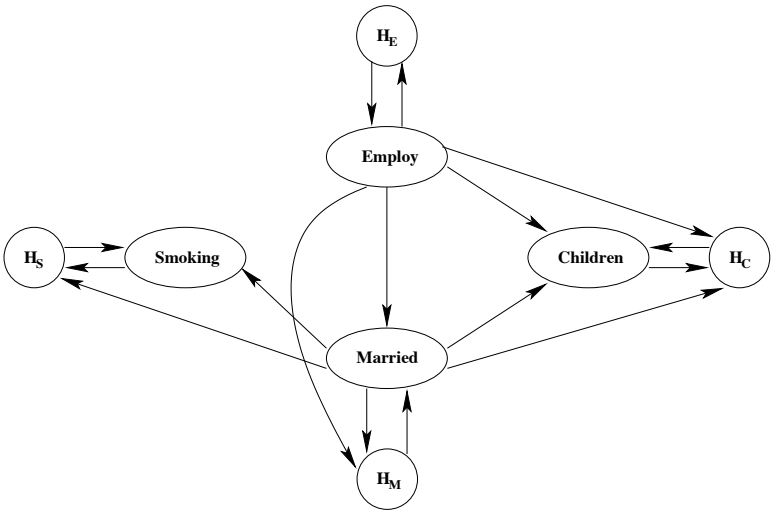

Figure 8: British Household Panel Survey Network

Chain Structured Network: The chain network contains five nodes $X_0, \ldots, X_5$, where X_i is the parent of X_{i+1} for $i < 5$. Each node has five states, $s_0, \ldots, s_4$. X_0 (usually) cycles in two loops: $s_0 \to s_1 \to s_3 \to s_0$ and $s_0 \to s_2 \to s_4 \to s_0$. All the other nodes stay at their current state if it matches their parent and otherwise transition to their parent's state with a high probability. Each variable starts in state s_0.

More specifically, the intensity matrix of X_0 is

$$\mathbf{Q}_{X_0} = \begin{bmatrix} -2.02 & 1 & 1 & 0.01 & 0.01 \\ 0.01 & -2.03 & 0.01 & 2 & 0.01 \\ 0.01 & 0.01 & -2.03 & 0.01 & 2 \\ 2 & 0.01 & 0.01 & -2.03 & 0.01 \\ 2 & 0.01 & 0.01 & 0.01 & -2.03 \end{bmatrix}.$$

For all other nodes, the off-diagonal elements of the intensity matrices are given by

$$q_{s_i,s_j|\mathbf{u}=s_k} = \begin{cases} 0.1 & \text{if } i \neq j \text{ and } j \neq k, \\ 10 & \text{if } i \neq j \text{ and } j = k. \end{cases}$$

BHPS Network: This network was learned from the British Household Panel Survey (BHPS) (ESRC Research Centre on Micro-social Change, 2003) data set. The data set provides information about British citizens. The data are collected yearly by asking thousands of households questions such as household organization, employment, income, wealth and health. Similar to Nodelman et al. (2005b), we keep a small set of variables so that exact inference could be applied. We chose four variables: employ (ternary: student, employed, unemployed), children (ternary: 0, 1, 2+), married (binary: not married, married), and smoking (binary: non-smoker, smoker), and we assumed there is a hidden variable (binary) for each of those four variables. We trained the network on 8935 trajectories of people's life histories. We applied the structural EM algorithm in Nodelman et al. (2005b) and learned the structure of the network shown in Figure 8. We then estimated the parameters of the network using the EM algorithm and exact inference. We consider the learned model as the true BHPS network model for these experiments.

4.2 Evaluation Method

We evaluated the performance of the approximate inference algorithms in two tasks: the inference task of answering queries given evidence and the learning task of parametric learning with partially observed data.

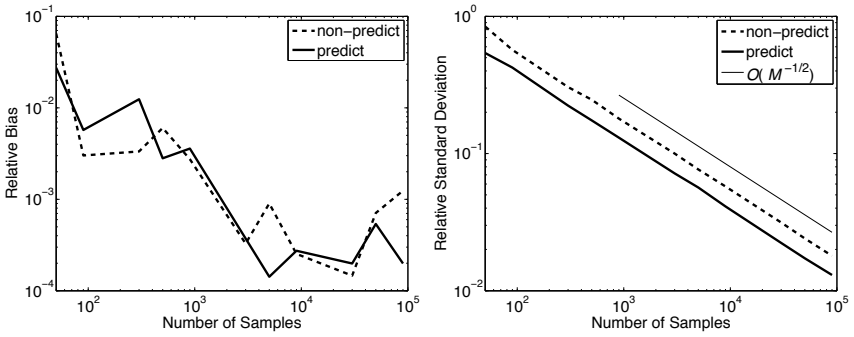

Figure 9: Relative bias and standard deviation of sampling with and without predictive lookahead.

In the inference task, each evidence is a partially observed trajectory of the CTBN network. The evidence is generated using two methods. The first method is to set it manually. The second is to generate a trajectory using the forward sampling algorithm and randomly remove some parts of the sampled trajectory. In particular, we repeated the following procedure n times: for each variable, we randomly removed the information of the trajectory from t_s to $t_s + \gamma T$, where T is the total length of the trajectory, t_s is randomly sampled from the $[0, T - \gamma T]$ uniform distribution and $\gamma < 1$. After we run the removing procedure n times, there are at most $n\gamma$ time units of information missing for each variable. In all comparisons, this procedure was applied once and the same evidence was given to all algorithms.

In our experiments, we set our query to be one of three types: the expected total amount of time a variable X stays on some state x_i, the expected total number of times that a variable transitions from state x_i to state x_j, or the distribution of variable at time t.

For each query, we ran the sampling based algorithms with different sample sizes, M. For each sample size, we ran the experiment N times. We calculated our query according to Equation 6 and compared the result to the true value calculated using exact inference. We used two metrics: the relative bias $\frac{|\sum v_M - v^*|}{v^* N}$, where v_M is the query value of sampling algorithm with sample size M, and v^* is the true value; and the relative standard deviation $\frac{\sigma_M}{v^*}$ where σ_M is the standard deviation from the true value when sample size is M. For each sample size, we also recorded the average running time $\bar{t}_M$ of each experiment and used $\bar{t}_M$ to evaluate the efficiency of the algorithm.

In the learning task, we used the sampling algorithms to estimate the parameters of a CTBN network given some partially observed data. Monte Carlo EM (Wei and Tanner, 1990) was applied in this task: In each iteration, we used the sampling based algorithm to estimate the expected sufficient statistics given the incomplete data and used Equation 4 to compute the parameters.

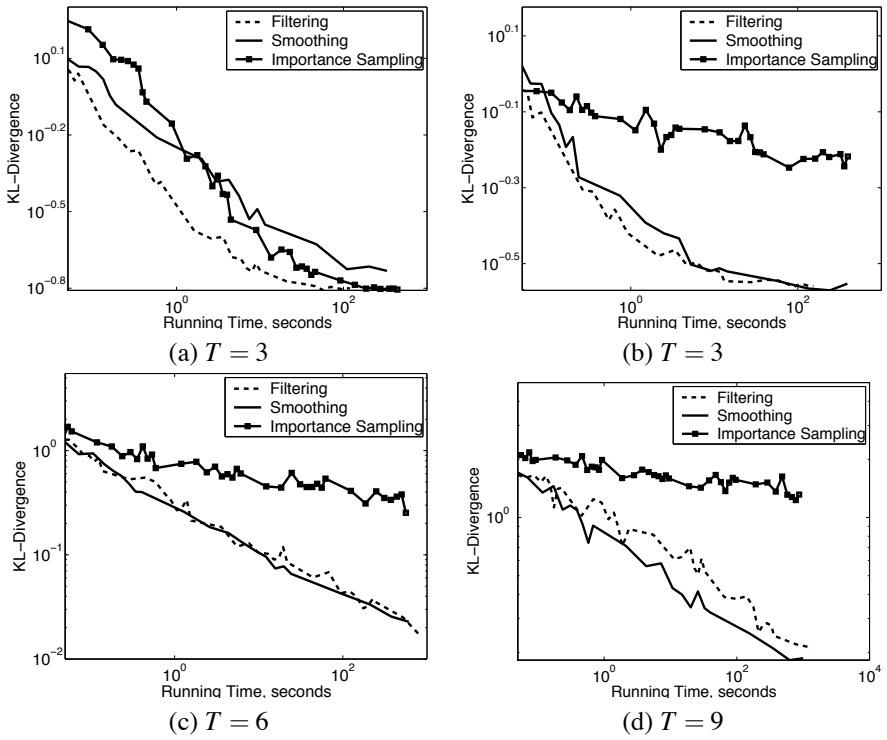
The training data were generated by sampling trajectories from the true model and randomly removing some portion of the information as described above. We sampled another set of trajectories from the true model as the testing data. We calculated the log-likelihood of the testing data under the learned model to evaluate the learning accuracy.

4.3 Inference Experimental Results

In this section, we evaluate the performance of our importance sampling based algorithms in answering queries and compare with the EP algorithm in Saria et al. (2007) and the Gibbs sampling algorithm in El-Hay et al. (2008).

4.3.1 COMPARISON OF IMPORTANCE SAMPLING AND PREDICTIVE LOOKAHEAD

We first tested the importance sampling algorithm and the predictive lookahead modification using the drug effect network. We set the observed evidence: on $t = [0,1)$ the stomach is empty, on $t = [0.5, 1.2)$ the



(a) $T = 3$ (b) $T = 3$

(c) $T = 6$ (d) $T = 9$

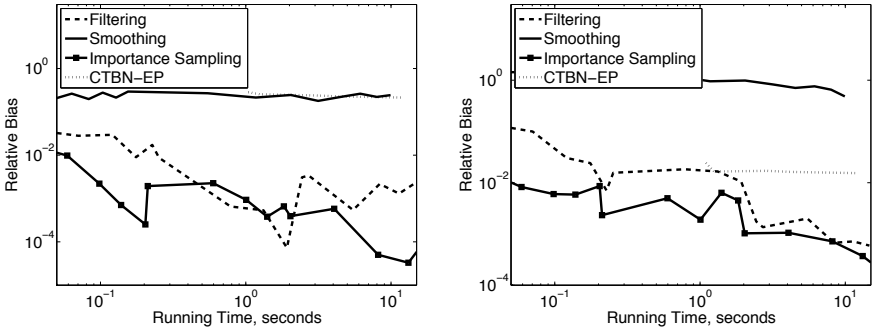
Figure 10: Time-efficiency comparison of particle filtering, smoothing and importance sampling

barometer is falling, and on $t = [1.5, 2.5)$ he is drowsy. Our query is the expected total amount of time that he has no joint pain on $[0, 2.5)$. (The true value is 0.1093). We ran the two algorithms with sample sizes, M, from 5 to 90000. For each sample size, we ran the algorithms $N = 1000$ times. The results are shown in Figure 9. Both algorithms achieve the correct result when the sample size is large. The standard deviation decreases at a rate of $O(\frac{1}{\sqrt{M}})$ (shown by the thin solid line). The sampling algorithm with prediction achieves lower standard deviation than the non-prediction version.

4.3.2 IMPORTANCE SAMPLING, PARTICLE FILTERING AND SMOOTHING

We then used the chain network to evaluate the efficiency of the importance sampling, particle filtering, and smoothing algorithms. We assumed that only X_4 was observed in this experiment. We used four different evidences. The first one is a simple evidence: only part of the behavior of X_4 is observed: on $[1, 1.7)$, $X_4 = s_3$, and on $[2, 2.5)$, $X_4 = s_2$. For the other three, the behavior of X_4 is fully observed during the interval $[0, T)$, where $T = 3, 6, 9$. This is done by forward sampling a trajectory from 0 to T and keeping only the information about X_4. Our query is the marginal distribution $P(X_2(\frac{T}{2})|\mathbf{e}_{[0,T)})$. Note that this is the most difficult case for the importance sampling algorithm since the chain network is nearly deterministic. We recorded the average running time and KL-divergence between the estimated and true distributions, for each sample size across $N = 300$ trials.

Figure 10 shows the efficiency of the three algorithms. In Figure 10(a), we used the simple evidence. In Figure 10 (b)-(d), we used the evidence with X_4 fully observed and $T = 3, 6, 9$ respectively. In all four cases, the particle filtering and smoothing algorithms both outperform the importance sampling algorithm when the sample size is small (small running time). For simple evidence (Figure 10(a)), the importance sampling algorithm achieves comparable performance when the sample size is large. When the evidence is complicated (Figure 10 (b)-(d)), the error of importance sampling is large, even when we use very large



(a) Concentration (b) Joint pain

Figure 11: Comparison to expectation propagation: Drug Network

sample sizes. When the trajectory is short, the particle filtering algorithm is slightly better than the particle smoothing algorithm. This is because the filtering algorithm can generate more samples than the smoothing algorithm with the same running time. However, as the trajectory length increases, the particle smoothing algorithm outperforms the filtering algorithm due to particle diversity problems.

4.3.3 COMPARISON OF IMPORTANCE SAMPLING AND EP

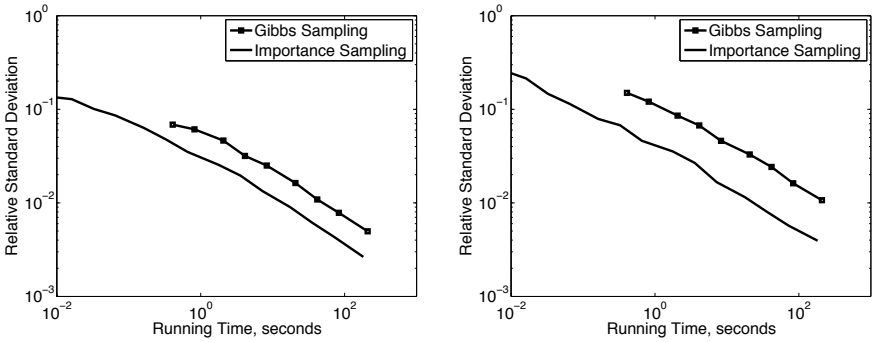
We also compared our three sampling algorithms to the approximate inference algorithm based on expectation propagation in Saria et al. (2007). We did not use their adaptive splitting method (for reasons we explain below). Even without the adaptive splitting, their method still differs from that of Nodelman et al. (2005a), in that it allows asynchronous propagation of messages along time.

We used the same evidence as in Section 4.3.1 on the drug effect network and answered two queries: the total amount of time that the concentration is low and the total amount of time the person has no joint pain. For the EP algorithm, we first tried a segmentation that split the timeline at the evidence. We then gradually decreased the time interval of the segments to 0.15. The results of accuracy with respect to running time are shown in Figure 11. The importance sampling algorithm and the particle filtering algorithm outperforms the EP algorithm in answering both queries. Among the sampling-based algorithms, the importance sampling algorithm performs the best and the smoothing algorithm is the worst. This is not surprising given that most of the nodes are binary. At each transition time, the sampled trajectory has no choice as to the next state. Therefore, smoothing (or filtering) has less effect as there is no need to intelligently select the next state. However, the extra computation time for resampling and backward simulation makes the filtering and smoothing algorithm less efficient.

As mentioned above, we did not employ the adaptive splitting method of Saria et al. (2007). It would not have changed our results much. The left-most points in our Figure 11 correspond to the minimum number of splits. (They are as fast as possible.) The right-most points of the Figure 11 correspond to many fine splits, and are about as accurate as possible, and we can see that the accuracy has flattened out. So, while the horizontal widths of the EP curves would have been shortened (by allowing for the better accuracy in less time), the vertical spread would have been approximately the same. In neither plot of Figure 11 would this have made a large difference in the comparisons to our sampling method.

4.3.4 COMPARISON OF IMPORTANCE SAMPLING AND GIBBS SAMPLING

We compared our importance sampling algorithm to the Gibbs Sampling algorithm in El-Hay et al. (2008). We used three CTBN network models: the drug effect network, the BHPS network and the chain structured network. For each network, we randomly generated evidence using the procedure described in Section 4.2.



(a) Query of Time (b) Query of Transition

Figure 12: Comparison to Gibbs Sampling: Drug Network. Note burn-in time for Gibbs Sampling is not included (3.94 seconds on average).

We ran the procedure 4 times for each variable and each time, we removed 20% of the content. Thus, there are at most 80% information missing for each variable.

For the importance sampling algorithm, we chose the sample size M from 10 to 500000. For Gibbs sampling algorithm, we chose the sample size M from 10 to 5000. We ran the experiments for each sample size $N = 100$ times and recorded the average running time for each algorithm. For Gibbs sampling algorithm, we first ran 100 "burn-in" iterations for each sample size before we sample trajectories from the sampler. The time spent on the "burn-in" iterations was not included in the final running time.

For the drug effect network, the evidence trajectory begins at time $t = 0$ and ends at time $t = 5$. We asked two queries: the expected total amount of time the person's stomach is half full, and the expected number of times that the person's stomach changes from empty to half full.

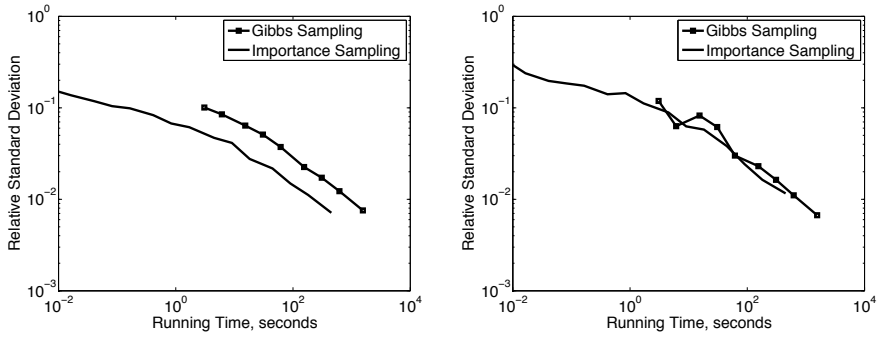
Using enough running time (sample size), we observed that both algorithms could answer the queries accurately (with a relative bias below 0.1%). The decreasing of the relative standard deviation with respect to the running time of the two algorithms are shown in Figure 12. The average "burn-in" time for Gibbs sampler is about 3.94 seconds. From the figure, we can see that importance sampling outperforms Gibbs sampling in answering both queries.

For the BHPS network, we set the evidence from $t = 0$ to $t = 50$ (years). We asked similar queries: the expected total amount of time a person's employment status is as a student and the expected number of times that he becomes employed. We chose the same sample sizes as on the drug effect network and ran each sample size $N = 100$ times. Figure 13 shows the result of the decreasing of the standard deviation of the two algorithms. The average "burn-in" time for Gibbs sampling algorithm in this experiment is 30.88 seconds.

We achieved similar result as the experiments with the drug effect network. The importance sampling algorithm outperformed the Gibbs sampling algorithm in answering the query of time. The performances on the query of transitions are almost the same.

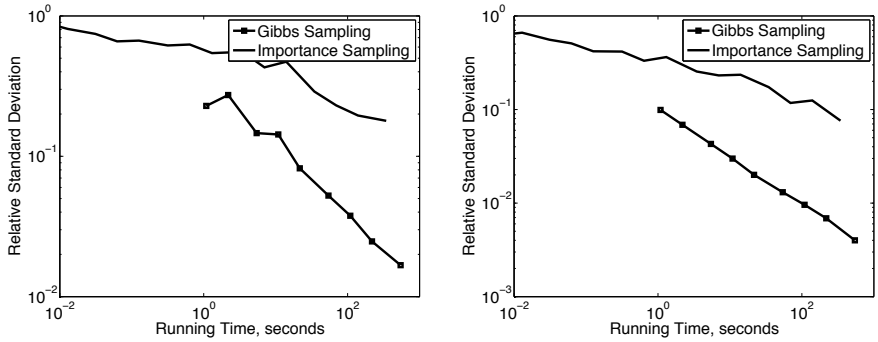
In both networks, importance sampling outperformed Gibbs sampling in three of the four cases, even when the running time on "burn-in" iterations was not considered. To achieve the same accuracy and standard deviation, Gibbs sampling algorithm requires fewer samples. This is because for each variable, Gibbs sampling samples from the true posterior distribution given the evidence and its Markov blanket. However, sampling from the true posterior distribution is computational costly, since it requires repeatedly computing the conditional cumulative distribution function. Using the same amount of time, importance sampling can sample far more trajectories, which outperforms Gibbs sampling.

We last compared these two algorithms using the chain structured network. The evidence trajectory begins at time $t = 0$ and ends at time $t = 5$. We set the queries to be the expected total amount of time X_2 stays in



(a) Query of Time (b) Query of Transition

Figure 13: Comparison to Gibbs Sampling: BHPS Network. Note burn-in time for Gibbs Sampling is not included (30.88 seconds on average).



(a) Query of Time (b) Query of Transition

Figure 14: Comparison to Gibbs Sampling: Chain Network. Note burn-in time for Gibbs Sampling is not included (11.42 seconds on average).

state s_1 and the expected number of times that X_2 transitions from s_0 to s_1. Figure 14 shows the result over $N = 100$ runs. The average "burn-in" time for Gibbs sampling algorithm in this experiment is 11.42 seconds.

The Gibbs sampling algorithm achieved better performance in this experiment. The result is not surprising. As we have mentioned before, the chain structured network is nearly deterministic, and it is the hardest case for the importance sampling algorithm. We further examined the randomly generated evidence. The only observed state on X_0 is s_0, which makes this experiment even harder for the importance sampling algorithm. However, it is a very easy case for the Gibbs sampling algorithm since it is nearly deterministic and is structurally simple. (There are only at most one parent and one child for each node.) Although importance sampling can generate many more samples in the same period of time, most of these samples are trajectories with very small weights.

4.4 Parameter Estimation Experimental Results

In this section, we evaluate the performance of importance sampling algorithm on parameter estimation and compare to the Gibbs sampling algorithm and the EP algorithm.

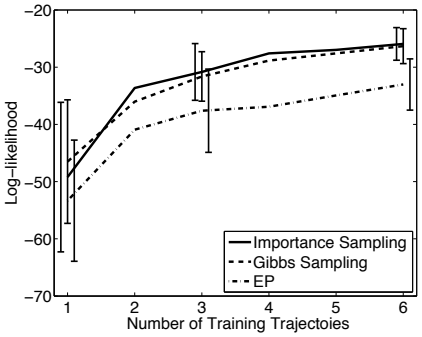


Figure 15: Learning results for the drug effect network. Standard deviations across training data selection (and random samples for the sampling methods) are shown jittered slightly for clarity.

We used the drug effect network for this experiment. We sampled increasing We sampled increasing numbers of trajectories of 5 time lengths. To hide part of the trajectory, we did the following: In each iteration, for each variable we randomly selected a time window of 0.5 time lengths and removed the content in that window. We repeated this until we dropped 50% of the content of the trajectory. We used these incomplete trajectories as our training data. We sampled another 50 trajectories with the same length as our testing data.

To estimate the parameters of the CTBN network, we followed the EM algorithm in Nodelman et al. (2005b). When calculating the expected sufficient statistics, importance sampling, Gibbs sampling, and expectation propagation were used. Therefore, the likelihood in the E-step was calculated approximately. In our experiment, we fixed the total number of iterations for the EM algorithm at 15. In each iteration, we compared the calculated likelihood to the likelihood in the previous iteration. If the likelihood decreased, we kept the parameters in the previous iteration.

We chose the initial parameters for the EM algorithm by sampling the diagonal elements of the conditional intensity matrices from the Gamma distribution with parameters $(0.5, 1)$ and sampling the transition probabilities from a Dirichlet distribution. We randomly sampled 5 models as the initial parameters for the EM algorithm. For each initial parameter set, we ran the EM algorithm 10 times for the sampling methods (and once for EP which is deterministic). We evaluated the learning accuracy by calculating the average log-likelihood of the testing data on the 50 learned networks. To compare the running efficiency of the two sampling-based algorithms, we fixed the total amount of time for the sampler to generate samples in each EM iteration to be the same time as the EP algorithm took (approximately 23 seconds). For the Gibbs sampling algorithm, we dropped the first 50 trajectories as "burn-in" iterations. Figure 15 shows the results as we increased the number of training trajectories from 1 to 6.

All algorithms obtain higher log-likelihood on the testing data when we increase the number of training trajectories. The sampling methods do better (and have lower variation), especially as the data size grows.

5. Conclusion

We have presented an approximate inference algorithm with two variations based on importance sampling. We naturally extended the algorithm to sequential Monte Carlo methods such as particle filtering and smoothing in CTBNs. We applied our sampling algorithm to synthetic networks and a network from real data. We evaluated the efficiency of our algorithms and compared to other approximate inference algorithms based on expectation propagation and Gibbs sampling. Our importance sampling algorithm outperformed both in most of the experiments presented in this paper. In the situation of a highly deterministic system, Gibbs sampling performed better.

The networks used in this paper are at the upper size limit for exact computation. For example, calculating the expected sufficient statistics of the chain structured network given evidence takes more than two days using exact inference. Thus, approximate inference methods are critical for tracking, predicting, and learning in continuous time Bayesian networks for real applications. Our importance sampling based algorithms are fast, simple to implement and can be used to calculate the expected value of any function of a trajectory, including the expected sufficient statistics necessary for expectation-maximization for parameter estimation with missing data.

Abstract

Microarray gene expressions provide new opportunities for molecular classification of heterogeneous diseases. Although various reported classification schemes show impressive performance, most existing gene selection methods are suboptimal and are not well-matched to the unique charac-

teristics of the multicategory classification problem. Matched design of the gene selection method and a committee classifier is needed for identifying a small set of gene markers that achieve accurate multicategory classification while being both statistically reproducible and biologically plausible. We report a simpler and yet more accurate strategy than previous works for multicategory classification of heterogeneous diseases. Our method selects the union of one-versus-everyone (OVE) *phenotypic up-regulated* genes (PUGs) and matches this gene selection with a one-versus-rest support vector machine (OVRSVM). Our approach provides even-handed gene resources for discriminating both neighboring and well-separated classes. Consistent with the OVRSVM structure, we evaluated the fold changes of OVE gene expressions and found that only a small number of high-ranked genes were required to achieve superior accuracy for multicategory classification. We tested the proposed PUG-OVRSVM method on six real microarray gene expression data sets (five public benchmarks and one in-house data set) and two simulation data sets, observing significantly improved performance with lower error rates, fewer marker genes, and higher performance sustainability, as compared to several widely-adopted gene selection and classification methods. The MATLAB toolbox, experiment data and supplement files are available at http://www.cbil.ece.vt.edu/software.htm.

Keywords: microarray gene expression, multiclass gene selection, phenotypic up-regulated gene, multicategory classification

1. Background

The rapid development of gene expression microarrays provides an opportunity to take a genome-wide approach for disease diagnosis, prognosis, and prediction of therapeutic responsiveness (Clarke et al., 2008; Wang et al., 2008). When the molecular signature is analyzed with pattern recognition algorithms, new classes of disease are identified and new insights into disease mechanisms and diagnostic or therapeutic targets emerge (Clarke et al., 2008). For example, many studies demonstrate that global gene expression profiling of human tumors can provide molecular classifications that reveal distinct tumor subtypes not evident by traditional histopathological methods (Golub et al., 1999; Ramaswamy et al., 2001; Shedden et al., 2003; Wang et al., 2006).

While molecular classification falls neatly within supervised pattern recognition, high gene dimensionality and paucity of microarray samples pose challenges for, and inspire novel developments in classifier design and gene selection methodologies (Wang et al., 2008). For multicategory classification using gene expression data, various classifiers have been proposed and have achieved promising performance, including k-Nearest Neighbor Rule (kNN) (Golub et al., 1999), artificial neural networks (Wang et al., 2006), Support Vector Machine (SVM) (Ramaswamy et al., 2001), Naïve Bayes Classifier (NBC) (Liu et al., 2002), Weighted Votes (Tibshirani et al., 2002), and Linear Regression (Fort and Lambert-Lacroix, 2005). Many comparative studies show that SVM based classifiers outperform other methods on most bench-mark microarray data sets (Li et al., 2004; Statnikov et al., 2005).

An integral part of classifier design is gene selection, which can improve both classification accuracy and diagnostic economy (Liu et al., 2002; Shi et al., 2008; Wang et al., 2008). Many microarray-based studies suggest that, irrespective of the classification method, gene selection is vital for achieving good generalization performance (Statnikov et al., 2005). For multicategory classification using gene expression data, the criterion function for gene selection should possess high sensitivity and specificity, well match the specific classifiers used, and identify gene markers that are both statistically reproducible and biologically plausible (Shi et al., 2008; Wang et al., 2008). There are limitations associated with existing gene selection methods (Li et al., 2004; Statnikov et al., 2005). While wrapper methods consider joint discrimination power of a gene subset, complex clas-

sifiers used in wrapper algorithms for small sample size may overfit, producing non-reproducible gene subsets (Li et al., 2004; Shi et al., 2008). Moreover, discernment of the (biologically plausible) gene interactions retained by wrapper methods is often difficult due to the black-box nature of most classifiers (Shedden et al., 2003).

Conversely, most filtering methods for multicategory classification are straightforward extensions of binary discriminant analysis. These methods are devised without well matching to the classifier that is used, which typically leads to suboptimal classification performance (Statnikov et al., 2005). Popular multicategory filtering methods (which are extensions of two-class methods) include Signal-to-Noise Ratio (SNR) (Dudoit et al., 2002; Golub et al., 1999), Student's t-statistics (Dudoit et al., 2002; Liu et al., 2002), the ratio of Between-groups to Within-groups sum of squares (BW) (Dudoit et al., 2002), and SVM based Recursive Feature Elimination (RFE) (Li and Yang, 2005; Ramaswamy et al., 2001; Zhou and Tuck, 2007). However, as pointed out by Loog et al. (2001) in proposing their weighted Fisher criterion (wFC), simple extensions of binary discriminant analysis to multicategory gene selection are suboptimal because they overemphasize large between-class distances, that is, these methods choose gene subsets that preserve the distances of (already) well-separated classes, without reducing (and possibly with increase in) the large overlap between neighboring classes. This observation and the application of wFC to multicategory classification are further evaluated experimentally by Wang et al. (2006) and Xuan et al. (2007).

The work most closely related to our gene selection scheme is that of Shedden et al. (2003). These investigators focused on marker genes that are highly expressed in one phenotype relative to one or more different phenotypes and proposed a tree-based *one-versus-rest* (OVR) fold change evaluation between mean expression levels. The potential limitation here is that the criterion function considers the "rest of the classes" as a "super class", and thus may select genes that can distinguish a single class from the remaining super class, yet without giving any benefit in discriminating between classes within the super class. Such genes may compromise multicategory classification accuracy, especially when a small gene subset is chosen.

It is also important to note that, while univariate or multivariate analysis methods using complex criterion functions may reveal subtle marker effects (Cai et al., 2007; Liu et al., 2005; Xuan et al., 2007; Zhou and Tuck, 2007), they are also prone to overfitting. Recent studies have found that for small sample sizes, univariate methods fared comparably to multivariate methods (Lai et al., 2006; Shedden et al., 2003) and simple fold change analysis produced more reproducible marker genes than significance analysis of variance-incorporated t-tests (Shi et al., 2008).

In this paper, we propose matched design of the gene selection mechanism and a committee classifier for multicategory molecular classification using microarray gene expression data. A key feature of our approach is to match a simple *one-versus-everyone* (OVE) gene selection scheme to the OVRSVM committee classifier (Ramaswamy et al., 2001). We focus on marker genes that are highly expressed in one phenotype relative to each of the remaining phenotypes, namely Phenotypic Up-regulated Genes (PUGs). PUGs are identified using the fold change ratio computed between the specified phenotype mean and each of the remaining phenotype means. Thus, we consider a gene to be a marker for the specified phenotype if the average expression associated with this phenotype is high relative to the average expressions in each of the other phenotypes. To assure evenhanded resources for discriminating both neighboring and well-separated classes, we use a fixed number of PUGs for each phenotypic class and pool all phenotype-specific PUGs together to form a gene marker subset used by the OVRSVM committee classifier. All PUGs referenced by the committee classifier are individually interpretable as potential markers for phenotypic classes, allowing each

gene to inform the classifier in a way that is consistent with its mechanistic role (Shedden, et al., 2003). Since PUGs are the union of subPUGs selected by simple univariate OVE fold change analysis, they are expected to be statistically reproducible (Lai et al., 2006; Shedden et al., 2003; Shi et al., 2008).

We tested PUG-OVRSVM on five publicly available benchmarks and one in-house microarray gene expression data set and on two simulation data sets, observing significantly improved performance with lower error rates, fewer marker genes, and higher performance stability, as compared to several widely-adopted gene selection and classification methods. The reference gene selection methods are OVRSNR (Golub et al., 1999), OVRt-stat (Liu et al., 2002), pooled BW (Dudoit et al., 2002), and OVRSVM-RFE (Guyon et al., 2002), and the reference classifiers are kNN, NBC, and one-versus-one (OVO) SVM. With accuracy estimated by leave-one-out cross-validation (LOOCV) (Hastie et al., 2001), our experimental results show that PUG-OVRSVM outperforms all combinations of the above referenced gene selection and classification methods in the two simulation data sets and 5 out of the 6 real microarray gene expression data sets, and produces comparable performance on the one remaining data set. Specifically, tested on the widely-used benchmark microarray gene expression data set "multicategory human cancers data" (GCM) (Ramaswamy et al., 2001; Statnikov et al., 2005), PUG-OVRSVM produces a lower error rate of 11.05% (88.95% correct classification rate) than the best known benchmark error rate of 16.72% (83.28% correct classification rate) (Cai et al., 2007; Zhou and Tuck, 2007).

2. Methods

In this section, we first discuss multicategory classification and associated feature selection, with an emphasis on OVRSVM and application to gene selection for the microarray domain. This discussion then naturally leads to our proposed PUG-OVRSVM scheme.

2.1 Maximum a Posteriori Decision Rule

Classification of heterogeneous diseases using gene expression data can be considered a Bayesian hypothesis testing problem (Hastie et al., 2001). Let $\mathbf{x}_i = [x_{i1}, ..., x_{ij}, ..., x_{id}]$ be the real-valued gene expression profile associated with sample i across d genes for $i = 1, \ldots, N$ and $j = 1, \ldots, d$. Assume that the sample points $\mathbf{x}_i$ come from M classes, and denote the class conditional probability density function and class prior probability by $p(\mathbf{x}_i \mid \omega_k)$ and $P(\omega_k)$, respectively, for $k = 1, \ldots, M$. To minimize the Bayes risk averaged over all classes, the optimum classifier uses the well-known maximum a posteriori (MAP) decision rule (Hastie et al., 2001). Based on Bayes' rule, the class posterior probability for a given sample $\mathbf{x}_i$ is

$$P(\omega_k \mid \mathbf{x}_i) = \frac{P(\omega_k)\, p(\mathbf{x}_i \mid \omega_k)}{\sum_{k'=1}^{M} P(\omega_{k'})\, p(\mathbf{x}_i \mid \omega_{k'})}$$

and is used to (MAP) classify $\mathbf{x}_i$ to ω_k when

$$P(\omega_k \mid \mathbf{x}_i) > P(\omega_l \mid \mathbf{x}_i) \tag{1}$$

for all $l \neq k$.

2.2 Supervised Learning and Committee Classifiers

Practically, multicategory classification using the MAP decision rule can be approximated using parameterized discriminant functions that are trained by supervised learning. Let $f_k(\mathbf{x}_i, \theta)$, $k = 1, 2, \ldots, M$, be the M outputs of a machine classifier designed to discriminate between M classes (>2), where θ represents the set of parameters that fully specify the classifier, and with the output values assumed to be in the range $[0, 1]$. The desired output of the classifier will be "1" for the class to which the sample belongs and "0" for all other classes. Suppose that the classifier parameters are selected based on a training set so as to minimize the mean squared error (MSE) between the outputs of the classifier and the desired (class target) outputs,

$$\text{MSE} = \frac{1}{N} \sum_{k=1}^{M} \sum_{\mathbf{x}_i \in \omega_k} \left[[f_k(\mathbf{x}_i, \theta) - 1]^2 + \sum_{l \neq k} f_l^2(\mathbf{x}_i, \theta) \right]. \tag{2}$$

Then, it can be shown that the classifier is being trained to approximate the posterior probability for class ω_k given the observed $\mathbf{x}_i$, that is, the classifier outputs will converge to the true posterior class probabilities

$$f_k(\mathbf{x}_i, \theta) \rightarrow P(\omega_k \mid \mathbf{x}_i)$$

if we allow the classifier to be arbitrarily complex and if N is made sufficiently large. This result is valid for any classifier trained with the MSE criterion, where the parameters of the classifier are adjusted to simultaneously approximate M discriminant functions $f_k(\mathbf{x}_i, \theta)$ (Gish, 1990).

While there are numerous machine classifiers that can be used to implement the MAP decision rule (1) (Hastie et al., 2001), a simple yet elegant way of discriminating between M classes, and which we adopt here, is based on an OVRSVM committee classifier (Ramaswamy et al., 2001; Rifkin and Klautau, 2002; Statnikov et al., 2005). Intuitively, each term within the sum over k in (2) corresponds to an OVR binary classification problem and can be effectively minimized by suitable training of a binary classifier (discriminating class k from all other classes). By separately minimizing the MSE associated with each term in (2) via binary classifier training and, thus, effectively minimizing the total MSE, a set of discriminant functions $\{f_k(\mathbf{x}_i, \theta_k \subseteq \theta)\}$ can be constructed which, given a new sample point, apply the decision rule (1), but with $f_k(\mathbf{x}_i, \theta)$ playing the role of the posterior probability.

Among the great variety of binary classifiers that use regularization to control the capacity of the function spaces they operate in, the best known example is the SVM (Hastie et al., 2001; Vapnik, 1998). To carry over the advantages of regularization approaches for binary classification tasks to multicategory classification, the OVRSVM committee classifier uses M different SVM binary classifiers, each one separately trained to distinguish the samples in a single class from the samples in all remaining classes. For classifying a new sample point, the M SVMs are run, and the SVM that produces the largest (most positive) output value is chosen as the "winner" (Ramaswamy et al., 2001). For more detailed discussion, see the critical review and experimental comparison by Rifkin and Klautau (2002). Figure 1 shows an illustrative OVRSVM committee classifier for three classes. The OVRSVM committee classifier has proved highly successful at multicategory classification tasks involving finite or limited amounts of high dimensional data in real-world applications. OVRSVM produces results that are often at least as accurate as other more complicated methods including single machine multicategory schemes (Statnikov et al., 2005). Perhaps more importantly for our purposes, the OVR scheme can be matched with an OVE gene selection method, as we elaborate next.

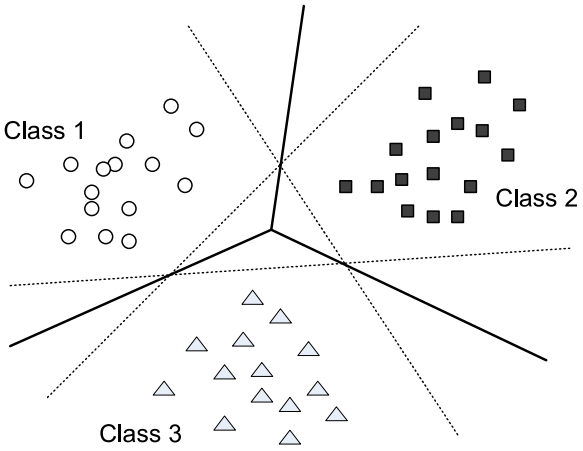

Figure 1: Conceptual illustration of OVR committee classifier for multicategory classification (three classes, in this case). The dotted lines are the decision hyperplanes associated with each of the component binary SVMs and the bold line-set represents the final decision boundary after the winner-take-all classification rule is applied.

2.3 One-Versus-Everyone Fold-change Gene Selection

While gene selection is vital for achieving good generalization performance (Guyon et al., 2002; Statnikov et al., 2005), perhaps even more importantly, the identified genes, if statistically reproducible and biologically plausible, are "markers", carrying information about the disease phenotype (Wang et al., 2008). We will propose two novel, effective gene selection methods for multicategory classification that are well-matched to OVRSVM committee classifiers, namely, OVR and OVE fold-change analyses.

OVR fold-change based PUG selection follows directly from the OVRSVM scheme. Let N_k be the number of sample points belonging to phenotype k; the geometric mean of the expression levels (on the untransformed scale) for gene j under phenotype k is

$$\mu_j(k) = \sqrt[N_k]{\prod_{i\in\omega_k} x_{ij}}$$

$j = 1,\ldots,d$; $k = 1,\ldots,M$. Then, we define the OVRPUGs as:

$$\mathbb{J}_{\text{PUG}} = \bigcup_{k=1}^{M} \mathbb{J}_{\text{PUG}}(k) = \bigcup_{k=1}^{M} \left\{ j \left| \frac{\mu_j(k)}{\sqrt[M-1]{\prod_{l\neq k}\mu_j(l)}} \geqslant \tau_k \right. \right\} \tag{3}$$

where $\{\tau_k\}$ are pre-defined thresholds chosen so as to select a fixed (equal) number of PUGs for each phenotype k. This PUG selection scheme (3) is similar to what has been previously proposed by Shedden et al. (2003):

$$\mathbb{J}_{\text{PUG}} = \bigcup_{k=1}^{M} \mathbb{J}_{\text{PUG}}(k) = \bigcup_{k=1}^{M} \left\{ j \left| \frac{\mu_j(k)}{\sqrt[N-N_k]{\prod_{i\notin\omega_k} x_{ij}}} \geqslant \tau_k \right. \right\}. \tag{4}$$

The critical difference between (3) and (4) is that the denominator term in (3) is the overall geometric center of the "geometric centers" associated with each of the remaining phenotypes while

the denominator term in (4) is the geometric center of all sample points belonging to the remaining phenotypes. When $\{N_k\}$ are significantly imbalanced for different k, the denominator term in (4) will be biased toward the dominant phenotype(s).

However, a problem associated with both PUG selection schemes specified by (3) and (4) (and with the OVRSNR criterion Golub et al., 1999) is that the criterion function considers the remaining classes as a single super class, which is suboptimal because it ignores a gene's ability to discriminate between classes *within* the super class.

We therefore propose OVE fold-change based PUG selection to fully support the objective of multicategory classification. Specifically, the OVEPUGs are defined as:

$$\mathbb{J}_{\mathrm{PUG}} = \bigcup_{k=1}^{M} \mathbb{J}_{\mathrm{PUG}}(k) = \bigcup_{k=1}^{M} \left\{ j \left| \frac{\mu_j(k)}{\max_{l \neq k} \{\mu_j(l)\}} \geqslant \tau_k \right. \right\} \tag{5}$$

where the denominator term is the maximum phenotypic mean expression level over the remaining phenotype classes. This seemingly technical modification turns out to have important consequences since it assures that the selected PUGs are highly expressed in one phenotype relative to *each* of the remaining phenotypes, that is, "high" (up-regulated) in phenotype k and "low" (down-regulated) in *all* phenotypes $l \neq k$. In our experimental results, we will demonstrate that (5) leads to better classification accuracy than (4) on a well-known multi-class cancer domain.

Adopting the same strategy as in Shedden et al. (2003), to assure even-handed gene resources for discriminating both neighboring and well-separated classes, we select a fixed (common) number of top-ranked phenotype-specific subPUGs for each phenotype, that is, $\|\mathbb{J}_{\mathrm{PUG}}(k)\| = N_{\mathrm{subPUG}}$ for all k, and pool all these subPUGs together to form the final gene marker subset $\mathbb{J}_{\mathrm{PUG}}$ for the OVRSVM committee classifier. In our experiments, the optimum number of PUGs per phenotype, N_{subPUG}, is determined by surveying the curve of classification accuracy versus N_{subPUG} and selecting the number that achieves the best classification performance. More generally, in practice, N_{subPUG} can be chosen via a cross validation procedure. Figure 2 shows the geometric distribution of the selected PUGs specified by (5), where the PUGs (highlighted data points) constitute the lateral-edge points of the convex pyramid defined by the scatter plot of the phenotypic mean expressions (Zhang et al., 2008). Different from the PUG selection schemes given by (3) and (4), the PUGs selected based on (5) are most compact yet informative, since the down-regulated genes that are not differentially expressed between the remaining phenotypes (the genes on the lateral faces of the scatter plot convex pyramid) are excluded. From a statistical point of view, extensive studies on the normalized scatter plot of microarray gene expression data by many groups including our own indicate that the PUGs selected by (5) approximately follow an independent multivariate super-Gaussian distribution (Zhao et al., 2005) where subPUGs are mutually exclusive and phenotypic gene expression patterns defined over the PUGs are statistically independent (Wang et al., 2003).

It is worth noting that the PUG selection by (5) also adopts a univariate fold-change evaluation that does not require calculation of either expression variance or of correlation between genes (Shi et al., 2008). For the small sample size case typical of microarray data, multivariate gene selection schemes may introduce additional uncertainty in estimating the correlation structure (Lai et al., 2006; Shedden et al., 2003) and thus may fail to identify true gene markers (Wang et al., 2008). The exclusion of the variance in our criterion is also supported by the variance stabilization theory (Durbin et al., 2002; Huber et al., 2002), because the geometric mean in (5) is equivalent to the arithmetic mean after logarithmic transformation and the gene expression after logarithmic transfor-

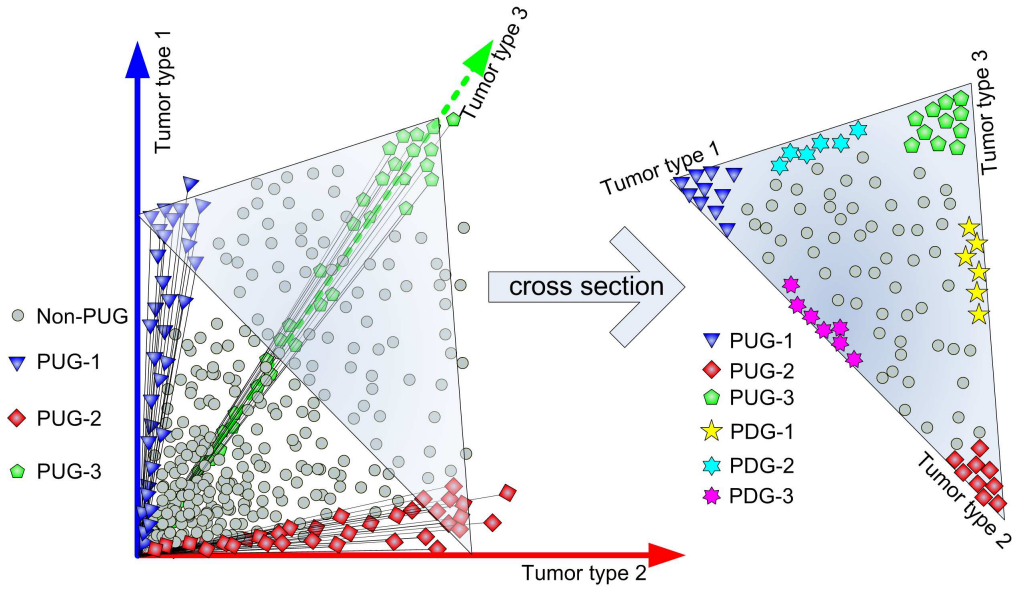

Figure 2: Geometric illustration of the selected one-versus-everyone phenotypic upregulated genes (OVEPUGs) associated with three phenotypic classes. Three-dimensional geometric distribution (on the untransformed scale) of the selected OVEPUGs, which reside around the lateral-edges of the phenotypic gene expression scatter plot convex pyramid, is shown in the left subfigure. A projected distribution of the selected OVEPUGs together with OVEPDGs is shown in the right cross-sectional plot, where OVEPDGs reside along the face-edges of the cross-sectional triangle.

mation approximately has the equal variance across different genes, especially for the up-regulated genes.

Corresponding to the definition of OVEPUGs, the OVEPDGs (which are down-regulated in one class while being up-regulated in all other classes) can be defined by the following criterion:

$$\mathbb{J}_{\mathrm{PDG}} = \bigcup_{k=1}^{M} \mathbb{J}_{\mathrm{PDG}}(k) = \bigcup_{k=1}^{M} \left\{ j \left| \frac{\min_{l \neq k} \{\mu_j(l)\}}{\mu_j(k)} \geqslant \tau_k \right. \right\}. \tag{6}$$

Furthermore, the combination of PUGs and PDGs can be defined as:

$$\mathbb{J}_{\mathrm{PUG+PDG}} = \bigcup_{k=1}^{M} \mathbb{J}_{\mathrm{PUG+PDG}}(k) = \bigcup_{k=1}^{M} \left\{ j \left| \max \left\{ \frac{\mu_j(k)}{\max_{l \neq k} \{\mu_j(l)\}}, \frac{\min_{l \neq k} \{\mu_j(l)\}}{\mu_j(k)} \right\} \geqslant \tau_k \right. \right\}. \tag{7}$$

Purely from the machine learning view, PDGs have the theoretical capability of being as discriminating as PUGs. Thus, PDGs merit consideration as candidate genes. However, there are several critical differences, with consequential implications, between lowly-expressed genes and highly-expressed genes, such as the extraordinarily large proportion and relatively large noise of the lowly-expressed genes. We have evaluated the classification performance of PUGs, PDGs, and

PUGs+PDGs, respectively. Experimental results show that PDGs have less discriminatory power than PUGs and the inclusion of PDGs actually worsens classification accuracy, compared to just using PUGs. Experiments and further discussion will be given in the results section.

2.4 Review of Relevant Gene Selection Methods

Here we briefly review four benchmark gene selection methods that have been previously proposed for multicategory classification, namely, OVRSNR (Golub et al., 1999), OVR t-statistic (OVRt-stat) (Liu et al., 2002), BW (Dudoit et al., 2002), and SVMRFE (Guyon et al., 2002).

Let $\mu_{j,k}$ and $\mu_{j,-k}$ be the arithmetic means of the expression levels of gene j associated with phenotype k and associated with the super class of remaining phenotypes, respectively, on the log-transformed scale, with $\sigma_{j,k}$ and $\sigma_{j,-k}$ the corresponding standard deviations. OVRSNR gene selection for multicategory classification is given by:

$$\mathbb{J}_{\text{OVRSNR}} = \bigcup_{k=1}^{M} \mathbb{J}_{\text{OVRSNR}}(k) = \bigcup_{k=1}^{M} \left\{ j \left| \frac{\left|\mu_{j,k} - \mu_{j,-k}\right|}{\sigma_{j,k} + \sigma_{j,-k}} \geqslant \tau_k \right. \right\}, \tag{8}$$

where τ_k is a pre-defined threshold (Golub et al., 1999). To assess the statistical significance of the difference between $\mu_{j,k}$ and $\mu_{j,-k}$, OVRt-stat applies a test of the null hypothesis that the means of two assumed normally distributed measurements are equal. Accordingly, OVRt-stat gene selection is given by Liu et al. (2002):

$$\mathbb{J}_{\text{OVR}t\text{-stat}} = \bigcup_{k=1}^{M} \mathbb{J}_{\text{OVR}t\text{-stat}}(k) = \bigcup_{k=1}^{M} \left\{ j \left| \frac{\left|\mu_{j,k} - \mu_{j,-k}\right|}{\sqrt{\sigma_{j,k}^2 \Big/ N_k + \sigma_{j,-k}^2 \Big/ (N - N_k)}} \geqslant \tau_k \right. \right\}, \tag{9}$$

where the p-values associated with each gene may be estimated. As aforementioned, one limitation of the gene selection schemes (8) and (9) is that the criterion function considers the remaining classes as a single group. Another is that they both require variance estimation.

Dudoit et al. (2002) proposed a pooled OVO gene selection method based on the BW sum of squares across all paired classes. Specifically, BW gene selection is specified by

$$\mathbb{J}_{\text{BW}} = \left\{ j \left| \frac{\sum_{i=1}^{N} \sum_{k=1}^{M} \mathbf{1}_{\omega_k}(i) \left(\mu_{j,k} - \mu_j\right)^2}{\sum_{i=1}^{N} \sum_{k=1}^{M} \mathbf{1}_{\omega_k}(i) \left(x_{ij} - \mu_{j,k}\right)^2} \geqslant \tau \right. \right\}, \tag{10}$$

where μ_j is the global arithmetic center of gene j over all sample points and $\mathbf{1}_{\omega_k}(i)$ is the indicator function reflecting membership of sample i in class k. As pointed out by Loog et al. (2001), BW gene selection may only preserve the distances of already well-separated classes rather than neighboring classes.

From a dimensionality reduction point of view, Guyon et al. (2002) proposed a feature subset ranking criterion for linear SVMs, dubbed the SVMRFE. Here, one first trains a linear SVM classifier on the full feature space. Features are then ranked based on the magnitude of their weights and are eliminated in the order of increasing weight magnitude. A widely adopted reduction strategy is to eliminate a fixed or decreasing percentage of features corresponding to the bottom portion of the ranked weights and then to retrain the SVM on the reduced feature space. Application to microarray gene expression data shows that the genes selected matter more than the classifiers with which they are paired (Guyon et al., 2002).

3. Results

We tested PUG-OVRSVM on five benchmarks and one in-house real microarray data set, and compared the performance to several widely-adopted gene selection and classification methods.

3.1 Description of the Real Data Sets

The numbers of samples, phenotypes, and genes, as well as the microarray platforms used to generate these gene expression data sets, are briefly summarized in Supplementary Tables 1∼7. The six data sets are the MIT 14 Global Cancer Map data set (GCM) (Ramaswamy et al., 2001), the NCI 60 cancer cell lines data set (NCI60) (Staunton et al., 2001), the University of Michigan cancer data set (UMich) (Shedden et al., 2003), the Central Nervous System tumors data set (CNS) (Pomeroy et al., 2002), the Muscular Dystrophy data set (MD) (Bakay et al., 2006), and the Norway Ascites data set (NAS). To assure a meaningful and well-grounded comparison, we emphasized data quality and suitability in choosing these test data sets. For example, the data sets cannot be too "simple" (if the classes are well-separated, all methods perform equally well) or too "complex" (no method will then perform reasonably well), and each class should contain sufficient samples to support some form of cross-validation assessment.

We also performed several important pre-processing steps widely adopted by other researchers (Guyon et al., 2002; Ramaswamy et al., 2001; Shedden et al., 2003; Statnikov et al., 2005). When the expression levels in the raw data take negative values, probably due to global probe-set calls and/or data normalization procedures, these negative values are replaced by a fixed small quantity (Shedden et al., 2003). On the log-transformed scale, we further conducted a variance-based unsupervised gene filtering operation to remove the genes whose expression standard deviations (across all samples) were less than a pre-determined small threshold; this effectively reduces the number of genes by half (Guyon et al., 2002; Shedden et al., 2003).

3.2 Experiment Design

We decoupled the two key steps of multicategory classification: 1) selecting an informative subset of marker genes and then 2) finding an accurate decision function. For the crucial first step we implemented five gene selection methods, including OVEPUG specified by (5), OVRSNR specified by (8), OVRt-stat specified by (9), pooled BW specified by (10), and SVMRFE described in Ramaswamy et al. (2001). We applied these methods to the six data sets, and for each data set, we selected a sequence of gene subsets with varying sizes, indexed by N_{subPUG}, the number of genes per class. In our experiments, this number was increased from 2 up to 100. There are several reasons why we do not go beyond 100 subPUGs per class. First, classification accuracy may be either flat or monotonically decreasing as the number of features increases beyond a certain point, due to the theoretical bias-variance dilemma. Second, even in some cases where best performance is achieved using all the gene features, the idea of feature selection is to find the minimum number of features needed to achieve good (near-optimal) classification accuracy. Third, when $N_{\text{subPUG}} = 100$, the total number of genes used for classification is already quite large (this number is maximized if the sets $\mathbb{J}_{\text{PUG}}(k)$ are mutually exclusive, in which case it is N_{subPUG} times the number of classes). Fourth, but not least important, a large feature reduction may be necessary not only complexity-wise, but also for interpreting the biological functions and pathway involvement when the selected PUGs are most relevant and statistically reproducible.

The quality of the marker gene subsets was then assessed by prediction performance on four subsequently trained classifiers, including OVRSVM, kNN, NBC, and OVOSVM. In relation to the proposed PUG-OVRSVM approach, we evaluated all combinations of these four different gene selection methods and three different classifiers on all six benchmark microarray gene expression data sets.

To properly estimate the accuracy of predictive classification, a validation procedure must be carefully designed, recognizing limits on the accuracy of estimated performance, in particular for small sample size. Clearly, classification accuracy must be assessed on labelled samples 'unseen' during training. However, for multicategory classification based on small, class-imbalanced data sets, single batch held-out test data may be precluded, as there will be insufficient samples for both accurate classifier training and accurate validation (Hastie et al., 2001). A practical alternative is a sound cross-validation procedure, wherein all the data are used for both training and testing, but with held-out samples in a testing fold not used for any phase of classifier training, including gene selection and classifier design (Wang et al., 2008). In our experiments, we chose LOOCV, wherein a test fold consists of a single sample; the rest of the samples are placed in the training set. Using only the training set, the informative genes are selected and the weights of the linear OVRSVM are fit to the data (Liu et al., 2005; Shedden et al., 2003; Yeang et al., 2001). It is worth noting that LOOCV is approximately unbiased, lessening the likelihood of misestimating the prediction error due to small sample size; however, LOOCV estimates do have considerable variance (Braga-Neto and Dougherty, 2004; Hastie et al., 2001). We evaluated both the lowest "sustainable" prediction error rate and the lowest prediction error rate, where the sequence of sustainable prediction error rates were determined based on a moving-average of error rates along the survey axis of the number of genes used for each class, N_{subPUG}, with a moving window of width 5. We also report the number of genes per class at which the best sustainable performance was obtained.

While the error rate is estimated through LOOCV and the optimum number of PUGs used per class is obtained by the aforementioned surveying strategy, we should point out that a two-level LOOCV could be applied to jointly determine the optimum N_{subPUG} and estimate the associated error rate; however, such an approach is computationally expensive (Statnikov et al., 2005). For the settings of structural parameters in the classifiers, we used $C = 1.0$ in the SVMs for all experiments (Vapnik, 1998), and chose $k = 1, 2, 3$ in kNNs under different training sample sizes per class, as recommended by Duda et al. (2001).

3.3 Experimental Results

Our first comparative study focused on the GCM data widely used for evaluating multicategory classification algorithms (Cai et al., 2007; Ramaswamy et al., 2001; Shedden et al., 2003; Zhou and Tuck, 2007). The performance curves of OVRSVM committee classifiers trained on the commonly pre-processed GCM data using the five different gene selection methods (OVEPUG, OVRSNR, OVRt-stat, BW, and SVMRFE) are detailed in Figure 3. It can be seen that our proposed OVEPUG selection significantly improved the overall multicategory classification when using different numbers of marker genes, as compared to the results produced by the four competing gene selection methods. For example, using as few as 9 genes per phenotypic class (with 126 distinct genes in total, that is, mutually exclusive PUGs for each class), we classified 164 of 190 (86.32%) of the tumors correctly. Furthermore, using LOOCV on the GCM data set of 190 primary malignant tumors, and using the optimal number of genes (61 genes per phenotypic class or 769 unique genes

in total), we achieved the best (88.95% or 169 of 190 tumors) sustainable correct predictions. In contrast, at its optimum performance, OVRSNR gene selection achieved 85.37% sustainable correct predictions using 25 genes per phenotypic class, OVRt-stat gene selection achieved 84.53% sustainable correct predictions using 71 genes per phenotypic class, BW gene selection achieved 80.53% sustainable correct predictions using 94 genes per phenotypic class, and SVMRFE gene selection achieved 84.74% sustainable correct predictions using 96 genes per phenotypic class. In our comparative study, instead of solely comparing the lowest error rates achieved by different gene selection methods, we also emphasized the sustainable correct prediction rates, as potential overfitting to the data may produce an (unsustainably) good prediction performance. For our experiments in Figure 3, based on the realistic assumption that the probability of good predictions purely "by chance" over a sequence of consecutive gene numbers is low, we defined the sustainable prediction/error rates based on the moving-averaged prediction/error rates over $\delta = 5$ consecutive gene numbers. Here, δ gives the sustainability requirement.

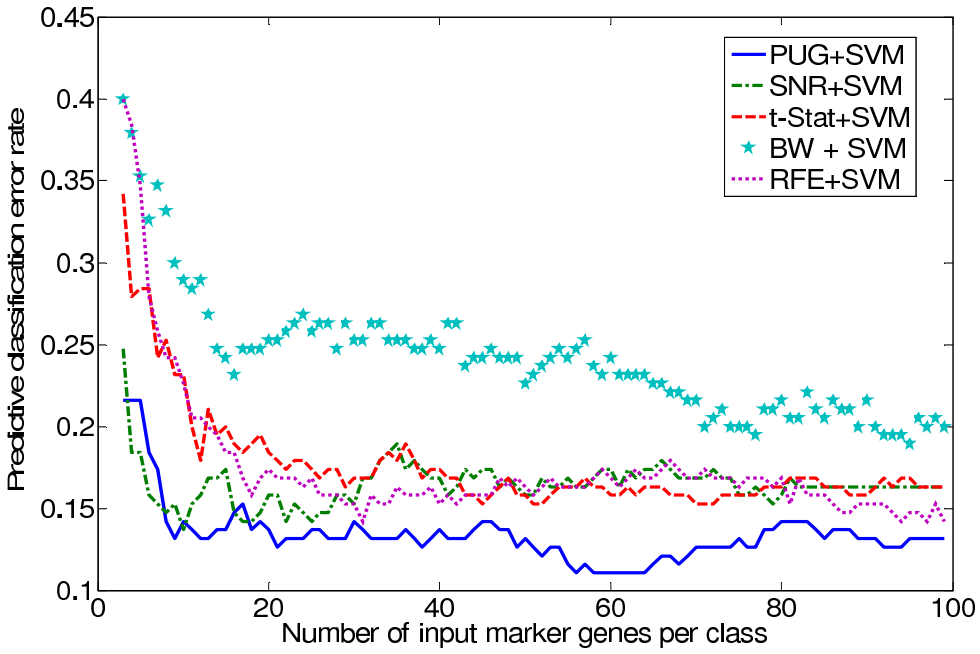

Figure 3: Comparative study on five gene selection methods (OVEPUG, OVRSNR, OVRt-stat, BW, and SVMRFE) using the GCM benchmark data set. The curves of classification error rates were generated by using OVRSVM committee classifiers with varying size of the input gene subset.

For the purpose of information sharing with readers, based on publicly reported optimal results for different methods, we have summarized in Table 1 the comparative performance achieved by PUG-OVRSVM and eight existing/competing methods on the benchmark GCM data set, along with the gene selection methods used, the chosen classifiers, sample sizes, and the chosen cross-validation schemes. Obviously, since the reported prediction error rates were generated by different algorithms and under different conditions, any conclusions based on simple/direct comparisons of the reported results must be carefully drawn. We have chosen not to independently reproduce results

by re-implementing the methods listed in Table 1, firstly because we typically do not have access to public domain code implementing other authors' methods and secondly because we feel that high reproducibility of previously published results may not be expected without knowing some likely undeclared optimization steps and/or additional control parameters used in the actual computer codes. Nevertheless, many reported prediction error rates on the GCM data set were actually based on the same/similar training sample set ($144 \sim 190$ primary tumors) and the LOOCV scheme used in our PUG-OVRSVM experiments; furthermore, it was reported that the prediction error rates estimated by LOOCV and 144/54 split/held-out test were very similar (Ramaswamy et al., 2001). Specifically, the initial work on GCM by Ramaswamy et al. (2001) reported an achieved 77.78% prediction rate, and some improved performance was later reported by Yeang et al. (2001) and Liu et al. (2002), achieving 81.75% and 79.99% prediction rates, respectively. In the work most closely related to our gene selection scheme by Shedden et al. (2003), using a kNN tree classifier and using OVR fold-change based gene selection specified by (4), a prediction rate of 82.63% was achieved. In relation to these reported results on GCM, as indicated in Table 1, our proposed PUG-OVRSVM method produced the best sustainable prediction rate of 88.95%.

Table 1: Summary of comparative performances by OVEPUG-OVRSVM and eight competing methods (based on publicly reported optimum results) on the GCM benchmark data set.

A more stringent evaluation of the robustness of a classification method is to carry out the predictions on multiple data sets and then assess the overall performance (Statnikov et al., 2005). Our second comparative study evaluated the aforementioned five gene selection methods using the six benchmark microarray gene expression data sets. To determine whether the genes selected matter more than the classifiers used (Guyon et al., 2002), we used a common OVRSVM committee classifier and LOOCV scheme in all the experiments, and summarized the corresponding results in Table 2. For each experiment that used a distinct gene selection scheme applied to a distinct data set, we reported both sustainable (with sustainability requirement $\delta = 5$) and lowest (within parentheses) prediction error rates, as well as the number of genes per class that were used to produce these results. Clearly, the selected PUGs based on (5) produced the highest overall sustainable prediction rates as compared to the other four competing gene selection methods. Specifically, PUG is the consistent winner in 22 of 24 competing experiments (combinations of four gene selection schemes and six testing data sets). It should be noted that although BW and OVRSNR achieved comparably low prediction error rates on the CNS data set (with relatively balanced mixture distributions), they

also produced high prediction error rates on the other testing data sets; the other competing gene selection methods also show some level of performance instability across data sets.

Table 2: Performance comparison between five different gene selection methods tested on six benchmark microarray gene expression data sets, where the predictive classification error rates for all methods were generated based on OVRSVM committee classification and an LOOCV scheme. Both sustainable and lowest (within parentheses) error rates are reported together with number of genes used per class.

To give more complete comparisons that also involved different classifiers (Statnikov et al., 2005), we further illustrate the superior prediction performance of the matched OVEPUG selection and OVRSVM classifier as compared to the best results produced by combinations of three different classifiers (OVOSVM, kNN, NBC) and four gene selection methods (PUG, OVRSNR, OVRt-stat, pooled BW). The optimum experimental results achieved over all combinations of these methods on the six data sets are summarized in Table 3, where we report both sustainable prediction error rates and the corresponding gene selection methods. Again, PUG-OVRSVM outperformed all other methods on all six data sets and was a clear winner in all 15 competing experiments. Our comparative studies also reveal that although gene selection is a critical step of multi-category classification, the classifiers used do indeed play an important role in achieving good prediction performance.

3.4 Comparison Results on the Realistic Simulation Data Sets

To more reliably validate and compare the performance of the different gene selection methods, we have conducted additional experiments involving realistic simulations. The advantage of using synthetic data is that, unlike the real data sets often with small sample size and with LOOCV as the only applicable validation method, large testing samples can be generated to allow an accurate and reliable assessment of a classifier's generalization performance. Two different simulation approaches were implemented. In both, we modeled the joint distribution for microarray data under each class and generated *i.i.d.* synthetic data sets consistent both with these distributions and with assumed class priors. In the first approach, we chose the class-conditional models consistent with commonly

	GCM	NCI60	UMich	CNS	MD	NAS

NBC	36.00% (OVRSNR)	51.67% (OVRSNR)	2.83% (OVRt-stat)	37.62% (BW)	37.69% (BW)	34.21% (OVEPUG)

Table 3: Performance comparison based on the lowest predictive classification error rates produced by OVEPUG-OVRSVM and the optimum combinations of five different gene selection methods and three different classifiers, tested on six benchmark microarray gene expression data sets and assessed via the LOOCV scheme.

accepted properties of microarray data (few discriminating features, many non-discriminating features, and with small sample size) (Hanczar and Dougherty, 2010; Wang et al., 2002). In the second approach, we directly estimated the class-conditional models based on a real microarray data set and then generated the *i.i.d.* samples according to the learned models.

3.4.1 DESIGN I

We simulated 5000 genes, with 90 "relevant" and 4910 "irrelevant" genes. Inspired by gene clustering concept in modelling local correlations, we divided the genes into 1000 blocks of size five, each containing exclusively either relevant or irrelevant genes. Within each block the correlation coefficient is 0.9, with zero correlation across blocks. Irrelevant genes are assumed to follow a (univariate) standard normal distribution, for all classes. Relevant genes also follow a normal distribution with variance 1 for all classes. There are three equally likely classes, A, B and C. The mean vectors of the 90 relevant genes under each class are shown in Table 4. The means were chosen to make the classification task neither too easy nor too difficult and to simulate unequal distances between the classes—A and B are relatively close, with C more distant from both A and B.

	The mean vector μ for each class

Table 4: The mean vectors of the 90 relevant genes under each of the three classes.

We randomly generated 100 synthetic data sets, each partitioned into a small training set of 60 samples (20 per class) and a large testing set of 6000 samples.

3.4.2 DESIGN II

The second approach models each class as a more realistic multivariate normal distribution $N(\mu,\Sigma)$, with the class's mean vector μ and covariance matrix Σ directly learned from the real microarray data set GCM. Estimation of a covariance matrix is certainly a challenging task, specifically due to the very high dimensionality of the gene space ($p = 15,927$ genes in the GCM data) and only a few dozen samples available for estimating $p(p-1)/2$ free covariate parameters per class. It is also computationally prohibitive to generate random vectors based on full covariances on a general desktop computer. To address both of these problems, we applied a factor model (McLachlan and Krishnan, 2008), which can significantly reduces the number of free parameters to be estimated while capturing the main correlation structure in the data.

In factor analysis, the observed $p \times 1$ vector $\mathbf{t}$ is modeled as

$$\mathbf{t} = \mu + \mathbf{W}\mathbf{x} + \varepsilon,$$

where μ is the mean vector of observation $\mathbf{t}$, $\mathbf{W}$ is a $p \times q$ matrix of factor loadings, $\mathbf{x}$ is the $q \times 1$ latent variable vector with standard normal distribution $N(\mathbf{0},\mathbf{I})$ and ε is noise with independent multivariate normal distribution $N(\mathbf{0},\Psi)$, $\Psi = \mathbf{diag}\left(\sigma_1^2,\ldots,\sigma_p^2\right)$. The resulting covariance matrix Σ is

$$\Sigma = \mathbf{W}\mathbf{W}^T + \Psi.$$

Estimation of Σ reduces to estimating $\mathbf{W}$ and Ψ, totaling $p(q+1)$ parameters. Usually, we have q much less than p. The factor model is learned via the EM algorithm (McLachlan and Krishnan, 2008), initialized by probabilistic principal component analysis (Tipping and Bishop, 1999).

In our experiments, we set $q = 5$, which typically accounted for 60% of the energy. We also tried $q = 3$ and 7 and observed that the relative performance remained unchanged, although the absolute performance of all methods does change with q.

Five phenotypic classes were used in our simulation: breast cancer, lymphoma, bladder cancer, leukemia and CNS. 100 synthetic data sets were generated randomly according to the learned class models from the real data of these five cancer types. The dimension for each sample is 15,927. For each data set, the training sample size was the same as used in the real data experiments, with 11, 22, 11, 30, and 20 samples in the five respective classes; and the testing set consisted of 3,000 samples, 600 per class.

3.5 Evaluation of Performance

For a given gene-selection method and for each data set (indexed by $i = 1,\ldots,100$), the classifier F_i is learned. We then evaluate F_i on the i-th testing set, and measure the error rate ε_i. Since the testing set has quite large sample size, we would expect ε_i to be close to the true classification error rate for F_i. Over 100 simulation data sets, we then calculated both the average classification error $\bar{\varepsilon}$ and the standard deviation σ.

Furthermore, let $\varepsilon_{i,PUG}$ denote the error rate associated with PUGs on testing set i, and similarly, let $\varepsilon_{i,SNR}$, $\varepsilon_{i,t\text{-}stat}$, $\varepsilon_{i,BW}$ and $\varepsilon_{i,SVMRFE}$ denote the error rates associated with the four peer gene selection methods. The error rate difference between two methods, for example, PUG and SNR, is defined by

$$D_i(PUG,SNR) = \varepsilon_{i,PUG} - \varepsilon_{i,SNR}.$$

For each synthetic data set, we define the "winner" as the one with the least testing error rate. For each method, the mean and standard deviation of the error rate and the frequency of winning are examined for performance evaluation. In addition, the histogram of error rate differences between PUG and peer methods are provided.

3.6 Experimental Results on the Simulation Data Sets

We tested all gene selection methods using the common OVRSVM classifier. All the experiments were done using the same procedure as on the real data sets, except with LOOCV error estimation replaced by the error estimation using large size independent testing data. Figure 4, analogous to Figure 3 while on the realistic synthetic data whose model was estimated from GCM data set (simulation data under design II), shows the comparative study on five gene selection methods (OVEPUG, OVRSNR, OVRt-stat, BW, and SVMRFE). Tables 5 and 6 show the average error, standard deviation, and frequency of winning, estimated based on the 100 simulation data sets. PUG has the smallest average error over all competing methods. PUG also is the most stable method (with the smallest standard deviation). Tables 7 and 8 provide the comparison results of the five competing methods on the first ten data sets.

Figures 5 and 6 show histograms of the error difference between PUG and other methods, where a negative value of the difference indicates better performance by PUG. The red bar shows the position where the two methods are equal. We can see that the vast majority of differences are negative. Actually, as indicated in Tables 5 and 6, there is no positive difference in the subfigures of Figure 5 and at most one positive difference in the subfigures of Figure 6.

3.7 Comparison Between PUGs and PDGs

In this experiment, we selected PDGs according to the definition given in (6) and evaluated gene selection based on PUGs, PDGs, and based on their union, as given in (7). Again, all gene selection methods were coupled with the OVRSVM classifier. Table 9 shows classification performance for

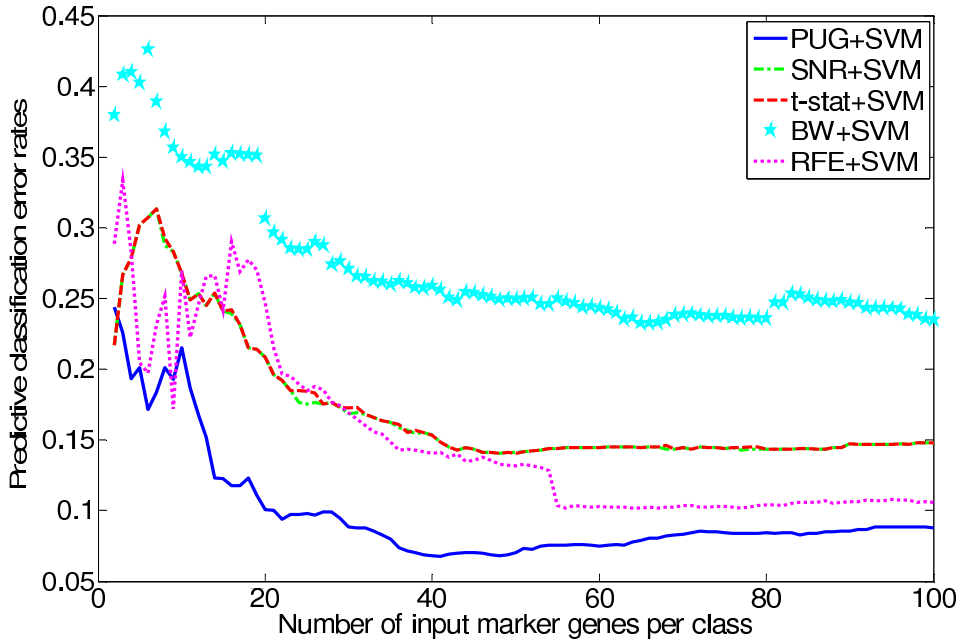

Figure 4: Comparative study on five gene selection methods (OVEPUG, OVRSNR, OVRt-stat, BW, and SVMRFE) on one simulation data set under design II. The curves of classification error rates were generated by using OVRSVM committee classifiers with varying size of the input gene subset.

Table 9: Classification comparison of PUG and PDG on the six benchmark data sets.

There are several potential reasons that may jointly explain the non-contributing or even negative role of the included PDGs. First, the number of PDGs are much less than that of PUGs, that is, PUGs represent the significant majority of informative genes when PUGs and PDGs are jointly considered, as shown in Table 10 (Top PUG+PDGs were selected with 10 genes per class and we counted how many PUGs are included in the total). Second, PDGs are less reliable than PUGs due to the noise characteristics of gene expression data, that is, low gene expressions contain relatively large additive noise after log-transformation (Huber et al., 2002; Rocke and Durbin, 2001). This is further exacerbated by the follow-up one-versus-rest classifier because there are many more samples in the 'rest' group than in the 'one' group. This practically increases the relative noise/variability associated with PDGs in the 'one' group. In addition, PUGs are consistent with the practice of molecular pathology and thus may have broader clinical utility, for example, most currently available disease gene markers are highly expressed (Shedden et al., 2003).

3.8 Marker Gene Validation by Biological Knowledge

We have applied existing biological knowledge to validate biological plausibility of the selected PUG markers for two data sets, GCM and NAS. The full list of genes most highly associated with each of the 14 tumor types in the GCM data set are detailed in the Supplementary Tables 8 and 9.

3.8.1 BIOLOGICAL INTERPRETATION FOR GCM DATA SET

Prolactin-induced protein, which is regulated by prolactin activation of its receptors, ranks highest among the PUGs associated with breast cancer. Postmenopausal breast cancer risk is strongly associated with elevated prolactin levels (PubMed IDs 15375001, 12373602, 10203283). Interestingly, prolactin release proportionally increases with increasing central fat in obese women (PubMed ID 15356045) and women with this pattern of obesity have an increased risk of breast cancer mortality (PubMed ID 14607804). Other genes of interest that rank among the top 10 breast cancer PUGs include CRABP2, which transports retinoic acid to the nucleus. Retinoids are important regulators of breast cell function and show activity as potential breast cancer chemopreventive agents (PubMed IDs 11250995, 12186376). Mammglobin is primarily expressed in normal breast epithelium and breast cancers (PubMed ID 12793902). Carbonic anhydrase XII is expressed in breast cancers and

is generally considered a marker of a good prognosis (PubMed ID 12671706). The selective expression and/or function of these genes in breast cancers are consistent with their selection as PUGs in the classification scheme.

The top 10 PUGs associated with prostate cancer include several genes strongly associated with the prostate including prostate specific antigen (PSA) and its alternatively spliced form 2, and prostatic secretory protein 57. The role of PSA gene KLK3 and KLK1 as a biomarker of prostate cancer is well established (PubMed ID 19213567). Increased NPY expression is associated with high-grade prostatic intraepithelial neoplasia and poor prognosis in prostate cancers (PubMed ID 10561252). ACPP is another prostate specific protein biomarker (PubMed ID 8244395). The strong representation of genes that show clear selectivity for expression within the prostate illustrates the potential of the PUGs as bio-markers linked to the biology of the underlying tissues.

Several of the selected PUG markers for uterine cancer fit very well with our current biological understanding of this disease. It is well-established that estrogen receptor alpha (ESR1) is expressed or amplified in human uterine cancer (PubMed IDs 18720455, 17911007, 15251938), while the Hox7 gene (MSX1) contributes to uterine function in cow and mouse models, especially at the onset of pregnancy (PubMed IDs 7908629, 14976223, 19007558). Mammaglobin 2 (SCGB2A1) is highly expressed in a specific type of well-differentiated uterine cancer (endometrial cancers) (PubMed ID 18021217), and PAM expression in the rat uterus is known to be regulated by estrogen (PubMed IDs 9618561, 9441675). Other PUGs provide novel insights into uterine cancer that are deserving of further study. Our PUG selection ranks HE4 higher than the well-established CA125 marker, which may suggest HE4 as a promising alternative for the clinical management of endometrial cancer. One recent study (PubMed ID 18495222) shows that, at 95% specificity, the sensitivity of differentiating between controls and all stages of uterine cancer is 44.9% using HE4 versus 25.2% using CA125 ($p = 0.0001$).

Osteopontin (OPN) is an integrin-binding protein that is involved in tumorigenesis and metastasis. OPN levels in the plasma of patients with ovarian cancer are much higher compared with plasma from healthy individuals (PubMed ID 11926891). OPN can increase the survival of ovarian cancer cells under stress conditions in vitro and can promote the late progression of ovarian cancer in vivo, and the survival-promoting functions of OPN are mediated through Akt activation (PubMed ID 19016748). Matrix metalloproteinase 2 (MMP2) is an enzyme degrading collagen type IV and other components of the basement membrane. MMP-2 is expressed by metastatic ovarian cancer cells and functionally regulates their attachment to peritoneal surfaces (PubMed ID 18340378). MMP2 facilitates the transmigration of human ovarian carcinoma cells across endothelial extracellular matrix (PubMed ID 15609323). Glutathione peroxidase 3 (GPX3) is one of several isoforms of peroxidases that reduce hydroperoxides to the corresponding alcohols by means of glutathione (GSH) (PubMed ID 17081103). GPX3 has been shown to be highly expressed in ovarian clear cell adenocarcinoma. Moreover, GPX3 has been associated with low cisplatin sensitivity (PubMed ID 19020706).

3.8.2 Biological Interpretation for NAS Data Set

Several top-ranking gene products identified by our computational method have been well established as tumor-type specific markers and many of them have been used in clinical diagnosis. For example, mucin 16, also known as CA125, is a FDA-approved serum marker to monitor disease progression and recurrence in ovarian cancer patients (PubMed ID 19042984). Likewise, kallikrein

family members including KLK6 and KLK8 are known to be ovarian cancer associated markers which can be detected in body fluids in ovarian cancer patients (PubMed ID 17303231). TITF1 (also known as TTF1) has been reported as a relatively specific marker in lung adenocarcinoma (PubMed ID 17982442) and it has been used to assist differential diagnosis of lung cancer from other types of carcinoma. Fatty acid synthase (FASN) is a well-known gene that is often upregulated in breast cancer (PubMed ID 17631500) and the enzyme is amenable for drug targeting using FASN inhibitors, suggesting that it can be used as a therapeutic target in breast cancer. The above findings indicate the robustness of our computational method in identifying tumor-type specific markers and in classifying different types of neoplastic diseases. Such information could be useful in translational studies (PubMed ID 12874019). Metastatic carcinoma of unknown origin is a relatively common presentation in cancer patients and an accurate diagnosis of the tumor type in the metastatic diseases is important to direct appropriate treatment and predict clinical outcome. The distinctive patterns of gene expression characteristic to various types of cancer may help pathologists and clinicians to better manage their patients.

3.9 Gene Comparisons Between Methods

It may be informative to provide some initial analysis on how the selected genes compare between methods; however, without definitive ground truth on cancer markers, the utility of this information is somewhat limited and should, thus, be treated as anecdotal, rather than conclusive. Specifically, we have now done some assessment of how differentially these gene selection methods rank some known cancer marker genes. The overlap rate is defined as the number of genes commonly selected by two methods over the maximum size of the two selected gene sets. Let G_1 and G_2 denote the gene sets selected by gene selection methods 1 and 2, respectively, and $|G|$ denote the cardinality (the size) of set G. The overlap rate between G_1 and G_2 is

$$R = \frac{|G_1 \cap G_2|}{\max(|G_1|, |G_2|)}.$$

Table 11 shows the overlap rate between methods on the top 100 genes per class. We can see that the overlap rates between methods are generally low except for the pair of SNR and t-stat. BW genes are quite different from the genes selected by all other methods and have only about 15% overlap rate with PUG and SVMRFE. The relatively high overlap rate between SNR and t-stat may be expected since they use quite similar summary statistics in their selection criteria.

We have also examined a total of 16 genes with known associations with 4 tumor types. These 16 genes are well-known markers supported by current biological knowledge. The rank of biomedical importance of these genes produced by each method is summarized in Table 12. When a gene is not listed in the top 100 genes by a wrapper method like SVMRFE, we simply assign the rank as '$>$100'. Generally but not uniformly across cancer types, these validated marker genes are highly ranked in the PUGs list as compared to other methods, and thus will be surely selected by PUG criterion.

4. Discussion

In this paper, we address several critical yet subtle issues in multicategory molecular classification applied to real-world biological and/or clinical applications. We propose a novel gene selection methodology matched to the multicategory classification approach (potentially with an unbalanced

Overlapping Rate	PUG	SNR	t-stat	BW	SVMRFE

Table 12: Detailed comparison between methods on several validated marker genes.

mixture distribution) that is not a straightforward pooled extension of binary (two-class) differential analysis. We emphasize the statistical reproducibility and biological plausibility of the selected gene markers under small sample size, supported by their detailed biological interpretations. We tested our method on six benchmark and in-house real microarray gene expression data sets and compared its performance with that of several existing methods. We imposed a rigorous performance assessment where each and all components of the scheme including gene selection are subjected to cross-validation, for example, held-out/unseen samples in a testing fold are not used for any phase of classifier training.

Tested on six benchmark real microarray data sets, the proposed PUG-OVRSVM method outperforms several widely-adopted gene selection and classification methods with lower error rates, fewer marker genes, and higher performance sustainability. Moreover, while for some data sets, the absolute gain in classification accuracy percentage of PUG-OVRSVM is not dramatically large, it must be recognized that the performance may be approaching the minimum Bayes error rate, in which case PUG-OVRSVM is achieving nearly all the improvement that is theoretically attainable. Furthermore, the improved performance is achieved by correct classifications on some of the most difficult cases, which is considered significant for clinical diagnosis (Ramaswamy et al., 2001). Lastly, although improvements will be data set-dependent, our multi-data set tests have shown that PUG-OVRSVM is the consistent winner as compared to several peer methods.

We note that we have opted for simplicity as opposed to theoretical optimality in designing our method. Our primary goal was to demonstrate that a small number of reproducible phenotypic-dependent genes are sufficient to achieve improved multicategory classification, that is, small sample sizes and a large number of classes need not preclude a high level of performance. Our studies suggest that using genes' marginal associations with the phenotypic categories as we do here has the potential to stabilize the learning process, leading to a substantial reduction in performance variability with small sample size; whereas, the current generation of complex gene selection techniques may not be stable or powerful enough to reliably exploit gene interactions and/or variations unless the sample size is sufficiently large. We have not explored the full flexibility that this method readily allows, with different numbers of subPUGs used by different classifiers. Presumably, equal or better performance could be achieved with fewer genes if more markers were selected for the most difficult classifications, involving the nearest phenotypes. However, such flexibility could actually degrade performance in practice since it introduces extra design choices and, thus, extra sources of variation in classification performance. We may also extend our method to account for variation in fold-changes, with the uncertainty estimated on bootstrap samples judiciously applied to eliminate those PUGs with high variations.

Notably, multicategory classification is intrinsically a nonlinear classification problem, and this method (using one-versus-everyone fold-change based PUG selection, linear kernel SVMs, and the MAP decision rule) is most practically suitable to discriminating unimodal classes. Future work will be required to extend PUG-OVRSVM for multimodal class distributions. An elegant yet simple strategy is to introduce unimodal pseudo-classes for the multi-modal classes via a pre-clustering step, with the final class decision readily made without the need of any decision combiner. Specifically, for each (pseudo-class, super pseudo-class) pair (where, for a pseudo-class originating from class k, the paired super pseudo-class is the union of all pseudo-classes that do not belong to class k), a separating hyperplane is constructed. Accordingly, in selecting subPUGs for each pseudo-class, the pseudo-classes originating from the same class will not be considered.

Editor: Cheng Soon Ong

Abstract

This paper describes the software package libDAI, a free & open source C++ library that provides implementations of various exact and approximate inference methods for graphical models with discrete-valued variables. libDAI supports directed graphical models (Bayesian networks) as well as undirected ones (Markov random fields and factor graphs). It offers various approximations of the partition sum, marginal probability distributions and maximum probability states. Parameter learning is also supported. A feature comparison with other open source software packages for approximate inference is given. libDAI is licensed under the GPL v2+ license and is available at `http://www.libdai.org`.

Keywords: probabilistic graphical models, approximate inference, open source software, factor graphs, Markov random fields, Bayesian networks

1. Introduction

Probabilistic graphical models (Koller and Friedman, 2009) are at the core of many applications in machine learning nowadays. Because exact inference in graphical models is often infeasible, an extensive literature has evolved in recent years describing various approximation methods for this task. Unfortunately, there exist only few free software implementations for many of these methods. The software package libDAI presented in this paper is the result of an ongoing attempt to improve this situation.

libDAI is a free and open source C++ library (licensed under the GNU General Public License version 2, or higher) that provides implementations of various exact and approximate inference methods for graphical models. libDAI supports factor graphs with discrete variables. This paper describes the most recent libDAI release, version 0.2.7.

The modular design of libDAI makes it easy to implement novel inference algorithms. The large number of inference algorithms already implemented in libDAI allows for easy comparison of accuracy and performance of various algorithms.

2. Inference in Factor Graphs

Although Bayesian networks and Markov random fields are the most commonly used graphical models, libDAI uses a slightly more general type of graphical model: factor graphs (Kschischang

et al., 2001). A *factor graph* is a bipartite graph consisting of *variable* nodes $i \in \mathcal{V}$ and *factor* nodes $I \in \mathcal{F}$, a family of random variables $(X_i)_{i\in\mathcal{V}}$, a family of *factors* $(f_I)_{I\in\mathcal{F}}$ (which are nonnegative functions depending on subsets $N_I \subseteq \mathcal{V}$ of the variables), and a set of edges $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{F}$, where variable node i and factor node I are connected by an undirected edge if and only if the factor f_I depends on variable X_i, that is, if $i \in N_I$. The probability distribution encoded by the factor graph is given by:

$$\mathbb{P}(X_{\mathcal{V}}) = \frac{1}{Z}\prod_{I\in\mathcal{F}} f_I(X_{N_I}), \qquad Z := \sum_{X_{\mathcal{V}}}\prod_{I\in\mathcal{F}} f_I(X_{N_I}).$$

A Bayesian network can easily be represented as a factor graph by introducing a factor for each variable, namely the (conditional) probability table of the variable given its parents in the Bayesian network. A Markov random field can be represented as a factor graph by taking the clique potentials as factors. Factor graphs naturally express the factorization structure of probability distributions. Therefore, they form a convenient representation for approximate inference algorithms that exploit this factorization. This is the reason that libDAI uses factor graphs as the basic representation for graphical models.

Given a factor graph, the following important inference tasks can be distinguished: calculating the *partition sum* Z; calculating *marginal* probability distributions $\mathbb{P}(X_A) = \frac{1}{Z}\sum_{X_{\mathcal{V}\setminus A}}\prod_{I\in\mathcal{F}} f_I(X_I)$ over subsets of variables $X_A, A \subseteq \mathcal{V}$; calculating the *Maximum A Posteriori* (MAP) state, that is, the joint configuration $\operatorname{argmax}_{X_{\mathcal{V}}}\prod_{I\in\mathcal{F}} f_I(X_I)$ which has the maximum probability mass. libDAI offers several inference algorithms which solve these tasks either approximately or exactly, for factor graphs with discrete variables.

2.1 Inference Methods Implemented in libDAI

Apart from exact inference by brute force enumeration and the junction-tree method, libDAI currently offers the following approximate inference methods for calculating partition sums, marginals and MAP states:[1] mean field, (loopy) belief propagation (Kschischang et al., 2001), fractional belief propagation (Wiegerinck and Heskes, 2003), tree-reweighted belief propagation (Wainwright et al., 2003), tree expectation propagation (Minka and Qi, 2004), generalized belief propagation (Yedidia et al., 2005), double-loop generalized belief propagation (Heskes et al., 2003), loop-corrected belief propagation (Mooij and Kappen, 2007; Montanari and Rizzo, 2005), conditioned belief propagation (Eaton and Ghahramani, 2009), a Gibbs sampler and a decimation method.

In addition, libDAI supports parameter learning of conditional probability tables by maximum likelihood or expectation maximization (in case of missing data).

3. Technical Details

libDAI is targeted at researchers that have a good understanding of graphical models. The best way to use libDAI is by writing C++ code that directly invokes the library functions and classes. In addition, part of the functionality is accessible by using various interfaces: a command line interface, a limited MatLab interface, and experimental Python and Octave interfaces (powered by SWIG, see `http://www.swig.org`). Because libDAI is implemented in C++, it is very fast compared with implementations in pure MatLab or Python; the difference in computation time can be up to a few orders of magnitude.

1. Not all inference tasks are implemented by each method.

Table 1: Feature comparison of various open source software packages for approximate inference on graphical models.

libDAI is designed to be cross-platform and is known to compile on GNU/Linux distributions and on Mac OS X using the `GCC` compiler suite, and also under Windows using either `CygWin` or `MS Visual Studio 2008`.

The libDAI sources and documentation can be downloaded or browsed from the libDAI website at `http://www.libdai.org`. The Google group libDAI (see `http://groups.google.com/group/libdai`) can be used for getting support and discussing development issues. Extensive documentation generated by Doxygen (see `http://www.doxygen.org`) is available, both as part of the source code and online. Unit tests and various example programs are provided, including the full source code of the solver which won in two categories of the *2010 UAI Approximate Inference Challenge* (see also `http://www.cs.huji.ac.il/project/UAI10/`) and uses several of the algorithms implemented in libDAI.

4. Related Work

Other prominent open source software packages supporting both directed and undirected graphical models are the Bayes Net Toolbox (BNT, see `http://bnt.googlecode.com`), the Probabilistic Networks Library (PNL, see `http://sourceforge.net/projects/openpnl`), FastInf (Jaimovich et al., 2010), GRMM (`http://mallet.cs.umass.edu/grmm`), Factorie (`http://code.google.com/p/factorie`), and JProGraM (`http://jprogram.sourceforge.net`). A feature comparison of libDAI with these other packages is provided in Table 1.

Acknowledgments

Part of this work was part of the Interactive Collaborative Information Systems (ICIS) project, supported by the Dutch Ministry of Economic Affairs, grant BSIK03024. I would like to express my gratitude to the following people who made major contributions to libDAI: Martijn Leisink (for laying down the foundations for the library), Frederik Eaton (for contributing the Gibbs sampler, conditioned BP, fractional BP and various other improvements), Charles Vaske (for contributing the parameter learning algorithms), Giuseppe Passino (for various improvements), Bastian Wemmenhove (for contributing the MR algorithm), Patrick Pletscher (for contributing the SWIG interface). I am also indebted to the following people for bug fixes and miscellaneous smaller patches: Claudio Lima, Christian Wojek, Sebastian Nowozin, Stefano Pellegrini, Ofer Meshi, Dan Preston, Peter Gober, Jiuxiang Hu, Peter Rockett, Dhruv Batra, Alexander Schwing, Alejandro Lage, Matt Dunham.

Abstract

The problems of dimension reduction and inference of statistical dependence are addressed by the modeling framework of learning gradients. The models we propose hold for Euclidean spaces as well as the manifold setting. The central quantity in this approach is an estimate of the gradient of the regression or classification function. Two quadratic forms are constructed from gradient estimates: the gradient outer product and gradient based diffusion maps. The first quantity can be used for supervised dimension reduction on manifolds as well as inference of a graphical model encoding dependencies that are predictive of a response variable. The second quantity can be used for nonlinear projections that incorporate both the geometric structure of the manifold as well as variation of the response variable on the manifold. We relate the gradient outer product to standard statistical quantities such as covariances and provide a simple and precise comparison of a variety of supervised dimensionality reduction methods. We provide rates of convergence for both inference of informative directions as well as inference of a graphical model of variable dependencies.

Keywords: gradient estimates, manifold learning, graphical models, inverse regression, dimension reduction, gradient diffusion maps

1. Introduction

The problem of developing predictive models given data from high-dimensional physical and biological systems is central to many fields such as computational biology. A premise in modeling natural phenomena of this type is that data generated by measuring thousands of variables lie on or near a low-dimensional manifold. This hearkens to the central idea of reducing data to only relevant

∗. Also in the Department of Computer Science.
†. Also in the Department of Computer Science and Institute for Genome Sciences & Policy.

information. This idea was fundamental to the paradigm of Fisher (1922) and goes back at least to Adcock (1878) and Edgeworth (1884). For an excellent review of this program see Cook (2007). In this paper we examine how this paradigm can be used to infer geometry of the data as well as statistical dependencies relevant to prediction.

The modern reprise of this program has been developed in the broad areas of manifold learning and simultaneous dimension reduction and regression. Manifold learning has focused on the problem of projecting high-dimensional data onto a few directions or dimensions while respecting local structure and distances. A variety of unsupervised methods have been proposed for this problem (Tenenbaum et al., 2000; Roweis and Saul, 2000; Belkin and Niyogi, 2003; Donoho and Grimes, 2003). Simultaneous dimension reduction and regression considers the problem of finding directions that are informative with respect to predicting the response variable. These methods can be summarized by three categories: (1) methods based on inverse regression (Li, 1991; Cook and Weisberg, 1991; Fukumizu et al., 2005; Wu et al., 2007), (2) methods based on gradients of the regression function (Xia et al., 2002; Mukherjee and Zhou, 2006; Mukherjee and Wu, 2006), (3) methods based on combining local classifiers (Hastie and Tibshirani, 1996; Sugiyama, 2007). Our focus is on the supervised problem. However, we will use the core idea in manifold learning, local estimation.

We first illustrate with a simple example how gradient information can be used for supervised dimension reduction. Both linear projections as well as nonlinear embeddings based on gradient estimates are used for supervised dimension reduction. In both approaches the importance of using the response variable is highlighted.

The main contributions in this paper consist of (1) development of gradient based diffusion maps, (2) precise statistical relations between the above three categories of supervised dimension reduction methods, (3) inference of graphical models or conditional independence structure given gradient estimates, (4) rates of convergence of the estimated graphical model. The rate of convergence depends on a geometric quantity, the intrinsic dimension of the gradient on the manifold supporting the data, rather than the sparsity of the graph.

2. A Statistical Foundation for Learning Gradients

The problem of regression can be summarized as estimating the function

$$f_r(x) = \mathbb{E}(Y \mid X = x)$$

from data $D = \{L_i = (Y_i, X_i)\}_{i=1}^n$ where X_i is a vector in a p-dimensional compact metric space $X \in \mathcal{X} \subset \mathbb{R}^p$ and $Y_i \in \mathbb{R}$ is a real valued output. Typically the data are drawn iid from a joint distribution, $L_i \overset{iid}{\sim} \rho(X,Y)$ thus specifying a model

$$y_i = f_r(x_i) + \varepsilon_i$$

with ε_i drawn iid from a specified noise model. We define ρ_X as the marginal distribution of the explanatory variables.

In this paper we will explain how inference of the gradient of the regression function

$$\nabla f_r = \left(\frac{\partial f_r}{\partial x^1}, ..., \frac{\partial f_r}{\partial x^p} \right)^T$$

provides information on the geometry and statistical dependencies relevant to predicting the response variable given the explanatory variables. Our work is motivated by the following ideas. The gradient is a local concept as it measures local changes of a function. Integrating information encoded by the gradient allows for inference of the geometric structure in the data relevant to the response. We will explore two approaches to integrate this local information. The first approach is averaging local gradient estimates and motivates the study of the gradient outer product (GOP) matrix. The GOP can be used to motivate a variety of linear supervised dimension reduction formulations. The GOP can also be considered as a covariance matrix and used for inference of conditional dependence between predictive explanatory variables. The second approach is to paste local gradient estimates together. This motivates the study of gradient based diffusion maps (GDM). This operator can be used for nonlinear supervised dimension reduction by embedding the support of the marginal distribution onto a much lower dimensional manifold that varies with respect to the response.

The gradient outer product Γ is a $p \times p$ matrix with elements

$$\Gamma_{ij} = \left\langle \frac{\partial f_r}{\partial x^i}, \frac{\partial f_r}{\partial x^j} \right\rangle_{L^2_{\rho_X}},$$

where ρ_X is the marginal distribution of the explanatory variables and $L^2_{\rho_X}$ is the space of square integrable functions with respect to the measure ρ_X. Using the notation $a \otimes b = ab^T$ for $a, b \in \mathbb{R}^p$, we can write

$$\Gamma = \mathbb{E}(\nabla f_r \otimes \nabla f_r).$$

This matrix provides global information about the predictive geometry of the data (developed in Section 2.2) as well as inference of conditional independence between variables (developed in Section 5). The GOP is meaningful in both the Euclidean as well as the manifold setting where the marginal distribution ρ_X is concentrated on a much lower dimensional manifold $\mathcal{M}$ of dimension $d_{\mathcal{M}}$ (developed in Section 4.1.2).

Since the GOP is a global quantity and is constructed by averaging the gradient over the marginal distribution of the data it cannot isolate local information or local geometry. This global summary of the joint distribution is advantageous in statistical analyses where global inferences are desired: global predictive factors comprised of the explanatory variables or global estimates of statistical dependence between explanatory variables. It is problematic to use a global summary for constructing a nonlinear projection or embedding that captures the local predictive geometry on the marginal distribution.

Random walks or diffusions on manifolds and graphs have been used for a variety of nonlinear dimension reduction or manifold embedding procedures (Belkin and Niyogi, 2003, 2004; Szummer and Jaakkola, 2001; Coifman et al., 2005a,b). Our basic idea is to use local gradient information to construct a random walk on a graph or manifold based on the ideas of diffusion analysis and diffusion geometry (Coifman and Lafon, 2006; Coifman and Maggioni, 2006). The central quantity in diffusion based approaches is the definition of a diffusion operator L based on a similarity metric W_{ij} between two points x_i and x_j. A commonly used diffusion operator is the graph Laplacian

$$L = I - D^{-1/2} W D^{-1/2}, \quad \text{where } D_{ii} = \sum_j W_{ij}.$$

Dimension reduction is achieved by projection onto a spectral decomposition of the operator L or powers of the operator L^t which corresponds to running the diffusion for some time t.

We propose the following similarity metric called the gradient based diffusion map (GDM) to smoothly paste together local gradient estimates

$$W_{ij} = W_f(x_i, x_j) = \exp\left(-\frac{\|x_i - x_j\|^2}{\sigma_1} - \frac{|\frac{1}{2}(\nabla f_r(x_i) + \nabla f_r(x_j)) \cdot (x_i - x_j)|^2}{\sigma_2} \right).$$

In the above equation the first term $\|x_i - x_j\|^2$ encodes the local geometry of the marginal distribution and the second term pastes together gradient estimates between neighboring points. The first term is used in unsupervised dimension reduction methods such as Laplacian eigenmaps or diffusion maps (Belkin and Niyogi, 2003). The second term can be interpreted as a diffusion map on the function values, the approximation is due to a first order Taylor expansion

$$\frac{1}{2}(\nabla f_r(x_i) + \nabla f_r(x_j)) \cdot (x_i - x_j) \approx f_r(x_i) - f_r(x_j) \qquad \text{if } x_i \approx x_j.$$

A related similarity was briefly mentioned in Coifman et al. (2005b) and used in Szlam et al. (2008) in the context of semi-supervised learning. In Section 4.2 we study this nonlinear projection method under the assumption that the marginal distribution is concentrated on a much lower dimensional manifold $\mathcal{M}$.

2.1 Illustration of Linear Projections and Nonlinear Embeddings

The simple example in this section fixes the differences between linear projections and nonlinear embeddings using either diffusion maps or gradient based diffusion maps. The marginal distribution is uniform on the following manifold

$$X_1 = t\cos(t), \quad X_2 = 70h, \quad X_3 = t\sin(t) \text{ where } t = \frac{3\pi}{2}(1 + 2\theta), \theta \in [0,1], h \in [0,1],$$

and the regression function is $Y = \sin(5\pi\theta)$, see Figure 1(a). In this example a two dimensional manifold is embedded in $\mathbb{R}^3$ and the variation of the response variable can be embedded onto one dimension. The points in Figure 1(a) are the points on the manifold and the false color signifies the function value at these points. In Figure 1(b) the data is embedded in two dimensions using diffusion maps with the function values displayed in false color. It is clear that the direction of greatest variation is X_2 which corresponds to h. It is not the direction along which the regression function has greatest variation. In Figure 1(c) the data is projected onto two axes using the GOP approach and we see that the relevant dimensions X_1, X_3 are recovered. This example also shows that linear dimension reduction may still make sense in the manifold setting. In Figure 1(d) the data is embedded using gradient based diffusion maps and we capture the direction θ in which the data varies with respect to the regression function.

2.2 Gradient Outer Product Matrix and Dimension Reduction

In the case of linear supervised dimension reduction we assume the following semi-parametric model holds

$$Y = f_r(X) + \varepsilon = g(b_1^T X, \ldots, b_d^T X) + \varepsilon, \tag{1}$$

where ε is noise and $B = (b_1^T, ..., b_d^T)$ is the dimension reduction (DR) space. In this case the number of explanatory variables p is large but the the response variable Y depends on a few directions in $\mathbb{R}^p$

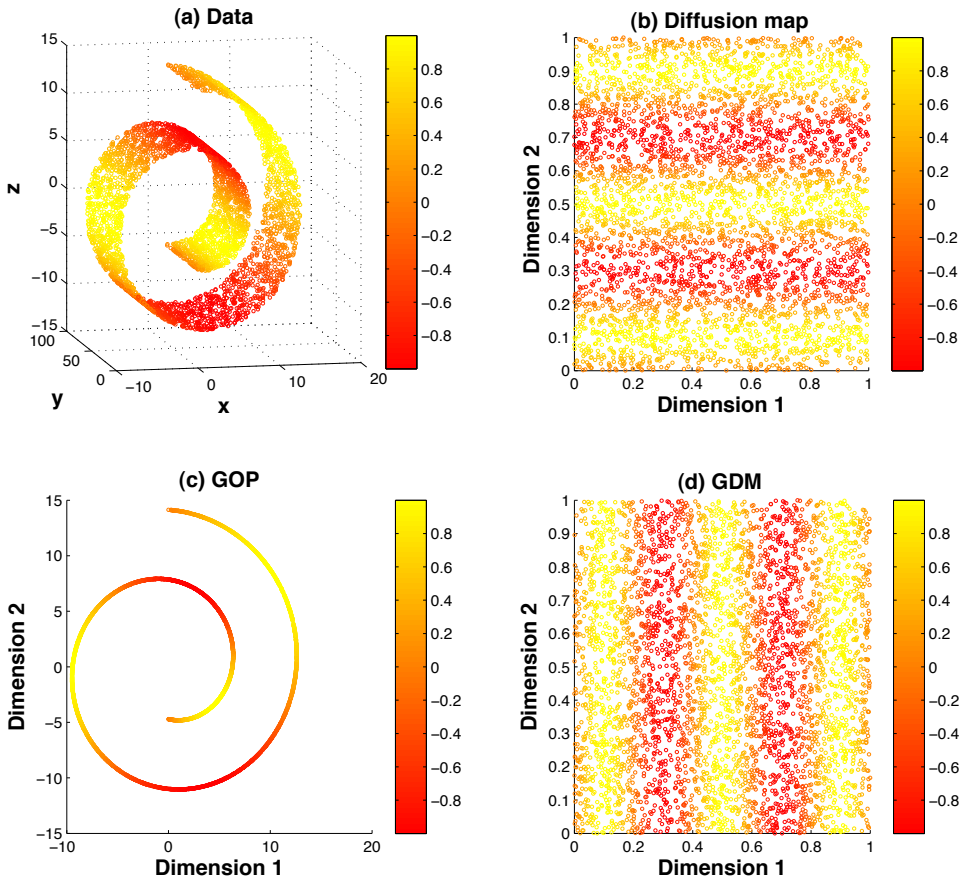

Figure 1: (a) Plot of the original three dimensional data with the color of the point corresponding to the function value; (b) Embedding the data onto two dimensions using diffusion maps, here dimensions 1 and 2 corresponds to h and θ respectively; (c) Projection of the data onto two dimensions using gradient based dimension reduction, here dimensions 1 and 2 corresponds to x and z respectively; (d) Embedding the data onto two dimensions using gradient based diffusion maps, here dimensions 1 and 2 corresponds to θ and h respectively.

and dimension reduction becomes the central problem in finding an accurate regression model. In the following we develop theory relating the gradient of the regression function to the above model of dimension reduction.

Observe that for a vector $v \in \mathbb{R}^p$, $\frac{\partial f_r(x)}{\partial v} = v \cdot \nabla f_r$ is identically zero if f_r does not depends on v and is not zero if f_r changes along the direction v. The following lemma relates the gradient outer product matrix to supervised dimension reduction.

Lemma 1 *Under the assumptions of the semi-parametric model* (1)*, the gradient outer product matrix* Γ *is of rank at most* d*. Denote by* $\{v_1, \ldots, v_d\}$ *the eigenvectors associated to the nonzero eigenvalues of* Γ*. The following holds*

$$\operatorname{span}(B) = \operatorname{span}(v_1, \ldots, v_d).$$

Lemma 1 states the dimension reduction space can be computed by a spectral decomposition of Γ. Notice that this method does not require additional geometric conditions on the distribution. This is in contrast to other supervised dimension reduction methods (Li, 1991; Cook and Weisberg, 1991; Li, 1992) that require a geometric or distributional requirement on X, namely that the level sets of the distribution are elliptical.

This observation motivates supervised dimension reduction methods based on consistent estimators Γ_D of Γ given data D. Several methods have been motivated by this idea, either implicitly as in minimum average variance estimation (MAVE) (Xia et al., 2002), or explicitly as in outer product of gradient (OPG) (Xia et al., 2002) and learning gradients (Mukherjee et al., 2010).

The gradient outer product matrix is defined globally and its relation to dimension reduction in Section 2.2 is based on global properties. However, since the gradient itself is a local concept we can also study the geometric structure encoded in the gradient outer product matrix from a local point of view.

2.3 Gradient Outer Product Matrix as a Covariance Matrix

A central concept used in dimension reduction is the covariance matrix of the inverse regression function $\Omega_{X|Y} = \operatorname{cov}_Y[\mathbb{E}_X(X \mid Y)]$. The fact that $\Omega_{X|Y}$ encodes the DR directions $B = (b_1, \ldots, b_d)$ under certain conditions was explored in Li (1991).

The main result of this subsection is to relate the two matrices: Γ and $\Omega_{X|Y}$. The first observation from this relation is that the gradient outer product matrix is a covariance matrix with a very particular construction. The second observation is that the gradient outer product matrix contains more information than the covariance of the inverse regression since it captures local information. This is outlined for linear regression and then generalized to nonlinear regression. Proofs of the propositions and the underlying mathematical ideas will be developed in Section 4.1.1.

The linear regression problem is often stated as

$$Y = \beta^T X + \varepsilon, \quad \mathbb{E}\,\varepsilon = 0. \tag{2}$$

For this model the following relation between gradient estimates and the inverse regression holds.

Proposition 2 *Suppose* (2) *holds. Given the covariance of the inverse regression,* $\Omega_{X|Y} = \operatorname{cov}_Y(\mathbb{E}_X(X \mid Y))$*, the variance of the output variable,* $\sigma_Y^2 = \operatorname{var}(Y)$*, and the covariance of the input variables,* $\Sigma_X = \operatorname{cov}(X)$*, the gradient outer product matrix is*

$$\Gamma = \sigma_Y^2 \left(1 - \frac{\sigma_\varepsilon^2}{\sigma_Y^2}\right)^2 \Sigma_X^{-1} \Omega_{X|Y} \Sigma_X^{-1}, \tag{3}$$

assuming that Σ_X *is full rank.*

The above result states that for a linear model the matrices Γ and $\Omega_{X|Y}$ are equivalent modulo a scale parameter—approximately the variance of the output variable—and a rotation—the precision matrix (inverse of the covariance matrix) of the input variables.

In order to generalize Proposition 2 to the nonlinear regression setting we first consider piecewise linear functions. Suppose there exists a non-overlapping partition of the input space

$$\mathcal{X} = \bigcup_{i=1}^{I} R_i$$

such that in each region R_i the regression function f_r is linear and the noise has zero mean

$$f_r(x) = \beta_i^T x, \quad \mathbb{E}\,\varepsilon_i = 0 \quad \text{for } x \in R_i. \tag{4}$$

The following corollary is true.

Corollary 3 *Given partitions R_i of the input space for which* (4) *holds, define in each partition R_i the following local quantities: the covariance of the input variables $\Sigma_i = \mathrm{cov}(X \in R_i)$, the covariance of the inverse regression $\Omega_i = \mathrm{cov}_Y(\mathbb{E}_X(X \in R_i \mid Y))$, the variance of the output variable $\sigma_i^2 = \mathrm{var}(Y \mid X \in R_i)$. Assuming that matrices Σ_i are full rank, the gradient outer product matrix can be computed in terms of these local quantities*

$$\Gamma = \sum_{i=1}^{I} \rho_X(R_i)\sigma_i^2 \left(1 - \frac{\sigma_{\varepsilon_i}^2}{\sigma_i^2}\right)^2 \Sigma_i^{-1}\,\Omega_i\,\Sigma_i^{-1}, \tag{5}$$

where $\rho_X(R_i)$ is the measure of partition R_i with respect to the marginal distribution ρ_X.

If the regression function is smooth it can be approximated by a first order Taylor series expansion in each partition R_i provided the region is small enough. Theoretically there always exist partitions such that the locally linear models (4) hold approximately (i.e., $\mathbb{E}\,\varepsilon_i \approx 0$). Therefore (5) holds approximately

$$\Gamma \approx \sum_{i=1}^{I} \rho_X(R_i)\sigma_i^2 \left(1 - \frac{\sigma_{\varepsilon_i}^2}{\sigma_i^2}\right)^2 \Sigma_i^{-1}\,\Omega_i\,\Sigma_i^{-1}.$$

Supervised dimension reduction methods based on the covariance of the inverse regression require an elliptic condition on X. This condition ensures that $\Omega_{X|Y}$ encodes the DR subspace but not necessarily the entire DR subspace. In the worst case it is possible that $\mathbb{E}(X \mid Y) = 0$, $\Omega_{X|Y} = \mathbf{0}$. and as a result $\Omega_{X|Y}$ contains no information. In the linear case $\Omega_{X|Y}$ will encode the full DR subspace, the one predictive direction. Since the GOP is an average the inverse covariance matrix of the locally linear models it contains all the predictive directions. This motivates the centrality of the gradient outer product.

This derivation of the gradient outer product matrix based on local variation has two potential implications. It provides a theoretical comparison between dimension reduction approaches based on the gradient outer product matrix and inverse regression. This will be explored in Section 4.1.1 in detail. The integration of local variation will be used to infer statistical dependence between the explanatory variables conditioned on the response variable in Section 5.

A common belief in high dimensional data analysis is that the data are concentrated on a low dimensional manifold. Both theoretical and empirical evidence of this belief is accumulating. In the manifold setting, the input space is a manifold $\mathcal{X} = \mathcal{M}$ of dimension $d_{\mathcal{M}} \ll p$. We assume the existence of an isometric embedding $\varphi : \mathcal{M} \to \mathbb{R}^p$ and the observed input variables $(x_i)_{i=1}^n$ are the image of points $(q_i)_{i=1}^n$ drawn from a distribution on the manifold: $x_i = \varphi(q_i)$. In this case, global

statistics are not as meaningful from a modeling perspective.[1] In this setting the gradient outer product matrix should be defined in terms of the gradient on the manifold, $\nabla_{\mathcal{M}} f_r$,

$$\Gamma = \mathbb{E}\left(d\varphi(\nabla_{\mathcal{M}} f_r) \otimes d\varphi(\nabla_{\mathcal{M}} f_r)\right) = \mathbb{E}\left(d\varphi(\nabla_{\mathcal{M}} f_r \otimes \nabla_{\mathcal{M}} f_r)(d\varphi)^T\right).$$

This quantity is meaningful from a modeling perspective because gradients on the manifold capture the local structure in the data. Note that the $d_{\mathcal{M}} \times d_{\mathcal{M}}$ matrix $\Gamma_{\mathcal{M}} = \nabla_{\mathcal{M}} f_r \otimes \nabla_{\mathcal{M}} f_r$ is the central quantity of interest in this setting. However, we know neither the manifold nor the coordinates on the manifold and are only provided points in the ambient space. For this reason we cannot compute $\Gamma_{\mathcal{M}}$. However, we can understand its properties by analyzing the gradient outer product matrix Γ in the ambient space, a $p \times p$ matrix. Details on conditions under which Γ provides information on $\Gamma_{\mathcal{M}}$ are developed in Section 4.1.2.

3. Estimating Gradients

An estimate of the gradient is required in order to estimate the gradient outer product matrix Γ. Many approaches for computing gradients exist including various numerical derivative algorithms, local linear/polynomial smoothing (Fan and Gijbels, 1996), and learning gradients by kernel models (Mukherjee and Zhou, 2006; Mukherjee and Wu, 2006). Our main focus is on what can be done given an estimate of Γ rather than estimation methods for the gradient. The application domain we focus on is the analysis of high-dimensional data with few observations, where $p \gg n$ and some traditional methods do not work well because of computational complexity or numerical stability. Learning gradients by kernel models was specifically developed for this type of data in the Euclidean setting for regression (Mukherjee and Zhou, 2006) and classification (Mukherjee and Wu, 2006). The same algorithms were shown to be valid for the manifold setting with a different interpretation in Mukherjee et al. (2010). In this section we review the formulation of the algorithms and state properties that will be relevant in subsequent sections.

The motivation for learning gradients is based on Taylor expanding the regression function

$$f_r(u) \approx f_r(x) + \nabla f_r(x) \cdot (u - x), \text{ for } x \approx u,$$

which can be evaluated at data points $(x_i)_{i=1}^n$

$$f_r(x_i) \approx f_r(x_j) + \nabla f_r(x_j) \cdot (x_i - x_j), \text{ for } x_i \approx x_j.$$

Given data $D = \{(y_i, x_i)\}_{i=1}^n$ the objective is to simultaneously estimate the regression function f_r by a function f_D and the gradient ∇f_r by the p-dimensional vector valued function $\vec{f}_D$.

In the regression setting the following regularized loss functional provides the estimates (Mukherjee and Zhou, 2006).

Definition 4 *Given the data $D = \{(x_i, y_i)\}_{i=1}^n$, define the first order difference error of function f and vector-valued function $\vec{f} = (f_1, \ldots, f_p)$ on D as*

$$\mathcal{E}_D(f, \vec{f}) = \frac{1}{n^2} \sum_{i,j=1}^{n} w_{i,j}^s \left(y_i - f(x_j) + \vec{f}(x_i) \cdot (x_j - x_i) \right)^2.$$

1. Consider $\Omega(X \mid Y)$ as an example. For any given y, the set $\{x \mid Y = y\}$ is a submanifold. The global mean will not necessarily lie on the manifold. Therefore, from a modeling perspective $\mathbb{E}(X \mid Y)$ and hence $\Omega(X \mid Y)$ may convey nothing about the manifold. Although this does not mean it is useless in practice, a theoretical justification seems impossible.

The regression function and gradient estimate is modeled by

$$(f_D, \vec{f}_D) := \arg \min_{(f,\vec{f}) \in \mathcal{H}_K^{p+1}} \left(\mathcal{E}_D(f,\vec{f}) + \lambda_1 \|f\|_K^2 + \lambda_2 \|\vec{f}\|_K^2 \right),$$

where f_D and $\vec{f}_D$ are estimates of f_r and ∇f_r given the data, $w_{i,j}^s$ is a weight function with bandwidth s, $\|\cdot\|_K$ is the reproducing kernel Hilbert space (RKHS) norm, λ_1 and λ_2 are positive constants called the regularization parameters, the RKHS norm of a p-vector valued function is the sum of the RKHS norm of its components $\|\vec{f}\|_K^2 := \sum_{t=1}^p \|\vec{f}_t\|_K^2$.

A typical weight function is a Gaussian $w_{i,j}^s = \exp(-\|x_i - x_j\|^2/2s^2)$. Note this definition is slightly different from that given in Mukherjee and Zhou (2006) where $f(x_j)$ is replaced by y_j and only the gradient estimate $\vec{f}_D$ is estimated.

In the classification setting we are given $D = \{(y_i, x_i)\}_{i=1}^n$ where $y_i \in \{-1, 1\}$ are labels. The central quantity here is the classification function which we can define by conditional probabilities

$$f_c(x) = \log \left[\frac{\rho(Y=1 \mid x)}{\rho(Y=-1 \mid x)} \right] = \arg\min \mathbb{E}\, \phi(Y f(X))$$

where $\phi(t) = \log(1 + e^{-t})$ and the sign of f_c is a Bayes optimal classifier. The following regularized loss functional provides estimates for the classification function and gradient (Mukherjee and Wu, 2006).

Definition 5 *Given a sample $D = \{(x_i, y_i)\}_{i=1}^n$ we define the empirical error as*

$$\mathcal{E}_D^\phi(f,\vec{f}) = \frac{1}{n^2} \sum_{i,j=1}^n w_{ij}^s \phi\Big(y_i \big(f(x_j) + \vec{f}(x_i) \cdot (x_i - x_j) \big) \Big).$$

The classification function and gradient estimate given a sample is modeled by

$$(f_D, \vec{f}_D) = \arg \min_{(f,\vec{f}) \in \mathcal{H}_K^{p+1}} \left(\mathcal{E}_D^\phi(f,\vec{f}) + \lambda_1 \|f\|_K^2 + \lambda_2 \|\vec{f}\|_K^2 \right),$$

where f_D and $\vec{f}_D$ are estimates of f_c and ∇f_c, and λ_1, λ_2 are the regularization parameters.

In the manifold setting the above algorithms are still valid. However the interpretation changes. We state the regression case, the classification case is analogous (Mukherjee et al., 2010).

Definition 6 *Let $\mathcal{M}$ be a Riemannian manifold and $\varphi : \mathcal{M} \to \mathbb{R}^p$ be an isometric embedding which is unknown. Denote $\mathcal{X} = \varphi(\mathcal{M})$ and $\mathcal{H}_K = \mathcal{H}_K(\mathcal{X})$. For the sample $D = \{(q_i, y_i)\}_{i=1}^n \in (\mathcal{M} \times \mathbb{R})^n$, $x_i = \varphi(q_i) \in \mathbb{R}^p$, the learning gradients algorithm on $\mathcal{M}$ provides estimates*

$$(f_D, \vec{f}_D) := \arg \min_{f,\vec{f} \in \mathcal{H}_K^{p+1}} \left\{ \frac{1}{n^2} \sum_{i,j=1}^n w_{i,j}^s \left(y_i - f(x_j) + \vec{f}(x_i) \cdot (x_j - x_i) \right)^2 + \lambda_1 \|f\| + \lambda_2 \|\vec{f}\|_K^2 \right\},$$

where $\vec{f}_D$ is a model for $\mathrm{d}\varphi(\nabla_{\mathcal{M}} f_r)$ and f_D is a model for f_r.

From a computational perspective the advantage of the RKHS framework is that in both regression and classification the solutions satisfy a representer theorem (Wahba, 1990; Mukherjee and Zhou, 2006; Mukherjee and Wu, 2006)

$$f_D(x) = \sum_{i=1}^{n} \alpha_{i,D} K(x, x_i), \;\; \vec{f}_D(x) = \sum_{i=1}^{n} c_{i,D} K(x, x_i), \tag{6}$$

with $c_D = (c_{1,D}, \ldots, c_{n,D}) \in \mathbb{R}^{p \times n}$, and $\alpha_D = (\alpha_{1,D}, ..., \alpha_{n,D})^T \in \mathbb{R}^p$. In Mukherjee and Zhou (2006) and Mukherjee and Wu (2006) methods for efficiently computing the minima were introduced in the setting where $p \gg n$. The methods involve linear systems of equations of dimension nd where $d \leq n$.

The consistency of the gradient estimates for both regression and classification were proven in Mukherjee and Zhou (2006) and Mukherjee and Wu (2006) respectively.

Proposition 7 *Under mild conditions (see Mukherjee and Zhou, 2006; Mukherjee and Wu, 2006 for details) the estimates of the gradients of the regression or classification function f converge to the true gradients: with probability greater than $1 - \delta$,*

$$\|\vec{f}_D - \nabla f\|_{L^2_{\rho_x}} \leq C \log\left(\frac{2}{\delta}\right) n^{-1/p}.$$

Consistency in the manifold setting was studied in Mukherjee et al. (2010) and the rate of convergence was determined by the dimension of the manifold, $d_{\mathcal{M}}$, not the dimension of the ambient space p.

Proposition 8 *Under mild conditions (see Mukherjee et al., 2010 for details), with probability greater than $1 - \delta$,*

$$||(d\varphi)^* \vec{f}_D - \nabla_{\mathcal{M}} f||_{L^2_{\rho_{\mathcal{M}}}} \leq C \log\left(\frac{2}{\delta}\right) n^{-1/d_{\mathcal{M}}},$$

where where $(d\varphi)^*$ is the dual of the map $d\varphi$.

4. Dimension Reduction Using Gradient Estimates

In this section we study some properties of dimension reduction using the gradient estimates. We also relate learning gradients to previous approaches for dimension reduction in regression.

4.1 Linear Dimension Reduction

The theoretical foundation for linear dimension reduction using the spectral decomposition of the gradient outer production matrix was developed in Section 2.2. The estimate of the gradient obtained by the kernel models in Section 3 provides the following empirical estimate of the gradient outer product matrix

$$\hat{\Gamma} := c_D K^2 c_D^T = \frac{1}{n} \sum_{i=1}^{n} \vec{f}_D(x_i) \otimes \vec{f}_D(x_i),$$

where K is the kernel matrix with $K_{ij} = K(x_i, x_j)$ and c_D is defined in (6). The eigenvectors corresponding to the top eigenvalues of $\hat{\Gamma}$ can be used to estimate the d dimension reduction directions. The following proposition states that the estimate is consistent.

Proposition 9 *Suppose that f satisfies the semi-parametric model* (1) *and $\vec{f}_D$ is an empirical approximation of ∇f. Let $\hat{v}_1, \ldots, \hat{v}_d$ be the eigenvectors of $\hat{\Gamma}$ associated to the top d eigenvalues. The following holds*

$$\lim_{n\to\infty} \text{span}(\hat{v}_1, \ldots, \hat{v}_d) = \text{span}(B).$$

Moreover, the remaining eigenvectors correspond to eigenvalues close to 0.

Proof : Proposition 7 implies that $\lim_{n\to\infty} \hat{\Gamma}_{ij} = \Gamma_{ij}$ and hence $\lim_{n\to\infty} \Gamma = \Gamma$ in matrix norm. By perturbation theory the eigenvalues (see Golub and Loan, 1996, Theorem 8.1.4 and Corollary 8.1.6) and eigenvectors (see Zwald and Blanchard, 2006) of $\hat{\Gamma}$ converge to those of Γ respectively. The conclusions then follow from Lemma 1. ■

Proposition 9 justifies linear dimension reduction using consistent gradient estimates from a global point of view.

In the next subsection we study the gradient outer product matrix from the local point of view and provide details on the relation between gradient based methods and sliced inverse regression.

4.1.1 RELATION TO SLICED INVERSE REGRESSION (SIR)

The SIR method computes the DR directions using a generalized eigen-decomposition problem

$$\Omega_{X|Y}\beta = \nu\Sigma_X\beta. \tag{7}$$

In order to study the relation between our method with SIR, we study the relation between the matrices $\Omega_{X|Y}$ and Γ.

We start with a simple model where the DR space contains only one direction which means the regression function satisfies the following semi-parametric model

$$Y = g(\beta^T X) + \varepsilon$$

where $\|\beta\| = 1$ and $\mathbb{E}\,\varepsilon = 0$. The following theorem holds and Proposition 2 is a special case.

Theorem 10 *Suppose that Σ_X is invertible. There exists a constant C such that*

$$\Gamma = C\Sigma_X^{-1}\Omega_{X|Y}\Sigma_X^{-1}.$$

If g is a linear function the constant is $C = \sigma_Y^2\left(1 - \frac{\sigma_\varepsilon^2}{\sigma_Y^2}\right)^2$.

Proof It is proven in Duan and Li (1991) that

$$\Omega_{X|Y} = \text{var}(h(Y))\Sigma_X\beta\beta^T\Sigma_X$$

where $h(y) = \frac{\mathbb{E}(\beta^T(X-\mu)|y)}{\beta^T\Sigma_X\beta}$ with $\mu = \mathbb{E}(X)$ and Σ_X is the covariance matrix of X. In this case, the computation of matrix Γ is direct:

$$\Gamma = \mathbb{E}[(g'(\beta^T X))^2]\beta\beta^T.$$

By the assumption Σ_X is invertible, we immediately obtain the first relation with

$$C = \mathbb{E}[(g'(\beta^T X))^2]\text{var}(h(Y))^{-1}.$$

If $g(t) = at + b$, we have $h(y) = \frac{y-b-\beta^T\mu}{a\beta^T\Sigma_X\beta}$ and consequently

$$\mathrm{var}(h(Y)) = \frac{\sigma_Y^2}{a^2(\beta^T\Sigma_X\beta)^2}.$$

By the simple fact $\mathbb{E}(g'(\beta^T X)^2] = a^2$ and $\sigma_Y^2 = a^2\beta^T\Sigma_X\beta + \sigma_\varepsilon^2$, we get

$$C = \frac{a^4(\beta^T\Sigma_X\beta)^2}{\sigma_Y^2} = \frac{(\sigma_Y^2 - \sigma_\varepsilon^2)^2}{\sigma_Y^2} = \sigma_Y^2\left(1 - \frac{\sigma_\varepsilon^2}{\sigma_Y^2}\right)^2.$$

This finishes the proof. ■

It is apparent that Γ and $\Omega_{X|Y}$ differ only up to a linear transformation. As a consequence the generalized eigen-decomposition (7) of $\Omega_{X|Y}$ with respect to Σ_X yields the same first direction as the eigen-decomposition of Γ.

Consider the linear case. Without loss of generality suppose X is normalized to satisfy $\Sigma_X = \sigma^2 I$, we see $\Omega_{X|Y}$ is the same as Γ up to a constant of about $\frac{\sigma_Y^2}{\sigma^4}$. Notice that this factor measures the ratio of the variation of the response to the variation over the input space as well as along the predictive direction. This implies that Γ is more informative because it not only contains the information of the descriptive directions but also measures their importance with respect to the change of the response variable.

When there are more than one DR directions as in model (1), we partition the input space into I small regions $X = \bigcup_{i=1}^I R_i$ such that over each region R_i the response variable y is approximately linear with respect to x and the descriptive direction is a linear combination of the column vectors of B. By the discussion in Section 2.2

$$\Gamma = \sum_i \rho_X(R_i)\,\Gamma_i \approx \sum_{i=1}^I \rho_X(R_i)\sigma_i^2\,\Sigma_i^{-1}\,\Omega_i\Sigma_i^{-1},$$

where Γ_i is the gradient outer product matrix on R_i and $\Omega_i = \mathrm{cov}_Y(\mathbb{E}_X(X \in R_i \mid Y))$. In this sense, the gradient covariance matrix Γ can be regarded as the weighted sum of the local covariance matrices of the inverse regression function. Recall that SIR suffers from the possible degeneracy of the covariance matrix of the inverse regression function over the entire input space while the local covariance matrix of the inverse regression function will not be degenerate unless the function is constant. Moreover, in the gradient outer product matrix, the importance of local descriptive directions are also taken into account. These observations partially explain the generality and some advantages of gradient based methods.

Note this theoretical comparison is independent of the method used to estimate the gradient. Hence the same comparison holds between SIR and other gradient based methods such as mean average variance estimation (MAVE) and outer product of gradients (OPG) developed in Xia et al. (2002).

4.1.2 THEORETICAL FEASIBILITY OF LINEAR PROJECTIONS FOR NONLINEAR MANIFOLDS

In this section we explore why linear projections based on the gradient outer product matrix are feasible and have meaning when the manifold structure is nonlinear. The crux of the analysis will be demonstrating that the estimated gradient outer product matrix $\hat{\Gamma}$ is still meaningful.

Again assume there exists an unknown isometric embedding of the manifold onto the ambient space, $\varphi : \mathcal{M} \to \mathbb{R}^p$. From a modeling perspective we would like the gradient estimate from data $\vec{f}_D$ to approximate $d\varphi(\nabla_{\mathcal{M}} f_r)$ (Mukherjee et al., 2010). Generally this is not true when the manifold is nonlinear, φ is a nonlinear map. Instead, the estimate provides the following information about $\nabla_{\mathcal{M}} f_r$

$$\lim_{n\to\infty} (d\varphi)^* \vec{f}_D = \nabla_{\mathcal{M}} f_r,$$

where $(d\varphi)^*$ is the dual of $d\varphi$, the differential of φ.

Note that f_r is not well defined on any open set of $\mathbb{R}^p$. Hence, it is not meaningful to consider the gradient of ∇f_r in the ambient space $\mathbb{R}^p$. Also, we cannot recover directly the gradient of f_r on the manifold since we know neither the manifold nor the embedding. However, we can still recover the DR directions from the matrix $\hat{\Gamma}$.

Assume f_r satisfies the semi-parametric model (1). The matrix Γ is not well defined but $\hat{\Gamma}$ is well defined. The following proposition ensures that the spectral decomposition of $\hat{\Gamma}$ provides the DR directions.

Proposition 11 *If $v \perp b_i$ for all $i = 1, \ldots, d$, then* $\lim_{n\to\infty} v^T \hat{\Gamma} v = 0$.

Proof Let $\vec{f}_\lambda$ be the sample limit of $\vec{f}_D$, that is

$$\vec{f}_\lambda = \arg\min_{\vec{f}\in\mathcal{H}_K^p} \left\{ \int_{\mathcal{M}} \int_{\mathcal{M}} e^{-\frac{\|x-\xi\|^2}{2s^2}} \left(f_r(x) - f_r(\xi) + \vec{f}(x)\cdot(\xi - x) \right)^2 d\rho_{\mathcal{M}}(x) d\rho_{\mathcal{M}}(\xi) + \lambda \|\vec{f}\|_K^2 \right\}.$$

By the assumption and a simple rotation argument we can show that $v \cdot \vec{f}_\lambda = 0$.

It was proven in Mukherjee and Zhou (2006) that $\lim_{n\to\infty} \|\vec{f}_D - \vec{f}_\lambda\|_K = 0$. A result of this is for $\hat{\Xi} = c_D K c_D^T$

$$v^T \hat{\Xi} v = \|v \cdot \vec{f}_D\|_K^2 \overset{n\to\infty}{\longrightarrow} \|v \cdot \vec{f}_\lambda\|_K^2 = 0.$$

This implies that $\lim_{n\to\infty} v^T \hat{\Gamma} v = 0$ and proves the proposition. ■

Proposition 11 states that all the vectors perpendicular to the DR space correspond to eigenvalues near zero of $\hat{\Gamma}$ and will be filtered out. This means the DR directions can be still found by the spectral decomposition of the estimated gradient outer product matrix.

4.2 Nonlinear Projections: Gradient Based Diffusion Maps (GDM)

As discussed in Section 2 the gradient of the regression function can be used for nonlinear projections. The basic idea was to use local gradient information to construct a diffusion operator L based on a similarity metric W_{ij} between two points x_i and x_j. A commonly used diffusion operator is the graph Laplacian

$$L = I - D^{-1/2} W D^{-1/2}, \quad \text{where } D_{ii} = \sum_j W_{ij}.$$

Dimension reduction is achieved by projection onto a spectral decomposition of the operator L or powers $(I-L)^t$ of the operator $(I-L)$ which corresponds to running the diffusion $(I-L)$ for some time t. The gradient based diffusion map (GDM) was defined as

$$W_{ij} = W_f(x_i, x_j) = \exp\left(-\frac{\|x_i - x_j\|^2}{\sigma_1} - \frac{|\frac{1}{2}(\nabla f_r(x_i) + \nabla f_r(x_j)) \cdot (x_i - x_j)|^2}{\sigma_2} \right). \tag{8}$$

In the above equation the first term $\|x_i - x_j\|^2$ encodes the local geometry of the marginal distribution and the second term pastes together gradient estimates between neighboring points. The first term is used in unsupervised dimension reduction methods such as Laplacian eigenmaps or diffusion maps (Belkin and Niyogi, 2003). The second term can be interpreted as a first order Taylor expansion leading to the following approximation

$$\frac{1}{2}(\nabla f_r(x_i) + \nabla f_r(x_j)) \cdot (x_i - x_j) \approx f_r(x_i) - f_r(x_j).$$

The form (8) is closely related to the following function adapted similarity proposed in Szlam et al. (2008)

$$W_f(x_i, x_j) = \exp\left(-\frac{\|x_i - x_j\|^2}{\sigma_1} - \frac{|f(x_i) - f(x_j)|^2}{\sigma_2} \right),$$

where the function evaluations $f(x_i)$ are computed based on a first rough estimate of the regression function from the data.

The utility of nonlinear dimension reduction has been shown to be dramatic with respect to prediction accuracy in the semi-supervised learning setting where a large set of unlabeled data, $\{x_1, ..., x_u\}$, drawn from the marginal distribution, were used to learn the projection and a small set of labeled data $\{(y_1, x_1), ..., (y_\ell, x_\ell)\}$ were used to learn the regression function on the projected data. Of practical importance in this setting is the need to evaluate the similarity function on out of sample data. The labeled data is used to compute the gradient estimate, which can be evaluated on out-of-sample data. Given the gradient estimate and the labeled and unlabeled data $(x_1, ..., x_\ell, x_{\ell+1}, x_{\ell+u})$ the following GDM can be defined on all the samples

$$\tilde{W}_{ij} = \exp\left(-\frac{\|x_i - x_j\|^2}{\sigma_1} - \frac{|\frac{1}{2}(\vec{f}_D(x_i) + \vec{f}_D(x_j)) \cdot (x_i - x_j)|^2}{\sigma_2} \right), \quad i, j = 1, .., u + \ell.$$

An analysis of the accuracy of the GDM approach is based on how well $f(x_i) - f(x_j)$ can be estimated using the gradient estimate $\vec{f}_D$. The first order Taylor expansion on the manifold results in the following approximation

$$f(x_i) - f(x_j) \approx \nabla_{\mathcal{M}} f(x_i) \cdot v_{ij}, \text{ for } v_{ij} \approx 0,$$

where $v_{ij} \in T_{x_i}\mathcal{M}$ is the tangent vector such that $x_j = \mathrm{Exp}_{x_i}(v_{ij})$ where Exp_{x_i} is the exponential map at x_i (see do Carmo, 1992; Mukherjee et al., 2010). Since we cannot compute $\nabla_{\mathcal{M}} f$ we use $\vec{f}_D$. The following proposition states that estimates of the function value differences can be accurately estimated from gradient estimate $\vec{f}_D$.

Proposition 12 *The following holds*

$$f_r(x_i) - f_r(x_j) \approx \vec{f}_D(x_i) \cdot (x_i - x_j), \textit{ for } x_i \approx x_j.$$

Proof By the fact $x_i - x_j \approx \mathrm{d}\varphi(v_{ij})$ we have

$$\vec{f}_D(x_i) \cdot (x_i - x_j) \approx \langle \vec{f}_D(x_i), \mathrm{d}\varphi(v_{ij}) \rangle = \langle (\mathrm{d}\varphi)^*(\vec{f}_D(x_i)), v_{ij} \rangle \approx \langle \nabla_{\mathcal{M}} f_r(x_i), v_{ij} \rangle$$

which implies the conclusion. ■

This proposition does not prove consistency of the GDM approach. This research program of proving convergence of the eigenvectors of a graph Laplacian to the eigenfunctions of a corresponding Laplace-Beltrami operator is a source of extensive research in diffusion maps (Belkin and Niyogi, 2005; Giné and Koltchinskii, 2006). It would be of interest to adapt these approaches to the gradient setting. The limiting operator will in general depend on how σ_1 and σ_2 approach 0 as the number of points tends to infinity. For example, it is easy to see that if $\sigma_1, \sigma_2 \to 0_+$ suitably as $n \to +\infty$, with $\sigma_1/\sigma_2 = \alpha$, then the limiting operator is the Laplacian on the manifold $(x, \alpha f(x)) \subset \mathcal{M} \times \mathbb{R}$.

4.2.1 EMPIRICAL RESULTS FOR GRADIENT BASED DIFFUSION MAPS

In this section we motivate the efficacy of the GDM approach with an empirical study of predictive accuracy in the semi-supervised setting on six benchmark data sets found in Chapelle et al. (2006). In the semi-supervised setting using the labeled as well as the unlabeled data for dimension reduction followed by fitting a regression model has often increased predictive accuracy. We used the benchmark data so we could compare the performance of DM and GDM to eleven algorithms (Chapelle et al., 2006, Table 21.11). The conclusion of our study is that GDM improves predictive accuracy over DM and that GDM is competitive with respect to the other algorithms.

For each data set twelve splits were generated with 100 samples labeled in each split. We applied DM and GDM to each of these sets to find DR directions. We projected the data (labeled and unlabeled) onto the DR directions and used a k-Nearest-Neighbor (kNN) classifier to classify the unlabeled data. The parameters of the DM, GDM, and number of neighbors were set using a validation set in each trial. The average classification error rate for the unlabeled data over the twelve splits are reported in Table 1. We also report in Table 1 the top performing algorithm for the data sets in Chapelle et al. (2006, Table 21.11). Laplacian RLS stands for Laplacian regularized least-squares, SGT stands for spectral graph transducer, Cluster-Kernel is an algorithm that uses two kernel functions, see (Chapelle et al., 2006, Chapter 11) for details.

A reasonable conclusion from Table 1 is that having label information improves the performance of diffusion operator with respect to prediction. In addition, dimension reduction using GDM followed by a simple classifier is competitive to other approaches. We suspect that integrating GDM with a penalized classification algorithm in the same spirit as Laplacian regularized least-squares can improve performance.

5. Graphical Models and Conditional Independence

One example of a statistical analysis where global inferences are desired or explanations with respect to the coordinates of the data is important is a graphical model over undirected graphs. In this setting it is of interest to understand how coordinates covary with respect to variation in response, as is provided by the GOP. Often of greater interest is to infer direct or conditional dependencies between two coordinates as a function of variation in the response. In this section we explore how this can be done using the GOP.

A natural idea in multivariate analysis is to model the conditional independence of a multivariate distribution using a graphical model over undirected graphs. The theory of Gauss-Markov graphs

Data	DM	GDM	Best
G241C	19.96%	18.61%	13.49% (Cluster-Kernel)
G241D	14.27%	13.64%	4.95% (Cluster-Kernel)
Digit1	1.8%	1.8%	1.8% (DM, GDM)
BCI	48.53%	31.36%	31.36% (GDM, Laplacian RLS)
USPS	12.85%	10.76%	4.68% (Laplacian RLS)
Text	24.71%	23.57%	23.09% (SGT)

Table 1: Error rates for DM and GDM over six data sets reported in Chapelle et al. (2006, Table 21.11). The column 'Best' reports the error rate for the algorithm with the smallest error of the 13 applied to the data.

(Speed and Kiiveri, 1986; Lauritzen, 1996) was developed for multivariate Gaussian densities

$$p(x) \propto \exp\left(-\frac{1}{2}x^T Jx + h^T x\right),$$

where the covariance is J^{-1} and the mean is $\mu = J^{-1}h$. The result of the theory is that the precision matrix J, given by $J = \Sigma_X^{-1}$, provides a measurement of conditional independence. The meaning of this dependence is highlighted by the partial correlation matrix R_X where each element R_{ij} is a measure of dependence between variables i and j conditioned on all other variables $S^{/ij}$ and $i \neq j$

$$R_{ij} = \frac{\text{cov}(X_i, X_j \mid S^{/ij})}{\sqrt{\text{var}(X_i \mid S^{/ij})}\sqrt{\text{var}(X_j \mid S^{/ij})}}.$$

The partial correlation matrix is typically computed from the precision matrix J

$$R_{ij} = -J_{ij}/\sqrt{J_{ii}J_{jj}}.$$

In the regression and classification framework inference of the conditional dependence between explanatory variables has limited information. Much more useful would be the conditional dependence of the explanatory variables conditioned on variation in the response variable. In Section 2 we stated that both the covariance of the inverse regression as well as the gradient outer product matrix provide estimates of the covariance of the explanatory variables conditioned on variation in the response variable. Given this observation, the inverses of these matrices

$$J_{X|Y} = \Omega_{X|Y}^{-1} \quad \text{and} \quad J_\Gamma = \Gamma^{-1},$$

provide evidence for the conditional dependence between explanatory variables conditioned on the response. We focus on the inverse of the gradient outer product matrix in this paper since it is of use for both linear and nonlinear functions.

The two main approaches to inferring graphical models in high-dimensional regression have been based on either sparse factor models (Carvalho et al., 2008) or sparse graphical models representing sparse partial correlations (Meinshausen and Buhlmann, 2006). Our approach differs from both of these approaches in that the response variable is always explicit. For sparse factor models

the factors can be estimated independent of the response variable and in the sparse graphical model the response variable is considered as just another node, the same as the explanatory variables. Our approach and the sparse factor models approach both share an assumption of sparsity in the number of factors or directions. Sparse graphical model approaches assume sparsity of the partial correlation matrix.

Our proof of the convergence of the estimated conditional dependence matrix $(\hat{\Gamma})^{-1}$ to the population conditional dependence matrix Γ^{-1} relies on the assumption that the gradient outer product matrix being low rank. This again highlights the difference between our modeling assumption of low rank versus sparsity of the conditional dependence matrix. Since we assume that both Γ and $\hat{\Gamma}$ are singular and low rank we use pseudo-inverses in order to construct the dependence graph.

Proposition 13 *Let Γ^{-1} be the pseudo-inverse of Γ. Let the eigenvalues and eigenvectors of $\hat{\Gamma}$ be $\hat{\lambda}_i$ and $\hat{v}_i$ respectively. If $\varepsilon > 0$ is chosen so that $\varepsilon = \varepsilon_n = o(1)$ and $\varepsilon_n^{-1}\|\hat{\Gamma} - \Gamma\| = o(1)$, then the convergence*

$$\sum_{\hat{\lambda}_i > \varepsilon} \hat{v}_i \hat{\lambda}_i^{-1} \hat{v}_i \stackrel{n\to\infty}{\longrightarrow} \Gamma^{-1}$$

holds in probability.

Proof We have shown in Proposition 9 that $\|\hat{\Gamma} - \Gamma\| = o(1)$. Denote the eigenvalues and eigenvectors of Γ as λ_i and v_i respectively. Then

$$|\hat{\lambda}_i - \lambda_i| = O(\|\hat{\Gamma} - \Gamma\|) \qquad \text{and} \qquad \|\hat{v}_i - v_i\| = O(\|\hat{\Gamma} - \Gamma\|).$$

By the condition $\varepsilon_n^{-1}\|\hat{\Gamma} - \Gamma\| = o(1)$ the following holds

$$\hat{\lambda}_i > \varepsilon \Longrightarrow \lambda_i > \varepsilon/2 \Longrightarrow \lambda_i > 0$$

implying $\{i : \hat{\lambda}_i > \varepsilon\} \subset \{i : \lambda_i > 0\}$ in probability. On the other hand, denoting $\tau = \min\{\lambda_i : \lambda_i > 0\}$, the condition $\varepsilon_n = o(1)$ implies

$$\{i : \lambda_i > 0\} = \{i : \lambda \geq \tau\} \subset \{i : \hat{\lambda}_i \geq \tau/2\} \subset \{i : \hat{\lambda}_i > \varepsilon\}$$

in probability. Hence we obtain

$$\{i : \lambda_i > 0\} = \{i : \hat{\lambda}_i > \varepsilon\}$$

in probability.

For each $j \in \{i : \lambda_i > 0\}$ we have $\lambda_j, \hat{\lambda}_j \geq \tau/2$ in probability, so

$$|\hat{\lambda}_j^{-1} - \lambda_j^{-1}| \leq |\hat{\lambda}_j - \lambda_j|/(2\tau) \stackrel{n\to\infty}{\longrightarrow} 0.$$

Thus we finally obtain

$$\sum_{\hat{\lambda}_i > \varepsilon} \hat{v}_i \hat{\lambda}_i^{-1} \hat{v}_i \stackrel{n\to\infty}{\longrightarrow} \sum_{\lambda_i > 0} v_i \lambda_i^{-1} v_i^T = \Gamma^{-1}.$$

This proves the conclusion. ■

5.1 Results on Simulated and Real Data

We first provide an intuition of the ideas behind our inference of graphical models using simple simulated data. We then apply the method to study dependencies in gene expression in the development of prostate cancer.

5.1.1 SIMULATED DATA

The following simple example clarifies the information contained in the covariance matrix as well as the gradient outer product matrix. Construct the following dependent explanatory variables from standard random normal variables $\theta_1, ..., \theta_5 \overset{iid}{\sim} \mathcal{N}(0,1)$

$$X_1 = \theta_1, X_2 = \theta_1 + \theta_2, X_3 = \theta_3 + \theta_4, X_4 = \theta_4, X_5 = \theta_5 - \theta_4,$$

and the following response

$$Y = X_1 + (X_3 + X_5)/2 + \varepsilon_1,$$

where $\varepsilon_1 \sim \mathcal{N}(0, .5^2)$.

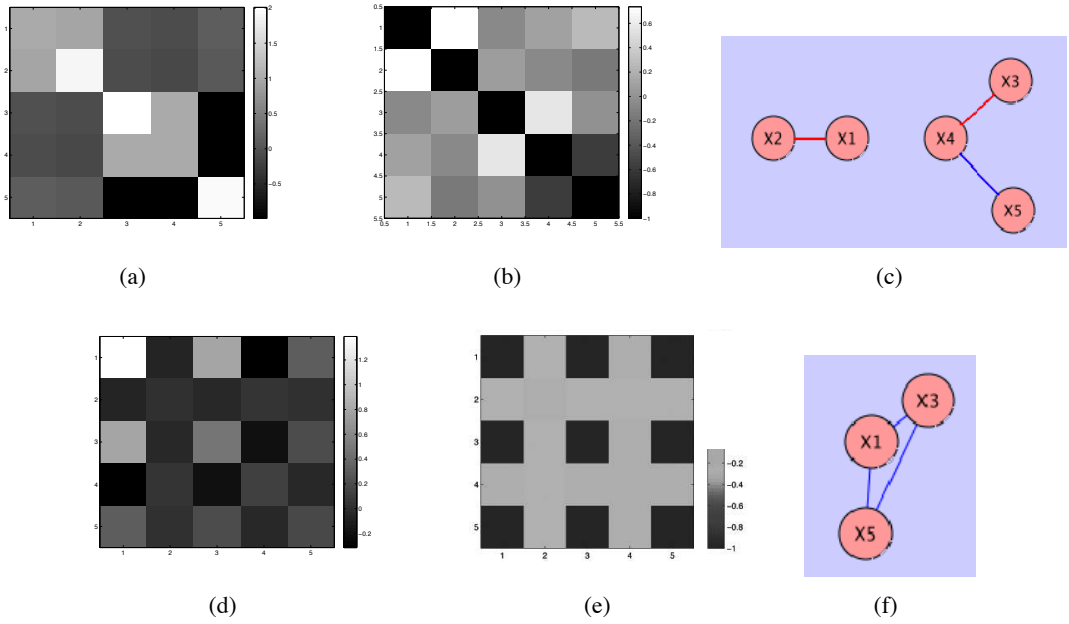
We drew 100 observations $(x_{i1}, x_{i2}, x_{i3}, x_{i4}, x_{i5}, y_i)_{i=1}^{100}$ from the above sampling design. From this data we estimate the covariance matrix of the marginals $\hat{\Sigma}_X$ and the gradient outer product matrix $\hat{\Gamma}$. From $\hat{\Sigma}_X$, Figure 2(a), we see that X_1 and X_2 covary with each other and X_3, X_4, X_5 covary. The conditional independence matrix $\hat{R}_X$, Figure 2(b), provides information on more direct relations between the coordinates as we see that X_5 is independent of X_3 given X_4, $X_5 \perp\!\!\!\perp X_3 \mid X_4$. The dependence relations are summarized in the graphical model in Figure 2(c). Taking the response variable into account, we find in the gradient outer product matrix, Figure 2(d), the variables X_2 and X_4 are irrelevant while X_1, X_3, X_5 are relevant. The matrix $\hat{R}_{\hat{\Gamma}}$ is shown in Figure 2(e) and implies that any pair of X_1, X_3, X_5 are negatively dependent conditioned on the other and the response variable Y. The graphical model is given in Figure 2(f).

5.1.2 GENES DRIVING PROGRESSION OF PROSTATE CANCER

A fundamental problem in cancer biology is to understand the molecular and genetic basis of the progression of a tumor from less serious states to more serious states. An example is the progression from a benign growth to malignant cancer. The key interest in this problem is to understand the genetic basis of cancer. A classic model for the genetic basis of cancer was proposed by Fearon and Vogelstein (1990) describing a series of genetic events that cause progression of colorectal cancer.

In Edelman et al. (2008) the inverse of the gradient outer product was used to infer the dependence between genes that drive tumor progression in prostate cancer and melanoma. In the case of melanoma the data consisted of genomewide expression data from normal, primary, and metastatic skin samples. Part of the analysis in this paper was inference of conditional dependence graphs or networks of genes that drive differential expression between stages of progression. The gradient outer product matrix was used to infer detailed models of gene networks that may drive tumor progression.

In this paper, we model gene networks relevant in driving progression in prostate cancer as an illustration of how the methodology can be used to posit biological hypotheses. The objective is to understand the dependence structure between genes that are predictive of progression from benign to malignant prostate cancer. in progressing from benign to malignant prostate cancer. The data consists of 22 benign and 32 advanced prostate tumor samples (Tomlins et al., 2007; Edelman et al.,



(a) (b) (c)

(d) (e) (f)

Figure 2: (a) Covariance matrix $\hat{\Sigma}_X$; (b) Partial correlation matrix $\hat{R}_X$; (c) Graphical model representation of partial correlation matrix; (d) Gradient outer product matrix $\hat{\Gamma}$; (e) Partial correlations $\hat{R}_{\hat{\Gamma}}$ with respect to $\hat{\Gamma}$; (f) Graphical model representation of $\hat{R}_{\hat{\Gamma}}$.

2008). For each sample the expression level of over 12,000 probes corresponding to genes were measured. We eliminated many of those probes with low variation across all samples resulting in a 4095 probes or variables. From this reduced data set we estimated the gradient outer product matrix, $\hat{\Gamma}$, and used the pseudo-inverse to compute the conditional independence matrix, $\hat{J} = (\hat{\Gamma})^{-1}$. From the conditional independence matrix we computed the partial correlation matrix $\hat{R}$ where $\hat{R}_{ij} = -\frac{\hat{J}_{ij}}{\sqrt{\hat{J}_{ii}\hat{J}_{jj}}}$ for $i \neq j$ and 0 otherwise. We again reduced the R matrix to obtain 139 nodes and 400 edges corresponding to the largest partial correlations and construct the graph seen in Figure 3.

The structure of the partial correlation graph recapitulates some known biological processes in the progression of prostate cancer. The most highly connected gene is MME (labeled green) which is known to have significant deregulation in prostate cancer and is associated with aggressive tumors (Tomlins et al., 2007). We also observe two distinct clusters annotated in yellow and purple in the graph that we call C_1 and C_2 respectively. These clusters derive their associations principally through 5 genes, annotated in light blue and dark blue in the graph. The light blue genes AMACR, ANXA1, and CD38 seem to have strong dependence with respect to the genes in C_1 wile C_2 is dependent on these genes in addition to the dark blue genes LMAN1L and SLC14A1. AMACR and ANXA1 as well as CD38 are well-known to have roles in prostate cancer progression (Jiang et al., 2004; Hsiang et al., 2004; Kramer et al., 1995). The other two genes LMAN1L and SLC14A1 are known to have tumorigenic properties and would be candidates for further experiments to better understand their role in prostate cancer.

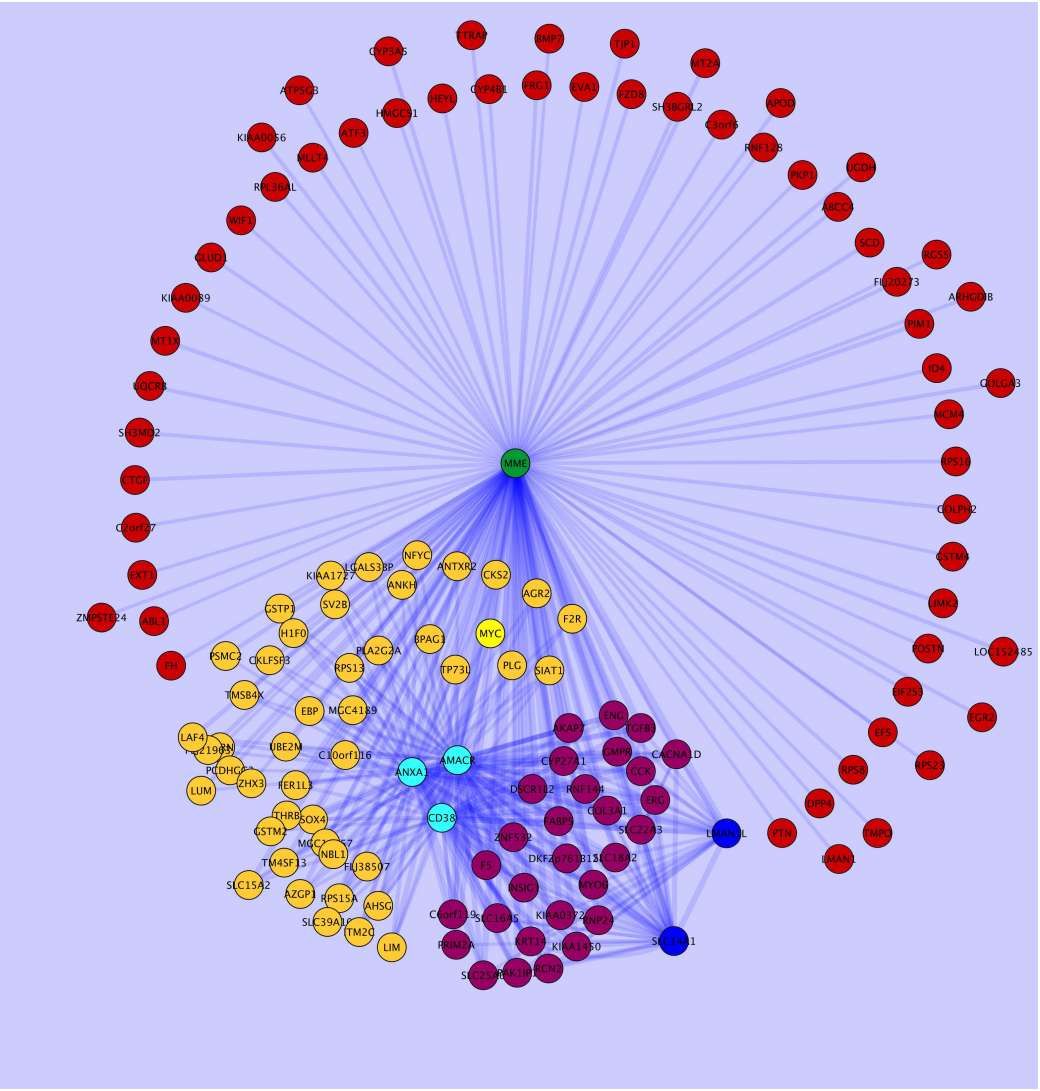


Figure 3: Graphical model of genes relevant in tumors progressing from benign to malignant prostate tissue. The edges correspond to partial correlations.

6. Discussion

The main contribution of this paper is to describe how inference of the gradient of the regression or classification function encodes information about the predictive geometry as well as the predictive conditional dependence in the data. Two methods are introduced gradient based diffusion maps and inference of conditional independence structure given gradient estimates. Precise statistical relations between different approaches to supervised dimension reduction are described. Simulated and real data are used to illustrate the utility of the methods developed. We prove convergence of the estimated graphical model to the population dependence graph. We find this direct link be-

tween graphical models and dimension reduction intriguing and suggest that the manifold learning perspective holds potential in the analysis and inference of graphical models.

Abstract

Fisher linear discriminant analysis (FDA) and its kernel extension—kernel discriminant analysis (KDA)—are well known methods that consider dimensionality reduction and classification jointly. While widely deployed in practical problems, there are still unresolved issues surrounding their efficient implementation and their relationship with least mean squares procedures. In this paper we address these issues within the framework of regularized estimation. Our approach leads to a flexible and efficient implementation of FDA as well as KDA. We also uncover a general relationship between regularized discriminant analysis and ridge regression. This relationship yields variations on conventional FDA based on the pseudoinverse and a direct equivalence to an ordinary least squares estimator.

Keywords: Fisher discriminant analysis, reproducing kernel, generalized eigenproblems, ridge regression, singular value decomposition, eigenvalue decomposition

1. Introduction

In this paper we are concerned with Fisher linear discriminant analysis (FDA), an enduring classification method in multivariate analysis and machine learning. It is well known that the FDA formulation reduces to the solution of a generalized eigenproblem (Golub and Van Loan, 1996) that involves the between-class scatter matrix and total scatter matrix of the data vectors. To solve the generalized eigenproblem, FDA typically requires the pooled scatter matrix to be nonsingular. This can become problematic when the dimensionality is high, because the scatter matrix is likely to be singular. In applications such as information retrieval, face recognition and microarray analysis, for example, we often meet undersampled problems which are in a "small n but large p" regime; that is, there are a small number of samples but a very large number of variables. There are two main variants of FDA in the literature that aim to deal with this issue: the *pseudoinverse* method and the *regularization* method (Hastie et al., 2001; Webb, 2002).

Another important family of methods for dealing with singularity is based on a two-stage process in which two symmetric eigenproblems are solved successively. This approach was pioneered by Kittler and Young (1973). Recently, Howland et al. (2003) used this approach to introduce the

generalized singular value decomposition (GSVD) (Paige and Saunders, 1981) into the FDA solution by using special representations of the pooled scatter matrix and between-class scatter matrix. A similar general approach has been used in the development of efficient approximation algorithms for FDA (Cheng et al., 1992; Ye et al., 2004). However, the challenge of developing an efficient general implementation methodology for FDA still remains.

In the binary classification problem, FDA is equivalent to a least mean squared error procedure (Duda et al., 2001). It is of great interest to obtain a similar relationship in multi-class problems. A significant literature has emerged to address this issue (Hastie et al., 2001; Park and Park, 2005b; Ye, 2007). However, the results obtained by these authors are subject to restrictive conditions. The problem of finding a general theoretical link between FDA and least mean squares is still open.

In this paper we address the issues within a regularization framework. We propose a novel algorithm for solving the regularized FDA (RFDA) problem. Our algorithm is more efficient than the GSVD-based algorithm (Howland et al., 2003), especially in the setting of "small n but large p" problems. More importantly, our algorithm leads us to an equivalence between RFDA and a ridge estimator for multivariate linear regression (Hoerl and Kennard, 1970). This equivalence is derived in a general setting and it is fully consistent with the established result in the binary problem (Duda et al., 2001).

Our algorithm is also appropriate for the pseudoinverse variant of FDA. Indeed, we establish an equivalence between the pseudoinverse variant and an ordinary least squares (OLS) estimation problem. Thus, we are able to resolve the open problem concerning the relationship between the multi-class FDA and multivariate linear estimation problems.

FDA relies on the assumption of linearity of the data manifold. In recent years, kernel methods (Shawe-Taylor and Cristianini, 2004) have aimed at removing such linearity assumptions. The kernel technology can circumvent the linearity assumption of FDA, because it works by nonlinearly mapping vectors in the input space to a higher-dimensional feature space and then implementing traditional versions of FDA in the feature space. Many different approaches have been proposed to extend FDA to kernel spaces in the existing literature (Baudat and Anouar, 2000; Mika et al., 2000; Roth and Steinhage, 2000).

The KDA method in Mika et al. (2000) was developed for binary problems only, and it was based on using the relationship between KDA and the least mean squared error procedure. A more general method, known as generalized discriminant analysis (GDA) (Baudat and Anouar, 2000), requires that the kernel matrix be nonsingular. Unfortunately, centering in the feature space will violate this requirement. Park and Park (2005a) argued that this might break down the theoretical justification for GDA and proposed their GSVD method to avoid this requirement for nonsingularity.

KDA methods have been successfully deployed in many practical problems. The approach to FDA that we present in the current paper not only handles the nonsingularity issue but also extends naturally to KDA, both in its regularization and pseudoinverse forms. We will see that our regularized KDA is different from the existing regularization methods for KDA (see, e.g., Park and Park, 2005a), where as we discuss later, there is a problem with inconsistency of solutions. Our methods for regularized KDA derive directly from the corresponding methods for regularized FDA and avoid the inconsistency problem.

Finally, we extend our approach for FDA as well as KDA to a certain family of generalized eigenvalue problems.

The paper is organized as follows. Section 2 reviews FDA and KDA, and Section 3 presents our KDA formulations. In Sections 4 and 5 we propose two new algorithms for FDA and KDA, respectively. An equivalence between FDA and multivariate linear regression problems is presented in Section 6. We conduct empirical comparisons in Section 7. We extend the approach to a certain family of generalized eigenproblems in Section 8 and conclude in Section 9.

2. Problem Formulation

We are concerned with a multi-class classification problem. Given a set of n p-dimensional data points, $\{\mathbf{x}_1,\ldots,\mathbf{x}_n\} \in \mathcal{X} \subset \mathbb{R}^p$, we assume that the $\mathbf{x}_i$ are to be grouped into c disjoint classes and that each $\mathbf{x}_i$ belongs to one and only one class. Let $V = \{1,2,\ldots,n\}$ denote the index set of the data points $\mathbf{x}_i$ and partition V into c disjoint subsets V_j; that is, $V_i \cap V_j = \varnothing$ for $i \neq j$ and $\cup_{j=1}^{c} V_j = V$, where the cardinality of V_j is n_j so that $\sum_{j=1}^{c} n_j = n$. We also make use of a matrix representation for the partitions. In particular, we let $\mathbf{E} = [e_{ij}]$ be an $n \times c$ indicator matrix with $e_{ij} = 1$ if input $\mathbf{x}_i$ is in class j and $e_{ij} = 0$ otherwise.

In this section we review FDA and KDA solutions to this multi-class classification problem. We begin by presenting our notation.

2.1 Preliminaries

Throughout this paper, $\mathbf{I}_m$ denotes the $m \times m$ identity matrix, $\mathbf{1}_m$ the $m \times 1$ vector of ones, $\mathbf{0}$ the zero vector or matrix with appropriate size, and $\mathbf{H} = \mathbf{I}_n - \frac{1}{n}\mathbf{1}_n\mathbf{1}_n'$ the $n \times n$ centering matrix. For an $m \times 1$ vector $\mathbf{a} = (a_1,\ldots,a_m)'$, $\mathrm{diag}(\mathbf{a})$ represents the $m \times m$ diagonal matrix with $a_1,\ldots,a_m$ as its diagonal entries. For an $m \times m$ matrix $\mathbf{A} = [a_{ij}]$, we let $\mathbf{A}^+$ be the Moore-Penrose inverse of $\mathbf{A}$, $\mathrm{tr}(\mathbf{A})$ be the trace of $\mathbf{A}$, $\mathrm{rk}(\mathbf{A})$ be the rank of $\mathbf{A}$ and $\|\mathbf{A}\|_F = \sqrt{\mathrm{tr}(\mathbf{A}'\mathbf{A})}$ be the Frobenius norm of $\mathbf{A}$. For an $m \times q$ real matrix $\mathbf{A}$, $\mathcal{R}(\mathbf{A})$ and $\mathcal{N}(\mathbf{A})$ denote its range and null spaces; that is, $\mathcal{R}(\mathbf{A}) = \{\mathbf{A}\mathbf{x} | \mathbf{x} \in \mathbb{R}^q\}$ and $\mathcal{N}(\mathbf{A}) = \{\mathbf{x} \in \mathbb{R}^q | \mathbf{A}\mathbf{x} = \mathbf{0}\}$.

For a matrix $\mathbf{A} \in \mathbb{R}^{m \times q}$ with $m \geq q$, we always express the (reduced) singular value decomposition (SVD) of $\mathbf{A}$ as $\mathbf{A} = \mathbf{U}\Gamma\mathbf{V}'$ where $\mathbf{U} \in \mathbb{R}^{m \times q}$ is a matrix with orthonormal columns (that is, $\mathbf{U}'\mathbf{U} = \mathbf{I}_q$), $\mathbf{V} \in \mathbb{R}^{q \times q}$ is orthogonal (i.e., $\mathbf{V}'\mathbf{V} = \mathbf{V}\mathbf{V}' = \mathbf{I}_q$), and $\Gamma = \mathrm{diag}(\gamma_1,\ldots,\gamma_q)$ is arrayed in descending order of $\gamma_1 \geq \gamma_2 \geq \cdots \geq \gamma_q$ (≥ 0). Let the rank of $\mathbf{A}$ be r ($\leq \min\{m,q\}$) and denote $\mathrm{rk}(\mathbf{A}) = r$. The condensed SVD of $\mathbf{A}$ is then $\mathbf{A} = \mathbf{U}_A\Gamma_A\mathbf{V}_A'$ where $\mathbf{U}_A \in \mathbb{R}^{m \times r}$ and $\mathbf{V}_A \in \mathbb{R}^{q \times r}$ are matrices with orthonormal columns (i.e., $\mathbf{U}_A'\mathbf{U}_A = \mathbf{I}_r$ and $\mathbf{V}_A'\mathbf{V}_A = \mathbf{I}_r$), and $\Gamma_A = \mathrm{diag}(\gamma_1,\ldots,\gamma_r)$ satisfies $\gamma_1 \geq \gamma_2 \geq \cdots \geq \gamma_r > 0$.

Given two matrices Σ_1 and $\Sigma_2 \in \mathbb{R}^{m \times m}$, we refer to $(\Lambda, \mathbf{B})$ where $\Lambda = \mathrm{diag}(\lambda_1,\ldots,\lambda_q)$ and $\mathbf{B} = [\mathbf{b}_1,\ldots,\mathbf{b}_q]$ as q eigenpairs of the matrix pencil (Σ_1,Σ_2) if $\Sigma_1\mathbf{B} = \Sigma_2\mathbf{B}\Lambda$; namely,

$$\Sigma_1\mathbf{b}_i = \lambda_i\Sigma_2\mathbf{b}_i, \quad \text{for } i = 1,\ldots,q.$$

The problem of finding eigenpairs of (Σ_1,Σ_2) is known as a *generalized eigenproblem*. In this paper, we especially consider the problem with the nonzero λ_i for $i = 1,\ldots,q$ and refer to $(\Lambda,\mathbf{B})$ as the nonzero eigenpairs of (Σ_1,Σ_2). If Σ_2 is nonsingular, $(\Lambda,\mathbf{B})$ is also referred to as the (nonzero) eigenpairs of $\Sigma_2^{-1}\Sigma_1$ because the generalized eigenproblem is equivalent to the eigenproblem:

$$\Sigma_2^{-1}\Sigma_1\mathbf{B} = \mathbf{B}\Lambda.$$

In the case that Σ_2 is singular, one typically resorts to a pseudoinverse eigenproblem:

$$\Sigma_2^{+}\Sigma_1\mathbf{B} = \mathbf{B}\Lambda.$$

Fortunately, we are able to establish a connection between the solutions of the generalized eigenproblem and its corresponding pseudoinverse eigenproblem. In particular, we have the following theorem, the proof of which is given in Appendix A.

Theorem 1 *Let Σ_1 and Σ_2 be two $m\times m$ real matrices. Assume $\mathcal{R}(\Sigma_1) \subseteq \mathcal{R}(\Sigma_2)$. Then, if $(\Lambda, \mathbf{B})$ are the nonzero eigenpairs of $\Sigma_2^+\Sigma_1$, we have that $(\Lambda, \mathbf{B})$ are the nonzero eigenpairs of the matrix pencil (Σ_1, Σ_2). Conversely, if $(\Lambda, \mathbf{B})$ are the nonzero eigenpairs of the matrix pencil (Σ_1, Σ_2), then $(\Lambda, \Sigma_2^+\Sigma_2\mathbf{B})$ are the nonzero eigenpairs of $\Sigma_2^+\Sigma_1$.*

As we see from Appendix A, a necessary and sufficient condition for $\mathcal{R}(\Sigma_1) \subseteq \mathcal{R}(\Sigma_2)$ is

$$\Sigma_2\Sigma_2^+\Sigma_1 = \Sigma_1.$$

Since $\mathbb{R}^m$ is equal to the direct sum of $\mathcal{R}(\Sigma_1)$ (or $\mathcal{R}(\Sigma_2)$) and $\mathcal{N}(\Sigma_1')$ (or $\mathcal{N}(\Sigma_2')$), we obtain that $\mathcal{R}(\Sigma_1) \subseteq \mathcal{R}(\Sigma_2)$ if and only if $\mathcal{N}(\Sigma_2') \subseteq \mathcal{N}(\Sigma_1')$. Furthermore, if both Σ_1 and Σ_2 are symmetric, then $\mathcal{N}(\Sigma_2) \subseteq \mathcal{N}(\Sigma_1)$ is equivalent to $\mathcal{R}(\Sigma_1) \subseteq \mathcal{R}(\Sigma_2)$.

2.2 Fisher Linear Discriminant Analysis

Let $\mathbf{m} = \frac{1}{n}\sum_{i=1}^n \mathbf{x}_i$ be the sample mean, and let $\mathbf{m}_j = \frac{1}{n_j}\sum_{i\in V_j} \mathbf{x}_i$ be the jth class mean for $j = 1,\ldots,c$. We then have the pooled scatter matrix $\mathbf{S}_t = \sum_{i=1}^n (\mathbf{x}_i - \mathbf{m})(\mathbf{x}_i - \mathbf{m})'$ and the between-class scatter matrix $\mathbf{S}_b = \sum_{j=1}^c n_j(\mathbf{m}_j - \mathbf{m})(\mathbf{m}_j - \mathbf{m})'$. Conventional FDA solves the following generalized eigenproblem:

$$\mathbf{S}_b\mathbf{a}_j = \lambda_j\mathbf{S}_t\mathbf{a}_j, \quad \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_q > \lambda_{q+1} = 0 \tag{1}$$

where $q \leq \min\{p,\ c-1\}$ and where we refer to $\mathbf{a}_j$ as the jth discriminant direction. Note that we ignore a multiplier $1/n$ in these scatter matrices for simplicity.

Since $\mathbf{S}_t = \mathbf{S}_b + \mathbf{S}_w$ where $\mathbf{S}_w$ is the pooled within-class scatter matrix, FDA is equivalent to finding a solution to

$$\mathbf{S}_b\mathbf{a} = \lambda/(1-\lambda)\mathbf{S}_w\mathbf{a}.$$

We see that FDA involves solving the generalized eigenproblem in (1), which can be expressed in matrix form:

$$\mathbf{S}_b\mathbf{A} = \mathbf{S}_t\mathbf{A}\Lambda. \tag{2}$$

Here $\mathbf{A} = [\mathbf{a}_1,\ldots,\mathbf{a}_q]$ $(n\times q)$ and $\Lambda = \mathrm{diag}(\lambda_1,\ldots,\lambda_q)$ $(q\times q)$. If $\mathbf{S}_t$ is nonsingular, we obtain

$$\mathbf{S}_t^{-1}\mathbf{S}_b\mathbf{A} = \mathbf{A}\Lambda.$$

Thus, the $(\lambda_j, \mathbf{a}_j)$ are the eigenpairs of $\mathbf{S}_t^{-1}\mathbf{S}_b$ and the eigenvectors corresponding to the largest eigenvalues of $\mathbf{S}_t^{-1}\mathbf{S}_b$ are used for the discriminant directions. Since $\mathrm{rk}(\mathbf{S}_b)$ is at most $c-1$, the projection will be onto a space of dimension at most $c-1$ (i.e., $q \leq c-1$).

In applications such as information retrieval, face recognition and microarray analysis, however, we often meet a "small n but large p" problem. Thus, $\mathbf{S}_t$ is usually ill-conditioned; that is, it is either singular or close to singular. In this case, $\mathbf{S}_t^{-1}\mathbf{S}_b$ is not well defined or cannot be computed accurately.

Let $\mathbf{X} = [\mathbf{x}_1, \ldots, \mathbf{x}_n]'$ $(n \times p)$, $\mathbf{M} = [\mathbf{m}_1, \ldots, \mathbf{m}_c]'$ $(c \times p)$, $\Pi = \mathrm{diag}(n_1, \ldots, n_c)$ $(c \times c)$, $\Pi^{\frac{1}{2}} = \mathrm{diag}(\sqrt{n}_1, \ldots, \sqrt{n}_c)$, $\pi = (n_1, \ldots, n_c)'$, $\sqrt{\pi} = (\sqrt{n}_1, \ldots, \sqrt{n}_c)'$ and $\mathbf{H}_\pi = \mathbf{I}_c - \frac{1}{n}\sqrt{\pi}\sqrt{\pi}'$. It then follows that $\mathbf{1}_n'\mathbf{E} = \mathbf{1}_c'\Pi = \pi'$, $\mathbf{E}\mathbf{1}_c = \mathbf{1}_n$, $\mathbf{1}_c'\pi = n$, $\mathbf{E}'\mathbf{E} = \Pi$, $\Pi^{-1}\pi = \mathbf{1}_c$, and

$$\mathbf{M} = \Pi^{-1}\mathbf{E}'\mathbf{X}.$$

In addition, we have

$$\mathbf{E}\Pi^{-\frac{1}{2}}\mathbf{H}_\pi = \mathbf{H}\mathbf{E}\Pi^{-\frac{1}{2}}$$

given that $\mathbf{E}\Pi^{-\frac{1}{2}}\mathbf{H}_\pi = \mathbf{E}\Pi^{-\frac{1}{2}} - \frac{1}{n}\mathbf{1}_n\sqrt{\pi}'$ and $\mathbf{H}\mathbf{E}\Pi^{-\frac{1}{2}} = \mathbf{E}\Pi^{-\frac{1}{2}} - \frac{1}{n}\mathbf{1}_n\sqrt{\pi}'$.

Based on these results and the idempotency of $\mathbf{H}$, $\mathbf{S}_t$ can be written as

$$\mathbf{S}_t = \mathbf{X}'\mathbf{H}\mathbf{H}\mathbf{X} = \mathbf{X}'\mathbf{H}\mathbf{X}, \tag{3}$$

and we have

$$\begin{aligned}
\mathbf{S}_b &= \mathbf{M}'\left[\Pi - \frac{1}{n}\pi\pi'\right]\mathbf{M} \\
&= \mathbf{M}'\left[\Pi^{\frac{1}{2}} - \frac{1}{n}\pi\sqrt{\pi}'\right]\left[\Pi^{\frac{1}{2}} - \frac{1}{n}\sqrt{\pi}\pi'\right]\mathbf{M} \\
&= \mathbf{X}'\mathbf{E}\Pi^{-1}\Pi^{\frac{1}{2}}\mathbf{H}_\pi\mathbf{H}_\pi\Pi^{\frac{1}{2}}\Pi^{-1}\mathbf{E}'\mathbf{X} \\
&= \mathbf{X}'\mathbf{H}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{H}\mathbf{X}.
\end{aligned} \tag{4}$$

Given these representations of $\mathbf{S}_t$ and $\mathbf{S}_b$, the problem in (2) can be solved by using the GSVD method (Van Loan, 1976; Paige and Saunders, 1981; Golub and Van Loan, 1996; Howland et al., 2003).

There are also two variants of conventional FDA in the literature that aim to handle the ill-conditioned problem (Webb, 2002). The first variant, the *pseudoinverse method*, involves replacing $\mathbf{S}_t^{-1}$ by $\mathbf{S}_t^+$ and solving the following eigenproblem:

$$\mathbf{S}_t^+\mathbf{S}_b\mathbf{A} = \mathbf{A}\Lambda. \tag{5}$$

Note that $\mathbf{S}_t^+$ exists and is unique (Golub and Van Loan, 1996). Moreover, $\mathbf{S}_t^+$ is equal to $\mathbf{S}_t^{-1}$ whenever $\mathbf{S}_t$ is nonsingular. Thus, we will use (5) when $\mathbf{S}_t$ is either nonsingular or singular.

The second variant is referred to as *regularized discriminant analysis* (RDA) (Friedman, 1989). It replaces $\mathbf{S}_t$ by $\mathbf{S}_t + \sigma^2\mathbf{I}_p$ and solves the following eigenproblem:

$$(\mathbf{S}_t + \sigma^2\mathbf{I}_p)^{-1}\mathbf{S}_b\mathbf{A} = \mathbf{A}\Lambda. \tag{6}$$

It is a well known result that FDA is equivalent to a least mean squared error procedure in the binary classification problem ($c = 2$) (Duda et al., 2001). Recently, similar relationships have been studied for multi-class ($c > 2$) problems (Hastie et al., 2001; Park and Park, 2005b; Ye, 2007). Moreover, Park and Park (2005b) proposed an efficient algorithm for FDA based on a least mean squared error procedure in the multi-class problem.

We can see that the solution $\mathbf{A}$ for (5) or (6) is not unique. For example, if $\mathbf{A}$ is the solution, then so is $\mathbf{A}\mathbf{D}$ where $\mathbf{D}$ is an arbitrary $q \times q$ nonsingular diagonal matrix. Thus, the constraint $\mathbf{A}'(\mathbf{S}_t + \sigma^2\mathbf{I}_p)\mathbf{A} = \mathbf{I}_q$ is typically imposed in the literature. In this paper we concentrate on the solution of (6) with or without this constraint, and investigate the connection with a ridge regression problem in the multi-class setting.

2.3 Kernel Discriminant Analysis

Kernel methods (Shawe-Taylor and Cristianini, 2004) work in a feature space $\mathcal{F}$, which is related to the original input space $\mathcal{X} \subset \mathbb{R}^p$ by a mapping,

$$\varphi : \mathcal{X} \to \mathcal{F}.$$

That is, φ is a vector-valued function which gives a vector $\varphi(\mathbf{s})$, called a *feature vector*, corresponding to an input $\mathbf{s} \in \mathcal{X}$. In kernel methods, we are given a reproducing kernel $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ such that $K(\mathbf{s},\mathbf{t}) = \varphi(\mathbf{s})'\varphi(\mathbf{t})$ for $\mathbf{s},\mathbf{t} \in \mathcal{X}$. The mapping $\varphi(\cdot)$ itself is typically not given explicitly.

In the sequel, we use the tilde notation to denote vectors and matrices in the feature space. For example, the data vectors and mean vectors in the feature space are denoted as $\tilde{\mathbf{x}}_i$ and $\tilde{\mathbf{m}}_j$. Accordingly, $\tilde{\mathbf{X}} = [\tilde{\mathbf{x}}_1,\ldots,\tilde{\mathbf{x}}_n]'$ $(n\times g)$ and $\tilde{\mathbf{M}} = [\tilde{\mathbf{m}}_1,\ldots,\tilde{\mathbf{m}}_c]'$ $(c\times g)$ are the data and mean matrices in the feature space. Here g is the dimension of the feature space. Although g is possibly infinite, we here assume that it is finite but not necessarily known.

Kernel discriminant analysis (KDA) seeks to solve the following generalized eigenproblem:

$$\tilde{\mathbf{S}}_b\tilde{\mathbf{A}} = \tilde{\mathbf{S}}_t\tilde{\mathbf{A}}\Lambda, \tag{7}$$

where $\tilde{\mathbf{S}}_t$ and $\tilde{\mathbf{S}}_b$ are the pooled scatter matrix and the between-class scatter matrix in $\mathcal{F}$, respectively:

$$\begin{aligned}
\tilde{\mathbf{S}}_t &= \sum_{i=1}^{n}(\tilde{\mathbf{x}}_i-\tilde{\mathbf{m}})(\tilde{\mathbf{x}}_i-\tilde{\mathbf{m}})' = \tilde{\mathbf{X}}'\mathbf{H}\tilde{\mathbf{X}},\\
\tilde{\mathbf{S}}_b &= \sum_{j=1}^{c} n_j(\tilde{\mathbf{m}}_j-\tilde{\mathbf{m}})(\tilde{\mathbf{m}}_j-\tilde{\mathbf{m}})' = \tilde{\mathbf{X}}'\mathbf{H}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{H}\tilde{\mathbf{X}}.
\end{aligned}$$

The KDA problem is to solve (7), doing so by working solely with the kernel matrix $\mathbf{K} = \tilde{\mathbf{X}}\tilde{\mathbf{X}}'$. This is done by noting that $\tilde{\mathbf{A}}$ can be expressed as

$$\tilde{\mathbf{A}} = \sum_{i=1}^{n}(\tilde{\mathbf{x}}_i-\tilde{\mathbf{m}})\beta_i' + \mathbf{N} = \tilde{\mathbf{X}}'\mathbf{H}\Upsilon + \mathbf{N}, \tag{8}$$

where $\Upsilon = [\beta_1,\ldots,\beta_n]$ $(n\times q)$ and $\mathbf{N} \in \mathbb{R}^{g\times q}$ such that $\mathbf{N}'\tilde{\mathbf{X}}'\mathbf{H} = \mathbf{0}$ (Park and Park, 2005a; Mika et al., 2000). It then follows from (7) that

$$\tilde{\mathbf{X}}'\mathbf{H}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{H}\tilde{\mathbf{X}}\tilde{\mathbf{X}}'\mathbf{H}\Upsilon = \tilde{\mathbf{X}}'\mathbf{H}\tilde{\mathbf{X}}\tilde{\mathbf{X}}'\mathbf{H}\Upsilon\Lambda. \tag{9}$$

This implies that $(\Lambda, \tilde{\mathbf{X}}'\mathbf{H}\Upsilon)$ are also the q eigenpairs of the matrix pencil $(\tilde{\mathbf{S}}_b, \tilde{\mathbf{S}}_t)$. Thus, in the literature the solution of (7) is typically restricted to $\mathcal{R}(\tilde{\mathbf{X}}'\mathbf{H})$; that is, $\mathbf{N} = \mathbf{0}$ is set.

Premultiplying both sides of the Equation (9) by $\mathbf{H}\tilde{\mathbf{X}}$, we have a new generalized eigenvalue problem

$$\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \mathbf{C}\mathbf{C}\Upsilon\Lambda, \tag{10}$$

which involves only the kernel matrix $\mathbf{K} = \tilde{\mathbf{X}}\tilde{\mathbf{X}}'$ via its centered form $\mathbf{C} = \mathbf{H}\mathbf{K}\mathbf{H}$.

The current concern then becomes that of solving the problem (10). Although $\mathbf{K}$ can be assumed to be nonsingular, $\mathbf{C}$ is positive semidefinite but not positive definite because the centering matrix

$\mathbf{H}$ is singular. In fact, the rank of $\mathbf{C}$ is not larger than $n-1$ because the rank of $\mathbf{H}$ is $n-1$. Thus the GDA method devised by Baudat and Anouar (2000) cannot be used directly for problem (10).

To address this problem Park and Park (2005a) proposed a GSVD-based algorithm to solve (10). Running this algorithm requires the complete orthogonal decomposition (Golub and Van Loan, 1996) of matrix $[\mathbf{CE\Pi}^{-\frac{1}{2}}, \mathbf{C}]'$, which is of size $(n+c)\times n$. This approach is infeasible for large values of n. Thus, Park and Park (2005a) developed an efficient alternative which consists of two SVD procedures but does not involve the complete orthogonal decomposition of an $(n+c)\times n$ matrix. We refer to it as the *SVD-based algorithm*.

Another approach to solving the problem (10) is based on the following regularized version of the problem:

$$\mathbf{CE\Pi}^{-1}\mathbf{E}'\mathbf{C}\Upsilon = (\mathbf{CC} + \sigma^2\mathbf{I}_n)\Upsilon\Lambda, \tag{11}$$

which was also studied by Park and Park (2005a). Note that this variant is not a directly regularized form of the original KDA problem in (7).

After having obtained Υ from (10) or (11), for a new input vector $\mathbf{x}$, the projection $\mathbf{z}$ of its feature vector $\tilde{\mathbf{x}}$ onto $\tilde{\mathbf{A}}$ is computed by

$$\mathbf{z} = \Upsilon'\mathbf{H}\tilde{\mathbf{X}}\Big(\tilde{\mathbf{x}} - \frac{1}{n}\tilde{\mathbf{X}}'\mathbf{1}_n\Big) = \Upsilon'\mathbf{H}\Big(\mathbf{k}_\mathbf{x} - \frac{1}{n}\mathbf{K}\mathbf{1}_n\Big), \tag{12}$$

where $\mathbf{k}_\mathbf{x} = \big(K(\mathbf{x},\mathbf{x}_1),\ldots,K(\mathbf{x},\mathbf{x}_n)\big)'$. This shows that the kernel trick can be used for KDA, and this approach has been widely deployed in practical problems. However, a theoretical justification for using the projection in (12) has been lacking in the literature. We are able to provide such as justification as follows. Recall that if $(\Lambda, \tilde{\mathbf{X}}'\mathbf{H}\Upsilon)$ is the solution of (7), then (Λ,Υ) is the solution of (10). As we will see in Theorem 3, if (Λ,Υ) is the solution of (10), $(\Lambda, \tilde{\mathbf{X}}'\mathbf{H}\Upsilon)$ is the solution of (7). This justifies the projection (12).

Note, however, that if (Λ,Υ) is the solution of (11) this does not imply that $(\Lambda, \tilde{\mathbf{X}}'\mathbf{H}\Upsilon)$ is the solution of (7). This shows that the projection (12) is inconsistent with (11). This is an inconsistency that underlies the regularized KDA methodology of Park and Park (2005a). The new methodology that we propose in the following section surmounts this problem.

3. New Approaches to Kernel Discriminant Analysis

Recall that we are interested in the pseudoinverse and regularization forms of (7), defined respectively by

$$\tilde{\mathbf{S}}_t^+\tilde{\mathbf{S}}_b\tilde{\mathbf{A}} = \tilde{\mathbf{A}}\Lambda \tag{13}$$

and

$$\tilde{\mathbf{S}}_b\tilde{\mathbf{A}} = (\tilde{\mathbf{S}}_t + \sigma^2\mathbf{I}_g)\tilde{\mathbf{A}}\Lambda. \tag{14}$$

We wish to find solutions of (7) and (13) or (14) that are consistent with each other.

Since $\mathcal{R}(\tilde{\mathbf{S}}_t) = \mathcal{R}(\tilde{\mathbf{X}}'\mathbf{H}\mathbf{H}\tilde{\mathbf{X}}) = \mathcal{R}(\tilde{\mathbf{X}}'\mathbf{H})$ and $\mathcal{R}(\tilde{\mathbf{S}}_b) = \mathcal{R}(\tilde{\mathbf{X}}'\mathbf{H}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{H}\tilde{\mathbf{X}}) = \mathcal{R}(\tilde{\mathbf{X}}'\mathbf{H}\mathbf{E})$, we have that $\mathcal{R}(\tilde{\mathbf{S}}_b) \subseteq \mathcal{R}(\tilde{\mathbf{S}}_t)$. As a direct corollary of Theorem 1, we thus obtain a connection between (7) and (13); that is,

Theorem 2 *If $(\Lambda,\tilde{\mathbf{A}})$ (nonzero eigenpairs) is the solution of (13), then $(\Lambda,\tilde{\mathbf{A}})$ is the solution of (7). Conversely, if $(\Lambda,\tilde{\mathbf{A}})$ is the solution of (7), then $(\Lambda,\tilde{\mathbf{S}}_t^+\tilde{\mathbf{S}}_t\tilde{\mathbf{A}})$ is the solution of (13).*

Theorem 2 implies that the solution of (7) can be obtained from (13). To solve (13), we consider the pseudoinverse form of (10), which is

$$\mathbf{C}^+\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \Upsilon\Lambda \tag{15}$$

due to $\mathbf{C}^+\mathbf{C}^+\mathbf{C} = \mathbf{C}^+$ (see Lemma 11). To obtain the solution of (14), we substitute (8) into (14) and then premultiply by $\mathbf{H}\tilde{\mathbf{X}}$. As a result, we have

$$\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = (\mathbf{C}\mathbf{C} + \sigma^2\mathbf{C})\Upsilon\Lambda. \tag{16}$$

The following theorem shows that we are able to obtain the solutions of (7), (13) and (14) respectively from the solutions of (10), (15) and (16). That is,

Theorem 3 *Considering the KDA problems, we have:*

(i) *If* (Λ,Υ) *is the solution of (10), then* $\left(\Lambda,\tilde{\mathbf{X}}'\mathbf{H}\Upsilon\right)$ *is the solution of (7).*

(ii) *If* (Λ,Υ) *is the solution of (15), then* $\left(\Lambda,\tilde{\mathbf{X}}'\mathbf{H}\Upsilon\right)$ *is the solution of (13).*

(iii) *If* (Λ,Υ) *is the solution of (16), then* $\left(\Lambda,\tilde{\mathbf{X}}'\mathbf{H}\Upsilon\right)$ *is the solution of (14).*

The proof of this theorem is given in Appendix C. Theorem 3 shows that the solutions of (7), (13) and (14) lie in span$\{\tilde{\mathbf{X}}'\mathbf{H}\}$. Moreover, we see that $\left(\Lambda,\tilde{\mathbf{X}}'\mathbf{H}\Upsilon\right)$ are their solutions. We also note that (16) is different from (11). Theorem 3 provides a relationship between (14) and (16); there is not a similar relationship between (14) and (11).

Finally, as a corollary of Theorems 2 and 3, we have

Corollary 4 *If* (Λ,Υ) *is the solution of (15), then* $\left(\Lambda,\tilde{\mathbf{X}}'\mathbf{H}\Upsilon\right)$ *is the solution of (7). Moreover, if* (Λ,Υ) *is the solution of (10), then* $\left(\Lambda,\tilde{\mathbf{X}}'\mathbf{H}\Upsilon\right)$ *is the solution of (13).*

We see from Corollary 4 that the solution of (7) can be also obtained from (15). We now concentrate our attention on the regularized KDA problem (14). We first handle (14) by using (16) and Theorem 3, and then we present an approach for directly solving (14).

4. SVD-based Algorithms for RDA Problems

It is clear that we can solve the regularized KDA (RKDA) problem in (11) by solving

$$(\mathbf{C}\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \Upsilon\Lambda.$$

However, since $\mathbf{C}\mathbf{C} + \sigma^2\mathbf{C}$ is singular, this approach is not appropriate for the RKDA problem in (16). In this section we show how to solve the RKDA problems in both (11) and (16), as well as the regularized FDA (RFDA) problem in (6).

In particular, we exploit the SVD-based algorithm developed for solving (10) by Park and Park (2005a). Our algorithms are summarized as Algorithm 1, which is an SVD-based method for solving RFDA problem (6), and Algorithms 2 and 3, which are SVD-based algorithms for RKDA problems (11) and (16). We defer the derivations to Section 8 in which we consider the SVD-based algorithm for a more general generalized eigenvalue problem. According to Theorem 3 and the following theorem, we immediately have the solution of (14) as $\tilde{\mathbf{A}} = \tilde{\mathbf{X}}'\mathbf{H}\Upsilon$.

Algorithm 1 SVD-based Algorithm for RFDA problem (6)

procedure RFDA($\mathbf{X}, \mathbf{E}, \pi, \Pi, \sigma^2$)
  Perform the condensed SVD of $\mathbf{HX}$ as $\mathbf{HX} = \mathbf{U}_X \Gamma_X \mathbf{V}_X'$;
  Calculate $\mathbf{F} = (\Gamma_X^2 + \sigma^2 \mathbf{I}_r)^{-\frac{1}{2}} \Gamma_X \mathbf{U}_X' \mathbf{E} \Pi^{-\frac{1}{2}}$ where $r = \mathrm{rk}(\Gamma_X)$;
  Perform the condensed SVD of $\mathbf{F}$ as $\mathbf{F} = \mathbf{U}_F \Gamma_F \mathbf{V}_F'$ and set $q = \mathrm{rk}(\Gamma_F)$;
  Return $\mathbf{A} = \mathbf{V}_X (\Gamma_X^2 + \sigma^2 \mathbf{I}_r)^{-\frac{1}{2}} \mathbf{U}_F$ as the solution of RFDA.
end procedure

Algorithm 2 SVD-based Algorithm for RKDA problem (11)

procedure RKDA($\mathbf{C}, \mathbf{E}, \pi, \Pi, \sigma^2$)
  Perform the condensed SVD of $\mathbf{C}$ as $\mathbf{C} = \mathbf{U}_C \Gamma_C \mathbf{U}_C'$;
  Calculate $\mathbf{F} = (\Gamma_C^2 + \sigma^2 \mathbf{I}_r)^{-\frac{1}{2}} \Gamma_C \mathbf{U}_C' \mathbf{E} \Pi^{-\frac{1}{2}}$ where $r = \mathrm{rk}(\Gamma_C)$;
  Perform the condensed SVD of $\mathbf{F}$ as $\mathbf{F} = \mathbf{U}_F \Gamma_F \mathbf{V}_F'$;
  Let $\Upsilon = \mathbf{U}_C (\Gamma_C^2 + \sigma^2 \mathbf{I}_r)^{-\frac{1}{2}} \mathbf{U}_F$ and set $q = \mathrm{rk}(\Gamma_F)$;
  Calculate $\mathbf{z}$ via (12) as the q-dimensional representation of $\mathbf{x}$.
end procedure

Theorem 5 *Consider Algorithms 1, 2 and 3 for the corresponding RDA problems.*

(i) *If* $\mathbf{A}$ *is obtained from Algorithm 1, then,*

$$\mathbf{A}'(\mathbf{S}_t + \sigma^2 \mathbf{I}_p)\mathbf{A} = \mathbf{I}_q \quad \textit{and} \quad \mathbf{A}'\mathbf{S}_b\mathbf{A} = \Gamma_F^2.$$

(ii) *If* Υ *is obtained from Algorithm 2, then*

$$\Upsilon'(\mathbf{CC} + \sigma^2 \mathbf{I}_n)\Upsilon = \mathbf{I}_q \quad \textit{and} \quad \Upsilon'\mathbf{CE}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \Gamma_F^2.$$

(iii) *If* Υ *is obtained from Algorithm 3 and* $\tilde{\mathbf{A}} = \tilde{\mathbf{X}}'\mathbf{H}\Upsilon$*, then*

$$\Upsilon'(\mathbf{CC} + \sigma^2 \mathbf{C})\Upsilon = \mathbf{I}_q \quad \textit{and} \quad \Upsilon'\mathbf{CE}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \Gamma_F^2,$$

and

$$\tilde{\mathbf{A}}'(\tilde{\mathbf{S}}_t + \sigma^2 \mathbf{I}_g)\tilde{\mathbf{A}} = \mathbf{I}_q \quad \textit{and} \quad \tilde{\mathbf{A}}'\tilde{\mathbf{S}}_b\tilde{\mathbf{A}} = \Gamma_F^2.$$

The proof of the theorem is given in Appendix D. According to this theorem, for a new $\mathbf{x}$, the projection $\mathbf{z}$ onto $\tilde{\mathbf{A}}$ is given by

$$\mathbf{z} = \Upsilon'\mathbf{H}\Big(\mathbf{k}_\mathbf{x} - \frac{1}{n}\mathbf{K}\mathbf{1}_n\Big). \tag{17}$$

Note that if $\sigma^2 = 0$, Algorithm 1 degenerates to the SVD-based algorithm for the conventional FDA in (2) (Howland et al., 2003) and Algorithms 2 and 3 become identical.

5. EVD-based Algorithms for RDA

It is desirable to directly find the solution of the RKDA problem (14), rather than obtaining the solution indirectly via (16). However, it is not feasible to devise a SVD-based algorithm for directly solving the RKDA problem in (14). In this section we propose a new approach to solving the RFDA problem (6). We then extend this approach for the solution of the RKDA problem (14).

Algorithm 3 SVD-based Algorithm for RKDA problem (16) as well as for (14)

procedure RKDA($\mathbf{C}, \mathbf{E}, \pi, \Pi, \sigma^2$)
  Perform the condensed SVD of $\mathbf{C}$ as $\mathbf{C} = \mathbf{U}_C \Gamma_C \mathbf{U}_C'$;
  Calculate $\mathbf{F} = (\Gamma_C^2 + \sigma^2 \Gamma_C)^{-\frac{1}{2}} \Gamma_C \mathbf{U}_C' \mathbf{E} \Pi^{-\frac{1}{2}}$ where $r = \mathrm{rk}(\Gamma_C)$;
  Perform the condensed SVD of $\mathbf{F}$ as $\mathbf{F} = \mathbf{U}_F \Gamma_F \mathbf{V}_F'$;
  Let $\Upsilon = \mathbf{U}_C (\Gamma_C^2 + \sigma^2 \Gamma_C)^{-\frac{1}{2}} \mathbf{U}_F$ and set $q = \mathrm{rk}(\Gamma_F)$;
  Calculate $\mathbf{z}$ via (17) as the q-dimensional representation of $\mathbf{x}$.
end procedure

5.1 The Algorithm for RFDA

We reformulate the eigenproblem in (6) as

$$\mathbf{G}\Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{H}\mathbf{X}\mathbf{A} = \mathbf{A}\Lambda,$$

where

$$\mathbf{G} = (\mathbf{X}'\mathbf{H}\mathbf{X} + \sigma^2 \mathbf{I}_p)^{-1} \mathbf{X}'\mathbf{H}\mathbf{E}\Pi^{-\frac{1}{2}} \tag{18}$$

due to (3) and (4). We also have

$$\mathbf{G} = \mathbf{X}'\mathbf{H}(\mathbf{H}\mathbf{X}\mathbf{X}'\mathbf{H} + \sigma^2 \mathbf{I}_n)^{-1} \mathbf{E}\Pi^{-\frac{1}{2}} \tag{19}$$

due to $(\mathbf{X}'\mathbf{H}\mathbf{X} + \sigma^2 \mathbf{I}_p)^{-1}\mathbf{X}'\mathbf{H} = \mathbf{X}'\mathbf{H}(\mathbf{H}\mathbf{X}\mathbf{X}'\mathbf{H} + \sigma^2 \mathbf{I}_n)^{-1}$. If $n < p$, we can use (19) to reduce the computational cost. Moreover, we will see that (19) plays a key role in the development of an efficient algorithm for KDA to be presented shortly.

Let $\mathbf{R} = \Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{H}\mathbf{X}\mathbf{G}$. Since $\mathbf{G}\Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{H}\mathbf{X}$ ($p \times p$) and $\mathbf{R}$ ($c \times c$) have the same nonzero eigenvalues (Horn and Johnson, 1985), the λ_j, $j = 1, \ldots, q$, are the nonzero eigenvalues of $\mathbf{R}$. Moreover, if $(\Lambda, \mathbf{V})$ is the nonzero eigenpair of $\mathbf{R}$, $(\Lambda, \mathbf{G}\mathbf{V})$ is the nonzero eigenpair of $\mathbf{G}\Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{H}\mathbf{X}$. Note that

$$\mathbf{R} = \Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{H}\mathbf{X}(\mathbf{X}'\mathbf{H}\mathbf{X} + \sigma^2 \mathbf{I}_p)^{-1}\mathbf{X}'\mathbf{H}\mathbf{E}\Pi^{-\frac{1}{2}}. \tag{20}$$

This shows that $\mathbf{R}$ is positive semidefinite.

We use these facts to develop an algorithm for solving the RFDA problem in (6). This is also a two-step process, which is presented in Algorithm 4. The first step computes $(\sigma^2 \mathbf{I}_p + \mathbf{X}'\mathbf{H}\mathbf{X})^{-1}$ (or $(\sigma^2 \mathbf{I}_n + \mathbf{H}\mathbf{X}\mathbf{X}'\mathbf{H})^{-1}$), while the second step is an SVD procedure. Note that the first step can be implemented by computing the condensed SVD of $\mathbf{X}'\mathbf{H}\mathbf{X}$ (or $\mathbf{H}\mathbf{X}\mathbf{X}'\mathbf{H}$). Since $\mathbf{R}$ and $\mathbf{X}'\mathbf{H}\mathbf{X}$ ($\mathbf{H}\mathbf{X}\mathbf{X}'\mathbf{H}$) are positive semidefinite, their SVD are equivalent to the eigenvalue decomposition (EVD). Thus, we refer to this two-step process as an *EVD-based algorithm*, distinguishing it from the SVD-based algorithm.

The first step calculates $\mathbf{G}$ by either (18) or (19). The computational complexity is $O(m^3)$ where $m = \min(n, p)$. The second step forms the condensed SVD of $\mathbf{R}$ for which the computational complexity is $O(c^3)$. If both n and p are large, we recommend an approximate strategy; that is, we first perform the incomplete Cholesky decomposition of $\mathbf{H}\mathbf{X}\mathbf{X}'\mathbf{H}$ (or $\mathbf{X}'\mathbf{H}\mathbf{X}$) and then calculate $(\mathbf{H}\mathbf{X}\mathbf{X}'\mathbf{H} + \sigma^2 \mathbf{I}_n)^{-1}$ (or $(\mathbf{X}'\mathbf{H}\mathbf{X} + \sigma^2 \mathbf{I}_p)^{-1}$) via the Sherman-Morrison-Woodbury formula (Golub and Van Loan, 1996). This strategy makes the first step still efficient.

When $\sigma^2 = 0$, we can solve the problem in (5) by simply adjusting the first step in the EVD-based algorithm. In particular, we calculate $\mathbf{G}$ by

$$\begin{aligned}\mathbf{G} &= (\mathbf{X}'\mathbf{H}\mathbf{X})^{+}\mathbf{X}'\mathbf{H}\mathbf{E}\Pi^{-\frac{1}{2}} \\ &\overset{(or)}{=} \mathbf{X}'\mathbf{H}(\mathbf{H}\mathbf{X}\mathbf{X}'\mathbf{H})^{+}\mathbf{E}\Pi^{-\frac{1}{2}}. \end{aligned} \tag{21}$$

Algorithm 4 EVD-based Algorithm for RFDA problem (6)

1: **procedure** RFDA($\mathbf{X}, \mathbf{E}, \Pi, \sigma^2$)
2: Calculate $\mathbf{G}$ by (18) or (19) and $\mathbf{R}$ by (20);
3: Perform the condensed SVD of $\mathbf{R}$ as $\mathbf{R} = \mathbf{V}_R\Gamma_R\mathbf{V}_R'$;
4: Return $\mathbf{A} = \mathbf{G}\mathbf{V}_R\Gamma_R^{-\frac{1}{2}}$ or $\mathbf{B} = \mathbf{G}\mathbf{V}_R$ as the solution of RFDA problem (6).
5: **end procedure**

Compared with the SVD-based algorithm, the EVD-based algorithm is more efficient, especially for "small n but large p" problems. Using the notation in Algorithms 1 and 4, we have

$$\mathbf{R} = \mathbf{F}'\mathbf{F}$$

by performing some matrix computations. This implies that $\Gamma_R = \Gamma_F^2$. Moreover, it is immediate to obtain the following result.

Theorem 6 *Let* $\mathbf{A}$ *be obtained from Algorithm 4. Then,*

$$\mathbf{A}'(\mathbf{S}_t + \sigma^2\mathbf{I}_p)\mathbf{A} = \mathbf{I}_q \quad \textit{and} \quad \mathbf{A}'\mathbf{S}_b\mathbf{A} = \Gamma_F^2.$$

This theorem shows that Algorithms 1 and 4 are essentially equivalent. As mentioned before, it is not feasible to develop an SVD-based algorithm for solving the RKDA problem (14), which is the kernel extension of RFDA in (6). On the other hand, in the next subsection we will see that Algorithm 4 can be used for solving the RKDA problem (14).

5.2 The Algorithm for RKDA

It follows immediately from (19) that

$$\tilde{\mathbf{G}} = \tilde{\mathbf{X}}'\mathbf{H}(\mathbf{H}\tilde{\mathbf{X}}\tilde{\mathbf{X}}'\mathbf{H} + \sigma^2\mathbf{I}_n)^{-1}\mathbf{E}\Pi^{-\frac{1}{2}}$$

from which, using (20), we calculate $\mathbf{R}$ by

$$\mathbf{R} = \Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{C}(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{E}\Pi^{-\frac{1}{2}}.$$

Moreover, given a new input vector $\mathbf{x}$, we can compute the projection $\mathbf{z}$ of the feature vector $\tilde{\mathbf{x}}$ onto $\tilde{\mathbf{A}}$ through

$$\begin{aligned}\mathbf{z} &= \tilde{\mathbf{A}}'(\tilde{\mathbf{x}} - \tilde{\mathbf{m}}) \\ &= \Gamma_R^{-\frac{1}{2}}\mathbf{V}_R'\Pi^{-\frac{1}{2}}\mathbf{E}'(\mathbf{C} + \sigma^2\mathbf{I}_n)^{-1}\mathbf{H}\tilde{\mathbf{X}}\Big(\tilde{\mathbf{x}} - \frac{1}{n}\tilde{\mathbf{X}}'\mathbf{1}_n\Big) \\ &= \Gamma_R^{-\frac{1}{2}}\mathbf{V}_R'\Pi^{-\frac{1}{2}}\mathbf{E}'(\mathbf{C} + \sigma^2\mathbf{I}_n)^{-1}\mathbf{H}\Big(\mathbf{k}_{\mathbf{x}} - \frac{1}{n}\mathbf{K}\mathbf{1}_n\Big). \end{aligned} \tag{22}$$

This shows that we can calculate $\mathbf{R}$ and $\mathbf{z}$ directly using $\mathbf{K}$ and $\mathbf{k_x}$. We thus obtain an EVD-based algorithm for RKDA, which is given in Algorithm 5. Also, when $\sigma^2 = 0$, we calculate $\mathbf{R}$ by

$$\mathbf{R} = \Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{C}\mathbf{C}^+\mathbf{E}\Pi^{-\frac{1}{2}}$$

and exploit the EVD-based algorithm to solve the following variant of KDA:

$$\tilde{\mathbf{S}}_t^+\tilde{\mathbf{S}}_b\tilde{\mathbf{A}} = \tilde{\mathbf{A}}\Lambda.$$

We see that the EVD-based algorithm is more efficient than the SVD-based algorithm (i.e., Algorithm 2) for the RKDA problem in (11). Recall that the RKDA problem (14) is not fully equivalent to that in (11). Moreover, we also have an EVD-based algorithm for solving (11), by replacing $\mathbf{C}$ by $\mathbf{C}\mathbf{C}$ in calculating $\mathbf{R}$ and (22) by (17) in calculating $\mathbf{z}$. However, the resulting algorithm is less efficient computationally.

Algorithm 5 EVD-based Algorithm for RKDA problem (14)

1: **procedure** RKDA($\mathbf{K}, \mathbf{E}, \mathbf{k_x}, \Pi, \sigma^2$)
2: Calculate $\mathbf{R} = \Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{C}(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{E}\Pi^{-\frac{1}{2}}$;
3: Perform the condensed SVD of $\mathbf{R}$ as $\mathbf{R} = \mathbf{V}_R\Gamma_R\mathbf{V}_R'$;
4: Calculate $\mathbf{z}$ by (22);
5: Return $\mathbf{z}$ as the q-dimensional representation of $\mathbf{x}$.
6: **end procedure**

Let us investigate the relationship between the solutions of (14) from Algorithms 3 and 5. First, let Υ be obtained from Algorithm 3. It follows from (16) that $(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \mathbf{C}\Upsilon\Lambda$, that is,

$$\mathbf{C}(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{E}\Pi^{-\frac{1}{2}}\Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{C}\Upsilon = \mathbf{C}\Upsilon\Lambda.$$

Thus, $(\Lambda, \Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{C}\Upsilon\Gamma_F^{-1})$ is the nonzero eigenpair of $\mathbf{R}$. Finally, we have $\Lambda = \Gamma_F^2 = \Gamma_R$. In addition, it follows from Theorem 5 that

$$\Gamma_F^{-1}\Upsilon'\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon\Gamma_F^{-1} = \mathbf{I}_q.$$

Moreover, we have

$$\begin{aligned}\tilde{\mathbf{G}}\Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{C}\Upsilon\Gamma_R^{-2} &= \tilde{\mathbf{X}}'\mathbf{H}(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon\Lambda^{-1} \\ &= \tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{C}(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon\Lambda^{-1} \\ &= \tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{C}\Upsilon = \tilde{\mathbf{X}}'\mathbf{H}\Upsilon \end{aligned} \tag{23}$$

because $\tilde{\mathbf{X}}'\mathbf{H} = \tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{C}$. This implies that $\tilde{\mathbf{A}} = \tilde{\mathbf{X}}'\mathbf{H}\Upsilon$ obtained from Algorithm 3 is equivalent to that obtained from Algorithm 5.

On the other hand, let $\mathbf{R} = \mathbf{V}_R\Gamma_R\mathbf{V}_R'$ be the condensed SVD of $\mathbf{R}$. Then

$$\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = (\mathbf{C}^2+\sigma^2\mathbf{C})\Upsilon\Gamma_R,$$

where $\Upsilon = (\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{E}\Pi^{-\frac{1}{2}}\mathbf{V}\Gamma_R^{-\frac{1}{2}}$. Moreover, it is easily checked that

$$\Upsilon'(\mathbf{C}^2+\sigma^2\mathbf{C})\Upsilon = \mathbf{I}_q \quad \text{and} \quad \Upsilon'\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \Gamma_R.$$

This implies that (Γ_R, Υ) is the solution of (16). Again, using (23), we conclude that the solution of (14) from Algorithm 5 is equivalent to the one from Algorithm 3.

In summary, Algorithms 5 and 3 yield equivalent solutions for (14). However, Algorithm 5 is more efficient than Algorithm 3.

6. Relationships Between RFDA and Ridge Regression

It is a well known result that FDA (or KDA) is equivalent to a least mean squared error procedure in the binary classification problem ($c = 2$) (Duda et al., 2001; Mika et al., 2000). Recently, relationships between FDA and a least mean squared error procedure in multi-class ($c > 2$) problems have been discussed by Hastie et al. (2001), Park and Park (2005b), and Ye (2007).

Motivated by this line of work, we investigate a possible equivalency between RFDA and ridge regression (Hoerl and Kennard, 1970). We then go on to consider a similar relationship between RKDA and the corresponding ridge regression problem.

Let $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_n]' = \mathbf{E}\Pi^{-\frac{1}{2}}\mathbf{H}_\pi$. That is, $\mathbf{y}_i = (y_{i1}, \ldots, y_{ic})$ is defined by

$$y_{ij} = \begin{cases} \frac{n-n_j}{n\sqrt{n_j}} & \text{if } i \in V_j, \\ -\frac{\sqrt{n_j}}{n} & \text{otherwise.} \end{cases}$$

Regarding $\{(\mathbf{x}_i, \mathbf{y}_i), i = 1, \ldots, n\}$ as the training samples, we fit the following multivariate linear function:

$$\mathbf{f}(\mathbf{x}) = \mathbf{w}_0 + \mathbf{W}'\mathbf{x}$$

where $\mathbf{w}_0 \in \mathbb{R}^c$ and $\mathbf{W} \in \mathbb{R}^{p\times c}$. We now find ridge estimates of $\mathbf{w}_0$ and $\mathbf{W}$. In particular, we consider the following minimization problem:

$$\min_{\mathbf{w}_0, \mathbf{W}} L(\mathbf{w}_0, \mathbf{W}) = \frac{1}{2}\|\mathbf{Y} - \mathbf{1}_n\mathbf{w}_0' - \mathbf{X}\mathbf{W}\|_F^2 + \frac{\sigma^2}{2}\mathrm{tr}(\mathbf{W}'\mathbf{W}). \tag{24}$$

We focus on the solution for $\mathbf{W}$:

$$\mathbf{W} = (\mathbf{X}'\mathbf{H}\mathbf{X} + \sigma^2\mathbf{I}_p)^{-1}\mathbf{M}'\Pi^{\frac{1}{2}}\mathbf{H}_\pi = (\mathbf{X}'\mathbf{H}\mathbf{X} + \sigma^2\mathbf{I}_p)^{-1}\mathbf{X}'\mathbf{H}\mathbf{E}\Pi^{-\frac{1}{2}}. \tag{25}$$

The derivation is given in Appendix E. It is then seen from (18) that $\mathbf{W} = \mathbf{G}$. Moreover, when $\sigma^2 = 0$, $\mathbf{W}$ reduces to the ordinary least squares (OLS) estimate of $\mathbf{W}$, which is the solution of the following minimization problem:

$$\min_{\mathbf{w}_0, \mathbf{W}} L(\mathbf{w}_0, \mathbf{W}) = \frac{1}{2}\|\mathbf{Y} - \mathbf{1}_n\mathbf{w}_0' - \mathbf{X}\mathbf{W}\|_F^2. \tag{26}$$

In this case, if $\mathbf{X}'\mathbf{H}\mathbf{X}$ is singular, a standard treatment uses $(\mathbf{X}'\mathbf{H}\mathbf{X})^+$ in (25). Such a $\mathbf{W}$ is identical with $\mathbf{G}$ in (21).

In summary, we have obtained a relationship between the ridge estimation problem in (24) and the RFDA problem in (6).

Theorem 7 *Let* $\mathbf{W}$ *be the solution of the ridge estimation problem in (24) (resp. the OLS estimation problem in (26)) and* $\mathbf{A}$ *be defined in Algorithm 4 for the solution of the RFDA problem in (6) (resp. the FDA problem in (5)). Then*

$$\mathbf{A} = \mathbf{W}\mathbf{V}_R\Gamma_R^{-\frac{1}{2}},$$

where $\mathbf{V}_R$ *and* Γ_R *are defined in Algorithm 4.*

This theorem provides an important connection between $\mathbf{A}$ and $\mathbf{W}$. Indeed $\mathbf{B} = \mathbf{A}\Gamma_R^{\frac{1}{2}}$ is also a solution of the RFDA problem (6). However, $\mathbf{B}$ satisfies the condition $\mathbf{B}'(\mathbf{S}_t + \sigma^2\mathbf{I}_p)\mathbf{B} = \Gamma_R$, rather than $\mathbf{B}'(\mathbf{S}_t + \sigma^2\mathbf{I}_p)\mathbf{B} = \mathbf{I}_q$. Thus, with this $\mathbf{B}$, we obtain the following result, which is the principal theoretical result of this paper.

Theorem 8 *Under the conditions in Theorem 7, we have*

$$\mathbf{B}\mathbf{B}' = \mathbf{W}\mathbf{W}'.$$

Moreover, we have

$$(\mathbf{x}_i - \mathbf{x}_j)'\mathbf{B}\mathbf{B}'(\mathbf{x}_i - \mathbf{x}_j) = (\mathbf{x}_i - \mathbf{x}_j)'\mathbf{W}\mathbf{W}'(\mathbf{x}_i - \mathbf{x}_j)$$

for any $\mathbf{x}_i$ *and* $\mathbf{x}_j \in \mathbb{R}^p$.

The proof of this theorem is given in Appendix F. Theorem 8 shows that when applying a distance-based classifier such as the K-nearest neighbor (KNN) in the reduced dimensional space, the classification results obtained by the multi-class FDA and multivariate linear estimators are same. Since Theorem 8 holds in general cases, we obtain a complete solution to the open problem concerning the relationship between multi-class FDA problems and multivariate linear estimators.

Similar results have been obtained by Park and Park (2005b); Ye (2007), but under restrictive conditions which arise from a different definition of the label scoring matrix $\mathbf{Y}$ than ours. The choice that of label scoring matrix that we have presented has also been used by Ye (2007), but Ye (2007) attempted to establish a connection between the solution $\mathbf{W}$ and $\mathbf{A}$ as given in Algorithm 1.

It is also worth noting that Zhang and Dai (2009) discussed a connection between the label scoring matrix $\mathbf{Y}$ and the optimal scoring procedure in Hastie et al. (1994). Moreover, Zhang and Jordan (2008) exploited this label scoring matrix in spectral clustering.

Our theorem also goes through immediately in the kernel setting. In particular, for the RKDA problem defined by (11), the corresponding ridge estimator is

$$\min_{\mathbf{w}_0, \mathbf{\Phi} \in \mathbb{R}^{n \times c}} L(\mathbf{w}_0, \Phi) \triangleq \frac{1}{2}\|\mathbf{Y} - \mathbf{1}_n\mathbf{w}_0' - \mathbf{K}\mathbf{H}\Phi\|_F^2 + \frac{\sigma^2}{2}\mathrm{tr}(\Phi'\Phi). \tag{27}$$

The ridge estimation problem corresponding to our RKDA in (14) is given by

$$\min_{\mathbf{w}_0, \tilde{\mathbf{W}} \in \mathbb{R}^{g \times c}} L(\mathbf{w}_0, \tilde{\mathbf{W}}) \triangleq \frac{1}{2}\|\mathbf{Y} - \mathbf{1}_n\mathbf{w}_0' - \tilde{\mathbf{X}}\tilde{\mathbf{W}}\|_F^2 + \frac{\sigma^2}{2}\mathrm{tr}(\tilde{\mathbf{W}}'\tilde{\mathbf{W}}),$$

while the estimation problem for the RKDA in (16) is

$$\min_{\mathbf{w}_0, \mathbf{\Phi} \in \mathbb{R}^{n \times c}} L(\mathbf{w}_0, \Phi) \triangleq \frac{1}{2}\|\mathbf{Y} - \mathbf{1}_n\mathbf{w}_0' - \mathbf{K}\mathbf{H}\Phi\|_F^2 + \frac{\sigma^2}{2}\mathrm{tr}(\Phi'\mathbf{C}\Phi), \tag{28}$$

which is no longer a conventional ridge regression problem. In fact, this problem can be regarded a multi-class extension of the least squares SVM (LS-SVM) (Suykens and Vandewalle, 1999; Suykens et al., 2002); (see, e.g., Van Gestel et al., 2002; Pelckmans et al., 2005). Our work thus provides the relationship between RKDA and the LS-SVM.

Note that when $\sigma^2 = 0$, the problems in (27) and (28) are identical. Moreover, the solution of the problems is given by

$$\Phi = (\mathbf{H}\mathbf{K}\mathbf{H}\mathbf{K}\mathbf{H})^+\mathbf{H}\mathbf{K}\mathbf{H}\mathbf{E}\Pi^{-\frac{1}{2}} = \mathbf{C}^+\mathbf{E}\Pi^{-\frac{1}{2}}.$$

In this case, the RKDA methods in (11) and (16) are also the same. As we see from Section 3, its corresponding pseudoinverse form is given by (15). Let the condensed SVD of $\mathbf{R} = \Pi^{-\frac{1}{2}}\mathbf{E}'\mathbf{C}\mathbf{C}^{+}\mathbf{E}\Pi^{-\frac{1}{2}}$ be $\mathbf{R} = \mathbf{V}_R\Gamma_R\mathbf{V}_R'$. Then $(\Gamma_R, \Phi\mathbf{V}_R\Gamma_R^{-\frac{1}{2}})$ is the solution of (15). This implies that in the case of $\sigma^2 = 0$, there is still the connection between the least squares kernel-based SVM and RKDA shown in Theorem 7.

7. Experimental Study

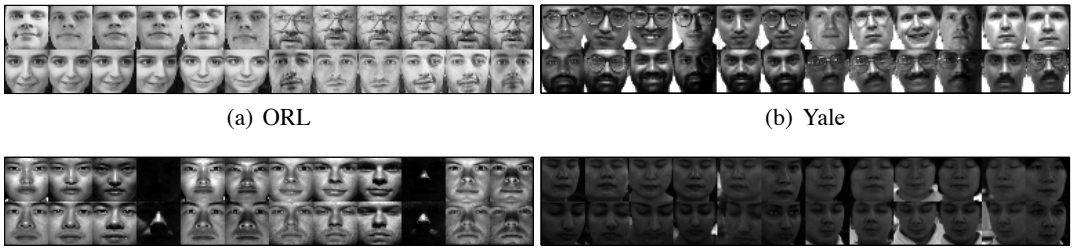
To evaluate the performance of the proposed algorithms for FDA and KDA, we conducted experimental comparisons with other closely related algorithms for FDA and KDA on several real-world data sets. In particular, the comparison was implemented on four face data sets, two handwritten digits data sets, the "letters" data set, and the WebKB data set. All algorithms were implemented in Matlab on a PC configured with an Intel Dual Core 2.0GHz CPU and 2.06GB of memory.

7.1 Setup

The four face data sets are the ORL face database, the Yale face database, the Yale face database B with extension, and the CMU PIE face database, respectively.

- The ORL face database contains 400 facial images of 40 subjects with 10 different images for each subject. This database was developed at the Olivetti Research Laboratories in Cambridge, U.K. The images were taken at different times with variations in facial details (glasses/no glasses), facial expressions (open/closed eyes, smiling/nonsimling), and facial poses (tilted and rotated up to 20 degrees). There is also variation in the scale of up to about 10%. The spatial resolution of the images is 112×92, with 256 gray levels.
- The Yale face images for each subject were captured under different facial expressions or configurations (e.g., center-light, w/glasses, happy, left-light, w/no glasses, normal, right-light, sad, sleepy, surprised, and wink).
- The Yale face database with extension includes the Yale face database B (Georghiades et al., 2001) and the extended Yale Face Database B (Lee et al., 2005). The Yale face database B contains 5760 face images of 10 subjects with 576 different images for each subject, and the extended Yale Face Database B contains 16128 face images of 28 subjects, with each subject having 576 different images. The facial images for each subject were captured under 9 poses and 64 illumination conditions. For the sake of simplicity, a subset called the YaleB&E was collected from two databases; it contains the 2414 face images of 38 subjects.
- The CMU PIE face database contains 41,368 face images of 68 subjects. The facial images for each subject were captured under 13 different poses, 43 different illumination conditions, and with 4 different expressions. In our experiments, we considered only the five near-frontal poses under different illuminations and expressions. For simplicity, we collected a subset of the PIE face database, containing the 6800 face images of 68 subjects with 100 different images for each subject.

In all of the experiments, each whole image was cropped and further resized to have a spatial resolution of 32×32 with 256 gray levels. Figure 1 shows some samples from the four data sets, where four subjects are randomly chosen from each data set and each subject has six sample images.



(a) ORL (b) Yale

(c) YaleB&E (d) PIE

Figure 1: Some sample images randomly chosen from the four data sets, where four subjects from each data set and each subject with six sample images.

The two handwritten digits data sets are the USPS data set and the Binary Alphadigits (BA) data set, respectively.

- The USPS data set was derived from the well-known United States Postal Service (USPS) set of handwritten digits, and contains 2000 images of 10 digits, each digit with 200 images. The spatial resolution of the images in the USPS data set is 16×16, with 256 gray levels.

- The Binary Alphadigits (BA) data set was collected from a binary 20×16 digits database of "0" through "9" and capital "A" through "Z," and thus contains 1404 images of 36 subjects, each subject with 39 image.

The "letters" data set can be obtained from Statlog(`http://www.liacc.up.pt/ML/`) and it consists of images of the letters "A," "B," "C," "D" and "E" with 789, 766, 736, 805 and 768 cases respectively.

Finally, the WebKB data set contains web pages gathered from computer science departments in several universities (Craven et al., 1998). The pages can be divided into seven categories. In our experiments, we used the four most populous categories, namely, student, faculty, course, and project, resulting in a total of 4192 pages. Based on information gain, 300 features were selected.

Table 1 summarizes these benchmark data sets. In our experiments, each data set was randomly partitioned into two disjoint subsets as the training and test data sets, according to the percentage n/k listed in the last column of Table 1. Ten random partitions were obtained for each data set, and several evaluation criteria were reported, including average classification accuracy rate, standard deviation, and average computational time.

The hyperparameters involved in the following methods were selected by cross-validation. After having obtained the q-dimensional representations $\mathbf{z}_i$ of the $\mathbf{x}_i$ from each method, we used a simple nearest neighbor classifier to evaluate the classification accuracy.

7.2 Comparison of FDA Methods

In the linear setting, we compared Algorithm 4 with Algorithm 1 (RFDA/SVD-based), the FDA/GSVD (Howland and Park, 2004) and FDA/MSE methods. Here the FDA/MSE method was derived by Park and Park (2005b) from the relationship between FDA and the minimum squared error solution. We refer

Data set	c	p	k	n/k
ORL	40	1024	400	40%
Yale	15	1024	165	50%
YaleB&E	38	1024	2414	30%
PIE	68	1024	6800	20%
USPS	10	256	2000	10%
BA	36	320	1404	50%
Letters	5	16	3864	10%
WebKB	4	300	4192	10%

Table 1: Summary of the benchmark data sets: $c-$the number of classes; $p-$the dimension of the input vector; $k-$the size of the data set; $n-$the number of the training data.

to Algorithm 4 working with $\mathbf{A}$ as the RFDA/EVD-based method. As we have shown, when $\mathbf{B}$ is used, Algorithm 4 provides the solution of ridge regression. We thus refer to the algorithm working with $\mathbf{B}$ as RFDA/RR. Similar notation also applies to the kernel setting in the next subsection.

Empirically, the performance of the RFDA/EVD-based method is fully identical to that of the RFDA/SVD-based method. This bears out the theoretical analysis in Theorem 6. Thus, we only report the classification accuracies of the RFDA/RR method for Algorithm 4.

Table 2 presents an overall comparison of the methods on all of the data sets and Figure 2 presents the comparative classification results on the four face data sets. It is seen that the RFDA methods have better classification accuracy overall than other methods throughout a range of choices of the number of discriminant variates. Particularly striking is the performance of the RFDA methods when the number of discriminant variates q is small.

From Figure 2, we see that the performance of RFDA/RR method is a little better than that of RFDA/SVD-based method. This implies that RFDA/RR outperforms RFDA/EVD-based method; that is, the performance using the transformation matrix $\mathbf{B}$ is better than that using the transformation matrix $\mathbf{A}$ in Algorithm 4. Therefore, the constraint $\mathbf{A}'(\mathbf{S}_t + \sigma^2\mathbf{I}_p)\mathbf{A} = \mathbf{I}_q$ is not necessarily the best choice for RFDA. This also shows that the ridge regression method given in Section 6 is effective and efficient.

We also compared the computational time of the different methods on the four face data sets. Figure 3 plots the results as a function of the training percentage n/k on the four face data sets. We see that our method has an overall favorable computational complexity in comparison with the other methods on the four face data sets. As the training percentage n/k increases, our method yields more efficient performance.

Note that when the training percentage n/k on the YaleB&E and PIE data sets increases, the singularity problem of the within-class scatter matrix $\mathbf{S}_w$, that is, the small sample size problem, tends to disappear. Figures 3 (c) and (d) show that the FDA/MSE method becomes more efficient in this case, and the corresponding computational time becomes flat with respect to the increase of the training percentage n/k. On the other hand, Figures 3 (c) and (d) also reveal that the computational time of the FDA/SVD-based method significantly increases as the size of training data increases.

Data Set	FDA/GSVD		FDA/MSE		RFDA/SVD-based		RFDA/RR	
	acc ($\pm std$)	*time*	*acc* ($\pm std$)	*time*	*acc* ($\pm std$)	*time*	*acc* ($\pm std$)	*time*

7.3 Comparison of RKDA Methods

In the kernel setting, we compared Algorithms 2, 3 and RKDA/RR (Algorithm 5 working with **B**). We also implemented the KDA/GSVD method (Park and Park, 2005a) as a baseline. The RBF kernel $K(\mathbf{x}_i, \mathbf{x}_j) = \exp(-\|\mathbf{x}_i - \mathbf{x}_j\|^2/\theta^2)$ was employed, and θ was set to the mean Euclidean distance among training data points. This setting was empirically found to be effective in real-world applications.

Table 3 summarizes the different evaluation criteria on all the data sets. Figures 4 and 5 further illustrate these results. As we see, our two RKDA methods yield better accuracy than the KDA/GSVD method and Algorithm 2. Moreover, RKDA/RR is more efficient computationally than the other methods, especially as the size of training data increases. It should be mentioned here that the data sets in our experiments range from small-sample to large-sample problems. Thus, Table 3 also confirms that the RKDA method based on (14) is more effective and efficient than the method based on (11).

Finally, Figure 6 presents the performance of the four regularized methods with respect to different regularization parameters σ on the four face data sets. From this figure, it can be seen that the regularized parameter σ plays an important role in our RFDA/RR and RKDA/RR methods. Similar results are obtained for the other regularized FDA or KDA methods compared here.

8. Beyond FDA

In this section we extend our results to a more general setting. We first apply the SVD-based algorithm to a family of generalized eigenvector problems, and then propose an efficient algorithm for penalized kernel canonical correlation analysis (KCCA) (Akaho, 2001; Van Gestel et al., 2001; Bach and Jordan, 2002).

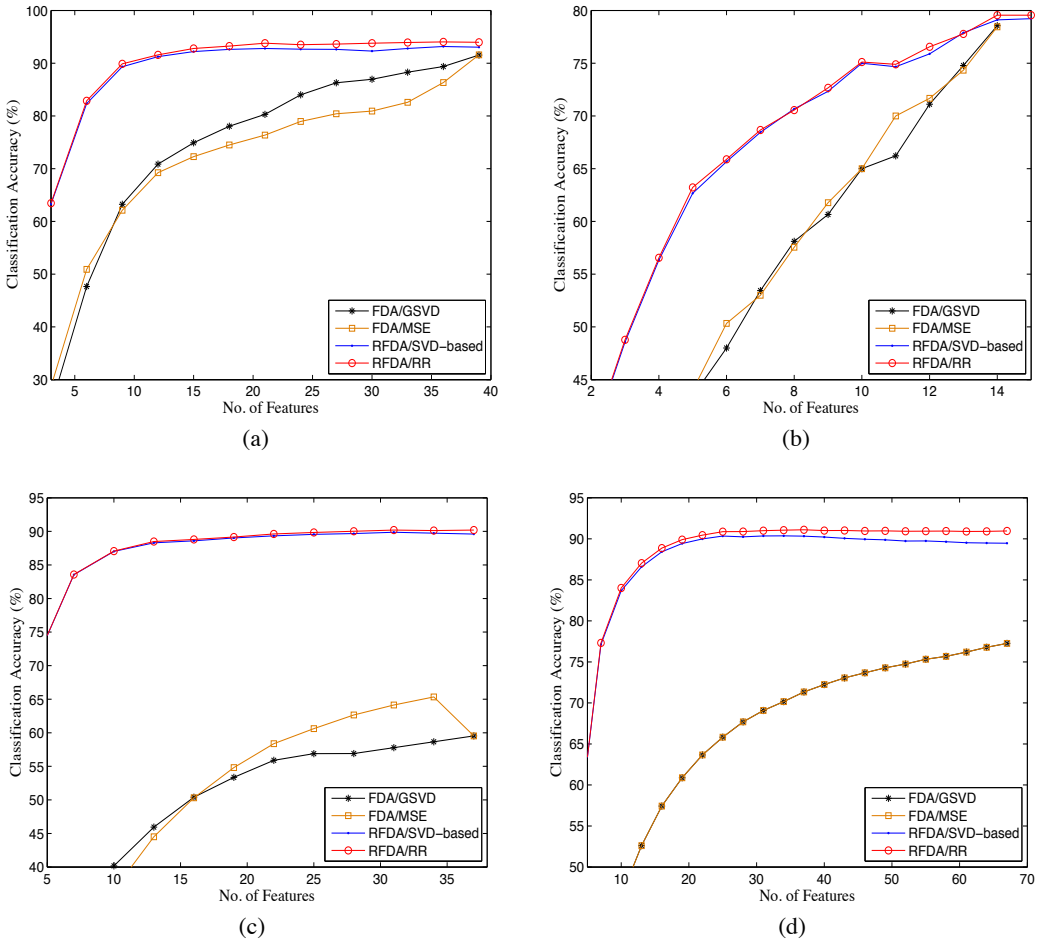

Figure 2: Comparison of the classification accuracies for FDA methods on the four face data sets: (a) ORL; (b) Yale; (c) YaleB&E; (d) PIE.

8.1 A Family of Generalized Eigenvector Problems

Assume that $\mathbf{Q}$ is a $p \times p$ semidefinite positive matrix. Here and later, we define

$$f(\mathbf{Q}) = \sum_{j=0}^{k} b_j \mathbf{Q}^j = b_0 \mathbf{I}_p + b_1 \mathbf{Q} + b_2 \mathbf{Q}^2 + \cdots + b_k \mathbf{Q}^k$$

where $b_0, \ldots, b_k$ are nonnegative real scalars for some positive integer k. We assume that there is at least one b_j such that $b_j > 0$. Let $\mathbf{Q} = \mathbf{V}\Gamma\mathbf{V}'$ be the SVD of $\mathbf{Q}$. We have

$$f(\mathbf{Q}) = \mathbf{V}(b_0 \mathbf{I}_p + b_1 \Gamma + b_2 \Gamma^2 + \cdots + b_k \Gamma^k)\mathbf{V}'.$$

This implies that $f(\mathbf{Q})$ is also semidefinite positive. Moreover, we have $\mathrm{rk}(\mathbf{Q}) \leq \mathrm{rk}(f(\mathbf{Q}))$. In fact, we have $\mathrm{rk}(\mathbf{Q}) = \mathrm{rk}(f(\mathbf{Q}))$ if $b_0 = 0$. However, $f(\mathbf{Q})$ is nonsingular whenever $b_0 > 0$.

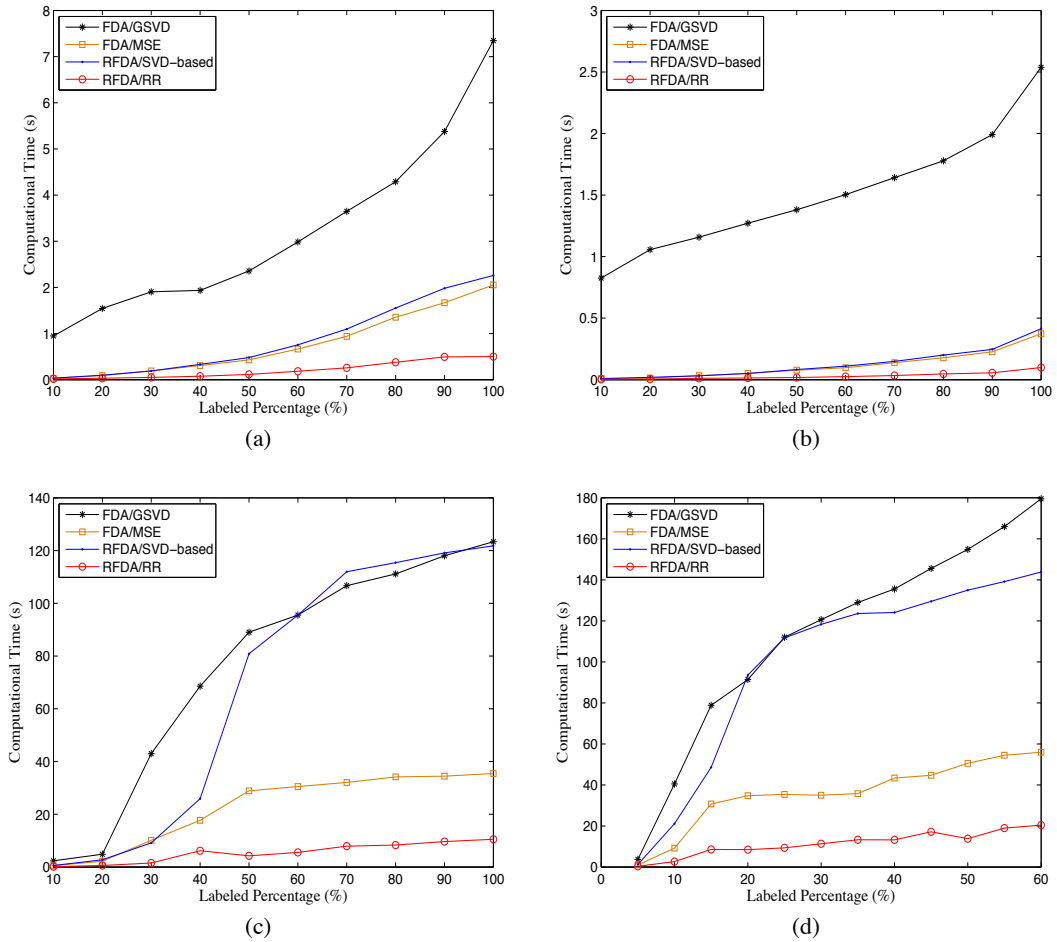

Figure 3: Comparison of the computational times for FDA methods as the training percentage k/n increases on the four face data sets: (a) ORL; (b) Yale; (c) YaleB&E; (d) PIE.

Letting $\mathbf{X} \in \mathbb{R}^{n\times p}$ and $\mathbf{Y} \in \mathbb{R}^{n\times m}$, we consider the following general optimization problem:

$$\max_{\mathbf{A}\in\mathbb{R}^{p\times q}} \operatorname{tr}\big(\mathbf{A}'\mathbf{X}'\mathbf{Y}\mathbf{Y}'\mathbf{X}\mathbf{A}(\mathbf{A}'f(\mathbf{Q})\mathbf{A})^{-1}\big). \tag{29}$$

where $\mathbf{Q} = (\mathbf{X}'\mathbf{X})^{1/2}$ and $\operatorname{rk}(\mathbf{Q}) = \operatorname{rk}(\mathbf{X}) \geq q$. This problem can be formulated as a generalized eigenproblem as follows:

$$\mathbf{X}'\mathbf{Y}\mathbf{Y}'\mathbf{X}\mathbf{A} = f(\mathbf{Q})\mathbf{A}\Lambda. \tag{30}$$

Thus, we consider the following eigenproblem:

$$\big(f(\mathbf{Q})\big)^{+}\mathbf{X}'\mathbf{Y}\mathbf{Y}'\mathbf{X}\mathbf{A} = \mathbf{A}\Lambda. \tag{31}$$

The following theorem shows a relationship between (30) and (31).

Theorem 9 *If $(\Lambda, \mathbf{A})$ (nonzero eigenpairs) is the solution of (31), then $(\Lambda, \mathbf{A})$ is the solution of (30). Conversely, if $(\Lambda, \mathbf{A})$ is the solution of (30), then $(\Lambda, (f(\mathbf{Q}))^{+}f(\mathbf{Q})\mathbf{A})$ is the solution of (31).*

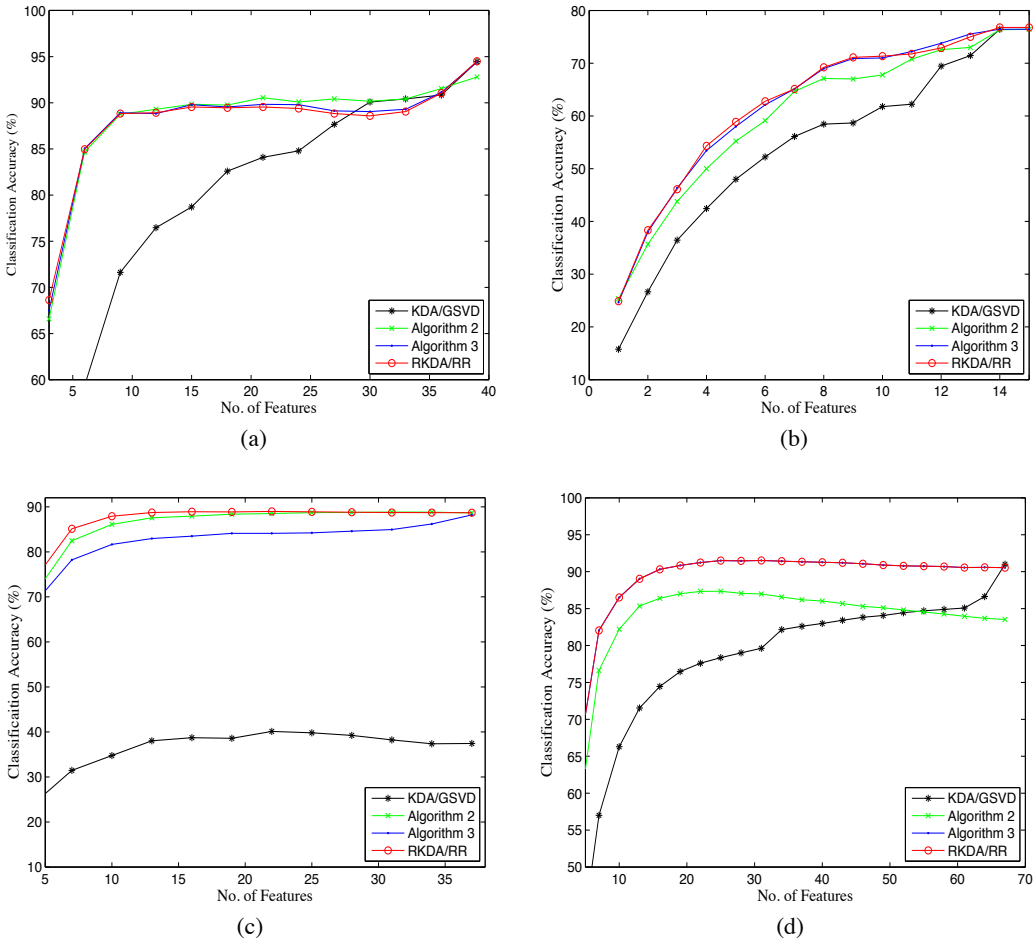

Figure 4: Comparison of the classification accuracies for KDA methods on the four face data sets: (a) ORL; (b) Yale; (c) YaleB&E; (d) PIE.

The theorem obviously holds when $b_0 > 0$, because $f(\mathbf{Q})$ is nonsingular. In the case that $b_0 = 0$, this theorem is a special case of Theorem 1.

Returning to the optimization problem in (29), we have the following theorem.

Theorem 10 *Assume that* $\mathrm{rk}(\mathbf{X}) = r \geq q$. *Let the condensed SVD of* $\mathbf{X}$ *be* $\mathbf{X} = \mathbf{U}_X \Gamma_X \mathbf{V}_X'$ *and the condensed SVD of* $\mathbf{F} = (f(\Gamma_X))^{-\frac{1}{2}} \Gamma_X \mathbf{U}_X' \mathbf{Y}$ *be* $\mathbf{F} = \mathbf{U}_F \Gamma_F \mathbf{V}_F'$. *We have: (i)* $(\Lambda, \mathbf{T})$ *where* $\mathbf{T} = \mathbf{V}_X (f(\Gamma_X))^{-\frac{1}{2}} \mathbf{U}_F$ *and* $\Lambda = \Gamma_F^2$ *are* r *eigenpairs of the pencil* $(\mathbf{X}'\mathbf{Y}\mathbf{Y}'\mathbf{X}, f(\mathbf{Q}))$; *(ii) the matrix* $\mathbf{T}_q$ *consisting of the first* q *columns of* $\mathbf{T}$ *is a maximizer of the generalized Rayleigh quotient in* (29).

The proof is given in Appendix G. This theorem shows that we can use the SVD-based algorithm to solve (29). That is, we obtain a derivation of Algorithm 6. Moreover, it is easily seen that the RFDA problems (6), (11), (14) and (16) are special cases of the problem (29) with different settings for the b_j.

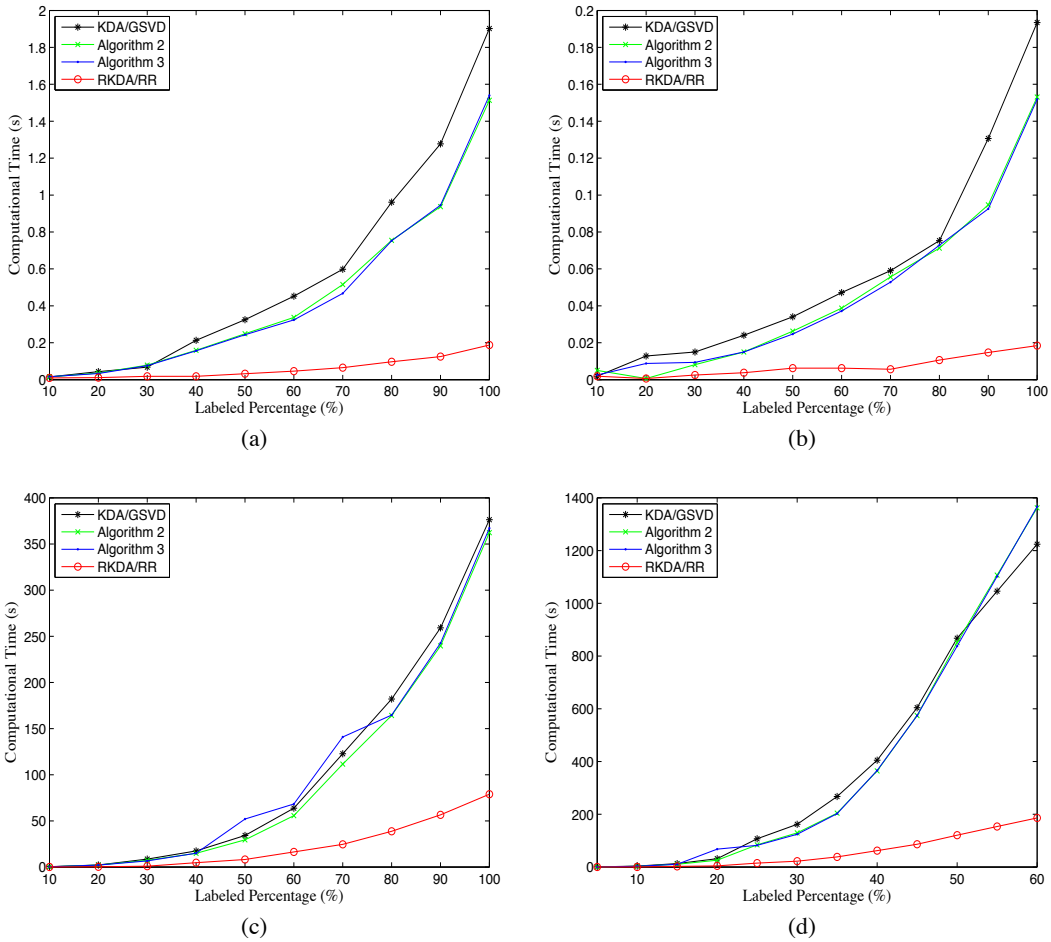

Figure 5: Comparison of the computational times for KDA methods as the training percentage k/n increases on the four face data sets: (a) ORL; (b) Yale; (c) YaleB&E; (d) PIE.

Algorithm 6 SVD-based Algorithm for Problem (29)

1: **procedure** GEP($\{\mathbf{X}, \mathbf{Y}, \sigma^2\}$)
2: Perform the condensed SVD of $\mathbf{X}$ as $\mathbf{X} = \mathbf{U}_X \Gamma_X \mathbf{V}_X'$.
3: Calculate $\mathbf{F} = (f(\Gamma_X))^{-\frac{1}{2}} \Gamma_X \mathbf{U}_X' \mathbf{Y}$ where $r = \mathrm{rk}(\Gamma_X)$.
4: Perform the condensed SVD of $\mathbf{F}$ as $\mathbf{F} = \mathbf{U}_F \Gamma_F \mathbf{V}_F'$.
5: Let $\mathbf{T} = \mathbf{V}_X (f(\Gamma_X))^{-\frac{1}{2}} \mathbf{U}_F$
6: Return $\mathbf{A} = \mathbf{T}(:, 1:q)$ for $q \leq r$ as a maximizer of Problem (29).
7: **end procedure**

8.2 Penalized KCCA

Given two data matrices $\mathbf{X} \in \mathcal{X} \subset \mathbb{R}^{n \times p}$ and $\mathbf{Y} \in \mathcal{Y} \subset \mathbb{R}^{n \times m}$, CCA finds two matrices $\mathbf{A}_x \in \mathbb{R}^{p \times q}$ and $\mathbf{A}_y \in \mathbb{R}^{m \times q}$ of canonical correlation vectors by solving the following optimization problem:

$$\max_{\mathbf{A}_x, \mathbf{A}_y} \mathrm{tr}(\mathbf{A}_x' \mathbf{S}_{xy} \mathbf{A}_y),$$

$$\text{s.t. } \mathbf{A}_x' \mathbf{S}_{xx} \mathbf{A}_x = \mathbf{I}_q \text{ and } \mathbf{A}_y' \mathbf{S}_{yy} \mathbf{A}_y = \mathbf{I}_q,$$

Data Set	KDA/GSVD		Algorithm 2		Algorithm 3		RKDA/RR

Table 3: Experimental results for the five methods on different data sets in the kernel setting: *acc*– the best classification accuracy percentage; *std*– the corresponding standard deviation; *time*– the corresponding computational time (*s*).

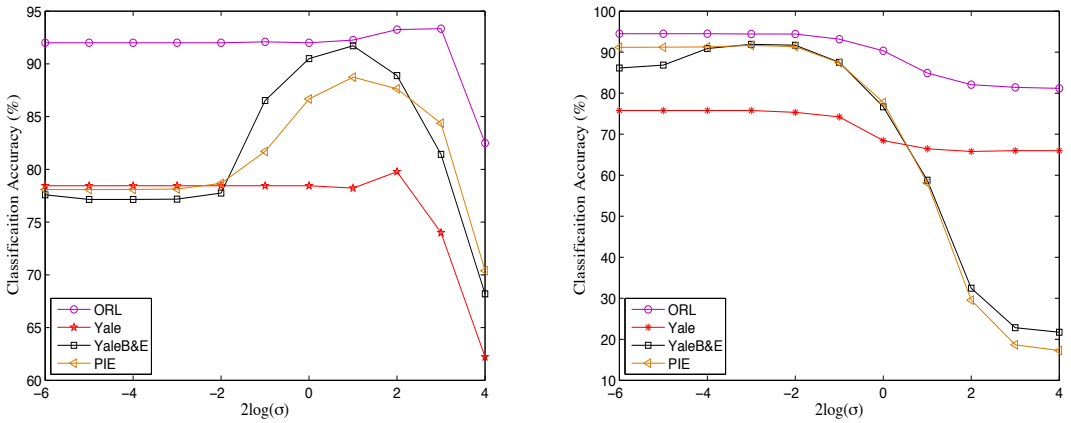

Figure 6: Performance of the RFDA/RR and RKDA/RR methods for different regularization parameters σ, where (a) displays the results of RFDA/RR on different data sets and (b) displays the results of RKDA/RR on different data sets.

where $q \leq \min\{p, m, n-1\}$, $\mathbf{S}_{xx} = \mathbf{X}'\mathbf{H}\mathbf{X}$ and $\mathbf{S}_{yy} = \mathbf{Y}'\mathbf{H}\mathbf{Y}$ are the pooled covariance matrices of $\mathbf{x}$ and $\mathbf{y}$, respectively, and $\mathbf{S}_{xy} = \mathbf{X}'\mathbf{H}\mathbf{Y} = \mathbf{S}'_{yx}$ is the pooled cross-covariance matrix between $\mathbf{x}$ and $\mathbf{y}$.

Consider that either $\mathbf{S}_{xx}$ or $\mathbf{S}_{yy}$ is ill-conditioned. The penalized CCA method (Hastie et al., 1995) solves the following optimization problem

$$\max_{\mathbf{A}_x, \mathbf{A}_y} \ \mathrm{tr}(\mathbf{A}'_x \mathbf{S}_{xy} \mathbf{A}_y),$$

$$\text{s.t. } \mathbf{A}'_x(\mathbf{S}_{xx} + \sigma_x^2 \mathbf{I}_p)\mathbf{A}_x = \mathbf{I}_q \ \text{ and } \ \mathbf{A}'_y(\mathbf{S}_{yy} + \sigma_y^2 \mathbf{I}_m)\mathbf{A}_y = \mathbf{I}_q.$$

This problem can be solved in a two-step process (Mardia et al., 1979). The first step solves the following generalized problem:

$$\mathbf{S}_{yx}(\mathbf{S}_{xx}+\sigma_x^2\mathbf{I}_p)^{-1}\mathbf{S}_{xy}\mathbf{A}_y = (\mathbf{S}_{yy}+\sigma_y^2\mathbf{I}_m)\mathbf{A}_y\Lambda,$$

where Λ is a $q\times q$ diagonal matrix with positive diagonal elements. The second step calculates $\mathbf{A}_x$ by

$$\mathbf{A}_x = (\mathbf{S}_{xx}+\sigma_x^2\mathbf{I}_p)^{-1}\mathbf{S}_{xy}\mathbf{A}_y\Lambda^{-\frac{1}{2}}.$$

Assume that we have kernel functions $K_x(\cdot,\cdot)$: $\mathcal{X}\times\mathcal{X}\to\mathbb{R}$, and $K_y(\cdot,\cdot)$: $\mathcal{Y}\times\mathcal{Y}\to\mathbb{R}$. Similar to the linear case, penalized KCCA first solves the following generalized problem:

$$\tilde{\mathbf{S}}_{xy}(\tilde{\mathbf{S}}_{yy}+\sigma_y^2\mathbf{I}_h)^{-1}\tilde{\mathbf{S}}_{yx}\tilde{\mathbf{A}}_x = (\tilde{\mathbf{S}}_{xx}+\sigma_x^2\mathbf{I}_g)\tilde{\mathbf{A}}_x\Lambda, \tag{32}$$

and then calculates $\tilde{\mathbf{A}}_y$ by

$$\tilde{\mathbf{A}}_y = (\tilde{\mathbf{S}}_{yy}+\sigma_y^2\mathbf{I}_h)^{-1}\tilde{\mathbf{S}}_{yx}\tilde{\mathbf{A}}_x\Lambda^{-\frac{1}{2}}.$$

Here g and h are the dimensions of the corresponding feature spaces. We now address the solution to the generalized eigenproblem in (32). Consider

$$\begin{aligned}
&(\tilde{\mathbf{S}}_{xx}+\sigma_x^2\mathbf{I}_g)^{-1}\tilde{\mathbf{S}}_{xy}(\tilde{\mathbf{S}}_{yy}+\sigma_y^2\mathbf{I}_h)^{-1}\tilde{\mathbf{S}}_{yx}\\
&= (\tilde{\mathbf{X}}'\mathbf{H}\tilde{\mathbf{X}}+\sigma_x^2\mathbf{I}_g)^{-1}\tilde{\mathbf{X}}'\mathbf{H}\tilde{\mathbf{Y}}(\tilde{\mathbf{Y}}'\mathbf{H}\tilde{\mathbf{Y}}+\sigma_y^2\mathbf{I}_h)^{-1}\tilde{\mathbf{Y}}'\mathbf{H}\tilde{\mathbf{X}}\\
&= \tilde{\mathbf{X}}'\mathbf{H}(\mathbf{H}\tilde{\mathbf{X}}\tilde{\mathbf{X}}'\mathbf{H}+\sigma_x^2\mathbf{I}_n)^{-1}(\mathbf{H}\tilde{\mathbf{Y}}\tilde{\mathbf{Y}}'\mathbf{H}+\sigma_y^2\mathbf{I}_n)^{-1}\mathbf{H}\tilde{\mathbf{Y}}\tilde{\mathbf{Y}}'\mathbf{H}\tilde{\mathbf{X}}\\
&= \tilde{\mathbf{X}}'\mathbf{H}(\mathbf{C}_x+\sigma_x^2\mathbf{I}_n)^{-1}(\mathbf{C}_y+\sigma_y^2\mathbf{I}_n)^{-1}\mathbf{C}_y\mathbf{H}\tilde{\mathbf{X}},
\end{aligned}$$

where $\mathbf{C}_x = \mathbf{H}\tilde{\mathbf{X}}\tilde{\mathbf{X}}'\mathbf{H}$ and $\mathbf{C}_y = \mathbf{H}\tilde{\mathbf{Y}}\tilde{\mathbf{Y}}'\mathbf{H}$. Since $\tilde{\mathbf{X}}'\mathbf{H}(\mathbf{C}_x+\sigma_x^2\mathbf{I}_n)^{-1}(\mathbf{C}_y+\sigma_y^2\mathbf{I}_n)^{-1}\mathbf{C}_y\mathbf{H}\tilde{\mathbf{X}}$ and $(\mathbf{C}_x+\sigma_x^2\mathbf{I}_n)^{-1}(\mathbf{C}_y+\sigma_y^2\mathbf{I}_n)^{-1}\mathbf{C}_y\mathbf{C}_x$ have the same nonzero eigenvalues, we let

$$(\mathbf{C}_x+\sigma_x^2\mathbf{I}_n)^{-1}(\mathbf{C}_y+\sigma_y^2\mathbf{I}_n)^{-1}\mathbf{C}_y\mathbf{C}_x\Upsilon = \Upsilon\Lambda$$

where Λ consists of the q largest nonzero eigenvalues of $(\mathbf{C}_x+\sigma_x^2\mathbf{I}_n)^{-1}(\mathbf{C}_y+\sigma_y^2\mathbf{I}_n)^{-1}\mathbf{C}_y\mathbf{C}_x$. We thus define

$$\tilde{\mathbf{A}}_x = \tilde{\mathbf{X}}'\mathbf{H}\Upsilon$$

and

$$\tilde{\mathbf{A}}_y = \tilde{\mathbf{Y}}'\mathbf{H}(\mathbf{C}_y+\sigma_y^2\mathbf{I}_n)^{-1}\mathbf{C}_x\Upsilon\Lambda^{-\frac{1}{2}}$$

as the solution of the KCCA problem. Given $\mathbf{x}\in\mathbb{R}^p$ and $\mathbf{y}\in\mathbb{R}^m$, we can directly calculate their canonical variables by

$$\mathbf{z}_x = \tilde{\mathbf{A}}_x'(\tilde{\mathbf{x}}-\tilde{\mathbf{m}}_x) = \Upsilon'\Big(\mathbf{k}_x-\frac{1}{n}\mathbf{K}_x\mathbf{1}_n\Big),$$

where $\tilde{\mathbf{m}}_x = \frac{1}{n}\sum_{i=1}^n\tilde{\mathbf{x}}_i$, $\mathbf{k}_x = (K_x(\mathbf{x},\mathbf{x}_1),\ldots,K_x(\mathbf{x},\mathbf{x}_n))'$ and $\mathbf{K}_x = \tilde{\mathbf{X}}\tilde{\mathbf{X}}'$, and

$$\mathbf{z}_y = \tilde{\mathbf{A}}_y'(\tilde{\mathbf{y}}-\tilde{\mathbf{m}}_y) = \Lambda^{-\frac{1}{2}}\Upsilon'\mathbf{C}_x(\mathbf{C}_y+\sigma_y^2\mathbf{I}_n)^{-1}\Big(\mathbf{k}_y-\frac{1}{n}\mathbf{K}_y\mathbf{1}_n\Big),$$

where $\tilde{\mathbf{m}}_y = \frac{1}{n}\sum_{i=1}^n\tilde{\mathbf{y}}_i$, $\mathbf{k}_y = (K_y(\mathbf{y},\mathbf{y}_1),\ldots,K_y(\mathbf{y},\mathbf{y}_n))'$ and $\mathbf{K}_y = \tilde{\mathbf{Y}}\tilde{\mathbf{Y}}'$.

As we see, the canonical vectors $\mathbf{z}_x$ and $\mathbf{z}_y$ can be calculated without the explicit use of $\tilde{\mathbf{X}}$ and $\tilde{\mathbf{Y}}$. Moreover, if $\sigma_x^2=0$ or $\sigma_y^2=0$, the algorithm still works by using $\mathbf{C}_x^+$ or $\mathbf{C}_y^+$ instead.

9. Conclusion

In this paper we have provided a solution to an open problem concerning the relationship between multi-class discriminant analysis problems and multivariate regression problems, both in the linear setting and the kernel setting. Our theory has yielded efficient and effective algorithms for FDA and KDA within both the regularization and pseudoinverse paradigms. The favorable performance of our algorithms has been demonstrated empirically on a collection of benchmark data sets. We have also extended our algorithms to a more general family of generalized eigenvalue problems.

Appendix A. Proof of Theorem 1

Let $\Sigma_1 = \mathbf{U}_1\Gamma_1\mathbf{V}_1'$ and $\Sigma_2 = \mathbf{U}_2\Gamma_2\mathbf{V}_2'$ be the condensed SVD of Σ_1 and Σ_2. Thus, we have $\mathcal{R}(\Sigma_1) = \mathcal{R}(\mathbf{U}_1)$ and $\mathcal{R}(\Sigma_2) = \mathcal{R}(\mathbf{U}_2)$. Moreover, we have $\Sigma_2^+ = \mathbf{V}_2\Gamma_2^{-1}\mathbf{U}_2'$ and $\Sigma_2\Sigma_2^+ = \mathbf{U}_2\mathbf{U}_2'$. It follows from $\mathcal{R}(\Sigma_1) \subseteq \mathcal{R}(\Sigma_2)$ that $\mathcal{R}(\mathbf{U}_1) \subseteq \mathcal{R}(\mathbf{U}_2)$. This implies that $\mathbf{U}_1$ can be expressed as $\mathbf{U}_1 = \mathbf{U}_2\mathbf{Q}$ where $\mathbf{Q}$ is some matrix of appropriate order. As a result, we have

$$\Sigma_2\Sigma_2^+\Sigma_1 = \mathbf{U}_2\mathbf{U}_2'\mathbf{U}_2\mathbf{Q}\Gamma_1\mathbf{V}_1' = \Sigma_1.$$

It is worth noting that the condition $\Sigma_2\Sigma_2^+\Sigma_1 = \Sigma_1$ is not only necessary but also sufficient for $\mathcal{R}(\Sigma_1) \subseteq \mathcal{R}(\Sigma_2)$.

If $(\Lambda, \mathbf{B})$ are the eigenpairs of $\Sigma_2^+\Sigma_1$, then it is easily seen that $(\Lambda, \mathbf{B})$ are also the eigenpairs of (Σ_1, Σ_2) due to $\Sigma_2\Sigma_2^+\Sigma_1 = \Sigma_1$.

Conversely, suppose $(\Lambda, \mathbf{B})$ are the eigenpairs of (Σ_1, Σ_2). Then we have $\Sigma_2\Sigma_2^+\Sigma_1\mathbf{B} = \Sigma_2\mathbf{B}\Lambda$. This implies that $(\Lambda, \Sigma_2^+\Sigma_2\mathbf{B})$ are the eigenpairs of $\Sigma_2^+\Sigma_1$ due to $\Sigma_2\Sigma_2^+\Sigma_1 = \Sigma_1$ and $\Sigma_2^+\Sigma_2\Sigma_2^+ = \Sigma_2^+$.

Appendix B. Some Properties of Moore-Penrose Inverses

In order to prove Theorem 3, we will need some properties of Moore-Penrose inverses.

Lemma 11 *Let* $\mathbf{C} = \mathbf{H}\tilde{\mathbf{X}}\tilde{\mathbf{X}}'\mathbf{H}$, $\tilde{\mathbf{S}}_t = \tilde{\mathbf{X}}'\mathbf{H}\tilde{\mathbf{X}}$ *and* $\tilde{\mathbf{S}}_b = \tilde{\mathbf{X}}'\mathbf{H}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{H}\tilde{\mathbf{X}}$. *Then*

(a) $\mathbf{C}\mathbf{C}^+ = (\mathbf{C}\mathbf{C}^+)' = \mathbf{C}^+\mathbf{C}$, $\mathbf{C}^+\mathbf{C}\mathbf{C} = \mathbf{C}\mathbf{C}^+\mathbf{C} = \mathbf{C}$, $\mathbf{C}^+\mathbf{C}^+\mathbf{C} = \mathbf{C}^+\mathbf{C}\mathbf{C}^+ = \mathbf{C}^+$;

(b) $\tilde{\mathbf{S}}_t^+\tilde{\mathbf{X}}'\mathbf{H} = (\tilde{\mathbf{X}}'\mathbf{H}\mathbf{H}\tilde{\mathbf{X}})^+\tilde{\mathbf{X}}'\mathbf{H} = \tilde{\mathbf{X}}'\mathbf{H}(\mathbf{H}\tilde{\mathbf{X}}\tilde{\mathbf{X}}'\mathbf{H})^+ = \tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+$;

(c) $\tilde{\mathbf{X}}'\mathbf{H} = \tilde{\mathbf{S}}_t\tilde{\mathbf{S}}_t^+\tilde{\mathbf{X}}'\mathbf{H} = \tilde{\mathbf{X}}'\mathbf{H}\mathbf{H}\tilde{\mathbf{X}}(\tilde{\mathbf{X}}'\mathbf{H}\mathbf{H}\tilde{\mathbf{X}})^+\tilde{\mathbf{X}}'\mathbf{H}$
$= \tilde{\mathbf{X}}'\mathbf{H}(\mathbf{H}\tilde{\mathbf{X}}\tilde{\mathbf{X}}'\mathbf{H})^+\mathbf{H}\tilde{\mathbf{X}}\tilde{\mathbf{X}}'\mathbf{H} = \tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{C}$;

(d) $\tilde{\mathbf{S}}_t\tilde{\mathbf{S}}_t^+\tilde{\mathbf{S}}_b = \tilde{\mathbf{S}}_b$.

These results can be found in Lütkepohl (1996).

Appendix C. Proof of Theorem 3

First, if (Λ, Υ) is the solution of (10), we have

$$\begin{aligned}\tilde{\mathbf{S}}_b\tilde{\mathbf{X}}'\mathbf{H}\Upsilon &= \tilde{\mathbf{X}}'\mathbf{H}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon \\ &= \tilde{\mathbf{X}}'\mathbf{H}\mathbf{H}\tilde{\mathbf{X}}(\tilde{\mathbf{X}}'\mathbf{H}\mathbf{H}\tilde{\mathbf{X}})^+\tilde{\mathbf{X}}'\mathbf{H}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon \\ &= \tilde{\mathbf{S}}_t\tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \tilde{\mathbf{S}}_t\tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{C}^+\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon \\ &= \tilde{\mathbf{S}}_t\tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{C}^+\mathbf{C}\mathbf{C}\Upsilon\Lambda = \tilde{\mathbf{S}}_t\tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{C}\Upsilon\Lambda \\ &= \tilde{\mathbf{S}}_t\tilde{\mathbf{X}}'\mathbf{H}\Upsilon\Lambda.\end{aligned}$$

This implies that $\left(\Lambda, \tilde{\mathbf{X}}'\mathbf{H}\Upsilon\right)$ is the solution of (7).

Second, if (Λ, Υ) is the solution of (15), we have

$$\begin{aligned}\tilde{\mathbf{S}}_t^+\tilde{\mathbf{S}}_b\tilde{\mathbf{X}}'\mathbf{H}\Upsilon &= (\tilde{\mathbf{X}}'\mathbf{H}\mathbf{H}\tilde{\mathbf{X}})^+\tilde{\mathbf{X}}'\mathbf{H}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{H}\tilde{\mathbf{X}}\tilde{\mathbf{X}}'\mathbf{H}\Upsilon \\ &= \tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon \\ &= \tilde{\mathbf{X}}'\mathbf{H}\Upsilon\Lambda.\end{aligned}$$

This implies that $(\Lambda, \tilde{\mathbf{X}}'\mathbf{H}\Upsilon)$ is the solution of (13).

Finally, it follows from (16) that

$$(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \mathbf{C}\Upsilon\Lambda.$$

In addition, note that $(\tilde{\mathbf{S}}_t+\sigma^2\mathbf{I}_g)^{-1}\tilde{\mathbf{X}}'\mathbf{H} = \tilde{\mathbf{X}}'\mathbf{H}(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}$. Hence, we have

$$\begin{aligned}(\tilde{\mathbf{S}}_t+\sigma^2\mathbf{I}_g)^{-1}\tilde{\mathbf{S}}_b\tilde{\mathbf{X}}'\mathbf{H}\Upsilon &= (\tilde{\mathbf{S}}_t+\sigma^2\mathbf{I}_g)^{-1}\tilde{\mathbf{X}}'\mathbf{H}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon \\ &= \tilde{\mathbf{X}}'\mathbf{H}(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon \\ &= \tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{C}(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon \\ &= \tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+(\mathbf{C}+\sigma^2\mathbf{I}_n)^{-1}\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \tilde{\mathbf{X}}'\mathbf{H}\mathbf{C}^+\mathbf{C}\Upsilon \\ &= \tilde{\mathbf{X}}'\mathbf{H}\Upsilon\Lambda.\end{aligned}$$

This completes the proof of part (iii).

Appendix D. Proof of Theorem 5

We prove the final part. As for other parts, their proof can be immediately obtained from Appendix G. In terms of Algorithm 3, we have

$$\begin{aligned}\tilde{\mathbf{A}}'(\tilde{\mathbf{S}}_t+\sigma^2\mathbf{I}_g)\tilde{\mathbf{A}} &= \Upsilon'\mathbf{H}\tilde{\mathbf{X}}(\tilde{\mathbf{S}}_t+\sigma^2\mathbf{I}_g)\tilde{\mathbf{X}}'\mathbf{H}\Upsilon \\ &= \Upsilon'\mathbf{C}(\mathbf{C}+\sigma^2\mathbf{I}_n)\Upsilon = \mathbf{I}_q\end{aligned}$$

and

$$\tilde{\mathbf{A}}'\tilde{\mathbf{S}}_b\tilde{\mathbf{A}} = \Upsilon'\mathbf{C}\mathbf{E}\Pi^{-1}\mathbf{E}'\mathbf{C}\Upsilon = \Gamma_F^2.$$

Appendix E. Derivation of Equation 25

The first-order derivatives of $L(\mathbf{w}_0, \mathbf{W})$ with respect to $\mathbf{w}_0$ and $\mathbf{W}$ are given by

$$\frac{\partial L}{\partial \mathbf{w}_0} = n\mathbf{w}_0 + \mathbf{W}'\mathbf{X}'\mathbf{1}_n - \mathbf{Y}'\mathbf{1}_n,$$
$$\frac{\partial L}{\partial \mathbf{W}} = (\mathbf{X}'\mathbf{X} + \sigma^2\mathbf{I}_p)\mathbf{W} + \mathbf{X}'\mathbf{1}_n\mathbf{w}_0' - \mathbf{X}'\mathbf{Y},$$

Letting $\frac{\partial L}{\partial \mathbf{w}_0} = \mathbf{0}$, $\frac{\partial L}{\partial \mathbf{W}} = \mathbf{0}$ and $\bar{\mathbf{x}} = \frac{1}{n}\sum_{i=1}^n \mathbf{x}_i = \frac{1}{n}\mathbf{X}'\mathbf{1}_n$, we obtain

$$\begin{cases} \mathbf{w}_0 + \mathbf{W}'\bar{\mathbf{x}} = \mathbf{0} \\ n\bar{\mathbf{x}}\mathbf{w}_0' + (\mathbf{X}'\mathbf{X} + \sigma^2\mathbf{I}_p)\mathbf{W} = \mathbf{M}'\Pi^{\frac{1}{2}}\mathbf{H}_\pi \end{cases}$$

due to $\mathbf{Y}'\mathbf{1}_n = \mathbf{0}$ and $\mathbf{X}'\mathbf{Y} = \mathbf{M}'\Pi^{\frac{1}{2}}\mathbf{H}_\pi$. Further, it follows that $\mathbf{w}_0 = -\mathbf{W}\bar{\mathbf{x}}$, and hence,

$$(\mathbf{X}'\mathbf{H}\mathbf{X} + \sigma^2\mathbf{I}_p)\mathbf{W} = \mathbf{M}'\Pi^{\frac{1}{2}}\mathbf{H}_\pi$$

because of $\mathbf{X}'\mathbf{X} - n\bar{\mathbf{x}}\bar{\mathbf{x}}' = \mathbf{X}'\mathbf{H}\mathbf{X}$. We thus obtain $\mathbf{W}$ in (25). It then follows from (18) that $\mathbf{W} = \mathbf{G}$. Moreover, when $\sigma^2 = 0$, $\mathbf{W}$ reduces to the solution of the minimization problem in (26). In this case, if $\mathbf{X}'\mathbf{H}\mathbf{X}$ is singular, a standard treatment is to use the Moore-Penrose inverse $(\mathbf{X}'\mathbf{H}\mathbf{X})^+$ in (25). Such a $\mathbf{W}$ is identical with $\mathbf{G}$ in (21).

Appendix F. Proof of Theorem 8

Since $\mathbf{V}_R$ is an $c\times q$ orthogonal matrix, there exists a $c\times(c-q)$ orthogonal matrix $\mathbf{V}_2$ such that $\mathbf{V} = [\mathbf{V}_R, \mathbf{V}_2]$ is a $c\times c$ orthogonal matrix. Noting that $\mathbf{R} = \mathbf{V}_R\Gamma_R\mathbf{V}_R'$, we have $\mathbf{R}\mathbf{V}_2 = \mathbf{0}$ and $\mathbf{V}_2'\mathbf{R}\mathbf{V}_2 = \mathbf{0}$. Let $\mathbf{Q} = \mathbf{M}'\Pi^{\frac{1}{2}}\mathbf{H}_\pi\mathbf{V}_2$. Then we obtain $\mathbf{Q}'(\mathbf{X}'\mathbf{H}\mathbf{X}+\sigma^2\mathbf{I}_p)^{-1}\mathbf{Q} = \mathbf{0}$. This implies $\mathbf{Q} = \mathbf{0}$ because $(\mathbf{X}'\mathbf{H}\mathbf{X} + \sigma^2\mathbf{I}_p)^{-1}$ is positive definite. Hence, $\mathbf{W}\mathbf{V}_2 = (\mathbf{X}'\mathbf{H}\mathbf{X} + \sigma^2\mathbf{I}_p)^{-1}\mathbf{Q} = \mathbf{0}$. As a result, we have

$$\begin{aligned} \mathbf{W}\mathbf{W}' &= \mathbf{W}\mathbf{V}\mathbf{V}'\mathbf{W}' \\ &= \mathbf{W}\mathbf{V}_R\mathbf{V}_R'\mathbf{W}' + \mathbf{W}\mathbf{V}_2\mathbf{V}_2'\mathbf{W}' \\ &= \mathbf{B}\mathbf{B}'. \end{aligned}$$

Note that if $\sigma^2 = 0$ and $\mathbf{X}'\mathbf{H}\mathbf{X}$ is nonsingular, we still have $\mathbf{W}\mathbf{W}' = \mathbf{B}\mathbf{B}'$. In the case that $\mathbf{X}'\mathbf{H}\mathbf{X}$ is singular, we have $\mathbf{Q}'(\mathbf{X}'\mathbf{H}\mathbf{X})^+\mathbf{Q} = \mathbf{0}$. Since $(\mathbf{X}'\mathbf{H}\mathbf{X})^+$ is positive semidefinite, its square root matrix exists and it is denoted by Ω. It thus follows from $\mathbf{Q}'(\mathbf{X}'\mathbf{H}\mathbf{X})^+\mathbf{Q} = \mathbf{Q}\Omega\Omega\mathbf{Q}' = \mathbf{0}$ that $\Omega\mathbf{Q}' = \mathbf{0}$. This shows that $\mathbf{W}\mathbf{V}_2 = (\mathbf{X}'\mathbf{H}\mathbf{X})^+\mathbf{Q} = \mathbf{0}$. Thus, we also obtain $\mathbf{W}\mathbf{W}' = \mathbf{B}\mathbf{B}'$. The proof is complete.

Appendix G. Proof of Theorem 10

It is immediate that

$$\begin{aligned} \mathbf{X}'\mathbf{Y}\mathbf{Y}'\mathbf{X}\mathbf{T} &= \mathbf{V}_X\Gamma_X\mathbf{U}_X'\mathbf{Y}\mathbf{Y}'\mathbf{U}_X\Gamma_X\mathbf{V}_X'\mathbf{V}_X(f(\Gamma_X))^{-\frac{1}{2}}\mathbf{U}_F \\ &= \mathbf{V}_X(f(\Gamma_X))^{\frac{1}{2}}\mathbf{U}_F\Gamma_F\mathbf{V}_F'\mathbf{V}_F\Gamma_F\mathbf{U}_F'\mathbf{U}_F \\ &= \mathbf{V}_X(f(\Gamma_X))^{\frac{1}{2}}\mathbf{U}_F\Gamma_F^2 \end{aligned}$$

and

$$f(\mathbf{Q})\mathbf{T}\Lambda = \mathbf{V}\begin{bmatrix} f(\Gamma_X) & \mathbf{0} \\ \mathbf{0} & b_0\mathbf{I}_{p-r} \end{bmatrix}\mathbf{V}'\mathbf{V}_X(f(\Gamma_X))^{-\frac{1}{2}}\mathbf{U}_F\Gamma_F^2$$
$$= \mathbf{V}_X(f(\Gamma_X))^{\frac{1}{2}}\mathbf{U}_F\Gamma_F^2.$$

where $\mathbf{V} = [\mathbf{V}_X, \mathbf{V}_2]$ such that $\mathbf{V}_X'\mathbf{V}_2 = \mathbf{0}$. In addition, we have

$$\mathbf{T}'f(\mathbf{Q})\mathbf{T} = \mathbf{I}_r \quad \text{and} \quad \mathbf{T}'\mathbf{X}'\mathbf{Y}\mathbf{Y}'\mathbf{X}\mathbf{T} = \Gamma_F^2.$$

Abstract

The SGD-QN algorithm described in Bordes et al. (2009) contains a subtle flaw that prevents it from reaching its design goals. Yet the flawed SGD-QN algorithm has worked well enough to be a winner of the first Pascal Large Scale Learning Challenge (Sonnenburg et al., 2008). This document clarifies the situation, proposes a corrected algorithm, and evaluates its performance.

Keywords: stochastic gradient descent, support vector machine, conditional random fields

1. Introduction

Bordes et al. (2009) propose to improve the practical speed of stochastic gradient descent by efficiently estimating a diagonal matrix for rescaling the gradient estimates. The proposed algorithm, SGD-QN, works well enough to be a winner of the first Pascal Large Scale Learning Challenge (Sonnenburg et al., 2008). A couple months after the publication of the paper, Jonathan Chang and S. Alex Smith contacted Léon Bottou regarding some curious aspects of the algorithm mathematics (see Section 4.1). This initial observation was then traced back to a more subtle flaw that prevents the proposed algorithm to truly reach is design objectives.

We first explain the flaw and present experimental results describing its consequences. Then we present a corrected algorithm and evaluate its performance for training both linear Support Vector Machines (SVMs) and Conditional Random Fields (CRFs). Finally we draw updated conclusions.

2. Setup

Consider a binary classification problem with examples $(\mathbf{x}, y) \in \mathbb{R}^d \times \{-1,+1\}$. Given a set of examples $\{(\mathbf{x}_1, y_1) \ldots (\mathbf{x}_n, y_n)\}$, we obtain a linear SVM classifier by minimizing the cost

$$\mathcal{P}_n(\mathbf{w}) \;=\; \frac{\lambda}{2}\|\mathbf{w}\|^2 + \frac{1}{n}\sum_{i=1}^{n} \ell(y_i \mathbf{w}^\top \mathbf{x}_i) \;=\; \frac{1}{n}\sum_{i=1}^{n}\left(\frac{\lambda}{2}\|\mathbf{w}\|^2 + \ell(y_i \mathbf{w}^\top \mathbf{x}_i)\right).$$

Each iteration of the SGD-QN algorithm consists of drawing an independent random example $(\mathbf{x}_t, y_t)$ from the training set and computing an updated parameter vector

$$\mathbf{w}_{t+1} \;=\; \mathbf{w}_t - \frac{1}{t+t_0}\mathbf{B}\,\mathbf{g}_t(\mathbf{w}_t) \quad \text{with} \quad \mathbf{g}_t(\mathbf{w}_t) = \lambda \mathbf{w}_t + \ell'(y_t \mathbf{w}_t^\top \mathbf{x}_t)\, y_t\, \mathbf{x}_t \tag{1}$$

where $\mathbf{B}$ is a diagonal scaling matrix estimated on-the-fly.

In the following, expectations and probabilities refer to the discrete distribution describing the training examples randomly picked from the finite training set at each iteration. Let $\mathcal{F}_t$ denote the examples $\{(\mathbf{x}_1, y_1) \ldots (\mathbf{x}_{t-1}, y_{t-1})\}$ picked before reaching the t-th iteration.

We would like to find $\mathbf{B}$ such that

$$\mathbf{w}_{t+1} - \mathbf{w}_t = \mathbf{B}\left(\mathcal{P}_n'(\mathbf{w}_{t+1}) - \mathcal{P}_n'(\mathbf{w}_t) + \xi_t\right), \tag{2}$$

with an error term ξ_t verifying $\mathbb{E}[\xi_t | \mathcal{F}_t] = 0$. Following Schraudolph et al. (2007), we replace the computationally expensive gradients $\mathcal{P}_n'$ by the cheap stochastic estimates $\mathbf{g}_\tau(\mathbf{w}_t)$ and $\mathbf{g}_\tau(\mathbf{w}_{t+1})$ computed on a same single example $(\mathbf{x}_\tau, y_\tau)$,

$$\mathbf{w}_{t+1} - \mathbf{w}_t = \mathbf{B}\left(\mathbf{g}_\tau(\mathbf{w}_{t+1}) - \mathbf{g}_\tau(\mathbf{w}_t) + \zeta_t + \xi_t\right), \tag{3}$$

where ζ_t represents the additional error term introduced by this substitution. Estimating B with (2) or (3) leads to the same solution if we make sure that $\mathbb{E}[\zeta_t | \mathcal{F}_t] = 0$ as well.

The SGD-QN algorithm updates the diagonal elements of matrix $\mathbf{B}$ on-the-fly on the basis of the term-by-term ratios of the observed differences $\mathbf{w}_{t+1} - \mathbf{w}_t$ and $\mathbf{g}_\tau(\mathbf{w}_{t+1}) - \mathbf{g}_\tau(\mathbf{w}_t)$. The obvious choices $\tau = t$ and $\tau = t+1$ only require one additional gradient evaluation because the parameter update formula (1) demands the computation of all the gradients $\mathbf{g}_t(\mathbf{w}_t)$ anyway.

3. The Flaw

Let us now evaluate

$$\mathbb{E}[\zeta_t | \mathcal{F}_t] = \mathbb{E}\left[\mathcal{P}_n'(\mathbf{w}_{t+1}) - \mathcal{P}_n'(\mathbf{w}_t) - \mathbf{g}_\tau(\mathbf{w}_{t+1}) + \mathbf{g}_\tau(\mathbf{w}_t) \middle| \mathcal{F}_t\right].$$

Let us first consider the case $\tau = t+1$. Since $\mathbf{g}_{t+1}(\mathbf{w}_{t+1})$ is a function of $(\mathbf{x}_{t+1}, y_{t+1}, \mathbf{x}_t, y_t, \mathcal{F}_t)$,

$$\begin{aligned}
\mathbb{E}[\mathbf{g}_\tau(\mathbf{w}_{t+1}) | \mathcal{F}_t] &= \int \mathbf{g}_{t+1}(\mathbf{w}_{t+1})\, dP(\mathbf{x}_{t+1}, y_{t+1}, \mathbf{x}_t, y_t \,|\, \mathcal{F}_t) \\
&= \int \left[\int \mathbf{g}_{t+1}(\mathbf{w}_{t+1})\, dP(\mathbf{x}_{t+1}, y_{t+1})\right] dP(\mathbf{x}_t, y_t \,|\, \mathcal{F}_t).
\end{aligned}$$

Since the variables $\mathbf{w}_{t+1}$ and $(\mathbf{x}_{t+1}, y_{t+1})$ are independent, the inner integral above is simply the average of $\mathbf{g}_{t+1}(\mathbf{w}_{t+1})$ for all possible $(\mathbf{x}_{t+1}, y_{t+1})$ picked from the training set. Therefore

$$\mathbb{E}\left[\mathbf{g}_\tau(\mathbf{w}_{t+1}) \middle| \mathcal{F}_t\right] \;=\; \int \mathcal{P}'_n(\mathbf{w}_{t+1})\, dP(\mathbf{x}_t, y_t \,|\, \mathcal{F}_t) \;=\; \mathbb{E}\left[\mathcal{P}'_n(\mathbf{w}_{t+1}) \middle| \mathcal{F}_t\right].$$

Using a similar derivation for $\mathbb{E}\left[\mathbf{g}_\tau(\mathbf{w}_t) \middle| \mathcal{F}_t\right]$ with $\tau = t+1$, we can easily establish that $\mathbb{E}\left[\zeta_t \middle| \mathcal{F}_t\right] = 0$. Therefore estimating $\mathbf{B}$ on the basis of (3) leads to the same solution as estimating $\mathbf{B}$ on the basis of (2), albeit with a higher noise level.

Such a derivation is impossible when $\tau = t$ because $(\mathbf{x}_t, y_t)$ and $\mathbf{w}_{t+1}$ are not independent. Therefore we cannot ensure that estimating $\mathbf{B}$ with (2) or (3) leads to the same result. Unfortunately, the SGD-QN paper (see Section 5.3 of Bordes et al., 2009) describes the algorithm with $\tau = t$.

4. The Consequences

In order to take maximal advantage of sparse data sets, the Flawed SGD-QN algorithm (see Figure 2 in the original paper) splits the stochastic parameter update (1) in two halves in order to schedule them separately. The first half involves only the gradient of the loss,

$$\mathbf{w} \leftarrow \mathbf{w} - (t+t_0)^{-1} \mathbf{B}\, \ell'(y_t\, \mathbf{w}^\top \mathbf{x}_t)\, y_t\, \mathbf{x}_t\,.$$

The second half involves only the gradient of the regularization term,

$$\mathbf{w} \leftarrow \begin{cases} \mathbf{w} & \text{most of the time,} \\ \mathbf{w} - \mathtt{skip}\, \lambda\, (t+t_0)^{-1} \mathbf{B}\, \mathbf{w} & \text{once every } \mathtt{skip} \text{ iterations.} \end{cases}$$

The Flawed SGD-QN algorithm measures the differences $\mathbf{w}_{t+1} - \mathbf{w}_t$ and $\mathbf{g}_t(\mathbf{w}_{t+1}) - \mathbf{g}_t(\mathbf{w}_t)$ during iterations for which the second half does nothing. Therefore, using notations $[\mathbf{x}]_i$ for the i-th coefficient of vector $\mathbf{x}$, and B_{ii} for the terms of the diagonal matrix $\mathbf{B}$, we always have

$$\frac{[\mathbf{g}_t(\mathbf{w}_{t+1}) - \mathbf{g}_t(\mathbf{w}_t)]_i}{[\mathbf{w}_{t+1} - \mathbf{w}_t]_i} \;=\; \lambda - \frac{\left(\ell'(y_t \mathbf{w}_{t+1}^\top \mathbf{x}_t) - \ell'(y_t \mathbf{w}_t^\top \mathbf{x}_t)\right) y_t\, [\mathbf{x}_t]_i}{B_{ii}\, (t+t_0)^{-1} \ell'(y_t \mathbf{w}^\top \mathbf{x}_t)\, y_t\, [\mathbf{x}_t]_i}\,.$$

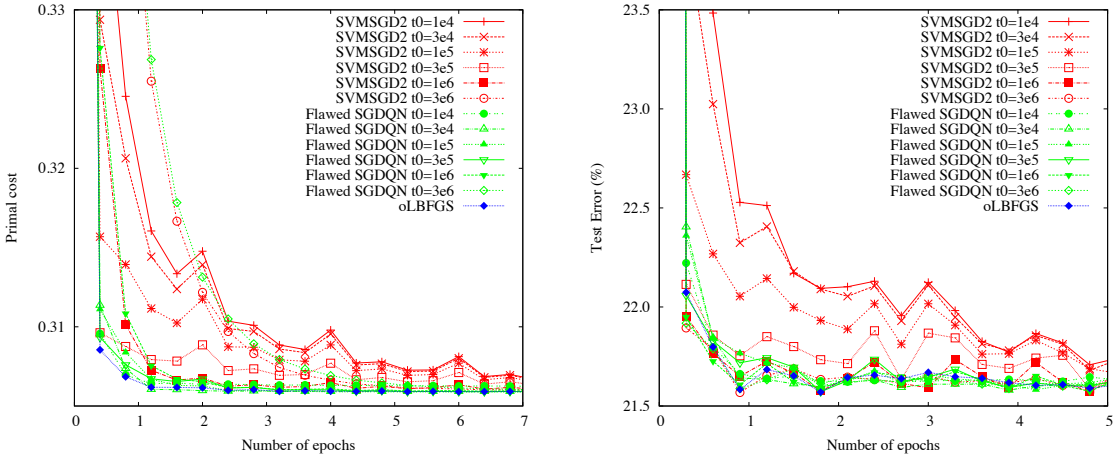
- When $[\mathbf{x}_t]_i$ is nonzero, we can simplify this expression as

$$\frac{[\mathbf{g}_t(\mathbf{w}_{t+1}) - \mathbf{g}_t(\mathbf{w}_t)]_i}{[\mathbf{w}_{t+1} - \mathbf{w}_t]_i} \;=\; \lambda - \frac{\ell'(y_t \mathbf{w}_{t+1}^\top \mathbf{x}_t) - \ell'(y_t \mathbf{w}_t^\top \mathbf{x}_t)}{B_{ii}\, (t+t_0)^{-1} \ell'(y_t \mathbf{w}_t^\top \mathbf{x}_t)}\,. \tag{4}$$

  This ratio is always greater than λ because of the loss function ℓ is convex. As explained in the original paper, the coefficients B_{ii} then remain smaller than λ^{-1}.

- When $[\mathbf{x}_t]_i$ is zero, the original paper uses a continuity argument to justify the equality

$$\frac{[\mathbf{g}_t(\mathbf{w}_{t+1}) - \mathbf{g}_t(\mathbf{w}_t)]_i}{[\mathbf{w}_{t+1} - \mathbf{w}_t]_i} \;=\; \lambda. \tag{5}$$



DELTA DATA SET

Figure 1: Plots of the training cost and test misclassification percentage versus the number of epochs for SVMSGD2 (red) and Flawed SGD-QN (green) for various values of t_0 on the dense Delta data set. The Flawed SGD-QN algorithm never outperforms the best SVMSGD2.

4.1 Impact on Dense Data Sets

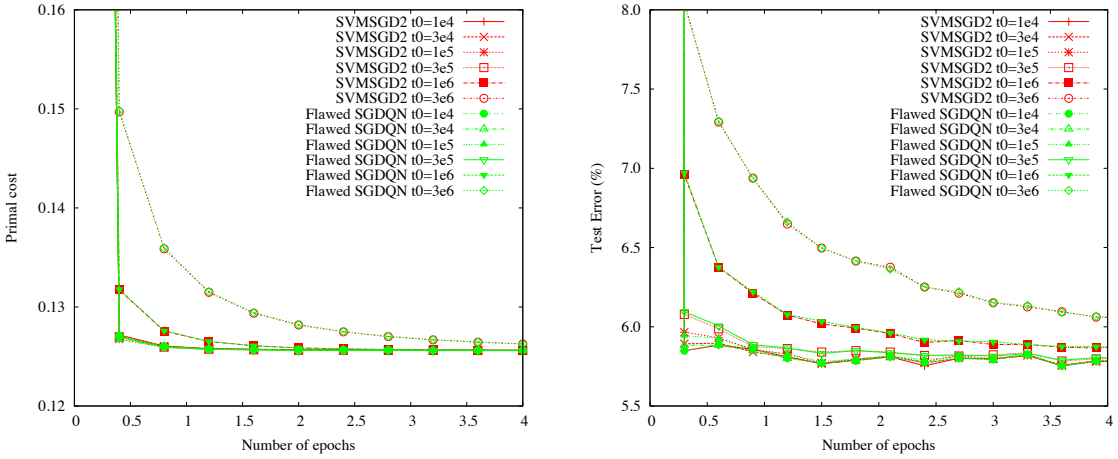
The coefficients $[\mathbf{x}_t]_i$ for dense data sets are rarely zero. Assume all the B_{ii} are equal before being updated. All the ratios (4) will then be equal. Therefore all the B_{ii} coefficients will be updated in exactly the same way and therefore remain equal. Since the B_{ii} coefficients are initially equal, they *remain equal all the time*, except maybe when encountering an occasional zero in the patterns $\mathbf{x}_t$. This observation led to the discovery of the flaw.

Since the scaling matrix reduces to a scalar gain, similar results could in principle be obtained using the ordinary stochastic gradient descent with a better gain schedule. This clearly defeats the purpose of the SGD-QN algorithm design.

Figure 1 compares the evolutions of the training cost and the test misclassification error for the SVMSGD2 and the Flawed SGD-QN algorithms for selected values of the parameter t_0 instead of the usual heuristic defaults. We observe that there is almost always a choice of t_0 in SVMSGD2 that performs as well as the best choice of t_0 for the Flawed SGD-QN. Both algorithms perform identically poorly for excessive values of t_0. On the other hand, when t_0 is too small, the performance of Flawed SGD-QN degrades much more gracefully than the performance of SVMSGD2. In some cases, Flawed SGD-QN can even slightly outperforms SVMSGD2 because, despite the flaw, it can still update its learning rate on the course of learning. This explains partially why we have consistently obtained better results with the flawed algorithm.

4.2 Impact on Sparse Data Sets

The situation is more complex in the case of sparse data sets because there is special case for updating the B_{ii} coefficients when dealing with zero coefficients (5). As a result, the Flawed SGD-QN algorithm gives higher values to the scaling coefficients B_{ii} when the i-th feature is more likely



RCV1 DATA SET

Figure 2: Plots of the training cost and test misclassification error versus the number of epochs for both SVMSGD2 (red) and Flawed SGD-QN (green) running on the RCV1 data set. Both algorithms reach optimal performance after seeing half the training set.

to be zero. Since this is a sensible scaling for such data sets, the Flawed SGD-QN algorithm works relatively well in the presence of sparse features.

Figure 2 compares the SVMSGD2 and Flawed SGD-QN algorithms for many choices for the t_0 parameter on the Reuters RCV1 data set. Unfortunately there is nothing to see there. Both algorithms reach optimal performance after processing only one half of the training set.

In order to find a more challenging sparse data set, we have adapted both the SVMSGD2 and the Flawed SGD-QN algorithms for the optimization of Conditional Random Fields (Lafferty et al., 2001). This is an interesting case where preconditioning is difficult because the features are generated on the fly on the basis of position-independent templates.

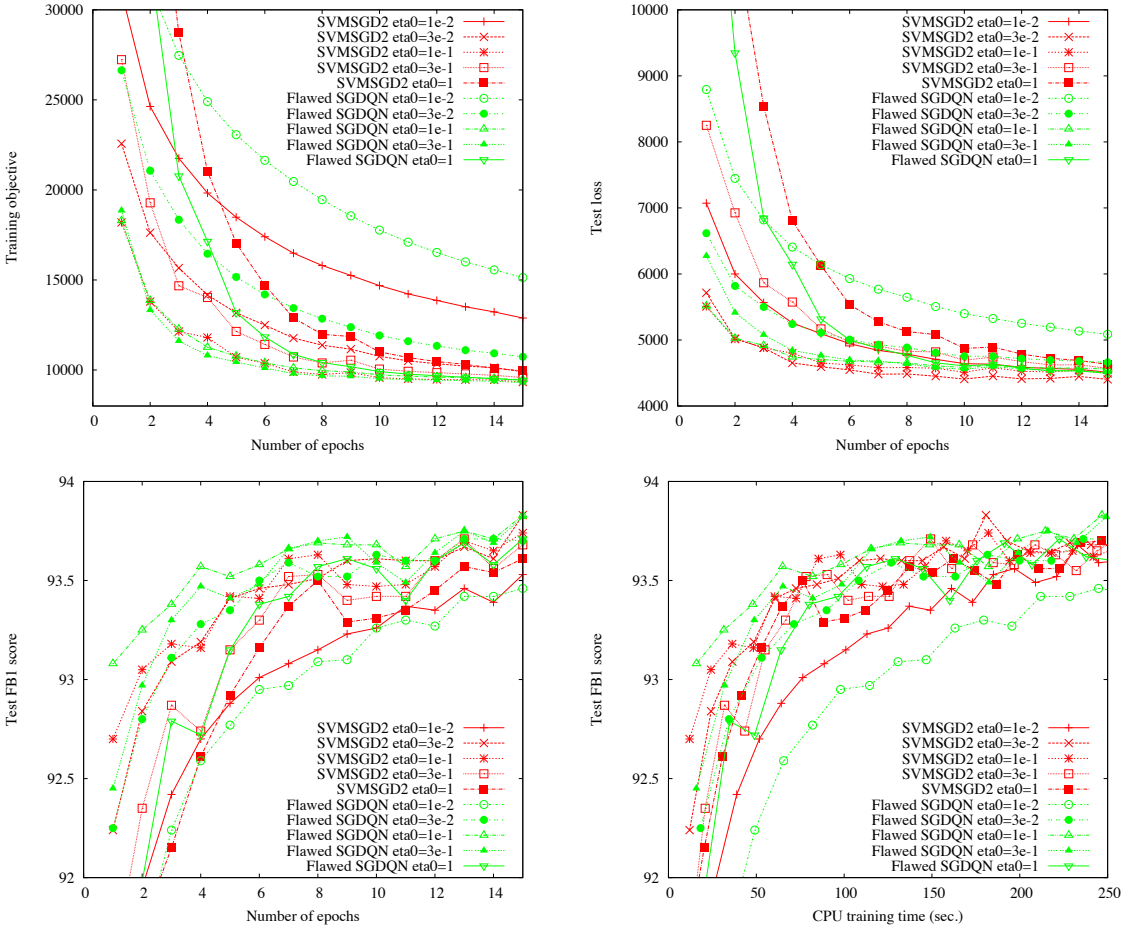
Figure 3 compares the algorithms on the CoNLL 2000 "chunking" task (Sang and Buchholz, 2000) using the template setup provided as an example with the CRF++ code (Kudo, 2007). The Flawed SGD-QN algorithm reaches the best test performance after less epochs than the SVMSGD2 algorithm, but this does not translate into a large improvement in terms of training time.

5. Correcting SGD-QN

At first glance, correcting SGD-QN simply involves computing the difference $\mathbf{g}_\tau(\mathbf{w}_{t+1}) - \mathbf{g}_\tau(\mathbf{w}_t)$ with $\tau = t+1$ instead of $\tau = t$. In fact, during the weeks preceding the Pascal challenge deadline, we tried both versions and found that picking $\tau = t+1$ performs significantly worse!

5.1 The Failure of the Straightforward Fix

When experimenting with the oLBFGS algorithm (Schraudolph et al., 2007), we observed and reported that setting the global learning gain was very difficult. We encounter the same difficulty when we modify the SGD-QN algorithm to use $\tau = t+1$.



CRF ON THE CONLL 2000 CHUNKING TASK

Figure 3: Plots of the training cost, test loss, and test F1 score for a CRF trained using both SVMSGD2 (red) and Flawed SGD-QN (green) for various initial rates $\eta_0 = \frac{1}{\lambda t_0}$.

In order to form an intuition about the learning rate, we must pay attention to its influence on the stochastic noise. Stochastic gradient descent with a constant learning rate generates a cloud of parameter estimates $\mathbf{w}_t$ covering a zone whose extent is defined by the learning rate and by the curvature of the cost function. When the rates decrease with an appropriate speed, this zone shrinks around the solution. Rewriting (1) term-by-term gives

$$[\mathbf{w}_{t+1}]_i \;=\; [\mathbf{w}_t]_i - \eta_{i,t}^{\text{flawQN}} \, [\mathbf{g}_t(\mathbf{w}_t)]_i \quad \text{with} \quad \eta_{i,t}^{\text{flawQN}} = \frac{B_{ii}}{t_0 + t} \,. \tag{6}$$

Since the algorithm periodically adapts B_{ii} on the basis of the observed differences $\mathbf{w}_{t+1} - \mathbf{w}_t$ and $\mathbf{g}_{t+1}(\mathbf{w}_{t+1}) - \mathbf{g}_{t+1}(\mathbf{w}_t)$, the sequence of learning rates $\eta_{i,t}^{\text{flawQN}}$ can occasionally increase. This is confirmed by the middle plot of Figure 5 which displays the evolution of the learning rates $\frac{B_{ii}}{t_0+t}$ for SGD-QN implementing this straightforward fix. Such fluctuations are the source of the difficulty.

5.2 Managing the Speed of the Learning Rate Decrease

The schedule with which the learning rate decreases during training appears to be a key factor, so we propose to fix SGD-QN by using the second-order information to manage this diminution. Hence, we use learning rates of the form

$$\eta_{i,t}^{\text{corQN}} = \left(\lambda t_0 + \sum_{k=1}^{t-1} r_{i,k} \right)^{-1} \quad \text{where} \quad r_{i,t} = \frac{[\mathbf{g}_{t+1}(\mathbf{w}_{t+1}) - \mathbf{g}_{t+1}(\mathbf{w}_t)]_i}{[\mathbf{w}_{t+1} - \mathbf{w}_t]_i} \,. \tag{7}$$

When t becomes large, we recover an expression comparable to the original formulation (6), $\eta_{i,t}^{\text{corQN}} = \frac{\bar{r}_i^{-1}}{\lambda t_0 \bar{r}_i^{-1} + t} + \mathrm{o}\left(\frac{1}{t}\right)$, where $\bar{r}_i$ denotes the average value of the ratios $r_{i,t}$ and can be viewed as the coefficient of a diagonal matrix $\mathbf{R}$ such that $\mathbf{R}\left(\mathbf{w}_{t+1} - \mathbf{w}_t\right) = \mathbf{g}_\tau(\mathbf{w}_{t+1}) - \mathbf{g}_\tau(\mathbf{w}_t) + \zeta_t + \xi_t$.

It is also interesting to compare the formula $\eta_{i,t}^{\text{corQN}}$ with the first order version $\eta_{i,t}^{\text{SGD}} = \frac{1}{\lambda t_0 + \sum_{k=1}^{t} \lambda}$ which decreases the learning rate after each iteration by adding λ to the denominator. Instead of adding a lower bound of the curvature, the proposed learning rate formula adds a stochastic estimate of the curvature.

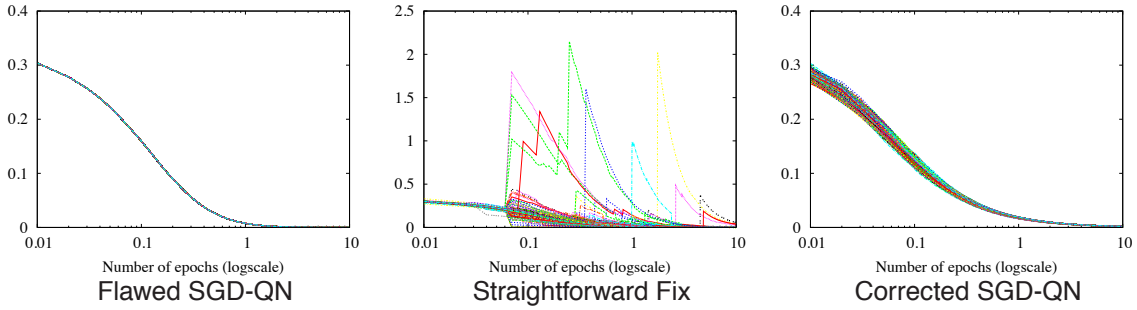

Figure 5: Plots of the learning rates corresponding to each feature on the course of learning on the Delta data set. All rates are equal for Flawed SGD-QN (left plot). As explained in Section 5.1, implementing the straightforward fix (middle plot) causes rates to alternatively increase or decrease very fast. The Corrected SGD-QN (right plot) proposes learning rates nicely decreasing at different speeds for each feature.

Interestingly, Equation (7) leads to a convenient recursive formula

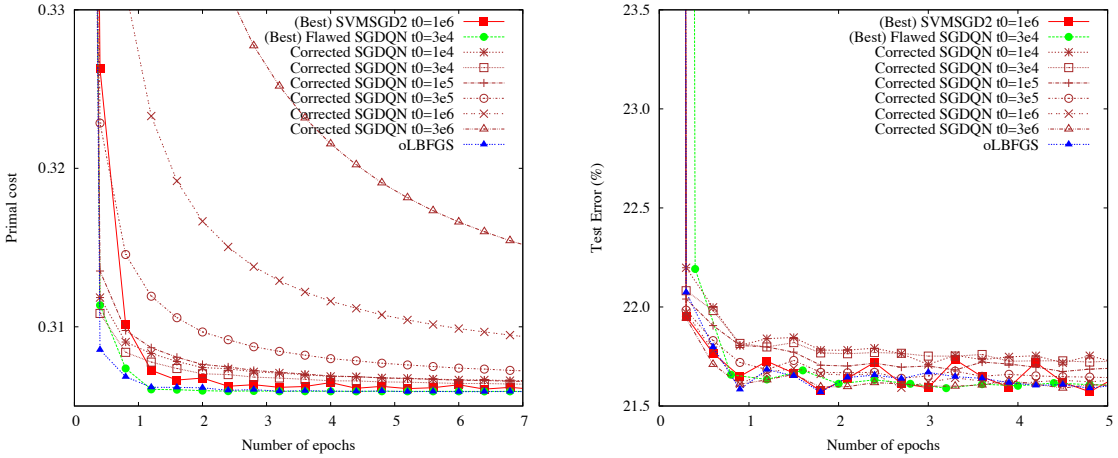
$$\eta_{i,t}^{\text{corQN}} = \left(\frac{1}{\eta_{i,t-1}^{\text{corQN}}} + r_{i,t-1} \right)^{-1} = \frac{\eta_{i,t-1}^{\text{corQN}}}{1 + r_{i,t-1}\, \eta_{i,t-1}^{\text{corQN}}} . \tag{8}$$

Figure 4 describes the Corrected SGD-QN algorithm and compares it with a slightly reorganized version of the Flawed SGD-QN algorithm. The diagonal matrix $\mathbf{B}$ is used to store the gains (7). The algorithm schedules a gain update (line 14) whenever it performs a regularization update (line 16). During the next iteration, the algorithm computes $r_{i,t-1}$ (line 6) and implements the learning rate update (8) with an additional multiplicative factor (line 8) because this only happens every `skip` iterations. The effect on the learning rates of using Corrected SGD-QN instead of Flawed SGD-QN is illustrated by Figure 5 if we compare the left and the right plots.

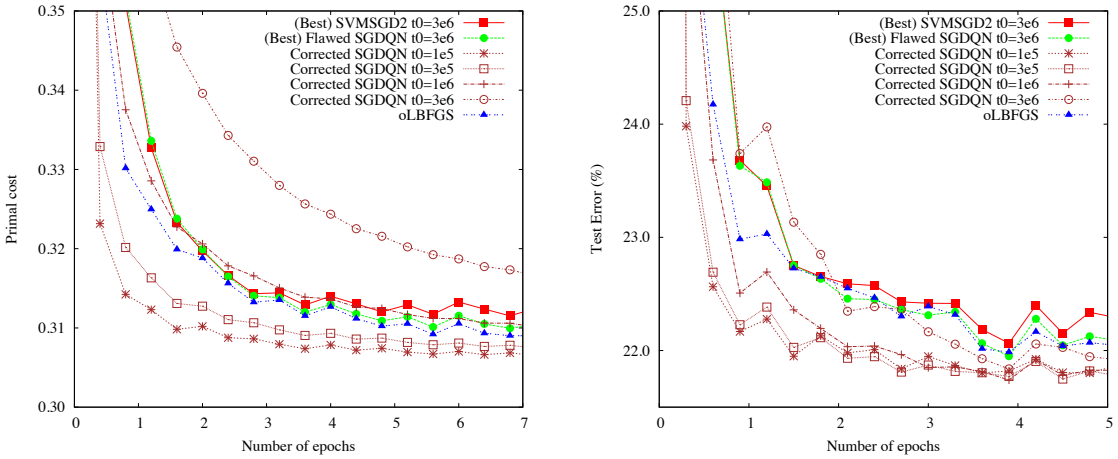
5.3 Performances on Dense Data Sets

Figure 6 (top row) compares the performances of Corrected SGD-QN with the best results of Flawed SGD-QN and SVMSGD2 on the Delta data set. We must recognize that the improvement is minimal. Before running the SGD algorithms, we always precondition the dense data sets by centering all the features, normalizing their variances, and rescaling every example to ensure that $\|\mathbf{x}_k\| = 1$. This operation in fact steals all the improvements SGD-QN can bring. With its adaptive learning rates, the Corrected SGD-QN does not perform worse than the first order SVMSGD2 algorithm. Yet, implementing a strategy involving a single learning rate for all the features appears already very rewarding and, for such cases, the Flawed SGD-QN algorithm is a strong choice because of its capacity to adapt its learning rate.

Corrected SGD-QN should be more efficient for ill-conditioned data. To illustrate this assertion, we created a "deconditioned" version of Delta by applying the usual normalization procedures and then multiplying every tenth feature by twelve. Figure 6 (bottom row) compares the performances of SVMSGD2, Flawed SGD-QN and Corrected SGD-QN on this deconditioned data. The Flawed



DELTA DATA SET (NORMALIZED)



DELTA DATA SET (DECONDITIONED)

Figure 6: Plots of the training cost and test misclassification error versus the number of epochs for SVMSGD2 (red) and Flawed SGD-QN (green) with their optimal t_0 parameter, and Corrected SGD-QN (brown) running on the Delta data set. Both *normalized* (top) and *deconditioned* (bottom) cases are considered; see the text for details. All methods can perform roughly identically well on normalized examples but only the Corrected SGD-QN algorithm is able to handle ill-conditioned data.

SGD-QN algorithm clearly suffers from the deconditioning operation because it can not assign a different learning rate per feature. The Corrected SGD-QN works much better. We also verified that the estimated learning rates replicate the deconditioning pattern.

In conclusion, on *dense data sets*, the Corrected SGD-QN bring little improvement over those associated with a *good preconditioning technique*. Preconditioning was probably the main reason of the good SGD-QN results on dense data sets in the Pascal Large Scale Challenge. This does not

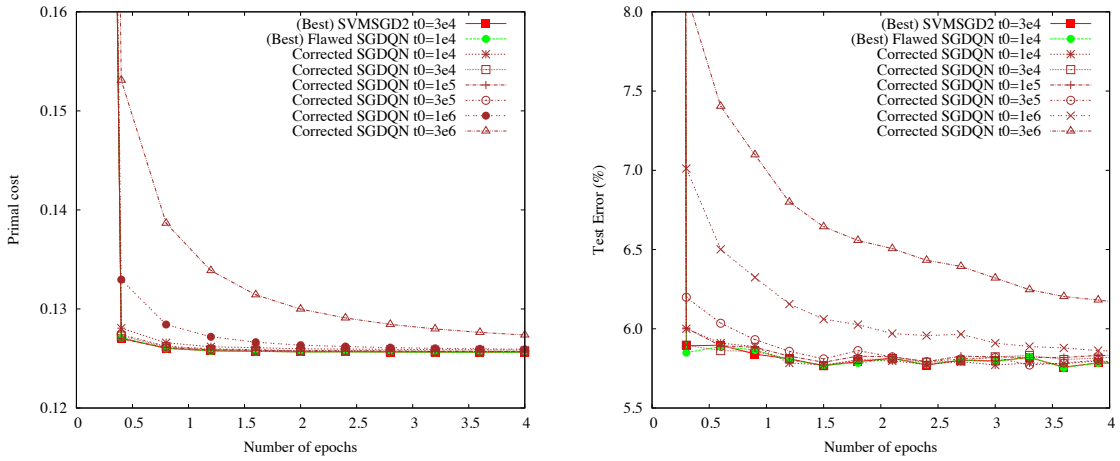


Figure 7: Plots of the training cost and test error versus the number of epochs for SVMSGD2 (red) and Flawed SGD-QN (green) with their optimal t_0 parameter, and Corrected SGD-QN (brown) running on the RCV1 data set. All algorithms quickly reach optimal performance.

mean that SGD algorithms cannot be improved. Xu (2010) reports impressive results on Linear SVMs using a well sorted Averaged SGD algorithm (Polyak and Juditsky, 1992).

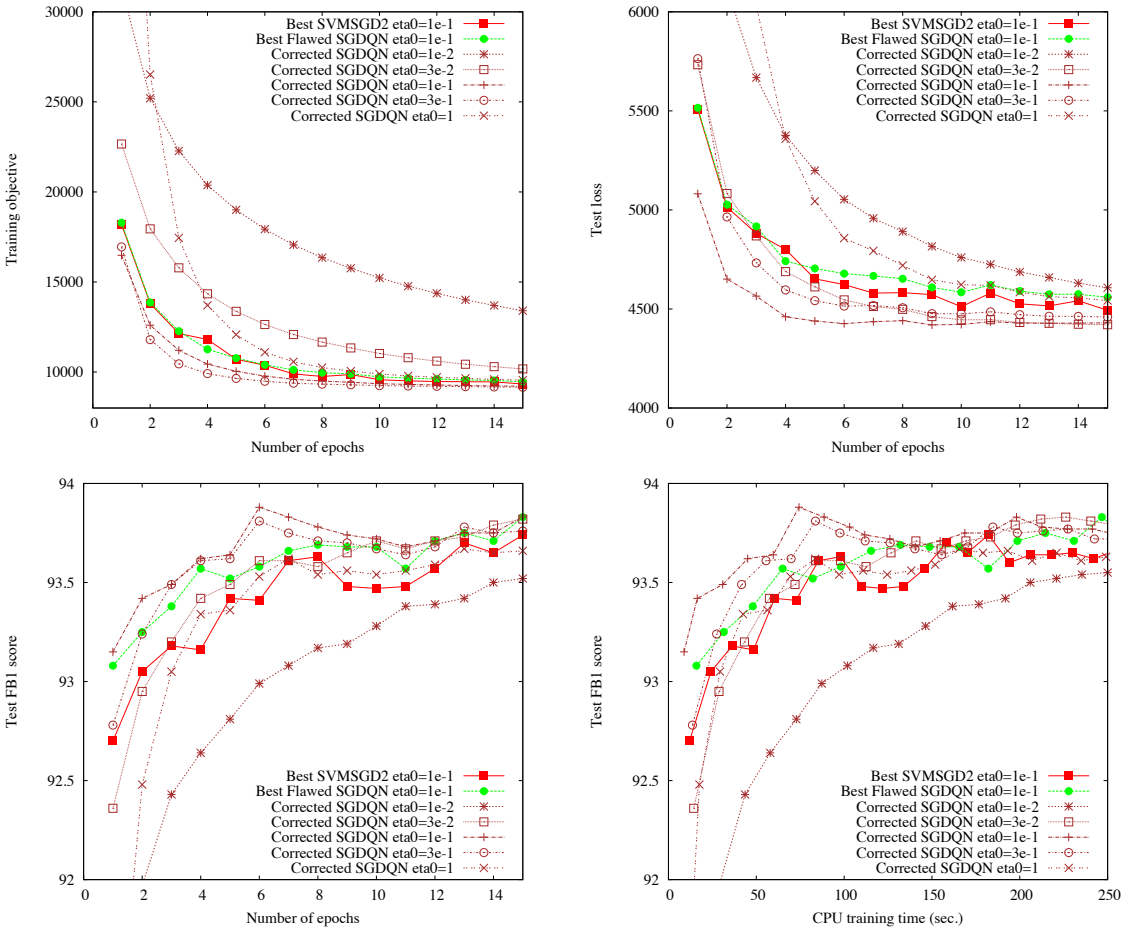
5.4 Performances on Sparse Data Sets

Preconditioning sparse data sets is much more difficult because it is impossible to center sparse features and keep them sparse. In addition, normalizing the variance of very rare features generates a small number of coefficients with high values. This fat tail distribution usually has very negative impact on the test performance. Figure 7 compares the SVMSGD2, Flawed SGD-QN and Corrected SGD-QN algorithms on the Reuters RCV1 data set, but, as we explained for Figure 2, this task is too easy to draw any conclusions.

Figure 8 then compares the adaptations of SVMSGD2, Flawed SGD-QN (with their best parameters) and Corrected SGD-QN for Conditional Random Fields on the CoNLL 2000 "chunking" task with the setup described in Section 4.2. The Corrected SGD-QN algorithm achieves its optimal test performance after only 75 seconds while SVMSGD2 and Flawed SGD-QN need around twice this time. For comparison, the CRF++ LBFGS optimizer needs 4300 seconds on a slightly faster machine.

6. Conclusion

Despite its flaw, the original SGD-QN algorithm works well enough to be a winner of the first PASCAL Large Scale Learning Challenge (Sonnenburg et al., 2008) because it benefits from our careful preconditioning and handles sparse examples efficiently. However, as explained in this document, this original version often does not achieve the full benefits of a diagonal scaling approach.



CRF ON THE CONLL 2000 CHUNKING TASK

Figure 8: Plots of the training cost, test loss, and test F1 score for a CRF trained using the best setups of SVMSGD2 (red) and Flawed SGD-QN (green), and Corrected SGD-QN for various initial rates $\eta_0 = \frac{1}{\lambda t_0}$ (brown). Corrected SGD-QN learns significantly faster.

This paper proposes a correction. Unlike the original SGD-QN algorithm, the Corrected SGD-QN algorithm discovers sensible diagonal scaling coefficients. However, experiments on dense data sets of intermediate dimensionality show that similar speed improvements can be achieved by simple preconditioning techniques such as normalizing the means and the variances of each feature and normalizing the length of each example. On the other hand, normalization is not always an attractive strategy. The Corrected SGD-QN algorithm then becomes interesting because it can adapt automatically to skewed feature distributions (see Section 5.3) or very sparse data (see Section 5.4.)

Abstract

Methods based on ℓ_1-relaxation, such as basis pursuit and the Lasso, are very popular for sparse regression in high dimensions. The conditions for success of these methods are now well-understood: (1) exact recovery in the noiseless setting is possible if and only if the design matrix X satisfies the restricted nullspace property, and (2) the squared ℓ_2-error of a Lasso estimate decays at the minimax optimal rate $\frac{k \log p}{n}$, where k is the sparsity of the p-dimensional regression problem with additive Gaussian noise, whenever the design satisfies a restricted eigenvalue condition. The key issue is thus to determine when the design matrix X satisfies these desirable properties. Thus far, there have been numerous results showing that the restricted isometry property, which implies both the restricted nullspace and eigenvalue conditions, is satisfied when all entries of X are independent and identically distributed (i.i.d.), or the rows are unitary. This paper proves directly that the restricted nullspace and eigenvalue conditions hold with high probability for quite general classes of Gaussian matrices for which the predictors may be highly dependent, and hence restricted isometry conditions can be violated with high probability. In this way, our results extend the attractive theoretical guarantees on ℓ_1-relaxations to a much broader class of problems than the case of completely independent or unitary designs.

1. Introduction

Many fields in modern science and engineering—among them computational biology, astrophysics, medical imaging, natural language processing, and remote sensing—involve collecting data sets in which the dimension of the data p exceeds the sample size n. Problems of statistical inference in this high-dimensional setting have attracted a great deal of attention in recent years. One concrete instance of a high-dimensional inference problem concerns the standard linear regression model, in which the goal is to estimate a vector $\beta^* \in \mathbb{R}^p$ that connects a real-valued response y to a vector of covariates $X = (X_1, \ldots, X_p)$. In the setting $p \gg n$, the classical linear regression model is unidentifiable, so that it is not meaningful to estimate the parameter vector $\beta^* \in \mathbb{R}^p$. However, many high-dimensional regression problems exhibit special structure that can lead to an identifiable model. In particular, sparsity in the regression vector β^* is an archetypal example of such struc-

*. Also in the Department of Electrical Engineering & Computer Science.

ture, and there is now a substantial and rapidly growing body of work on high-dimensional linear regression with sparsity constraints.

Using the ℓ_1-norm to enforce sparsity has been very successful, as evidenced by the widespread use of methods such as basis pursuit (Chen et al., 1998), the Lasso (Tibshirani, 1996) and the Dantzig selector (Candes and Tao, 2007). There is now a well-developed theory on what conditions are required on the design matrix $X \in \mathbb{R}^{n \times p}$ for such ℓ_1-based relaxations to reliably estimate β^*. In the case of noiseless observation models, it is known that imposing a *restricted nullspace property* on the design matrix $X \in \mathbb{R}^{n \times p}$ is both necessary and sufficient for the basis pursuit linear program to recover β^* exactly. The nullspace property and its link to the basis pursuit linear program has been discussed in various papers (Cohen et al., 2009; Donoho and Huo, 2001; Feuer and Nemirovski, 2003). In the case of noisy observations, exact recovery of β^* is no longer possible, and one goal is to obtain an estimate $\widehat{\beta}$ such that the ℓ_2-error $\|\widehat{\beta} - \beta^*\|_2$ is well-controlled. To this end, various sufficient conditions for the success of ℓ_1-relaxations have been proposed, including restricted eigenvalue conditions (Bickel et al., 2009; Meinshausen and Yu, 2009) and the restricted Riesz property (Zhang and Huang, 2008). Of the conditions mentioned, one of weakest known sufficient conditions for bounding ℓ_2-error are the restricted eigenvalue (RE) conditions due to Bickel et al. (2009) and van de Geer (2007). In this paper, we consider a restricted eigenvalue condition that is essentially equivalent to the RE condition in Bickel et al. (2009). As shown by Raskutti et al. (2009), a related restriction is actually necessary for obtaining good control on the ℓ_2-error in the minimax setting.

Thus, in the setting of linear regression with random design, the interesting question is the following: for what ensembles of design matrices do the restricted nullspace and eigenvalue conditions hold with high probability? To date, the main routes to establishing these properties have been via either incoherence conditions (Donoho and Huo, 2001; Feuer and Nemirovski, 2003) or via the restricted isometry property (Candes and Tao, 2005), both of which are sufficient but not necessary conditions (Cohen et al., 2009; van de Geer and Buhlmann, 2009). The restricted isometry property (RIP) holds with high probability for various classes of random matrices with i.i.d. entries, including sub-Gaussian matrices (Mendelson et al., 2008) with sample size $n = \Omega(k \log(p/k))$, and for i.i.d. subexponential random matrices (Adamczak et al., 2009) provided that $n = \Omega(k \log^2(p/k))$. It has also been demonstrated that RIP is satisfied for matrices from unitary ensembles (e.g., Guédon et al., 2007, 2008; Romberg, 2009; Rudelson and Vershynin, 2008), for which the rows are generated based on independent draws from a set of uncorrelated basis functions.

Design matrices based on i.i.d. or unitary ensembles are well-suited to the task of compressed sensing (Candes and Tao, 2005; Donoho, 2006), where the matrix X can be chosen by the user. However, in most of machine learning and statistics, the design matrix is not under control of the statistician, but rather is specified by nature. As a concrete example, suppose that we are fitting a linear regression model to predict heart disease on the basis of a set of p covariates (e.g., diet, exercise, smoking). In this setting, it is not reasonable to assume that the different covariates are i.i.d. or unitary—for instance, one would expect a strong positive correlation between amount of exercise and healthiness of diet. Nonetheless, at least in practice, ℓ_1-methods still work very well in settings where the covariates are correlated and non-unitary, but currently lacking is the corresponding theory that guarantees the performance of ℓ_1-relaxations for dependent designs.

The main contribution of this paper is a direct proof that both the restricted nullspace and eigenvalue conditions hold with high probability for a broad class of dependent Gaussian design matrices. In conjunction with known results on ℓ_1-relaxation, our main result implies as corollaries that the

basis pursuit algorithm reliably recovers β^* exactly in the noiseless setting, and that in the case of observations contaminated by Gaussian noise, the Lasso and Dantzig selectors produces a solution $\widehat{\beta}$ such that $\|\widehat{\beta} - \beta^*\|_2 = O(\sqrt{\frac{k \log p}{n}})$. Our theory requires that the sample size n scale as $n = \Omega(k \log p)$, where k is the sparsity index of the regression vector β^* and p is its dimensions. For sub-linear sparsity ($k/p \to 0$), this scaling matches known optimal rates in a minimax sense for the sparse regression problem (Raskutti et al., 2009), and hence cannot be improved upon by any algorithm. The class of matrices covered by our result allows for correlation among different covariates, and hence covers many matrices for which restricted isometry or incoherence conditions fail to hold but the restricted eigenvalue condition holds. Interestingly, one can even sample the rows of the design matrix X from a multivariate Gaussian with a degenerate covariance matrix Σ, and nonetheless, our results still guarantee that the restricted nullspace and eigenvalue conditions will hold with high probability (see Section 3.3). Consequently, our results extend theoretical guarantees on ℓ_1-relaxations with optimal rates of convergence to a much broader class of random designs.

The remainder of this paper is organized as follows. We begin in Section 2 with background on sparse linear models, the basis pursuit and Lasso ℓ_1-relaxations, and sufficient conditions for their success. In Section 3, we state our main result, discuss its consequences for ℓ_1-relaxations, and illustrate it with some examples. Section 4 contains the proof of our main result, which exploits Gaussian comparison inequalities and concentration of measure for Lipschitz functions.

2. Background

We begin with background on sparse linear models and sufficient conditions for the success of ℓ_1-relaxations.

2.1 High-dimensional Sparse Models and ℓ_1-relaxation

In the classical linear model, a scalar output $y_i \in \mathbb{R}$ is linked to a p-dimensional vector $X_i \in \mathbb{R}^p$ of covariates via the relation $y_i = X_i^T \beta^* + w_i$, where w_i is a scalar observation noise. If we make a set of n such observations, then they can be written in the matrix-vector form

$$y \quad = \quad X\beta^* + w, \tag{1}$$

where $y \in \mathbb{R}^n$ is the vector of outputs, the matrix $X \in \mathbb{R}^{n \times p}$ is the set of covariates (in which row $X_i \in \mathbb{R}^p$ represents the covariates for i^{th} observation), and $w \in \mathbb{R}^n$ is a noise vector where $w \sim \mathcal{N}(0, \sigma^2 I_{n \times n})$. Given the pair (y, X), the goal is to estimate the unknown regression vector $\beta^* \in \mathbb{R}^p$.

In many applications, the linear regression model is high-dimensional in nature, meaning that the number of observations n may be substantially smaller than the number of covariates p. In this $p \gg n$ regime, it is easy to see that without further constraints on β^*, the statistical model (1) is not identifiable, since (even when $w = 0$), there are many vectors β^* that are consistent[1] with the observations y and X. This identifiability concern may be eliminated by imposing some type of sparsity assumption on the regression vector $\beta^* \in \mathbb{R}^p$. The simplest assumption is that of *exact sparsity*: in particular, we say that $\beta^* \in \mathbb{R}^p$ is s-sparse if its support set

$$S(\beta^*) := \{ j \in \{1, \ldots, p\} \mid \beta_j^* \neq 0 \}$$

1. Indeed, any vector β^* in the nullspace of X, which has dimension at least $p - n$, leads to $y = 0$ when $w = 0$.

has cardinality at most s.

Disregarding computational cost, the most direct approach to estimating an s-sparse β^* in the linear regression model would be solving a quadratic optimization problem with an ℓ_0-constraint, say

$$\widehat{\beta} \in \arg\min_{\beta \in \mathbb{R}^p} \|y - X\beta\|_2^2 \qquad \text{such that } \|\beta\|_0 \leq s,$$

where $\|\beta\|_0$ simply counts the number of non-zero entries in β. Of course, this problem is non-convex and combinatorial in nature, since it involves searching over all $\binom{p}{s}$ subsets of size s. A natural relaxation is to replace the non-convex ℓ_0 constraint with the ℓ_1-norm, which leads to the *constrained form of the Lasso* (Chen et al., 1998; Tibshirani, 1996), given by

$$\widehat{\beta} \in \arg\min_{\beta \in \mathbb{R}^p} \|y - X\beta\|_2^2 \qquad \text{such that } \|\beta\|_1 \leq R,$$

where R is a radius to be chosen by the user. Equivalently, by Lagrangian duality, this program can also be written in the penalized form

$$\widehat{\beta} \in \arg\min_{\beta \in \mathbb{R}^p} \left\{ \|y - X\beta\|_2^2 + \lambda \|\beta\|_1 \right\},$$

where $\lambda > 0$ is a regularization parameter. In the case of noiseless observations, obtained by setting $w = 0$ in the observation model (1), a closely related convex program is the *basis pursuit linear program* (Chen et al., 1998), given by

$$\widehat{\beta} \in \arg\min_{\widehat{\beta} \in \mathbb{R}^p} \|\beta\|_1 \qquad \text{such that } X\beta = y. \tag{2}$$

Chen et al. (1998) also study the constrained Lasso (2.1), which they refer to as relaxed basis pursuit. Another closely related estimator based on ℓ_1-relaxation is the Dantzig selector (Candes and Tao, 2007).

2.2 Sufficient Conditions for Success

The high-dimensional linear model under the exact sparsity constraint has been extensively analyzed. Accordingly, as we discuss here, there is a good understanding of the necessary and sufficient conditions for the success of ℓ_1-based relaxations such as basis pursuit and the Lasso.

2.2.1 RESTRICTED NULLSPACE IN NOISELESS SETTING

In the noiseless setting ($w = 0$), it is known that the basis pursuit linear program (LP) (2) recovers β^* exactly if and only if the design matrix X satisfies a restricted nullspace condition. In particular, for a given subset $S \subset \{1, \ldots, p\}$ and constant $\alpha \geq 1$, let us define the set

$$\mathcal{C}(S; \alpha) := \left\{ \theta \in \mathbb{R}^p \mid \|\theta_{S^c}\|_1 \leq \alpha \|\theta_S\|_1 \right\}.$$

For a given sparsity index $k \leq p$, we say that the matrix X satisfies the *restricted nullspace (RN) condition* of order k if $\text{null}(X) \cap \mathcal{C}(S; 1) = \{0\}$ for all subsets S of cardinality k. Although this definition appeared in earlier work (Donoho and Huo, 2001; Feuer and Nemirovski, 2003), the terminology of restricted nullspace is due to Cohen et al. (2009).

This restricted nullspace property is important, because the basis pursuit LP recovers any vector k-sparse vector β^* exactly if and only if X satisfies the restricted nullspace property of order k. See the papers (Cohen et al., 2009; Donoho and Huo, 2001; Elad and Bruckstein, 2002; Feuer and Nemirovski, 2003) for more discussion of restricted nullspaces and equivalence to exact recovery of basis pursuit.

2.2.2 RESTRICTED EIGENVALUE CONDITION FOR ℓ_2 ERROR

In the noisy setting, it is impossible to recover β^* exactly, and a more natural criterion is to bound the ℓ_2-error between β^* and an estimate $\widehat{\beta}$. Various conditions have been used to analyze the ℓ_2-norm convergence rate of ℓ_1-based methods, including the restricted isometry property (Candes and Tao, 2007), various types of restricted eigenvalue conditions (van de Geer, 2007; Bickel et al., 2009; Meinshausen and Yu, 2009), and a partial Riesz condition (Zhang and Huang, 2008). Of all these conditions, the least restrictive are the restricted eigenvalue conditions due to Bickel et al. (2009) and van de Geer (2007). As shown by Bickel et al. (2009), their restricted eigenvalue (RE) condition is less severe than both the RIP condition (Candes and Tao, 2007) and an earlier set of restricted eigenvalue conditions due to Meinshausen and Yu (2009). All of these conditions involve lower bounds on $\|X\theta\|_2$ that hold uniformly over the previously defined set $\mathcal{C}(S;\alpha)$,

Here we state a condition that is essentially equivalent to the restricted eigenvalue condition due to Bickel et al. (2009). In particular, we say that the $p \times p$ sample covariance matrix $X^T X/n$ satisfies the *restricted eigenvalue (RE) condition* over S with parameters $(\alpha,\gamma) \in [1,\infty) \times (0,\infty)$ if

$$\frac{1}{n}\theta^T X^T X\theta \;=\; \frac{1}{n}\|X\theta\|_2^2 \;\geq\; \gamma^2\,\|\theta\|_2^2 \qquad \text{for all } \theta \in \mathcal{C}(S;\alpha).$$

If this condition holds uniformly for all subsets S with cardinality k, we say that $X^T X/n$ *satisfies a restricted eigenvalue condition of order k with parameters* (α,γ). On occasion, we will also say that a deterministic $p \times p$ covariance matrix Σ satisfies an RE condition, by which we mean that $\|\Sigma^{1/2}\theta\|_2 \geq \gamma\|\theta\|_2$ for all $\theta \in \mathcal{C}(S;\alpha)$. It is straightforward to show that the RE condition for some α implies the restricted nullspace condition for the same α, so that the RE condition is slightly stronger than the RN property.

Again, the RE condition is important because it yields guarantees on the ℓ_2-error of any Lasso estimate $\widehat{\beta}$. For instance, if X satisfies the RE condition of order k with parameters $\alpha \geq 3$ and $\gamma > 0$, then it can be shown that (with appropriate choice of the regularization parameter) any Lasso estimate $\widehat{\beta}$ satisfies the error bound $\|\widehat{\beta} - \beta^*\|_2 = O(\sqrt{\frac{k\log p}{n}})$ with high probability over the Gaussian noise vector w. A similar result holds for the Dantzig selector provided the RE condition is satisfied for $\alpha \geq 1$. Bounds with this scaling have appeared in various papers on sparse linear models (Bunea et al., 2007; Bickel et al., 2009; Candes and Tao, 2007; Meinshausen and Yu, 2009; van de Geer, 2007; van de Geer and Buhlmann, 2009). Moreover, this ℓ_2-convergence rate is known to be minimax optimal (Raskutti et al., 2009) in the regime $k/p \to 0$.

3. Main Result and Its Consequences

Thus, in order to provide performance guarantees (either exact recovery or ℓ_2-error bounds) for ℓ_1-relaxations applied to sparse linear models, it is sufficient to show that the RE or RN conditions hold. Given that our interest is in providing sufficient conditions for these properties, the remainder

of the paper focuses on providing conditions for the RE condition to hold for random designs, which implies that the RN condition is satisfied.

3.1 Statement of Main Result

Our main result guarantees that the restricted eigenvalue (and hence restricted nullspace) conditions hold for a broad class of random Gaussian designs. In particular, we consider the linear model $y_i = X_i^T \beta^* + w_i$, in which each row $X_i \sim \mathcal{N}(0, \Sigma)$. We define $\rho^2(\Sigma) = \max_{j=1,\ldots,p} \Sigma_{jj}$ to be the maximal variance, and let $\Sigma^{1/2}$ denote the square root of Σ.

Theorem 1 *For any Gaussian random design $X \in \mathbb{R}^{n \times p}$ with i.i.d. $\mathcal{N}(0, \Sigma)$ rows, there are universal positive constants c, c' such that*

$$\frac{\|Xv\|_2}{\sqrt{n}} \;\geq\; \frac{1}{4}\|\Sigma^{1/2} v\|_2 - 9\,\rho(\Sigma)\,\sqrt{\frac{\log p}{n}}\,\|v\|_1 \qquad \text{for all } v \in \mathbb{R}^p, \tag{3}$$

with probability at least $1 - c' \exp(-cn)$.

The proof of this claim is given later in Section 4. Note that we have not tried to obtain sharpest possible leading constants (i.e., the factors of $1/4$ and 9 can easily be improved).

In intuitive terms, Theorem 1 provides some insight into the eigenstructure of the sample covariance matrix $\widehat{\Sigma} = X^T X/n$. One implication of the lower bound (3) is that the nullspace of X cannot contain any vectors that are "overly" sparse. In particular, for any vector $v \in \mathbb{R}^p$ such that $\|v\|_1 / \|\Sigma^{1/2} v\|_2 = o(\sqrt{\frac{n}{\log p}})$, the right-hand side of the lower bound (3) will be strictly positive, showing that v cannot belong to the nullspace of X. In the following corollary, we formalize this intuition by showing how Theorem 1 guarantees that whenever the population covariance Σ satisfies the RE condition of order k, then the sample covariance $\widehat{\Sigma} = X^T X/n$ satisfies the same property as long as the sample size is sufficiently large.

Corollary 1 (Restricted eigenvalue property) *Suppose that Σ satisfies the RE condition of order k with parameters (α, γ). Then for universal positive constants c, c', c'', if the sample size satisfies*

$$n \;>\; c'' \,\frac{\rho^2(\Sigma)\,(1+\alpha)^2}{\gamma^2}\, k \log p, \tag{4}$$

then the matrix $\widehat{\Sigma} = X^T X/n$ satisfies the RE condition with parameters $(\alpha, \frac{\gamma}{8})$ with probability at least $1 - c' \exp(-cn)$.

Proof Let S be an arbitrary subset of cardinality k, and suppose that $v \in \mathcal{C}(S; \alpha)$. By definition, we have

$$\|v\|_1 = \|v_S\|_1 + \|v_{S^c}\|_1 \;\leq\; (1+\alpha)\|v_S\|_1,$$

and consequently $\|v\|_1 \leq (1+\alpha)\sqrt{k}\|v\|_2$. By assumption, we also have $\|\Sigma^{1/2} v\|_2 \geq \gamma \|v\|_2$ for all $v \in \mathcal{C}(S; \alpha)$. Substituting these two inequalities into the bound (3) yields

$$\frac{\|Xv\|_2}{\sqrt{n}} \geq \left\{ \frac{\gamma}{4} - 9\,(1+\alpha)\,\rho(\Sigma)\,\sqrt{\frac{k \log p}{n}} \right\} \|v\|_2.$$

Under the assumed scaling (4) of the sample size, we have

$$9\,(1+\alpha)\,\rho(\Sigma)\,\sqrt{\frac{k\log p}{n}} \leq \gamma/8,$$

which shows that the RE condition holds for X^TX/n with parameter $(\alpha,\gamma/8)$ as claimed. ■

Remarks:

(a) From the definitions, it is easy to see that if the RE condition holds with $\alpha = 1$ and any $\gamma > 0$ (even arbitrarily small), then the RN condition also holds. Indeed, if the matrix X^TX/n satisfies the $(1,\gamma)$-RE condition, then for any $v \in \mathcal{C}(S;1)\backslash\{0\}$, we have $\frac{\|Xv\|_2}{\sqrt{n}} \geq \gamma\|v\|_2 > 0$, which implies that $\mathcal{C}(S,1) \cap (X) = \{0\}$.

(b) As previously discussed, it is known (Bickel et al., 2009; van de Geer, 2000; van de Geer and Buhlmann, 2009) that if X^TX/n satisfies the RE condition, then the ℓ_2 error of the Lasso under the sparse linear model with Gaussian noise satisfies the bound

$$\|\widehat{\beta} - \beta^*\|_2 = O(\sqrt{\frac{k\log p}{n}}) \qquad \text{with high probability.}$$

Consequently, in order to ensure that the ℓ_2-error is bounded, the sample size must scale as $n = \Omega(k\log p)$, which matches the scaling (4) required in Corollary 1, as long as the sequence of covariance matrices Σ have diagonal entries that stay bounded.

(c) Finally, we note that Theorem 1 guarantees that the sample covariance X^TX/n satisfies a property that is slightly stronger than the RE condition. As shown by Negahban et al. (2009), this strengthening also leads to error bounds for the Lasso when β^* is not exactly k-sparse, but belongs to an ℓ_q-ball. The resulting rates are known to be minimax-optimal for these ℓ_q-balls (Raskutti et al., 2009).

3.2 Comparison to Related Work

At this point, we provide a brief comparison of our results with some related results in the literature beyond the papers discussed in the introduction. Haupt et al. (2010) showed that a certain class of random Toeplitz matrices, where the entries in the first row and first column are Bernoulli random variables and the rest fill out the Toeplitz structure satisfy RIP (and hence the weaker RE condition) provided that $n = \Omega(k^3\log(p/k))$. In Section 3.3, we demonstrate that Gausssian design matrices where the covariance matrix is a Toeplitz matrix satisfies the RE condition under the milder scaling requirement $n = \Omega(k\log(p))$. It would be of interest to determine such scaling can be established for the random Toeplitz matrices considered by Haupt et al. (2010).

It is worth comparing the scaling (4) to a related result due to van de Geer and Buhlmann (2009). In particular, their Lemma 10.1 also provides sufficient conditions for a restricted eigenvalue condition to hold for design matrices with dependent columns. They show that if the true covariance matrix satisfies an RE condition, and if the elementwise maximum $\|\widehat{\Sigma} - \Sigma\|_\infty$ between the sample covariance $\widehat{\Sigma} = X^TX/n$ and true covariance Σ is suitably bounded, then the sample covariance also satisfies the RE condition. Their result applied to the case of Gaussian random matrices guarantees

that $\widehat{\Sigma}$ satisfies the RE property as long as $n = \Omega(k^2 \log p)$ and Σ satisfies the RE condition. By contrast, Corollary 1 guarantees the RE condition with the less restrictive scaling $n = \Omega(k \log p)$. Note that if $k = O(\sqrt{n})$, our scaling condition is satisfied while their condition fails. This quadratic-linear gap in sparsity between k^2 and k arises from the difference between a local analysis (looking at individual entries of $\widehat{\Sigma}$) versus the global analysis of this paper, which studies the full random matrix. On the other hand, the result of van de Geer and Buhlmann (2009) applies more generally, including the case of sub-Gaussian random matrices (e.g., those with bounded entries) in addition to the Gaussian matrices considered in Theorem 1.

Finally, in work that followed up on the initial posting of this work (Raskutti et al., 2009), a paper by Zhou (2009) provides an extension of Theorem 1 to the case of correlated random matrices with sub-Gaussian entries. Theorem 1.6 in her paper establishes that certain families of sub-Gaussian matrices satisfy the RE condition w.h.p. with sample size $n = \Omega(s \log(p/s))$. This extension is based on techniques developed by Mendelson et al. (2008), while we use Gaussian comparison inequalities and simple concentration results for the case of Gaussian design.

3.3 Some Illustrative Examples

Let us illustrate some classes of matrices to which our theory applies. We will see that Corollary 1 applies to many sequences of covariance matrices $\Sigma = \Sigma_{p \times p}$ that have much more structure than the identity matrix. Our theory allows for the maximal eigenvalue of Σ to be arbitrarily large, or for Σ to be rank-degenerate, or for both of these degeneracies to occur at the same time. In all cases, we consider sequences of matrices for which the maximum variance $\rho^2(\Sigma) = \max_{j=1,\ldots,p} \Sigma_{jj}$ stays bounded. Under this mild restriction, we provide several examples where the RE condition is satisfied with high probability. For suitable choices, these same examples show that the RE condition can hold with high probability, even when the restricted isometry property (RIP) of Candes and Tao (2005) is violated with probability converging to one.

Example 1 (Toeplitz matrices) *Consider a covariance matrix with the Toeplitz structure $\Sigma_{ij} = a^{|i-j|}$ for some parameter $a \in [0,1)$. This type of covariance structure arises naturally from autoregressive processes, where the parameter a allows for tuning of the memory in the process. The minimum eigenvalue of Σ is $1-a > 0$, independent of the dimension p, so that the population matrix Σ clearly satisfies the RE condition. Since $\rho^2(\Sigma) = 1$, Theorem 1 implies that the sample covariance matrix $\widehat{\Sigma} = X^T X/n$ obtained by sampling from this distribution will also satisfy the RE condition with high probability as long as $n = \Omega(k \log p)$. This provides an example of a matrix family with substantial correlation between covariates for which the RE property still holds.*

However, regardless of the sample size, the submatrices of the sample covariance $\widehat{\Sigma}$ will not satisfy restricted isometry properties (RIP) if the parameter a is sufficiently large. For instance, defining $S = \{1,2,\ldots,k\}$, consider the sub-block $\widehat{\Sigma}_{SS}$ of the sample covariance matrix. Satisfying RIP requires that that the condition number $\lambda_{\max}(\widehat{\Sigma}_{SS})/\lambda_{\min}(\widehat{\Sigma}_{SS})$ be very close to one. As long as $n = \Omega(k \log p)$, known results in random matrix theory (Davidson and Szarek, 2001) guarantee that the eigenvalues of $\widehat{\Sigma}_{SS}$ will be very close to the population versions Σ_{SS}; see also the concrete calculation in Example 2 to follow. Consequently, imposing RIP amounts to requiring that the population condition number $\lambda_{\max}(\Sigma_{SS})/\lambda_{\min}(\Sigma_{SS})$ be very close to one. This condition number grows as the parameter $a \in [0,1)$ increases towards one (Gray, 1990), so RIP will be violated once $a < 1$ is sufficiently large.

We now consider a matrix family with an even higher amount of dependency among the covariates, where the RIP constants are actually unbounded as the sparsity k increases, but the RE condition is still satisfied.

Example 2 (Spiked identity model) *For a parameter $a \in [0,1)$, the spiked identity model is given by the family of covariance matrices*

$$\Sigma := (1-a) I_{p \times p} + a \vec{1}\, \vec{1}^T,$$

where $\vec{1} \in \mathbb{R}^p$ is the vector of all ones. The minimum eigenvalue of Σ is $1-a$, so that the population covariance clearly satisfies the RE condition for any fixed $a \in [0,1)$. Since this covariance matrix has maximum variance $\rho^2(\Sigma) = 1$, Corollary 1 implies that a sample covariance matrix $\widehat{\Sigma} = X^T X/n$ will satisfy the RE property with high probability with sample size $n = \Omega(k \log p)$.

On the other hand, the spiked identity matrix Σ has very poorly conditioned sub-matrices, which implies that a sample covariance matrix $\widehat{\Sigma} = X^T X/n$ will violate the restricted isometry property (RIP) with high probability as n grows. To see this fact, for an arbitrary subset S of size k, consider the associated $k \times k$ submatrix Σ_{SS}. An easy calculation shows that $\lambda_{\min}(\Sigma_{SS}) = 1-a > 0$ and $\lambda_{\max}(\Sigma_{SS}) = 1 + a(k-1)$, so that the population condition number of this sub-matrix is

$$\frac{\lambda_{\max}(\Sigma_{SS})}{\lambda_{\min}(\Sigma_{SS})} = \frac{1+a(k-1)}{1-a}.$$

For any fixed $a \in (0,1)$, this condition number diverges as k increases. We now show that the same statement applies to the sample covariance with high probability, showing that the RIP is violated. Let $u \in \mathbb{R}^k$ and $v \in \mathbb{R}^k$ denote (respectively) unit-norm eigenvectors corresponding to the minimum and maximum eigenvalues of Σ_{SS}, and define the random variables $Z_u = \|Xu\|_2^2/n$ and $Z_v = \|Xv\|_2^2/n$. Since $\langle X_i, v\rangle \sim N(0, \lambda_{\max}(\Sigma_{SS}))$ by construction, we have

$$Z_v = \frac{1}{n}\sum_{i=1}^n \langle X_i, v\rangle^2 \stackrel{d}{=} \lambda_{\max}(\Sigma_{SS}) \Big\{ \frac{1}{n}\sum_{i=1}^n y_i^2 \Big\},$$

where $y_i \sim N(0,1)$ are i.i.d. standard Gaussians, and $\stackrel{d}{=}$ denotes equality in distribution. By χ^2 tail bounds, we have $\mathbb{P}[\frac{1}{n}\sum_{i=1}^n y_i^2 \geq \frac{1}{2}] \leq c_1 \exp(-c_2 n)$, so that $Z_v \geq \lambda_{\max}(\Sigma_{SS})/2$ with high probability. A similar argument shows that $Z_u \leq 2\lambda_{\min}(\Sigma_{SS})$ with high probability, and putting together the pieces shows that w.h.p.

$$\frac{\lambda_{\max}(\widehat{\Sigma}_{SS})}{\lambda_{\min}(\widehat{\Sigma}_{SS})} \geq \frac{1}{4}\frac{\lambda_{\max}(\Sigma_{SS})}{\lambda_{\min}(\Sigma_{SS})} \geq \frac{1}{4}\,\frac{1+a(k-1)}{1-a},$$

which diverges as k increases.

In both of the preceding examples, the minimum eigenvalue of Σ was bounded from below and the diagonal entries of Σ were bounded from above, which allowed us to assert immediately that the RE condition was satisfied for the population covariance matrix. As a final example, we now consider sampling from population covariance matrices that are actually rank degenerate, but for which our theory still provides guarantees.

Example 3 (Highly degenerate covariance matrices) *Let Σ be any matrix with bounded diagonal that satisfies the RE property of some order k. Suppose that we sample n times from a $N(0,\Sigma)$ distribution, and then form the empirical covariance matrix $\widehat{\Sigma} = X^T X/n$. If $n < p$, then $\widehat{\Sigma}$ must be rank degenerate, but Corollary 1 guarantees that $\widehat{\Sigma}$ will satisfy the RE property of order k with high probability as long as $n = \Omega(k \log p)$. Moreover, by χ^2-tail bounds, the maximal diagonal element $\rho^2(\widehat{\Sigma})$ will be bounded with high probability under this same scaling.*

Now if we condition on the original design matrix X in the high probability set, we may view $\widehat{\Sigma}$ as a fixed but highly rank-degenerate matrix. Suppose that we draw a new set of n i.i.d. vectors $\widetilde{X}_i \sim N(0,\widehat{\Sigma})$ using this degenerate covariance matrix. Such a resampling procedure could be relevant for a bootstrap-type calculation for assessing errors of the Lasso. We may then form a second empirical covariance matrix $\widetilde{\Sigma} = \frac{1}{n}\widetilde{X}^T\widetilde{X}$. Conditionally on $\widehat{\Sigma}$ having the RE property of order k and a bounded diagonal, Corollary 1 shows that the resampled empirical covariance $\widetilde{\Sigma}$ will also have the RE property of order k with high probability, again for $n = \Omega(k \log p)$.

This simple example shows that in the high-dimensional setting $p \gg n$, it is possible for the RE condition to hold with high probability even when the original population covariance matrix ($\widehat{\Sigma}$ in this example) has a $p-n$-dimensional nullspace. Note moreover that this is not an isolated phenomenon—rather, it will hold for almost every sample covariance matrix $\widehat{\Sigma}$ constructed in the way that we have described.

4. Proof of Theorem 1

We now turn to the proof of Theorem 1. The main ingredients are the Gordon-Slepian comparison inequalities (Gordon, 1985) for Gaussian processes, concentration of measure for Lipschitz functions (Ledoux, 2001), and a peeling argument. The first two ingredients underlie classical proofs on the ordinary eigenvalues of Gaussian random matrices (Davidson and Szarek, 2001), whereas the latter tool is used in empirical process theory (van de Geer, 2000).

4.1 Proof Outline

Recall that Theorem 1 states that the condition

$$\frac{\|Xv\|_2}{\sqrt{n}} \geq \frac{1}{4}\|\Sigma^{1/2}v\|_2 - 9\,\rho(\Sigma)\sqrt{\frac{\log p}{n}}\,\|v\|_1 \qquad \text{for all } v \in \mathbb{R}^p, \tag{5}$$

holds with probability at least $1 - c'\exp(-cn)$, where c, c' are universal positive constants. Hence, we are bounding the random quantity $\|Xv\|_2$ in terms of $\|\Sigma^{1/2}v\|_2$ and $\|v\|_1$ for all v with high probability. It suffices to prove Theorem 1 for $\|\Sigma^{1/2}v\|_2 = 1$. Indeed, for any vector $v \in \mathbb{R}^p$ such that $\Sigma^{1/2}v = 0$, the claim holds holds trivially. Otherwise, we may consider the re-scaled vector $\check{v} = v/\|\Sigma^{1/2}v\|_2$, and note that $\|\Sigma^{1/2}\check{v}\|_2 = 1$ by construction. By scale invariance of the condition (5), if it holds for the re-scaled vector $\check{v}$, it also holds for v.

Therefore, in the remainder of the proof, our goal is to lower bound the quantity $\|Xv\|_2$ over the set of v such that $\|\Sigma^{1/2}v\|_2 = 1$ in terms of $\|v\|_1$. At a high level, there are three main steps to the proof:

(1) We begin by considering the set $V(r) := \{v \in \mathbb{R}^p \mid \|\Sigma^{1/2}v\|_2 = 1, \|v\|_1 \leq r\}$, for a fixed radius r. Although this set may be empty for certain choices of $r > 0$, our analysis only concerns

those choices for which it is non-empty. Define the random variable

$$M(r,X) := 1 - \inf_{v \in V(r)} \frac{\|Xv\|_2}{\sqrt{n}} = \sup_{v \in V(r)} \left\{ 1 - \frac{\|Xv\|_2}{\sqrt{n}} \right\}.$$

Our first step is to upper bound the expectation $\mathbb{E}[M(r,X)]$, where the expectation is taken over the random Gaussian matrix X.

(2) Second, we establish that $M(r,X)$ is a Lipschitz function of its Gaussian arguments, and then use concentration inequalities to assert that for each fixed $r > 0$, the random variable $M(r,X)$ is sharply concentrated around its expectation with high probability.

(3) Third, we use a peeling argument to show that our analysis holds with high probability and uniformly over all possible choice of the ℓ_1-radius r, which then implies that the condition (5) holds with high probability as claimed.

In the remainder of this section, we provide the details of each of these steps.

4.2 Bounding the Expectation $\mathbb{E}[M(r,X)]$

This subsection is devoted to a proof of the following lemma:

Lemma 1 *For any radius $r > 0$ such that $V(r)$ is non-empty, we have*

$$\mathbb{E}[M(r,X)] \leq \frac{1}{4} + 3\rho(\Sigma)\sqrt{\frac{\log p}{n}}\, r.$$

Proof: Let $S^{n-1} = \{u \in \mathbb{R}^n \mid \|u\|_2 = 1\}$ be the Euclidean sphere of radius 1, and recall the previously defined set $V(r) := \{v \in \mathbb{R}^p \mid \|\Sigma^{1/2} v\|_2 = 1, \|v\|_1 \leq r\}$. For each pair $(u,v) \in S^{n-1} \times V(r)$, we may define an associated zero-mean Gaussian random variable $Y_{u,v} := u^T X v$. This representation is useful, because it allows us to write the quantity of interest as a min-max problem in terms of this Gaussian process. In particular, we have

$$-\inf_{v \in V(r)} \|Xv\|_2 = -\inf_{v \in V(r)} \sup_{u \in S^{n-1}} u^T X v = \sup_{v \in V(r)} \inf_{u \in S^{n-1}} u^T X v.$$

We may now upper bound the expected value of the above quantity via a Gaussian comparison inequality; here we state a form of Gordon's inequality used in past work on Gaussian random matrices (Davidson and Szarek, 2001). Suppose that $\{Y_{u,v}, (u,v) \in U \times V\}$ and $\{Z_{u,v}, (u,v) \in U \times V\}$ are two zero-mean Gaussian processes on $U \times V$. Using $\sigma(\cdot)$ to denote the standard deviation of its argument, suppose that these two processes satisfy the inequality

$$\sigma(Y_{u,v} - Y_{u',v'}) \leq \sigma(Z_{u,v} - Z_{u',v'}) \qquad \text{for all pairs } (u,v) \text{ and } (u',v') \text{ in } U \times V,$$

and this inequality holds with equality when $v = v'$. Then we are guaranteed that

$$\mathbb{E}[\sup_{v \in V} \inf_{u \in U} Y_{u,v}] \quad \leq \quad \mathbb{E}[\sup_{v \in V} \inf_{u \in U} Z_{u,v}].$$

We use Gordon's inequality to show that

$$\mathbb{E}[M(r,X)] = 1 + \mathbb{E}[\sup_{v \in V(r)} \inf_{u \in S^{n-1}} Y_{u,v}] \leq 1 + \mathbb{E}[\sup_{v \in V(r)} \inf_{u \in S^{n-1}} Z_{u,v}],$$

where we recall that $Y_{u,v} = u^T X v$ and $Z_{u,v}$ is a different Gaussian process to be defined shortly.

We begin by computing $\sigma^2(Y_{u,v} - Y_{u',v'})$. To simplify notation, we note that the $X \in \mathbb{R}^{n\times p}$ can be written as $W\Sigma^{1/2}$, where $W \in \mathbb{R}^{n\times p}$ is a matrix with i.i.d. $\mathcal{N}(0,1)$ entries, and $\Sigma^{1/2}$ is the symmetric matrix square root. In terms of W, we can write

$$Y_{u,v} = u^T W \Sigma^{1/2} v \;=\; u^T W \tilde{v},$$

where $\tilde{v} = \Sigma^{1/2} v$. It follows that

$$\sigma^2(Y_{u,v} - Y_{u',v'}) := \mathbb{E}\big(\sum_{i=1}^n \sum_{j=1}^p W_{i,j}(u_i\tilde{v}_j - u'_i\tilde{v}'_j)\big)^2 \;=\; |||u\tilde{v}^T - (u')(\tilde{v}')^T|||_F^2,$$

where $|||\cdot|||_F$ is the Frobenius norm (ℓ_2-norm applied elementwise to the matrix). This equality follows immediately since the W_{ij} variables are i.i.d $\mathcal{N}(0,1)$.

Now consider a second zero-mean Gaussian process $Z_{u,v}$ indexed by $S^{n-1} \times V(r)$, and given by

$$Z_{u,v} \;\;=\;\; \vec{g}^T u + \vec{h}^T \Sigma^{1/2} v,$$

where $\vec{g} \sim N(0, I_{n\times n})$ and $\vec{h} \sim N(0, I_{p\times p})$ are standard Gaussian random vectors. With $\tilde{v} = \Sigma^{1/2} v$, we see immediately that

$$\sigma^2(Z_{u,v} - Z_{u',v'}) = \|u - u'\|_2^2 + \|\tilde{v} - \tilde{v}'\|_2^2.$$

Consequently, in order to apply the Gaussian comparison principle to $\{Y_{u,v}\}$ and $\{Z_{u,v}\}$, we need to show that

$$|||u\tilde{v}^T - (u')(\tilde{v}')^T|||_F^2 \leq \|u - u'\|_2^2 + \|\tilde{v} - \tilde{v}'\|_2^2 \tag{6}$$

for all pairs $(u, \tilde{v})$ and $(u', \tilde{v}')$ in the set of interest. Since the Frobenius norm $|||\cdot|||_F$ is simply the ℓ_2-norm on the vectorized form of a matrix, we can compute

$$\begin{aligned}
|||u\tilde{v}^T - u'(\tilde{v}')^T|||_F^2 &= |||(u-u')\tilde{v}^T + u'(\tilde{v} - \tilde{v}')^T|||_F^2 \\
&= \sum_{i=1}^n \sum_{j=1}^p [(u_i - u'_i)\tilde{v}_j + u'_i(\tilde{v}_j - \tilde{v}'_j)]^2 \\
&= \|\tilde{v}\|_2^2 \|u - u'\|_2^2 + \|u'\|_2^2 \|\tilde{v} - \tilde{v}'\|_2^2 + 2(u^T u' - \|u'\|_2^2)(\|\tilde{v}\|_2^2 - \tilde{v}^T\tilde{v}') \\
&= \|u - u'\|_2^2 + \|\tilde{v} - \tilde{v}'\|_2^2 - 2(\|u'\|_2^2 - u^T u')(\|\tilde{v}\|_2^2 - \tilde{v}^T\tilde{v}'),
\end{aligned}$$

where we have used equalities $\|u\|_2 = \|u'\|_2 = 1$ and $\|\tilde{v}\|_2 = \|\tilde{v}'\|_2 = 1$. By the Cauchy-Schwarz inequality, we have $\|u\|_2^2 - u^T u' \geq 0$, and $\|\tilde{v}\|_2^2 - \tilde{v}^T\tilde{v}' \geq 0$, from which the claimed inequality (6) follows. When $v = v'$, we also have $\tilde{v} = \Sigma^{1/2} v = \Sigma^{1/2} v' = \tilde{v}'$, so that equality holds in the condition (6) when $\tilde{v} = \tilde{v}'$.

Consequently, we may apply Gordon's inequality to conclude that

$$\begin{aligned}
\mathbb{E}\big[\sup_{v\in V(r)} \inf_{u\in S^{n-1}} u^T X v\big] &\leq \mathbb{E}\big[\sup_{v\in V(r)} \inf_{u\in S^{n-1}} Z_{u,v}\big] \\
&= \mathbb{E}[\inf_{u\in S^{n-1}} \vec{g}^T u] + \mathbb{E}[\sup_{v\in V(r)} \vec{h}^T \Sigma^{1/2} v] \\
&= -\mathbb{E}[\|\vec{g}\|_2] + \mathbb{E}[\sup_{v\in V(r)} \vec{h}^T \Sigma^{1/2} v].
\end{aligned}$$

We now observe that by definition of $V(r)$, we have

$$\sup_{v \in V(r)} |\vec{h}^T \Sigma^{1/2} v| \leq \sup_{v \in V(r)} \|v\|_1 \, \|\Sigma^{1/2}\vec{h}\|_\infty \leq r \|\Sigma^{1/2}\vec{h}\|_\infty.$$

Each element $(\Sigma^{1/2}\vec{h})_j$ is zero-mean Gaussian with variance Σ_{jj}. Consequently, known results on Gaussian maxima (cf. Ledoux and Talagrand, 1991, Equation (3.13)) imply that $\mathbb{E}[\|\Sigma^{1/2}h\|_\infty] \leq 3\sqrt{\rho^2(\Sigma)\log p}$, where $\rho^2(\Sigma) = \max_j \Sigma_{jj}$. Noting[2] that $\mathbb{E}[\|\vec{g}\|_2] \geq \frac{3}{4}\sqrt{n}$ for all $n \geq 10$ by standard χ^2 tail bounds and putting together the pieces, we obtain the bound

$$\mathbb{E}[-\inf_{v \in V(r)} \|Xv\|_2] \quad \leq \quad -\frac{3}{4}\sqrt{n} + 3\big[\rho^2(\Sigma)\log p\big]^{1/2} r.$$

Dividing by $\sqrt{n}$ and adding 1 to both sides yields

$$\mathbb{E}[M(r,X)] = \mathbb{E}[1 - \inf_{v \in V(r)} \|Xv\|_2/\sqrt{n}] \leq 1/4 + 3\rho(\Sigma)\sqrt{\frac{\log p}{n}}\, r,$$

as claimed.

■

4.3 Concentration Around the Mean for $M(r,X)$

Having controlled the expectation, the next step is to establish concentration of $M(r,X)$ around its mean. Note that Lemma 1 shows that $\mathbb{E}[M(r,X)] \leq t(r)$, where

$$t(r) := \frac{1}{4} + 3r\,\rho(\Sigma)\sqrt{\frac{\log p}{n}}. \tag{7}$$

Now we prove the following claim:

Lemma 2 *For any r such that $V(r)$ is non-empty, we have*

$$\mathbb{P}\left[M(r,X) \geq \frac{3t(r)}{2}\right] \leq 2\exp(-nt^2(r)/8).$$

Proof In order to prove this lemma, it suffices to show that

$$\mathbb{P}\big[|M(r,X) - \mathbb{E}[M(r,X)]| \geq t(r)/2\big] \leq 2\exp(-nt^2(r)/8),$$

and use the upper bound on $\mathbb{E}[M(r,X)]$ derived in Lemma 1.

By concentration of measure for Lipschitz functions of Gaussians (see Appendix B), this tail bound will follow if we show that the Lipschitz constant of $M(r,X)$ as a function of the Gaussian random matrix is less than $1/\sqrt{n}$. To make this functional dependence explicit, let us write $M(r,X)$ as the function $h(W) = \sup_{v \in V(r)} \big(1 - \|W\Sigma^{1/2}v\|_2/\sqrt{n}\big)$. We find that

$$\sqrt{n}\big[h(W) - h(W')\big] = \sup_{v \in V(r)} -\|W\Sigma^{1/2}v\|_2 - \sup_{v \in V(r)} -\|W'\Sigma^{1/2}v\|_2.$$

2. In fact, $|\mathbb{E}[\|\vec{g}\|_2] - \sqrt{n}| = o(\sqrt{n})$, but this simple bound is sufficient for our purposes.

Since $V(r)$ is closed and bounded and the objective function is continuous, there exists $\hat{v} \in V(r)$ such that $\hat{v} = \arg\max_{v \in V(r)} -\|W\Sigma^{1/2}v\|_2$. Therefore

$$\begin{aligned}\sup_{v\in V(r)} \big(-\|W\Sigma^{1/2}v\|_2\big) - \sup_{v\in V(r)} \big(-\|W'\Sigma^{1/2}v\|_2\big) &= -\|W\Sigma^{1/2}\hat{v}\|_2 - \sup_{v\in V(r)} \big(-\|W'\Sigma^{1/2}v\|_2\big) \\ &\leq \|W'\Sigma^{1/2}\hat{v}\|_2 - \|W\Sigma^{1/2}\hat{v}\|_2 \\ &\leq \sup_{v\in V(r)} \big(\|(W'-W)\Sigma^{1/2}v\|_2\big).\end{aligned}$$

For a matrix A, we define its spectral norm $|||A|||_2 = \sup_{\|u\|_2=1} \|Au\|_2$. With this notation, we can bound the Lipschitz constant of h as

$$\begin{aligned}\sqrt{n}\big[h(W) - h(W')\big] &\leq \sup_{v\in V(r)} \big(\|(W-W')\Sigma^{1/2}v\|_2\big) \\ &\overset{(a)}{\leq} \big\{\sup_{v\in V(r)} \big(\|\Sigma^{1/2}v\|_2\big)\big\} |||(W-W')|||_2 \\ &\overset{(b)}{\leq} \big\{\sup_{v\in V(r)} \big(\|\Sigma^{1/2}v\|_2\big)\big\}\ |||(W-W')|||_F \\ &\overset{(c)}{=} |||W-W'|||_F.\end{aligned}$$

In this argument, inequality (a) follows by definition of the matrix spectral norm $|||\cdot|||_2$; inequality (b) follows from the bound $|||(W-W')|||_2 \leq |||(W-W')|||_F$ between the spectral and Frobenius matrix norms (Horn and Johnson, 1985); and equality (c) follows since $\|\Sigma^{1/2}v\|_2 = 1$ for all $v \in V(r)$. Thus, we have shown that h has Lipschitz constant $L \leq 1/\sqrt{n}$ with respect to the Euclidean norm on W (viewed as a vector with np entries). Finally we use a standard result on the concentration for Lipschitz functions of Gaussian random variables (Ledoux, 2001; Massart, 2003)—see Appendix B for one statement. Applying the concentration result (9) with $m = np$, $\tilde{g} = W$, and $t = t(r)/2$ completes the proof. ■

4.4 Extension to All Vectors Via Peeling

Thus far, we have shown that

$$M(r,X) = 1 - \inf_{v\in V(r)} \frac{\|Xv\|_2}{\sqrt{n}} = \sup_{v\in V(r)} \left\{1 - \frac{\|Xv\|_2}{\sqrt{n}}\right\} \geq 3t(r)/2, \tag{8}$$

with probability no larger than $2\exp(-nt^2(r)/8)$ where $t(r) = \frac{1}{4} + 3\,r\,\rho(\Sigma)\sqrt{\frac{\log p}{n}}$. The set $V(r)$ requires that $\|v\|_1 \leq r$ for some *fixed* radius r, whereas the claim of Theorem 1 applies to all vectors v. Consequently, we need to extend the bound (8) to an arbitrary ℓ_1 radius.

In order do so, we define the event

$$\mathcal{T} := \big\{\exists\, v \in \mathbb{R}^p \text{ s.t. } \|\Sigma^{1/2}v\|_2 = 1 \text{ and } \big(1 - \|Xv\|_2/\sqrt{n}\big) \geq 3t(\|v\|_1)\big\}.$$

Note that there is no r in the definition of $\mathcal{T}$, because we are setting $\|v\|_1$ to be the argument of the function t. We claim that there are constants positive constants c, c' such that $\mathbb{P}[\mathcal{T}] \leq c\exp(-c'n)$,

from which Theorem 1 will follow. We establish this claim by using a device known as peeling (Alexander, 1985; van de Geer, 2000); for the version used here, see Lemma 3 proved in the Appendix. In particular, we apply Lemma 3 with the functions

$$f(v,X) = 1 - \|Xv\|_2/\sqrt{n}, \qquad h(v) = \|v\|_1, \quad \text{and} \quad g(r) = 3t(r)/2,$$

the sequence $a_n = n$, and the set $A = \{v \in \mathbb{R}^p \mid \|\Sigma^{1/2}v\|_2 = 1\}$. Recall that the quantity t, as previously defined (7), satisfies $t(r) \geq 1/4$ for all $r > 0$ and is strictly increasing. Therefore, the function $g(r) = 3t(r)/2$ is non-negative and strictly increasing as a function of r, and moreover satisfies $g(r) \geq 3/8$, so that Lemma 3 is applicable with $\mu = 3/8$. We can thus conclude that $\mathbb{P}[\mathcal{T}^c] \geq 1 - c\exp(-c'n)$ for some numerical constants c and c'.

Finally, conditioned on the event $\mathcal{T}^c$, for all $v \in \mathbb{R}^p$ with $\|\Sigma^{1/2}v\|_2 = 1$, we have

$$1 - \|Xv\|_2/\sqrt{n} \;\leq\; 3t(\|v\|_1) \;=\; \frac{3}{4} + 9\,\|v\|_1\,\rho(\Sigma)\sqrt{\frac{\log p}{n}},$$

which implies that

$$\|Xv\|_2/\sqrt{n} \geq \frac{1}{4} - 9\,\|v\|_1\,\rho(\Sigma)\,\sqrt{\frac{\log p}{n}}.$$

As noted in the proof outline, this suffices to establish the general claim.

5. Conclusion

Methods based on ℓ_1-relaxations are very popular, and the weakest possible conditions on the design matrix X required to provide performance guarantees—namely, the restricted nullspace and eigenvalue conditions—are well-understood. In this paper, we have proved that these conditions hold with high probability for a broad class of Gaussian design matrices allowing for quite general dependency among the columns, as captured by a covariance matrix Σ representing the dependence among the different covariates. As a corollary, our result guarantees that known performance guarantees for ℓ_1-relaxations such as basis pursuit and Lasso hold with high probability for such problems, provided the population matrix Σ satisfies the RE condition. Interestingly, our theory shows that ℓ_1-methods can perform well when the covariates are sampled from a Gaussian distribution with a degenerate covariance matrix. Some follow-up work (Zhou, 2009) has extended these results to random matrices with sub-Gaussian rows. In addition, there are a number of other ways in which this work could be extended. One is to incorporate additional dependence across the rows of the design matrix, as would arise in modeling time series data for example. It would also be interesting to relate the allowable degeneracy structures of Σ to applications involving real data. Finally, although this paper provides various conditions under which the RE condition holds with high probability, it does not address the issue of how to determine whether a given sample covariance matrix matrix $\widehat{\Sigma} = X^T X/n$ satisfies the RE condition. It would be interesting to study if there are computationally efficient methods for verifying the RE condition.

Acknowledgments

We thank Arash Amini for useful discussion, particularly regarding the proofs of Theorem 1 and Lemma 3, and Rob Nowak for helpful comments on an earlier draft. This work was partially

supported by NSF grants DMS-0605165 and DMS-0907632 to MJW and BY. In addition, BY was partially supported by the NSF grant SES-0835531 (CDI), and a grant from the MSRA. Appendix A. Peeling Argument

In this appendix, we state a result on large deviations of the constrained optimum of random objective functions of the form $f(v;X)$, where $v \in \mathbb{R}^p$ is the vector to be optimized over, and X is some random vector. Of interest is the problem $\sup_{h(v)\leq r,\, v\in A} f(v;X)$, where $h : \mathbb{R}^p \to \mathbb{R}_+$ is some non-negative and increasing constraint function, and A is a non-empty set. With this set-up, our goal is to bound the probability of the event defined by

$$\mathcal{E} \quad := \quad \big\{\exists\, v \in A \text{ such that } f(v;X) \geq 2g(h(v)))\big\},$$

where $g : \mathbb{R} \to \mathbb{R}$ is non-negative and strictly increasing.

Lemma 3 *Suppose that $g(r) \geq \mu$ for all $r \geq 0$, and that there exists some constant $c > 0$ such that for all $r > 0$, we have the tail bound*

$$\mathbb{P}\big[\sup_{v\in A,\, h(v)\leq r} f(v;X) \geq g(r)\big] \quad \leq \quad 2\exp(-c\, a_n\, g^2(r)),$$

for some $a_n > 0$. Then we have

$$\mathbb{P}[\mathcal{E}] \quad \leq \quad \frac{2\exp(-4ca_n\mu^2)}{1-\exp(-4ca_n\mu^2)}.$$

Proof : Our proof is based on a standard peeling technique (e.g., see van de Geer, 2000, p. 82). By assumption, as v varies over A, we have $g(r) \in [\mu, \infty)$. Accordingly, for $m = 1, 2, \ldots$, defining the sets

$$A_m \quad := \quad \big\{v \in A \mid 2^{m-1}\mu \leq g(h(v)) \leq 2^m\mu\big\},$$

we may conclude that if there exists $v \in A$ such that $f(v,X) \geq 2g(h(v))$, then this must occur for some m and $v \in A_m$. By union bound, we have

$$\mathbb{P}[\mathcal{E}] \quad \leq \quad \sum_{m=1}^{\infty} \mathbb{P}\big[\exists\, v \in A_m \text{ such that } f(v,X) \geq 2g(h(v))\big].$$

If $v \in A_m$ and $f(v,X) \geq 2g(h(v))$, then by definition of A_m, we have $f(v,X) \geq 2\,(2^{m-1})\mu = 2^m\mu$. Since for any $v \in A_m$, we have $g(h(v)) \leq 2^m\mu$, we combine these inequalities to obtain

$$\begin{aligned}
\mathbb{P}[\mathcal{E}] \quad &\leq \quad \sum_{m=1}^{\infty} \mathbb{P}\big[\sup_{h(v)\leq g^{-1}(2^m\mu)} f(v,X) \geq 2^m\mu\big] \\
&\leq \quad \sum_{m=1}^{\infty} 2\exp\big(-ca_n\,[g(g^{-1}(2^m\mu))]^2\big) \\
&= \quad 2\sum_{m=1}^{\infty} \exp\big(-ca_n\,2^{2m}\mu^2\big),
\end{aligned}$$

from which the stated claim follows by upper bounding this geometric sum. ■

Appendix B. Concentration for Gaussian Lipschitz Functions

We say that a function $F : \mathbb{R}^m \to \mathbb{R}$ is Lipschitz with constant L if $|F(x) - F(y)| \leq L\|x - y\|_2$ for all $x, y \in \mathbb{R}^m$. It is a classical fact that Lipschitz functions of standard Gaussian vectors exhibit Gaussian concentration. We summarize one version of this fact in the following:

Theorem 2 (Theorem 3.8 from Massart 2003) *Let $w \sim \mathcal{N}(0, I_{m\times m})$ be an m-dimensional Gaussian random variable. Then for any L-Lipschitz function F, we have*

$$\mathbb{P}\left[|F(w) - \mathbb{E}[F(w)]| \geq t\right] \leq 2\exp\left(-\frac{t^2}{2L^2}\right), \text{ for all } t \geq 0. \tag{9}$$

This result can be interpreted as saying that in terms of tail behavior, the random variable $F(w) - \mathbb{E}[F(w)]$ behaves like a zero-mean Gaussian with variance L^2.

Editor: John Lafferty

Abstract

This paper considers the problem of estimating a high dimensional inverse covariance matrix that can be well approximated by "sparse" matrices. Taking advantage of the connection between multivariate linear regression and entries of the inverse covariance matrix, we propose an estimating procedure that can effectively exploit such "sparsity". The proposed method can be computed using linear programming and therefore has the potential to be used in very high dimensional problems. Oracle inequalities are established for the estimation error in terms of several operator norms, showing that the method is adaptive to different types of sparsity of the problem.

Keywords: covariance selection, Dantzig selector, Gaussian graphical model, inverse covariance matrix, Lasso, linear programming, oracle inequality, sparsity

1. Introduction

One of the classical problems in multivariate statistics is to estimate the covariance matrix or its inverse. Let $X = (X_1, \ldots, X_p)'$ be a p-dimensional random vector with an unknown covariance matrix Σ_0. The goal is to estimate Σ_0 or its inverse $\Omega_0 := \Sigma_0^{-1}$ based on n independent copies of X, $X^{(1)}, \ldots, X^{(n)}$. The usual sample covariance matrix is most often adopted for this purpose:

$$S = \frac{1}{n}\sum_{i=1}^{n}(X^{(i)} - \bar{X})(X^{(i)} - \bar{X})',$$

where $\bar{X} = \sum X^{(i)}/n$. The behavior of S is well understood and it is known to perform well in the classical setting when the dimensionality p is small (see, e.g., Anderson, 2003; Muirhead, 2005). On the other hand, with the recent advances in science and technology, we are more and more often faced with the problem of high dimensional covariance matrix estimation where the dimensionality p is large when compared with the sample size n. Given the large number of parameters ($p(p+1)/2$) involved, exploiting the sparse nature of the problem becomes critical. In particular, traditional estimates such as S do not take advantage of the possible sparsity and are known to perform poorly under many usual matrix norms when p is large. Motivated by the practical demands and the failure of classical methods, a number of sparse models and approaches have been introduced in recent years to deal with high dimensional covariance matrix estimation. See, for example, Ledoit and Wolf (2004), Levina, Rothman and Zhu (2007), Deng and Yuan (2008), El Karoui (2008), Fan, Fan and Lv (2008), Ravikumar, Raskutti, Wainwright and Yu (2008), Ravikumar, Wainwright, Ruskutti

and Yu (2008), Rocha, Zhao and Yu (2008), Lam and Fan (2009), and Rothman, Levina and Zhu (2009) among others.

Bickel and Levina (2008a) pioneered the theoretical study of high dimensional sparse covariance matrices. They consider the case where the magnitude of the entries of Σ_0 decays at a polynomial rate of their distance from the diagonal; and show that banding the sample covariance matrix or S leads to well-behaved estimates. More recently, Cai, Zhang and Zhou (2010) established minimax convergence rates for estimating this type of covariance matrices. A more general class of covariance matrix model is investigated in Bickel and Levina (2008b) where the rows or columns of Σ_0 is assumed to come from an ℓ_α ball with $0 < \alpha < 1$. They suggest thresholding the entries of S and study its theoretical behavior when p is large. In addition to the aforementioned methods, sparse models have also been proposed for the modified Cholesky factor of the covariance matrix in a series of papers by Pourahmadi and co-authors (Pourahmadi, 1999; Pourahmadi, 2000; Wu and Pourahmadi, 2003; Huang et al., 2006).

In this paper, we focus on another type of sparsity—sparsity in terms of the entries of the inverse covariance matrix. This type of sparsity naturally connects with the problem of covariance selection (Dempster, 1972) and Gaussian graphical models (see, e.g., Whittaker, 1990; Lauritzen, 1996; Edwards, 2000), which makes it particularly appealing in a number of applications. Methods to exploit such sparsity have been proposed recently. Inspired by the nonnegative garrote (Breiman, 1995) and Lasso (Tibshirani, 1996) for the linear regression, Yuan and Lin (2007) propose to impose ℓ_1 type of penalty on the entries of the inverse covariance matrix when maximizing the normal log-likelihood and therefore encourages some of the entries of the estimated inverse covariance matrix to be exact zero. Similar approaches are also taken by Banerjee, El Ghaoui and d'Aspremont (2008). One of the main challenges for this type of methods is computation which has been recently addressed by d'Aspremont, Banerjee and El Ghaoui (2008), Friedman, Hastie and Tibshirani (2008), Rocha, Zhao and Yu (2008), Rothman et al. (2008) and Yuan (2008). Some theoretical properties of this type of methods have also been developed by Yuan and Lin (2007), Ravikumar et al. (2008), Rothman et al. (2008) and Lam and Fan (2009) among others. In particular, the results from Ravikumar et al. (2008) and Rothman et al. (2008) suggest that, although better than the sample covariance matrix, these methods may not perform well when p is larger than the sample size n. It remains unclear to what extent the sparsity of inverse covariance matrix entails well-behaved covariance matrix estimates.

Through the study of a new estimating procedure, we show here that the estimability of a high dimensional inverse covariance matrix is related to how well it can be approximated by a graphical model with a relatively low degree. The revelation that the degree of a graph dictates the difficulty of estimating a high dimensional covariance matrix suggests that the proposed method may be more appropriate to harness sparsity in the inverse covariance matrix than those mentioned earlier in which the ℓ_1 penalty serves as a proxy to control the total number of edges in the graph as opposed to its degree. The proposed method proceeds in two steps. A preliminary estimate is first constructed using a well known relationship between inverse covariance matrix and multivariate linear regression. We show that the preliminary estimate, although often dismissed as an estimate of the inverse covariance matrix, can be easily modified to produce a satisfactory estimate for the inverse covariance matrix. We show that the resulting estimate enjoys very good theoretical properties by establishing oracle inequalities for the estimation error.

The probabilistic bounds we prove suggest that the estimation error of the proposed method adapts to the sparseness of the true inverse covariance matrix. The implications of these oracle in-

equalities are demonstrated on a couple of popular covariance matrix models. When Ω_0 corresponds to a Gaussian graphical model of degree d, we show that the proposed method can achieve convergence rate of the order $O_p[d(n^{-1}\log p)^{-1/2}]$ in terms of several matrix operator norms. We also examine the more general case where the rows or columns of Ω_0 belong to an ℓ_α ball ($0 < \alpha < 1$), the family of positive definite matrices introduced by Bickel and Levina (2008b). We show that the proposed method achieves the convergence rate of $O_p[(n^{-1}\log p)^{(1-\alpha)/2}]$, the same as that obtained by Bickel and Levina (2008b) when assuming that Σ_0 rather than Ω_0 belongs to the same family of matrices. For both examples, we also show that the obtained rates are optimal in a minimax sense when considering estimation error in terms of matrix ℓ_1 or ℓ_∞ norms.

The proposed method shares similar spirits with the neighborhood selection approach proposed by Meinshausen and Bühlmann (2006). However, the two techniques are developed for different purposes. Neighborhood selection aims at identifying the correct graphical model whereas our goal is to estimate the covariance matrix. The distinction is clear when the inverse covariance matrix is only "approximately" sparse and does not have many zero entries. Even when the inverse covariance matrix is indeed sparse, the two tasks of estimation and selection can be different. In particular, our results suggest that good estimation can be achieved under conditions weaker than those often assumed to ensure good selection.

The rest of the paper is organized as follows. In the next section, we describe in details the estimating procedure. Theoretical properties of the method are established in Section 3. All detailed proofs are relegated to Section 6. Numerical experiments are presented in Section 4 to illustrate the merits of the proposed method before concluding with some remarks in Section 5.

2. Methodology

In what follows, we shall write $X_{-i} = (X_1, \ldots, X_{i-1}, X_{i+1}, \ldots, X_p)'$. Similarly, denote by $\Sigma_{-i,-j}$ the submatrix of Σ with its ith row and jth column removed. Other notation can also be interpreted in the same fashion. For example, $\Sigma_{i,-j}$ or $\Sigma_{-i,j}$ represents the ith row of Σ with its j entry removed or the jth column with its ith entry removed respectively.

2.1 Regression and Inverse Covariance Matrix

It is well known that if X follows a multivariate normal distribution $\mathcal{N}(\mu, \Sigma)$, then the conditional distribution of X_i given X_{-i} remains normally distributed (Anderson, 2003), that is,

$$X_i | X_{-i} \sim \mathcal{N}\left(\mu_i + \Sigma_{i,-i}\Sigma_{-i,-i}^{-1}(X_{-i} - \mu_{-i}), \Sigma_{ii} - \Sigma_{i,-i}\Sigma_{-i,-i}^{-1}\Sigma_{-i,i}\right).$$

This can be equivalently expressed as the following regression equation:

$$X_i = \alpha_i + X_{-i}'\theta_{(i)} + \varepsilon_i, \tag{1}$$

where $\alpha_i = \mu_i - \Sigma_{i,-i}\Sigma_{-i,-i}^{-1}\mu_{-i}$ is a scalar, $\theta_{(i)} = \Sigma_{-i,-i}^{-1}\Sigma_{-i,i}$ is a $p-1$ dimensional vector and $\varepsilon_i \sim \mathcal{N}(0, \Sigma_{ii} - \Sigma_{i,-i}\Sigma_{-i,-i}^{-1}\Sigma_{-i,i})$ is independent of X_{-i}. When X follows a more general distribution, similar relationship holds in that $\alpha_i + X_{-i}'\theta_{(i)}$ is the best linear unbiased estimate of X_i given X_{-i} whereas $\mathrm{Var}(\varepsilon_i) = \Sigma_{ii} - \Sigma_{i,-i}\Sigma_{-i,-i}^{-1}\Sigma_{-i,i}$.

Now by the inverse formula for block matrices, $\Omega := \Sigma^{-1}$ is given by

$$\begin{pmatrix} \Sigma_{11} & \Sigma_{1,-1} \\ \Sigma_{-1,1} & \Sigma_{-1,-1} \end{pmatrix}^{-1} = \begin{pmatrix} \overbrace{\left(\Sigma_{11} - \Sigma_{1,-1}\Sigma_{-1,-1}^{-1}\Sigma_{-1,1}\right)^{-1}}^{\Omega_{11}} & -\Omega_{11}\Sigma_{1,-1}\Sigma_{-1,-1}^{-1} \\ -\Sigma_{-1,-1}^{-1}\Sigma_{-1,1}\Omega_{11} & * \end{pmatrix}.$$

More generally, the ith column of Ω can be written as

$$\begin{aligned} \Omega_{ii} &= \left(\Sigma_{ii} - \Sigma_{i,-i}\Sigma_{-i,-i}^{-1}\Sigma_{-i,i}\right)^{-1}; \\ \Omega_{-i,i} &= -\left(\Sigma_{ii} - \Sigma_{i,-i}\Sigma_{-i,-i}^{-1}\Sigma_{-i,i}\right)^{-1}\Sigma_{-i,-i}^{-1}\Sigma_{-i,i}. \end{aligned}$$

This immediately connects with (1):

$$\begin{aligned} \Omega_{ii} &= (\mathrm{Var}(\varepsilon_i))^{-1}; \\ \Omega_{-i,i} &= -(\mathrm{Var}(\varepsilon_i))^{-1}\theta_{(i)}. \end{aligned}$$

Therefore, an estimate of Ω can potentially be obtained by regressing X_i over X_{-i} for $i = 1, \ldots, p$. Furthermore, the sparsity in the entries of Ω can be translated into sparsity in regression coefficients $\theta_{(i)}$s.

2.2 Initial Estimate

From the aforementioned relationship, a zero entry on the ith column of the inverse covariance matrix implies a zero entry in the regression coefficient $\theta_{(i)}$ and vice versa. This property is exploited by Meinshausen and Bühlmann (2006) to identify the zero pattern of the inverse covariance matrix. Specifically, in the so-called neighborhood selection method, the zero entries of the ith column of Ω_0 are identified by doing variable selection when regressing X_i over X_{-i}. More specifically, they suggest to use Lasso (Tibshirani, 1996) for the purpose of variable selection.

Our goal here, however, is rather different. Instead of identifying which entries of Ω_0 are zero, our focus is on estimating it. The distinction is apparent when Ω_0 is only "approximately" sparse instead of having a lot of zero entries. Even if Ω_0 indeed has lot of zeros, the two tasks can still be quite different in high dimensional problems. For example, in identifying the nonzero entries of Ω_0, it is necessary to assume that all nonzero entries are sufficiently different from zero (see, e.g., Meinshausen and Bühlmann, 2006). Such assumptions may be unrealistic and can be relaxed if the purpose is to estimate the covariance matrix. With such a distinction in mind, the question now is whether or not similar strategies of applying sparse multivariate linear regression to recover the inverse covariance matrix remains useful. The answer is affirmative.

To this end, we consider estimating Ω_0 as follows:

$$\begin{aligned} \tilde{\Omega}_{ii} &= \left(\widehat{\mathrm{Var}}(\varepsilon_i)\right)^{-1}; \\ \tilde{\Omega}_{-i,i} &= -\left(\widehat{\mathrm{Var}}(\varepsilon_i)\right)^{-1}\hat{\theta}_{(i)}, \end{aligned}$$

where $\widehat{\mathrm{Var}}(\varepsilon_i)$ and $\hat{\theta}_{(i)}$ are estimated from regressing X_i over X_{-i}. In particular, we suggest to use the so-called Dantzig selector (Candès and Tao, 2007) for estimating the regression coefficients. We

begin by centering each variable X_i to eliminate the intercept α_i in (1). Denote by $Z_i = X_i - \bar{X}_i$ where $\bar{X}_i$ is the sample average of X_i. The Dantzig selector estimate of $\theta_{(i)}$ is the solution to

$$\min_{\beta \in \mathbb{R}^{p-1}, \beta_0 \in \mathbb{R}} \|\beta\|_{\ell_1} \qquad \text{subject to } \left\| \mathbb{E}_n \left[\left(Z_i - Z'_{-i}\beta \right) Z_{-i} \right] \right\|_{\ell_\infty} \leq \delta,$$

where $\mathbb{E}_n$ represents the sample average, and $\delta > 0$ is a tuning parameter. Recall that $\mathbb{E}_n Z_i Z_j = S_{ij}$. The above problem can also be written in terms of S:

$$\min_{\beta \in \mathbb{R}^{p-1}, \beta_0 \in \mathbb{R}} \|\beta\|_{\ell_1} \qquad \text{subject to } \left\| S_{-i,i} - S_{-i,-i}\beta \right\|_{\ell_\infty} \leq \delta. \tag{2}$$

The minimization of the ℓ_1 norm of the regression coefficient reflects our preference towards sparse models which is particularly important when dealing with high dimensional problems. Once an estimate of $\theta_{(i)}$ is obtained, we can then estimate the variance of ε_i by the mean squared error of the residuals:

$$\widehat{\mathrm{Var}}(\varepsilon_i) = \mathbb{E}_n \left(X_i - X'_{-i}\hat{\theta}_{(i)} \right)^2 = S_{ii} - 2\hat{\theta}'_{(i)} S_{-i,i} + \hat{\theta}'_{(i)} S_{-i,-i} \hat{\theta}_{(i)}.$$

We obtain $\tilde{\Omega}$ by repeating this procedure for $i = 1, \ldots, p$.

We emphasize that for practical purposes, one can also use the Lasso in place of the Dantzig selector for constructing $\tilde{\Omega}$. The choice of Dantzig selector is made for the sake of our further technical developments. In the light of the results of Bickel, Ritov and Tsybakov (2009), similar performance can be expected with either the Lasso or the Dantzig selector although a more rigorous proof when using the Lasso is beyond the scope of the current paper.

2.3 Symmetrization

$\tilde{\Omega}$ is is usually dismissed as an estimate of Ω for it is not even symmetric. In fact, it is not obvious that $\tilde{\Omega}$ is in any sense a reasonable estimate of Ω_0. But a more careful examination suggests otherwise. It reveals that $\tilde{\Omega}$ could be a good estimate in a certain matrix operator norm.

The matrix operator norm is a class of matrix norms induced by vector norms. Let $\|\mathbf{x}\|_{\ell_q}$ be the ℓ_q norm of an p dimensional vector $\mathbf{x} = (x_1, \ldots, x_p)'$, that is,

$$\|\mathbf{x}\|_{\ell_q} = \left(|x_1|^q + \ldots + |x_p|^q \right)^{1/q}.$$

Then the matrix ℓ_q norm for an $p \times p$ square matrix $A = (a_{ij})_{1 \leq i,j \leq p}$ is given by

$$\|A\|_{\ell_q} = \sup_{\mathbf{x} \neq 0} \frac{\|A\mathbf{x}\|_{\ell_q}}{\|\mathbf{x}\|_{\ell_q}}.$$

In the case of $q = 1$ and $q = \infty$, the matrix norm can be given more explicitly as

$$\begin{aligned} \|A\|_{\ell_1} &= \max_{1 \leq j \leq p} \sum_{i=1}^{p} \left| a_{ij} \right|; \\ \|A\|_{\ell_\infty} &= \max_{1 \leq i \leq p} \sum_{j=1}^{p} \left| a_{ij} \right|. \end{aligned}$$

When $q = 2$, the matrix operator norm of A amounts to its leading singular value, and is often referred to as the spectral norm.

A careful study shows that $\tilde{\Omega}$ can be a good estimate of Ω in terms of the matrix ℓ_1 norm in sparse circumstances. It is therefore of interest to consider improved estimates from $\tilde{\Omega}$ that inherits this property. To this end, we propose to adjust $\tilde{\Omega}$ by seeking a symmetric matrix $\hat{\Omega}$ that is the the closest to $\tilde{\Omega}$ in the sense of the matrix ℓ_1 norm, that is, it solves the following problem:

$$\min_{\Omega \text{ is symmetric}} \|\Omega - \tilde{\Omega}\|_{\ell_1}. \tag{3}$$

Recall that

$$\|\Omega - \tilde{\Omega}\|_{\ell_1} = \max_{1 \le j \le p} \sum_{i=1}^{p} \left|\Omega_{ij} - \tilde{\Omega}_{ij}\right|.$$

Problem (3) can therefore be re-formulated as a linear program just like the computation of $\tilde{\Omega}$.

To sum up, our estimate of the inverse covariance matrix is obtained in the following steps:

ALGORITHM FOR COMPUTING $\hat{\Omega}$

Input: Sample covariance matrix – S, tuning parameter – δ.
Output: An estimate of the inverse covariance matrix – $\hat{\Omega}$.

- **Construct $\tilde{\Omega}$**
  for $i = 1$ to p
  - Estimate $\theta_{(i)}$ by $\hat{\theta}_{(i)}$, the solution to

$$\min_{\beta \in \mathbb{R}^{p-1}} \|\beta\|_{\ell_1} \qquad \text{subject to } \left\|S_{-i,i} - S_{-i,-i}\beta\right\|_{\ell_\infty} \le \delta.$$

  - Set

$$\tilde{\Omega}_{ii} = \left(S_{ii} - 2\hat{\theta}'_{(i)}S_{-i,i} + \hat{\theta}'_{(i)}S_{-i,-i}\hat{\theta}_{(i)}\right)^{-1}.$$

  - Set

$$\tilde{\Omega}_{-i,i} = -\tilde{\Omega}_{ii}\hat{\theta}_{(i)}.$$

  end

- **Construct $\hat{\Omega}$**
  - Set $\hat{\Omega}$ as the solution to

$$\min_{\Omega \text{ is symmetric}} \|\Omega - \tilde{\Omega}\|_{\ell_1}.$$

It is worth pointing out that that proposed method depends on the data only through the sample covariance matrix. This fact is of great practical importance since it suggests that a large sample size will not affect the computational complexity in calculating $\hat{\Omega}$ more than the evaluation of S. Furthermore, only linear programs are involved in the computation of $\hat{\Omega}$, which makes the approach appealing when dealing with very high dimensional problems.

3. Theory

In what follows, we shall assume that the components of X are uniformly sub-gaussian, that is, there exist constants $c_0 \geq 0$, and $T > 0$ such that for any $|t| \leq T$

$$\mathbb{E}e^{tX_i^2} \leq c_0, \qquad i = 1, 2, \ldots, p.$$

This condition is clearly satisfied when X follows a multivariate normal distribution. It also holds true when X_is are bounded.

3.1 Oracle Inequality

Our main tool to study the theoretical properties of $\hat{\Omega}$ is an oracle type of inequality regarding the estimation error $\|\hat{\Omega} - \Omega_0\|_{\ell_1}$. To this end, we introduce the following set of "oracle" inverse covariance matrices:

$$O(\nu, \eta, \tau) = \left\{ \Omega \succ 0 : \begin{array}{ll} \nu^{-1} \leq \lambda_{\min}(\Omega) \leq \lambda_{\max}(\Omega) \leq \nu & \text{(Bounded Eigenvalues)} \\ \|\Sigma_0 \Omega - I\|_{\max} \leq \eta & \text{(“Good” Approximation)} \\ \|\Omega\|_{\ell_1} \leq \tau & \text{(Sparsity)} \end{array} \right\},$$

where $A \succ 0$ indicates that a matrix A is symmetric and positive definite; $\nu > 1, \tau > 0$, and $\eta \geq 0$ are parameters; $\lambda_{\min}$ and $\lambda_{\max}$ represent the smallest and largest eigenvalue respectively; and $\|\cdot\|_{\max}$ represents the entry-wise ℓ_∞ norm, that is,

$$\|A\|_{\max} = \max_{1 \leq i,j \leq p} |a_{ij}|.$$

We refer to $O(\nu, \eta, \tau)$ as an "oracle" set because its definition requires the knowledge of the true covariance matrix Σ_0. Every member of $O(\nu, \eta, \tau)$ is symmetric, positive definite with eigenvalues bounded away from 0 and ∞, and belongs to an ℓ_1 ball. Moreover, $O(\nu, \eta, \tau)$ consists of matrices that approximate Ω_0 well. It is worth noting that different from the usual vector case, the choice of metric is critical when evaluating approximating error for matrices. In particular for our purpose, the approximation error is measured by $\|\Sigma_0 \Omega - I\|_{\max}$, which vanishes if and only if $\Omega = \Omega_0$. We are now in position to state our main result.

Theorem 1 *There exist constants C_1, C_2 depending only on ν, τ, $\lambda_{\min}(\Omega_0)$ and $\lambda_{\max}(\Omega_0)$, and C_3 depending only on c_0 such that, for any $A > 0$, with probability at least $1 - p^{-A}$,*

$$\left\|\hat{\Omega} - \Omega_0\right\|_{\ell_1} \leq C_1 \inf_{\Omega \in O(\nu,\eta,\tau)} \left(\left\|\Omega - \Omega_0\right\|_{\ell_1} + \deg(\Omega)\delta \right), \tag{4}$$

provided that

$$\inf_{\Omega \in O(\nu,\eta,\tau)} \left(\left\|\Omega - \Omega_0\right\|_{\ell_1} + \deg(\Omega)\delta \right) \leq C_2, \tag{5}$$

and

$$\delta \geq \nu\eta + C_3 \nu\tau \lambda_{\min}^{-1}(\Omega_0)((A+1)n^{-1}\log p)^{1/2}, \tag{6}$$

where $\deg(\Omega) = \max_i \sum_j \mathbb{I}(\Omega_{ij} \neq 0)$.

We remark that the oracle inequality given in Theorem 1 is of probabilistic nature and non-asymptotic. However, (4) holds with overwhelming probability as we are interested in the case when p is very large. The requirement (5) is in place to ensure that the true inverse covariance matrix is indeed "approximately" sparse. Another note is on the choice of the tuning parameter δ. To ensure an tight upper bound in (4), smaller δs are preferred. On the other hand, Condition (6) specifies how small they can be. For simplicity, we have used the same tuning parameter δ for estimating all $\theta_{(i)}$s. In practice, it may be beneficial to use different δs for different $\theta_{(i)}$s. Following the same argument, it can be shown that the statement of Theorem 1 continue to hold if all tuning parameters used satisfy Condition (6).

Recall that for a symmetric matrix A, $\|A\|_{\ell_\infty} = \|A\|_{\ell_1}$ and

$$\|A\|_{\ell_2} \le (\|A\|_{\ell_1}\|A\|_{\ell_\infty})^{1/2} = \|A\|_{\ell_1}.$$

A direct consequence of Theorem 1 is that the same upper bound holds true under matrix ℓ_∞ and ℓ_2 norms.

Corollary 2 *There exist constants C_1, C_2 depending only on ν, τ, $\lambda_{\min}(\Omega_0)$ and $\lambda_{\max}(\Omega_0)$, and C_3 depending only on c_0 such that, for any $A > 0$, with probability at least $1 - p^{-A}$,*

$$\left\|\hat{\Omega} - \Omega_0\right\|_{\ell_\infty}, \left\|\hat{\Omega} - \Omega_0\right\|_{\ell_2} \le C_1 \inf_{\Omega \in O(\nu,\eta,\tau)} \left(\left\|\Omega - \Omega_0\right\|_{\ell_1} + \deg(\Omega)\delta\right),$$

provided that

$$\inf_{\Omega \in O(\nu,\eta,\tau)} \left(\left\|\Omega - \Omega_0\right\|_{\ell_1} + \deg(\Omega)\delta\right) \le C_2,$$

and

$$\delta \ge \nu\eta + C_3\nu\tau\lambda_{\min}^{-1}(\Omega_0)((A+1)n^{-1}\log p)^{1/2}.$$

The bound on the matrix ℓ_2 has great practical implications when we are interested in estimating the covariance matrix or need to a positive definite estimate of Ω. The proposed estimate $\hat{\Omega}$ is symmetric but not guaranteed to be positive definite. However, Corollary 2 suggests that with overwhelming probability, it is indeed positive definite provided that the upper bound is sufficiently small because

$$\lambda_{\min}(\hat{\Omega}) \ge \lambda_{\min}(\Omega_0) - \left\|\hat{\Omega} - \Omega_0\right\|_{\ell_2}.$$

Moreover, a positive definite estimate of Ω can always be constructed by replacing its negative eigenvalues with δ. Denote the resulting estimate by $\hat{\hat{\Omega}}$. By Corollary 2, it can be shown that

Corollary 3 *There exist constants C_1, C_2 depending only on ν, τ, $\lambda_{\min}(\Omega_0)$ and $\lambda_{\max}(\Omega_0)$, and C_3 depending only on c_0 such that, for any $A > 0$, with probability at least $1 - p^{-A}$,*

$$\left\|\hat{\hat{\Omega}}^{-1} - \Sigma_0\right\|_{\ell_2}, \left\|\hat{\hat{\Omega}} - \Omega_0\right\|_{\ell_2} \le C_1 \inf_{\Omega \in O(\nu,\eta,\tau)} \left(\left\|\Omega - \Omega_0\right\|_{\ell_1} + \deg(\Omega)\delta\right),$$

provided that

$$\inf_{\Omega \in O(\nu,\eta,\tau)} \left(\left\|\Omega - \Omega_0\right\|_{\ell_1} + \deg(\Omega)\delta\right) \le C_2,$$

and

$$\delta \ge \nu\eta + C_3\nu\tau\lambda_{\min}^{-1}(\Omega_0)((A+1)n^{-1}\log p)^{1/2}.$$

When considering a particular class of inverse covariance matrices, we can use the oracle inequalities established here with a proper choice of the oracle set O. Typically in choosing a good oracle set O, we take ν and τ to be of finite magnitude whereas the approximation error η sufficiently small. To further illustrate their practical implications, we now turn to a couple of more concrete examples.

3.2 Sparse Models

We begin with a class of matrix models that are closely connected with graphical models. When X follows a multivariate normal distribution, the sparsity of the entries of the inverse covariance matrix relates to the notion of conditional independence: the (i, j) entry of Ω_0 being zero implies that X_i is independent of X_j conditional on the remaining variables and vice versa. The conditional independence relationships among the coordinates of the Gaussian random vector X can be represented by an undirected graph $G = (V, E)$, often referred to as a Gaussian graphical model, where V contains p vertices corresponding to the p coordinates and the edge between X_i and X_j is present if and only if X_i and X_j are not independent conditional on the others. The complexity of a graphical model is commonly measured by its degree:

$$\deg(G) = \max_{1 \le i \le p} \sum_j e_{ij},$$

where $e_{ij} = 1$ if there is an edge between X_i and X_j and 0 otherwise. Gaussian graphical models are an indispensable statistical tool in studying communication networks and gene pathways among many other subjects. The readers are referred to Whittaker (1990), Lauritzen (1996) and Edwards (2000) for further details.

Motivated by this connection, we consider the following class of inverse covariance matrices:

$$\mathcal{M}_1(\tau_0, \nu_0, d) = \left\{ A \succ 0 : \|A\|_{\ell_1} < \tau_0, \nu_0^{-1} < \lambda_{\min}(A) < \lambda_{\max}(A) < \nu_0, \deg(A) < d \right\},$$

where $\tau_0, \nu_0 > 1$, and $\deg(A) = \max_i \sum_j \mathbb{I}(A_{ij} \neq 0)$. In this case, taking an oracle set such that $\Omega_0 \in O$ yields the following result:

Theorem 4 *Assume that $d(n^{-1} \log p)^{1/2} = o(1)$. Then*

$$\sup_{\Omega_0 \in \mathcal{M}_1(\tau_0, \nu_0, d)} \left\| \hat{\Omega} - \Omega_0 \right\|_{\ell_q} = O_p\left(d \sqrt{\frac{\log p}{n}} \right), \tag{7}$$

provided that $\delta = C(n^{-1} \log p)^{1/2}$ and C is large enough.

Theorem 4 follows immediately from Theorem 1 and Corollary 2 by taking $\eta = 0, \tau = \|\Omega_0\|_{\ell_1}$, and $\nu = \max\{\lambda_{\min}^{-1}(\Omega_0), \lambda_{\max}(\Omega_0)\}$, which ensures that $\Omega_0 \in O(\nu, \eta, \tau)$. We note that the rate of convergence given by (7) is also optimal in the minimax sense when considering matrix ℓ_1 norm.

Theorem 5 *Assume that $d(n^{-1} \log p)^{1/2} = o(1)$. Then there exists a constant $C > 0$ depending only on τ_0, and ν_0 such that*

$$\inf_{\bar{\Omega}} \sup_{\Omega_0 \in \mathcal{M}_1(\tau_0, \nu_0, d)} \mathbb{P}\left\{ \left\| \bar{\Omega} - \Omega_0 \right\|_{\ell_1} \ge C d \sqrt{\frac{\log p}{n}} \right\} > 0,$$

where the infimum is taken over all estimate $\bar{\Omega}$ based on observations $X^{(1)}, \ldots, X^{(n)}$.

Theorem 5 indicates that the estimability of a sparse inverse covariance matrix is dictated by its degree as opposed to the total number of nonzero entries. This observation gives a plausible explanation on why the usual ℓ_1 penalized likelihood estimate (see, e.g., Yuan and Lin, 2007; Banarjee, El Ghaoui and d'Aspremont, 2008) may not be the best to exploit this type of sparsity because the penalty employed by these methods is convex relaxations of the constraint on total number of edges in a graphical model instead of its degree.

It is also of interest to compare our results with those from Meinshausen and Bühlmann (2006). As mentioned before, the goal of the neighborhood selection from Meinshausen and Bühlmann (2006) is to select the correct graphical model whereas our focus here is on estimating the covariance matrix. However, the neighborhood selection method can be followed by the maximum likelihood estimation based on the selected graphical model to yield a covariance matrix estimate. Clearly the success of this method hinges upon the ability of the neighborhood selection to choose a correct graphical model. It turns out that selecting the graphical model can be more difficult than estimating the covariance matrix as reflected by the more restrictive assumptions made in Meinshausen and Bühlmann (2006). In particular, to be able to identify the nonzero entries of the inverse covariance matrix, it is necessary that they are sufficiently large in magnitude whereas such requirement is generally not needed for the purpose of estimation. Moreover, Meinshausen and Bühlmann (2006) only deals with the case when the dimensionality is of a polynomial order of the sample size, that is, $p = O(n^\gamma)$ for some $\gamma > 0$.

3.3 Approximately Sparse Models

In many applications, the inverse covariance matrix is only approximately sparse. A popular way to model this class of covariance matrix is to assume that its rows or columns belong to an ℓ_α ball ($0 < \alpha < 1$):

$$\mathcal{M}_2(\tau_0, \nu_0, \alpha, M) = \left\{ A \succ 0 : \|A^{-1}\|_{\ell_1} < \tau_0, \nu_0^{-1} \le \lambda_{\min}(A) \le \lambda_{\max}(A) \le \nu_0, \sum_{j=1}^{p} \left|A_{ij}\right|^\alpha \le M \right\},$$

where $\tau_0, \nu_0 > 1$ and $0 < \alpha < 1$. $\mathcal{M}_2$ can be viewed as a natural extension of the sparse model $\mathcal{M}_1$. In particular, $\mathcal{M}_1$ can be viewed as the limiting case of $\mathcal{M}_2$ when α approaches 0. By relaxing α, $\mathcal{M}_2$ includes matrices that are less sparse than those included in $\mathcal{M}_1$. The particular class of matrices were first introduced by Bickel and Levina (2008b) who investigate the case when $\Sigma_0 \in \mathcal{M}_2(\tau_0, \nu_0, \alpha, M)$. We note that their setting is different from ours as $\mathcal{M}_2$ is not closed with respect to inversion. An application of Theorem 1 and Corollary 2 yields:

Theorem 6 *Assume that* $M\left(n^{-1}\log p\right)^{\frac{1-\alpha}{2}} = o(1)$. *Then*

$$\sup_{\Omega_0 \in \mathcal{M}_2(\tau_0, \nu_0, \alpha, M)} \|\hat{\Omega} - \Omega_0\|_{\ell_q} = O_p\left(M \left(\frac{\log p}{n} \right)^{\frac{1-\alpha}{2}} \right), \tag{8}$$

provided that $\delta = C(n^{-1}\log p)^{1/2}$ *and* C *is sufficiently large*.

Assuming that $\Sigma_0 \in \mathcal{M}_2$, Bickel and Levina (2008b) study thresholding estimator of the covariance matrix. Their setting is different from ours because $\mathcal{M}_2$ is not closed under inversion. It is

however interesting to note that Bickel and Levina (2008b) show that thresholding the sample covariance matrix S at an appropriate level can achieve the same rate given by right hand side of (8). The coincidence should not come as a surprise despite the difference in problem setting because the size of the parameter space in both problems are the same. Moreover, the following theorem shows that in both settings, the rate is optimal in the minimax sense.

Theorem 7 *Assume that* $M\left(n^{-1}\log p\right)^{\frac{1-\alpha}{2}} = o(1)$. *Then there exists a constant* $C > 0$ *depending only on* τ_0, *and* ν_0 *such that*

$$\inf_{\bar{\Omega}} \sup_{\Omega_0 \in \mathcal{M}_2(\tau_0,\nu_0,\alpha,M)} \mathbb{P}\left\{ \left\|\bar{\Omega} - \Omega_0\right\|_{\ell_1} \geq CM\left(\frac{\log p}{n}\right)^{\frac{1-\alpha}{2}} \right\} > 0, \tag{9}$$

and

$$\inf_{\bar{\Sigma}} \sup_{\Sigma_0 \in \mathcal{M}_2(\tau_0,\nu_0,\alpha,M)} \mathbb{P}\left\{ \left\|\bar{\Sigma} - \Sigma_0\right\|_{\ell_1} \geq CM\left(\frac{\log p}{n}\right)^{\frac{1-\alpha}{2}} \right\} > 0, \tag{10}$$

where the infimum is taken over all estimate, $\bar{\Omega}$ *or* $\bar{\Sigma}$, *based on observations* $X^{(1)},\ldots,X^{(n)}$.

4. Numerical Experiments

To illustrate the merits of the proposed method and compare it with other popular alternatives, we now conduct a set of numerical studies. Specifically, we generated $n = 50$ observations from a multivariate normal distribution with mean 0 and variance covariance matrix given by $\Sigma^0_{ij} = \rho^{|i-j|}$ for some $\rho \neq 0$. Such covariance structure corresponds to an AR(1) model. Its inverse covariance matrix is banded with the magnitude of ρ determining the strength of the dependence among the coordinates. We consider combinations of seven different values of $\rho, 0.1, 0.2,\ldots, 0.7$ and four values of the dimensionality, $p = 25, 50, 100$ or 200. Two hundred data sets were simulated for each combination. For each simulated data set, we ran the proposed method to construct estimate of the inverse covariance matrix. As suggested by the theoretical developments, we set $\delta = (2n^{-1}\log p)^{-1}$ throughout all simulation studies. For comparison purposes, we included a couple of popular alternative covariance matrix estimates in the study. The first is the ℓ_1 penalized likelihood estimate of Yuan and Lin (2007). As suggested by Yuan and Lin (2007), the BIC criterion was used to choose the tuning parameter among a total of 20 pre-specified values. The second is a variant of the neighborhood selection approach of Meinshausen and Bühlmann (2006). As pointed out earlier, the goal of the neighborhood selection is to identify the underlying graphical model rather than estimating the covariance matrix. We consider here a simple two-step procedure where the maximum likelihood estimate based on the selected graphical model is employed. As advocated by Meinshausen and Bühlmann (2006), the level of significance is set at $\alpha = 0.05$ in identifying the graphical model. Figure 1 summarizes the estimation error measured by the spectral norm, that is, $\|\hat{C} - C\|_{\ell_2}$, for the three methods, averaged over two hundred runs.

A few observations can be made from Figure 1. We first note that the proposed method tends to outperform the other two methods when ρ is small and the advantage becomes more evident as the dimensionality increases. On the other hand, the advantage over the neighborhood selection based method gradually vanishes as ρ increases yet the proposed method remains competitive. A plausible explanation is the distinction between estimation and selection in high dimensional problems as pointed out earlier. The success of the neighbor selection based method hinges upon a good selection

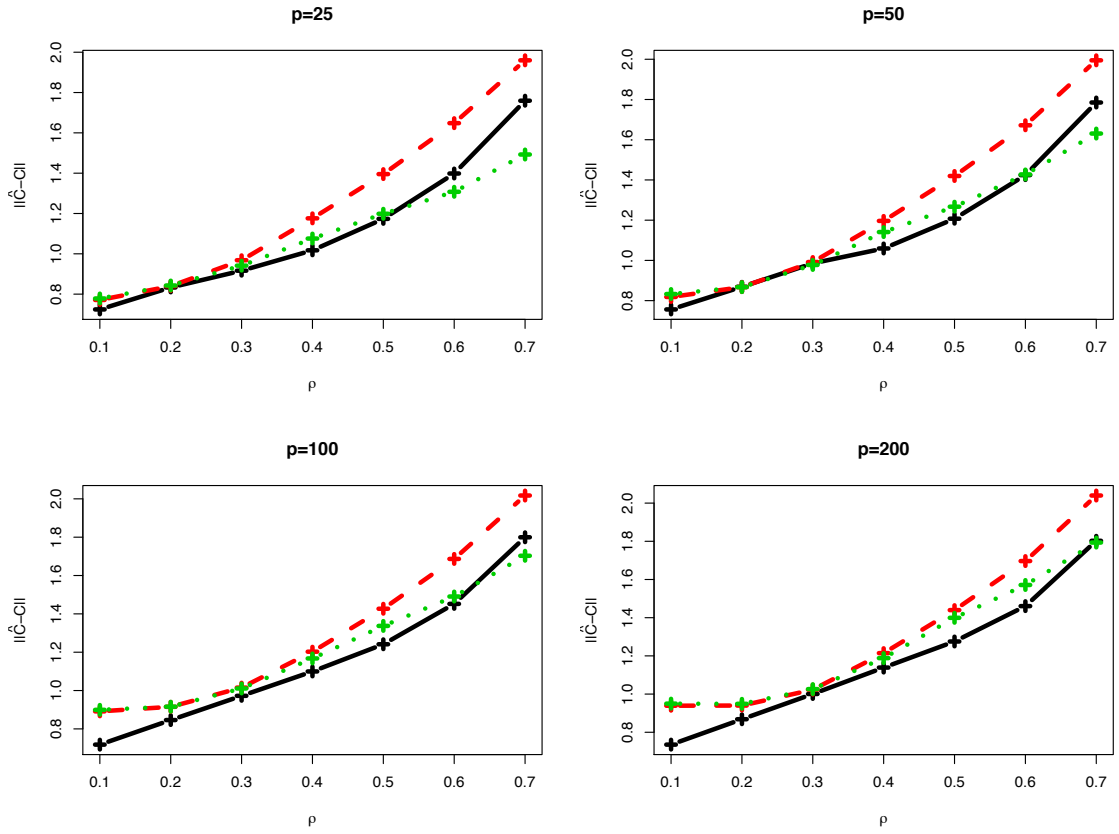

Figure 1: Estimation error of the proposed method (black solid lines), the ℓ_1 penalized likelihood estimate (red dashed lines) and the maximum likelihood estimate based on the graphical model selected through neighborhood selection (green dotted lines). Each panel corresponds to a different value of the dimensionality. X-axes represent the value of ρ. The estimation errors are averaged over two hundred runs.

of the graphical model. Recall that the inverse covariance matrix is banded with nonzero entries increasing in magnitude with ρ. For large values of ρ, the task of identifying the correct graphical model is relatively easier. With a good graphical model chosen, refitting it with the maximum likelihood estimator could reduce biases often associated with regularization approaches. Such benefit diminishes for small values of ρ as identifying nonzero entries in the inverse covariance matrix becomes more difficult.

At last, we note that all three methods are relatively efficient to compute. For example, when $p = 200$ and $\rho = 0.5$, the averaged CPU time for the ℓ_1 penalized likelihood estimate is 0.53 seconds, for the neighborhood selection based method is 1.42 seconds, and for the proposed method is 3.21 seconds. Both the ℓ_1 penalized likelihood estimate and the neighborhood selection based method are computed using the graphical Lasso algorithm of Friedman, Hastie and Tibshirani (2008) which iteratively solves a sequence of p Lasso problems using a modified Lars algorithm (Efron et al., 2004). The algorithm is specially developed to take advantage of the sparse nature of the problem

and available in the `glasso` package in R. The proposed method is implemented in MATLAB using its general purpose interior-point algorithm based linear programming solver and could be further improved using more specialized algorithms (see, e.g., Asif, 2008).

5. Discussions

High dimensional (inverse) covariance matrix estimation is becoming more and more common in various scientific and technological areas. Most of the existing methods are designed to benefit from sparsity of the covariance matrix, and based on banding or thresholding the sample covariance matrix. Sparse models for the inverse covariance matrix, despite its practical appeal and close connection to graphical modeling, are more difficult to be taken advantage of due to heavy computational cost as well as the lack of a coherent theory on how such sparsity can be effectively exploited. In this paper, we propose an estimating procedure that addresses both challenges. The proposed method can be formulated using linear programming and therefore computed very efficiently. We also show that the resulting estimate enjoys nice probabilistic properties, which translates to sharp convergence rates in terms of matrix operator norms under a couple of common settings.

The choice of the tuning parameter δ is of great practical importance. Our theoretical developments have suggested reasonable choices of the tuning parameter and it seems to work well in the well-controlled simulation settings. In practice, however, a data-driven choice such as those determined by multi-fold cross-validation may yield improved performance.

We also note that the method can be easily extended to handle prior information regarding the sparsity patterns of the inverse covariance matrices. Such situations often arise in the context of, for example, genomics. In a typical gene expression experiment, tens of thousands of genes are often studied simultaneously. Among these genes, there are often known pathways which corresponding to conditional (in)dependence among a subset of the genes, or in our notation, variables. This can be naturally interpreted as some of the entries of Ω_0 being known to be nonzero or zero. Such prior information can be easily incorporated in our procedure. In particular, it suffices to set some of the entries of β to be exact zero apriori in (2). Likewise, if a particular entry of β is known to be nonzero, we can also opt to minimize the ℓ_1 norm of only the remaining entries.

6. Proofs

We now present the proofs to Theorems 1, 5, 6 and 7.

6.1 Proof of Theorem 1

We begin by comparing $\hat{\theta}_{(i)}$ with $\theta_{(i)}$. For brevity, we shall abbreviate the subscript (i) in what follows when no confusion occurs. Recall that $\theta = -\Omega^0_{-i,i}/\Omega^0_{ii}$ and

$$\hat{\theta} = \underset{\beta \in \mathcal{F}}{\operatorname{argmin}} \|\beta\|_{\ell_1},$$

where $\mathcal{F} = \{\beta : \|S_{-i,i} - S_{-i,-i}\beta\|_{\ell_\infty} \le \delta\}$. For a given $\Omega \in O(\nu, \eta, \tau)$, let $\Omega \in O$ and $\gamma = -\Omega_{-i,i}/\Omega_{ii}$. We first show that $\gamma \in \mathcal{F}$.

Lemma 8 *Under the event that* $\|S - \Sigma_0\|_{\max} < C_0 \lambda_{\max}(\Sigma_0)((A+1)n^{-1}\log p)^{1/2}$,

$$\|S_{-i,i} - S_{-i,-i}\gamma\|_{\ell_\infty} \le \delta,$$

provided that

$$\delta \geq \eta\nu + C_0\tau\nu\lambda_{\max}(\Sigma_0)((A+1)n^{-1}\log p)^{1/2}.$$

Proof By the definition of $O(\nu,\eta,\tau)$, for any $j \neq i$,

$$\left|\Sigma^0_{j\cdot}\Omega_{\cdot i}\right| = \Omega_{ii}\left|\Sigma^0_{ji} - \Sigma^0_{j,-i}\gamma\right| \leq \|\Sigma_0\Omega - I\|_{\max} \leq \eta,$$

which implies that

$$\left\|\Sigma^0_{-i,i} - \Sigma^0_{-i,-i}\gamma\right\|_{\ell_\infty} = \max_{j\neq i}\left|\Sigma^0_{ji} - \Sigma^0_{j,-i}\gamma\right| \leq \Omega^{-1}_{ii}\eta \leq \lambda^{-1}_{\min}(\Omega)\eta \leq \eta\nu.$$

An application of the triangular inequality now yields

$$\begin{aligned}
\|S_{-i,i} - S_{-i,-i}\gamma\|_{\ell_\infty} &\leq \left\|S_{-i,i} - \Sigma^0_{-i,i}\right\|_{\ell_\infty} + \left\|\left(S_{-i,-i} - \Sigma^0_{-i,-i}\right)\gamma\right\|_{\ell_\infty} + \left\|\Sigma^0_{-i,i} - \Sigma^0_{-i,-i}\gamma\right\|_{\ell_\infty} \\
&\leq \|S - \Sigma_0\|_{\max} + \|S - \Sigma_0\|_{\max}\|\gamma\|_{\ell_1} + \eta\nu \\
&= \|S - \Sigma_0\|_{\max}\|\Omega_{\cdot i}\|_{\ell_1}/\Omega_{ii} + \eta\nu \\
&\leq \tau\nu\|S - \Sigma_0\|_{\max} + \eta\nu.
\end{aligned}$$

The claim now follows. ■

Now that $\gamma \in \mathcal{F}$, by the definition of $\hat{\theta}$,

$$\|\hat{\theta}\|_{\ell_1} \leq \|\gamma\|_{\ell_1} \leq \Omega^{-1}_{ii}\|\Omega_{\cdot i}\|_{\ell_1} - 1 \leq \lambda^{-1}_{\min}(\Omega)\|\Omega\|_{\ell_1} - 1 \leq \nu\tau - 1. \tag{11}$$

Write $\mathcal{J} = \{j : \gamma_j \neq 0\}$. Denote by $d_{\mathcal{J}} = \mathrm{card}(\mathcal{J})$. It is clear that $d_{\mathcal{J}} \leq \deg(\Omega)$. From (11),

$$0 \leq \|\gamma\|_{\ell_1} - \|\hat{\theta}\|_{\ell_1} \leq \|\hat{\theta}_{\mathcal{J}} - \gamma_{\mathcal{J}}\|_{\ell_1} - \|\hat{\theta}_{\mathcal{J}^c}\|_{\ell_1}.$$

Thus,

$$\begin{aligned}
\|\hat{\theta} - \gamma\|_{\ell_1} &= \|\hat{\theta}_{\mathcal{J}} - \gamma_{\mathcal{J}}\|_{\ell_1} + \|\hat{\theta}_{\mathcal{J}^c}\|_{\ell_1} \\
&\leq 2\|\hat{\theta}_{\mathcal{J}} - \gamma_{\mathcal{J}}\|_{\ell_1} \\
&\leq 2d^{1/2}_{\mathcal{J}}\|\hat{\theta}_{\mathcal{J}} - \gamma_{\mathcal{J}}\|_{\ell_2} \\
&\leq 2d^{1/2}_{\mathcal{J}}\|\hat{\theta} - \gamma\|_{\ell_2} \\
&\leq 2d^{1/2}_{\mathcal{J}}\lambda^{-1}_{\min}(\Sigma^0_{-i,-i})\left[\left(\hat{\theta} - \gamma\right)'\Sigma^0_{-i,-i}\left(\hat{\theta} - \gamma\right)\right]^{1/2} \\
&\leq 2\lambda^{-1}_{\min}(\Sigma_0)d^{1/2}_{\mathcal{J}}\left[\left(\hat{\theta} - \gamma\right)'\Sigma^0_{-i,-i}\left(\hat{\theta} - \gamma\right)\right]^{1/2} \\
&= 2\lambda_{\max}(\Omega_0)d^{1/2}_{\mathcal{J}}\left[\left(\hat{\theta} - \gamma\right)'\Sigma^0_{-i,-i}\left(\hat{\theta} - \gamma\right)\right]^{1/2}.
\end{aligned}$$

Observe that

$$\left(\hat{\theta} - \gamma\right)'\Sigma^0_{-i,-i}\left(\hat{\theta} - \gamma\right) \leq \|\hat{\theta} - \gamma\|_{\ell_1}\left\|\Sigma^0_{-i,-i}\left(\hat{\theta} - \gamma\right)\right\|_{\ell_\infty}.$$

Therefore,

$$\|\hat{\theta} - \gamma\|_{\ell_1} \leq 2\lambda_{\max}(\Omega_0)d^{1/2}_{\mathcal{J}}\|\hat{\theta} - \gamma\|^{1/2}_{\ell_1}\left\|\Sigma^0_{-i,-i}\left(\hat{\theta} - \gamma\right)\right\|^{1/2}_{\ell_\infty},$$

which implies that

$$\|\hat{\theta}-\gamma\|_{\ell_1} \leq 4\lambda_{\max}^2(\Omega_0) d_{\mathcal{G}} \left\|\Sigma^0_{-i,-i}\left(\hat{\theta}-\gamma\right)\right\|_{\ell_\infty}. \tag{12}$$

We now set up to further bound the last term on the right hand side. We appeal to the following result.

Lemma 9 *Under the event that* $\|S-\Sigma_0\|_{\max} < C_0\lambda_{\max}(\Sigma_0)((A+1)n^{-1}\log p)^{1/2}$, *we have*

$$\left\|\Sigma^0_{-i,-i}\left(\hat{\theta}-\gamma\right)\right\|_{\ell_\infty} \leq 2\delta,$$

provided that

$$\delta \geq \eta\nu + C_0\tau\nu\lambda_{\max}(\Sigma_0)((A+1)n^{-1}\log p)^{1/2}.$$

Proof By triangular inequality,

$$\left\|\Sigma^0_{-i,-i}\left(\hat{\theta}-\gamma\right)\right\|_{\ell_\infty} \leq \left\|\Sigma^0_{-i,-i}(\theta-\gamma)\right\|_{\ell_\infty} + \left\|\Sigma^0_{-i,-i}\left(\hat{\theta}-\theta\right)\right\|_{\ell_\infty}. \tag{13}$$

We begin with the first term on the right hand side. Recall that

$$\Sigma^0_{-i,i}\Omega^0_{ii} + \Sigma^0_{-i,-i}\Omega^0_{-i,-i} = \mathbf{0},$$

which implies that

$$\Sigma^0_{-i,-i}\theta = \Sigma^0_{-i,i}. \tag{14}$$

Hence,

$$\left\|\Sigma^0_{-i,-i}(\theta-\gamma)\right\|_{\ell_\infty} = \left\|\Sigma^0_{-i,i}-\Sigma^0_{-i,-i}\gamma\right\|_{\ell_\infty} = \Omega_{ii}^{-1}\left\|\Sigma^0_{-i,i}\Omega_{ii}+\Sigma^0_{-i,-i}\Omega_{-i,i}\right\|_{\ell_\infty} \leq \nu\eta.$$

We now turn to the second term on the right hand side of (13). Again by triangular inequality

$$\left\|\Sigma^0_{-i,-i}\left(\hat{\theta}-\theta\right)\right\|_{\ell_\infty} \leq \left\|\left(S_{-i,-i}-\Sigma^0_{-i,-i}\right)\hat{\theta}\right\|_{\ell_\infty} + \left\|S_{-i,-i}\hat{\theta}-\Sigma^0_{-i,-i}\theta\right\|_{\ell_\infty}.$$

To bound the first term on the right hand side, note that

$$\left\|\left(S_{-i,-i}-\Sigma^0_{-i,-i}\right)\hat{\theta}\right\|_{\ell_\infty} \leq \left\|S_{-i,-i}-\Sigma^0_{-i,-i}\right\|_{\max}\|\hat{\theta}\|_{\ell_1} \leq \|S-\Sigma_0\|_{\max}\|\hat{\theta}\|_{\ell_1}.$$

Also recall that

$$\left\|S_{-i,i}-S_{-i,-i}\hat{\theta}\right\|_{\ell_\infty} \leq \delta,$$

and $\Sigma^0_{-i,-i}\theta = \Sigma^0_{-i,i}$. Therefore, by triangular inequality and (14),

$$\left\|S_{-i,-i}\hat{\theta}-\Sigma^0_{-i,-i}\theta\right\|_{\ell_\infty} \leq \delta + \|\Sigma^0_{-i,i}-S_{-i,i}\|_{\ell_\infty} \leq \delta + \|S-\Sigma_0\|_{\max}.$$

To sum up,

$$\begin{aligned}
\left\|\Sigma^0_{-i,-i}\left(\hat{\theta}-\gamma\right)\right\|_{\ell_\infty} &\leq \delta+\nu\eta+\|S-\Sigma_0\|_{\max}+\|S-\Sigma_0\|_{\max}\|\hat{\theta}\|_{\ell_1} \\
&\leq \delta+\nu\eta+\|S-\Sigma_0\|_{\max}(1+\|\gamma\|_{\ell_1}) \\
&\leq \delta+\nu\eta+\|S-\Sigma_0\|_{\max}\|\Omega\|_{\ell_1}/\Omega_{ii} \\
&\leq \delta+\nu\eta+\|S-\Sigma_0\|_{\max}\|\Omega\|_{\ell_1}\lambda_{\min}^{-1}(\Omega) \\
&\leq \delta+\nu\eta+\tau\nu\|S-\Sigma_0\|_{\max},
\end{aligned}$$

which, under the event that $\|S-\Sigma_0\|_{\max} < C_0\lambda_{\max}(\Sigma_0)((A+1)n^{-1}\log p)^{1/2}$, can be further bounded by 2δ by Lemma 8. ■

Together with (12), Lemma 9 implies that for all $i = 1,\ldots,p$

$$\|\hat{\theta}-\gamma\|_{\ell_1} \le 8\lambda^2_{\max}(\Omega_0)d_{\mathcal{J}}\delta,$$

if $\|S-\Sigma_0\|_{\max} < C_0\lambda_{\max}(\Sigma_0)((A+1)n^{-1}\log p)^{1/2}$. We are now in position to bound $\|\tilde{\Omega}-\Omega_0\|_{\ell_1}$. We begin with the diagonal elements $|\tilde{\Omega}_{ii}-\Omega^0_{ii}|$.

Lemma 10 *Assume that* $\|S-\Sigma_0\|_{\max} < C_0\lambda_{\max}(\Sigma_0)((A+1)n^{-1}\log p)^{1/2}$ *and*

$$\delta\lambda_{\max}(\Omega_0)\left(\nu\tau + 8\lambda^2_{\max}(\Omega_0)\lambda^{-1}_{\min}(\Omega_0)d_{\mathcal{J}}\right) + \nu\tau\lambda_{\max}(\Omega_0)\lambda^{-2}_{\min}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1} \le c_0$$

for some numerical constant $0 < c_0 < 1$. *Then*

$$\left|\Omega^0_{ii}-\tilde{\Omega}_{ii}\right| \le \frac{1}{1-c_0}\left(\delta\lambda^2_{\max}(\Omega_0)\left(\nu\tau + 8\lambda^2_{\max}(\Omega_0)d_{\mathcal{J}}\lambda^{-1}_{\min}(\Omega_0)\right) + \nu\tau\lambda^{-2}_{\min}(\Omega_0)\lambda^2_{\max}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1}\right),$$

provided that

$$\delta \ge \eta\nu + C_0\tau\nu\lambda_{\max}(\Sigma_0)((A+1)n^{-1}\log p)^{1/2}.$$

Proof Recall that $\Sigma^0_{-i,i} = \Sigma^0_{-i,-i}\theta$. Therefore

$$\Omega^0_{ii} = \left(\Sigma^0_{ii} - 2\Sigma^0_{i,-i}\theta + \theta'\Sigma^0_{-i,-i}\theta\right)^{-1} = \left(\Sigma^0_{ii} - \Sigma^0_{i,-i}\theta\right)^{-1}.$$

Because

$$\tilde{\Omega}_{ii} = \left(S_{ii} - 2S_{i,-i}\hat{\theta} + \hat{\theta}'S_{-i,-i}\hat{\theta}\right)^{-1},$$

we have

$$\left|\tilde{\Omega}^{-1}_{ii} - \left(\Omega^0_{ii}\right)^{-1}\right| \le |S_{ii}-\Sigma^0_{ii}| + \left|\hat{\theta}'S_{-i,-i}\hat{\theta} - S_{i,-i}\hat{\theta}\right| + \left|S_{i,-i}\hat{\theta} - \Sigma^0_{i,-i}\theta\right|. \tag{15}$$

We now bound the three terms on the right hand side separately. It is clear that the first term can be bounded by $\|S-\Sigma_0\|_{\max}$. Recall that $\hat{\theta} \in \mathcal{F}$. Hence the second term can be bounded as follows:

$$\left|\hat{\theta}'S_{-i,-i}\hat{\theta} - S_{i,-i}\hat{\theta}\right| \le \left\|S_{-i,-i}\hat{\theta} - S_{-i,i}\right\|_{\ell_\infty}\|\hat{\theta}\|_{\ell_1} \le \delta\|\hat{\theta}\|_{\ell_1}.$$

The last term on the right hand side of (15) can also be bounded similarly.

$$\begin{aligned}
\left|S_{i,-i}\hat{\theta} - \Sigma^0_{i,-i}\theta\right| &\le \left|\left(S_{i,-i}-\Sigma^0_{i,-i}\right)\hat{\theta}\right| + \left|\Sigma^0_{i,-i}\left(\hat{\theta}-\theta\right)\right| \\
&\le \|S-\Sigma_0\|_{\max}\|\hat{\theta}\|_{\ell_1} + \|\Sigma^0_{i,-i}\|_{\ell_\infty}\|\hat{\theta}-\theta\|_{\ell_1} \\
&\le \|S-\Sigma_0\|_{\max}\|\hat{\theta}\|_{\ell_1} + \lambda_{\max}(\Sigma_0)\left(\|\hat{\theta}-\gamma\|_{\ell_1} + \|\gamma-\theta\|_{\ell_1}\right) \\
&= \|S-\Sigma_0\|_{\max}\|\hat{\theta}\|_{\ell_1} + \lambda^{-1}_{\min}(\Omega_0)\left(\|\hat{\theta}-\gamma\|_{\ell_1} + \|\gamma-\theta\|_{\ell_1}\right).
\end{aligned}$$

In summary, we have

$$\begin{aligned}
\left|\tilde{\Omega}^{-1}_{ii} - \left(\Omega^0_{ii}\right)^{-1}\right| &\le \|S-\Sigma_0\|_{\max} + \delta\|\hat{\theta}\|_{\ell_1} + \|S-\Sigma_0\|_{\max}\|\hat{\theta}\|_{\ell_1} \\
&\qquad + \lambda^{-1}_{\min}(\Omega_0)\left(\|\hat{\theta}-\gamma\|_{\ell_1} + \|\gamma-\theta\|_{\ell_1}\right) \\
&\le \nu\tau\|S-\Sigma_0\|_{\max} + \delta\|\hat{\theta}\|_{\ell_1} + \lambda^{-1}_{\min}(\Omega_0)\left(8\lambda^2_{\max}(\Omega_0)d_{\mathcal{J}}\delta + \|\gamma-\theta\|_{\ell_1}\right) \\
&\le \delta\left(\nu\tau + 8\lambda^2_{\max}(\Omega_0)\lambda^{-1}_{\min}(\Omega_0)d_{\mathcal{J}}\right) + \lambda^{-1}_{\min}(\Omega_0)\|\gamma-\theta\|_{\ell_1},
\end{aligned}$$

provided that $\|S-\Sigma_0\|_{\max} < C_0\lambda_{\max}(\Sigma_0)((A+1)n^{-1}\log p)^{1/2}$. Together with the fact that $\Omega^0_{ii} \leq \lambda_{\max}(\Omega_0)$, this yields

$$\left|\frac{\Omega^0_{ii}}{\tilde{\Omega}_{ii}} - 1\right| \leq \delta\lambda_{\max}(\Omega_0)\left(\nu\tau + 8\lambda^2_{\max}(\Omega_0)\lambda^{-1}_{\min}(\Omega_0)d_{\mathcal{J}}\right) + \lambda_{\max}(\Omega_0)\lambda^{-1}_{\min}(\Omega_0)\|\gamma-\theta\|_{\ell_1}.$$

Moreover, observe that

$$\begin{aligned}\|\gamma-\theta\|_{\ell_1} &\leq \left(\Omega^0_{ii}\right)^{-1}\|\Omega_{-i,i}-\Omega^0_{-i,i}\|_{\ell_1} + \Omega^{-1}_{ii}\left(\Omega^0_{ii}\right)^{-1}|\Omega_{ii}-\Omega^0_{ii}|\|\Omega_{-i,i}\|_{\ell_1} \\ &\leq \lambda^{-1}_{\min}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1} + \lambda^{-1}_{\min}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1}(\nu\tau-1) \\ &\leq \nu\tau\lambda^{-1}_{\min}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1}.\end{aligned}$$

Therefore,

$$\left|\frac{\Omega^0_{ii}}{\tilde{\Omega}_{ii}} - 1\right| \leq \delta\lambda_{\max}(\Omega_0)\left(\nu\tau + 8\lambda^2_{\max}(\Omega_0)\lambda^{-1}_{\min}(\Omega_0)d_{\mathcal{J}}\right) + \nu\tau\lambda_{\max}(\Omega_0)\lambda^{-2}_{\min}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1}, \quad (16)$$

which implies that

$$\frac{\Omega^0_{ii}}{\tilde{\Omega}_{ii}} \geq 1 - c_0.$$

Subsequently,

$$\tilde{\Omega}_{ii} \leq \frac{1}{1-c_0}\Omega^0_{ii} \leq \frac{1}{1-c_0}\lambda_{\max}(\Omega_0).$$

Together with (16), this implies

$$\begin{aligned}\left|\Omega^0_{ii}-\tilde{\Omega}_{ii}\right| &\leq \tilde{\Omega}_{ii}\left|\frac{\Omega^0_{ii}}{\tilde{\Omega}_{ii}} - 1\right| \\ &\leq \frac{1}{1-c_0}\delta\lambda^2_{\max}(\Omega_0)\left(\nu\tau + 8\lambda^2_{\max}(\Omega_0)\lambda^{-1}_{\min}(\Omega_0)d_{\mathcal{J}}\right) \\ &\qquad + \frac{1}{1-c_0}\nu\tau\lambda^{-2}_{\min}(\Omega_0)\lambda^2_{\max}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1}.\end{aligned}$$

■

We now turn to the off-diagonal entries of $\tilde{\Omega}-\Omega_0$.

Lemma 11 *Under the assumptions of Lemma 10, there exist positive constants C_1, C_2 and C_3 depending only on ν, τ, $\lambda_{\min}(\Omega_0)$ and $\lambda_{\max}(\Omega_0)$ such that*

$$\|\tilde{\Omega}_{-i,\cdot} - \Omega^0_{-i,\cdot}\|_{\ell_1} \leq (C_1 + C_2 d_{\mathcal{J}})\delta + C_3\|\Omega-\Omega_0\|_{\ell_1}.$$

Proof Note that

$$\begin{aligned}
\|\tilde{\Omega}_{-i,i}-\Omega^0_{-i,i}\|_{\ell_1} &= \left\|\tilde{\Omega}_{ii}\hat{\theta}-\Omega^0_{ii}\theta\right\|_{\ell_1} \\
&\le \Omega^0_{ii}\|\hat{\theta}-\theta\|_{\ell_1}+\left|\tilde{\Omega}_{ii}-\Omega^0_{ii}\right|\|\hat{\theta}\|_{\ell_1} \\
&\le \lambda^{-1}_{\min}(\Omega_0)\left(\|\hat{\theta}-\gamma\|_{\ell_1}+\|\gamma-\theta\|_{\ell_1}\right) \\
&\qquad +\frac{\nu\tau-1}{1-c_0}\delta\lambda^2_{\max}(\Omega_0)\left(\nu\tau+8\lambda^2_{\max}(\Omega_0)d_J\lambda^{-1}_{\min}(\Omega_0)\right) \\
&\qquad +\frac{\nu\tau-1}{1-c_0}\nu\tau\lambda^{-2}_{\min}(\Omega_0)\lambda^2_{\max}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1} \\
&\le 8\nu^2 d_J\lambda^{-1}_{\min}(\Omega_0)\delta+\nu\tau\lambda^{-2}_{\min}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1} \\
&\qquad +\frac{\nu\tau-1}{1-c_0}\delta\lambda^2_{\max}(\Omega_0)\left(\nu\tau+8\lambda^2_{\max}(\Omega_0)d_J\lambda^{-1}_{\min}(\Omega_0)\right) \\
&\qquad +\frac{\nu\tau-1}{1-c_0}\nu\tau\lambda^{-2}_{\min}(\Omega_0)\lambda^2_{\max}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1}.
\end{aligned}$$

Therefore,

$$\begin{aligned}
\|\tilde{\Omega}_{-i,\cdot}-\Omega^0_{-i,\cdot}\|_{\ell_1} &= \left|\Omega^0_{ii}-\tilde{\Omega}_{ii}\right|+\|\tilde{\Omega}_{-i,i}-\Omega^0_{-i,i}\|_{\ell_1} \\
&\le \delta\left(\frac{1}{1-c_0}\nu^2\tau^2\lambda^2_{\max}(\Omega_0)+8\left(1+\frac{\nu\tau}{1-c_0}\right)\lambda^2_{\max}(\Omega_0)d_J\lambda^{-1}_{\min}(\Omega_0)\right) \\
&\qquad +\left(1+\frac{\nu\tau}{1-c_0}\lambda^2_{\max}(\Omega_0)\right)\nu\tau\lambda^{-2}_{\min}(\Omega_0)\|\Omega-\Omega_0\|_{\ell_1}.
\end{aligned}$$

■

From Lemma 11, it is clear that under the assumptions of Lemma 10,

$$\|\tilde{\Omega}-\Omega^0\|_{\ell_1} \le C\inf_{\Omega\in O(\nu,\eta,\tau)}\left(\|\Omega-\Omega_0\|_{\ell_1}+\deg(\Omega)\delta\right), \tag{17}$$

where $C=\max\{C_1,C_2,C_3\}$ is a positive constant depending only on ν,τ, $\lambda_{\min}(\Omega_0)$ and $\lambda_{\max}(\Omega_0)$. By the definition of $\hat{\Omega}$,

$$\|\hat{\Omega}-\tilde{\Omega}\|_{\ell_1} \le \|\tilde{\Omega}-\Omega_0\|_{\ell_1} \le C\inf_{\Omega\in O(\nu,\eta,\tau)}\left(\|\Omega-\Omega_0\|_{\ell_1}+\deg(\Omega)\delta\right).$$

An application of triangular inequality immediately gives

$$\begin{aligned}
\|\hat{\Omega}-\Omega_0\|_{\ell_1} &\le \|\hat{\Omega}-\tilde{\Omega}\|_{\ell_1}+\|\tilde{\Omega}-\Omega_0\|_{\ell_1} \\
&\le 2C\inf_{\Omega\in O(\nu,\eta,\tau)}\left(\|\Omega-\Omega_0\|_{\ell_1}+\deg(\Omega)\delta\right).
\end{aligned}$$

To complete the proof, we appeal to the following lemma showing that

$$\|S-\Sigma_0\|_{\max} \le C_0\lambda_{\max}(\Sigma_0)\sqrt{\frac{t+\log p}{n}},$$

for a numerical constant $C_0>0$, with probability at least $1-e^{-t}$. Taking $t=A\log p$ yields

$$\mathbb{P}\left\{\|S-\Sigma_0\|_{\max} < C_0\lambda_{\max}(\Sigma_0)((A+1)n^{-1}\log p)^{1/2}\right\} \ge 1-p^{-A}.$$

Lemma 12 *Assume that there exist constants $c_0 \geq 0$, and $T > 0$ such that for any $|t| \leq T$*

$$\mathbb{E}e^{tX_i^2} \leq c_0, \qquad i = 1, 2, \ldots, p.$$

Then there exists a constant $C > 0$ depending on c_0 and T such that

$$\|S - \Sigma_0\|_{\max} \leq C\sqrt{\frac{t + \log p}{n}}$$

with probability at least $1 - e^{-t}$ for all $t > 0$.

Proof Observe that S is invariant to $\mathbb{E}X$. We shall assume that $\mathbb{E}X = \mathbf{0}$ without loss of generality. Note that $S_{ij} = \mathbb{E}_n X_i X_j - \mathbb{E}_n X_i \mathbb{E}_n X_j$. We have

$$|S_{ij} - \Sigma^0_{ij}| \leq |\mathbb{E}_n X_i X_j - \mathbb{E}X_i X_j| + |\mathbb{E}_n X_i||\mathbb{E}_n X_j| =: \Delta_1 + \Delta_2.$$

We begin by bounding Δ_1.

$$\begin{aligned} \left|(\mathbb{E}_n - \mathbb{E})X_i X_j\right| &= \frac{1}{4}\left|(\mathbb{E}_n - \mathbb{E})\left((X_i + X_j)^2 - (X_i - X_j)^2\right)\right| \\ &\leq \frac{1}{4}\left|(\mathbb{E}_n - \mathbb{E})(X_i + X_j)^2\right| + \frac{1}{4}\left|(\mathbb{E}_n - \mathbb{E})(X_i - X_j)^2\right|. \end{aligned}$$

The two terms in the upper bound can be bounded similarly and we focus only on the first term. By the sub-Gaussianity of X_i and X_j, for any $|t| \leq T/4$,

$$\mathbb{E}e^{t(X_i + X_j)^2} \leq \mathbb{E}e^{2tX_i^2} e^{2tX_j^2} \leq \mathbb{E}^{1/2} e^{4tX_i^2} \mathbb{E}^{1/2} e^{4tX_j^2} \leq c_0.$$

In other words, $\{X_i + X_j : 1 \leq i, j \leq p\}$ are also sub-Gaussian. Observe that

$$\begin{aligned} \ln\left(\mathbb{E}e^{t[(X_i + X_j)^2 - \mathbb{E}(X_i + X_j)^2]}\right) &= \ln \mathbb{E}e^{t(X_i + X_j)^2} - t\mathbb{E}(X_i + X_j)^2 \\ &\leq \mathbb{E}\left[e^{t(X_i + X_j)^2} - t(X_i + X_j)^2 - 1\right], \end{aligned}$$

where we used the fact that $\ln u \leq u - 1$ for all $u > 0$. An application of the Taylor expansion now yields that there exist constants $c_1, T_1 > 0$ such that

$$\ln\left(\mathbb{E}e^{t[(X_i + X_j)^2 - \mathbb{E}(X_i + X_j)^2]}\right) \leq c_1 t^2$$

for all $|t| < T_1$. In other words,

$$\mathbb{E}e^{t[(X_i + X_j)^2 - \mathbb{E}(X_i + X_j)^2]} \leq e^{c_1 t^2}$$

for any $|t| < T_1$. Therefore,

$$\mathbb{E}e^{t[(\mathbb{E}_n - \mathbb{E})(X_i + X_j)^2]} \leq e^{c_1 t^2/n}.$$

By Markov inequality

$$\mathbb{P}\left\{(\mathbb{E}_n - \mathbb{E})(X_i + X_j)^2 \geq x\right\} \leq e^{-tx}\mathbb{E}e^{t[(\mathbb{E}_n - \mathbb{E})(X_i + X_j)^2]} \leq \exp\left(c_1 t^2/n - tx\right).$$

Taking $t = nx/2c_1$ yields

$$\mathbb{P}\left\{(\mathbb{E}_n - \mathbb{E})(X_i + X_j)^2 \geq x\right\} \leq \exp\left\{-\frac{nx^2}{4c_1}\right\}.$$

Similarly,

$$\mathbb{P}\left\{(\mathbb{E}_n - \mathbb{E})(X_i + X_j)^2 \leq -x\right\} \leq \exp\left\{-\frac{nx^2}{4c_1}\right\}.$$

Therefore,

$$\mathbb{P}\left\{\left|(\mathbb{E}_n - \mathbb{E})(X_i + X_j)^2\right| \geq x\right\} \leq 2\exp\left\{-\frac{nx^2}{4c_1}\right\}.$$

Following the same argument, one can show that

$$\mathbb{P}\left\{\left|(\mathbb{E}_n - \mathbb{E})(X_i - X_j)^2\right| \geq x\right\} \leq 2\exp\left\{-\frac{nx^2}{4c_1}\right\}.$$

Note also that this inequality holds trivially when $i = j$. In summary, we have

$$\begin{aligned}\mathbb{P}\{\Delta_1 \geq x\} &\leq \mathbb{P}\left\{\left|(\mathbb{E}_n - \mathbb{E})(X_i + X_j)^2\right| \geq 2x\right\} + \mathbb{P}\left\{\left|(\mathbb{E}_n - \mathbb{E})(X_i - X_j)^2\right| \geq 2x\right\} \\ &\leq 4\exp\left\{-c_1^{-1}nx^2\right\}.\end{aligned}$$

Now consider Δ_2.

$$\mathbb{E}e^{t\mathbb{E}_n X_i \mathbb{E}_n X_j} \leq \mathbb{E}^{1/2} e^{2t\mathbb{E}_n X_i} \mathbb{E}^{1/2} e^{2t\mathbb{E}_n X_j} \leq \max_{1\leq i\leq p} \mathbb{E}e^{2t\mathbb{E}_n X_i}.$$

Following a similar argument as before, we can show that there exist constants $c_2, T_2 > 0$ such that

$$\mathbb{E}e^{2t\mathbb{E}_n X_i} \leq e^{c_2 t^2/n}$$

for all $|t| < T_2$. This further leads to, similar to before,

$$\mathbb{P}\{\Delta_1 \geq x\} \leq 2\exp\left\{-c_2^{-1}nx^2\right\}.$$

To sum up,

$$\begin{aligned}\mathbb{P}\left\{\|S - \Sigma_0\|_{\max} \geq x\right\} &\leq p^2 \max_{1\leq i,j\leq p} \mathbb{P}\left\{|S_{ij} - \Sigma^0_{ij}\| \geq x\right\} \\ &\leq p^2\left[\mathbb{P}\left(\Delta_1 \geq x/2\right) + \mathbb{P}\left(\Delta_2 \geq x/2\right)\right] \\ &\leq 4p^2\exp\left\{-c_3 nx^2\right\}.\end{aligned}$$

for some constant $c_3 > 0$. The claimed result now follows. ■

6.2 Proof of Theorem 5

First note that the claim follows from

$$\inf_{\bar{\Omega}} \sup_{\Omega_0 \in \mathcal{M}_1(\tau_0,\nu_0,d)} \mathbb{E}\left\|\bar{\Omega}-\Omega_0\right\|_{\ell_1} \geq C' d\sqrt{\frac{\log p}{n}} \tag{18}$$

for some constant $C' > 0$. We establish the minimax lower bound (18) using the tools from Korostelev and Tsybakov (1993), which is based upon testing many hypotheses as well as statistical applications of Fano's lemma and the Varshamov-Gilbert bound. More specifically, it suffices to find a collection of inverse covariance matrices $\mathcal{M}' = \{\Omega_1, \ldots, \Omega_{K+1}\} \subset \mathcal{M}_1(\tau_0, \nu_0, d)$ such that

(a) for any two distinct members $\Omega_j, \Omega_k \in \mathcal{M}'$, $\|\Omega_j - \Omega_k\|_{\ell_1} > Ad(n^{-1}\log p)^{1/2}$ for some constant $A > 0$;

(b) there exists a numerical constant $0 < c_0 < 1/8$ such that

$$\frac{1}{K}\sum_{k=1}^{K} \mathcal{K}(\mathcal{P}(\Omega_k), \mathcal{P}(\Omega_{K+1})) \leq c_0 \log K,$$

where $\mathcal{K}$ stands for the Kullback-Leibler divergence and $\mathcal{P}(\Omega)$ is the probability measure $\mathcal{N}(\mathbf{0}, \Omega)$.

To construct $\mathcal{M}'$, we assume that $d(n^{-1}\log p)^{1/2} < 1/2$, $\tau_0, \nu_0 > 2$ without loss of generality. As shown by Birgé and Massart (1998), from the Varshamov-Gilbert bound, there is a set of binary vectors of length $p-1$, $\mathcal{B} = \{b_1, \ldots, b_K\} \subset \{0,1\}^{p-1}$ such that (i) there are d ones in a vector b_j for any $j = 1, \ldots, p-1$; (ii) the Hamming distance between b_j and b_k is at least $d/2$ for any $j \neq k$; (iii) $\log K > 0.233 d \log(p/d)$. We now take Ω_k for $k = 1, \ldots, K$ as follows. It differs from the identity matrix only by its first row and column. More specifically, $\Omega^k_{11} = 1$, $\Omega^k_{-1,1} = (\Omega^k_{1,-1})' = a_n b_k$, $\Omega^k_{-1,-1} = I_{p-1}$, that is,

$$\Omega_k = \begin{pmatrix} 1 & a_n b_k' \\ a_n b_k & I \end{pmatrix},$$

where $a_n = a_0(n^{-1}\log p)^{1/2}$ with a constant $0 < a_0 < 1$ to be determined later. Finally, we take $\Omega_{K+1} = I$. It is clear that Condition (a) is satisfied with this choice of $\mathcal{M}'$ and $A = a_0/2$. It remains to verify Condition (b). Simple algebraic manipulations yield that for any $1 \leq k \leq K$,

$$\mathcal{K}(\mathcal{P}(\Omega_k), \mathcal{P}(\Omega_{K+1})) = -\frac{n}{2}\log\det(\Omega_k) = -\frac{n}{2}\log(1 - a_n^2 b_k' b_k).$$

Recall that $a_n^2 b_k' b_k = d a_n^2 < d^2 a_n^2 < 1/4$. Together with the fact that $-\log(1-x) \leq \log(1+2x) \leq 2x$ for $0 < x < 1/2$, we have

$$\mathcal{K}(\mathcal{P}(\Omega_k), \mathcal{P}(\Omega_{K+1})) \leq n d a_n^2.$$

By setting a_0 small enough, this can be further bounded by $0.233 c_0 d \log(p/d)$ and subsequently $c_0 \log K$. The proof is now completed. ∎

6.3 Proof of Theorem 6

We prove the theorem by applying the oracle inequality from Theorem 1. To this end, we need to find an "oracle" inverse covariance matrix Ω. Let

$$\Omega_{ij} = \Omega^0_{ij} \mathbf{1}\left(\left|\Omega^0_{ij}\right| \geq \zeta\right),$$

where $\zeta > 0$ is to be specified later. We now verify that $\Omega \in O(\nu, \eta, \tau)$ with appropriate choices of the three parameters.

First observe that

$$\begin{aligned}
\|\Omega - \Omega_0\|_{\ell_1} &\leq \max_{1\leq i\leq p} \sum_{j=1}^{p} \left|\Omega^0_{ij}\right| \mathbf{1}\left(\left|\Omega^0_{ij}\right| \leq \zeta\right) \\
&\leq \zeta^{1-\alpha} \max_{1\leq i\leq p} \sum_{j=1}^{p} \left|\Omega^0_{ij}\right|^{\alpha} \mathbf{1}\left(\left|\Omega^0_{ij}\right| \leq \zeta\right) \\
&\leq M\zeta^{1-\alpha}.
\end{aligned}$$

Thus,

$$\nu_0^{-1} - M\zeta^{1-\alpha} \leq \lambda_{\min}(\Omega) \leq \lambda_{\max}(\Omega) \leq \nu_0 + M\zeta^{1-\alpha}.$$

In particular, setting ζ small enough such that $M\zeta^{1-\alpha} < (2\nu_0)^{-1}$ yields

$$(2\nu_0)^{-1} \leq \lambda_{\min}(\Omega) \leq \lambda_{\max}(\Omega) \leq 2\nu_0.$$

We can therefore take $\nu = 2\nu_0$.

Now consider the approximation error $\|\Sigma_0\Omega - I\|_{\max}$. Note that the (i,j) entry of $\Sigma_0\Omega - I = \Sigma_0(\Omega - \Omega_0)$ can be bounded as follows

$$\begin{aligned}
\left|\sum_{k=1}^{p} \Sigma^0_{ik}\Omega^0_{kj} \mathbf{1}\left(\left|\Omega^0_{kj}\right| \leq \zeta\right)\right| &\leq \sum_{k=1}^{p} \left|\Sigma^0_{ik}\right| \left|\Omega^0_{kj}\right| \mathbf{1}\left(\left|\Omega^0_{kj}\right| \leq \zeta\right) \\
&\leq \zeta \max_{1\leq k\leq p} \sum_{k=1}^{p} \left|\Sigma^0_{ik}\right| \\
&= \zeta\|\Sigma_0\|_{\ell_1}.
\end{aligned}$$

This implies that

$$\|\Sigma_0\Omega - I\|_{\max} \leq \zeta\|\Sigma_0\|_{\ell_1}.$$

In other words, we can take $\eta = \zeta\|\Sigma_0\|_{\ell_1}$.

Furthermore, it is clear that we can take $\|\Omega\|_{\ell_1} \leq \|\Omega_0\|_{\ell_1}$. Therefore, by Theorem 1, there exist constants $C_1, C_2 > 0$ depending only on $\|\Omega_0\|_{\ell_1}$, $\|\Sigma_0\|_{\ell_1}$, and ν_0 such that for any

$$\delta \geq C_1 \left(\zeta + \sqrt{\frac{(A+1)\log p}{n}}\right) \qquad (i = 1, 2, \ldots, p),$$

we have

$$\|\hat{\Omega} - \Omega_0\|_{\ell_1} \leq C_2\left(M\zeta^{1-\alpha} + \deg(\Omega)\delta\right)$$

with probability at least $1-p^{-A}$. Now note that

$$\deg(\Omega) = \max_{1\le i\le p} \sum_{j=1}^{p} \mathbf{1}\left(\left|\Omega_{ij}^0\right| \ge \zeta\right) \le M\zeta^{-\alpha}.$$

The claimed the results then follows by taking $\zeta = C_3((A+1)n^{-1}\log p)^{1/2}$ for a small enough constant $C_3 > 0$ such that $M\zeta^{1-\alpha} < (2\nu_0)^{-1}$.

6.4 Proof of Theorem 7

Assume that $M(n^{-1}\log p)^{(1-\alpha)/2} < 1/2, \tau_0, \nu_0 > 2$ without loss of generality. Similar to Theorem 5, there eixs a collection of inverse covariance matrices $\mathcal{M}' = \{\Omega_1, \ldots, \Omega_{K+1}\} \subset \mathcal{M}_2$ such that

(a) for any two distinct members $\Omega_j, \Omega_k \in \mathcal{M}'$, $\|\Omega_j - \Omega_k\|_{\ell_1} > AM(n^{-1}\log p)^{(1-\alpha)/2}$ for some constant $A > 0$;

(b) there exists a numerical constant $0 < c_0 < 1/8$ such that

$$\frac{1}{K}\sum_{k=1}^{K} \mathcal{K}(\mathcal{P}(\Omega_k), \mathcal{P}(\Omega_{K+1})) \le c_0 \log K.$$

To this end, we follow the same construction as in the proof of Theorem 5 by taking

$$d = \left\lfloor M\left(\frac{\log p}{n}\right)^{-\frac{\alpha}{2}} \right\rfloor,$$

and $\lfloor x \rfloor$ stands for the integer part of x. First, we need to show that $\mathcal{M}' \subset \mathcal{M}_2$. Because $d(n^{-1}\log p)^{1/2} < 1/2$, it is clear that the bounded eigenvalue condition and $\|\Omega_k\|_{\ell_1} < \tau_0$ can ensured by setting a_0 small enough. It is also obvious that

$$\max_{1\le j\le p} \sum_{i=1}^{p} |\Omega_{ij}^k|^{\alpha} \le M.$$

It remains to check that $\|\Sigma_k\|_{\ell_1}$ is bounded. By the block matrix inversion formula

$$\Sigma_k = \begin{pmatrix} \frac{1}{1-a_n^2 b_k' b_k} & -\frac{a_n}{1-a_n^2 b_k' b_k} b_k' \\ -\frac{a_n}{1-a_n^2 b_k' b_k} b_k & I + \frac{a_n^2}{1-a_n^2 b_k' b_k} b_k b_k' \end{pmatrix}.$$

It can then be readily checked that $\|\Sigma_k\|_{\ell_1}$ can also be bounded from above by setting a_0 small enough.

Next we verify Conditions (a) and (b). It is clear that Condition (a) is satisfied with this choice of $\mathcal{M}'$ and $A = a_0/2$. It remains to verify Condition (b). Simple algebraic manipulations yield that for any $1 \le k \le K$,

$$\mathcal{K}(\mathcal{P}(\Omega_k), \mathcal{P}(\Omega_{K+1})) = -\frac{n}{2}\log\det(\Omega_k) = -\frac{n}{2}\log(1 - a_n^2 b_k' b_k).$$

Recall that $a_n^2 b_k' b_k = d a_n^2 < d^2 a_n^2 < 1/4$. Together with the fact that $-\log(1-x) \le \log(1+2x) \le 2x$ for $0 < x < 1/2$, we have

$$\mathcal{K}(\mathcal{P}(\Omega_k), \mathcal{P}(\Omega_{K+1})) \le n d a_n^2.$$

By setting a_0 small enough, this can be further bounded by $0.233c_0d\log(p/d)$ and subsequently $c_0\log K$. The proof of (9) is now completed.

The proof of (10) follows from a similar argument. We essentially construct the same subset $\mathcal{M}'$ but with

$$\Sigma_k = \begin{pmatrix} 1 & a_n b_k' \\ a_n b_k & I \end{pmatrix}.$$

The only difference from before is the calculation of Kullback-Leibler divergence, which in this case is

$$\mathcal{K}(\mathcal{P}(\Sigma_k), \mathcal{P}(\Sigma_{K+1})) = \frac{n}{2}\left(\text{trace}(\Omega_k) + \log\det(\Sigma_k) - p\right)$$

where

$$\Omega_k = \begin{pmatrix} \frac{1}{1-a_n^2 b_k' b_k} & -\frac{a_n}{1-a_n^2 b_k' b_k} b_k' \\ -\frac{a_n}{1-a_n^2 b_k' b_k} b_k & I + \frac{a_n^2}{1-a_n^2 b_k' b_k} b_k b_k' \end{pmatrix}.$$

Therefore, $\text{trace}(\Omega_k) = p + 2da_n^2/(1-da_n^2)$. Together with the fact that $\det(\Sigma_k) = 1 - da_n^2$, we conclude that

$$\mathcal{K}(\mathcal{P}(\Sigma_k), \mathcal{P}(\Sigma_{K+1})) = \frac{n}{2}\left(\frac{2da_n^2}{(1-da_n^2)} + \log(1-da_n^2)\right) \leq \frac{1}{2} n d a_n^2.$$

where we used the fact that $\log(1-x) \leq -x$. The rest of the argument proceeds in the same fashion as before.

Abstract

We use convex relaxation techniques to provide a sequence of regularized low-rank solutions for large-scale matrix completion problems. Using the nuclear norm as a regularizer, we provide a simple and very efficient convex algorithm for minimizing the reconstruction error subject to a bound on the nuclear norm. Our algorithm SOFT-IMPUTE iteratively replaces the missing elements with those obtained from a soft-thresholded SVD. With warm starts this allows us to efficiently compute an entire regularization path of solutions on a grid of values of the regularization parameter. The computationally intensive part of our algorithm is in computing a low-rank SVD of a dense matrix. Exploiting the problem structure, we show that the task can be performed with a complexity of order linear in the matrix dimensions. Our semidefinite-programming algorithm is readily scalable to large matrices; for example SOFT-IMPUTE takes a few hours to compute low-rank approximations of a $10^6 \times 10^6$ incomplete matrix with 10^7 observed entries, and fits a rank-95 approximation to the full Netflix training set in 3.3 hours. Our methods achieve good training and test errors and exhibit superior timings when compared to other competitive state-of-the-art techniques.

Keywords: collaborative filtering, nuclear norm, spectral regularization, netflix prize, large scale convex optimization

1. Introduction

In many applications measured data can be represented in a matrix $X_{m\times n}$, for which only a relatively small number of entries are observed. The problem is to "complete" the matrix based on the observed entries, and has been dubbed the matrix completion problem (Candès and Recht, 2008; Candès and Tao, 2009; Rennie and Srebro, 2005). The "Netflix" competition (for example, SIGKDD and Netflix, 2007) is a popular example, where the data is the basis for a recommender system. The rows correspond to viewers and the columns to movies, with the entry X_{ij} being the rating $\in \{1,\ldots,5\}$ by viewer i for movie j. There are about 480K viewers and 18K movies, and hence 8.6 billion (8.6×10^9) potential entries. However, on average each viewer rates about 200

*. Also in the Department of Health, Research and Policy.
†. Also in the Department of Statistics.

movies, so only 1.2% or 10^8 entries are observed. The task is to predict the ratings that viewers would give to movies they have not yet rated.

These problems can be phrased as learning an unknown parameter (a matrix $Z_{m\times n}$) with very high dimensionality, based on very few observations. In order for such inference to be meaningful, we assume that the parameter Z lies in a much lower dimensional manifold. In this paper, as is relevant in many real life applications, we assume that Z can be well represented by a matrix of low rank, that is, $Z \approx V_{m\times k}G_{k\times n}$, where $k \ll \min(n,m)$. In this recommender-system example, low rank structure suggests that movies can be grouped into a small number of "genres", with $G_{\ell j}$ the relative score for movie j in genre ℓ. Viewer i on the other hand has an affinity $V_{i\ell}$ for genre ℓ, and hence the modeled score for viewer i on movie j is the sum $\sum_{\ell=1}^{k} V_{i\ell}G_{\ell j}$ of genre affinities times genre scores. Typically we view the observed entries in X as the corresponding entries from Z contaminated with noise.

Srebro et al. (2005a) studied generalization error bounds for learning low-rank matrices. Recently Candès and Recht (2008), Candès and Tao (2009), and Keshavan et al. (2009) showed theoretically that under certain assumptions on the entries of the matrix, locations, and proportion of unobserved entries, the true underlying matrix can be recovered within very high accuracy.

For a matrix $X_{m\times n}$ let $\Omega \subset \{1,\ldots,m\}\times\{1,\ldots,n\}$ denote the indices of observed entries. We consider the following optimization problem:

$$\begin{aligned} &\text{minimize} && \operatorname{rank}(Z) \\ &\text{subject to} && \sum_{(i,j)\in\Omega} (X_{ij}-Z_{ij})^2 \le \delta, \end{aligned} \tag{1}$$

where $\delta \ge 0$ is a regularization parameter controlling the tolerance in training error. The rank constraint in (1) makes the problem for general Ω combinatorially hard (Srebro and Jaakkola, 2003). For a fully-observed X on the other hand, the solution is given by a truncated singular value decomposition (SVD) of X. The following seemingly small modification to (1),

$$\begin{aligned} &\text{minimize} && \|Z\|_* \\ &\text{subject to} && \sum_{(i,j)\in\Omega} (X_{ij}-Z_{ij})^2 \le \delta, \end{aligned} \tag{2}$$

makes the problem convex (Fazel, 2002). Here $\|Z\|_*$ is the nuclear norm, or the sum of the singular values of Z. Under many situations the nuclear norm is an effective convex relaxation to the rank constraint (Fazel, 2002; Candès and Recht, 2008; Candès and Tao, 2009; Recht et al., 2007). Optimization of (2) is a semi-definite programming problem (Boyd and Vandenberghe, 2004) and can be solved efficiently for small problems, using modern convex optimization software like SeDuMi and SDPT3 (Grant and Boyd., 2009). However, since these algorithms are based on second order methods (Liu and Vandenberghe, 2009), they can become prohibitively expensive if the dimensions of the matrix get large (Cai et al., 2008). Equivalently we can reformulate (2) in *Lagrange* form

$$\underset{Z}{\text{minimize}}\, \frac{1}{2}\sum_{(i,j)\in\Omega} (X_{ij}-Z_{ij})^2 + \lambda\|Z\|_*. \tag{3}$$

Here $\lambda \ge 0$ is a regularization parameter controlling the nuclear norm of the minimizer $\hat{Z}_\lambda$ of (3); there is a 1-1 mapping between $\delta \ge 0$ and $\lambda \ge 0$ over their active domains.

In this paper we propose an algorithm SOFT-IMPUTE for the nuclear norm regularized least-squares problem (3) that scales to large problems with $m,n \approx 10^5$–10^6 with around 10^6–10^8 or more observed entries. At every iteration SOFT-IMPUTE decreases the value of the objective function towards its minimum, and at the same time gets closer to the set of optimal solutions of the problem (2). We study the convergence properties of this algorithm and discuss how it can be extended to other more sophisticated forms of spectral regularization.

To summarize some performance results[1]

- We obtain a rank-40 solution to (2) for a problem of size $10^5 \times 10^5$ and $|\Omega| = 5 \times 10^6$ observed entries in less than 18 minutes.
- For the same sized matrix with $|\Omega| = 10^7$ we obtain a rank-5 solution in less than 21 minutes.
- For a $10^6 \times 10^5$ sized matrix with $|\Omega| = 10^8$ a rank-5 solution is obtained in approximately 4.3 hours.
- We fit a rank-66 solution for the Netflix data in 2.2 hours. Here there are 10^8 observed entries in a matrix with 4.8×10^5 rows and 1.8×10^4 columns. A rank 95 solution takes 3.27 hours.

The paper is organized as follows. In Section 2, we discuss related work and provide some context for this paper. In Section 3 we introduce the SOFT-IMPUTE algorithm and study its convergence properties in Section 4. The computational aspects of the algorithm are described in Section 5, and Section 6 discusses how nuclear norm regularization can be generalized to more aggressive and general types of spectral regularization. Section 7 describes post-processing of "selectors" and initialization. We discuss comparisons with related work, simulations and experimental studies in Section 9 and application to the Netflix data in Section 10.

2. Context and Related Work

Candès and Tao (2009), Cai et al. (2008), and Candès and Recht (2008) consider the criterion

$$\begin{aligned} &\text{minimize} && \|Z\|_* \\ &\text{subject to} && Z_{ij} = X_{ij},\ \forall (i,j) \in \Omega. \end{aligned} \tag{4}$$

With $\delta = 0$, the criterion (1) is equivalent to (4), in that it requires the training error to be zero. Cai et al. (2008) propose a first-order singular-value-thresholding algorithm SVT scalable to large matrices for the problem (4). They comment on the problem (2) with $\delta > 0$, but dismiss it as being computationally prohibitive for large problems.

We believe that (4) will almost always be too rigid and will result in over-fitting. If minimization of prediction error is an important goal, then the optimal solution $\hat{Z}$ will typically lie somewhere in the interior of the path indexed by δ (Figures 2, 3 and 4).

In this paper we provide an algorithm SOFT-IMPUTE for computing solutions of (3) on a grid of λ values, based on warm restarts. The algorithm is inspired by SVD-IMPUTE (Troyanskaya et al.,

1. For large problems data transfer, access and reading take quite a lot of time and is dependent upon the platform and machine. Over here we report the times taken for the computational bottle-neck, that is, the SVD computations over all iterations. All times are reported based on computations done in a Intel Xeon Linux 3GHz processor using MATLAB, with no C or Fortran interlacing.

2001)—an EM-type (Dempster et al., 1977) iterative algorithm that alternates between imputing the missing values from a current SVD, and updating the SVD using the "complete" data matrix. In its very motivation, SOFT-IMPUTE is different from generic first order algorithms (Cai et al., 2008; Ma et al.; Ji and Ye, 2009). The latter require the specification of a step size, and can be quite sensitive to the chosen value. Our algorithm does not require a step-size, or any such parameter.

The iterative algorithms proposed in Ma et al. and Ji and Ye (2009) require the computation of a SVD of a dense matrix (with dimensions equal to the size of the matrix X) at every iteration, as the bottleneck. This makes the algorithms prohibitive for large scale computations. Ma et al. use randomized algorithms for the SVD computation. Our algorithm SOFT-IMPUTE also requires an SVD computation at every iteration, but by exploiting the *problem structure*, can easily handle matrices of very large dimensions. At each iteration the non-sparse matrix has the structure:

$$Y = Y_{SP} \ \text{(Sparse)} \quad + \quad Y_{LR} \ \text{(Low Rank)}. \tag{5}$$

In (5) Y_{SP} has the same sparsity structure as the observed X, and Y_{LR} has rank $\tilde{r} \ll m,n$, where $\tilde{r}$ is very close to $r \ll m,n$ the rank of the estimated matrix Z (upon convergence of the algorithm). For large scale problems, we use iterative methods based on Lanczos bidiagonalization with partial re-orthogonalization (as in the PROPACK algorithm, Larsen, 1998), for computing the first $\tilde{r}$ singular vectors/values of Y. Due to the specific structure of (5), multiplication by Y and Y' can both be achieved in a cost-efficient way. In decomposition (5), the computationally burdensome work in computing a low-rank SVD is of an order that depends linearly on the matrix dimensions. More precisely, evaluating each singular vector requires computation of the order of $O((m+n)\tilde{r}) + O(|\Omega|)$ flops and evaluating r' of them requires $O((m+n)\tilde{r}r') + O(|\Omega|r')$ flops. Exploiting warm-starts, we observe that $\tilde{r} \approx r$—hence every SVD step of our algorithm computes r singular vectors, with complexity of the order $O((m+n)r^2) + O(|\Omega|r)$ flops. This computation is performed for the number of iterations SOFT-IMPUTE requires to run till convergence or a certain tolerance.

In this paper we show asymptotic convergence of SOFT-IMPUTE and further derive its non-asymptotic rate of convergence which scales as $O(1/k)$ (k denotes the iteration number). However, in our experimental studies on low-rank matrix completion, we have observed that our algorithm is faster (based on timing comparisons) than the accelerated version of Nesterov (Ji and Ye, 2009; Nesterov, 2007), having a provable (worst case) convergence rate of $O(\frac{1}{k^2})$. With warm-starts SOFT-IMPUTE computes the entire regularization path very efficiently along a dense series of values for λ.

Although the nuclear norm is motivated here as a convex relaxation to a rank constraint, we believe in many situations it will outperform the rank-restricted estimator (1). This is supported by our experimental studies. We draw the natural analogy with model selection in linear regression, and compare best-subset regression (ℓ_0 regularization) with the LASSO (ℓ_1 regularization, Tibshirani, 1996; Hastie et al., 2009). There too the ℓ_1 penalty can be viewed as a convex relaxation of the ℓ_0 penalty. But in many situations with moderate sparsity, the LASSO will outperform best subset in terms of prediction accuracy (Friedman, 2008; Hastie et al., 2009; Mazumder et al., 2009). By shrinking the parameters in the model (and hence reducing their variance), the lasso permits more parameters to be included. The nuclear norm is the ℓ_1 penalty in matrix completion, as compared to the ℓ_0 rank. By shrinking the singular values, we allow more dimensions to be included without incurring undue estimation variance.

Another class of techniques used in collaborative filtering problems are close in spirit to (2). These are known as *maximum margin matrix factorization* methods—in short MMMF—and use

a factor model for the matrix Z (Srebro et al., 2005b). Let $Z = UV'$ where $U_{m\times r'}$ and $V_{n\times r'}$, and consider the following problem

$$\underset{U,V}{\text{minimize}}\, \frac{1}{2}\sum_{(i,j)\in\Omega}(X_{ij}-(UV')_{ij})^2+\frac{\lambda}{2}(\|U\|_F^2+\|V\|_F^2). \tag{6}$$

It turns out that (6) is intimately related to (3), since (see Lemma 6)

$$||Z||_* = \min_{U,V:\, Z=UV'} \frac{1}{2}\left(\|U\|_F^2+\|V\|_F^2\right).$$

For example, if $r' = \min(m,n)$, the solution to (6) coincides with the solution to (3).[2] However, (6) is not convex in its arguments, while (3) is. We compare these two criteria in detail in Section 8, and the relative performance of their respective algorithms in Section 9.2.

3. SOFT-IMPUTE–an Algorithm for Nuclear Norm Regularization

We first introduce some notation that will be used for the rest of this article.

3.1 Notation

We adopt the notation of Cai et al. (2008). Define a matrix $P_\Omega(Y)$ (with dimension $m\times n$)

$$P_\Omega(Y)\,(i,j) = \begin{cases} Y_{ij} & \text{if } (i,j)\in\Omega \\ 0 & \text{if } (i,j)\notin\Omega, \end{cases} \tag{7}$$

which is a projection of the matrix $Y_{m\times n}$ onto the observed entries. In the same spirit, define the complementary projection $P_\Omega^\perp(Y)$ via $P_\Omega^\perp(Y)+P_\Omega(Y)=Y$. Using (7) we can rewrite $\sum_{(i,j)\in\Omega}(X_{ij}-Z_{ij})^2$ as $\|P_\Omega(X)-P_\Omega(Z)\|_F^2$.

3.2 Nuclear Norm Regularization

We present the following lemma, which forms a basic ingredient in our algorithm.

Lemma 1 *Suppose the matrix $W_{m\times n}$ has rank r. The solution to the optimization problem*

$$\underset{Z}{\text{minimize}} \quad \frac{1}{2}\|W-Z\|_F^2+\lambda\|Z\|_* \tag{8}$$

is given by $\hat{Z} = \mathbf{S}_\lambda(W)$ where

$$\mathbf{S}_\lambda(W) \equiv UD_\lambda V' \quad \textit{with} \quad D_\lambda = \text{diag}\left[(d_1-\lambda)_+,\ldots,(d_r-\lambda)_+\right], \tag{9}$$

UDV' is the SVD of W, $D=\text{diag}\,[d_1,\ldots,d_r]$, and $t_+ = \max(t,0)$.

The notation $\mathbf{S}_\lambda(W)$ refers to *soft-thresholding* (Donoho et al., 1995). Lemma 1 appears in Cai et al. (2008) and Ma et al. where the proof uses the sub-gradient characterization of the nuclear norm. In Appendix A.1 we present an entirely different proof, which can be extended in a relatively straightforward way to other complicated forms of spectral regularization discussed in Section 6. Our proof is followed by a remark that covers these more general cases.

2. We note here that the original MMMF formulation uses $r' = \min\{m,n\}$. In this paper we will consider it for a family of r' values.

3.3 Algorithm

Using the notation in 3.1, we rewrite (3) as:

$$\underset{Z}{\text{minimize}} \quad f_\lambda(Z) := \frac{1}{2}\|P_\Omega(X) - P_\Omega(Z)\|_F^2 + \lambda\|Z\|_* \,. \tag{10}$$

We now present Algorithm 1—SOFT-IMPUTE—for computing a series of solutions to (10) for different values of λ using warm starts.

Algorithm 1 SOFT-IMPUTE

1. Initialize $Z^{\text{old}} = 0$.
2. Do for $\lambda_1 > \lambda_2 > \ldots > \lambda_K$:
   (a) Repeat:
      i. Compute $Z^{\text{new}} \leftarrow \mathbf{S}_{\lambda_k}(P_\Omega(X) + P_\Omega^\perp(Z^{\text{old}}))$.
      ii. If $\frac{\|Z^{\text{new}} - Z^{\text{old}}\|_F^2}{\|Z^{\text{old}}\|_F^2} < \varepsilon$ exit.
      iii. Assign $Z^{\text{old}} \leftarrow Z^{\text{new}}$.
   (b) Assign $\hat{Z}_{\lambda_k} \leftarrow Z^{\text{new}}$.
3. Output the sequence of solutions $\hat{Z}_{\lambda_1}, \ldots, \hat{Z}_{\lambda_K}$.

The algorithm repeatedly replaces the missing entries with the current guess, and then updates the guess by solving (8). Figures 2, 3 and 4 show some examples of solutions using SOFT-IMPUTE (blue continuous curves). We see test and training error in the top rows as a function of the nuclear norm, obtained from a grid of values Λ. These error curves show a smooth and very competitive performance.

4. Convergence Analysis

In this section we study the convergence properties of Algorithm 1. Unlike generic first-order methods (Nesterov, 2003) including competitive first-order methods for nuclear norm regularized problems (Cai et al., 2008; Ma et al.), SOFT-IMPUTE does not involve the choice of any additional step-size. Most importantly our algorithm is readily scalable for solving large scale semidefinite programming problems (2) and (10) as will be explained later in Section 5.

For an arbitrary matrix $\tilde{Z}$, define

$$Q_\lambda(Z|\tilde{Z}) = \frac{1}{2}\|P_\Omega(X) + P_\Omega^\perp(\tilde{Z}) - Z\|_F^2 + \lambda\|Z\|_* \tag{11}$$

as a surrogate of the objective function $f_\lambda(z)$. Note that $f_\lambda(\tilde{Z}) = Q_\lambda(\tilde{Z}|\tilde{Z})$ for any $\tilde{Z}$.

In Section 4.1, we show that the sequence Z_λ^k generated via SOFT-IMPUTE *converges* asymptotically, that is, as $k \to \infty$ to a minimizer of the objective function $f_\lambda(Z)$. SOFT-IMPUTE produces a sequence of solutions for which the criterion decreases to the optimal solution with every iteration and the successive iterates get closer to the optimal set of solutions of the problem 10. Section 4.2

derives the non-asymptotic convergence rate of the algorithm. The latter analysis concentrates on the objective values $f_\lambda(Z_\lambda^k)$. Due to computational resources if one wishes to stop the algorithm after K iterations, then Theorem 2 provides a certificate of how *far* Z_λ^k is from the solution. Though Section 4.1 alone establishes the convergence of $f_\lambda(Z_\lambda^k)$ to the minimum of $f_\lambda(Z)$, this does not, in general, settle the *convergence* of Z_λ^k unless further conditions (like strong convexity) are imposed on $f_\lambda(\cdot)$.

4.1 Asymptotic Convergence

Lemma 2 *For every fixed $\lambda \geq 0$, define a sequence Z_λ^k by*

$$Z_\lambda^{k+1} = \arg\min_Z Q_\lambda(Z|Z_\lambda^k)$$

with any starting point Z_λ^0. The sequence Z_λ^k satisfies

$$f_\lambda(Z_\lambda^{k+1}) \leq Q_\lambda(Z_\lambda^{k+1}|Z_\lambda^k) \leq f_\lambda(Z_\lambda^k).$$

Proof Note that

$$Z_\lambda^{k+1} = \mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^k)). \tag{12}$$

By Lemma 1 and the definition (11) of $Q_\lambda(Z|Z_\lambda^k)$, we have:

$$\begin{aligned}
f_\lambda(Z_\lambda^k) &= Q_\lambda(Z_\lambda^k|Z_\lambda^k) \\
&= \frac{1}{2}\|P_\Omega(X) + P_\Omega^\perp(Z_\lambda^k) - Z_\lambda^k\|_F^2 + \lambda\|Z_\lambda^k\|_* \\
&\geq \min_Z \frac{1}{2}\left\{\|P_\Omega(X) + P_\Omega^\perp(Z_\lambda^k) - Z\|_F^2\right\} + \lambda\|Z\|_* \\
&= Q_\lambda(Z_\lambda^{k+1}|Z_\lambda^k) \\
&= \frac{1}{2}\|\left\{P_\Omega(X) - P_\Omega(Z_\lambda^{k+1})\right\} + \left\{P_\Omega^\perp(Z_\lambda^k) - P_\Omega^\perp(Z_\lambda^{k+1})\right\}\|_F^2 + \lambda\|Z_\lambda^{k+1}\|_* \\
&= \frac{1}{2}\left\{\|P_\Omega(X) - P_\Omega(Z_\lambda^{k+1})\|_F^2 + \|P_\Omega^\perp(Z_\lambda^k) - P_\Omega^\perp(Z_\lambda^{k+1})\|_F^2\right\} + \lambda\|Z_\lambda^{k+1}\|_* \qquad (13) \\
&\geq \frac{1}{2}\|P_\Omega(X) - P_\Omega(Z_\lambda^{k+1})\|_F^2 + \lambda\|Z_\lambda^{k+1}\|_* \qquad (14) \\
&= Q_\lambda(Z_\lambda^{k+1}|Z_\lambda^{k+1}) \\
&= f(Z_\lambda^{k+1}).
\end{aligned}$$

■

Lemma 3 *The nuclear norm shrinkage operator $\mathbf{S}_\lambda(\cdot)$ satisfies the following for any W_1, W_2 (with matching dimensions)*

$$\|\mathbf{S}_\lambda(W_1) - \mathbf{S}_\lambda(W_2)\|_F^2 \leq \|W_1 - W_2\|_F^2.$$

In particular this implies that $\mathbf{S}_\lambda(W)$ is a continuous map in W.

Lemma 3 is proved in Ma et al.; their proof is complex and based on trace inequalities. We give a concise proof based on elementary convex analysis in Appendix A.2.

Lemma 4 *The successive differences $\|Z_\lambda^k - Z_\lambda^{k-1}\|_F^2$ of the sequence Z_λ^k are monotone decreasing:*

$$\|Z_\lambda^{k+1} - Z_\lambda^k\|_F^2 \leq \|Z_\lambda^k - Z_\lambda^{k-1}\|_F^2 \quad \forall k. \tag{15}$$

Moreover the difference sequence converges to zero. That is

$$Z_\lambda^{k+1} - Z_\lambda^k \to 0 \text{ as } k \to \infty.$$

The proof of Lemma 4 is given in Appendix A.3.

Lemma 5 *Every limit point of the sequence Z_λ^k defined in Lemma 2 is a stationary point of*

$$\frac{1}{2}\|P_\Omega(X) - P_\Omega(Z)\|_F^2 + \lambda\|Z\|_*.$$

Hence it is a solution to the fixed point equation

$$Z = \mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z)). \tag{16}$$

The proof of Lemma 5 is given in Appendix A.4.

Theorem 1 *The sequence Z_λ^k defined in Lemma 2 converges to a limit Z_λ^∞ that solves*

$$\underset{Z}{\text{minimize}} \quad \frac{1}{2}\|P_\Omega(X) - P_\Omega(Z)\|_F^2 + \lambda\|Z\|_*. \tag{17}$$

Proof It suffices to prove that Z_λ^k converges; the theorem then follows from Lemma 5.

Let $\hat{Z}_\lambda$ be a limit point of the sequence Z_λ^k. There exists a subsequence m_k such that $Z_\lambda^{m_k} \to \hat{Z}_\lambda$. By Lemma 5, $\hat{Z}_\lambda$ solves the problem (17) and satisfies the fixed point equation (16).

Hence

$$\begin{aligned}
\|\hat{Z}_\lambda - Z_\lambda^k\|_F^2 &= \|\mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(\hat{Z}_\lambda)) - \mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^{k-1}))\|_F^2 && (18)\\
&\leq \|(P_\Omega(X) + P_\Omega^\perp(\hat{Z}_\lambda)) - (P_\Omega(X) + P_\Omega^\perp(Z_\lambda^{k-1}))\|_F^2\\
&= \|P_\Omega^\perp(\hat{Z}_\lambda - Z_\lambda^{k-1})\|_F^2\\
&\leq \|\hat{Z}_\lambda - Z_\lambda^{k-1}\|_F^2. && (19)
\end{aligned}$$

In (18) two substitutions were made; the left one using (16) in Lemma 5, the right one using (12). Inequality (19) implies that the sequence $\|\hat{Z}_\lambda - Z_\lambda^{k-1}\|_F^2$ converges as $k \to \infty$. To show the convergence of the sequence Z_λ^k it suffices to prove that the sequence $\hat{Z}_\lambda - Z_\lambda^k$ converges to zero. We prove this by contradiction.

Suppose the sequence Z_λ^k has another limit point $Z_\lambda^+ \neq \hat{Z}_\lambda$. Then $\hat{Z}_\lambda - Z_\lambda^k$ has two distinct limit points 0 and $Z_\lambda^+ - \hat{Z}_\lambda \neq 0$. This contradicts the convergence of the sequence $\|\hat{Z}_\lambda - Z_\lambda^{k-1}\|_F^2$. Hence the sequence Z_λ^k converges to $\hat{Z}_\lambda := Z_\lambda^\infty$. ■

The inequality in (19) implies that at every iteration Z_λ^k gets closer to an optimal solution for the problem (17).[3] This property holds in addition to the decrease of the objective function (Lemma 2) at every iteration.

3. In fact this statement can be strengthened further—at every iteration the distance of the estimate decreases from the set of optimal solutions.

4.2 Convergence Rate

In this section we derive the worst case convergence rate of SOFT-IMPUTE.

Theorem 2 *For every fixed $\lambda \geq 0$, the sequence $Z_\lambda^k; k \geq 0$ defined in Lemma 2 has the following non-asymptotic (worst) rate of convergence:*

$$f_\lambda(Z_\lambda^k) - f_\lambda(Z_\lambda^\infty) \leq \frac{2\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2}{k+1}. \tag{20}$$

The proof of this theorem is in Appendix A.6.

In light of Theorem 2, a $\delta > 0$ accurate solution of $f_\lambda(Z)$ is obtained after a maximum of $\frac{2}{\delta}\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2$ iterations. Using warm-starts, SOFT-IMPUTE traces out the path of solutions on a grid of λ values $\lambda_1 > \lambda_2 > \ldots > \lambda_K$ with a total of [4]

$$\sum_{i=1}^{K} \frac{2}{\delta}\|\hat{Z}_{\lambda_{i-1}} - Z_{\lambda_i}^\infty\|_F^2 \tag{21}$$

iterations. Here $\hat{Z}_{\lambda_0} = 0$ and $\hat{Z}_{\lambda_i}$ denotes the output of SOFT-IMPUTE (upon convergence) for $\lambda = \lambda_i$ ($i \in \{1, \ldots, K-1\}$). The solutions $Z_{\lambda_i}^\infty$ and $Z_{\lambda_{i-1}}^\infty$ are likely to be *close* to each other, especially on a dense grid of λ_i's. Hence every summand of (21) and the total number of iterations is expected to be significantly smaller than that obtained via arbitrary cold-starts.

5. Computational Complexity

The computationally demanding part of Algorithm 1 is in $\mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^k))$. This requires calculating a low-rank SVD of a matrix, since the underlying model assumption is that $\text{rank}(Z) \ll \min\{m,n\}$. In Algorithm 1, for fixed λ, the entire sequence of matrices Z_λ^k have explicit[5] low-rank representations of the form $U_k D_k V_k'$ corresponding to $\mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^{k-1}))$.

In addition, observe that $P_\Omega(X) + P_\Omega^\perp(Z_\lambda^k)$ can be rewritten as

$$\begin{array}{rcccc} P_\Omega(X) + P_\Omega^\perp(Z_\lambda^k) & = & \{P_\Omega(X) - P_\Omega(Z_\lambda^k)\} & + & Z_\lambda^k \\ & = & \textit{Sparse} & + & \textit{Low Rank}. \end{array} \tag{22}$$

In the numerical linear algebra literature, there are very efficient direct matrix factorization methods for calculating the SVD of matrices of moderate size (at most a few thousand). When the matrix is sparse, larger problems can be solved but the computational cost depends heavily upon the sparsity structure of the matrix. In general however, for large matrices one has to resort to indirect iterative methods for calculating the leading singular vectors/values of a matrix. There is a lot research in numerical linear algebra for developing sophisticated algorithms for this purpose. In this paper we will use the PROPACK algorithm (Larsen, 2004, 1998) because of its low storage requirements, effective flop count and its well documented MATLAB version. The algorithm for calculating the truncated SVD for a matrix W (say), becomes efficient if multiplication operations Wb_1 and $W'b_2$ (with $b_1 \in \Re^n$, $b_2 \in \Re^m$) can be done with minimal cost.

4. We assume the solution $\hat{Z}_\lambda$ at every $\lambda \in \{\lambda_1, \ldots, \lambda_K\}$ is computed to an accuracy of $\delta > 0$.

5. Though we cannot prove theoretically that every iterate of the sequence Z_λ^k will be of low-rank; this observation is rather practical based on the manner in which we trace out the entire path of solutions based on warm-starts. Our simulation results support this observation as well.

Algorithm SOFT-IMPUTE requires repeated computation of a truncated SVD for a matrix W with structure as in (22). Assume that at the current iterate, the matrix Z_λ^k has rank $\tilde{r}$. Note that in (22) the term $P_\Omega(Z_\lambda^k)$ can be computed in $O(|\Omega|\tilde{r})$ flops using only the required outer products (i.e., our algorithm does not compute the matrix explicitly).

The cost of computing the truncated SVD will depend upon the cost in the operations Wb_1 and $W'b_2$ (which are equal). For the sparse part these multiplications cost $O(|\Omega|)$. Although it costs $O(|\Omega|\tilde{r})$ to create the matrix $P_\Omega(Z_\lambda^k)$, this is used for each of the $\tilde{r}$ such multiplications (which also cost $O(|\Omega|\tilde{r})$), so we need not include that cost here. The Low Rank part costs $O((m+n)\tilde{r})$ for the multiplication by b_1. Hence the cost is $O(|\Omega|)+O((m+n)\tilde{r})$ per vector multiplication. Supposing we want a $\tilde{r}$ rank SVD of the matrix (22), the cost will be of the order of $O(|\Omega|\tilde{r})+O((m+n)(\tilde{r})^2)$ (for that iteration, that is, to obtain Z_λ^{k+1} from Z_λ^k). Suppose the rank of the solution Z_λ^k is r, then in light of our above observations $\tilde{r} \approx r \ll \min\{m,n\}$ and the order is $O(|\Omega|r)+O((m+n)r^2)$.

For the reconstruction problem to be theoretically meaningful in the sense of Candès and Tao (2009) we require that $|\Omega| \approx nr \cdot \text{poly}(\log n)$. In practice often $|\Omega|$ is very small. Hence introducing the *Low Rank* part does not add any further complexity in the multiplication by W and W'. So the dominant cost in calculating the truncated SVD in our algorithm is $O(|\Omega|)$. The SVT algorithm (Cai et al., 2008) for exact matrix completion (4) involves calculating the SVD of a sparse matrix with cost $O(|\Omega|)$. This implies that the computational order of SOFT-IMPUTE and that of SVT is the same. This order computation does not include the number of iterations required for convergence. In our experimental studies we use warm-starts for efficiently computing the entire regularization path. On small scale examples, based on comparisons with the accelerated gradient method of Nesterov (see Section 9.3; Ji and Ye, 2009; Nesterov, 2007) we find that our algorithm converges faster than the latter in terms of run-time and number of SVD computations/ iterations. This supports the computational effectiveness of SOFT-IMPUTE. In addition, since the true rank of the matrix $r \ll \min\{m,n\}$, the computational cost of evaluating the truncated SVD (with rank $\approx r$) is linear in matrix dimensions. This justifies the large-scale computational feasibility of our algorithm.

The above discussions focus on the computational complexity for obtaining a low-rank SVD, which is to be performed at every iteration of SOFT-IMPUTE. Similar to the total iteration complexity bound of SOFT-IMPUTE (21), the total cost to compute the regularization path on a grid of λ values is given by:

$$\sum_{i=1}^{K} O\left((|\Omega|\bar{r}_{\lambda_i} + (m+n)\bar{r}_{\lambda_i}^2)\frac{2}{\delta}\|\hat{Z}_{\lambda_{i-1}} - Z_{\lambda_i}^{\infty}\|_F^2 \right).$$

Here $\bar{r}_\lambda$ denotes the rank[6] (on an average) of the iterates Z_λ^k generated by SOFT-IMPUTE for fixed λ.

The PROPACK package does not allow one to request (and hence compute) only the singular values larger than a threshold λ—one has to specify the number in advance. So once all the computed singular values fall above the current threshold λ, our algorithm increases the number to be computed until the smallest is smaller than λ. In large scale problems, we put an absolute limit on the maximum number.

6. We assume, above that the grid of values $\lambda_1 > \ldots \lambda_K$ is such that *all* the solutions $Z_\lambda, \lambda \in \{\lambda_1, \ldots, \lambda_K\}$ are of *small* rank, as they appear in Section 5.

6. Generalized Spectral Regularization: From Soft to Hard Thresholding

In Section 1 we discussed the role of the nuclear norm as a convex surrogate for the rank of a matrix, and drew the analogy with LASSO regression versus best-subset selection. We argued that in many problems ℓ_1 regularization gives better prediction accuracy. However, if the underlying model is very sparse, then the LASSO with its uniform shrinkage can both overestimate the number of non-zero coefficients (Friedman, 2008) in the model, and overly shrink (bias) those included toward zero. In this section we propose a natural generalization of SOFT-IMPUTE to overcome these problems.

Consider again the problem

$$\underset{\text{rank}(Z)\le k}{\text{minimize}} \ \frac{1}{2}\|P_\Omega(X)-P_\Omega(Z)\|_F^2,$$

a rephrasing of (1). This best rank-k solution also solves

$$\text{minimize}\,\frac{1}{2}\|P_\Omega(X)-P_\Omega(Z)\|_F^2+\lambda\sum_j I(\gamma_j(Z)>0),$$

where $\gamma_j(Z)$ is the jth singular value of Z, and for a suitable choice of λ that produces a solution with rank k.

The "fully observed" matrix version of the above problem is given by the ℓ_0 version of (8) as follows:

$$\underset{Z}{\text{minimize}} \ \frac{1}{2}\|W-Z\|_F^2+\lambda\|Z\|_0, \tag{23}$$

where $\|Z\|_0=\text{rank}(Z)$. The solution of (23) is given by a reduced-rank SVD of W; for every λ there is a corresponding $q=q(\lambda)$ number of singular-values to be retained in the SVD decomposition. Problem (23) is non-convex in W but its global minimizer can be evaluated. As in (9) the thresholding operator resulting from (23) is

$$\mathbf{S}_\lambda^H(W)=UD_qV' \quad \text{where} \quad D_q=\text{diag}\,(d_1,\ldots,d_q,0,\ldots,0)\,.$$

Similar to SOFT-IMPUTE (Algorithm 1), we present below HARD-IMPUTE (Algorithm 2) for the ℓ_0 penalty. The continuous parameterization via λ does not appear to offer obvious advantages over rank-truncation methods. We note that it does allow for a continuum of warm starts, and is a natural post-processor for the output of SOFT-IMPUTE (next section). But it also allows for further generalizations that bridge the gap between hard and soft regularization methods.

In penalized regression there have been recent developments directed towards "bridging" the gap between the ℓ_1 and ℓ_0 penalties (Friedman, 2008; Zhang, 2010; Mazumder et al., 2009). This is done via using non-convex penalties that are a better surrogate (in the sense of approximating the penalty) to ℓ_0 over the ℓ_1. They also produce less biased estimates than those produced by the ℓ_1 penalized solutions. When the underlying model is very sparse they often perform very well, and enjoy superior prediction accuracy when compared to softer penalties like ℓ_1. These methods still shrink, but are less aggressive than the best-subset selection.

By analogy, we propose using a more sophisticated version of spectral regularization. This goes beyond nuclear norm regularization by using slightly more aggressive penalties that bridge the gap between ℓ_1 (nuclear norm) and ℓ_0(rank constraint). We propose minimizing

$$f_{\mathbf{p},\lambda}(Z) \ = \ \frac{1}{2}\|P_\Omega(X)-P_\Omega(Z)\|_F^2+\lambda\sum_j \mathbf{p}(\gamma_j(Z);\mu), \tag{24}$$

Algorithm 2 HARD-IMPUTE

1. Initialize $\tilde{Z}_{\lambda_k}$ $k = 1, \ldots, K$ (for example, using SOFT-IMPUTE; see Section 7).
2. Do for $\lambda_1 > \lambda_2 > \ldots > \lambda_K$:
   (a) Repeat:
      i. Compute $Z^{\text{new}} \leftarrow \mathbf{S}^H_{\lambda_k}(P_\Omega(X) + P^\perp_\Omega(Z^{\text{old}}))$.
      ii. If $\frac{\|Z^{\text{new}} - Z^{\text{old}}\|_F^2}{\|Z^{\text{old}}\|_F^2} < \varepsilon$ exit.
      iii. Assign $Z^{\text{old}} \leftarrow Z^{\text{new}}$.
   (b) Assign $\hat{Z}_{H,\lambda_k} \leftarrow Z^{\text{new}}$.
3. Output the sequence of solutions $\hat{Z}_{H,\lambda_1}, \ldots, \hat{Z}_{H,\lambda_K}$.

where $\mathbf{p}(|t|;\mu)$ is concave in $|t|$. The parameter $\mu \in [\mu_{\text{inf}}, \mu_{\text{sup}}]$ controls the degree of concavity. We may think of $p(|t|;\mu_{\text{inf}}) = |t|$ (ℓ_1 penalty) on one end and $p(|t|;\mu_{\text{sup}}) = \|t\|_0$ (ℓ_0 penalty) on the other. In particular for the ℓ_0 penalty denote $f_{\mathbf{p},\lambda}(Z)$ by $f_{H,\lambda}(Z)$ for "hard" thresholding. See Friedman (2008), Mazumder et al. (2009) and Zhang (2010) for examples of such penalties.

In Remark 1 in Appendix A.1 we argue how the proof can be modified for general types of spectral regularization. Hence for minimizing the objective (24) we will look at the analogous version of (8, 23) which is

$$\underset{Z}{\text{minimize}} \quad \frac{1}{2}\|W - Z\|_F^2 + \lambda \sum_j \mathbf{p}(\gamma_j(Z);\mu).$$

The solution is given by a thresholded SVD of W,

$$\mathbf{S}^{\mathbf{p}}_\lambda(W) = U D_{\mathbf{p},\lambda} V',$$

where $D_{\mathbf{p},\lambda}$ is a entry-wise thresholding of the diagonal entries of the matrix D consisting of singular values of the matrix W. The exact form of the thresholding depends upon the form of the penalty function $\mathbf{p}(\cdot;\cdot)$, as discussed in Remark 1. Algorithm 1 and Algorithm 2 can be modified for the penalty $\mathbf{p}(\cdot;\mu)$ by using a more general thresholding function $\mathbf{S}^{\text{p}}_\lambda(\cdot)$ in Step 2(a)i. The corresponding step becomes:

$$Z^{\text{new}} \leftarrow \mathbf{S}^{\mathbf{p}}_\lambda(P_\Omega(X) + P^\perp_\Omega(Z^{\text{old}})).$$

However these types of spectral regularization make the criterion (24) non-convex and hence it becomes difficult to optimize globally. Recht et al. (2007) and Bach (2008) also consider the rank estimation problem from a theoretical standpoint.

7. Post-processing of "Selectors" and Initialization

Because the ℓ_1 norm regularizes by shrinking the singular values, the number of singular values retained (through cross-validation, say) may exceed the actual rank of the matrix. In such cases it is reasonable to *undo* the shrinkage of the chosen models, which might permit a lower-rank solution.

If Z_λ is the solution to (10), then its *post-processed* version Z_λ^u obtained by "unshrinking" the eigen-values of the matrix Z_λ is obtained by

$$\begin{aligned} \alpha &= \underset{\alpha_i \geq 0,\, i=1,\ldots,r_\lambda}{\arg\min} \quad \|P_\Omega(X) - \sum_{i=1}^{r_\lambda} \alpha_i P_\Omega(u_i v_i')\|^2 \\ Z_\lambda^u &= UD_\alpha V', \end{aligned} \tag{25}$$

where $D_\alpha = \mathrm{diag}(\alpha_1, \ldots, \alpha_{r_\lambda})$. Here r_λ is the rank of Z_λ and $Z_\lambda = UD_\lambda V'$ is its SVD. The estimation in (25) can be done via ordinary least squares, which is feasible because of the sparsity of $P_\Omega(u_i v_i')$ and that r_λ is small.[7] If the least squares solutions α do not meet the positivity constraints, then the negative sign can be absorbed into the corresponding singular vector.

Rather than estimating a diagonal matrix D_α as above, one can insert a matrix $M_{r_\lambda \times r_\lambda}$ between U and V above to obtain better training error for the same rank. Hence given U, V (each of rank r_λ) from the SOFT-IMPUTE algorithm, we solve

$$\begin{aligned} \hat{M} &= \underset{M}{\arg\min} \quad \|P_\Omega(X) - P_\Omega(UMV')\|^2, \\ \text{where, } \hat{Z}_\lambda &= U\hat{M}V'. \end{aligned} \tag{26}$$

The objective function in (26) is the Frobenius norm of an affine function of M and hence can be optimized very efficiently. Scalability issues pertaining to the optimization problem (26) can be handled fairly efficiently via conjugate gradients. Criterion (26) will definitely lead to a decrease in training error as that attained by $\hat{Z} = UD_\lambda V'$ for the same rank and is potentially an attractive proposal for the original problem (1). However this heuristic cannot be caste as a (jointly) convex problem in (U, M, V). In addition, this requires the estimation of up to r_λ^2 parameters, and has the potential for over-fitting. In this paper we report experiments based on (25).

In many simulated examples we have observed that this post-processing step gives a good estimate of the underlying true rank of the matrix (based on prediction error). Since fixed points of Algorithm 2 correspond to local minima of the function (24), well-chosen warm starts $\tilde{Z}_\lambda$ are helpful. A reasonable prescription for warms-starts is the nuclear norm solution via (SOFT-IMPUTE), or the post processed version (25). The latter appears to significantly speed up convergence for HARD-IMPUTE. This observation is based on our simulation studies.

8. Soft-Impute and Maximum-Margin Matrix Factorization

In this section we compare in detail the MMMF criterion (6) with the SOFT-IMPUTE criterion (3). For ease of comparison here, we put down these criteria again using our P_Ω notation.

MMMF solves

$$\underset{U,V}{\text{minimize}} \quad \frac{1}{2}||P_\Omega(X - UV)||_F^2 + \frac{\lambda}{2}(\|U\|_F^2 + \|V\|_F^2), \tag{27}$$

where $U_{m\times r'}$ and $V_{n\times r'}$ are arbitrary (non-orthogonal) matrices. This problem formulation and related optimization methods have been explored by Srebro et al. (2005b) and Rennie and Srebro (2005).

7. Observe that the $P_\Omega(u_i v_i')$, $i = 1, \ldots, r_\lambda$ are not orthogonal, though the $u_i v_i'$ are.

SOFT-IMPUTE solves

$$\underset{Z}{\text{minimize}} \quad \frac{1}{2}||P_\Omega(X-Z)||_F^2 + \lambda\|Z\|_*. \tag{28}$$

For each given maximum rank, MMMF produces an estimate by doing further shrinkage with its quadratic regularization. SOFT-IMPUTE performs rank reduction and shrinkage at the same time, in one smooth convex operation. The following theorem shows that this one-dimensional SOFT-IMPUTE family lies exactly in the two-dimensional MMMF family.

Theorem 3 *Let X be $m \times n$ with observed entries indexed by Ω.*

1. *Let $r' = \min(m,n)$. Then the solutions to (27) and (28) coincide for all $\lambda \geq 0$.*
2. *Suppose $\hat{Z}^*$ is a solution to (28) for $\lambda^* > 0$, and let r^* be its rank. Then for any solution $\hat{U}, \hat{V}$ to (27) with $r' = r^*$ and $\lambda = \lambda^*$, $\hat{U}\hat{V}^T$ is a solution to (28). The SVD factorization of $\hat{Z}^*$ provides one such solution to (27). This implies that the solution space of (28) is contained in that of (27).*

Remarks:

1. Part 1 of this theorem appears in a slightly different form in Srebro et al. (2005b).
2. In part 1, we could use $r' > \min(m,n)$ and get the same equivalence. While this might seem unnecessary, there may be computational advantages; searching over a bigger space might protect against local minima. Likewise in part 2, we could use $r' > r^*$ and achieve the same equivalence. In either case, no matter what r' we use, the solution matrices $\hat{U}$ and $\hat{V}$ have the same rank as $\hat{Z}$.
3. Let $\hat{Z}(\lambda)$ be a solution to (28) at λ. We conjecture that rank $[\hat{Z}(\lambda)]$ is monotone non-increasing in λ. If this is the case, then Theorem 3, part 2 can be further strengthened to say that for all $\lambda \geq \lambda^*$ and $r' = r^*$ the solutions of (27) coincide with that of (28).

The MMMF criterion (27) defines a two-dimensional family of models indexed by (r', λ), while the SOFT-IMPUTE criterion (28) defines a one-dimensional family. In light of Theorem 3, this family is a special path in the two-dimensional grid of solutions $[\hat{U}_{(r',\lambda)}, \hat{V}_{(r',\lambda)}]$. Figure 1 depicts the situation. Any MMMF model at parameter combinations above the red squares are redundant, since their fit is the same at the red square. However, in practice the red squares are not known to MMMF, nor is the actual rank of the solution. Further orthogonalization of $\hat{U}$ and $\hat{V}$ would be required to reveal the rank, which would only be approximate (depending on the convergence criterion of the MMMF algorithm).

Despite the equivalence of (27) and (28) when $r' = \min(m,n)$, the criteria are quite different. While (28) is a convex optimization problem in Z, (27) is a non-convex problem in the variables U, V and has possibly several local minima; see also Abernethy et al. (2009). It has been observed empirically and theoretically (Burer and Monteiro, 2005; Rennie and Srebro, 2005) that bi-convex methods used in the optimization of (27) can get stuck in sub-optimal local minima for a small value of r' or a poorly chosen starting point. For a large number of factors r' and large dimensions m,n the computational cost may be quite high (See also experimental studies in Section 9.2).

Criterion (28) is convex in Z for every value of λ, and it outputs the solution $\hat{Z}$ in the form of its soft-thresholded SVD, implying that the "factors" U, V are already orthogonal and the rank is known.

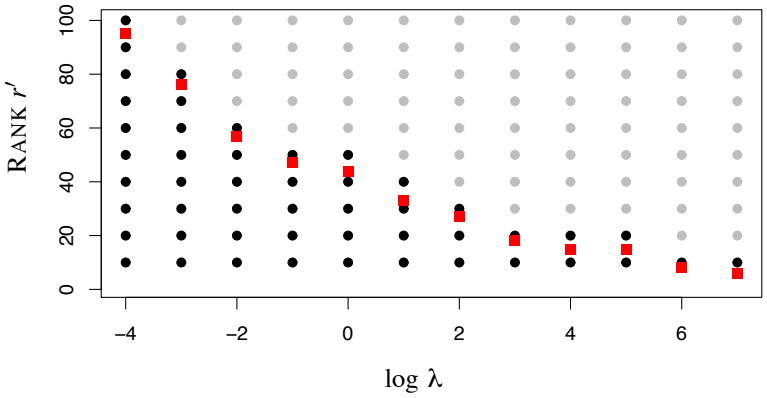

Figure 1: Comparison of the parameter space for MMMF (grey and black points), and SOFT-IMPUTE (red squares) for a simple example. Since all MMMF solutions with parameters above the red squares are identical to the SOFT-IMPUTE solutions at the red squares, all the grey points are redundant.

MMMF has two different tuning parameters r' and λ, both of which are related to the rank or spectral properties of the matrices U, V. SOFT-IMPUTE has only one tuning parameter λ. The presence of two tuning parameters is problematic:

- It results in a significant increase in computational burden, since for every given value of r', one needs to compute an entire system of solutions by varying λ (see Section 9 for illustrations).
- In practice when neither the optimal values of r' and λ are known, a two-dimensional search (for example, by cross validation) is required to select suitable values.

Further discussions and connections between the tuning parameters and spectral properties of the matrices can be found in Burer and Monteiro (2005) and Abernethy et al. (2009).

The proof of Theorem 3 requires a lemma.

Lemma 6 *For any matrix Z, the following holds:*

$$||Z||_* = \min_{U,V:\, Z=UV^T} \frac{1}{2}\left(\|U\|_F^2 + \|V\|_F^2\right). \tag{29}$$

If $\text{rank}(Z) = k \leq \min\{m,n\}$*, then the minimum above is attained at a factor decomposition* $Z = U_{m\times k}V_{n\times k}^T$.

Note that in the decomposition $Z = UV^T$ in (29) there is no constraint on the number of columns r of the factor matrices $U_{m\times r}$ and $V_{n\times r}$. Lemma 6 is stronger than similar results appearing in Rennie and Srebro (2005) and Abernethy et al. (2009) which establish (29) for $r = \min\{m,n\}$—we give a tighter estimate of the rank k of the underlying matrices. The proof is given in Appendix A.5.

8.1 Proof of Theorem 3

Part 1. For $r = \min(m,n)$, any matrix $Z_{m\times n}$ can be written in the form of $Z = UV^T$. The criterion (27) can be written as

$$\min_{U,V} \quad \tfrac{1}{2}||P_\Omega(X - UV^T)||_F^2 + \tfrac{\lambda}{2}(\|U\|_F^2 + \|V\|_F^2) \tag{30}$$

$$= \min_{U,V} \quad \tfrac{1}{2}||P_\Omega(X - UV^T)||_F^2 + \lambda\|UV^T\|_* \qquad \text{(by Lemma 6)}$$

$$= \min_{Z} \quad \tfrac{1}{2}||P_\Omega(X - Z)||_F^2 + \lambda\|Z\|_*. \tag{31}$$

The equivalence of the criteria in (30) and (31) completes the proof of part 1.
Part 2. Note that if we know that the solution $\hat{Z}^*$ to (28) with $\lambda = \lambda^*$ has rank r^*, then $\hat{Z}^*$ also solves

$$\min_{Z,\, \mathrm{rank}(Z)=r^*} \quad \tfrac{1}{2}||P_\Omega(X - Z)||_F^2 \quad + \lambda\|Z\|_*.$$

We now repeat the steps (30)—(31), restricting the rank r' of U and V to be $r' = r^*$, and the result follows. ■

9. Numerical Experiments and Comparisons

In this section we study the performance of SOFT-IMPUTE, its post-processed variants, and HARD-IMPUTE for noisy matrix completion problems. The examples assert our claim that the matrix reconstruction criterion (4) (Cai et al., 2008) is too rigid if one seeks good predictive models. We include the related procedures of Rennie and Srebro (2005) and Keshavan et al. (2009) in our comparisons.

The reconstruction algorithm OPTSPACE, described in Keshavan et al. (2009) considers criterion (1) (in the presence of noise). It uses the representation $Z = USV'$ (which need not correspond to the SVD). OPTSPACE alternates between estimating S and U,V (in a Grassmann manifold) for computing a rank-r decomposition $\hat{Z} = \hat{U}\hat{S}\hat{V}'$. It starts with a sparse SVD on a *clean* version of the observed matrix $P_\Omega(X)$. This is similar to the formulation of MMMF (27) as detailed in Section 8, without the squared Frobenius norm regularization on the components U,V.

To summarize, we study the following methods:

1. SOFT-IMPUTE–Algorithm 1;
2. SOFT-IMPUTE+–post-processing on the output of SOFT-IMPUTE, as in Section 7;
3. HARD-IMPUTE–Algorithm 2, starting with the output of SOFT-IMPUTE+;
4. SVT–algorithm by Cai et al. (2008);
5. OPTSPACE–reconstruction algorithm by Keshavan et al. (2009);
6. MMMF–algorithm for (6) as in Rennie and Srebro (2005).

In all our simulation studies we use the underlying model $Z_{m\times n} = U_{m\times r}V'_{r\times n} + \varepsilon$, where U and V are random matrices with standard normal Gaussian entries, and ε is i.i.d. Gaussian. Ω is uniformly random over the indices of the matrix with $p\%$ percent of missing entries. These are the models under which the coherence conditions hold true for the matrix completion problem to be meaningful (Candès and Tao, 2009; Keshavan et al., 2009). The signal to noise ratio for the model and the test-error (standardized) are defined as

$$\text{SNR} = \sqrt{\frac{\text{var}(UV')}{\text{var}(\varepsilon)}}; \quad \text{Test Error} = \frac{\|P_\Omega^\perp(UV' - \hat{Z})\|_F^2}{\|P_\Omega^\perp(UV')\|_F^2}.$$

Training error (standardized) is defined as

$$\text{Training Error} = \frac{\|P_\Omega(Z - \hat{Z})\|_F^2}{\|P_\Omega(Z)\|_F^2},$$

the fraction of the error explained on the observed entries by the estimate relative to a zero estimate.

Figures 2, 3 and 4 show training and test error for all of the algorithms mentioned above—both as a function of nuclear norm and rank—for the three problem instances. The results displayed in the figures are averaged over 50 simulations, and also show one-standard-error bands (hardly visible). In all examples $(m,n) = (100,100)$. For MMMF we use $r' = \min(m,n) = 100$, the number of columns in U and V. The performance of MMMF is displayed only in the plots with the nuclear norm along the horizontal axis, since the algorithm does not deliver a precise rank. SNR, true rank and percentage of missing entries are indicated in the figures. There is a unique correspondence between λ and nuclear norm. The plots versus rank indicate how effective the nuclear norm is as a rank approximation—that is whether it recovers the true rank while minimizing prediction error.

For routines not our own we use the MATLAB code as supplied on webpages by the authors. For SVT second author of Cai et al. (2008), for OPTSPACE third author of Keshavan et al. (2009), and for MMMF first author of Rennie and Srebro (2005).

9.1 Observations

The captions of each of Figures 2–4 detail the results, which we summarize here. For the first two figures, the noise is quite high with SNR$= 1$, and 50% of the entries are missing. In Figure 2 the true rank is 10, while in Figure 3 it is 6. SOFT-IMPUTE, MMMF and SOFT-IMPUTE+ have the best prediction performance, while SOFT-IMPUTE+ is better at estimating the correct rank. The other procedures perform poorly here, although OPTSPACE improves somewhat in Figure 3. SVT has very poor prediction error, suggesting once again that exactly fitting the training data is far too rigid. SOFT-IMPUTE+ has the best performance in Figure 3 (smaller rank—more aggressive fitting), and HARD-IMPUTE starts recovering here. In both figures the training error for SOFT-IMPUTE (and hence MMMF) wins as a function of nuclear norm (as it must, by construction), but the more aggressive fitters SOFT-IMPUTE+ and HARD-IMPUTE have better training error as a function of rank.

Though the nuclear norm is often viewed as a surrogate for the rank of a matrix, we see in these examples that it can provide a superior mechanism for regularization. This is similar to the performance of LASSO in the context of regression. Although the LASSO penalty can be viewed as a convex surrogate for the ℓ_0 penalty in model selection, its ℓ_1 penalty provides a smoother and often better basis for regularization.

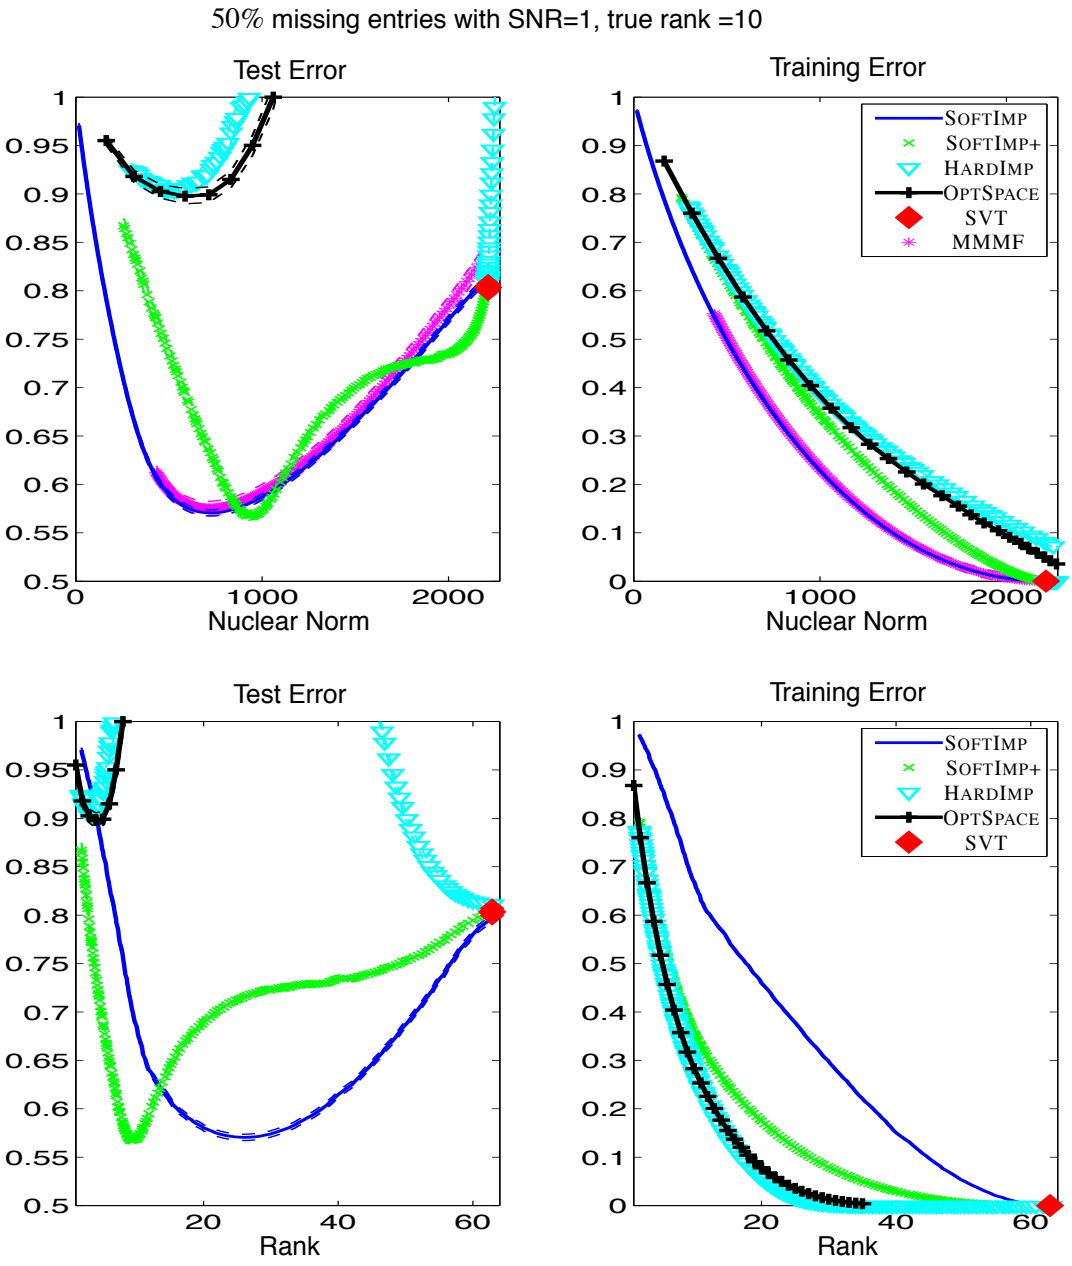

Figure 2: SOFTIMP+ refers to the post-processing after SOFT-IMPUTE; HARD-IMPUTE uses SOFT-IMP+ as starting values. Both SOFT-IMPUTE and SOFT-IMPUTE+ perform well (prediction error) in the presence of noise; the latter estimates the actual rank of the matrix. MMMF (with full rank 100 factor matrices) has performance similar to SOFT-IMPUTE. HARD-IMPUTE and OPTSPACE show poor prediction error. SVT also has poor prediction error, confirming our claim in this example that criterion (4) can result in overfitting; it recovers a matrix with high nuclear norm and rank > 60 where the true rank is only 10. Values of test error larger than one are not shown in the figure. OPTSPACE is evaluated for a series of ranks ≤ 30.

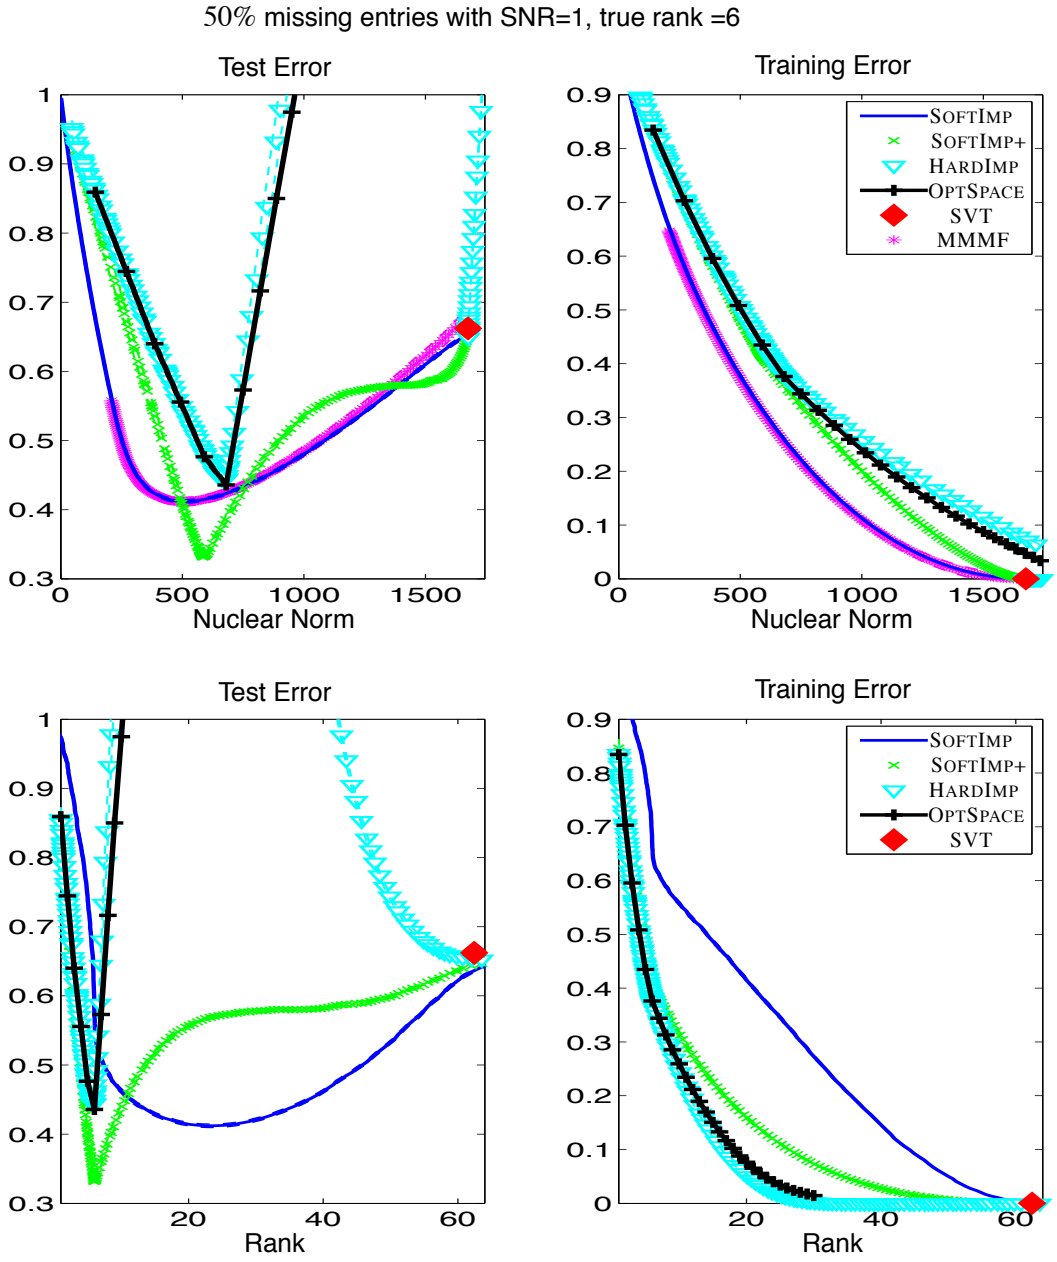

Figure 3: SOFT-IMPUTE+ has the best prediction error, closely followed by SOFT-IMPUTE and MMMF. Both HARD-IMPUTE and OPTSPACE have poor prediction error apart from near the true rank 6 of the matrix, where they show reasonable performance. SVT has very poor prediction error; it recovers a matrix with high nuclear norm and rank > 60, where the true rank is only 6. OPTSPACE is evaluated for a series of ranks ≤ 35.

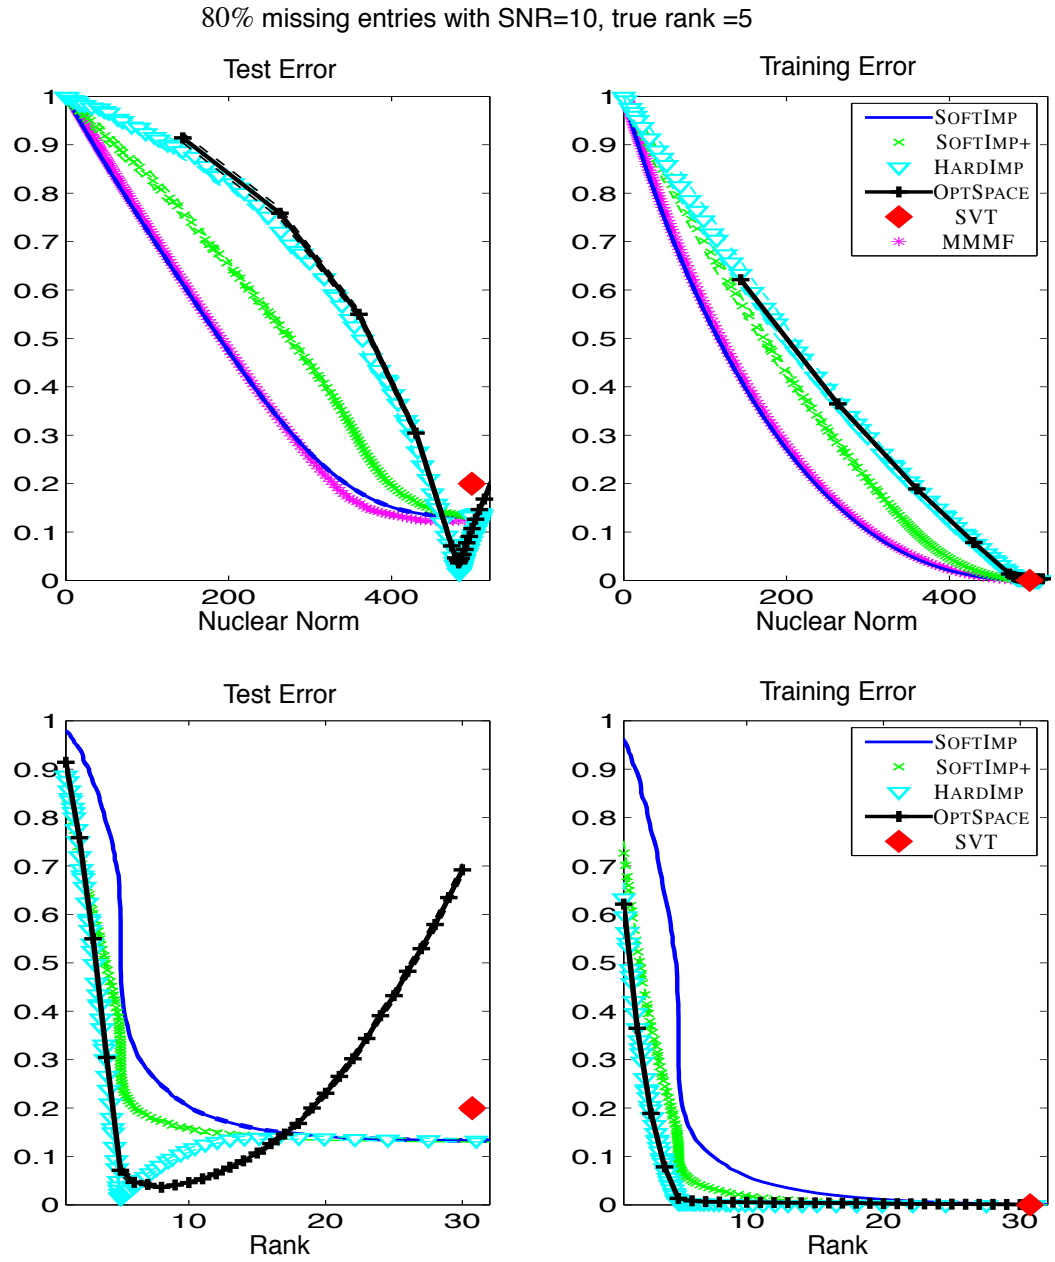

Figure 4: With low noise the performance of HARD-IMPUTE improves. It gets the correct rank whereas OPTSPACE slightly overestimates the rank. HARD-IMPUTE has the best prediction error, followed by OPTSPACE. Here MMMF has slightly better prediction error than SOFT-IMPUTE. Although the noise is low here, SVT recovers a matrix with high rank (approximately 30) and has poor prediction error as well. The test error of SVT is found to be different from the limiting solution of SOFT-IMPUTE; although in theory the limiting solution of (10) should coincide with that of SVT, in practice we never go to the limit.

In Figure 4 with SNR= 10 the noise is relatively small compared to the other two cases. The true underlying rank is 5, but the proportion of missing entries is much higher at eighty percent. Test errors of both SOFT-IMPUTE+ and SOFT-IMPUTE are found to decrease till a large nuclear norm after which they become roughly the same, suggesting no further impact of regularization. MMMF has slightly better test error than SOFT-IMPUTE around a nuclear norm of 350, while in theory they should be identical. Notice, however, that the training error is slightly worse (everywhere), suggesting that MMMF is sometimes trapped in local minima. The fact that this slightly underfit solution does better in test error is a quirk of this particular example. OPTSPACE performs well in this high-SNR example, achieving a sharp minima at the true rank of the matrix. HARD-IMPUTE performs the best in this example. The better performance of both OPTSPACE and HARD-IMPUTE over SOFT-IMPUTE can be attributed both to the low-rank truth and the high SNR. This is reminiscent of the better predictive performance of best-subset or concave penalized regression often seen over LASSO in setups where the underlying model is very sparse (Friedman, 2008).

9.2 Comparison with Fast MMMF (Rennie and Srebro, 2005)

In this section we compare SOFT-IMPUTE with MMMF in terms of computational efficiency. We also examine the consequences of two regularization parameters (r', λ) for MMMF over one for SOFT-IMPUTE.

Rennie and Srebro (2005) describes a fast algorithm based on conjugate-gradient descent for minimization of the MMMF criterion (6). With (6) being non-convex, it is hard to provide theoretical optimality guarantees for the algorithm for arbitrary r', λ—that is, what type of solution it converges to or how far it is from the global minimizer.

In Table 1 we summarize the performance results of the two algorithms. For both SOFT-IMPUTE and MMMF we consider a equi-spaced grid of 150 $\lambda \in [\lambda_{\min}, \lambda_{\max}]$, with $\lambda_{\min}$ corresponding to a full-rank solution of SOFT-IMPUTE and $\lambda_{\max}$ the zero solution. For MMMF, three different values of r' were used, and for each $(\hat{U}, \hat{V})$ were solved for over the grid of λ values. A separate held-out validation set with twenty percent of the missing entries sampled from $\Omega^{\perp}$ were used to train the tuning parameter λ (for each value of r') for MMMF and SOFT-IMPUTE. Finally we evaluate the standardized prediction errors on a test set consisting of the remaining eighty percent of the missing entries in $\Omega^{\perp}$. In all cases we report the training errors and test errors on the optimally tuned λ. SOFT-IMPUTE was run till a tolerance of 10^{-4} was achieved (fraction of decrease of objective value). Likewise for MMMF we set the tolerance of the conjugate gradient method to 10^{-4}.

In Table 1, for every algorithm total time indicates the time required for evaluating solutions over the entire grid of λ values. In these examples, we used direct SVD factorization based methods for the SVD computation, since the size of the problems were quite small. In all these examples we observe that SOFT-IMPUTE performs very favorably in terms of total times. For MMMF the time to train the models increase with increasing rank r'; and in case the underlying matrix has rank which is larger than r', the computational cost will be large in order to get competitive predictive accuracy. This point is supported in the examples of Table 1. It is important to note that, the prediction error of SOFT-IMPUTE as obtained on the validation set is actually within standard error of the best prediction error produced by all the MMMF models. In addition we also performed some medium-scale examples increasing the dimensions of the matrices. To make comparisons fair, SOFT-IMPUTE made use of *direct* SVD computations (in MATLAB) instead of iterative algorithms

Data	Method (rank)	Test error	Training error	Time (secs)
$(m,n) = (10^2, 10^2)$	SOFT-IMPUTE (39)	0.7238 (0.0027)	0.0720	4.1745
$\|\Omega\| = 5 \times 10^3 (50\%)$	MMMF (20)	0.7318 (0.0031)	0.2875	48.1090
SNR= 3	MMMF (60)	0.7236 (0.0027)	0.1730	62.0230
rank (R)= 30	MMMF (100)	0.7237 (0.0027)	0.1784	96.2750
$(m,n) = (10^2, 10^2)$	SOFT-IMPUTE (37)	0.5877 (0.0047)	0.0017	4.0976
$\|\Omega\| = 2 \times 10^3 (20\%)$	MMMF (20)	0.5807 (0.0049)	0.0186	53.7533
SNR= 10	MMMF (60)	0.5823 (0.0049)	0.0197	62.0230
rank(R)= 10	MMMF (100)	0.5823 (0.0049)	0.0197	84.0375
$(m,n) = (10^2, 10^2)$	SOFT-IMPUTE (59)	0.6008 (0.0028)	0.0086	3.8447
$\|\Omega\| = 8 \times 10^3 (80\%)$	MMMF (20)	0.6880 (0.0029)	0.4037	33.8685
SNR= 10	MMMF (60)	0.5999 (0.0028)	0.0275	57.3488
rank(R)= 45	MMMF (100)	0.5999 (0.0028)	0.0275	89.4525

Table 1: Performances of SOFT-IMPUTE and MMMF for different problem instances, in terms of test error (with standard errors in parentheses), training error and times for learning the models. SOFT-IMPUTE,"rank" denotes the rank of the recovered matrix, at the optimally chosen value of λ. For the MMMF, "rank" indicates the value of r' in $U_{m\times r'}, V_{n\times r'}$. Results are averaged over 50 simulations.

exploiting the specialized *Sparse+Low-Rank* structure (22). We report our findings on one such simulation example:

- For $(m,n) = (2000, 1000)$, $|\Omega|/(m \cdot n) = 0.2$, rank $= 500$ and SNR=10; SOFT-IMPUTE takes 1.29 hours to compute solutions on a grid of 100 λ values. The test error on the validation set and training error are 0.9630 and 0.4375 with the recovered solution having a rank of 225.

  For the same problem, MMMF with $r' = 200$ takes 6.67 hours returning a solution with test-error 0.9678 and training error 0.6624. With $r' = 400$ it takes 12.89 hrs with test and training errors 0.9659 and 0.6564 respectively.

We will like to note that DeCoste (2006) proposed an efficient implementation of MMMF via an ensemble based approach, which is quite different in spirit from the batch optimization algorithms we are studying in this paper. Hence we do not compare it with SOFT-IMPUTE.

9.3 Comparison with Nesterov's Accelerated Gradient Method

Ji and Ye (2009) proposed a first-order algorithm based on Nesterov's acceleration scheme (Nesterov, 2007), for nuclear norm minimization for a generic multi-task learning problem (Argyriou et al., 2008, 2007). Their algorithm (Liu et al., 2009; Ji and Ye, 2009) can be adapted to the SOFT-IMPUTE problem (10); hereafter we refer to it as NESTEROV. It requires one to compute the SVD of a dense matrix having the dimensions of X, which makes it prohibitive for large-scale problems. We instead would make use of the structure (22) for the SVD computation, a special characteristic of matrix completion which is not present in a generic multi-task learning problem. Here we compare the performances of SOFT-IMPUTE and NESTEROV on small scale examples, where direct SVDs can be computed easily.

Since both algorithms solve the same criterion, the quality of the solutions—objective values, training and test errors—will be the same (within tolerance). We hence compare their performances based on the times taken by the algorithms to converge to the optimal solution of (10) on a grid of values of λ. Both algorithms compute a path of solutions using warm starts. Results are shown in Figure 5, for four different scenarios described in Table 2.

Example	(m,n)	$\|\Omega\|/(m\cdot n)$	Rank	Test Error
i	$(100,100)$	0.5	5	0.4757
ii	$(100,100)$	0.2	5	0.0668
iii	$(100,100)$	0.8	5	0.0022
iv	$(1000,500)$	0.5	30	0.0028

Table 2: Four different examples used for timing comparisons of SOFT-IMPUTE and NESTEROV (accelerated Nesterov algorithm of Ji and Ye 2009). In all cases the SNR= 10.

Figure 5 shows the time to convergence for the two algorithms. Their respective number of iterations are not comparable. This is because NESTEROV uses a line-search to compute an adaptive step-size (approximate the Lipschitz constant) at every iteration, whereas SOFT-IMPUTE does not.

SOFT-IMPUTE has a rate of convergence given by Theorem 2, which for large k is worse than the accelerated version NESTEROV with rate $O(1/k^2)$. However, timing comparisons in Figure 5 show that SOFT-IMPUTE performs very favorably. We do not know the exact reason behind this, but mention some possibilities. Firstly the rates are *worst case* convergence rates. On particular problem instances of the form (10), the rates of convergence in *practice* of SOFT-IMPUTE and NESTEROV may be quite similar. Since Ji and Ye (2009) uses an adaptive step-size strategy, the choice of a step-size may be time consuming. SOFT-IMPUTE on the other hand, uses a constant step size.

Additionally, it appears that the use of the *momentum* term in NESTEROV affects the *Sparse+Low-rank* decomposition (22). This may prevent the algorithm to be adapted for solving large problems, due to costly SVD computations.

9.4 Large Scale Simulations for SOFT-IMPUTE

Table 3 reports the performance of SOFT-IMPUTE on some large-scale problems. All computations are performed in MATLAB and the MATLAB implementation of PROPACK is used. Data input, access and transfer in MATLAB take a sizable portion of the total computational time, given the size of these problems. However, the main computational bottle neck in our algorithm is the structured SVD computation. In order to focus more on the essential computational task, Table 3 displays the total time required to perform the SVD computations over all iterations of the algorithm. Note that for all the examples considered in Table 3, the implementations of algorithms NESTEROV (Liu et al., 2009; Ji and Ye, 2009) and MMMF (Rennie and Srebro, 2005) are prohibitively expensive both in terms of computational time and memory requirements, and hence could not be run. We used the value $\lambda = ||P_\Omega(X)||_2/K$ with SOFT-IMPUTE, with $K = 1.5$ for all examples but the last, where $K = 2$. $\lambda_0 = ||P_\Omega(X)||_2$ is the largest singular value of the input matrix X (padded with zeros); this is the smallest value of λ for which $\mathbf{S}_{\lambda_0}(P_\Omega(X)) = 0$ in the first iteration of SOFT-IMPUTE (Section 3).

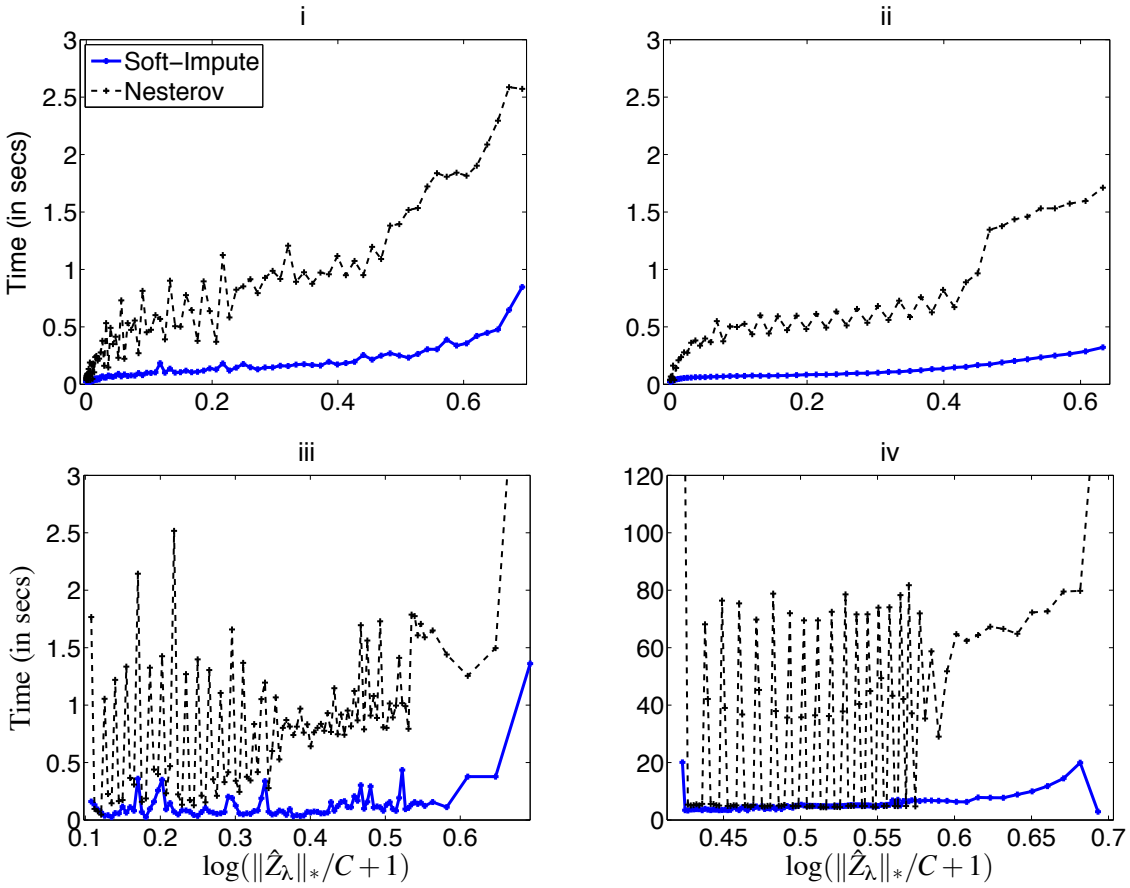

Figure 5: Timing comparisons of SOFT-IMPUTE and NESTEROV (accelerated Nesterov algorithm of Ji and Ye 2009). The horizontal axis corresponds to the standardized nuclear norm, with $C = \max_\lambda \|\hat{Z}_\lambda\|_*$. Shown are the times till convergence for the two algorithms over an entire grid of λ values for examples i–iv (in the last the matrix dimensions are much larger). The overall time differences between Examples i–iii and Example iv is due to the increased cost of the SVD computations. Results are averaged over 10 simulations. The times for NESTEROV change far more erratically with λ than they do for SOFT-IMPUTE.

The prediction performance is awful for all but one of the models, because in most cases the fraction of observed data is very small. These simulations were mainly to show the computational capabilities of SOFT-IMPUTE on very large problems.

10. Application to the Netflix Data Set

The Netflix training data consists of the ratings of 17,770 movies by 480,189 Netflix customers. The resulting data matrix is extremely sparse, with 100,480,507 or 1% of the entries observed. The task was to predict the unseen ratings for a qualifying set and a test set of about 1.4 million ratings each, with the true ratings in these data sets held in secret by Netflix. A probe set of about 1.4 million

(m,n)	$\|\Omega\|$	$\|\Omega\|/(m\cdot n)$ $\times 100\%$	Recovered rank	Time (mins)	Test error	Training error
$(10^4,10^4)$	10^5	0.1	40^*	0.2754	0.9946	0.6160
$(10^4,10^4)$	10^5	0.1	40^*	0.3770	0.9959	0.6217
$(10^4,10^4)$	10^5	0.1	50^*	0.4292	0.9962	0.3862
$(10^4,10^4)$	10^6	1.0	5	1.6664	0.6930	0.6600
$(10^5,10^5)$	5×10^6	0.05	40^*	17.2518	0.9887	0.8156
$(10^5,10^5)$	10^7	0.1	5	20.3142	0.9803	0.9761
$(10^6,10^5)$	10^8	0.1	5	259.9620	0.9913	0.9901
$(10^6,10^6)$	10^7	0.001	20^*	99.6780	0.9998	0.5834

Table 3: Performance of SOFT-IMPUTE on different problem instances. All models are generated with SNR=10 and underlying rank=5. Recovered rank is the rank of the solution matrix $\hat{Z}$ at the value of λ used in (10). Those with stars reached the "maximum rank" threshold, and option in our algorithm. Convergence criterion is taken as "fraction of improvement of objective value" less than 10^{-4} or a maximum of 15 iterations for the last four examples. All implementations are done in MATLAB including the MATLAB implementation of PROPACK on a Intel Xeon Linux 3GHz processor.

ratings was distributed to participants, for calibration purposes. The movies and customers in the qualifying, test and probe sets are all subsets of those in the training set.

The ratings are integers from 1 (poor) to 5 (best). Netflix's own algorithm has an RMSE of 0.9525, and the contest goal was to improve this by 10%, or an RMSE of 0.8572 or better. The contest ran for about 3 years, and the winning team was "Bellkor's Pragmatic Chaos", a merger of three earlier teams (see `http://www.netflixprize.com/` for details). They claimed the grand prize of $1M on September 21, 2009.

Many of the competitive algorithms build on a regularized low-rank factor model similar to (6) using randomization schemes like mini-batch, stochastic gradient descent or sub-sampling to reduce the computational cost over making several passes over the entire data-set (see Salakhutdinov et al., 2007; Bell and Koren., 2007; Takacs et al., 2009, for example). In this paper, our focus is not on using randomized or sub-sampling schemes. Here we demonstrate that our nuclear-norm regularization algorithm can be applied in batch mode on the entire Netflix training set with a reasonable computation time. We note however that the conditions under which the nuclear-norm regularization is theoretically meaningful (Candès and Tao, 2009; Srebro et al., 2005a) are not met on the Netflix data set.

We applied SOFT-IMPUTE to the training data matrix and then performed a least-squares unshrinking on the singular values with the singular vectors and the training data row and column means as the bases. The latter was performed on a data-set of size 10^5 randomly drawn from the probe set. The prediction error (RMSE) is obtained on a left out portion of the probe set. Table 4 reports the performance of the procedure for different choices of the tuning parameter λ (and the corresponding rank); times indicate the total time taken for the SVD computations over all iterations. A maximum of 10 iterations were performed for each of the examples. Again, these results are not competitive with those of the competition leaders, but rather demonstrate the feasibility of applying SOFT-IMPUTE to such a large data set.

λ	Rank	Time (hrs)	RMSE
$\lambda_0/250$	42	1.36	0.9622
$\lambda_0/300$	66	2.21	0.9572
$\lambda_0/500$	81	2.83	0.9543
$\lambda_0/600$	95	3.27	0.9497

Table 4: Results of applying SOFT-IMPUTE to the Netflix data. $\lambda_0 = ||P_\Omega(X)||_2$; see Section 9.4. The computations were done on a Intel Xeon Linux 3GHz processor; timings are reported based on MATLAB implementations of PROPACK and our algorithm. RMSE is root-mean squared error, as defined in the text.

Acknowledgments

We thank the reviewers for their suggestions that lead to improvements in this paper. We thank Stephen Boyd, Emmanuel Candes, Andrea Montanari, and Nathan Srebro for helpful discussions. Appendix A. Proofs

We begin with the proof of Lemma 1.

A.1 Proof of Lemma 1

Proof Let $Z = \tilde{U}_{m\times n}\tilde{D}_{n\times n}\tilde{V}'_{n\times n}$ be the SVD of Z. Assume without loss of generality, $m \geq n$. We will explicitly evaluate the closed form solution of the problem (8). Note that

$$\frac{1}{2}\|Z - W\|_F^2 + \lambda\|Z\|_* = \frac{1}{2}\left\{\|Z\|_F^2 - 2\sum_{i=1}^n \tilde{d}_i\tilde{u}_i' W\tilde{v}_i + \sum_{i=1}^n \tilde{d}_i^2\right\} + \lambda\sum_{i=1}^n \tilde{d}_i \tag{32}$$

where

$$\tilde{D} = \text{diag}\left[\tilde{d}_1,\ldots,\tilde{d}_n\right],\ \tilde{U} = [\tilde{u}_1,\ldots,\tilde{u}_n],\ \tilde{V} = [\tilde{v}_1,\ldots,\tilde{v}_n].$$

Minimizing (32) is equivalent to minimizing

$$-2\sum_{i=1}^n \tilde{d}_i\tilde{u}_i' W\tilde{v}_i + \sum_{i=1}^n \tilde{d}_i^2 + \sum_{i=1}^n 2\lambda\tilde{d}_i;\ \text{ w.r.t. } (\tilde{u}_i,\tilde{v}_i,\tilde{d}_i),\ i = 1,\ldots,n,$$

under the constraints $\tilde{U}'\tilde{U} = I_n$, $\tilde{V}'\tilde{V} = I_n$ and $\tilde{d}_i \geq 0\ \ \forall i$.

Observe the above is equivalent to minimizing (w.r.t. $\tilde{U},\tilde{V}$) the function $Q(\tilde{U},\tilde{V})$:

$$Q(\tilde{U},\tilde{V}) = \min_{\tilde{D}\geq 0}\quad \frac{1}{2}\left\{-2\sum_{i=1}^n \tilde{d}_i\tilde{u}_i' W\tilde{v}_i + \sum_{i=1}^n \tilde{d}_i^2\right\} + \lambda\sum_{i=1}^n \tilde{d}_i. \tag{33}$$

Since the objective (33) to be minimized w.r.t. $\tilde{D}$, is separable in $\tilde{d}_i, i = 1,\ldots,n$; it suffices to minimize it w.r.t. each $\tilde{d}_i$ separately.

The problem

$$\underset{\tilde{d}_i \geq 0}{\text{minimize}} \frac{1}{2}\left\{-2\tilde{d}_i\tilde{u}_i' W\tilde{v}_i + \tilde{d}_i^2\right\} + \lambda\tilde{d}_i \tag{34}$$

can be solved looking at the stationary conditions of the function using its sub-gradient (Nesterov, 2003). The solution of the above problem is given by $S_\lambda(\tilde{u}_i' W\tilde{v}_i) = (\tilde{u}_i' W\tilde{v}_i - \lambda)_+$, the soft-thresholding of $\tilde{u}_i' W\tilde{v}_i$ (without loss of generality, we can take $\tilde{u}_i' W\tilde{v}_i$ to be non-negative). More generally the soft-thresholding operator (Friedman et al., 2007; Hastie et al., 2009) is given by $S_\lambda(x) = \text{sgn}(x)(|x| - \lambda)_+$. See Friedman et al. (2007) for more elaborate discussions on how the soft-thresholding operator arises in univariate penalized least-squares problems with the ℓ_1 penalization.

Plugging the values of optimal $\tilde{d}_i, i = 1,\ldots,n$; obtained from (34) in (33) we get

$$Q(\tilde{U},\tilde{V}) = \frac{1}{2}\left\{\|Z\|_F^2 - 2\sum_{i=1}^{n}(\tilde{u}_i' W\tilde{v}_i - \lambda)_+(\tilde{u}_i' W\tilde{v}_i - \lambda) + (\tilde{u}_i' X\tilde{v}_i - \lambda)_+^2\right\}. \tag{35}$$

Minimizing $Q(\tilde{U},\tilde{V})$ w.r.t. $(\tilde{U},\tilde{V})$ is equivalent to maximizing

$$\sum_{i=1}^{n}\left\{2(\tilde{u}_i' W\tilde{v}_i - \lambda)_+(\tilde{u}_i' W\tilde{v}_i - \lambda) - (\tilde{u}_i' W\tilde{v}_i - \lambda)_+^2\right\} = \sum_{\tilde{u}_i' W\tilde{v}_i > \lambda}(\tilde{u}_i' W\tilde{v}_i - \lambda)^2. \tag{36}$$

It is a standard fact that for every i the problem

$$\underset{\|u\|_2^2 \leq 1, \|v\|_2^2 \leq 1}{\text{maximize}} \; u' W v; \;\; \text{such that } \; u \perp \{\hat{u}_1,\ldots,\hat{u}_{i-1}\},\; v \perp \{\hat{v}_1,\ldots,\hat{v}_{i-1}\}$$

is solved by $\hat{u}_i, \hat{v}_i$, the left and right singular vectors of the matrix W corresponding to its i^{th} largest singular value. The maximum value equals the singular value. It is easy to see that maximizing the expression to the right of (36) wrt $(u_i, v_i), i = 1,\ldots,n$ is equivalent to maximizing the individual terms $\tilde{u}_i' W\tilde{v}_i$. If $r(\lambda)$ denotes the number of singular values of W larger than λ then the $(\tilde{u}_i, \tilde{v}_i), i = 1,\ldots$ that maximize the expression (36) correspond to $\left[u_1,\ldots,u_{r(\lambda)}\right]$ and $\left[v_1,\ldots,v_{r(\lambda)}\right]$; the $r(\lambda)$ left and right singular vectors of W corresponding to the largest singular values. From (34) the optimal $\tilde{D} = \text{diag}\left[\tilde{d}_1,\ldots,\tilde{d}_n\right]$ is given by $D_\lambda = \text{diag}\left[(d_1 - \lambda)_+,\ldots,(d_n - \lambda)_+\right]$.

Since the rank of W is r, the minimizer $\hat{Z}$ of (8) is given by $UD_\lambda V'$ as in (9). ■

Remark 1 *For a more general spectral regularization of the form $\lambda\sum_i \mathbf{p}(\gamma_i(Z))$ (as compared to $\sum_i \lambda\gamma_i(Z)$ used above) the optimization problem (34) will be modified accordingly. The solution of the resultant univariate minimization problem will be given by $S_\lambda^{\mathbf{p}}(\tilde{u}_i' W\tilde{v}_i)$ for some generalized "thresholding operator" $S_\lambda^{\mathbf{p}}(\cdot)$, where*

$$S_\lambda^{\mathbf{p}}(\tilde{u}_i' W\tilde{v}_i) = \underset{\tilde{d}_i \geq 0}{\arg\min}\frac{1}{2}\left\{-2\tilde{d}_i\tilde{u}_i' W\tilde{v}_i + \tilde{d}_i^2\right\} + \lambda\mathbf{p}(\tilde{d}_i).$$

The optimization problem analogous to (35) will be

$$\underset{\tilde{U},\tilde{V}}{\text{minimize}} \;\; \frac{1}{2}\left\{\|Z\|_F^2 - 2\sum_{i=1}^{n}\hat{d}_i\tilde{u}_i' W\tilde{v}_i + \sum_{i=1}^{n}\hat{d}_i^2\right\} + \lambda\sum_i \mathbf{p}(\hat{d}_i), \tag{37}$$

where $\hat{d}_i = S^{\mathbf{p}}_{\lambda}(\tilde{u}_i' W \tilde{v}_i), \forall i$. Any spectral function for which the above (37) is monotonically increasing in $\tilde{u}_i' W \tilde{v}_i$ for every i can be solved by a similar argument as given in the above proof. The solution will correspond to the first few largest left and right singular vectors of the matrix W. The optimal singular values will correspond to the relevant shrinkage/ threshold operator $S^{\mathbf{p}}_{\lambda}(\cdot)$ operated on the singular values of W. In particular for the indicator function $\mathbf{p}(t) = \lambda \mathbf{1}(t \neq 0)$, the top few singular values (un-shrunk) and the corresponding singular vectors is the solution.

A.2 Proof of Lemma 3

This proof is based on sub-gradient characterizations and is inspired by some techniques used in Cai et al. (2008).

Proof From Lemma 1, we know that if $\hat{Z}$ solves the problem (8), then it satisfies the sub-gradient stationary conditions:

$$0 \in -(W - \hat{Z}) + \lambda \partial \|\hat{Z}\|_*. \tag{38}$$

$\mathbf{S}_\lambda(W_1)$ and $\mathbf{S}_\lambda(W_2)$ solve the problem (8) with $W = W_1$ and $W = W_2$ respectively, hence (38) holds with $W = W_1, \hat{Z}_1 = \mathbf{S}_\lambda(W_1)$ and $W = W_2, \hat{Z}_2 = \mathbf{S}_\lambda(W_1)$.

The sub-gradients of the nuclear norm $\|Z\|_*$ are given by

$$\partial \|Z\|_* = \{UV' + \omega : \omega_{m \times n},\ U'\omega = 0,\ \omega V = 0,\ \|\omega\|_2 \leq 1\}, \tag{39}$$

where $Z = UDV'$ is the SVD of Z.

Let $p(\hat{Z}_i)$ denote an element in $\partial \|\hat{Z}_i\|_*$. Then

$$\hat{Z}_i - W_i + \lambda p(\hat{Z}_i) = 0,\ i = 1,2.$$

The above gives

$$(\hat{Z}_1 - \hat{Z}_2) - (W_1 - W_2) + \lambda(p(\hat{Z}_1) - p(\hat{Z}_2)) = 0, \tag{40}$$

from which we obtain

$$\langle \hat{Z}_1 - \hat{Z}_2, \hat{Z}_1 - \hat{Z}_2 \rangle - \langle W_1 - W_2, \hat{Z}_1 - \hat{Z}_2 \rangle + \lambda \langle p(\hat{Z}_1) - p(\hat{Z}_2), \hat{Z}_1 - \hat{Z}_2 \rangle = 0,$$

where $\langle a, b \rangle = \text{trace}(a'b)$.

Now observe that

$$\langle p(\hat{Z}_1) - p(\hat{Z}_2), \hat{Z}_1 - \hat{Z}_2 \rangle = \langle p(\hat{Z}_1), \hat{Z}_1 \rangle - \langle p(\hat{Z}_1), \hat{Z}_2 \rangle - \langle p(\hat{Z}_2), \hat{Z}_1 \rangle + \langle p(\hat{Z}_2), \hat{Z}_2 \rangle. \tag{41}$$

By the characterization of subgradients as in (39), we have

$$\langle p(\hat{Z}_i), \hat{Z}_i \rangle = \|\hat{Z}_i\|_* \text{ and } \|p(\hat{Z}_i)\|_2 \leq 1,\ i = 1,2.$$

This implies

$$|\langle p(\hat{Z}_i), \hat{Z}_j \rangle| \leq \|p(\hat{Z}_i)\|_2 \|\hat{Z}_j\|_* \leq \|\hat{Z}_j\|_* \text{ for } i \neq j \in \{1,2\}.$$

Using the above inequalities in (41) we obtain:

$$\begin{aligned} \langle p(\hat{Z}_1), \hat{Z}_1 \rangle + \langle p(\hat{Z}_2), \hat{Z}_2 \rangle &= \|\hat{Z}_1\|_* + \|\hat{Z}_2\|_* & (42) \\ -\langle p(\hat{Z}_1), \hat{Z}_2 \rangle - \langle p(\hat{Z}_2), \hat{Z}_1 \rangle &\geq -\|\hat{Z}_2\|_* - \|\hat{Z}_1\|_*. & (43) \end{aligned}$$

Using (42,43) we see that the r.h.s. of (41) is non-negative. Hence

$$\langle p(\hat{Z}_1) - p(\hat{Z}_2), \hat{Z}_1 - \hat{Z}_2 \rangle \geq 0.$$

Using the above in (40), we obtain:

$$\|\hat{Z}_1 - \hat{Z}_2\|_F^2 = \langle \hat{Z}_1 - \hat{Z}_2, \hat{Z}_1 - \hat{Z}_2 \rangle \leq \langle W_1 - W_2, \hat{Z}_1 - \hat{Z}_2 \rangle. \tag{44}$$

Using the Cauchy-Schwarz Inequality, $\|\hat{Z}_1 - \hat{Z}_2\|_F \|W_1 - W_2\|_F \geq \langle \hat{Z}_1 - \hat{Z}_2, W_1 - W_2 \rangle$ in (44) we get

$$\|\hat{Z}_1 - \hat{Z}_2\|_F^2 \leq \langle \hat{Z}_1 - \hat{Z}_2, W_1 - W_2 \rangle \leq \|\hat{Z}_1 - \hat{Z}_2\|_F \|W_1 - W_2\|_F$$

and in particular

$$\|\hat{Z}_1 - \hat{Z}_2\|_F^2 \leq \|\hat{Z}_1 - \hat{Z}_2\|_F \|W_1 - W_2\|_F.$$

The above further simplifies to

$$\|W_1 - W_2\|_F^2 \geq \|\hat{Z}_1 - \hat{Z}_2\|_F^2 = \|\mathbf{S}_\lambda(W_1) - \mathbf{S}_\lambda(W_2)\|_F^2.$$

■

A.3 Proof of Lemma 4

Proof We will first show (15) by observing the following inequalities:

$$\begin{aligned}
\|Z_\lambda^{k+1} - Z_\lambda^k\|_F^2 &= \|\mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^k)) - \mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^{k-1}))\|_F^2 \\
\text{(by Lemma 3)} \quad &\leq \| \left(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^k)\right) - \left(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^{k-1})\right) \|_F^2 \\
&= \|P_\Omega^\perp(Z_\lambda^k - Z_\lambda^{k-1})\|_F^2 \qquad (45) \\
&\leq \|Z_\lambda^k - Z_\lambda^{k-1}\|_F^2. \qquad (46)
\end{aligned}$$

The above implies that the sequence $\{\|Z_\lambda^k - Z_\lambda^{k-1}\|_F^2\}$ converges (since it is decreasing and bounded below). We still require to show that $\{\|Z_\lambda^k - Z_\lambda^{k-1}\|_F^2\}$ converges to zero.

The convergence of $\{\|Z_\lambda^k - Z_\lambda^{k-1}\|_F^2\}$ implies that:

$$\|Z_\lambda^{k+1} - Z_\lambda^k\|_F^2 - \|Z_\lambda^k - Z_\lambda^{k-1}\|_F^2 \to 0 \text{ as } k \to \infty.$$

The above observation along with the inequality in (45,46) gives

$$\|P_\Omega^\perp(Z_\lambda^k - Z_\lambda^{k-1})\|_F^2 - \|Z_\lambda^k - Z_\lambda^{k-1}\|_F^2 \to 0 \implies P_\Omega(Z_\lambda^k - Z_\lambda^{k-1}) \to 0, \tag{47}$$

as $k \to \infty$.

Lemma 2 shows that the non-negative sequence $f_\lambda(Z_\lambda^k)$ is decreasing in k. So as $k \to \infty$ the sequence $f_\lambda(Z_\lambda^k)$ converges.

Furthermore from (13,14) we have

$$Q_\lambda(Z_\lambda^{k+1}|Z_\lambda^k) - Q_\lambda(Z_\lambda^{k+1}|Z_\lambda^{k+1}) \to 0 \text{ as } k \to \infty,$$

which implies that

$$\|P_\Omega^\perp(Z_\lambda^k) - P_\Omega^\perp(Z_\lambda^{k+1})\|_F^2 \to 0 \text{ as } k \to \infty.$$

The above along with (47) gives

$$Z_\lambda^k - Z_\lambda^{k-1} \to 0 \text{ as } k \to \infty.$$

This completes the proof. ■

A.4 Proof of Lemma 5

Proof The sub-gradients of the nuclear norm $\|Z\|_*$ are given by

$$\partial\|Z\|_* = \{UV' + W : W_{m\times n},\ U'W = 0,\ WV = 0,\ \|W\|_2 \le 1\}, \tag{48}$$

where $Z = UDV'$ is the SVD of Z. Since Z_λ^k minimizes $Q_\lambda(Z|Z_\lambda^{k-1})$, it satisfies:

$$0 \in -(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^{k-1}) - Z_\lambda^k) + \partial\|Z_\lambda^k\|_* \ \ \forall k. \tag{49}$$

Suppose Z^* is a limit point of the sequence Z_λ^k. Then there exists a subsequence $\{n_k\} \subset \{1,2,\ldots\}$ such that $Z_\lambda^{n_k} \to Z^*$ as $k \to \infty$.

By Lemma 4 this subsequence $Z_\lambda^{n_k}$ satisfies

$$Z_\lambda^{n_k} - Z_\lambda^{n_k-1} \to 0$$

implying

$$P_\Omega^\perp(Z_\lambda^{n_k-1}) - Z_\lambda^{n_k} \longrightarrow P_\Omega^\perp(Z_\lambda^*) - Z_\lambda^* = -P_\Omega(Z^*).$$

Hence,

$$(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^{n_k-1}) - Z_\lambda^{n_k}) \longrightarrow (P_\Omega(X) - P_\Omega(Z_\lambda^*)). \tag{50}$$

For every k, a sub-gradient $p(Z_\lambda^k) \in \partial\|Z_\lambda^k\|_*$ corresponds to a tuple (u_k, v_k, w_k) satisfying the properties of the set $\partial\|Z_\lambda^k\|_*$ (48).

Consider $p(Z_\lambda^{n_k})$ along the sub-sequence n_k. As $n_k \longrightarrow \infty$, $Z_\lambda^{n_k} \longrightarrow Z_\lambda^*$.

Let

$$Z_\lambda^{n_k} = u_{n_k} D_{n_k} v_{n_k}',\ \ Z^* = u_\infty D^* v_\infty'$$

denote the SVD's. The product of the singular vectors converge $u_{n_k}' v_{n_k} \to u_\infty' v_\infty$. Furthermore due to boundedness (passing on to a further subsequence if necessary) $w_{n_k} \to w_\infty$. The limit $u_\infty v_\infty' + w_\infty$ clearly satisfies the criterion of being a sub-gradient of Z^*. Hence this limit corresponds to $p(Z_\lambda^*) \in \partial\|Z_\lambda^*\|_*$.

Furthermore from (49, 50), passing on to the limits along the subsequence n_k, we have

$$\mathbf{0} \in -(P_\Omega(X) - P_\Omega(Z_\lambda^*)) + \partial\|Z_\lambda^*\|_*.$$

Hence the limit point Z_λ^* is a stationary point of $f_\lambda(Z)$.

We shall now prove (16). We know that for every n_k

$$Z_\lambda^{n_k} = \mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^{n_k-1})). \tag{51}$$

From Lemma 4, we know $Z_\lambda^{n_k} - Z_\lambda^{n_k-1} \to 0$. This observation along with the continuity of $\mathbf{S}_\lambda(\cdot)$ gives

$$\mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^{n_k-1})) \to \mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^*)).$$

Thus passing over to the limits on both sides of (51) we get

$$Z_\lambda^* = \mathbf{S}_\lambda(P_\Omega(X) + P_\Omega^\perp(Z_\lambda^*)),$$

therefore completing the proof. ■

A.5 Proof of Lemma 6

The proof is motivated by the principle of embedding an arbitrary matrix into a positive semidefinite matrix (Fazel, 2002). We require the following proposition, which we prove using techniques used in the same reference.

Proposition 1 *Suppose matrices $W_{m\times m}, \tilde{W}_{n\times n}, Z_{m\times n}$ satisfy the following:*

$$\begin{pmatrix} W & Z \\ Z^T & \tilde{W} \end{pmatrix} \succeq 0.$$

Then $\text{trace}(W) + \text{trace}(\tilde{W}) \geq 2\|Z\|_*$.

Proof Let $Z_{m\times n} = L_{m\times r}\Sigma_{r\times r}R_{n\times r}^T$ denote the SVD of Z, where r is the rank of the matrix Z. Observe that the trace of the product of two positive semidefinite matrices is always non-negative. Hence we have the following inequality:

$$\text{trace}\begin{pmatrix} LL^T & -LR^T \\ -RL^T & RR^T \end{pmatrix}\begin{pmatrix} W & Z \\ Z^T & \tilde{W} \end{pmatrix} \succeq 0.$$

Simplifying the above expression we get:

$$\text{trace}(LL^TW) - \text{trace}(LR^TZ^T) - \text{trace}(RL^TZ) + \text{trace}(RR^T\tilde{W}) \geq 0. \tag{52}$$

Due to the orthogonality of the columns of L, R we have the following inequalities:

$$\text{trace}(LL^TW) \leq \text{trace}(W) \text{ and } \text{trace}(RR^T\tilde{W}) \leq \text{trace}(\tilde{W}).$$

Furthermore, using the SVD of Z:

$$\text{trace}(LR^TZ^T) = \text{trace}(\Sigma) = \text{trace}(LR^TZ^T).$$

Using the above in (52), we have:

$$\text{trace}(W) + \text{trace}(\tilde{W}) \geq 2\,\text{trace}(\Sigma) = 2\,\|Z\|_*.$$

■

Proof [Proof of Lemma 6.] For the matrix Z, consider any decomposition of the form $Z = \tilde{U}_{m\times r}\tilde{V}^T_{n\times r}$ and construct the following matrix

$$\begin{pmatrix} \tilde{U}\tilde{U}^T & Z \\ Z^T & \tilde{V}\tilde{V}^T \end{pmatrix} = \begin{pmatrix} \tilde{U} \\ \tilde{V} \end{pmatrix} (\tilde{U}^T\tilde{V}^T), \tag{53}$$

which is positive semidefinite. Applying Proposition 1 to the left hand matrix in (53), we have:

$$\text{trace}(\tilde{U}\tilde{U}^T) + \text{trace}(\tilde{V}\tilde{V}^T) \geq 2\,\|Z\|_*.$$

Minimizing both sides above w.r.t. the decompositions $Z = \tilde{U}_{m\times r}\tilde{V}^T_{n\times r}$; we have

$$\min_{\tilde{U},\tilde{V};\, Z=\tilde{U}\tilde{V}^T} \left\{\text{trace}(\tilde{U}\tilde{U}^T) + \text{trace}(\tilde{V}\tilde{V}^T)\right\} \geq 2\,\|Z\|_*. \tag{54}$$

Through the SVD of Z we now show that equality is attained in (54). Suppose Z is of rank $k \leq \min(m,n)$, and denote its SVD by $Z_{m\times n} = L_{m\times k}\Sigma_{k\times k}R^T_{n\times k}$. Then for $\tilde{U} = L_{m\times k}\Sigma^{\frac{1}{2}}_{k\times k}$ and $\tilde{V} = R_{n\times k}\Sigma^{\frac{1}{2}}_{k\times k}$ the equality in (54) is attained.

Hence, we have:

$$\begin{aligned} \|Z\|_* &= \min_{\tilde{U},\tilde{V};Z=\tilde{U}\tilde{V}^T} \left\{\text{trace}(\tilde{U}\tilde{U}^T) + \text{trace}(\tilde{V}\tilde{V}^T)\right\} \\ &= \min_{\tilde{U},\tilde{V};Z=\tilde{U}_{m\times k}\tilde{V}^T_{n\times k}} \left\{\text{trace}(\tilde{U}\tilde{U}^T) + \text{trace}(\tilde{V}\tilde{V}^T)\right\}. \end{aligned}$$

Note that the minimum can also be attained for matrices with $r \geq k$ or even $r \geq \min(m,n)$; however, it suffices to consider matrices with $r = k$. Also it is easily seen that the minimum cannot be attained for any $r < k$; hence the minimal rank r for which (29) holds true is $r = k$. ■

A.6 Proof of Theorem 2

There is a close resemblance between SOFT-IMPUTE and Nesterov's gradient method (Nesterov, 2007, Section 3). However, as mentioned earlier the original motivation of our algorithm is very different.

The techniques used in this proof are adapted from Nesterov (2007).

Proof Plugging $Z^k_\lambda = \tilde{Z}$ in (11), we have

$$\begin{aligned} Q_\lambda(Z|Z^k_\lambda) &= f_\lambda(Z^k_\lambda) + \frac{1}{2}\|P^\perp_\Omega(Z^k_\lambda - Z)\|^2_F \\ &\geq f_\lambda(Z^k_\lambda). \end{aligned} \tag{55}$$

Let $Z^k_\lambda(\theta)$ denote a convex combination of the optimal solution (Z^∞_λ) and the k^{th} iterate (Z^k_λ):

$$Z^k_\lambda(\theta) = \theta Z^\infty_\lambda + (1-\theta)Z^k_\lambda. \tag{56}$$

Using the convexity of $f_\lambda(\cdot)$ we get:

$$f_\lambda(Z_\lambda^k(\theta)) \leq (1-\theta) f_\lambda(Z_\lambda^k) + \theta f_\lambda(Z_\lambda^\infty). \tag{57}$$

Expanding $Z_\lambda^k(\theta)$ using (56), and simplifying $P_\Omega^\perp(Z_\lambda^k - Z_\lambda^k(\theta))$ we have:

$$\begin{aligned} \|P_\Omega^\perp(Z_\lambda^k - Z_\lambda^k(\theta))\|_F^2 &= \theta^2 \|P_\Omega^\perp(Z_\lambda^k - Z_\lambda^\infty)\|_F^2 \\ &\leq \theta^2 \|Z_\lambda^k - Z_\lambda^\infty\|_F^2 \qquad (58) \\ &\leq \theta^2 \|Z_\lambda^0 - Z_\lambda^\infty\|_F^2. \qquad (59) \end{aligned}$$

Line 59 follows from (58) by observing that $\|Z_\lambda^m - Z_\lambda^\infty\|_F^2 \leq \|Z_\lambda^{m-1} - Z_\lambda^\infty\|_F^2$, $\forall m$—a consequence of the inequalities (19) and (18), established in Theorem 1.

Using (55), the value of $f_\lambda(Z)$ at the $(k+1)^{\text{th}}$ iterate satisfies the following chain of inequalities:

$$\begin{aligned} f_\lambda(Z_\lambda^{k+1}) &\leq \min_Z \left\{ f_\lambda(Z) + \frac{1}{2}\|P_\Omega^\perp(Z_\lambda^k - Z)\|_F^2 \right\} \\ &\leq \min_{\theta\in[0,1]} \left\{ f_\lambda(Z_\lambda^k(\theta)) + \frac{1}{2}\|P_\Omega^\perp(Z_\lambda^k - Z_\lambda^k(\theta))\|_F^2 \right\} \qquad (60) \\ &\leq \min_{\theta\in[0,1]} \left\{ f_\lambda(Z_\lambda^k) + \theta(f_\lambda(Z_\lambda^\infty) - f_\lambda(Z_\lambda^k)) + \frac{1}{2}\theta^2 \|Z_\lambda^0 - Z_\lambda^\infty\|_F^2 \right\}. \qquad (61) \end{aligned}$$

Line 61 follows from Line 60, by using (57) and (59).

The r.h.s. expression in (61), is minimized at $\widehat{\theta}(k+1)$ given by

$$\begin{aligned} \widehat{\theta}(k+1) &= \min\{1, \theta_k\} \in [0,1], \text{ where,} \\ \theta_k &= \frac{f_\lambda(Z_\lambda^k) - f_\lambda(Z_\lambda^\infty)}{\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2}. \end{aligned}$$

If $\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2 = 0$, then we take $\theta_k = \infty$.

Note that θ_k is a decreasing sequence. This implies that if $\theta_{k_0} \leq 1$ then $\theta_m \leq 1$ for all $m \geq k_0$.

Suppose, $\theta_0 > 1$. Then $\widehat{\theta}(1) = 1$. Hence using (61) we have:

$$f_\lambda(Z_\lambda^1) - f_\lambda(Z_\lambda^\infty) \leq \frac{1}{2}\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2 \implies \theta_1 \leq \frac{1}{2}.$$

Thus we get back to the former case.

Hence $\theta_k \leq 1$ for all $k \geq 1$.

In addition, observe the previous deductions show that, if $\theta_0 > 1$ then (20) holds true for $k = 1$.

Combining the above observations, plugging in the value of $\widehat{\theta}$ in (61) and simplifying, we get:

$$f_\lambda(Z_\lambda^{k+1}) - f_\lambda(Z_\lambda^k) \leq -\frac{(f_\lambda(Z_\lambda^k) - f_\lambda(Z_\lambda^\infty))^2}{2\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2}. \tag{62}$$

For the sake of notational convenience, we define the sequence $\alpha_k = f_\lambda(Z_\lambda^k) - f_\lambda(Z_\lambda^\infty)$. It is easily seen that α_k is a non-negative decreasing sequence.

Using this notation in (62) we get:

$$\begin{aligned} \alpha_k &\geq \frac{\alpha_k^2}{2\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2} + \alpha_{k+1} \\ (\text{Since } \alpha_k \downarrow) &\geq \frac{\alpha_k \alpha_{k+1}}{2\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2} + \alpha_{k+1}. \end{aligned} \tag{63}$$

Dividing both sides of the inequality in (63), by $\alpha_k \alpha_{k+1}$ we have:

$$\alpha_{k+1}^{-1} \geq \frac{1}{2\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2} + \alpha_k^{-1}. \tag{64}$$

Summing both sides of (64) over $1 \leq k \leq (k-1)$ we get:

$$\alpha_k^{-1} \geq \frac{k-1}{2\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2} + \alpha_1^{-1}. \tag{65}$$

Since $\theta_1 \leq 1$, we observe $\alpha_1/(2\|Z_\lambda^0 - Z_\lambda^\infty\|_F^2) \leq 1/2$—using this in (65) and rearranging terms we get, the desired inequality (20)—completing the proof of the Theorem. ■

Abstract

We introduce a simple order-based greedy heuristic for learning discriminative structure within generative Bayesian network classifiers. We propose two methods for establishing an order of N features. They are based on the conditional mutual information and classification rate (i.e., risk), respectively. Given an ordering, we can find a discriminative structure with $O\left(N^{k+1}\right)$ score evaluations (where constant k is the tree-width of the sub-graph over the attributes). We present results on 25 data sets from the UCI repository, for phonetic classification using the TIMIT database, for a visual surface inspection task, and for two handwritten digit recognition tasks. We provide classification performance for *both* discriminative *and* generative parameter learning on *both* discriminatively *and* generatively structured networks. The discriminative structure found by our new procedures significantly outperforms generatively produced structures, and achieves a classification accuracy on par with the best discriminative (greedy) Bayesian network learning approach, but does so with a factor of $\sim$10-40 speedup. We also show that the advantages of generative discriminatively structured Bayesian network classifiers still hold in the case of missing features, a case where generative classifiers have an advantage over discriminative classifiers.

Keywords: Bayesian networks, classification, discriminative learning, structure learning, graphical model, missing feature

1. Introduction

Bayesian networks (Pearl, 1988; Cowell et al., 1999) have been widely used as a space within which to search for high performing statistical pattern classifiers. Such networks can be produced in a number of ways, and ideally the structure of such networks will be learned discriminatively. By "discriminative learning" of Bayesian network structure, we mean simply that the process of learning corresponds to optimizing an objective function that is highly representative of classification error, such as maximizing class conditional likelihood, or minimizing classification error under the 0/1-loss function or some smooth convex upper-bound surrogate (Bartlett et al., 2006).

Unfortunately, learning the structure of Bayesian networks is hard. There have been a number of negative results over the past years, showing that optimally learning various forms of constrained Bayesian networks is NP-complete even in the "generative" sense. For example, it has been shown

that learning paths (Meek, 1995), polytrees (Dasgupta, 1997), k-trees (Arnborg et al., 1987) or bounded tree-width graphs (Karger and Srebro, 2001; Srebro, 2003), and general Bayesian networks (Geiger and Heckerman, 1996) are all instances of NP-complete optimization problems. Learning the best "discriminative structure" is no less difficult, largely because the cost functions that are needed to be optimized do not in general decompose (Lauritzen, 1996), but there has as of yet not been any formal hardness results in the discriminative case.

Discriminative optimization of a Bayesian network structure for the purposes of classification does have its advantages, however. For example, the resulting networks are amenable to interpretation compared to a purely discriminative model (the structure specifies conditional independencies between variables that may indicate distinctive aspects of how best to discern between objects Bilmes et al., 2001), it is simple to work with missing features and latent variables (as we show in this paper), and to incorporate prior knowledge (see below for further details). Since discriminative learning of such networks optimizes for only one inference scenario (e.g., classification) the resulting networks might be simpler or more parsimonious than generatively derived networks, may better abide Occam's razor, and may restore some of the benefits mentioned in Vapnik (1998).

Many heuristic methods have been produced in the past to learn the structure of Bayesian network classifiers. For example, Friedman et al. (1997) introduced the tree-augmented naive (TAN) Bayes approach, where a naive Bayes (NB) classifier is augmented with edges according to various conditional mutual information criteria. Bilmes (1999, 2000) introduced the *explaining away residual* (EAR) for discriminative structure learning of dynamic Bayesian networks for speech recognition applications, which also happens to correspond to "synergy" in the neural code (Brenner et al., 2000). The EAR measure is in fact an approximation to the expected class conditional distribution, and so improving EAR is likely to decrease the KL-divergence between the true class posterior and the resultant approximate class posterior. A procedure for providing a local optimum of the EAR measure was outlined in Narasimhan and Bilmes (2005) but it may be computationally expensive. Greiner and Zhou (2002); Greiner et al. (2005) express general Bayesian networks as standard logistic regression—they optimize parameters with respect to the conditional likelihood (CL) using a conjugate gradient method. Similarly, Roos et al. (2005) provide conditions for general Bayesian networks under which the correspondence to logistic regression holds. In Grossman and Domingos (2004) the conditional log likelihood (CLL) function is used to learn a discriminative structure. The parameters are set using maximum likelihood (ML) learning. They use a greedy hill climbing search with the CLL function as a scoring measure, where at each iteration one edge is added to the structure which conforms with the restrictions of the network topology (e.g., TAN) and the acyclicity property of Bayesian networks. In a similar algorithm, the classification rate (CR)[1] has also been used for discriminative structure learning (Keogh and Pazzani, 1999; Pernkopf, 2005). The hill climbing search is terminated when there is no edge which further improves the CR. The CR is the discriminative criterion with the fewest approximations, so it is expected to perform well given sufficient data. The problem, however, is that this approach is extremely computationally expensive, as a complete re-evaluation of the training set is needed for each considered edge. Many generative structure learning algorithms have been proposed and are reviewed in Heckerman (1995), Murphy (2002), Jordan (1999) and Cooper and Herskovits (1992). Independence tests may also be used for generative structure learning using, say, mutual information (de Campos, 2006) while other recent

1. Maximizing CR is equivalent to minimizing classification error which is identical to empirical risk (Vapnik, 1998) under the 0/1-loss function. We use the CR terminology in this paper since it is somewhat more consistent with previous Bayesian network discriminative structure learning literature.

independence test work includes Gretton and Gÿorfi (2008) and Zhang et al. (2009). An experimental comparison of discriminative and generative parameter training on both discriminatively and generatively structured Bayesian network classifiers has been performed in Pernkopf and Bilmes (2005). An empirical and theoretical comparison of certain discriminative and generative classifiers (specifically logistic regression and NB) is given in Ng and Jordan (2002). It is shown that for small sample sizes the generative NB classifier can outperform the discriminative model.

This work contains the following offerings. First, a new case is made for why and when discriminatively structured generative models can be usefully used to solve multi-class classification problems.

Second, we introduce a new order-based greedy search heuristic for finding discriminative structures in generative Bayesian network classifiers that is computationally efficient and that matches the performance of the currently top-performing but computationally expensive greedy "classification rate" approach. Our resulting classifiers are restricted to TAN 1-tree and TAN 2-trees, and so our method is a form of search within a complexity-constrained model space. The approach we employ looks first for an ordering of the N features according to classification based information measures. Given the resulting ordering, the algorithm efficiently discovers high-performing discriminative network structure with no more than $O\left(N^{k+1}\right)$ score evaluations where k indicates the tree-width of the sub-graph over the attributes, and where a score evaluation can either be a mutual-information or a classification error-rate query. Our order-based structure learning is based on the observations in Buntine (1991) and the framework is similar to the K2 algorithm proposed in Cooper and Herskovits (1992). We use, however, a discriminative scoring metric and suggest approaches for establishing the variable ordering based on conditional mutual information (CMI) (Cover and Thomas, 1991) and CR.

Lastly, we provide a wide variety of empirical results on a diverse collection of data sets showing that the order-based heuristic provides comparable classification results to the best procedure - the greedy heuristic using the CR score, but our approach is computationally much cheaper. Furthermore, we empirically show that the chosen approaches for ordering the variables improve the classification performance compared to simple random orderings. We experimentally compare both discriminative and generative parameter training on *both* discriminative *and* generatively structured Bayesian network classifiers. Moreover, one of the key advantages of generative models over discriminative ones is that it is still possible to marginalize away any missing features. If it is not known at training time which features might be missing, a typical discriminative model is rendered unusable. We provide empirical results showing that discriminatively learned generative models are reasonably insensitive to such missing features and retain their advantages over generative models in such case.

The organization of the paper is as follows: In Section 2, Bayesian networks are reviewed and our notation is introduced. We briefly present the NB, TAN, and 2-tree network structures. In Section 3, a practical case is made for why discriminative structure can be desirable. The most commonly used approaches for generative and discriminative structure and parameter learning are summarized in Section 4. Section 5 introduces our order-based greedy heuristic. In Section 6, we report classification results on 25 data sets from the UCI repository (Merz et al., 1997) and from Kohavi and John (1997) using all combinations of generative/discriminative structure/parameter learning. Additionally, we present classification experiments for synthetic data, for frame- and segment-based phonetic classification using the TIMIT speech corpus (Lamel et al., 1986), for a visual surface inspection task (Pernkopf, 2004), and for handwritten digit recognition using the MNIST (LeCun

et al., 1998) and USPS data set. Last, Section 7 concludes. We note that a preliminary version of a subset of our results appeared in Pernkopf and Bilmes (2008b).

2. Bayesian Network Classifiers

A Bayesian network (BN) (Pearl, 1988; Cowell et al., 1999) $\mathcal{B} = \langle \mathcal{G}, \Theta \rangle$ is a directed acyclic graph $\mathcal{G} = (\mathbf{Z}, \mathbf{E})$ consisting of a set of nodes $\mathbf{Z}$ and a set of directed edges $\mathbf{E} = \{E_{Z_i,Z_j}, E_{Z_i,Z_k}, \ldots\}$ connecting the nodes where E_{Z_i,Z_j} is an edge directed from Z_i to Z_j. This graph represents factorization properties of the distribution of a set of random variables $\mathbf{Z} = \{Z_1, \ldots, Z_{N+1}\}$. Each variable in $\mathbf{Z}$ has values denoted by lower case letters $\{z_1, z_2, \ldots, z_{N+1}\}$. We use boldface capital letters, for example, $\mathbf{Z}$, to denote a set of random variables and correspondingly boldface lower case letters denote a set of instantiations (values). Without loss of generality, in Bayesian network classifiers the random variable Z_1 represents the class variable $C \in \{1, \ldots, |C|\}$, $|C|$ is the cardinality of C or equivalently the number of classes, $\mathbf{X}_{1:N} = \{X_1, \ldots, X_N\} = \{Z_2, \ldots, Z_{N+1}\}$ denote the set of random variables of the N attributes of the classifier. Each graph node represents a random variable, while the lack of edges in a graph specifies some conditional independence relationships. Specifically, in a Bayesian network each node is independent of its non-descendants given its parents (Lauritzen, 1996). A Bayesian network's conditional independence relationships arise due to missing parents in the graph. Moreover, conditional independence can reduce computation for exact inference on such a graph. The set of parameters which quantify the network are represented by Θ. Each node Z_j is represented as a local conditional probability distribution given its parents Z_{Π_j}. We use $\theta^j_{i|h}$ to denote a specific conditional probability table entry (assuming discrete variables), the probability that variable Z_j takes on its i^{th} value assignment given that its parents Z_{Π_j} take their h^{th} (lexicographically ordered) assignment, that is, $\theta^j_{i|h} = P_\Theta\left(Z_j = i | Z_{\Pi_j} = h\right)$. Hence, h contains the parent configuration assuming that the first element of h, that is, h_1, relates to the conditioning class and the remaining elements $h \backslash h_1$ denote the conditioning on parent attribute values. The training data consists of M independent and identically distributed samples $\mathcal{S} = \{\mathbf{z}^m\}_{m=1}^M = \left\{\left(c^m, \mathbf{x}^m_{1:N}\right)\right\}_{m=1}^M$. For most of this work, we assume a complete data set with no missing values (the exception being Section 6.6 where input features are missing at test time). The joint probability distribution of the network is determined by the local conditional probability distributions as

$$P_\Theta(\mathbf{Z}) = \prod_{j=1}^{N+1} P_\Theta\left(Z_j | Z_{\Pi_j}\right)$$

and the probability of a sample $\mathbf{z}^m$ is

$$P_\Theta(\mathbf{Z} = \mathbf{z}^m) = \prod_{j=1}^{N+1} \prod_{i=1}^{|Z_j|} \prod_h \left(\theta^j_{i|h}\right)^{u^{j,m}_{i|h}},$$

where we introduced an indicator function $u^{j,m}_{i|h}$ of the m^{th} sample

$$u^{j,m}_{i|h} = \begin{cases} 1, & \text{if } z^m_j = i \text{ and } z^m_{\Pi_j} = h \\ 0, & \text{otherwise} \end{cases}.$$

In this paper, we restrict our experiments to NB, TAN 1-tree (Friedman et al., 1997), and TAN 2-tree classifier structures (defined in the next several paragraphs). The NB network assumes that

all the attributes are conditionally independent given the class label. This means that, given C, any subset of $\mathbf{X}$ is independent of any other disjoint subset of $\mathbf{X}$. As reported in the literature (Friedman et al., 1997; Domingos and Pazzani, 1997), the performance of the NB classifier is surprisingly good even if the conditional independence assumption between attributes is unrealistic or even false in most of the data. Reasons for the utility of the NB classifier range between benefits from the bias/variance tradeoff perspective (Friedman et al., 1997) to structures that are inherently poor from a generative perspective but good from a discriminative perspective (Bilmes, 2000). The structure of the naive Bayes classifier represented as a Bayesian network is illustrated in Figure 1a.

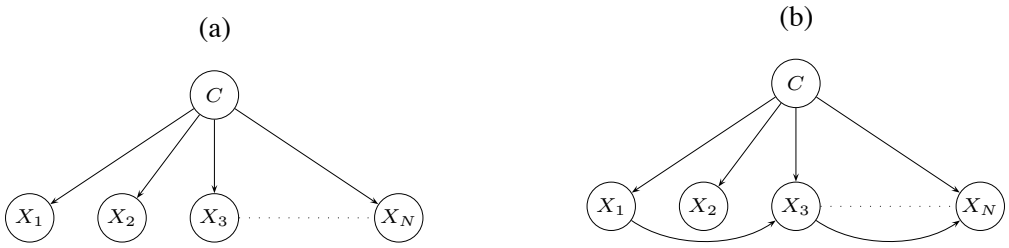

Figure 1: Bayesian Network: (a) NB, (b) TAN.

In order to correct some of the limitations of the NB classifier, Friedman et al. (1997) introduced the TAN classifier. A TAN is based on structural augmentations of the NB network, where additional edges are added between attributes in order to relax some of the most flagrant conditional independence properties of NB. Each attribute may have at most one other attribute as an additional parent which means that the tree-width of the attribute induced sub-graph is unity, that is, we have to learn a 1-tree over the attributes. The maximum number of edges added to relax the independence assumption between the attributes is $N-1$. Thus, two attributes might not be conditionally independent given the class label in a TAN. An example of a TAN 1-tree network is shown in Figure 1b. A TAN network is typically initialized as a NB network and additional edges between attributes are determined through structure learning. An extension of the TAN network is to use a k-tree, that is, each attribute can have a maximum of k attribute nodes as parents. In this work, TAN and k-tree structures are restricted such that the class node remains parent-less, that is, $C_\Pi = \emptyset$. While many other network topologies have been suggested in the past (and a good overview is provided in Acid et al., 2005), in this work we keep the class variable parent-less since it allows us to achieve one of our goals, which is to concentrating on generative models and their structures.

3. Discriminative Learning in Generative Models

A dichotomy exists between the two primary approaches to statistical pattern classifiers, *generative* and *discriminative* (Bishop and Lasserre, 2007; Jebara, 2001; Ng and Jordan, 2002; Bishop, 2006; Raina et al., 2004; Juang et al., 1997; Juang and Katagiri, 1992; Bahl et al., 1986). Under generative models, what is learned is a model of the joint probability of the features $\mathbf{X}$ and the corresponding class random variables C. Complexity penalized likelihood of the data is often the objective used for optimization, leading to standard maximum likelihood (ML) learning. Prediction with such a model is then performed either by using Bayes rule to form the class posterior probability or equivalently by forming class-prior penalized likelihood. Generative models have been widely studied, and are

desirable because they are amenable to interpretation (e.g., the structure of a generative Bayesian network specifies conditional independencies between variables that might have a useful high-level explanation). Additionally, they are amenable to a variety of probabilistic inference scenarios owing to the fact that they often decompose (Lauritzen, 1996)—the decomposition (or factorization) properties of a model are often crucial to their efficient computation.

Discriminative approaches, on the other hand, more directly represent aspects of the distribution that are important for classification accuracy, and there are a number of ways this can be done. For example, some approaches model only the class posterior probability (the conditional probability of the class given the features) or $p(C|\mathbf{X})$. Other approaches, such as support vector machines (SVMs) (Schölkopf and Smola, 2001; Burges, 1998) or neural networks (Bishop, 2006, 1995), directly model information about decision boundary sometimes without needing to concentrate on obtaining an accurate conditional distribution (neural networks, however, are also used to produce conditional distributions above and beyond just getting the class ranks correct Bishop, 1995). In each case, the objective function that is optimized is one whose minima occur not necessarily when the joint distribution $p(C,\mathbf{X})$ is accurate, but rather when the classification error rate on a training set is small. Discriminative models are usually restricted to one particular inference scenario, that is, the mapping from observed input features $\mathbf{X}$ to the unknown class output variable C, and not the other way around.

There are several reasons for using discriminative rather than generative classifiers, one of which is that the classification problem should be solved most simply and directly, and never via a more general problem such as the intermediate step of estimating the joint distribution (Vapnik, 1998). The superior performance of discriminative classifiers has been reported in many application domains (Ng and Jordan, 2002; Raina et al., 2004; Juang et al., 1997; Juang and Katagiri, 1992; Bahl et al., 1986).

Why then should we have an interest in generative models for discrimination? We address this question in the next several paragraphs. The distinction between generative and discriminative models becomes somewhat blurred when one considers that there are both generative and discriminative methods to learn a generative model, and within a generative model one may make a distinction between learning model structure and learning its parameters. In fact, in this paper, we make a clear distinction between learning the parameters of a generative model and learning the structure of a generative model. When using Bayesian networks to describe factorization properties of generative models, the structure of the model corresponds to the graph: fixing the graph, the parameters of the model are such that they must respect the factorization properties expressed by that graph. The structure of the model, however, can be independently learned, and different structures correspond to different families of graph (each family is spanned by the parameters respecting a particular structure). A given structure is then evaluated under a particular "best" set of parameter values, one possibility being the maximum likelihood settings. Of course, one could consider optimizing both parameters and structure simultaneously. Indeed, both structure and parameters are "parameters" of the model, and it is possible to learn the structure along with the parameters when a complexity penalty is applied that encourages sparse solutions, such as ℓ_1-regularization (Tibshirani, 1996) in linear regression and other models. We, however, find it useful to maintain this distinction between structure and parameters for the reason that parameter learning is inherently a continuous optimization procedure, while structure learning is inherently a combinatorial optimization problem. In our case, moreover, it is possible to stay within a given fixed-complexity model family—if we wish to stay within the family of say k-trees for fixed k, ℓ_1 regularization is not guaranteed to oblige.

Moreover, both parameters and structure of a generative model can be learned either generatively or discriminatively. Discriminative parameter learning of generative models, such as hidden Markov models (HMMs) has occurred for many years in the speech recognition community (Bahl et al., 1986; Ephraim et al., 1989; Ephraim and Rabiner, 1990; Juang and Katagiri, 1992; Juang et al., 1997; Heigold et al., 2008), and more recently in the machine learning community (Greiner and Zhou, 2002; Greiner et al., 2005; Roos et al., 2005; Ng and Jordan, 2002; Bishop and Lasserre, 2007; Pernkopf and Wohlmayr, 2009). Discriminative structure learning has also more recently received some attention (Bilmes, 1999, 2000; Pernkopf and Bilmes, 2005; Keogh and Pazzani, 1999; Grossman and Domingos, 2004). In fact, there are four possible cases of learning a generative model as depicted in Figure 2. Case A is when both structure and parameter learning is generative. Case B is when the structure is learned generatively, but the parameters are learned discriminatively. Case C is the mirror image of case B. Case D, potentially the most preferable case for classification, is where both the structure and parameters are discriminatively learned.

		Parameter Learning	
		Generative	Discriminative
Structure Learning	Generative	Case A	Case B
	Discriminative	Case C	Case D

Figure 2: Learning generative-model based classifiers: Cases for each possible combination of generative and discriminative learning of either the parameters or the structure of Bayesian network classifiers.

In this paper, we are particularly interested in learning the discriminative structure of a generative model. With a generative model, even discriminatively structured, some aspect of the joint distribution $p(C,\mathbf{X})$ is still being represented. Of course, a discriminatively structured generative model needs only represent that aspect of the joint distribution that is beneficial from a classification error rate perspective, and need not "generate" well (Bilmes et al., 2001). For this reason, it is likely that a discriminatively trained generative model will not need to be as complex as an accurate generatively trained model. In other words, the advantage of parsimony of a discriminative model over a generative model will likely be partially if not mostly recovered when one trains a generative model discriminatively. Moreover, there are a number of reasons why one might, in certain contexts, prefer a generative to a discriminative model including: parameter tying and domain knowledge-based hierarchical decomposition is facilitated; it is easy to work with structured data; there is less sensitivity to training data class skew; generative models can still be trained and structured discriminatively (as mentioned above); and it is easy to work with missing features by marginalizing over the unknown variables. This last point is particularly important: a discriminatively structured generative model still has the ability to go from $p(C,\mathbf{X})$ to $p(C,\mathbf{X}')$ where $\mathbf{X}'$ is a subset of the features in $\mathbf{X}$. This amounts to performing the marginalization $p(C,\mathbf{X}') = \sum_{\mathbf{X}\setminus\mathbf{X}'} p(C,\mathbf{X})$, something that can be tractable if the complexity class of $p(C,\mathbf{X})$ is limited (e.g., k-trees) and the variable order in the summation is chosen appropriately. In this work, we verify that a discriminatively structured model retains its advantages in the missing feature case (see Section 6.6). A discriminative model, however, is inherently conditional and it is not possible in general when some of the features are missing to go from $p(C|\mathbf{X})$ to $p(C|\mathbf{X}')$. This problem is also true for SVMs, logistic regression, and multi-layered perceptrons.

Learning a discriminatively structured generative model is inherently a combinatorial optimization problem on a "discriminative" objective function. This means that there is an algorithm that operates by tending to prefer structures that perform better on some measure that is related to classification error. Assuming sufficient training data, the ideal objective function is empirical risk under the 0/1-loss (what we call CR, or the average error rate over training data), which can be implicitly regularized by constraining the optimization process to consider only a limited complexity model family (e.g., k-trees for fixed k). In the case of discriminative parameter learning, CR can be used, but typically alternative continuous and differentiable cost functions, which may upper-bound CR and might be convex (Bartlett et al., 2006), are used and include conditional (log) likelihood $CLL(\mathcal{B}|\mathcal{S}) = \log \prod_{m=1}^{M} P_\Theta\left(C = c^m | \mathbf{X}_{1:N} = \mathbf{x}_{1:N}^m\right)$—this last objective function in fact corresponds to maximizing the mutual information between the class variable and the features (Bilmes, 2000), and can easily be augmented by a regularization term as well.

One may ask, given discriminative parameter learning, is discriminative structure still necessary? In the following, we present a simple synthetic example (similar to Narasimhan and Bilmes, 2005) and actual training and test results that indicate when a discriminative structure would be necessary for good classification performance in a generative model. The model consists of 3 binary valued attributes X_1, X_2, X_3 and a binary uniformly distributed class variable C. $\bar{X}_1$ denotes the negation of X_1. For both classes, X_1 is uniformly distributed and $X_2 = X_1$ with probability 0.5 and a uniformly distributed random number with probability 0.5. So we have the following probabilities for both classes:

$$X_1 := \begin{cases} 0 & \text{with probability } 0.5 \\ 1 & \text{with probability } 0.5 \end{cases}$$

$$X_2 := \begin{cases} X_1 & \text{with probability } 0.5 \\ 0 & \text{with probability } 0.25 \\ 1 & \text{with probability } 0.25 \end{cases}$$

For class 1, X_3 is determined according to the following:

$$X_3 := \begin{cases} X_1 & \text{with probability } 0.3 \\ X_2 & \text{with probability } 0.5 \\ 0 & \text{with probability } 0.1 \\ 1 & \text{with probability } 0.1 \end{cases}.$$

For class 2, X_3 is given by:

$$X_3 := \begin{cases} \bar{X}_1 & \text{with probability } 0.3 \\ X_2 & \text{with probability } 0.5 \\ 0 & \text{with probability } 0.1 \\ 1 & \text{with probability } 0.1 \end{cases}.$$

For both classes, the dependence between $X_1 - X_2$ is strong. The dependence $X_2 - X_3$ is stronger than $X_1 - X_3$, but only from a generative perspective (i.e., $I(X_2;X_3) > I(X_1;X_3)$ and $I(X_2;X_3|C) > I(X_1;X_3|C)$). Hence, if we were to use the strength of mutual information, or conditional mutual information, to choose the edge, we would choose $X_2 - X_3$. However, it is the $X_1 - X_3$ dependency that enables discrimination between the classes. Sampling from this distribution, we first learn structures using generative and discriminative methods, and then we perform parameter training

on these structures using either ML or CL (Greiner et al., 2005). For learning a generative TAN structure, we use the algorithm proposed by Friedman et al. (1997) which is based on optimizing the CMI between attributes given the class variable. For learning a discriminative structure, we apply our order-based algorithm proposed in Section 5 (we note that optimizing the EAR measure (Pernkopf and Bilmes, 2005) leads to similar results in this case).

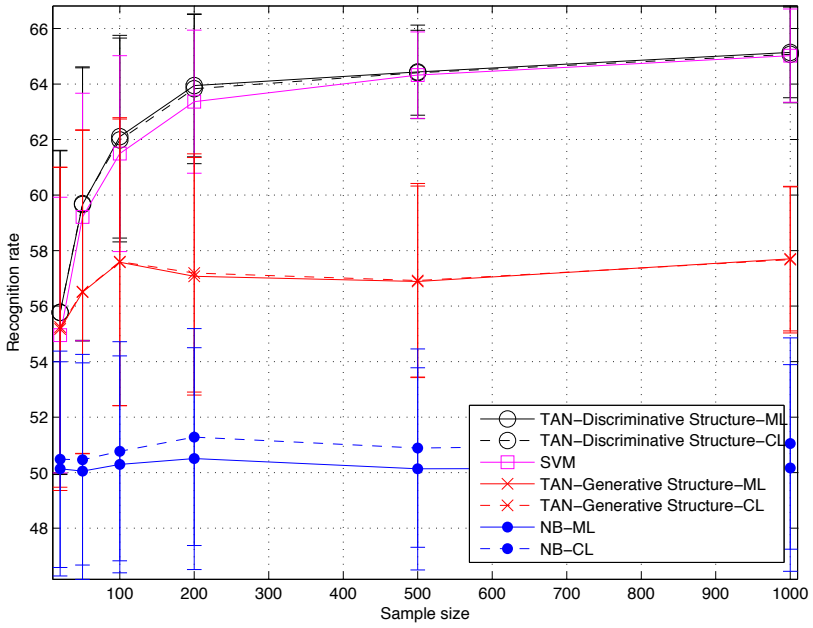

Figure 3: Generative and discriminative learning of Bayesian network classifiers on synthetic data.

Figure 3 compares the classification performance of these various cases, and in addition we show results for a NB classifier, which resorts to random guessing between both classes due to the lack of any feature dependency. Additionally, we provide the classification performance achieved with SVMs using a radial basis function (RBF) kernel.[2] On the x-axis, the training set *sample size* varies according to $\{20, 50, 100, 200, 500, 1000\}$ and the test data set contains 1000 samples. Plots are averaged over 100 independent simulations. The solid line is the performance of the classifiers using ML parameter learning, whereas, the dashed line corresponds to CL parameter training.

(a) (b)

Figure 4: (a) Generatively learned 1-tree, (b) Discriminatively learned 1-tree.

Figure 4 shows (a) the generative (b) the discriminative 1-tree over the attributes of the resulting TAN network (the class variable which is the parent of each feature is not shown in this figure). A generative model prefers edges between $X_1 - X_2$ and $X_2 - X_3$ which do not help discrimination.

2. The SVM uses two parameters C^* and σ, where C^* is the penalty parameter for the errors of the non-separable case and σ is the variance parameter for the RBF kernel. We set the values for these parameters to $C^* = 3$ and $\sigma = 1$.

The dependency between X_1 and X_3 enables discrimination to occur. Note that for this example the difference between ML and CL parameter learning is insignificant and for the generative model, only a discriminative structure enables correct classification. The performance of the non-generative SVM is similar to our discriminatively structured Bayesian network classifier. Therefore, when a generative model is desirable (see the reasons why this might be the case above), there is clearly a need for good discriminative structure learning.

In this paper, we show that the loss of a "generative meaning" of a generative model (when it is structured discriminatively) does not impair the generative model's ability to easily deal with missing features (Figure 11).

4. Learning Bayesian Networks

In the following sections, we briefly summarize state-of-the-art generative and discriminative structure and parameter learning procedures that are used to compare our order-based discriminative structure learning heuristics (which will be described in Section 5 and evaluated in Section 6).

4.1 Generative Parameter Learning

The parameters of the generative model are learned by maximizing the log likelihood of the data which leads to the ML estimation of $\theta^j_{i|h}$. The log likelihood function of a fixed structure of $\mathcal{B}$ is

$$\begin{aligned} LL(\mathcal{B}|\mathcal{S}) = \sum_{m=1}^{M} \log P_\Theta(\mathbf{Z}=\mathbf{z}^m) = \sum_{m=1}^{M}\sum_{j=1}^{N+1} \log P_\Theta\left(Z_j = z_j^m | Z_{\Pi_j} = z_{\Pi_j}^m\right) = \\ \sum_{m=1}^{M}\sum_{j=1}^{N+1}\sum_{i=1}^{|Z_j|}\sum_{h} u_{i|h}^{j,m} \log\left(\theta^j_{i|h}\right). \end{aligned} \tag{1}$$

It is easy to show that the ML estimate of the parameters is

$$\theta^j_{i|h} = \frac{\sum_{m=1}^{M} u_{i|h}^{j,m}}{\sum_{m=1}^{M}\sum_{l=1}^{|Z_j|} u_{l|h}^{j,m}},$$

using Lagrange multipliers to constrain the parameters to a valid normalized probability distribution. Since we are optimizing over constrained BN structures (k-trees), we do not perform any further regularization during training other than simple smoothing to remove zero-probability entries (see Section 6.1).

4.2 Discriminative Parameter Learning

As mentioned above, for classification purposes, having a good approximation to the posterior probability is sufficient. Hence, we want to learn parameters so that CL is maximized. Unfortunately, CL does not decompose as ML does. Consequently, there is no closed-form solution and we have to resort to iterative optimization techniques. The objective function of the conditional log likelihood

is

$$CLL(\mathcal{B}|\mathcal{S}) = \log \prod_{m=1}^{M} P_\Theta\left(C = c^m | \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right) = \sum_{m=1}^{M} \log \frac{P_\Theta\left(C = c^m, \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right)}{\sum_{c=1}^{|C|} P_\Theta\left(C = c, \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right)} =$$

$$\sum_{m=1}^{M} \left[\log P_\Theta\left(C = c^m, \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right) - \log \sum_{c=1}^{|C|} P_\Theta\left(C = c, \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right) \right].$$

Similar to Greiner and Zhou (2002) we use a conjugate gradient algorithm with line-search (Press et al., 1992). In particular, the *Polak-Ribiere* method is used (Bishop, 1995). The derivative of the objective function is

$$\frac{\partial CLL(\mathcal{B}|\mathcal{S})}{\partial \theta^j_{i|h}} = \sum_{m=1}^{M} \left[\frac{\partial}{\partial \theta^j_{i|h}} \log P_\Theta\left(C = c^m, \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right) - \right.$$

$$\left. \frac{1}{\sum_{c=1}^{|C|} P_\Theta\left(C = c, \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right)} \frac{\partial}{\partial \theta^j_{i|h}} \sum_{c=1}^{|C|} P_\Theta\left(C = c, \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right) \right].$$

Further, we distinguish two cases for deriving $\frac{\partial CLL(\mathcal{B}|\mathcal{S})}{\partial \theta^j_{i|h}}$. For TAN, NB, or 2-tree structures each parameter $\theta^j_{i|h}$ involves the class node value, either $C = i$ for $j = 1$ (Case A) or $C = h_1$ for $j > 1$ (Case B) where h_1 denotes the class instantiation $h_1 \in h$.

4.2.1 CASE A

For the class variable, that is, $j = 1$ and $h = \emptyset$, we get

$$\frac{\partial CLL(\mathcal{B}|\mathcal{S})}{\partial \theta^1_i} = \sum_{m=1}^{M} \left[\frac{u^{1,m}_i}{\theta^1_i} - \frac{W^m_i}{\theta^1_i} \right],$$

where we use Equation 1 for deriving the first term (omitting the sum over j and h) and we introduced the posterior

$$W^m_i = P_\Theta\left(C = i | \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right) = \frac{P_\Theta\left(C = i, \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right)}{\sum_{c=1}^{|C|} P_\Theta\left(C = c, \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right)}.$$

4.2.2 CASE B

For the attribute variables, that is, $j > 1$, we derive correspondingly and have

$$\frac{\partial CLL(\mathcal{B}|\mathcal{S})}{\partial \theta^j_{i|h}} = \sum_{m=1}^{M} \left[\frac{u^{j,m}_{i|h}}{\theta^j_{i|h}} - W^m_{h_1} \frac{v^{j,m}_{i|h\backslash h_1}}{\theta^j_{i|h}} \right],$$

where $W^m_{h_1} = P_\Theta\left(C = h_1 | \mathbf{X}_{1:N} = \mathbf{x}^m_{1:N}\right)$ is the posterior for class h_1 and sample m, and

$$v^{j,m}_{i|h\backslash h_1} = \begin{cases} 1, & \text{if } z^m_j = i \text{ and } z^m_{\Pi_j} = h\backslash h_1 \\ 0, & \text{otherwise} \end{cases}.$$

The probability $\theta^j_{i|h}$ is constrained to $\theta^j_{i|h} \geq 0$ and $\sum_{i=1}^{|Z_j|} \theta^j_{i|h} = 1$. We re-parameterize the problem to incorporate the constraints of $\theta^j_{i|h}$ in the conjugate gradient algorithm. Thus, we use different parameters $\beta^j_{i|h}$ as follows

$$\theta^j_{i|h} = \frac{\exp\left(\beta^j_{i|h}\right)}{\sum_{l=1}^{|Z_j|} \exp\left(\beta^j_{l|h}\right)}.$$

This requires the gradient $\frac{\partial CLL(\mathcal{B}|\mathcal{S})}{\partial \beta^j_{i|h}}$ which is computed after some modifications as

$$\frac{\partial CLL(\mathcal{B}|\mathcal{S})}{\partial \beta^j_{i|h}} = \sum_{k=1}^{|Z_j|} \frac{\partial CLL(\mathcal{B}|\mathcal{S})}{\partial \theta^j_{k|h}} \frac{\partial \theta^j_{k|h}}{\partial \beta^j_{i|h}} = \sum_{m=1}^{M} \left[u_i^{1,m} - W_i^m\right] - \theta^1_i \sum_{m=1}^{M} \sum_{c=1}^{|C|} \left[u_c^{1,m} - W_c^m\right]$$

for Case A and similarly for Case B we get the gradient

$$\frac{\partial CLL(\mathcal{B}|\mathcal{S})}{\partial \beta^j_{i|h}} = \sum_{m=1}^{M} \left[u^{j,m}_{i|h} - W^m_{h_1} v^{j,m}_{i|h\setminus h_1}\right] - \theta^j_{i|h} \sum_{m=1}^{M} \sum_{l=1}^{|Z_j|} \left[u^{j,m}_{l|h} - W^m_{h_1} v^{j,m}_{l|h\setminus h_1}\right].$$

4.3 Generative Structure Learning

The conditional mutual information between the attributes given the class variable is computed as:

$$I(X_i;X_j|C) = E_{P(X_i,X_j,C)} \log \frac{P(X_i,X_j|C)}{P(X_i|C)\,P(X_j|C)}.$$

This measures the information between X_i and X_j in the context of C. Friedman et al. (1997) gives an algorithm for constructing a TAN network using this measure. This algorithm is an extension of the approach in Chow and Liu (1968). We briefly review this algorithm in the following:

1. Compute the pairwise CMI $I(X_i;X_j|C) \quad \forall \quad 1 \leq i \leq N$ and $i < j \leq N$.
2. Build an undirected 1-tree using the maximal weighted spanning tree algorithm (Kruskal, 1956) where each edge connecting X_i and X_j is weighted by $I(X_i;X_j|C)$.
3. Transform the undirected 1-tree to a directed tree. That is, select a root variable and direct all edges away from this root. Add to this tree the class node C and the edges from C to all attributes $X_1,\ldots,X_N$.

4.4 Discriminative Structure Learning

As a baseline discriminative structure learning method, we use a greedy edge augmentation method and also the *SuperParent* algorithm (Keogh and Pazzani, 1999).

4.4.1 GREEDY HEURISTICS

While this method is expected to perform well, it is much more computationally costly then the method we propose below. The method proceeds as follows: a network is initialized to NB and at

each iteration we add the edge that, while maintaining a partial 1-tree, gives the largest improvement of the scoring function (defined below). This process is terminated when there is no edge which further improves the score. This process might thus result in a partial 1-tree (forest) over the attributes. This approach is computationally expensive since each time an edge is added, the scores for all $O\left(N^2\right)$ edges need to be re-evaluated due to the discriminative non-decomposable scoring functions we employ. This method overall has cost $O\left(N^3\right)$ score evaluations to produce a 1-tree, which in the case of an $O(NM)$) score evaluation cost (such as the below), has an overall complexity of $O\left(N^4\right)$. There are two score functions we consider: the CR (Keogh and Pazzani, 1999; Pernkopf, 2005)

$$CR\left(\mathcal{B}_{\mathcal{S}}|\mathcal{S}\right)=\frac{1}{M}\sum_{m=1}^{M}\delta\left(\mathcal{B}_{\mathcal{S}}\left(\mathbf{x}_{1:N}^{m}\right),c^{m}\right)$$

and the CL (Grossman and Domingos, 2004)

$$CL\left(\mathcal{B}|\mathcal{S}\right)=\prod_{m=1}^{M}P_{\Theta}\left(C=c^{m}|\mathbf{X}_{1:N}=\mathbf{x}_{1:N}^{m}\right),$$

where the expression $\delta\left(\mathcal{B}_{\mathcal{S}}\left(\mathbf{x}_{1:N}^{m}\right),c^{m}\right)=1$ if the Bayesian network classifier $B_{\mathcal{S}}\left(\mathbf{x}_{1:N}^{m}\right)$ trained with samples in $\mathcal{S}$ assigns the correct class label c^{m} to the attribute values $\mathbf{x}_{1:N}^{m}$, and is equal to 0 otherwise.[3] In our experiments, we consider the CR score which is directly related to the empirical risk in Vapnik (1998). The CR is the discriminative criterion that, given sufficient training data, most directly judges what we wish to optimize (error rate), while an alternative would be to use a convex upper-bound on the 0/1-loss function (Bartlett et al., 2006). Like in the generative case above, since we are optimizing over a constrained model space (k-trees), and are performing simple parameter smoothing, again regularization is implicit. This approach has in the literature been shown to be the algorithm that produces the best performing discriminative structure (Keogh and Pazzani, 1999; Pernkopf, 2005) but at the cost of a very expensive optimization procedure. To accelerate this algorithm in our implementation of this procedure (which we use as a baseline to compare against our still to-be-defined proposed approach), we apply two techniques:

1. The data samples are reordered during structure learning so that misclassified samples from previous evaluations are classified first. The classification is terminated as soon as the performance drops below the currently best network score (Pazzani, 1996).

2. During structure learning the parameters are set to the ML values. When learning the structure we only have to update the parameters of those nodes where the set of parents Z_{Π_j} changes. This observation can be also used for computing the joint probability during classification. We can memorize the joint probability and exchange only the probabilities of those nodes where the set of parents changed to get the new joint probability (Keogh and Pazzani, 1999).

In the experiments this greedy heuristic is labeled as TAN-CR and 2-tree-CR for 1-tree and 2-tree structures, respectively.

4.4.2 SUPERPARENT AND ITS k-TREE GENERALIZATION

Keogh and Pazzani (1999) introduced the *SuperParent* algorithm to efficiently learn a discriminative TAN structure. The algorithm starts with a NB network and the edges pointing from the class

3. Note that the CR scoring measure is determined from a classifier trained and tested on the same data $\mathcal{S}$.

variable to each attribute remain fixed throughout the algorithm. In the first step, each attribute in turn is considered as a parent of all other parentless attributes (except the class variable). If there are no parentless attributes left, the algorithm terminates. The parent which improves the CR the most is selected and designated the current superparent. The second step fixes the most recently chosen superparent and keeps only the single best child attribute of that superparent. The single edge between superparent and best child is then kept and the process of selecting a new superparent is repeated, unless no improvement is found at which point the algorithm terminates. The number of CR evaluations therefore in a complete run of the algorithm is $O\left(N^2\right)$. Moreover, CR determination can be accelerated as mentioned above.

We can extend this heuristic to learn 2-trees by simply modifying the first step accordingly: consider each attribute as an additional parent of all parentless or single-parented attributes (while ensuring acyclicity), and choose as the superparent the one that evaluates best, requiring $O(N)$ CR evaluations. Next, we retain the pair of edges between superparent and (parentless or single-parented) children that evaluates best using CR, requiring $O\left(N^2\right)$ CR evaluations. The process repeats if successful and otherwise terminates. The obvious k-tree generalization modifies the first step to choose an additional parent of all attributes with fewer than k parents, and then selects the best children for edge retention, leading overall to a process with $O\left(N^{k+1}\right)$ score evaluations. In this paper, we compare against this heuristic in the case of $k = 1$ and $k = 2$, abbreviating them, respectively, as *TAN-SuperParent* and *2-tree-SuperParent*.

5. New Heuristics: Order-based Greedy Algorithms

It was first noticed in Buntine (1991); Cooper and Herskovits (1992) that the best network consistent with a given variable ordering can be found with $O(N^{q+c})$ score evaluations where q is the maximum number of parents per node in a Bayesian network, and where c is a small fixed constant. These facts were recently exploited in Teyssier and Koller (2005) where generative structures were learned. Here, we are inspired by these ideas and apply them to the case of learning discriminative structures. Also, unlike Teyssier and Koller (2005), we establish only one ordering, and since our scoring cost is discriminative, it does not decompose and the learned discriminative structure is not guaranteed to be optimal. However, experiments show good results at relatively low computational learning costs.

Our procedure looks first for a total ordering $\prec$ of the variables $\mathbf{X}_{1:N}$ according to certain criteria which are outlined below. The parents of each node are chosen in such a way that the ordering is respected, and that the procedure results in at most a k-tree. We note here, a k-tree is typically defined on an undirected graphical model as one that has a tree-width of k—equivalently, there exists an elimination order in the graph such that at each elimination step, the node being eliminated has no more than k neighbors at the time of elimination. When we speak of a Bayesian network being a k-tree, what we really mean is that the moralized version of the Bayesian network is a k-tree. As a reminder, our approach is to learn a k-tree (i.e., a computationally and parameter constrained Bayesian network) over the features $\mathbf{X}_{1:N}$. We still assume, as is done with a naive Bayes model, that C is a parent of each X_i and this additional is not counted in k—thus, a 1-tree would have two parents for each X_i, both C and one additional feature. As mentioned above, in order to stay strictly within the realm of generative models, we do not consider the case where C has any parents.

5.1 Step 1: Establishing an Order $\prec$

We propose three separate heuristics for establishing an ordering $\prec$ of the attribute nodes prior to parent selection. In each case as we will see later, we use the resulting ordering such that later features may only have earlier features as parents—this limit placed on the set of parents leads to reduced computational complexity. Two of the heuristics are based on the conditional mutual information $I(C;\mathbf{X}_A|\mathbf{X}_B)$ between the class variable C and some subset of the features $\mathbf{X}_A$ given some disjoint subset of variables $\mathbf{X}_B$ (so $A \cap B = \emptyset$). The conditional mutual information (CMI) measures the degree of dependence between the class variable and $\mathbf{X}_A$ given $\mathbf{X}_B$ and it may be expressed entirely in terms of entropy via $I(C;\mathbf{X}_A|\mathbf{X}_B) = -H(C,\mathbf{X}_A,\mathbf{X}_B) + H(\mathbf{X}_A,\mathbf{X}_B) + H(C,\mathbf{X}_B) - H(\mathbf{X}_B)$, where entropy of X is defined as $H(X) = -\sum_x p(x)\log p(x)$. When $B = \emptyset$, we of course obtain (unconditional) mutual information. A structure that maximizes the mutual information between C and $\mathbf{X}$ is one that will lead to the best approximation of the posterior probability. In other words, an ideal form of optimization would do the following:

$$\mathcal{B}^* \in \operatorname*{argmax}_{\mathcal{B}\in\mathcal{F}_{\mathcal{B}}} I_{\mathcal{B}}(\mathbf{X}_{1:N};C),$$

where $\mathcal{F}_{\mathcal{B}}$ is a complexity constrained class of BNs (e.g., k-trees), and $\mathcal{B}^*$ is an optimum network. Of course, this procedure being intractable, we use mutual information to produce efficient heuristics but that we show work well in practice on a wide variety of tasks (Section 6). The third heuristic we describe is similar to the first two except that it is based directly on CR (i.e., empirical error or 0/1-loss) itself. The heuristics detailed in the following are compared against *random orderings* (RO) of the attributes in Section 6 to show that they are doing better than chance.

1: OMI: Our initial approach to finding an order is a greedy algorithm that first chooses the attribute node that is most informative about C. The next attribute in the order is the attribute node that is most informative about C conditioned on the first attribute, and subsequent nodes are chosen to be most informative about C conditioned on previously chosen attribute nodes. More specifically, our algorithm forms an ordered sequence of attribute nodes $\mathbf{X}_{\prec}^{1:N} = \left\{X_{\prec}^1, X_{\prec}^2, \ldots, X_{\prec}^N\right\}$ according to

$$X_{\prec}^j \leftarrow \operatorname*{argmax}_{X\in\mathbf{X}_{1:N}\setminus\mathbf{X}_{\prec}^{1:j-1}} \left[I\left(C;X|\mathbf{X}_{\prec}^{1:j-1}\right)\right], \tag{2}$$

where $j \in \{1,\ldots,N\}$.

It is not possible to describe the motivation for this approach without considering at least the general way parents of each attribute node are ultimately selected—more details are given below, but for now it is sufficient to say that each node's set of potential parents is restricted to come from nodes earlier in the ordering. Let $\mathbf{X}_{\Pi_j} \subseteq \mathbf{X}_{\prec}^{1:j-1}$ be the set of chosen parents for X_j in an ordering. There are several reasons why the above ordering should be useful. First, suppose we consider two potential next variables X_{j_1} and X_{j_2} as the j^{th} variable in the ordering, where $I(X_{j_1};C|\mathbf{X}_{1:j-1}) \ll I(X_{j_2};C|\mathbf{X}_{1:j-1})$. Choosing X_{j_1} could potentially lead to the case that no additional variable within the allowable set of parents $\mathbf{X}_{1:j-1}$ could be beneficially added to the model as a parent of X_{j_1}. The reason is that, conditioning on all of the potential parents of X_{j_1}, the variable X_{j_1} is less informative about C. If X_{j_2} is chosen, however, then there is a possibility that some edge augmentation as parents of X_{j_2} will render X_{j_2} residually informative about C—the reason for this is that X_{j_2} chosen to have this property, and one set of parents that renders X_{j_2} residually informative about C is the set $\mathbf{X}_{\prec}^{1:j-1}$. Stated more concisely, we wish to choose as a next variable in the ordering one that has the

potential to be strongly and residually predictive of C when choosing earlier variables as parents. When choosing X_j such that $I\left(C;X_j|\mathbf{X}_{\prec}^{1:j-1}\right)$ is large, this is possible at least in the case when X may have up to $j-1$ additional parents.

Of course, only a subset of these nodes will ultimately be chosen to ensure that the model is a k-tree and remains tractable and just because $I(X_j;C|\mathbf{X}_{1:j-1})$ is large does not necessarily mean that $I(X_j;C|\mathbf{X}_B)$ is also large for some $B \subset \{1,\ldots,(j-1)\}$. The strict sub-set relationship, where $|B| < (j-1)$, is necessary to restrict the complexity class of our models, but this goal involves an accuracy-computation tradeoff. Our approach, therefore, is only a heuristic. Nevertheless, one justification for our ordering heuristic is based on the aspect of our algorithm that achieves computational tractability, namely the parent-selection strategy where variables are only allowed to have previously ordered variables as their parents (as we describe in more detail below). Moreover, we have empirically found this property to be the case in both real and artificial random data (see below). Loosely speaking, we see our ordering as somewhat analogous to Ada-boost but applied to feature selection, where later decisions on the ordering are chosen to correct for the deficiencies of earlier decisions.

A second reason our ordering may be beneficial stems from the reason that a naive Bayes model is itself useful. In a NB, we have that each X_i is independent of X_j given C. This has beneficial properties both from the bias-variance (Friedman et al., 1997) and from the discriminative structure perspective (Bilmes, 2000). In any given ordering, variables chosen earlier in the order have more of a chance *in the resulting model* to render later variables conditionally independent of each other conditioned on both C and the earlier variable. For example, if two later variables both ask for the same earlier single parent, the two later variables are modeled as independent given C and that earlier parent. This normally would not be useful, but in our ordering, since the earlier variables are in general more correlated with C, this mimics the situation in NB: C and variables similar to C render conditionally independent other variables that are less similar to C (with NB alone, C renders all other variables conditionally independent). For reasons similar to NB (Friedman et al., 1997), such an ordering will tend to work well.

Our approach rests on being able to compute CMI queries over a large number of variables, something that requires both solving a potentially difficult inference problem and also is sensitive to training-data sparsity. In our case, however, a conditional mutual information query can be computed efficiently by making only one pass over the training data, albeit with a potential problem with bias and variance of the mutual information estimate. As mentioned above, each CMI query can be represented as a sum of signed entropy terms. Moreover, since all variables are discrete in our studies, an entropy query can be obtained in one pass over the data by computing an empirical histogram of random variable values only that exist in the data, then summing over only the resulting non-zero values. Let us assume, for simplicity, that integer variable Y represents the Cartesian product of all possible values of the vector random variable for we wish to obtain an entropy value. Normally, $H(Y) = -\sum_y p(y)\log p(y)$ would require an exponential number of terms, but we avoid this by computing $H(Y) = -\sum_{y\in\mathcal{T}_y} p(y)\log p(y) - |\mathcal{D}_y \setminus \mathcal{T}_y|\varepsilon\log\varepsilon$, where $\mathcal{T}_y$ are the set of y values that occur in the training data, and $\mathcal{D}_y$ is the set of all possible y values, and ε is any smoothing value that we might use to fill in zeros in the empirical histogram. Therefore, if our algorithm requires only a polynomial number of CMI queries, then the complexity of the algorithm is still only polynomial in the size of the training data. Of course, as the number of actual variables increases, the quality of this estimate decreases. To mitigate these problems, we can restrict the number of variables in $\mathbf{X}_{\prec}^{1:j-1}$ for a CMI query, leading to the following second heuristic based on CMI.

2: OMISP: For a 1-tree each variable $X_{\prec}^{j}$ has one single parent (SP) X_{Π_j} which is selected from the variables $\mathbf{X}_{\prec}^{1:j-1}$ appearing before $X_{\prec}^{j}$ in the ordering (i.e., $|\Pi_j| = 1, \forall j$). This leads to a simple variant of the above, where CMI conditions only on a single variable within $\mathbf{X}_{\prec}^{1:j-1}$. Under this heuristic, an ordered sequence is determined by

$$X_{\prec}^{j} \leftarrow \operatorname*{argmax}_{X \in \mathbf{X}_{1:N} \setminus \mathbf{X}_{\prec}^{1:j-1}} \left[\max_{X_{\prec} \in \mathbf{X}_{\prec}^{1:j-1}} \left[I\left(C; X | X_{\prec}\right) \right] \right].$$

Note, in this work, we do not present results using OMISP since the results were not significantly different than OMI. We refer the interested reader to Pernkopf and Bilmes (2008a) which gives the results for this heuristic, and more, in their full glory.

3: OCR: Here, CR on the training data is used in a way similar to the aforementioned greedy OMI approach. The ordered sequence of nodes $\mathbf{X}_{\prec}^{1:N}$ is determined according to

$$X_{\prec}^{j} \leftarrow \operatorname*{argmax}_{X \in \mathbf{X}_{1:N} \setminus \mathbf{X}_{\prec}^{1:j-1}} CR\left(\mathcal{B}_{\mathcal{S}} | \mathcal{S}\right),$$

where $j \in \{1, \ldots, N\}$ and the graph of $\mathcal{B}_{\mathcal{S}}$ at each evaluation is a fully connected sub-graph only over the nodes C, X, and $\mathbf{X}_{\prec}^{1:j-1}$, that is, we have a *saturated* sub-graph (note, here $\mathcal{B}_{\mathcal{S}}$ depends on the current X and the previously chosen attribute nodes in the order, but this is not indicated for notational simplicity). This can of course lead to very large local conditional probability tables. We thus perform this computation by using sparse probability tables that have been slightly smoothed as described above. We then compute CR on the basis of $P\left(C | X, \mathbf{X}_{\prec}^{1:j-1}\right) \propto P\left(X, \mathbf{X}_{\prec}^{1:j-1} | C\right) P\left(C\right)$. The justification for this approach is that it produces an ordering based not on mutual information but on a measure more directly related to classification accuracy.

5.2 Step 2: Heuristic for Selecting Parents w.r.t. a Given Order to Form a k-tree

Once we have the ordering $\mathbf{X}_{\prec}^{1:N}$, we select $X_{\Pi_j} \subseteq \mathbf{X}_{\prec}^{1:j-1}$ for each $X_{\prec}^{j}$, with $j \in \{2, \ldots, N\}$. When the size of $\mathbf{X}_{\Pi_j}$ (i.e., N) and of k are small we can use even a computational costly scoring function to find X_{Π_j}. In case of a large N, we can restrict the size of the parent set $\mathbf{X}_{\Pi_j}$ similar to the *sparse candidate algorithm* (Friedman et al., 1999). While either the CL or the CR can be used as a cost function for selecting parents, we in this work restrict our experiments to CR for parent selection (empirical results show it performed better). The parent selection proceeds as follows. For each $j \in \{2, \ldots, N\}$, we choose the best k parents $X_{\Pi_j} \subseteq \mathbf{X}_{\prec}^{1:j-1}$ for $X_{\prec}^{j}$ by scoring each of the $O\left(\binom{N}{k}\right)$ possibilities with CR. We note that for $j \in \{2, \ldots, N-1\}$ there will be a set of variables that have not yet had their parents chosen, namely variables $\mathbf{X}_{\prec}^{j+1:N}$—for these variables, we simply use the NB assumption. That is, those variables have no parents other than C for the selection of parents for $X_{\prec}^{j}$ (we relax this property in Pernkopf and Bilmes, 2008a). Note that the set of parents is judged using CR, but the model parameters for any given candidate set of parents selected are trained using ML (we did not find further advantages, in addition to using CR for parent selection, in also using discriminative parameter training). We also note that the parents for each attribute node are retained in the model only when CR is improved, and otherwise the node $X_{\prec}^{j}$ is left parent-less. This therefore might result in a partial k-tree (forest) over the attributes. We evaluate our algorithm for $k = 1$ and $k = 2$, but is defined above to learn k-trees ($k \geq 1$), and thus uses $O\left(N^{k+1}\right)$ score evaluations where,

due to ML training, each CR evaluation is $O(NM)$. Overall, for learning a 1-tree, the ordering and the parent selection costs $O\left(N^2\right)$ score evaluations. We see that the computation is comparable to that of the *SuperParent* algorithm and its k-tree generalization.

Algorithm 1 OMI-CR

Input: $\mathbf{X}_{1:N}, C, \mathcal{S}$
Output: set of edges $\mathbf{E}$ for TAN network
$X^1_\prec, X^2_\prec \leftarrow \text{argmax}_{X,X' \in \mathbf{X}_{1:N}} \left[I(C; X, X') \right]$
if $I\left(C; X^1_\prec\right) < I\left(C; X^2_\prec\right)$ **then**
  $X^2_\prec \leftrightarrow X^1_\prec$
end if
$\mathbf{E} \leftarrow \left\{ \mathbf{E}_{\text{Naive Bayes}} \cup E_{X^1_\prec, X^2_\prec} \right\}$
$j \leftarrow 2$
$CR_{old} \leftarrow 0$
repeat
  $j \leftarrow j+1$
  $X^j_\prec \leftarrow \text{argmax}_{X \in \mathbf{X}_{1:N} \setminus \mathbf{X}^{1:j-1}_\prec} \left[I\left(C; X | \mathbf{X}^{1:j-1}_\prec\right) \right]$
  $X^*_\prec \leftarrow \text{argmax}_{X \in \mathbf{X}^{1:j-1}_\prec} CR(\mathcal{B}_\mathcal{S} | \mathcal{S})$ where edges of $\mathcal{B}_\mathcal{S}$ are $\left\{ \mathbf{E} \cup E_{X, X^j_\prec} \right\}$
  $CR_{new} \leftarrow CR(\mathcal{B}_\mathcal{S} | \mathcal{S})$ where edges of $\mathcal{B}_\mathcal{S}$ are $\left\{ \mathbf{E} \cup E_{X^*_\prec, X^j_\prec} \right\}$
  if $CR_{new} > CR_{old}$ **then**
    $CR_{old} \leftarrow CR_{new}$
    $\mathbf{E} \leftarrow \left\{ \mathbf{E} \cup E_{X^*_\prec, X^j_\prec} \right\}$
  end if
until $j = N$

5.3 OMI-CR Algorithm

Recapitulating, we have introduced three order-based greedy heuristics for producing discriminative structures in Bayesian network classifiers: First, there is OMI-CR (Order based on Mutual Information with CR used for parent selection); Second, there is OMISP-CR (Order based on Mutual Information conditioned on a Single Parent, with CR used for parent selection); and third OCR-CR (Order based on Classification Rate, with CR used for parent selection). For evaluation purposes, we also consider random orderings in step 1 and CR for parent selection (RO-CR). The OMI-CR procedure is summarized in Algorithm 1 where both steps (order and parent selection) are merged at each loop iteration (which is of course equivalent to considering both steps separately). The different algorithmic variants are obtained by modifying the ordering criterion.

6. Experiments

We present classification results on 25 data sets from the UCI repository (Merz et al., 1997) and from Kohavi and John (1997), for frame- and segment-based phonetic classification experiments using the TIMIT database (Lamel et al., 1986), for a visual surface inspection task (Pernkopf, 2004), and for handwritten digit recognition using the MNIST (LeCun et al., 1998) and USPS data set.

Additionally, we show performance results on synthetic data. We use NB, TAN, and 2-tree network structures. Different combinations of the following parameter/structure learning approaches are used to learn the classifiers:

- Generative (ML) (Pearl, 1988) and discriminative (CL) (Greiner et al., 2005) parameter learning.
- CMI: Generative structure learning using CMI as proposed in Friedman et al. (1997).
- CR: Discriminative structure learning with greedy heuristic using CR as scoring function (Keogh and Pazzani, 1999; Pernkopf, 2005) (see Section 4.4).
- RO-CR: Discriminative structure learning using random ordering (RO) in step 1 and CR for parent selection in step 2 of the order-based heuristic.
- SuperParent k-tree: Discriminative structure learning using the SuperParent algorithm (Keogh and Pazzani, 1999) with $k = 1, 2$ (see Section 4.4).
- OMI-CR: Discriminative structure learning using CMI for ordering the variables (step 1) and CR for parent selection in step 2 of the order-based heuristic.
- For OMI-CR, we also evaluate discriminative parameter learning by optimizing CL during the selection of the parent in step 2. We call this OMI-CRCL. Discriminative parameter learning while optimizing discriminative structure is computationally feasible only on rather small data sets due to the cost of the conjugate gradient parameter optimization.

We do not include experimental results for OMISP-CR and OCR-CR for space reasons. The results, however, show similar performance to OMI-CR, and can be found in an extended technical-report version of this paper (Pernkopf and Bilmes, 2008a).

While we have attempted to avoid a proliferation of algorithm names, some name abundance has unavoidably occurred in this paper. We therefore have attempted to use a simple 2-, 3-, or even 4-tag naming scheme where A-B-C-D is such that "A" (if given) refers to either TAN (1-tree) or 2-tree, "B" and "C" refer to the structure learning approach, and "D" (if given) refers to the parameter training method of the *final* resultant model structure. For the ordering heuristics "B" refers to the ordering method, "C" refers to the parent selection and internal parameter learning strategy. For the remaining structure learning heuristics only "B" is present. Thus, TAN-OMI-CRML-CL would be the OMI procedure for ordering, parent selection evaluated using CR (with ML training used at that time), and with CL used to train the final model which would be a 1-tree (note moreover that TAN-OMI-CR-CL is equivalent since ML is the default training method).

6.1 Experimental Setup

Any continuous features were discretized using recursive minimal entropy partitioning (Fayyad and Irani, 1993) where the codebook is produced using only the training data. This discretization method uses the class entropy of candidate partitions to determine the bin boundaries. The candidate partition with the minimal entropy is selected. This is applied recursively on the established partitions and the minimum description length approach is used as stopping criteria for the recursive partitioning. In Dougherty et al. (1995), an empirical comparison of different discretization methods has been performed and the best results have been achieved with this entropy-based discretization. Throughout our experiments, we use exactly the same data partitioning for each training procedure. We performed simple smoothing, where zero probabilities in the conditional probability tables are replaced with small values ($\varepsilon = 0.00001$). For discriminative parameter learning, the parameters are

initialized to the values obtained by the ML approach (Greiner et al., 2005). The gradient descent parameter optimization is terminated using *cross tuning* as suggested in Greiner et al. (2005).

6.2 Data Characteristics

In the following, we introduce several data sets used in the experiments.

6.2.1 UCI DATA

We use 25 data sets from the UCI repository (Merz et al., 1997) and from Kohavi and John (1997). The same data sets, 5-fold cross-validation, and train/test learning schemes as in Friedman et al. (1997) are employed. The characteristics of the data sets are summarized in Table 7 in the Appendix A.

6.2.2 TIMIT-4/6 DATA

This data set is extracted from the TIMIT speech corpus using the dialect speaking region 4 which consists of 320 utterances from 16 male and 16 female speakers. The speech is sampled at 16 kHz. Speech frames are classified into the following classes, voiced (V), unvoiced (U), silence (S), mixed sounds (M), voiced closure (VC), and release (R) of plosives. We therefore are performing frame-by-frame phone classification (contrasted with phone *recognition* using, say, a hidden Markov model). We perform experiments with only four classes V/U/S/M and all six classes V/U/S/M/VC/R using 110134 and 121629 samples, respectively. The class distribution of the four class experiment V/U/S/M is 23.08%, 60.37%, 13.54%, 3.01% and of the six class case V/U/S/M/VC/R is 20.9%, 54.66%, 12.26%, 2.74%, 6.08%, 3.36%. Additionally, we perform classification experiments on data of male speakers (Ma), female speakers (Fe), and both genders (Ma+Fe). For each gender we have approximately the same number of samples. The data have been split into 2 mutually exclusive subsets of $\mathcal{D} \in \{\mathcal{S}_1, \mathcal{S}_2\}$ where the size of the training data $\mathcal{S}_1$ is 70% and of the test data $\mathcal{S}_2$ is 30% of $\mathcal{D}$. The classification experiments have been performed with 8 wavelet-based features combined with 12 mel-frequency cepstral coefficients (MFCC) features, that is, 20 features. More details about the features can be found in Pernkopf et al. (2008). We have 6 different classification tasks for each classifier, that is, Ma+Fe, Ma, Fe $\times$ 4 or 6 Classes.

6.2.3 TIMIT-39 DATA

This again is a phone classification test but with a larger number of classes. In accordance with Halberstadt and Glass (1997) we cluster the 61 phonetic labels into 39 classes, ignoring glottal stops. For training, 462 speakers from the standard NIST training set have been used. For testing the remaining 168 speakers from the overall 630 speakers were employed. Each speaker speaks 10 sentences including two sentences which are the same among all speakers (labeled as *sa*), five sentences which were read from a list of phonetically balanced sentences (labeled as *sx*), and 3 randomly selected sentences (labeled as *si*). In the experiments, we only use the *sx* and *si* sentences since the *sa* sentences introduce a bias for certain phonemes in a particular context. This means that we have 3696 and 1344 utterances in the training and test set, respectively. We derive from each phonetic segment one feature vector which results in 140173 training samples and 50735 testing samples. The features are derived similarly as proposed in Halberstadt and Glass (1997). First, 12 MFCC + log-energy feature (13 MFCC's) and their derivatives (13 Derivatives) are calculated for

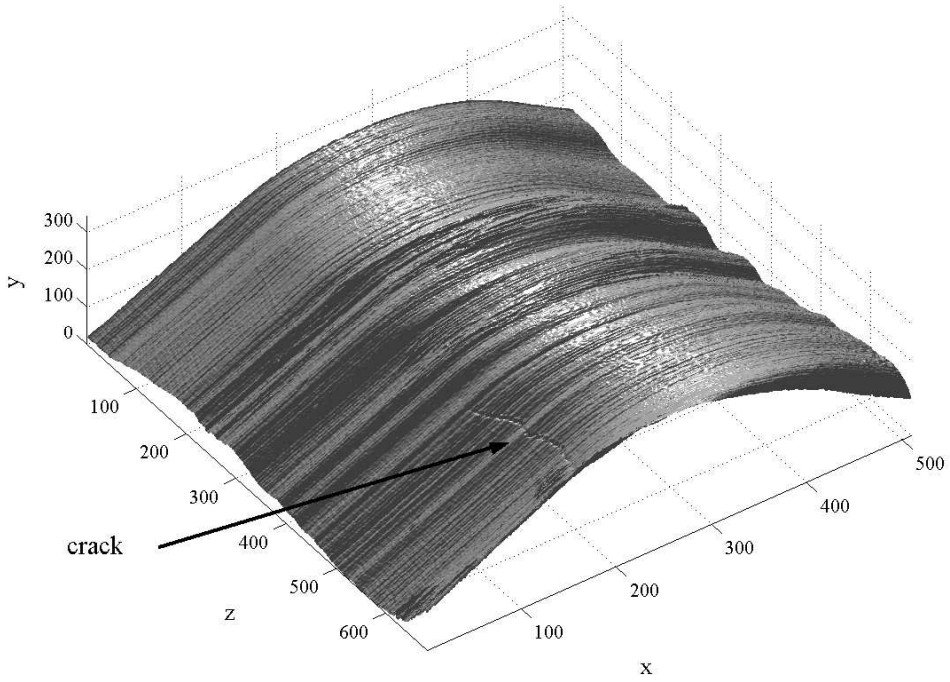

Figure 5: Acquired surface data with an embedded crack.

every 10ms of the utterance with a window size of 25ms. A phonetic segment, which can be variable length, is split at a 3:4:3 ratio into 3 parts. The fixed-length feature vector is composed of: 1) three averages of the 13 MFCC's calculated from the 3 portions (39 features); 2) the 13 Derivatives of the beginning of the first and the end of the third segment part (26 features); and 3) the log duration of the segment (1 feature). Hence, each phonetic segment is represented by 66 features.

6.2.4 SURFACE INSPECTION DATA (SURFINSP)

This data set was acquired from a surface inspection task. Surface defects with three-dimensional characteristics on scale-covered steel blocks have to be classified into 3 classes. The 3-dimensional raw data showing the case of an embedded surface crack is given in Figure 5. The data set consists of 450 surface segments uniformly distributed into three classes. Each sample (surface segment) is represented by 40 features. More details on the inspection task and the features used can be found elsewhere (Pernkopf, 2004).

6.2.5 MNIST DATA

We evaluate our classifiers on the MNIST data set of handwritten digits (LeCun et al., 1998) which contains 60000 samples for training and 10000 digits for testing. The digits are centered in a 28×28 gray-level image. We re-sample these images at a resolution of 14×14 pixels. This gives 196 features where the gray-levels are discretized using the procedure from Fayyad and Irani (1993).

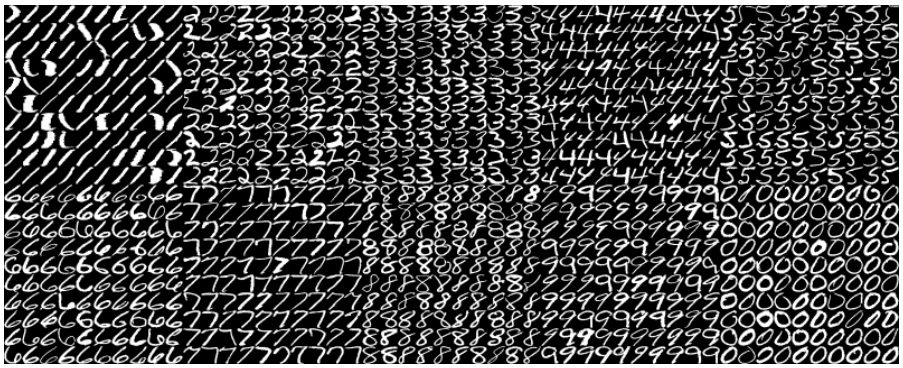

Figure 6: USPS data.

6.2.6 USPS DATA

This data set contains 11000 handwritten digit images (uniformly distributed) collected from zip codes of mail envelopes. Each digit is represented as a 16×16 grayscale image, where each pixel is considered as individual feature. Figure 6 shows a random sample of the data set. We use 8000 digits for training and the remaining images as a test set.

6.3 Conditional Likelihood and Maximum Mutual Information Orderings

In the following, we evaluate the ordering heuristics using 31 different classification scenarios (from the UCI and the TIMIT-4/6 data sets) comprising differing input features and differing numbers of classes. We compare our ordering procedure (i.e., OMI, where we maximize the mutual information as in Equation 2) with several other possible orderings in an attempt to empirically show that our aforementioned intuition regarding order (see Section 5.1) is sound in the majority of cases. In particular, we compare against an ordering produced by minimizing the mutual information (replacing argmax with argmin in Equation 2). Additionally, we also compare against 100 uniformly-at-random orderings. For the selection of the conditioning variables (see Section 5.2) the CL score is used in each case. ML parameter estimation is used for all examples in this section.

Figure 7 and Figure 8 show the resulting conditional log likelihoods (CLL) of the model scoring the training data after the TAN network structures (1-trees in this case) have been determined for the various data sets. As can be seen, our ordering heuristic performs better than both the random and the minimum mutual information orderings on 28 of the 31 cases. The random case shows the mean and $\pm$ one standard deviation out of 100 orderings. For *Corral*, *Glass*, and *Heart* there is no benefit, but the data sets are on the smaller side where it is less unexpected that generative structure learning would perform better (Ng and Jordan, 2002).

To further verify that our ordering tends to produce better conditional likelihood values on training data, we also evaluate on random data. For each number of variables (from 10 up to 14) we generate 1000 random distributions and draw 100000 samples from each one. Using these samples, we learn generative and discriminative TAN structures by the following heuristics and report the resulting conditional log likelihood on the training data: (i) order variables by maximizing mutual information (TAN-OMI-CL), (ii) order variables by minimizing mutual information, (iii) random ordering of variables and CL parent selection (TAN-RO-CL), (iv) optimal generative 1-tree, that

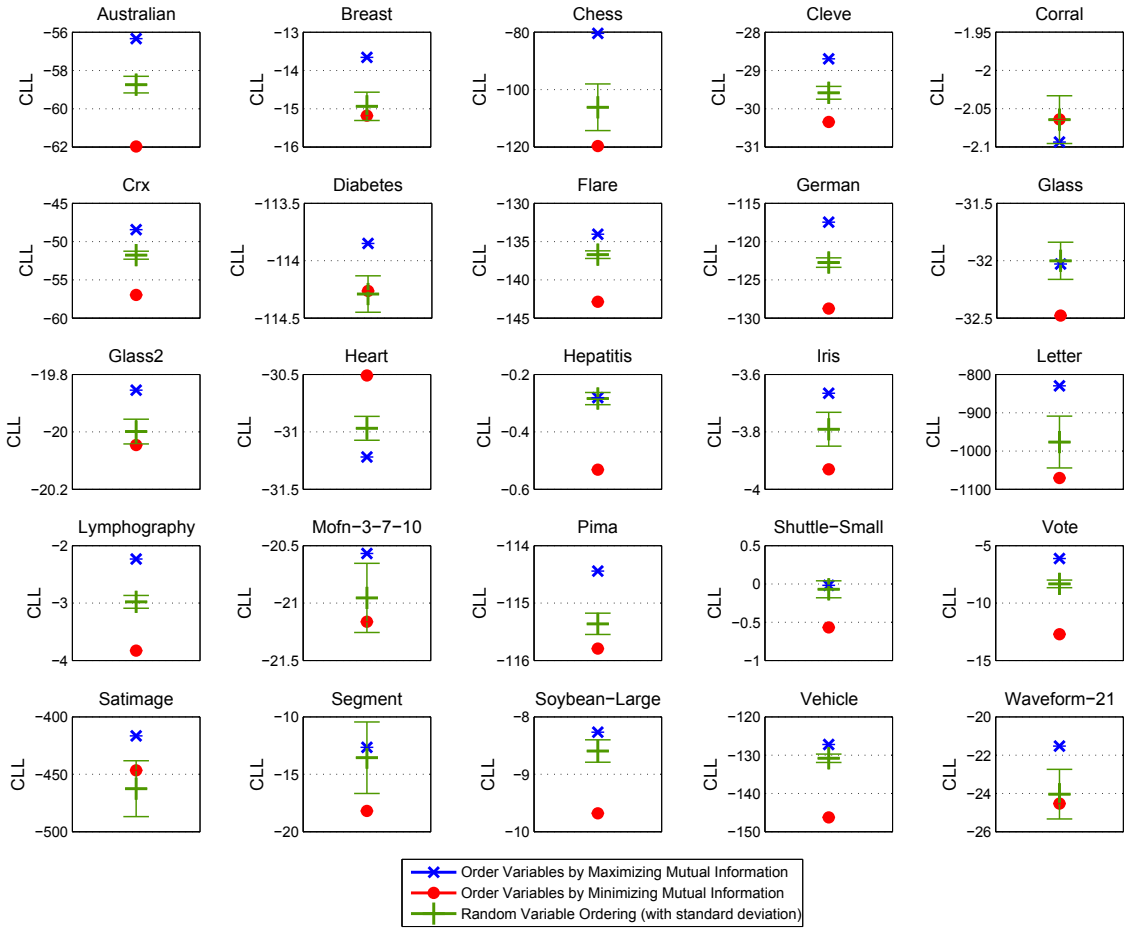

Figure 7: Resulting CLL on the UCI data sets for a maximum mutual information (i.e., OMI), a minimum mutual information, and a random based ordering scheme.

is, TAN-CMI (Friedman et al., 1997), (v) the computationally expensive greedy heuristic using CL (see Section 4.4.1), what we call TAN-CL. In addition we show CLL results for the NB classifier.

Figure 9 shows the CLL values for various algorithms. The CLL is still high even with the much less computationally costly OMI-CL procedure. Additionally, the generative 1-tree method improves likelihood but it does not necessarily produce good conditional likelihood results. We performed a one-sided paired t-test (Mitchell, 1997) for all different structure learning approaches. This test indicates that the CLL differences among the methods are significant at a level of 0.05 for each number of variables. This figure shows that the CLL gets smaller when more attributes are involved. With increasing the number of variables the random distribution becomes more *complex* (i.e., the number of dependencies among variables increases). However, we approximate the true distribution in any case with a 1-tree.

While we have shown empirically that our ordering heuristic tends to produce models that score the training data highly in the conditional likelihood sense, a higher conditional likelihood does not guarantee a higher accuracy, and training data results do not guarantee good generalization. In the

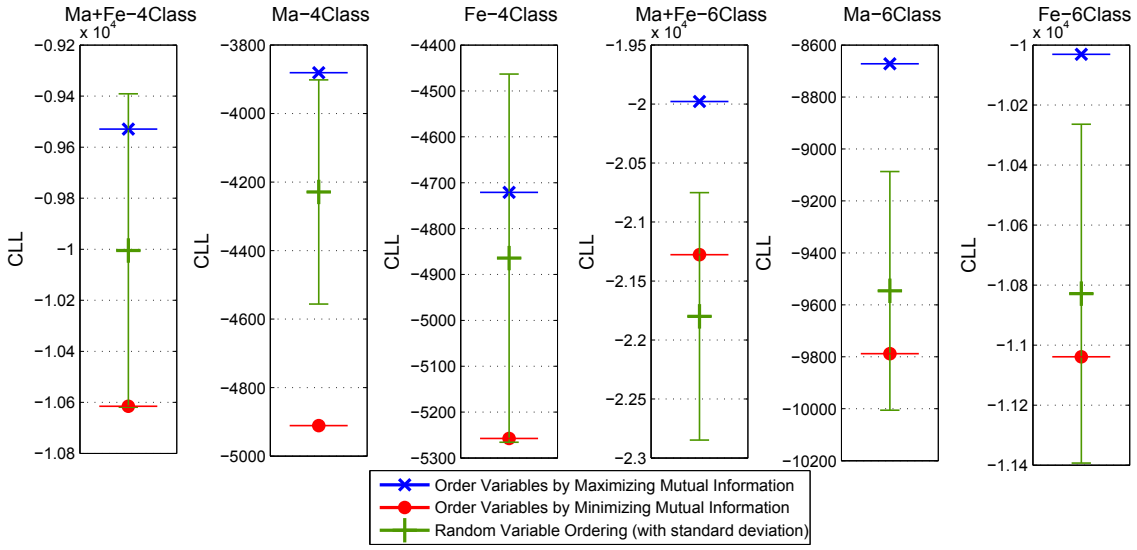

Figure 8: Resulting CLL on the TIMIT-4/6 data sets for a maximum mutual information (i.e., OMI), a minimum mutual information, and a random based ordering scheme.

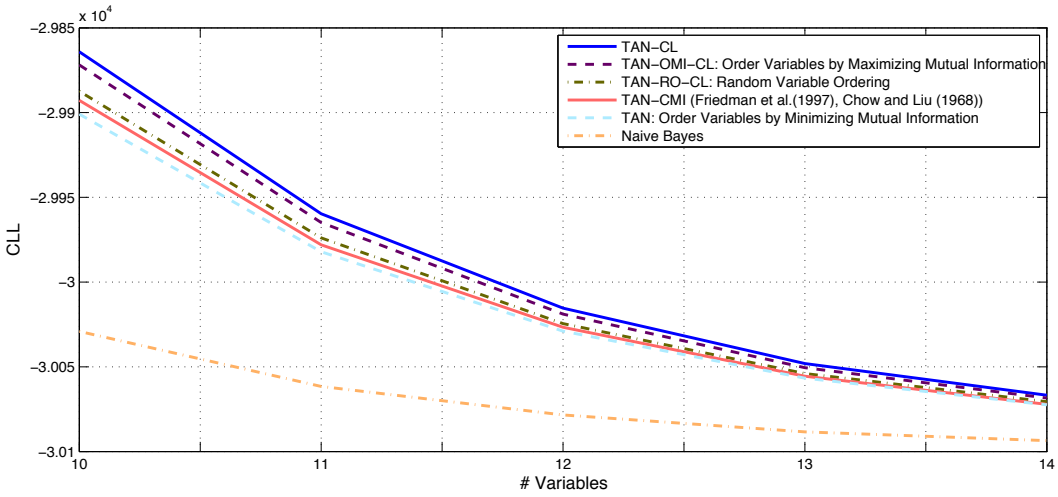

Figure 9: Optimized CLL of TAN structures learned by various algorithms. For each number of variables (x-axis) we generated 1000 random distributions.

next sections, however, we show that on balance, accuracy on test data using our ordering procedure is on par with the expensive greedy procedure, but with significantly less computation.

6.4 Synthetic Data

We show the benefit of the structure learning algorithms for the case where the class-dependent data are sampled from different 1-tree structures. In particular, we randomly determine for each class a 1-tree. The probabilities for each attribute variable are sampled from an uniform distribution, whereas the cardinality is set to 10, that is, $|X_i| = 10$. We use five classes. From the tree for $C = 1$ we draw 25000 samples. Additionally, we sample 6250 samples for each of the remaining four

classes from the same structure for confusion. For the remaining classes we draw 6250 samples from the corresponding random trees. This gives in total 75000 samples for training. The test set also consists of 75000 samples generated likewise. We perform this experiment for varying number of attributes, that is, $N \in \{5, 10, 15, 20, 25, 30\}$. The recognition results are shown in Figure 10, whereas the performance of each algorithm is averaged over 20 independent runs with randomly selected conditional probability distributions and trees. In each run, all algorithms have exactly the same data available.

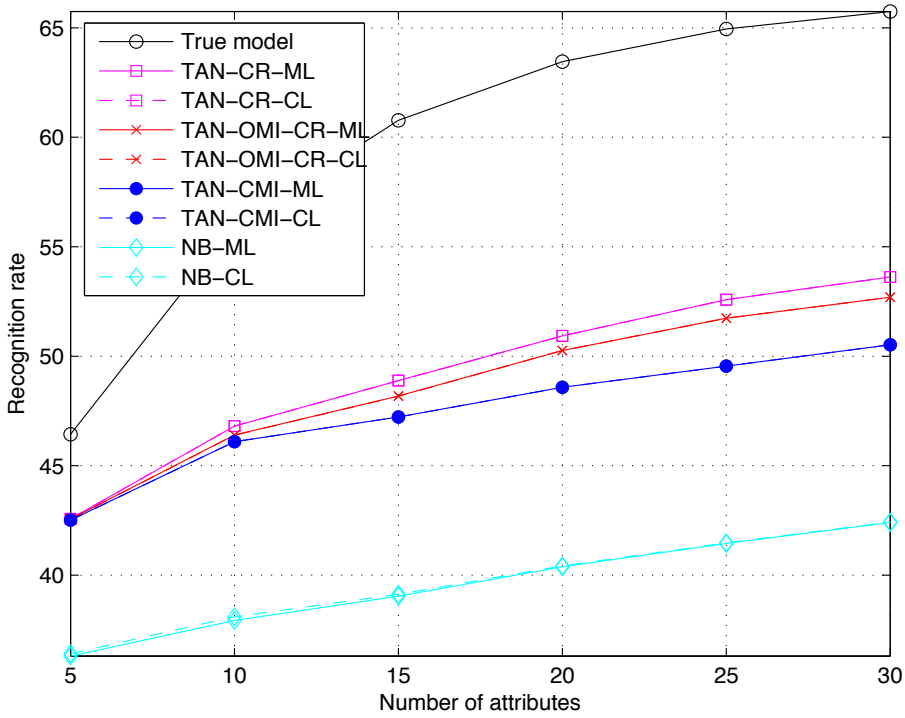

Figure 10: Synthetic data: Recognition performance is averaged over 20 runs.

We compare our OMI-CR heuristic to greedy discriminative structure learning. Additionally, we provide results for NB and generatively optimized TAN structures using CMI. To give a flavor about the data, the classification rates achieved with the true model used to generate the data are reported. This figure indicates that OMI-CR performs slightly worse than the greedy heuristic. However, the one-sided paired t-test (Mitchell, 1997) indicates that TAN-OMI-CR performs significantly better than TAN-CMI for more than 5 attributes at a level of 0.05. Generally, discriminative parameter optimization (i.e., CL) does not help for this data.

6.5 Classification Results and Discussion

Table 1 presents the averaged classification rates over the 25 UCI and 6 TIMIT-4/6 data sets.[4] Additionally, we report the CR on TIMIT-39, SurfInsp, MNIST, and USPS. The individual classification performance of all classification approaches on the 25 UCI data sets are summarized in Pernkopf

4. The average CR is determined by first weighting the CR of each data set with the number of samples in the test set. These values are accumulated and normalized by the total amount of samples in all test sets.

Table 1: Averaged classification results for 25 UCI and 6 TIMIT-4/6 data sets and classification results for TIMIT-39, SurfInsp, MNIST, and USPS with standard deviations. Best results use bold font. ML and CL denote generative and discriminative parameter learning, respectively. The order-based greedy heuristics are OMI-CR (order mutual information-CR) and RO-CR (random order-CR). CRCL refers to using discriminative parameter learning during structure learning. The generative structure learning algorithm is abbreviated as CMI and the greedy discriminative structure learning is TAN-CR and 2-tree-CR.

and Bilmes (2008a), whereas the random order experiment is presented in Table 8 (see Appendix A). For the TIMIT-4/6 data sets the individual classification performances for various classifier learning methods can be found in Table 9 (see Appendix B). The random order experiment for these data sets using a 2-tree is summarized in Appendix B in Table 10.

6.5.1 DISCUSSION: DISCRIMINATIVE VERSUS GENERATIVE PARAMETER LEARNING

Discriminative parameter learning produces mostly a significantly better classification performance than ML parameter learning on the same classifier structure. Especially, for cases where the structure of the underlying model is not optimized for classification (Greiner et al., 2005)—the average improvement of discriminative parameter learning over ML estimation on NB and generative TAN-CMI structures is large. In particular, for TIMIT-4/6 and TIMIT-39 the discriminatively optimized NB classifier (i.e., NB-CL) achieves the overall best classification performance. One reason is that the final step of MFCC features extraction includes a discrete cosine transform, that is, the features are decorrelated. Hence, the independence assumptions of the NB structure might be a good choice for these data sets. A second reason is that CL parameter learning for the TAN and 2-tree structures overfit the data (even with cross tuning)—the NB structure implicitly keeps the number of parameters low. Analyzing the results of CL parameter learning over various structures (especially for

2-trees) reveal that *cross tuning* is for some cases too restrictive concerning the number of conjugate gradient iterations—an alternative regularization method is required. CL parameter learning of NB classifiers is known to be equivalent to logistic regression. It can be shown that the CLL is concave when using $\log \theta^j_{i|h}$, that is, the global maximum can be found during discriminative parameter learning. Roos et al. (2005) showed that this also holds for more general network structures, for example, TAN.

In Section 6.6, we show that the classification performance of a discriminatively structured model may be superior to discriminatively parameterized models in the case of missing features.

6.5.2 DISCUSSION: DISCRIMINATIVE VERSUS GENERATIVE STRUCTURE LEARNING USING ML PARAMETER LEARNING

The CR objective function produces the best performing network structures. Evaluation of the CR measure is computationally expensive as mentioned above. However, due to the ordering of the variables in the order-based heuristics, we can reduce the number of CR evaluations from $O\left(N^3\right)$ to $O\left(N^2\right)$ for TAN structures. Hence, TAN-CR and 2-tree-CR are restricted to rather small data sets. The order-based heuristic OMI-CR achieve a similar performance at a much lower computational cost. Discriminative parameter learning during discriminative structure learning using our order-based heuristics can slightly improve the performance. This is possible only on small data sets due to the computational burden for the conjugate gradient parameter optimization.

The discriminative SuperParent algorithm performs slightly but not significantly worse compared to the other discriminative structure learning algorithms OMI-CR, OMI-CRCL, and greedy heuristic using CR on the UCI data set—similarly, the performance of SuperParent on TIMIT-4/6 for learning TAN structures, however, the performance using 2-tree structures is low. In summary, SuperParent achieves a lower classification rate compared to other discriminative structure learning algorithms on most of the data sets. The main reason for the degraded performance is an early termination of the algorithm.

For RO-CR we summarize the performance over 1000 random orderings using the mean (Mean), minimum (Min), and maximum (Max) CR (we use only 100 random orders for TIMIT-4/6 though). Min (Max) reports the classification rate on the test set using the structure which achieves the minimum (maximum) performance over 1000 random orderings (resp. 100 orders for TIMIT-4/6) on the training data. In some cases, the average over the data sets show that the worst RO-CR structures scored on the training sets perform better on the test sets than the best structures on the training sets, presumably due to overfitting. These results do show, however, that choosing from a collection of arbitrary orders and judging them based on the training set performance is not likely to perform well on the test set. Our heuristics do improve over these orders.

The TIMIT-39, MNIST, and USPS experiments show that we can perform discriminative structure learning for relatively large classification problems ($\sim$140000 samples, 66 features, 39 classes, $\sim$60000 samples, 196 features, 10 classes, and $\sim$8000 samples, 256 features, 10 classes, resp.). For these data sets, OMI-CR significantly outperform NB and TAN-CMI.

On MNIST we achieve a classification performance of $\sim$92.58% with the discriminative TAN classifier. A number of state-of-the-art algorithms, that is, convolutional net and virtual SVM, achieve an error rate below 1% (LeCun and Cortes). Due to resampling we use only 196 features in contrast to the 784 features of the original data set which might explain some of the loss in classification rate. Another reason why the convolutional neural net and virtual SVM perform better

Table 3: Comparison of different classifiers using the one-sided paired t-test for the 6 TIMIT-4/6 data sets: Each entry of the table gives the significance of the difference of the classification rate of two classifiers over the data sets. The arrow points to the superior learning algorithm. We use a double arrow if the difference is significant at the level of 0.05. The order-based greedy heuristics are OMI-CR (order mutual information-CR) and RO-CR (random order-CR). CRCL refers to algorithms using discriminative parameter learning during structure learning. The generative structure learning algorithm is abbreviated as CMI and the naive greedy discriminative structure learning is TAN-CR and 2-tree-CR.

on digit recognition is probably that images are not treated as unstructured feature vectors, that is, the convolutional neural net has built-in parts that look at particular areas of the image, and the virtual SVM is trained on augmented data that reflects invariance to small translations and rotations.

For the SurfInsp data the standard deviation of the five-fold cross-validation classification accuracy estimate is relatively large. Unfortunately, the size of the data set is limited to 450 samples.

The structure of Bayesian networks is implicitly regularized when we restrict the optimization over a model structure (e.g., 1-trees) assuming sufficient training data. For 2-trees we noticed that the data tended to overfit without further regularization. Therefore, we introduce 5-fold cross validation on the *training* data to find the optimal classifier structure.

Table 2 and Table 6.5.2 present a summary of the classification results over all structure learning experiments using ML parameter learning of the UCI and TIMIT-4/6 data sets.

We compare all pairs of classifiers using the one-sided paired t-test (Mitchell, 1997). The t-test determines whether the classifiers differ significantly under the assumption that the classification differences over the data set are independent and identically normally distributed. In these tables, each entry gives the significance of the difference in classification rate of two classification approaches. The arrow points to the superior learning algorithm and a double arrow indicates whether the difference is significant at a level of 0.05.

These tables show that TAN-OMI-CR, TAN-OMI-CRCL-CR, and TAN-CR significantly outperform the generative structure learning approach TAN-CMI (similar for 2-trees). However, the computationally expensive greedy heuristic TAN-CR and 2-tree-CR do not significantly outperform our discriminative order-based heuristics TAN-OMI-CR and 2-tree-OMI-CR, respectively.

6.5.3 DISCUSSION: COMPUTATIONAL REQUIREMENTS FOR STRUCTURE LEARNING

The running time of the TAN-CMI, TAN-OMI-CR, and TAN-CR structure learning algorithms for the UCI, TIMIT-4/6, TIMIT-39, and the MNIST data sets is summarized in Table 4. The numbers represent the percentage of time that is needed for a particular algorithm compared to TAN-CR. TAN-CMI is roughly 3-10 times faster than TAN-OMI-CR and TAN-CR takes about 10-40 times longer for establishing the discriminative structure than TAN-OMI-CR.

Data set	TAN-CMI	TAN-OMI-CR	TAN-CR
UCI	0.649%	3.155%	100.00%
TIMIT-4/6	3.56%	11.47%	100.00%
TIMIT-39	0.11%	2.08%	100.00%
MNIST	0.21%	2.23%	100.00%

Table 4: Running time of structure learning algorithms relative to TAN-CR.

6.6 Results with Randomly Missing Input Features

As mentioned in Section 3, generative models can easily deal with missing features simply by marginalizing out from the model the missing feature. We are particularly interested in a testing context which has arbitrary sets of missing features for each classification sample. In such a case, it is not possible to re-train the model for each potential set of missing features without also memorizing the training set. Due to the local-normalization property of Bayesian networks and the structure of any model with a parent-less class node, marginalization is as easy as an $O(r^{k+1})$ operation for a k-tree, where r is the domain size of each feature.

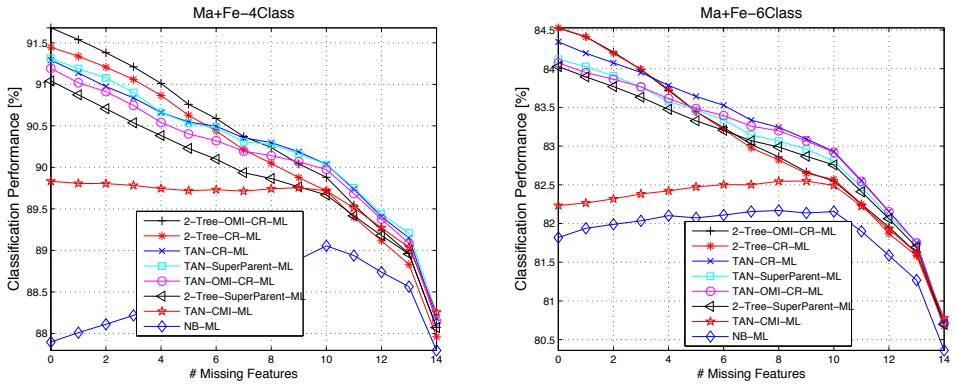

Figure 11: Classification performance of different structure learning methods assuming missing features using Ma+Fe data of TIMIT-4/6.

In Figure 11, we present the classification performance of discriminative and generative structures assuming missing features using the Ma+Fe data of TIMIT-4/6. The x-axis denotes the number of missing features. The curves are averaged over 100 classifications of the test data with uniformly at random selected missing features. We use exactly the same missing features for each classifier. Variance bars are omitted to improve readability, but indicate that the resulting differences are significant between NB-ML, TAN-CMI-ML, and discriminatively structured classifiers for a low number of missing features. Hence, discriminatively structured Bayesian network classifiers outperform TAN-CMI-ML even in the case of missing features. This demonstrates, at least empirically, that discriminatively structured generative models do not lose their ability to impute missing features.

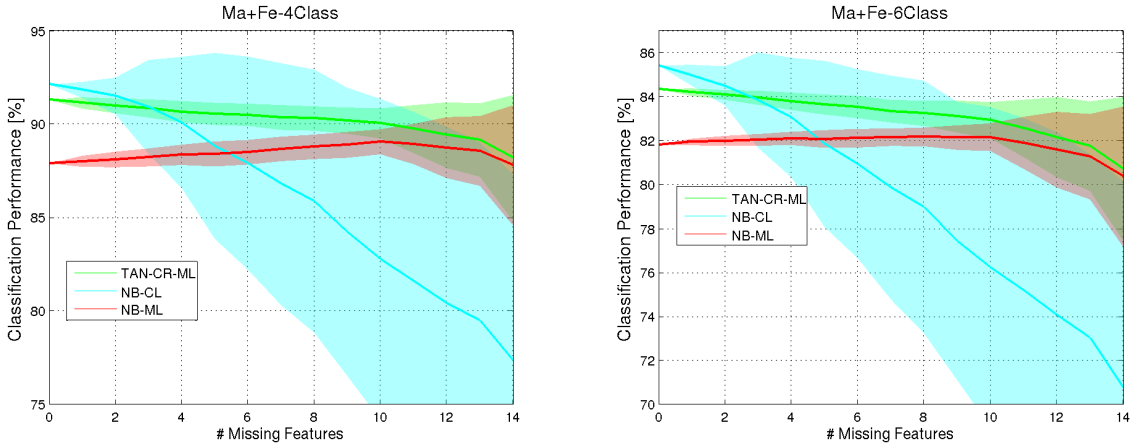

Figure 12: Classification performance of NB-ML, NB-CL, and TAN-CR-ML assuming missing features using Ma+Fe data of TIMIT-4/6. The shaded region corresponds to the standard deviation over 100 classifications.

In Figure 12, we show for the same data sets and experimental setup that the classification performance of a discriminatively structured model may be superior to discriminatively parameterized models in the case of missing features. In particular, for more than three missing features TAN-CR-ML outperforms NB-CL. Similar results can be shown for MNIST in Figure 13.

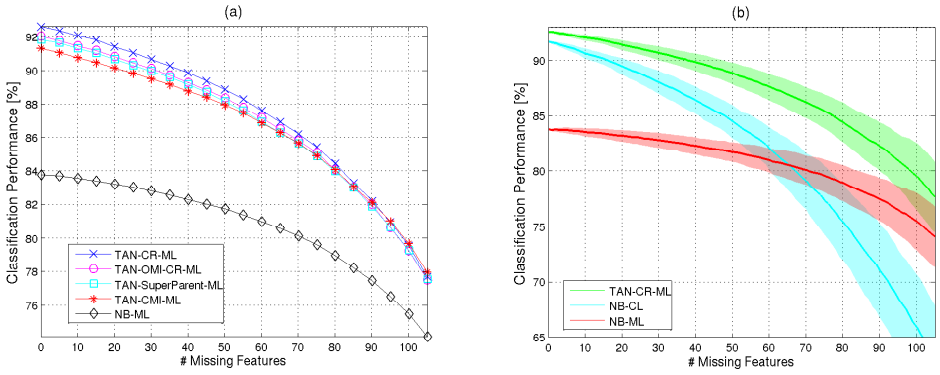

Figure 13: Classification performance using MNIST. The shaded region corresponds to the standard deviation over 100 classifications: (a) Different structure learning methods, (b) NB-ML, NB-CL, and TAN-CR-ML.

6.7 Results with SVMs

In Table 6, we compare classification performances between the best performing Bayesian network classifiers (in Table 1) and SVMs using RBF kernels. SVMs outperform our discriminative Bayesian network classifier. For TIMIT-4/6 one reason might be that SVMs are applied to the continuous feature domain. In Table 5 we compare the model complexity (i.e., number of parameters) between both SVMs and Bayesian network classifiers. This table reveals that the Bayesian network uses $\sim$108, $\sim$66, $\sim$212, and $\sim$259 times fewer parameters for MNIST, USPS, Ma+Fe-4, and Ma+Fe-6 than the SVM. This might also explain the loss in classification performance of discriminative Bayesian networks. Furthermore, Bayesian network classifiers can be directly applied to problems with more than two classes, whereas SVMs in its traditional formulation are limited to binary problems—the multiclass problem is decomposed into binary problems. Additionally, for SVMs we have to select C^* and σ. A substantial difference is that SVMs determine the number of support vectors automatically while in the case of Bayesian networks the number of parameters is specified by the structure. A limited complexity class (e.g., 1-tree) restricts the number of parameters which might be advantageous. In contrast to SVMs, a Bayesian network might be preferred since it is easy to work with missing features (see Section 6.6), parameter tying and knowledge-based hierarchical decomposition is facilitated, and it is easy to work with structured data.

7. Conclusion

We introduced a simple order-based heuristic for learning discriminative network structure. The metric for establishing the ordering of N features is based on either the conditional mutual infor-

Table 6: Classification results for TIMIT-4/6 data sets (averaged), MNIST, and USPS using best performing Bayesian network classifier (see Table 1) and SVMs.

mation or the classification rate. Given an ordering, we can find a discriminative classifier structure using $O\left(N^{k+1}\right)$ score evaluations (where constant k is the tree-width of the sub-graph over the attributes). We empirically compare the performance of our algorithms to state-of-the-art discriminative and generative parameter and structure learning algorithms using real data from the TIMIT speech corpus, the UCI repository, a visual surface inspection task, and from handwritten digit recognition tasks. The experiments show that the discriminative structures found by our order-based heuristics achieve on average a significantly better classification performance than the generative approach. Our obtained classification performance is very similar to the greedy search using CR. Our order-based heuristics however, are about 10-40 times faster. Additionally, we show that discriminatively structured Bayesian network classifiers are superior even in the case of missing features.

Abstract

We consider the problem of high-dimensional variable selection: given n noisy observations of a k-sparse vector $\beta^* \in \mathbb{R}^p$, estimate the subset of non-zero entries of β^*. A significant body of work has studied behavior of ℓ_1-relaxations when applied to random measurement matrices that are dense (e.g., Gaussian, Bernoulli). In this paper, we analyze *sparsified* measurement ensembles, and consider the trade-off between measurement sparsity, as measured by the fraction γ of non-zero entries, and the statistical efficiency, as measured by the minimal number of observations n required for correct variable selection with probability converging to one. Our main result is to prove that it is possible to let the fraction on non-zero entries $\gamma \to 0$ at some rate, yielding measurement matrices with a vanishing fraction of non-zeros per row, while retaining the same statistical efficiency as dense ensembles. A variety of simulation results confirm the sharpness of our theoretical predictions.

Keywords: variable selection, sparse random projections, high-dimensional statistics, Lasso, consistency, ℓ_1-regularization

1. Introduction

Recent years have witnessed a flurry of research on the recovery of high-dimensional models satisfying some type of sparsity constraint. These types of sparse recovery problems arise in a variety of domains, including variable selection in regression (Tibshirani, 1996), graphical model selection (Meinshausen and Buhlmann, 2006; Ravikumar et al., 2010), sparse principal components analysis (Johnstone and Lu, 2009; Paul, 2007), sparse approximation (Tropp, 2006), and compressed sensing (Candes and Tao, 2005; Donoho, 2006). In all of these settings, the basic problem is to recover information about a high-dimensional signal $\beta^* \in \mathbb{R}^p$, based on a set of n observations. The signal β^* is assumed *a priori* to be sparse: either exactly k-sparse, or lying within some ℓ_q-ball with $q < 1$.

A particular instance of high-dimensional sparse recovery involves the linear regression model $Y = X\beta^* + W$, where $Y \in \mathbb{R}^n$ is the observation vector, $W \in \mathbb{R}^n$ is observation noise, and $X \in \mathbb{R}^{n \times p}$ is the measurement matrix. In this context, high-dimensional scaling means that the sample size n can be of the same order of magnitude, or substantially smaller than the ambient dimension p. A particularly simple version of this model, studied extensively within the compressed sensing com-

*. Also in the Department of Statistics.

munity (Candes and Tao, 2005; Donoho, 2006), is the *noiseless version* in which $W = 0$, so that the model reduces to the under-determined linear system $Y = X\beta^*$. Here the model is only interesting when $n \ll p$, so that the linear system is not fully determined. Other work in machine learning and statistics (e.g., Meinshausen and Buhlmann, 2006; Zhao and Yu, 2006; Wainwright, 2009; Zhou et al., 2007) has focused on the noisy version of the model, say with $W \sim N(0, \sigma^2 I_p)$ for some noise variance σ^2. The problem of high-dimensional regression can be studied either for deterministic designs, for which the measurement matrix X is fixed, or for random designs in which X is drawn randomly from some ensemble. Past work on random designs has focused on the behavior of various ℓ_1-relaxations when applied to measurement matrices drawn from the standard Gaussian ensemble (e.g., Donoho, 2006; Candes and Tao, 2005), or more general random ensembles satisfying mutual incoherence conditions (Meinshausen and Buhlmann, 2006; Wainwright, 2009). A measurement matrix X drawn from such a standard random ensemble is dense, in that each row of X has p non-zero entries with high probability. In various applications of the sparse regression problem, the measurement matrix is itself a design variable, and dense measurement matrices are undesirable. For instance, in applications such as sensor networks (Wang et al., 2007), digital imaging (Wakin et al., 2006) or database management (Achlioptas, 2001; Li et al., 2006), it would be preferable to take measurements of the signal β^* based on sparse inner products, using measurement matrices X in which each row has a relatively small fraction of non-zero entries. Furthermore, sparse measurement matrices require significantly less storage space, and have the potential for reduced algorithmic complexity for signal recovery, since many algorithms for linear programming and conic programming more generally (Boyd and Vandenberghe, 2004), can be accelerated by exploiting problem structure.

In the noiseless instance of the regression problem (with $n \ll p$), the standard approach to estimating β^* is by solving the basis pursuit linear program (Chen et al., 1998). Recent work by Baraniuk et al. (2007) has established connections between the success of this method and the behavior of random projections, as characterized by the Johnson-Lindenstrauss lemma (Johnson and Lindenstrauss, 1984; Dasgupta and Gupta, 2003). Random projections and their applications have been studied extensively in machine learning and related fields, with applications to dimensionality reduction (Dasgupta, 1999; Li et al., 2007), data stream processing (Alon et al., 1996; Indyk, 2006), databases (Achlioptas, 2001; Li et al., 2006) and compressed sensing (Wang et al., 2007; Baraniuk et al., 2007). One standard proof of the Johnson-Lindenstrauss lemma is based on random Gaussian matrices. Achlioptas (2001) was the first to apply sparse random projections, with each entry distributed on $\{-1, 0, 1\}$ with probabilities $[\frac{1}{6}, \frac{2}{3}, \frac{1}{6}]$, to the Johnson-Lindenstrauss problem setting, and to provide the same guarantees as dense projections. Unfortunately, his proof technique does not allow the non-zero mass to be decreased much beyond $\frac{1}{3}$. Other recent work (Li et al., 2006) provides theoretical and experimental justification for scaling the non-zero mass aggressively to zero. Stemming from different sources than the random projection literature, another line of recent work (e.g., Cormode and Muthukrishnan, 2005; Gilbert et al., 2006; Sarvotham et al., 2006; Xu and Hassibi, 2007) has studied compressed sensing methods based on sparse measurement matrices, using constructions motivated by group testing and coding theory.

Whereas this past work focuses on the noiseless recovery problem, our primary interest in this paper is the noisy linear observation model which, as we show, exhibits qualitatively different behavior than the noiseless case. At a high level, our primary goal in this paper is not to design sparse measurement matrices, but rather to gain a theoretical understanding of the *trade-off between the*

degree of measurement sparsity, and statistical efficiency. We assess measurement sparsity in terms of the fraction γ of non-zero entries in any particular row of the measurement matrix, and we define statistical efficiency in terms of the minimal number of measurements n required to recover the correct support with probability converging to one. Our interest can be viewed in terms of experimental design: more precisely we ask, what degree of measurement sparsity can be permitted without increasing the number of observations required for correct variable selection or subset recovery?

To bring sharp focus to the issue, we analyze this question for exact subset recovery using ℓ_1-constrained quadratic programming, also known as the Lasso in the statistics literature (Chen et al., 1998; Tibshirani, 1996), where past work on dense Gaussian measurement ensembles (Wainwright, 2009) provides a precise characterization of its success/failure. We characterize the density of our measurement ensembles with a positive parameter $\gamma \in (0,1]$, corresponding to the fraction of non-zero entries per row. We first show that for all fixed $\gamma \in (0,1]$, the statistical efficiency of the Lasso remains the same as with dense measurement matrices. We then prove that it is possible to let $\gamma \to 0$ at some rate, as a function of the sample size n, signal length p and signal sparsity k, yielding measurement matrices with a vanishing fraction of non-zeroes per row while requiring exactly the same number of observations as dense measurement ensembles. In general, in contrast to the noiseless setting (Xu and Hassibi, 2007), our theory still requires that the average number of non-zeroes per column of the measurement matrix (i.e., γn) tend to infinity, however, under the loss function considered here (exact signed support recovery), we prove that no method can succeed with probability one if this condition does not hold.

The remainder of this paper is organized as follows. In Section 2, we set up the problem more precisely, state our main result, and discuss some of its implications. In Section 3, we provide a high-level outline of the proof with more technical aspects of the argument deferred to the appendices. We provide some illustrative simulations in Section 4 that illustrate the sharpness of our theoretical predictions. Work in this paper was presented in part at the International Symposium on Information Theory in Toronto, Canada (July, 2008). We note that concurrent and complementary work (Wang et al., 2010) analyzes the information-theoretic limitations of sparse measurement matrices for exact support recovery.

1.1 Notation

Throughout this paper, we use the following standard asymptotic notation: $f(n) = O(g(n))$ if $f(n) \leq Cg(n)$ for some constant $C < +\infty$; $f(n) = \Omega(g(n))$ if $f(n) \geq cg(n)$ for some constant $c > 0$; and $f(n) = \Theta(g(n))$ if $f(n) = O(g(n))$ and $f(n) = \Omega(g(n))$. In addition, we use $\log(x)$ to denote the natural logarithm of x.

2. Problem Set-up and Main Result

We begin by setting up the problem, stating our main result, and discussing some of its consequences.

2.1 Observation Model

Define the *support set* of a signal $\beta \in \mathbb{R}^p$

$$S(\beta) \quad := \quad \{i \in \{1,\ldots,p\} \mid \beta_i \neq 0\},$$

and consider the class of k-sparse signals of length p:

$$\mathcal{C}(p,k,\beta^*_{\min}) \quad := \quad \left\{\beta \in \mathbb{R}^p \mid |S(\beta)| = k \leq \frac{p}{2}, \min_{i \in S} |\beta_i| \geq \beta^*_{\min}\right\}. \tag{1}$$

Let $\beta^* \in \mathbb{R}^p$ be a fixed but unknown vector in $\mathcal{C}(p,k,\beta^*_{\min})$, and suppose that we make a set $\{Y_1,\ldots,Y_n\}$ of n independent and identically distributed (i.i.d.) observations of the unknown vector β^*, each of the form

$$Y_i \quad := \quad x_i^T \beta^* + W_i, \tag{2}$$

where $W_i \sim \mathcal{N}(0,1)$ is observation noise, and $x_i \in \mathbb{R}^p$ is a measurement vector. Note that there is no loss in generality in assuming that the noise variance is one, since the observation model with signal class $\mathcal{C}(p,k,\beta^*_{\min})$ and $W_i \sim \mathcal{N}(0,1)$ is equivalent to the observation model with signal class $\mathcal{C}(p,k,\frac{\beta^*_{\min}}{\sigma})$ with noise variance $W_i \sim \mathcal{N}(0,\sigma^2)$.

It is convenient to use $Y = \begin{bmatrix} Y_1 & Y_2 & \ldots & Y_n \end{bmatrix}^T$ to denote the n-vector of measurements, with similar notation for the noise vector $W \in \mathbb{R}^n$, and

$$X \quad = \quad \begin{bmatrix} x_1^T \\ x_2^T \\ \vdots \\ x_n^T \end{bmatrix} \quad = \quad \begin{bmatrix} X_1 & X_2 & \ldots & X_p \end{bmatrix}.$$

to denote the $n \times p$ measurement matrix. With this notation, the observation model can be written compactly as $Y = X\beta^* + W$.

2.2 Sign Consistency and Statistical Efficiency

Given some estimate $\widehat{\beta}$, its error relative to the true β^* can be assessed in various ways, depending on the underlying application of interest. For applications in compressed sensing, various types of ℓ_r norms (i.e., $\mathbb{E}\|\widehat{\beta} - \beta^*\|_r^r$) are well-motivated, whereas for statistical prediction, it is most natural to study a predictive loss (e.g., $\|X(\widehat{\beta} - \beta^*)\|_2^2/n$). For reasons of scientific interpretation or for model selection purposes, the object of primary interest is the support S of β^*. In this paper, we consider a slightly stronger notion of model selection: in particular, our goal is to recover the *signed support* of the unknown β^*, as defined by the p-vector $S_+(\beta^*)$ with elements

$$[S_+(\beta^*)]_i \quad := \quad \begin{cases} \operatorname{sign}(\beta^*_i) & \text{if } \beta^*_i \neq 0 \\ 0 & \text{otherwise.} \end{cases}$$

Given some estimate $\widehat{\beta}$, we study the probability $\mathbb{P}[S_+(\widehat{\beta}) = S_+(\beta^*)]$ that it correctly specifies the signed support. In particular, a sequence of estimates $\widehat{\beta}_{n,p,k}$ is *sign consistent* if

$$\mathbb{P}[S_+(\widehat{\beta}_{n,p,k}) = S_+(\beta^*)] \to 1, \text{ as } n,p,k \to \infty. \tag{3}$$

The estimator that we analyze is ℓ_1-constrained quadratic programming (QP), also known as the Lasso (Tibshirani, 1996) in the statistics literature. The Lasso generates an estimate $\widehat{\beta}$ by solving the regularized QP

$$\widehat{\beta} \quad = \quad \arg\min_{\beta \in \mathbb{R}^p} \left\{ \frac{1}{2n}\|Y - X\beta\|_2^2 + \rho_n \|\beta\|_1 \right\}, \tag{4}$$

where $\rho_n > 0$ is a user-defined regularization parameter. A large body of past work has focused on the model selection behavior of the Lasso for both deterministic and random measurement matrices (e.g., Tropp, 2006; Zhao and Yu, 2006; Wainwright, 2009).

Tropp (2006) demonstrates that under some technical conditions the Lasso produces an estimate with support contained in the true support set, while Zhao and Yu (2006) prove the sign consistency of the Lasso for certain sequences (n, k_n, p_n) and measurement ensemble covariances. The main contribution of Wainwright (2009) is to identify the smallest n required for sign consistency of the Lasso when applied to measurement matrices X drawn randomly from Gaussian ensembles, with the standard Gaussian ensemble (i.e., each element $X_{ij} \sim \mathcal{N}(0,1)$ i.i.d.) being one special case. Define the function $n_{crit}(p,k) := 2k\log(p-k)$. The paper (Wainwright, 2009) shows the Lasso undergoes a phase transition as a function of the control parameter

$$\theta(n,p,k) \quad := \quad \frac{n}{n_{crit}(p,k)}. \tag{5}$$

In more detail, for the special case of the standard Gaussian ensemble, for any sequence (n,p,k) such that $\theta(n,p,k) > 1+\varepsilon$ for some $\varepsilon > 0$, the Lasso (with an appropriate choice of regularization parameter ρ_n) is sign consistent with probability converging to one. In contrast, it fails to be sign consistent with high probability, regardless of the choice of ρ_n, for any sequences such that $\theta(n,p,k) < 1-\varepsilon$.

The main contribution of this paper is to show that sparse measurement ensembles are *statistically efficient*: the same sharp threshold (5) holds for γ-sparsified measurement ensembles, including a subset for which $\gamma \to 0$, so that each row of the measurement matrix has a vanishing fraction of non-zero entries.

2.3 Statement of Main Result

A measurement matrix $X \in \mathbb{R}^{n\times p}$ drawn randomly from a Gaussian ensemble is dense, in that each row has $\Theta(p)$ non-zero entries. The main focus of this paper is the observation model (2), using measurement ensembles that are designed to be sparse. To formalize the notion of sparsity, we let $\gamma \in (0,1]$ represent a *measurement sparsity parameter*, corresponding to the (average) fraction of non-zero entries per row. Our analysis allows the sparsity parameter $\gamma(n,p,k)$ to be a function of the triple (n,p,k), but we typically suppress this explicit dependence so as to simplify notation. For a given choice of γ, we consider measurement matrices X with i.i.d. entries of the form

$$X_{ij} \quad \stackrel{d}{=} \quad \begin{cases} Z \sim \mathcal{N}(0,1) & \text{with probability } \gamma \\ 0 & \text{with probability } 1-\gamma. \end{cases} \tag{6}$$

By construction, the expected number of non-zero entries in each row of X is γp. In fact, the analysis of this paper establishes exactly the same control parameter threshold (5) for γ-sparsified measurement ensembles, for any fixed $\gamma \in (0,1)$, as the completely dense case ($\gamma = 1$). In particular, we state the following result on conditions under which the Lasso applied to sparsified ensembles has the same *sample complexity* as when applied to the dense (standard Gaussian) ensemble:

Theorem 1 *Suppose that the measurement matrix $X \in \mathbb{R}^{n\times p}$ is drawn with i.i.d. entries according to the γ-sparsified distribution* (6)*. Then for any $\varepsilon > 0$, if the sample size satisfies*

$$n \quad > \quad (2+\varepsilon)k\log(p-k), \tag{7}$$

then the Lasso is sign consistent as $(n,p,k) \to +\infty$ so long as

$$\frac{n\rho_n^2\gamma}{\log(p-k)} \quad \to \quad \infty, \tag{8}$$

$$\frac{\rho_n}{\beta^*_{\min}} \max\Big\{1, \frac{\sqrt{k}}{\gamma}\sqrt{\frac{\log\log(p-k)}{\log(p-k)}}\Big\} \quad \to \quad 0, \tag{9}$$

$$\gamma^3 \min\Big\{k, \frac{\log(p-k)}{\log\log(p-k)}\Big\} \quad \to \quad \infty. \tag{10}$$

Remark 2 *(a) Note that the sample complexity* (7) *is identical to the Lasso threshold proven in past work (Wainwright, 2009). To gain intuition on the remaining conditions, it is helpful to consider various special cases of the sparsity parameter γ. If γ is a constant fixed to some value in $(0,1]$, then it plays no role in the scaling, and condition* (10) *is always satisfied. Conditions* (8) *and* (9) *are slightly weaker than the corresponding condition from previous work, in that they require that ρ_n be slightly larger, and hence that $\beta^*_{\min}$ must approach zero more slowly than the requirement of this previous work. Depending on the exact behavior of $\beta^*_{\min}$, choosing ρ_n^2 to decay slightly more slowly than $\log p/n$ is sufficient to guarantee exact recovery with $n = \Theta(k\log(p-k))$, meaning that we recover exactly the same statistical efficiency as the dense case ($\gamma = 1$) for all constant measurement sparsities $\gamma \in (0,1)$. At least initially, one might think that reducing γ should increase the required number of observations, since it effectively reduces the signal-to-noise ratio by a factor of γ. However, under high-dimensional scaling ($p \to +\infty$), a major effect limiting the Lasso performance is the number $(p-k)$ of irrelevant factors, and under the scaling considered here, this effect is dominant.*

(b) However, Theorem 1 also allows for general scalings of the measurement sparsity γ along with the triplet (n,p,k). More concretely, let us suppose for simplicity that $\beta^*_{\min} = \Theta(1)$. Then over a range of signal sparsities—say $k = \alpha p$, $k = \Theta(\sqrt{p})$ or $k = \Theta(\log(p-k))$, corresponding respectively to linear sparsity, polynomial sparsity, and exponential sparsity—we can choose a decaying measurement sparsity, for instance

$$\gamma \quad = \quad \Big[\frac{\log\log(p-k)}{\log(p-k)}\Big]^{\frac{1}{6}} \to 0 \tag{11}$$

along with the regularization parameter $\rho_n^2 = \frac{\log(p-k)}{n}\sqrt{\frac{\log(p-k)}{\log\log(p-k)}}$ while maintaining the same sample complexity (required number of observations for support recovery) as the Lasso with dense measurement matrices.

(c) Of course, the conditions of Theorem 1 do not allow the measurement sparsity γ to approach zero arbitrarily quickly. Rather, for any γ guaranteeing exact recovery, condition (8) *implies that the average number of non-zero entries per column of X (namely, γn) must tend to infinity. (Indeed, with $n = \Omega(k\log(p-k))$, our specific choice* (11) *certainly satisfies this constraint.) A natural question is whether exact recovery is possible using measurement matrices, either randomly drawn or deterministically designed, with the average number of non-zeros per column (namely γn) remaining bounded. In fact, under the criterion of exactly recovering the signed support* (3)*, as shown by the following result, if $\beta^*_{\min} = O(1)$, then no method can succeed with probability converging to one unless γn tends to infinity.*

Proposition 1 *If $\gamma n[\beta^*_{\min}]^2$ does not tend to infinity, then no method can recover the signed support with probability one.*

Proof We construct a sub-problem that must be solvable by any method capable of performing exact signed support recovery. Suppose that $\beta^*_1 = \beta^*_{\min} \neq 0$ and that the column X_1 has n_1 non-zero entries, say without loss of generality indices $i = 1, \ldots, n_1$. Now consider the problem of recovering the sign of β^*_1. Let us extract the observations $i = 1, \ldots, n_1$ that explicitly involve β^*_1, writing

$$Y_i \quad = \quad X_{i1}\beta^*_1 + \sum_{j \in T(i)} X_{ij}\beta^*_j + W_i, \qquad i = 1, \ldots, n_1 \tag{12}$$

where $T(i)$ denotes the set of indices in row i for which X_{ij} is non-zero, excluding index 1. Even assuming that $\{\beta^*_j, j \in T(i)\}$ were perfectly known, this observation model (12) is at best equivalent to observing β^*_1 contaminated by constant variance additive Gaussian noise, and our task is to distinguish whether $\beta^*_1 = \beta^*_{\min}$ or $\beta^*_1 = -\beta^*_{\min}$. The average $\bar{Y} = \frac{1}{n_1}\sum_{i=1}^{n_1}[Y_i - \sum_{j \in T(i)} X_{ij}\beta^*_j]$ is a sufficient statistic, following the distribution $\bar{Y} \sim \mathcal{N}(\beta^*_{\min}, \frac{1}{n_1})$. Unless the effective signal-to-noise ratio, which is of the order $n_1[\beta^*_{\min}]^2$, goes to infinity, there will always be a constant probability of error in distinguishing $\beta^*_1 = \beta^*_{\min}$ from $\beta^*_1 = -\beta^*_{\min}$. Under the γ-sparsified random ensemble, we have $n_1 \leq (1 + o(1))\gamma n$ with high probability, so that no method can succeed unless $\gamma n[\beta^*_{\min}]^2$ goes to infinity, as claimed. ■

Note that the conditions in Theorem 1 imply that $n\gamma[\beta^*_{\min}]^2 \to +\infty$. In particular, condition (9) implies that $\rho^2_n = o([\beta^*_{\min}]^2)$, and condition (8) implies that $n\gamma\rho^2_n \to +\infty$, which verifies the condition of Proposition 1.

3. Proof of Theorem 1

This section is devoted to the proof of Theorem 1. We begin with a high-level outline of the proof; as with previous work on dense Gaussian ensembles (Wainwright, 2009), the key is the notion of a *primal-dual witness* for exact signed support recovery. The proof itself involves a number of additional steps not needed in this past work, in order to gain good control on sparse matrices as opposed to generic Gaussian matrices (see Appendix D). The proof is divided into a sequence of separate lemmas, with some of the more technical results deferred to the appendices.

3.1 High-level Overview of Proof

For the purposes of our proof, it is convenient to consider matrices $X \in \mathbb{R}^{n \times p}$ with i.i.d. entries of the form

$$X_{ij} \quad \stackrel{d}{=} \quad \begin{cases} Z \sim \mathcal{N}(0, \frac{1}{\gamma}) & \text{with probability } \gamma \\ 0 & \text{with probability } 1 - \gamma. \end{cases}$$

So as to obtain an equivalent observation model, we also reset the variance of each noise term W_i to be $\frac{1}{\gamma}$. Finally, we can assume without loss of generality that $S_+(\beta^*_S) = \vec{1} \in \mathbb{R}^k$.

Define the *sample covariance matrix*

$$\widehat{\Sigma} \quad := \quad \frac{1}{n}X^T X \; = \; \frac{1}{n}\sum_{i=1}^{n} x_i x_i^T.$$

Of particular importance to our analysis is the $k \times k$ sub-matrix $\widehat{\Sigma}_{SS}$. For future reference, we state the following claim, proved in Appendix D:

Lemma 1 *Under the conditions of Theorem 1, the submatrix $\widehat{\Sigma}_{SS}$ is invertible with probability greater than $1 - O(\frac{1}{(p-k)^2})$.*

The foundation of our proof is the following lemma: it provides sufficient conditions for the Lasso (4) to recover the signed support set.

Lemma 2 (Primal-dual conditions for support recovery) *Suppose that $\widehat{\Sigma}_{SS} \succ 0$, and that we can find a primal vector $\widehat{\beta} \in \mathbb{R}^p$, and a subgradient vector $\widehat{z} \in \mathbb{R}^p$ that satisfy the* zero-subgradient condition

$$\widehat{\Sigma}\big(\widehat{\beta} - \beta^*\big) - \frac{1}{n} X^T W + \rho_n \widehat{z} \;\; = \;\; 0, \tag{13}$$

and the signed-support-recovery conditions

$$\widehat{z}_i \;\; = \;\; \mathrm{sign}(\beta^*_i) \qquad \textit{for all } i \in S, \tag{14}$$

$$\widehat{\beta}_j \;\; = \;\; 0 \qquad \textit{for all } j \in S^c, \tag{15}$$

$$|\widehat{z}_j| \;\; < \;\; 1 \qquad \textit{for all } j \in S^c, \textit{ and} \tag{16}$$

$$\mathrm{sign}(\widehat{\beta}_i) \;\; = \;\; \mathrm{sign}(\beta^*_i) \qquad \textit{for all } i \in S. \tag{17}$$

Then $\widehat{\beta}$ is the unique optimal solution to the Lasso (4)*, and recovers the correct signed support.*

See Appendix B.1 for the proof of this claim.

On the basis of Lemmas 1 and 2, it suffices to show that under the specified scaling of (n, p, k), there exists a primal-dual pair $(\widehat{\beta}, \widehat{z})$ satisfying the conditions of Lemma 2. We establish the existence of such a pair with the following constructive procedure:

(a) We begin by setting $\widehat{\beta}_{S^c} = 0$, and $\widehat{z}_S = \mathrm{sign}(\beta^*_S)$.

(b) Next we determine $\widehat{\beta}_S$ by solving the linear system

$$\widehat{\Sigma}_{SS}\big(\widehat{\beta}_S - \beta^*_S\big) - \frac{1}{n} X_S^T W + \rho_n \,\mathrm{sign}(\beta^*_S) \;\; = \;\; 0.$$

(c) Finally, we determine $\widehat{z}_{S^c}$ by solving the linear system:

$$-\rho_n \widehat{z}_{S^c} \;\; = \;\; \widehat{\Sigma}_{S^c S}\big(\widehat{\beta}_S - \beta^*_S\big) - \frac{1}{n} X_{S^c}^T W.$$

By construction, this procedure satisfies the zero sub-gradient condition (13), as well as auxiliary conditions (14) and (15); it remains to verify conditions (16) and (17).

In order to complete these final two steps, it is helpful to define for $i \in S$ and $j \in S^c$ the following random variables:

$$V_j^a \;\; := \;\; X_j{}^T \big[\frac{1}{n} X_S (\widehat{\Sigma}_{SS})^{-1} \vec{1}\big] \rho_n, \tag{18}$$

$$V_j^b \;\; := \;\; X_j{}^T \big[I_{n\times n} - \frac{1}{n} X_S (\widehat{\Sigma}_{SS})^{-1} X_S^T\big] \frac{W}{n}, \quad \text{and} \tag{19}$$

$$U_i \;\; := \;\; e_i^T \widehat{\Sigma}_{SS}^{-1} \big[\frac{1}{n} X_S^T W - \rho_n \vec{1}\big], \tag{20}$$

where $e_i \in \mathbb{R}^k$ is the unit vector with one in position i, and $\vec{1} \in \mathbb{R}^k$ is the all-ones vector.

A little bit of algebra (see Appendix B.2 for details) shows that $\rho_n \widehat{z}_j = V_j^a + V_j^b$, and that $U_i = \widehat{\beta}_i - \beta_i^*$. Consequently, if we define the events

$$\mathcal{E}(V) \quad := \quad \big\{ \max_{j \in S^c} |V_j^a + V_j^b| < \rho_n \big\}, \tag{21}$$

$$\mathcal{E}(U) \quad := \quad \big\{ \max_{i \in S} |U_i| \leq \beta^*_{\min} \big\}, \tag{22}$$

where $\beta^*_{\min}$ was defined previously as the minimum value of $|\beta^*|$ on its support, then in order to establish that the Lasso succeeds in recovering the exact signed support, it suffices to show that $\mathbb{P}[\mathcal{E}(V) \cap \mathcal{E}(U)] \to 1$,

We decompose the proof of this final claim in the following three lemmas. As in the statement of Theorem 1, suppose that $n > (2+\varepsilon) k \log(p-k)$, for some fixed $\varepsilon > 0$.

Lemma 3 (Control of V^a) *Under the conditions of Theorem 1, there exists a fixed positive value δ (dependent on ε) such that*

$$\mathbb{P}[\max_{j \in S^c} |V_j^a| \geq (1-\delta)\rho_n] \quad \to \quad 0.$$

Lemma 4 (Control of V^b) *Under the conditions of Theorem 1, there exists a fixed positive value δ (dependent on ε)*

$$\mathbb{P}[\max_{j \in S^c} |V_j^b| \geq \delta \rho_n] \quad \to \quad 0.$$

Lemma 5 (Control of U) *Under the conditions of Theorem 1, we have*

$$\mathbb{P}[(\mathcal{E}(U))^c] \; = \; \mathbb{P}[\max_{i \in S} |U_i| > \beta^*_{\min}] \quad \to \quad 0.$$

3.2 Proof of Lemma 3

We assume throughout that $\widehat{\Sigma}_{SS}$ is invertible, an event which occurs with probability $1 - o(1)$ under the stated assumptions (see Lemma 1). If we define the n-dimensional vector

$$h \quad := \quad X_S (\widehat{\Sigma}_{SS})^{-1} \vec{1}, \tag{23}$$

then the variable V_j^a can be written compactly as

$$\frac{V_j^a}{\rho_n} \; = \; X_j^T h = \sum_{\ell=1}^n h_\ell X_{\ell j}.$$

Note that each term $X_{\ell j}$ in this sum is distributed as a mixture variable, taking the value 0 with probability $1-\gamma$, and distributed as $\mathcal{N}(0, \frac{1}{\gamma})$ variable with probability γ. For $\ell = 1, \ldots, n$ and each j, define the random vector H^j, with entries

$$H_\ell^j \quad \stackrel{d}{=} \quad \begin{cases} h_\ell & \text{with probability } \gamma \\ 0 & \text{with probability } 1-\gamma. \end{cases}$$

For each index $\ell = 1, \ldots, n$, let $Z_{\ell j} \sim \mathcal{N}(0, \frac{1}{\gamma})$. With these definitions, by construction, we have that

$$\frac{V_j^a}{\rho_n} \stackrel{d}{=} \sum_{\ell=1}^n H_\ell^j Z_{\ell j}.$$

To gain some intuition for the behavior of this sum, note that the variables $\{Z_{\ell j}, \ell = 1, \ldots, n\}$ are independent of the vector H^j. (In particular, H^j is a function of X_S, whereas $Z_{\ell j}$ is a function of $X_{\ell j}$, with $j \notin S$.) Consequently, we may condition on H^j without affecting Z, and since Z is Gaussian, we have $(\frac{V_j^a}{\rho_n} \mid H^j) \sim \mathcal{N}(0, \frac{\|H^j\|_2^2}{\gamma})$. Therefore, if we can obtain good control on the norm $\|H^j\|_2$, then we can use standard Gaussian tail bounds (see Appendix A) to control the maximum $\max_{j \in S^c} V_j^a / \rho_n$. The following lemma is proved in Appendix C:

Lemma 6 *Under condition* (10)*, then for any fixed* $\delta > 0$*, we have*

$$\mathbb{P}\big[\|H^j\|_2^2 \leq \frac{\gamma k(1+\delta)}{n}\big] \geq 1 - O\big[\exp(-\min\{2\log(p-k), \frac{n}{2k}\})\big].$$

The primary implication of the above bound is that each V_j^a / ρ_n variable is (essentially) no larger than a $\mathcal{N}(0, \frac{k}{n})$ variable. We can then use standard techniques for bounding the tails of Gaussian variables to obtain good control over the random variable $\max_{j \in S^c} |V_j^a| / \rho_n$. In particular, by the union bound, we have

$$\mathbb{P}[\max_{j \in S^c} |V_j^a| \geq (1-\delta)\rho_n] \leq (p-k)\, \mathbb{P}[\sum_{\ell=1}^n H_\ell^j Z_{\ell j} \geq (1-\delta)].$$

For any $\delta > 0$, define the event $\mathcal{T}^j(\delta) := \{\|H^j\|_2^2 \leq \frac{k\gamma(1+\delta)}{n}\}$. With this definition, we have

$$\begin{aligned}
\mathbb{P}[\max_{j \in S^c} |V_j^a| \geq (1-\delta)\rho_n] &\leq (p-k)\left\{\mathbb{P}[\sum_{\ell=1}^n H_\ell^j Z_{\ell j} \geq (1-\delta) \mid \mathcal{T}^j(\delta)] + \mathbb{P}[(\mathcal{T}^j(\delta)^c)]\right\} \\
&\leq (p-k)\left\{2\exp(-\frac{n(1-\delta)^2}{2k(1+\delta)}) + c_1 \exp\big(-\min\big(2\log(p-k), \frac{n}{2k}\big)\big)\right\},
\end{aligned}$$

where the second inequality uses a standard Gaussian tail bound (see Appendix A), and Lemma 6. Finally, let us assume the condition $n > (2+\varepsilon)k\log(p-k)$ for some fixed $\varepsilon > 0$. Then there exists a numerical constant c_1 such that

$$\begin{aligned}
\mathbb{P}[\max_{j \in S^c} |V_j^a| \geq (1-\delta)\rho_n] &\leq (p-k)\left\{2\exp\big(-\frac{n(1-\delta)^2}{2k(1+\delta)}\big) + c_1 \exp(-\min\big(2\log(p-k), \frac{n}{2k}\big))\right\} \\
&= (p-k)\left\{2\exp\big(-\frac{n(1-\delta)^2}{2k(1+\delta)}\big) + c_1 \exp(-2\log(p-k))\right\} \\
&\leq (p-k)\left\{2\exp\big(-(2+\varepsilon)\log(p-k)\frac{(1-\delta)^2}{2(1+\delta)}\big)\right. \\
&+ \left. c_1 \exp(-2\log(p-k))\right\}.
\end{aligned}$$

Note that the above inequality holds for all values of ε. Since $\varepsilon > 0$ is fixed, we can choose a fixed value of δ such that $\frac{(1-\delta)^2}{1+\delta} > \frac{2}{2+\varepsilon/2}$. With this choice, we then have

$$\begin{aligned}
\mathbb{P}[\max_{j \in S^c} |V_j^a| \geq (1-\delta)\rho_n] &\leq (p-k)\left\{2\exp\big(-\frac{(2+\varepsilon)}{(2+\varepsilon/2)}\log(p-k)\big) + c_1 \exp(-2\log(p-k))\right\} \\
&\leq (p-k)\left\{(2+c_1)\exp\big(-\frac{(2+\varepsilon)}{(2+\varepsilon/2)}\log(p-k)\big)\right\},
\end{aligned}$$

thereby establishing that $\mathbb{P}[\max_{j\in S^c}|V_j^a| \geq (1-\delta)\rho_n] \to 0$, as claimed.

3.3 Proof of Lemma 4

Defining the orthogonal projection matrix $\Pi_S^{\perp} := I_{n\times n} - X_S(X_S^T X_S)^{-1}X_S^T$, we then have

$$\begin{aligned}\mathbb{P}[\max_{j\in S^c}|V_j^b| \geq \delta\rho_n] &= \mathbb{P}[\max_{j\in S^c}\big|X_j^T\Pi_S^{\perp}(\frac{W}{n})\big| \geq \delta\rho_n] \\ &\leq (p-k)\,\mathbb{P}\big[\big|X_j^T\Pi_S^{\perp}(\frac{W}{n})\big| \geq \delta\rho_n\big]. \end{aligned} \tag{24}$$

Now since $\Pi_S^{\perp}$ is an orthogonal projection matrix, and the column vector X_j, noise vector W and randomness in $\Pi_S^{\perp}$ are all independent, we have the bound

$$\mathbb{P}\big[\big|X_j^T\Pi_S^{\perp}(W/n)\big| \geq \delta\rho_n\big] \leq \mathbb{P}\big[\big|X_j^T(W/n)\big| \geq \delta\rho_n\big], \tag{25}$$

For each $\ell = 1,\ldots,n$ and $j = 1,\ldots,p$, let $B_{\ell j}$ be a Bernoulli variable with parameter γ, and let $Z_{\ell j} \sim \mathcal{N}(0,\frac{1}{\gamma})$. In terms of these random variables, we have the representation $X_{\ell j} = B_{\ell j}Z_{\ell j}$. Note moreover that the the sum $\sum_{\ell=1}^n B_{\ell j}$ is a binomial random variable, and define the event

$$\mathcal{T} := \big\{\frac{1}{n}\big|\sum_{\ell=1}^n B_{\ell j} - \gamma n\big| \leq \frac{1}{2\sqrt{k}}\big\}.$$

From the Hoeffding bound (see Lemma 7), we have $\mathbb{P}[\mathcal{T}^c] \leq 2\exp(-\frac{n}{2k})$. Using the representation $X_{\ell j} = B_{\ell j}Z_{\ell j}$ and conditioning on $\mathcal{T}$, we obtain

$$\begin{aligned}\mathbb{P}\big[\big|X_j^T W/n\big| \geq \delta\rho_n\big] &\leq \mathbb{P}\big[\big|\frac{1}{n}\sum_{\ell=1}^n B_{\ell j}Z_{\ell j}W_\ell\big| \geq \delta\rho_n \mid \mathcal{T}\big] + \mathbb{P}[\mathcal{T}^c] \\ &\leq \mathbb{P}\big[\big|\frac{1}{n}\sum_{\ell=1}^{n(\gamma+\frac{1}{2\sqrt{k}})} Z_{\ell j}W_\ell\big| \geq \delta\rho_n\big] + 2\exp(-\frac{n}{2k}),\end{aligned}$$

where we have assumed without loss of generality that the first $n(\gamma+\frac{1}{2\sqrt{k}})$ variables in the collection $\{B_{\ell j}\}_{\ell=1}^n$ are non-zero.

Conditioned on W, the random variable $M_j := \frac{1}{n}\sum_{\ell=1}^{n(\gamma+\frac{1}{2\sqrt{k}})} Z_{\ell j}W_\ell$ is zero-mean Gaussian with variance $\nu(W;\gamma) := \frac{1}{n^2\gamma}\sum_{\ell=1}^{n(\gamma+\frac{1}{2\sqrt{k}})} W_\ell^2$. For some $\delta_1 > 0$, define the event

$$\mathcal{T}_2(\delta_1) := \Big\{\nu(W;\gamma) \leq (1+\delta_1)\frac{1}{n\gamma^2}\,(\gamma+\frac{1}{2\sqrt{k}})\Big\}.$$

In order to bound the probability of this event, we begin by observing that since $W_\ell \sim N(0,1/\gamma)$, the variable $n^2\gamma^2\nu(W;\gamma)$ is chi-squared with $d = n(\gamma+\frac{1}{2\sqrt{k}})$ degrees of freedom. Consequently, using χ^2-tail bounds (see Appendix A), we have

$$\mathbb{P}[(\mathcal{T}_2(\delta_1))^c] \leq \exp\big(-n(\gamma+\frac{1}{2\sqrt{k}})\frac{3\delta_1^2}{16}\big).$$

Now, by conditioning on $\mathcal{T}_2(\delta_1)$ and its complement and using tail bounds on Gaussian variates (see Appendix A), we obtain

$$\begin{aligned}\mathbb{P}\big[\big|\frac{1}{n}\sum_{\ell=1}^{n(\gamma+\frac{1}{2\sqrt{k}})} Z_{\ell j}W_\ell\big| \geq \delta\rho_n\big] &\leq \mathbb{P}\big[\big|\frac{1}{n}\sum_{\ell=1}^{n(\gamma+\frac{1}{2\sqrt{k}})} Z_{\ell j}W_\ell\big| \geq \delta\rho_n \mid \mathcal{T}_2(\delta_1)\big] + \mathbb{P}[(\mathcal{T}_2(\delta_1))^c] \\ &\leq 2\exp\big(-\frac{n\gamma^2(\delta^2\rho_n^2)}{2(1+\delta_1)(\gamma+\frac{1}{2\sqrt{k}})}\big) + \\ &\qquad \exp\big(-n(\gamma+\frac{1}{2\sqrt{k}})\frac{3\delta_1^2}{16}\big). \end{aligned} \tag{26}$$

Finally, putting together the pieces from Equations (26), (25), and (24) we obtain that $\mathbb{P}[\max_{j\in S^c}|V_j^b| \geq \delta\rho_n]$ is upper bounded by

$$(p-k)\left\{2\exp(-\frac{n}{2k}) + 2\exp\big(-\frac{n\gamma^2(\delta^2\rho_n^2)}{2(1+\delta_1)(\gamma+\frac{1}{2\sqrt{k}})}\big) + \exp\big(-n(\gamma+\frac{1}{2\sqrt{k}})\frac{3\delta_1^2}{16}\big)\right\}. \tag{27}$$

The first term in Equation (27) goes to zero since $n > (2+\varepsilon)k\log(p-k)$. Condition (10) implies that $\gamma\sqrt{k} \to \infty$. In particular, this means that eventually $1 \leq 2\gamma\sqrt{k}$. Once this occurs, we have the inequality $\frac{\gamma^2}{\gamma+\frac{1}{2\sqrt{k}}} > \frac{\gamma}{2}$, and hence

$$\begin{aligned}(p-k)\exp\big(-\frac{n\gamma^2(\delta^2\rho_n^2)}{2(1+\delta_1)(\gamma+\frac{1}{2\sqrt{k}})}\big) &\leq (p-k)\exp\big(-\frac{n\gamma\delta^2\rho_n^2}{4(1+\delta_1)}\big) \\ &= (p-k)\exp\big(-\log(p-k)\frac{n\gamma\delta^2\rho_n^2}{4(1+\delta_1)\log(p-k)}\big).\end{aligned}$$

Recalling that the terms δ and δ_1 are fixed constants, condition (10) implies that eventually

$$(p-k)\exp\big(-\log(p-k)\frac{n\gamma\delta^2\rho_n^2}{4(1+\delta_1)\log(p-k)}\big) \leq (p-k)\exp\big(-3\log(p-k)\big),$$

showing that the middle term of Equation (27) goes to zero. Finally, using the condition $n \geq (2+\varepsilon)k\log(p-k)$, we obtain

$$\begin{aligned}(p-k)\exp\big(-n(\gamma+\frac{1}{2\sqrt{k}})\frac{3\delta_1^2}{16}\big) &\leq (p-k)\exp\big(-n(\frac{1}{2\sqrt{k}})\frac{3\delta_1^2}{16}\big) \\ &\leq (p-k)\exp\big(-\big[\frac{(2+\varepsilon)\sqrt{k}}{2}\big]\log(p-k)\frac{3\delta_1^2}{16}\big).\end{aligned}$$

This quantity tends to zero, because ε and δ_1 are fixed constants and $\sqrt{k}$ tends to infinity. We conclude that the last term in Equation (27) goes to zero, thereby concluding the proof.

3.4 Proof of Lemma 5

We first observe that conditioned on X_S, each U_i is Gaussian with mean and variance

$$\begin{aligned}m_i &:= \mathbb{E}[U_i \mid X_S] = e_i^T\big(\frac{1}{n}X_S^TX_S\big)^{-1}\big[-\rho_n\vec{1}\big], \quad \text{and} \\ \psi_i &:= \operatorname{var}[U_i \mid X_S] = \frac{1}{\gamma n}e_i^T\big(\frac{1}{n}X_S^TX_S\big)^{-1}e_i,\end{aligned}$$

respectively. Let us define the function

$$T(\gamma,k,p,\theta,t) \quad := \quad \frac{1}{\gamma}\sqrt{\max\big\{\frac{\log(t)}{\theta k\log(p-k)},\frac{\log[\theta\log(p-k)]}{\theta\log(p-k)}\big\}}, \tag{28}$$

as well as the the upper bounds

$$m^* := \rho_n(1+C\sqrt{k}T(\gamma,k,p,1,k)), \quad \text{and} \quad \psi^* := \frac{1}{\gamma n}(1+CT(\gamma,k,p,1,k)).$$

Now consider the event

$$\mathcal{T}(m^*,\psi^*) \quad := \quad \{\max_{i\in S}|m_i| \le m^* \text{ and } \max_{i\in S}|\psi_i| \le \psi^*\}.$$

Conditioning on $\mathcal{T}$ and its complement, we have

$$\begin{aligned}\mathbb{P}[(\mathcal{E}(U))^c] &= \mathbb{P}[\frac{1}{\beta^*_{\min}}\max_{i\in S}U_i| > 1] \\ &\le \mathbb{P}[\frac{1}{\beta^*_{\min}}\max_{i\in S}|U_i| > 1 \;\mid\; \mathcal{T}(m^*,\psi^*)] + \mathbb{P}[(\mathcal{T}(m^*,\psi^*))^c]. \end{aligned} \tag{29}$$

In order to upper bound $\mathbb{P}[(\mathcal{T}(m^*,\psi^*))^c]$, we first upper bound the terms $\mathbb{P}(|m_i| > m^*)$ and $\mathbb{P}(|\psi_i| > \psi^*)$, and then apply the union bound. Beginning with the mean, we have

$$\begin{aligned}|m_i| &:= \rho_n\big|e_i^T\big(\frac{1}{n}X_S^TX_S\big)^{-1}\vec{1}\big| \\ &= \rho_n\big|e_i^T\big[\big(\frac{1}{n}X_S^TX_S\big)^{-1} - I_{k,k}\big]\vec{1} + e_i^TI_{k,k}\vec{1}\big| \\ &\le \rho_n\big|e_i^T\big[\big(\frac{1}{n}X_S^TX_S\big)^{-1} - I_{k,k}\Big\}\vec{1}\big| + \rho_n.\end{aligned}$$

Our next step is to upper bound the operator norm of the matrix within curly braces, which we do by applying Lemma 10 from Section D, with the parameters $\theta = 1$ and $t = k$. We conclude there is an universal constant C such that $\|\|(\frac{1}{n}X_S^TX_S)^{-1} - I_{k,k}\|\|_2 \le CT(\gamma,k,p,1,k)$ with probability at least $1 - O(k^{-2})$. Consequently, if we define $m^* := \rho_n\big[\sqrt{k}CT(\gamma,k,p,1,k)\big] + \rho_n$, then we have the bound

$$\mathbb{P}\big[|m_i| \ge m^*\big] \quad = \quad O(1/k^2).$$

A similar argument can be used to bound each term ψ_i, thereby obtaining

$$\mathbb{P}[\big|\psi_i\big| > \psi^*] \quad = \quad O(k^{-2}).$$

Since there are k versions of each of m_i and ψ_i, the union bound implies that

$$\mathbb{P}[(\mathcal{T}(m^*,\psi^*))^c] \le 2kO(k^{-2}) = O(k^{-1}).$$

We now turn to the first term of Equation (29). Letting $Y_i \sim \mathcal{N}(0,\psi_i)$, and using $\mathcal{T}$ as shorthand for the event $\mathcal{T}(m^*,\psi^*)$, we have

$$\begin{aligned}
\mathbb{P}[\frac{1}{\beta^*_{\min}}\max_{i\in S}|U_i| > 1 \mid \mathcal{T}] &= \mathbb{E}\big\{\mathbb{P}\big[\max_{i\in S}|U_i| > \beta^*_{\min} \mid X_S, \mathcal{T}\big]\big\} \\
&\leq \mathbb{E}\big\{\mathbb{P}\big[\max_{i\in S}\big(|m_i|+|Y_i|\big) > \beta^*_{\min} \mid X_S, \mathcal{T}\big]\big\} \\
&\leq \mathbb{E}\big\{\mathbb{P}\big[m^* + \max_{i\in S}|Y_i| > \beta^*_{\min} \mid X_S, \mathcal{T}\big]\big\} \\
&= \mathbb{E}\big\{\mathbb{P}\big[\frac{1}{\beta^*_{\min}}\max_{i\in S}|Y_i| > 1 - \frac{m^*}{\beta^*_{\min}} \mid X_S, \mathcal{T}\big]\big\}.
\end{aligned}$$

For sufficiently large p and k, we have

$$\begin{aligned}
T(\gamma,k,p,1,k) &= \frac{1}{\gamma}\sqrt{\max\big\{\frac{\log(k)}{k\log(p-k)}, \frac{\log[\log(p-k)]}{\log(p-k)}\big\}} \\
&\leq \frac{1}{\gamma}\sqrt{\big\{\frac{\log[\log(p-k)]}{\log(p-k)}\big\}},
\end{aligned}$$

using the facts that $\frac{\log(k)}{k} \to 0$ and $\log[\log(p-k)] \to \infty$, so that the maximum is dominated by the second term. As a result, applying condition (9) yields that $\frac{m^*}{\beta^*_{\min}} \to 0$. Letting $Y^* \sim \mathcal{N}(0,\psi^*)$, we have

$$\begin{aligned}
\mathbb{E}\big\{\mathbb{P}\big[\frac{1}{\beta^*_{\min}}\max_{i\in S}|Y_i| > \frac{1}{2} \mid X_S, \mathcal{T}\big]\big\} &\leq \mathbb{E}\big\{k\,\mathbb{P}[|Y^*| \geq \frac{\beta^*_{\min}}{2} \mid X_S, \mathcal{T}\big]\big\} \\
&\leq 2k\,\exp\big(-\frac{[\beta^*_{\min}]^2}{8\psi^*}\big),
\end{aligned}$$

where the last inequality follows from Gaussian tail bounds (see Appendix A). It remains to verify that this final term converges to zero. Taking logarithms and ignoring constant terms, we have

$$\log(k)\big(1 - \frac{[\beta^*_{\min}]^2}{\log(k)\,8\psi^*}\big) = \log(k)\big(1 - \frac{[\beta^*_{\min}]^2\gamma n}{8\log(k)\,(1+CT(\gamma,k,p,1,k))}\big).$$

Our goal is to show that that this quantity diverges to $-\infty$. Condition (10) implies that

$$T(\gamma,k,p,1,k) = \frac{1}{\gamma}\sqrt{\max\big\{\frac{\log(k)}{k\log(p-k)}, \frac{\log\log(p-k)}{\log(p-k)}\big\}} \to 0.$$

Hence, it suffices to show that $\log k\,\big(1 - \frac{[\beta^*_{\min}]^2\gamma n}{16\log k}\big)$ diverges to $-\infty$. We have

$$\begin{aligned}
\log(k)\,\big(1 - \frac{[\beta^*_{\min}]^2\gamma n}{16\log(k)}\big) &= \log(k)\,(1 - \frac{[\beta^*_{\min}]^2}{\rho_n^2}\frac{\gamma n\rho_n^2}{16\log(k)}) \\
&= \log(k)\,(1 - \frac{[\beta^*_{\min}]^2}{\rho_n^2}\frac{\gamma n\rho_n^2}{16\log(p-k)}\frac{\log(p-k)}{\log(k)}).
\end{aligned}$$

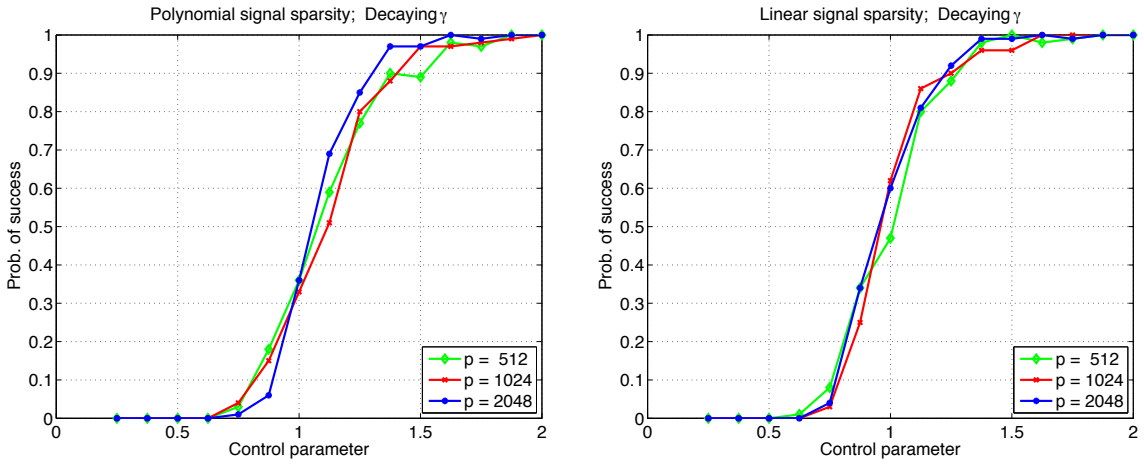
Condition (9) implies that $\frac{[\beta^*_{\min}]^2}{\rho_n^2} \to \infty$, whereas condition (8) ensures that $\frac{\gamma n\rho_n^2}{\log(p-k)} \to \infty$. The signal class $\mathcal{C}(p,k,\beta^*_{\min})$, as previously defined (1), ensures that $k \leq \frac{p}{2}$, so that the third term is greater than one. Putting together the pieces, we conclude that $\mathbb{P}[\mathcal{E}(U)^c]$ tends to zero.

4. Experimental Results

In this section, we provide some experimental results to illustrate the claims of Theorem 1. We consider two different sparsity regimes, namely linear sparsity ($k = \alpha p$) and polynomial sparsity ($k = \sqrt{p}$), and we show simulations in which the fraction γ of non-zero entries in each row of the measurement matrix X converges to zero. For all experiments, the additive noise standard deviation is set to $\sigma = 0.25$ and we fix the vector β^* by setting the first k entries are set to one, and the remaining entries to zero. There is no loss of generality in fixing the support in this way, since the ensemble of models is invariant under permutations.

Although it is possible to solve the Lasso using a variety of methods, our theory (in particular, Lemma 2) shows that it suffices to simulate the random variables $\{V_j^a, V_j^b, j \in S^c\}$ and $\{U_i, i \in S\}$, and then check the equivalent conditions (21) and (22). (These necessary and sufficient conditions give the same result for support recovery as solving the Lasso; however, they are much faster to simulate.) In all cases, we plot the success probability $\mathbb{P}[S(\widehat{\beta}) = S(\beta^*)]$ versus the *control parameter* $\theta(n,p,k) = \frac{n}{2k\log(p-k)}$. Note that Theorem 1 predicts that the Lasso should transition from failure to success at $\theta \approx 1$.

In Figure 1, the empirical success rate of the Lasso is plotted against the control parameter $\theta(n,p,k) = \frac{n}{2k\log(p-k)}$. Each panel shows three curves, corresponding to the problem sizes $p \in \{512, 1024, 2048\}$, and each point on the curve represents the average of 100 trials. For all trials shown, we set $\gamma = 0.5\frac{\log(p-k)}{\sqrt{p-k}}$, which converges to zero at a rate slightly faster than that guaranteed by Theorem 1. Nonetheless, we still observe the "stacking" behavior around the predicted threshold $\theta^* = 1$.



(a) (b)

Figure 1: Plots of the success probability $\mathbb{P}[\widehat{S} = S]$ versus the control parameter $\theta(n,p,k) = \frac{n}{k\log(p-k)}$ for γ-sparsified ensembles, with decaying measurement sparsity $\gamma = \frac{.5\log(p-k)}{\sqrt{p-k}}$. (a) Polynomial signal sparsity $k = O(\sqrt{p})$. (b) Linear signal sparsity $k = \Theta(p)$.

5. Discussion

In this paper, we have studied the problem of recovery the support set of a sparse vector β^* based on noisy observations. The main result is to show that it is possible to "sparsify" standard dense measurement matrices, so that they have a vanishing fraction of non-zeroes per row, while retaining the same sample complexity (number of observations n) required for exact recovery. We also showed that under the support recovery metric and in the presence of noise, no method can succeed without the number of non-zeroes per column tending to infinity, so that our results cannot be improved substantially. Thus, our results show that it is possible to use sparse measurement matrices while retaining the same guarantees regarding the recovery of the support. Note that our sparsification scheme is the simplest one, and requires no additional overhead to implement. Although this paper focused on sparsified Gaussian measurement matrices, it is possible to obtain qualitatively similar results for sparsified sub-Gaussian ensembles (for instance, the discrete uniform distribution on $\{-1,1\}$).

The approach taken in this paper is to find rates which γ (as a function of n, p, k) can safely tend towards zero while maintaining the same statistical efficiency as dense random matrices. In various practical settings (Wakin et al., 2006), it may be preferable to make the measurement ensembles even sparser at the cost of taking more measurements n, thereby decreasing statistical efficiency relative to dense random matrices. A natural question is the sample complexity $n(\gamma, p, k)$ in this regime as well. Finally, this work has focused only on a randomly sparsified matrices, as opposed to particular sparse designs (e.g., based on LDPC or expander-type constructions Feldman et al., 2007; Sarvotham et al., 2006; Xu and Hassibi, 2007). Although our results imply that exact support recovery with noisy observations is impossible with bounded degree designs, it would be interesting to examine the trade-off between other loss functions (e.g., ℓ_2 reconstruction error) and sparse measurement matrices.

Appendix A. Standard Concentration Results

In this appendix, we collect some tail bounds used repeatedly throughout this paper.

Lemma 7 (Hoeffding bound—Hoeffding, 1963) *Given a binomial variate $Z \sim \mathrm{Bin}(n,\gamma)$, we have for any $\delta > 0$*

$$\mathbb{P}[|Z - \gamma n| \geq \delta n] \quad \leq \quad 2\exp\big(-2n\delta^2\big).$$

Lemma 8 (χ^2-concentration—Johnstone, 2001) *Let $X \sim \chi^2_m$ be a chi-squared variate with m degrees of freedom. Then for all $\frac{1}{2} > \delta \geq 0$, we have*

$$\mathbb{P}[X - m \geq \delta m] \quad \leq \quad \exp\big(-\frac{3}{16}m\delta^2\big).$$

We will also find the following standard Gaussian tail bound (e.g., Ledoux and Talagrand, 1991) useful:

Lemma 9 (Gaussian tail behavior) *Let $V \sim \mathcal{N}(0,\sigma^2)$ be a zero-mean Gaussian with variance σ^2. Then for all $\delta > 0$, we have*

$$\mathbb{P}[|V| > \delta] \quad \leq \quad 2\,\exp\big(-\frac{\delta^2}{2\sigma^2}\big).$$

Appendix B. Convex Optimality Conditions

In this section we discuss the optimality conditions that the Lasso must satisfy and some implications that follow.

B.1 Proof of Lemma 2

Let $f(\beta) := \frac{1}{2n}\|Y - X\beta\|_2^2 + \rho_n\|\beta\|_1$ denote the objective function of the Lasso (4). By standard convex optimality conditions (Rockafellar, 1970), a vector $\widehat{\beta} \in \mathbb{R}^p$ is a solution to the Lasso if and only if $0 \in \mathbb{R}^p$ is an element of the subdifferential of $f(\beta)$ at $\widehat{\beta}$. These conditions lead to

$$\frac{1}{n}X^T(X\widehat{\beta} - Y) + \rho_n\widehat{z} \quad = \quad 0,$$

where the dual vector $\widehat{z} \in \mathbb{R}^p$ is an element of the subdifferential of the ℓ_1-norm, given by

$$\partial\|\widehat{\beta}\|_1 \quad = \quad \big\{z \in \mathbb{R}^p \;\mid\; z_i = \mathrm{sign}(\widehat{\beta}_i) \text{ if } \widehat{\beta}_i \neq 0, \qquad z_i \in [-1,1] \text{ otherwise}\big\}.$$

Now suppose that we are given a pair $(\widehat{\beta},\widehat{z}) \in \mathbb{R}^p \times \mathbb{R}^p$ that satisfy the assumptions of Lemma 2. Condition (13) is equivalent to $(\widehat{\beta},\widehat{z})$ satisfying the zero subgradient condition. Conditions (14), (16) and (17) ensure that $\widehat{z}$ is an element of the subdifferential of the ℓ_1-norm at $\widehat{\beta}$. Finally, conditions (15) and (17) ensure that $\widehat{\beta}$ correctly specifies the signed support.

It remains to verify that $\widehat{\beta}$ is the *unique* optimal solution. By Lagrangian duality, the Lasso problem (4) (given in penalized form) can be written as an equivalent constrained optimization problem over the ball $\|\beta\|_1 \leq C(\rho_n)$, for some constant $C(\rho_n) < +\infty$. Equivalently, we can express this single ℓ_1-constraint as a set of 2^p linear constraints $\vec{v}^T\beta \leq C$, one for each sign vector $\vec{v} \in \{-1,+1\}^p$. The vector $\widehat{z}$ can be written as a convex combination $\widehat{z} = \sum_{\vec{v}} \alpha^*_{\vec{v}}\vec{v}$, where the weights $\alpha^*_{\vec{v}}$ are non-negative and sum to one. By construction of $\widehat{\beta}$ and $\widehat{z}$, the weights α^* form an optimal Lagrange multiplier vector for the problem. Consequently, any other optimal solution—say $\widetilde{\beta}$—must also minimize the associated Lagrangian

$$L(\beta;\alpha^*) \quad = \quad f(\beta) + \sum_{\vec{v}} \alpha^*_{\vec{v}}\big[\vec{v}^T\beta - C\big],$$

and satisfy the complementary slackness conditions $\alpha^*_{\vec{v}}\big(\vec{v}^T\widetilde{\beta} - C\big) = 0$ for every $\vec{v}$.

Note that these complementary slackness conditions imply that $\widehat{z}^T\widetilde{\beta} = C$. But this can only happen if $\widetilde{\beta}_j = 0$ for all indices where $|\widehat{z}_j| < 1$. Therefore, any optimal solution $\widetilde{\beta}$ satisfies $\widetilde{\beta}_{S^c} = 0$. Finally, given that all optimal solutions satisfy $\beta_{S^c} = 0$, we may consider the restricted optimization problem subject to this set of constraints. If the Hessian submatrix $\widehat{\Sigma}_{SS}$ is strictly positive definite, then this sub-problem is strictly convex, so that $\widehat{\beta}$ must be the unique optimal solution, as claimed.

B.2 Derivation of $\{V_j^a, V_j^b, U_i\}$

In this appendix, we derive the form of the $\{V_j^a, V_j^b\}$ and $\{U_i\}$ variables defined in Equations (18) through (20). We begin by writing the zero sub-gradient condition in a block-form, and substituting the relations specified in conditions (14) and (15):

$$\begin{bmatrix} \widehat{\Sigma}_{SS} & \widehat{\Sigma}_{SS^c} \\ \widehat{\Sigma}_{S^cS} & \widehat{\Sigma}_{S^cS^c} \end{bmatrix} \begin{bmatrix} \widehat{\beta}_S - \beta_S^* \\ 0 \end{bmatrix} - \begin{bmatrix} \frac{1}{n} X_S^T W \\ \frac{1}{n} X_{S^c}^T W \end{bmatrix} + \rho_n \begin{bmatrix} \text{sign}(\beta_S^*) \\ \widehat{z}_{S^c} \end{bmatrix} \quad = \quad 0.$$

By solving the top block, we obtain

$$U := \widehat{\beta}_S - \beta_S^* \quad = \quad \widehat{\Sigma}_{SS}^{-1} \big\{ \frac{1}{n} X_S^T W - \rho_n \, \text{sign}(\beta_S^*) \big\}.$$

By back-substituting this relation into the lower block, we can solve explicitly for $\widehat{z}_{S^c}$; doing so yields that $\rho_n \widehat{z}_{S^c} = V^a + V^b$, where the $(p-k)$-vectors are defined in Equations (18) and (19).

Appendix C. Proof of Lemma 6

Let $Z \in \mathbb{R}^{n \times n}$ denote a $n \times n$ matrix, for which the off-diagonal elements $Z_{ij} = 0$ for all $i \neq j$, and the diagonal elements $Z_{ii} \sim \text{Ber}(\gamma)$ are i.i.d. With this notation, we can write $H \stackrel{d}{=} Zh$. Using the definition (23) of h, we have

$$\begin{aligned} \| H \|_2^2 &= \|Zh\|_2^2 \\ &= \|Z \frac{X_S}{n} (\widehat{\Sigma}_{SS})^{-1} \vec{1} \|_2^2 \\ &= \vec{1}^T (\widehat{\Sigma}_{SS})^{-1} (Z\frac{X_S}{n})^T (Z\frac{X_S}{n}) (\widehat{\Sigma}_{SS})^{-1} \vec{1} \\ &= \frac{\gamma}{n} \vec{1}^T (\widehat{\Sigma}_{SS})^{-1} \underbrace{\big\{ \frac{1}{\gamma n} \sum_{i=1}^n \mathbb{I}[Z_{ii} = 1] \, x_i x_i^T \big\}}_{\Gamma(Z)} (\widehat{\Sigma}_{SS})^{-1} \vec{1}, \end{aligned}$$

where x_i is the i^{th} row of the matrix X_S. We can apply Lemma 10 from Appendix D with parameters $\theta = 1$ and $t = (p-k)$ yielding

$$\mathbb{P}\big[|||\widehat{\Sigma}_{SS}^{-1}|||_2 \geq f_1(p,k,\gamma) \big] \quad \leq \quad O\big(\frac{1}{(p-k)^2}\big), \tag{30}$$

where $f_1(p,k,\gamma) := 1 + T(\gamma, k, p, 1, p-k)$, and the function $T(\gamma, k, p, \theta, t)$ was defined in Equation (28).

Next we control the spectral norm of the random matrix $\Gamma(Z)$, conditioned on the total number $\sum_{i=1}^n Z_{ii}$ of non-zero entries. In particular, applying Lemma 10 with $t = p-k$, and $\theta = \frac{z}{n}$, we have

$$\mathbb{P}\big[\| \Gamma(Z) \|_2 \geq \frac{z}{n\gamma} \big[1 + T(\gamma, k, p, \frac{z}{n}, p-k) \big] \; \big| \; \sum_{i=1}^n Z_{ii} = z \big] \quad \leq \quad \frac{1}{(p-k)^2}, \tag{31}$$

as long as $k\frac{z}{n} \to \infty$.

The next step is to deal with the conditioning. Define the event

$$\mathcal{T}(k,\gamma) \;:=\; \big\{Z \mid \gamma - \frac{1}{2\sqrt{k}} \leq \frac{1}{n}\sum_{i=1}^{n} Z_{ii} \leq \gamma + \frac{1}{2\sqrt{k}}\big\}.$$

We need to find an upper bound on $\|\Gamma(Z)\|_2$ that will hold with high probability for all Z that satisfy the above property. One function that suffices is

$$f_2(p,k,\gamma) \;:=\; \left(1+\frac{1}{2\sqrt{k}\gamma}\right)\left[1+C\Big(\frac{1}{\gamma}\sqrt{\max\left\{\frac{1}{k(\gamma-\frac{1}{2\sqrt{k}})}, \frac{\log[(\gamma+\frac{1}{2\sqrt{k}})\log(p-k)]}{(\gamma-\frac{1}{2\sqrt{k}})\log(p-k)}\right\}}\Big)\right].$$

We then have that

$$\begin{aligned}
\mathbb{P}[|||\Gamma(Z)|||_2 \geq f_2(p,k,\gamma)] &\leq \mathbb{P}[|||\Gamma(Z)|||_2 \geq f_2(p,k,\gamma) \mid \mathcal{T}(k,\gamma)] + \mathbb{P}[(\mathcal{T}(k,\gamma))^c] \\
&\leq \exp(-2\log(p-k)) + 2\exp(-\frac{n}{2k}) \\
&\leq 3\exp(-\min\{2\log(p-k), \frac{n}{2k}\}), \qquad (32)
\end{aligned}$$

where we have used the bound (31), and the Hoeffding bound (see Lemma 7).

Combining the bounds (30) and (32), we conclude that as long as $\gamma k \to \infty$, then:

$$\mathbb{P}\big[|||\widehat{\Sigma}^{-1}\Gamma(Z)\widehat{\Sigma}^{-1}|||_2 \geq f_1^2 f_2\big] \;\leq\; 4\exp(-\min\{2\log(p-k), \frac{n}{2k}\}).$$

Since $\|\vec{1}\|_2 = \sqrt{k}$, we have

$$\mathbb{P}[\|H\|_2^2 \geq \frac{\gamma k}{n} f_1^2 f_2] \;\leq\; 4\exp(-\min\{2\log(p-k), \frac{n}{2k}\}).$$

To conclude the proof, we must show that both $f_1(p,k,\gamma)$ and $f_2(p,k,\gamma)$ converge to 1 as (p,k,γ) scale. The term $f_1(p,k,\gamma) = 1 + T(\gamma,k,p,1,p-k)$ converges to one, since the quantity

$$T(\gamma,k,p,1,p-k) \;=\; \frac{1}{\gamma}\sqrt{\max\big\{\frac{1}{k}, \frac{\log[\log(p-k)]}{\log(p-k)}\big\}}$$

converges[1] to zero under assumption (10). Next, we need to demonstrate that $f_2(p,k,\gamma)$ converge to 1 as (p,k,γ) scale. Since assumption (10) ensures that $\gamma\sqrt{k} \to \infty$, it suffices to study the simpler function

$$f_3(p,k,\gamma) \;:=\; 1 + C\Big(\frac{1}{\gamma}\sqrt{\max\left\{\frac{1}{k\gamma}, \frac{\log[\gamma\log(p-k)]}{\gamma\log(p-k)}\right\}}\Big),$$

which has the same asymptotic behavior as $f_2(p,k,\gamma)$. Observe that $f_3(p,k,\gamma)$ satisfies the sandwich relation

$$1 \;\leq\; f_3(p,k,\gamma) \;\leq\; 1 + C\Big(\sqrt{\max\big\{\frac{1}{k\gamma^3}, \frac{\log[\log(p-k)]}{\gamma^3\log(p-k)}\big\}}\Big),$$

By assumption (10), this upper bound converges to one, showing that f_3 and hence f_2 converge to one, as desired. In particular, for any fixed $\delta > 0$, we have $f_1^2 f_2 < (1+\delta)$ for p,k sufficiently large, thereby completing the proof of Lemma 6.

1. In particular, the left-hand side of the expression (10) satisfies $\frac{\gamma}{[T(\gamma,k,p,1,p-k)]^2} \leq \frac{1}{[T(\gamma,k,p,1,p-k)]^2}$.

Appendix D. Singular Values of Sparsified Matrices

Let $\theta(p,k) \in (0,1]$ and $t(p,k) \in \{1,2,3,\ldots\}$ be functions. Let X be an $\theta n \times k$ random matrix with i.i.d. entries X_{ij} distributed according to the γ-sparsified ensemble (6). Recall the definition of the function $T(\gamma,k,p,\theta,t)$ defined in Equation (28), and let $t > 0$ be arbitrary.

Lemma 10 *Suppose that $n \geq (2+\nu)k\log(p-k)$ for some $\nu > 0$. If as k and $p-k \to \infty$, we have $T(\gamma,k,p,\theta,t) \longrightarrow 0$, then there are universal positive constants C_i such that*

$$\mathbb{P}\big[\sup_{\|u\|_2=1} \big|\frac{1}{\sqrt{\theta n}}\|Xu\|_2 - 1\big| \geq C_1 T(\gamma,k,p,\theta,t)\big] \;=\; O(\frac{1}{t^2}), \quad \textit{and} \tag{33}$$

$$\mathbb{P}\big[\big|\|(\frac{1}{\theta n}X^TX)^{-1} - I_{k\times k}\|_2 \geq C_2 T(\gamma,k,p,\theta,t)\big] \;=\; O(\frac{1}{t^2}). \tag{34}$$

Remark 3 *(a) Note that Equation* (33) *implies that the eigenvalues of the matrix $\frac{1}{\theta n}X^TX$ are contained in the interval $(1-C_1T(\gamma,k,p,\theta,t), 1+C_1T(\gamma,k,p,\theta,t))$. Since $T(\gamma,k,p,\theta,t) = o(1)$ by assumption, we can always find a constant C_2 such that the eigenvalues of the inverted matrix $(\frac{1}{\theta n}X^TX)^{-1}$ are contained in the interval $(1-C_2T(\gamma,k,p,\theta,t), 1+C_2T(\gamma,k,p,\theta,t))$. Consequently, Equation* (34) *is a consequence of the assumptions of Lemma 10 and Equation* (33).

(b) In addition, observe that Lemma 10 with $\theta = 1$ and $t = p-k$ implies that $\widehat{\Sigma} = \frac{1}{n}X_S^TX_S$ is invertible with probability greater than $1 - O(\frac{1}{(p-k)^2})$, there establishing Lemma 1. Other settings in which this lemma is applied are $(\theta,t) = (\gamma, p-k)$ and $(\theta,t) = (1,k)$.

The remainder of this section is devoted to the proof of Lemma 10.

D.1 Bounds on Expected Values

Let $X \in \mathbb{R}^{\theta n \times k}$ be a random matrix with i.i.d. entries from the γ-sparsified ensemble

$$X_{ij} \;\sim\; (1-\gamma)\delta_X(0) + \gamma\mathcal{N}(0,\frac{1}{\gamma}).$$

Note that $\mathbb{E}[X_{ij}] = 0$ and $\mathrm{var}(X_{ij}) = 1$ by construction.

We follow the proof technique outlined in the lecture notes (Vershynin, 2006). We first note the tail bound:

Lemma 11 *Let $Q_1,\ldots,Q_d$ be i.i.d. samples of the γ-sparsified Gaussian ensemble. Given any vector $a \in \mathbb{R}^d$ and $t > 0$, we have $\mathbb{P}[\sum_{i=1}^d a_iQ_i > t] \leq \exp\big(-\frac{\gamma t^2}{2\|a\|_2^2}\big)$.*

To establish this bound, note that each Y_i is dominated (stochastically) by the random variable $Z \sim \mathcal{N}(0,\frac{1}{\gamma})$. In particular, for any $\lambda > 0$ we have

$$\mathbb{M}_{Q_i}(\lambda) \;=\; \mathbb{E}[\exp(\lambda Q_i)] \;=\; (1-\gamma) + \gamma\mathbb{E}[\exp(\lambda Z)] \leq \exp(\lambda^2/2\gamma),$$

from which the claim follows by optimizing the Chernoff bound.

Now let us bound the maximum singular value $s_{\max}(X)$ of the random matrix X. Letting S^{d-1} denote the ℓ_2 unit ball in d dimensions, we begin with the variational representation

$$\begin{aligned} s_{\max}(X) &= \max_{u \in S^{k-1}} \|Xu\| \\ &= \max_{v \in S^{\theta n-1}} \max_{u \in S^{k-1}} v^T X u. \end{aligned}$$

For an arbitrary $\varepsilon \in (0,1)$, we can find ε-covers (in ℓ_2 norm) of $S^{\theta n-1}$ and S^{k-1} with $M_{\theta n}(\varepsilon) = (3/\varepsilon)^{\theta n}$ and $M_k(\varepsilon) = (3/\varepsilon)^k$ points respectively (Matousek, 2002). Denote these covers by $C_{\theta n}(\varepsilon)$ and $C_k(\varepsilon)$ respectively. A standard argument shows that for all $\varepsilon \in (0,1)$, we have

$$\|X\|_2 \leq \frac{1}{(1-\varepsilon)^2} \max_{u_\alpha \in C_k(\varepsilon)} \max_{v_\beta \in C_{\theta n}(\varepsilon)} v_\beta^T X u_\alpha.$$

Let us analyze the maximum on the RHS: for a fixed pair (u,v) in our covers, we have

$$u^T X v = \sum_{i=1}^{k} \sum_{j=1}^{\theta n} X_{ij} u_i v_j.$$

Let us apply Lemma 11 with $d = \theta n k$, and weights $a_{ij} = u_i v_j$. Note that we have

$$\|a\|_2^2 = \sum_{i,j} a_{ij}^2 = \sum_i u_i^2 (\sum_j v_j^2) = 1,$$

since each u and v are unit norm. Consequently, for any fixed u, v in the covers, we have

$$\mathbb{P}[u^T X v > t] \leq \exp\big(-\frac{\gamma t^2}{2}\big).$$

By the union bound, we have

$$\begin{aligned} \mathbb{P}\big[\max_{u_\alpha \in C_k(\varepsilon)} \max_{v_\beta \in C_{\theta n}(\varepsilon)} v_\beta^T X u_\alpha > t\big] &\leq M_k(\varepsilon) M_{\theta n}(\varepsilon) \exp\big(-\frac{\gamma t^2}{2}\big) \\ &\leq \exp\big((k+\theta n)\log(3/\varepsilon) - \frac{\gamma t^2}{2}\big). \end{aligned}$$

By choosing $\varepsilon = \frac{1}{2}$ and $t = \sqrt{\frac{4}{\gamma}(k+\theta n)\log 6}$, we can conclude that

$$s_{\max}(X)/\sqrt{\theta n} = \|X\|_2/\sqrt{\theta n} \leq C\sqrt{\frac{1}{\gamma}}\sqrt{1+\frac{k}{\theta n}},$$

with probability at least $1 - \exp(-(k+\theta n)\log 6)$. Note that

$$\frac{k}{\theta n} = O\big(\frac{1}{(2+\nu)\theta \log(p-k)}\big) \to 0,$$

since $\frac{\log[\theta\log(p-k)]}{\theta\log(p-k)} \to 0$, which implies that $\theta \log(p-k) \to \infty$.

Consequently, we can conclude that

$$\|X\|_2/\sqrt{\theta n} \leq O(1/\sqrt{\gamma}),$$

w.p. one as $\theta n, k \to \infty$. Although this bound is essentially correct for a $\mathcal{N}(0, \frac{1}{\gamma})$ ensemble with γ *fixed*, it is very crude for the sparsified case with $\gamma \to 0$, but will useful in obtaining tighter control on $s_{\max}(X)$ and $s_{\min}(X) := \min_{u \in S^{k-1}} \|Xu\|$ in the sequel.

D.2 Tightening the Bound

For a given $u \in S^{k-1}$, consider the random variable $\|Xu\|_2^2 := \sum_{i=1}^{\theta n}(Xu)_i^2$. We first claim that each variate $Z_i = (Xu)_i^2$ is subexponential, or more precisely:

Lemma 12 *For any $s > 0$, we have $\mathbb{P}[Z_i > s] \leq 2\exp\big(-\frac{\gamma s}{2}\big)$.*

Proof We can write $(Xu)_i = \sum_{j=1}^k X_{ij}u_j$ where $\|u\|_2 = 1$. Consequently, Lemma 11 implies that $\mathbb{P}[\sum_{j=1}^k X_{ij}u_j > \delta] \leq \exp(-\frac{\gamma\delta^2}{2})$. By symmetry, we have

$$\mathbb{P}[Z_i > s] = \mathbb{P}[|\sum_{j=1}^k X_{ij}u_j| > \sqrt{s}] \;\leq\; 2\exp(-\frac{\gamma s}{2}),$$

from which the claim follows. ■

Now consider the event

$$\big\{\big|\frac{\|Xu\|_2^2}{\theta n} - 1\big| > \delta\big\} \quad = \quad \big\{\big|\sum_{i=1}^{\theta n} Z_i - \mathbb{E}[\sum_{i=1}^{\theta n} Z_i]\big| > \delta\theta n\big\}.$$

Let us apply Theorem 1.4 from Vershynin (2000) with $a = 2$, $b = 8\theta n/\gamma^2$ and $d = 2/\gamma$. With these choices, we have $4b/d = 16\theta n/\gamma$, which grows at least linearly in θn. Consequently, for any $\delta > 0$ less than $16/\gamma$ (we will in fact take $\delta \to 0$), we have

$$\mathbb{P}\big[\big|\frac{\|Xu\|_2^2}{\theta n} - 1\big| > \delta\big] \quad \leq \quad 2\exp\big(-\frac{\delta^2(\theta n)^2}{256\theta n/\gamma^2}\big) \;=\; 2\exp\big(-\frac{\gamma^2\,\delta^2\theta n}{256}\big).$$

Now take an ε-cover of the k-dimensional ℓ_2 ball, say with $N(\varepsilon) \;=\; (3/\varepsilon)^k$ elements. By the union bound, we have

$$\mathbb{P}\big[\inf_{i=1,\ldots,N(\varepsilon)} \frac{\|Xu_i\|_2^2}{\theta n} < 1-\delta\big] \quad \leq \quad \exp\big(-\frac{\gamma^2\,\delta^2\theta n}{256} + k\log(3/\varepsilon)\big).$$

Now set

$$\delta = \frac{\sqrt{2}}{\gamma}\sqrt{\frac{256 f(k,p) k\log(3/\varepsilon)}{\theta n}},$$

where $f(k,p) \geq 1$ is a function to be specified. Doing so yields that the infimum is bounded by $1+\delta$ with probability $1-\exp(-kf(k,p)\log(3/\varepsilon))$. (Note that the choice of $f(k,p)$ influences the rate of convergence, hence its utility.)

For any element $u \in S^{k-1}$, we have some u_i in the cover, and moreover

$$\begin{aligned}\big|\|Xu\|^2 - \|Xu_i\|^2\big| \quad &= \quad \big|\big\{\|Xu\| - \|Xu_i\|\big\}\,\big\{\|Xu\| + \|Xu_i\|\big\}\big| \\ &\leq \quad \big|\big\{\|Xu\| - \|Xu_i\|\big\}\big|\,(2\|X\|) \\ &\leq \quad (\|X\|\,\|u-u_i\|)\;(2\|X\|) \;\leq\; 2\|X\|^2\varepsilon.\end{aligned}$$

From our earlier result, we know that $\|X\|^2 = O(\theta n/\gamma)$ with probability $1-\exp(\log 6(k+\theta n))$. Putting together the pieces, we have there is a universal constant $C_2 > 0$, independent of $((\theta n), k, \gamma)$, such that the bound

$$\frac{1}{\theta n} \inf_{u \in S^{k-1}} \|Xu\|^2 \;\geq\; 1-\delta - C_3\varepsilon/\gamma \;=\; 1 - \frac{2}{\gamma}\sqrt{\frac{32 f(k,p) k \log(3/\varepsilon)}{\theta n}} - \frac{C_2}{\gamma}\varepsilon,$$

holds with probability at least

$$1 - \exp(-k f(k,p)\log(3/\varepsilon)) - \exp(-\log 6(k+\theta n)). \tag{35}$$

Setting $\varepsilon = 3k/\theta n$ yields the bound

$$\frac{1}{\theta n} \inf_{u \in S^{k-1}} \|Xu\|^2 \;\geq\; 1 - \frac{C_3}{\gamma}\sqrt{f(k,p)\frac{k}{\theta n}\log(\frac{\theta n}{k})},$$

where we have used the fact that $\frac{k}{\theta n} = o\big(\sqrt{f(k,p)\frac{k}{\theta n}\log(\frac{\theta n}{k})}\big)$. To understand how to choose the function $f(k,p)$, let us consider the rate of convergence (35). To establish the claim (33), we need rates fast enough to dominate a $2\log(t)$ term in the exponent, which guides our choice of $f(k,p)$. Recall that we are seeking to prove a scaling of the form $n = \Theta(k\log(p-k))$, so that this requirement (with $\varepsilon = 3k/\theta n = \frac{3}{\theta\log(p-k)}$) is equivalent to the quantity

$$k f(k,p)\log(3/\varepsilon) - 2\log(t) \;=\; k f(k,p)\log[\theta\log(p-k)] - 2\log(t) \tag{36}$$

tending to infinity.

D.2.1 CASE 1

If $k > \frac{\log(t)}{\log[\theta\log(p-k)]}$, then we may set $f(k,p) = 4$. With this choice, the condition (36) is satisfied, and we have

$$f(k,p)\frac{k}{\theta n}\log(\frac{\theta n}{k}) \;=\; 4\frac{\log[\theta\log(p-k)]}{\theta\log(p-k)} \;\to\; 0,$$

where we have used the assumption that $T(\gamma,k,p,\theta,t) = o(1)$.

D.2.2 CASE 2

Otherwise, if $k \leq \frac{\log(t)}{\log\theta\log(p-k)}$, then we may set

$$f(k,p) = 4\frac{\log(t)}{k\log\theta\log(p-k)} \geq 4,$$

so that condition (36) is satisfied, and we have

$$f(k,p)\frac{k}{\theta n}\log(\frac{\theta n}{k}) \;\leq\; 4\frac{\log(t)}{k\log\theta\log(p-k)}\frac{1}{\theta\log(p-k)}\log\theta\log(p-k) \;=\; \frac{4}{k}\frac{\log t}{\theta\log(p-k)} \to 0,$$

where we have again used the assumption $T(\gamma,k,p,\theta,t) = o(1)$ from Lemma 10.

Recalling the definition of $T(\gamma,k,p,\theta,t)$ from Equation (28), we can summarize both cases cleanly as

$$\mathbb{P}\left[\frac{1}{\theta n}\inf_{u\in S^{k-1}}\|Xu\|^2 \leq 1-CT(\gamma,k,p,\theta,t)\right] \quad = \quad O(1/t^2).$$

For (p,k) sufficiently large, we have $CT(\gamma,k,p,\theta,t)<1$, so that we can take square roots. Using the expansion $\sqrt{1+x}=1+\frac{x}{2}+o(x)$ for x small, we conclude that

$$\frac{1}{\sqrt{\theta n}}\inf_{u\in S^{k-1}}\|Xu\| \quad \geq \quad 1-\frac{C}{2}T(\gamma,k,p,\theta,t)-o(T(\gamma,k,p,\theta,t)),$$

with probability greater than $1-O(1/t^2)$. For (k,p) sufficiently large, the second term is smaller than $\frac{C}{4}T(\gamma,k,p,\theta,t)$, so that we conclude that

$$\mathbb{P}\left[\frac{1}{\sqrt{\theta n}}\inf_{u\in S^{k-1}}\|Xu\| \geq 1-\frac{3C}{4}T(\gamma,k,p,\theta,t)\right] \quad \geq \quad 1-O(1/t^2)$$

for (k,p) sufficiently large.

This same process can be repeated to bound the maximum singular value, yielding the bound

$$\mathbb{P}\left[\frac{1}{\sqrt{\theta n}}\sup_{u\in S^{k-1}}\|Xu\| \leq 1+\frac{3C}{4}T(\gamma,k,p,\theta,t)\right] \quad \geq \quad 1-O(1/t^2)$$

for (k,p) sufficiently large. Combining these two bounds yields the claim of Lemma 10.

Abstract

We study losses for binary classification and class probability estimation and extend the understanding of them from margin losses to general composite losses which are the composition of a proper loss with a link function. We characterise when margin losses can be proper composite losses, explicitly show how to determine a symmetric loss in full from half of one of its partial losses, introduce an intrinsic parametrisation of composite binary losses and give a complete characterisation of the relationship between proper losses and "classification calibrated" losses. We also consider the question of the "best" surrogate binary loss. We introduce a precise notion of "best" and show there exist situations where two convex surrogate losses are incommensurable. We provide a complete explicit characterisation of the convexity of composite binary losses in terms of the link function and the weight function associated with the proper loss which make up the composite loss. This characterisation suggests new ways of "surrogate tuning" as well as providing an explicit characterisation of when Bregman divergences on the unit interval are convex in their second argument. Finally, in an appendix we present some new algorithm-independent results on the relationship between properness, convexity and robustness to misclassification noise for binary losses and show that all convex proper losses are non-robust to misclassification noise.

Keywords: surrogate loss, convexity, probability estimation, classification, Fisher consistency, classification-calibrated, regret bound, proper scoring rule, Bregman divergence, robustness, misclassification noise

1. Introduction

A *loss* function is the means by which a learning algorithm's performance is judged. A *binary* loss function is a loss for a supervised prediction problem where there are two possible labels associated with the examples. A *composite* loss is the composition of a proper loss (defined below) and a link function (also defined below). In this paper we study composite binary losses and develop a number of new characterisation results. Several of these results can be seen as an extension of the work by Buja et al. (2005) applied to an analysis of composite losses by Masnadi-Shirazi and Vasconcelos (2009).

Informally, proper losses are well-calibrated losses for class probability estimation, that is for the problem of not only predicting a binary classification label, but providing an estimate of the probability that an example will have a positive label. Link functions are often used to map the outputs of a predictor to the interval $[0,1]$ so that they can be interpreted as probabilities. Having such

*. Also at National ICT Australia.

probabilities is often important in applications, and there has been considerable interest in understanding how to get accurate probability estimates (Platt, 2000; Gneiting and Raftery, 2007; Cohen and Goldszmidt, 2004) and understanding the implications of requiring loss functions provide good probability estimates (Bartlett and Tewari, 2007).

Much previous work in the machine learning literature has focussed on *margin losses* which intrinsically treat positive and negative classes symmetrically. However it is now well understood how important it is to be able to deal with the non-symmetric case (Zellner, 1986; Elkan, 2001; Provost and Fawcett, 2001; Buja et al., 2005; Bach et al., 2006; Beygelzimer et al., 2008; Christoffersen and Diebold, 2009). A key goal of the present work is to consider composite losses in the general (non-symmetric) situation. Since our development is for completely general losses, we automatically cover non-symmetric losses. The generalised notion of classification calibration developed in §5 is intrinsically non-symmetric.

1.1 Overview and Contributions

We now provide an overview of the paper's structure, highlighting the novel contributions and how they relate to existing work. Central to this work are the notions of a loss and its associated conditional and full risk. These are introduced and briefly discussed in §2.

In §3 we introduce losses for Class Probability Estimation (CPE), define some technical properties of them, and present some structural results originally by Shuford et al. (1966) and Savage (1971) and recently studied in a machine learning context by Buja et al. (2005) and Masnadi-Shirazi and Vasconcelos (2009). The most important of these are Theorem 4 which gives a representation of proper losses in terms of its associated conditional Bayes risk function, and Theorem 1 which relates a proper loss's partial losses to its "weight function"—the negative second derivative of the conditional Bayes risk (see Corollary 3). We use these to provide a novel characterisation of proper symmetric CPE losses. Specifically, Theorem 9 shows these losses are completely determined by the behaviour of one of its partial losses on half the unit interval.

Learning algorithms often make real-valued predictions that are not directly interpretable as probability estimates but require a link function which maps their output to the interval $[0,1]$. In §4 we define composite losses as the composition of a CPE loss and a link. The new contributions of this section are Theorem 10 which generalises Theorem 1 to composite losses, and Corollaries 12 and 14 which shows how requiring properness completely determines the link function for composite and margin losses. We also introduce a natural and intrinsic parametrisation of proper composite losses that is a generalisation of the weight function and show how it can be used to easily derive gradients for stochastic descent algorithms.

In §5 we generalise the notion of classification calibrated losses (as studied, for example, by Bartlett et al., 2006) so it applies to non-symmetric composite losses (i.e., not just margin losses) and provide a characterisation of it in Theorem 17. We also describe how this new notion of classification calibrated relates to proper CPE and composite losses via its connection with the weight function.

The main results of this paper are found in §6: Theorems 24 and 29 characterise when proper composite losses are convex. These characterisation are in terms of some easily testable constraints relating the losses' weight and link functions. The results also characterise when a Bregman divergence on $[0,1]$ is convex in its second argument (§6.3).

In §7 we study how the above insights can be applied to the problem of choosing a surrogate loss. Here, a *surrogate* loss function is a loss function which is not exactly what one wishes to minimise but is easier to work with algorithmically. This is still a relatively new area of research and our aim here is to open up a discussion rather than have the final word. To do so we define a well founded notion of "best" surrogate loss and show that some convex surrogate losses are incommensurable on some problems. We also consider some other notions of "best" and explicitly determine the surrogate loss that has the best surrogate regret bound in a certain sense.

Finally, in §8 we draw some more general conclusions. In particular, we argue that the weight and link function parametrisation of losses provides a convenient way to work with an entire class of losses that are central to probability estimation and may provide new ways of approaching the problem of "surrogate tuning" (Nock and Nielsen, 2009b).

Appendix C collects several observations which build upon some of the results in the main paper but are digressions from its central themes. In it, we present some new algorithm-independent results on the relationship between properness, convexity and robustness to misclassification noise for binary losses and show that all convex proper losses are non-robust to misclassification noise.

2. Losses and Risks

We write $x \wedge y := \min(x, y)$ and $[\![p]\!] = 1$ if p is true and $[\![p]\!] = 0$ otherwise.[1] The generalised function $\delta(\cdot)$ is defined by $\int_a^b \delta(x) f(x) dx = f(0)$ when f is continuous at 0 and $a < 0 < b$. Random variables are written in sans-serif font: X, Y.

Given a set of labels $\mathcal{Y} := \{-1, 1\}$ and a set of prediction values $\mathcal{V}$ we will say a *loss* is any function[2] $\ell : \mathcal{Y} \times \mathcal{V} \to [0, \infty)$. We interpret such a loss as giving a penalty $\ell(y, v)$ when predicting the value v when an observed label is y. We can always write an arbitrary loss in terms of its *partial losses* $\ell_1 := \ell(1, \cdot)$ and $\ell_{-1} := \ell(-1, \cdot)$ using

$$\ell(y, v) = [\![y = 1]\!] \ell_1(v) + [\![y = -1]\!] \ell_{-1}(v).$$

Our definition of a loss function covers all commonly used *margin losses* (i.e., those which can be expressed as $\ell(y, v) = \phi(yv)$ for some function $\phi : \mathbb{R} \to [0, \infty)$) such as the *0-1 loss* $\ell(y, v) = [\![yv < 0]\!]$, the *hinge loss* $\ell(y, v) = \max(1 - yv, 0)$, the *logistic loss* $\ell(y, v) = \log(1 + e^{yv})$, and the *exponential loss* $\ell(y, v) = e^{-yv}$ commonly used in boosting. It also covers *class probability estimation losses* where the predicted values $\hat{\eta} \in \mathcal{V} = [0, 1]$ are directly interpreted as probability estimates.[3] We will use $\hat{\eta}$ instead of v as an argument to indicate losses for class probability estimation and use the shorthand *CPE losses* to distinguish them from general losses. For example, *square loss* has partial losses $\ell_{-1}(\hat{\eta}) = \hat{\eta}^2$ and $\ell_1(\hat{\eta}) = (1 - \hat{\eta})^2$, the *log loss* $\ell_{-1}(\hat{\eta}) = \log(1 - \hat{\eta})$ and $\ell_1(\hat{\eta}) = \log(\hat{\eta})$, and the family of *cost-weighted misclassification losses* parametrised by $c \in (0, 1)$ is given by

$$\ell_c(-1, \hat{\eta}) = c [\![\hat{\eta} \geq c]\!] \text{ and } \ell_c(1, \hat{\eta}) = (1 - c) [\![\hat{\eta} < c]\!]. \tag{1}$$

1. This is the Iverson bracket notation as recommended by Knuth (1992).
2. Restricting the output of a loss to $[0, \infty)$ is equivalent to assuming the loss has a lower bound and then translating its output.
3. These are known as *scoring rules* in the statistical literature (Gneiting and Raftery, 2007).

2.1 Conditional and Full Risks

Suppose we have random examples X with associated labels $\mathsf{Y} \in \{-1,1\}$ The joint distribution of (X,Y) is denoted $\mathbb{P}$ and the marginal distribution of X is denoted M. Let the observation conditional density $\eta(x) := \Pr(\mathsf{Y}=1|\mathsf{X}=x)$. Thus one can specify an experiment by either $\mathbb{P}$ or (η, M).

If $\eta \in [0,1]$ is the probability of observing the label $y=1$ the *point-wise risk* (or *conditional risk*) of the estimate $v \in \mathcal{V}$ is defined as the η-average of the point-wise loss for v:

$$L(\eta, v) := \mathbb{E}_{\mathsf{Y}\sim\eta}[\ell(\mathsf{Y}, v)] = \eta\ell_1(v) + (1-\eta)\ell_{-1}(v).$$

Here, $\mathsf{Y} \sim \eta$ is a shorthand for labels being drawn from a Bernoulli distribution with parameter η. When $\eta : \mathcal{X} \to [0,1]$ is an observation-conditional density, taking the M-average of the point-wise risk gives the *(full) risk* of the estimator v, now interpreted as a function $v : \mathcal{X} \to \mathcal{V}$:

$$\mathbb{L}(\eta, v, M) := \mathbb{E}_{\mathsf{X}\sim M}[L(\eta(\mathsf{X}), v(\mathsf{X}))].$$

We sometimes write $\mathbb{L}(v, \mathbb{P})$ for $\mathbb{L}(\eta, v, M)$ where (η, M) corresponds to the joint distribution $\mathbb{P}$. We write ℓ, L and $\mathbb{L}$ for the loss, point-wise and full risk throughout this paper. The *Bayes risk* is the minimal achievable value of the risk and is denoted

$$\underline{\mathbb{L}}(\eta, M) := \inf_{v \in \mathcal{V}^{\mathcal{X}}} \mathbb{L}(\eta, v, M) = \mathbb{E}_{\mathsf{X}\sim M}\left[\underline{L}(\eta(\mathsf{X}))\right],$$

where

$$[0,1] \ni \eta \mapsto \underline{L}(\eta) := \inf_{v \in \mathcal{V}} L(\eta, v)$$

is the *point-wise* or *conditional Bayes risk*.

There has been increasing awareness of the importance of the conditional Bayes risk curve $\underline{L}(\eta)$—also known as "generalized entropy" (Grünwald and Dawid, 2004)—in the analysis of losses for probability estimation (Kalnishkan et al., 2004, 2007; Abernethy et al., 2009; Masnadi-Shirazi and Vasconcelos, 2009). Below we will see how it is effectively the curvature of $\underline{L}$ that determines much of the structure of these losses.

3. Losses for Class Probability Estimation

We begin by considering CPE losses, that is, functions $\ell : \{-1,1\} \times [0,1] \to [0,\infty)$ and briefly summarise a number of important existing structural results for *proper losses*—a large, natural class of losses for class probability estimation.

3.1 Proper, Fair, Definite and Regular Losses

There are a few properties of losses for probability estimation that we will require. If $\hat{\eta}$ is to be interpreted as an estimate of the true positive class probability η (i.e., when $y=1$) then it is desirable to require that $L(\eta, \hat{\eta})$ be minimised by $\hat{\eta} = \eta$ for all $\eta \in [0,1]$. Losses that satisfy this constraint are said to be *Fisher consistent* and are known as *proper losses* (Buja et al., 2005; Gneiting and Raftery, 2007). That is, a proper loss ℓ satisfies $\underline{L}(\eta) = L(\eta, \eta)$ for all $\eta \in [0,1]$. A *strictly proper* loss is a proper loss for which the minimiser of $L(\eta, \hat{\eta})$ over $\hat{\eta}$ is unique.

We will say a loss is *fair* whenever

$$\ell_{-1}(0) = \ell_1(1) = 0.$$

That is, there is no loss incurred for perfect prediction. The main place fairness is relied upon is in the integral representation of Theorem 6 where it is used to get rid of some constants of integration. In order to explicitly construct losses from their associated "weight functions" as shown in Theorem 7, we will require that the loss be *definite*, that is, its point-wise Bayes risk for deterministic events (i.e., $\eta = 0$ or $\eta = 1$) must be bounded from below:

$$\underline{L}(0) > -\infty \ , \ \underline{L}(1) > -\infty.$$

Since properness of a loss ensures $\underline{L}(\eta) = L(\eta, \eta)$ we see that a fair proper loss is necessarily definite since $L(0,0) = \ell_{-1}(0) = 0 > -\infty$, and similarly for $L(1,1)$. Conversely, if a proper loss is definite then the finite values $\ell_{-1}(0)$ and $\ell_1(1)$ can be subtracted from $\ell_{-1}(\cdot)$ and $\ell_1(\cdot)$ to make it fair.

Finally, for Theorem 4 to hold at the endpoints of the unit interval, we require a loss to be *regular*;[4] that is,

$$\lim_{\eta \searrow 0} \eta \ell_1(\eta) = \lim_{\eta \nearrow 1} (1-\eta)\ell_{-1}(\eta) = 0.$$

Intuitively, this condition ensures that making mistakes on events that never happen should not incur a penalty. In most of the situations we consider in the remainder of this paper will involve losses which are proper, fair, definite and regular.

3.2 The Structure of Proper Losses

A key result in the study of proper losses is originally due to Shuford et al. (1966) and Staël von Holstein (1970) (confer Aczel and Pfanzagl, 1967) though our presentation follows that of Buja et al. (2005). The following theorem[5] characterises proper losses for probability estimation via a constraint on the relationship between its partial losses.

Theorem 1 (Shuford *et al.*) *Suppose $\ell : \{-1,1\} \times [0,1] \to \mathbb{R}$ is a loss and that its partial losses ℓ_1 and ℓ_{-1} are both differentiable. Then ℓ is a proper loss if and only if for all $\hat{\eta} \in (0,1)$*

$$\frac{-\ell_1'(\hat{\eta})}{1-\hat{\eta}} = \frac{\ell_{-1}'(\hat{\eta})}{\hat{\eta}} = w(\hat{\eta}) \tag{2}$$

for some weight function $w : (0,1) \to \mathbb{R}^+$ *such that $\int_\varepsilon^{1-\varepsilon} w(c)\,dc < \infty$ for all $\varepsilon > 0$.*

The equalities in (2) should be interpreted in the distributional sense.

This simple characterisation of the structure of proper losses has a number of interesting implications. Observe from (2) that if ℓ is proper, given ℓ_1 we can determine ℓ_{-1} or vice versa. Also, the partial derivative of the conditional risk can be seen to be the product of a linear term and the weight function:

Corollary 2 *If ℓ is a differentiable proper loss then for all $\eta \in [0,1]$*

$$\frac{\partial}{\partial \hat{\eta}} L(\eta, \hat{\eta}) = (1-\eta)\ell_{-1}'(\hat{\eta}) + \eta \ell_1'(\hat{\eta}) = (\hat{\eta} - \eta) w(\hat{\eta}). \tag{3}$$

Another corollary, observed by Buja et al. (2005), is that the weight function is related to the curvature of the conditional Bayes risk $\underline{L}$.

4. This is equivalent to the conditions of Savage (1971) and Schervish (1989).
5. This is a restatement of Theorem 1 in Shuford et al. (1966).

Corollary 3 *Let ℓ be a a twice differentiable*[6] *proper loss with weight function w defined as in Equation (2). Then for all $c \in (0,1)$ its conditional Bayes risk $\underline{L}$ satisfies*

$$w(c) = -\underline{L}''(c).$$

One immediate consequence of this corollary is that the conditional Bayes risk for a proper loss is always concave. Along with an extra constraint, this gives another characterisation of proper losses (Savage, 1971; Reid and Williamson, 2009a).

Theorem 4 (Savage) *A loss function ℓ is proper if and only if its point-wise Bayes risk $\underline{L}(\eta)$ is concave and for each $\eta, \hat{\eta} \in (0,1)$*

$$L(\eta, \hat{\eta}) = \underline{L}(\hat{\eta}) + (\eta - \hat{\eta})\underline{L}'(\hat{\eta}).$$

Furthermore if ℓ is regular this characterisation also holds at the endpoints $\eta, \hat{\eta} \in \{0,1\}$.

This link between loss and concave functions makes it easy to establish a connection, as Buja et al. (2005) do, between *regret* $\Delta L(\eta, \hat{\eta}) := L(\eta, \hat{\eta}) - \underline{L}(\eta)$ for proper losses and *Bregman divergences*. The latter are generalisations of distances and are defined in terms of convex functions. Specifically, if $f : \mathcal{S} \to \mathbb{R}$ is a convex function over some convex set $\mathcal{S} \subseteq \mathbb{R}^n$ then its associated Bregman divergence[7] is

$$D_f(s, s_0) := f(s) - f(s_0) - \langle s - s_0, \nabla f(s_0) \rangle$$

for any $s, s_0 \in \mathcal{S}$, where $\nabla f(s_0)$ is the gradient of f at s_0. By noting that over $\mathcal{S} = [0,1]$ we have $\nabla f = f'$, these definitions lead immediately to the following corollary of Theorem 4.

Corollary 5 *If ℓ is a proper loss then its regret is the Bregman divergence associated with $f = -\underline{L}$. That is,*

$$\Delta L(\eta, \hat{\eta}) = D_{-\underline{L}}(\eta, \hat{\eta}).$$

Many of the above results can be observed graphically by plotting the conditional risk for a proper loss as in Figure 1. Here we see the two partial losses on the left and right sides of the figure are related, for each fixed $\hat{\eta}$, by the linear map $\eta \mapsto L(\eta, \hat{\eta}) = (1-\eta)\ell_{-1}(\hat{\eta}) + \eta\ell_1(\hat{\eta})$. For each fixed η the properness of ℓ requires that these convex combinations of the partial losses (each slice parallel to the left and right faces) are minimised when $\hat{\eta} = \eta$. Thus, the lines joining the partial losses are tangent to the conditional Bayes risk curve $\eta \mapsto \underline{L}(\eta) = L(\eta, \eta)$ shown above the dotted diagonal. Since the conditional Bayes risk curve is the lower envelope of these tangents it is necessarily concave. The coupling of the partial losses via the tangents to the conditional Bayes risk curve demonstrates why much of the structure of proper losses is determined by the curvature of $\underline{L}$—that is, by the weight function w.

The relationship between a proper loss and its associated weight function is captured succinctly by Schervish (1989) via the following representation of proper losses as a weighted integral of the cost-weighted misclassification losses ℓ_c defined in (1). The reader is referred to Reid and Williamson (2009b) for the details, proof and the history of this result.

6. The restriction to differentiable losses can be removed in most cases if generalised weight functions—that is, possibly infinite but defining a measure on $(0,1)$—are permitted. For example, the weight function for the 0-1 loss is $w(c) = \delta(c - \frac{1}{2})$.

7. A concise summary of Bregman divergences and their properties is given by Banerjee et al. (2005, Appendix A).

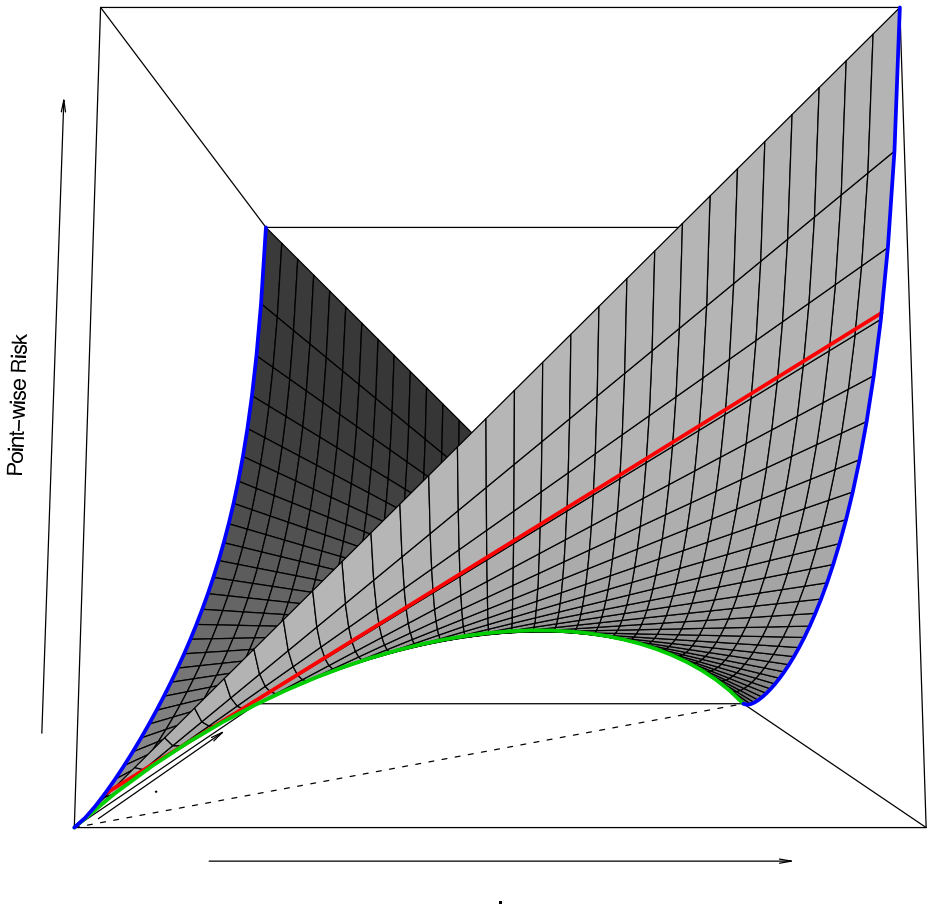

Figure 1: The structure of the conditional risk $L(\eta,\hat{\eta})$ for a proper loss (surface). The loss is log loss and its partials $\ell_{-1}(\hat{\eta}) = -\log(\hat{\eta})$ and $\ell_1(\hat{\eta}) = -\log(1-\hat{\eta})$ shown on the left and right faces of the box. The conditional Bayes risk is the curve on the surface above the dotted line $\hat{\eta} = \eta$. The line connecting points on the partial loss curves shows the conditional risk for a fixed prediction $\hat{\eta}$.

Theorem 6 (Schervish) *Let $\ell : \mathcal{Y} \times [0,1] \to \mathbb{R}$ be a fair, proper loss. Then for each $\hat{\eta} \in (0,1)$ and $y \in \mathcal{Y}$*

$$\ell(y,\hat{\eta}) = \int_0^1 \ell_c(y,\hat{\eta})\, w(c)\, dc, \tag{4}$$

where $w = -\underline{L}''$. Conversely, if ℓ is defined by (4) for some weight function $w : (0,1) \to [0,\infty)$ then it is proper.

Some example losses and their associated weight functions are given in Table 1. Buja et al. (2005) show that ℓ is strictly proper if and only if $w(c) > 0$ in the sense that w has non-zero mass on every open subset of $(0,1)$. The following theorem from Reid and Williamson (2009a) shows how to explicitly construct a loss in terms of a weight function.

$w(c)$	$\ell_{-1}(\hat{\eta})$	$\ell_1(\hat{\eta})$	Loss
$2\delta\left(\frac{1}{2}-c\right)$	$[\![\hat{\eta} > \frac{1}{2}]\!]$	$[\![\hat{\eta} \leq \frac{1}{2}]\!]$	0-1
$\delta(c-c_0)$	$c_0[\![\hat{\eta} \geq c_0]\!]$	$(1-c_0)[\![\hat{\eta} < c_0]\!]$	$\ell_{c_0}, c_0 \in [0,1]$
$\frac{1}{(1-c)^2 c}$	$\left[2\ln(1-\hat{\eta}) + \frac{\hat{\eta}}{1-\hat{\eta}}\right]$	$\left[\ln\frac{1-\hat{\eta}}{\hat{\eta}} - 1\right]$	—
1	$\hat{\eta}^2/2$	$(1-\hat{\eta})^2/2$	Square
$\frac{1}{(1-c)c}$	$-\ln(1-\hat{\eta})$	$-\ln(\hat{\eta})$	Log
$\frac{1}{(1-c)^2 c^2}$	$\left[\ln((1-\hat{\eta})\hat{\eta}) - \frac{1-2\hat{\eta}}{\hat{\eta}}\right]$	$\left[\ln((1-\hat{\eta})\hat{\eta}) + \frac{1-2\hat{\eta}}{\hat{\eta}}\right]$	—
$\frac{1}{[(1-c)c]^{3/2}}$	$2\sqrt{\frac{\hat{\eta}}{1-\hat{\eta}}}$	$2\sqrt{\frac{1-\hat{\eta}}{\hat{\eta}}}$	Boosting

Table 1: Weight functions and associated partial losses.

Theorem 7 (Reid and Williamson) *Given a weight function $w : [0,1] \to [0,\infty)$, let $W(t) = \int^t w(c)\,dc$ and $\overline{W}(t) = \int^t W(c)\,dc$. Then the loss ℓ_w defined by*

$$\ell_w(y,\hat{\eta}) = -\overline{W}(\hat{\eta}) - (y-\hat{\eta})W(\hat{\eta})$$

is a proper loss. Additionally, if $\overline{W}(0)$ and $\overline{W}(1)$ are both finite then

$$\ell_w(y,\hat{\eta}) + (\overline{W}(1) - \overline{W}(0))y + \overline{W}(0)$$

is a fair, proper loss.

Observe that if w and v are weight functions which differ on a set of measure zero then they will lead to the same loss. A simple corollary to Theorem 6 is that the partial losses are given by

$$\ell_1(\hat{\eta}) = \int_{\hat{\eta}}^1 (1-c)w(c)dc \;\text{ and }\; \ell_{-1}(\hat{\eta}) = \int_0^{\hat{\eta}} cw(c)dc. \tag{5}$$

A similar[8] integral representation of the partial losses can also be found in Shuford et al. (1966, Theorem 2) and Staël von Holstein (1970).

3.3 Symmetric Losses

We will say a loss is *symmetric* if $\ell_1(\hat{\eta}) = \ell_{-1}(1-\hat{\eta})$ for all $\hat{\eta} \in [0,1]$. We say a weight function for a proper loss or the conditional Bayes risk is *symmetric* if $w(c) = w(1-c)$ or $\underline{L}(c) = \underline{L}(1-c)$ for all $c \in [0,1]$. Perhaps unsurprisingly, an immediate consequence of Theorem 1 is that these two notions are identical.[9]

8. The weight function h in Theorem 2 of Shuford et al. (1966) is related to the w here by $h(c) = (1-c)w(c)$.
9. The relationship between a symmetric $\underline{L}$ and symmetric behaviour of the loss has been previously recognised by Masnadi-Shirazi and Vasconcelos (2009).

Corollary 8 *A proper loss is symmetric if and only if its weight function is symmetric.*

Proof If ℓ is symmetric, then $\ell_1'(\hat{\eta}) = -\ell_{-1}'(1-\hat{\eta})$ and so Equation (2) implies $w(1-\hat{\eta}) = \frac{\ell_{-1}'(1-\hat{\eta})}{1-\hat{\eta}} = \frac{-\ell_1'(\hat{\eta})}{1-\hat{\eta}} = w(\hat{\eta})$. Conversely, the symmetry of w applied to Equation (5) establishes the symmetry of ℓ. ■

Requiring a loss to be proper and symmetric constrains the partial losses significantly. Properness alone completely specifies one partial loss from the other. Now suppose in addition that ℓ is symmetric. Combining $\ell_1(\hat{\eta}) = \ell_{-1}(1-\hat{\eta})$ with (2) implies

$$\ell_{-1}'(1-\hat{\eta}) = \frac{1-\hat{\eta}}{\hat{\eta}}\ell_{-1}'(\hat{\eta}). \tag{6}$$

This shows that ℓ_{-1} is completely determined by $\ell_{-1}(\hat{\eta})$ for $\hat{\eta} \in [0, \frac{1}{2}]$ (or $\hat{\eta} \in [\frac{1}{2}, 1]$). Thus in order to specify a symmetric proper loss, one needs to only specify one of the partial losses on one half of the interval $[0,1]$. Assuming ℓ_{-1} is continuous at $\frac{1}{2}$ (or equivalently that w has no atoms at $\frac{1}{2}$), by integrating both sides of (6) we can derive an explicit formula for the other half of ℓ_{-1} in terms of that which is specified:

$$\ell_{-1}(\hat{\eta}) = \ell_{-1}(\tfrac{1}{2}) + \int_{\frac{1}{2}}^{\hat{\eta}} \frac{x}{1-x}\ell_{-1}'(1-x)dx, \tag{7}$$

which works for determining ℓ_{-1} on either $[0, \frac{1}{2}]$ or $[\frac{1}{2}, 1]$ when ℓ_{-1} is specified on $[\frac{1}{2}, 1]$ or $[0, \frac{1}{2}]$ respectively (recalling the usual convention that $\int_a^b = -\int_b^a$). We have thus shown:

Theorem 9 *If a loss is proper and symmetric, then it is completely determined by specifying one of the partial losses on half the unit interval (either* $[0, \frac{1}{2}]$ *or* $[\frac{1}{2}, 0]$*) and using (6) and (7).*

We demonstrate (7) with four examples. Suppose that $\ell_{-1}(\hat{\eta}) = \frac{1}{1-\hat{\eta}}$ for $\hat{\eta} \in [0, \frac{1}{2}]$. Then one can readily determine the complete partial loss to be

$$\ell_{-1}(\hat{\eta}) = \frac{[\![\hat{\eta} \leq \frac{1}{2}]\!]}{1-\hat{\eta}} + [\![\hat{\eta} > \tfrac{1}{2}]\!]\left(2 + \log\frac{\hat{\eta}}{1-\hat{\eta}}\right).$$

Suppose instead that $\ell_{-1}(\hat{\eta}) = \frac{1}{1-\hat{\eta}}$ for $\hat{\eta} \in [\frac{1}{2}, 1]$. In that case we obtain

$$\ell_{-1}(\hat{\eta}) = [\![\hat{\eta} \leq \frac{1}{2}]\!]\left(2 + \log\frac{\hat{\eta}}{1-\hat{\eta}}\right) + \frac{[\![\hat{\eta} \geq \frac{1}{2}]\!]}{1-\hat{\eta}}.$$

Suppose $\ell_{-1}(\hat{\eta}) = \frac{1}{(1-\hat{\eta})^2}$ for $\hat{\eta} \in [0, \frac{1}{2}]$. Then one can determine that

$$\ell_{-1}(\hat{\eta}) = \frac{[\![\hat{\eta} < \frac{1}{2}]\!]}{(1-\hat{\eta})^2} + \frac{[\![\hat{\eta} \geq \frac{1}{2}]\!]\,(4 + 2(2\hat{\eta} + \hat{\eta}\log\hat{\eta} - \hat{\eta}\log(1-\hat{\eta}) - 1))}{\hat{\eta}}.$$

Finally consider specifying that $\ell_{-1}(\hat{\eta}) = \hat{\eta}$ for $\hat{\eta} \in [0, \frac{1}{2}]$. In this case we obtain that

$$\ell_{-1}(\hat{\eta}) = [\![\hat{\eta} \leq \tfrac{1}{2}]\!]\hat{\eta} + [\![\hat{\eta} \geq \tfrac{1}{2}]\!]\,(1 - \log 2 - \hat{\eta} - \log(1-\hat{\eta})).$$

4. Composite Losses

General loss functions are often constructed with the aid of a *link function*. For a particular set of prediction values $\mathcal{V}$ this is any continuous mapping $\psi\colon [0,1] \to \mathcal{V}$. In this paper, our focus will be *composite losses* for binary class probability estimation. These are the composition of a CPE loss $\ell\colon \{-1,1\} \times [0,1] \to \mathbb{R}$ and the inverse of a *link function* ψ, an invertible mapping from the unit interval to some range of values. Unless stated otherwise we will assume $\psi\colon [0,1] \to \mathbb{R}$. We will denote a composite loss by

$$\ell^{\psi}(y,v) := \ell(y,\psi^{-1}(v)). \tag{8}$$

The classical motivation for link functions (McCullagh and Nelder, 1989) is that often in estimating η one uses a parametric representation of $\hat{\eta}\colon \mathcal{X} \to$[0,1] which has a natural scale not matching $[0,1]$. Traditionally one writes $\hat{\eta} = \psi^{-1}(\hat{h})$ where ψ^{-1} is the "inverse link" (and ψ is of course the forward link). The function $\hat{h}\colon \mathcal{X} \to \mathbb{R}$ is the *hypothesis*. Often $\hat{h} = \hat{h}_{\boldsymbol{\alpha}}$ is parametrised linearly in a parameter vector $\boldsymbol{\alpha}$. In such a situation it is computationally convenient if $\ell(y,\psi^{-1}(\hat{h}))$ is convex in $\hat{h}$ (which implies it is convex in $\boldsymbol{\alpha}$ when $\hat{h}_{\boldsymbol{\alpha}}$ is linear in $\boldsymbol{\alpha}$). The idea of a link function is not as well known as it should be and is thus reinvented—see for example Granger and Machina (2006).

Often one will choose the loss first (tailoring its properties by the weighting given according to $w(c)$), and *then* choose the link somewhat arbitrarily to map the hypotheses appropriately. An interesting alternative perspective arises in the literature on "elicitability". Lambert et al. (2008)[10] provide a general characterisation of proper scoring rules (i.e., losses) for general *properties* of distributions, that is, continuous and locally non-constant functions Γ which assign a real value to each distribution over a finite sample space. In the binary case, these properties provide another interpretation of links that is complementary to the usual one that treats the inverse link ψ^{-1} as a way of interpreting scores as class probabilities.

To see this, we first identify distributions over $\{-1,1\}$ with the probability η of observing 1. In this case properties are continuous, locally non-constant maps $\Gamma : [0,1] \to \mathbb{R}$. When a link function ψ is continuous it can therefore be interpreted as a property since its assumed invertibility implies it is locally non-constant. A property Γ is said to be *elicitable* whenever there exists a strictly proper loss ℓ for it so that the composite loss ℓ^{Γ} satisfies for all $\hat{\eta} \neq \eta$

$$L^{\Gamma}(\eta,\hat{\eta}) := \mathbb{E}_{Y\sim\eta}[\ell^{\Gamma}(Y,\hat{\eta})] > L^{\Gamma}(\eta,\eta).$$

Theorem 1 of Lambert et al. (2008) shows that Γ is elicitable if and only if $\Gamma^{-1}(r)$ is convex for all $r \in \text{range}(\Gamma)$. This immediately gives us a characterisation of "proper" link functions: those that are both continuous and have convex level sets in $[0,1]$—they are the non-decreasing continuous functions. Thus in Lambert's perspective, one chooses a "property" first (i.e., the invertible link) and *then* chooses the proper loss.

4.1 Proper Composite Losses

We will call a composite loss ℓ^{ψ} (8) a *proper composite loss* if ℓ in (8) is a proper loss for class probability estimation. As in the case for losses for probability estimation, the requirement that a composite loss be proper imposes some constraints on its partial losses. Many of the results for proper losses carry over to composite losses with some extra factors to account for the link function.

10. See also Gneiting (2009).

Theorem 10 *Let $\lambda = \ell^\psi$ be a composite loss with differentiable and strictly monotone link ψ and suppose the partial losses $\lambda_{-1}(v)$ and $\lambda_1(v)$ are both differentiable. Then λ is a proper composite loss if and only if there exists a weight function $w : (0,1) \to \mathbb{R}^+$ such that for all $\hat{\eta} \in (0,1)$*

$$\frac{-\lambda_1'(\psi(\hat{\eta}))}{1-\hat{\eta}} = \frac{\lambda_{-1}'(\psi(\hat{\eta}))}{\hat{\eta}} = \frac{w(\hat{\eta})}{\psi'(\hat{\eta})} =: \rho(\hat{\eta}), \tag{9}$$

where equality is interpreted in the distributional sense. Furthermore, $\rho(\hat{\eta}) \geq 0$ for all $\hat{\eta} \in (0,1)$.

Proof This is a direct consequence of Theorem 1 for proper losses for probability estimation and the chain rule applied to $\ell_y(\hat{\eta}) = \lambda_y(\psi(\hat{\eta}))$. Since ψ is assumed to be strictly monotonic we know $\psi' > 0$ and so, since $w \geq 0$ we have $\rho \geq 0$. ■

As we shall see, the ratio $\rho(\hat{\eta})$ is a key quantity in the analysis of proper composite losses. For example, Corollary 2 has natural analogue in terms of ρ that will be of use later. It is obtained by letting $\hat{\eta} = \psi^{-1}(v)$ and using the chain rule.

Corollary 11 *Suppose ℓ^ψ is a proper composite loss with conditional risk denoted L^ψ. Then*

$$\frac{\partial}{\partial v} L^\psi(\eta, v) = (\psi^{-1}(v) - \eta)\rho(\psi^{-1}(v)). \tag{10}$$

Loosely speaking then, ρ is a "co-ordinate free" weight function for composite losses where the link function ψ is interpreted as a mapping from arbitrary $v \in \mathcal{V}$ to values which can be interpreted as probabilities.

Another immediate corollary of Theorem 10 shows how properness is characterised by a particular relationship between the choice of link function and the choice of partial composite losses.

Corollary 12 *Let $\lambda := \ell^\psi$ be a composite loss with differentiable partial losses λ_1 and λ_{-1}. Then ℓ^ψ is proper if and only if the link ψ satisfies*

$$\psi^{-1}(v) = \frac{\lambda_{-1}'(v)}{\lambda_{-1}'(v) - \lambda_1'(v)}, \quad \forall v \in \mathcal{V}. \tag{11}$$

Proof Substituting $\hat{\eta} = \psi^{-1}(v)$ into (9) yields $-\psi^{-1}(v)\lambda_1'(v) = (1-\psi^{-1}(v))\lambda_{-1}'(v)$ and solving this for $\psi^{-1}(v)$ gives the result. ■

These results give some insight into the "degrees of freedom" available when specifying proper composite losses. Theorem 10 shows that the partial losses are completely determined once the weight function w and ψ (up to an additive constant) is fixed. Corollary 12 shows that for a given link ψ one can specify one of the partial losses λ_y but then properness fixes the other partial loss λ_{-y}. Similarly, given an arbitrary choice of the partial losses, Equation 11 gives the single link which will guarantee the overall loss is proper.

We see then that Corollary 12 provides us with a way of constructing a *reference link* for arbitrary composite losses specified by their partial losses. The reference link can be seen to satisfy

$$\psi(\eta) = \operatorname*{arg\,min}_{v \in \mathbb{R}} L^\psi(\eta, v)$$

for $\eta \in (0,1)$ and thus *calibrates* a given composite loss in the sense of Cohen and Goldszmidt (2004).

Finally, we make a note of an analogue of Corollary 5 for composite losses. It shows that the regret for an arbitrary composite loss is related to a Bregman divergence via its link.

Corollary 13 *Let ℓ^ψ be a proper composite loss with invertible link. Then for all $\eta, \hat{\eta} \in (0,1)$,*

$$\Delta L^\psi(\eta, v) = D_{-\underline{L}}(\eta, \psi^{-1}(v)). \tag{12}$$

This corollary generalises the results due to Zhang (2004b) and Masnadi-Shirazi and Vasconcelos (2009) who considered only margin losses respectively without and with links.

4.2 Derivatives of Composite Losses

We now briefly consider an application of the parametrisation of proper losses as a weight function and link. In order to implement Stochastic Gradient Descent (SGD) algorithms one needs to compute the derivative of the loss with respect to predictions $v \in \mathbb{R}$. Letting $\hat{\eta}(v) = \psi^{-1}(v)$ be the probability estimate associated with the prediction v, we can use (10) when $\eta \in \{0,1\}$ to obtain the update rules for positive and negative examples:

$$\begin{aligned} \frac{\partial}{\partial v}\ell_1^\psi(v) &= (\hat{\eta}(v) - 1)\,\rho(\hat{\eta}(v)), \\ \frac{\partial}{\partial v}\ell_{-1}^\psi(v) &= \hat{\eta}(v)\,\rho(\hat{\eta}(v)). \end{aligned}$$

Given an arbitrary weight function w (which defines a proper loss via Corollary 2 and Theorem 4) and link ψ, the above equations show that one could implement SGD directly parametrised in terms of ρ without needing to explicitly compute the partial losses themselves.

4.3 Margin Losses

The *margin* associated with a real-valued prediction $v \in \mathbb{R}$ and label $y \in \{-1,1\}$ is the product $z = yv$. Any function $\phi\colon \mathbb{R} \to \mathbb{R}^+$ can be used as a *margin loss* by interpreting $\phi(yv)$ as the penalty for predicting v for an instance with label y. Margin losses are inherently symmetric since $yv = (-y)(-v)$ and so the penalty $\phi(yv)$ given for predicting v when the label is y is necessarily the same as the penalty for predicting $-v$ when the label is $-y$. Margin losses have attracted a lot of attention (Bartlett et al., 2000) because of their central role in Support Vector Machines (Cortes and Vapnik, 1995). In this section we explore the relationship between these margin losses and the more general class of composite losses and, in particular, symmetric composite losses.

Recall that a general composite loss is of the form $\ell^\psi(y,v) = \ell(y, \psi^{-1}(v))$ for a loss $\ell\colon \mathcal{Y} \times [0,1] \to [0,\infty)$ and an invertible link $\psi\colon \mathbb{R} \to [0,1]$. We would like to understand when margin losses are suitable for probability estimation tasks. As discussed above, proper losses are a natural class of losses over $[0,1]$ for probability estimation so a natural question in this vein is the following: given a margin loss ϕ can we choose a link ψ so that there exists a proper loss ℓ such that $\phi(yv) = \ell^\psi(y,v)$? In this case the proper loss will be $\ell(y,\hat{\eta}) = \phi(y\psi(\hat{\eta}))$.

The following corollary of Theorem 10 gives necessary and sufficient conditions on the choice of link ψ to guarantee when a margin loss ϕ can be expressed as a proper composite loss.

Corollary 14 *Suppose $\phi\colon \mathbb{R} \to \mathbb{R}$ is a differentiable margin loss. Then, $\phi(yv)$ can be expressed as a proper composite loss $\ell^\psi(y,v)$ if and only if the link ψ satisfies*

$$\psi^{-1}(v) = \frac{\phi'(-v)}{\phi'(-v)+\phi'(v)}.$$

Proof Margin losses, by definition, have partial losses $\lambda_y(v) = \phi(yv)$ which means $\lambda'_1(v) = \phi'(v)$ and $\lambda'_{-1}(v) = -\phi'(-v)$. Substituting these into (11) gives the result. ■

This result provides a way of interpreting predictions v as probabilities $\hat{\eta} = \psi^{-1}(v)$ in a consistent manner, for a problem defined by a margin loss. Conversely, it also guarantees that using any other link to interpret predictions as probabilities will be inconsistent.[11] Another immediate implication is that for a margin loss to be considered a proper loss its link function must be *symmetric* in the sense that

$$\psi^{-1}(-v) = \frac{\phi'(v)}{\phi'(v)+\phi'(-v)} = 1 - \frac{\phi'(-v)}{\phi'(-v)+\phi'(v)} = 1 - \psi^{-1}(v),$$

and so, by letting $v = \psi(\hat{\eta})$, we have $\psi(1-\hat{\eta}) = -\psi(\hat{\eta})$ and thus $\psi(\frac{1}{2}) = 0$.

Corollary 14 can also be seen as a simplified and generalised version of the argument by Masnadi-Shirazi and Vasconcelos (2009) that a concave minimal conditional risk function and a symmetric link completely determines a margin loss.[12]

We now consider a couple of specific margin losses and show how they can be associated with a proper loss through the choice of link given in Corollary 14. The exponential loss $\phi(v) = e^{-v}$ gives rise to a proper loss $\ell(y,\hat{\eta}) = \phi(y\psi(\hat{\eta}))$ via the link

$$\psi^{-1}(v) = \frac{-e^v}{-e^v - e^{-v}} = \frac{1}{1+e^{-2v}}$$

which has non-zero denominator. In this case $\psi(\hat{\eta}) = \frac{1}{2}\log\left(\frac{\hat{\eta}}{1-\hat{\eta}}\right)$ is just the logistic link. Now consider the family of margin losses parametrised by $\alpha \in (0,\infty)$

$$\phi_\alpha(v) = \frac{\log(\exp((1-v)\alpha)+1)}{\alpha}.$$

This family of differentiable convex losses approximates the hinge loss as $\alpha \to \infty$ and was studied in the multiclass case by Zhang et al. (2009). Since these are all differentiable functions with $\phi'_\alpha(v) = \frac{-e^{\alpha(1-v)}}{e^{\alpha(1-v)}+1}$, Corollary 14 and a little algebra gives

$$\psi^{-1}(v) = \left[1 + \frac{e^{2\alpha}+e^{\alpha(1-v)}}{e^{2\alpha}+e^{\alpha(1+v)}}\right]^{-1}.$$

Examining this family of inverse links as $\alpha \to 0$ gives some insight into why the hinge loss is a surrogate for classification but not probability estimation. When $\alpha \approx 0$ an estimate $\hat{\eta} = \psi^{-1}(v) \approx \frac{1}{2}$ for all but very large $v \in \mathbb{R}$. That is, in the limit all probability estimates sit infinitesimally to the right or left of $\frac{1}{2}$ depending on the sign of v.

11. Strictly speaking, if the margin loss has "flat spots"—that is, where $\phi'(v) = 0$—then the choice of link may not be unique.

12. Shen (2005, Section 4.4) seems to have been the first to view margin losses from this more general perspective.

5. Classification Calibration and Proper Losses

The notion of properness of a loss designed for class probability estimation is a natural one. If one is only interested in classification (rather than estimating probabilities) a weaker condition suffices. In this section we will relate the weaker condition to properness.

5.1 Classification Calibration for CPE Losses

We begin by giving a definition of classification calibration for CPE losses (i.e., over the unit interval $[0,1]$) and relate it to composite losses via a link.

Definition 15 *We say a CPE loss ℓ is* classification calibrated at $c \in (0,1)$ *and write ℓ is CC_c if the associated conditional risk L satisfies*

$$\forall \eta \neq c,\ \underline{L}(\eta) < \inf_{\hat{\eta}:\ (\hat{\eta}-c)(\eta-c)\leq 0} L(\eta,\hat{\eta}). \tag{13}$$

The expression constraining the infimum ensures that $\hat{\eta}$ is on the opposite side of c to η, or $\hat{\eta} = c$.

The condition $\mathrm{CC}_{\frac{1}{2}}$ is equivalent to what is called "classification calibrated" by Bartlett et al. (2006) and "Fisher consistent for classification problems" by Lin (2002) although their definitions were only for margin losses. One situation where this more general CC_c notion is more appropriate is when the false positive and false negative costs for a classification problem are unequal.

One might suspect that there is a connection between classification calibrated at c and standard Fisher consistency for class probability estimation losses. The following theorem, which captures the intuition behind the "probing" reduction (Langford and Zadrozny, 2005), characterises the situation.

Theorem 16 *A CPE loss ℓ is CC_c for all $c \in (0,1)$ if and only if ℓ is strictly proper.*

Proof The loss ℓ is CC_c for all $c \in (0,1)$ is equivalent to

$$\begin{aligned}
& \forall c \in (0,1),\ \forall \eta \neq c \begin{cases} \underline{L}(\eta) < \inf_{\hat{\eta}\geq c} L(\eta,\hat{\eta}), & \eta < c \\ \underline{L}(\eta) < \inf_{\hat{\eta}\leq c} L(\eta,\hat{\eta}), & \eta > c \end{cases} \\
\Leftrightarrow\ & \forall \eta \in (0,1),\ \forall c \neq \eta \begin{cases} \forall c > \eta,\ \underline{L}(\eta) < \inf_{\hat{\eta}\geq c} L(\eta,\hat{\eta}) \\ \forall c < \eta,\ \underline{L}(\eta) < \inf_{\hat{\eta}\leq c} L(\eta,\hat{\eta}) \end{cases} \\
\Leftrightarrow\ & \forall \eta \in (0,1),\ \begin{cases} \underline{L}(\eta) < \inf_{\hat{\eta}\geq c>\eta} L(\eta,\hat{\eta}) \\ \underline{L}(\eta) < \inf_{\hat{\eta}\leq c<\eta} L(\eta,\hat{\eta}) \end{cases} \\
\Leftrightarrow\ & \forall \eta \in (0,1),\ \underline{L}(\eta) < \inf_{(\hat{\eta}>\eta) \text{ or } (\hat{\eta}<\eta)} L(\eta,\hat{\eta}) \\
\Leftrightarrow\ & \forall \eta \in (0,1),\ \underline{L}(\eta) < \inf_{\hat{\eta}\neq\eta} L(\eta,\hat{\eta})
\end{aligned}$$

which means L is strictly proper. ■

The following theorem is a generalisation of the characterisation of $\mathrm{CC}_{\frac{1}{2}}$ for margin losses via $\phi'(0)$ due to Bartlett et al. (2006).

Theorem 17 *Suppose ℓ is a loss and suppose that ℓ'_1 and ℓ'_{-1} exist everywhere. Then for any $c \in (0,1)$ ℓ is CC_c if and only if*

$$\ell'_{-1}(c) > 0 \ \text{ and } \ \ell'_1(c) < 0 \ \text{ and } \ c\ell'_1(c) + (1-c)\ell'_{-1}(c) = 0. \tag{14}$$

Proof Since ℓ'_1 and ℓ'_{-1} are assumed to exist everywhere

$$\frac{\partial}{\partial\hat{\eta}}L(\eta,\hat{\eta}) = \eta\ell'_1(\hat{\eta}) + (1-\eta)\ell'_{-1}(\hat{\eta})$$

exists for all $\hat{\eta}$. L is CC_c is equivalent to

$$\begin{aligned}
&\frac{\partial}{\partial\hat{\eta}}L(\eta,\hat{\eta})\bigg|_{\hat{\eta}=c} \begin{cases} >0, & \eta < c < \hat{\eta} \\ <0, & \hat{\eta} < c < \eta \end{cases} \\
\Leftrightarrow\quad &\begin{cases} \forall\eta < c, & \eta\ell'_1(c) + (1-\eta)\ell'_{-1}(c) > 0 \\ \forall\eta > c, & \eta\ell'_1(c) + (1-\eta)\ell'_{-1}(c) < 0 \end{cases} \qquad (15) \\
\Leftrightarrow\quad &\begin{array}{l} c\ell'_1(c) + (1-c)\ell'_{-1}(c) = 0 \\ \text{and } \ell'_{-1}(c) > 0 \text{ and } \ell'_1(c) < 0, \end{array} \qquad (16)
\end{aligned}$$

where we have used the fact that (15) with $\eta = 0$ and $\eta = 1$ respectively substituted implies $\ell'_{-1}(c) > 0$ and $\ell'_1(c) < 0$. ■

If ℓ is proper, then by evaluating (3) at $\eta = 0$ and $\eta = 1$ we obtain $\ell'_1(\hat{\eta}) = -w(\hat{\eta})(1-\hat{\eta})$ and $\ell'_{-1}(\hat{\eta}) = w(\hat{\eta})\hat{\eta}$. Thus (16) implies $-w(c)(1-c) < 0$ and $w(c)c > 0$ which holds if and only if $w(c) \neq 0$. We have thus shown the following corollary.

Corollary 18 *If ℓ is proper with weight w, then for any $c \in (0,1)$,*

$$w(c) \neq 0 \;\Leftrightarrow\; \ell \text{ is } \mathrm{CC}_c.$$

The simple form of the weight function for the cost-sensitive misclassification loss ℓ_{c_0} ($w(c) = \delta(c - c_0)$) gives the following corollary (confer Bartlett et al., 2006):

Corollary 19 *ℓ_{c_0} is CC_c if and only if $c_0 = c$.*

5.2 Calibration for Composite Losses

The translation of the above results to general proper composite losses with invertible differentiable link ψ is straight forward. Condition (13) becomes

$$\forall\eta \neq c,\;\; \underline{L}^{\psi}(\eta) < \inf_{v:\; (\psi^{-1}(v)-c)(\eta-c)\leq 0} L^{\psi}(\eta, \psi^{-1}(v)).$$

Theorem 16 then immediately gives:

Corollary 20 *A composite loss $\ell^{\psi}(\cdot,\cdot) = \ell(\cdot, \psi^{-1}(\cdot))$ with invertible and differentiable link ψ is CC_c for all $c \in (0,1)$ if and only if the associated proper loss ℓ is strictly proper.*

Theorem 17 immediately gives:

Corollary 21 *Suppose ℓ^{ψ} is as in Corollary 20 and that the partial losses ℓ_1 and ℓ_{-1} of the associated proper loss ℓ are differentiable. Then for any $c \in (0,1)$, ℓ^{ψ} is CC_c if and only if (14) holds.*

It can be shown that in the special case of margin losses L_{ϕ}, which satisfy the conditions of Corollary 14 such that they are proper composite losses, Corollary 21 leads to the condition $\phi'(0) < 0$ which is the same as obtained by Bartlett et al. (2006).

6. Convexity of Composite Losses

We have seen that composite losses are defined by the proper loss ℓ and the link ψ. We have further seen from (14) that it is natural to parametrise composite losses in terms of w and ψ', and combine them as ρ. One may wish to choose a weight function w and determine which links ψ lead to a convex loss; or choose a link ψ and determine which weight functions w (and hence proper losses) lead to a convex composite loss. The main result of this section is Theorem 29 answers these questions by characterising the convexity of composite losses in terms of (w,ψ') or ρ.

We first establish some convexity results for losses and their conditional and full risks.

Lemma 22 *Let $\ell : \mathcal{Y} \times \mathcal{V} \to [0,\infty)$ denote an arbitrary loss. Then the following are equivalent:*

1. *$v \mapsto \ell(y,v)$ is convex for all $y \in \{-1,1\}$,*
2. *$v \mapsto L(\eta,v)$ is convex for all $\eta \in [0,1]$,*
3. *$v \mapsto \hat{\mathbb{L}}(v,S) := \frac{1}{|S|}\sum_{(x,y)\in S} \ell(y,v(x))$ is convex for all finite $S \subset \mathcal{X} \times \mathcal{Y}$.*

Proof $1 \Rightarrow 2$: By definition, $L(\eta,v) = (1-\eta)\ell(-1,v) + \eta\ell(1,v)$ which is just a convex combination of convex functions and hence convex.

$2 \Rightarrow 1$: Choose $\eta = 0$ and $\eta = 1$ in the definition of L.

$1 \Rightarrow 3$: For a fixed (x,y), the function $v \mapsto \ell(y,v(x))$ is convex since ℓ is convex. Thus, $\hat{\mathbb{L}}$ is convex as it is a non-negative weighted sum of convex functions.

$3 \Rightarrow 1$: The convexity of $\hat{\mathbb{L}}$ holds for every S so for each $y \in \{-1,1\}$ choose $S = \{(x,y)\}$ for some x. In each case $v \mapsto \hat{\mathbb{L}}(v,S) = \ell(y,v(x))$ is convex as required. ■

The following theorem generalises the corollary on page 12 of Buja et al. (2005) to arbitrary composite losses with invertible links. It has less practical value than the previous lemma since, in general, sums of quasi-convex functions are not necessarily quasi-convex (a function f is quasi-convex if the set $\{x\colon f(x) \geq \alpha\}$ is convex for all $\alpha \in \mathbb{R}$). Thus, assuming properness of the loss ℓ does not guarantee its empirical risk $\hat{\mathbb{L}}(\cdot,S)$ will not have local minima.

Theorem 23 *If $\ell^\psi(y,v) = \ell(y,\psi^{-1}(v))$ is a composite loss where ℓ is proper and ψ is invertible and differentiable then $L^\psi(\eta,v)$ is quasi-convex in v for all $\eta \in [0,1]$.*

Proof Since ℓ is proper we know by Corollary 11 that the conditional Bayes risk satisfies

$$\frac{\partial}{\partial v} L^\psi(\eta,v) \quad = \quad (\psi^{-1}(v) - \eta)\rho(\psi^{-1}(v)).$$

Since ψ is invertible and $\rho \geq 0$ we see that $\frac{\partial}{\partial v} L^\psi(\eta,v)$ only changes sign at $\eta = \psi^{-1}(v)$ and so L^ψ is quasi-convex as required. ■

The following theorem characterises convexity of composite losses with invertible links.

Theorem 24 *Let $\ell^\psi(y,v)$ be a composite loss comprising an invertible link ψ with inverse $q := \psi^{-1}$ and strictly proper loss with weight function w. Assume $q'(\cdot) > 0$. Then $v \mapsto \ell^\psi(y,v)$ is convex for $y \in \{-1,1\}$ if and only if*

$$-\frac{1}{x} \;\leq\; \frac{w'(x)}{w(x)} - \frac{\psi''(x)}{\psi'(x)} \;\leq\; \frac{1}{1-x}, \quad \forall x \in (0,1). \tag{17}$$

This theorem suggests a very natural parametrisation of composite losses is via (w, ψ'). Observe that $w, \psi' \colon [0,1] \to \mathbb{R}^+$. (But also see the comment following Theorem 29.)

Proof We can write the conditional composite loss as

$$L^\psi(\eta, v) = \eta \ell_1(q(v)) + (1-\eta)\ell_{-1}(q(v))$$

and by substituting $q = \psi^{-1}$ into (10) we have

$$\frac{\partial}{\partial v} L^\psi(\eta, v) \quad = \quad w(q(v))q'(v)[q(v) - \eta]. \tag{18}$$

A necessary and sufficient condition for $v \mapsto \ell^\psi(y, v) = L^\psi(y, v)$ to be convex for $y \in \{-1, 1\}$ is that

$$\frac{\partial^2}{\partial v^2} L^\psi(y, v) \geq 0, \quad \forall v \in \mathbb{R},\ \forall y \in \{-1, 1\}.$$

Using (18) the above condition is equivalent to

$$[w(q(v))q'(v)]'(q(v) - [\![y = 1]\!]) + w(q(v))q'(v)q'(v) \ \geq \ 0, \quad \forall v \in \mathbb{R}, \tag{19}$$

where

$$[w(q(v))q'(v)]' := \frac{\partial}{\partial v} w(q(v))q'(v).$$

Inequality (19) is equivalent to (Buja et al., 2005, Equation 39). By further manipulations, we can simplify (19) considerably.

Since $[\![y = 1]\!]$ is either 0 or 1 we equivalently have the two inequalities

$$\begin{aligned} [w(q(v))q'(v)]'q(v) + w(q(v))(q'(v))^2 &\geq 0, \quad \forall v \in \mathbb{R}, \quad (y = -1) \\ [w(q(v))q'(v)]'(q(v) - 1) + w(q(v))(q'(v))^2 &\geq 0, \quad \forall v \in \mathbb{R}, \quad (y = 1), \end{aligned}$$

which we shall rewrite as the pair of inequalities

$$w(q(v))(q'(v))^2 \ \geq \ -q(v)[w(q(v))q'(v)]', \qquad \forall v \in \mathbb{R}, \tag{20}$$

$$w(q(v))(q'(v))^2 \ \geq \ (1 - q(v))[w(q(v))q'(v)]', \quad \forall v \in \mathbb{R}. \tag{21}$$

Observe that if $q(\cdot) = 0$ (resp. $1 - q(\cdot) = 0$) then (20) (resp. (21)) is satisfied anyway because of the assumption on q' and the fact that w is non-negative. It is thus equivalent to restrict consideration to v in the set

$$\{x \colon q(x) \neq 0 \ \text{ and } \ (1 - q(x)) \neq 0\} = q^{-1}((0,1)) = \psi((0,1)).$$

Combining (20) and (21) we obtain the equivalent condition

$$\frac{(q'(v))^2}{1 - q(v)} \ \geq \ \frac{[w(q(v))q'(v)]'}{w(q(v))} \ \geq \ \frac{-(q'(v))^2}{q(v)}, \quad \forall v \in \psi((0,1)), \tag{22}$$

where we have used the fact that $q \colon \mathbb{R} \to [0,1]$ and is thus sign-definite and consequently $-q(\cdot)$ is always negative and division by $q(v)$ and $1 - q(v)$ is permissible since as argued we can neglect the cases when these take on the value zero, and division by $w(q(v))$ is permissible by the assumption of *strict* properness since that implies $w(\cdot) > 0$. Now

$$[w(q(\cdot))q'(\cdot)]' = w'(q(\cdot))q'(\cdot)q'(\cdot) + w(q(\cdot))q''(\cdot)$$

and thus (22) is equivalent to

$$\frac{(q'(v))^2}{1-q(v)} \;\geq\; \frac{w'(q(v))(q'(v))^2 + w(q(v))q''(v)}{w(q(v))} \;\geq\; \frac{-(q'(v))^2}{q(v)}, \quad \forall v \in \psi((0,1)) \tag{23}$$

Now divide all sides of (23) by $(q'(\cdot))^2$ (which is permissible by assumption). This gives the equivalent condition

$$\frac{1}{1-q(v)} \;\geq\; \frac{w'(q(v))}{w(q(v))} + \frac{q''(v)}{(q'(v))^2} \;\geq\; \frac{-1}{q(v)}, \quad \forall v \in \psi((0,1)). \tag{24}$$

Let $x = q(v)$ and so $v = q^{-1}(x) = \psi(x)$. Then (24) is equivalent to

$$\frac{1}{1-x} \;\geq\; \frac{w'(x)}{w(x)} + \frac{q''(\psi(x))}{(q'(\psi(x)))^2} \;\geq\; \frac{-1}{x}, \quad \forall x \in (0,1). \tag{25}$$

Now $\frac{1}{q'(\psi(x))} = \frac{1}{q'(q^{-1}(x))} = (q^{-1})'(x) = \psi'(x)$. Thus (25) is equivalent to

$$\frac{1}{1-x} \;\geq\; \frac{w'(x)}{w(x)} + \Phi_\psi(x) \;\geq\; \frac{-1}{x}, \quad \forall x \in (0,1), \tag{26}$$

where

$$\Phi_\psi(x) := q''\left(\psi(x)\right)\left(\psi'(x)\right)^2.$$

All of the above steps are equivalences. We have thus shown that

$$\text{(26) is true} \;\Leftrightarrow\; v \mapsto L^\psi(y,v) \text{ is convex for } y \in \{-1,1\}$$

where the right hand side is equivalent to the assertion in the theorem by Lemma 22.

Finally we simplify Φ_ψ. We first compute q'' in terms of $\psi = q^{-1}$. Observe that $q' = (\psi^{-1})' = \frac{1}{\psi'(\psi^{-1}(\cdot))}$. Thus

$$\begin{aligned}
q''(\cdot) &= (\psi^{-1})''(\cdot) \\
&= \left(\frac{1}{\psi'(\psi^{-1}(\cdot))}\right)' \\
&= \frac{-1}{\left(\psi'(\psi^{-1}(\cdot))\right)^2}\psi''(\psi^{-1}(\cdot))\left(\psi^{-1}(\cdot)\right)' \\
&= \frac{-1}{\left(\psi'(\psi^{-1}(\cdot))\right)^3}\psi''(\psi^{-1}(\cdot)).
\end{aligned}$$

Thus by substitution

$$\begin{aligned}
\Phi_\psi(\cdot) &= \frac{-1}{\left(\psi'(\psi^{-1}(\psi(\cdot)))\right)^3}\psi''(\psi(\psi^{-1}(\cdot)))\left(\psi'(\cdot)\right)^2 \\
&= \frac{-1}{\left(\psi'(\cdot)\right)^3}\psi''(\cdot)\left(\psi'(\cdot)\right)^2 \\
&= -\frac{\psi''(\cdot)}{\psi'(\cdot)}.
\end{aligned} \tag{27}$$

Substituting the simpler expression (27) for Φ_ψ into (26) completes the proof. ■

Lemma 25 *If q is affine then $\Phi_\psi = 0$.*

Proof Using (27), this is immediate since in this case $\psi''(\cdot) = 0$. ■

Corollary 26 *Composite losses with a linear link (including as a special case the identity link) are convex if and only if*

$$-\frac{1}{x} \leq \frac{w'(x)}{w(x)} \leq \frac{1}{1-x}, \quad \forall x \in (0,1).$$

6.1 Canonical Links

Buja et al. (2005) introduced the notion of a *canonical link* defined by $\psi'(v) = w(v)$. The canonical link corresponds to the notion of "matching loss" as developed by Helmbold et al. (1999) and Kivinen and Warmuth (2001). Note that choice of canonical link implies $\rho(c) = w(c)/\psi'(c) = 1$.

Lemma 27 *Suppose ℓ is a proper loss with weight function w and ψ is the corresponding canonical link, then*

$$\Phi_\psi(x) = -\frac{w'(x)}{w(x)}. \tag{28}$$

Proof Substitute $\psi' = w$ into (27). ■

This lemma gives an immediate proof of the following result due to Buja et al. (2005).

Theorem 28 *A composite loss comprising a proper loss with weight function w combined with its canonical link is always convex.*

Proof Substitute (28) into (17) to obtain

$$-\frac{1}{x} \leq 0 \leq \frac{1}{1-x}, \quad \forall x \in (0,1)$$

which holds for any w. ■

An alternative view of canonical links is given in Appendix B.

6.2 A Simpler Characterisation of Convex Composite Losses

The following theorem prrovides a simpler characterisation of the convexity of composite losses. Noting that loss functions can be multiplied by a scalar without affecting what a learning algorithm will do, it is convenient to normalise them. If w satisfies (17) then so does αw for all $\alpha \in (0,\infty)$. Thus without loss of generality we will normalise w such that $w(\frac{1}{2}) = 1$. We chose to normalise about $\frac{1}{2}$ for two reasons: symmetry and the fact that w can have non-integrable singularities at 0 and 1; see, for example, Buja et al. (2005).

Theorem 29 *Consider a proper composite loss ℓ^ψ with invertible link ψ and (strictly proper) weight w normalised such that $w(\frac{1}{2}) = 1$. Then ℓ is convex if and only if*

$$\frac{\psi'(x)}{x} \lesseqgtr 2\psi'(\tfrac{1}{2})\, w(x) \lesseqgtr \frac{\psi'(x)}{1-x}, \quad \forall x \in (0,1), \tag{29}$$

where $\lesseqgtr$ denotes $\leq$ for $x \geq \frac{1}{2}$ and denotes $\geq$ for $x \leq \frac{1}{2}$.

Observe that the condition (29) is equivalent to

$$\frac{1}{2\psi'(\frac{1}{2})x} \begin{matrix}\leqq\\ \geqq\end{matrix} \rho(x) \begin{matrix}\leqq\\ \geqq\end{matrix} \frac{1}{2\psi'(\frac{1}{2})(1-x)}, \quad \forall x \in (0,1),$$

which suggests the importance of the function $\rho(\cdot)$.

Proof Observing that $\frac{w'(x)}{w(x)} = (\log w)'(x)$ we let $g(x) := \log w(x)$. Observe that $g(v) = \int_{\frac{1}{2}}^{v} g'(x)dx + g(\frac{1}{2})$ and $g(\frac{1}{2}) = \log w(\frac{1}{2}) = 0$. From Theorem 24, we know that ℓ is convex iff (17) holds. Using the newly introduced notation, this is equivalent to

$$-\frac{1}{x} - \Phi_\psi(x) \;\leq\; g'(x) \;\leq\; \frac{1}{1-x} - \Phi_\psi(x).$$

For $v \geq \frac{1}{2}$ we thus have

$$\int_{\frac{1}{2}}^{v} -\frac{1}{x} - \Phi_\psi(x)dx \;\leq\; g(v) \;\leq\; \int_{\frac{1}{2}}^{v} \frac{1}{1-x} - \Phi_\psi(x)dx.$$

Similarly, for $v \leq \frac{1}{2}$ we have

$$\int_{\frac{1}{2}}^{v} -\frac{1}{x} - \Phi_\psi(x)dx \;\geq\; g(v) \;\geq\; \int_{\frac{1}{2}}^{v} \frac{1}{1-x} - \Phi_\psi(x)dx,$$

and thus

$$-\ln v - \ln 2 - \int_{\frac{1}{2}}^{v} \Phi_\psi(x)dx \begin{matrix}\leqq\\ \geqq\end{matrix} g(v) \begin{matrix}\leqq\\ \geqq\end{matrix} -\ln 2 - \ln(1-v) - \int_{\frac{1}{2}}^{v} \Phi_\psi(x)dx.$$

Since $\exp(\cdot)$ is monotone increasing we can apply it to all terms and obtain

$$\frac{1}{2v}\exp\left(-\int_{\frac{1}{2}}^{v} \Phi_\psi(x)dx\right) \begin{matrix}\leqq\\ \geqq\end{matrix} w(v) \begin{matrix}\leqq\\ \geqq\end{matrix} \frac{1}{2(1-v)}\exp\left(-\int_{\frac{1}{2}}^{v} \Phi_\psi(x)dx\right). \tag{30}$$

Now

$$\int_{\frac{1}{2}}^{v} \Phi_\psi(x)dv = \int_{\frac{1}{2}}^{v} -\frac{\psi''(x)}{\psi'(x)}dx = -\int_{\frac{1}{2}}^{v} (\log\psi')'(x)dx = -\log\psi'(v) + \log\psi'(\tfrac{1}{2})$$

and so

$$\exp\left(-\int_{\frac{1}{2}}^{v} \Phi_\psi(x)dx\right) = \frac{\psi'(v)}{\psi'(\frac{1}{2})}.$$

Substituting into (30) completes the proof. ■

If ψ is the identity (i.e., if ℓ^ψ is itself proper) we get the simpler constraints

$$\frac{1}{2x} \begin{matrix}\leqq\\ \geqq\end{matrix} w(x) \begin{matrix}\leqq\\ \geqq\end{matrix} \frac{1}{2(1-x)}, \quad \forall x \in (0,1), \tag{31}$$

which are illustrated as the shaded region in Figure 2. Observe that the (normalised) weight function for squared loss is $w(c) = 1$ which is indeed within the shaded region as one would expect.

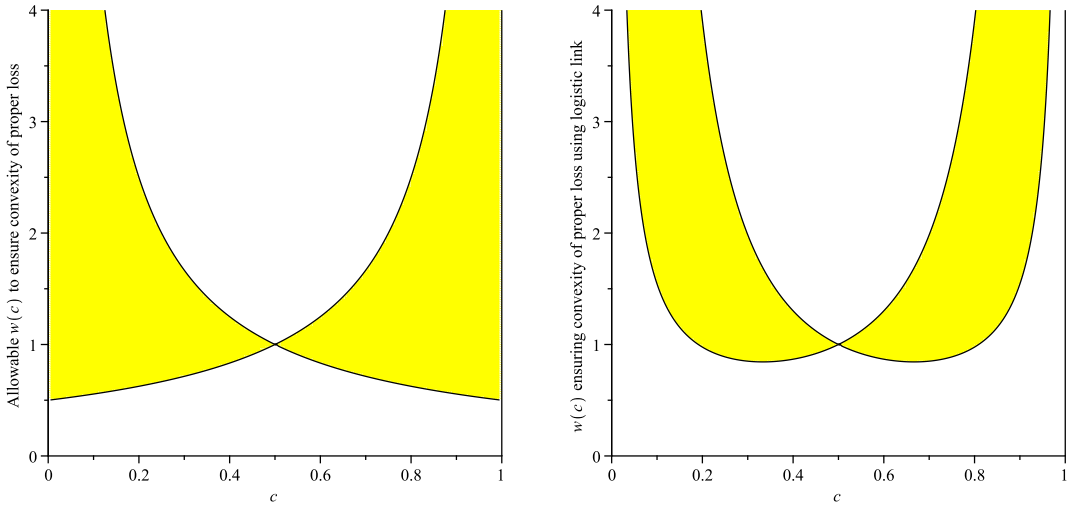

Figure 2: Allowable normalised weight functions to ensure convexity of composite loss functions with identity link (left) and logistic link (right).

Consider the link $\psi^{\text{logit}}(c) := \log\left(\frac{c}{1-c}\right)$ with corresponding inverse link $q(c) = \frac{1}{1+e^{-c}}$. One can check that $\psi'(c) = \frac{1}{c(1-c)}$. Thus the constraints on the weight function w to ensure convexity of the composite loss are

$$\frac{1}{8x^2(1-x)} \leqq w(x) \geqq \frac{1}{8x(1-x)^2}, \quad \forall x \in (0,1).$$

This is shown graphically in Figure 2. One can compute similar regions for any link. Two other examples are the Complementary Log-Log link $\psi^{\text{CLL}}(x) = \log(-\log(1-x))$ (confer McCullagh and Nelder, 1989), the "square link" $\psi^{\text{sq}}(x) = x^2$ and the "cosine link" $\psi^{\cos}(x) = 1 - \cos(\pi x)$. All of these are illustrated in Figure 3. The reason for considering these last two rather unusual links is to illustrate the following fact. Observing that the allowable region in Figure 2 precludes weight functions that approach zero at the endpoints of the interval, and noting that in order to well approximate the behaviour of 0-1 loss (with its weight function being $w_{0-1}(c) = \delta(c - \frac{1}{2})$) one would like a weight function that does indeed approach zero at the end points, it is natural to ask what constraints are imposed upon a link ψ such that a composite loss with that link and a weight function $w(c)$ such that

$$\lim_{c \searrow 0} w(c) = \lim_{c \nearrow 1} w(c) = 0 \tag{32}$$

is convex. Inspection of (29) reveals it is necessary that $\psi'(x) \to 0$ as $x \to 0$ and $x \to 1$. Such ψ necessarily have bounded range and thus the inverse link ψ^{-1} is only defined on a finite interval and furthermore the gradient of ψ^{-1} will be arbitrarily large. If one wants inverse links defined on the whole real line (such as the logistic link) then one can not obtain a convex composite link with the associated proper loss having a weight function satisfying (32). Thus one can not choose an effectively usable link to ensure convexity of a proper loss that is arbitrarily "close to" 0-1 loss in the sense of the corresponding weight functions.

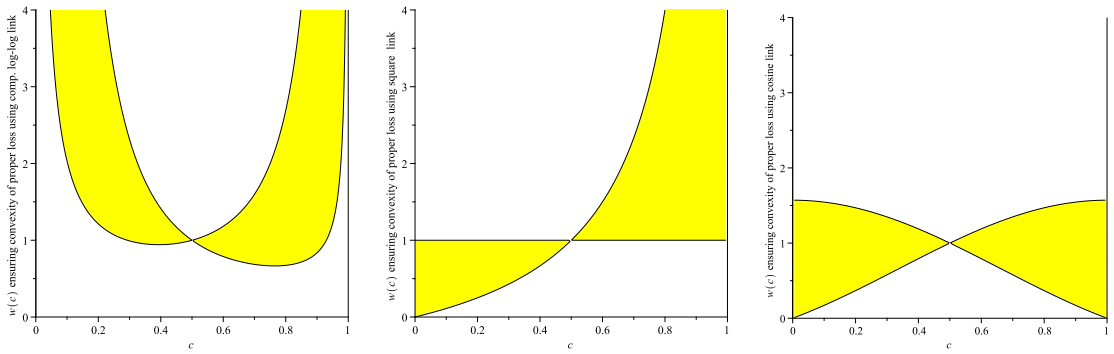

Figure 3: Allowable normalised weight functions to ensure convexity of loss functions with complementary log-log, square and cosine links.

Corollary 30 *If a loss is proper and convex, then it is strictly proper.*

The proof of Corollary 30 makes use of the following special case of the Gronwall style Lemma 1.1.1 of Bainov and Simeonov (1992).

Lemma 31 *Let $b\colon \mathbb{R} \to \mathbb{R}$ be continuous for $t \geq \alpha$. Let $v(t)$ be differentiable for $t \geq \alpha$ and suppose $v'(t) \leq b(t)v(t)$, for $t \geq \alpha$ and $v(\alpha) \leq v_0$. Then for $t \geq \alpha$,*

$$v(t) \leq v_0 \exp\left(\int_\alpha^t b(s)ds\right).$$

Proof (Corollary 30) Observe that the RHS of (17) implies

$$w'(v) \leq \frac{w(v)}{1-v},\ v \geq 0.$$

Suppose $w(0) = 0$. Then $v_0 = 0$ and the setting $\alpha = 0$ the lemma implies

$$w(t) \leq v_0 \exp\left(\int_0^t \frac{1}{1-s}ds\right) = \frac{v_0}{1-t} = 0, \quad t \in (0,1].$$

Thus if $w(0) = 0$ then $w(t) = 0$ for all $t \in (0,1)$. Choosing any other $\alpha \in (0,1)$ leads to a similar conclusion. Thus if $w(t) = 0$ for some $t \in [0,1)$, $w(s) = 0$ for all $s \in [t,1]$. Hence $w(t) > 0$ for all $t \in [0,1]$ and hence by the remark immediately following Theorem 6 ℓ is strictly proper. ■

6.3 Convexity of Bregman Divergences in their Second Argument

Bregman divergences are always convex in the first argument but only sometimes in their second. Corollary 5 and Equation 31 together characterise when the Bregman divergence $D_\phi(\eta, \hat{\eta})$ defined on $(0,1) \times (0,1)$ is convex in $\hat{\eta}$, providing a more direct result that that in Bauschke and Borwein (2001): Setting $\phi = -\underline{L}$ we immediately obtain that $\hat{\eta} \mapsto D_\phi(\eta, \hat{\eta})$ is convex for all $\eta \in (0,1)$ iff (31) holds, where $w(c) = \phi''(c)$.

7. Choosing a Surrogate Loss

A *surrogate* loss function is a loss function which is not exactly what one wishes to minimise but is easier to work with algorithmically. Convex surrogate losses are often used in place of the 0-1 loss which is not convex.

Surrogate losses have garnered increasing interest in the machine learning community (Zhang, 2004b; Bartlett et al., 2006; Steinwart, 2007; Steinwart and Christmann, 2008). Some of the questions considered to date are bounding the regret of a desired loss in terms of a surrogate ("surrogate regret bounds"—see Reid and Williamson, 2009b and references therein), the relationship between the decision theoretic perspective and the elicitability perspective (Masnadi-Shirazi and Vasconcelos, 2009), and efficient algorithms for minimising convex surrogate margin losses (Nock and Nielsen, 2009b,a).

Typically convex surrogates are used because they lead to convex, and thus tractable, optimisation problems. To date, work on surrogate losses has focussed on margin losses which necessarily are symmetric with respect to false positives and false negatives (Buja et al., 2005). In line with the rest of this paper, our treatment will not be so restricted.

The aim here is put forward some plausible definitions of what it might mean to select a "best" surrogate from a class of losses—for example, the class of proper, convex composite losses. We make use of the weight function perspective and the convexity results given in the previous section to investigate some new definitions for "best" surrogate and put forward some conjectures regarding them.

7.1 The "Best" Surrogate Loss

There are many choices of surrogate loss one can choose. A natural question is thus "which is best?". In order to do this we need to first define how we are evaluating losses as surrogates. To do this we require notation to describe the set of minimisers of the conditional and full risk associated with a loss. Given a loss $\ell\colon \{-1,1\} \times \mathcal{V} \to \mathbb{R}$ its *conditional minimisers at* $\eta \in [0,1]$ is the set

$$H(\ell,\eta) := \{v \in \mathcal{V}\colon L(\eta,v) = \underline{L}(\eta)\}. \tag{33}$$

Given a set of hypotheses $\mathcal{H} \subseteq \mathcal{V}^{\mathcal{X}}$, the (constrained) Bayes optimal risk is

$$\underline{\mathbb{L}}_{\mathcal{H}} := \inf_{h\in\mathcal{H}} \mathbb{L}(h,\mathbb{P}).$$

The *(full) minimisers over* $\mathcal{H}$ *for* $\mathbb{P}$ is the set

$$\mathcal{H}(\ell,\mathbb{P}) := \{h \in \mathcal{H}\colon \mathbb{L}(h) = \underline{\mathbb{L}}_{\mathcal{H}}\},$$

where $\mathcal{H} \subseteq \mathcal{V}^{\mathcal{X}}$ is some restricted set of functions and $\mathbb{L}(h) := \mathbb{E}_{(\mathsf{X},\mathsf{Y})\sim\mathbb{P}}[\ell(\mathsf{Y},h(\mathsf{X}))]$ and the expectation is with respect to $\mathbb{P}$. Given a *reference loss* ℓ_{ref}, we will say the ℓ_{ref}*-surrogate penalty* of a loss ℓ over the function class $\mathcal{H}$ on a problem (η,M) (or equivalently $\mathbb{P}$) is

$$S_{\ell_{\text{ref}}}(\ell,\eta,M) = S_{\ell_{\text{ref}}}(\ell,\mathbb{P}) := \inf_{h\in\mathcal{H}(\ell,\mathbb{P})} \mathbb{L}_{\text{ref}}(h),$$

where it is important to remember that $\mathbb{L}$ is with respect to $\mathbb{P}$. That is, $S_{\ell_{\text{ref}}}(\ell,\mathbb{P})$ is the minimum ℓ_{ref} risk obtainable by a function in $\mathcal{H}$ that minimises the ℓ risk.

Given a fixed experiment $\mathbb{P}$, if $\mathcal{L}$ is a class of losses then the *best surrogate losses in* $\mathcal{L}$ for the reference loss ℓ_{ref} are those that minimise the ℓ_{ref}-surrogate penalty. This definition is motivated by the manner in which surrogate losses are used—one minimizes $\mathbb{L}(h)$ over h to obtain the minimiser h^* and one hopes that $\mathbb{L}_{\text{ref}}(h^*)$ is small. Clearly, if the class of losses contains the reference loss (i.e., $\ell_{\text{ref}} \in \mathcal{L}$) then ℓ_{ref} will be a best surrogate loss. Therefore, the question of best surrogate loss is only interesting when $\ell_{\text{ref}} \notin \mathcal{L}$. One particular case we will consider is when the reference loss is the 0-1 loss and the class of surrogates $\mathcal{L}$ is the set of convex proper losses. Since 0-1 loss is not convex the question of which surrogate is best is non-trivial.

It would be nice if one could reason about the "best" surrogate loss using the conditional perspective (that is working with L instead of $\mathbb{L}$) and in a manner independent of $\mathcal{H}$. It is simple to see why this can not be done. Since all the losses we consider are proper, the minimiser over $\hat{\eta}$ of $L(\eta, \hat{\eta})$ is η. Thus any proper loss would lead to the same $\hat{\eta} \in [0,1]$. It is only the introduction of the restricted class of hypotheses $\mathcal{H}$ that prevents this reasoning being applied for $\mathbb{L}$: restrictions on $h \in \mathcal{H}$ prevent $h(x) = \eta(x)$ for all $x \in \mathcal{X}$. We conclude that the problem of best surrogate loss only makes sense when one both takes expectations over X *and* restricts the class of hypotheses h to be drawn from some set $\mathcal{H} \subsetneq [0,1]^{\mathcal{X}}$.

This reasoning accords with that of Nock and Nielsen (2009b,a) who examined which surrogate to use and proposed a data-dependent scheme that tunes surrogates for a problem. They explicitly considered proper losses and said that "minimizing any [lower-bounded, symmetric proper] loss amounts to the *same* ultimate goal" and concluded that "the crux of the choice of the [loss] relies on data-dependent considerations".

We demonstrate the difficulty of finding a universal best surrogate loss in by constructing a simple example. One can construct experiments (η_1, M) and (η_2, M) and proper losses ℓ_1 and ℓ_2 such that

$$S_{\ell_{0-1}}(\ell_1, (\eta_1, M)) > S_{\ell_{0-1}}(\ell_2, (\eta_1, M)) \text{ but } S_{\ell_{0-1}}(\ell_1, (\eta_2, M)) < S_{\ell_{0-1}}(\ell_2, (\eta_2, M)).$$

(The examples we construct have weight functions that "cross-over" each other; the details are in Appendix A.) However, this does not imply there can not exist a particular convex ℓ^* that minorizes all proper losses in this sense. Indeed, we conjecture that, in the sense described above, there is no best proper, convex surrogate loss.

Conjecture 32 *Given a proper, convex loss ℓ there exists a second proper, convex loss $\ell^* \neq \ell$, a hypothesis class $\mathcal{H}$, and an experiment $\mathbb{P}$ such that $S_{\ell_{0-1}}(\ell^*, \mathbb{P}) < S_{\ell_{0-1}}(\ell, \mathbb{P})$ for the class $\mathcal{H}$.*

To prove the above conjecture it would suffice to show that for a fixed hypothesis class and any pair of losses one can construct two experiments such that one loss minorises the other loss on one experiment and *vice versa* on the other experiment.

Supposing the above conjecture is true, one might then ask for a best surrogate loss for some reference loss ℓ_{ref} in a minimax sense. Formally, we would like the loss $\ell^* \in \mathcal{L}$ such that the worst-case penalty for using ℓ^*,

$$\Upsilon_{\mathcal{L}}(\ell^*) := \sup_{\mathbb{P}} \left\{ S_{\ell_{\text{ref}}}(\ell^*, \mathbb{P}) - \inf_{\ell \in \mathcal{L}} S_{\ell_{\text{ref}}}(\ell, \mathbb{P}) \right\}$$

is minimised. That is, $\Upsilon_{\mathcal{L}}(\ell^*) \leq \Upsilon_{\mathcal{L}}(\ell)$ for all $\ell \in \mathcal{L}$.

7.2 The "Minimal" Symmetric Convex Proper Loss

Theorem 29 suggests an answer to the question "What is the proper convex loss closest to the 0-1 loss?" A way of making this question precise follows. Since ℓ is presumed proper, it has a weight function w. Suppose w.l.o.g. that $w(\frac{1}{2}) = 1$. Suppose the link is the identity. The constraints in (17) imply that the weight function that is most similar to that for 0-1 loss meets the constraints. Thus from (31)

$$w^{\text{minimal}}(c) = \frac{1}{2}\left(\frac{1}{c} \wedge \frac{1}{1-c}\right) \tag{34}$$

is the weight for the convex proper loss closest to 0-1 loss in this sense. It is the weight function that forms the lower envelope of the shaded region in the left diagram of Figure 2. Using (5) one can readily compute the corresponding partial losses explicitly

$$\ell_{-1}^{\text{minimal}}(\hat{\eta}) = \frac{1}{2}\left([\![\hat{\eta} < \tfrac{1}{2}]\!](-\hat{\eta} - \ln(1-\hat{\eta})) + [\![\hat{\eta} \geq \tfrac{1}{2}]\!](\hat{\eta} - 1 - \ln(\tfrac{1}{2}))\right) \tag{35}$$

and

$$\ell_{1}^{\text{minimal}}(\hat{\eta}) = \frac{1}{2}\left([\![\hat{\eta} < \tfrac{1}{2}]\!](-\hat{\eta} - \log(\tfrac{1}{2})) + [\![\hat{\eta} \geq \tfrac{1}{2}]\!](\hat{\eta} - 1 - \ln\hat{\eta})\right). \tag{36}$$

Observe that the partial losses are (in part) linear, which is unsurprising as linear functions are on the boundary of the set convex functions. This loss is also best in another more precise (but ultimately unsatisfactory) sense, as we shall now show.

Surrogate regret bounds are theoretical bounds on the regret of a desired loss (say 0-1 loss) in terms of the regret with respect to a surrogate. Reid and Williamson (2009b) have shown the following (we only quote the simpler symmetric case here):

Theorem 33 *Suppose ℓ is a proper loss with corresponding conditional Bayes risk $\underline{L}$ which is symmetric about $\frac{1}{2}$: $\underline{L}(\frac{1}{2} - c) = \underline{L}(\frac{1}{2} + c)$ for $c \in [0, \frac{1}{2}]$. If the regret for the $\ell_{\frac{1}{2}}$ loss $\Delta L_{\frac{1}{2}}(\eta, \hat{\eta}) = \alpha$, then the regret ΔL with respect to ℓ satisfies*

$$\Delta L(\eta, \hat{\eta}) \geq \underline{L}(\tfrac{1}{2}) - \underline{L}(\tfrac{1}{2} + \alpha). \tag{37}$$

The bound in the theorem can be inverted to upper bound $\Delta L_{\frac{1}{2}}$ given an upper bound on $\Delta L(\eta, \hat{\eta})$. Considering all symmetric proper losses normalised such that $w(\frac{1}{2}) = 1$, the right side of (37) is maximised and thus the bound on $\Delta L_{\frac{1}{2}}$ in terms of ΔL is minimised when $\underline{L}(\frac{1}{2} + \alpha)$ is maximised (over all losses normalised as mentioned). But since $w = -\underline{L}''$, that occurs for the pointwise minimiser of w (subject to $w(\frac{1}{2}) = 1$). Since we are interested in convex losses, the minimising w is given by (34). In this case the right hand side of (37) can be explicitly determined to be $(\frac{\alpha}{2} + \frac{1}{4})\log(2\alpha + 1) - \frac{\alpha}{2}$, and the bound can be inverted to obtain the result that if $\Delta L^{\text{minimal}}(\eta, \hat{\eta}) = x$ then

$$\Delta L_{\frac{1}{2}}(\eta, \hat{\eta}) \leq \frac{1}{2}\exp\left(\text{LambertW}\left(\frac{(4x-1)}{\mathrm{e}}\right) + 1\right) - \frac{1}{2} \tag{38}$$

which is plotted in Figure 4.[13]

The above argument does *not* show that the loss given by (35,36) is the *best* surrogate loss. The reason is that the above is optimising a *bound* on the regret, not the *actual* regret; the argument in

13. The LambertW function is the real-valued solution of $x \mapsto W(x)e^{W(x)}$. It is commonly found in solutions to differential equations, has no closed form. Its details are not relevant to this discussion except for computing Figure 4.

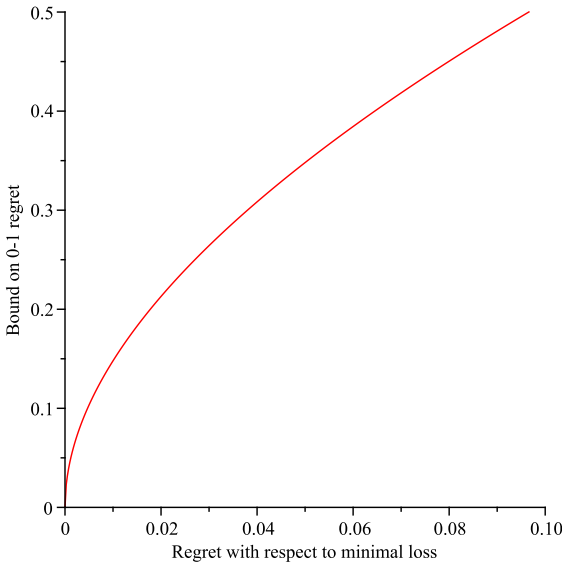

Figure 4: Upper bound on the 0-1 regret in terms of $\Delta L^{\text{minimal}}$ as given by (38).

Appendix A demonstrates there can in general be no universally best surrogate loss (independent of the underlying distribution). Nevertheless it does suggest it is at least worth considering using ℓ^{minimal} as a convex proper surrogate binary loss.

We conjecture that ℓ^{minimal} is somehow special in the class of proper convex losses in some way other than being the pointwise minimiser of weights (and the normalised loss with smallest regret bound with respect to ℓ^{0-1}), but the exact nature of the specialness still eludes us. Perhaps it is optimal in some weaker (minimax) sense. The reason for this suggestion is that it is not hard to show that for reasonable $\mathbb{P}$ there exists $\mathcal{H}$ such that $c \mapsto \mathbb{L}_c(h,\mathbb{P})$ takes on all possible values within the constraints

$$0 \leq \mathbb{L}_c(h,\mathbb{P}) \leq \max(c, 1-c)$$

which follows immediately from the definition of cost-sensitive misclassification loss. Furthermore the example in the appendix below seems to require loss functions whose corresponding weight functions cross over each other and there is no weight function corresponding to a convex proper loss that crosses over w^{minimal}.

8. Conclusions

Composite losses are widely used. As outlined in §1.1, we have characterised a number of aspects of them: their relationship to margin losses, the connection between properness and classification calibration, the constraints symmetry imposes, when composite losses are convex, and natural ways to parametrise them. We have also considered the question of the "best" surrogate loss.

The parametrisation of a composite loss in terms (w,ψ') (or ρ) has advantages over using (ϕ,ψ) or $(\underline{L},\psi)$. As explained by Masnadi-Shirazi and Vasconcelos (2009), the representation in terms of (ϕ,ψ) is in general not unique. The representation in terms of $\underline{L}$ is harder to intuit: whilst indeed the Bayes risk for squared loss and 0-1 loss are "close" (compare the graph of $c \mapsto c(1-c)$ with that of

$c \mapsto c \wedge (1-c)$), by examining their weight functions they are seen to be very different ($w(c) = 1$ versus $w(c) = 2\delta(c - \frac{1}{2})$). We have also seen that on the basis of Theorem 24, the parametrisation (w, ψ') is perhaps the most natural—there is a pleasing symmetry between the loss and the link as they are in this form both parametrised in terms of non-negative weight functions on $[0,1]$. Recall too that the canonical link sets ψ' equal to w.

The observation suggests an alternate inductive principle known as *surrogate tuning*, which seems to have been first suggested by Nock and Nielsen (2009b).[14] The idea of surrogate tuning is simple: noting that the best surrogate depends on the problem, adapt the surrogate you are using to the problem. In order to do so it is important to have a good parametrisation of the loss. The weight function perspective does just that, especially given Theorem 29. It would be straight forward to develop low dimensional parametrisations of w that satisfy the conditions of this theorem which would thus allow a learning algorithm to explore the space of convex losses. One could (taking due care with the subsequent multiple hypothesis testing problem) regularly *evaluate* the 0-1 loss of the hypotheses so obtained. The observations made in Section 4 regarding stochastic gradient descent algorithms may be of help in this regard.

Acknowledgments

This work was motivated in part by a question due to John Langford. Thanks to Fangfang Lu for discussions and finding several bugs in an earlier version. Thanks to Ingo Steinwart for pointing out the η_α trick. Thanks to Tim van Erven and the anonymous reviewers for comments and corrections. This work was supported by the Australian Research Council and NICTA through Backing Australia's Ability.

Appendix A. Example Showing Incommensurability of Two Proper Surrogate Losses

We consider $\mathcal{X} = [0,1]$ with M being uniform on $\mathcal{X}$, and consider the two problems that are induced by

$$\eta_1(x) = x^2 \quad \text{and} \quad \eta_2(x) = \frac{1}{3} + \frac{x}{3}.$$

We use a simple linear hypothesis class

$$\mathcal{H} := \{h_\alpha(x) := \alpha x \colon \alpha \in [0,1]\},$$

with identity link function and consider the two surrogate proper losses ℓ_1 and ℓ_2 with weight functions

$$w_1(c) = \frac{1}{c}, \qquad w_2(c) = \frac{1}{1-c}.$$

These weight functions correspond to the two curves that construct the left diagram in Figure 2. The corresponding conditional losses can be readily calculated to be

$$\begin{aligned} L_1(\eta, h) &:= \eta(h - 1 - \log(h)) + (1-\eta)h \\ L_2(\eta, h) &:= \eta(1-h) + (1-\eta)(-h - \log(1-h)). \end{aligned}$$

14. Surrogate tuning differs from loss *tailoring* (Hand, 1994; Hand and Vinciotti, 2003; Buja et al., 2005) which involves adapting the loss to what you really think is important.

One can numerically compute the parameters for the constrained Bayes optimal for each problem and for each surrogate loss:

$$\begin{aligned}
\alpha^*_{1,1} &= \arg\min_{\alpha\in[0,1]} \mathbb{L}_1(\eta_1, h_\alpha, M) = 0.66666667 \\
\alpha^*_{2,1} &= \arg\min_{\alpha\in[0,1]} \mathbb{L}_2(\eta_1, h_\alpha, M) = 0.81779259 \\
\alpha^*_{1,2} &= \arg\min_{\alpha\in[0,1]} \mathbb{L}_1(\eta_2, h_\alpha, M) = 1.00000000 \\
\alpha^*_{2,1} &= \arg\min_{\alpha\in[0,1]} \mathbb{L}_2(\eta_2, h_\alpha, M) = 0.77763472.
\end{aligned}$$

Furthermore

$$\begin{aligned}
&\mathbb{L}_{0-1}(\eta_1, h_{\alpha^*_{1,1}}, M) = 0.3580272, \qquad \mathbb{L}_{0-1}(\eta_1, h_{\alpha^*_{2,1}}, M) = 0.3033476, \\
&\mathbb{L}_{0-1}(\eta_2, h_{\alpha^*_{1,2}}, M) = 0.4166666, \qquad \mathbb{L}_{0-1}(\eta_2, h_{\alpha^*_{2,2}}, M) = 0.4207872.
\end{aligned}$$

Thus for problem η_1 the surrogate loss L_2 has a constrained Bayes optimal hypothesis $h_{\alpha^*_{2,1}}$ which has a lower 0-1 risk than the constrained Bayes optimal hypothesis $h_{\alpha^*_{1,1}}$ for the surrogate loss L_1. Thus for problem η_1 surrogate L_2 is better than surrogate L_1. However for problem η_2 the situation is reversed: surrogate L_2 is *worse* than surrogate L_1.

Appendix B. An Alternate View of Canonical Links

This appendix contains an alternate approach to understanding canonical links using convex duality. In doing so we present an improved formulation of a result on the duality of Bregman divergences that may be of independent interest.

The *Legendre-Fenchel* (LF) dual $\phi^\star$ of a function $\phi\colon \mathbb{R} \to \mathbb{R}$ is a function defined by

$$\phi^\star(s^\star) := \sup_{s\in\mathbb{R}} \{\langle s, s^\star\rangle - \phi(s)\}.$$

The LF dual of any function is convex.

When $\phi(s)$ is a function of a real argument s and the derivative $\phi'(s)$ exists, the Legendre-Fenchel conjugate $\phi^\star$ is given by the *Legendre transform* (Rockafellar, 1970; Hiriart-Urruty and Lemaréchal, 2001)

$$\phi^\star(s) = s \cdot (\phi')^{-1}(s) - \phi\left((\phi')^{-1}(s)\right). \tag{39}$$

Thus (writing $\partial f := f'$) $f' = (\partial f^\star)^{-1}$. Thus with w, W, and $\overline{W}$ defined as above,

$$W = (\partial(\overline{W}^\star))^{-1}, \quad W^{-1} = \partial(\overline{W}^\star), \ \ \overline{W}^\star = \int W^{-1}. \tag{40}$$

Let $w, W, \overline{W}$ be as in Theorem 7. Denote by L_W the w-weighted conditional loss parametrised by $W = \int w$ and let ΔL_W be the corresponding regret (we can interchange ΔL and D here by (12) since $\psi_L = \mathrm{id}$.

$$D_w(\eta, \hat{\eta}) = \overline{W}(\eta) - \overline{W}(\hat{\eta}) - (\eta - \hat{\eta})W(\hat{\eta}). \tag{41}$$

We now further consider D_w as given by (41). It will be convenient to parametrise D by W instead of w. Note that the standard parametrisation for a Bregman divergence is in terms of the convex function $\overline{W}$. Thus will write $D_{\overline{W}}, D_W$ and D_w to all represent (41). The following theorem is known (e.g., Zhang, 2004a) but as will be seen, stating it in terms of D_W provides some advantages.

Theorem 34 *Let w, W, $\overline{W}$ and D_W be as above. Then for all $x, y \in [0,1]$,*

$$D_W(x,y) = D_{W^{-1}}(W(y), W(x)). \tag{42}$$

Proof Using (39) we have

$$\begin{aligned} & \overline{W}^\star(u) = u \cdot W^{-1}(u) - \overline{W}(W^{-1}(u)) \\ \Rightarrow \quad & \overline{W}(W^{-1}(u)) = u \cdot W^{-1}(u) - \overline{W}^\star(u). \end{aligned} \tag{43}$$

Equivalently (using (40))

$$\overline{W}^\star(W(u)) = u \cdot W(u) - \overline{W}(u). \tag{44}$$

Thus substituting and then using (43) we have

$$\begin{aligned} D_W(x, W^{-1}(v)) &= \overline{W}(x) - \overline{W}(W^{-1}(v)) - (x - W^{-1}(v)) \cdot W(W^{-1}(v)) \\ &= \overline{W}(x) + \overline{W}^\star(v) - vW^{-1}(v) - (x - W^{-1}(v)) \cdot v \\ &= \overline{W}(x) + \overline{W}^\star(v) - x \cdot v. \end{aligned} \tag{45}$$

Similarly (this time using (44) we have

$$\begin{aligned} D_{W^{-1}}(v, W(x)) &= \overline{W}^\star(v) - \overline{W}^\star(W(x)) - (v - W(x)) \cdot W^{-1}(W(x)) \\ &= \overline{W}^\star(v) - xW(x) + \overline{W}(x) - v \cdot x + xW(x) \\ &= \overline{W}^\star(v) + \overline{W}(x) - v \cdot x \end{aligned} \tag{46}$$

Comparing (45) and (46) we see that

$$D_W(x, W^{-1}(v)) = D_{W^{-1}}(v, W(x))$$

Let $y = W^{-1}(v)$. Thus subsitituting $v = W(y)$ leads to (42). ■

The weight function corresponding to $D_{W^{-1}}$ is $\frac{\partial}{\partial x} W^{-1}(x) = \frac{1}{w(W^{-1}(x))}$.

Theorem 35 *If the inverse link $\psi^{-1} = W^{-1}$ (and thus $\hat{\eta} = W^{-1}(\hat{h})$) then*

$$\begin{aligned} D_W(\eta, \hat{\eta}) &= D_W(\eta, W^{-1}(\hat{h})) = \overline{W}(\eta) + \overline{W}^\star(\hat{h}) - \eta \cdot \hat{h} \\ L_W(\eta, \hat{\eta}) &= L_W(\eta, W^{-1}(\hat{h})) = \overline{W}^\star(\hat{h}) - \eta \cdot \hat{h} + \eta(\overline{W}(1) + \overline{W}(0)) - \overline{W}(0) \\ \frac{\partial}{\partial \hat{h}} L_W(\eta, W^{-1}(\hat{h})) &= \hat{\eta} - \eta \end{aligned}$$

and furthermore $D_W(\eta, W^{-1}(\hat{h}))$ and $L_W(\eta, W^{-1}(\hat{h}))$ are convex in $\hat{h}$.

Proof The first two expressions follow immediately from (45) and (46) by substitution. The derivative follows from calculation: $\frac{\partial}{\partial \hat{h}} L_W(\eta, W^{-1}(\hat{h})) = \frac{\partial}{\partial \hat{h}} (\overline{W}^\star(\hat{h}) - \eta \cdot \hat{h}) = W^{-1}(\hat{h}) - \eta = \hat{\eta} - \eta$. The convexity follows from the fact that $\overline{W}^\star$ is convex (since it is the LF dual of a convex function $\overline{W}$) and the overall expression is the sum of this and a linear term, and thus convex. ■

Buja et al. (2005) call W the *canonical link*. We have already seen (Theorem 27) that the composite loss constructed using the canonical link is convex.

Appendix C. Convexity and Robustness

In this appendix we show how the characterisation of the convexity of proper losses (Theorem 29) allows one to make general algorithm independent statements about the robustness of convex proper losses to random mis-classification noise.

Long and Servedio (2008) have shown that boosting with convex potential functions (i.e., convex margin losses) is not robust to random class noise.[15] That is, they are susceptible to random class noise. In particular they present a very simple learning task which is "boostable"—can be perfectly solved using a linear combination of base classifiers—but for which, in the presence of any amount of label noise, idealised, early stopping and L_1 regularised boosting algorithms will learn a classifier with only 50% accuracy.

This has led to the recent proposal of boosting algorithms that use non-convex margin losses and experimental evidence suggests that these are more robust to class noise than their convex counterparts. Freund (2009) recently described RobustBoost, which uses a parameterised family of non-convex surrogate losses that approximates the 0-1 loss as the number of boosting iterations increases. Experiments on a variant of the task proposed by Long and Servedio (2008) show that RobustBoost is very insensitive to class noise. Masnadi-Shirazi and Vasconcelos (2009) presented SavageBoost, a boosting algorithm built upon a non-convex margin function. They argued that even when the margin function is non-convex the conditional risk may still be convex. We elucidate this via our characterisation of the convexity of composite losses. Although all these results are suggestive, it is not clear from these results whether the robustness or not is a property of the loss function, the algorithm or a combination. We study that question by considering robustness in an algorithm-independent fashion.

For $\alpha \in (0, \frac{1}{2})$ and $\eta \in [0,1]$ we will define

$$\eta_\alpha := \alpha(1-\eta) + (1-\alpha)\eta$$

as the α-*corrupted version* of η. This captures the idea that instead of drawing a positive label for the point x with probability $\eta(x)$ there is a random class flip with probability α. This might be done on purpose in order to avoid problems with losses (e.g., log loss) that assign infinite penalty to 0 or 1 valued probability predictions. Since η_α is a convex combination of α and $1-\alpha$ it follows that $\eta_\alpha \in [\alpha, 1-\alpha]$. The effect of α-corruption on the conditional risk of a loss can be seen as a transformation of the loss (Steinwart, 2009).

Lemma 36 *If ℓ^ψ is any composite loss then its conditional risk satisfies*

$$L^\psi(\eta_\alpha, v) = L^\psi_\alpha(\eta, v), \quad \eta \in [0,1], \ \ v \in \mathcal{V},$$

where $\ell^\psi_\alpha(y,v) = (1-\alpha)\ell^\psi(y,v) + \alpha\ell^\psi(-y,v)$.

15. We define exactly what we mean by robustness below. The notion that Long and Servedio (2008) examine is akin to that studied for instance by Kearns (1998). There are many other meanings of "robust" which are different to that which we consider. The classical notion of robust statistics (Huber, 1981) is motivated by robustness to contamination of additive observation noise (some heavy-tail noise mixed in with the Gaussian noise often assumed in designing estimators). There are some results about particular machine learning algorithms being robust in that sense (Schölkopf et al., 2000). "Robust" is also used to mean robustness with respect to random attribute noise (Trafalis and Gilbert, 2006), robustness to unknown prior class probabilities (Provost and Fawcett, 2001), or a Huber-style robustness to attribute noise ("outliers") for classification (Fidler et al., 2006). We only study robustness in the sense of random label noise.

Proof By simple algebraic manipulation we have

$$\begin{aligned} L^\psi(\eta_\alpha, v) &= (1-\eta_\alpha)\ell^\psi(-1,v) + \eta_\alpha \ell^\psi(1,v) \\ &= [(1-\alpha)(1-\eta)+\alpha\eta]\ell^\psi(-1,v) + [\alpha(1-\eta)+(1-\alpha)\eta]\ell^\psi(1,v) \\ &= (1-\eta)[(1-\alpha)\ell^\psi(-1,v)+\alpha\ell^\psi(1,v)] + \eta[\alpha\ell^\psi(-1,v)+(1-\alpha)\ell^\psi(1,v)] \\ &= (1-\eta)\ell^\psi_\alpha(-1,v) + \eta\ell^\psi_\alpha(1,v) \\ &= L^\psi_\alpha(\eta, v) \end{aligned}$$

proving the result. ■

In particular, if ℓ is strictly proper then ℓ_α cannot be proper because the minimiser of $L(\eta_\alpha, \cdot)$ is η_α and so $\eta_\alpha \neq \eta$ must also be the minimiser of $L_\alpha(\eta, \cdot)$. This suggests that strictly proper losses are not robust to any class noise.

C.1 Robustness Implies Non-convexity

We now define a general notion of robustness for losses for class probability estimation.

Definition 37 *Given an* $\alpha \in [0, \frac{1}{2})$*, we will say a loss* $\ell\colon \{-1,1\} \times [0,1] \to \mathbb{R}$ *is* α-robust at η *if the set of minimisers of the conditional risk for* η *and the set of minimisers of the conditional risk for* η_α *have some common points*.

That is, a loss is α-robust for a particular η if minimising the noisy conditional risk can potentially give an estimate that is also a minimiser of the non-noisy conditional risk. Formally, ℓ *is* α*-robust at* η when

$$H(\ell, \eta_\alpha) \cap H(\ell, \eta) \neq \emptyset,$$

where $H(\ell, \eta)$ is defined in (33). Due to the equivalence of α-corruption of data and a transformed loss, another way to think about this type of robustness is the following: under what conditions can using non-proper losses still lead to the recovery of accurate conditional probability estimates?

Label noise is symmetric about $\frac{1}{2}$ and so the map $\eta \mapsto \eta_\alpha$ preserves the side of $\frac{1}{2}$ on which the values η and η_α are found. That is, $\eta \leq \frac{1}{2}$ if and only if $\eta_\alpha \leq \frac{1}{2}$ for all $\alpha \in [0, \frac{1}{2})$. This means that 0-1 misclassification loss or, equivalently, $\ell_{\frac{1}{2}}$ is α-robust for all η and for all α. For other c, the range of η for which ℓ_c is α-robust is more limited.

Theorem 38 *For each* $c \in (0,1)$*, the loss* ℓ_c *is* α*-robust at* η *if and only if*

$$\eta \notin \left[\frac{c-\alpha}{1-2\alpha}, c\right) \text{ for } c < \tfrac{1}{2} \quad \text{or} \quad \eta \notin \left[c, \frac{c-\alpha}{1-2\alpha}\right) \text{ for } c \geq \tfrac{1}{2}.$$

Proof By the definition of L_c and $[\![\hat{\eta} < c]\!] = 1 - [\![\hat{\eta} \geq c]\!]$ we have

$$L_c(\eta, \hat{\eta}) = (1-\eta)c[\![\hat{\eta} \geq c]\!] + \eta(1-c)[\![\hat{\eta} < c]\!] = \eta(1-c) + (c-\eta)[\![\hat{\eta} \geq c]\!].$$

Since $c - \eta$ is positive iff $c > \eta$ we see $L_c(\eta, \hat{\eta})$ is minimised for $\eta < c$ when $\hat{\eta} < c$ and for $\eta \geq c$ when $\hat{\eta} \geq c$. So $H(\ell_c, \eta) = [0, c)$ for $\eta < c$ and $H(\ell_c, \eta) = [c, 1]$ for $\eta \geq c$. Since $[0, c)$ and $[c, 1]$

are disjoint for all $c \in [0,1]$ we see that $H(\ell_c, \eta)$ and $H(\ell_c, \eta_\alpha)$ coincide if and only if $\eta, \eta_\alpha < c$ or $\eta, \eta_\alpha \geq c$ and are disjoint otherwise.

We proceed by cases. First, suppose $c < \frac{1}{2}$. For $\eta < c < \frac{1}{2}$ it is easy to show $\eta_\alpha \geq c$ iff $\eta \geq \frac{c-\alpha}{1-2\alpha}$ and so ℓ_c is not α-robust for $\eta \in [\frac{c-\alpha}{1-2\alpha}, c)$. For $c \leq \eta$ we see ℓ_c must be α-robust since $\eta_\alpha < c$ iff $\eta < \frac{c-\alpha}{1-2\alpha}$ but $\frac{c-\alpha}{1-2\alpha} < c$ for $c < \frac{1}{2}$ which is a contradiction. Thus, for $c < \frac{1}{2}$ we have ℓ_c is α-robust iff $\eta \notin [\frac{c-\alpha}{1-2\alpha}, c)$.

For $c > \frac{1}{2}$ the main differences are that $\frac{c-\alpha}{1-2\alpha} > c$ for $c > \frac{1}{2}$ and $\eta_\alpha < \eta$ for $\eta > \frac{1}{2}$. Thus, by a similar argument as above we see that ℓ_c is α-robust iff $\eta \notin [c, \frac{c-\alpha}{1-2\alpha})$. ■

This theorem allows us to characterise the robustness of arbitrary proper losses by appealing to the integral representation in (4).

Lemma 39 *If ℓ is a proper loss with weight function w then $H(\ell, \eta) = \bigcap_{c:\, w(c)>0} H(\ell_c, \eta)$ and so*

$$H(\ell, \eta) \cap H(\ell, \eta_\alpha) = \bigcap_{c:\, w(c)>0} H(\ell_c, \eta) \cap H(\ell_c, \eta_\alpha).$$

Proof We first show that $H(\ell, \eta) \subseteq \bigcap_{c:\, w(c)>0} H(\ell_c, \eta)$ by contradiction. Assume there is an $\hat{\eta} \in H(\ell, \eta)$ but for which there is some c_0 such that $w(c_0) > 0$ and $\hat{\eta} \notin H(\ell_{c_0}, \eta)$. Then there is a $\hat{\eta}' \in H(\ell_{c_0}, \eta)$ and $\hat{\eta}' \in H(\ell_c)$ for all other c for which $w(c) > 0$ (otherwise $H(\ell, \eta) = \{\hat{\eta}\}$). Thus, $L_{c_0}(\eta, \hat{\eta}') < L_{c_0}(\eta, \hat{\eta}')$ and so $\int_0^1 L_c(\eta, \hat{\eta}')\, w(c)\, dc < \int_0^1 L_c(\eta, \hat{\eta})\, w(c)\, dc$ since $w(c_0) > 0$.

Now suppose $\hat{\eta} \in \bigcap_{c:\, w(c)>0} H(\ell_c, \eta)$. That is, $\hat{\eta}$ is a minimiser of $L_c(\eta, \cdot)$ for all c such that $w(c) > 0$ and therefore must also be a minimiser of $L(\eta, \cdot) = \int_0^1 L_c(\eta, \cdot)\, w(c)\, dc$ and is therefore in $H(\ell, \eta)$, proving the converse. ■

One consequence of this lemma is that if $w(c) > 0$ and ℓ_c is not α-robust at η then, by definition, $H(\ell_c, \eta) \cap H(\ell_c, \eta_\alpha) = \emptyset$ and so ℓ cannot be α-robust at η. This means we have established the following theorem regarding the α-robustness of an arbitrary proper loss in terms of its weight function.

Theorem 40 *If ℓ is a proper loss with weight function w then it is not α-robust for any*

$$\eta \in \bigcup_{c:\, w(c)>0} \left[\frac{c-\alpha}{1-2\alpha}, c\right) \cup \left[c, \frac{c-\alpha}{1-2\alpha}\right).$$

By Corollary 30 we see that convex proper losses are strictly proper and thus have weight functions which are non-zero for all $c \in [0,1]$ and so by Theorem 40 we have the following corollary.

Corollary 41 *If a proper loss is convex, then for all $\alpha \in (0, \frac{1}{2})$ it is not α-robust at any $\eta \in [0,1]$.*

At a high level, this result—"convexity implies non-robustness"—appears to be logically equivalent to Long and Servedio's result that "robustness implies non-convexity". However, there are a few discrepancies that mean they are not directly comparable. The definitions of robustness differ. We focus on the point-wise minimisation of conditional risk as this is, ideally, what most risk minimisation approach try to achieve. However, this means that robustness of ERM with regularisation or restricted function classes is not directly captured with our definition whereas Long and Servedio

analyse this latter case directly. In our definition the focus is on probability estimation robustness while the earlier work is focussed on classification accuracy. Our work could be extended to this case by analysing $H(\ell,\eta)\cap H(\ell_{\frac{1}{2}},\eta)$.

Additionally, their work restricts attention to the robustness of boosting algorithms that use convex potential functions whereas our analysis is not tied to any specific algorithm. By restricting their attention to a specific learning task and class of functions they are able to show a very strong result: that convex losses for boosting lead to arbitrarily bad performance with arbitrarily little noise. Also, our focus on proper losses excludes some convex losses (such as the hinge loss) that is covered by Long and Servedio's results.

Finally, it is worth noting that there are non-convex loss functions that are strictly proper and so are not robust in the sense we use here. That is, the converse of Corollary 41 is not true. For example, any loss with weight function that sits above 0 but outside the shaded region in Figure 2 will be non-convex and non-robust. This suggests that the arguments made by Masnadi-Shirazi and Vasconcelos (2009); Freund (2009) for the robustness of non-convex losses need further investigation.

Abstract

In this paper, we propose a general framework for sparse semi-supervised learning, which concerns using a small portion of unlabeled data and a few labeled data to represent target functions and thus has the merit of accelerating function evaluations when predicting the output of a new example. This framework makes use of Fenchel-Legendre conjugates to rewrite a convex insensitive loss involving a regularization with unlabeled data, and is applicable to a family of semi-supervised learning methods such as multi-view co-regularized least squares and single-view Laplacian support vector machines (SVMs). As an instantiation of this framework, we propose sparse multi-view SVMs which use a squared ε-insensitive loss. The resultant optimization is an inf-sup problem and the optimal solutions have arguably saddle-point properties. We present a globally optimal iterative algorithm to optimize the problem. We give the margin bound on the generalization error of the sparse multi-view SVMs, and derive the empirical Rademacher complexity for the induced function class. Experiments on artificial and real-world data show their effectiveness. We further give a sequential training approach to show their possibility and potential for uses in large-scale problems and provide encouraging experimental results indicating the efficacy of the margin bound and empirical Rademacher complexity on characterizing the roles of unlabeled data for semi-supervised learning.

Keywords: semi-supervised learning, Fenchel-Legendre conjugate, representer theorem, multi-view regularization, support vector machine, statistical learning theory

1. Introduction

Semi-supervised learning, considering how to estimate a target function from a few labeled examples and a large quantity of unlabeled examples, is one of currently active research directions. If the unlabeled data are properly used, it can get a superior performance over the counterpart supervised learning approaches. For an overview of semi-supervised learning methods, refer to Chapelle et al. (2006) and Zhu (2008).

Although semi-supervised learning was largely motivated by different real-world applications where obtaining labels is expensive or time-consuming, a lot of theoretical outcomes have also been accomplished. Typical applications of semi-supervised learning include natural image classification and text classification, where it is inexpensive to collect large numbers of images and texts by

automatic programs, but needs a high cost to label them manually. Theoretical results on semi-supervised learning include PAC-analysis (Balcan and Blum, 2005), manifold regularization (Belkin et al., 2006), and multi-view regularization theories (Sindhwani and Rosenberg, 2008), etc.

Among the methods proposed for semi-supervised learning, a family of them, for example, Laplacian regularized least squares (RLS), Laplacian support vector machines (SVMs), Co-RLS, Co-Laplacian RLS, Co-Laplacian SVMs, and manifold co-regularization (Belkin et al., 2006; Sindhwani et al., 2005; Sindhwani and Rosenberg, 2008), make use of the following representer theorem (Kimeldorf and Wahba, 1971) to represent the target function in a reproducing kernel Hilbert space (RKHS).

Theorem 1 (Representer theorem) *Let $\mathcal{H}$ be an RKHS with kernel $k : \mathcal{X} \times \mathcal{X} \to \boldsymbol{R}$. Fix any function $V : \boldsymbol{R}^n \to \boldsymbol{R}$ and any nondecreasing function $\Psi : \boldsymbol{R} \to \boldsymbol{R}$. Define*

$$J(f) = V(f(x_1), ..., f(x_n)) + \Psi(\|f\|^2),$$

and linear space $\mathcal{L} = span\{k(x_1, \cdot), ..., k(x_n, \cdot)\}$. Then for any $f \in \mathcal{H}$ we have $J(f_{\mathcal{L}}) \leq J(f)$ with $f_{\mathcal{L}}$ being the projection of f onto $\mathcal{L}$ in the following form

$$f_{\mathcal{L}} = \sum_{i=1}^{n} \alpha_i k(x_i, \cdot).$$

Thus if $J^* = \min_f J(f)$ exists, this minimum is attained for some $f \in \mathcal{L}$. Moreover, if Ψ is strictly increasing, each minimizer of $J(f)$ over $\mathcal{H}$ must be contained in $\mathcal{L}$.

Generally, in the objective function $J(f)$ of these semi-supervised learning methods, labeled examples are used to calculate an empirical loss of the target function and simultaneously unlabeled examples are used for some regularization purpose. By the representer theorem, the target function would involve kernel evaluations on all the labeled and unlabeled examples. This is computationally undesirable, because for semi-supervised learning usually a considerably large number of unlabeled examples are available. Consequently, sparsity in the number of unlabeled data used to represent target functions is crucial, which constitutes the focus of this paper.

However, little work has been done on this theme. In particular, there is no unified framework proposed yet to deal with this sparsity concern. While the sparse Laplacian core vector machines (Tsang and Kwok, 2007) touched this problem, it has a complicated optimization and is not generic enough to generalize to other similar semi-supervised learning methods. In contrast with this, the technique developed in this paper, based on Fenchel-Legendre conjugates, is computationally simple and widely applicable.

As far as multi-view learning is concerned there has been work that introduces sparsity of the unlabeled data into the representation of the classifiers (Szedmak and Shawe-Taylor, 2007). This builds on the ideas developed for two view learning known as the SVM-2K (Farquhar et al., 2006). The approach adopted is the use of an ε-insensitive loss function for the similarity constraint between the two functions from two views. Unfortunately the resulting optimization is somewhat unmanageable and only scales to small-scale data sets despite interesting theoretical bounds that show the improvement gained using the unlabeled data.

The work by Szedmak and Shawe-Taylor (2007) forms the starting point for the current paper which aims to develop related methods that are possible to be scaled to very large data sets. Our approach is to go back to consider l_2 loss between the outputs of the classifiers arising from two

views and shows that this problem can be solved implicitly with variables only indexed by the labeled data. To compute the value of this function on new data would still require a non-sparse dual representation in terms of the unlabeled data. However, we show that through optimizing weights of the unlabeled data the solution of the l_2 problem converges to the solution of an ε-insensitive problem ensuring that we subsequently obtain sparsity in the unlabeled data. Furthermore, we develop the generalization analysis of Szedmak and Shawe-Taylor (2007) to this case giving computable expressions for the corresponding empirical Rademacher complexity.

To show the application of Fenchel-Legendre conjugates, in Section 2 we propose a novel sparse semi-supervised learning approach: sparse multi-view SVMs, where the conjugate functions play a central role in reformulating the optimization problem. The dual optimization of a subroutine of the sparse multi-view SVMs is converted to a quadratic programming problem in Section 3 whose scale only depends on the number of labeled examples, indicating the advantages of using conjugate functions. The generalization error of the sparse multi-view SVMs is given in Section 4 in terms of Rademacher complexity theory, followed by a derivation of empirical Rademacher complexity of the class of functions induced by this new method in Section 5. Section 6 reports experimental results of the sparse multi-view SVMs, comparisons with related methods, and the possibility and potential for large-scale applications through sequential training. Extensions of the use of conjugate functions to a general convex loss and other related semi-supervised learning approaches are discussed in Section 7. Finally, Section 8 concludes this paper.

2. Sparse Multi-view SVMs

Multi-view semi-supervised learning, an important branch of semi-supervised learning, combines different sets of properties of an example to learn a target function. These different sets of properties are often referred to as views. Typical applications of multi-view learning are web-page categorization and content-based multimedia information retrieval. In web-page categorization, each web-page can be simultaneously described by disparate properties such as main text, inbound and outbound hyper-links. In content-based multimedia information retrieval, a multimedia segment can include both audio and video components. For such scenarios learning with multiple views is usually very beneficial. Even for problems with no natural multiple views, artificially generated views can still work favorably (Nigam and Ghani, 2000).

A useful assumption for multi-view learning is that features from each view are sufficient to train a good learner (Blum and Mitchell, 1998; Balcan et al., 2005; Farquhar et al., 2006). Making good use of this assumption through collaborative training or regularization between views can remove many false hypotheses from the hypothesis space, and thus facilitates effective learning.

For multi-view learning, an input x consists of multiple components from different views, for example, $x = (x^1, \ldots, x^m)$ for an m-view representation. A function f_j defined on view j only depends on x^j, that is $f_j(x) := f_j(x^j)$. Suppose we have a set of ℓ labeled examples $\{(x_i, y_i)\}_{i=1}^{\ell}$ with $y_i \in \{1, -1\}$, and a set of u unlabeled examples $\{x_i\}_{i=\ell+1}^{\ell+u}$. The objective function of our sparse multi-view SVMs in the case of two views is given as follows, which can be readily extended to

more than two views.

$$\min_{f_1\in\mathcal{H}_1, f_2\in\mathcal{H}_2} \quad \frac{1}{2\ell}\sum_{i=1}^{\ell}[(1-y_i f_1(x_i))_+ + (1-y_i f_2(x_i))_+] + \gamma_n(\|f_1\|^2+\|f_2\|^2) + \gamma_v \sum_{i=1}^{\ell+u}(|f_1(x_i)-f_2(x_i)|-\varepsilon)_+^2, \tag{1}$$

where nonnegative scalars γ_n, γ_v are respectively norm regularization and multi-view regularization coefficients, and the last term is an ε-insensitive loss between two views with function $(\cdot)_+ := \max(0,\cdot)$ being the hinge loss. The final classifier for predicting the label of a new example is

$$f_c(x) = \operatorname{sgn}\left(\frac{f_1(x)+f_2(x)}{2}\right). \tag{2}$$

In the rest of this section, we will show that the use of the ε-insensitive loss indeed enforces sparsity, and Fenchel-Legendre conjugates can be adopted to reformulate the optimization problem. We also show the saddle-point properties for optimal solutions and give a (globally optimal) iterative optimization algorithm.

2.1 Sparsity

In order to show the role of the ε-insensitive loss for sparsity pursuit, here we represent $f_1(x)$ and $f_2(x)$ in feature spaces as

$$f_1(x) = \mathbf{w}_1^\top \phi_1(x) + b_1, \quad f_2(x) = \mathbf{w}_2^\top \phi_2(x) + b_2,$$

where $\phi_i(x)$ $(i=1,2)$ is the image of x in feature spaces. Problem (1) can be rewritten as

$$\begin{aligned} \min_{\mathbf{w}_1,\mathbf{w}_2,\xi_1,\xi_2,b_1,b_2} \quad & P_0 = \frac{1}{2\ell}\sum_{i=1}^{\ell}(\xi_1^i+\xi_2^i) + \gamma_n(\|\mathbf{w}_1\|^2+\|\mathbf{w}_2\|^2) + \\ & \gamma_v\sum_{i=1}^{\ell+u}(|\mathbf{w}_1^\top\phi_1(x_i)+b_1-\mathbf{w}_2^\top\phi_2(x_i)-b_2|-\varepsilon)_+^2 \\ \text{s.t.} \quad & \begin{cases} y_i(\mathbf{w}_1^\top\phi_1(x_i)+b_1) \geq 1-\xi_1^i, \\ y_i(\mathbf{w}_2^\top\phi_2(x_i)+b_2) \geq 1-\xi_2^i, \\ \xi_1^i,\ \xi_2^i \geq 0, \quad i=1,\ldots,\ell\,, \end{cases} \end{aligned}$$

where $\xi_1 := [\xi_1^1,\ldots,\xi_1^\ell]$ and $\xi_2 := [\xi_2^1,\ldots,\xi_2^\ell]$.

The Lagrangian is

$$\begin{aligned} L = \quad & P_0 - \sum_{i=1}^{\ell}[\lambda_1^i(y_i(\mathbf{w}_1^\top\phi_1(x_i)+b_1)-1+\xi_1^i) + \\ & \lambda_2^i(y_i(\mathbf{w}_2^\top\phi_2(x_i)+b_2)-1+\xi_2^i) + \nu_1^i\xi_1^i + \nu_2^i\xi_2^i], \end{aligned}$$

where $\lambda_1^i, \lambda_2^i, \nu_1^i, \nu_2^i \geq 0$ $(i=1,\ldots,\ell)$ are Lagrange multipliers.

Suppose $\mathbf{w}_{1*}, \mathbf{w}_{2*}$ are the optimal solutions. By the KKT conditions, the optimal solutions $\mathbf{w}_{1*}$ should satisfy $\frac{\partial L}{\partial \mathbf{w}_{1*}} = 0$. Therefore, we get

$$\mathbf{w}_{1*} = -\frac{\gamma_v}{\gamma_n}\sum_{i=1}^{\ell+u}(|\mathbf{w}_1^\top\phi_1(x_i)+b_1-\mathbf{w}_2^\top\phi_2(x_i)-b_2|-\varepsilon)_+\tilde{\phi}_i + \frac{1}{2\gamma_n}\sum_{i=1}^{\ell}\lambda_1^i y_i\phi_1(x_i),$$

where we suppose the derivative exists everywhere and $\tilde{\phi}_i := \text{sgn}\{\mathbf{w}_1^\top \phi_1(x_i) + b_1 - \mathbf{w}_2^\top \phi_2(x_i) - b_2\}\phi_1(x_i)$. Now we can assess the sparsity of problem (1). From the above equation, $\mathbf{w}_{1*}$ is the linear combination of labeled examples with $\lambda_1^i > 0$, and those unlabeled examples on which the difference of predictions from two views exceeds ε. In this sense, we can get sparse solutions by providing a non-zero ε. Similar analysis applies to $\mathbf{w}_{2*}$. Therefore, function $f(x)$ is sparse in the number of used unlabeled examples. This analysis on sparsity is also well justified by the representer theorem.

2.2 Reformulation Using Conjugate Functions

Define $t_i := [f_1(x_i) - f_2(x_i)]^2$. Then the ε-insensitive loss term can be written as

$$f_\varepsilon(\mathbf{t}) = \sum_{i=1}^{\ell+u} (\sqrt{t_i} - \varepsilon)_+^2, \tag{3}$$

where vector $\mathbf{t} := [t_1, \ldots, t_{\ell+u}]^\top$. We give a theorem affirming the convexity of function $f_\varepsilon(\mathbf{t})$.

Theorem 2 *Function $f_\varepsilon(\boldsymbol{t})$ defined by (3) is convex.*

Proof First, we show that $f_\varepsilon(t_i) := (\sqrt{t_i} - \varepsilon)_+^2$ with a convex domain $[0, +\infty)$ is convex. When $t_i \in (\varepsilon^2, +\infty)$, the second derivative $\nabla^2 f_\varepsilon(t_i) = \frac{1}{2}\varepsilon t_i^{-3/2} \geq 0$. Thus, function $f_\varepsilon(t_i)$ is convex for $t_i \in (\varepsilon^2, +\infty)$. Moreover, the value of function $f_\varepsilon(t_i)$ for $t_i \in (\varepsilon^2, +\infty)$ is larger than 0 which is the value of $f_\varepsilon(t_i)$ for $t_i \in [0, \varepsilon^2]$, and function $f_\varepsilon(t_i)$ with domain $[0, +\infty)$ is continuous at ε^2. Hence, $f_\varepsilon(t_i)$ is convex on the domain $[0, +\infty)$.

Then, being a nonnegative weighted sum of convex functions, $f_\varepsilon(\mathbf{t})$ is indeed convex. ■

Define conjugate vector $z = [z_1, \ldots, z_{\ell+u}]^\top$ with entries being conjugate variables. The Fenchel-Legendre conjugate (which is also often called convex conjugate or conjugate function) $f_\varepsilon^*(z)$ is

$$f_\varepsilon^*(z) = \sup_{\mathbf{t} \in \mathbf{dom} f_\varepsilon} (\mathbf{t}^\top z - f_\varepsilon(\mathbf{t})) = \sup_{\mathbf{t}} \sum_{i=1}^{\ell+u} [z_i t_i - (\sqrt{t_i} - \varepsilon)_+^2] = \sum_{i=1}^{\ell+u} \sup_{t_i} [z_i t_i - (\sqrt{t_i} - \varepsilon)_+^2].$$

The domain of the conjugate function consists of $z \in \mathbf{R}^{\ell+u}$ for which the supremum is finite (i.e., bounded above) (Boyd and Vandenberghe, 2004). Define

$$f_\varepsilon^*(z_i) = \sup_{t_i} [z_i t_i - (\sqrt{t_i} - \varepsilon)_+^2]. \tag{4}$$

Then, $f_\varepsilon^*(z) = \sum_{i=1}^{\ell+u} f_\varepsilon^*(z_i)$. As a pointwise supremum of a family of affine functions, $f_\varepsilon^*(z_i)$ is convex. Being a nonnegative weighted sum of convex functions, $f_\varepsilon^*(z)$ is also convex. Below we derive the formulation of $f_\varepsilon^*(z_i)$.

Theorem 3 *Function $f_\varepsilon^*(z_i)$ defined by (4) has the following form*

$$f_\varepsilon^*(z_i) = \begin{cases} \frac{z_i \varepsilon^2}{1 - z_i}, & \text{for } 0 < z_i < 1 \\ 0, & \text{for } z_i \leq 0\,. \end{cases} \tag{5}$$

Proof By definition, we have

$$f_\varepsilon^*(z_i) = \max_{t_i} \left\{ \sup_{0 \le t_i \le \varepsilon^2} z_i t_i, \sup_{t_i > \varepsilon^2} [z_i t_i - (\sqrt{t_i} - \varepsilon)^2] \right\}. \tag{6}$$

The value of function $\sup_{0 \le t_i \le \varepsilon^2} z_i t_i$ is simple to characterize. We now characterize the second term $\sup_{t_i > \varepsilon^2} [z_i t_i - (\sqrt{t_i} - \varepsilon)^2] = \sup_{t_i > \varepsilon^2} (z_i t_i - t_i - \varepsilon^2 + 2\varepsilon\sqrt{t_i})$. For $0 < z_i < 1$, we let the first derivative equal to zero to find the supremum. For $z_i \le 0$ or $z_i \ge 1$ the derivative does not exist and thus we use function values at end points to find the supremum. As a result, we have

$$\sup_{t_i > \varepsilon^2} [z_i t_i - (\sqrt{t_i} - \varepsilon)^2] = \begin{cases} \frac{z_i \varepsilon^2}{1 - z_i}, & \text{for } 0 < z_i < 1 \\ z_i \varepsilon^2, & \text{for } z_i \le 0 \\ +\infty, & \text{for } z_i \ge 1 \,. \end{cases}$$

According to (6) and further removing the range where $f_\varepsilon^*(z_i)$ is unbounded above, we reach the conjugate given in (5). ■

Now the Fenchel-Legendre conjugate $f_\varepsilon^*(z)$ can be represented by $\sum_{i=1}^{\ell+u} f_\varepsilon^*(z_i)$, which is also well justified by the following theorem.

Theorem 4 (Boyd and Vandenberghe, 2004) *If $\varphi(u,v) = \varphi_1(u) + \varphi_2(v)$, where φ_1 and φ_2 are independent convex functions (independent means they are functions of different variables) with conjugates φ_1^* and φ_2^*, respectively, then*

$$\varphi^*(\omega, z) = \varphi_1^*(\omega) + \varphi_2^*(z).$$

A nice property of the conjugate function is on the conjugate of the conjugate, which is central to the reformulation of our optimization problem. This property is stated by Lemma 5.

Lemma 5 (Rifkin and Lippert, 2007) *If function f is closed, convex, and proper, then the conjugate function of the conjugate is itself, that is, $f^{**} = f$, where we have defined function f is closed if its epigraph is closed, and f is proper if $\mathbf{dom} f \neq \emptyset$ and $f > -\infty$.*

It is true that function $f_\varepsilon(\mathbf{t})$ is closed and proper. Moreover, we have proved the convexity of $f_\varepsilon(\mathbf{t})$ in Theorem 2. Therefore, we can use Lemma 5 to get the following equality

$$f_\varepsilon(\mathbf{t}) = \sup_z (z^\top \mathbf{t} - f_\varepsilon^*(z)). \tag{7}$$

That is

$$\sum_{i=1}^{\ell+u} (\sqrt{t_i} - \varepsilon)_+^2 = \sup_z (z^\top \mathbf{t} - f_\varepsilon^*(z)) = \sup_z \sum_{i=1}^{\ell+u} [z_i t_i - f_\varepsilon^*(z_i)].$$

By (7), we have

$$\sum_{i=1}^{\ell+u} (|f_1(x_i) - f_2(x_i)| - \varepsilon)_+^2 = \sum_{i=1}^{\ell+u} (\sqrt{t_i} - \varepsilon)_+^2 = \sup_z \sum_{i=1}^{\ell+u} [z_i t_i - f_\varepsilon^*(z_i)].$$

Therefore, the objective function for sparse multi-view SVMs becomes

$$\min_{f_1\in\mathcal{H}_1, f_2\in\mathcal{H}_2} \quad \frac{1}{2\ell}\sum_{i=1}^{\ell}[(1-y_i f_1(x_i))_+ + (1-y_i f_2(x_i))_+] + \gamma_n(\|f_1\|^2+\|f_2\|^2) + \gamma_v \sup_z \sum_{i=1}^{\ell+u}\{z_i[f_1(x_i)-f_2(x_i)]^2 - f_\varepsilon^*(z_i)\}. \tag{8}$$

As an application of Theorem 1, the solution to problem (8) has the following form

$$f_1(x)=\sum_{i=1}^{\ell+u}\alpha_1^i k_1(x_i,x),\ f_2(x)=\sum_{i=1}^{\ell+u}\alpha_2^i k_2(x_i,x). \tag{9}$$

Applying the reproducing properties of kernels, we get

$$\|f_1\|^2=\alpha_1^\top K_1\alpha_1,\ \|f_2\|^2=\alpha_2^\top K_2\alpha_2,$$

where K_1 and K_2 are $(\ell+u)\times(\ell+u)$ Gram matrices from two views $\mathcal{V}^1$ and $\mathcal{V}^2$, respectively, and vector $\alpha_1=(\alpha_1^1,...,\alpha_1^{\ell+u})^\top$, $\alpha_2=(\alpha_2^1,...,\alpha_2^{\ell+u})^\top$. Moreover, we have

$$\mathbf{f}_1=K_1\alpha_1,\ \mathbf{f}_2=K_2\alpha_2,$$

with $\mathbf{f}_1 := (f_1(x_1),...,f_1(x_{\ell+u}))^\top$, $\mathbf{f}_2 := (f_2(x_1),...,f_2(x_{\ell+u}))^\top$. Define diagonal matrix $U=diag(z_1,\ldots,z_{\ell+u})$ with every element taking values in the range $[0,1)$. Problem (8) can be reformulated as

$$\min_{\alpha_1,\alpha_2,\xi_1,\xi_2,b_1,b_2}\sup_z \quad \frac{1}{2\ell}\sum_{i=1}^{\ell}(\xi_1^i+\xi_2^i)+\gamma_n(\alpha_1^\top K_1\alpha_1+\alpha_2^\top K_2\alpha_2)+ \gamma_v[(K_1\alpha_1-K_2\alpha_2)^\top U(K_1\alpha_1-K_2\alpha_2)-\sum_{i=1}^{\ell+u}f_\varepsilon^*(z_i)]$$
$$\text{s.t.} \quad \begin{cases} y_i(\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1)\geq 1-\xi_1^i, \\ y_i(\sum_{j=1}^{\ell+u}\alpha_2^j k_2(x_j,x_i)+b_2)\geq 1-\xi_2^i, \\ \xi_1^i,\ \xi_2^i\geq 0, \quad i=1,\ldots,\ell\,. \end{cases} \tag{10}$$

2.3 Saddle-Point Property

We present a theorem concerning the convexity and concavity of optimization problem (10).

Theorem 6 *The objective function in problem (10) is convex with respect to* α_1,α_2, ξ_1, ξ_2, b_1, *and* b_2, *and concave with respect to* z.

Proof First, we show the convexity. The standard form of this optimization problem is

$$\min_{\alpha_1,\alpha_2,\xi_1,\xi_2,b_1,b_2}\sup_z \quad \frac{1}{2\ell}\sum_{i=1}^{\ell}(\xi_1^i+\xi_2^i)+\gamma_n(\alpha_1^\top K_1\alpha_1+\alpha_2^\top K_2\alpha_2)+ \gamma_v[(K_1\alpha_1-K_2\alpha_2)^\top U(K_1\alpha_1-K_2\alpha_2)-\sum_{i=1}^{\ell+u}f_\varepsilon^*(z_i)]$$
$$\text{s.t.} \quad \begin{cases} -y_i(\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1)+1-\xi_1^i\leq 0, \\ -y_i(\sum_{j=1}^{\ell+u}\alpha_2^j k_2(x_j,x_i)+b_2)+1-\xi_2^i\leq 0, \\ -\xi_1^i,\ -\xi_2^i\leq 0, \quad i=1,\ldots,\ell\,. \end{cases}$$

This problem involves one objective function and three sets of inequality constraint functions (on the left hand side of each inequality). Clearly, the domain of each objective and constraint function is a convex set. Now it suffices to prove the convexity of this problem by assessing the convexity of these functions. As all constraint functions are affine, they are convex. Then, we use the second-order condition, positive semidefinite property of a function's Hessian or second derivative to judge the convexity of the objective function (Boyd and Vandenberghe, 2004). According to this condition, the first two items of the objective function are clear to be convex. The third part can be rewritten as

$$(K_1\alpha_1 - K_2\alpha_2)^\top U(K_1\alpha_1 - K_2\alpha_2) = \|U^{1/2}\begin{pmatrix} K_1 & -K_2 \end{pmatrix}\begin{pmatrix} \alpha_1 \\ \alpha_2 \end{pmatrix}\|^2,$$

which is a convex function $\|\cdot\|^2$ composed with an affine mapping and thus also convex (Boyd and Vandenberghe, 2004). Being a nonnegative weighted sums of convex functions, the objective function is therefore convex with respect to $\alpha_1, \alpha_2, \xi_1, \xi_2, b_1, b_2$.

Then, we show the concavity using (8). As $f_\varepsilon^*(z_i)$ is convex, $z_i[f_1(x_i) - f_2(x_i)]^2 - f_\varepsilon^*(z_i)$ is concave with respect to z_i. The concavity of $\sum_{i=1}^{\ell+u}\{z_i[f_1(x_i) - f_2(x_i)]^2 - f_\varepsilon^*(z_i)\}$ follows from the fact that a nonnegative weighted sum of concave functions is concave (Boyd and Vandenberghe, 2004). Hence, the objective function in problem (10) is concave with respect to z. ■

Let θ denote the parameters $\alpha_1, \alpha_2, \xi_1, \xi_2, b_1, b_2$. We can simply denote the above optimization problem as

$$\inf_\theta \sup_z f(\theta, z) \tag{11}$$

associated with constraints on the labeled examples, where $f(\theta, z)$ is convex with respect to θ, and concave with respect to z. We give the following theorem on the equivalence of swapping the infimum and supremum for our optimization problem and include a proof for completeness.

Theorem 7 (Boyd and Vandenberghe, 2004) *If $f(\theta, \boldsymbol{z})$ with domain Θ and Z is convex with respect to $\theta \in \Theta$, and concave with respect to $\boldsymbol{z} \in Z$, the following equality holds*

$$\inf_\theta \sup_{\boldsymbol{z}} f(\theta, \boldsymbol{z}) = \sup_{\boldsymbol{z}} \inf_\theta f(\theta, \boldsymbol{z})$$

under some slight assumptions.

Proof The idea is first to represent the left-hand side as a value of a convex function, and then show that the conjugate of its conjugate is equal to the right-hand side when the same input value is plugged in Boyd and Vandenberghe (2004).

The left-hand side can be expressed as $p(0)$, where

$$p(\mathbf{u}) = \inf_\theta \sup_z [f(\theta, z) + \mathbf{u}^\top z] .$$

It is not difficult to show that p is a convex function. Being a pointwise supremum of convex function $f(\theta, z) + \mathbf{u}^\top z$, $\sup_z[f(\theta, z) + \mathbf{u}^\top z]$ is a convex function of $(\theta, \mathbf{u})$. Because $\sup_z[f(\theta, z) + \mathbf{u}^\top z]$ is convex with respect to $(\theta, \mathbf{u})$, we have $p(\mathbf{u})$ is convex.

The Fenchel-Legendre conjugate of $p(\mathbf{u})$ is

$$p^*(\mathbf{v}) = \sup_{\mathbf{u}}[\mathbf{u}^\top \mathbf{v} - \inf_\theta \sup_z (f(\theta, z) + \mathbf{u}^\top z)] ,$$

which would be $+\infty$ if $z \neq \mathbf{v}$. Therefore,

$$p^*(\mathbf{v}) = \begin{cases} -\inf_\theta f(\theta, \mathbf{v}), & \text{for } \mathbf{v} \in Z \\ +\infty, & \text{otherwise .} \end{cases}$$

The conjugate of $p^*(z)$ is given by

$$p^{**}(\mathbf{u}) = \sup_{z \in Z}(\mathbf{u}^\top z - p^*(z)) = \sup_{z \in Z}(\mathbf{u}^\top z + \inf_\theta f(\theta, z)) = \sup_z \inf_\theta [f(\theta, z) + \mathbf{u}^\top z] .$$

Suppose $0 \in \mathbf{dom} p(\mathbf{u})$ and $p(\mathbf{u})$ is closed and proper. Then by Lemma 5 we have $p(0) = p^{**}(0)$ which completes the proof. ■

Now we give a theorem showing that the optimal pair $\tilde{\theta}, \tilde{z}$ is a saddle-point.

Theorem 8 *If the following equality holds for function $f(\theta, z)$*

$$\inf_\theta \sup_z f(\theta, z) = \sup_z \inf_\theta f(\theta, z) = f(\tilde{\theta}, \tilde{z}) ,$$

then the optimal pair $\tilde{\theta}, \tilde{z}$ forms a saddle-point.

Proof From the given equality, we have

$$\inf_\theta \sup_z f(\theta, z) = \sup_z f(\tilde{\theta}, z) = f(\tilde{\theta}, \tilde{z}) ,$$

and

$$\sup_z \inf_\theta f(\theta, z) = \inf_\theta f(\theta, \tilde{z}) = f(\tilde{\theta}, \tilde{z}) ,$$

Therefore,

$$f(\tilde{\theta}, z) \leq f(\tilde{\theta}, \tilde{z}) \leq f(\theta, \tilde{z}),$$

which indeed satisfies the definition of a saddle-point. The proof is completed. ■

2.4 Iterative Optimization Algorithm

To solve the optimization problem $\sup_z \inf_\theta f(\theta, z)$ which is respectively concave and convex with respect to z and θ, we give an algorithm with guaranteed convergence by the following theorem.

Theorem 9 *Given an initial value z_0 for z, solve $\inf_\theta f(\theta, z_0)$ and obtain the global optimal point θ_0. Then we find $\arg\max_z f(\theta_0, z)$ to get z_1 from which we can get θ_1 as a result of optimize $\inf_\theta f(\theta, z_1)$. Repeat this process until a convergence point $(\hat{\theta}, \hat{z})$ is reached. Suppose $\tilde{\theta}, \tilde{z}$ is a saddle point. We have $f(\hat{\theta}, \hat{z}) = f(\tilde{\theta}, \tilde{z})$. That is, we got the optimal values of the objective function. If f is strictly concave and strictly convex with respect to the variables, we further have $\hat{\theta} = \tilde{\theta}$ and $\hat{z} = \tilde{z}$.*

Proof According to the properties of function f and the algorithm procedure, we know that the convergence point is a saddle point. Thus, we have

$$f(\tilde{\theta}, \hat{z}) \geq f(\hat{\theta}, \hat{z}) \geq f(\hat{\theta}, \tilde{z}) .$$

By the saddle-point property of $(\tilde{\theta},\tilde{z})$, we have

$$f(\tilde{\theta},\tilde{z}) \geq f(\tilde{\theta},\hat{z}) ,$$

and

$$f(\tilde{\theta},\tilde{z}) \leq f(\hat{\theta},\tilde{z}) .$$

Therefore, the above inequalities should hold with equalities and we have $f(\tilde{\theta},\tilde{z}) = f(\hat{\theta},\hat{z})$. Furthermore, if f is strictly concave and strictly convex with respect to the variables, it is true that $\hat{\theta} = \tilde{\theta}$ and $\hat{z} = \tilde{z}$. ■

On solving $\arg\max_{\mathbf{z}} f(\theta,\mathbf{z})$ required in Theorem 9, we can maximize the term related to $\mathbf{z}$, namely $z^\top \mathbf{t} - f_\varepsilon^*(z) = \sum_{i=1}^{\ell+u}[z_i t_i - f_\varepsilon^*(z_i)]$. For this purpose, we have the following theorem.

Theorem 10

$$\sup_{z_i \in \mathbf{dom} f_\varepsilon^*(z_i)} [z_i t_i - f_\varepsilon^*(z_i)] = (\sqrt{t_i} - \varepsilon)_+^2,$$

and

$$\arg \sup_{z_i \in \mathbf{dom} f_\varepsilon^*(z_i)} [z_i t_i - f_\varepsilon^*(z_i)] = \begin{cases} 1 - \frac{\varepsilon}{\sqrt{t_i}}, & \text{for } t_i > \varepsilon^2 \\ 0, & \text{for } 0 \leq t_i \leq \varepsilon^2 . \end{cases}$$

Without loss of generality, we can confine the range of z_i to $[0,1)$.

Proof We have

$$\sup_{z_i \in \mathbf{dom} f_\varepsilon^*(z_i)} [z_i t_i - f_\varepsilon^*(z_i)] = \max_{z_i} \{ \sup_{0<z_i<1} z_i t_i - \frac{z_i \varepsilon^2}{1-z_i}, \sup_{z_i \leq 0} z_i t_i \} .$$

The first supremum can be solved by setting the derivative with respect to z_i to zero. We have

$$\sup_{0<z_i<1} z_i t_i - \frac{z_i \varepsilon^2}{1-z_i} = (\sqrt{t_i} - \varepsilon)^2$$

where $t_i > \varepsilon^2$, and the supremum is attained with $z_i = 1 - \frac{\varepsilon}{\sqrt{t_i}}$.

When $t_i < 0$, $\sup_{z_i \leq 0} z_i t_i$ is unbounded above. When $0 \leq t_i \leq \varepsilon^2$, $\sup_{z_i \leq 0} z_i t_i = 0$ with the supremum attained at $z_i = 0$. Therefore, $\max_{z_i}\{\sup_{0<z_i<1} z_i t_i - \frac{z_i \varepsilon^2}{1-z_i}, \sup_{z_i \leq 0} z_i t_i\} = (\sqrt{t_i} - \varepsilon)_+^2$ with the supremum attained when $z_i \in [0,1)$, which completes the proof. ■

For sparsity pursuit, during each iteration we remove those unlabeled examples whose corresponding z_i's are zero. By the representer theorem, this would not influence the value of the objective function. For Theorem 9, this means that the element of z whose values are zero in the last iteration will remain zero for the next iteration. When there are no unlabeled examples eligible for elimination, the iteration will terminate and the convergence point $(\hat{\theta},\hat{\mathbf{z}})$ is reached.

3. Dual Optimization

According to the iterative optimization algorithm, when optimizing problem (10), we start from an initial value z_0 and then solve θ_0. In this section, we show how to solve this subroutine with fixed z.

Now the optimization problem is equivalent to

$$\begin{aligned}\min_{\alpha_1,\alpha_2,\xi_1,\xi_2,b_1,b_2} \quad & F_0 = \frac{1}{2\ell}\sum_{i=1}^{\ell}(\xi_1^i+\xi_2^i)+\gamma_n(\alpha_1^\top K_1\alpha_1+\alpha_2^\top K_2\alpha_2)+ \\ & \gamma_v(K_1\alpha_1-K_2\alpha_2)^\top U(K_1\alpha_1-K_2\alpha_2) \\ \text{s.t.} \quad & \begin{cases} y_i(\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1)\geq 1-\xi_1^i, \\ y_i(\sum_{j=1}^{\ell+u}\alpha_2^j k_2(x_j,x_i)+b_2)\geq 1-\xi_2^i, \\ \xi_1^i,\ \xi_2^i\geq 0, \quad i=1,\ldots,\ell\,. \end{cases}\end{aligned} \tag{12}$$

3.1 Lagrange Dual Function

We will solve problem (12) through optimizing its dual problem which is simpler to solve. Now we derive its Lagrange dual function.

Suppose $\lambda_1^i,\lambda_2^i,\nu_1^i,\nu_2^i\geq 0$ $(i=1,\ldots,\ell)$ be the Lagrange multipliers associated with the inequality constraints. Define $\lambda_j=[\lambda_j^1,\ldots,\lambda_j^\ell]^\top$ and $\nu_j=[\nu_j^1,\ldots,\nu_j^\ell]^\top$ $(j=1,2)$. The Lagrangian $L(\alpha_1,\alpha_2,\xi_1,\xi_2,b_1,b_2,\lambda_1,\lambda_2,\nu_1,\nu_2)$ can be written as

$$\begin{aligned}L= \quad & F_0-\sum_{i=1}^{\ell}[\lambda_1^i(y_i(\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1)-1+\xi_1^i)+ \\ & \lambda_2^i(y_i(\sum_{j=1}^{\ell+u}\alpha_2^j k_2(x_j,x_i)+b_2)-1+\xi_2^i)+\nu_1^i\xi_1^i+\nu_2^i\xi_2^i].\end{aligned}$$

Note that

$$\begin{aligned}& (K_1\alpha_1-K_2\alpha_2)^\top U(K_1\alpha_1-K_2\alpha_2) \\ = \quad & \alpha_1^\top K_1UK_1\alpha_1-2\alpha_1^\top K_1UK_2\alpha_2+\alpha_2^\top K_2UK_2\alpha_2.\end{aligned}$$

To obtain the Lagrangian dual function, L has to be minimized with respect to the primal variables $\alpha_1,\alpha_2,\xi_1,\xi_2,b_1,b_2$. To eliminate these variables, we compute the corresponding partial derivatives and set them to 0, obtaining the following conditions

$$2J_1\alpha_1-2\gamma_v K_1UK_2\alpha_2=\Lambda_1, \tag{13}$$

$$2J_2\alpha_2-2\gamma_v K_2UK_1\alpha_1=\Lambda_2, \tag{14}$$

$$\lambda_1^i+\nu_1^i=\frac{1}{2\ell}, \tag{15}$$

$$\lambda_2^i+\nu_2^i=\frac{1}{2\ell}, \tag{16}$$

$$\sum_{i=1}^{\ell}\lambda_1^i y_i=0,$$

$$\sum_{i=1}^{\ell}\lambda_2^i y_i=0, \tag{17}$$

where

$$\begin{aligned} J_1 &:= \gamma_n K_1 + \gamma_v K_1 U K_1, \\ J_2 &:= \gamma_n K_2 + \gamma_v K_2 U K_2, \\ \Lambda_1 &:= \sum_{i=1}^{\ell} \lambda_1^i y_i K_1(:,i), \\ \Lambda_2 &:= \sum_{i=1}^{\ell} \lambda_2^i y_i K_2(:,i), \end{aligned}$$

with $K_1(:,i)$ and $K_2(:,i)$ being the ith column of the corresponding Gram matrices.

Substituting (13)$\sim$(17) into L results in the following expression of the Lagrangian dual function $g_L(\lambda_1, \lambda_2, \nu_1, \nu_2)$

$$\begin{aligned} g_L &= \gamma_n(\alpha_1^\top K_1 \alpha_1 + \alpha_2^\top K_2 \alpha_2) + \gamma_v(\alpha_1^\top K_1 U K_1 \alpha_1 - 2\alpha_1^\top K_1 U K_2 \alpha_2 + \\ &\quad \alpha_2^\top K_2 U K_2 \alpha_2) - \alpha_1^\top \Lambda_1 - \alpha_2^\top \Lambda_2 + \sum_{i=1}^{\ell} (\lambda_1^i + \lambda_2^i) \\ &= \frac{1}{2}\alpha_1^\top \Lambda_1 + \frac{1}{2}\alpha_2^\top \Lambda_2 - \alpha_1^\top \Lambda_1 - \alpha_2^\top \Lambda_2 + \sum_{i=1}^{\ell} (\lambda_1^i + \lambda_2^i) \\ &= -\frac{1}{2}\alpha_1^\top \Lambda_1 - \frac{1}{2}\alpha_2^\top \Lambda_2 + \sum_{i=1}^{\ell} (\lambda_1^i + \lambda_2^i). \end{aligned} \tag{18}$$

We obtain the following from (13) and (14)

$$\alpha_1 = \frac{1}{2} J_1^{-1}(\Lambda_1 + 2\gamma_v K_1 U K_2 \alpha_2) \tag{19}$$

$$\alpha_2 = \frac{1}{2} J_2^{-1}(\Lambda_2 + 2\gamma_v K_2 U K_1 \alpha_1). \tag{20}$$

From (13) and (20), we have

$$(2J_1 - 2\gamma_v^2 K_1 U K_2 J_2^{-1} K_2 U K_1)\alpha_1 = \Lambda_1 + \gamma_v K_1 U K_2 J_2^{-1} \Lambda_2.$$

Define $M_1 = 2J_1 - 2\gamma_v^2 K_1 U K_2 J_2^{-1} K_2 U K_1$. Suppose the above linear system is well-posed (if ill-posed we can employ approximate numerical analysis techniques). We get

$$\alpha_1 = M_1^{-1}(\Lambda_1 + \gamma_v K_1 U K_2 J_2^{-1} \Lambda_2).$$

From (14) and (19), we have

$$(2J_2 - 2\gamma_v^2 K_2 U K_1 J_1^{-1} K_1 U K_2)\alpha_2 = \Lambda_2 + \gamma_v K_2 U K_1 J_1^{-1} \Lambda_1.$$

Define $M_2 = 2J_2 - 2\gamma_v^2 K_2 U K_1 J_1^{-1} K_1 U K_2$. Thus we get

$$\alpha_2 = M_2^{-1}(\Lambda_2 + \gamma_v K_2 U K_1 J_1^{-1} \Lambda_1).$$

Now with α_1 and α_2 substituted into (18), the Lagrange dual function $g_L(\lambda_1,\lambda_2,\nu_1,\nu_2)$ is

$$\begin{aligned} g_L &= \inf_{\alpha_1,\alpha_2,\xi_1,\xi_2,b_1,b_2} L = -\frac{1}{2}\alpha_1^\top \Lambda_1 - \frac{1}{2}\alpha_2^\top \Lambda_2 + \sum_{i=1}^{\ell}(\lambda_1^i+\lambda_2^i) \\ &= -\frac{1}{2}(\Lambda_1+\gamma_v K_1 U K_2 J_2^{-1}\Lambda_2)^\top M_1^{-1}\Lambda_1 - \frac{1}{2}(\Lambda_2 + \\ &\quad \gamma_v K_2 U K_1 J_1^{-1}\Lambda_1)^\top M_2^{-1}\Lambda_2 + \sum_{i=1}^{\ell}(\lambda_1^i+\lambda_2^i). \end{aligned}$$

3.2 Solving the Dual Problem

The Lagrange dual problem is given by

$$\begin{aligned} \max_{\lambda_1,\lambda_2} \quad & g_L \\ \text{s.t.} \quad & \begin{cases} 0 \le \lambda_1^i \le \frac{1}{2\ell}, & i=1,\ldots,\ell \\ 0 \le \lambda_2^i \le \frac{1}{2\ell}, & i=1,\ldots,\ell \\ \sum_{i=1}^{\ell}\lambda_1^i y_i = 0, & \\ \sum_{i=1}^{\ell}\lambda_2^i y_i = 0. & \end{cases} \end{aligned}$$

As Lagrange dual functions are always concave (Boyd and Vandenberghe, 2004), we can formulate the above problem as a convex optimization problem

$$\begin{aligned} \min_{\lambda_1,\lambda_2} \quad & -g_L \\ \text{s.t.} \quad & \begin{cases} 0 \le \lambda_1^i \le \frac{1}{2\ell}, & i=1,\ldots,\ell \\ 0 \le \lambda_2^i \le \frac{1}{2\ell}, & i=1,\ldots,\ell \\ \sum_{i=1}^{\ell}\lambda_1^i y_i = 0, & \\ \sum_{i=1}^{\ell}\lambda_2^i y_i = 0. & \end{cases} \end{aligned} \tag{21}$$

Define matrix $Y = diag(y_1,\ldots,y_\ell)$. Then, $\Lambda_1 = K_{\ell 1} Y \lambda_1$ and $\Lambda_2 = K_{\ell 2} Y \lambda_2$ with $K_{\ell 1} = K_1(:,1:\ell)$ and $K_{\ell 2} = K_2(:,1:\ell)$. We have

$$\begin{aligned} -g_L &= \frac{1}{2}(\Lambda_1+\gamma_v K_1 U K_2 J_2^{-1}\Lambda_2)^\top M_1^{-1}\Lambda_1 + \frac{1}{2}(\Lambda_2 + \\ &\quad \gamma_v K_2 U K_1 J_1^{-1}\Lambda_1)^\top M_2^{-1}\Lambda_2 - \sum_{i=1}^{\ell}(\lambda_1^i+\lambda_2^i) \\ &= \frac{1}{2}(\lambda_1^\top \lambda_2^\top)\begin{pmatrix} A & B \\ C & D \end{pmatrix}\begin{pmatrix} \lambda_1 \\ \lambda_2 \end{pmatrix} - \mathbf{1}^\top(\lambda_1+\lambda_2), \end{aligned}$$

where

$$\begin{aligned} A &:= Y K_{\ell 1}^\top M_1^{-1} K_{\ell 1} Y, \\ B &:= \gamma_v Y K_{\ell 1}^\top J_1^{-1} K_1 U K_2 M_2^{-1} K_{\ell 2} Y, \\ C &:= \gamma_v Y K_{\ell 2}^\top J_2^{-1} K_2 U K_1 M_1^{-1} K_{\ell 1} Y, \\ D &:= Y K_{\ell 2}^\top M_2^{-1} K_{\ell 2} Y, \end{aligned}$$

and $\mathbf{1} = (1, \ldots, 1_{(\ell)})^\top$.

Substituting M_1 and M_2 into the expressions of B and C, we can prove that $B = C^\top$. In addition, because of the convexity of function $-g$, we affirm that matrix $\begin{pmatrix} A & B \\ C & D \end{pmatrix}$ is positive semi-definite.

Hence, the optimization problem in (21) can be rewritten as

$$\begin{aligned} \min_{\lambda_1,\lambda_2} \quad & \frac{1}{2}(\lambda_1^\top \lambda_2^\top)\begin{pmatrix} A & B \\ C & D \end{pmatrix}\begin{pmatrix} \lambda_1 \\ \lambda_2 \end{pmatrix} - \mathbf{1}^\top(\lambda_1+\lambda_2) \\ \text{s.t.} \quad & \begin{cases} 0 \preceq \lambda_1 \preceq \frac{1}{2l}\mathbf{1}, \\ 0 \preceq \lambda_2 \preceq \frac{1}{2l}\mathbf{1}, \\ \lambda_1^\top \mathbf{y} = 0, \\ \lambda_2^\top \mathbf{y} = 0, \end{cases} \end{aligned}$$

where $\mathbf{y} = (y_1, \ldots, y_\ell)^\top$. After solving this problem using standard software, we then obtain ν_1^i and ν_2^i by (15) and (16).

We now state the advantages of optimizing this dual problem over optimizing the primal problem (12):

- Less optimization variables as for typical semi-supervised learning $\ell \ll u$, and
- Simpler constraint functions.

The solution of bias terms b_1 and b_2 can be obtained through support vectors. Due to KKT conditions, the following equalities hold

$$\begin{aligned} &\lambda_1^i(y_i(\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1)-1+\xi_1^i)=0, \\ &\lambda_2^i(y_i(\sum_{j=1}^{\ell+u}\alpha_2^j k_2(x_j,x_i)+b_2)-1+\xi_2^i)=0, \\ &\nu_1^i\xi_1^i=0, \\ &\nu_2^i\xi_2^i=0, \quad i=1,\ldots,\ell. \end{aligned}$$

For support vectors x_i, we have $\nu_j^i > 0$ (and thus $\xi_j^i = 0$) and $\lambda_j^i > 0$ $(j = 1,2)$. Therefore, we can resolve the bias terms by averaging $y_i(\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1)-1=0$ and $y_i(\sum_{j=1}^{\ell+u}\alpha_2^j k_2(x_j,x_i)+b_2)-1=0$ over all support vectors.

3.3 Advantages of Using Conjugate Functions

In this subsection, we show the direct optimization of problem (1) without the use of conjugate functions is of large scale and time-consuming, which justifies the advantages of using conjugate functions.

The primal problem can be rewritten as

$$\min_{\alpha_1,\alpha_2,\xi_1,\xi_2,b_1,b_2,\delta_i} D_0 = \frac{1}{2\ell}\sum_{i=1}^{\ell}(\xi_1^i+\xi_2^i)+\gamma_n(\alpha_1^\top K_1\alpha_1+\alpha_2^\top K_2\alpha_2)+\gamma_v\sum_{i=1}^{\ell+u}\delta_i^2$$

$$\text{s.t.}\begin{cases} y_i(\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1)\geq 1-\xi_1^i, \quad i=1,\ldots,\ell\,, \\ y_i(\sum_{j=1}^{\ell+u}\alpha_2^j k_2(x_j,x_i)+b_2)\geq 1-\xi_2^i, \quad i=1,\ldots,\ell\,, \\ \xi_1^i,\ \xi_2^i\geq 0, \quad i=1,\ldots,\ell\,, \\ (\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1)-(\sum_{j=1}^{l+u}\alpha_2^j k_2(x_j,x_i)+b_2)\geq -\delta_i-\varepsilon, \quad i=1,\ldots,\ell+u\,, \\ (\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1)-(\sum_{j=1}^{l+u}\alpha_2^j k_2(x_j,x_i)+b_2)\leq \delta_i+\varepsilon, \quad i=1,\ldots,\ell+u\,, \end{cases} \tag{22}$$

where $y_i\in\{1,-1\}, \gamma_n,\gamma_v\geq 0$.

We will solve problem (22) through optimizing its dual problem which can be simpler to solve. Suppose $\lambda_1^i,\lambda_2^i,\nu_1^i,\nu_2^i\geq 0$ $(i=1,\ldots,\ell)$ and μ_1^i,μ_2^i $(i=1,\ldots,\ell+u)$ are the Lagrange multipliers associated with the inequality constraints of problem (22). Define $\delta=[\delta_1,\ldots,\delta_{\ell+u}]^\top, \lambda_j=[\lambda_j^1,\ldots,\lambda_j^\ell]^\top$, $\nu_j=[\nu_j^1,\ldots,\nu_j^\ell]^\top$, and $\mu_j=[\mu_j^1,\ldots,\mu_j^{\ell+u}]^\top$ $(j=1,2)$. The Lagrangian $L(\alpha_1,\alpha_2,\xi_1,\xi_2,b_1,b_2,\delta,\lambda_1,\lambda_2,\nu_1,\nu_2,\mu_1,\mu_2)$ can be written as

$$\begin{aligned} L= \quad & D_0-\sum_{i=1}^{\ell}[\lambda_1^i(y_i(\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1)-1+\xi_1^i)+ \\ & \lambda_2^i(y_i(\sum_{j=1}^{\ell+u}\alpha_2^j k_2(x_j,x_i)+b_2)-1+\xi_2^i)+\nu_1^i\xi_1^i+\nu_2^i\xi_2^i]- \\ & \sum_{i=1}^{\ell+u}\mu_1^i[\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1-\sum_{j=1}^{\ell+u}\alpha_2^j k_2(x_j,x_i)-b_2+\delta_i+\varepsilon]+ \\ & \sum_{i=1}^{\ell+u}\mu_2^i[\sum_{j=1}^{\ell+u}\alpha_1^j k_1(x_j,x_i)+b_1-\sum_{j=1}^{\ell+u}\alpha_2^j k_2(x_j,x_i)-b_2-\delta_i-\varepsilon]. \end{aligned}$$

To obtain the Lagrangian dual function, L has to be minimized with respect to the primal variables $\alpha_1,\alpha_2,\xi_1,\xi_2,b_1,b_2,\delta$. To eliminate these variables, we compute the corresponding partial

derivatives and set them to 0, obtaining the following conditions

$$
\begin{aligned}
&2\gamma_n K_1\alpha_1 = \sum_{i=1}^{\ell}\lambda_1^i y_i K_1(:,i) + \sum_{i=1}^{\ell+u}(\mu_1^i - \mu_2^i)K_1(:,i),\\
&2\gamma_n K_2\alpha_2 = \sum_{i=1}^{\ell}\lambda_2^i y_i K_2(:,i) - \sum_{i=1}^{\ell+u}(\mu_1^i - \mu_2^i)K_2(:,i),\\
&\lambda_1^i + \nu_1^i = \frac{1}{2\ell}, \quad i = 1,\ldots,\ell\\
&\lambda_2^i + \nu_2^i = \frac{1}{2\ell}, \quad i = 1,\ldots,\ell\\
&-\sum_{i=1}^{\ell}\lambda_1^i y_i - \sum_{i=1}^{\ell+u}\mu_1^i + \sum_{i=1}^{\ell+u}\mu_2^i = 0,\\
&-\sum_{i=1}^{\ell}\lambda_2^i y_i + \sum_{i=1}^{\ell+u}\mu_1^i - \sum_{i=1}^{\ell+u}\mu_2^i = 0,\\
&2\gamma_v\delta_i - \mu_1^i - \mu_2^i = 0, \quad i = 1,\ldots,\ell+u.
\end{aligned}
$$

Substituting these equations into the Lagrangian as what was done in Section 3.1, it is clear that finally L is a quadratic function involving $\lambda_1,\lambda_2,\mu_1,\mu_2$. The dual optimization problem would be a quadratic optimization involving $2\ell+2(\ell+u)$ parameters. Now we see this direct optimization is indeed of large-scale and time-consuming.

4. Generalization Error

In this section, we analyze the generalization performance of the sparse multi-view SVMs making use of Rademacher complexity theory and the margin bound.

4.1 Rademacher Complexity Theory

Important background on Rademacher complexity theory (Bartlett and Mendelson, 2002; Shawe-Taylor and Cristianini, 2004) is introduced below.

Definition 11 *For a sample $S = \{x_1,\ldots,x_\ell\}$ generated by a distribution $\mathcal{D}$ on a set $\mathcal{X}$ and a real-valued function class $\mathcal{F}$ with domain $\mathcal{X}$, the empirical Rademacher complexity of $\mathcal{F}$ is the random variable*

$$\hat{R}_\ell(\mathcal{F}) = \mathbb{E}_\sigma\left[\sup_{f\in\mathcal{F}}\left|\frac{2}{\ell}\sum_{i=1}^{\ell}\sigma_i f(x_i)\right| \Big| x_1,\ldots,x_\ell\right],$$

where $\sigma = \{\sigma_1,\ldots,\sigma_\ell\}$ are independent uniform $\{\pm1\}$-valued (Rademacher) random variables. The Rademacher complexity of $\mathcal{F}$ is

$$R_\ell(\mathcal{F}) = \mathbb{E}_S[\hat{R}_\ell(\mathcal{F})] = \mathbb{E}_{S\sigma}\left[\sup_{f\in\mathcal{F}}\left|\frac{2}{\ell}\sum_{i=1}^{\ell}\sigma_i f(x_i)\right|\right].$$

Lemma 12 *Fix $\delta\in(0,1)$ and let $\mathcal{F}$ be a class of functions mapping from an input space $\tilde{\mathcal{X}}$ ($\tilde{\mathcal{X}} = \mathcal{X}\times\mathcal{Y}$ or $\tilde{\mathcal{X}} = \mathcal{X}$) to $[0,1]$. Let $(\tilde{x}_i)_{i=1}^{\ell}$ be drawn independently according to a probability distribution*

$\mathcal{D}$. Then with probability at least $1-\delta$ over random draws of samples of size ℓ, every $f \in \mathcal{F}$ satisfies

$$\begin{aligned}\mathbb{E}_{\mathcal{D}}[f(\tilde{x})] &\leq \hat{\mathbb{E}}[f(\tilde{x})] + R_\ell(\mathcal{F}) + \sqrt{\frac{\ln(2/\delta)}{2\ell}} \\ &\leq \hat{\mathbb{E}}[f(\tilde{x})] + \hat{R}_\ell(\mathcal{F}) + 3\sqrt{\frac{\ln(2/\delta)}{2\ell}},\end{aligned}$$

where $\hat{\mathbb{E}}[f(\tilde{x})]$ is the empirical error averaged on the ℓ examples.

4.2 Margin Bound for Sparse Multi-view SVMs

By (2), the prediction function of the sparse multi-view SVMs is derived from the average of predictions from two views. Define the soft prediction function as

$$g(x) = \frac{1}{2}(f_1(x) + f_2(x)).$$

We obtain the following margin bound regarding the generalization error of sparse multi-view SVMs. This bound is widely applicable to multi-view SVMs, for example, Szedmak and Shawe-Taylor (2007) independently provided a similar bound for the SVM-2K method.

Theorem 13 *Fix $\delta \in (0,1)$ and let $\mathcal{F}$ be the class of functions mapping from $\tilde{\mathcal{X}} = \mathcal{X} \times \mathcal{Y}$ to $\boldsymbol{R}$ given by $\tilde{f}(x,y) = -yg(x)$ where $g = \frac{1}{2}(f_1 + f_2) \in \mathcal{G}$ and $\tilde{f} \in \mathcal{F}$. Let $S = \{(x_1,y_1), \cdots, (x_\ell, y_\ell)\}$ be drawn independently according to a probability distribution $\mathcal{D}$. Then with probability at least $1-\delta$ over samples of size ℓ, every $g \in \mathcal{G}$ satisfies*

$$P_{\mathcal{D}}(y \neq sgn(g(\boldsymbol{x}))) \leq \quad \frac{1}{2\ell}\sum_{i=1}^{\ell}(\xi_1^i + \xi_2^i) + 2\hat{R}_\ell(\mathcal{G}) + 3\sqrt{\frac{\ln(2/\delta)}{2\ell}},$$

where $\xi_1^i := (1 - y_i f_1(x_i))_+$, $\xi_2^i := (1 - y_i f_2(x_i))_+$. Function $y_i f_1(x_i)$ and $y_i f_2(x_i)$ are called margins.

Proof Let $H(\cdot)$ be the Heaviside function that returns 1 if its argument is greater than 0 and zero otherwise. We have

$$P_{\mathcal{D}}(y \neq sgn(g(\mathbf{x}))) = \mathbb{E}_{\mathcal{D}}[H(-yg(\mathbf{x}))]. \tag{23}$$

Consider a loss function $\mathcal{A} : \mathbf{R} \to [0,1]$, given by

$$\mathcal{A}(a) = \begin{cases} 1, & \text{if } a \geq 0; \\ 1+a, & \text{if } -1 \leq a \leq 0; \\ 0, & \text{otherwise.} \end{cases}$$

By Lemma 12 and since function $\mathcal{A} - 1$ dominates $H - 1$, we have (Shawe-Taylor and Cristianini, 2004)

$$\begin{aligned}&\mathbb{E}_{\mathcal{D}}[H(\tilde{f}(x,y)) - 1] \leq \mathbb{E}_{\mathcal{D}}[\mathcal{A}(\tilde{f}(x,y)) - 1] \\ &\leq \hat{\mathbb{E}}[\mathcal{A}(\tilde{f}(x,y)) - 1] + \hat{R}_\ell((\mathcal{A} - 1) \circ \mathcal{F}) + 3\sqrt{\frac{\ln(2/\delta)}{2\ell}}.\end{aligned}$$

Therefore,

$$\mathbb{E}_{\mathcal{D}}[H(\tilde{f}(x,y))] \leq \quad \hat{\mathbb{E}}[\mathcal{A}(\tilde{f}(x,y))] + \hat{R}_\ell((\mathcal{A}-1)\circ\mathcal{F}) + 3\sqrt{\frac{\ln(2/\delta)}{2\ell}}.$$

In addition, we have

$$\begin{aligned}
\hat{E}[\mathcal{A}(\tilde{f}(x,y))] &\leq \frac{1}{\ell}\sum_{i=1}^{\ell}(1-y_i g(x_i))_+ \\
&= \frac{1}{2\ell}\sum_{i=1}^{\ell}(1-y_i f_1(x_i)+1-y_i f_2(x_i))_+ \\
&\leq \frac{1}{2\ell}\sum_{i=1}^{\ell}[(1-y_i f_1(x_i))_+ + (1-y_i f_2(x_i))_+] \\
&= \frac{1}{2\ell}\sum_{i=1}^{\ell}(\xi_1^i + \xi_2^i),
\end{aligned}$$

where ξ_1^i denotes the amount by which function f_1 fails to achieve margin 1 for (x_i, y_i) and ξ_2^i applies similarly to function f_2.

Since $(\mathcal{A}-1)(0) = 0$, we can apply the Lipschitz condition (Bartlett and Mendelson, 2002) of function $(\mathcal{A}-1)$ to get

$$\hat{R}_\ell((\mathcal{A}-1)\circ\mathcal{F}) \leq 2\hat{R}_\ell(\mathcal{F}).$$

It remains to bound the empirical Rademacher complexity of the class $\mathcal{F}$.

With $y_i \in \{1,-1\}$, we have

$$\begin{aligned}
\hat{R}_\ell(\mathcal{F}) &= \mathbb{E}_\sigma[\sup_{f\in\mathcal{F}}|\frac{2}{\ell}\sum_{i=1}^{\ell}\sigma_i\tilde{f}(x_i,y_i)|] \\
&= \mathbb{E}_\sigma[\sup_{g\in\mathcal{G}}|\frac{2}{\ell}\sum_{i=1}^{\ell}\sigma_i y_i g(x_i)|] \\
&= \mathbb{E}_\sigma[\sup_{g\in\mathcal{G}}|\frac{2}{\ell}\sum_{i=1}^{\ell}\sigma_i g(x_i)|] \\
&= \hat{R}_\ell(\mathcal{G}). \qquad (24)
\end{aligned}$$

Finally, combining (23)∼(24) completes the proof. ■

5. Empirical Rademacher Complexity

Our optimization algorithm iteratively updates z to solve θ. In this section, we first derive the empirical Rademacher complexity of $\hat{R}_\ell(\mathcal{G})$ for the function class induced after one iteration with an initially fixed z, and then give its formulation applicable for any number of subsequent iterations including the termination case. This Rademacher complexity is crucial for Theorem 13 when analyzing the performance of the corresponding classifiers obtained by our iterative optimization algorithm. Specifically, for the empirical Rademacher complexity we give the following theorem

Theorem 14 *Suppose* $\mathcal{S} = \frac{1}{\gamma_n}(K_{1\ell}K_1^{-1}K_{1\ell}^\top + K_{2\ell}K_2^{-1}K_{2\ell}^\top)$, $\Theta = \frac{1}{\gamma_n}U_u^{1/2}(K_{1u}K_1^{-1}K_{1u}^\top + K_{2u}K_2^{-1}K_{2u}^\top)U_u^{1/2}$, $\mathcal{J} = \frac{1}{\gamma_n}U_u^{1/2}(K_{1u}K_1^{-1}K_{1\ell}^\top - K_{2u}K_2^{-1}K_{2\ell}^\top)$, *where* $K_{1\ell}$ *and* $K_{2\ell}$ *are respectively the first* ℓ *rows of the Gram matrices* K_1 *and* K_2, K_{1u} *and* K_{2u} *are respectively the last* u *rows of matrix* K_1 *and* K_2, *and* U_u *is the diagonal matrix including the last* u *diagonal elements (initially fixed* $z_{\ell+1},\ldots,z_{\ell+u}$*) of* U. *Then the empirical Rademacher complexity* $\hat{R}_\ell(\mathcal{G})$ *is bounded as* $\frac{\mathcal{U}}{\sqrt{2\ell}} \le \hat{R}_\ell(\mathcal{G}) \le \frac{\mathcal{U}}{\ell}$, *where* $\mathcal{U}^2 = tr(\mathcal{S}) - \gamma_v tr(\mathcal{J}^\top(I+\gamma_v\Theta)^{-1}\mathcal{J})$ *for the first iteration of sparse multi-view SVMs, and* $\mathcal{U}^2 = tr(\mathcal{S})$ *for subsequent iterations*.

The remainder of this section before Section 5.4 completes the proof of this theorem, which was partially inspired by Rosenberg and Bartlett (2007) for analyzing co-regularized least squares.

We use problem (8) to reason about $\hat{R}_\ell(\mathcal{G})$. As a result of fixed z, we can remove $f_\varepsilon^*(z_i)$ without loss of generality to resolve f_1 and f_2. It is true that the loss function $\hat{L} : \mathcal{H}^1 \times \mathcal{H}^2 \to [0,\infty)$ with $\hat{L} := \frac{1}{2\ell}\sum_{i=1}^{\ell}[(1-y_i f_1(x_i))_+ + (1-y_i f_2(x_i))_+]$ satisfies

$$\hat{L}(0,0) = 1.$$

Let $Q(f_1,f_2)$ denote the objective function in (8) with $f_\varepsilon^*(z_i)$ removed. Substituting in the trivial predictors $f_1 \equiv 0$ and $f_2 \equiv 0$ gives the following upper bound

$$\min_{f_1,f_2\in\mathcal{H}^1\times\mathcal{H}^2} Q(f_1,f_2) \le Q(0,0) = \hat{L}(0,0) = 1.$$

Since all terms of $Q(f_1,f_2)$ are nonnegative, we conclude that any (f_1^*,f_2^*) minimizing $Q(f_1,f_2)$ is contained in

$$\hat{\mathcal{H}} \;=\; \{(f_1,f_2) : \gamma_n(\|f_1\|^2 + \|f_2\|^2) + \gamma_v \sum_{i=\ell+1}^{\ell+u} z_i[f_1(x_i) - f_2(x_i)]^2 \le 1\}. \tag{25}$$

Therefore, the final predictor is chosen from the function class

$$\mathcal{G} = \{x \to \frac{1}{2}[f_1(x) + f_2(x)] : (f_1,f_2) \in \hat{\mathcal{H}}\}.$$

The complexity $\hat{R}_\ell(\mathcal{G})$ is

$$\hat{R}_\ell(\mathcal{G}) = \mathbb{E}_\sigma\left[\sup_{(f_1,f_2)\in\hat{\mathcal{H}}}\left|\frac{1}{\ell}\sum_{i=1}^{\ell}\sigma_i(f_1(x_i)+f_2(x_i))\right|\right]. \tag{26}$$

As it only depends on the values of function $f_1(\cdot)$ and $f_2(\cdot)$ on the ℓ labeled examples, by the reproducing kernel property which says the projection of function f onto a closed subspace containing $k(x,\cdot)$ has the same value at x as f itself does (Rosenberg and Bartlett, 2007) we can restrict the function class $\hat{\mathcal{H}}$ to the span of labeled and unlabeled data and thus write it as

$$\begin{aligned}\hat{\mathcal{H}} \;&=\; \{(f_1,f_2) : \gamma_n(\alpha_1^\top K_1\alpha_1 + \alpha_2^\top K_2\alpha_2) + \\ &\quad\; \gamma_v(K_{1u}\alpha_1 - K_{2u}\alpha_2)^\top U_u(K_{1u}\alpha_1 - K_{2u}\alpha_2) \le 1\} \\ &=\; \{(f_1,f_2) : (\alpha_1^\top\;\alpha_2^\top)N\begin{pmatrix}\alpha_1\\ \alpha_2\end{pmatrix} \le 1\},\end{aligned}$$

where K_{1u} and K_{2u} are respectively the last u rows of matrix K_1 and K_2, U_u is the diagonal matrix including the last u diagonal elements of U, and

$$N := \gamma_n\begin{pmatrix}K_1 & \mathbf{0}\\ \mathbf{0} & K_2\end{pmatrix} + \gamma_v\begin{pmatrix}K_{1u}^\top\\ -K_{2u}^\top\end{pmatrix}U_u(K_{1u}\;\; -K_{2u}). \tag{27}$$

5.1 Evaluating the Supremum in Euclidean Space

Since $(f_1, f_2) \in \hat{\mathcal{H}}$ implies $(-f_1, -f_2) \in \hat{\mathcal{H}}$, we can drop the absolute sign in (26). Now we can write

$$\begin{aligned}\hat{R}_\ell(\mathcal{G}) &= \frac{1}{\ell}\mathbb{E}_\sigma \sup_{\alpha_1,\alpha_2\in\mathcal{R}^{\ell+u}} \{\sigma^\top K_{1\ell}\alpha_1 + \sigma^\top K_{2\ell}\alpha_2 : (\alpha_1^\top\ \alpha_2^\top)N\begin{pmatrix}\alpha_1\\ \alpha_2\end{pmatrix} \le 1\} \\ &= \frac{1}{\ell}\mathbb{E}_\sigma \sup_{\alpha_1,\alpha_2\in\mathcal{R}^{\ell+u}} \{\sigma^\top (K_{1\ell}\ K_{2\ell})\begin{pmatrix}\alpha_1\\ \alpha_2\end{pmatrix} : (\alpha_1^\top\ \alpha_2^\top)N\begin{pmatrix}\alpha_1\\ \alpha_2\end{pmatrix} \le 1\}, \qquad (28)\end{aligned}$$

where $K_{1\ell}, K_{2\ell}$ represent the first ℓ rows of the Gram matrices K_1 and K_2, respectively.

For a symmetric positive definite matrix M, it is simple to show that (Rosenberg and Bartlett, 2007)

$$\sup_{\alpha:\alpha^\top M\alpha\le 1} \mathbf{v}^\top\alpha = \|M^{-1/2}\mathbf{v}\|.$$

Without loss of generality, suppose positive semi-definite matrix N in (28) is positive definite and thus has full rank. If N does not have full rank, we can use subspace decomposition to rewrite $\hat{R}_\ell(\mathcal{G})$ to obtain a similar representation. Thus, we can evaluate the supremum as described above to get

$$\hat{R}_\ell(\mathcal{G}) = \frac{1}{\ell}\mathbb{E}_\sigma\|N^{-1/2}\begin{pmatrix}K_{1\ell}^\top\\ K_{2\ell}^\top\end{pmatrix}\sigma\|.$$

5.2 Bounding $\hat{R}_\ell(\mathcal{G})$ above and below

We make use of the Kahane-Khintchine inequality (Latala and Oleszkiewicz, 1994), stated here for convenience, to bound $\hat{R}_\ell(\mathcal{G})$.

Lemma 15 *For any vectors $\boldsymbol{a}_1, \cdots, \boldsymbol{a}_n$ in a Hilbert space and independent Rademacher random variables $\sigma_1, \cdots, \sigma_n$, we have*

$$\frac{1}{2}\mathbb{E}\|\sum_{i=1}^n \sigma_i\boldsymbol{a}_i\|^2 \le (\mathbb{E}\|\sum_{i=1}^n \sigma_i\boldsymbol{a}_i\|)^2 \le \mathbb{E}\|\sum_{i=1}^n \sigma_i\boldsymbol{a}_i\|^2.$$

By Lemma 15 we have

$$\frac{\mathcal{U}}{\sqrt{2}\ell} \le \hat{R}_\ell(\mathcal{G}) \le \frac{\mathcal{U}}{\ell}, \qquad (29)$$

where

$$\begin{aligned}\mathcal{U}^2 &= \mathbb{E}_\sigma\|N^{-1/2}\begin{pmatrix}K_{1\ell}^\top\\ K_{2\ell}^\top\end{pmatrix}\sigma\|^2 \\ &= \mathbb{E}_\sigma tr[(K_{1\ell}\ K_{2\ell})N^{-1}\begin{pmatrix}K_{1\ell}^\top\\ K_{2\ell}^\top\end{pmatrix}\sigma\sigma^\top] \\ &= tr[(K_{1\ell}\ K_{2\ell})N^{-1}\begin{pmatrix}K_{1\ell}^\top\\ K_{2\ell}^\top\end{pmatrix}].\end{aligned}$$

Recall that

$$N = \gamma_n\begin{pmatrix}K_1 & \mathbf{0}\\ \mathbf{0} & K_2\end{pmatrix} + \gamma_v\begin{pmatrix}K_{1u}^\top\\ -K_{2u}^\top\end{pmatrix}U_u(K_{1u}\ \ -K_{2u}).$$

Define

$$\Sigma = \gamma_n \begin{pmatrix} K_1 & \mathbf{0} \\ \mathbf{0} & K_2 \end{pmatrix}, \quad R = \begin{pmatrix} K_{1u}^\top \\ -K_{2u}^\top \end{pmatrix} U_u^{1/2}.$$

Using the Sherman-Morrison-Woodbury formula (Golub and Loan, 1996), we expand N^{-1} as

$$N^{-1} = \Sigma^{-1} - \gamma_v \Sigma^{-1} R (I + \gamma_v R^\top \Sigma^{-1} R)^{-1} R^\top \Sigma^{-1}.$$

Define $\Omega = (K_{1\ell}\ K_{2\ell})$. We get

$$\mathcal{U}^2 = tr(\Omega\Sigma^{-1}\Omega^\top) - \gamma_v tr[\Omega\Sigma^{-1} R (I + \gamma_v R^\top \Sigma^{-1} R)^{-1} R^\top \Sigma^{-1} \Omega^\top].$$

Define

$$\begin{aligned} \mathcal{S} &= \Omega\Sigma^{-1}\Omega^\top = \frac{1}{\gamma_n}(K_{1\ell}K_1^{-1}K_{1\ell}^\top + K_{2\ell}K_2^{-1}K_{2\ell}^\top), \\ \Theta &= R^\top\Sigma^{-1}R = \frac{1}{\gamma_n}U_u^{1/2}(K_{1u}K_1^{-1}K_{1u}^\top + K_{2u}K_2^{-1}K_{2u}^\top)U_u^{1/2}, \\ \mathcal{J} &= R^\top\Sigma^{-1}\Omega^\top = \frac{1}{\gamma_n}U_u^{1/2}(K_{1u}K_1^{-1}K_{1\ell}^\top - K_{2u}K_2^{-1}K_{2\ell}^\top). \end{aligned} \tag{30}$$

Putting expressions together, we get

$$\mathcal{U}^2 = tr(\mathcal{S}) - \gamma_v tr(\mathcal{J}^\top (I + \gamma_v \Theta)^{-1} \mathcal{J}). \tag{31}$$

5.2.1 REGULARIZATION TERM ANALYSIS

From (29) and (31), it is clear to see the roles the regularization parameters γ_n and γ_v play in the empirical Rademacher complexity $\hat{R}_l(\mathcal{G})$.

The amount of reduction in the Rademacher complexity brought by γ_v is

$$\Delta(\gamma_v) = \gamma_v tr(\mathcal{J}^\top (I + \gamma_v \Theta)^{-1} \mathcal{J}).$$

This term has the property shown by the following lemma given by Rosenberg and Bartlett (2007) when analyzing co-regularized least squares. Here the meanings of $\mathcal{J}$ and Θ are different from Rosenberg and Bartlett (2007).

Lemma 16 (Rosenberg and Bartlett, 2007) *$\Delta(0) = 0$, $\Delta(\gamma_v)$ is nondecreasing on $\gamma_v \geq 0$, and given that Θ is positive definite, we have*

$$\lim_{\gamma_v \to \infty} \Delta(\gamma_v) = tr(\mathcal{J}^\top \Theta^{-1} \mathcal{J}).$$

5.3 Extending to Iterative Optimization

As our sparse multi-view SVMs employ an iterative optimization procedure for sparsity pursuit, the former outcome for empirical Rademacher complexity would not apply if we use more than one iteration to update z. However, we can extend the former analysis to suit this case.

Recall that $z_i \in [0,1)$ $(i = \ell+1,\ldots,\ell+u)$ and $U_u = diag(z_{\ell+1},\ldots,z_{\ell+u})$. During iterations, it is possible that U_u becomes a zero matrix or other arbitrary matrix with diagonal elements in the range $[0,1)$. In any case, the resultant function class can be covered by

$$\hat{\mathcal{H}} \quad = \quad \{(f_1,f_2) : \gamma_n(\|f_1\|^2 + \|f_2\|^2) \leq 1\},$$

which is obtained by omitting the term containing z_i in (25). Following a similar derivation, the matrix N in (27) would be

$$N = \gamma_n \begin{pmatrix} K_1 & \mathbf{0} \\ \mathbf{0} & K_2 \end{pmatrix}.$$

Finally, we can obtain a bound on the empirical Rademacher complexity $\hat{R}_l(\mathcal{G})$ identical to (29) but now $\mathcal{U}^2 = tr(\mathcal{S})$ with $\mathcal{S}$ defined in (30). The proof of Theorem 14 is completed.

5.4 Examining $\hat{R}_l(\mathcal{G})$

Here, we examine the role $\hat{R}_l(\mathcal{G})$ plays in the margin bound. Since $K_{1\ell}$ and $K_{2\ell}$ are the first ℓ rows of K_1 and K_2, the formulation of $tr(\mathcal{S})$ can be simplified as

$$tr(\mathcal{S}) \quad = \quad \frac{1}{\gamma_n} tr(K_{1\ell} K_1^{-1} K_{1\ell}^\top + K_{2\ell} K_2^{-1} K_{2\ell}^\top) = \frac{1}{\gamma_n} \sum_{i=1}^{\ell} (K_1(i,i) + K_2(i,i)). \tag{32}$$

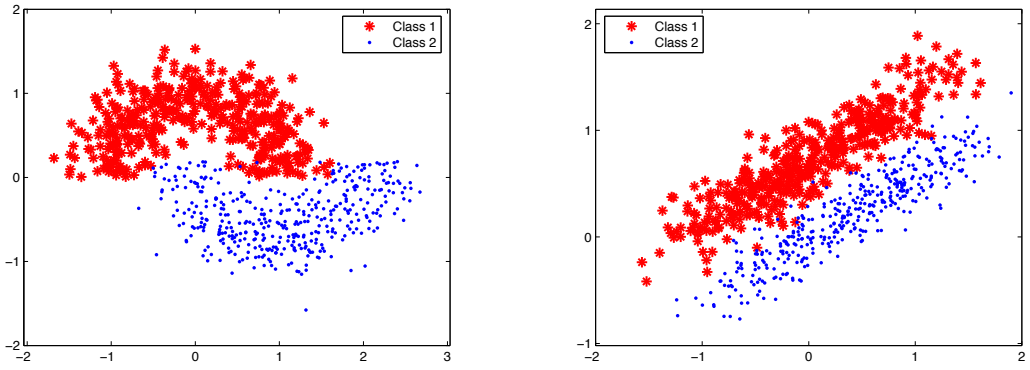
Now, we see that for iterative optimization of sparse multi-view SVMs, the empirical Rademacher complexity $\hat{R}_l(\mathcal{G})$ with $\mathcal{U}^2 = tr(\mathcal{S})$ only depends on the ℓ labeled examples and the chosen kernel functions. Consequently, the margin bound does not rely on the unlabeled training sets. In this case the margin bound is quite straightforward to reason.

If we do not use iterative optimization, the empirical Rademacher complexity $\hat{R}_l(\mathcal{G})$ will involve other two terms Θ and $\mathcal{J}$. By a similar technique as in (32), we can show that Θ only depends on the unlabeled data and the kernel functions, while $\mathcal{J}$ encodes the interaction between labeled and unlabeled data. As a result, the margin bound relies on both labeled and unlabeled data. For this case, we will give an evaluation of the margin bound with different sizes of unlabeled sets in Section 6.4.

6. Experiments

We performed experiments on artificial data and real-world data to evaluate the proposed sparse multi-view SVMs (SpMvSVMs). For SpMvSVMs with $\varepsilon > 0$, the entries of $\mathbf{z}$ were fixed as 1 for labeled data and initialized as 0.995 for unlabeled data. The termination condition for iterative optimization is either no unlabeled examples can be removed or the maximum iteration number surpasses 50. Comparisons are made with supervised SVMs, and the unsupervised SVM-2K method. Each accuracy/error reported in this paper is an averaged accuracy/error value over ten random splits of data into labeled, unlabeled and test data.

Later in this section, we also provide a sequential training strategy for SpMvSVMs, which shows an accuracy improvement over the gradual adding of unlabeled data while with roughly linear and sub-linear increases of running time. This indicates the possibility and potential of applying SpMvSVMs to large-scale data sets. At the end, margin bound evaluation results are reported.



(a) View 1 (b) View 2

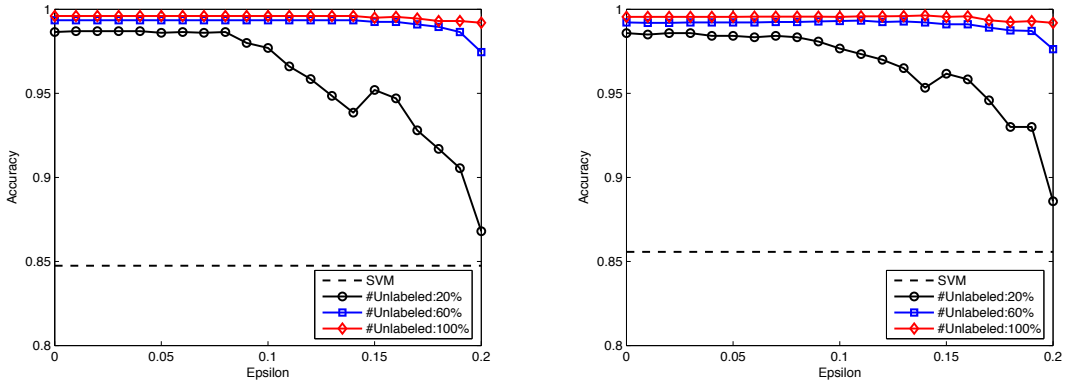
Figure 1: Examples in the two-moons-two-lines data set.

6.1 Artificial Data

This two-moons-two-lines synthetic data set was generated according to Sindhwani et al. (2005). Examples in two classes scatter like two moons in one view and two parallel lines in the other. To link the two views, points on one moon were enforced to associate at random with points on one line. Each class has 400 examples and a total of 800 examples were generated as shown in Figure 1. For SpMvSVMs, the numbers of examples in the labeled training set, unlabeled training set and test set were fixed as four, 596, and 200, respectively. Gaussian kernel with bandwidth 0.35 and the linear kernel were used for view 1 and view 2, respectively. The parameters γ_n and γ_v were selected from a small grid $\{10^{-6}, 10^{-4}, 10^{-2}, 1, 10, 100\}$ by five-fold cross validation on the whole data set. The chosen values are $\gamma_n = 10^{-4}$ and $\gamma_v = 1$. In this paper, γ_v is normalized by the number of labeled and unlabeled examples involved in the multi-view regularization term. For supervised SVMs, which concatenated features from the two views, we also found the regularization coefficient from this grid by five-fold cross validation.

To evaluate SpMvSVMs, we varied the size of the unlabeled training set from 20%, 60% to 100% of the total number of unlabeled data, and used different values for the insensitive parameter ε, which ranged from 0 to 0.2 with an interval 0.01 (when ε is zero, sparsity is not considered). The test accuracies and transductive accuracies (on the corresponding unlabeled set) are given in Figure 2(a) and Figure 2(b), respectively. It should be noted that the numbers of data used to calculate transductive accuracies are different for the three curves in Figure 2(b). The numbers of removed unlabeled examples for different ε values are shown in Figure 3.

From Figure 2 and Figure 3, we find that with the increase of ε, more and more unlabeled data are removed, and the remove of a small number of unlabeled data can hardly decrease the performance of the resultant classifiers, especially when the original size of unlabeled set is large. Therefore, we can find a good balance between sparsity and accuracy using an appropriate ε. In addition, more unlabeled data can benefit the performance of the learned classifiers with the same ε.



(a) Test accuracy (b) Transductive accuracy

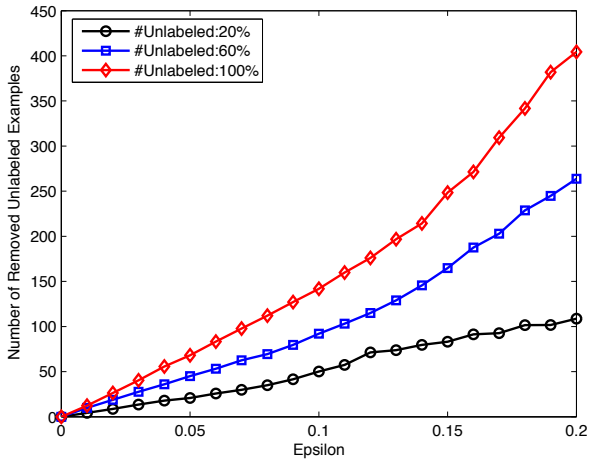

Figure 3: The numbers of unlabeled examples removed by SpMvSVMs for different ε values on the artificial data.

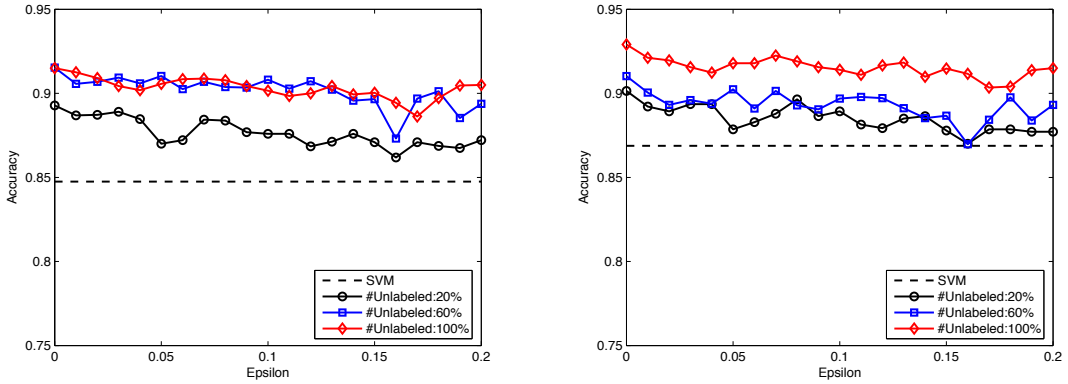
6.2 Text Classification

We applied the SpMvSVMs to the WebKB text classification task studied in Blum and Mitchell (1998); Sindhwani et al. (2005); Sun (2008). The data set consists of 1051 two-view web pages collected from the computer science department web sites at four U.S. universities: Cornell, University of Washington, University of Wisconsin, and University of Texas. The task is to predict whether a web page is a course home page or not. This problem has an unbalanced class distribution since there are a total of 230 course home pages (positive examples). The first view of the data is the words appearing on the web page itself, whereas the second view is the underlined words



(a) Test accuracy

(b) Transductive accuracy

Figure 4: Classification accuracies of SpMvSVMs with different sizes of unlabeled set and ε values on text classification. The accuracies of SVMs are also shown.

in all links pointing to the web page from other pages. We preprocessed each view by removing stop words, punctuation and numbers and then applied Porter's stemming to the text (Porter, 1980). In addition, words that occur in five or fewer documents were ignored. This resulted in 2332 and 87-dimensional vectors in the first and second view, respectively. Finally, document vectors were normalized to $tf.idf$ (the product of term frequency and inverse document frequency) features (Salton and Buckley, 1988).

For SpMvSVMs, the numbers of examples in the labeled training set, unlabeled training set and test set were fixed as 32, 699, and 320, respectively. In the training set and test set, the numbers of negative examples are three times of those of positive examples to reflect the overall proportion of positive and negative examples. The linear kernel was used for both views. The parameters γ_n and γ_v for SpMvSVMs and the regularziation coefficient for SVMs were selected using the same method as in Section 6.1. The chosen values for SpMvSVMs are $\gamma_n = 10^{-6}$ and $\gamma_v = 0.01$.

To evaluate SpMvSVMs, we also varied the size of the unlabeled training set from 20%, 60% to 100% of the total number of unlabeled data, and used different values for the insensitive parameter ε ranging from 0 to 0.2 with an interval 0.01. The test accuracies and transductive accuracies are given in Figure 4(a) and Figure 4(b), respectively. The numbers of removed unlabeled examples for different ε values are shown in Figure 5.

From Figure 5, we find that with the increase of ε, more and more unlabeled data can be removed. Reflected by Figure 4, the remove of unlabeled data only slightly decrease the performance of the resultant classifiers, and this decrease is less when more unlabeled data is used. We draw a same conclusion as before: an appropriate ε can be adopted to keep a good balance between sparsity and accuracy. We also observe a different phenomenon, that is, using 60% and 100% unlabeled data result in similar test accuracies as shown in Figure 4(a). This is reasonable because the performance improvement of any classifier is always bounded no matter how many data are used.

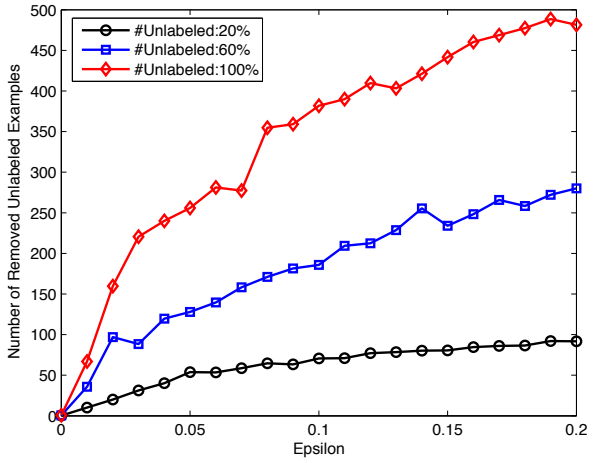


Figure 5: The numbers of unlabeled examples removed by SpMvSVMs for different ε values on text classification.

6.3 Comparison with SVM-2K, and Sequential Training

The SVM-2K method proposed by Szedmak and Shawe-Taylor (2007) can exploit unlabeled data for multi-view learning. Similar to SpMvSVMs, it also combines the maximum margin and multi-view regularization principles. However, it adopts l_1 norm for multi-view regularization, and this regularization only uses unlabeled data. Specifically, the SVM-2K method has the following optimization for classifier parameters $\mathbf{w}_1$, $\mathbf{w}_2$, b_1, and b_2 in two views

$$\begin{aligned}
\min \quad & \frac{1}{2}\|\mathbf{w}_1\|^2+\frac{1}{2}\|\mathbf{w}_2\|^2+C_1\sum_{i=1}^{\ell}\xi_1^i+C_2\sum_{i=1}^{\ell}\xi_2^i+C_\eta\sum_{j=\ell+1}^{\ell+u}\eta_j \\
\text{s.t.} \quad & \begin{cases} |\mathbf{w}_1^\top\phi_1(x_j)+b_1-\mathbf{w}_2^\top\phi_2(x_j)-b_2|\le\eta_j+\varepsilon \\ y_i(\mathbf{w}_1^\top\phi_1(x_i)+b_1)\ge 1-\xi_1^i \\ y_i(\mathbf{w}_2^\top\phi_2(x_i)+b_2)\ge 1-\xi_2^i \\ \xi_1^i\ge 0,\xi_2^i\ge 0,\eta_j\ge 0 \text{ for all } i=1,\ldots,\ell, \text{and } j=\ell+1,\ldots,\ell+u\,, \end{cases}
\end{aligned}$$

where an ε-insensitive parameter is used to relax the prediction consistency between views. In this subsection, we carry out an empirical comparison between SVM-2K and our SpMvSVMs for semi-supervised learning with identical data splits.

Our first comparison takes the ε-insensitive parameter in both SpMvSVMs and SVM-2K as zero and uses the above two data sets with different sizes of unlabeled training sets, namely, from 20% to 60% to 100%. For SVM-2K, we adopted the same parameter selection approach as in Szedmak and Shawe-Taylor (2007) through five-fold cross-validation. That is, the values of C_1 and C_2 were fixed to 1 and C_η were selected from the range $\{0.01\times 2^i\}$ $(i=1,\ldots,10)$. The experimental results are listed in Table 1, from which we see that both the test accuracies and transductive accuracies of SpMvSVMs are superior to those counterparts of SVM-2K.

The second comparison considers sequential training of SpMvSVMs and SVM-2K. The purpose is to show the relationship between running time, classification accuracies and the number of

# Unlabeled	SVM-2K		SpMvSVMs	
	Test Acc.	Transductive Acc.	Test Acc.	Transductive Acc.
20%	95.70	97.75	98.65	98.58
60%	98.50	99.19	99.35	99.22
100%	98.35	99.18	99.60	99.55
20%	84.72	84.71	89.28	90.14
60%	85.88	84.79	91.53	91.02
100%	85.84	87.85	91.50	92.90

Table 1: Test and transductive accuracies (%) of SVM-2K and SpMvSVMs with different sizes of unlabeled training sets on the artificial data (the first three lines) and text classification data (the last three lines).

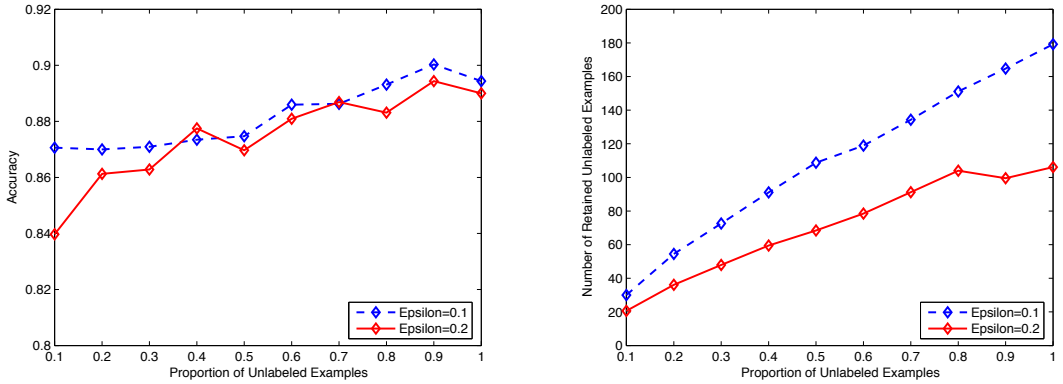
gradually added unlabeled examples, and thus evaluate the possibility and potential of applying the methods to large-scale problems. The text classification data were used where all the unlabeled training data were divided into ten equal sizes. For sequential training of SpMvSVMs, we adopted two different ε values 0.1 and 0.2. The procedure is as follows. First, we train SpMvSVMs using the labeled data and the first portion of unlabeled data. Then, we combine the retained unlabeled data from the last training with the next portion of unlabeled data together to train SpMvSVMs (with the original labeled data). We repeat this progress for ten times to complete the whole procedure.

The test accuracies and total numbers of retained unlabeled data after each step are shown in Figure 6(a) and Figure 6(b). The averaged classifier training time is given in Figure 7. Figure 6(a) indicates the effectiveness of sequential training, which is reflected by the fact that the test accuracies have an overall increasing tendency. Figure 6(b) shows that SpMvSVMs obtain sparse solutions in the sense that the number of retained unlabeled data is small compared to the number of all the added unlabeled data. Figure 7 shows that when $\varepsilon = 0.1$ the running time is roughly linear with respect to the gradual adding of unlabeled data, and when $\varepsilon = 0.2$ the relationship is roughly sub-linear. In fact, the running time can be further reduced if larger ε values rather than the given values are properly used. In practice, we can also vary the value of ε during the sequential training process.

Though the SVM-2K method was not initially proposed for sparse semi-supervised learning, we find that with $\varepsilon > 0$ it can reduce the number of unlabeled data used for representing classifiers. For this reason, we attempted to explore its possibility on sequential training using this data set under the same setting with the sequential training of SpMvSVMs. However, for different ε values we did not observe an improvement of test accuracies with the gradual adding of unlabeled data. Actually, for this data set when $\varepsilon > 0.05$ SVM-2K would not use any unlabeled data at all. This indicates that the roles of ε for SpMvSVMs and SVM-2K are quantitatively different.

6.4 Margin Bound Evaluation

To evaluate the margin bound in Theorem 13 for SpMvSVMs, we carried out experiments on the text classification data with a priori fixed regularization values $\gamma_n = 10^{-5}$ and $\gamma_v = 0.1$. This choice of parameters did not intend to be optimal in terms of test errors, but attempted to show the relationship, if any, between the generalization bound and the test error. The empirical Rademacher complexity



(a) Test accuracy (b) # Retained Unlabeled Examples

Figure 6: Classification accuracies and numbers of retained unlabeled examples for sequential training of SpMvSVMs. Parameter ε varies in $\{0.1, 0.2\}$.

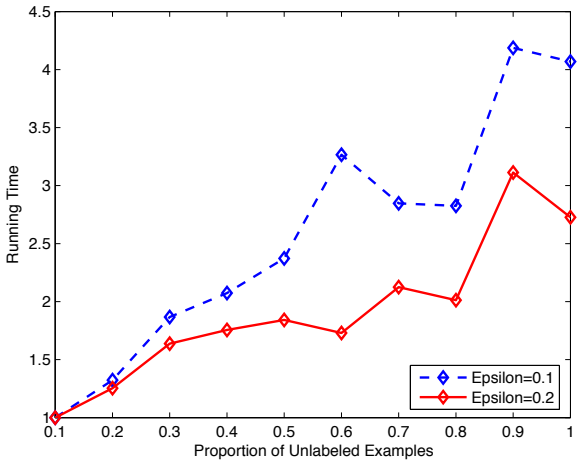


Figure 7: Running time for sequential training of SpMvSVMs. Parameter ε varies in $\{0.1, 0.2\}$. We have normalized the running times with 10% unlabeled examples to be 1.

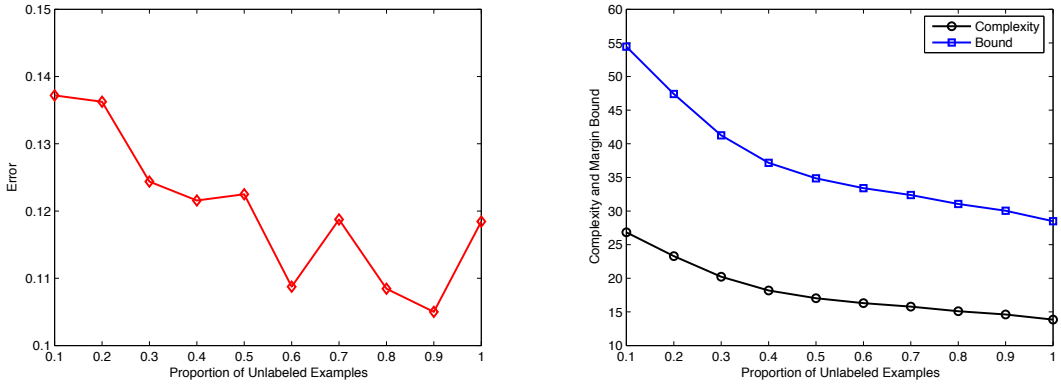
$\hat{R}_\ell(\mathcal{G})$ in the margin bound is replaced by its upper bound $\mathcal{U}/\ell$ with $\mathcal{U}^2 = tr(\mathcal{S}) - \gamma_v tr(\mathcal{J}^\top (I + \gamma_v \Theta)^{-1} \mathcal{J})$.

For SpMvSVMs, only one iteration was performed in order to apply the margin bound. In other words, we learned classifiers only with the initially provided conjugate vector $\mathbf{z}$ whose entries were fixed as 1 for labeled data and 0.995 for unlabeled data. We used the same data split as in Section 6.2, but varied the size of unlabeled training set from $\{10\%, 20\%, \ldots, 100\%\}$ of all the available unlabeled data. To compute the margin bound, the confidence level in Theorem 13 is fixed as 95% ($\delta = 0.05$). The test error rate, empirical Rademacher complexity, and margin bound are



(a) Test error rate

(b) Complexity and margin bound

Figure 8: Classification error rates, empirical Rademacher complexity, and the margin bound of SpMvSVMs with different sizes of unlabeled sets.

shown in Figure 8. The overall decrease of error rates is well explained by the drop of the margin bound and empirical Rademacher complexity brought by the regularization role of more and more unlabeled data. Figure 8(b) also indicates that after adding a certain number of unlabeled data, including more unlabeled data will only improve the performance marginally. This phenomenon is observed in Figure 8(a) as well.

7. Extensions

In this section, we discuss possible extensions of using conjugate functions for sparse semi-supervised learning. In particular, the ε-insensitive loss term can be replaced by a somewhat general convex function. We also briefly discuss two sparse variants for Co-RLS and Laplacian SVMs using the same approach as sparse multi-view SVMs.

7.1 Arbitrary Convex Loss

In Section 2.2, for each example the ε-insensitive loss used is $f_\varepsilon(t_i) = (\sqrt{t_i} - \varepsilon)_+^2$ with $t_i = [f_1(x_i) - f_2(x_i)]^2$. This can be relaxed to a general class of user-designed losses that can be defined as a convex function of t_i, for example, using existing convex functions or compositions of convex functions with some good properties (Boyd and Vandenberghe, 2004).

Provided the ε-insensitive loss conforms the slight assumptions closed, convex, and proper listed in Lemma 5, the methodology used for sparse multi-view SVMs and the advantages of using Fenchel-Legendre conjugates apply well to the new optimization problem. This is an important contribution of this paper, which gives a framework for solving problems involving different ε-insensitive loss functions. Also, this framework applies to problems with a single view or more than two views, as long as the objective function is convex with respect to θ (parameters of classifiers or regressors) as in (11).

7.2 A Sparse Variant for Co-RLS

The objective function of Co-RLS in the case of two views is given as follows (Sindhwani et al., 2005; Brefeld et al., 2006)

$$\min_{f_1\in\mathcal{H}_1, f_2\in\mathcal{H}_2} \quad \frac{1}{2\ell}\sum_{i=1}^{\ell}[(f_1(x_i)-y_i)^2+(f_2(x_i)-y_i)^2]+ \\ \gamma_n(\|f_1\|^2+\|f_2\|^2)+\gamma_v\sum_{i=1}^{\ell+u}(f_1(x_i)-f_2(x_i))^2,$$

where nonnegative scalars γ_n, γ_v are respectively norm regularization and multi-view regularization coefficients. This optimization problem is indeed convex with respect to expansion coefficients α_1 and α_2 which have the same meanings as in (9).

Replacing the last term with $\sum_{i=1}^{\ell+u}(|f_1(x_i)-f_2(x_i)|-\varepsilon)_+^2$ results in the sparse Co-RLS algorithm

$$\min_{f_1\in\mathcal{H}_1, f_2\in\mathcal{H}_2} \quad \frac{1}{2\ell}\sum_{i=1}^{\ell}[(f_1(x_i)-y_i)^2+(f_2(x_i)-y_i)^2]+ \\ \gamma_n(\|f_1\|^2+\|f_2\|^2)+\gamma_v\sum_{i=1}^{\ell+u}(|f_1(x_i)-f_2(x_i)|-\varepsilon)_+^2.$$

This ε-insensitive loss is identical to that used in sparse multi-view SVMs, and therefore we can directly use the technique developed in this paper to solve this optimization.

7.3 A Sparse Variant for Laplacian SVMs

By including a penalty term on the intrinsic manifold smoothness, Belkin et al. (2006) proposed the Laplacian SVMs as an extension of SVMs by solving the following problem in an RKHS

$$\min_{f\in\mathcal{H}}\frac{1}{\ell}\sum_{i=1}^{\ell}(1-y_i f(x_i))_+ +\gamma_A\|f\|^2+\gamma_I\sum_{i,j=1}^{\ell+u}W_{ij}(f(x_i)-f(x_j))^2, \tag{33}$$

where $\mathcal{H}$ is the RKHS induced by a kernel, γ_A and γ_I are respectively ambient and intrinsic regularization coefficients, and $W_{ij}\geq 0$ are entries of the weight matrix W of the graph representing the manifold. The last term can be rewritten as

$$\begin{aligned}\sum_{i,j=1}^{\ell+u}W_{ij}(f(x_i)-f(x_j))^2 &= 2\left[\sum_{i=1}^{\ell+u}(\sum_{j=1}^{\ell+u}W_{ij})f^2(x_i)-\sum_{i,j=1}^{\ell+u}W_{ij}f(x_i)f(x_j)\right]\\ &= 2\mathbf{f}^\top(V-W)\mathbf{f}=2\mathbf{f}^\top\mathcal{L}\mathbf{f},\end{aligned}$$

where $\mathbf{f}=[f(x_1),\ldots,f(x_{\ell+u})]^\top$, matrix V is diagonal with the ith diagonal entry $V_{ii}=\sum_{j=1}^{\ell+u}W_{ij}$, and $\mathcal{L}$ is the positive semi-definite graph Laplacian.

This optimization problem is also convex with respect to expansion coefficient α, slack variable ξ and bias b if we formulate it as in (12). Replacing the last term in (33) with $\sum_{i,j=1}^{\ell+u}W_{ij}(|f(x_i)-f(x_j)|-\varepsilon)_+^2$ results in the sparse Laplacian SVMs

$$\min_{f\in\mathcal{H}}\frac{1}{\ell}\sum_{i=1}^{\ell}(1-y_i f(x_i))_+ +\gamma_A\|f\|^2+\gamma_I\sum_{i,j=1}^{\ell+u}W_{ij}(|f(x_i)-f(x_j)|-\varepsilon)_+^2,$$

This ε-insensitive loss has a similar form with that used in sparse multi-view SVMs, and thus facilitates an extension of the technique developed in this paper to solve this optimization.

8. Conclusion

In this paper, we proposed a sparse semi-supervised learning framework using Fenchel-Legendre conjugates. It is extendable to a wide range of semi-supervised learning methods. In particular, we formulated and solved the sparse multi-view SVMs, which incorporate an ε-insensitive multi-view regularization term. By rewriting this regularization in terms of conjugate functions, we obtained an inf-sup optimization problem whose globally optimal solutions can be found by our proposed iterative algorithm. We also showed that the quadratic program involved in each iteration only depends on the size of the labeled set, which would be very efficient for semi-supervised learning problems. For sparse multi-view SVMs, we characterized their generalization error in terms of the margin bound and derived the empirical Rademacher complexity of the considered function class. The empirical Rademacher complexity has two different forms depending on whether the iterative algorithm iterates only once or multiple steps.

Experimental results on sparse multi-view SVMs with different ε values showed that it is unnecessary to retain all the unlabeled data to represent target functions and using sparse semi-supervised learning can effectively reach a good balance between classifier performance and the number of unlabeled examples retained. This would be beneficial to speed up function evaluations during the classification of new examples. Comparisons with SVM-2K showed the superiority of our proposed method both on classification accuracies and the possibility and potential to be applied to large-scale problems when a sequential training strategy is adopted. As in this paper we only concern the possibility and potential for large-scale applications, we employed a moderate data set. It leaves as future work to apply the approach to much larger data sets. We also performed experiments to validate the usefulness of the margin bound and empirical Rademacher complexity, which explain well the regularization role unlabeled data play for multi-view learning.

Acknowledgments

We would like to thank Dr. Sandor Szedmak for providing the code of SVM-2K and related discussions. Editor: Gabor Lugosi

Abstract

Sequential algorithms of active learning based on the estimation of the level sets of the empirical risk are discussed in the paper. Localized Rademacher complexities are used in the algorithms to estimate the sample sizes needed to achieve the required accuracy of learning in an adaptive way. Probabilistic bounds on the number of active examples have been proved and several applications to binary classification problems are considered.

Keywords: active learning, excess risk, Rademacher complexities, capacity function, disagreement coefficient

1. Introduction

Let $(S,\mathcal{A})$ be a measurable space and $T \subset \mathbb{R}$. Consider a standard **prediction problem** in which (X,Y) is a random couple in $S \times T$ with unknown distribution P. Here X is a **design point** whose distribution will be denoted Π and Y is a **response variable** with conditional distribution (given X) $P_{Y|X}(\cdot|X=x)$. The response variable Y is to be predicted based on an observation of X. This class of problems includes many versions of regression and classification. For instance, in the binary classification, $T=\{-1,1\}$ and the conditional distribution of Y given X is completely characterized by the regression function

$$\eta(x) := \mathbb{E}(Y|X=x).$$

In the framework of **passive learning**, a learning algorithm inputs the training data $(X_1,Y_1),\dots (X_n,Y_n)$ that consists of n independent examples sampled from the distribution P. The goal is to construct a data dependent prediction rule $\hat{g}: S \mapsto T$ whose risk with respect to a properly chosen loss function is "close" to the minimal possible risk. More precisely, given a loss function $\ell : T \times T \mapsto \mathbb{R}$, the risk of a prediction rule $g : S \mapsto T$ is defined as

$$P(\ell \bullet g) = \mathbb{E}\ell(Y; g(X)),$$

where we used the notation $(\ell \bullet g)(x,y) := \ell(y; g(x))$. For instance, in the binary classification setting, the binary loss $\ell(y,u) := I(y \neq u)$ is usually used. In this case, the risk of a classification rule $g : S \mapsto \{-1,1\}$ is its generalization error:

$$P(\ell \bullet g) = \mathbb{P}\{Y \neq g(X)\}.$$

∗. Partially supported by NSF grants MSPA-MCS-0624841, DMS-0906880 and CCF-0808863.

Suppose $\mathcal{G}$ is a class of prediction rules $g : S \mapsto T$. The quantity

$$\mathcal{E}_P(\ell \bullet g) := P(\ell \bullet g) - \inf_{g \in \mathcal{G}} P(\ell \bullet g)$$

is called the **excess risk** of g. One of the main goals of statistical analysis of learning algorithms is to understand how the excess risk $\mathcal{E}_P(\ell \bullet \hat{g})$ of a data dependent decision rule $\hat{g}$ output by such an algorithm depends on the sample size n, on the "complexity" of the class $\mathcal{G}$ of prediction rules and on the underlying complexity of the prediction problem itself.

In the recent years, there has been a lot of interest in **active learning** algorithms. In this framework, the algorithm can modify the design distribution in the process of learning. More precisely, suppose that the training examples (X_j, Y_j) are sampled sequentially. At each iteration (say, iteration number k), the algorithm requests a design point X_{k+1} sampled from a distribution $\hat{\Pi}_k$ that depends on the training data $(X_1, Y_1), \ldots, (X_k, Y_k)$. Given $X_{k+1} = x$, the response variable (the label) Y_{k+1} is sampled from the conditional distribution $P_{Y|X}(\cdot|X = x)$. The question is whether there are such active learning algorithms for which the excess risk after n iterations is provably smaller than for the passive prediction rules based on the same number n of training examples. It happens that the answer depends on the type of learning problem. A minimax analysis by Castro et al. (2005) and Castro and Nowak (2008) shows that such an improvement is possible in classification problems and in some special classes of regression problems with non-smooth regression function (for instance, if the regression function is a step function). In such cases, the improvement can be very significant. In some classification problems, the excess risk of active learning algorithms can converge to zero with an **exponential rate** as $n \to \infty$ (comparing with the rate $O(n^{-1})$ in the case of passive learning). Castro and Nowak (2008) studied several examples of binary classification problems in which the active learning approach is beneficial and suggested nice active learning algorithms in these problems. However, the drawback of these algorithms is that they are not adaptive in the sense that they require the prior knowledge of distribution dependent parameters of the problem, such as noise characteristics in classification. The development of active learning methods that are adaptive and, at the same time, computationally tractable remains a challenge. There has been a progress in the design of active learning algorithms that possess some degree of adaptivity, in particular, see Dasgupta et al. (2007), Balcan et al. (2009), Balcan et al. (2008) and Hanneke (2009a,b). In the last two interesting papers by Hanneke, some versions of the algorithms of Balcan et al. (2009) and of Dasgupta et al. (2007) were studied using the technique of **Rademacher complexities** that much earlier proved to be very useful in the analysis of passive learning, see Bartlett et al. (2002), Koltchinskii (2001), Koltchinskii and Panchenko (2000), Bartlett et al. (2005), Koltchinskii (2006, 2008) and references therein. Hanneke showed that incorporating Rademacher complexities in active learning algorithms allows one to develop rather general versions of such algorithms that are adaptive under broad assumptions on the underlying distributions.

In the current paper, we continue this line of research. We consider the following model of active learning. At each iteration, a learning algorithm has to choose a set $\hat{A} \subset S$ of "good" design points and also the number of training examples needed at the current iteration. Both the set $\hat{A}$ and the required number of the examples might depend on the training data that is already available. The algorithm has an access to an oracle that is asked to provide the required number of examples (X, Y) sampled from the conditional distribution $P(\cdot|x \in \hat{A})$. Alternatively, it can be described as follows. The oracle provides training examples (X, Y) sampled from an unknown probability distribution P. At each iteration, the algorithm chooses a set $\hat{A}$ of "good" design points and asks the oracle

whether the next design point X_k is "good". If it is "good", the algorithm accepts the point, the oracle provides it with a label Y_k and returns the couple (X_k, Y_k). Testing whether the example is "good" costs the algorithm nothing, but each "good" labeled training example costs \$ 1. Thus, only the number of "good" examples matters for determining the total cost of learning. The question is how many "good" examples are needed for the excess risk $\mathcal{E}_P(\ell \bullet \hat{g})$ of the resulting classifier $\hat{g}$ to become smaller than δ with a guaranteed probability at least $1-\alpha$.

We will develop active learning algorithms that are somewhat akin to what is done by Hanneke (2009a,b), but they are more closely related to the construction of localized Rademacher complexities used in the definitions of distribution dependent and data dependent excess risk bounds in empirical risk minimization, see Koltchinskii (2006, 2008). The main idea of this construction is to characterize the complexity of the problem by the sup-norm of a special Rademacher process indexed by the level sets of the risk. To be more specific, suppose that we are dealing with a binary classification problem and that the empirical risk (with respect to the binary loss) is being minimized over a class $\mathcal{G}$ of binary functions. Then what matters is the collection of δ-minimal sets

$$\mathcal{G}(\delta) := \Big\{ g \in \mathcal{G} : \mathcal{E}_P(\ell \bullet g) \leq \delta \Big\}, \ \delta > 0.$$

These sets can be estimated based on the empirical data and Rademacher complexities of such estimated sets for small enough values of δ are used to define reasonably tight bounds on the excess risk. In many learning problems, the δ-minimal sets become small as $\delta \to 0$, for instance, in the sense that their $L_2(\Pi)$-diameter is small. It turns out that an important role in the development of active classification algorithms is played by the sets of the following type

$$A(\delta) := \Big\{ x \in S | \exists g_1, g_2 \in \mathcal{G}(\delta) : g_1(x) \neq g_2(x) \Big\}.$$

Such a set is called a **disagreement set** since it consists of the points for which there are two classifiers in $\mathcal{G}(\delta)$ whose predictions at point x disagree with each other. If the δ-minimal sets are small for small enough values of δ, one can expect that the corresponding disagreement sets are also small. This is not always the case, but there are natural examples in which indeed the measure $\Pi(A(\delta))$ tends to 0 as $\delta \to 0$ (sometimes, even $\Pi(A(\delta)) = O(\delta)$). Note that if the empirical risk is being minimized over the δ-minimal set $\mathcal{G}(\delta)$, one can eliminate from the sample all the design points X_j such that $X_j \notin A(\delta)$: the minimizers of the empirical risk are not going to change since the value of the binary loss at such training examples (X_j, Y_j) is a constant on the δ-minimal set. So, only the examples for which X_j belongs to a small disagreement set $A(\delta)$ are really needed. This simple observation opens a possibility of reducing the sample size in the process of active learning, and this has already been exploited in several algorithms described in the literature: see Dasgupta et al. (2007), Balcan et al. (2009), Hanneke (2009a,b) and references therein. It is interesting to mention that some notions similar to the "disagreement sets" were used much earlier in the study of ratio type empirical processes (for instance, in the work of Alexander in the 80s; see, Giné and Koltchinskii, 2006 and references therein). Moreover, it was used by Giné and Koltchinskii (2006) to obtain refined excess risk bounds in binary classification (in the passive learning case). This will be discussed in some detail in Section 4.

Our approach is based on iterative estimation of the δ-minimal sets for a decreasing sequence $\{\delta_j\}$ of values of δ. It happens that, for larger values of δ, it is possible to construct a rough estimate of the δ-minimal sets based on a relatively small number of training examples. The required

sample sizes $\bar{n}(\delta)$ can be estimated using Rademacher complexities. For smaller values of δ, more examples are needed, but, at the same time, for the smaller values of δ the disagreement sets are also small, and these sets again can be estimated based on the training examples that have been already sampled. Thus, there is a possibility to come up with an active learning strategy that, at each iteration, computes an estimate $\hat{A}$ of the disagreement set and determines the required sample size, and then samples the required number of design points from the conditional distribution $\Pi(\cdot|x \in \hat{A})$. Each of these points $X_j = x$ is provided with a label Y_j sampled from the conditional distribution $P_{Y|X}(\cdot|X = x)$. The algorithm stops as soon as δ_j becomes smaller than the required accuracy of learning δ. At this stage, it outputs an estimate of the δ-minimal set $\mathcal{G}(\delta)$. The number of labeled examples needed to achieve this goal is roughly

$$\sum_{\delta_j \geq \delta} \bar{n}(\delta_j)\Pi(A(\delta_j))$$

(see theorems 7, 8, 9 for more precise formulations). For binary classification problems with a VC-class $\mathcal{G}$ such that $\Pi(A(\delta)) = O(\delta)$, this leads to the bound on the number of labeled examples of the order $\log(1/\delta)\log\log(1/\delta)$.

The need to estimate the whole δ-minimal set in this learning strategy rather than simply minimizing the empirical risk might look like too strong of an assumption. However, in the alternative general versions of adaptive strategies of active learning due to Hanneke (2009a,b) this is also needed. Hanneke uses previously suggested agnostic learning methods of Dasgupta et al. (2007) and of Balcan et al. (2009) in combination with Rademacher complexities that are based on estimated level sets of the empirical risk. So, currently, this seems to be unavoidable in general adaptive methods and our approach is just based on a more direct use of the δ-minimal sets.

To give a precise description of a version of active learning method considered in this paper and to study its statistical properties, several facts from the general theory of empirical risk minimization will be needed. In particular, in Section 2, we describe a construction of distribution dependent and data dependent bounds on the excess risk based on localized Rademacher complexities, see Koltchinskii (2006, 2008). In Section 3, we describe our active learning algorithms. These algorithms are sequential in the sense that the training data is being sampled until the desired accuracy of learning is achieved. We prove several bounds on the number of active examples needed to achieve this goal with a specified probability. In sections 2 and 3, it is convenient to study the problem in a more abstract framework, in which we suppress the labels Y_j and write S instead of $S \times \{-1,1\}$, X instead of (X,Y), f instead of $\ell \bullet g$, etc. This allows us to simplify the notations and the description of the algorithms, and, at the same time, it makes the results a little more general. In principle, it should be possible to apply these results to more general classes of learning problems than binary classification (for instance, to special regression models with a non-smooth regression function or to the problem of estimation of the level sets of an unknown probability density). However, we do not pursue this possibility here and, instead, we concentrate in Section 4 on the binary classification problems, which still remains the most interesting class of learning problems where the active learning approach leads to faster convergence rates.

2. Empirical Risk Minimization: Bounds on the Excess Risk

Let $(S,\mathcal{A})$ be a measurable space, let P be a probability measure in $(S,\mathcal{A})$ and let $X, X_1, X_2, \ldots$ be i.i.d. random variables in $(S,\mathcal{A})$ with common distribution P. Let $\mathcal{F}$ be a class of $\mathcal{A}$-measurable

functions $f : S \mapsto [0,1]$. The values of functions $f \in \mathcal{F}$ will be interpreted as "losses" associated with some decisions and the integral

$$Pf := \int_S f dP = \mathbb{E} f(X)$$

represents the expected loss, or the (true) risk. The optimization problem

$$Pf \longrightarrow \min,\ f \in \mathcal{F}$$

is interpreted as a "risk minimization" problem and the quantity

$$\mathcal{E}_P(f) := Pf - \inf_{g \in \mathcal{F}} Pg$$

is called the excess risk of f. The δ-minimal set of the true risk is defined as

$$\mathcal{F}_P(\delta) := \left\{ f \in \mathcal{F} : \mathcal{E}_P(f) \le \delta \right\},\ \delta \ge 0.$$

In learning theory problems, the distribution P is usually unknown and the risk Pf is to be estimated by the empirical risk. The empirical measure based on the sample $(X_1, \dots, X_n)$ of size n is defined as

$$P_n := n^{-1} \sum_{j=1}^{n} \delta_{X_j}$$

and the problem of risk minimization is replaced by the "empirical risk minimization":

$$P_n f \longrightarrow \min,\ f \in \mathcal{F}. \tag{1}$$

Naturally, this also leads to the definitions of the "excess empirical risk" $\mathcal{E}_{P_n}(f)$ and of the δ-minimal sets of the empirical risk $\mathcal{F}_{P_n}(\delta),\ \delta > 0$.

Given a solution $\hat{f}$ of the empirical risk minimization problem (1), a basic question is to provide reasonably tight upper confidence bounds on the excess risk $\mathcal{E}_P(\hat{f})$ that depend on complexity characteristics of the class $\mathcal{F}$. It is also of importance to understand when the δ-minimal sets of the empirical risk are reasonably good estimates of the δ-minimal sets of the true risk. We will need below several results of this type that can be found in the papers by Koltchinskii (2006, 2008).

First of all, we will need an upper confidence bound on the size of the empirical process

$$\sup_{f,g \in \mathcal{F}_P(\delta)} |(P_n - P)(f-g)|.$$

To construct such a bound, we use Talagrand's famous concentration inequalities. Suppose $\rho_P : L_2(P) \times L_2(P) \mapsto [0, +\infty)$ and

$$\rho_P^2(f,g) \ge P(f-g)^2 - (P(f-g))^2,\ f,g \in L_2(P).$$

Define the diameter of $\mathcal{F}_P(\delta)$ as

$$D(\delta) := D_P(\delta) := \sup_{f,g \in \mathcal{F}(\delta)} \rho_P(f,g).$$

It provides a measure of the size of the δ-minimal sets. We will also use the following quantity that characterizes the accuracy of "empirical approximation" of P by P_n on the δ-minimal sets:

$$\phi_n(\delta) := \mathbb{E} \sup_{f,g\in\mathcal{F}(\delta)} |(P_n - P)(f-g)|.$$

Given a decreasing sequence $\{\delta_j\}$ of positive numbers with $\delta_0 := 1$ and a sequence $\{t_j\}$ of positive numbers, define a step function $U_n(\delta),\ \delta \in (0,1]$ as follows:

$$\bar{U}_n(\delta) := 2\sum_{j\geq 0}\left[\phi_n(\delta_j) + D(\delta_j)\sqrt{\frac{t_j}{n}} + \frac{t_j}{n}\right] I_{(\delta_{j+1},\delta_j]}(\delta).$$

A version of Talagrand's concentration inequality with explicit constants due to Bousquet implies that, for all $j \geq 0$ and for all $\delta \in (\delta_{j+1},\delta_j]$, with probability at least $1 - e^{-t_j}$

$$\sup_{f,g\in\mathcal{F}_P(\delta)} |(P_n - P)(f-g)| \leq \bar{U}_n(\delta).$$

Given $\psi : \mathbb{R}_+ \mapsto \mathbb{R}_+$, define

$$\psi^\flat(\delta) := \sup_{\sigma\geq\delta} \frac{\psi(\sigma)}{\sigma}$$

and

$$\psi^\sharp(\varepsilon) := \inf\left\{\delta > 0 : \psi^\flat(\delta) \leq \varepsilon\right\}.$$

Let

$$\delta_n(\mathcal{F};P) := \sup\left\{\delta \in (0,1] : \delta \leq \bar{U}_n(\delta)\right\}.$$

The following bounds were proved by Koltchinskii (2006, 2008).

Theorem 1 *For all* $\delta \geq \delta_n(\mathcal{F};P)$,

$$\mathbb{P}\left\{\mathcal{E}_P(\hat{f}) > \delta\right\} \leq \sum_{\delta_j\geq\delta} e^{-t_j}$$

and

$$\mathbb{P}\left\{\sup_{f\in\mathcal{F},\mathcal{E}_P(f)\geq\delta}\left|\frac{\mathcal{E}_{P_n}(f)}{\mathcal{E}_P(f)} - 1\right| > \bar{U}_n^\flat(\delta)\right\} \leq \sum_{\delta_j\geq\delta} e^{-t_j}.$$

Thus, the quantity $\delta_n(\mathcal{F};P)$ is a distribution dependent upper bound on the excess risk $\mathcal{E}_P(\hat{f})$ that holds with a guaranteed probability. Moreover, for all $\delta \geq \delta_n(\mathcal{F};P)$ and for all $f \in \mathcal{F}$ with $\mathcal{E}_P(f) \geq \delta$ it is possible to control the size of the ratio $\frac{\mathcal{E}_{P_n}(f)}{\mathcal{E}_P(f)}$ in terms of the quantity $\bar{U}_n^\flat(\delta)$. This ratio bound for the excess risk immediately implies the following statement showing that for all the values of δ above certain threshold the δ-minimal sets of empirical risk provide estimates of the δ-minimal sets of the true risk.

Proposition 2 *Let* $\bar{\delta}_n := \bar{U}_n^{\sharp}\left(\frac{1}{2}\right)$. *For all* $\delta \geq \bar{\delta}_n$, *with probability at least*

$$1 - \sum_{\delta_j \geq \delta} e^{-t_j}$$

the following inclusions hold:

$$\forall \sigma \geq \delta \;\; \mathcal{F}_P(\sigma) \subset \mathcal{F}_{P_n}(3/2\sigma) \;\text{ and }\; \mathcal{F}_{P_n}(\sigma) \subset \mathcal{F}_P(2\sigma).$$

Data dependent upper confidence bounds on the excess risk can be constructed using localized sup-norms of Rademacher processes that provide a way to estimate the size of the empirical process. Given i.i.d. Rademacher random variables $\{\varepsilon_i\}$ independent of $\{X_i\}$, the Rademacher process is defined as

$$R_n(f) := n^{-1} \sum_{j=1}^{n} \varepsilon_j f(X_j).$$

We will assume that

$$\rho_P^2(f,g) := P(f-g)^2.$$

Define

$$\hat{\phi}_n(\delta) := \sup_{f,g \in \mathcal{F}_{P_n}(\delta)} |R_n(f-g)|$$

and

$$\hat{D}_n(\delta) := \sup_{f,g \in \mathcal{F}_{P_n}(\delta)} \rho_{P_n}(f,g).$$

These quantities are empirical versions of $\phi_n(\delta)$ and $D_P(\delta)$ and they can be used to define an empirical version of the function $\bar{U}_n$:

$$\hat{U}_n(\delta) := \hat{K} \sum_{j \geq 0} \left[\hat{\phi}_n(\hat{c}\delta_j) + \hat{D}_n(\hat{c}\delta_j)\sqrt{\frac{t_j}{n}} + \frac{t_j}{n} \right] I_{(\delta_{j+1},\delta_j]}(\delta),$$

where $\hat{K}, \hat{c}$ are numerical constants. We will also define

$$\tilde{U}_n(\delta) := \tilde{K} \sum_{j \geq 0} \left[\phi_n(\tilde{c}\delta_j) + D(\tilde{c}\delta_j)\sqrt{\frac{t_j}{n}} + \frac{t_j}{n} \right] I_{(\delta_{j+1},\delta_j]}(\delta)$$

with some numerical constants $\tilde{K}, \tilde{c}$.

It can be shown (see Koltchinskii, 2006, 2008) that for large enough numerical constants $\hat{K}, \tilde{K}, \hat{c}, \tilde{c}$ and for all $\delta \geq \bar{\delta}_n$, $\bar{U}_n(\delta) \leq \hat{U}_n(\delta) \leq \tilde{U}_n(\delta)$ with a high probability. More precisely, the following statement holds. Denote

$$\hat{\delta}_n := \hat{U}_n^{\sharp}\left(\frac{1}{2}\right),\ \tilde{\delta}_n := \tilde{U}_n^{\sharp}\left(\frac{1}{2}\right).$$

Theorem 3 *There exists a choice of numerical constants* $\hat{K}, \tilde{K}, \hat{c}, \tilde{c}$ *in the definitions of the functions* $\hat{U}_n, \tilde{U}_n$ *such that the following holds. For all* $\delta \geq \bar{\delta}_n$, *there exists an event* E *of probability*

$$\mathbb{P}(E) \geq 1 - 3 \sum_{\delta_j \geq \delta} e^{-t_j}$$

such that on this event

$$\bar{U}_n(\sigma) \le \hat{U}_n(\sigma) \le \tilde{U}_n(\sigma),\ \sigma \ge \delta.$$

As a consequence,

$$\mathbb{P}\left\{\bar{\delta}_n \le \hat{\delta}_n \le \tilde{\delta}_n\right\} \ge 1 - 3\sum_{\delta_j \ge \bar{\delta}_n} e^{-t_j}.$$

The proof is based on the following "statistical version" of Talagrand's concentration inequality (which, in turn, follows from the usual Talagrand's concentration inequality for empirical processes and standard symmetrization and contraction arguments, see Koltchinskii, 2008). Suppose that $\mathcal{F}$ is a class of measurable functions on S uniformly bounded by $U > 0$. Denote

$$\sigma_P^2(\mathcal{F}) := \sup_{f\in\mathcal{F}} Pf^2 \text{ and } \sigma_n^2(\mathcal{F}) := \sup_{f\in\mathcal{F}} P_n f^2.$$

For a function $Y : \mathcal{F} \mapsto \mathbb{R}$, denote

$$\|Y\|_{\mathcal{F}} := \sup_{f\in\mathcal{F}} |Y(f)|.$$

Theorem 4 *There exists a numerical constant $K > 0$ such that for all $t \ge 1$ with probability at least $1 - e^{-t}$ the following bounds hold:*

$$\left|\|R_n\|_{\mathcal{F}} - \mathbb{E}\|R_n\|_{\mathcal{F}}\right| \le K\left[\sqrt{\frac{t}{n}\left(\sigma_n^2(\mathcal{F}) + U\|R_n\|_{\mathcal{F}}\right)} + \frac{tU}{n}\right],$$

$$\mathbb{E}\|R_n\|_{\mathcal{F}} \le K\left[\|R_n\|_{\mathcal{F}} + \sigma_n(\mathcal{F})\sqrt{\frac{t}{n}} + \frac{tU}{n}\right],$$

$$\sigma_P^2(\mathcal{F}) \le K\left(\sigma_n^2(\mathcal{F}) + U\|R_n\|_{\mathcal{F}} + \frac{tU}{n}\right)$$

and

$$\sigma_n^2(\mathcal{F}) \le K\left(\sigma_P^2(\mathcal{F}) + U\|R_n\|_{\mathcal{F}} + \frac{tU}{n}\right).$$

Also,

$$\mathbb{E}\|P_n - P\|_{\mathcal{F}} \le K\left[\|R_n\|_{\mathcal{F}} + \sigma_n(\mathcal{F})\sqrt{\frac{t}{n}} + \frac{tU}{n}\right]$$

and

$$\left|\|P_n - P\|_{\mathcal{F}} - \mathbb{E}\|P_n - P\|_{\mathcal{F}}\right| \le K\left[\sqrt{\frac{t}{n}\left(\sigma_n^2(\mathcal{F}) + U\|R_n\|_{\mathcal{F}}\right)} + \frac{tU}{n}\right].$$

In what follows, it will be of interest to consider sequential learning algorithms in which the sample size is being gradually increased until the excess risk becomes smaller than a given level δ. The following quantities are used in the analysis of such algorithms. Let us fix a set $M \subset \mathbb{N}$. A possible choice is $M = \mathbb{N}$, but, usually, we will take $M = \{2^k : k \ge 0\}$. Denote

$$\bar{n}(\delta) := \inf\left\{n \in M : \bar{\delta}_n \le \delta\right\} = \inf\left\{n \in M : \bar{U}_n^{\flat}(\delta) \le \frac{1}{2}\right\},$$

$$\hat{n}(\delta) := \inf\left\{ n \in M : \hat{\delta}_n \le \delta \right\} = \inf\left\{ n \in M : \hat{U}_n^{\flat}(\delta) \le \frac{1}{2} \right\}$$

and

$$\tilde{n}(\delta) := \inf\left\{ n \in M : \tilde{\delta}_n \le \delta \right\} = \inf\left\{ n \in M : \tilde{U}_n^{\flat}(\delta) \le \frac{1}{2} \right\}.$$

If

$$\mathbb{E}\|P_n - P\|_{\mathcal{F}} \to 0 \text{ as } n \to \infty,$$

which is true for so called Glivenko-Cantelli classes of functions with respect to P (see, e.g., van der Vaart and Wellner, 1996), then it is easy to see that

$$\bar{\delta}_n \to 0 \text{ and } \tilde{\delta}_n \to 0 \text{ as } n \to \infty.$$

In this case, we have

$$\tilde{n}(\delta) < +\infty, \bar{n}(\delta) < +\infty, \delta \in (0,1].$$

It is also easy to see that the functions $n \mapsto \bar{U}_n(\delta)$ and $n \mapsto \tilde{U}_n(\delta)$ are nonincreasing (it follows from the well known reverse supermartingale properties of empirical processes; see, van der Vaart and Wellner, 1996, Lemma 2.4.5). This implies that, for all $n \ge \bar{n}(\delta)$, $\bar{\delta}_n \le \delta$ and, for all $n \ge \tilde{n}(\delta)$, $\tilde{\delta}_n \le \delta$. Since $\bar{U}_n(\delta) \le \tilde{U}_n(\delta),\ \delta \in (0,1]$, it is also clear that

$$\bar{n}(\delta) \le \tilde{n}(\delta),\ \delta \in (0,1].$$

The next proposition immediately follows from the definition of $\bar{n}(\delta)$ (it is, in fact, just a reformulation of the statements of Proposition 2 and Theorem 3):

Proposition 5 *(i) For all $n \ge \bar{n}(\delta)$,*

$$\mathbb{P}\left\{ \mathcal{E}_P(\hat{f}_n) > \delta \right\} \le \sum_{\delta_j \ge \delta} e^{-t_j};$$

(ii) For all $n \ge \bar{n}(\delta)$, with probability at least

$$1 - \sum_{\delta_j \ge \delta} e^{-t_j}$$

the following inclusions hold:

$$\forall \sigma \ge \delta \ \ \mathcal{F}_P(\sigma) \subset \mathcal{F}_{P_n}(3/2\sigma) \ \text{ and } \ \mathcal{F}_{P_n}(\sigma) \subset \mathcal{F}_P(2\sigma).$$

(iii) For all $n \ge \bar{n}(\delta)$, there exists an event E of probability

$$\mathbb{P}(E) \ge 1 - 3\sum_{\delta_j \ge \delta} e^{-t_j}$$

such that on this event

$$\bar{U}_n(\sigma) \le \hat{U}_n(\sigma) \le \tilde{U}_n(\sigma),\ \sigma \ge \delta.$$

We will also need a version of the statements of Proposition 5 that are uniform in $n \in M$. To this end, assume that the numbers t_j in the definitions of the functions $\bar{U}_n, \hat{U}_n, \tilde{U}_n$ depend also on n. We will denote these numbers $t_j^{(n)}$. Assume that, for all j, $\frac{t_j^{(n)}}{n}$ is a nonincreasing function of n. Then the next statement immediately follows from Theorem 3 and the union bound.

Proposition 6 *There exists an event H of probability*

$$\mathbb{P}(H) \geq 1 - \sum_{n \in M} \sum_{j \geq 0} e^{-t_j^{(n)}}$$

such that on this event, for all $n \in M$,

$$\mathcal{E}_P(\hat{f}_n) \leq \bar{\delta}_n,$$

$$\forall \delta \geq \bar{\delta}_n \;\; \mathcal{F}_P(\delta) \subset \mathcal{F}_{P_n}(3/2\delta) \;\text{ and }\; \mathcal{F}_{P_n}(\delta) \subset \mathcal{F}_P(2\delta).$$

Moreover, there exists an event E of probability

$$\mathbb{P}(E) \geq 1 - 3 \sum_{n \in M} \sum_{j \geq 0} e^{-t_j^{(n)}}$$

such that on this event, for all $n \in M$,

$$\bar{U}_n(\delta) \leq \hat{U}_n(\delta) \leq \tilde{U}_n(\delta), \; \sigma \geq \bar{\delta}_n$$

and

$$\bar{\delta}_n \leq \hat{\delta}_n \leq \tilde{\delta}_n.$$

As a consequence, we also have that for all $\delta \in (0,1]$

$$\bar{n}(\delta) \leq \hat{n}(\delta) \leq \tilde{n}(\delta).$$

The simplest choice of the numbers $t_j^{(n)}$, in the case when $M = \{2^k : k \geq 0\}$ and $\delta_j = 2^{-j}, \; j \geq 0$, is

$$t_j^{(n)} = 2\log(\log_2 n + 1) + 2\log(j+1) + \log\frac{1}{\alpha} + \log(12), \; j \geq 0, \; n \in M,$$

where $\alpha \in (0,1)$. With this choice, all the claims of Proposition 6 hold with a guaranteed probability at least $1 - \alpha$.

The main conclusion one can draw from Proposition 6 is that the sample size needed to achieve the desired "accuracy of learning" δ (i.e., to "learn" a function for which the excess risk is smaller than δ) can itself be learned from the data. More precisely, the estimator $\hat{n}(\delta)$ of the required sample size can be computed sequentially by increasing the sample size n gradually, computing for each n the data dependent excess risk bound $\hat{\delta}_n$ and stopping as soon as $\hat{\delta}_n \leq \delta$. With a high probability, the stopping time $\hat{n}(\delta)$ provides a "correct" estimate of the sample size (up to a numerical constant) in the sense that it is between two distribution dependent estimates ($\bar{n}(\delta)$ and $\tilde{n}(\delta)$) that are typically of the same order of magnitude (up to numerical constants). At the same time, the sample size $\hat{n}(\delta)$ is sufficient for estimating the σ-minimal sets of the true risk by the σ-minimal sets of the empirical risk for all $\sigma \geq \delta$ (in the sense of the inclusions of Proposition 6). These facts will play a crucial role in our design of active learning methods in the next section.

3. Sequential Active Learning

We first describe a simplified (non-adaptive) version of active learning in which it is assumed that the minimal sample size $\bar{n}(\delta)$ needed to achieve the desired "accuracy of learning" of the order δ is given. As before, suppose that $\{\delta_k\}_{k\geq 0}$ is a nonincreasing sequence of positive numbers with $\delta_0 = 1$. Denote $\bar{n}_k := \bar{n}(\delta_k)$, $k \geq 1$.

Algorithm 1

$\hat{\mathcal{F}}_0 := \mathcal{F}$;
for $k = 1, 2, \ldots,$
$\hat{A}_k := \left\{x : \sup_{f,g\in\hat{\mathcal{F}}_{k-1}} |f(x) - g(x)| > \delta_k\right\}$;
$\hat{P}_k := \frac{1}{\bar{n}_k}\sum_{j=1}^{\bar{n}_k} I_{\hat{A}_k}(X_j)\delta_{X_j}$;
$\hat{\mathcal{F}}_k := \hat{\mathcal{F}}_{k-1}\bigcap \mathcal{F}_{\hat{P}_k}(3\delta_k)$;
end

The set $\hat{A}_k$ defined at each iteration of the algorithm is viewed as a set of "active examples" (or "active set"). The examples $X_j \in \hat{A}_k$ are needed to compute the "active empirical measure" $\hat{P}_k$. The underlying assumption is that there exists a "base algorithm" that computes the δ-minimal set

$$\mathcal{F}_Q(\delta) := \left\{f : \mathcal{E}_Q(f) := Qf - \inf_{f\in\mathcal{F}} Qf \leq \delta\right\}$$

for an arbitrary discrete measure Q with a finite number of atoms. This algorithm is used to compute the set $\mathcal{F}_{\hat{P}_k}(3\delta_k)$. In principle, it would be enough only to ensure that, given $\delta > 0$ and measure Q, the "base algorithm" outputs a set $\bar{\mathcal{F}}_Q(\delta)$ such that

$$\mathcal{F}_Q(c_1\delta) \subset \bar{\mathcal{F}}_Q(\delta) \subset \mathcal{F}_Q(c_2\delta)$$

for some numerical constants $0 < c_1 < c_2$. However, to simplify the notations, we will assume that $c_1 = c_2 = 1$.

Of course, in reality, **Algorithm 1** stops after a finite number of iterations. A possible choice could be

$$L := \sum_{j\geq 0} I(\delta_j \geq \delta),$$

which can be viewed as the number of iterations needed to achieve the "desired accuracy" of learning $\delta \in (0,1)$. In other words, the algorithm stops when δ_j becomes smaller than δ. For instance, if $\delta_j = 2^{-j}$, $j \geq 0$, then the number of iterations L is of the order $\log_2(1/\delta)$. Let $\nu(\delta)$ denote the total number of active examples used by the algorithm in the first L iterations. Then

$$\nu(\delta) \leq \sum_{\delta_k\geq\delta}\sum_{j=1}^{\bar{n}_k} I_{\hat{A}_k}(X_j).$$

Denote

$$A(\delta) := \left\{x : \sup_{f,g\in\mathcal{F}(8\delta)} |f(x) - g(x)| > \delta\right\}$$

and

$$\pi(\delta) := P(A(\delta)).$$

The following statement will be easily proved by induction.

Theorem 7 *With probability at least*

$$1-\sum_{n\in M}\sum_{j\geq 0}e^{-t_j^{(n)}},$$

the following inclusions hold for the classes $\hat{\mathcal{F}}_k$ *output by* **Algorithm 1***: for all* $k\geq 0$

$$\mathcal{F}_P(\delta_k)\subset\hat{\mathcal{F}}_k\subset\mathcal{F}_P(8\delta_k). \tag{2}$$

Also, for all $t\geq 1$ *and all* $\delta\in(0,1]$, *with probability at least*

$$1-\sum_{n\in M}\sum_{j\geq 0}\exp\{-t_j^{(n)}\}-\sum_{\delta_j\geq\delta}\exp\{-\bar{n}(\delta_j)\pi(\delta_{j-1})t\log t\}$$

the following bound holds:

$$\nu(\delta)\leq et\sum_{\delta_j\geq\delta}\bar{n}(\delta_j)\pi(\delta_{j-1}).$$

Proof The inclusions (2) obviously hold for $k=0$. Assuming that, for all $j<k$,

$$\mathcal{F}_P(\delta_j)\subset\hat{\mathcal{F}}_j\subset\mathcal{F}_P(8\delta_j),$$

we will prove that the same inclusions hold also for k. Let H be the event of probability at least

$$1-\sum_{n\in M}\sum_{j\geq 0}e^{-t_j^{(n)}}$$

defined in Proposition 6. By the induction assumption,

$$\mathcal{F}_P(\delta_k)\subset\mathcal{F}_P(\delta_{k-1})\subset\hat{\mathcal{F}}_{k-1}$$

and, by the definition of $\hat{A}_k$, we have for all $f,g\in\hat{\mathcal{F}}_{k-1}$,

$$|P_{\bar{n}_k}(f-g)-\hat{P}_k(f-g)|=\left|\bar{n}_k^{-1}\sum_{i=1}^{\bar{n}_k}(f-g)(X_i)-\bar{n}_k^{-1}\sum_{i:X_i\in\hat{A}_k}(f-g)(X_i)\right|$$

$$=\left|\bar{n}_k^{-1}\sum_{i:X_i\notin\hat{A}_k}(f-g)(X_i)\right|\leq\delta_k.$$

We can conclude that, for all $f\in\mathcal{F}_P(\delta_k)$,

$$\left|\mathcal{E}_{P_{\bar{n}_k}}(f)-\mathcal{E}_{\hat{P}_k}(f)\right|\leq\delta_k.$$

Also, by the inclusions of Proposition 6 and the definition of $\bar{n}_k=\bar{n}(\delta_k)$, we have on the event H that

$$\mathcal{F}_P(\delta_k)\subset\mathcal{F}_{P_{\bar{n}_k}}(2\delta_k).$$

Hence, for all $f\in\mathcal{F}_P(\delta_k)$,

$$\mathcal{E}_{P_{\bar{n}_k}}(f)\leq 2\delta_k \text{ and } \mathcal{E}_{\hat{P}_k}(f)\leq 3\delta_k.$$

This implies the inclusion

$$\mathcal{F}_P(\delta_k) \subset \hat{\mathcal{F}}_{k-1} \bigcap \mathcal{F}_{\hat{P}_k}(3\delta_k) = \hat{\mathcal{F}}_k.$$

On the other hand, since $\hat{\mathcal{F}}_k \subset \hat{\mathcal{F}}_{k-1}$, we have, for all $f \in \hat{\mathcal{F}}_k$,

$$\left| \mathcal{E}_{P_{\bar{n}_k}}(f) - \mathcal{E}_{\hat{P}_k}(f) \right| \leq \delta_k.$$

Since for all $f \in \hat{\mathcal{F}}_k$, $\mathcal{E}_{\hat{P}_k}(f) \leq 3\delta_k$, we also have $\mathcal{E}_{P_{\bar{n}_k}}(f) \leq 4\delta_k$. Thus, using again the inclusions of Proposition 6, we get

$$\hat{\mathcal{F}}_k \subset \mathcal{F}_{P_{\bar{n}_k}}(4\delta_k) \subset \mathcal{F}_P(8\delta_k),$$

proving the inclusions (2)

To prove the bound on $\nu(\delta)$, note that on the event H, where the inclusions (2) hold for all k such that $\delta_k \geq \delta$, we have

$$\hat{A}_k \subset A(8\delta_{k-1}).$$

Hence, on the event H,

$$\nu(\delta) \leq \sum_{\delta_k \geq \delta} \nu_k,$$

where

$$\nu_k := \sum_{j=1}^{\bar{n}_k} I_{A(8\delta_{k-1})}(X_j).$$

Clearly, ν_k is a binomial random variable with parameters $\bar{n}_k$ and $\pi(\delta_{k-1})$. Therefore, we have

$$\mathbb{P}\{\nu_k \geq s\} \leq \left(\frac{e\bar{n}_k \pi(\delta_{k-1})}{s} \right)^s$$

(see, e.g., Dudley, 1999, p. 16). Taking $s := et\bar{n}_k\pi(\delta_{k-1})$ yields

$$\mathbb{P}\Big\{ \nu_k \geq et\bar{n}_k\pi(\delta_{k-1}) \Big\} \leq \exp\{-\bar{n}_k\pi(\delta_{k-1})t\log t\}.$$

Applying the union bound, we get

$$\mathbb{P}\left\{ \nu(\delta) \geq et \sum_{\delta_k \geq \delta} \bar{n}_k\pi(\delta_{k-1}) \right\} \leq \mathbb{P}(H^c) + \sum_{\delta_k \geq \delta} \exp\{-\bar{n}_k\pi(\delta_{k-1})t\log t\}.$$

Since

$$\mathbb{P}(H^c) \leq \sum_{n \in M} \sum_{j \geq 0} e^{-t_j^{(n)}},$$

the result follows. ■

The simplest way to make the method data dependent is to replace in **Algorithm 1** the sample sizes $\bar{n}_k = \bar{n}(\delta_k)$ by their estimates $\hat{n}_k := \hat{n}(\delta_k)$, $k \geq 1$ and to redefine $\hat{P}_k$ in the iterative procedure for $\hat{A}_k, \hat{P}_k$ and $\hat{\mathcal{F}}_k$ as follows:

$$\hat{P}_k := \frac{1}{\hat{n}_k} \sum_{j=1}^{\hat{n}_k} I_{\hat{A}_k}(X_j)\delta_{X_j}.$$

This modification of **Algorithm 1** will be called **Algorithm 2**. The following statement can be proved quite similarly to Theorem 7 (using Proposition 6).

Recall the definition of the number of iterations L and also that $\nu(\delta)$ denotes the number of active examples used by the algorithm in the first L iterations.

Theorem 8 *With probability at least*

$$1-3\sum_{j\geq 0}\sum_{n\in M} e^{-t_j^{(n)}},$$

the following inclusions hold for the classes $\hat{\mathcal{F}}_k$ output by **Algorithm 2***: for all $k\geq 0$,*

$$\mathcal{F}_P(\delta_k)\subset \hat{\mathcal{F}}_k\subset \mathcal{F}_P(8\delta_k).$$

Moreover, for all $t\geq 1$ and for all $\delta\in(0,1]$, with probability at least

$$1-3\sum_{j\geq 0}\sum_{n\in M}\exp\{-t_j^{(n)}\}-\sum_{\delta_j\geq\delta}\exp\{-\tilde{n}(\delta_j)\pi(\delta_{j-1})t\log t\}$$

the following bound holds:

$$\nu(\delta)\leq et\sum_{\delta_j\geq\delta}\tilde{n}(\delta_j)\pi(\delta_{j-1}).$$

Note that in this version of the algorithm all the training examples X_j (not only the examples in the active sets $\hat{A}_k$) are used to determine the sample sizes $\hat{n}_k$. So, from this point of view, **Algorithm 2** can not be viewed as really "active". However, it is easy to see that in a more concrete framework of prediction problems (such as, for instance, the binary classification) one can modify the definitions of the localized Rademacher complexities and of the sample sizes $\hat{n}_k$ in such a way that they depend only on the design points, but not on the response variables (labels). Thus, in the cases when sampling the design points is "cheap" and only assigning the labels to them is "expensive" (which is a common motivational assumption in the literature on active learning), the algorithms of this type make some sense (see Section 4 for more details).

It is more interesting, however, that even in the abstract framework of empirical risk minimization it is possible to change the definition of Rademacher complexities and the estimates of the sample sizes based on them so that only the active examples that belong to the sets $\hat{A}_k$ are being used in the computation. We will describe such a data driven algorithm of active learning below.

Let $\delta_j:=2^{-j},\ j\geq 0$. As before, we will define iteratively data dependent function classes $\hat{\mathcal{F}}_k$ beginning with $\hat{\mathcal{F}}_0:=\mathcal{F}$ that provide estimates of the δ-minimal sets $\mathcal{F}_P(\delta)$ for sufficiently small values of δ and we set

$$\hat{A}_k:=\Big\{x:\ \sup_{f,g\in\hat{\mathcal{F}}_{k-1}}|f(x)-g(x)|>c\delta_k\Big\}\ \text{with some constant } c>0.$$

Define

$$\hat{P}_n^{(k)}:=n^{-1}\sum_{j=1}^n I_{\hat{A}_k}(X_j)\delta_{X_j}$$

and

$$\hat{R}_n^{(k)}(f):=n^{-1}\sum_{j=1}^n \varepsilon_j f(X_j)I_{\hat{A}_k}(X_j).$$

Denote

$$\hat{U}_n^{(k)} := \hat{K}\left[\sup_{f,g\in\hat{\mathcal{F}}_{k-1}}\left|\hat{R}_n^{(k)}(f-g)\right| + D_{\hat{P}_n^{(k)}}(\hat{\mathcal{F}}_{k-1})\sqrt{\frac{t_k^{(n)}}{n}} + \frac{t_k^{(n)}}{n}\right]$$

and define iteratively a nondecreasing data dependent sequence $\hat{n}_k$:

$$\hat{n}_k := \min\left\{n \in M, n \geq \hat{n}_{k-1} : \hat{U}_n^{(k)} \leq \frac{1}{2}\delta_{k+1}\right\}$$

with the initial condition $\hat{n}_0 := \inf M$.

Note that the following iterative relationships hold for the distribution dependent sample sizes $\bar{n}_k := \bar{n}(\delta_{k+1})$ and $\tilde{n}_k := \tilde{n}(\delta_{k+1})$:

$$\bar{n}_k = \min\left\{n \in M, n \geq \bar{n}_{k-1} : \bar{U}_n(\delta_k) \leq \frac{1}{2}\delta_{k+1}\right\},\ \ \bar{n}_0 := \inf M$$

and

$$\tilde{n}_k = \min\left\{n \in M, n \geq \tilde{n}_{k-1} : \tilde{U}_n(\delta_k) \leq \frac{1}{2}\delta_{k+1}\right\},\ \ \tilde{n}_0 := \inf M.$$

(which easily follows from the definitions of $\bar{n}(\delta), \tilde{n}(\delta)$).

We will write, for brevity, $\hat{P}_k := \hat{P}_{\hat{n}_k}^{(k)}$. With these definitions and notations, we can define $\hat{\mathcal{F}}_k$ iteratively exactly as before:

$$\hat{\mathcal{F}}_k := \hat{\mathcal{F}}_{k-1} \bigcap \mathcal{F}_{\hat{P}_k}(3\delta_k).$$

In short, the algorithm can be described as follows:

Algorithm 3

$\hat{\mathcal{F}}_0 := \mathcal{F}$;

for $k = 1, 2, \ldots,$

$\hat{A}_k := \left\{x : \sup_{f,g\in\hat{\mathcal{F}}_{k-1}} |f(x) - g(x)| > c\delta_k\right\}$;

$\hat{n}_k := \min\left\{n \in M, n \geq \hat{n}_{k-1} : \hat{U}_n^{(k)} \leq \frac{1}{2}\delta_{k+1}\right\}$;

$\hat{\mathcal{F}}_k := \hat{\mathcal{F}}_{k-1} \bigcap \mathcal{F}_{\hat{P}_k}(3\delta_k)$;

end

As before, we define

$$A(\delta) := \left\{x : \sup_{f,g\in\mathcal{F}(8\delta)} |f(x) - g(x)| > c\delta\right\}$$

and

$$\pi(\delta) := P(A(\delta)).$$

The properties of **Algorithm 3** are summarized in the following theorem.

Theorem 9 *There exist numerical constants c in the definition of the active sets $\hat{A}_k$, $\hat{K}$ in the definition of $\hat{U}_n^{(k)}$ and $\tilde{K}, \tilde{c}$ in the definition of the function $\tilde{U}_n$ such that the following holds. With probability at least*

$$1 - 3\sum_{j\geq 0}\sum_{n\in M} e^{-t_j^{(n)}},$$

the following inequalities and inclusions hold for all $k \geq 0$:

$$\bar{n}_k \leq \hat{n}_k \leq \tilde{n}_k,$$

$$\mathcal{F}_P(\delta_k) \subset \hat{\mathcal{F}}_k \subset \mathcal{F}_P(8\delta_k).$$

Moreover, for all $t \geq 1$, *with probability at least*

$$1 - 3\sum_{j\geq 0}\sum_{n\in M}\exp\{-t_j^{(n)}\} - \sum_{\delta_j \geq \delta}\exp\{-\tilde{n}(\delta_{j+1})\pi(\delta_{j-1})t\log t\}$$

the following bound holds:

$$\nu(\delta) \leq et\sum_{\delta_j\geq\delta}\tilde{n}(\delta_{j+1})\pi(\delta_{j-1}).$$

Proof There exists an event E of probability at least

$$1 - 3\sum_{n\in M}\sum_{j\geq 0} e^{-t_j^{(n)}}$$

on which the following holds. For all k and for all $n \in M$

$$\hat{K}\left[\sup_{f,g\in\mathcal{F}_P(8\delta_{k-1})}\left|R_n(f-g)\right| + D_{P_n}(\mathcal{F}_P(8\delta_{k-1}))\sqrt{\frac{t_k^{(n)}}{n}} + \frac{t_k^{(n)}}{n}\right] \leq \frac{1}{2}\tilde{U}_n(\delta_k) \tag{3}$$

and

$$\hat{K}\left[\sup_{f,g\in\mathcal{F}_P(\delta_{k-1})}\left|R_n(f-g)\right| + D_{P_n}(\mathcal{F}_P(\delta_{k-1}))\sqrt{\frac{t_k^{(n)}}{n}} + \frac{t_k^{(n)}}{n}\right] \geq 2\bar{U}_n(\delta_k) \tag{4}$$

with properly chosen constants in the definitions of the functions $\bar{U}_n, \tilde{U}_n$ and constant $\hat{K}$. At the same time, on the same event E, for all $n \in M, n \geq \bar{n}(\delta)$ and all $\sigma \geq \delta$,

$$\mathcal{F}_P(\sigma) \subset \mathcal{F}_{P_n}(2\sigma) \text{ and } \mathcal{F}_{P_n}(\sigma) \subset \mathcal{F}_P(2\sigma). \tag{5}$$

To construct such an event, first consider the event H of Proposition 6 on which the inclusions (5) hold. Then define

$$E_{k,n} := \left\{\hat{K}\left[\sup_{f,g\in\mathcal{F}_P(8\delta_{k-1})}\left|R_n(f-g)\right| + D_{P_n}(\mathcal{F}_P(8\delta_{k-1}))\sqrt{\frac{t_k^{(n)}}{n}} + \frac{t_k^{(n)}}{n}\right] \leq \frac{1}{2}\tilde{U}_n(\delta_k)\right\}$$

and

$$E'_{k,n} := \left\{\hat{K}\left[\sup_{f,g\in\mathcal{F}_P(\delta_{k-1})}\left|R_n(f-g)\right| + D_{P_n}(\mathcal{F}_P(\delta_{k-1}))\sqrt{\frac{t_k^{(n)}}{n}} + \frac{t_k^{(n)}}{n}\right] \geq 2\bar{U}_n(\delta_k)\right\}.$$

Using the "statistical version" of Talagrand's concentration inequality (Theorem 4) one can show that with a proper choice of $\hat{K}$ and the constants in the definitions of the functions $\bar{U}_n, \tilde{U}_n$,

$$\mathbb{P}(E_{n,k}) \leq 1 - e^{-t_k^{(n)}}, \ \ \mathbb{P}(E'_{n,k}) \geq 1 - e^{-t_k^{(n)}}$$

for all $k \geq 0$ and for all $n \in M$. Define

$$E := \bigcap_{k \geq 0, n \in M} (E_{n,k} \cap E'_{n,k}) \cap H.$$

Then

$$\mathbb{P}(E) \geq 1 - 3 \sum_{n \in M} \sum_{j \geq 0} e^{-t_j^{(n)}}$$

and all the desired properties hold on the event E.

We will now show by induction that, on the event E for $k = 0, 1, \ldots$

$$\bar{n}_k \leq \hat{n}_k \leq \tilde{n}_k,$$

$$\mathcal{F}_P(\delta_k) \subset \hat{\mathcal{F}}_k \subset \mathcal{F}_P(8\delta_k)$$

and also for $k = 1, 2, \ldots$ and for all $n \in M$

$$2\bar{U}_n(\delta_k) - \frac{\delta_{k+1}}{2} \leq \hat{U}_n^{(k)} \leq \frac{1}{2}\Big[\tilde{U}_n(\delta_k) + \frac{\delta_{k+1}}{2}\Big]. \tag{6}$$

By the definitions, the claims are obviously true for $k = 0$. Assume that they have been proved up to $k-1$. By this induction assumption, we have $\hat{\mathcal{F}}_{k-1} \subset \mathcal{F}_P(8\delta_{k-1})$ and, by the definition of the set $\hat{A}_k$,

$$\sup_{f,g \in \hat{\mathcal{F}}_{k-1}} \Big|\hat{R}_n^{(k)}(f-g)\Big| \leq \sup_{f,g \in \hat{\mathcal{F}}_{k-1}} \Big|R_n(f-g)\Big| + c\delta_k$$

and

$$D^2_{\hat{P}_n^{(k)}}(\hat{\mathcal{F}}_{k-1}) \leq D^2_{P_n}(\hat{\mathcal{F}}_{k-1}) + c^2\delta_k^2.$$

This implies the following upper bound on $\hat{U}_n^{(k)}$:

$$\hat{U}_n^{(k)} \leq \hat{K}\Bigg[\sup_{f,g \in \mathcal{F}_P(8\delta_{k-1})} \Big|R_n(f-g)\Big| + D_{P_n}(\mathcal{F}_P(8\delta_{k-1}))\sqrt{\frac{t_k^{(n)}}{n}} + \frac{t_k^{(n)}}{n} + c\delta_k + c\delta_k\sqrt{\frac{t_k^{(n)}}{n}}\Bigg].$$

Applying to the last term the inequality $ab \leq (a^2+b^2)/2$ and taking into account the fact that $\delta_k \leq 1$, it is easy to deduce from this that with c satisfying the condition

$$\hat{K}c + \hat{K}^2c^2/2 \leq 1/8,$$

we have

$$\hat{U}_n^{(k)} \leq \hat{K}\Bigg[\sup_{f,g \in \mathcal{F}_P(8\delta_{k-1})} \Big|R_n(f-g)\Big| + D_{P_n}(\mathcal{F}_P(8\delta_{k-1}))\sqrt{\frac{t_k^{(n)}}{n}} + \frac{t_k^{(n)}}{n}\Bigg] + \delta_{k+1}/4.$$

Quite similarly, using the inclusion $\mathcal{F}_P(\delta_{k-1}) \subset \hat{\mathcal{F}}_{k-1}$ that also holds under the induction assumption, one can show that with a proper choice of constant c in the definition of the set $\hat{A}_k$

$$\hat{U}_n^{(k)} \geq \hat{K}\Bigg[\sup_{f,g \in \mathcal{F}_P(\delta_{k-1})} \Big|R_n(f-g)\Big| + D_{P_n}(\mathcal{F}_P(\delta_{k-1}))\sqrt{\frac{t_k^{(n)}}{n}} + \frac{t_k^{(n)}}{n}\Bigg] - \delta_{k+1}/2.$$

Combining this with bounds (3) and (4) immediately implies (6).

Applying (6) to $n = \hat{n}_k$, we get

$$2\bar{U}_{\hat{n}_k}(\delta_k) - \frac{\delta_{k+1}}{2} \le \hat{U}^{(k)}_{\hat{n}_k} \le \frac{\delta_{k+1}}{2},$$

which yields

$$\bar{U}_{\hat{n}_k}(\delta_k) \le \frac{\delta_{k+1}}{2}.$$

We also have $\hat{n}_k \ge \hat{n}_{k-1} \ge \bar{n}_{k-1}$ (by the induction assumption). By the definition of $\bar{n}_k$, this implies that $\hat{n}_k \ge \bar{n}_k$.

On the other hand, denote $\hat{n}_k^-$ the element of the ordered set M preceding $\hat{n}_k$. We will use inequality (6) with $n = \hat{n}_k^-$. It gives

$$\hat{U}^{(k)}_{\hat{n}_k^-} \le \frac{1}{2}\Big[\tilde{U}_{\hat{n}_k^-}(\delta_k) + \frac{\delta_{k+1}}{2}\Big]. \tag{7}$$

If it happened that $\hat{n}_k^- < \hat{n}_{k-1}$, then we must have $\hat{n}_k = \hat{n}_{k-1}$, which, by the induction assumption, implies that $\hat{n}_k = \hat{n}_{k-1} \le \tilde{n}_{k-1} \le \tilde{n}_k$. If $\hat{n}_k^- \ge \hat{n}_{k-1}$, then the definition of $\hat{n}_k$ implies that

$$\hat{U}^{(k)}_{\hat{n}_k^-} > \frac{\delta_{k+1}}{2},$$

which together with (7) implies that

$$\tilde{U}_{\hat{n}_k^-}(\delta_k) > \frac{\delta_{k+1}}{2}.$$

But, if $\hat{n}_k > \tilde{n}_k$, then $\hat{n}_k^- \ge \tilde{n}_k$, which would imply that

$$\tilde{U}_{\tilde{n}_k}(\delta_k) > \frac{\delta_{k+1}}{2}$$

(since for all δ, $\tilde{U}_n(\delta)$ is a nonincreasing function of n). The last inequality contradicts the definition of $\tilde{n}_k$ implying that $\hat{n}_k \le \tilde{n}_k$.

The proof of the inclusions

$$\mathcal{F}_P(\delta_k) \subset \hat{\mathcal{F}}_k \subset \mathcal{F}_P(8\delta_k)$$

and the derivation of the bound on $\nu(\delta)$ repeat the argument of Theorem 7. ■

Note that in the bounds on $\nu(\delta)$ of theorems 7, 8 and 9 one can replace functions $\pi(\delta)$, $\bar{n}(\delta)$ and $\tilde{n}(\delta)$ by arbitrary upper bounds (with the same change in the bounds on the probability).

As soon as $\pi(\delta) \to 0$ as $\delta \to 0$, the upper bounds on $\nu(\delta)$ show that, in the case of active learning, there is a reduction of the number of training examples needed to achieve a desired accuracy of learning comparing with passive learning. In the next section, we explore in some detail what is happening in the case of binary classification.

4. Active Learning in Binary Classification

Let (X,Y) be a random couple with values in $S\times\{-1,1\}$ and with distribution P, where $(S,\mathcal{A})$ is an arbitrary measurable space. In binary classification problems, the first component X is viewed as an observable instance and the second component Y is an unobservable "label". The value of Y is to be predicted based on an observation of X and on the training data $(X_1,Y_1),\dots,(X_n,Y_n)$ consisting of n independent copies of (X,Y). Measurable functions $g:S\mapsto\{-1,1\}$ are called (binary) classifiers. Let $\ell:\{-1,1\}\times\{-1,1\}\mapsto\{0,1\}$ be the binary loss function $\ell(y,u):=I(y\neq u)$, and, as before, $(\ell\bullet g)(x,y):=\ell(y,g(x))$ be the "loss" of classifier g for the example $(x,y)\in S\times\{-1,1\}$. The quantity

$$P(\ell\bullet g)=P\{(x,y):y\neq g(x)\}=\mathbb{P}\{Y\neq g(X)\}$$

is called the generalization error, or the risk of g. We still denote $\eta(x):=\mathbb{E}(Y|X=x)$ the regression function. It is well known that the minimum of the generalization error over the set of all binary classifiers is attained at the Bayes classifier

$$g_*(x)=\mathrm{sign}(\eta(x)).$$

We will assume in what follows that $\mathcal{G}$ is a class of binary classifiers such that $g_*\in\mathcal{G}$.

For a binary classifier g, define its excess risk as

$$\mathcal{E}_P(\ell\bullet g):=P(\ell\bullet g)-P(\ell\bullet g_*).$$

The following formula is well known (see, e.g., Devroye et al., 1996, Theorem 2.2).

$$\mathcal{E}_P(\ell\bullet g)=\int_{\{g\neq g_*\}}|\eta(x)|\Pi(dx), \tag{8}$$

where Π is the marginal distribution of X.

A standard approach to learning the Bayes classifier is based on the empirical risk minimization:

$$\hat{g}:=\mathrm{argmin}_{g\in\mathcal{G}}P_n(\ell\bullet g)=\mathrm{argmin}_{g\in\mathcal{G}}P_n\{(x,y):y\neq g(x)\}=$$

$$\mathrm{argmin}_{g\in\mathcal{G}}n^{-1}\sum_{j=1}^{n}I(Y_j\neq g(X_j)),$$

where P_n denotes the empirical distribution based on the training data $(X_1,Y_1),\dots,(X_n,Y_n)$ (we will also use the notation Π_n for the empirical distribution based on $(X_1,\dots,X_n)$).

If $\mathcal{F}:=\ell\bullet\mathcal{G}:=\{\ell\bullet g:g\in\mathcal{G}\}$ denotes the loss class, then we are in the framework of abstract empirical risk minimization of sections 2,3 and general results of these sections can be now specialized for the classification context.

It is natural to characterize the quality of the classifier $\hat{g}$ in terms of its excess risk $\mathcal{E}_P(\ell\bullet\hat{g})$ and to study how it depends on the complexity of the class $\mathcal{G}$ as well as on the complexity of the classification problem itself. The simplest complexity assumption on the class $\mathcal{G}$ is that it is a VC-class of binary functions of VC-dimension V (in other words, $\mathcal{C}:=\Big\{\{x:g(x)=+1:g\in\mathcal{G}\}\Big\}$ is a VC-class of sets of VC-dimension V). Under this assumption, a well known result, essentially due to Vapnik and Chervonenkis, is that, for some constant $K>0$ and for all $t>0$, with probability at least $1-e^{-t}$

$$\mathcal{E}_P(\ell\bullet\hat{g})\leq K\left[\sqrt{\frac{V}{n}}+\sqrt{\frac{t}{n}}\right].$$

In principle, this bound is minimax optimal, but it can be significantly improved for special families of distributions P under further assumptions on the complexity of the classification problem. For instance, the following **Massart's low noise assumption** is frequently used: for some constant $h \in (0,1]$

$$|\eta(x)| \geq h,\ x \in S.$$

The parameter h is a characteristic of the level of noise in binary labels Y_j. In other words, it is a simple measure of complexity of a binary classification problem. The following theorem is a version of the result proved by Massart and Nedelec (2006):

Theorem 10 *There exists a constant $K > 0$ such that, for all $t > 0$, with probability at least $1 - e^{-t}$*

$$\mathcal{E}_P(\ell \bullet \hat{g}) \leq K\left[\frac{V}{nh}\log\Big(\frac{nh^2}{V}\Big) + \frac{t}{nh}\right] \bigwedge \left[\sqrt{\frac{V}{n}} + \sqrt{\frac{t}{n}}\right].$$

This upper bound on the excess risk is optimal in a minimax sense (as it was also shown by Massart and Nedelec, 2006). However, it still can be refined using the following function τ (which is a local version of Alexander's **capacity function** introduced in the 80s and used in the theory of ratio type empirical processes, see Giné and Koltchinskii, 2006, and references therein). Define

$$\mathcal{G}_\delta := \{g \in \mathcal{G} : \Pi\{x : g(x) \neq g_*(x)\} \leq \delta\}$$

and let

$$\tau(\delta) := \frac{\Pi\Big\{x | \exists g \in \mathcal{G}_\delta : g(x) \neq g_*(x)\Big\}}{\delta}.$$

Clearly, the set $\mathcal{G}_\delta$ consists of the classifiers from $\mathcal{G}$ that are in a neighborhood of size δ of the Bayes classifier g_* and the set

$$D_\delta := \Big\{x | \exists g \in \mathcal{G}_\delta : g(x) \neq g_*(x)\Big\}$$

consists of all the points x such that there exists a classifier g in the neighborhood $\mathcal{G}_\delta$ that "disagrees" with the Bayes classifier at x. The function $\tau(\delta)$ is always upper bounded by $\frac{1}{\delta}$. However, if it happens that the measure Π of the "disagreement set" D_δ is small when δ is small, then $\tau(\delta)$ might grow slower than $\frac{1}{\delta}$ as $\delta \to 0$, or even it can be bounded by a constant. If $\mathcal{C} := \{\{g = +1\} : g \in \mathcal{G}\}$ and $C_* := \{g_* = +1\}$, then

$$\tau(\delta) = \frac{\Pi\Big(\bigcup_{C \in \mathcal{C}, \Pi(C \triangle C_*) \leq \delta}(C \triangle C_*)\Big)}{\delta},$$

so, roughly, $\tau(\delta)$ shows how many disjoint sets $C \triangle C_*$ of "size" δ can be "packed" in the union of all such sets. For instance, if $\mathcal{C}$ is a class of convex sets in $[0,1]^d$, Π is the Lebesgue measure in $[0,1]^d$ and $C_* \in \mathcal{C}, \Pi(C_*) > 0$, then it can be shown that τ is uniformly bounded by a constant, see Giné and Koltchinskii (2006). A more detailed analysis of disagreement sets, capacity functions and their connections to the geometry of the class $\mathcal{G}$ can be found in the paper by Friedman (2009).

The following result was proved by Giné and Koltchinskii (2006).

Theorem 11 *There exists a constant $K > 0$ such that, for all $t > 0$, with probability at least $1 - e^{-t}$*

$$\mathcal{E}_P(\ell \bullet \hat{g}) \le K\left[\frac{V}{nh}\log\tau\Big(\frac{V}{nh^2}\Big) + \frac{t}{nh}\right] \bigwedge \left[\sqrt{\frac{V}{n}} + \sqrt{\frac{t}{n}}\right].$$

Clearly, this result implies the theorem of Massart and Nedelec (since $\tau(\delta) \le \frac{1}{\delta}$). The proof is based on applying subtle bounds for empirical processes (see Giné and Koltchinskii, 2006) to compute the excess risk bound $\bar{\delta}_n$ of Section 2. Then, the general result of Theorem 1 (see also Proposition 2) can be used to bound the excess risk.

The case when $\tau(\delta)$ is uniformly bounded from above by a constant τ_0 is of special interest. In this case, with probability at least $1 - e^{-t}$,

$$\mathcal{E}_P(\ell \bullet \hat{g}) \le K\left[\frac{V}{nh}\log\tau_0 + \frac{t}{nh}\right],$$

so the main term of the bound is of the order $O(\frac{V}{nh})$ and it does not contain logarithmic factors depending on n and h. It will be convenient for our purposes to phrase this result in a slightly different form. Namely, given $\delta \in (0,1)$ and $\alpha \in (0,1)$, denote

$$n(\delta,\alpha) := \inf\left\{n : \mathbb{P}\{\mathcal{E}_P(\hat{g}_n) \ge \delta\} \le \alpha\right\}.$$

Then

$$n(\delta,\alpha) \le K\left(\left[\frac{V}{\delta h}\log\tau_0 + \frac{\log(1/\alpha)}{\delta h}\right] \bigwedge \left[\frac{V}{\delta^2} + \frac{\log(1/\alpha)}{\delta^2}\right]\right).$$

The quantity $n(\delta,\alpha)$ shows how many training examples are needed to make the excess risk of the classifier $\hat{g}$ smaller than δ with a guaranteed probability of at least $1-\alpha$. It characterizes the sample complexity of passive learning. In the case of empirical risk minimization over a VC-class with a bounded capacity function τ, the sample complexity is of the order $O(\frac{V}{h}\frac{1}{\delta})$.

The role of the capacity function is rather modest in the case of passive learning since it only allows one to refine the excess risk and the sample complexity bounds by making the logarithmic factors more precise. However, the capacity function τ happened to be of crucial importance in the analysis of active learning methods of binary classification. This function was rediscovered in active learning literature and its supremum is being used there under the name of **disagreement coefficient**, see, for example, Hanneke (2009a,b) and references therein.

We will describe an active learning algorithm that is a specialized version of more abstract **Algorithm 3** of Section 3. As before, we denote $\delta_j := 2^{-j},\ j \ge 0$ and choose a set $M \subset \mathbb{N}$ of natural numbers as well as nonnegative real numbers $t_k^{(n)},\ n \in M, k \ge 0$.

Given a class $\mathcal{G}$ of binary classifiers, denote

$$\mathcal{G}_P(\delta) := \left\{g : \mathcal{E}_P(\ell \bullet g) \le \delta\right\},\ \delta > 0.$$

These sets will be called δ-minimal sets of the true risk. Clearly, if $\mathcal{F} = \ell \bullet \mathcal{G}$, then under the notations of Section 2

$$\mathcal{F}_P(\delta) = \left\{\ell \bullet g : g \in \mathcal{G}_P(\delta)\right\}.$$

In principle, one can directly use **Algorithm 3** for the class $\mathcal{F}$. However, we will modify it slightly in order to adapt it to the binary classification framework.

We will define iteratively data dependent function classes $\hat{\mathcal{G}}_k$ that provide estimates of the δ-minimal sets $\mathcal{G}_P(\delta)$. and also a nondecreasing data dependent sequence of estimated sample sizes $\hat{n}_k$. It will be assumed that we have an access to an algorithm that, given a discrete measure Q on $S\times\{-1,1\}$ and $\delta>0$, computes the δ-minimal set $\mathcal{G}_Q(\delta)$ of Q.

Several definitions and notations will be needed. Note that for the binary loss ℓ, for all binary classifiers g_1,g_2 and for all $\delta\in(0,1)$, the condition $|\ell(y,g_1(x))-\ell(y,g_2(x))|\geq\delta$ is equivalent to the condition $g_1(x)\neq g_2(x)$. This leads to the following definition of sets $\hat{A}_k$ (that are subsets of S, not of $S\times\{-1,1\}$). Assuming that $\hat{\mathcal{G}}_{k-1}$ has been already defined, let

$$\hat{A}_k:=\Big\{x:\exists g_1,g_2\in\hat{\mathcal{G}}_{k-1},g_1(x)\neq g_2(x)\Big\}$$

be the set of all the points where at least two classifiers in $\hat{\mathcal{G}}_{k-1}$ disagree with each other. This set will be used as a set of active design points at the k-th iteration.

Next define active empirical distributions based on the unlabeled examples $\{X_j\}$ and on the labeled examples $\{(X_j,Y_j)\}$:

$$\hat{\Pi}_n^{(k)}:=n^{-1}\sum_{j=1}^n I_{\hat{A}_k}(X_j)\delta_{X_j}$$

and

$$\hat{P}_n^{(k)}:=n^{-1}\sum_{j=1}^n I_{\hat{A}_k}(X_j)\delta_{(X_j,Y_j)}$$

For simplicity, we will also use the notation $\hat{P}_k:=\hat{P}_{\hat{n}_k}^{(k)}$. Let

$$\hat{D}_n^{(k)}:=\frac{1}{2}\sup_{g_1,g_2\in\hat{\mathcal{G}}_{k-1}}\Big(\hat{\Pi}_n^{(k)}(g_1-g_2)^2\Big)^{1/2}$$

be the $L_2(\hat{\Pi}_n^{(k)})$-diameter of the class $\hat{\mathcal{G}}_{k-1}$. Note that, if we literally followed the definitions of Section 3, we would have to define the diameter as

$$\sup_{g_1,g_2\in\hat{\mathcal{G}}_{k-1}}\Big(\hat{P}_n^{(k)}(\ell\bullet g_1-\ell\bullet g_2)^2\Big)^{1/2}.$$

However, it is easy to check that for all $(x,y)\in S\times\{-1,1\}$ and all binary classifiers g_1,g_2

$$(\ell\bullet g_1)(x,y)-(\ell\bullet g_2)(x,y)=\frac{1}{2}y(g_2(x)-g_1(x)),$$

which justifies the new definition. This simple identity also implies that the function $\phi_n(\delta)$, defined in Section 2 and used in the construction of the excess risk bounds, can be upper bounded as follows:

$$\phi_n(\delta)\leq 2\mathbb{E}\sup_{f_1,f_2\in\mathcal{F}(\delta)}|R_n(f_1-f_2)|=2\mathbb{E}\sup_{g_1,g_2\in\mathcal{G}(\delta)}|R_n(\ell\bullet g_1-\ell\bullet g_2)|=$$

$$\mathbb{E}\sup_{g_1,g_2\in\mathcal{G}(\delta)}\Big|n^{-1}\sum_{j=1}^n\varepsilon_jY_j(g_2(X_j)-g_1(X_j))\Big|,$$

where at the beginning we used the symmetrization inequality (see, e.g., van der Vaart and Wellner, 1996). Note that, conditionally on $(X_1,Y_1),\dots,(X_n,Y_n)$, the distribution of the random vector $(\varepsilon_1 Y_1,\dots,\varepsilon_n Y_n)$ is the same as the distribution of $(\varepsilon_1,\dots,\varepsilon_n)$. Because of this,

$$\phi_n(\delta) \le \mathbb{E} \sup_{g_1,g_2\in\mathcal{G}(\delta)} \left| n^{-1} \sum_{j=1}^n \varepsilon_j Y_j (g_2(X_j)-g_1(X_j)) \right| =$$

$$\mathbb{E}\mathbb{E}\left(\sup_{g_1,g_2\in\mathcal{G}(\delta)} \left| n^{-1} \sum_{j=1}^n \varepsilon_j Y_j (g_2(X_j)-g_1(X_j)) \right| \Big| (X_1,Y_1),\dots,(X_n,Y_n) \right) =$$

$$\mathbb{E}\mathbb{E}\left(\sup_{g_1,g_2\in\mathcal{G}(\delta)} \left| n^{-1} \sum_{j=1}^n \varepsilon_j (g_2(X_j)-g_1(X_j)) \right| \Big| (X_1,Y_1),\dots,(X_n,Y_n) \right) =$$

$$\mathbb{E} \sup_{g_1,g_2\in\mathcal{G}(\delta)} |R_n(g_1-g_2)|.$$

This simple observation allows one to replace the Rademacher complexities for the loss class $\mathcal{F} = \ell \bullet \mathcal{G}$ by the Rademacher complexities for the class $\mathcal{G}$ itself (and the proofs of the excess risk bounds and other results cited in Section 2 go through with no changes). Of course, the same applies to all the constructions and the results of Section 3.

Because of this, we now define the Rademacher complexity based only on the "active" examples as

$$\hat{R}_n^{(k)} := \sup_{g_1,g_2\in\hat{\mathcal{G}}_{k-1}} \left| n^{-1} \sum_{j=1}^n \varepsilon_j (g_1-g_2)(X_j) I_{\hat{A}_k}(X_j) \right|.$$

Finally, denote

$$\hat{U}_n^{(k)} := \hat{K}\left[\hat{R}_n^{(k)} + \hat{D}_n^{(k)} \sqrt{\frac{t_k^{(n)}}{n}} + \frac{t_k^{(n)}}{n} \right].$$

With these definitions and notations, we can now introduce the following modification of **Algorithm 3** of Section 3.

Algorithm 4
$\hat{\mathcal{G}}_0 := \mathcal{G}$;
for $k = 1,2,\dots,$
$\hat{A}_k := \left\{ x : \exists g_1,g_2 \in \hat{\mathcal{G}}_{k-1}, g_1(x) \ne g_2(x) \right\}$;
$\hat{n}_k := \min\left\{ n \in M, n \ge \hat{n}_{k-1} : \hat{U}_n^{(k)} \le \frac{1}{2}\delta_{k+1} \right\}$;
$\hat{\mathcal{G}}_k := \hat{\mathcal{G}}_{k-1} \bigcap \mathcal{G}_{\hat{P}_k}(3\delta_k)$;
end

Remark 12 *One can also use in* **Algorithm 4** *the Rademacher complexities defined as follows:*

$$\hat{R}_n^{(k)} := \sup_{g_1,g_2\in\hat{\mathcal{G}}_{k-1}} \left| n^{-1} \sum_{j=1}^n \varepsilon_j (g_1-g_2)(X_j) \right|.$$

In this case, not only the active design points, but all the design points X_j are used to compute the Rademacher complexities and to estimate the sample sizes $\hat{n}_k$. Note, however, that the labels Y_j are not involved in this computation, so, the algorithm still can be viewed as "active". The resulting algorithm is a modification of **Algorithm 3** *from Section 3.*

In the case when $\mathcal{G}$ is a VC-class of VC-dimension V, we will choose $M := \{2^k : k \geq 0\}$. We will also define

$$t_k^{(n)} := \log(1/\alpha) + 2\log(k+1) + 2\log(\log_2 n + 1) + \log(24). \tag{9}$$

This leads to the following result that is a corollary of Theorem 9.

Corollary 13 *Let $\delta \in (0,1)$. Suppose that Massart's low noise assumption holds with some $h \in (0,1)$. Suppose that*

$$\tau_0 := \sup_{u \in (0,1]} \tau(u) < +\infty.$$

Then there exists an event of probability at least $1-\alpha$ such that the following inclusions hold for the classes $\hat{\mathcal{G}}_k$ output by **Algorithm 4***: for all $k \geq 0$,*

$$\mathcal{G}_P(\delta_k) \subset \hat{\mathcal{G}}_k \subset \mathcal{G}_P(8\delta_k). \tag{10}$$

Also with probability at least $1-\alpha$, the following bound on the number $\nu(\delta)$ of active training examples used by **Algorithm 4** *in the first $L = \left\lfloor \log_2(1/\delta) \right\rfloor$ iterations holds with some numerical constant $C > 0$:*

$$\nu(\delta) \leq C \frac{\tau_0 \log(1/\delta)}{h^2} \left[V \log \tau_0 + \log(1/\alpha) + \log\log(1/\delta) + \log\log(1/h) \right].$$

In particular, it means that with probability at least $1-\alpha$

$$\mathcal{G}_P(\delta/2) \subset \hat{\mathcal{G}}_L \subset \mathcal{G}_P(16\delta).$$

Proof We only sketch the proof here, the missing details are not very complicated. The result follows from Theorem 9, more precisely, from its modified version that takes into account the slight changes we made in the definition of the Rademacher complexities. The inclusions (10) follow from this theorem in a straightforward way. To prove the bound on $\nu(\delta)$, one has first to bound the quantity $\bar{\delta}_n$. This computation was essentially done by Giné and Koltchinskii (2006) (it actually leads to the bound of Theorem 11). Namely, with some constant C_1,

$$\bar{\delta}_n \leq C_1 \left[\frac{V}{nh} \log \tau\Big(\frac{V}{nh^2}\Big) + \frac{\log(1/\alpha) + \log\log n}{nh} \right] \bigwedge \left[\sqrt{\frac{V}{n}} + \sqrt{\frac{\log(1/\alpha) + \log\log n}{n}} \right].$$

As a result, the following upper bound on $\tilde{n}(\sigma), \sigma \geq \delta$ holds with some constant K_1 :

$$\tilde{n}(\sigma) \leq K_1 \Bigg(\left[\frac{V}{\sigma h} \log \tau_0 + \frac{\log(1/\alpha) + \log\log_2(1/\delta) + \log\log(1/h)}{\sigma h} \right] \bigwedge$$

$$\left[\frac{V}{\sigma^2} + \frac{\log(1/\alpha) + \log\log_2(1/\delta)}{\sigma^2} \right] \Bigg).$$

Note that, under Massart's low noise assumption, formula (8) for the excess risk implies that for all binary classifiers g

$$\mathcal{E}(\ell \bullet g) \geq h \Pi\{x : g(x) \neq g_*(x)\}.$$

Hence

$$\mathcal{F}(\sigma) \subset \Big\{\ell \bullet g : g \in \mathcal{G}_{\sigma/h}\Big\}.$$

For the sets $A(\sigma)$ used in Theorems 9, this implies the following:

$$A(\sigma) = \Big\{(x,y) : \sup_{f_1,f_2\in\mathcal{F}(8\sigma)} |f_1(x,y) - f_2(x,y)| > c\sigma\Big\} \subset$$

$$\Big\{(x,y) : \sup_{g_1,g_2\in\mathcal{G}(8\sigma/h)} |(\ell \bullet g_1)(x,y) - (\ell \bullet g_2)(x,y)| > c\sigma\Big\} =$$

$$\Big\{x : \exists g_1, g_2 \in \mathcal{G}(8\sigma/h) : g_1(x) \neq g_2(x)\Big\} \times \{-1,1\} = \Big\{x : \exists g \in \mathcal{G}(8\sigma/h) : g(x) \neq g_*(x)\Big\} \times \{-1,1\}$$

(we used the assumption that $g_* \in \mathcal{G}$ and, hence, $g_* \in \mathcal{G}(8\sigma/h)$). This implies, by the definitions of the functions π and τ, that

$$\pi(\sigma) = P(A(\sigma)) \leq \Pi\Big(\Big\{x : \exists g \in \mathcal{G}(8\sigma/h) : g(x) \neq g_*(x)\Big\}\Big) \leq \frac{8\sigma}{h}\tau(8\sigma/h).$$

Using the definition of τ_0, we conclude that for all $\sigma \geq \delta$ $\pi(\sigma) \leq \frac{8\tau_0}{h}\sigma$. It remains to substitute the bounds on $\tilde{n}(\sigma)$ and $\pi(\sigma)$ into the bound on $\nu(\delta)$ of Theorem 9

$$\nu(\delta) \leq et \sum_{\delta_j \geq \delta} \tilde{n}(\delta_{j+1})\pi(\delta_{j-1}),$$

say, with $t = e$. This gives

$$\nu(\delta) \leq e^2 \sum_{\delta_j \geq \delta} K_1\left(\left[\frac{V}{\delta_{j+1}h}\log\tau_0 + \frac{\log(1/\alpha) + \log\log_2(1/\delta) + \log\log(1/h)}{\delta_{j+1}h}\right]\frac{8\tau_0}{h}\delta_{j-1},\right.$$

which is bounded from above by

$$C\frac{\tau_0\log(1/\delta)}{h^2}\Big[V\log\tau_0 + \log(1/\alpha) + \log\log(1/\delta) + \log\log(1/h)\Big].$$

with a properly chosen numerical constant C. Also, it easily follows from the probability estimates of Theorem 9 that the above bound on $\nu(\delta)$ holds with probability at least $1-\alpha$. ■

Finally, we discuss the properties of **Algorithm 4** under **Tsybakov's low noise assumption**. Namely, we assume that for some $\gamma > 0$, for some constant B and for all $t > 0$

$$\Pi\{x : |\eta(x)| \leq t\} \leq Bt^{\gamma}.$$

It is well known that under this assumption the following bound on the excess risk holds for an arbitrary classifier g :

$$\mathcal{E}_P(\ell \bullet g) \geq c\Pi^{\kappa}(\{g \neq g_*\}),$$

where $\kappa = \frac{1+\gamma}{\gamma}$ and c is a constant that depends on B, κ. We will assume in this case that $\mathcal{G}$ is not necessarily a VC-class, but it can be more massive. For instance, denote $N(\mathcal{G}; L_2(\Pi_n); \varepsilon)$ the

minimal number of $L_2(\Pi_n)$-balls of radius ε needed to cover $\mathcal{G}$ and suppose that these covering numbers satisfy the condition:

$$\log N(\mathcal{G}; L_2(\Pi_n); \varepsilon) \le \left(\frac{A}{\varepsilon}\right)^{2\rho}, \ \varepsilon > 0.$$

for some $\rho \in (0,1]$ and some constant $A > 0$. Then, the following upper bound on the excess risk of an empirical risk minimizer $\hat{g}$ holds with probability at least $1 - e^{-t}$:

$$\mathcal{E}_P(\ell \bullet \hat{g}) \le K\left(\left(\frac{1}{n}\right)^{-\kappa/(2\kappa+\rho-1)} + \left(\frac{t}{n}\right)^{\kappa/(2\kappa-1)}\right),$$

where K is a constant depending on κ, ρ, A, B. The bounds of this type were first proved by Tsybakov (2004) (see also Koltchinskii, 2006, 2008). It easily follows from this bound that in order to achieve the excess risk of order δ one needs $O\left(\delta^{-2+(1-\rho)/\kappa}\right)$ training examples.

We will now consider **Algorithm 4** with $M := \{2^k : k \ge 0\}$, and with the real numbers $t_k^{(n)}$ defined by (9).

This leads to the following result that is also a corollary of Theorem 9.

Corollary 14 *Let $\delta \in (0,1)$. Suppose that Tsybakov's low noise assumption holds with some $\gamma > 0$ and $B > 0$. Let $\kappa := \frac{1+\gamma}{\gamma}$. Suppose that*

$$\tau_0 := \sup_{u \in (0,1]} \tau(u) < +\infty.$$

Then there exists an event of probability at least $1 - \alpha$ such that the following inclusions hold for the classes $\hat{\mathcal{G}}_k$ output by **Algorithm 4***: for all k with $\delta_k \ge \delta$,*

$$\mathcal{G}_P(\delta_k) \subset \hat{\mathcal{G}}_k \subset \mathcal{G}_P(8\delta_k).$$

Also with probability at least $1 - \alpha$, the following bound on the number $\nu(\delta)$ of active training examples used by **Algorithm 4** *holds with some constant $C > 0$ depending on κ, ρ, A, B :*

$$\nu(\delta) \le C\tau_0\left[\delta^{-2+(2-\rho)/\kappa} + \delta^{-2+2/\kappa}(\log(1/\alpha) + \log\log(1/\delta))\right].$$

The proof is similar to that of Corollary 13. In this case, the improvement comparing with passive learning is by a factor $\delta^{1/\kappa}$.

Remark 15 *Alternatively, one can assume that the active learning algorithm stops as soon as the specified number of active examples, say, n has been achieved. If $\hat{L}$ denotes the number of iterations needed to achieve this target, then $8\delta_{\hat{L}}$ is an upper bound on the excess risk of the classifiers from the set $\hat{\mathcal{G}}_{\hat{L}}$. Under the assumptions of Corollary 13, inverting the bound on $\nu(\delta)$ easily gives that $\delta_{\hat{L}}$ is upper bounded by*

$$\exp\left\{-\beta\frac{nh^2}{C_2\tau_0}\right\},$$

where

$$\beta := \frac{1}{V\log\tau_0 \vee \log(1/\alpha) \vee \log(nh^2/C_2\tau_0) \vee \log\log(1/h)}$$

with some numerical constant C_2. Thus, the excess risk of such classifiers tends to zero exponentially fast as $n \to \infty$. This is the form in which the excess risk bounds in active learning are usually stated in the literature (see, e.g., Hanneke, 2009a,b). In fact, this is a refinement of the bounds of Hanneke that were proved for somewhat different active learning algorithms (see Hanneke, 2009b, Theorems 4, 5). Similarly, under the conditions of Corollary 14, the bound on $\delta_{\hat{L}}$ becomes

$$\left(\frac{\tau_0}{n}\right)^{\kappa/(2\kappa+\rho-2)} \bigvee \left(\frac{\tau_0(\log(1/\alpha)+\log\log n)}{n}\right)^{\kappa/(2\kappa-2)}.$$

(compare with Theorem 6 by Hanneke, 2009b).

Remark 16 *Although we concentrated in this section only on binary classification problems, the active learning algorithms described in Section 3 can be also used in the context of multiclass classification and some other problems (e.g., estimation of non-smooth regression function and estimation of level sets of a probability density). Recall that in the framework of prediction with a general loss function ℓ described in the Introduction,*

$$\mathcal{F} := \ell \bullet \mathcal{G} := \Big\{\ell \bullet g : g \in \mathcal{G}\Big\}.$$

Following an idea of Beygelzimer et al. (2009), one can now replace the disagreement set $\hat{A}_k$ for the class $\hat{\mathcal{F}}_{k-1} = \ell \bullet \hat{\mathcal{G}}_{k-1}$ involved in **Algorithm 3** *by a larger set*

$$\hat{A}_k^+ := \left\{(x,y) : \exists g_1, g_2 \in \hat{\mathcal{G}}_{k-1} \ \sup_{y' \in T} |\ell(y', g_1(x)) - \ell(y', g_2(x))| > c\delta_k\right\} =$$

$$\left\{x : \exists g_1, g_2 \in \hat{\mathcal{G}}_{k-1} \ \sup_{y \in T} |\ell(y, g_1(x)) - \ell(y, g_2(x))| > c\delta_k\right\} \times T.$$

This leads to the following modification of **Algorithm 3***:*

Algorithm 5
$\hat{\mathcal{G}}_0 := \mathcal{G}$;
for $k = 1, 2, \ldots,$
$\hat{A}_k^+ := \left\{x : \exists g_1, g_2 \in \hat{\mathcal{G}}_{k-1} \ \sup_{y \in T} |\ell(y, g_1(x)) - \ell(y, g_2(x))| > c\delta_k\right\} \times T.$
$\hat{n}_k := \min\Big\{n \in M, n \geq \hat{n}_{k-1} : \hat{U}_n^{(k)} \leq \frac{1}{2}\delta_{k+1}\Big\}$;
$\hat{\mathcal{G}}_k := \hat{\mathcal{G}}_{k-1} \bigcap \mathcal{G}_{\hat{P}_k}(3\delta_k)$;
end

The Rademacher complexities of classes $\hat{\mathcal{F}}_k = \ell \bullet \hat{\mathcal{G}}_k$ (the quantities $\hat{U}_n^{(k)}$) as well as active empirical measures $\hat{P}_k$ involved in this algorithm are now based on active sets $\hat{A}_k^+$. Clearly, only the labels of active examples are used in this version of the algorithm. If now we define

$$\pi(\delta) := \Pi\Big(\Big\{x : \exists g_1, g_2 \in \mathcal{G}_P(8\delta) \ \sup_{y \in T} |\ell(y, g_1(x)) - \ell(y, g_2(x))| > c\delta\Big\}\Big),$$

it is very easy to check that the statement of Theorem 9 still holds for such a modification of the algorithm. At the same time, it is not clear at this point whether a modified definition of disagreement coefficient in the paper by Beygelzimer et al. (2009) can be used to analyze the properties of

active learning algorithms of this type and whether it is possible to extend such an analysis beyond classification and similar problems.

Abstract

Different aspects of the curse of dimensionality are known to present serious challenges to various machine-learning methods and tasks. This paper explores a new aspect of the dimensionality curse, referred to as *hubness*, that affects the distribution of k-occurrences: the number of times a point appears among the k nearest neighbors of other points in a data set. Through theoretical and empirical analysis involving synthetic and real data sets we show that under commonly used assumptions this distribution becomes considerably skewed as dimensionality increases, causing the emergence of *hubs*, that is, points with very high k-occurrences which effectively represent "popular" nearest neighbors. We examine the origins of this phenomenon, showing that it is an inherent property of data distributions in high-dimensional vector space, discuss its interaction with dimensionality reduction, and explore its influence on a wide range of machine-learning tasks directly or indirectly based on measuring distances, belonging to supervised, semi-supervised, and unsupervised learning families.

Keywords: nearest neighbors, curse of dimensionality, classification, semi-supervised learning, clustering

1. Introduction

The curse of dimensionality, a term originally introduced by Bellman (1961), is nowadays commonly used in many fields to refer to challenges posed by high dimensionality of data space. In the field of machine learning, affected methods and tasks include Bayesian modeling (Bishop, 2006), nearest-neighbor prediction (Hastie et al., 2009) and search (Korn et al., 2001), neural networks (Bishop, 1996), and many others. One aspect of the dimensionality curse is *distance concentration*, which denotes the tendency of distances between all pairs of points in high-dimensional data to become almost equal. Distance concentration and the meaningfulness of nearest neighbors in high

*. A preliminary version of this paper appeared in the Proceedings of the 26th International Conference on Machine Learning (Radovanović et al., 2009).

dimensions has been thoroughly explored (Beyer et al., 1999; Hinneburg et al., 2000; Aggarwal et al., 2001; François et al., 2007). The effect of the phenomenon on machine learning was demonstrated, for example, in studies of the behavior of kernels in the context of support vector machines, lazy learning, and radial basis function networks (Evangelista et al., 2006; François, 2007).

There exists another aspect of the curse of dimensionality that is related to nearest neighbors (NNs), which we will refer to as *hubness*. Let $D \subset \mathbb{R}^d$ be a set of d-dimensional points and $N_k(\mathbf{x})$ the number of *k-occurrences* of each point $\mathbf{x} \in D$, that is, the number of times $\mathbf{x}$ occurs among the k nearest neighbors of all other points in D, according to some distance measure. Under widely applicable conditions, as dimensionality increases, the distribution of N_k becomes considerably skewed to the right, resulting in the emergence of *hubs*, that is, points which appear in many more k-NN lists than other points, effectively making them "popular" nearest neighbors. Unlike distance concentration, hubness and its influence on machine learning have not been explored in depth. In this paper we study the causes and implications of this aspect of the dimensionality curse.

As will be described in Section 4, the phenomena of distance concentration and hubness are related, but distinct. Traditionally, distance concentration is studied through asymptotic behavior of norms, that is, distances to the origin, with increasing dimensionality. The obtained results trivially extend to reference points other than the origin, and to pairwise distances between all points. However, the asymptotic tendencies of distances of all points to different reference points do not necessarily occur at the same *speed*, which will be shown for normally distributed data by our main theoretical result outlined in Section 4.2, and given with full details in Section 5.1. The main consequence of the analysis, which is further discussed in Section 5.2 and supported by theoretical results by Newman et al. (1983) and Newman and Rinott (1985), is that the hubness phenomenon is an inherent property of data distributions in high-dimensional space under widely used assumptions, and not an artefact of a finite sample or specific properties of a particular data set.

The above result is relevant to machine learning because many families of ML algorithms, regardless of whether they are supervised, semi-supervised, or unsupervised, directly or indirectly make use of distances between data points (and, with them, k-NN graphs) in the process of building a model. Moreover, the hubness phenomenon recently started to be observed in application fields like music retrieval (Aucouturier and Pachet, 2007), speech recognition (Doddington et al., 1998), and fingerprint identification (Hicklin et al., 2005), where it is described as a problematic situation, but little or no insight is offered into the origins of the phenomenon. In this paper we present a unifying view of the hubness phenomenon through theoretical analysis of data distributions, and empirical investigation including numerous synthetic and real data sets, explaining the origins of the phenomenon and the mechanism through which hubs emerge, discussing the role of *antihubs* (points which appear in very few, if any, k-NN lists of other points), and studying the effects on common supervised, semi-supervised, and unsupervised machine-learning algorithms.

After discussing related work in the next section, we make the following contributions. First, we demonstrate the emergence of hubness on synthetic and real data in Section 3. The following section provides a comprehensive explanation of the origins of the phenomenon, through empirical and theoretical analysis of artificial data distributions, as well as observations on a large collection of real data sets, linking hubness with the *intrinsic* dimensionality of data. Section 5 presents the details of our main theoretical result which describes the mechanism through which hubs emerge as dimensionality increases, and provides discussion and further illustration of the behavior of nearest-neighbor relations in high dimensions, connecting our findings with existing theoretical results. The role of dimensionality reduction is discussed in Section 6, adding further support to the previ-

ously established link between intrinsic dimensionality and hubness, and demonstrating that dimensionality reduction may not constitute an easy mitigation of the phenomenon. Section 7 explores the impact of hubness on common supervised, semi-supervised, and unsupervised machine-learning algorithms, showing that the information provided by hubness can be used to significantly affect the success of the generated models. Finally, Section 8 concludes the paper, and provides guidelines for future work.

2. Related Work

The hubness phenomenon has been recently observed in several application areas involving sound and image data (Aucouturier and Pachet, 2007; Doddington et al., 1998; Hicklin et al., 2005). Also, Jebara et al. (2009) briefly mention hubness in the context of graph construction for semi-supervised learning. In addition, there have been attempts to avoid the influence of hubs in 1-NN time-series classification, apparently without clear awareness about the existence of the phenomenon (Islam et al., 2008), and to account for possible skewness of the distribution of N_1 in reverse nearest-neighbor search (Singh et al., 2003),[1] where $N_k(\mathbf{x})$ denotes the number of times point $\mathbf{x}$ occurs among the k nearest neighbors of all other points in the data set. None of the mentioned papers, however, successfully analyze the causes of hubness or generalize it to other applications. One recent work that makes the connection between hubness and dimensionality is the thesis by Berenzweig (2007), who observed the hubness phenomenon in the application area of music retrieval and identified high dimensionality as a cause, but did not provide practical or theoretical support that would explain the mechanism through which high dimensionality causes hubness in music data.

The distribution of N_1 has been explicitly studied in the applied probability community (Newman et al., 1983; Maloney, 1983; Newman and Rinott, 1985; Yao and Simons, 1996), and by mathematical psychologists (Tversky et al., 1983; Tversky and Hutchinson, 1986). In the vast majority of studied settings (for example, Poisson process, d-dimensional torus), coupled with Euclidean distance, it was shown that the distribution of N_1 converges to the Poisson distribution with mean 1, as the number of points n and dimensionality d go to infinity. Moreover, from the results by Yao and Simons (1996) it immediately follows that, in the Poisson process case, the distribution of N_k converges to the Poisson distribution with mean k, for any $k \geq 1$. All these results imply that no hubness is to be expected within the settings in question. On the other hand, in the case of continuous distributions with i.i.d. components, for the following specific order of limits it was shown that $\lim_{n\to\infty} \lim_{d\to\infty} \mathrm{Var}(N_1) = \infty$, while $\lim_{n\to\infty} \lim_{d\to\infty} N_1 = 0$, in distribution (Newman et al., 1983, p. 730, Theorem 7), with a more general result provided by Newman and Rinott (1985). According to the interpretation by Tversky et al. (1983), this suggests that if the number of dimensions is large relative to the number of points one may expect a small proportion of points to become hubs. However, the importance of this finding was downplayed to a certain extent (Tversky et al., 1983; Newman and Rinott, 1985), citing empirically observed slow convergence (Maloney, 1983), with the attention of the authors shifting more towards similarity measurements obtained directly from psychological and cognitive experiments (Tversky et al., 1983; Tversky and Hutchinson, 1986) that do not involve vector-space data. In Section 5.2 we will discuss the above results in more detail, as well as their relations with our theoretical and empirical findings.

It is worth noting that in ε-neighborhood graphs, that is, graphs where two points are connected if the *distance* between them is less than a given limit ε, the hubness phenomenon does not occur.

1. Reverse nearest-neighbor queries retrieve data points that have the query point $\mathbf{q}$ as their nearest neighbor.

Settings involving randomly generated points forming ε-neighborhood graphs are typically referred to as random geometric graphs, and are discussed in detail by Penrose (2003).

Concentration of distances, a phenomenon related to hubness, was studied for general distance measures (Beyer et al., 1999; Durrant and Kabán, 2009) and specifically for Minkowski and fractional distances (Demartines, 1994; Hinneburg et al., 2000; Aggarwal et al., 2001; François et al., 2007; François, 2007; Hsu and Chen, 2009). Concentration of cosine similarity was explored by Nanopoulos et al. (2009).

In our recent work (Radovanović et al., 2009), we performed an empirical analysis of hubness, its causes, and effects on techniques for classification, clustering, and information retrieval. In this paper we extend our findings with additional theoretical and empirical insight, offering a unified view of the origins and mechanics of the phenomenon, and its significance to various machine-learning applications.

3. The Hubness Phenomenon

In Section 1 we gave a simple set-based deterministic definition of N_k. To complement this definition and introduce N_k into a probabilistic setting that will also be considered in this paper, let $\mathbf{x}, \mathbf{x}_1, \ldots, \mathbf{x}_n$, be $n+1$ random vectors drawn from the same continuous probability distribution with support $\mathcal{S} \subseteq \mathbb{R}^d$, $d \in \{1,2,\ldots\}$, and let *dist* be a distance function defined on $\mathbb{R}^d$ (not necessarily a metric). Let functions $p_{i,k}$, where $i,k \in \{1,2,\ldots,n\}$, be defined as

$$p_{i,k}(\mathbf{x}) = \begin{cases} 1, & \text{if } \mathbf{x} \text{ is among the } k \text{ nearest neighbors of } \mathbf{x}_i, \text{ according to } dist, \\ 0, & \text{otherwise.} \end{cases}$$

In this setting, we define $N_k(\mathbf{x}) = \sum_{i=1}^{n} p_{i,k}(\mathbf{x})$, that is, $N_k(\mathbf{x})$ is the random number of vectors from $\mathbb{R}^d$ that have $\mathbf{x}$ included in their list of k nearest neighbors. In this section we will empirically demonstrate the emergence of hubness through increasing skewness of the distribution of N_k on synthetic (Section 3.1) and real data (Section 3.2), relating the increase of skewness with the dimensionality of data sets, and motivating the subsequent study into the origins of the phenomenon in Section 4.

3.1 A Motivating Example

We start with an illustrative experiment which demonstrates the changes in the distribution of N_k with varying dimensionality. Let us consider a random data set consisting of 10000 d-dimensional points, whose components are independently drawn from the uniform distribution in range $[0,1]$, and the following distance functions: Euclidean (l_2), fractional $l_{0.5}$ (proposed for high-dimensional data by Aggarwal et al., 2001), and cosine. Figure 1(a–c) shows the empirically observed distributions of N_k, with $k = 5$, for (a) $d = 3$, (b) $d = 20$, and (c) $d = 100$. In the same way, Figure 1(d–f) depicts the empirically observed N_k for points randomly drawn from the i.i.d. normal distribution.

For $d = 3$ the empirical distributions of N_5 for the three distance functions (Figure 1(a,d)) are consistent with the binomial distribution. This is expected by considering k-occurrences as node in-degrees in the k-nearest neighbor digraph. For randomly distributed points in low dimensions, the degree distributions of the digraphs closely resemble the degree distribution of the Erdős-Rényi (ER) random graph model, which is is binomial and Poisson in the limit (Erdős and Rényi, 1959).

As dimensionality increases, the observed distributions of N_5 depart from the random graph model and become more skewed to the right (Figure 1(b,c), and Figure 1(e,f) for l_2 and $l_{0.5}$).

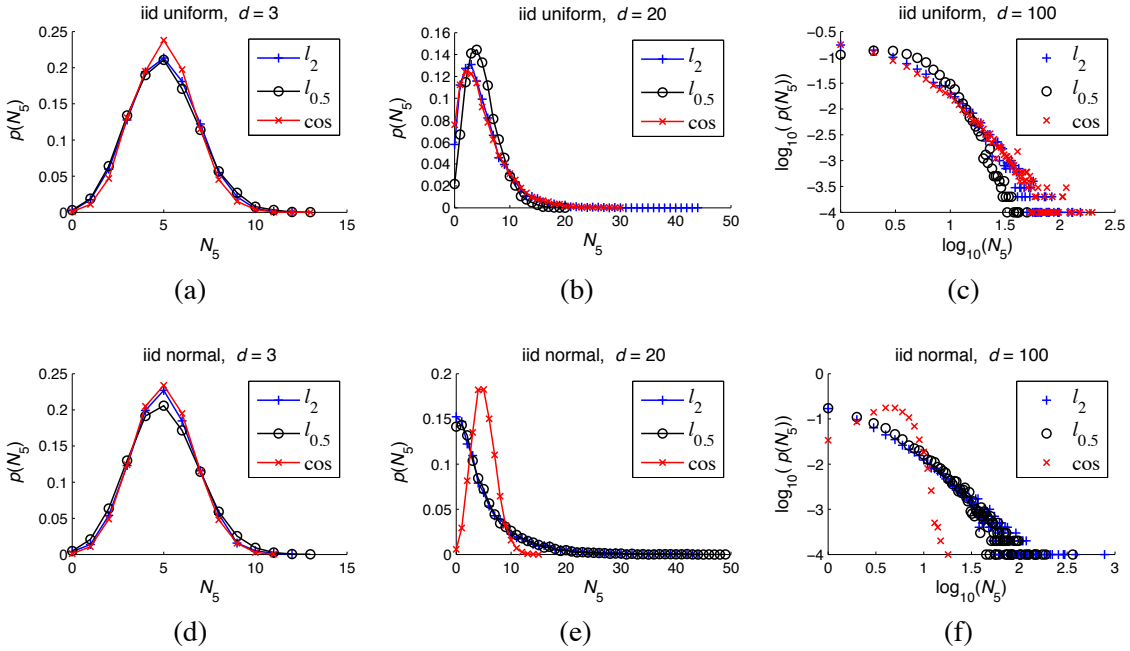

Figure 1: Empirical distribution of N_5 for Euclidean, $l_{0.5}$, and cosine distances on (a–c) i.i.d. uniform, and (d–f) i.i.d. normal random data sets with $n = 10000$ points and dimensionality (a,d) $d = 3$, (b,e) $d = 20$, and (c,f) $d = 100$ (log-log plot).

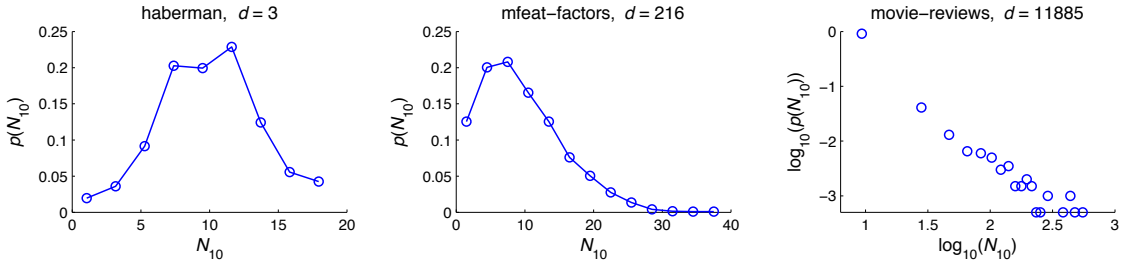
We verified this by being able to fit major right portions (that is, tails) of the observed distributions with the log-normal distribution, which is highly skewed.[2] We made similar observations with various k values (generally focusing on the common case $k \ll n$, where n is the number of points in a data set), distance measures (l_p-norm distances for both $p \geq 1$ and $0 < p < 1$, Bray-Curtis, normalized Euclidean, and Canberra), and data distributions. In virtually all these cases, skewness exists and produces hubs, that is, points with high k-occurrences. One exception visible in Figure 1 is the combination of cosine distance and normally distributed data. In most practical settings, however, such situations are not expected, and a thorough discussion of the necessary conditions for hubness to occur in high dimensions will be given in Section 5.2.

3.2 Hubness in Real Data

To illustrate the hubness phenomenon on real data, let us consider the empirical distribution of N_k ($k = 10$) for three real data sets, given in Figure 2. As in the previous section, a considerable increase in the skewness of the distributions can be observed with increasing dimensionality.

In all, we examined 50 real data sets from well known sources, belonging to three categories: UCI multidimensional data, gene expression microarray data, and textual data in the bag-of-words

2. Fits were supported by the χ^2 goodness-of-fit test at 0.05 significance level, where bins represent the number of observations of individual N_k values. These empirical distributions were compared with the expected output of a (discretized) log-normal distribution, making sure that counts in the bins do not fall below 5 by pooling the rightmost bins together.



(a) (b) (c)

Figure 2: Empirical distribution of N_{10} for three real data sets of different dimensionalities.

representation,[3] listed in Table 1. The table includes columns that describe data-set sources (2nd column), basic statistics (data transformation (3rd column): whether standardization was applied, or for textual data the used bag-of-words document representation; the number of points (n, 4th column); dimensionality (d, 5th column); the number of classes (7th column)), and the distance measure used (Euclidean or cosine, 8th column). We took care to ensure that the choice of distance measure and preprocessing (transformation) corresponds to a realistic scenario for the particular data set.

To characterize the asymmetry of N_k we use the standardized third moment of the distribution of k-occurrences,

$$S_{N_k} = \frac{\mathrm{E}(N_k - \mu_{N_k})^3}{\sigma_{N_k}^3},$$

where μ_{N_k} and σ_{N_k} are the mean and standard deviation of N_k, respectively. The corresponding (9th) column of Table 1, which shows the empirical $S_{N_{10}}$ values for the real data sets, indicates that the distributions of N_{10} for most examined data sets are skewed to the right.[4] The value of k is fixed at 10, but analogous observations can be made with other values of k.

It can be observed that some S_{N_k} values in Table 1 are quite high, indicating strong hubness in the corresponding data sets.[5] Moreover, computing the Spearman correlation between d and S_{N_k} over all 50 data sets reveals it to be strong (0.62), signifying that the relationship between dimensionality and hubness extends from synthetic to real data in general. On the other hand, careful scrutiny of the charts in Figure 2 and S_{N_k} values in Table 1 reveals that for real data the impact of dimensionality on hubness may not be as strong as could be expected after viewing hubness on synthetic data in Figure 1. Explanations for this observation will be given in the next section.

3. We used the movie review polarity data set v2.0 initially introduced by Pang and Lee (2004), while the computers and sports data sets were first used by Radovanović and Ivanović (2006). Preprocessing of all text data sets (except dexter, which is already preprocessed) involved stop-word removal and stemming using the Porter stemmer. Documents were transformed into the bag-of-words representation with word weights being either term frequencies (tf), or term frequencies multiplied by inverse document frequencies (tf-idf), with the choice based on independent experiments involving several classifiers. All term frequency vectors were normalized to average document length.
4. If $S_{N_k} = 0$ there is no skewness, positive (negative) values signify skewness to the right (left).
5. For comparison, sample skewness values for i.i.d. uniform data and Euclidean distance, shown in Figure 1(a–c), are 0.121, 1.541, and 5.445 for dimensionalities 3, 20, and 100, respectively. The values for i.i.d. normal data from Figure 1(d–f) are 0.118, 2.055, and 19.210.

4. The Origins of Hubness

This section moves on to exploring the causes of hubness and the mechanisms through which hubs emerge. Section 4.1 investigates the relationship between the position of a point in data space and hubness. Next, Section 4.2 explains the mechanism through which hubs emerge as points in high-dimensional space that become closer to other points than their low-dimensional counterparts, outlining our main theoretical result. The emergence of hubness in real data is studied in Section 4.3, while Section 4.4 discusses hubs and their opposites—antihubs—and the relationships between hubs, antihubs, and different notions of outliers.

4.1 The Position of Hubs

Let us consider again the i.i.d. uniform and i.i.d. normal random data examined in the previous section. We will demonstrate that the position of a point in data space has a significant effect on its k-occurrences value, by observing the sample mean of the data distribution as a point of reference. Figure 3 plots, for each point $\mathbf{x}$, its $N_5(\mathbf{x})$ against its Euclidean distance from the empirical data mean, for $d = 3,\ 20,\ 100$. As dimensionality increases, stronger correlation emerges, implying that points closer to the mean tend to become hubs. We made analogous observations with other values of k, and combinations of data distributions and distance measures for which hubness occurs. It is important to note that proximity to one global data-set mean correlates with hubness in high dimensions when the underlying data distribution is *unimodal*. For multimodal data distributions, for example those obtained through a mixture of unimodal distributions, hubs tend to appear close to the means of individual component distributions of the mixture. In the discussion that follows in Section 4.2 we will assume a unimodal data distribution, and defer the analysis of multimodal distributions until Section 4.3, which studies real data.

4.2 Mechanisms Behind Hubness

Although one may expect that some random points are closer to the data-set mean than others, in order to explain the mechanism behind hub formation we need to (1) understand the geometrical and distributional setting in which some points tend to be closer to the mean than others, and then (2) understand why such points become hubs in higher dimensions.[6]

Hubness appears to be related to the phenomenon of distance concentration, which is usually expressed as the ratio between some measure of spread (for example, standard deviation) and some measure of magnitude (for example, the mean) of distances of all points in a data set to some arbitrary reference point (Aggarwal et al., 2001; François et al., 2007). If this ratio converges to 0 as dimensionality goes to infinity, it is said that the distances concentrate. Based on existing theoretical results discussing distance concentration (Beyer et al., 1999; Aggarwal et al., 2001), high-dimensional points are approximately lying on a hypersphere centered at the data-set mean. Moreover, the results by Demartines (1994) and François et al. (2007) specify that the distribution of distances to the data-set mean has a non-negligible variance for any finite d.[7] Hence, the existence of a non-negligible number of points closer to the data-set mean is *expected* in high dimensions.

6. We will assume that random points originate from a unimodal data distribution. In the multimodal case, it can be said that the observations which follow are applicable around one of the "peaks" in the pdf of the data distribution.

7. These results apply to l_p-norm distances, but our numerical simulations suggest that other distance functions mentioned in Section 3.1 behave similarly. Moreover, any point can be used as a reference instead of the data mean, but we observe the data mean since it plays a special role with respect to hubness.

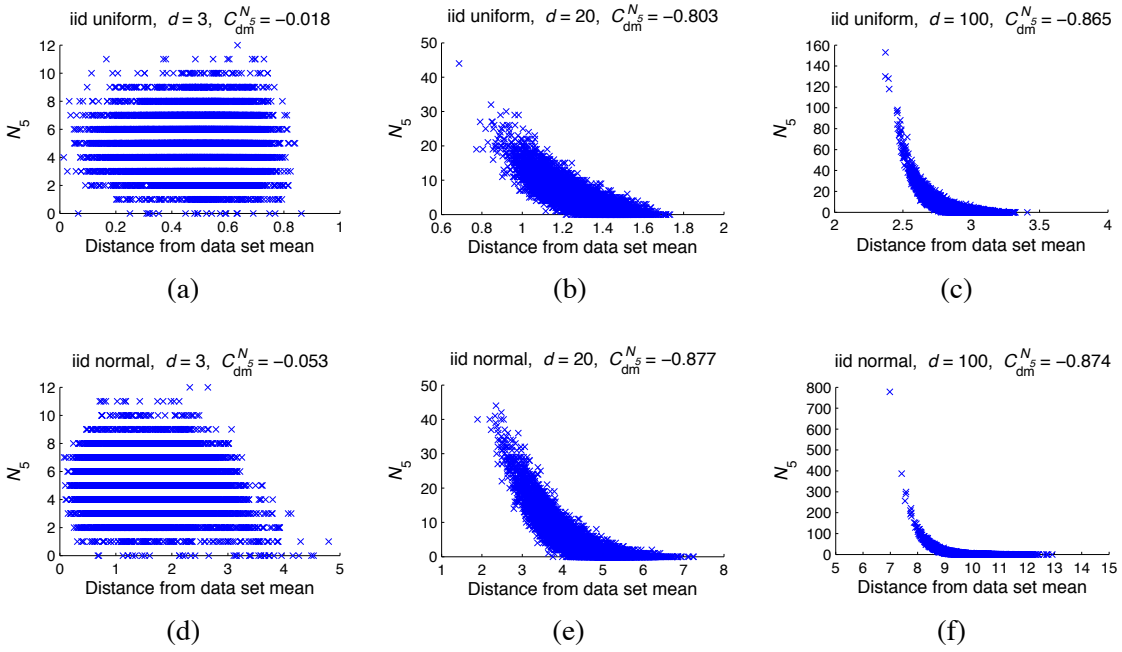

Figure 3: Scatter plots and Spearman correlation of $N_5(\mathbf{x})$ against the Euclidean distance of point $\mathbf{x}$ to the sample data-set mean for (a–c) i.i.d. uniform and (d–f) i.i.d. normal random data sets with (a, d) $d = 3$, (b, e) $d = 20$, and (c, f) $d = 100$.

To illustrate the above discussion, Figure 4 depicts, for i.i.d. normal data, the distribution of Euclidean distances of all points to the true data mean (the origin) for several d values. By definition, the distribution of distances is actually the Chi distribution with d degrees of freedom (as the square root of the sum of squares of i.i.d. normal variables, Johnson et al., 1994).[8] In this setting, distance concentration refers to the fact that the standard deviation of distance distributions is asymptotically constant with respect to increasing d, while the means of the distance distributions asymptotically behave like $\sqrt{d}$ (a direct consequence of the results by François et al., 2007, discussed further in Section 5.1). On the other hand, for l_p-norm distances with $p > 2$, the standard deviation would tend to 0 (François et al., 2007). However, for any finite d, existing variation in the values of random coordinates causes some points to become closer to the distribution mean than others. This happens despite the fact that all distance values, in general, may be increasing together with d.

To understand why points closer to the data mean become hubs in high dimensions, let us consider the following example. We observe, within the i.i.d. normal setting, two points drawn from the data, but at specific positions with respect to the origin: point $\mathbf{b}_d$ which is at the expected distance from the origin, and point $\mathbf{a}_d$ which is two standard deviations closer. In light of the above, the distances of $\mathbf{a}_d$ and $\mathbf{b}_d$ from the origin change with increasing d, and it could be said that different $\mathbf{a}_d$-s (and $\mathbf{b}_d$-s) occupy analogous positions in the data spaces, with respect to changing d. The distances of $\mathbf{a}_d$ (and $\mathbf{b}_d$) to all other points, again following directly from the definition (Oberto and Pennecchi, 2006), are distributed according to *noncentral* Chi distributions with d degrees of

8. For this reason, in Figure 4 we plot the known pdf, not the empirically obtained distribution.

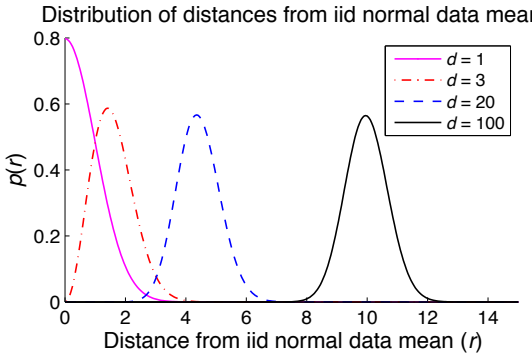

Figure 4: Probability density function of observing a point at distance r from the mean of a multivariate d-dimensional normal distribution, for $d = 1,\ 3,\ 20,\ 100$.

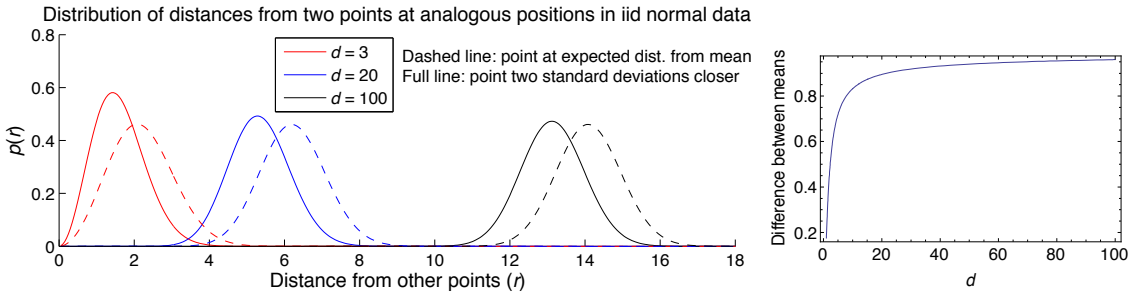

(a) (b)

Figure 5: (a) Distribution of distances to other points from i.i.d. normal random data for a point at the expected distance from the origin (dashed line), and a point two standard deviations closer (full line). (b) Difference between the means of the two distributions, with respect to increasing d.

freedom and noncentrality parameter λ equaling the distance of $\mathbf{a}_d$ ($\mathbf{b}_d$) to the origin. Figure 5(a) plots the probability density functions of these distributions for several values of d. It can be seen that, as d increases, the distance distributions for $\mathbf{a}_d$ and $\mathbf{b}_d$ move away from each other. This tendency is depicted more clearly in Figure 5(b) which plots the difference between the means of the two distributions with respect to d.

It is known, and expected, for points that are closer to the mean of the data distribution to be closer, on average, to all other points, for any value of d. However, the above analysis indicates that this tendency is amplified by high dimensionality, making points that reside in the proximity of the data mean become closer (in relative terms) to all other points than their low-dimensional analogues are. This tendency causes high-dimensional points that are closer to the mean to have increased inclusion probability into k-NN lists of other points, even for small values of k. We will discuss this relationship further in Section 5.2.

In terms of the notion of node *centrality* typically used in network analysis (Scott, 2000), the above discussion indicates that high dimensionality amplifies what we will call the *spatial centrality*

of a point (by increasing its proximity to other points), which, in turn, affects the *degree centrality* of the corresponding node in the k-NN graph (by increasing its degree, that is, N_k). Other notions of node centrality, and the structure of the k-NN graph in general, will be studied in more detail in Section 5.2.1. The rest of this section will focus on describing the mechanism of the observed spatial centrality amplification.

In the preceding discussion we selected two points from i.i.d. normal data with specific distances from the origin expressed in terms of expected distance and deviation from it, and tracked the analogues of the two points for increasing values of dimensionality d. Generally, we can express the distances of the two points to the origin in terms of "offsets" from the expected distance measured by standard deviation, which in the case of i.i.d. normal random data would be $\lambda_{d,1} = \mu_{\chi(d)} + c_1\sigma_{\chi(d)}$ and $\lambda_{d,2} = \mu_{\chi(d)} + c_2\sigma_{\chi(d)}$, where $\lambda_{d,1}$ and $\lambda_{d,2}$ are the distances of the first and second point to the origin, $\mu_{\chi(d)}$ and $\sigma_{\chi(d)}$ are the mean and standard deviation of the Chi distribution with d degrees of freedom, and c_1 and c_2 are selected constants (the offsets). In the preceding example involving points $\mathbf{a}_d$ and $\mathbf{b}_d$, we set $c_1 = -2$ and $c_2 = 0$, respectively. However, analogous behavior can be observed with arbitrary two points whose distance to the data mean is below the expected distance, that is, for $c_1, c_2 \leq 0$. We describe this behavior by introducing the following notation: $\Delta\mu_d(\lambda_{d,1}, \lambda_{d,2}) = |\mu_{\chi(d,\lambda_{d,2})} - \mu_{\chi(d,\lambda_{d,1})}|$, where $\mu_{\chi(d,\lambda_{d,i})}$ is the mean of the noncentral Chi distribution with d degrees of freedom and noncentrality parameter $\lambda_{d,i}$ ($i \in \{1,2\}$). In the following theorem, which we prove in Section 5.1, we show that $\Delta\mu_d(\lambda_{d,1}, \lambda_{d,2})$ increases with increasing values of d.

Theorem 1 *Let $\lambda_{d,1} = \mu_{\chi(d)} + c_1\sigma_{\chi(d)}$ and $\lambda_{d,2} = \mu_{\chi(d)} + c_2\sigma_{\chi(d)}$, where $d \in \mathbb{N}^+$, $c_1, c_2 \leq 0$, $c_1 < c_2$, and $\mu_{\chi(d)}$ and $\sigma_{\chi(d)}$ are the mean and standard deviation of the Chi distribution with d degrees of freedom, respectively. Define*

$$\Delta\mu_d(\lambda_{d,1}, \lambda_{d,2}) = \mu_{\chi(d,\lambda_{d,2})} - \mu_{\chi(d,\lambda_{d,1})}\,,$$

where $\mu_{\chi(d,\lambda_{d,i})}$ is the mean of the noncentral Chi distribution with d degrees of freedom and noncentrality parameter $\lambda_{d,i}$ ($i \in \{1,2\}$).

There exists $d_0 \in \mathbb{N}$ such that for every $d > d_0$,

$$\Delta\mu_d(\lambda_{d,1}, \lambda_{d,2}) > 0\,,$$

and

$$\Delta\mu_{d+2}(\lambda_{d+2,1}, \lambda_{d+2,2}) > \Delta\mu_d(\lambda_{d,1}, \lambda_{d,2})\,. \tag{1}$$

The main statement of the theorem is given by Equation 1, which expresses the tendency of the difference between the means of the two distance distributions to increase with increasing dimensionality d. It is important to note that this tendency is obtained through analysis of *distributions* of data and distances, implying that the behavior is an inherent property of data distributions in high-dimensional space, rather than an artefact of other factors, such as finite sample size, etc. Through simulation involving randomly generated points we verified the behavior for i.i.d. normal data by replicating very closely the chart shown in Figure 5(b). Furthermore, simulations suggest that the same behavior emerges in i.i.d. uniform data,[9] as well as numerous other unimodal random data distributions, producing charts of the same shape as in Figure 5(b). Real data, on the other hand,

9. The uniform cube setting will be discussed in more detail in Section 5.2, in the context of results from related work (Newman and Rinott, 1985).

tends to be clustered, and can be viewed as originating from a *mixture* of distributions resulting in a multimodal distribution of data. In this case, the behavior described by Theorem 1, and illustrated in Figure 5(b), is manifested primarily on the individual component distributions of the mixture, that is, on clusters of data points. The next section takes a closer look at the hubness phenomenon in real data sets.

4.3 Hubness in Real Data

Results describing the origins of hubness given in the previous sections were obtained by examining data sets that follow specific distributions and generated as i.i.d. samples from these distributions. To extend these results to real data, we need to take into account two additional factors: (1) real data sets usually contain dependent attributes, and (2) real data sets are usually clustered, that is, points are organized into groups produced by a mixture of distributions instead of originating from a single (unimodal) distribution.

To examine the first factor (dependent attributes), we adopt the approach of François et al. (2007) used in the context of distance concentration. For each data set we randomly permute the elements within every attribute. This way, attributes preserve their individual distributions, but the dependencies between them are lost and the *intrinsic dimensionality* of data sets increases, becoming equal to their embedding dimensionality d (François et al., 2007). In Table 1 (10th column) we give the empirical skewness, denoted as $S^S_{N_k}$, of the shuffled data. For the vast majority of high-dimensional data sets, $S^S_{N_k}$ is considerably higher than S_{N_k}, indicating that hubness actually depends on the intrinsic rather than embedding dimensionality. This provides an explanation for the apparent weaker influence of d on hubness in real data than in synthetic data sets, which was observed in Section 3.2.

To examine the second factor (many groups), for every data set we measured: (i) the Spearman correlation, denoted as $C^{N_{10}}_{\mathrm{dm}}$ (12th column), of the observed N_k and distance from the data-set mean, and (ii) the correlation, denoted as $C^{N_{10}}_{\mathrm{cm}}$ (13th column), of the observed N_k and distance to the closest group mean. Groups are determined with K-means clustering, where the number of clusters for each data set, given in column 11 of Table 1, was determined by exhaustive search of values between 2 and $\lfloor\sqrt{n}\rfloor$, to maximize $C^{N_{10}}_{\mathrm{cm}}$.[10] In most cases, $C^{N_{10}}_{\mathrm{cm}}$ is considerably stronger than $C^{N_{10}}_{\mathrm{dm}}$. Consequently, in real data, hubs tend to be closer than other points to their respective cluster centers (which we verified by examining the individual scatter plots).

To further support the above findings, we include the 6th column (d_{mle}) to Table 1, corresponding to intrinsic dimensionality measured by the maximum likelihood estimator (Levina and Bickel, 2005). Next, we compute Spearman correlations between various measurements from Table 1 over all 50 examined data sets, given in Table 2. The observed skewness of N_k, besides being strongly correlated with d, is even more strongly correlated with the intrinsic dimensionality d_{mle}. Moreover, intrinsic dimensionality positively affects the correlations between N_k and the distance to the data-set mean / closest cluster mean, implying that in higher (intrinsic) dimensions the positions of hubs become increasingly localized to the proximity of centers.

Section 6, which discusses the interaction of hubness with dimensionality reduction, will provide even more support to the observation that hubness depends on intrinsic, rather than embedding dimensionality.

10. We report averages of $C^{N_{10}}_{\mathrm{cm}}$ over 10 runs of K-means clustering with different random seeding, in order to reduce the effects of chance.

	d	d_{mle}	$S_{N_{10}}$	$C_{\text{dm}}^{N_{10}}$	$C_{\text{cm}}^{N_{10}}$	$\widetilde{BN}_{10}$	$C_{BN_{10}}^{N_{10}}$

4.4 Hubs and Outliers

The non-negligible variance of the distribution of distances to the data mean described in Section 4.2 has an additional "side": we also expect points farther from the mean and, therefore, with much lower observed N_k than the rest.[11] Such points correspond to the bottom-right parts of Figure 3(b, c, e, f), and will be referred to as *antihubs*. Since antihubs are far away from all other points, in high dimensions they can be regarded as distance-based *outliers* (Tan et al., 2005).

To further support the connection between antihubs and distance-based outliers, let us consider a common outlier score of a point as the distance from its kth nearest neighbor (Tan et al., 2005). Low N_k values and high outlier scores are correlated as exemplified in Figure 6(a, b) (in their lower-right parts) for two data sets from Table 1.

Next, let us recall the i.i.d. normal random data setting, and the probability density function corresponding to observing a point at a specified distance from the mean, plotted in Figure 4. An analogous chart for real data is given in Figure 7, which shows the empirical distributions of distances from the closest cluster mean for three real data sets, as described in Section 4.3. In both figures it can be seen that in low dimensions the probability of observing a point near a center is quite high, while as dimensionality increases it becomes close to zero. If we now consider a *probabilistic* definition of an outlier as a point with a low probability of occurrence (Tan et al., 2005), in high

11. Assuming the presence of hubs, the existence of points with low N_k is implied by the constant-sum property of N_k: for any data set D, $\sum_{\mathbf{x}\in D} N_k(\mathbf{x}) = k|D|$ (Aucouturier and Pachet, 2007).

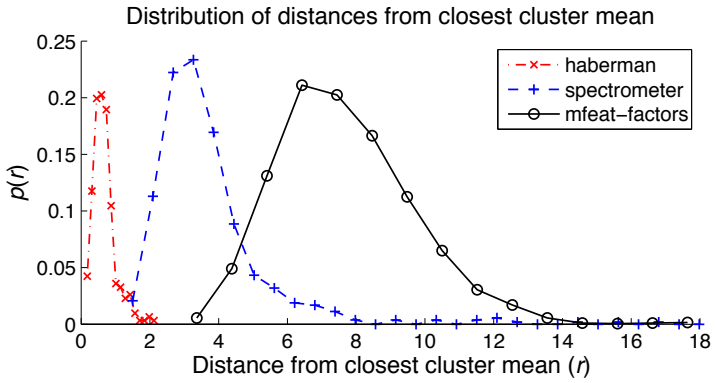

Figure 7: Probability density function of observing a point at distance r from the closest cluster mean for three real data sets.

dimensions hubs actually *are* outliers, as points closer to the distribution (or cluster) mean than the majority of other points. Therefore, somewhat counterintuitively, it can be said that hubs are points that reside in low-density regions of the high-dimensional data space, and are at the same time close to many other points. On the other hand, distance-based outliers correspond to probabilistic outliers that are farther away from the center(s). It follows that the definitions of distance-based and probabilistic outliers significantly diverge from one another in high dimensions, with distance-based outliers only partially corresponding to probabilistic outliers. To prevent confusion in the rest of the paper, we shall continue to refer to "hubs" and "outliers" in the distance-based sense. Outliers will be analyzed further in Section 7.3.2.

5. Proofs and Discussion

This section is predominantly devoted to the theoretical aspects of the behavior of distances in high-dimensional space and the hubness phenomenon. Section 5.1 provides a step-by-step proof of Theorem 1 which was introduced in Section 4.2, while Section 5.2 discusses additional aspects of the phenomenon in the context of the geometry of high-dimensional spaces and the properties of data distributions which occupy them.

5.1 Proof of Theorem 1

In this section we analyze the behavior of distances that provides the mechanism for the formation of hubs, introduced in Section 4.2, culminating with the proof of Theorem 1. Section 5.1.1 reviews distance concentration results by François et al. (2007), while Section 5.1.2 discusses distance distributions in i.i.d. normal random data and extended interpretations of the results by François et al. (2007) in this setting. The notion of asymptotic equivalence that will be used in the proof of Theorem 1 is the subject of Section 5.1.3. The expectation of the noncentral Chi distribution, which is a key feature in the analysis of distance distributions in i.i.d. normal random data, is defined in Section 5.1.4, together with the generalized Laguerre function on which it relies. Properties of the generalized Laguerre function that will be used in the proof of Theorem 1 are presented in Section 5.1.5. Finally, the proof of Theorem 1 is given in Section 5.1.6.

5.1.1 DISTANCE CONCENTRATION RESULTS

We begin by reviewing the main results of François et al. (2007) regarding distance concentration. Let $\mathbf{X}_d = (X_1, X_2, \ldots, X_d)$ be a random d-dimensional variable with i.i.d. components: $X_i \sim \mathcal{F}$, and let $\|\mathbf{X}_d\|$ denote its Euclidean norm. For random variables $|X_i|^2$, let $\mu_{|\mathcal{F}|^2}$ and $\sigma^2_{|\mathcal{F}|^2}$ signify their mean and variance, respectively. François et al. (2007) prove the following two lemmas.[12]

Lemma 2 (François et al., 2007, Equation 17, adapted)

$$\lim_{d\to\infty} \frac{\mathrm{E}(\|\mathbf{X}_d\|)}{\sqrt{d}} = \mu_{|\mathcal{F}|^2}\,.$$

Lemma 3 (François et al., 2007, Equation 21, adapted)

$$\lim_{d\to\infty} \mathrm{Var}(\|\mathbf{X}_d\|) = \frac{\sigma^2_{|\mathcal{F}|^2}}{4\mu_{|\mathcal{F}|^2}}\,.$$

The above lemmas imply that, for i.i.d. random data, the expectation of the distribution of Euclidean distances to the origin (Euclidean norms) asymptotically behaves like $\sqrt{d}$, while the standard deviation is asymptotically constant. From now on, we will denote the mean and variance of random variables that are distributed according to some distribution $\mathcal{F}$ by $\mu_{\mathcal{F}}$ and $\sigma^2_{\mathcal{F}}$, respectively.

5.1.2 DISTANCES IN I.I.D. NORMAL DATA

We now observe more closely the behavior of distances in i.i.d. normal random data. Let $\mathbf{Z}_d = (Z_1, Z_2, \ldots, Z_d)$ be a random d-dimensional vector whose components independently follow the standard normal distribution: $Z_i \sim \mathcal{N}(0;1)$, for every $i \in \{1, 2, \ldots, d\}$. Then, by definition, random variable $\|\mathbf{Z}_d\|$ follows the Chi distribution with d degrees of freedom: $\|\mathbf{Z}_d\| \sim \chi(d)$. In other words, $\chi(d)$ is the distribution of Euclidean distances of vectors drawn from $\mathbf{Z}_d$ to the origin. If one were to fix another reference vector $\mathbf{x}_d$ instead of the origin, the distribution of distances of vectors drawn from $\mathbf{Z}_d$ to $\mathbf{x}_d$ would be completely determined by $\|\mathbf{x}_d\|$ since, again by definition, random variable $\|\mathbf{Z}_d - \mathbf{x}_d\|$ follows the noncentral Chi distribution with d degrees of freedom and noncentrality parameter $\lambda = \|\mathbf{x}_d\|$: $\|\mathbf{Z}_d - \mathbf{x}_d\| \sim \chi(d, \|\mathbf{x}_d\|)$.

In light of the above, let us observe two points, $\mathbf{x}_{d,1}$ and $\mathbf{x}_{d,2}$, drawn from $\mathbf{Z}_d$, and express their distances from the origin in terms of offsets from the expected distance, with the offsets described using standard deviations: $\|\mathbf{x}_{d,1}\| = \mu_{\chi(d)} + c_1\sigma_{\chi(d)}$ and $\|\mathbf{x}_{d,2}\| = \mu_{\chi(d)} + c_2\sigma_{\chi(d)}$, where $c_1, c_2 \leq 0$. We will assume $c_1 < c_2$, that is, $\mathbf{x}_{d,1}$ is closer to the data distribution mean (the origin) than $\mathbf{x}_{d,2}$. By treating c_1 and c_2 as constants, and varying d, we observe analogues of two points in spaces of different dimensionalities (roughly speaking, points $\mathbf{x}_{d,1}$ have identical "probability" of occurrence at the specified distance from the origin for every d, and the same holds for $\mathbf{x}_{d,2}$). Let $\lambda_{d,1} = \|\mathbf{x}_{d,1}\|$ and $\lambda_{d,2} = \|\mathbf{x}_{d,2}\|$. Then, the distributions of distances of points $\mathbf{x}_{d,1}$ and $\mathbf{x}_{d,2}$ to all points from the data distribution $\mathbf{Z}_d$ (that is, the distributions of random variables $\|\mathbf{Z}_d - \mathbf{x}_{d,1}\|$ and $\|\mathbf{Z}_d - \mathbf{x}_{d,2}\|$) are noncentral Chi distributions $\chi(d, \lambda_{d,1})$ and $\chi(d, \lambda_{d,2})$, respectively. We study the behavior of these two distributions with increasing values of d.

Lemmas 2 and 3, taking $\mathcal{F}$ to be the standard normal distribution $\mathcal{N}(0;1)$, and translating the space so that $\mathbf{x}_{d,1}$ or $\mathbf{x}_{d,2}$ become the origin, imply that both $\mu_{\chi(d,\lambda_{d,1})}$ and $\mu_{\chi(d,\lambda_{d,2})}$ asymptotically

12. François et al. (2007) provide a more general result for l_p norms with arbitrary $p > 0$.

behave like $\sqrt{d}$ as $d \to \infty$, while $\sigma^2_{\chi(d,\lambda_{d,1})}$ and $\sigma^2_{\chi(d,\lambda_{d,2})}$ are both asymptotically constant.[13] However, for $\mathbf{x}_{d,1}$ and $\mathbf{x}_{d,2}$ placed at different distances form the origin ($\lambda_{d,1} \neq \lambda_{d,2}$, that is, $c_1 \neq c_2$), these asymptotic tendencies do not occur at the same *speed*. In particular, we will show that as d increases, the difference between $\mu_{\chi(d,\lambda_{d,1})}$ and $\mu_{\chi(d,\lambda_{d,2})}$ actually *increases*. If we take $\mathbf{x}_{d,1}$ to be closer to the origin than $\mathbf{x}_{d,2}$ ($c_1 < c_2$), this means that $\mathbf{x}_{d,1}$ becomes closer to all other points from the data distribution $\mathbf{Z}_d$ than $\mathbf{x}_{d,2}$, simply by virtue of increasing dimensionality, since for different values of d we place the two points at analogous positions in the data space with regards to the distance from the origin.

5.1.3 ASYMPTOTIC EQUIVALENCE

Before describing our main theoretical result, we present several definitions and lemmas, beginning with the notion of asymptotic equivalence that will be relied upon.

Definition 4 *Two real-valued functions $f(x)$ and $g(x)$ are* asymptotically equal, *$f(x) \approx g(x)$, iff for every $\varepsilon > 0$ there exists $x_0 \in \mathbb{R}$ such that for every $x > x_0$, $|f(x) - g(x)| < \varepsilon$.*

Equivalently, $f(x) \approx g(x)$ iff $\lim_{x\to\infty} |f(x) - g(x)| = 0$. Note that the $\approx$ relation is different from the divisive notion of asymptotic equivalence, where $f(x) \sim g(x)$ iff $\lim_{x\to\infty} f(x)/g(x) = 1$.

The following two lemmas describe approximations that will be used in the proof of Theorem 1, based on the $\approx$ relation.

Lemma 5 *For any constant $c \in \mathbb{R}$, let $f(d) = \sqrt{d+c}$, and $g(d) = \sqrt{d}$. Then, $f(d) \approx g(d)$.*

Proof

$$\lim_{d\to\infty} \left|\sqrt{d+c} - \sqrt{d}\right| = \lim_{d\to\infty} \left|\left(\sqrt{d+c} - \sqrt{d}\right) \frac{\sqrt{d+c}+\sqrt{d}}{\sqrt{d+c}+\sqrt{d}}\right| = \lim_{d\to\infty} \left|\frac{c}{\sqrt{d+c}+\sqrt{d}}\right| = 0. \qquad \blacksquare$$

Lemma 6 *$\mu_{\chi(d)} \approx \sqrt{d}$, and $\sigma_{\chi(d)} \approx 1/\sqrt{2}$.*

Proof Observe the expression for the mean of the $\chi(d)$ distribution,

$$\mu_{\chi(d)} = \sqrt{2}\,\frac{\Gamma\left(\frac{d+1}{2}\right)}{\Gamma\left(\frac{d}{2}\right)}.$$

The equality $x\Gamma(x) = \Gamma(x+1)$ and the convexity of $\log\Gamma(x)$ yield (Haagerup, 1982, p. 237):

$$\Gamma\left(\frac{d+1}{2}\right)^2 \leq \Gamma\left(\frac{d}{2}\right)\Gamma\left(\frac{d+2}{2}\right) = \frac{d}{2}\,\Gamma\left(\frac{d}{2}\right)^2,$$

13. More precisely, the lemmas can be applied only for points $\mathbf{x}'_{d,i}$ that have equal values of all components, since after translation data components need to be i.i.d. Because of the symmetry of the Gaussian distribution, the same expectations and variances of distance distributions are obtained, for every d, with any $\mathbf{x}_{d,i}$ that has the same norm as $\mathbf{x}'_{d,i}$, thereby producing identical asymptotic results.

and

$$\Gamma\left(\frac{d+1}{2}\right)^2 = \frac{d-1}{2}\Gamma\left(\frac{d-1}{2}\right)\Gamma\left(\frac{d+1}{2}\right) \geq \frac{d-1}{2}\Gamma\left(\frac{d}{2}\right)^2,$$

from which we have

$$\sqrt{d-1} \leq \sqrt{2}\frac{\Gamma\left(\frac{d+1}{2}\right)}{\Gamma\left(\frac{d}{2}\right)} \leq \sqrt{d}.$$

From Lemma 5 it now follows that $\mu_{\chi(d)} \approx \sqrt{d}$.

Regarding the standard deviation of the $\chi(d)$ distribution, from Lemma 3, taking $\mathcal{F}$ to be the standard normal distribution, we obtain

$$\lim_{d\to\infty} \sigma^2_{\chi(d)} = \frac{\sigma^2_{\chi^2(1)}}{4\mu_{\chi^2(1)}} = \frac{1}{2},$$

since the square of a standard normal random variable follows the chi-square distribution with one degree of freedom, $\chi^2(1)$, whose mean and variance are known: $\mu_{\chi^2(1)} = 1$, $\sigma^2_{\chi^2(1)} = 2$. It now directly follows that $\sigma_{\chi(d)} \approx 1/\sqrt{2}$. ■

5.1.4 Expectation of the Noncentral Chi Distribution

The central notion in Theorem 1 is the noncentral Chi distribution. To express the expectation of the noncentral Chi distribution, the following two definitions are needed, introducing the Kummer confluent hypergeometric function ${}_1F_1$, and the generalized Laguerre function.

Definition 7 (Itô, 1993, p. 1799, Appendix A, Table 19.I)
For $a,b,z \in \mathbb{R}$, the Kummer confluent hypergeometric function ${}_1F_1(a;b;z)$ is given by

$${}_1F_1(a;b;z) = \sum_{k=0}^{\infty} \frac{(a)_k}{(b)_k} \cdot \frac{z^k}{\Gamma(k+1)},$$

where $(\cdot)_k$ is the Pochhammer symbol, $(x)_k = \frac{\Gamma(x+k)}{\Gamma(x)}$.

Definition 8 (Itô, 1993, p. 1811, Appendix A, Table 20.VI)
For $\nu,\alpha,z \in \mathbb{R}$, the generalized Laguerre function $L_\nu^{(\alpha)}(z)$ is given by

$$L_\nu^{(\alpha)}(z) = \frac{\Gamma(\nu+\alpha+1)}{\Gamma(\nu+1)} \cdot \frac{{}_1F_1(-\nu;\alpha+1;z)}{\Gamma(\alpha+1)}.$$

The expectation of the noncentral Chi distribution with d degrees of freedom and noncentrality parameter λ, denoted by $\mu_{\chi(d,\lambda)}$, can now be expressed via the generalized Laguerre function (Oberto and Pennecchi, 2006):

$$\mu_{\chi(d,\lambda)} = \sqrt{\frac{\pi}{2}} L_{1/2}^{(d/2-1)}\left(-\frac{\lambda^2}{2}\right). \tag{2}$$

5.1.5 PROPERTIES OF THE GENERALIZED LAGUERRE FUNCTION

The proof of Theorem 1 will rely on several properties of the generalized Laguerre function. In this section we will review two known properties and prove several additional ones as lemmas.

An important property of the generalized Laguerre function is its infinite differentiability in z, with the result of differentiation again being a generalized Laguerre function:

$$\frac{\partial}{\partial z} L_{\nu}^{(\alpha)}(z) = -L_{\nu-1}^{(\alpha+1)}(z)\,. \tag{3}$$

Another useful property is the following recurrence relation:

$$L_{\nu}^{(\alpha)}(z) = L_{\nu-1}^{(\alpha)}(z) + L_{\nu}^{(\alpha-1)}(z)\,. \tag{4}$$

Lemma 9 *For $\alpha > 0$ and $z < 0$:*
(a) $L_{-1/2}^{(\alpha)}(z)$ *is a positive monotonically increasing function in z, while*
(b) $L_{1/2}^{(\alpha)}(z)$ *is a positive monotonically decreasing concave function in z.*

Proof (a) From Definition 8,

$$L_{-1/2}^{(\alpha)}(z) = \frac{\Gamma(\alpha+1/2)}{\Gamma(1/2)} \cdot \frac{{}_1F_1(1/2;\alpha+1;z)}{\Gamma(\alpha+1)}\,.$$

Since $\alpha > 0$ all three terms involving the Gamma function are positive. We transform the remaining term using the equality (Itô, 1993, p. 1799, Appendix A, Table 19.I):

$${}_1F_1(a;b;z) = e^z\,{}_1F_1(b-a;b;-z)\,, \tag{5}$$

which holds arbitrary $a, b, z \in \mathbb{R}$, obtaining

$${}_1F_1(1/2;\alpha+1;z) = e^z\,{}_1F_1(\alpha+1/2;\alpha+1;-z)\,.$$

From Definition 7 it now directly follows that $L_{-1/2}^{(\alpha)}(z)$ is positive for $\alpha > 0$ and $z < 0$.

To show that $L_{-1/2}^{(\alpha)}(z)$ is monotonically increasing in z, from Equation 3 and Definition 8 we have

$$\frac{\partial}{\partial z} L_{-1/2}^{(\alpha)}(z) = -L_{-3/2}^{(\alpha+1)}(z) = -\frac{\Gamma(\alpha+1/2)}{\Gamma(-1/2)} \cdot \frac{{}_1F_1(3/2;\alpha+2;z)}{\Gamma(\alpha+2)}\,.$$

For $\alpha > 0$ and $z < 0$, from Equation 5 it follows that ${}_1F_1(3/2;\alpha+2;z) > 0$. Since $\Gamma(-1/2) < 0$ and all remaining terms are positive, it follows that $-L_{-3/2}^{(\alpha+1)}(z) > 0$. Thus, $L_{-1/2}^{(\alpha)}(z)$ is monotonically increasing in z.

(b) Proofs that $L_{1/2}^{(\alpha)}(z)$ is positive and monotonically decreasing are very similar to the proofs in part (a), and will be omitted. To address concavity, we observe the second derivative of $L_{1/2}^{(\alpha)}(z)$:

$$\frac{\partial^2}{\partial z} L_{1/2}^{(\alpha)}(z) = L_{-3/2}^{(\alpha+2)}(z) = \frac{\Gamma(\alpha+3/2)}{\Gamma(-1/2)} \cdot \frac{{}_1F_1(3/2;\alpha+3;z)}{\Gamma(\alpha+3)}\,.$$

Similarly to part (a), from Equation 5, Definition 7, and basic properties of the gamma function it follows that $L_{-3/2}^{(\alpha+2)}(z) < 0$ for $\alpha > 0$ and $z < 0$. Thus, $L_{1/2}^{(\alpha)}(z)$ is concave in z. ■

Lemma 10 *For* $\alpha > 0$ *and* $z < 0$, $L_{1/2}^{(\alpha+1)}(z) \approx L_{1/2}^{(\alpha)}(z)$.

Proof From the recurrence relation in Equation 4 we obtain

$$L_{1/2}^{(\alpha+1)}(z) = L_{-1/2}^{(\alpha+1)}(z) + L_{1/2}^{(\alpha)}(z).$$

Therefore, to prove the lemma it needs to be shown that for $z < 0$,

$$\lim_{\alpha\to\infty} L_{-1/2}^{(\alpha)}(z) = 0. \tag{6}$$

From Definition 8 and Equation 5 we have

$$L_{-1/2}^{(\alpha)}(z) = \frac{e^{-z}}{\Gamma(1/2)} \cdot \frac{\Gamma(\alpha+1/2)}{\Gamma(\alpha+1)} \cdot {}_1F_1(\alpha+1/2;\alpha+1;-z).$$

From the asymptotic expansion by Fujikoshi (2007, p. 16, adapted),

$${}_1F_1\left(\frac{1}{2}n;\frac{1}{2}(n+b);x\right) = e^x\left(1+O(n^{-1})\right), \tag{7}$$

where n is large and $x \geq 0$, it follows that $\lim_{\alpha\to\infty} {}_1F_1(\alpha+1/2;\alpha+1;-z) < \infty$. Thus, to prove Equation 6 and the lemma it remains to be shown that

$$\lim_{\alpha\to\infty} \frac{\Gamma(\alpha+1/2)}{\Gamma(\alpha+1)} = 0. \tag{8}$$

As in the proof of Lemma 6, from the inequalities derived by Haagerup (1982) we have

$$\sqrt{\beta-1} \leq \sqrt{2}\,\frac{\Gamma\left(\frac{\beta+1}{2}\right)}{\Gamma\left(\frac{\beta}{2}\right)} \leq \sqrt{\beta},$$

where $\beta > 1$. Applying inversion and substituting β with $2\alpha+1$ yields the desired limit. ■

Lemma 11 *For* $\alpha > 1/2$ *and* $z < 0$:
(a) $\lim_{z\to-\infty} L_{-3/2}^{(\alpha)}(z) = 0$, *and*
(b) $\lim_{\alpha\to\infty} L_{-3/2}^{(\alpha)}(z) = 0$.

Proof (a) From Definition 8 we have

$$L_{-3/2}^{(\alpha)}(z) = \frac{\Gamma(\alpha-1/2)}{\Gamma(-1/2)} \cdot \frac{{}_1F_1(3/2;\alpha+1;z)}{\Gamma(\alpha+1)}. \tag{9}$$

The following property (Abramowitz and Stegun, 1964, p. 504, Equation 13.1.5),

$${}_1F_1(a;b;z) = \frac{\Gamma(b)}{\Gamma(b-a)}(-z)^a\left(1+O(|z|^{-1})\right) \quad (z<0),$$

when substituted into Equation 9, taking $a = 3/2$ and $b = \alpha + 1$, yields

$$L_{-3/2}^{(\alpha)}(z) = \frac{1}{\Gamma(-1/2)}(-z)^{-3/2}\left(1 + O(|z|^{-1})\right). \tag{10}$$

From Equation 10 the desired limit directly follows.

(b) The proof of part (b) is analogous to the proof of Lemma 10, that is, Equation 6. From Definition 8 and Equation 5, after applying the expansion by Fujikoshi (2007) given in Equation 7, it remains to be shown that

$$\lim_{\alpha\to\infty} \frac{\Gamma(\alpha - 1/2)}{\Gamma(\alpha + 1)} = 0. \tag{11}$$

Since $\Gamma(\alpha - 1/2) < \Gamma(\alpha + 1/2)$ for every $\alpha \geq 2$, the desired limit in Equation 11 follows directly from Equation 8. ■

5.1.6 THE MAIN RESULT

This section restates and proves our main theoretical result.

Theorem 1 *Let $\lambda_{d,1} = \mu_{\chi(d)} + c_1\sigma_{\chi(d)}$ and $\lambda_{d,2} = \mu_{\chi(d)} + c_2\sigma_{\chi(d)}$, where $d \in \mathbb{N}^+$, $c_1, c_2 \leq 0$, $c_1 < c_2$, and $\mu_{\chi(d)}$ and $\sigma_{\chi(d)}$ are the mean and standard deviation of the Chi distribution with d degrees of freedom, respectively. Define*

$$\Delta\mu_d(\lambda_{d,1}, \lambda_{d,2}) = \mu_{\chi(d,\lambda_{d,2})} - \mu_{\chi(d,\lambda_{d,1})},$$

where $\mu_{\chi(d,\lambda_{d,i})}$ is the mean of the noncentral Chi distribution with d degrees of freedom and noncentrality parameter $\lambda_{d,i}$ ($i \in \{1,2\}$).

There exists $d_0 \in \mathbb{N}$ such that for every $d > d_0$,

$$\Delta\mu_d(\lambda_{d,1}, \lambda_{d,2}) > 0, \tag{12}$$

and

$$\Delta\mu_{d+2}(\lambda_{d+2,1}, \lambda_{d+2,2}) > \Delta\mu_d(\lambda_{d,1}, \lambda_{d,2}). \tag{13}$$

Proof To prove Equation 12, we observe that for $d > 2$,

$$\begin{aligned}
\Delta\mu_d(\lambda_{d,1}, \lambda_{d,2}) &= \mu_{\chi(d,\lambda_{d,2})} - \mu_{\chi(d,\lambda_{d,1})} \\
&= \sqrt{\frac{\pi}{2}}\, L_{1/2}^{(\frac{d}{2}-1)}\left(-\frac{\lambda_{d,2}^2}{2}\right) - \sqrt{\frac{\pi}{2}}\, L_{1/2}^{(\frac{d}{2}-1)}\left(-\frac{\lambda_{d,1}^2}{2}\right) \\
&> 0,
\end{aligned}$$

where the last inequality holds for $d > 2$ because $\lambda_{d,1} < \lambda_{d,2}$, and $L_{1/2}^{(d/2-1)}(z)$ is a monotonically decreasing function in $z < 0$ for $d/2 - 1 > 0$ (Lemma 9).

In order to prove Equation 13, we will use approximate values of noncentrality parameters $\lambda_{d,1}$ and $\lambda_{d,2}$. Let $\widehat{\lambda}_{d,1} = \sqrt{d} + c_1/\sqrt{2}$, and $\widehat{\lambda}_{d,2} = \sqrt{d} + c_2/\sqrt{2}$. From Lemma 6 it follows that $\widehat{\lambda}_{d,1} \approx \lambda_{d,1}$ and $\widehat{\lambda}_{d,2} \approx \lambda_{d,2}$. Thus, by proving that there exists $d_2 \in \mathbb{N}$ such that for every $d > d_2$,

$$\Delta\mu_{d+2}(\widehat{\lambda}_{d+2,1}, \widehat{\lambda}_{d+2,2}) > \Delta\mu_d(\widehat{\lambda}_{d,1}, \widehat{\lambda}_{d,2}), \tag{14}$$

we prove that there exists $d_1 \in \mathbb{N}$ such that for every $d > d_1$ Equation 13 holds. The existence of such d_1, when approximations are used as function arguments, is ensured by the fact that $L_{1/2}^{(\alpha)}(z)$ is a monotonically decreasing *concave* function in z (Lemma 9), and by the transition from α to $\alpha+1$ having an insignificant impact on the value of the Laguerre function for large enough α (Lemma 10). Once Equation 14 is proven, Equations 12 and 13 will hold for every $d > d_0$, where $d_0 = \max(2, d_1)$.

To prove Equation 14, from Equation 2 it follows we need to show that

$$\begin{aligned} & L_{1/2}^{(d/2)}\left(-\frac{1}{2}\left(\sqrt{d+2}+c_2/\sqrt{2}\right)^2\right) - L_{1/2}^{(d/2)}\left(-\frac{1}{2}\left(\sqrt{d+2}+c_1/\sqrt{2}\right)^2\right) \\ & \quad > \; L_{1/2}^{(d/2-1)}\left(-\frac{1}{2}\left(\sqrt{d}+c_2/\sqrt{2}\right)^2\right) - L_{1/2}^{(d/2-1)}\left(-\frac{1}{2}\left(\sqrt{d}+c_1/\sqrt{2}\right)^2\right). \end{aligned} \tag{15}$$

We observe the second derivative of $L_{1/2}^{(\alpha)}(z)$:

$$\frac{\partial^2}{\partial z} L_{1/2}^{(\alpha)}(z) = L_{-3/2}^{(\alpha+2)}(z).$$

Since $L_{-3/2}^{(\alpha+2)}(z)$ tends to 0 as $z \to -\infty$, and tends to 0 also as $\alpha \to \infty$ (Lemma 11), it follows that the two Laguerre functions on the left side of Equation 15 can be approximated by a linear function with an arbitrary degree of accuracy for large enough d. More precisely, since $L_{1/2}^{(\alpha)}(z)$ is monotonically decreasing in z (Lemma 9) there exist $a, b \in \mathbb{R}$, $a > 0$, such that the left side of Equation 15, for large enough d, can be replaced by

$$\begin{aligned} & -a\left(-\frac{1}{2}\left(\sqrt{d+2}+c_2/\sqrt{2}\right)^2\right)+b - \left(-a\left(-\frac{1}{2}\left(\sqrt{d+2}+c_1/\sqrt{2}\right)^2\right)+b\right) \\ & \quad = \; \frac{a}{2}\left(\sqrt{d+2}+c_2/\sqrt{2}\right)^2 - \frac{a}{2}\left(\sqrt{d+2}+c_1/\sqrt{2}\right)^2. \end{aligned} \tag{16}$$

From Lemma 10 it follows that the same linear approximation can be used for the right side of Equation 15, replacing it by

$$\frac{a}{2}\left(\sqrt{d}+c_2/\sqrt{2}\right)^2 - \frac{a}{2}\left(\sqrt{d}+c_1/\sqrt{2}\right)^2. \tag{17}$$

After substituting the left and right side of Equation 15 with Equations 16 and 17, respectively, it remains to be shown that

$$\begin{aligned} & \frac{a}{2}\left(\sqrt{d+2}+c_2/\sqrt{2}\right)^2 - \frac{a}{2}\left(\sqrt{d+2}+c_1/\sqrt{2}\right)^2 \\ & \quad > \frac{a}{2}\left(\sqrt{d}+c_2/\sqrt{2}\right)^2 - \frac{a}{2}\left(\sqrt{d}+c_1/\sqrt{2}\right)^2. \end{aligned} \tag{18}$$

Multiplying both sides by $\sqrt{2}/a$, moving the right side to the left, and applying algebraic simplification reduces Equation 18 to

$$\left(c_2 - c_1\right)\left(\sqrt{d+2} - \sqrt{d}\right) > 0,$$

which holds for $c_1 < c_2$, thus concluding the proof. ■

5.2 Discussion

This section will discuss several additional considerations and related work regarding the geometry of high-dimensional spaces and the behavior of data distributions within them. First, let us consider the geometric upper limit to the number of points that point $\mathbf{x}$ can be a nearest neighbor of, in Euclidean space. In one dimension, this number is 2, in two dimensions it is 5, while in 3 dimensions it equals 11 (Tversky and Hutchinson, 1986). Generally, for Euclidean space of dimensionality d this number is equal to the *kissing number*, which is the maximal number of hyperspheres that can be placed to touch a given hypersphere without overlapping, with all hyperspheres being of the same size.[14] Exact kissing numbers for arbitrary d are generally not known, however there exist bounds which imply that they progress exponentially with d (Odlyzko and Sloane, 1979; Zeger and Gersho, 1994). Furthermore, when considering k nearest neighbors for $k > 1$, the bounds become even larger. Therefore, only for very low values of d geometrical constraints of vector space prevent hubness. On the other hand, for higher values of d hubness may or may not occur, and the geometric bounds, besides providing "room" for hubness (even for values of k as low as 1) do not contribute much in fully characterizing the hubness phenomenon. Therefore, in high dimensions the behavior of *data distributions* needed to be studied.

We focus the rest of the discussion around the following important result,[15] drawing parallels with our results and analysis, and extending existing interpretations.

Theorem 12 (Newman and Rinott, 1985, p. 803, Theorem 3, adapted)

Let $\mathbf{x}^{(i)} = (x_1^{(i)}, \ldots, x_d^{(i)})$, $i = 0, \ldots, n$ *be a sample of* $n+1$ *i.i.d. points from distribution* $\mathbf{F}(\mathbf{X})$, $\mathbf{X} = (X_1, \ldots, X_d) \in \mathbb{R}^d$. *Assume that* $\mathbf{F}$ *is of the form* $\mathbf{F}(\mathbf{X}) = \prod_{k=1}^{d} \mathcal{F}(X_k)$, *that is, the coordinates* $X_1, \ldots, X_d$ *are i.i.d. Let the distance measure be of the form* $D(\mathbf{x}^{(i)}, \mathbf{x}^{(j)}) = \sum_{k=1}^{d} g(x_k^{(i)}, x_k^{(j)})$. *Let* $N_1^{n,d}$ *denote the number of points among* $\{\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(n)}\}$ *whose nearest neighbor is* $\mathbf{x}^{(0)}$.

Suppose $0 < \mathrm{Var}(g(X,Y)) < \infty$ *and set*

$$\beta = \mathrm{Correlation}(g(X,Y), g(X,Z)), \tag{19}$$

where X, Y, Z *are i.i.d. with common distribution* $\mathcal{F}$ *(the marginal distribution of* X_k*).*
(a) *If* $\beta = 0$ *then*

$$\lim_{n\to\infty} \lim_{d\to\infty} N_1^{n,d} = \mathrm{Poisson}(\lambda = 1) \ \textit{in distribution} \tag{20}$$

and

$$\lim_{n\to\infty} \lim_{d\to\infty} \mathrm{Var}(N_1^{n,d}) = 1. \tag{21}$$

(b) *If* $\beta > 0$ *then*

$$\lim_{n\to\infty} \lim_{d\to\infty} N_1^{n,d} = 0 \ \textit{in distribution} \tag{22}$$

while

$$\lim_{n\to\infty} \lim_{d\to\infty} \mathrm{Var}(N_1^{n,d}) = \infty. \tag{23}$$

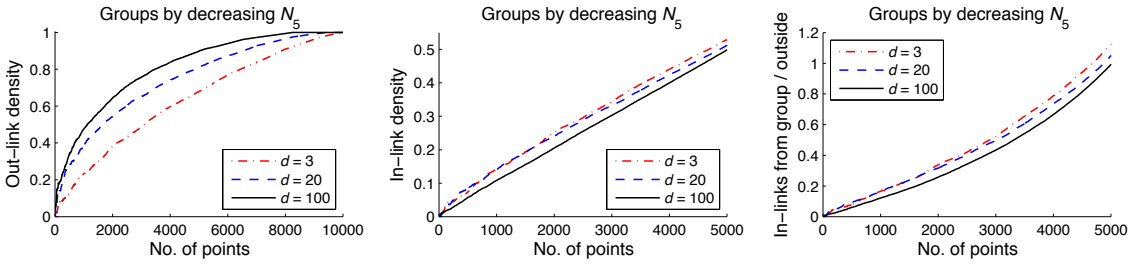
14. If ties are disallowed, it may be necessary to subtract 1 from the kissing number to obtain the maximum of N_1.
15. A theorem that is effectively a special case of this result was proven previously (Newman et al., 1983, Theorem 7) for continuous distributions with finite kurtosis and Euclidean distance.

What is exceptional in this theorem are Equations 22 and 23. According to the interpretation by Tversky et al. (1983), they suggest that if the number of dimensions is large relative to the number of points, one may expect to have a large proportion of points with N_1 equaling 0, and a small proportion of points with high N_1 values, that is, hubs.[16] Trivially, Equation 23 also holds for N_k with $k > 1$, since for any point $\mathbf{x}$, $N_k(\mathbf{x}) \geq N_1(\mathbf{x})$.

The setting involving i.i.d. normal random data and Euclidean distance, used in our Theorem 1 (and, generally, any i.i.d. random data distribution with Euclidean distance), fulfills the conditions of Theorem 12 for Equations 22 and 23 to be applied, since the correlation parameter $\beta > 0$. This correlation exists because, for example, if we view vector component variable X_j ($j \in \{1, 2, \ldots, d\}$) and the distribution of data points within it, if a random point drawn from X_j is closer to the mean of X_j it is more likely to be close to other random points drawn from X_j, and vice versa, producing the case $\beta > 0$.[17] Therefore, Equations 22 and 23 from Theorem 12 directly apply to the setting studied in Theorem 1, providing asymptotic evidence for hubness. However, since the proof of Equations 22 and 23 in Theorem 12 relies on applying the central limit theorem to the (normalized) distributions of pairwise distances between vectors $\mathbf{x}^{(i)}$ and $\mathbf{x}^{(j)}$ ($0 \leq i \neq j \leq n$) as $d \to \infty$ (obtaining limit distance distributions which are Gaussian), the results of Theorem 12 are inherently asymptotic in nature. Theorem 1, on the other hand, describes the behavior of distances in finite dimensionalities,[18] providing the means to characterize the behavior of N_k in high, but finite-dimensional space. What remains to be done is to formally connect Theorem 1 with the skewness of N_k in finite dimensionalities, for example by observing point $\mathbf{x}$ with a fixed position relative to the data distribution mean (the origin) across dimensionalities, in terms of being at distance $\mu_{\chi(d)} + c\,\sigma_{\chi(d)}$ from the origin, and expressing how the probability of $\mathbf{x}$ to be the nearest neighbor (or among the k nearest neighbors) of a randomly drawn point changes with increasing dimensionality.[19] We address this investigation as a point of future work.

Returning to Theorem 12 and the value of β from Equation 19, as previously discussed, $\beta > 0$ signifies that the position of a vector component value makes a difference when computing distances between vectors, causing some component values to be more "special" than others. Another contribution of Theorem 1 is that it illustrates how the individual differences in component values combine to make positions of whole vectors more special (by being closer to the data center). On the other hand, if $\beta = 0$ no point can have a special position with respect to all others. In this case, Equations 20 and 21 hold, which imply there is no hubness. This setting is relevant, for example, to points being generated by a Poisson process which spreads the vectors uniformly over $\mathbb{R}^d$, where all positions within the space (both at component-level and globally) become basically equivalent. Although it does not directly fit into the framework of Theorem 12, the same principle can be used to explain the absence of hubness for normally distributed data and cosine distance from Section 3.1: in this setting no vector is more spatially central than any other. Equations 20 and 21, which imply no hubness, hold for many more "centerless" settings, including random graphs, settings with exchangeable distances, and d-dimensional toruses (Newman and Rinott, 1985).

16. Reversing the order of limits, which corresponds to having a large number of points relative to the number of dimensions, produces the same asymptotic behavior as in Equations 20 and 21, that is, no hubness, in all studied settings.
17. Similarly to Section 4.2, this argument holds for unimodal distributions of component variables; for multimodal distributions the driving force behind nonzero β is the proximity to a peak in the probability density function.
18. Although the statement of Theorem 1 relies on dimensionality being greater than some d_0 which is finite, but can be arbitrarily high, empirical evidence suggests that actual d_0 values are low, often equaling 0.
19. For $c < 0$ we expect this probability to increase since $\mathbf{x}$ is closer to the data distribution mean, and becomes closer to other points as dimensionality increases.



(a) (b) (c)

Figure 8: (a) Out-link, and (b) in-link densities of groups of hubs with increasing size; (c) ratio of the number of in-links originating from points within the group and in-links originating from outside points, for i.i.d. uniform random data with dimensionality $d = 3,\ 20,\ 100$.

The following two subsections will address several additional issues concerning the interpretation of Theorem 12.

5.2.1 NEAREST-NEIGHBOR GRAPH STRUCTURE

The interpretation of Theorem 12 by Tversky et al. (1983) may be understood in the sense that, with increasing dimensionality, *very few* exceptional points become hubs, while all others are relegated to antihubs. In this section we will empirically examine the structural change of the k-NN graph as the number of dimensions increases. We will also discuss and consolidate different notions node centrality in the k-NN graph, and their dependence on the (intrinsic) dimensionality of data.

First, as in Section 3.1, we consider $n = 10000$ i.i.d. uniform random data points of different dimensionality. Let us observe hubs, that is, points with highest N_5, collected in groups of progressively increasing size: $5, 10, 15, \ldots, 10000$. In analogy with the notion of network density from social network analysis (Scott, 2000), we define group *out-link density* as the proportion of the number of arcs that originate and end in nodes from the group, and the total number of arcs that originate from nodes in the group. Conversely, we define group *in-link density* as the proportion of the number of arcs that originate and end in nodes from the group, and the total number of arcs that *end* in nodes from the group. Figure 8(a, b) shows the out-link and in-link densities of groups of strongest hubs in i.i.d. uniform random data (similar tendencies can be observed with other synthetic data distributions). It can be seen in Figure 8(a) that hubs are more cohesive in high dimensions, with more of their out-links leading to other hubs. On the other hand, Figure 8(b) suggests that hubs also receive more in-links from non-hub points in high dimensions than in low dimensions. Moreover, Figure 8(c), which plots the ratio of the number of in-links that originate within the group, and the number of in-links which originate outside, shows that hubs receive a larger proportion of in-links from non-hub points in high dimensions than in low dimensions. We have reported our findings for $k = 5$, however similar results are obtained with other values of k.

Overall, it can be said that in high dimensions hubs receive more in-links than in low dimensions from both hubs and non-hubs, and that the range of influence of hubs gradually widens as dimensionality increases. We can therefore conclude that the transition of hubness from low to high dimensionalities is "smooth," both in the sense of the change in the overall distribution of N_k, and the change in the degree of influence of data points, as expressed by the above analysis of links.

So far, we have viewed hubs primarily through their exhibited high values of N_k, that is, high degree centrality in the k-NN directed graph. However, (scale-free) network analysis literature often attributes other properties to hubs (Albert and Barabási, 2002), viewing them as nodes that are important for preserving network structure due to their central positions within the *graph*, indicated, for example, by their *betweenness centrality* (Scott, 2000). On the other hand, as discussed by Li et al. (2005), in both synthetic and real-world networks high-degree nodes do not necessarily need to correspond to nodes that are central in the graph, that is, high-degree nodes can be concentrated at the *periphery* of the network and bear little structural significance. For this reason, we computed the betweenness centrality of nodes in k-NN graphs of synthetic and real data sets studied in this paper, and calculated its Spearman correlation with node degree, denoting the measure by $C_{\mathrm{BC}}^{N_k}$. For i.i.d. uniform data ($k=5$), when $d=3$ the measured correlation is $C_{\mathrm{BC}}^{N_5}=0.311$, when $d=20$ the correlation is $C_{\mathrm{BC}}^{N_5}=0.539$, and finally when $d=100$ the correlation rises to $C_{\mathrm{BC}}^{N_5}=0.647$.[20] This suggests that with increasing dimensionality the centrality of nodes increases not only in the sense of higher node degree or spatial centrality of vectors (as discussed in Section 4.2), but also in the structural graph-based sense. We support this observation further by computing, over the 50 real data sets listed in Table 1, the correlation between $C_{\mathrm{BC}}^{N_{10}}$ and $S_{N_{10}}$, finding it to be significant: 0.548.[21] This indicates that real data sets which exhibit strong skewness in the distribution of N_{10} also tend to have strong correlation between N_{10} and betweenness centrality of nodes, giving hubs a broader significance for the structure of the k-NN graphs.

5.2.2 Rate of Convergence and the Role of Boundaries

On several occasions, the authors of Theorem 12 have somewhat downplayed the significance of equations 22 and 23 (Tversky et al., 1983; Newman and Rinott, 1985), citing empirically observed slow convergence (Maloney, 1983), even to the extent of not observing significant differences between hubness in the Poisson process and i.i.d. uniform cube settings. However, results in the preceding sections of this paper suggest that this convergence is fast enough to produce notable hubness in high-dimensional data. In order to directly illustrate the difference between a setting which provides no possibility for spatial centrality of points, and one that does, we will observe the Poisson process vs. the i.i.d. unit cube setting. We will be focusing on the location of the nearest neighbor of a point from the cube, that is, on determining whether it stays within the boundaries of the cube as dimensionality increases.

Lemma 13 *Let points be spread in $\mathbb{R}^d$ according to a Poisson process with constant intensity $\lambda > 1$. Observe a unit hypercube $C \subset \mathbb{R}^d$, and an arbitrary point $\mathbf{x} = (x_1, x_2, \ldots, x_d) \in C$, generated by the Poisson process. Let $p_{\lambda,d}$ denote the probability that the nearest neighbor of $\mathbf{x}$, with respect to Euclidean distance, is not situated in C. Then,*

$$\lim_{d\to\infty} p_{\lambda,d} = 1\,.$$

Proof Out of the 3^d-1 unit hypercubes that surround C, let us observe only the $2d$ hypercubes that differ from C only in one coordinate. We will restrict the set of considered points to these $2d$ cubes, and prove that the probability that the nearest neighbor of $\mathbf{x}$ comes from one of the $2d$ cubes, $\widehat{p}_{\lambda,d}$, converges to 1 as $d\to\infty$. From this, the convergence of $p_{\lambda,d}$ directly follows, since $p_{\lambda,d} \geq \widehat{p}_{\lambda,d}$.

20. Betweenness centrality is computed on directed k-NN graphs. We obtained similar correlations when undirected graphs were used.

21. When betweenness centrality is computed on undirected graphs, the correlation is even stronger: 0.585.

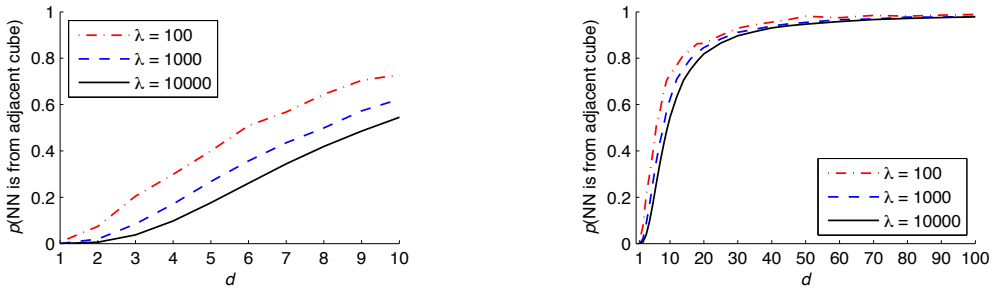


Figure 9: Probability that the nearest neighbor of a point from the unit hypercube originates from one of the adjacent hypercubes, for Poisson processes with $\lambda = 100$, 1000, and 10000 expected points per hypercube, obtained through simulation and averaged over 10 runs.

Let $\widehat{p}_{\lambda,d}(i)$ denote the probability that the nearest neighbor of $\mathbf{x}$ comes from one of the two hypercubes which differ from C only in the ith coordinate, $i \in \{1,2,\ldots,d\}$. For a given coordinate i and point $\mathbf{x}$, let the *1-dimensional nearest neighbor* of x_i denote the closest y_i value of all other points $\mathbf{y}$ from the Poisson process, observed when all coordinates except i are disregarded. Conversely, for a given coordinate i and point $\mathbf{x}$, let the $(d-1)$*-dimensional nearest neighbor* of $(x_1,\ldots,x_{i-1},x_{i+1},\ldots,x_d)$ denote the closest point $(y_1,\ldots,y_{i-1},y_{i+1},\ldots,y_d)$, obtained when coordinate i is disregarded.

Observing the ith coordinate only, the probability for the 1-dimensional nearest neighbor of x_i to come from one of the surrounding unit intervals is $\widehat{p}_{\lambda,1}$. Although small, $\widehat{p}_{\lambda,1} > 0$. Assuming this event has occurred, let $\mathbf{y} \in \mathbb{R}^d$ be the point whose component y_i is the 1-dimensional nearest neighbor of x_i that is not within the unit interval containing x_i. Let r_λ denote the probability that the remaining coordinates of $\mathbf{y}$, $(y_1,\ldots,y_{i-1},y_{i+1},\ldots,y_d)$, constitute a $(d-1)$-dimensional nearest neighbor of $(x_1,\ldots,x_{i-1},x_{i+1},\ldots,x_d)$, within the confines of C. It can be observed that r_λ is strictly greater than 0, inversely proportional to λ (roughly equaling $1/(\lambda-1)$), and independent of d. Thus, $\widehat{p}_{\lambda,d}(i) \geq \widehat{p}_{\lambda,1} \cdot r_\lambda > 0$.

Let $\widehat{q}_{\lambda,d} = 1 - \widehat{p}_{\lambda,d}$, the probability that the nearest neighbor of $\mathbf{x}$ comes from C (recall the restriction of the location of the nearest neighbor to C and its immediately surrounding $2d$ hypercubes). In light of the above, $\widehat{q}_{\lambda,d} = \prod_{i=1}^{d} \widehat{q}_{\lambda,d}(i) = \prod_{i=1}^{d} (1 - \widehat{p}_{\lambda,d}(i))$. Since each $\widehat{p}_{\lambda,d}(i)$ is bounded from below by a constant strictly greater than 0 (which depends only on λ), each $\widehat{q}_{\lambda,d}(i)$ is bounded from above by a constant strictly smaller than 1. It follows that $\lim_{d\to\infty} \widehat{q}_{\lambda,d} = 0$, and therefore $\lim_{d\to\infty} \widehat{p}_{\lambda,d} = 1$. ■

To illustrate the rate of convergence in Lemma 13, Figure 9 plots the empirically observed probabilities that the nearest neighbor of a point from a unit hypercube originates in one of the $2d$ immediately adjacent unit hypercubes ($\widehat{p}_{\lambda,d}$). It can be seen that the probability that the nearest neighbor comes from outside of the cube quickly becomes close to 1 as dimensionality increases. Please note that due to feasibility of simulation the plots in Figure 9 represent the empirical lower bounds (that is, the empirical estimates of $\widehat{p}_{\lambda,d}$) of the true probabilities from Lemma 13 ($p_{\lambda,d}$) by considering only the $2d$ immediately adjacent hypercubes.

The above indicates that when boundaries are introduced in high dimensions, the setting completely changes, in the sense that new nearest neighbors need to be located inside the boundaries. Under such circumstances, points which are closer to the center have a better chance of becoming nearest neighbors, with the mechanism described in previous sections. Another implication of the above observations, stemming from Figure 9, is that the number of dimensions does not need to be very large compared to the number of points for the setting to change. As for boundaries, they can be viewed as a dual notion to spatial centrality discussed earlier. With Poisson processes and cubes this duality is rather straightforward, however for continuous distributions in general there exist no boundaries in a strict mathematical sense. Nevertheless, since data sets contain a finite number of points, it can be said that "practical" boundaries exist in this case as well.

6. Hubness and Dimensionality Reduction

In this section we elaborate further on the interplay of skewness of N_k and intrinsic dimensionality by considering dimensionality-reduction (DR) techniques. The main question motivating the discussion in this section is whether dimensionality reduction can alleviate the issue of the skewness of k-occurrences altogether. We leave a more detailed and general investigation of the interaction between hubness and dimensionality reduction as a point of future work.
