Third, in many situations, $\mathbf{x}_i$ are not directly available. Instead, the product between the data matrix X and a vector can be efficiently obtained through certain operators. We briefly review some of the many optimization methods for least-square regression. If we use formulation (14) with non-smooth constraints, the problem reduces to LASSO proposed by Tibshirani (1996) and some early optimization studies include, for example, Fu (1998) and Osborne et al. (2000a,b). Fu (1998) applied a cyclic coordinate descent method. For least-square loss, the minimization of the one-variable sub-problem (11) has a closed-form solution. Sardy et al. (2000) also considered coordinate descent methods, although they allowed a block of variables at each iteration. Wu and Lange (2008) considered a coordinate descent method, but used the gradient information for selecting the working variable at each iteration. Osborne et al. (2000a) reported one of the earliest active set methods for L1-regularized problems. Roth's (2004) method for general losses (see Section 2.2.2) reduces to this method if the least-square loss is used. Friedman et al. (2007) extended Fu's coordinate descent method to find a solution path. Donoho and Tsaig (2008) also obtained a solution path. Their procedure requires solving a linear system of a matrix $X_{:,J}^T X_{:,J}$, where J is a subset of $\{1,\ldots,n\}$. Figueiredo et al. (2007) transformed the regression problem to a bound-constrained formula in (12) and applied a projected gradient method. Wright et al. (2009) proposed the iterative minimization of the sum of the L1 regularization term and a quadratic approximation of the loss term. In the quadratic approximation, they used a diagonal matrix instead of the Hessian of the loss term, and therefore, the minimization can be easily carried out. Hale et al. (2008) proposed a fixed point method to solve (1) with the least-square loss (16). Their update rule is generated from a fixed-point view; however, it is very similar to a gradient projection algorithm.

The dual of LASSO and the dual of (1) have been discussed in Osborne et al. (2000b) and Kim et al. (2007), respectively. However, thus far, there have been few optimization methods for the dual problem. Tomioka and Sugiyama (2009) proposed a dual augmented Lagrangian method for L1-regularized least-square regression that theoretically converges super-linearly.

Most optimization methods for classification discussed in the earlier sections can handle general smooth loss functions, and therefore, they can be applied to the regression problem. However, data for classification applications may be very different from those for regression applications. For example, in text classification, the numbers of instances and features are both large and data are very sparse. However, in certain signal processing applications, the number of instances may be much smaller than the number of features (i.e., $l \ll n$) and the data may be dense. Moreover, in classification, the parameter C is often selected by cross validation; however, in signal processing, the selection may be application dependent. Few optimization studies have investigated both types

of applications. The interior point method for logistic regression by solving (13) has been applied to the least-square regression problem (Kim et al., 2007). Duchi et al. (2008) compared their gradient projection implementation (see Section 2.2.2) with interior point methods using both logistic and least-square losses. In Section 2.1.2, we mentioned a decomposition method CGD-GS by Yun and Toh (2009). In the same paper, Yun and Toh have also investigated the performance of CGD-GS on regression problems.

In this paper, we focus on data classification, and therefore, our conclusions may not apply to regression applications. In particular, the efficient calculation between X and a vector in some signal processing applications may afford advantages to some optimization methods.

3. Methods and Software Included for Comparison

In the rest of this paper, we compare some state-of-the-art software BBR, SCD, CGD-GS, IPM, BMRM, OWL-QN, Lassplore and GLMNET. We further develop two efficient implementations. One is a coordinate descent method (CDN) and the other is a trust region Newton method (TRON). These packages are selected because of two reasons. First, they are publicly available. Second, they are able to handle large and sparse data sets. We categorize these packages into three groups:

- decomposition methods,
- methods by solving constrained optimization problems,
- other methods,

and describe their algorithms in Sections 4–6. The comparison results are described in Sections 8. Note that classification (logistic regression and L2-loss SVMs) is our focus, and therefore, software for regression problems using the least-square loss (16) is not considered.

4. Decomposition Methods

This section discusses three methods sequentially or randomly choosing variables for update, and one method using gradient information for the working set selection.

4.1 Cyclic Coordinate Descent Methods

From the current solution $\mathbf{w}^k$, a coordinate descent method updates one variable at a time to generate $\mathbf{w}^{k,j} \in R^n,\ j = 1,\ldots,n+1$, such that $\mathbf{w}^{k,1} = \mathbf{w}^k$, $\mathbf{w}^{k,n+1} = \mathbf{w}^{k+1}$, and

$$\mathbf{w}^{k,j} = \left[w_1^{k+1},\ldots,w_{j-1}^{k+1},w_j^k,\ldots,w_n^k\right]^T \text{ for } j = 2,\ldots,n.$$

To update $\mathbf{w}^{k,j}$ to $\mathbf{w}^{k,j+1}$, the following one-variable optimization problem is solved:

$$\min_z \quad g_j(z) = |w_j^{k,j} + z| - |w_j^{k,j}| + L_j(z;\mathbf{w}^{k,j}) - L_j(0;\mathbf{w}^{k,j}), \tag{17}$$

where

$$L_j(z;\mathbf{w}^{k,j}) \equiv L(\mathbf{w}^{k,j} + z\mathbf{e}_j).$$

Algorithm 1 A framework of coordinate descent methods

1. Given $\mathbf{w}^1$.
2. For $k = 1, 2, 3, \ldots$ (outer iterations)
   (a) $\mathbf{w}^{k,1} = \mathbf{w}^k$.
   (b) For $j = 1, 2, \ldots, n$ (inner iterations)
      - Find d by solving the sub-problem (17) exactly or approximately.
      - $\mathbf{w}^{k,j+1} = \mathbf{w}^{k,j} + d\mathbf{e}_j$.
   (c) $\mathbf{w}^{k+1} = \mathbf{w}^{k,n+1}$.

For simplicity, hereafter, we use $L_j(z)$ in most places. If the solution of (17) is d, then we update the jth element by

$$w_j^{k,j+1} = w_j^{k,j} + d.$$

Typically, a coordinate descent method sequentially goes through all variables and then repeats the same process; see the framework in Algorithm 1. We refer to the process of updating every n elements (i.e., from $\mathbf{w}^k$ to $\mathbf{w}^{k+1}$) as an outer iteration and the step of updating one element (i.e., from $\mathbf{w}^{k,j}$ to $\mathbf{w}^{k,j+1}$) as an inner iteration. Practically, we only approximately solve (17), where several approaches are discussed below.

Using the same way to obtain the optimality condition in (6), for the one-variable function $g_j(z)$, we have that $z = 0$ is optimal for (17) if and only if

$$\begin{cases} L_j'(0) + 1 = 0 & \text{if } w_j^{k,j} > 0, \\ L_j'(0) - 1 = 0 & \text{if } w_j^{k,j} < 0, \\ -1 \le L_j'(0) \le 1 & \text{if } w_j^{k,j} = 0. \end{cases} \tag{18}$$

The optimality condition at $z = 0$ shows if modifying $w_j^{k,j}$ may decrease the function value or not.

4.1.1 BBR

Genkin et al. (2007) propose a coordinate descent method BBR for (1) and (5) with logistic loss. This method is extended from Zhang and Oles (2001) for L2-regularized logistic regression. At each inner iteration, BBR approximately solves the sub-problem (17) by a trust region Newton method. With the trust region Δ_j, it requires the step z to satisfy

$$|z| \le \Delta_j \quad \text{and} \quad w_j^{k,j} + z \begin{cases} \ge 0 & \text{if } w_j^{k,j} > 0, \\ \le 0 & \text{if } w_j^{k,j} < 0. \end{cases} \tag{19}$$

The first constraint confines the step size to be in the trust region and Δ_j is updated at the end of each inner iteration. Due to the non-differentiable point at $z = -w_j^{k,j}$, the second constraint ensures that the function is differentiable in the search space.

To approximately solve (17), BBR minimizes a quadratic function upper-bounding the function $g_j(z)$ in the trust region. Though $g_j(z)$ is not differentiable, by considering both cases of $w_j^{k,j} > 0$ and $w_j^{k,j} < 0$, we obtain the following form:

$$g_j(z) = g_j(0) + g_j'(0)z + \frac{1}{2} g_j''(\eta z) z^2, \tag{20}$$

where $0 < \eta < 1$,

$$g'_j(0) \equiv \begin{cases} L'_j(0)+1 & \text{if } w_j^{k,j} > 0, \\ L'_j(0)-1 & \text{if } w_j^{k,j} < 0, \end{cases} \text{ and } g''_j(\eta z) \equiv L''_j(\eta z). \tag{21}$$

Notice that when $w_j^{k,j} = 0$, $g_j(z)$ is non-differentiable at $z = 0$ and $g'_j(0)$ is not well-defined. We will discuss this situation later. BBR finds an upper bound U_j of $g''_j(z)$ such that

$$U_j \geq g''_j(z),\ \forall |z| \leq \Delta_j.$$

Then $\hat{g}_j(z)$ is an upper-bound function of $g_j(z)$:

$$\hat{g}_j(z) \equiv g_j(0) + g'_j(0)z + \frac{1}{2}U_j z^2.$$

Any step z satisfying $\hat{g}_j(z) < \hat{g}_j(0)$ leads to

$$g_j(z) - g_j(0) = g_j(z) - \hat{g}_j(0) \leq \hat{g}_j(z) - \hat{g}_j(0) < 0,$$

so the function value is decreased. If logistic loss (2) is used, BBR suggests setting U_j as

$$U_j \equiv C \sum_{i=1}^{l} x_{ij}^2 F\left(y_i (\mathbf{w}^{k,j})^T \mathbf{x}_i, \Delta_j |x_{ij}|\right), \tag{22}$$

where

$$F(r,\delta) = \begin{cases} 0.25 & \text{if } |r| \leq \delta, \\ \frac{1}{2+e^{(|r|-\delta)}+e^{(\delta-|r|)}} & \text{otherwise.} \end{cases}$$

If $w_j^{k,j} \neq 0$, BBR minimizes $\hat{g}_j(z)$ under the constraints (19) to obtain

$$d = \min\left(\max\left(P(-\frac{g'_j(0)}{U_j}, w_j^{k,j}), -\Delta_j\right), \Delta_j\right), \tag{23}$$

where

$$P(z,w) \equiv \begin{cases} z & \text{if } \operatorname{sgn}(w+z) = \operatorname{sgn}(w), \\ -w & \text{otherwise.} \end{cases}$$

Now consider the case of $w_j^{k,j} = 0$, where $g'_j(0)$ is not well-defined at this point. If $L'_j(0)+1 < 0$, by defining $g'_j(0) \equiv L'_j(0)+1$, any $0 < z \leq -g'_j(0)/U_j$ gives a smaller $\hat{g}_j(z)$ than $\hat{g}_j(0)$. We thus obtain the new point by mapping $-g'_j(0)/U_j$ back to the trust region. The situation for $L'_j(0)-1 > 0$ is similar. We do not need to handle the situation $-1 \leq L'_j(0) \leq 1$ as (18) and $w_j^{k,j} = 0$ indicate that $z = 0$ is the minimum of $g_j(z)$.

The procedure of BBR to approximately solve (17) is described in Algorithm 2. The major cost is on calculating $g'_j(0)$ and U_j. For logistic loss, $L'_j(0)$ needed for calculating $g'_j(0)$ is

$$L'_j(0) = C \sum_{i=1}^{l} y_i x_{ij} \left(\tau(y_i (\mathbf{w}^{k,j})^T \mathbf{x}_i) - 1\right), \tag{24}$$

Algorithm 2 BBR: Approximately solving the sub-problem by a trust region method

1. Given $\mathbf{w}^{k,j}$ and Δ_j.
2. Calculate U_j by (22).
3. Find a step d by (23).
4. Update Δ_j by $\Delta_j \leftarrow \max(2|d|, \Delta_j/2)$.

where $\tau(\cdot)$ is defined in (9). From (22) and (24), the most expensive operation is on obtaining $\mathbf{w}^T\mathbf{x}_i$, $\forall i$. A common trick for saving the running time is to store $\mathbf{w}^T\mathbf{x}_i$, $\forall i$ and update them according to

$$\mathbf{w}^T\mathbf{x}_i \leftarrow \mathbf{w}^T\mathbf{x}_i + d \cdot x_{ij}. \tag{25}$$

If $\mathbf{w}^T\mathbf{x}_i$, $\forall i$ are available, both (22) and (24) need $O(l)$ operations. Because maintaining $\mathbf{w}^T\mathbf{x}_i$ via (25) also takes $O(l)$, the cost per inner iteration is $O(l)$.

Unfortunately, there is no convergence proof yet for the method BBR.

4.1.2 COORDINATE DESCENT METHOD USING ONE-DIMENSIONAL NEWTON DIRECTIONS (CDN)

BBR replaces the second derivative term in (20) with an upper bound U_j. If we keep using $g_j''(0)$ and obtain the one-dimensional Newton direction at $z = 0$, the local convergence may be faster. This issue has been studied in L2-regularized logistic regression/SVMs, where BBR reduces to the approach by Zhang and Oles (2001), and Chang et al. (2008) showed that a coordinate descent method using one-dimensional Newton directions is faster. Here, we extend Chang et al.'s method for L1-regularized problems. The new approach, referred to as CDN, is expected to be faster than BBR following a similar reason.

A Newton direction is obtained from minimizing the second-order approximation, but $g_j(z)$ is not differentiable due to the L1-regularization term. Thus, we consider only the second-order approximation of the loss term $L_j(z)$ and solve

$$\min_z \quad |w_j^{k,j} + z| - |w_j^{k,j}| + L_j'(0)z + \frac{1}{2}L_j''(0)z^2. \tag{26}$$

This problem can be reduced to a form commonly referred to as "soft-thresholding" in signal processing. We show in Appendix B that (26) has the following closed-form solution:

$$d = \begin{cases} -\frac{L_j'(0)+1}{L_j''(0)} & \text{if } L_j'(0)+1 \le L_j''(0)w_j^{k,j}, \\ -\frac{L_j'(0)-1}{L_j''(0)} & \text{if } L_j'(0)-1 \ge L_j''(0)w_j^{k,j}, \\ -w_j^{k,j} & \text{otherwise.} \end{cases} \tag{27}$$

Because (26) is only a quadratic approximation of $f(\mathbf{w}^{k,j} + z\mathbf{e}_j) - f(\mathbf{w}^{k,j})$, the direction d may not ensure the decrease of the function value. For the convergence, Chang et al. (2008) consider a line search procedure to find $\lambda \in (0,1)$ such that the step λd satisfies the sufficient decrease condition:

$$f(\mathbf{w}^{k,j} + \lambda d\mathbf{e}_j) - f(\mathbf{w}^{k,j}) = g_j(\lambda d) - g_j(0) \le -\sigma(\lambda d)^2,$$

where σ is any constant in $(0,1)$. However, as pointed out by Tseng and Yun (2007), this condition may not be suitable here due to the non-smooth regularization term $\|\mathbf{w}\|_1$. We follow Tseng and

Algorithm 3 CDN: Approximately solving the sub-problem by Newton directions with line search

1. Given $\mathbf{w}^{k,j}$. Choose $\beta \in (0,1)$.
2. Calculate the Newton direction d by (27).
3. Compute $\lambda = \max\{1, \beta, \beta^2, \dots\}$ such that λd satisfies (28).

Yun (2007) to use a modified condition:

$$g_j(\lambda d) - g_j(0) \le \sigma\lambda \left(L_j'(0)d + |w_j^{k,j} + d| - |w_j^{k,j}| \right). \tag{28}$$

To find λ, CDN adopts a backtrack line search to sequentially check $\lambda = 1,\ \beta,\ \beta^2,\ \dots$, where $\beta \in (0,1)$, until λd satisfies (28). A description of how CDN approximately solves the sub-problem (17) is in Algorithm 3.

In Appendix D, we explain that Algorithm 3 falls into a class of Gauss-Seidel coordinate descent methods in Tseng and Yun (2007). By showing that all required assumptions are satisfied, we can directly enjoy some nice theoretical properties. First, following Lemma 3.4(b) in Tseng and Yun (2007), the line search procedure stops in a finite number of steps. Second, for (1) with logistic loss, any limit point of $\{\mathbf{w}^k\}$ is an optimum.

We discuss the computational cost. To obtain the sub-problem (26), we must calculate $L_j'(0)$ and $L_j''(0)$. For logistic loss, $L_j'(0)$ is shown in (24) and

$$L_j''(0) = C \sum_{i=1}^{l} x_{ij}^2 \left(\tau(y_i(\mathbf{w}^{k,j})^T \mathbf{x}_i) \right) \left(1 - \tau(y_i(\mathbf{w}^{k,j})^T \mathbf{x}_i) \right). \tag{29}$$

Similar to the situation in BBR, calculating $\mathbf{w}^T\mathbf{x}_i,\ \forall i$ is the major cost here. We can apply the same trick in (25) to maintain $\mathbf{w}^T\mathbf{x}_i,\ \forall i$. In our implementation, we maintain $e^{\mathbf{w}^T\mathbf{x}_i}$ instead:

$$e^{\mathbf{w}^T\mathbf{x}_i} \leftarrow e^{\mathbf{w}^T\mathbf{x}_i} \cdot e^{\lambda d x_{ij}}. \tag{30}$$

The line search procedure needs to calculate $g_j(\lambda d)$. From (2), the main cost is still on obtaining $(\mathbf{w} + \lambda d\mathbf{e}_j)^T\mathbf{x}_i,\ \forall i$, so the trick in (30) is again useful. If $e^{\mathbf{w}^T\mathbf{x}_i},\ \forall i$ are available, from (24), (29) and (2), the cost per inner iteration is

$$(1 + \#\text{ line search steps}) \times O(l).$$

To reduce the cost for line search, Chang et al. (2008) obtain a function $\hat{g}_j(\cdot)$ satisfying $\hat{g}_j(\lambda d) > g_j(\lambda d)$ and check $\hat{g}_j(\lambda d) - g_j(0)$ in (28). Calculating $\hat{g}_j(\lambda d)$ is much easier than $g_j(\lambda d)$, so we may avoid calculating the last $g_j(\lambda d)$ in the line search procedure. In some iterations, $\lambda = 1$ already satisfies (28), and therefore, this trick makes the cost of the line search procedure negligible. We do not show details here; however, derivations can be found in Fan et al. (2008, Appendix G).

Next we describe two implementation techniques to improve the convergence speed. The first one is to use a random permutation of sub-problems. In Algorithm 1, we cyclically consider variables to form one-variable sub-problems. Chang et al. (2008) show that solving sub-problems in a random order may lead to faster convergence. That is, at the kth iteration, we randomly permute $\{1, 2, \dots, n\}$ to $\{\pi_k(1), \pi_k(2), \dots, \pi_k(n)\}$ and update the elements of $\mathbf{w}$ in the order of $\{w_{\pi_k(1)}, w_{\pi_k(2)}, \dots, w_{\pi_k(n)}\}$.

The second implementation technique is shrinking. Past works such as Hsieh et al. (2008), Joachims (1998), and Krishnapuram et al. (2005, Section 3.5) heuristically remove some variables to obtain a smaller optimization problem. If w_j has remained zero at many iterations, it is very possible that the optimal w_j^* is also zero. Therefore, we can remove such variables. Our shrinking implementation is related to that in the software LIBSVM (Chang and Lin, 2001). From the optimality condition (6),

$$-1 < \nabla_j L(\mathbf{w}^*) < 1 \quad \text{implies} \quad w_j^* = 0. \tag{31}$$

We prove in Appendix C the following theorem:

Theorem 1 *Assume $\{\mathbf{w}^k\}$ globally converges to $\mathbf{w}^*$. If $-1 < \nabla_j L(\mathbf{w}^*) < 1$, then there is K_j such that for all $k \geq K_j$,*

$$-1 < \nabla_j L(\mathbf{w}^{k,j}) < 1 \quad \textit{and} \quad w_j^{k,j} = 0.$$

Using this theorem, we design the following shrinking strategy. Before updating $w_j^{k,j}$ via approximately solving the sub-problem (17), if

$$w_j^{k,j} = 0 \quad \text{and} \quad -1 + M^{k-1} < \nabla_j L(\mathbf{w}^{k,j}) < 1 - M^{k-1}, \tag{32}$$

we conjecture that $w_j^{k,j}$ may remain zero and hence remove it for optimization. We choose

$$M^{k-1} \equiv \frac{\max_j v_j}{l},$$

where

$$v_j \equiv \begin{cases} |\nabla_j L(\mathbf{w}^{k-1,j}) + 1| & \text{if } w_j^{k-1,j} > 0, \\ |\nabla_j L(\mathbf{w}^{k-1,j}) - 1| & \text{if } w_j^{k-1,j} < 0, \\ \max\left(\nabla_j L(\mathbf{w}^{k-1,j}) - 1,\ -1 - \nabla_j L(\mathbf{w}^{k-1,j}),\ 0\right) & \text{if } w_j^{k-1,j} = 0, \end{cases}$$

From (6), $v_j, j = 1, \ldots, n$ measure the violation of the optimality condition at the $(k-1)$st iteration. The value M^{k-1} reflects how aggressive we remove variables. It is large in the beginning, but approaches zero in the end.

The shrinking implementation introduces little extra cost. When updating the jth component at the kth iteration, we calculate

$$\nabla_j L(\mathbf{w}^{k,j}) = L_j'(0; \mathbf{w}^{k,j})$$

for the direction d in (27), regardless of implementing shrinking or not. Thus, $\nabla_j L(\mathbf{w}^{k,j})$ needed for checking (32) is already available. Moreover, it can be used to calculate v_j and M^k, which are needed for the next iteration.

4.1.3 STOCHASTIC COORDINATE DESCENT METHOD (SCD)

Shalev-Shwartz and Tewari (2009) propose a stochastic coordinate descent method (SCD) to solve the bound-constrained problem in (12). At the kth iteration, SCD randomly chooses a working variable from $\{w_1^+, \ldots, w_n^+, w_1^-, \ldots, w_n^-\}$. The one-variable sub-problem is

$$\min_z \quad g_j(z) \equiv z + L_j(z; \mathbf{w}^{k,+} - \mathbf{w}^{k,-}) - L_j(0; \mathbf{w}^{k,+} - \mathbf{w}^{k,-}),$$

Algorithm 4 SCD for L1-regularized logistic regression

1. Given $(\mathbf{w}^+, \mathbf{w}^-)$ and $U_j > 0$.
2. While $(\mathbf{w}^+, \mathbf{w}^-)$ is not optimal for (12)
   (a) Select an element from $\{w_1^+, \ldots, w_n^+, w_1^-, \ldots, w_n^-\}$.
   (b) Update w_j^+ or w_j^- by (36)–(37).

subject to the non-negativity constraint

$$w_j^{k,+} + z \geq 0 \quad \text{or} \quad w_j^{k,-} + z \geq 0,$$

according to whether w_j^+ or w_j^- is the working variable. SCD considers a second-order approximation similar to BBR:

$$\hat{g}_j(z) = g_j(0) + g_j'(0)z + \frac{1}{2}U_j z^2, \tag{33}$$

where

$$g_j'(0) = \begin{cases} 1 + L_j'(0) & \text{for } w_j^+ \\ 1 - L_j'(0) & \text{for } w_j^- \end{cases} \quad \text{and} \quad U_j \geq g_j''(z),\ \forall z.$$

BBR considers U_j to be an upper bound of $g_j''(z)$ only in the trust region, while SCD finds a global upper bound of $g_j''(z)$. For logistic regression, following (9) and (29), we have $\tau(\cdot)\,(1-\tau(\cdot)) \leq 0.25$ and

$$U_j = 0.25C \sum_{i=1}^{l} x_{ij}^2 \geq g_j''(z),\ \forall z. \tag{34}$$

Shalev-Shwartz and Tewari (2009) assume $-1 \leq x_{ij} \leq 1,\ \forall i, j$, so a simpler upper bound is

$$U_j = 0.25Cl. \tag{35}$$

Using the direction obtained by minimizing (33) and taking the non-negativity into consideration, SCD updates $\mathbf{w}$ by the following way:

If w_j^+ is selected

$$w_j^+ \leftarrow w_j^+ + \max(-w_j^+,\ -\frac{1 + L_j'(0)}{U_j}) \tag{36}$$

Else

$$w_j^- \leftarrow w_j^- + \max(-w_j^-,\ -\frac{1 - L_j'(0)}{U_j}) \tag{37}$$

A description of SCD is in Algorithm 4.

4.2 CGD-GS: a Decomposition Method Using Gradients for Selecting Variables

Instead of updating one variable at a time, some decomposition methods choose a larger working set $J \subset N \equiv \{1, \ldots, n\}$. We discuss a Gauss-Southwell method for selecting J (Tseng and Yun, 2007; Yun and Toh, 2009). This method, referred to as CGD-GS, can handle any smooth loss function including $\xi_{\log}$.

Following the principle of decomposition methods, if $\mathbf{w}^k$ is the current solution and J is the set of working variables, one should solve the following sub-problem:

$$\begin{aligned} \min_{\mathbf{d}} \quad & L(\mathbf{w}^k+\mathbf{d})-L(\mathbf{w}^k)+\|\mathbf{w}^k+\mathbf{d}\|_1-\|\mathbf{w}^k\|_1 \\ \text{subject to} \quad & d_j=0,\ \forall j\notin J. \end{aligned}$$

Because it is still difficult to solve this sub-problem, CGD-GS considers a quadratic approximation of the loss term:

$$\begin{aligned} \min_{\mathbf{d}} \quad & q_k(\mathbf{d}) \equiv \nabla L(\mathbf{w}^k)^T\mathbf{d}+\frac{1}{2}\mathbf{d}^T H\mathbf{d}+\|\mathbf{w}^k+\mathbf{d}\|_1-\|\mathbf{w}^k\|_1 \\ \text{subject to} \quad & d_j=0,\ \forall j\notin J, \end{aligned} \tag{38}$$

where H is either $\nabla^2 L(\mathbf{w}^k)$ or its approximation. To ensure the convergence, CGD-GS conducts a backtrack line search to find λ such that $\lambda\mathbf{d}$ satisfies

$$f(\mathbf{w}^k+\lambda\mathbf{d})-f(\mathbf{w}^k)\le\sigma\lambda\left(\nabla L(\mathbf{w}^k)^T\mathbf{d}+\gamma\mathbf{d}^T H\mathbf{d}+\|\mathbf{w}^k+\mathbf{d}\|_1-\|\mathbf{w}^k\|_1\right), \tag{39}$$

where $0<\sigma<1$ and $0\le\gamma<1$. This condition is the same as (28) if $\gamma=0$ and J contains only one element. Tseng and Yun (2007) used (39) for both the cyclic selection (Gauss-Seidel) or the selection using gradient information (Gauss-Southwell).

For selecting J using gradients, Tseng and Yun (2007) proposed two possible ways. The first one, referred to as the Gauss-Southwell-r rule, requires J to satisfy

$$\|\mathbf{d}(J)\|_\infty\ge v\|\mathbf{d}(N)\|_\infty, \tag{40}$$

where $v\in(0,1)$ is a constant and $\mathbf{d}(J)$ and $\mathbf{d}(N)$ are the solution of (38) by considering J and N as the working set, respectively. This condition connects the directions of solving sub-problems using a subset and a full set. The other condition for selecting J is

$$q_k(\mathbf{d}(J))\le v\cdot q_k(\mathbf{d}(N)), \tag{41}$$

where $v\in(0,1)$ and $q_k(\mathbf{d})$ is defined in (38). This condition is referred to as the Gauss-Southwell-q rule. Algorithm 5 summarizes the procedure.

The remaining issues are how to solve the sub-problem (38) and how to obtain J satisfying (40) or (41). The CGD-GS implementation considers a diagonal matrix with positive entries as H. For example, $H_{jj}=\max(\nabla^2_{jj}L(\mathbf{w}^k),\varepsilon)$, where ε is a small positive value. Then, the sub-problem becomes $|J|$ separable one-variable problems like (26). Each one-variable problem has a simple closed-form solution. Further, it is easy to find indices satisfying (40) or (41). For example, the rule (40) becomes to find the larger elements of $\mathbf{d}(N)$. Tseng and Yun (2007) proved that any limit point of $\{\mathbf{w}^k\}$ is an optimum of (1).

We discuss the computational cost for logistic regression. If H is diagonal, then solving (38) takes only $O(|J|)$ operations. Constructing (38) is more expensive because we need to calculate

$$\nabla L(\mathbf{w})=C\sum_{i=1}^{l}\big(\tau(y_i\mathbf{w}^T\mathbf{x}_i)-1\big)y_i\mathbf{x}_i. \tag{42}$$

Yun and Toh (2009) apply a trick similar to (30) and maintain $e^{\mathbf{w}^T\mathbf{x}_i}$, $\forall i$, but the gradient calculation still needs $O(ln)$. This high cost may not pay off, and therefore, Hsieh et al. (2008) favor decomposition methods without maintaining the gradient. Finding the working set J is another potentially expensive step, but it is cheap for a diagonal H.

Algorithm 5 CGD-GS for L1-regularized logistic regression

1. Given $\mathbf{w}^1$. Choose (40) or (41) as the strategy for selecting working sets. Given $0 < \beta, \sigma < 1$ and $0 \le \gamma < 1$.
2. For $k = 1, 2, 3, \ldots$
   - Choose an H and a working set J.
   - Get $\mathbf{d}^k$ by solving the sub-problem (38).
   - Compute $\lambda = \max\{1, \beta, \beta^2, \ldots\}$ such that $\lambda \mathbf{d}^k$ satisfies (39).
   - $\mathbf{w}^{k+1} = \mathbf{w}^k + \lambda \mathbf{d}^k$.

5. Methods by Solving Constrained Optimization Problems

Section 2.2 lists several methods for L1-regularized classification by solving the bound-constrained problems (12), (13), and (14). In this section, we discuss TRON, IPM, and Lassplore in detail.

5.1 A Trust Region Newton Method (TRON)

We apply the trust region Newton method in Lin and Moré (1999) to solve (12). A previous study of this method for L1-regularized logistic regression is by Lee (2008). For convenience, in this section, we slightly abuse the notation by redefining

$$\mathbf{w} \equiv \begin{bmatrix} \mathbf{w}^+ \\ \mathbf{w}^- \end{bmatrix} \in R^{2n}. \tag{43}$$

Then, problem (12) can be written in a general form of bounded-constrained problems:

$$\begin{aligned} \min_{\mathbf{w}} \quad & \bar{f}(\mathbf{w}) \\ \text{subject to} \quad & \mathbf{w} \in \Omega \equiv \{\mathbf{w} \mid l_j \le w_j \le u_j, \forall j\}, \end{aligned}$$

where $\bar{f}(\mathbf{w})$ denotes the objective function of (12), and $\mathbf{l}$ and $\mathbf{u}$ are lower and upper bounds, respectively.

At the kth iteration of the trust region Newton method, we have an iterate $\mathbf{w}^k$, a size Δ_k of the trust region, and a quadratic model

$$q_k(\mathbf{d}) \equiv \frac{1}{2}\mathbf{d}^T \nabla^2 \bar{f}(\mathbf{w}^k)\mathbf{d} + \nabla \bar{f}(\mathbf{w}^k)^T \mathbf{d}$$

to approximate the value $\bar{f}(\mathbf{w}^k + \mathbf{d}) - \bar{f}(\mathbf{w}^k)$. Next, we find a step $\mathbf{d}^k$ by approximately solving the following trust region problem

$$\begin{aligned} \min_{\mathbf{d}} \quad & q_k(\mathbf{d}) \\ \text{subject to} \quad & \|\mathbf{d}\| \le \Delta_k, \ \mathbf{w}^k + \mathbf{d} \in \Omega. \end{aligned} \tag{44}$$

We then update $\mathbf{w}^k$ and Δ_k by checking the ratio

$$\rho_k = \frac{\bar{f}(\mathbf{w}^k + \mathbf{d}^k) - \bar{f}(\mathbf{w}^k)}{q_k(\mathbf{d}^k)} \tag{45}$$

Algorithm 6 A trust region method for L1-regularized logistic regression

1. Given $\mathbf{w}^1$.
2. For $k = 1, 2, 3, \ldots$ (outer iterations)
   - Approximately solve (44) and obtain a direction $\mathbf{d}^k$; see Algorithm 7.
   - Compute ρ_k via (45).
   - Update $\mathbf{w}^k$ to $\mathbf{w}^{k+1}$ according to (46) and update Δ_k to Δ_{k+1}.

Algorithm 7 TRON: Finding a direction $\mathbf{d}^k$ by approximately solving (44)

1. Given $0 < \varepsilon < 1$. Find the Cauchy step $\mathbf{d}^{k,C}$ and the Cauchy point
$$\mathbf{w}^{k,1} = \mathbf{w}^k + \mathbf{d}^{k,C} \quad \text{and} \quad \mathbf{d}^{k,1} = \mathbf{d}^{k,C}.$$
2. For $t = 1, \ldots, 2n+1$ (inner iterations)
   - Find F_t and B_t (free/bounded sets) at $\mathbf{w}^{k,t}$ by (50).
   - If $F_t = \emptyset$, then stop and return $\mathbf{d}^k = \mathbf{w}^{k,t} - \mathbf{w}^k$.
   - Approximately solve
$$\begin{aligned} \min_{\mathbf{v}_{F_t}} \quad & q_k(\mathbf{d}^{k,t} + \mathbf{v}) \\ \text{subject to} \quad & \|\mathbf{d}^{k,t} + \mathbf{v}\| \le \Delta_k,\ \mathbf{v}_{B_t} = \mathbf{0}, \end{aligned}$$
     by Conjugate Gradient (CG) methods. Denote the solution as $\mathbf{v}^{k,t}$.
   - Projected line search on $\mathbf{w}^{k,t} + \lambda \mathbf{v}^{k,t}$ to obtain $\mathbf{w}^{k,t+1}$ and $\mathbf{d}^{k,t+1}$; see Equation (55). We ensure that $F_t \subset F_{t+1}$ and $|F_t| < |F_{t+1}|$.
   - If one of the following situations occurs:
$$\|\nabla q_k(\mathbf{d}^{k,t+1})_{F_t}\| \le \varepsilon \|\nabla \bar{f}(\mathbf{w}^k)_{F_t}\|,$$
     or CG abnormally stops (explained in text), then stop and return
$$\mathbf{d}^k = \mathbf{w}^{k,t+1} - \mathbf{w}^k.$$

of the actual reduction in the function to the predicted reduction in the quadratic model. The direction $\mathbf{d}^k$ is accepted if ρ_k is large enough:

$$\mathbf{w}^{k+1} = \begin{cases} \mathbf{w}^k + \mathbf{d}^k & \text{if } \rho_k > \eta_0, \\ \mathbf{w}^k & \text{if } \rho_k \le \eta_0, \end{cases} \tag{46}$$

where $\eta_0 > 0$ is a pre-specified value. The size Δ_k of the trust region is then updated according to the reduction of the function value. If the reduction is significant, then Δ_k is enlarged. Otherwise, we reduce Δ_k. More details can be found in Lin and Moré (1999). The framework of our trust region method is given in Algorithm 6. Earlier works applying trust region methods for L2-regularized problems include, for example, Lin et al. (2008). The algorithm here is more complicated due to the bound constraints.

5.1.1 CAUCHY POINT

A challenge for minimizing bound-constrained problems is to quickly identify bounded components at an optimal solution (i.e., components which are upper- or lower-bounded). Because each w_j can be either bounded or free, the number of combinations is exponential. One commonly used approach takes the negative gradient direction to obtain a new point and projects it back to the feasible region Ω. With a proper line search to ensure the reduction of the quadratic model $q_k(\mathbf{d})$, not only do we effectively guess the set of bounded components at an optimum, but also the convergence is guaranteed. To be more precise, we find a step size $\lambda > 0$ so that

$$q_k(\mathbf{d}^{k,C}) \le q_k(\mathbf{0}) + \sigma \nabla q_k(\mathbf{0})^T \mathbf{d}^{k,C} \quad \text{and} \quad \|\mathbf{d}^{k,C}\| \le \Delta_k, \tag{47}$$

where

$$\mathbf{d}^{k,C} = P[\mathbf{w}^k - \lambda \nabla \bar{f}(\mathbf{w}^k)] - \mathbf{w}^k \tag{48}$$

is called the Cauchy step in bound-constrained optimization and $\sigma \in (0, 1/2)$ is a constant. The projection operator $P[\cdot]$ maps $\mathbf{w}^k - \lambda \nabla \bar{f}(\mathbf{w}^k)$ back to the feasible region Ω:

$$P[w_j] = \min\left(u_j,\ \max(w_j, l_j)\right), \tag{49}$$

so some components become bounded. Although the negative gradient direction is projected in (48), the resulting direction is still a descending one (i.e., $\nabla q_k(\mathbf{0})^T \mathbf{d}^{k,C} < 0$). Hence, one can always find a small $\lambda > 0$ such that (47) is satisfied. The point $\mathbf{w}^{k,C} \equiv \mathbf{w}^k + \mathbf{d}^{k,C}$ is referred to as the Cauchy point.

5.1.2 NEWTON DIRECTION

Gradient descent methods suffer from slow convergence, so in (48) we should have used the Newton direction. However, the second-order information is accurate only if there are no bound constraints. Lin and Moré (1999) propose using Newton directions on the subspace of the Cauchy point's free components. Recall that we find the Cauchy point to predict the bounded elements at an optimum. We obtain the free/bounded sets at the Cauchy point

$$F \equiv F(\mathbf{w}^{k,C}) = \{j \mid l_j < w_j^{k,C} < u_j\} \quad \text{and} \quad B \equiv B(\mathbf{w}^{k,C}) = \{j \mid j \notin F\}, \tag{50}$$

and find a Newton direction on the space F by solving

$$\begin{aligned} \min_{\mathbf{v}_F} \quad & q_k(\mathbf{d}^{k,C} + \mathbf{v}) \\ \text{subject to} \quad & \|\mathbf{d}^{k,C} + \mathbf{v}\| \le \Delta_k,\ \mathbf{v}_B = \mathbf{0}. \end{aligned} \tag{51}$$

If the free set at the Cauchy point is close to that at an optimum, using a Newton direction on this sub-space leads to fast convergence.

Because (51) does not enforce the feasibility of $\mathbf{w}^{k,C} + \mathbf{v}$, one needs a projected line search procedure similar to (47)–(48). Details are shown later in (55). The resulting point may contain more bounded components than the Cauchy point. In this situation, Lin and Moré (1999) continue to minimize a quadratic approximation on the new sub-space. They thus generate inner iterates $\mathbf{w}^{k,1} = \mathbf{w}^{k,C}, \mathbf{w}^{k,2}, \mathbf{w}^{k,3}, \ldots$, until that the free/bounded sets do not change. If m inner iterations are taken, then the direction $\mathbf{d}^k$ for the kth trust region iteration in Algorithm 6 is

$$\mathbf{d}^k = \mathbf{w}^{k,m+1} - \mathbf{w}^k.$$

Details of our procedure are described in Algorithm 7. Because each inner iteration enlarges the bounded set, the number of inner iterations is bounded by $2n$, the number of variables. In practice, very few inner iterations (one or two) are taken. Another reason to take inner iterations is for the quadratic convergence proof in Lin and Moré (1999).

Let t be the inner-iteration index and B_t, F_t be bounded/free sets at $\mathbf{w}^{k,t}$. With $\mathbf{v}_{B_t} = \mathbf{0}$,

$$q_k(\mathbf{d}^{k,t}+\mathbf{v}) = \frac{1}{2}\mathbf{v}_{F_t}^T \nabla^2 \bar{f}(\mathbf{w}^k)_{F_t,F_t}\mathbf{v}_{F_t} + \nabla q_k(\mathbf{d}^{k,t})_{F_t}^T \mathbf{v}_{F_t} + q_k(\mathbf{d}^{k,t}), \tag{52}$$

so minimizing $q_k(\mathbf{d}^{k,t}+\mathbf{v})$ is equivalent to solving the following linear system

$$\nabla^2 \bar{f}(\mathbf{w}^k)_{F_t,F_t}\mathbf{v}_{F_t} = -\nabla q_k(\mathbf{d}^{k,t})_{F_t}. \tag{53}$$

To solve (53), we conduct conjugate gradient (CG) iterations until

$$\|\nabla^2 \bar{f}(\mathbf{w}^k)_{F_t,F_t}\mathbf{v}_{F_t} + \nabla q_k(\mathbf{d}^{k,t})_{F_t}\| = \|\nabla q_k(\mathbf{d}^{k,t+1})_{F_t}\| \le \varepsilon \|\nabla \bar{f}(\mathbf{w}^k)_{F_t}\| \tag{54}$$

is satisfied, where ε is a given positive constant. See Section 5.1.3 for reasons to choose CG. CG may stop before reaching (54) if either the iterate causes our search direction to exceed the trust region boundary or the singularity of the matrix $\nabla^2 \bar{f}(\mathbf{w}^k)_{F_t,F_t}$ is detected.

Once a direction $\mathbf{v}^{k,t}$ is identified, we conduct a projected line search to ensure the feasibility and the sufficient decrease of $q_k(\mathbf{d})$. This procedure is similar to (47)–(48) for the Cauchy step. We find λ (e.g., by a backtrack line search) such that

$$\begin{aligned} &\mathbf{w}^{k,t+1} = P[\mathbf{w}^{k,t} + \lambda \mathbf{v}^{k,t}],\ \mathbf{d}^{k,t+1} = \mathbf{w}^{k,t+1} - \mathbf{w}^k, \text{ and} \\ &q_k(\mathbf{d}^{k,t+1}) \le q_k(\mathbf{d}^{k,t}) + \sigma \nabla q_k(\mathbf{d}^{k,t})_{F_t}^T (\mathbf{d}^{k,t+1} - \mathbf{d}^{k,t})_{F_t}, \end{aligned} \tag{55}$$

where $P[\cdot]$ is defined in (49) and σ is the same as that in (47).

5.1.3 HESSIAN-VECTOR PRODUCT

CG is very suitable for solving the linear system (53) as it requires only Hessian-vector products. For logistic regression,

$$\nabla^2 \bar{f}(\mathbf{w})_{F_t,F_t} = C \begin{bmatrix} X^T \\ -X^T \end{bmatrix}_{F_t,:} D \begin{bmatrix} X & -X \end{bmatrix}_{:,F_t}, \tag{56}$$

where D is an $l \times l$ diagonal matrix with

$$D_{ii} = \tau\left(y_i(\mathbf{w}^+ - \mathbf{w}^-)^T \mathbf{x}_i\right)\left(1 - \tau(y_i(\mathbf{w}^+ - \mathbf{w}^-)^T \mathbf{x}_i)\right). \tag{57}$$

The matrix $\nabla^2 \bar{f}(\mathbf{w})_{F_t,F_t}$ may be too large to be stored. If using CG, the Hessian-vector product can be conducted by a sequence of matrix-vector products:

$$\nabla^2 \bar{f}(\mathbf{w}^{k,t})_{F_t,F_t}\mathbf{v}_{F_t} = C \begin{bmatrix} X^T \\ -X^T \end{bmatrix}_{F_t,:} \left(D\left(\begin{bmatrix} X & -X \end{bmatrix}_{:,F_t} \mathbf{v}_{F_t}\right)\right). \tag{58}$$

Thus, the memory problem is solved.

In Lin et al. (2008) for L2-regularized problems, Hessian-vector products are only needed in CG, but here they are also used in the projected line search for calculating $q_k(\mathbf{d}^{k,t+1}) - q_k(\mathbf{d}^{k,t})$; see (52) and (55). Moreover, in (58) we use only a sub-matrix of the Hessian, so $|F_t|$ columns of $\begin{bmatrix} X & -X \end{bmatrix}$ are needed. Because in general $|F_t|$ is smaller than the number of variables, calculating (58) may be faster than the product between the whole Hessian and a vector. To quickly access X's columns, storing the data matrix X in the column format is more suitable. For a discussion between row and column formats, see Lin et al. (2008, Section 4.3).

5.1.4 CONVERGENCE

From Theorem 2.1 of Lin and Moré (1999), any limit point of $\{\mathbf{w}^k\}$ is an optimum of (12). For the local convergence rate, in Appendix E, we indicate that in general TRON can achieve quadratic convergence.

5.2 An Interior Point Method (IPM)

Koh et al. (2007) proposed an interior point method to solve (13) with logistic loss. In (13), we omit the bias term b, but Koh et al. (2007) included this term. They consider a log barrier function so that $(\mathbf{w},\mathbf{u})$ is an interior point of the feasible region:

$$\phi_t(b,\mathbf{w},\mathbf{u}) \equiv t\left(\sum_{j=1}^{n} u_j + C\sum_{i=1}^{l}\xi(\mathbf{w},b;\mathbf{x}_i,y_i)\right) - \sum_{j=1}^{n}\log(u_j^2 - w_j^2),$$

where $t > 0$ is a parameter. The unique minimizer $(b^*(t),\mathbf{w}^*(t),\mathbf{u}^*(t))$ under any given t forms a curve called the "central path," which approaches an optimal solution of (13) as $t \to \infty$. An interior point method thus alternatively minimizes $\phi_t(b,\mathbf{w},\mathbf{u})$ and adjusts t. From a set of $(\mathbf{w},b)$ on the search path, we can construct a feasible solution to the dual problem of (13) and evaluate the duality gap. The duality gap is guaranteed to converge to 0 as we walk along the central path when $t \to \infty$. Thus, we can check the duality gap for the stopping condition.

At the kth iteration, using the current t_k, interior point methods approximately minimize $\phi_{t_k}(b,\mathbf{w},\mathbf{u})$ by finding a Newton direction. The following linear system is solved:

$$\nabla^2\phi_{t_k}(b^k,\mathbf{w}^k,\mathbf{u}^k)\begin{bmatrix}\Delta b\\ \Delta\mathbf{w}\\ \Delta\mathbf{u}\end{bmatrix} = -\nabla\phi_{t_k}(b^k,\mathbf{w}^k,\mathbf{u}^k). \tag{59}$$

For logistic loss,

$$\nabla\phi_t(b,\mathbf{w},\mathbf{u}) = \begin{bmatrix} tC\sum_{i=1}^{l} y_i\left(\tau(y_i(\mathbf{w}^T\mathbf{x}_i+b))-1\right)\\ tC\sum_{i=1}^{l}\left(\tau(y_i(\mathbf{w}^T\mathbf{x}_i+b))-1\right)y_i\mathbf{x}_i + \begin{bmatrix}2w_1/\left(u_1^2-w_1^2\right)\\ \vdots\\ 2w_n/\left(u_n^2-w_n^2\right)\end{bmatrix}\\ t\mathbf{e}_n - \begin{bmatrix}2u_1/\left(u_1^2-w_1^2\right)\\ \vdots\\ 2u_n/\left(u_n^2-w_n^2\right)\end{bmatrix}\end{bmatrix}$$

and

$$\nabla^2\phi_t(b,\mathbf{w},\mathbf{u}) = \begin{bmatrix} tC\mathbf{y}^TD\mathbf{y} & tC\mathbf{e}_l^TDX & \mathbf{0}^T\\ tCX^TD\mathbf{e}_l & tCX^TDX+D_1 & D_2\\ \mathbf{0} & D_2 & D_1\end{bmatrix},$$

where $\tau(\cdot)$ is defined in (9), $\mathbf{e}_n \in R^n$ and $\mathbf{e}_l \in R^l$ are the vectors of all ones, D is similar to (57) but includes b, and D_1 and D_2 are $n \times n$ diagonal matrices:

$$(D_1)_{jj} = 2\left(u_j^2+w_j^2\right)/\left(u_j^2-w_j^2\right)^2 \quad \text{and} \quad (D_2)_{jj} = -4u_jw_j/\left(u_j^2-w_j^2\right)^2.$$

Algorithm 8 IPM for L1-regularized logistic regression

1. Given b^1 and an interior point $(\mathbf{w}^1, \mathbf{u}^1)$. Let $t^1 = \frac{1}{Cl}$.
2. For $k = 1, 2, 3, \ldots$
   - Obtain a Newton direction $\begin{bmatrix} \Delta b \\ \Delta \mathbf{w} \\ \Delta \mathbf{u} \end{bmatrix}$ by solving (59).
   - A backtrack line search procedure to ensure the sufficient decrease of $\phi_{t_k}(\cdot)$
   - Update
   $$\begin{bmatrix} b^{k+1} \\ \mathbf{w}^{k+1} \\ \mathbf{u}^{k+1} \end{bmatrix} = \begin{bmatrix} b^k + \lambda \Delta b \\ \mathbf{w}^k + \lambda \Delta \mathbf{w} \\ \mathbf{u}^k + \lambda \Delta \mathbf{u} \end{bmatrix}.$$
   - Construct a dual feasible point and evaluate the duality gap η.
   - Set
   $$t^{k+1} = \begin{cases} \max\left(\mu \min(2n/\eta, t^k),\, t^k\right) & \text{if } \lambda \geq s_{\min}, \\ t^k & \text{otherwise,} \end{cases}$$
   where μ and $s_{\min}$ are constants.

Koh et al. (2007) apply preconditioned conjugate gradient methods (PCG) to solve (59) with diagonal preconditioning.

For the convergence, a backtrack line search procedure is needed to ensure the sufficient decrease of $\phi_{t_k}(\cdot)$. Koh et al. (2007) did not discuss details of their method's convergence. However, because interior point methods are a type of Newton methods, they often enjoy fast local convergence.

5.3 Lassplore Method

Liu et al. (2009) apply Nesterov's method (Nesterov, 2003) to solve (14). This method can handle (14) with and without the bias term. For simplicity, we do not consider the bias term. In addition to the sequence of iterations $\{\mathbf{w}^k\}$, for faster convergence, Nesterov's method uses another sequence of searching points $\{\mathbf{s}^k\}$, where

$$\mathbf{s}^k = \mathbf{w}^k + \beta_k(\mathbf{w}^k - \mathbf{w}^{k-1}),$$

for some positive parameter β_k. From $\mathbf{s}^k$, we obtain $\mathbf{w}^{k+1}$ by taking the negative gradient direction:

$$\mathbf{w}^{k+1} = \mathbf{s}^k - \lambda_k \nabla \bar{L}(\mathbf{s}^k),$$

where

$$\bar{L}(\mathbf{w}) \equiv \sum_{i=1}^{l} \xi_i(\mathbf{w}; \mathbf{x}_i, y_i)$$

is the objective function of (14) and λ_k is the step size. Note that $\bar{L}(\mathbf{w})$ is different from $L(\mathbf{w})$ defined in (7) because the penalty parameter C is not needed in (14). Liu et al. (2009) suggest to estimate β_k by

$$\beta_k = \frac{\gamma_k(1 - \alpha_{k-1})}{\alpha_{k-1}(\gamma_k + \frac{\alpha_k}{\lambda_k})}, \tag{60}$$

Algorithm 9 Lassplore for solving (14)

- Given $\mathbf{w}^0$ and $\mathbf{w}^1$, $\alpha_0 = 0.5, \lambda_1 > 0, \gamma_1 \geq 0$.
- For $k = 1, 2, 3, \ldots$
  1. While 1 do
     - Compute $\alpha_k \in (0,1)$ as the root of $\eta_k(\alpha)$, β_k by (60), and γ_{k+1} by (61).
     - Compute $\mathbf{s}^k = \mathbf{x}^k + \beta_k(\mathbf{w}^k - \mathbf{w}^{k-1})$.
     - Compute $\mathbf{w}^{k+1}$ by (63).
     - If $\bar{L}(\mathbf{w}^{k+1})$ satisfies (62)
       goto Step 2.
       Else
       $\lambda_k \leftarrow \lambda_k/2$.
  2. Find the initial λ_{k+1} for the next iteration by an adaptive scheme.[3]

where $\alpha_k \in (0,1)$ is the root of a quadratic function

$$\eta_k(\alpha) \equiv \frac{\alpha^2}{\lambda_k} + \gamma_k \alpha - \gamma_k$$

and $\gamma_k \geq 0$ satisfies

$$\gamma_{k+1} = (1 - \alpha_k)\gamma_k \text{ if } k \geq 1 \text{ and } \gamma_1 \geq 0. \tag{61}$$

We have $\alpha_k \in (0,1)$ because $\eta_k(0) = -\gamma_k < 0$ and $\eta_k(1) = 1/\lambda_k > 0$.

Lassplore applies an adaptive line search scheme that adjusts λ_k so that $\mathbf{w}^{k+1}$ satisfies

$$\bar{L}(\mathbf{w}^{k+1}) \leq \bar{L}(\mathbf{s}^k) + \nabla \bar{L}(\mathbf{s}^k)^T(\mathbf{w}^{k+1} - \mathbf{s}^k) + \frac{1}{2\lambda_k}\|\mathbf{w}^{k+1} - \mathbf{s}^k\|_2^2. \tag{62}$$

The new solution $\mathbf{w}^{k+1}$ generated from the above process may not satisfy the constraint in (14), so Lassplore projects the solution to the feasible region:

$$\mathbf{w}^{k+1} \equiv \arg\min_{\mathbf{w}} \{\|(\mathbf{s}^k - \lambda_k \nabla L(\mathbf{s}^k)) - \mathbf{w}\| \mid \|\mathbf{w}\|_1 \leq K\}. \tag{63}$$

This projection is related to (15) in Section 2.2.2, but Lassplore applies the method in Liu and Ye (2009) to efficiently compute (63).

A summary of Lassplore is given in Algorithm 9.

6. Three Other Methods for L1-regularized Logistic Regression

We describe details of three more methods because they are included in our comparison.

6.1 Orthant-Wise Limited-memory Quasi-Newton (OWL-QN)

LBFGS (Liu and Nocedal, 1989) is a limited memory quasi Newton method for unconstrained smooth optimization. It can not deal with (1) because of the non-differentiability. Andrew and Gao (2007) modified LBFGS to solve (1) and named their method as OWL-QN. Here, we discuss how they handle the non-differentiability.

3. See Liu et al. (2009, Algorithm 3) for details.

From earlier discussion, we know that (1) is differentiable in a region where the sign of w_j does not change. Thus, OWL-QN restricts the search space to such a region (called orthant). At the kth iteration, it searches $\mathbf{w}^{k+1}$ on the space:

$$\Omega_k \equiv \{\mathbf{w} \in R^n \mid \text{sgn}(w_j) = s_j^k, j = 1, \ldots, n\},$$

where

$$s_j^k \equiv \begin{cases} \text{sgn}(w_j^k) & \text{if } w_j^k \neq 0, \\ \text{sgn}(-\bar{\nabla}_j f(\mathbf{w}^k)) & \text{otherwise}, \end{cases} \tag{64}$$

and

$$\bar{\nabla}_j f(\mathbf{w}) \equiv \begin{cases} L'_j(\mathbf{w}) + 1 & \text{if } w_j > 0 \text{ or } (w_j = 0 \text{ and } L'_j(\mathbf{w}) + 1 < 0), \\ L'_j(\mathbf{w}) - 1 & \text{if } w_j < 0 \text{ or } (w_j = 0 \text{ and } L'_j(\mathbf{w}) - 1 > 0), \\ 0 & \text{otherwise} \end{cases} \tag{65}$$

is defined as the pseudo gradient of $f(\mathbf{w})$. In (64), if $w_j^k = 0$, we consider the space where w_j can be moved by taking the negative gradient direction. OWL-QN then approximately minimizes a quadratic approximation of (1) in the search space Ω_k:

$$\begin{aligned} \min_{\mathbf{d}} \quad & f(\mathbf{w}^k) + \bar{\nabla} f(\mathbf{w}^k)^T \mathbf{d} + \frac{1}{2} \mathbf{d}^T H_k \mathbf{d} \\ \text{subject to} \quad & \mathbf{w}^k + \mathbf{d} \in \Omega_k, \end{aligned} \tag{66}$$

where H_k approximates the Hessian of $f(\mathbf{w}^k)$ by the first-order information gathered from previous iterations. Details for getting H_k can be found in Liu and Nocedal (1989). To approximately solve (66), OWL-QN finds the minimum of the quadratic objective function:

$$\mathbf{d}^k = -H_k^{-1} \bar{\nabla} f(\mathbf{w}^k), \tag{67}$$

obtains a direction $\bar{\mathbf{d}}^k$ by confining $\mathbf{d}^k$ on the same orthant as $-\bar{\nabla} f(\mathbf{w}^k)$:

$$\bar{d}_j^k = \begin{cases} d_j^k & \text{if } \text{sgn}(d_j^k) = \text{sgn}(-\bar{\nabla}_j f(\mathbf{w}^k)), \\ 0 & \text{otherwise}, \end{cases} \tag{68}$$

and then conducts a backtracking line search to find λ such that the sufficient decrease of the function value is satisfied. Note that $\mathbf{w}^{k+1}$ must be in Ω_k, so following (64),

$$w_j^{k+1} = \begin{cases} w_j^k + \lambda \bar{d}_j^k & \text{if } \text{sgn}(w_j^k + \lambda \bar{d}_j^k) = s_j^k, \\ 0 & \text{otherwise}. \end{cases}$$

Algorithm 10 summarizes the procedure.

Regarding the convergence, Yu et al. (2010, Appendix D) point out that the proof by Andrew and Gao (2007) is flawed. Yu et al. (2010) give the convergence proof for a slightly modified algorithm.

Algorithm 10 OWL-QN: An extension of LBFGS for L1-regularized logistic regression

1. Given $\mathbf{w}^1$.
2. For $k = 1, 2, 3, \ldots$
   - Compute $\bar{\nabla} f(\mathbf{w}^k)$ by (65).
   - Obtain H^k by information gathered from previous iterations and compute $\mathbf{d}^k$ by (67).
   - Compute $\bar{\mathbf{d}}^k$ by (68).
   - Find $\mathbf{w}^{k+1} \in \Omega_k$ by a backtracking line search.

6.2 Generalized Linear Model with Elastic Net

Friedman et al. (2010) proposed GLMNET to handle least-square and log-linear losses with L1/L2 regularization. Here, we discuss how GLMNET solves L1-regularized logistic regression. Although GLMNET can solve (5) with the bias term, for simplicity, we only indicate how GLMNET solves (1).

Because of the twice differentiability of the logistic loss function, the gradient of $L(\mathbf{w})$ is shown in (42) and the Hessian is

$$\nabla^2 L(\mathbf{w}) = CX^T DX, \tag{69}$$

where $D \in R^{l \times l}$ is a diagonal matrix with

$$D_{ii} = \tau(y_i \mathbf{w}^T \mathbf{x}_i)\big(1 - \tau(y_i \mathbf{w}^T \mathbf{x}_i)\big) \tag{70}$$

and $\tau(\cdot)$ is defined in (9). See similar formulations derived earlier for TRON in (56) and (57). Given the current solution $\mathbf{w}^k$, GLMNET considers a quadratic approximation of $L(\mathbf{w})$. By the second-order Taylor expansion,

$$\begin{aligned} & f(\mathbf{w}^k + \mathbf{d}) - f(\mathbf{w}^k) \\ =& \Big(\|\mathbf{w}^k + \mathbf{d}\|_1 + L(\mathbf{w}^k + \mathbf{d}) \Big) - \Big(\|\mathbf{w}^k\|_1 + L(\mathbf{w}^k) \Big) \\ \approx& \nabla L(\mathbf{w}^k)^T \mathbf{d} + \frac{1}{2} \mathbf{d}^T \nabla^2 L(\mathbf{w}^k) \mathbf{d} + \|\mathbf{w}^k + \mathbf{d}\|_1 - \|\mathbf{w}^k\|_1. \end{aligned}$$

Then, GLMNET solves the Newton-like system

$$\min_{\mathbf{d}} \quad q_k(\mathbf{d}) \equiv \nabla L(\mathbf{w}^k)^T \mathbf{d} + \frac{1}{2} \mathbf{d}^T \nabla^2 L(\mathbf{w}^k) \mathbf{d} + \|\mathbf{w}^k + \mathbf{d}\|_1 - \|\mathbf{w}^k\|_1 \tag{71}$$

by a cyclic coordinate descent method. Following the framework in Algorithm 1, $\mathbf{d}$'s values are sequentially updated by minimizing the following one-variable function:

$$\begin{aligned} g_j(z) &\equiv q_k(\mathbf{d} + z\mathbf{e}_j) - q_k(\mathbf{d}) \\ &= |w_j^k + d_j + z| - |w_j^k + d_j| + Bz + \frac{1}{2} A z^2, \end{aligned}$$

where

$$B \equiv \nabla_j L(\mathbf{w}^k) + \sum_t \nabla^2_{jt} L(\mathbf{w}^k) d_t \quad \text{and} \quad A \equiv \nabla^2_{jj} L(\mathbf{w}^k)$$

can be calculated using (42) and (69). It is easy to minimize $g_j(z)$ by (27).[4]

4. In GLMNET implementation, instead of finding z, a different but equivalent update is used to get new $w_j^k + d_j$.

Algorithm 11 GLMNET for L1-regularized logistic regression

1. Given $\mathbf{w}^1$.
2. For $k = 1, 2, 3, \ldots$
   - Let $\mathbf{d}^k \leftarrow \mathbf{0}$.
   - While $\mathbf{d}^k$ is not optimal for minimizing $q_k(\mathbf{d})$
     - For $j = 1, \ldots, n$
       - Solve the following one-variable problem by (27):

$$\bar{z} = \arg\min_{z} \quad q_k(\mathbf{d}^k + z\mathbf{e}_j) - q_k(\mathbf{d}^k).$$

       - $d_j^k \leftarrow d_j^k + \bar{z}$.
   - $\mathbf{w}^{k+1} = \mathbf{w}^k + \mathbf{d}^k$.

Because calculating the matrix D involves many exponential operations, GLMNET also considers using an approximation of $\nabla^2 L(\mathbf{w})$ and minimizes

$$q_k(\mathbf{d}) \equiv \nabla L(\mathbf{w}^k)^T \mathbf{d} + \frac{1}{2}\mathbf{d}^T H \mathbf{d} + \|\mathbf{w}^k + \mathbf{d}\|_1 - \|\mathbf{w}^k\|_1,$$

where $H \equiv 0.25CX^T IX$ and I is an identity matrix. That is, we use a cheaper but less accurate approximation of $f(\mathbf{w}^k + \mathbf{d}) - f(\mathbf{w}^k)$. A sketch of GLMNET is in Algorithm 11.

We briefly describe some GLMNET's implementation details. GLMNET applies a shrinking technique to solve a smaller optimization problem than (71); see similar techniques for decomposition methods in Section 4.1.2. Using a sparse representation of $\mathbf{w}$ and maintaining an index set Ω to indicate the non-zero elements of $\mathbf{d}$, GLMNET solves a smaller problem by a coordinate descent method:

$$\min_{\mathbf{d}_\Omega} \quad \nabla L(\mathbf{w}^k)^T \mathbf{d} + \frac{1}{2}\mathbf{d}^T H \mathbf{d} + \|\mathbf{w}^k + \mathbf{d}\|_1 - \|\mathbf{w}^k\|_1.$$

GLMNET conducts feature-wise normalization before solving the optimization problem. That is, it solves (1) by replacing $\mathbf{x}_i$ with $\tilde{\mathbf{x}}_i$, where

$$\tilde{x}_{ij} \equiv \frac{x_{ij} - \bar{x}_j}{\sigma_j}, \forall i, j, \quad \bar{x}_j = \frac{\sum_{i=1}^{l} x_{ij}}{l}, \forall j, \quad \text{and } \sigma_j = \sqrt{\sum_{i=1}^{l} x_{ij}^2 - \sum_{i=1}^{l} \bar{x}_j^2}, \forall j.$$

Notice that there is no guarantee that GLMNET converges to an optimum. Furthermore, the function value may not decrease because GLMNET does not conduct a line search procedure on the direction $\mathbf{d}$. For minimizing the quadratic approximation $q_k(\mathbf{d})$, GLMNET measures the relative step change in the successive coordinate descent iterations. Deciding when to stop minimizing $q_k(\mathbf{d})$ is an issue because a strict stopping condition may already cause long running time for $q_1(\mathbf{d})$.

6.3 Bundle Method

Bundle method is a cutting plane approach for minimizing non-smooth convex problems. Teo et al. (2010) proposed a bundle method BMRM to handle non-differentiable loss functions (e.g., L1 loss). They provide an extension to handle L1 regularization. Interestingly, BMRM applies cutting planes only to the loss function, regardless of whether it is differentiable or not. Therefore, for problem (1)

Algorithm 12 BMRM for L1-regularized logistic regression

1. Given $\mathbf{w}^1$.
2. For $k = 1, 2, 3, \ldots$
   - Compute and store $\mathbf{a}_k$ and b_k by (73).
   - Obtain $\mathbf{w}^{k+1}$ by solving the linear program (76).

with logistic loss, BMRM uses a non-smooth method to handle the smooth loss function and some other ways for the non-smooth regularization term $\|\mathbf{w}\|_1$.

Let $\mathbf{w}^k$ be the solution at the kth iteration. Using the convexity of the loss function, BMRM builds a cutting plane (i.e., the first-order Taylor expansion) of $L(\mathbf{w})$ at $\mathbf{w} = \mathbf{w}^k$:

$$\begin{aligned} L(\mathbf{w}) \geq & \nabla L(\mathbf{w}^k)^T(\mathbf{w} - \mathbf{w}^k) + L(\mathbf{w}^k) \\ = & \mathbf{a}_k^T \mathbf{w} + b_k, \ \forall \mathbf{w}, \end{aligned} \tag{72}$$

where

$$\mathbf{a}_k \equiv \nabla L(\mathbf{w}^k) \quad \text{and} \quad b_k \equiv L(\mathbf{w}^k) - \mathbf{a}_k^T \mathbf{w}^k. \tag{73}$$

If $L(\mathbf{w})$ is non-differentiable, in (72), BMRM substitutes $\nabla L(\mathbf{w})$ with the sub-gradient of $L(\mathbf{w})$.

BMRM maintains all cutting planes from the earlier iterations to form a lower-bound function for $L(\mathbf{w})$:

$$L(\mathbf{w}) \geq L_k^{\mathrm{CP}}(\mathbf{w}) \equiv \max_{1 \leq t \leq k} \mathbf{a}_t^T \mathbf{w} + b_t, \ \forall \mathbf{w}. \tag{74}$$

BMRM obtains $\mathbf{w}^{k+1}$ by solving the following sub-problem:

$$\min_{\mathbf{w}} \quad \|\mathbf{w}\|_1 + L_k^{\mathrm{CP}}(\mathbf{w}). \tag{75}$$

Using (74) and the splitting of $\mathbf{w}$ in (12) by $\mathbf{w} = \mathbf{w}^+ - \mathbf{w}^-$, Equation (75) can be reformulated to the following linear programming problem:

$$\begin{aligned} \min_{\mathbf{w}^+, \mathbf{w}^-, \zeta} \quad & \sum_{j=1}^{n} w_j^+ + \sum_{j=1}^{n} w_j^- + \zeta \\ \text{subject to} \quad & \mathbf{a}_t^T (\mathbf{w}^+ - \mathbf{w}^-) + b_t \leq \zeta, \quad t = 1, \ldots, k, \\ & w_j^+ \geq 0, \ w_j^- \geq 0, \quad j = 1, \ldots, n. \end{aligned} \tag{76}$$

A summary of the BMRM approach is given in Algorithm 12. Teo et al. (2010, Appendix C) indicated that because of the L1 regularization, the convergence result has not been fully established yet.

7. L1-regularized L2-loss Support Vector Machines

Previous sections have focused on L1-regularized logistic regression. Now we consider (1) with the L2-loss function (4). The optimization problem can be rewritten as

$$\min_{\mathbf{w}} \quad f(\mathbf{w}) \equiv \|\mathbf{w}\|_1 + C \sum_{i \in I(\mathbf{w})} b_i(\mathbf{w})^2, \tag{77}$$

where

$$b_i(\mathbf{w}) \equiv 1 - y_i \mathbf{w}^T \mathbf{x}_i \quad \text{and} \quad I(\mathbf{w}) \equiv \{i \mid b_i(\mathbf{w}) > 0\}. \tag{78}$$

Therefore, the sum of losses is

$$L(\mathbf{w}) = C \sum_{i \in I(\mathbf{w})} b_i(\mathbf{w})^2. \tag{79}$$

In contrast to logistic loss, the L2-loss function is differentiable but not twice differentiable (Mangasarian, 2002). Thus, some methods discussed in Sections 4–6 may not be directly applicable because they use second-order information. However, as shown in Mangasarian (2002, Section 3), (79) is twice differentiable at all but $\{\mathbf{w} \mid b_i(\mathbf{w}) = 0 \text{ for some } i\}$. Moreover, $\nabla L(\mathbf{w})$ is globally Lipschitz continuous, so a generalized Hessian exists everywhere. Using a generalized Hessian, we may modify algorithms using the second-order information for L1-regularized L2-loss SVMs. In the following two sections, we extend CDN and TRON to solve (77).

7.1 CDN for L2-loss SVMs

To apply CDN for L2-loss SVMs, in the sub-problem (17), we have

$$L_j(z) = C \sum_{i \in I(\mathbf{w}^{k,j} + z\mathbf{e}_j)} b_i(\mathbf{w}^{k,j} + z\mathbf{e}_j)^2.$$

For a second-order approximation similar to (26), we need $L_j'(0)$ and $L_j''(0)$:

$$L_j'(0) = -2C \sum_{i \in I(\mathbf{w}^{k,j})} y_i x_{ij} b_i(\mathbf{w}^{k,j}).$$

Unfortunately, $L_j''(0)$ is not well-defined if there exists some i such that $b_i(\mathbf{w}^{k,j}) = 0$. Following Chang et al. (2008), we consider the generalized second derivative:

$$2C \sum_{i \in I(\mathbf{w}^{k,j})} x_{ij}^2. \tag{80}$$

By replacing $L_j''(0)$ in (26) with the above quantity, we can easily obtain a direction d. However, the value in (80) may be zero if $x_{ij} = 0,\ \forall i \in I(\mathbf{w}^{k,j})$. To apply the convergence result in Tseng and Yun (2007), we ensure the strict positivity by taking

$$\max\left(2C \sum_{i \in I(\mathbf{w}^{k,j})} x_{ij}^2,\ \varepsilon\right), \tag{81}$$

where ε is a small positive value. Following the explanation in Appendix F, we have the finite termination of the line search procedure and the asymptotic convergence of the function value.

Like the situation for logistic regression, the major cost for finding the Newton direction d and for the line search procedure is to calculate $\mathbf{w}^T \mathbf{x}_i,\ \forall i \in I$. We maintain $b_i(\mathbf{w}),\ \forall i$ using the same trick in (25). All other implementation techniques discussed in Section 4.1.2 for logistic regression can be applied here.

7.2 TRON for L2-loss SVMs

We apply TRON to solve the bound-constrained problem (12) using L2 loss. Following the notation in Section 5.1, $\mathbf{w} \in R^{2n}$ is defined in (43) and $\bar{f}(\mathbf{w})$ is the objective function in (12).

The quadratic model $q_k(\mathbf{d})$ requires the gradient and the Hessian of $\bar{f}(\mathbf{w})$. We have

$$\nabla \bar{f}(\mathbf{w}) = \mathbf{e} + 2C\left(\bar{X}_{I,:}^T \bar{X}_{I,:}\mathbf{w} - \bar{X}_{I,:}^T \mathbf{y}_I\right),$$

where $\mathbf{e} \in R^{2n}$ is a vector of all ones, $\bar{X} \equiv \begin{bmatrix} X & -X \end{bmatrix}$, and I is defined in (78). $\bar{X}_{I,:}$ denotes a sub-matrix including $\bar{X}$'s rows corresponding to I; see (8). Note that $b_i(\mathbf{w})$ defined in (78) is now calculated by

$$1 - y_i(\mathbf{w}_{1:n} - \mathbf{w}_{(n+1):2n})^T \mathbf{x}_i.$$

Following Mangasarian (2002) and Fan et al. (2008, Appendix D), we consider the generalized Hessian matrix:

$$2C\bar{X}^T D \bar{X},$$

where $D \in R^{l \times l}$ is a diagonal matrix with

$$D_{ii} = \begin{cases} 1 & \text{if } b_i(\mathbf{w}) > 0, \\ 0 & \text{if } b_i(\mathbf{w}) \le 0. \end{cases}$$

We then apply Algorithm 7 to approximately minimize $q_k(\mathbf{d})$. For the Hessian-vector product, only instances in the index set I and variables in the free set F are considered. Thus, the Hessian-vector product in (58) becomes

$$2C\bar{X}_{I,F}^T \left(D_{I,I}\left(\bar{X}_{I,F}\mathbf{v}_F\right)\right),$$

where $\mathbf{v}$ is a vector in R^{2n}.

Regarding the convergence, from Theorem 2.1 of Lin and Moré (1999), any limit point of $\{\mathbf{w}^k\}$ is an optimal solution. However, without the twice differentiability, it is unclear if the local quadratic convergence holds.

8. Numerical Experiments

In Sections 4–7, we have described details of several large-scale optimization methods for L1-regularized linear classification. In this section, we conduct experiments to investigate their performances. We describe data sets and experimental settings first. Then, we comprehensively compare methods for logistic regression and L2-loss SVMs. Programs used in this paper are available at `http://www.csie.ntu.edu.tw/~cjlin/liblinear/exp.html`.

8.1 Data Sets

Table 1 lists data statistics. Most data sets include documents, where the numbers of both features and instances are large. An exception is the problem a9a from UCI "adults" data sets; it has $l \gg n$. For other document sets, real-sim includes some Usenet articles, news20 is a collection of news documents, rcv1 is an archive of manually categorized newswire stories from Reuters, and yahoo-japan/yahoo-korea are document data from Yahoo!. Except yahoo-japan and yahoo-korea, other data sets are publicly available at `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/`

Data set	l	n	#nz
a9a	32,561	123	451,592
real-sim	72,309	20,958	3,709,083
news20	19,996	1,355,191	9,097,916
rcv1	677,399	47,236	49,556,258
yahoo-japan	176,203	832,026	23,506,415
yahoo-korea	460,554	3,052,939	156,436,656

Table 1: Statistics of data sets: l and n denote the numbers of instances and features in a data set, respectively. The column #nz indicates the number of non-zero entries.

Data set	LR without bias			LR with bias			L2-loss SVM		
	C	Density	Acc.	C	Density	Acc.	C	Density	Acc.
a9a	4.0	94.3	85.2	2.0	89.3	85.3	0.5	90.2	85.2
real-sim	4.0	16.8	97.1	4.0	16.2	97.0	1.0	18.9	97.1
news20	64.0	0.2	95.1	64.0	0.2	94.9	64.0	0.7	96.1
rcv1	4.0	23.8	97.8	4.0	23.0	97.8	1.0	25.9	97.8
yahoo-japan	4.0	1.3	91.9	4.0	1.0	93.1	1.0	1.4	92.2
yahoo-korea	4.0	1.0	87.6	4.0	0.9	87.7	1.0	1.0	87.7

Table 2: The best parameter C, the model density (%), and the testing accuracy (%). We conduct five-fold cross validation on the training set to select C in $\{2^k \mid k = -4, -3, \ldots, 6\}$. Using the selected C, we build a model to predict the testing set.

`datasets/`. For every document data set, instance-wise normalization has been conducted so that the length of each instance is one.

To estimate the testing accuracy, a stratified selection is taken to split each data set into one fifth for testing and the rest for training.

8.2 Experimental Settings

We consider the following implementations discussed in Sections 4–7.

- BBR: the cyclic coordinate descent method for logistic regression is described in Section 4.1.1. We download version 4.03 from `http://www.bayesianregression.org/`.
- CDN: the cyclic coordinate descent methods for logistic regression and L2-loss SVMs are respectively described in Sections 4.1.2 and 7.1. To check the sufficient decrease condition, we use $\sigma = 0.01$ and $\beta = 1/2$. For L2-loss SVM, we use $\varepsilon = 10^{-12}$ in (81). The implementation is the same as that included in version 1.6 of our software LIBLINEAR (`http://www.csie.ntu.edu.tw/~cjlin/liblinear/`).
  In Section 4.1.2, we discuss the shrinking technique for CDN. We defer the investigation of its effectiveness to Section 8.4. In all other places of the comparison, we run CDN with the shrinking strategy.
- SCD: the stochastic coordinate descent method for logistic regression is described in Section 4.1.3. The source code is available at `http://ttic.uchicago.edu/~tewari/code/scd/`.

- CGD-GS: the block coordinate gradient descent method for logistic regression is described in Section 4.2. Following Yun and Toh's (2009) settings, we choose

$$H = \text{diag}\left[\min\left(\max(\nabla^2_{jj} L(\mathbf{w}^k), 10^{-10}), 10^{10}\right)\right]_{j=1,\ldots,n}$$

  and apply the Gauss-Southwell-r rule to choose the working set J; see Equation (40). Note that from Table 9 of Yun and Toh (2009), implementations using Gauss-Southwell-r and Gauss-Southwell-q rules perform similarly on document data. We use default values for all parameters; see Section 5.1 in Yun and Toh (2009). In particular, $\sigma = 0.1$, $\beta = 1/2$, and $\gamma = 0$. The source code is available at `http://www.math.nus.edu.sg/~matys/`.
- TRON: the trust region Newton methods for logistic regression and L2-loss SVMs are respectively described in Sections 5.1 and 7.2. In the projected line search (47) and (55), we use $\sigma = 0.01$ and $\beta = 0.1$. For the stopping condition of the CG procedure in Algorithm 7, we use $\varepsilon = 0.1$. The parameter η_0 in (46) is 0.0001.
- IPM: the interior point method for logistic regression is described in Section 5.2. For small and dense data sets, IPM solves a linear system in Algorithm 8 by Cholesky factorization. For large and sparse data sets, it applies a preconditioned conjugate gradient method to approximately solve the linear system. In the experiment, we only consider the large and sparse setting. We use default parameters: $\sigma = 0.01$ and $\beta = 1/2$ for the line search procedure. To update t^k, we use $s_{\min} = 1/2$ and $\mu = 2$. The source code (version 0.8.2) is downloaded from `http://www.stanford.edu/~boyd/l1_logreg/`.

  As $\mathbf{w}$ lies in the interior of the feasible region, every w_j is non-zero after IPM stops. To gain the sparsity, following the condition (31), Koh et al. (2007) assign those w_j satisfying $|\nabla_j L(\mathbf{w})| \leq 0.9999$ to zero. However, if we have not run enough iterations to obtain an accurate solution, this modification of $\mathbf{w}$ may result in an erroneous model. We thus add another condition $|w_j| < 1$ in deciding if w_j should be assigned to zero. We will address this issue again in Section 8.3.

  We find that because of a problem of not initializing an element in an array, the previous version (0.8.1) of IPM is two or three times slower than the latest version (0.8.2). This observation indicates the difficulty in comparing software. Some minor issues may significantly affect the conclusions.
- OWL-QN: the quasi Newton method is described in Section 6.1. The source code (version 1.1.2) is available at `http://research.microsoft.com/en-us/um/people/jfgao/`.
- GLMNET: the method is described in Section 6.2 for logistic regression. Following the default setting, we use the full Hessian in (71) instead of an approximation. We gradually reduce the stopping tolerance to obtain different models. The coordinate descent method for minimizing the quadratic approximation $q_k(\mathbf{d})$ stops according to a tolerance the same as the overall stopping tolerance. The source code (version 1.5) is available at `http://cran.r-project.org/web/packages/glmnet/index.html`.
- Lassplore: this method is described in Section 5.3. We check the 1-norm of the optimal solution (obtained by other solvers) to calculate the value K in (14). The source code (version 1.0) is available at `http://www.public.asu.edu/~jye02/Software/lassplore`.
- BMRM: this bundle method is described in Section 6.3. We apply it to both logistic regression and L2-loss SVMs. The linear programming problem (76) is solved via GNU Linear Programming Kit (GLPK). The source code (version 2.2) and GLPK are available at `http://users.rsise.anu.edu.au/~chteo/BMRM.html` and `http://www.gnu.org/software/glpk/`, respectively.

GLMNET is implemented in Fortran along with an R interface. CGD-GS and Lassplore are primarily implemented in MATLAB, but expensive operations are coded in C/C++. All other solvers are implemented in C/C++ with double precision.

Some implementations (SCD, TRON, OWL-QN, and BMRM) solve (1), while some (CGD-GS, IPM, GLMNET, and Lassplore) consider the bias term and solve (5). BBR[5] and our CDN implementation can handle both (1) and (5). According to whether the bias term is considered, we categorize methods into two groups for comparison.[6] Moreover, for certain solvers their formulations are scaled by a constant. We ensure that equivalent optimization problems are solved.

Software such as IPM and GLMNET supports finding a solution path of various C values. However, in our experiments, we focus on the performance of an algorithm using a fixed C. For all methods, we set the initial solution $\mathbf{w}^1 = \mathbf{0}$.

The parameter C is chosen by five-fold cross validation (CV) on the training set. Using models trained under the best C, we predict the testing set to obtain the testing accuracy. The best C, the model density (the number of non-zero coefficients in $\mathbf{w}$ divided by n), and the corresponding testing accuracy are recorded in Table 2.

In the rest of this section, we compare the training speed of solvers for logistic regression and L2-loss SVMs by using the best parameter C of each data set. We run all experiments on a 64-bit machine with Intel Xeon 2.0GHz CPU (E5504), 128KB L1 cache, 1GB L2 cache, and 32GB main memory. We use GNU C/C++/Fortran compilers (version 4.4.1) and ensure that for each package the "-O3" optimization flag is set.

8.3 Comparing Methods for L1-regularized Logistic Regression

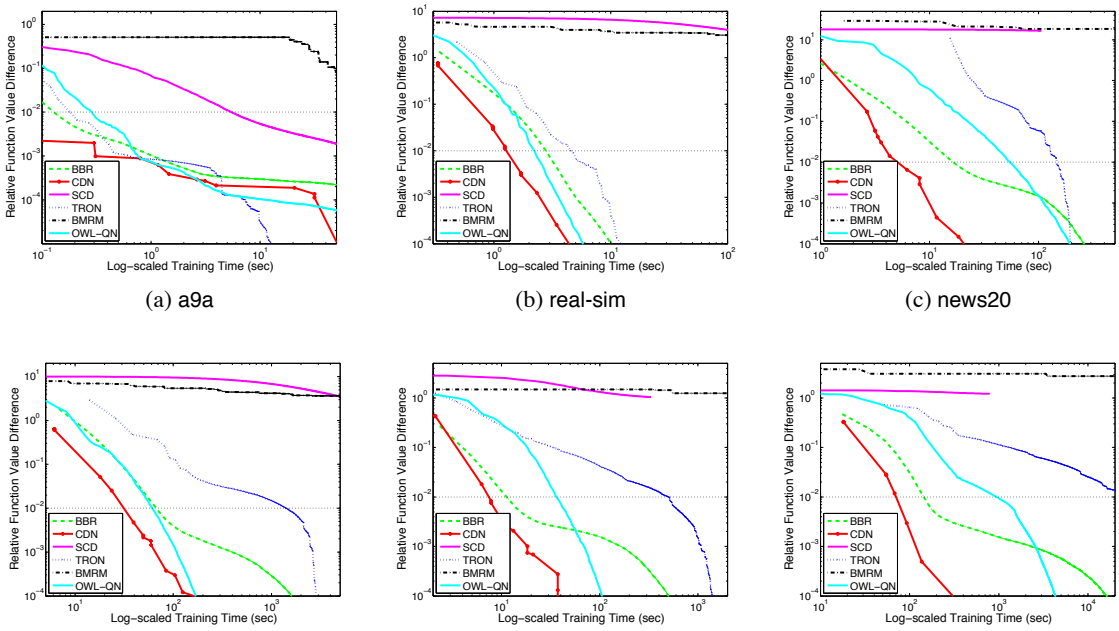
We separately compare solvers for optimization problems without/with the bias term. The first group, which solves (1), includes BBR, CDN, SCD, TRON, OWL-QN, and BMRM. We begin at showing in Figure 1 the relation between the function value and the training time. In each figure, the x-axis is the training time and the y-axis is the relative difference to the optimal function value:

$$\frac{f(\mathbf{w}) - f^*}{f^*}, \tag{82}$$

where f^* is obtained by running TRON with a strict stopping condition. Both x-axis and y-axis are log-scaled. We draw a dotted reference line in Figure 1 to indicate the relative error 0.1. From Figure 1, BBR and CDN can more quickly give a good solution than SCD, TRON, OWL-QN, and BMRM. However, quasi Newton and Newton methods may have faster local convergence. In Figures 1(c) and 1(d), TRON's curve is almost vertical in the end. This fast local convergence is mainly useful for problems such as a9a, for which BBR and CDN are less competitive. We note that a9a is not a document data set and its number of features is much smaller than the number of instances. Earlier studies for L2-regularized classifiers have shown that coordinate descent methods are less competitive for this type of data (Hsieh et al., 2008). The same situation seems to occur here for L1 regularization.

It is surprising that SCD is much slower than CDN and BBR because they are all coordinate descent methods. We modify CDN to randomly select working variables, a stochastic method similar to SCD; the result was still much faster than SCD, suggesting that the stochastic selection is not the

5. BBR considers bias term as a feature and allows users to use an option "-l" to specify weights to individual features.
6. For simplicity, we apply BBR only to solve (1).



(a) a9a (b) real-sim (c) news20

(d) rcv1 (e) yahoo-japan (f) yahoo-korea

Figure 1: Relative difference between the objective function and the optimum value, versus training time. Logistic regression without using the bias term. Both x-axis and y-axis are log-scaled.

culprit. It turns out that a too large upper bound of the second derivative causes the slow convergence of SCD. When $x_{ij} \in [-1,1]$, SCD replaces $\sum_{i=1}^{l} x_{ij}^2$ in (34) with l. Then its U_j in (35) is much larger than U_j in (22) for BBR. Therefore, SCD's step size $-g_j'(0)/U_j$ is often too small.

Equation (82) cannot be used for a practical stopping condition because f^* is not easily available. Instead, we often rely on the gradient information. Now (1) is not differentiable, so we follow the optimality condition (6) to define the minimum-norm sub-gradient:

$$\nabla_j^S f(\mathbf{w}) \equiv \begin{cases} \nabla_j L(\mathbf{w}) + 1 & \text{if } w_j > 0, \\ \nabla_j L(\mathbf{w}) - 1 & \text{if } w_j < 0, \\ \operatorname{sgn}(\nabla_j L(\mathbf{w})) \max(|\nabla_j L(\mathbf{w})| - 1, 0) & \text{otherwise.} \end{cases}$$

Since $\nabla^S f(\mathbf{w}) = \mathbf{0}$ if and only if $\mathbf{w}$ is optimal, we can check $\|\nabla^S f(\mathbf{w})\|$ for the stopping condition. Figure 2 shows the scaled 2-norm of the minimum-norm sub-gradient,

$$\frac{l}{\min(\sum_{i:y_i=1} 1, \sum_{i:y_i=-1} 1)\|\nabla^S f(\mathbf{w}^1)\|} \|\nabla^S f(\mathbf{w})\|, \tag{83}$$

along the training time. From Figure 2, CDN and BBR are the best in the early stage of the procedure, while Newton and quasi Newton methods such as TRON and OWL-QN have faster local convergence. This observation is consistent with Figure 1. Some methods (e.g., decomposition methods) do not calculate $\nabla^S f(\mathbf{w})$ in their procedures, so a gradient-based stopping condition may introduce extra cost. However, these methods may be able to use approximate gradient values obtained during the calculation. For example, coordinate descent methods calculate only $\nabla_j f(\mathbf{w}^{k,j}),\ j = 1,\ldots,n$

instead of $\nabla f(\mathbf{w}^{k+1})$, but these values can be directly used in a stopping condition; see details in Appendix F of Fan et al. (2008).

In Figure 3, we investigate how the testing accuracy is improved along the training time. The testing accuracy is the percentage of correct predictions on the testing set. Results show that BBR and CDN achieve the final accuracy more quickly. In addition, we are interested in the progress of these methods on gaining the sparsity. Figure 4 shows the number of non-zero coefficients of $\mathbf{w}$ and the training time. For most data sets, BBR and CDN more efficiently obtain a sparse solution.

Next, we compare methods solving (5) with the bias term. These solvers include CDN, CGD-GS, IPM, Lassplore, and GLMNET. Although BBR can solve (5), we omit it in the comparison as its performance is similar to that of solving (1). Following the comparison for methods solving (1), we begin with checking the running time to reduce the relative error of the function value and the scaled norm of the minimum-norm sub-gradient; see (82) and (83), respectively. The results are given in Figures 5 and 6. The reference value f^* is obtained using IPM with a strict stopping condition. From Figure 5, CDN is the fastest, IPM comes the second, and CGD-GS is the third. However, in Figure 6 for reducing the gradient norm, IPM often surpasses CDN in the final stage.

GLMNET gives good performances in Figures 5(b)–5(d). In particular, it has fast local convergence; see curves that are close to vertical in Figures 5(c) and 5(d). This fast local convergence is due to using the quadratic approximation $q_k(\mathbf{d})$, which generates a Newton-like direction. We find that the approximation of replacing D in (69) with a constant diagonal matrix is effective for micro-array data used in Friedman et al. (2010). However, for large document sets, using the exact Hessian is better. Unfortunately, GLMNET fails to generates results for yahoo-japan and yahoo-korea after sufficient running time. We find that setting an appropriate stopping tolerance for minimizing the

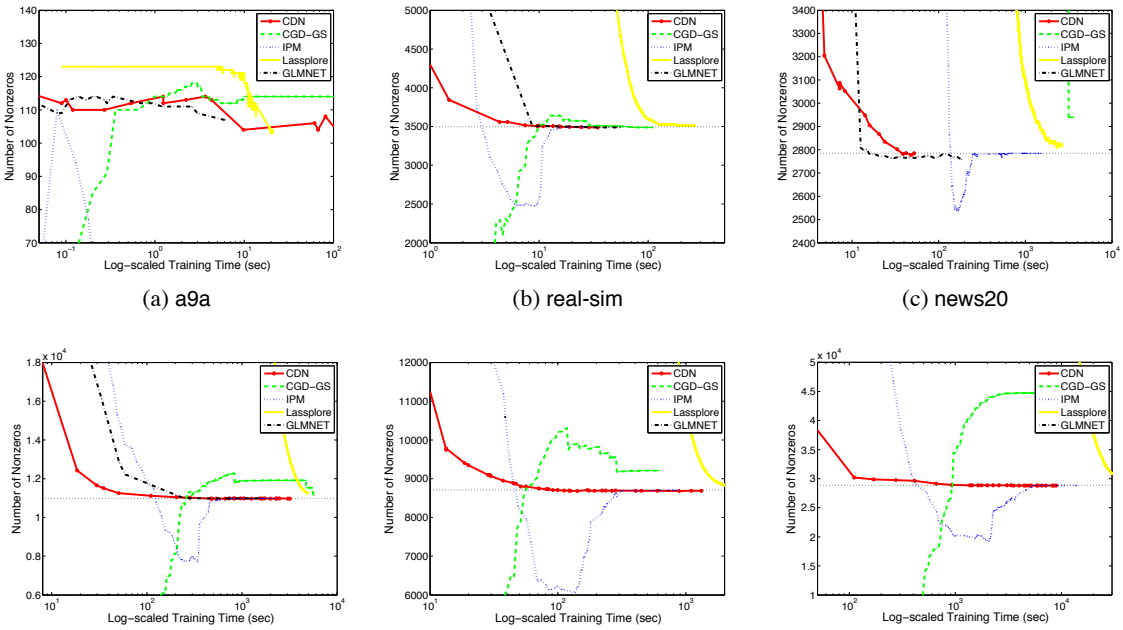
quadratic approximation in (71) is sometimes difficult. This issue might cause the problem in training yahoo-japan and yahoo-korea. For IPM, the performance is in general competitive. Because IPM is a type of Newton method, it has fast local convergence.

The result that CDN is faster than CGD-GS is worth for further discussion. Tseng and Yun (2007) show that for some least-square regression problems, an implementation similar to CDN (i.e., a Gauss-Seidel rule for selecting working variables) is slower than CGD-GS, which selects variables using the gradient information. This result is opposite to ours. Two issues might cause the different results. First, problems are different. We aim at classifying large and sparse document data, but they solve regression problems. Second, we implement two techniques (permutation of sub-problems and shrinking) to improve the convergence.

Yun and Toh (2009) show that for some document data sets used here, their CGD-GS is faster than IPM. However, our results indicate that IPM is better. This difference is apparently due to that Yun and Toh (2009) run an earlier version (0.8.1) of IPM. We indicate in Section 8.2 that a minor problem in this version causes this version to be two or three times slower than a later version (0.8.2) used here.

Figure 7 indicates the testing accuracy versus the training time. We can see in Figures 7(e) and 7(f) that IPM's accuracy may not improve as the training time increases. As we mentioned in Section 8.2, this result is because we modify certain $\mathbf{w}$ elements to zero. In the middle of the procedure, $\mathbf{w}$ is not close to an optimum yet, but many elements have satisfied $|\nabla_j L(\mathbf{w})| \leq 0.9999$ and are trimmed to zero. Hence, the resulting accuracy may be worse than that in the early stage of the procedure. In fact, due to IPM's dense $\mathbf{w}$ throughout iterations, to get the final sparsity and the testing accuracy, we need to accurately solve the optimization problem.



(a) a9a (b) real-sim (c) news20

(d) rcv1 (e) yahoo-japan (f) yahoo-korea

Figure 8: The number of non-zero coefficients versus training time (log-scaled). Logistic regression with the bias term. The solid horizontal line indicates the final number of non-zero coefficients.

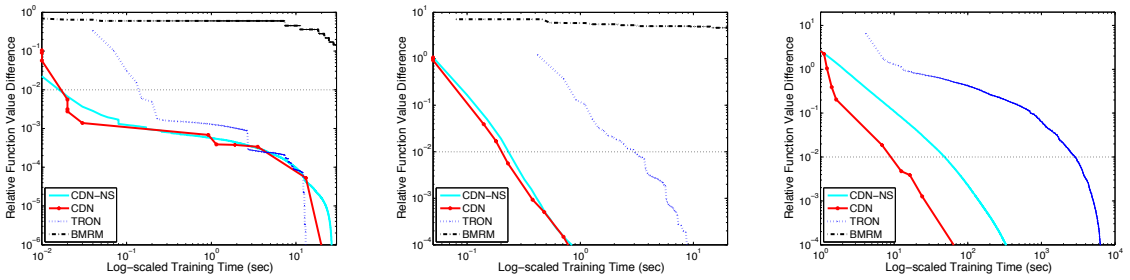
Figure 8 presents the number of $\mathbf{w}$'s non-zero coefficients. Similar to methods solving (1), all methods here, except CGD-GS, have solutions with many non-zero coefficients in the beginning and gradually gain the sparsity. In contrast, CGD-GS's numbers of non-zero coefficients in the whole optimization process are not much more than those of the final solutions. We find that this nice property is from using the gradient information for selecting working variables. In contrast, without the gradient information, CDN wrongly updates some elements of $\mathbf{w}$ to be non-zeros in the early stage of the procedure.

In summary, for large document data, coordinate descents methods such as CDN perform well in the early stage of the optimization procedure. As a result, they achieve the final accuracy more quickly. However, for some applications, a correct sparsity pattern of the model is important and a more accurate solution is sought. Then, GLMNET by combining both Newton-type and coordinate descent approaches is useful.

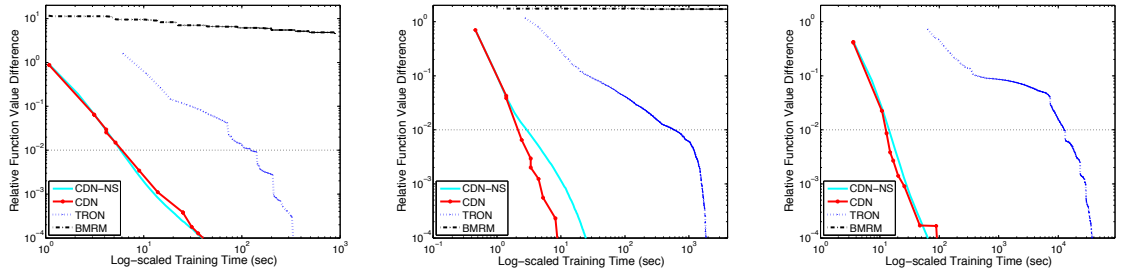
8.4 Comparing Methods for L1-regularized L2-loss SVMs and Investigating CDN's Shrinking Strategy

In Section 7, we have extended CDN and TRON to handle L2 loss, so methods included for comparison are CDN, TRON, and BMRM. Note that we solve (77) without considering the bias term.

Following the experiment for logistic regression, we plot the relative difference to the optimal function value in Figure 9 and the scaled norm of the minimum-norm sub-gradient in Figure 10. The reference f^* is obtained by running TRON with a strict stopping condition. One can see that



(a) a9a (b) real-sim (c) news20



(d) rcv1 (e) yahoo-japan (f) yahoo-korea

Figure 9: Relative difference between the objective function and the optimum value, versus training time. L2-loss SVMs without using the bias term. Both x-axis and y-axis are log-scaled.

CDN's training time is the shortest among the three solvers and TRON is better than BMRM. BMRM does not properly decrease the function value and the norm of gradient on large data sets.

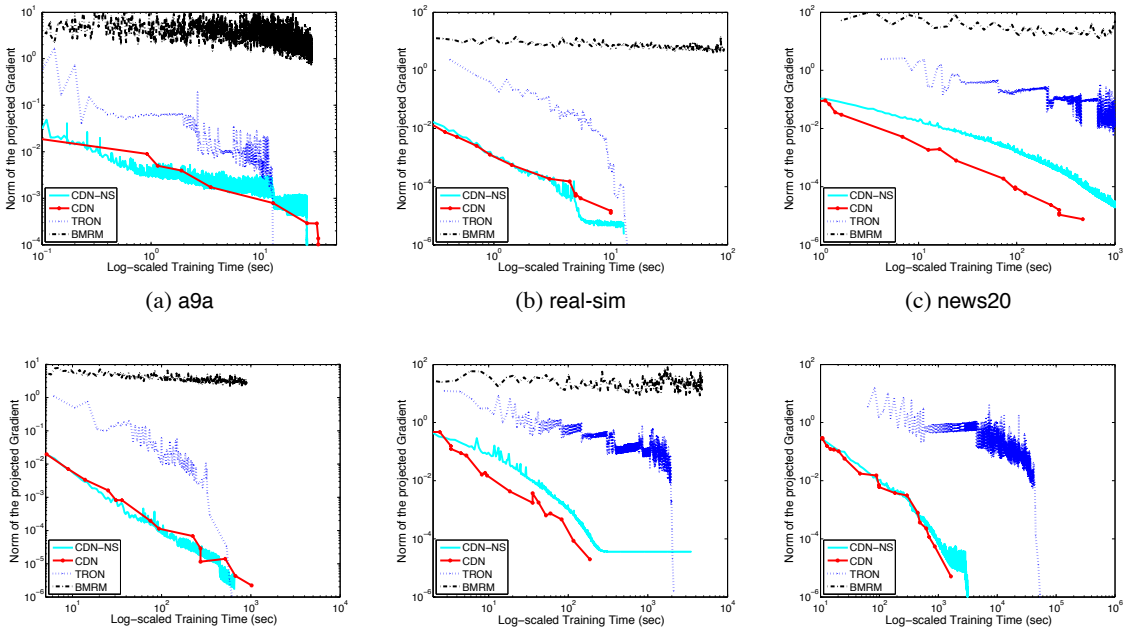
In Figures 9 and 10, we also present results of CDN without implementing the shrinking strategy (denoted as CDN-NS). In most cases, the implementation with shrinking is only slightly better. However, shrinking is effective if the sparsity is high (e.g., news20 and yahoo-japan). In such a situation, most $\mathbf{w}$ components are zero. We can safely remove some zero components and more efficiently solve smaller optimization problems.

9. Discussions and Conclusions

In Section 2.5, we briefly discuss optimization methods for L1-regularized least-square regression. Some comparisons can be seen in, for example, the experiment section of Wright et al. (2009) and Yun and Toh (2009). Note that an optimization method may perform differently on classification and regression problems. For instance, Yun and Toh (2009) show that CGD-GS is faster than CDN for regression problems, but here we have an opposite observation for document classification.

Figures 1–8 indicate that CDN is faster for solving (1) than (5). Our past work (Huang et al., 2010, Section 5) has indicated that the bias term may affect the running time of the same optimization method. As the accuracy does not differ much, it seems that in general the bias term should not be considered.

Among quasi Newton and Newton approaches, IPM and OWL-QN are faster than TRON. This result seems to indicate that TRON suffers from the difficulty for finding $\mathbf{w}$'s final non-zero coeffi-



(a) a9a (b) real-sim (c) news20

(d) rcv1 (e) yahoo-japan (f) yahoo-korea

Figure 10: The 2-norm of the minimum-norm sub-gradient (83) versus training time. L2-loss SVMs without using the bias term. Both x-axis and y-axis are log-scaled.

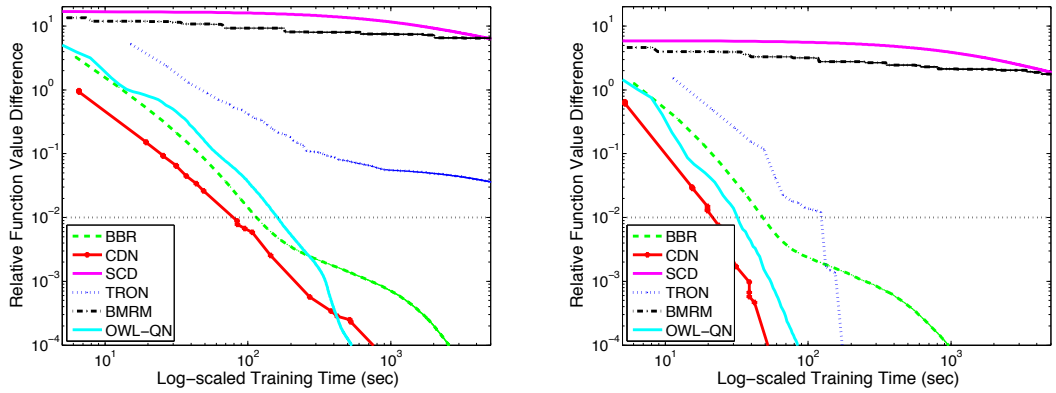
cients. However, IPM's $\mathbf{w}$ elements are all non-zeros, so we must accurately solve the optimization problem before trimming some elements to zero.

Figures 9 and 10 indicate that CDN/TRON for L2-loss SVMs is faster than CDN/TRON for logistic regression. Each iteration of CDN/TRON for L2-loss SVMs is cheaper because no exp/log operations are involved. Because the accuracy is similar, in general we prefer L2-loss SVMs over logistic regression.

The choice of the regularization parameter C affects the performance of solvers. In Figure 11, we present results on the rcv1 data set with regularization parameters $10C^*$ and $0.1C^*$, respectively, where $C^* = 4$ is the best parameter obtained from cross validation; see Table 2. Results show that all solvers take longer running time when C is large. Therefore, one should avoid a value much larger than C^* by trying from a small C. Moreover, methods using low-order (e.g., gradient only) information seem to be more sensitive to the change of C. For example, with C^* and $0.1C^*$ we respectively observe in Figures 1(d) and 11(b) that CDN is faster than OWL-QN, but with $10C^*$, OWL-QN surpasses CDN in the final stage.

GLMNET iteratively considers quadratic approximations and applies coordinate descent methods at each iteration. The discussion in Section 8.3 indicates that GLMNET's speed may be further improved if an adaptive stopping condition is properly designed for minimizing each quadratic approximation.

It is challenging to efficiently solve L1-regularized linear classification problems. The 1-norm term causes the non-differentiability of the objective function. In this paper, we review many existing methods for logistic regression and L2-loss SVMs. We discuss some state-of-the-art methods



(a) rcv1 with $10C^*$ (b) rcv1 with $0.1C^*$

in detail. Our extensive comparison shows that carefully implemented coordinate descent methods are effective for L1-regularized classification with large-scale document data.

Appendix A. Existence of Optimal Solutions of (1)

Consider the following level set:

$$S \equiv \{\mathbf{w} \mid f(\mathbf{w}) \leq f(\mathbf{0})\}.$$

We prove that S is compact (closed and bounded). Clearly, S is closed due to the continuity of $f(\mathbf{w})$. If S is not bounded, then there is a sequence $\{\mathbf{w}^k\} \subset S$ such that $\|\mathbf{w}^k\|_1 \to \infty$. Because we assume that $\xi(\mathbf{w};\mathbf{x}_i,y_i) \geq 0$, $f(\mathbf{w}^k) \geq \|\mathbf{w}^k\|_1$. Then, $f(\mathbf{w}^k) \to \infty$ contradicts $f(\mathbf{w}^k) \leq f(\mathbf{0})$. Thus, S is a compact set. From Weierstrass' Theorem, $f(\mathbf{w})$ has at least one minimum in S.

Appendix B. Solution of (26)

We consider the following general form with $A > 0$:

$$\min_z \quad |w_j + z| + Bz + \frac{1}{2}Az^2. \tag{84}$$

Clearly,

$$|w_j + z| + Bz + \frac{1}{2}Az^2 = \begin{cases} g_1(z) & \text{if } z \geq -w_j, \\ g_2(z) & \text{if } z \leq -w_j, \end{cases}$$

where

$$g_1(z) \equiv w_j + z + Bz + \frac{1}{2}Az^2 \quad \text{and} \quad g_2(z) \equiv -w_j - z + Bz + \frac{1}{2}Az^2.$$

By checking if the minimum of the quadratic function occurs on the right or the left side of $-w_j$, we know

$$\arg\min_{z \geq -w_j} g_1(z) = \begin{cases} -\frac{B+1}{A} & \text{if } B+1 \leq Aw_j, \\ -w_j & \text{otherwise,} \end{cases}$$

and

$$\arg\min_{z \leq -w_j} g_2(z) = \begin{cases} -\frac{B-1}{A} & \text{if } B-1 \geq Aw_j, \\ -w_j & \text{otherwise.} \end{cases}$$

Because $B+1 \leq Aw_j$ and $B-1 \geq Aw_j$ cannot hold at the same time, and $g_1(-w_j) = g_2(-w_j)$, we can easily conclude that the solution of (84) is

$$\begin{cases} -\frac{B+1}{A} & \text{if } B+1 \leq Aw_j, \\ -\frac{B-1}{A} & \text{if } B-1 \geq Aw_j, \\ -w_j & \text{otherwise.} \end{cases}$$

Appendix C. Proof of Theorem 1

From the assumption that $\mathbf{w}^k \to \mathbf{w}^*$ and the way that $\mathbf{w}$ is cyclically updated, we have $\mathbf{w}^{k,j} \to \mathbf{w}^*$ as well. The first result $-1 < \nabla_j L(\mathbf{w}^{k,j}) < 1$ immediately follows from the assumption $-1 < \nabla_j L(\mathbf{w}^*) < 1$ and the continuity of $\nabla L(\mathbf{w})$.

We then focus on the second result to show that $w_j^{k,j} = 0$ after k is large enough. The optimality condition (6) and the assumption $-1 < \nabla_j L(\mathbf{w}^*) < 1$ imply that $w_j^* = 0$. From the continuity of $\nabla^2 L(\mathbf{w})$ and the compactness of the level set S proved in Appendix A, we can define

$$M \equiv \max\{\nabla_{jj}^2 L(\mathbf{w}) \mid \mathbf{w} \in S\} \geq 0. \tag{85}$$

With the assumption $-1 < \nabla_j L(\mathbf{w}^*) < 1$ and the property $w_j^{k,j} \to w_j^* = 0$, for any $\sigma \in (0,1)$, there exists an iteration index K_j such that for all $k \geq K_j$,

$$-1 + \frac{M}{1-\sigma}|w_j^{k,j}| \leq L_j'(0; \mathbf{w}^{k,j}) = \nabla_j L(\mathbf{w}^{k,j}) \leq 1 - \frac{M}{1-\sigma}|w_j^{k,j}| \tag{86}$$

and

$$\left\{\mathbf{w} \;\middle|\; \|\mathbf{w} - \mathbf{w}^{k,j}\| \leq \|\mathbf{w}^{k,j} - \mathbf{w}^*\| \text{ for some } k \geq K_j\right\} \subset S.^7 \tag{87}$$

We prove that $w_j^{k,j} = 0$, $\forall k \geq K_j$. Recall that in the decomposition method we use (27) to obtain a direction d. From (86), we see that at $k = K_j$, the third case in (27) is taken. That is, $d = -w_j^{k,j}$. If σ in (86) is chosen to be the constant used in the sufficient decrease condition (28), we claim that

7. We need $f(\mathbf{w}^*) < f(\mathbf{0})$. This property generally holds. If not, we can slightly enlarge S so that (87) and all subsequent derivations still follow.

$d = -w_j^{k,j}$ satisfies (28) with $\lambda = 1$: If $w_j^{k,j} \geq 0$,

$$\begin{aligned} & g_j(-w_j^{k,j}) - g_j(0) - \sigma\left(-w_j^{k,j} - L_j'(0;\mathbf{w}^{k,j})w_j^{k,j}\right) \\ =&(1-\sigma)\left(-w_j^{k,j} - L_j'(0;\mathbf{w}^{k,j})w_j^{k,j}\right) + \frac{1}{2}L_j''(\tilde{z};\mathbf{w}^{k,j})(w_j^{k,j})^2 \qquad (88) \\ \leq&(1-\sigma)\left(-w_j^{k,j} - L_j'(0;\mathbf{w}^{k,j})w_j^{k,j}\right) + \frac{1}{2}M(w_j^{k,j})^2 \qquad (89) \\ \leq&\frac{-1}{2}M(w_j^{k,j})^2 \leq 0, \qquad (90) \end{aligned}$$

where $\tilde{z}$ is between 0 and $-w_j^{k,j}$, Equation (88) follows from (20)–(21), Equation (89) is from (87) and (85),[8] and Equation (90) is from the first inequality of (86). The above result is precisely the sufficient decrease condition (28) with $\lambda = 1$. The situation for $w_j^{k,j} < 0$ is similar. By taking the step $d = -w_j^{k,j}$, we have $w_j^{k+1,j} = 0$. At the $(k+1)$st iteration, $w_j^{k+1,j} = 0$ and (86) imply that the optimality condition (18) for the sub-problem has been satisfied. Thus, the jth element of $\mathbf{w}$ remains zero in all subsequent iterations.

Appendix D. Convergence of CDN: Logistic Regression

If each time one variable is used, the sub-problem considered in Tseng and Yun (2007) is

$$\min_z \quad |w_j + z| - |w_j| + L_j'(0)z + \frac{1}{2}Hz^2. \qquad (91)$$

Clearly, (26) is a special case of (91) by taking $H = L_j''(0)$. Therefore, we can apply results proved in Tseng and Yun (2007).

To have the finite termination of the line search procedure, Tseng and Yun (2007, Lemma 3.4) require that there exists $A > 0$ such that

$$\|\nabla L(\mathbf{w}_1) - \nabla L(\mathbf{w}_2)\| \leq A\|\mathbf{w}_1 - \mathbf{w}_2\|, \ \forall \mathbf{w}_1, \mathbf{w}_2 \in R^n \qquad (92)$$

and

$$L_j''(0;\mathbf{w}) > 0, \qquad (93)$$

where $\mathbf{w}$ is the current solution used to generate the direction d in (27). Equation (92) means that $L(\cdot)$ is globally Lipschitz continuous. For logistic regression, we have

$$\|\nabla L(\mathbf{w}_1) - \nabla L(\mathbf{w}_2)\| \leq \|\nabla^2 L(\tilde{\mathbf{w}})\|\|\mathbf{w}_1 - \mathbf{w}_2\|,$$

where $\tilde{\mathbf{w}}$ is between $\mathbf{w}_1$ and $\mathbf{w}_2$. Moreover,

$$\|\nabla^2 L(\tilde{\mathbf{w}})\| = C\|X^T D(\tilde{\mathbf{w}})X\| \leq C\|X^T\|\|X\|, \qquad (94)$$

where $D(\tilde{\mathbf{w}}) \in R^{l\times l}$ is a diagonal matrix similar to (70). Because any diagonal element of $D(\tilde{\mathbf{w}})$ is less than one, we have the inequality in (94). Thus, we can use $C\|X^T\|\|X\|$ as the constant A in (92).

8. More precisely,

$$\|\mathbf{w}^{k,j} + \tilde{z}\mathbf{e}_j - \mathbf{w}^{k,j}\| \leq |w_j^{k,j}| = |w_j^{k,j} - w_j^*| \leq \|\mathbf{w}^{k,j} - \mathbf{w}^*\|.$$

For (93), from (29), $L_j''(0;\mathbf{w})$ in the level set S is lower bounded by a positive value. The only exception is that $L_j''(0;\mathbf{w}) = 0$ when $x_{ij} = 0,\ \forall i = 1,\ldots,l$. In this situation, $L_j'(0;\mathbf{w}) = 0$ and the optimal $w_j^* = 0$. The one-variable function $g_j(z)$ is reduced to

$$g_j(z) = |w_j + z| - |w_j|,$$

so $d = -w_j$ from (27) and d satisfies the sufficient decrease condition (28). Therefore, w_j becomes zero after the first iteration and is not changed after. It is like that the jth feature has been removed in the beginning.

Next, we discuss the asymptotic convergence of function values. Tseng and Yun (2007) impose certain conditions on choosing the working set; see Equation (12) in their paper. If one variable is updated at a time, their condition is reduced to that between $\mathbf{w}^k$ and $\mathbf{w}^{k+1}$, one must go through n sub-problems covering all $w_1,\ldots,w_n$. This setting is exactly what we do, regardless of using a sequential order of $1,\ldots,n$ or a permutation $\pi(1),\ldots,\pi(n)$.

Tseng and Yun (2007) need an additional assumption for the asymptotic convergence (see Assumption 1 in their paper):

$$0 < \lambda_{\min} \le \nabla_{jj}^2 L(\mathbf{w}^{k,j}) \le \lambda_{\max}, \forall j = 1,\ldots,n, k = 1,\ldots, \tag{95}$$

where $\lambda_{\min}$ and $\lambda_{\max}$ are positive constants. From (29) and the boundedness of the level set S (see Appendix A), this assumption holds except that for some $j, x_{ij} = 0, \forall i$. For such $j, \nabla_j L(\mathbf{w}) = 0, \forall \mathbf{w}$. Hence, w_j becomes zero by (27) at the first iteration and is not changed subsequently. Because $w_j = 0$ is optimal in this situation, it is like that the jth variable has been removed for optimization. Therefore, we have (95) without problems.

Following Tseng and Yun (2007, Theorem 4.1(e)), any limit point of $\{\mathbf{w}^k\}$ is an optimum of (1) with logistic loss.

Appendix E. Convergence of TRON: Logistic Regression

Consider any limit point $\bar{\mathbf{w}}$ generated by $\{\mathbf{w}^k\}$. Lin and Moré (1999) proved that if

$$\nabla^2 \bar{f}(\bar{\mathbf{w}})_{J,J} \text{ is positive definite,} \tag{96}$$

where

$$J \equiv \{j \mid \nabla_j \bar{f}(\bar{\mathbf{w}}) = 0\},$$

then the following two results hold:

1. $\{\mathbf{w}^k\}$ globally converges to $\bar{\mathbf{w}}$.
2. $\{\mathbf{w}^k\}$ quadratically converges. That is, there exist $\mu \in (0,1)$ and a positive integer K such that

$$\|\mathbf{w}^{k+1} - \bar{\mathbf{w}}\| \le (1-\mu)\|\mathbf{w}^k - \bar{\mathbf{w}}\|^2,\ \forall k > K.$$

The remaining question is whether (96) holds. From (58), we have

$$\nabla^2 \bar{f}(\bar{\mathbf{w}}) = C \begin{bmatrix} X^T \\ -X^T \end{bmatrix} D \begin{bmatrix} X & -X \end{bmatrix}, \tag{97}$$

where D is defined in (57). $\nabla^2 \bar{f}(\bar{\mathbf{w}})$ cannot be positive definite if there exists $1 \le j \le n$ such that $\{j, j+n\} \subset J$. The reason is that one can easily find a vector $\mathbf{v} \in R^{2n}$ such that $\mathbf{v}^T \nabla^2 \bar{f}(\bar{\mathbf{w}})\mathbf{v} = 0$. For

example, let $v_j = v_{j+n} \neq 0$ and other elements be zero. However, we claim that $\{j, j+n\} \subset J$ does not happen. Otherwise,

$$\nabla_j \bar{f}(\bar{\mathbf{w}}) = 1 + \nabla_j L(\bar{\mathbf{w}}_{1:n} - \bar{\mathbf{w}}_{n+1:2n}) \quad \text{and}$$
$$\nabla_{j+n} \bar{f}(\bar{\mathbf{w}}) = 1 - \nabla_j L(\bar{\mathbf{w}}_{1:n} - \bar{\mathbf{w}}_{n+1:2n})$$

are both zero, but this situation is not possible.

From the optimality condition (6), J is the same as the following set:

$$\{j \mid \bar{w}_j > 0 \text{ or } \bar{w}_j = \nabla_j \bar{f}(\bar{\mathbf{w}}) = 0\}.$$

Therefore, if the solution is sparse and those $\bar{w}_j = 0$ or $\bar{w}_{j+n} = 0, 1 \leq j \leq n$ satisfy

$$\begin{cases} \nabla_j \bar{f}(\bar{\mathbf{w}}) > 0 & \text{if } \bar{w}_j = 0, \\ \nabla_{j+n} \bar{f}(\bar{\mathbf{w}}) > 0 & \text{if } \bar{w}_{j+n} = 0, \end{cases}$$

(i.e., the optimization problem is non-degenerate), then $|J|$ is small. From (97), $\nabla^2 \bar{f}(\bar{\mathbf{w}})_{J,J}$ tends to be positive definite if $|J|$ is small. Then, we can have the quadratic convergence.

Appendix F. Convergence of CDN: L2-loss SVM

To have the finite termination of the line search procedure, we need conditions similar to (92) and (93). The condition (92) means that $\nabla L(\mathbf{w})$ is globally Lipschitz continuous. L2-loss SVM satisfies this property (Mangasarian, 2002, Section 3). For (93), the setting in (81) ensures that H in (91) is always positive. Therefore, the line search procedure stops in a finite number of steps.

For the asymptotic convergence, we need again the condition (95). Our setting in (81) meets this assumption, so any limit point of $\{\mathbf{w}^k\}$ is an optimal solution of (77).

Editor: Manfred Opper

Abstract

Variational Bayesian (VB) methods are typically only applied to models in the conjugate-exponential family using the variational Bayesian expectation maximisation (VB EM) algorithm or one of its variants. In this paper we present an efficient algorithm for applying VB to more general models. The method is based on specifying the functional form of the approximation, such as multivariate Gaussian. The parameters of the approximation are optimised using a conjugate gradient algorithm that utilises the Riemannian geometry of the space of the approximations. This leads to a very efficient algorithm for suitably structured approximations. It is shown empirically that the proposed method is comparable or superior in efficiency to the VB EM in a case where both are applicable. We also apply the algorithm to learning a nonlinear state-space model and a nonlinear factor analysis model for which the VB EM is not applicable. For these models, the proposed algorithm outperforms alternative gradient-based methods by a significant margin.

Keywords: variational inference, approximate Riemannian conjugate gradient, fixed-form approximation, Gaussian approximation

1. Introduction

Bayesian methods have recently gained popularity in machine learning. This is at least partially due to their robustness against overfitting compared to maximum likelihood and other methods based on point estimates. Variational Bayesian (VB) methods provide an efficient and often sufficiently accurate deterministic approximation to Bayesian learning (Bishop, 2006). Mean field type VB also has the benefit that its objective function can be used for choosing the model structure or model order. Most work on variational methods has focused on the class of conjugate exponential models for which simple EM-like learning algorithms can be derived easily (Ghahramani and Beal, 2001; Winn and Bishop, 2005). These models and algorithms are computationally convenient but they rule out many interesting model types.

*. These authors contributed equally to this work. This project may be found at `http://www.cis.hut.fi/projects/bayes/`.

Many practically important models are not in the conjugate-exponential family and they have received far less attention in the VB literature. In this paper we present an efficient general method for applying VB learning to these more general models. The method could be used to speed up, for instance, the Gaussian variational approximation method of Opper and Archambeau (2009), or other previous more specific methods (e.g., Lappalainen and Honkela, 2000; Valpola and Karhunen, 2002).

Our method is based on first selecting the functional form of the approximation. For parts of the model that are conjugate-exponential, the corresponding factorised exponential family distribution is often a good choice, while in general we may use something else such as a multivariate Gaussian.

After fixing the functional form, we must be able to evaluate the variational free energy as a function of the variational parameters. The details of this step depend on the model—often most terms can be evaluated analytically while others may require computing some bounds (Jordan et al., 1999) or applying some linearisation techniques (see, e.g., Honkela and Valpola, 2005) or other approximations.

Once the free energy is known, we are left with a typically high-dimensional optimisation problem. Here[1] we propose using an approximate conjugate gradient algorithm that utilises the Riemannian geometry of the space of the approximations to speed up convergence. One of the main contributions of this paper is to use the geometry of the approximations. This is in contrast to more common applications of Riemannian geometry in natural gradient methods using the geometry of the predictive model. The geometry of the approximations is the natural choice if the variational inference is viewed as an optimisation problem in the space of approximating distributions. Furthermore, the geometry of the approximation is often much simpler, leading to more efficient computation and generic algorithms. The computational complexity of operations with the Fisher information matrix determining the geometry can be linear if the approximation is fully factorising or if its multivariate Gaussian blocks have a tree-like dependence structure, for instance. The resulting algorithm can provide dramatic speedups of potentially several orders of magnitude over state-of-the-art Euclidean conjugate gradient methods.

In previous machine learning algorithms Riemannian geometry is usually invoked through the natural gradient of Amari (1998). There, the aim has been to use maximum likelihood to directly update the model parameters $\boldsymbol{\theta}$ taking into account the geometry imposed by the predictive distribution of the data $p(\boldsymbol{X}|\boldsymbol{\theta})$. The resulting geometry is often quite complicated as the effects of different parameters cannot be separated and the Fisher information matrix is relatively dense. Recently Girolami and Calderhead (2011) have applied this in a Bayesian setting as a method to speed up Hamiltonian Monte Carlo samplers. In this paper, only the simpler geometry of the VB approximating distributions $q(\boldsymbol{\theta}|\boldsymbol{\xi})$ is used. Because the approximations are often chosen to minimise dependencies between different parameters $\boldsymbol{\theta}$, the resulting Fisher information matrix with respect to the variational parameters $\boldsymbol{\xi}$ will be mostly diagonal and hence easy to work with.

The rest of the paper is organised as follows. Section 2 introduces the background in variational Bayes and information geometry. The proposed approximate Riemannian conjugate gradient learning algorithm is introduced in Section 3. The method is demonstrated in three case studies: a Gaussian mixture model, a nonlinear state-space model and a nonlinear factor analysis model in Secs. 4, 5 and 6, respectively. We end with discussion in Section 7.

1. This paper is an extended version of the earlier conference paper (Honkela et al., 2008).

2. Background

The approximate Riemannian conjugate gradient learning algorithm follows very naturally from an optimisation view of variational Bayes and the Riemannian geometry of probability distributions in information geometry. We will start with a brief introduction to both of these techniques separately.

2.1 Variational Bayes

Variational Bayesian (VB) learning (Jordan et al., 1999; Ghahramani and Beal, 2001; Bishop, 2006) is based on approximating the posterior distribution $p(\boldsymbol{\theta}|\boldsymbol{X})$ with a tractable approximation $q(\boldsymbol{\theta}|\boldsymbol{\xi})$, where $\boldsymbol{X}$ is the data, $\boldsymbol{\theta}$ are the unobserved variables (including both the parameters of the model and the latent variables), and $\boldsymbol{\xi}$ are the variational parameters of the approximation (such as the mean and the variance of a Gaussian approximation). The approximation is fitted by minimising the free energy

$$\mathcal{F}(q(\boldsymbol{\theta}|\boldsymbol{\xi})) = E_{q(\boldsymbol{\theta}|\boldsymbol{\xi})}\left\{\log \frac{q(\boldsymbol{\theta}|\boldsymbol{\xi})}{p(\boldsymbol{X},\boldsymbol{\theta})}\right\} = D_{\mathrm{KL}}(q(\boldsymbol{\theta}|\boldsymbol{\xi})\|p(\boldsymbol{\theta}|\boldsymbol{X})) - \log p(\boldsymbol{X}). \tag{1}$$

This is equivalent to minimising the Kullback-Leibler (KL) divergence $D_{\mathrm{KL}}(q\|p)$ between q and p (Bishop, 2006). The negative free energy also provides a lower bound on the marginal log-likelihood, that is, $\log p(\boldsymbol{X}) \geq -\mathcal{F}(q(\boldsymbol{\theta}|\boldsymbol{\xi}))$ due to non-negativity of the KL-divergence.

Typical classes of approximations used in VB include factorising approximations, most often starting from assuming the latent variables and parameters to be independent and extending to the fully factorising mean-field approximation, and approximations having a fixed functional form, such as a Gaussian.

In the former case, learning is typically performed using the variational Bayesian expectation maximisation (VB EM) algorithm which alternates between minimising the free energy with respect to the distribution of the latent variables (VB-E step) and the distribution of the parameters (VB-M step) (Bishop, 2006).

In the case of approximation with a fixed functional form, EM-like updates are usually not available and generic gradient-based optimisation methods have to be used (see, e.g., Opper and Archambeau, 2009). This is often very challenging in practice, as the problems are quite high dimensional and the lack of specific knowledge of interactions of the parameters that define the geometry of the problem can seriously hinder generic optimisation tools. Such methods have nevertheless been applied to a number of models that are not in the conjugate exponential family, such as multi-layer perceptron (MLP) networks (Barber and Bishop, 1998), kernel classifiers (Seeger, 2000), nonlinear factor analysis (Lappalainen and Honkela, 2000; Honkela and Valpola, 2005; Honkela et al., 2007) and nonlinear dynamical models (Valpola and Karhunen, 2002; Archambeau et al., 2008), non-conjugate variance models (Valpola et al., 2004; Raiko et al., 2007) as well as Gaussian process latent variable models (Titsias and Lawrence, 2010). Optimisation methods have included the conjugate gradient algorithm and heuristic speed-ups, but the use of a Riemannian conjugate gradient algorithm for VB as proposed in this paper is novel.

In practice, convergence of conjugate gradient algorithms in latent variable models is often really slow. To get an intuition of why this is the case, let us consider a generic latent variable model with latent variables that connect to one observation each and parameters that connect to a number of observations. As we increase the number of observations, the gradient with respect to the parameters grows linearly, whereas the gradient with respect to the latent variables stays constant.

As a result, with a reasonable number of observations, conjugate gradient algorithms are forced to take very small steps to avoid overshooting the parameters, and as a result the latent variables are hardly changed at all. The Riemannian gradient provides an automatic remedy to this problem by properly scaling the gradient.

2.2 Information Geometry and Optimisation on Riemannian Manifolds

When applying a generic optimisation algorithm to a problem such as optimising the free energy (1), a lot of background information on the geometry of the problem is lost. The parameters $\boldsymbol{\xi}$ of $q(\boldsymbol{\theta}|\boldsymbol{\xi})$ can have different roles as location, shape, and scale parameters, and their effect is influenced by other parameters. This implies that the geometry of the problem is in most cases not Euclidean.

Riemannian geometry studies smooth manifolds $\{\mathcal{M}|\boldsymbol{\xi}\}$ that are locally diffeomorphic with $\mathbb{R}^n$. The manifold has an inner product $\langle\cdot,\cdot\rangle_k$ defined at every point $\boldsymbol{\xi}_k$ of the manifold. The inner product is defined for vectors in tangent space $T_{\boldsymbol{\xi}_k}$ of $\mathcal{M}$ at $\boldsymbol{\xi}_k$ as

$$\langle \mathbf{x}, \mathbf{y} \rangle_k = \mathbf{x}^T \mathbf{G}(\boldsymbol{\xi}_k) \mathbf{y} = \sum_{i,j} x_i y_j g_{ij}(\boldsymbol{\xi}_k), \tag{2}$$

where $\mathbf{G}(\boldsymbol{\xi}_k)$ is the Riemannian metric tensor at $\boldsymbol{\xi}_k$. Most Riemannian manifolds are curved, with geodesics as the counterparts of Euclidean straight lines as length-minimising curves between two points (Murray and Rice, 1993).

Information geometry studies the Riemannian geometric structure of the manifold of probability distributions (Amari, 1985). It has been applied to derive efficient natural gradient learning rules for maximum likelihood algorithms in independent component analysis (ICA) and multi-layer perceptron (MLP) networks (Amari, 1998). The approach has been used in several other problems as well, for example in analysing the properties of an on-line variational Bayesian EM method (Sato, 2001).

For probability distributions, the most natural metric is given by the Fisher information

$$g_{ij}(\boldsymbol{\xi}) = I_{ij}(\boldsymbol{\xi}) = E\left\{ \frac{\partial \log q(\boldsymbol{\theta}|\boldsymbol{\xi})}{\partial \xi_i} \frac{\partial \log q(\boldsymbol{\theta}|\boldsymbol{\xi})}{\partial \xi_j} \right\} = E\left\{ -\frac{\partial^2 \log q(\boldsymbol{\theta}|\boldsymbol{\xi})}{\partial \xi_i \partial \xi_j} \right\}. \tag{3}$$

Here the last equality is valid if $q(\boldsymbol{\theta}|\boldsymbol{\xi})$ is twice continuously differentiable (Murray and Rice, 1993). Fisher information is a unique metric for probability distributions in the sense that it is the only metric which is invariant with respect to transformations to sufficient statistics (Amari and Nagaoka, 2000).

In a Riemannian space, the direction of steepest ascent of a function $\mathcal{F}(\boldsymbol{\xi})$ is given by the Riemannian or natural gradient

$$\tilde{\nabla}\mathcal{F}(\boldsymbol{\xi}) = \mathbf{G}^{-1}(\boldsymbol{\xi}) \nabla \mathcal{F}(\boldsymbol{\xi}) \tag{4}$$

instead of the regular gradient $\nabla\mathcal{F}(\boldsymbol{\xi})$. This can be verified by finding the maximum of $\mathcal{F}(\boldsymbol{\xi}+\Delta\boldsymbol{\xi})$ subject to the constraint $||\Delta\boldsymbol{\xi}||^2_{\boldsymbol{\xi}} = \langle \Delta\boldsymbol{\xi}, \Delta\boldsymbol{\xi} \rangle_{\boldsymbol{\xi}} = \Delta\boldsymbol{\xi}^T \mathbf{G}(\boldsymbol{\xi}) \Delta\boldsymbol{\xi} < \varepsilon^2$. The relation between gradient and Riemannian gradient is illustrated in Figure 1.

This choice of geometry between Euclidean and Riemannian is, however, independent of the choice of the optimisation algorithm, and recently several authors have combined conjugate gradient methods with the Riemannian or natural gradient (Smith, 1993; González and Dorronsoro, 2008; Honkela et al., 2008). In principle this can be achieved by replacing all vector space operations in

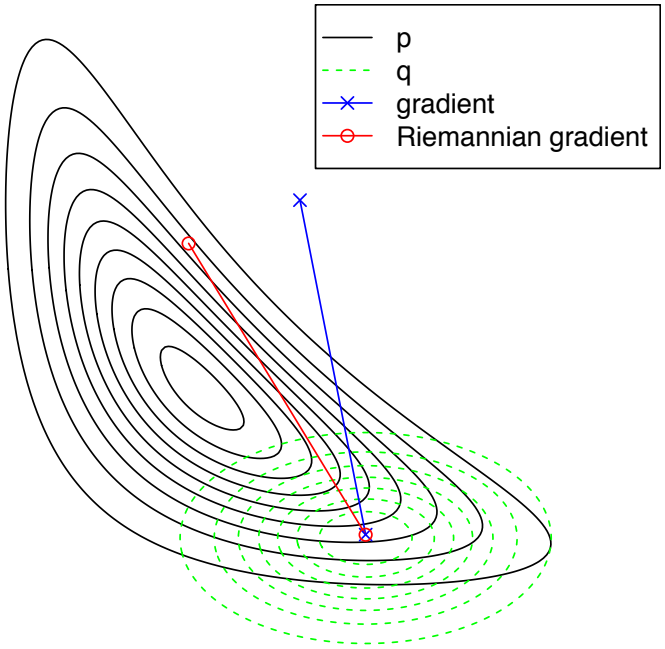

Figure 1: Gradient and Riemannian gradient directions are shown for the mean of distribution q. VB learning with a diagonal covariance is applied to the posterior $p(x,y) \propto \exp[-9(xy-1)^2 - x^2 - y^2]$. The Riemannian gradient strengthens the updates in the directions where the uncertainty is large.

the conjugate gradient algorithm with their Riemannian counterparts: Riemannian inner products and norms, parallel transport of gradient vectors between different tangent spaces as well as line searches and steps along geodesics in the Riemannian space. In practical algorithms some of these can be approximated by their flat-space counterparts. We shall apply the approximate Riemannian conjugate gradient (RCG) method which implements Riemannian (natural) gradients, inner products and norms but uses flat-space approximations of the others as our optimisation algorithm of choice throughout the paper. As shown in Appendix A, these approximations do not affect the asymptotic convergence properties of the algorithm. The difference between gradient and conjugate gradient methods is illustrated in Figure 2.

In this paper we propose using the Riemannian structure of the distributions $q(\boldsymbol{\theta}|\boldsymbol{\xi})$ to derive more efficient algorithms for approximate inference and especially VB using approximations with a fixed functional form. This differs from the traditional natural gradient learning by Amari (1998) which uses the Riemannian structure of the predictive distribution $p(\boldsymbol{X}|\boldsymbol{\theta})$. The proposed method can be used to jointly optimise all the parameters $\boldsymbol{\xi}$ of the approximation $q(\boldsymbol{\theta}|\boldsymbol{\xi})$, or in conjunction with VB EM for some parameters.

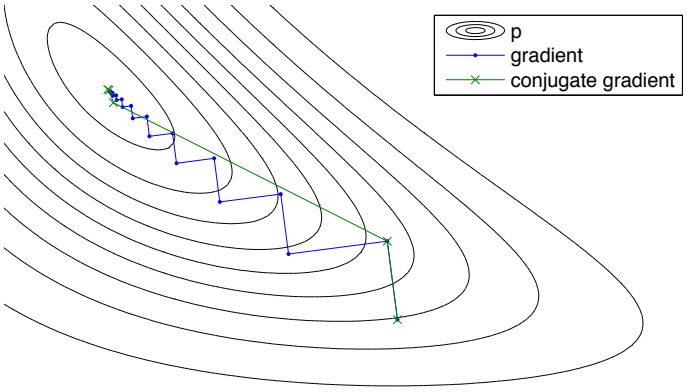

Figure 2: Gradient and conjugate gradient updates are applied to finding the maximum of the posterior $p(x,y) \propto \exp[-9(xy-1)^2 - x^2 - y^2]$. The step sizes that maximise p are used. Note that the first steps are the same, but following gradient updates are orthogonal whereas conjugate gradient finds a much better direction.

2.3 Information Geometry of VB EM

The optimal VB approximation has an information-geometric interpretation as a specific projection of the true posterior to a manifold of tractable distributions (Tanaka, 2001). This interpretation is equally valid for all optimisation methods.

Amari (1995) has also presented the geometric interpretation of the EM algorithm as alternating projections for E- and M-steps. This asymmetric view does not directly generalise to the VB EM method when used to infer distributions over all parameters, because VB EM is symmetric with respect to different parameters.

By embedding the VB-E step update within the VB-M step with point estimates and considering the resulting update, the VB EM algorithm for conjugate exponential family models can be interpreted as a natural gradient method (Sato, 2001). It therefore implicitly optimally utilises the Riemannian geometric structure of $q(\boldsymbol{\theta}|\boldsymbol{\xi})$ (Amari, 1998). Nevertheless, the EM-based methods are prone to slow convergence, especially under low noise, even though more elaborate optimisation schemes can speed up their convergence somewhat. It is worth pointing out that this correspondence of VB EM is with the regular natural gradient algorithm, not Riemannian (natural) conjugate gradients as proposed in this paper.

3. Approximate Riemannian Conjugate Gradient Learning for Fixed-Form VB

Given a fixed-form approximation $q(\boldsymbol{\theta}|\boldsymbol{\xi})$ and the free energy $\mathcal{F}(q(\boldsymbol{\theta}|\boldsymbol{\xi}))$, it is possible to use standard gradient-based optimisation techniques to minimise the free energy with respect to $\boldsymbol{\xi}$. We will use VB EM updates for some variational parameters $\boldsymbol{\xi}^{\mathrm{EM}}$ and RCG for others $\boldsymbol{\xi}^{\mathrm{RCG}}$.

Instead of a regular Euclidean gradient algorithm, we optimise the free energy using a conjugate gradient algorithm that is adapted to Riemannian space by using Riemannian inner products and norms instead of Euclidean ones. Steps are still taken along Euclidean straight lines and the step

length is determined using a line search. We call this the (approximate) Riemannian conjugate gradient (RCG) algorithm.

Our RCG is an approximation of a true Riemannian conjugate gradient algorithm (Smith, 1993), in which the steps are taken along geodesic curves and tangent vectors evaluated at different points are transformed to the same tangent space using parallel transport along a geodesic. For small step sizes and geometries which are locally close to Euclidean, the approximations that we have made still retain many of the benefits of the exact algorithm while greatly simplifying the computations. Edelman et al. (1998) showed that near the solution Riemannian conjugate gradient method differs from the flat space version of conjugate gradient only by third order terms, and therefore both algorithms converge quadratically near the optimum. This convergence property is demonstrated in detail for our approximation in Appendix A.

The search direction for the RCG method is given by

$$\mathbf{p}_k = -\tilde{\mathbf{g}}_k + \beta \mathbf{p}_{k-1},$$

where $\tilde{\mathbf{g}}_k = \tilde{\nabla}\mathcal{F}(\boldsymbol{\xi})$ is the Riemannian gradient of Equation (4). The coefficient β is evaluated using the Polak-Ribiére formula (Nocedal, 1992; Smith, 1993; Edelman et al., 1998)

$$\beta = \frac{\langle \tilde{\mathbf{g}}_k, \tilde{\mathbf{g}}_k - \tilde{\mathbf{g}}_{k-1} \rangle_k}{||\tilde{\mathbf{g}}_{k-1}||^2_{k-1}}, \tag{5}$$

where $||\tilde{\mathbf{g}}_k||^2_k = \langle \tilde{\mathbf{g}}_k, \tilde{\mathbf{g}}_k \rangle_k$ is the squared Riemannian norm of $\tilde{\mathbf{g}}_k$ in the tangent space where $\tilde{\mathbf{g}}_k$ is defined, and $\langle \mathbf{x}, \mathbf{y} \rangle_k$ denotes the Riemannian inner product of Equation (2) in the same tangent space.

We also apply a Riemannian version of the Powell-Beale restart method (Powell, 1977): the search direction is reset to the negative gradient direction if

$$|\langle \tilde{\mathbf{g}}_{k-1}, \tilde{\mathbf{g}}_k \rangle_k| \geq 0.2 ||\tilde{\mathbf{g}}_k||^2_k. \tag{6}$$

Compared to the traditional conjugate gradient, the Equations (5) and (6) are similar with just the dot products of the vectors replaced with Riemannian inner products.

Once the search direction is determined, we use standard line search to find the final update. Because the evaluation of the objective function is computationally costly, it is worthwhile to consider line search methods that stop earlier rather than wasting many function evaluations on fine tuning the parameters.

An example implementation of the algorithm is summarised in Algorithm 1. The inputs include the probabilistic model p, the form of used posterior approximation q, the initialisations for the variational parameters $\boldsymbol{\xi}$, and the data set $\boldsymbol{X}$ which is implicitly used in the objective function $\mathcal{F}$. The algorithm returns the variational parameters $\boldsymbol{\xi}$ that solve the learning and inference problem of $q(\boldsymbol{\theta}|\boldsymbol{\xi})$.

3.1 Computational Considerations

The RCG method is efficient as the geometry is defined by the approximation $q(\boldsymbol{\theta}|\boldsymbol{\xi})$ and not the full model $p(\boldsymbol{X}|\boldsymbol{\theta})$ as in typical natural gradient methods. If the approximation $q(\boldsymbol{\theta}|\boldsymbol{\xi})$ is chosen such that disjoint groups of variables are independent, that is,

$$q(\boldsymbol{\theta}|\boldsymbol{\xi}) = \prod_i q_i(\boldsymbol{\theta}_i|\boldsymbol{\xi}_i),$$

Algorithm 1 An outline of an example Riemannian conjugate gradient algorithm for fixed-form VB. The presented method of integrating VB EM updates is only one of many possible alternatives.

function VB-RCG($p, q, \boldsymbol{\xi}_0 = (\boldsymbol{\xi}_0^{\mathrm{EM}}, \boldsymbol{\xi}_0^{\mathrm{RCG}}), \boldsymbol{X}$)
  $\mathbf{p}_0 = \mathbf{0}, \tilde{\mathbf{g}}_0 = \mathbf{1}$
  for $k = 1, 2, \ldots$ **do** ▷ Repeat until convergence
    for $\boldsymbol{\xi}^{(i)} \in \boldsymbol{\xi}^{\mathrm{EM}} = (\boldsymbol{\xi}^{(1)}, \ldots, \boldsymbol{\xi}^{(N)})$ **do**
      $\boldsymbol{\xi}_k^{(i)} \leftarrow \arg\min_{\boldsymbol{\xi}^{(i)}} \mathcal{F}(q(\boldsymbol{\theta}|\boldsymbol{\xi}_k^{(1)}, \ldots, \boldsymbol{\xi}_k^{(i-1)}, \boldsymbol{\xi}^{(i)}, \boldsymbol{\xi}_{k-1}^{(i+1)}, \ldots, \boldsymbol{\xi}_{k-1}^{(N)}, \boldsymbol{\xi}_{k-1}^{\mathrm{RCG}}))$
      ▷ VB EM for some parameters
    $\tilde{\mathbf{g}}_k \leftarrow \mathbf{G}^{-1}(\boldsymbol{\xi}_{k-1}^{\mathrm{RCG}}) \nabla_{\boldsymbol{\xi}_{k-1}^{\mathrm{RCG}}} \mathcal{F}(q(\boldsymbol{\theta}|\boldsymbol{\xi}_k^{\mathrm{EM}}, \boldsymbol{\xi}_{k-1}^{\mathrm{RCG}}))$ ▷ Riemannian gradient
    $\beta \leftarrow \frac{\langle \tilde{\mathbf{g}}_k, \tilde{\mathbf{g}}_k - \tilde{\mathbf{g}}_{k-1} \rangle_k}{||\tilde{\mathbf{g}}_{k-1}||_{k-1}^2}$ ▷ Polak-Ribiére formula
    $\mathbf{p}_k \leftarrow -\tilde{\mathbf{g}}_k + \beta \mathbf{p}_{k-1}$ ▷ Update direction
    $\alpha \leftarrow \arg\min_\alpha \mathcal{F}(q(\boldsymbol{\theta}|\boldsymbol{\xi}_k^{\mathrm{EM}}, \boldsymbol{\xi}_{k-1}^{\mathrm{RCG}} + \alpha \mathbf{p}_k))$ ▷ Line search
    $\boldsymbol{\xi}_k^{\mathrm{RCG}} \leftarrow \boldsymbol{\xi}_{k-1}^{\mathrm{RCG}} + \alpha \mathbf{p}_k$

the computation of the Riemannian gradient is simplified as the Fisher information matrix becomes block-diagonal. The required matrix operations can be performed very efficiently because

$$\mathrm{diag}(\mathbf{A}_1, \ldots, \mathbf{A}_n)^{-1} = \mathrm{diag}(\mathbf{A}_1^{-1}, \ldots, \mathbf{A}_n^{-1}).$$

The dimensionality of the problem space is often so high that working with the full matrix would not be feasible.

All vector operations needed in the RCG algorithm are of the form

$$\langle \tilde{\mathbf{g}}_k, \tilde{\mathbf{g}}_l \rangle_m = \langle \mathbf{G}_k^{-1} \mathbf{g}_k, \mathbf{G}_l^{-1} \mathbf{g}_l \rangle_m = \mathbf{g}_k^T \mathbf{G}_k^{-T} \mathbf{G}_m \mathbf{G}_l^{-1} \mathbf{g}_l \tag{7}$$

for some iterate indices k, l, m. This is further simplified in case $m = k$ where $\mathbf{G}_k^{-T} \mathbf{G}_m = \mathbf{I}$ and in case $m = l$ where $\mathbf{G}_m \mathbf{G}_l^{-1} = \mathbf{I}$. Depending on the structure of the Fisher information matrix, the operations can be performed as a series of solving linear systems and matrix products to exploit the sparsity. A practical example of this in the case of a Gaussian approximation is presented in Section 3.2.1.

Finally, it is worth to note that when updating only a subset of variational parameters $\boldsymbol{\xi}$ at a time, many terms in $\mathcal{F}$ are constant and can be disregarded when finding a minimum.

3.2 Gaussian Approximation

Most obvious applications of the Riemannian gradient method are with a Gaussian approximation. In that case, it is most convenient to use a simple fixed-point update rule for the covariance and a Riemannian conjugate gradient update only for the mean.

Let us consider the optimisation of the free energy (1) when the approximation $q(\boldsymbol{\theta}|\boldsymbol{\xi})$ is a multivariate Gaussian. The free energy can be decomposed as

$$\mathcal{F}(q(\boldsymbol{\theta}|\boldsymbol{\xi})) = E_{q(\boldsymbol{\theta}|\boldsymbol{\xi})} \left\{ \log \frac{q(\boldsymbol{\theta}|\boldsymbol{\xi})}{p(\boldsymbol{X}, \boldsymbol{\theta})} \right\} = E_{q(\boldsymbol{\theta}|\boldsymbol{\xi})} \left\{ \log q(\boldsymbol{\theta}|\boldsymbol{\xi}) \right\} + E_{q(\boldsymbol{\theta}|\boldsymbol{\xi})} \left\{ -\log p(\boldsymbol{X}, \boldsymbol{\theta}) \right\}.$$

The former term is the negative entropy of the approximation, which in the case of a multivariate Gaussian $q(\boldsymbol{\theta}|\boldsymbol{\mu},\boldsymbol{\Sigma})$ with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$ is

$$E_{q(\boldsymbol{\theta}|\boldsymbol{\xi})}\left\{\log q(\boldsymbol{\theta}|\boldsymbol{\xi})\right\} = -\frac{1}{2}\log\det(2\pi e\boldsymbol{\Sigma}).$$

Straightforward differentiation yields a fixed point update rule for the covariance (Lappalainen and Miskin, 2000; Opper and Archambeau, 2009):

$$\boldsymbol{\Sigma}^{-1} = -2\nabla_{\boldsymbol{\Sigma}} E_{q(\boldsymbol{\theta}|\boldsymbol{\xi})}\left\{\log p(\boldsymbol{X},\boldsymbol{\theta})\right\}, \tag{8}$$

where $\nabla_{\boldsymbol{\Sigma}}$ denotes the gradient with respect to $\boldsymbol{\Sigma}$. If the covariance matrix is assumed (block) diagonal, the same update rule applies for the (block) diagonal terms.

3.2.1 COMPUTING THE RIEMANNIAN METRIC TENSOR

For the univariate Gaussian distribution parametrised by mean and variance $q(\theta|\mu,v) = \mathcal{N}(\theta|\mu,v)$, we have

$$\log q(\theta|\mu,v) = -\frac{1}{2v}(\theta-\mu)^2 - \frac{1}{2}\log(v) - \frac{1}{2}\log(2\pi).$$

Furthermore,

$$E\left\{-\frac{\partial^2 \log q(\theta|\mu,v)}{\partial\mu^2}\right\} = \frac{1}{v}, \tag{9}$$

$$E\left\{-\frac{\partial^2 \log q(\theta|\mu,v)}{\partial v\partial\mu}\right\} = 0, \text{ and} \tag{10}$$

$$E\left\{-\frac{\partial^2 \log q(\theta|\mu,v)}{\partial v^2}\right\} = \frac{1}{2v^2}. \tag{11}$$

The vanishing of the cross term between the mean and the variance further supports using the simpler fixed point rule (8) to update the variances.

(a) (b) (c) (d)

Figure 3: The absolute change in the mean of the Gaussian in figures (a) and (b) and the absolute change in the variance of the Gaussian in figures (c) and (d) is the same. However, the relative effect is much larger when the variance is small as in figures (a) and (c) compared to the case when the variance is high as in figures (b) and (d) (Valpola, 2000).

In the case of univariate Gaussian distribution, the Riemannian gradient has a rather straightforward intuitive interpretation, which is illustrated in Figure 3. Compared to conventional gradient, Riemannian gradient compensates for the fact that changing the parameters of a Gaussian with small variance has much more pronounced effects than when the variance is large.

In case of multivariate Gaussian distribution parametrised by mean and covariance $q(\boldsymbol{\theta}|\boldsymbol{\mu},\boldsymbol{\Sigma}) = \mathcal{N}(\boldsymbol{\theta}|\boldsymbol{\mu},\boldsymbol{\Sigma})$, the elements of the Fisher information matrix corresponding to the mean are simply

$$E\left\{-\frac{\partial^2 \log q(\boldsymbol{\theta}|\boldsymbol{\mu},\boldsymbol{\Sigma})}{\partial \boldsymbol{\mu}^T \partial \boldsymbol{\mu}}\right\} = \boldsymbol{\Sigma}^{-1}. \tag{12}$$

The Fisher information matrix is thus equal to the precision matrix $\mathbf{G}_k = \boldsymbol{\Lambda}_k = \boldsymbol{\Sigma}_k^{-1}$.

Typically the covariance matrix $\boldsymbol{\Sigma}$ is assumed to have a simple structure that makes working with it very efficient. Possible structures for a covariance matrix include full, diagonal, block diagonal, a Gaussian Markov random field with a specific structure, and a factor analysis covariance $\boldsymbol{\Sigma} = \mathbf{D} + \sum_{i=1}^{k} \mathbf{v}\mathbf{v}^T$, where $\mathbf{D}$ is a diagonal matrix, or $\boldsymbol{\Sigma}^{-1} = \mathbf{K}^{-1} + \mathrm{diag}(\mathbf{v})$ with a fixed $\mathbf{K}$ and only N parameters in $\mathbf{v}$ for an N-variate Gaussian (Opper and Archambeau, 2009). It is also possible to derive the geometry for the covariance of a multivariate Gaussian. The result does, however, depend on the specific structure of the covariance.

Assuming a structured Gaussian Markov random field approximation with a tree or blocked tree structure, the precision matrix will be sparse with a simple structure. This allows efficient computation of the operations needed in Equation (7). $\boldsymbol{\Lambda}_l^{-1}\mathbf{g}_l$ (and correspondingly for k) can be computed by solving the linear system $\boldsymbol{\Lambda}_l\mathbf{x} = \mathbf{g}_l$, which can be done in $O(N)$ time for N variables using a propagation algorithm in the tree. For a blocked tree formed of N/n blocks of size n, the complexity is $O(n^2N)$. Examples of such algorithms for chains are given in Golub and Loan (1996), but a general tree can be handled analogously. The complexity of multiplication by $\boldsymbol{\Lambda}$ is similar.

Examples of Gaussian Markov random fields with this structure can be easily found in time series models, where the approximation for the state sequence $\boldsymbol{S} = (\mathbf{s}(1),\ldots,\mathbf{s}(T))$ is typically either a single "blocked" chain

$$q(\boldsymbol{S}) = \prod_{t=2}^{T} q(\mathbf{s}(t)|\mathbf{s}(t-1))q(\mathbf{s}(1))$$

or a product of independent chains

$$q(\boldsymbol{S}) = \prod_i \left[q(s_i(1)) \prod_{t=2}^{T} q(s_i(t)|s_i(t-1)) \right]. \tag{13}$$

In a d dimensional model of length T, the time complexity of the Riemannian vector operations in RCG is $O(d^3T)$ for the former and $O(dT)$ for the latter.

4. Case Study: Mixture of Gaussians

As the first case study, we consider the mixture-of-Gaussians (MoG) model as was done by Kuusela et al. (2009). In this case, we applied the RCG also for variables with a non-Gaussian approximation. Furthermore, the conjugate-exponential nature of the MoG model allows direct comparison with VB EM.

4.1 The Mixture-of-Gaussians Model

We consider a finite mixture of K Gaussians (Attias, 2000; Bishop, 2006)

$$p(\mathbf{x}|\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\Lambda}) = \sum_{k=1}^{K} \pi_k \mathcal{N}(\mathbf{x}|\boldsymbol{\mu}_k,\boldsymbol{\Lambda}_k),$$

The model	$p(\mathbf{X}\|\mathbf{Z},\boldsymbol{\mu},\boldsymbol{\Lambda}) = \prod_{n=1}^{N}\prod_{k=1}^{K}\mathcal{N}(\mathbf{x}_n\|\boldsymbol{\mu}_k,\boldsymbol{\Lambda}_k^{-1})^{z_{nk}}$ $p(\mathbf{Z}\|\boldsymbol{\pi}) = \prod_{n=1}^{N}\prod_{k=1}^{K}\pi_k^{z_{nk}}$
Key variables	$\mathbf{Z} = (z_{nk}), \boldsymbol{\theta} = (\boldsymbol{\mu}_k, \boldsymbol{\Lambda}_k, \boldsymbol{\pi})$
The approximation	$q(\mathbf{Z},\boldsymbol{\theta}) = q(\mathbf{Z})q(\boldsymbol{\theta})$
The update algorithm	Joint RCG updates for $\mathbf{Z}$ and means of $\boldsymbol{\mu}_k$, fixed point updates for variances of $\boldsymbol{\mu}_k$, VB EM updates for the rest

Table 1: Summary of the mixture-of-Gaussians model

where $\mathbf{x}$ is a D-dimensional random vector, $\boldsymbol{\pi} = [\pi_1 \cdots \pi_K]^T$ are the mixing coefficients, and $\boldsymbol{\mu}_k$ and $\boldsymbol{\Lambda}_k$ are the mean vector and the precision matrix of the kth Gaussian component, respectively.

In the case of the MoG model, the binary latent variables $\mathbf{Z}$ denote which one of the K Gaussian components has generated a particular observation $\mathbf{x}_n$ with $z_{nk} = 1$ denoting the component responsible for generating the observed data point $\mathbf{x}_n$. Let N denote the total number of observed data points.

Given the mixing coefficients $\boldsymbol{\pi}$, the probability distribution over the latent variables is given by

$$p(\mathbf{Z}|\boldsymbol{\pi}) = \prod_{n=1}^{N}\prod_{k=1}^{K}\pi_k^{z_{nk}}.$$

The mixing coefficients have a conjugate Dirichlet prior

$$p(\boldsymbol{\pi}) = \mathrm{Dir}(\boldsymbol{\pi}|\boldsymbol{\alpha}_0),$$

where $\boldsymbol{\alpha}_0 = [\alpha_0, \ldots, \alpha_0]^T$.

Similarly, the likelihood can be written as

$$p(\mathbf{X}|\mathbf{Z},\boldsymbol{\mu},\boldsymbol{\Lambda}) = \prod_{n=1}^{N}\prod_{k=1}^{K}\mathcal{N}(\mathbf{x}_n|\boldsymbol{\mu}_k,\boldsymbol{\Lambda}_k^{-1})^{z_{nk}}.$$

In this case, the conjugate prior for the component parameters $\boldsymbol{\mu}$ and $\boldsymbol{\Lambda}$ is given by the Gaussian-Wishart distribution

$$p(\boldsymbol{\mu},\boldsymbol{\Lambda}) = p(\boldsymbol{\mu}|\boldsymbol{\Lambda})p(\boldsymbol{\Lambda}) = \prod_{k=1}^{K}\mathcal{N}(\boldsymbol{\mu}_k|\mathbf{m}_0,(\beta_0\boldsymbol{\Lambda}_k)^{-1})\mathcal{W}(\boldsymbol{\Lambda}_k|\mathbf{W}_0,\nu_0),$$

where the Wishart distribution is defined up to a normalising constant by the equation

$$\mathcal{W}(\boldsymbol{\Lambda}|\mathbf{W},\nu) \propto |\boldsymbol{\Lambda}|^{(\nu-D-1)/2}\exp\left(-\frac{1}{2}\mathrm{Tr}(\mathbf{W}^{-1}\boldsymbol{\Lambda})\right).$$

The joint distribution over all the random variables of the model is then given by

$$p(\mathbf{X},\mathbf{Z},\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\Lambda}) = p(\mathbf{X}|\mathbf{Z},\boldsymbol{\mu},\boldsymbol{\Lambda})p(\mathbf{Z}|\boldsymbol{\pi})p(\boldsymbol{\pi})p(\boldsymbol{\mu}|\boldsymbol{\Lambda})p(\boldsymbol{\Lambda}).$$

This resulting model can be illustrated with the graphical model shown in Figure 4.

We now make the factorising approximation

$$q(\mathbf{Z},\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\Lambda}) = q(\mathbf{Z})q(\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\Lambda}),$$

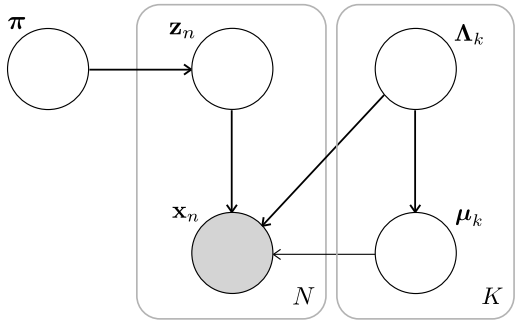

Figure 4: A graphical model representing the MoG model (Attias, 2000; Bishop, 2006), where the hyperparameters have been omitted for clarity. The observed data $\mathbf{X}$ are marked with a shaded circle. The rectangular plates denote the repetition of N observations $\mathbf{x}_n$ along with corresponding latent variables $\mathbf{z}_n$, and of the parameters of K mixture components.

which leads to an update rule for $q(\mathbf{Z})$ (VB-E step) and subsequently an update rule for $q(\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\Lambda})$ (VB-M step). The resulting approximate posterior distributions are

$$q(\mathbf{Z}) = \prod_{n=1}^{N}\prod_{k=1}^{K} r_{nk}^{z_{nk}} \tag{14}$$

and

$$q(\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\Lambda}) = q(\boldsymbol{\pi})q(\boldsymbol{\mu},\boldsymbol{\Lambda}) = q(\boldsymbol{\pi})\prod_{k=1}^{K} q(\boldsymbol{\mu}_k,\boldsymbol{\Lambda}_k),$$

where

$$q(\boldsymbol{\pi}) = \mathrm{Dir}(\boldsymbol{\pi}|\boldsymbol{\alpha}) \tag{15}$$

and

$$q(\boldsymbol{\mu}_k,\boldsymbol{\Lambda}_k) = \mathcal{N}(\boldsymbol{\mu}_k|\mathbf{m}_k,(\beta_k\boldsymbol{\Lambda}_k)^{-1})\,\mathcal{W}(\boldsymbol{\Lambda}_k|\mathbf{W}_k,\nu_k). \tag{16}$$

The derivations of the VB EM and RCG learning algorithms for the MoG model are presented in Appendix B.

4.2 Experiments

The hyperparameters are set to the following values for all the experiments: $\alpha_0 = 1$, $\beta_0 = 1$, $\nu_0 = D$, $\mathbf{W}_0 = \frac{4}{D}\mathbf{I}$ and $\mathbf{m}_0 = \mathbf{0}$. These values can be interpreted to describe our prior beliefs of the model when we anticipate having Gaussian components near the origin but are fairly uncertain about the number of the components.

The maximum number of components is set to $K = 8$ unless otherwise mentioned with each component having a randomly generated initial mean $\mathbf{m}_k$ drawn from a Gaussian distribution with zero mean and covariance $0.16\mathbf{I}$. Other distribution parameters are initially set to the following values: $\alpha_k = 1$, $\beta_k = 10$, $\nu_k = D$ and $\mathbf{W}_k = \frac{4}{D}\mathbf{I}$ for all k. The Powell-Beale restart scheme of Equation (6) is not used. Instead, the search direction is reset to the negative gradient direction

after $\sqrt{n}$ iterations, where n is the number of parameters updated with the gradient method. The optimisation is assumed to have converged when the improvement in free energy $|\mathcal{F}^t - \mathcal{F}^{t-1}| < \varepsilon$ for two consecutive iterations with ε being separately specified for each of the experiments below.

It should be noted that this convergence criterion favours methods such as VB EM which typically takes more of cheaper and smaller steps, while the Riemannian gradient algorithm takes fewer larger steps that are computationally more demanding and take longer to reach the preset improvement threshold.

Because different initial means can produce significantly different results in terms of the required CPU time and achieved final free energy, all the experiments are repeated 30 times with different initialisations.

The artificial data set used to compare the different algorithms in learning the MoG model was drawn from a mixture of 5 spherical two-dimensional Gaussians with equal weights. The mean of the first component is at the origin while the means of the others are $(\pm R, \pm R)$. The constant $R = 0.3$ unless otherwise mentioned and the covariance of all the components is $0.03\mathbf{I}$.

When different gradient-based algorithms are compared using the artificial data containing $N = 500$ data points, the results shown in Figure 5 are obtained. It can be seen that the standard gradient descent and conjugate gradient (CG) algorithms have problems locating even a decent optimum within a reasonable time. Clearly the convergence criterion, which was set to $\varepsilon = 10^{-7}N$, is too lax for these algorithms as the simulations are terminated before convergence to a good solution. Using the Riemannian gradient (RG) and further RCG radically improves the performance. Based on the curves, even the standard CG algorithm is more than 10 times slower than RCG. This experiment was conducted using a fairly small number of observations, a lax convergence criterion and the maximum number of components $K = 5$ in order to allow the standard gradient to finish in a reasonable time.

We also considered the L-BFGS algorithm (Byrd et al., 1995; Carbonetto, 2007) as a higher order Euclidean algorithm. L-BFGS is a limited-memory version of the popular quasi-Newton BFGS algorithm. It can be seen as a compromise between the fast converging but memory-intensive quasi-Newton methods and the less efficient conjugate gradient methods better suited for medium- to large-scale problems. The degree of this compromise is controlled by the memory length parameter m which was set to $m = 20$ in Figure 5. It was found out that, regardless of the value of m, the performance of L-BFGS was very similar to CG with the small deviations explained by the differences in the line search methods employed by the algorithms. It also turned out that the line search subroutine of the L-BFGS implementation had a tendency to converge prematurely to a poor solution. In order to circumvent this, the convergence criterion of the L-BFGS had to be tightened by a factor of 10^{-9} compared to the gradient-based algorithms.

We next compare RCG, RG and VB EM using different values of R. The number of observations was increased to $N = 1000$ and the convergence criterion was set to $\varepsilon = 10^{-12}N$ in order to maximise the quality of the optima found. Figure 6 shows the median CPU time required for convergence for the different algorithms in 30 repeated experiments. It can be seen that with small values of R, RCG outperforms VB EM, while with large values of R, VB EM performs slightly better. This means that, at least in terms of this experiment, RCG performs better than VB EM when the latent variables are difficult to infer from the data.

Given the discussion of Section 2.3, it is not surprising to note that both VB EM and RG perform qualitatively in a fairly similar manner in the experiment of Figure 6. It should especially be noted that both methods suffer from significant slowdowns near the values of $R = 0.2$ and $R = 0.325$. On

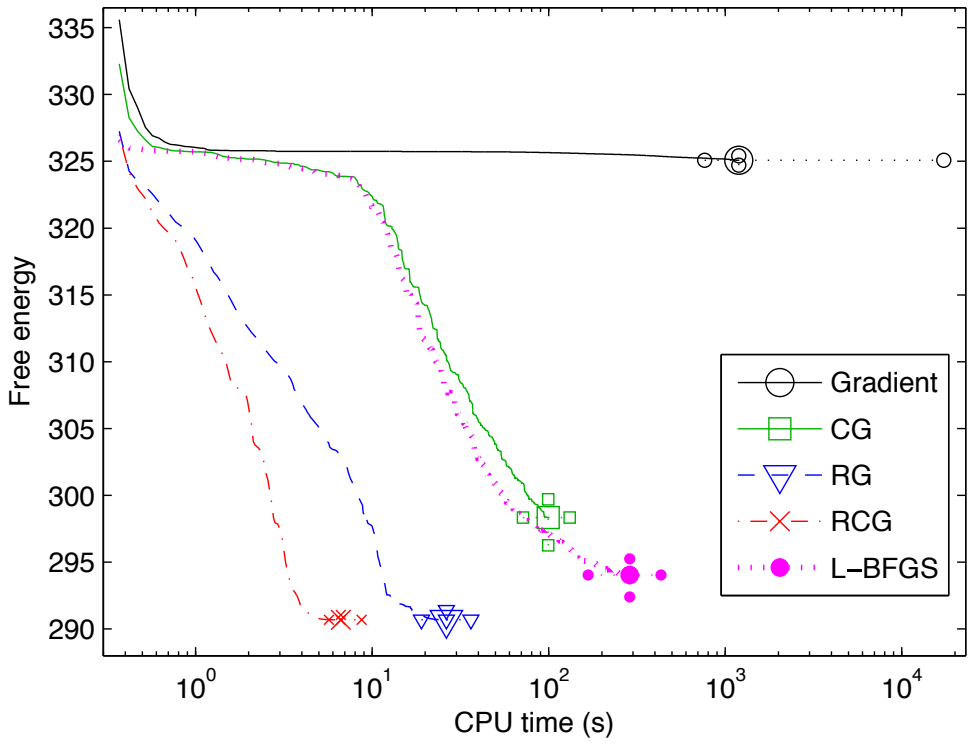

Figure 5: Convergence curves of gradient-based algorithms using the MoG model for artificial data with $R = 0.3$. The algorithms compared are the standard gradient descent, the conjugate gradient (CG), the Riemannian gradient (RG) and the Riemannian conjugate gradient (RCG) methods as well as the limited-memory BFGS (L-BFGS) algorithm. The curves shown are medians of 30 simulations drawn up to the median termination time. The smaller marks denote 25% and 75% quantiles of the termination time in the horizontal direction and the corresponding quantiles of the free energy at the median termination time in the vertical direction. Note that the time scale is logarithmic.

the other hand, the use of conjugate directions in the Riemannian space seems to result in a fairly uniform performance across all values of R.

There is some variation in the quality of the optima the different methods converge to. This is illustrated in Figure 7 for RCG and VB EM. There is no evidence for either algorithm consistently producing better results than the other. The only outlier in this data is with $R = 0.225$ where VB EM is the only algorithm to discover the global optimum. This is by no means typical, and with other data sets we have seen RCG sometimes consistently finding better optima. Based on the figure, RCG seems slightly more sensitive to local optima, but the result is not qualitatively different from VB EM which, to some extent, also suffers from the same problem.

Although the time complexity of one step of each of the compared algorithms is linear in the number of samples, the algorithms nevertheless perform differently as the number of samples in-

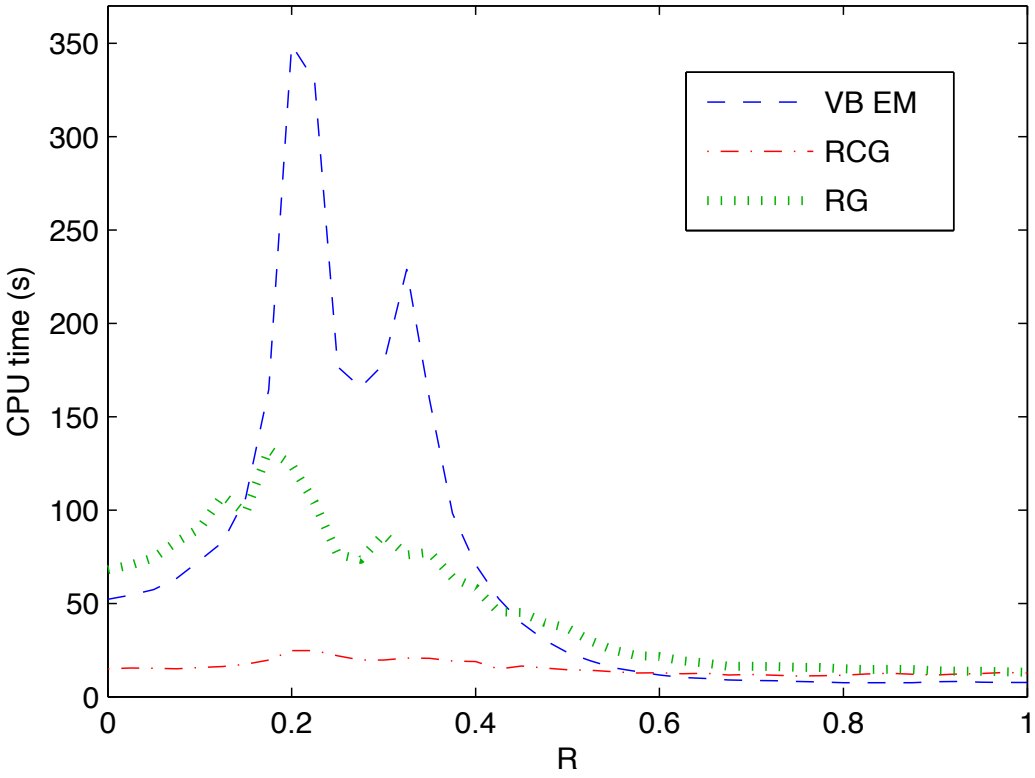

Figure 6: Comparison of VB EM with the Riemannian gradient (RG) and the Riemannian conjugate gradient (RCG) methods using the MoG model with the artificial data. The curves show the median CPU time required for convergence as a function of R. VB EM slows down significantly at the critical overlap of $R \approx 0.2$, while RCG is almost unaffected. A similar slowdown also affects RG implying that the use of conjugate directions contributes to the nearly uniform running time of RCG.

creases. To see this, we set $\varepsilon = 10^{-8}N$ and probed a wide range of values of N. The results are illustrated in Figure 8 which shows that VB EM slows down faster than linearly as the number of samples increases. The most likely reason for this behaviour is that the posterior will be more peaked when the number of observations is large and this slows down the alternating VB EM iteration. The same phenomenon also affects RCG, but the effect is much stronger in VB EM. The results suggest that especially for large data sets, it can be worthwhile to consider alternatives to basic batch VB EM, such as on-line algorithms (Sato, 2001) or gradient-based methods.

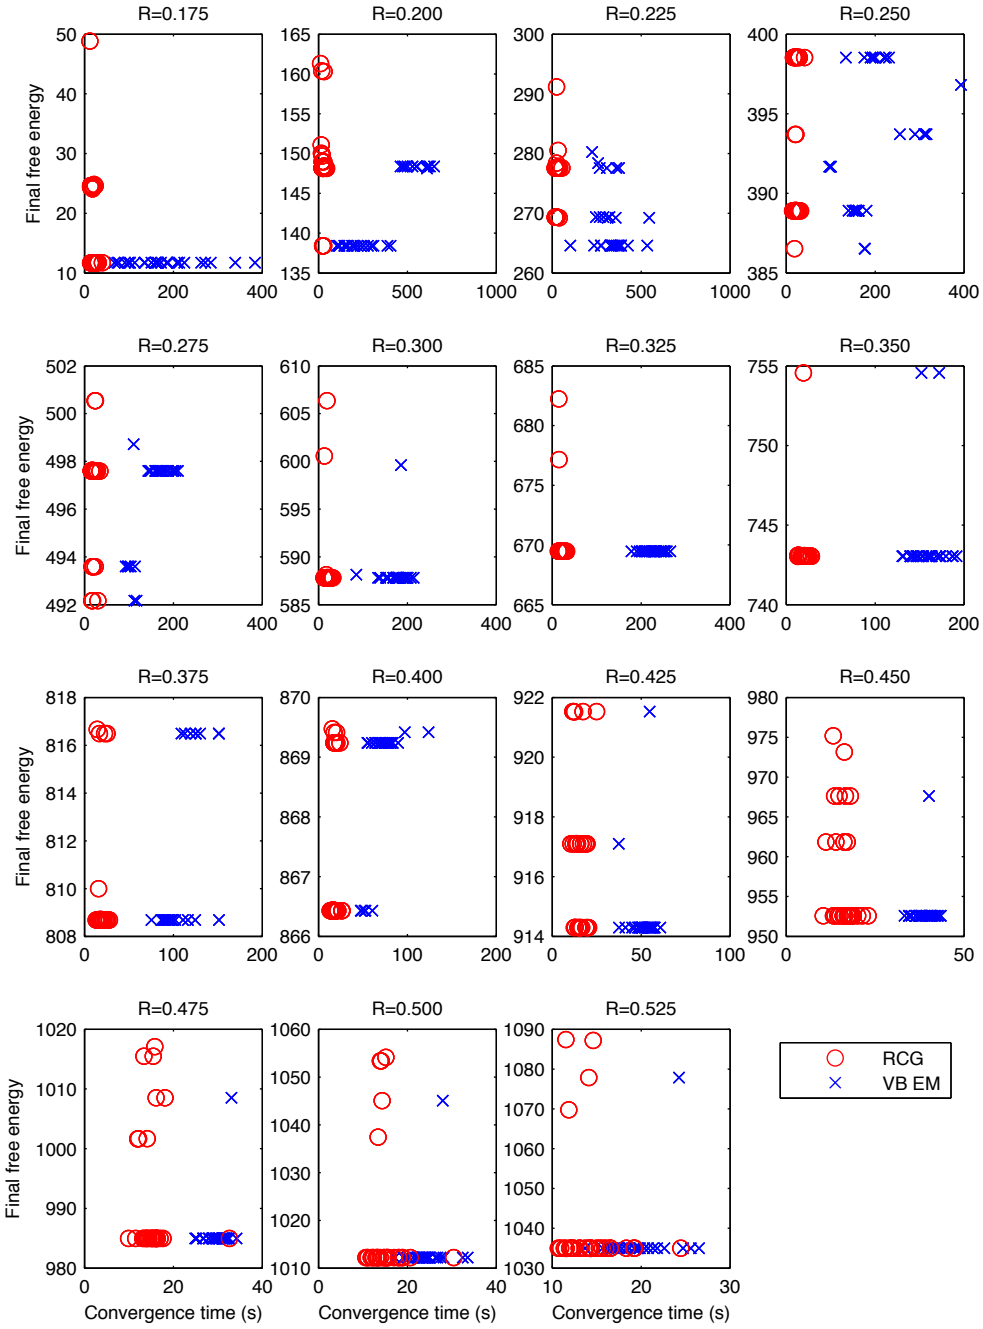

Figure 7: Final free energy value as a function of running time in the critical parameter range in the MoG experiment with varying R. Both RCG and VB EM sometimes fail to converge to the global optimum. Interestingly, there usually is no correlation between the quality of the solution and convergence time.

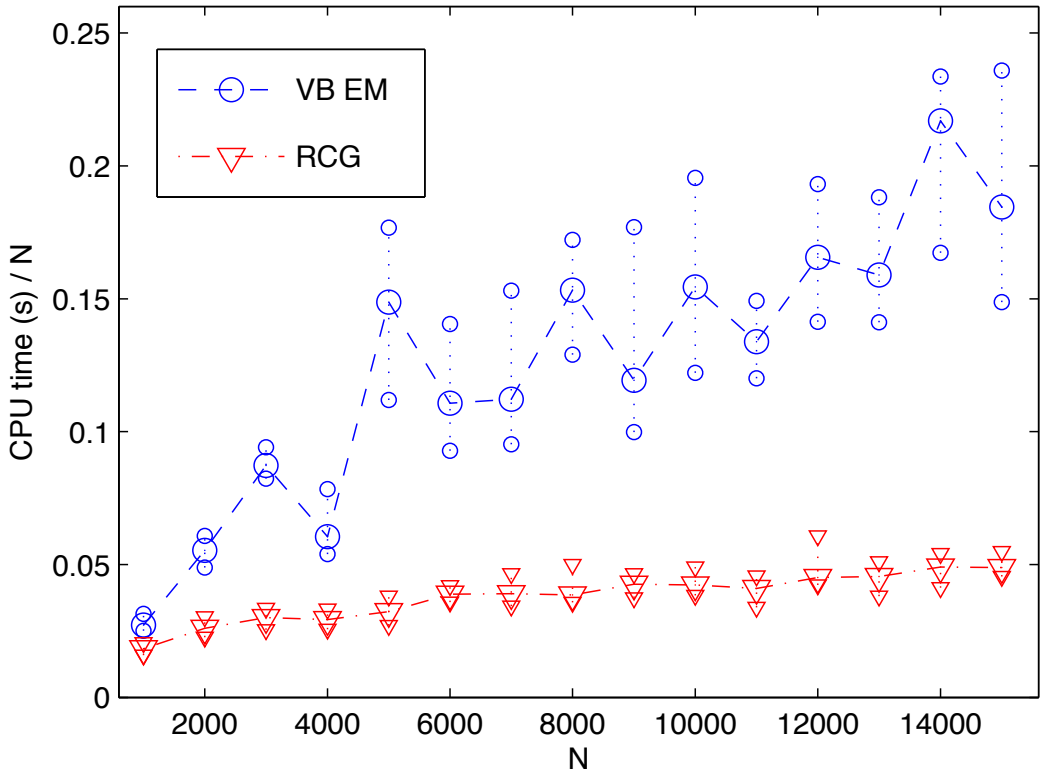

Figure 8: Median convergence times of 30 simulations of the MoG model on artificial data as a function of the number of observations N with VB EM and the Riemannian conjugate gradient (RCG) algorithms. The smaller marks indicate 25% and 75% quantiles.

The model	$\mathbf{x}(t) = \mathbf{f}(\mathbf{s}(t), \boldsymbol{\theta}_\mathbf{f}) + \mathbf{n}(t)$ $\mathbf{s}(t) = \mathbf{s}(t-1) + \mathbf{g}(\mathbf{s}(t-1), \boldsymbol{\theta}_\mathbf{g}) + \mathbf{m}(t)$
Key variables	$\boldsymbol{\theta}_S = (\mathbf{s}(t))$, $\boldsymbol{\theta}_\boldsymbol{\theta} = (\boldsymbol{\theta}_\mathbf{f}, \boldsymbol{\theta}_\mathbf{g}, \mathbf{v}_m, \mathbf{v}_n)$
The approximation	$q(\boldsymbol{\theta}_S, \boldsymbol{\theta}_\boldsymbol{\theta}) = q(\boldsymbol{\theta}_S) q(\boldsymbol{\theta}_\boldsymbol{\theta})$, where $q(\boldsymbol{\theta}_\boldsymbol{\theta})$ is Gaussian with diagonal covariance and $q(\boldsymbol{\theta}_S)$ Gaussian with tridiagonal precision (see text)
The update algorithm	Joint RCG updates for the means of $\boldsymbol{\theta}_S, \boldsymbol{\theta}_\mathbf{f}, \boldsymbol{\theta}_\mathbf{g}$, fixed point updates for their covariances, VB EM updates for the rest

Table 2: Summary of the nonlinear state-space model

5. Case Study: Nonlinear State-Space Models

As the second case study, we consider the nonlinear state-space model (NSSM) introduced by Valpola and Karhunen (2002). The model is specified by the generative model

$$\mathbf{x}(t) = \mathbf{f}(\mathbf{s}(t), \boldsymbol{\theta}_\mathbf{f}) + \mathbf{n}(t), \tag{17}$$

$$\mathbf{s}(t) = \mathbf{s}(t-1) + \mathbf{g}(\mathbf{s}(t-1), \boldsymbol{\theta}_\mathbf{g}) + \mathbf{m}(t), \tag{18}$$

where t is time, $\mathbf{x}(t)$ are the observations, and $\mathbf{s}(t)$ are the hidden states. The observation mapping $\mathbf{f}$ and the dynamical mapping $\mathbf{g}$ are nonlinear and they are modelled with multi-layer perceptron (MLP) networks whose weight matrices are included in $\boldsymbol{\theta}_\mathbf{f}$ and $\boldsymbol{\theta}_\mathbf{g}$. The observation noise vector $\mathbf{n}$ and process noise vector $\mathbf{m}$ are assumed Gaussian with zero mean and covariances $\mathrm{diag}(\exp(2\mathbf{v}_n))$ and $\mathrm{diag}(\exp(2\mathbf{v}_m))$. The latent states $\mathbf{s}(t)$ are commonly denoted by $\boldsymbol{\theta}_{\boldsymbol{S}}$. The model parameters include both the weights of the MLP networks and a number of hyperparameters. The posterior approximation of these parameters is a Gaussian with a diagonal covariance matrix. The posterior approximation of the states $q(\boldsymbol{\theta}_{\boldsymbol{S}}|\boldsymbol{\xi}_{\boldsymbol{S}})$ is a Gaussian Markov random field with a correlation between the corresponding components of subsequent state vectors $s_j(t)$ and $s_j(t-1)$, as in Equation (13). This is a realistic minimum assumption for modelling the dependence of the state vectors $\mathbf{s}(t)$ and $\mathbf{s}(t-1)$ (Valpola and Karhunen, 2002). Omitted details of the model are presented in Appendix C and a summary is given in Table 2.

Because of the nonlinearities the model is not in the conjugate exponential family, and the standard VB learning methods are only applicable to hyperparameters but not to the latent states or weights of the MLPs. The free energy (1) can nevertheless be evaluated by linearising the MLP networks $\mathbf{f}$ and $\mathbf{g}$ (Honkela and Valpola, 2005; Honkela et al., 2007). This allows evaluating the gradient with respect to $\boldsymbol{\xi}_{\boldsymbol{S}}$, $\boldsymbol{\xi}_\mathbf{f}$, and $\boldsymbol{\xi}_\mathbf{g}$ and using a gradient based optimiser to adapt the parameters. Combining Equations (4) and (12), the Riemannian gradient for the mean elements is given by

$$\tilde{\nabla}_{\boldsymbol{\mu}_q} \mathcal{F}(\boldsymbol{\xi}) = \boldsymbol{\Sigma}_q \nabla_{\boldsymbol{\mu}_q} \mathcal{F}(\boldsymbol{\xi}),$$

where $\boldsymbol{\mu}_q$ is the mean of the variational approximation $q(\boldsymbol{\theta}|\boldsymbol{\xi})$ and $\boldsymbol{\Sigma}_q$ is the corresponding covariance. The covariance matrix of the model parameters is diagonal while the inverse covariance matrix of the latent states $\mathbf{s}(t)$ is block-diagonal with tridiagonal blocks. This implies that all computations with these can be done in linear time with respect to the number of the parameters. The covariances are updated separately using a fixed-point update rule similar to (8) as described by Valpola and Karhunen (2002). A complete derivation of the free energy of the model is presented in Appendix C.

5.1 Experiments

We applied the method for learning nonlinear state-space models presented above to real world speech data. Experiments were conducted with different data sizes to study the performance differences between the algorithms. The data consisted of 21 dimensional mel-frequency log power speech spectra of continuous human speech. This is a detailed representation of speech signals similar to those often used in speech recognition. A segment of 100 samples corresponds to approximately 0.8 seconds of speech. The task is to learn a nonlinear dynamical model for this data.

To study the performance differences between the Riemannian conjugate gradient (RCG) method, standard Riemannian gradient (RG) method, standard conjugate gradient (CG) method and the heuristic algorithm from Valpola and Karhunen (2002), the algorithms were applied to different sized parts of the speech data set. Unfortunately a reasonable comparison with a VB EM algorithm was impossible because an extended-Kalman-filter-based VB EM algorithm failed with the nonlinear model.

The size of the data subsets varied between 200 and 500 samples. A five-dimensional state-space was used. The MLP networks for the observation and dynamical mappings had 20 hidden nodes. Four different initialisations and two different segments of data of each size were used, resulting in eight repetitions for each algorithm and data size. The results for different data segments of the

same size were pooled together as the convergence times were in general very similar. An algorithm was assumed to have converged when $|\mathcal{F}^t - \mathcal{F}^{t-1}| < \varepsilon = (10^{-5}N/80)$ for 5 consecutive iterations, where $\mathcal{F}^t$ is the free energy at iteration t and N is the size of the data set. Alternatively, the iteration was stopped after 24 hours even if it had not converged.

The MLP network is notoriously prone to local optima. Practically all our simulations converged to local optima with different parameter estimates, but there were no statistically significant differences in the free energies corresponding to these optima attained by different algorithms (Wilcoxon rank-sum test, 5 % significance level). In practice, the free energy values tend to have a very strong correlation with predictive performance of the model (Honkela et al., 2007). There were still some differences, and especially the RG algorithm with smaller data sizes often appeared to converge very early to an extremely poor solution. These were filtered by removing results where the attained free energy that was more than two RCG standard deviations worse than RCG average for the particular data set. Thus all the used results are from runs converging to a roughly equally good solution. The results of one run where the heuristic algorithm diverged were also discarded from the analysis.

The results can be seen in Figure 9. The plain CG and RG methods were clearly slower than others and the maximum runtime was reached by most CG and some RG runs. RCG was clearly the fastest algorithm with the heuristic method of Valpola and Karhunen (2002) between these extremes. The observed differences are, save for a few exceptions mostly with smaller data sets, statistically significant (Wilcoxon rank-sum test, 5 % significance level).

As a more realistic example, a larger data set of 1000 samples was used to train a seven-dimensional state-space model. In this experiment both MLP networks of the NSSM had 30 hidden nodes. The convergence criterion was $\varepsilon = 10^{-6}$ and the maximum runtime was 72 hours. The performances of the RCG, RG, CG methods and the heuristic algorithm were compared. The results can be seen in Figure 10. The results show the convergence for five different initialisations with markers at the end showing when the convergence was reached. It should be noted that the scale of the CPU time axis is logarithmic.

RCG clearly outperformed the other algorithms in this experiment as well. In particular, both RG and CG hit the maximum runtime in every run, and especially CG was nowhere near convergence at this time. RCG also outperformed the heuristic algorithm (Valpola and Karhunen, 2002) by a factor of more than 10.

6. Case Study: Nonlinear Factor Analysis

The model	$\mathbf{x}(t) = \mathbf{f}(\mathbf{s}(t), \boldsymbol{\theta}_\mathbf{f}) + \mathbf{n}(t)$ $\mathbf{s}(t) = \mathcal{N}(0, \mathrm{diag}(\exp(2\mathbf{v}_s)))$
Key variables	$\boldsymbol{S} = (\mathbf{s}(t)), \boldsymbol{\theta} = (\boldsymbol{\theta}_\mathbf{f}, \mathbf{v}_s, \mathbf{v}_n)$
The approximation	$q(\boldsymbol{S}, \boldsymbol{\theta}) = q(\boldsymbol{S})q(\boldsymbol{\theta})$, where both $q(\boldsymbol{\theta})$ and $q(\boldsymbol{S})$ are Gaussian with diagonal covariances
The update algorithm	Joint RCG updates for means of $\boldsymbol{S}, \boldsymbol{\theta}_\mathbf{f}$, fixed point update for their covariances, VB EM updates for the rest

Table 3: Summary of the nonlinear factor analysis model

As the final case study, the RCG and RG methods were implemented as extensions to the VB nonlinear factor analysis (NFA) method (Lappalainen and Honkela, 2000; Honkela and Valpola,

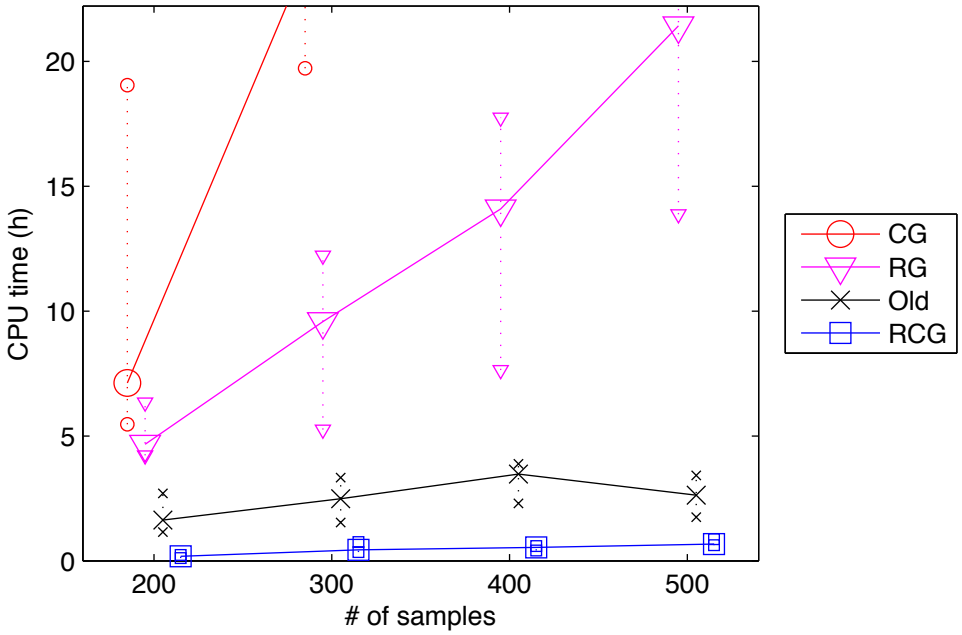

Figure 9: Convergence speed of the Riemannian conjugate gradient (RCG), the Riemannian gradient (RG) and the conjugate gradient (CG) methods as well as the heuristic algorithm (Old) with different data sizes of the speech data set and the nonlinear state-space model. The lines show median times with 25 % and 75 % quantiles shown by the smaller marks. The times were limited to at most 24 hours, which was reached by a number of simulations.

2005; Honkela et al., 2007). NFA models the mapping between latent factors $\mathbf{s}(t)$ and observations $\mathbf{x}(t)$ with an MLP as in Equation (17):

$$\mathbf{x}(t) = \mathbf{f}(\mathbf{s}(t), \boldsymbol{\theta}_\mathbf{f}) + \mathbf{n}(t).$$

Instead of the dynamical model of Equation (18), $\mathbf{s}(t)$ has independent Gaussian priors with a unit covariance. As NFA can be seen as a special case of NSSM with no dynamic mapping, the implementation is straightforward. The model is summarised in Table 3. Complete derivation of the model and a learning algorithm based on conjugate gradients is presented by Honkela et al. (2007). The generalisation for Riemannian gradient is straightforward as the Fisher information matrix is diagonal.

The RCG, RG and CG methods were applied for learning an NFA model for parts of the speech data set, a different part of which was also used in the NSSM experiments. As the NFA model cannot capture the dynamics of speech, the experiment aimed at finding a nonlinear embedding of speech on a lower dimensional manifold. To stimulate this, we drew a suitable subset of samples randomly from the full data set of 7860 samples, excluding any dynamical relations in the data. Silent segments were excluded from the data.

We tested each algorithm for data sets ranging in size from 300 to 1000 samples, running 10 simulations with different random initialisations for every setting. The results are shown in Figure

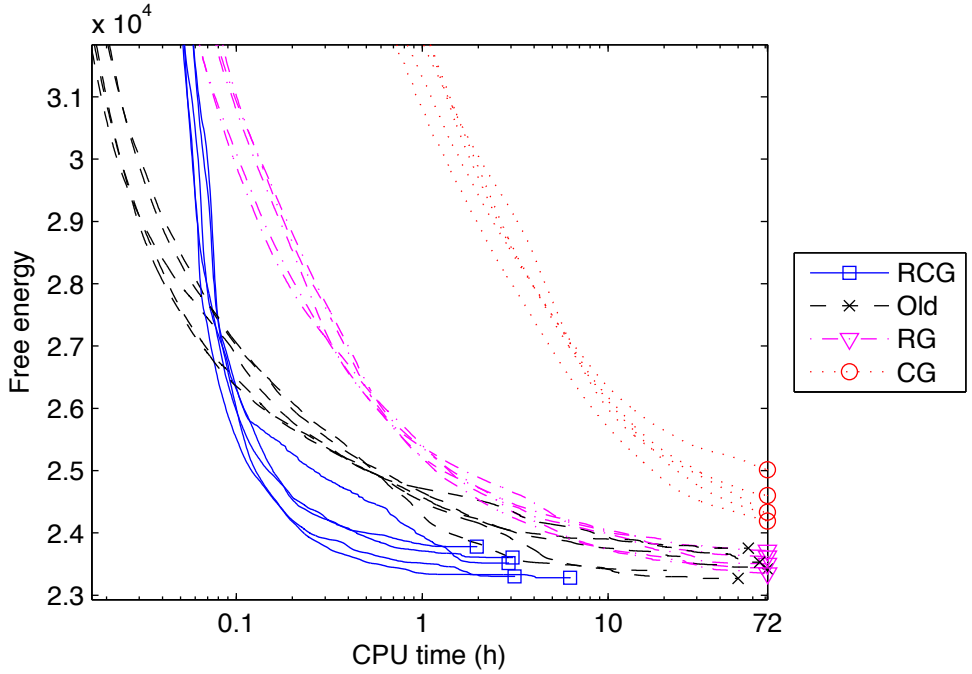

Figure 10: Comparison of the performance of the Riemannian conjugate gradient (RCG), the Riemannian gradient (RG), the conjugate gradient (CG) methods and the heuristic algorithm with the full speech data set of 1000 samples using the nonlinear state-space model. The free energy $\mathcal{F}$ is plotted against computation time using a logarithmic time scale. The tick marks show when simulations either converged or were terminated after 72 hours.

11. RCG is again clearly superior to both RG and CG, but CG is now faster than RG. The observed differences are statistically significant (Wilcoxon rank-sum test, 5 % significance level), except between CG and RG for 300 samples.

7. Discussion

The proposed RCG algorithm combines two improvements over plain gradient optimisation: use of Riemannian gradient and conjugate gradients. One interesting feature in the experimental results is the relative performance of the conjugate gradient and Riemannian gradient algorithms that implement only one of these. Conjugate gradient is faster than Riemannian gradient for NFA, but the opposite is true for NSSM and MoG. Especially the latter differences are quite significant and consistent across several different data sets. One obvious difference between the models is that for NFA the Fisher information matrix is diagonal while for NSSM and MoG this is not the case. This suggests that the Riemannian gradient approach may be the most useful when the metric is more complex, although more careful analysis would be needed to properly understand the effects of different improvements.

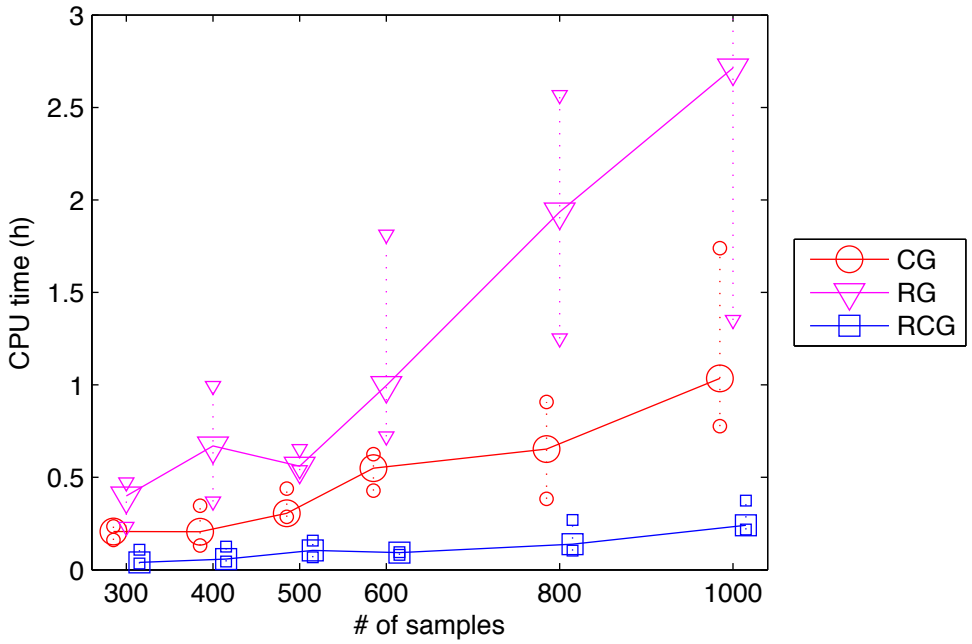

Figure 11: Convergence speed of the Riemannian conjugate gradient (RCG), the Riemannian gradient (RG) and the conjugate gradient (CG) methods with different data sizes of the speech dimensionality reduction data set with the nonlinear factor analysis model. The lines show median times with 25 % and 75 % quantiles shown by the smaller marks.

As illustrated by the MoG example, the RCG algorithm can also be applied to conjugate-exponential models to replace the more common VB EM algorithm. In practice, simpler and more straightforward EM acceleration methods based on, for example, pattern search or adaptive over-relaxation (see, e.g., Honkela et al., 2003; Salakhutdinov and Roweis, 2003) may still provide comparable or better results with less human effort. These methods are only applicable when EM itself is applicable, though.

The experiments in this paper show that using even a greatly simplified variant of the Riemannian conjugate gradient method for some variables is enough to acquire a large speedup. Considering univariate Gaussian distributions, the regular gradient is prone to overemphasise changes to model variables with small posterior variance and underemphasise variables with large posterior variance, as seen from Equations (9)–(11). The posterior variance of latent variables is often much larger than the posterior variance of model parameters and the Riemannian gradient takes this into account in a very natural manner.

The Riemannian conjugate gradient method differs from Euclidean superlinear optimisation methods such as quasi-Newton methods in that it uses higher-order information of the geometry of the parameter space, but not of the function being optimised. These are essentially two independent avenues for improvement: it would be possible, although complicated, to derive a Riemannian quasi-Newton method. Our experiments clearly show that in these problems, a proper model of the

geometry appears significantly more important than using higher-order information of the objective function.

In this paper, we have presented a Riemannian conjugate gradient learning algorithm for fixed-form variational Bayes. The RCG algorithm provides an efficient method for VB learning in models that do not belong to the conjugate-exponential family as required by the standard variational EM algorithm. For suitably structured approximations, the computational overhead from using Riemannian gradients instead of conventional gradients is negligible. In practical examples, the Riemannian gradient approach provided several orders of magnitude speedups over conventional gradient algorithms, thus making VB learning of these models practical on a much larger scale.

MATLAB code for all the models used in the case studies is available at `http://www.cis.hut.fi/projects/bayes/software/ncg/`.

Appendix A. Convergence of the Riemannian Conjugate Gradient Algorithm

The Riemannian conjugate gradient algorithm has similar superlinear convergence properties to the Euclidean space conjugate gradient algorithm. Assuming the objective $\mathcal{F}(\boldsymbol{\xi})$ has continuous third order derivatives and that there exist $m > 0, M$ such that the Hessian $H(\boldsymbol{\xi})$ satisfies

$$m\mathbf{x}^T\mathbf{x} \leq \mathbf{x}^T H(\boldsymbol{\xi})\mathbf{x} \leq M\mathbf{x}^T\mathbf{x}$$

for all $\boldsymbol{\xi}$ and $\mathbf{x}$, the error decreases quadratically over N steps in an N-dimensional problem. Thus, denoting the optimum by $\boldsymbol{\alpha}$ and the iterates by $\boldsymbol{\xi}_i$, we have (Edelman et al., 1998; Cohen, 1972)

$$||\boldsymbol{\alpha} - \boldsymbol{\xi}_{i+N}|| \leq C||\boldsymbol{\alpha} - \boldsymbol{\xi}_i||^2 \tag{19}$$

in some neighbourhood of $\boldsymbol{\alpha}$.

We now show that the approximations in the RCG algorithm, namely ignoring the parallel transports and performing line searches along straight lines instead of geodesics, do not effect the convergence rate of Equation (19).

Theorem 1 *Assuming the objective $\mathcal{F}(\boldsymbol{\xi})$ has bounded derivatives for up to third order and that the Fisher information $\mathbf{G}(\boldsymbol{\xi})$ is smooth in a neighbourhood of the solution, the RCG algorithm performing a line search along a straight line in the direction*

$$\mathbf{p}_k = -\tilde{\mathbf{g}}_k + \beta\mathbf{p}_{k-1},$$

where $\tilde{\mathbf{g}}_k$ is the Riemannian gradient and

$$\beta = \frac{\langle \tilde{\mathbf{g}}_k, \tilde{\mathbf{g}}_k - \tilde{\mathbf{g}}_{k-1}\rangle_k}{||\tilde{\mathbf{g}}_{k-1}||^2_{k-1}}$$

to find the sequence of iterates $\boldsymbol{\xi}_k$ shares the same convergence property of Equation (19) in some ε-neighbourhood of the solution as the Riemannian conjugate gradient algorithm performing a line search along a geodesic in the direction

$$\mathbf{p}_k^* = -\tilde{\mathbf{g}}_k^* + \beta^* \boldsymbol{\tau} \mathbf{p}_{k-1}^*,$$

where $\tilde{\mathbf{g}}_k$ is the Riemannian gradient, $\boldsymbol{\tau}\mathbf{p}_{k-1}^*$ is the vector $\mathbf{p}_{k-1}^*$ after parallel transport to the starting point of the new search and

$$\beta^* = \frac{\langle \tilde{\mathbf{g}}_k^*, \tilde{\mathbf{g}}_k^* - \boldsymbol{\tau}\tilde{\mathbf{g}}_{k-1}^* \rangle_{k^*}}{||\tilde{\mathbf{g}}_{k-1}^*||^2_{(k-1)^*}},$$

where $\langle \cdot, \cdot \rangle_{k^*}$ is the inner product at $\boldsymbol{\xi}_k^*$, to find the sequence of iterates $\boldsymbol{\xi}_k^*$.

Proof Let us assume that the two algorithms are started at $\boldsymbol{\xi}_k = \boldsymbol{\xi}_k^*$ and $||\boldsymbol{\xi}_k - \boldsymbol{\alpha}|| < \varepsilon$ for some $\varepsilon > 0$. We show by induction on i that $\mathbf{p}_{i-1} = \mathbf{p}_{i-1}^* + O(\varepsilon^2)$ and $\boldsymbol{\xi}_i = \boldsymbol{\xi}_i^* + O(\varepsilon^2)$ for $i \geq k$ which is sufficient to prove the theorem.

The base case is trivial as $\boldsymbol{\xi}_k = \boldsymbol{\xi}_k^*$ and $\mathbf{p}_{k-1} = \mathbf{p}_{k-1}^* = 0$ at the start of the algorithm.

Assume now that the claim is valid for $i = k, \ldots, K$, and let us prove it for $i = K+1$. From Edelman et al. (1998) we know that

$$\begin{aligned} \boldsymbol{\xi}(\varepsilon) &= \boldsymbol{\xi}(0) + \varepsilon \Delta / ||\Delta|| + O(\varepsilon^3), \\ \boldsymbol{\tau}\tilde{\mathbf{g}}(\varepsilon) &= \tilde{\mathbf{g}} + O(\varepsilon^2), \end{aligned}$$

where $\boldsymbol{\xi}(\varepsilon)$ is a geodesic in direction Δ, $\boldsymbol{\tau}\tilde{\mathbf{g}}(\varepsilon)$ is the parallel transport of $\tilde{\mathbf{g}}$ to $\boldsymbol{\xi}(\varepsilon)$. The norms of $\tilde{\mathbf{g}}$ and $\mathbf{p}$ are also of the order $O(\varepsilon)$.

The assumption $\boldsymbol{\xi}_K = \boldsymbol{\xi}_K^* + O(\varepsilon^2)$ implies that the gradients evaluated at these points satisfy $\tilde{\mathbf{g}}_K = \tilde{\mathbf{g}}_K^* + O(\varepsilon^2)$. Furthermore,

$$\langle \mathbf{x}, \mathbf{y} \rangle_{K^*} = \mathbf{x}^T \mathbf{G}(\boldsymbol{\xi}_K^*) \mathbf{y} = \mathbf{x}^T (\mathbf{G}(\boldsymbol{\xi}_K) + O(\varepsilon^2)) \mathbf{y} = \langle \mathbf{x}, \mathbf{y} \rangle_K + O(\varepsilon^2 ||\mathbf{x}||_K ||\mathbf{y}||_K).$$

Using the above asymptotics,

$$\begin{aligned} \beta^* &= \frac{\langle \tilde{\mathbf{g}}_K^*, \tilde{\mathbf{g}}_K^* - \boldsymbol{\tau}\tilde{\mathbf{g}}_{K-1}^* \rangle_{K^*}}{||\tilde{\mathbf{g}}_{K-1}^*||^2_{(K-1)^*}} = \frac{\langle \tilde{\mathbf{g}}_K + O(\varepsilon^2), \tilde{\mathbf{g}}_K - \tilde{\mathbf{g}}_{K-1} + O(\varepsilon^2) \rangle_{K^*}}{||\tilde{\mathbf{g}}_{K-1} + O(\varepsilon^2)||^2_{(K-1)^*}} \\ &= (1 + O(\varepsilon)) \frac{\langle \tilde{\mathbf{g}}_K, \tilde{\mathbf{g}}_K - \tilde{\mathbf{g}}_{K-1} \rangle_{K^*} + O(\varepsilon^3)}{||\tilde{\mathbf{g}}_{K-1}||^2_{(K-1)^*}} = (1 + O(\varepsilon)) \frac{\langle \tilde{\mathbf{g}}_K, \tilde{\mathbf{g}}_K - \tilde{\mathbf{g}}_{K-1} \rangle_K + O(\varepsilon^3)}{||\tilde{\mathbf{g}}_{K-1}||^2_{(K-1)} + O(\varepsilon^3)} \\ &= (1 + O(\varepsilon)) \left(\frac{\langle \tilde{\mathbf{g}}_K, \tilde{\mathbf{g}}_K - \tilde{\mathbf{g}}_{K-1} \rangle_K}{||\tilde{\mathbf{g}}_{K-1}||^2_{(K-1)}} + O(\varepsilon) \right) = \beta + O(\varepsilon). \end{aligned}$$

Similarly we can find the difference in the search direction,

$$\begin{aligned} \mathbf{p}_K^* &= -\tilde{\mathbf{g}}_K^* + \beta^* \boldsymbol{\tau} \mathbf{p}_{K-1}^* = -\tilde{\mathbf{g}}_K + \beta^* \mathbf{p}_{K-1}^* + O(\varepsilon^2) = -\tilde{\mathbf{g}}_K + \beta \mathbf{p}_{K-1} + O(\varepsilon^2) \\ &= \mathbf{p}_K + O(\varepsilon^2), \end{aligned}$$

which completes the first part of the induction step.

The corresponding step lengths, t^* and t, also differ by $O(\varepsilon)$. To show this, let us use the Taylor expansion of f about the optimum $\boldsymbol{\alpha}$:

$$\begin{aligned}\mathcal{F}(\boldsymbol{\xi}) &= \mathcal{F}(\boldsymbol{\alpha}) + \frac{1}{2}(\boldsymbol{\xi}-\boldsymbol{\alpha})^T H(\boldsymbol{\alpha})(\boldsymbol{\xi}-\boldsymbol{\alpha}) + O(\varepsilon^3),\\ \nabla\mathcal{F}(\boldsymbol{\xi}) &= H(\boldsymbol{\alpha})(\boldsymbol{\xi}-\boldsymbol{\alpha}) + O(\varepsilon^2).\end{aligned}$$

The line search finds the zero of $\mathbf{p}_K \cdot \nabla\mathcal{F}(\boldsymbol{\xi})$ along the line $\boldsymbol{\xi} = \boldsymbol{\xi}_{K-1} + t\mathbf{p}_K$, which yields

$$\mathbf{p}_K^T H(\boldsymbol{\alpha}) \left[(\boldsymbol{\xi}_{K-1} + t\mathbf{p}_K - \boldsymbol{\alpha}) + O(\varepsilon^2)\right] = 0,$$

which can be solved to obtain

$$t = -\frac{\mathbf{p}_K^T H(\boldsymbol{\alpha})(\boldsymbol{\xi}_{K-1}-\boldsymbol{\alpha})}{\mathbf{p}_K^T H(\boldsymbol{\alpha})\mathbf{p}_K} + O(\varepsilon),$$

where we have used the fact that $\mathbf{p}_K^T H(\boldsymbol{\alpha})\mathbf{p}_K \geq m||\mathbf{p}_K||^2$.

Correspondingly, the exact algorithm finds the zero along the geodesic from $\boldsymbol{\xi}^*_{K-1}$ in the direction $\mathbf{p}^*_K$ of $(\tau\mathbf{p}^*_K)^T\nabla\mathcal{F}(\boldsymbol{\xi})$

$$\begin{aligned}&(\tau\mathbf{p}^*_K(t^*||\mathbf{p}^*_K||))^T H(\boldsymbol{\alpha})[\boldsymbol{\xi}^*_{K-1}(t^*||\mathbf{p}^*_K||) - \boldsymbol{\alpha} + O(\varepsilon^2)] =\\ &\qquad (\mathbf{p}^*_K + O(\varepsilon^2))^T H(\boldsymbol{\alpha})[\boldsymbol{\xi}^*_{K-1} + t^*\mathbf{p}^*_K - \boldsymbol{\alpha} + O(\varepsilon^2)] + O(\varepsilon^3) = 0,\end{aligned}$$

where $\boldsymbol{\xi}_{K-1}(t^*||\mathbf{p}^*_K||)$ is the geodesic starting from $\boldsymbol{\xi}^*_{K-1}$ in the direction $\mathbf{p}^*_K$, and $\tau\mathbf{p}^*_K(t^*||\mathbf{p}^*_K||)$ is the parallel transport of $\mathbf{p}^*_K$ along this geodesic. The solution of this equation yields

$$\begin{aligned}t^* &= -\frac{(\mathbf{p}^*_K + O(\varepsilon^2))^T H(\boldsymbol{\alpha})[\boldsymbol{\xi}^*_{K-1} - \boldsymbol{\alpha} + O(\varepsilon^3)]}{(\mathbf{p}^*_K + O(\varepsilon^2))^T H(\boldsymbol{\alpha})\mathbf{p}^*_K} + O(\varepsilon)\\ &= -\frac{(\mathbf{p}_K + O(\varepsilon^2))^T H(\boldsymbol{\alpha})[\boldsymbol{\xi}_{K-1} - \boldsymbol{\alpha} + O(\varepsilon^2)]}{(\mathbf{p}_K + O(\varepsilon^2))^T H(\boldsymbol{\alpha})[\mathbf{p}_K + O(\varepsilon^2)]} + O(\varepsilon)\\ &= -(1+O(\varepsilon))\frac{\mathbf{p}_K^T H(\boldsymbol{\alpha})[\boldsymbol{\xi}_{K-1} - \boldsymbol{\alpha}] + O(\varepsilon^3)}{\mathbf{p}_K^T H(\boldsymbol{\alpha})\mathbf{p}_K} + O(\varepsilon) = t + O(\varepsilon).\end{aligned}$$

Now

$$\begin{aligned}\boldsymbol{\xi}^*_K &= \boldsymbol{\xi}^*_{K-1}(t^*||\mathbf{p}^*_K||) = \boldsymbol{\xi}^*_{K-1} + t^*\mathbf{p}^*_K + O(\varepsilon^3)\\ &= \boldsymbol{\xi}_{K-1} + O(\varepsilon^2) + [t + O(\varepsilon)][\mathbf{p}_K + O(\varepsilon^2)] + O(\varepsilon^3) = \boldsymbol{\xi}_K + O(\varepsilon^2),\end{aligned}$$

which completes the proof. ■

Appendix B. Derivations of the Mixture-of-Gaussians Model

In this section we present details of the variational MoG model, including necessary EM updates, the free energy and the metric tensor for the RCG algorithm.

B.1 VB EM for the Mixture-of-Gaussians Model

This section is completely based on the variational treatment of the MoG model of Attias (2000) and Bishop (2006). Because of this, some details of the derivation of the VB EM algorithm for the MoG model will be omitted here and we will concentrate only on the most important results.

In expressing the update rules for the distribution parameters in Equations (14), (15) and (16), we will find the following definitions useful:

$$
\begin{aligned}
N_k &= \sum_{n=1}^{N} r_{nk}, \\
\bar{\mathbf{x}}_k &= \frac{1}{N_k} \sum_{n=1}^{N} r_{nk} \mathbf{x}_n, \\
\mathbf{S}_k &= \frac{1}{N_k} \sum_{n=1}^{N} r_{nk} (\mathbf{x}_n - \bar{\mathbf{x}}_k)(\mathbf{x}_n - \bar{\mathbf{x}}_k)^T, \\
\log \tilde{\Lambda}_k &= \sum_{i=1}^{D} \psi\left(\frac{\nu_k + 1 - i}{2} \right) + D \log 2 + \log |\mathbf{W}_k|, \\
\log \tilde{\pi}_k &= \psi(\alpha_k) - \psi\left(\sum_{k'=1}^{K} \alpha_{k'} \right),
\end{aligned}
$$

where D is the dimensionality of the data and $\psi(\cdot)$ is the digamma function which is defined as the derivative of the logarithmic gamma function, that is

$$
\psi(x) = \frac{d}{dx} \log \Gamma(x).
$$

Using these definitions, the parameters r_{nk} of the approximate posterior over latent variables $q(\mathbf{Z})$ which are updated in the E-step are given by

$$
r_{nk} = \frac{\rho_{nk}}{\sum_{l=1}^{K} \rho_{nl}},
$$

where

$$
\rho_{nk} = \tilde{\pi}_k \tilde{\Lambda}_k^{1/2} \exp\left(-\frac{D}{2\beta_k} - \frac{\nu_k}{2} (\mathbf{x}_n - \mathbf{m}_k)^T \mathbf{W}_k (\mathbf{x}_n - \mathbf{m}_k) \right).
$$

The parameters r_{nk} are called *responsibilities* because they represent the responsibility the kth component takes in explaining the nth observation. The responsibilities can be arranged into a matrix $\mathbf{R} = (r_{nk})$ and will have to satisfy the following conditions

$$
0 \leq r_{nk} \leq 1, \tag{20}
$$

$$
\sum_{k=1}^{K} r_{nk} = 1. \tag{21}
$$

The parameter update equations for the M-step are then given by

$$\alpha_k = \alpha_0 + N_k, \tag{22}$$
$$\beta_k = \beta_0 + N_k, \tag{23}$$
$$\nu_k = \nu_0 + N_k + 1, \tag{24}$$
$$\mathbf{m}_k = \frac{1}{\beta_0 + N_k}(\beta_0 \mathbf{m}_0 + N_k \bar{\mathbf{x}}_k),$$
$$\mathbf{W}_k^{-1} = \mathbf{W}_0^{-1} + N_k \mathbf{S}_k + \frac{\beta_0 N_k}{\beta_0 + N_k}(\bar{\mathbf{x}}_k - \mathbf{m}_0)(\bar{\mathbf{x}}_k - \mathbf{m}_0)^T. \tag{25}$$

B.2 The Free Energy

The free energy of Equation (1) is

$$\begin{aligned}
\mathcal{F} &= \sum_{\mathbf{Z}} \int_{\boldsymbol{\pi}} \int_{\boldsymbol{\mu}} \int_{\boldsymbol{\Lambda}} q(\mathbf{Z}, \boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\Lambda}) \log \frac{q(\mathbf{Z}, \boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\Lambda})}{p(\mathbf{X}, \mathbf{Z}, \boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\Lambda})} d\boldsymbol{\pi} d\boldsymbol{\mu} d\boldsymbol{\Lambda} \\
&= E_q\{\log q(\mathbf{Z}, \boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\Lambda})\} - E_q\{\log p(\mathbf{X}, \mathbf{Z}, \boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\Lambda})\} \\
&= E_q\{\log q(\mathbf{Z})\} + E_q\{\log q(\boldsymbol{\pi})\} + E_q\{\log q(\boldsymbol{\mu}, \boldsymbol{\Lambda})\} \\
&\quad - E_q\{\log p(\mathbf{X}|\mathbf{Z}, \boldsymbol{\mu}, \boldsymbol{\Lambda})\} - E_q\{\log p(\mathbf{Z}|\boldsymbol{\pi})\} \\
&\quad - E_q\{\log p(\boldsymbol{\pi})\} - E_q\{\log p(\boldsymbol{\mu}, \boldsymbol{\Lambda})\}.
\end{aligned} \tag{26}$$

These expectations can be evaluated to give (Bishop, 2006)

$$E_q\{\log q(\mathbf{Z})\} = \sum_{n=1}^{N} \sum_{k=1}^{K} r_{nk} \log r_{nk},$$
$$E_q\{\log q(\boldsymbol{\pi})\} = \sum_{k=1}^{K} (\alpha_k - 1) \log \tilde{\pi}_k + \log C(\boldsymbol{\alpha}),$$
$$E_q\{\log q(\boldsymbol{\mu}, \boldsymbol{\Lambda})\} = \sum_{k=1}^{K} \left\{ \frac{1}{2} \log \tilde{\Lambda}_k + \frac{D}{2} \log \frac{\beta_k}{2\pi} - \frac{D}{2} - H_q\{\boldsymbol{\Lambda}_k\} \right\},$$
$$E_q\{\log p(\mathbf{Z}|\boldsymbol{\pi})\} = \sum_{n=1}^{N} \sum_{k=1}^{K} r_{nk} \log \tilde{\pi}_k,$$
$$E_q\{\log p(\boldsymbol{\pi})\} = \log C(\boldsymbol{\alpha}_0) + (\alpha_0 - 1) \sum_{k=1}^{K} \log \tilde{\pi}_k,$$

$$E_q\{\log p(\mathbf{X}|\mathbf{Z}, \boldsymbol{\mu}, \boldsymbol{\Lambda})\} = \frac{1}{2} \sum_{k=1}^{K} N_k \left\{ \log \tilde{\Lambda}_k - \frac{D}{\beta_k} - \nu_k \operatorname{Tr}(\mathbf{S}_k \mathbf{W}_k) - \nu_k (\bar{\mathbf{x}}_k - \mathbf{m}_k)^T \mathbf{W}_k (\bar{\mathbf{x}}_k - \mathbf{m}_k) - D \log 2\pi \right\},$$

$$E_q\{\log p(\boldsymbol{\mu}, \boldsymbol{\Lambda})\} = \frac{1}{2} \sum_{k=1}^{K} \left\{ D \log \frac{\beta_0}{2\pi} + \log \tilde{\Lambda}_k - \frac{D\beta_0}{\beta_k} - \beta_0 \nu_k (\mathbf{m}_k - \mathbf{m}_0)^T \mathbf{W}_k (\mathbf{m}_k - \mathbf{m}_0) \right\}$$
$$+ K \log B(\mathbf{W}_0, \nu_0) + \frac{\nu_0 - D - 1}{2} \sum_{k=1}^{K} \log \tilde{\Lambda}_k - \frac{1}{2} \sum_{k=1}^{K} \nu_k \operatorname{Tr}(\mathbf{W}_0^{-1} \mathbf{W}_k),$$

where $\mathrm{Tr}(\mathbf{A})$ denotes the trace of matrix $\mathbf{A}$ and $H_q\{\mathbf{\Lambda}_k\}$ is the entropy of the distribution $q(\mathbf{\Lambda}_k)$. The functions C and B are defined by the following two equations:

$$C(\boldsymbol{\alpha}) = \Gamma\left(\sum_{k=1}^{K}\alpha_k\right)\left(\prod_{k=1}^{K}\Gamma(\alpha_k)\right)^{-1},$$

$$B(\mathbf{W},\nu) = |\mathbf{W}|^{-\nu/2}\left(2^{\nu D/2}\pi^{D(D-1)/4}\prod_{i=1}^{D}\Gamma\left(\frac{\nu+1-i}{2}\right)\right)^{-1}.$$

B.3 Riemannian Conjugate Gradient for the Mixture-of-Gaussians Model

To be able to compare the VB EM and RCG algorithms, we assume that the approximate posterior distribution $q(\mathbf{Z},\boldsymbol{\pi},\boldsymbol{\mu},\mathbf{\Lambda})$ takes the same functional form as in the case of the VB EM algorithm. Thus, the fixed form posterior distributions are given by Equations (14), (15) and (16) and the free energy which is to be minimised by the RCG algorithm is given Equation (26). In this work, we will only be optimising the responsibilities r_{nk} and the means $\mathbf{m}_k$ using gradient-based methods. All other model parameters, namely the parameters α_k of the Dirichlet distribution, the parameters β_k controlling the covariance of the component means as well as the parameters $\mathbf{W}_k$ and ν_k of the Wishart distribution, are updated using the VB EM update Equations (22), (23), (24) and (25).

There are a few things that have to be taken into account when deriving gradient-based algorithms for the MoG model. Firstly, the responsibilities have to satisfy the constraints given by Equations (20) and (21). This can be enforced by using the *softmax* parametrisation

$$r_{nk} = \frac{e^{\gamma_{nk}}}{\sum_{l=1}^{K} e^{\gamma_{nl}}}. \tag{27}$$

It can be easily seen that by using this parametrisation the responsibilities are always positive and $\sum_{k=1}^{K} r_{nk} = 1$. As a results it holds that $0 \leq r_{nk} \leq 1$ and we can conduct unconstrained optimisation in the $\boldsymbol{\gamma}$ space.

Secondly, if we set the responsibilities $r_{nk}, n = 1\ldots N, k = 1\ldots K-1$ to some values, the values of $r_{nK}, n = 1\ldots N$ are given by condition (21), that is $r_{nK} = 1 - \sum_{k=1}^{K-1} r_{nk}$. As a result, the number of degrees of freedom in the responsibilities of the model is not the number of responsibilities NK but instead $N(K-1)$. When we are using the parametrisation (27), this means that we can regard the parameters γ_{nK} as constants and only optimise the free energy with respect to parameters $\gamma_{nk}, n = 1\ldots N, k = 1\ldots K-1$. This is especially important when using the Riemannian gradient.

The gradient of the free energy (26) with respect to $\mathbf{m}_k$ is given by

$$\nabla_{\mathbf{m}_k}\mathcal{F} = \nu_k\mathbf{W}_k(N_k(\mathbf{m}_k - \bar{\mathbf{x}}_k) + \beta_0(\mathbf{m}_k - \mathbf{m}_0))$$

and the derivative with respect to γ_{nk} is given by

$$\frac{\partial\mathcal{F}}{\partial\gamma_{nk}} = E_{nk} - r_{nk}F_n,$$

where

$$E_{nk} = r_{nk}\left(\log r_{nk} - \log\tilde{\pi}_k - \frac{1}{2}\left(\log\tilde{\Lambda}_k - \frac{D}{\beta_k} - D\log 2\pi - \nu_k(\mathbf{x}_n - \mathbf{m}_k)^T\mathbf{W}_k(\mathbf{x}_n - \mathbf{m}_k)\right)\right)$$

and

$$F_n = \sum_{k=1}^{K} E_{nk}.$$

We can update the responsibilities r_{nk} without having to evaluate and store the parameters γ_{nk} by noting that

$$\begin{aligned} r'_{nk} &= \frac{e^{\gamma_{nk}+\Delta\gamma_{nk}}}{\sum_{l=1}^{K} e^{\gamma_{nl}+\Delta\gamma_{nl}}} \\ &= \frac{\sum_{l=1}^{K} e^{\gamma_{nl}}}{\sum_{l=1}^{K} e^{\gamma_{nl}+\Delta\gamma_{nl}}} \frac{e^{\gamma_{nk}}}{\sum_{l=1}^{K} e^{\gamma_{nl}}} e^{\Delta\gamma_{nk}} = c_n r_{nk} e^{\Delta\gamma_{nk}}, \end{aligned}$$

where r'_{nk} is the new responsibility, $\Delta\gamma_{nk}$ is the change in parameter γ_{nk} determined by a line search in the search direction and c_n is a normalising constant which makes sure that $\sum_{k=1}^{K} r'_{nk} = 1$. Thus c_n can also be expressed in the form $c_n = (\sum_{k=1}^{K} r_{nk} e^{\Delta\gamma_{nk}})^{-1}$ and we can update the responsibilities using the formula

$$r'_{nk} = \frac{r_{nk} e^{\Delta\gamma_{nk}}}{\sum_{l=1}^{K} r_{nl} e^{\Delta\gamma_{nl}}}.$$

In order to use the Riemannian gradient, we need to know the Riemannian metric tensor $\mathbf{G}$ of the parameter space $(\mathbf{m},\boldsymbol{\gamma})$ which is given by Equation (3). The resulting matrix is a block diagonal matrix with blocks $\mathbf{A}_k = \beta_k \nu_k \mathbf{W}_k$ for each $\mathbf{m}_k$ and blocks $\mathbf{B}_n = -\mathbf{r}_n^T \mathbf{r}_n + \mathrm{diag}(\mathbf{r}_n)$ for each sample, where $\mathbf{r}_n$ is the nth row of the responsibility matrix $\mathbf{R}$ except for element r_{nK}, that is $\mathbf{r}_n = [r_{n1} \cdots r_{nK-1}]$. $\mathrm{diag}(\mathbf{a})$ is used here to denote a square matrix which has the elements of vector $\mathbf{a}$ on its main diagonal. This block-diagonal structure of the matrix makes the Riemannian vector operations easy and efficient to implement.

Since the EM updates of parameters are computationally efficient compared to the evaluation of the objective function, it is more efficient to do them also within the line search of the RCG update rather than as a separate step as in Algorithm 1.

Appendix C. Derivation of the Nonlinear State-Space Model

In this section we review the details of the nonlinear state-space model of Valpola and Karhunen (2002).

C.1 Probability Model and Priors

The nonlinear state-space model of Valpola and Karhunen (2002) can be described with these two equations:

$$\mathbf{s}(t) \sim \mathcal{N}(\mathbf{s}(t-1) + \mathbf{g}(\mathbf{s}(t-1), \boldsymbol{\theta}_\mathbf{g}), \mathrm{diag}(\exp(2\mathbf{v}_m))), \tag{28}$$

$$\mathbf{x}(t) \sim \mathcal{N}(\mathbf{f}(\mathbf{s}(t), \boldsymbol{\theta}_\mathbf{f}), \mathrm{diag}(\exp(2\mathbf{v}_n))), \tag{29}$$

where $\mathcal{N}(\boldsymbol{\mu},\boldsymbol{\Sigma})$ denotes a multivariate Gaussian distribution with mean $\boldsymbol{\mu}$ and covariance $\boldsymbol{\Sigma}$. The nonlinear mappings are modelled with MLP networks:

$$\begin{aligned} \mathbf{g}(\mathbf{s}(t-1), \boldsymbol{\theta}_\mathbf{g}) &= \mathbf{D}\tanh[\mathbf{C}\mathbf{s}(t-1) + \mathbf{c}] + \mathbf{d}, \\ \mathbf{f}(\mathbf{s}(t), \boldsymbol{\theta}_\mathbf{f}) &= \mathbf{B}\tanh[\mathbf{A}\mathbf{s}(t) + \mathbf{a}] + \mathbf{b}. \end{aligned}$$

The model for data $\mathbf{X}$ is thus described using unobserved variables

$$\boldsymbol{\theta} = (\mathbf{s}(t), \mathbf{A}, \mathbf{a}, \mathbf{B}, \mathbf{b}, \mathbf{C}, \mathbf{c}, \mathbf{D}, \mathbf{d}, \mathbf{v}_m, \mathbf{v}_n).$$

The priors of the variables are specified to fix the scaling ambiguity between $\mathbf{s}$ and $\mathbf{A}$ and to have a hierarchical prior allowing automatic relevance determination (ARD) (Bishop, 2006) like decisions to inactivate parts of the model:

$$\begin{aligned}
A_{ij} &\sim \mathcal{N}(0,1),\\
\Phi_{ij} &\sim \mathcal{N}(0, \exp(2v_{\Phi_j})),\\
\phi_i &\sim \mathcal{N}(m_\phi, \exp(2v_\phi)),\\
v_{\nu_i} &\sim \mathcal{N}(m_{v_\nu}, \exp(2v_{v_\nu})),\\
v_{\Phi_j} &\sim \mathcal{N}(m_{v_\Phi}, \exp(2v_{v_\Phi})),
\end{aligned}$$

where $\nu \in \{m,n\}$, $\phi \in \{a,b,c,d\}$ and $\Phi \in \{B,C,D\}$. All the hyperparameters have vague priors $\mathcal{N}(0, 100^2)$.

C.2 Posterior Approximation

In order to allow efficient learning, the posterior approximation $q(\boldsymbol{\theta}) = \mathcal{N}(\boldsymbol{\theta}|\boldsymbol{\mu}_{\boldsymbol{\theta}}, \boldsymbol{\Lambda}_{\boldsymbol{\theta}}^{-1})$ is restricted to be Gaussian with mean $\boldsymbol{\mu}_{\boldsymbol{\theta}}$ and precision (inverse covariance) $\boldsymbol{\Lambda}_{\boldsymbol{\theta}}$. Furthermore, the precision of the approximation is restricted to be almost diagonal. The only allowed off-diagonal terms are in the approximation of $\mathbf{s}(t)$ which includes a correlation between $s_i(t)$ and $s_i(t+1)$. Different components of the state vector $\mathbf{s}(t)$ are still assumed independent, and the posterior approximation of the states is a product of independent chains.

Following the theory of Gaussian Markov random fields, this assumption translates to a tridiagonal precision (inverse covariance) matrix with non-zero elements only on the main diagonal and on the diagonal corresponding to the assumed links. The corresponding covariance matrix has full blocks for each component of the state.

C.3 The Free Energy

In order to derive the value of the free energy (1), we note that

$$\mathcal{F}(q(\boldsymbol{\theta})) = E_{q(\boldsymbol{\theta})}\{\log q(\boldsymbol{\theta})\} + E_{q(\boldsymbol{\theta})}\{-\log p(\mathbf{X}, \boldsymbol{\theta})\}.$$

The first term is the negative entropy of a Gaussian

$$E_{q(\boldsymbol{\theta})}\{\log q(\boldsymbol{\theta})\} = -\frac{N}{2}\log(2\pi e) - \frac{1}{2}\log\det\boldsymbol{\Lambda}_{\boldsymbol{\theta}},$$

where N is the dimensionality of $\boldsymbol{\theta}$. The second term splits to a sum of a number of terms according to Equations (28)–(29).

$$E_{q(\boldsymbol{\theta})}\{-\log p(\mathbf{X}, \boldsymbol{\theta})\} = \sum_{t,i} E_{q(\boldsymbol{\theta})}\{-\log p(x_i(t)|\boldsymbol{\theta})\} + \sum_{\gamma \in \boldsymbol{\theta}} E_{q(\boldsymbol{\theta})}\left\{-\log p(\gamma|\boldsymbol{\theta}_{\setminus\gamma})\right\},$$

where $\boldsymbol{\theta}_{\setminus\gamma}$ denotes the parameters γ depends on.

The terms in the sum are expectations for parameters γ following a normal model $\mathcal{N}(m, e^{2v})$. The negative logarithm of the pdf is

$$-\log p(\gamma|\boldsymbol{\theta}_{\setminus\gamma}) = \frac{1}{2}\log(2\pi) + v + \frac{1}{2}(\gamma - m)^2 \exp(-2v).$$

Assuming independent Gaussian approximations[2] for γ, m and v with means $\bar{\gamma}, \bar{m}, \bar{v}$ and variances $\tilde{\gamma}, \tilde{m}, \tilde{v}$, respectively, the expectation is

$$E_{q(\boldsymbol{\theta})}\left\{-\log p(\gamma|\boldsymbol{\theta}_{\setminus\gamma})\right\} = \frac{1}{2}\log(2\pi) + \bar{v} + \frac{1}{2}[(\bar{\gamma} - \bar{m})^2 + \tilde{\gamma} + \tilde{m}]\exp(2\tilde{v} - 2\bar{v}).$$

For the observations $x_i(t)$ we obtain similarly

$$E_{q(\boldsymbol{\theta})}\left\{-\log p(x_i(t)|\boldsymbol{\theta})\right\} = \frac{1}{2}\log(2\pi) + \bar{v}_{n_i} + \frac{1}{2}[(x - \bar{f}_i(t))^2 + \tilde{f}_i(t)]\exp(2\tilde{v}_{n_i} - 2\bar{v}_{n_i}),$$

where the means $\bar{f}_i(t)$ and variances $\tilde{f}_i(t)$ of $\mathbf{f}(\mathbf{s}(t))$ are evaluated as explained in Honkela and Valpola (2005); Honkela et al. (2007).

For the states $s_i(t)$ we can similarly derive (Valpola and Karhunen, 2002)

$$\begin{aligned} E_{q(\boldsymbol{\theta})}\left\{-\log p(s_i(t)|\boldsymbol{\theta}_{\setminus\mathbf{s}(t)})\right\} &= \frac{1}{2}\log(2\pi) + \bar{v}_{m_i} \\ &+ \frac{1}{2}\left[(\bar{s}_i(t) - \bar{g}_i(t))^2 + \tilde{s}_i(t) + \tilde{g}_i(t) - 2\check{s}_i(t, t-1)\frac{g_i(t)}{s_i(t-1)}\tilde{s}_i(t-1)\right]\exp(2\tilde{v}_{m_i} - 2\bar{v}_{m_i}), \end{aligned}$$

where $\bar{g}_i(t)$ and $\tilde{g}_i(t)$ are the mean and variance of $\mathbf{g}(\mathbf{s}(t-1))$ evaluated similarly as those of $\mathbf{f}(\mathbf{s}(t))$, and $\check{s}_i(t, t-1)$ is the linear correlation between $s_i(t-1)$ and $s_i(t)$ as explained in Valpola and Karhunen (2002). The partial derivative $\frac{g_i(t)}{s_i(t-1)}$ is evaluated naturally as a by-product of evaluation of $\tilde{g}_i(t)$ as explained previously (Honkela and Valpola, 2005; Honkela et al., 2007).

C.4 Update Rules

The hyperparameters $v_{\Phi_j}, m_\phi, v_\phi, v_{\nu_i}, m_{v_\nu}, v_{v_\nu}, v_{\Phi_j}, m_{v_\Phi}, v_{v_\Phi}$ are updated using a VB EM type scheme to find a global optimum, given current values of the other parameters (Lappalainen and Miskin, 2000). The variances of the states and the weights of the MLP networks are updated using the fixed-point rule and the means by the RCG algorithm, as described in Section 5.

Abstract

A non-parametric hierarchical Bayesian framework is developed for designing a classifier, based on a mixture of simple (linear) classifiers. Each simple classifier is termed a local "expert", and the number of experts and their construction are manifested via a Dirichlet process formulation. The simple form of the "experts" allows analytical handling of incomplete data. The model is extended to allow simultaneous design of classifiers on multiple data sets, termed multi-task learning, with this also performed non-parametrically via the Dirichlet process. Fast inference is performed using variational Bayesian (VB) analysis, and example results are presented for several data sets. We also perform inference via Gibbs sampling, to which we compare the VB results.

Keywords: classification, incomplete data, expert, Dirichlet process, variational Bayesian, multi-task learning

1. Introduction

In many applications one must deal with data that have been collected incompletely. For example, in censuses and surveys, some participants may not respond to certain questions (Rubin, 1987); in email spam filtering, server information may be unavailable for emails from external sources (Dick et al., 2008); in medical studies, measurements on some subjects may be partially lost at certain stages of the treatment (Ibrahim, 1990); in DNA analysis, gene-expression microarrays may be incomplete due to insufficient resolution, image corruption, or simply dust or scratches on the slide (Wang et al., 2006); in sensing applications, a subset of sensors may be absent or fail to operate at certain regions (Williams and Carin, 2005). Unlike in semi-supervised learning (Ando and Zhang, 2005) where missing labels (responses) must be addressed, features (inputs) are partially missing in the aforementioned incomplete-data problems. Since most data analysis procedures (for example, regression and classification) are designed for complete data, and cannot be directly applied to incomplete data, the appropriate handling of missing data is challenging.

Traditionally, data are often "completed" by *ad hoc* editing, such as case deletion and single imputation, where feature vectors with missing values are simply discarded or completed with specific values in the initial stage of analysis, before the main inference (for example, mean im-

putation and regression imputation see Schafer and Graham, 2002). Although analysis procedures designed for complete data become applicable after these edits, shortcomings are clear. For case deletion, discarding information is generally inefficient, especially when data are scarce. Secondly, the remaining complete data may be statistically unrepresentative. More importantly, even if the incomplete-data problem is eliminated by ignoring data with missing features in the training phase, it is still inevitable in the test stage since test data cannot be ignored simply because a portion of features are missing. For single imputation, the main concern is that the uncertainty of the missing features is ignored by imputing fixed values.

The work of Rubin (1976) developed a theoretical framework for incomplete-data problems, where widely-cited terminology for missing patterns was first defined. It was proven that ignoring the *missing mechanism* is appropriate (Rubin, 1976) under the *missing at random* (MAR) assumption, meaning that the *missing mechanism* is conditionally independent of the missing features given the observed data. As elaborated later, given the MAR assumption (Dick et al., 2008; Ibrahim, 1990; Williams and Carin, 2005), incomplete data can generally be handled by full maximum likelihood and Bayesian approaches; however, when the *missing mechanism* does depend on the missing values (*missing not at random* or MNAR), a problem-specific model is necessary to describe the *missing mechanism*, and no general approach exists. In this paper, we address missing features under the MAR assumption. Previous work in this setting may be placed into two groups, depending on whether the missing data are handled before algorithm learning or within the algorithm.

For the former, an extra step is required to estimate $p(\boldsymbol{x}^m|\boldsymbol{x}^o)$, conditional distributions of missing values given observed ones, with this step distinct from the main inference algorithm. After $p(\boldsymbol{x}^m|\boldsymbol{x}^o)$ is learned, various imputation methods may be performed. As a Monte Carlo approach, Bayesian multiple imputation (MI) (Rubin, 1987) is widely used, where multiple ($M > 1$) samples from $p(\boldsymbol{x}^m|\boldsymbol{x}^o)$ are imputed to form M "complete" data sets, with the complete-data algorithm applied on each, and results of those imputed data sets combined to yield a final result. The MI method "completes" data sets so that algorithms designed for complete data become applicable. Furthermore, Rubin (1987) showed that MI does not require as many samples as Monte Carlo methods usually do. With a mild Gaussian mixture model (GMM) assumption for the joint distribution of observed and missing data, Williams et al. (2007) managed to analytically integrate out missing values over $p(\boldsymbol{x}^m|\boldsymbol{x}^o)$ and performed essentially infinite imputations. Since explicit imputations are avoided, this method is more efficient than the MI method, as suggested by empirical results (Williams et al., 2007). Other examples of these two-step methods include Williams and Carin (2005), Smola et al. (2005) and Shivaswamy et al. (2006).

The other class of methods explicitly addresses missing values during the model-learning procedure. The work proposed by Chechik et al. (2008) represents a special case, in which no model is assumed for *structurally absent* values; the margin for the support vector machine (SVM) is re-scaled according to the observed features for each instance. Empirical results (Chechik et al., 2008) show that this procedure is comparable to several single-imputation methods when values are *missing at random*. Another recent work (Dick et al., 2008) handles the missing features inside the procedure of learning a support vector machine (SVM), without constraining the distribution of missing features to any specific class. The main concern is that this method can only handle missing features in the training data; however, in many applications one cannot control whether missing values occur in the training or test data.

A widely employed approach for handling missing values within the algorithm involves maximum likelihood (ML) estimation via expectation maximization (EM) (Dempster et al., 1977). Be-

sides the latent variables (e.g., mixture component indicators), the missing features are also integrated out in the E-step so that the likelihood is maximized with respect to model parameters in the M-step. The main difficulty is that the integral in the E-step is analytically tractable only when an assumption is made on the distribution of the missing features. For example, the intractable integral is avoided by requiring the features to be discrete (Ibrahim, 1990), or assuming a Gaussian mixture model (GMM) for the features (Ghahramani and Jordan, 1994; Liao et al., 2007). The discreteness requirement is often too restrictive, while the GMM assumption is mild since it is well known that a GMM can approximate arbitrary continuous distributions.

In Liao et al. (2007) the authors proposed a quadratically gated mixture of experts (QGME) where the GMM is used to form the gating network, statistically partitioning the feature space into quadratic subregions. In each subregion, one linear classifier works as a local "expert". As a mixture of experts (Jacobs et al., 1991), the QGME is capable of addressing a classification problem with a nonlinear decision boundary in terms of multiple local experts; the simple form of this model makes it straightforward to handle incomplete data without completing kernel functions (Graepel, 2002; Williams and Carin, 2005). However, as in many mixture-of-expert models (Jacobs et al., 1991; Waterhouse and Robinson, 1994; Xu et al., 1995), the number of local experts in the QGME must be specified initially, and thus a model-selection stage is in general necessary. Moreover, since the expectation-maximization method renders a point (single) solution that maximizes the likelihood, over-fitting may occur when data are scarce relative to the model complexity.

In this paper, we first extend the finite QGME (Liao et al., 2007) to an infinite QGME (iQGME), with theoretically an infinite number of experts realized via a Dirichlet process (DP) (Ferguson, 1973) prior; this yields a fully Bayesian solution, rather than a point estimate. In this manner model selection is avoided and the uncertainty on the number of experts is captured in the posterior density function.

The Dirichlet process (Ferguson, 1973) has been an active topic in many applications since the middle 1990s, for example, density estimation (Escobar and West, 1995; MacEachern and Müller, 1998; Dunson et al., 2007) and regression/curve fitting (Müller et al., 1996; Rasmussen and Ghahramani, 2002; Meeds and Osindero, 2006; Shahbaba and Neal, 2009; Rodríguez et al., 2009; Hannah et al., 2010). The latter group is relevant to classification problems of interest in this paper. The work in Müller et al. (1996) jointly modeled inputs and responses as a Dirichlet process mixture of multivariate normals, while Rodríguez et al. (2009) extended this model to simultaneously estimate multiple curves using dependent DP. In Rasmussen and Ghahramani (2002) and Meeds and Osindero (2006) two approaches to constructing infinite mixtures of Gaussian Process (GP) experts were proposed. The difference is that Meeds and Osindero (2006) specified the gating network using a multivariate Gaussian mixture instead of a (fixed) input-dependent Dirichlet Process. In Shahbaba and Neal (2009) another form of infinite mixtures of experts was proposed, where experts are specified by a multinomial logit (MNL) model (also called softmax) and the gating network is Gaussian mixture model with independent covariates. Further, Hannah et al. (2010) generalized existing DP-based nonparametric regression models to accommodate different types of covariates and responses, and further gave theoretical guarantees for this class of models.

Our focus in this paper is on developing classification models that handle incomplete inputs/covariates efficiently using Dirichlet process. Some of the above Dirichlet process regression models are potentially capable of handling incomplete inputs/features; however, none of them actually deal with such problems. In Müller et al. (1996), although the joint multivariate normal assumption over inputs and responses endow this approach with the potential of handling missing

features and/or missing responses naturally, a good estimation for the joint distribution does not guarantee a good estimation for classification boundaries. Other than a full joint Gaussian distribution assumption, explicit classifiers were used to model the conditional distribution of responses given covariates in the models proposed in Meeds and Osindero (2006) and Shahbaba and Neal (2009). These two models are highly related to the iQGME proposed here. The independence assumption of covariates in Shahbaba and Neal (2009) leads to efficient computation but is not appealing for handling missing features. With Gaussian process experts (Meeds and Osindero, 2006), the inference for missing features is not analytical for fast inference algorithms such as variational Bayesian (Beal, 2003) and EM, and the computation could be prohibitive for large data sets. The iQGME seeks a balance between the ease of inference, computational burden and the ability of handling missing features. For high-dimensional data sets, we develop a variant of our model based on mixtures of factor analyzers (MFA) (Ghahramani and Hinton, 1996; Ghahramani and Beal, 2000), where a low-rank assumption is made for the covariance matrices of high-dimensional inputs in each cluster.

In addition to challenges with incomplete data, one must often address an insufficient quantity of labeled data. In Williams et al. (2007) the authors employed semi-supervised learning (Zhu, 2005) to address this challenge, using the contextual information in the unlabeled data to augment the limited labeled data, all done in the presence of missing/incomplete data. Another form of context one may employ to address limited labeled data is multi-task learning (MTL) (Caruana, 1997; Ando and Zhang, 2005), which allows the learning of multiple tasks simultaneously to improve generalization performance. The work of Caruana (1997) provided an overview of MTL and demonstrated it on multiple problems. In recent research, a hierarchical statistical structure has been favored for such models, where information is transferred via a common prior within a hierarchical Bayesian model (Yu et al., 2003; Zhang et al., 2006). Specifically, information may be transferred among related tasks (Xue et al., 2007) when the Dirichlet process (DP) (Ferguson, 1973) is introduced as a common prior. To the best of our knowledge, there is no previous example of addressing incomplete data in a multi-task setting, this problem constituting an important aspect of this paper.

The main contributions of this paper may be summarized as follows. The problem of missing data in classifier design is addressed by extending QGME (Liao et al., 2007) to a fully Bayesian setting, with the number of local experts inferred automatically via a DP prior. The algorithm is further extended to a multi-task setting, again using a non-parametric Bayesian model, simultaneously learning J missing-data classification problems, with appropriate sharing (could be global or local). Throughout, efficient inference is implemented via the variational Bayesian (VB) method (Beal, 2003). To quantify the accuracy of the VB results, we also perform comparative studies based on Gibbs sampling.

The remainder of the paper is organized as follows. In Section 2 we extend the finite QGME (Liao et al., 2007) to an infinite QGME via a Dirichlet process prior. The incomplete-data problem is defined and discussed in Section 3. Extension to the multi-task learning case is considered in Section 4, and variational Bayesian inference is developed in Section 5. Experimental results for synthetic data and multiple real data sets are presented in Section 6, followed in Section 7 by conclusions and a discussions of future research directions.

2. Infinite Quadratically Gated Mixture of Experts

In this section, we first provide a brief review of the quadratically gated mixture of experts (QGME) (Liao et al., 2007) and Dirichlet process (DP) (Ferguson, 1973), and then extend the number of experts to be infinite via DP.

2.1 Quadratically Gated Mixture of Experts

Consider a binary classification problem with real-valued P-dimensional column feature vectors $\boldsymbol{x}_i$ and corresponding class labels $y_i \in \{1,-1\}$. We assume binary labels for simplicity, while the proposed method may be directly extended to cases with more than two classes. Latent variables t_i are introduced as "soft labels" associated with y_i, as in probit models (Albert and Chib, 1993), where $y_i = 1$ if $t_i > 0$ and $y_i = -1$ if $t_i \leq 0$. The finite quadratically gated mixture of experts (QGME) (Liao et al., 2007) is defined as

$$(t_i|z_i = h) \sim \mathcal{N}(\boldsymbol{w}_h^T \boldsymbol{x}_i^b, 1), \tag{1}$$

$$(\boldsymbol{x}_i|z_i = h) \sim \mathcal{N}_P(\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h^{-1}), \tag{2}$$

$$(z_i|\boldsymbol{\pi}) \sim \sum_{h=1}^{K} \pi_h \delta_h, \tag{3}$$

with $\sum_{h=1}^{K} \pi_h = 1$, and where δ_h is a point measure concentrated at h (with probability one, a draw from δ_h will be h). The $(P+1) \times K$ matrix $\boldsymbol{W}$ has columns $\boldsymbol{w}_h$, where each $\boldsymbol{w}_h$ are the weights on a local linear classifier, and the $\boldsymbol{x}_i^b$ are feature vectors with an intercept, that is, $\boldsymbol{x}_i^b = [\boldsymbol{x}_i^T, 1]^T$. A total of K groups of $\boldsymbol{w}_h$ are introduced to parameterize the K experts. With probability π_h the indicator for the ith data point satisfies $z_i = h$, which means the hth local expert is selected, and $\boldsymbol{x}_i$ is distributed according to a P-variate Gaussian distribution with mean $\boldsymbol{\mu}_h$ and precision $\boldsymbol{\Lambda}_h$.

It can be seen that the QGME is highly related to the mixture of experts (ME) (Jacobs et al., 1991) and the hierarchical mixture of experts (HME) (Jordan and Jacobs, 1994) if we write the conditional distribution of labels as

$$p(y_i|\boldsymbol{x}_i) = \sum_{h=1}^{K} p(z_i = h|\boldsymbol{x}_i) p(y_i|z_i = h, \boldsymbol{x}_i), \tag{4}$$

where

$$p(y_i|z_i = h, \boldsymbol{x}_i) = \int_{t_i y_i > 0} \mathcal{N}(t_i|\boldsymbol{w}_h^T \boldsymbol{x}_i^b, 1) dt_i, \tag{5}$$

$$p(z_i = h|\boldsymbol{x}_i) = \frac{\pi_h \mathcal{N}_P(\boldsymbol{x}_i|\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h^{-1})}{\sum_{k=1}^{K} \pi_k \mathcal{N}_P(\boldsymbol{x}_i|\boldsymbol{\mu}_k, \boldsymbol{\Lambda}_k^{-1})}. \tag{6}$$

From (4), as a special case of the ME, the QGME is capable of handling nonlinear problems with linear experts characterized in (5). However, unlike other ME models, the QGME probabilistically partitions the feature space through a mixture of K Gaussian distributions for $\boldsymbol{x}_i$ as in (6). This assumption on the distribution of $\boldsymbol{x}_i$ is mild since it is well known that a Gaussian mixture model (GMM) is general enough to approximate any continuous distribution. In the QGME, $\boldsymbol{x}_i$ as well as y_i are treated as random variables (generative model) and we consider a joint probability $p(y_i, \boldsymbol{x}_i)$ instead of a conditional probability $p(y_i|\boldsymbol{x}_i)$ for fixed $\boldsymbol{x}_i$ as in most ME models (which are typically

discriminative). Previous work on the comparison between discriminative and generative models may be found in Ng and Jordan (2002) and Liang and Jordan (2008). In the QGME, the GMM of the inputs $\boldsymbol{x}_i$ plays two important roles: (*i*) as a gating network, while (*ii*) enabling analytic incorporation of incomplete data during classifier inference (as discussed further below).

The QGME (Liao et al., 2007) is inferred via the expectation-maximization (EM) method, which renders a point-estimate solution for an initially specified model (1)-(3), with a fixed number K of local experts. Since learning the correct model requires model selection, and moreover in many applications there may exist no such fixed "correct" model, in the work reported here we infer the full posterior for a QGME model with the number of experts data-driven. The objective can be achieved by imposing a nonparametric Dirichlet process (DP) prior.

2.2 Dirichlet Process

The Dirichlet process (DP) (Ferguson, 1973) is a random measure defined on measures of random variables, denoted as $\mathcal{DP}(\alpha G_0)$, with a real scaling parameter $\alpha \geq 0$ and a base measure G_0. Assuming that a measure is drawn $G \sim \mathcal{DP}(\alpha G_0)$, the base measure G_0 reflects the prior expectation of G and the scaling parameter α controls how much G is allowed to deviate from G_0. In the limit $\alpha \to \infty$, G goes to G_0; in the limit $\alpha \to 0$, G reduces to a delta function at a random point in the support of G_0.

The stick-breaking construction (Sethuraman, 1994) provides an explicit form of a draw from a DP prior. Specifically, it has been proven that a draw G may be constructed as

$$G = \sum_{h=1}^{\infty} \pi_h \delta_{\boldsymbol{\theta}_h^*}, \tag{7}$$

with $0 \leq \pi_h \leq 1$ and $\sum_{h=1}^{\infty} \pi_h = 1$, and

$$\pi_h = V_h \prod_{l=1}^{h-1} (1 - V_l), \quad V_h \overset{iid}{\sim} Be(1, \alpha), \quad \boldsymbol{\theta}_h^* \overset{iid}{\sim} G_0.$$

From (7), it is clear that G is discrete (with probability one) with an infinite set of weights π_h at atoms $\boldsymbol{\theta}_h^*$. Since the weights π_h decrease stochastically with h, the summation in (7) may be truncated with N terms, yielding an N-level truncated approximation to a draw from the Dirichlet process (Ishwaran and James, 2001).

Assuming that underlying variables $\boldsymbol{\theta}_i$ are drawn i.i.d. from G, the associated data $\chi_i \sim F(\boldsymbol{\theta}_i)$ will naturally cluster with $\boldsymbol{\theta}_i$ taking distinct values $\boldsymbol{\theta}_h^*$, where the function $F(\boldsymbol{\theta})$ represents an arbitrary parametric model for the observed data, with hidden parameters $\boldsymbol{\theta}$. Therefore, the number of clusters is automatically determined by the data and could be "infinite" in principle. Since $\boldsymbol{\theta}_i$ take distinct values $\boldsymbol{\theta}_h^*$ with probabilities π_h, this clustering is a statistical procedure instead of a hard partition, and thus we only have a belief on the number of clusters, which is affected by the scaling parameter α. As the value of α influences the prior belief on the clustering, a gamma hyper-prior is usually employed on α.

2.3 Infinite QGME via DP

Consider a classification task with a training data set $\mathcal{D} = \{(\boldsymbol{x}_i, y_i) : i = 1, \ldots, n\}$, where $\boldsymbol{x}_i \in \mathbb{R}^P$ and $y_i \in \{-1, 1\}$. With soft labels t_i introduced as in Section 2.1, the infinite QGME (iQGME)

model is achieved via a DP prior imposed on the measure G of $(\boldsymbol{\mu}_i, \boldsymbol{\Lambda}_i, \boldsymbol{w}_i)$, the hidden variables characterizing the density function of each data point $(\boldsymbol{x}_i, t_i)$. For simplicity, the same symbols are used to denote parameters associated with each data point and the distinct values, with subscripts i and h indexing data points and unique values, respectively:

$$\begin{aligned}(\boldsymbol{x}_i, t_i) &\sim \mathcal{N}_P(\boldsymbol{x}_i|\boldsymbol{\mu}_i, \boldsymbol{\Lambda}_i^{-1})\mathcal{N}(t_i|\boldsymbol{w}_i^T\boldsymbol{x}_i^b, 1),\\ (\boldsymbol{\mu}_i, \boldsymbol{\Lambda}_i, \boldsymbol{w}_i) &\overset{iid}{\sim} G,\\ G &\sim \mathcal{DP}(\alpha G_0),\end{aligned} \tag{8}$$

where the base measure G_0 is factorized as the product of a normal-Wishart prior for $(\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h)$ and a normal prior for $\boldsymbol{w}_h$, for the sake of conjugacy. As discussed in Section 2.2, data samples cluster automatically, and the same mean $\boldsymbol{\mu}_h$, covariance matrix $\boldsymbol{\Lambda}_h$ and regression coefficients (expert) $\boldsymbol{w}_h$ are shared for a given cluster h. Using the stick-breaking construction, we elaborate (8) as follows for $i = 1, \ldots, n$ and $h = 1, \ldots, \infty$:

Data generation:

$$\begin{aligned}(t_i|z_i = h) &\sim \mathcal{N}(\boldsymbol{w}_h^T\boldsymbol{x}_i^b, 1),\\ (\boldsymbol{x}_i|z_i = h) &\sim \mathcal{N}_P(\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h^{-1}),\end{aligned}$$

Drawing indicators:

$$\begin{aligned}z_i &\sim \sum_{h=1}^{\infty}\pi_h\delta_h, \quad \text{where} \quad \pi_h = V_h\prod_{l<h}(1-V_l),\\ V_h &\sim Be(1, \alpha),\end{aligned}$$

Drawing parameters from G_0 :

$$\begin{aligned}(\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h) &\sim \mathcal{N}_P(\boldsymbol{\mu}_h|\boldsymbol{m}_0, u_0^{-1}\boldsymbol{\Lambda}_h^{-1})\mathcal{W}(\boldsymbol{\Lambda}_h|\boldsymbol{B}_0, \nu_0),\\ \boldsymbol{w}_h &\sim \mathcal{N}_{P+1}(\boldsymbol{\zeta}, [\mathrm{diag}(\boldsymbol{\lambda})]^{-1}), \quad \text{where} \quad \boldsymbol{\lambda} = [\lambda_1, \ldots, \lambda_{P+1}].\end{aligned}$$

Furthermore, to achieve a more robust algorithm, we assign diffuse hyper-priors on several crucial parameters. As discussed in Section 2.2, the scaling parameter α reflects our prior belief on the number of clusters. For the sake of conjugacy, a diffuse Gamma prior is usually assumed for α as suggested by West et al. (1994). In addition, parameters $\boldsymbol{\zeta}, \boldsymbol{\lambda}$ characterizing the prior of the distinct local classifiers $\boldsymbol{w}_h$ are another set of important parameters, since we focus on classification tasks. Normal-Gamma priors are the conjugate priors for the mean and precision of a normal density. Therefore,

$$\begin{aligned}\alpha &\sim Ga(\tau_{10}, \tau_{20}),\\ (\boldsymbol{\zeta}|\boldsymbol{\lambda}) &\sim \mathcal{N}_{P+1}(\boldsymbol{0}, \gamma_0^{-1}[\mathrm{diag}(\boldsymbol{\lambda})]^{-1}),\\ \lambda_p &\sim Ga(a_0, b_0), \quad p = 1, \ldots, P+1,\end{aligned}$$

where $\tau_{10}, \tau_{20}, a_0, b_0$ are usually set to be much less than one and of about the same magnitude, so that the constructed Gamma distributions with means about one and large variances are diffuse; γ_0 is usually set to be around one.

The graphical representation of the iQGME for single-task learning is shown in Figure 1. We notice that a possible variant with sparse local classifiers could be obtained if we impose zero mean for the local classifiers $\boldsymbol{w}_h$, that is, $\boldsymbol{\zeta} = \boldsymbol{0}$, and retain the Gamma hyper-prior for the precision $\boldsymbol{\lambda}$, as

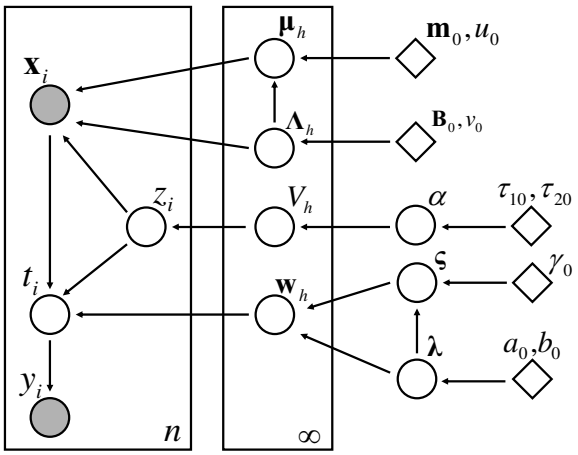

Figure 1: Graphical representation of the iQGME for single-task leaning. All circles denote random variables, with shaded ones indicating observable data, and bright ones representing hidden variables. Diamonds denote fixed hyper-parameters, boxes represent independent replicates with numbers at the lower right corner indicating the numbers of i.i.d. copies, and arrows indicate the dependence between variables (pointing from parents to children).

in the relevance vector machine (RVM) (Tipping, 2000), which employs a corresponding Student-t sparseness prior on the weights. Although this sparseness prior is useful for seeking relevant features in many applications, imposing the same sparse pattern for all the local experts is not desirable.

2.4 Variant for High-Dimensional Problems

For the classification problem, we assume access to a training data set $\mathcal{D} = \{(\boldsymbol{x}_i, y_i) : i = 1, \ldots, n\}$, where feature vectors $\boldsymbol{x}_i \in \mathbb{R}^P$ and labels $y_i \in \{-1, 1\}$. We have assumed that the feature vectors of objects in cluster h are generated from a P-variate normal distribution with mean $\boldsymbol{\mu}_h$ and covariance matrix $\boldsymbol{\Lambda}_h^{-1}$, that is,

$$(\boldsymbol{x}_i | z_i = h) \quad \sim \quad \mathcal{N}_P(\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h^{-1}) \tag{9}$$

It is well known that each covariance matrix has $P(P+1)/2$ parameters to be estimated. Without any further assumption, the estimation of these parameters could be computationally prohibitive for large P, especially when the number of available training data n is small, which is common for classification applications. By imposing an approximately low-rank constraint on the covariances, as in well-studied mixtures of factor analyzers (MFA) models (Ghahramani and Hinton, 1996; Ghahramani and Beal, 2000), the number of unknowns could be significantly reduced. Specifically, assume a vector of standard normal latent factors $\boldsymbol{s}_i \in \mathbb{R}^{T \times 1}$ for data $\boldsymbol{x}_i$, a factor loading matrix $\boldsymbol{A}_h \in \mathbb{R}^{P \times T}$ for cluster h, and Gaussian residues $\boldsymbol{\epsilon}_i$ with diagonal covariance matrix $\psi_h \boldsymbol{I}_P$, then

$$(\boldsymbol{x}_i | z_i = h) \quad \sim \quad \mathcal{N}_P(\boldsymbol{A}_h \boldsymbol{s}_i + \boldsymbol{\mu}_h, \psi_h^{-1} \boldsymbol{I}_P).$$

Marginalizing $\boldsymbol{s}_i$ with $\boldsymbol{s}_i \sim \mathcal{N}_T(\boldsymbol{0}, \boldsymbol{I}_T)$, we recover (9), with $\boldsymbol{\Lambda}_h^{-1} = \boldsymbol{A}_h \boldsymbol{A}_h^T + \psi_h^{-1} \boldsymbol{I}_P$. The number of free parameters is significantly reduced if $T << P$.

In this paper, we modify the MFA model for classification applications with scarce samples. First, we consider a common loading matrix $\boldsymbol{A}$ for all the clusters, and introduce a binary vector $\boldsymbol{b}_h$ for each cluster to select which columns of $\boldsymbol{A}$ are used, that is,

$$(\boldsymbol{x}_i|z_i=h) \quad \sim \quad \mathcal{N}_P(\boldsymbol{A}\text{diag}(\boldsymbol{d}\circ\boldsymbol{b}_h)\boldsymbol{s}_i+\boldsymbol{\mu}_h,\psi_h^{-1}\boldsymbol{I}_P),$$

where each column of $\boldsymbol{A}$, $\boldsymbol{A}_l \sim \mathcal{N}_P(\boldsymbol{0},P^{-1}\boldsymbol{I}_P)$, $\boldsymbol{s}_i \sim \mathcal{N}_L(\boldsymbol{0},\boldsymbol{I}_L)$, $\boldsymbol{d}$ is a vector responsible for scale, and $\circ$ is a component-wise (Hadamard) product. For $\boldsymbol{d}$ we employ the prior $d_l \sim \mathcal{N}(0,\beta_l^{-1})$ with $\beta_l \sim Ga(c_0,d_0)$. Furthermore, we let the algorithm infer the intrinsic number of factors by imposing a low-rank belief for each cluster through the prior of $\boldsymbol{b}_h$, that is,

$$b_{hl} \quad \sim \quad Bern(\pi_{hl}), \quad \pi_{hl} \sim Be(a_0/L, b_0(L-1)/L), \quad l=1,\ldots,L,$$

where L is a large number, which defines the largest possible dimensionality the algorithm may infer. Through the choice of a_0 and b_0 we impose our prior belief about the intrinsic dimensionality of cluster h (upon integrating out the draw $\boldsymbol{\pi}_h$, the number of non-zero components of $\boldsymbol{b}_h$ is drawn from $Binomial[L, a_0/(a_0+b_0(L-1))]$). As a result, both the number of clusters and the dimensionality of each cluster is inferred by this variant of iQGME.

With this form of iQGME, we could build local linear classifiers in either the original feature space or the (low-dimensional) space of latent factors $\boldsymbol{s}_i$. For the sake of computational simplicity, we choose to classify in the low-dimensional factor space.

3. Incomplete Data Problem

In the above discussion it was assumed that all components of the feature vectors were available (no missing data). In this section, we consider the situation for which feature vectors $\boldsymbol{x}_i$ are partially observed. We partition each feature vector $\boldsymbol{x}_i$ into observed and missing parts, $\boldsymbol{x}_i = [\boldsymbol{x}_i^{o_i};\boldsymbol{x}_i^{m_i}]$, where $\boldsymbol{x}_i^{o_i} = \{x_{ip} : p \in o_i\}$ denotes the subvector of observed features and $\boldsymbol{x}_i^{m_i} = \{x_{ip} : p \in m_i\}$ represents the subvector of missing features, with o_i and m_i denoting the set of indices for observed and missing features, respectively. Each $\boldsymbol{x}_i$ has its own observed set o_i and missing set m_i, which may be different for each i. Following a generic notation (Schafer and Graham, 2002), we refer to $\boldsymbol{R}$ as the missingness. For an arbitrary missing pattern, $\boldsymbol{R}$ could be defined as a missing data indicator matrix, that is,

$$R_{ip} = \begin{cases} 1, & x_{ip} \text{ observed,} \\ 0, & x_{ip} \text{ missing.} \end{cases}$$

We use $\boldsymbol{\xi}$ to denote parameters characterizing the distribution of $\boldsymbol{R}$, which is usually called the *missing mechanism*. In the classification context, the joint distribution of class labels, observed features and the missingness $\boldsymbol{R}$ may be given by integrating out the missing features $\boldsymbol{x}^m$,

$$p(y,\boldsymbol{x}^o,\boldsymbol{R}|\boldsymbol{\theta},\boldsymbol{\xi}) = \int p(y,\boldsymbol{x}|\boldsymbol{\theta})p(\boldsymbol{R}|\boldsymbol{x},\boldsymbol{\xi})d\boldsymbol{x}^m. \tag{10}$$

To handle such a problem analytically, assumptions must be made on the distribution of $\boldsymbol{R}$. If the *missing mechanism* is conditionally independent of missing values $\boldsymbol{x}^m$ given the observed data, that is, $p(\boldsymbol{R}|\boldsymbol{x},\boldsymbol{\xi}) = p(\boldsymbol{R}|\boldsymbol{x}^o,\boldsymbol{\xi})$, the missing data are defined to be *missing at random* (MAR) (Rubin, 1976). Consequently, (10) reduces to

$$p(y,\boldsymbol{x}^o,\boldsymbol{R}|\boldsymbol{\theta},\boldsymbol{\xi}) = p(\boldsymbol{R}|\boldsymbol{x}^o,\boldsymbol{\xi})\int p(y,\boldsymbol{x}|\boldsymbol{\theta})d\boldsymbol{x}^m = p(\boldsymbol{R}|\boldsymbol{x}^o,\boldsymbol{\xi})p(y,\boldsymbol{x}^o|\boldsymbol{\theta}). \tag{11}$$

According to (11), the likelihood is factorizable under the assumption of MAR. As long as the prior $p(\boldsymbol{\theta},\boldsymbol{\xi}) = p(\boldsymbol{\theta})p(\boldsymbol{\xi})$ (factorizable), the posterior

$$p(\boldsymbol{\theta},\boldsymbol{\xi}|y,\boldsymbol{x}^o,\boldsymbol{R}) \propto p(y,\boldsymbol{x}^o,\boldsymbol{R}|\boldsymbol{\theta},\boldsymbol{\xi})p(\boldsymbol{\theta},\boldsymbol{\xi}) = p(\boldsymbol{R}|\boldsymbol{x}^o,\boldsymbol{\xi})p(\boldsymbol{\xi})p(y,\boldsymbol{x}^o|\boldsymbol{\theta})p(\boldsymbol{\theta})$$

is also factorizable. For the purpose of inferring model parameters $\boldsymbol{\theta}$, no explicit specification is necessary on the distribution of the missingness. As an important special case of MAR, *missing completely at random* (MCAR) occurs if we can further assume that $p(\boldsymbol{R}|\boldsymbol{x},\boldsymbol{\xi}) = p(\boldsymbol{R}|\boldsymbol{\xi})$, which means the distribution of missingness is independent of observed values $\boldsymbol{x}^o$ as well. When the *missing mechanism* depends on missing values $\boldsymbol{x}^m$, the data are termed to be *missing not at random* (MNAR). From (10), an explicit form has to be assumed for the distribution of the missingness, and both the accuracy and the computational efficiency should be concerned.

When missingness is not totally controlled, as in most realistic applications, we cannot tell from the data alone whether the MCAR or MAR assumption is valid. Since the MCAR or MAR assumption is unlikely to be precisely satisfied in practice, inference based on these assumptions may lead to a bias. However, as demonstrated in many cases, it is believed that for realistic problems departures from MAR are usually not large enough to significantly impact the analysis (Collins et al., 2001). On the other hand, without the MAR assumption, one must explicitly specify a model for the missingness $\boldsymbol{R}$, which is a difficult task in most cases. As a result, the data are typically assumed to be either MCAR or MAR in the literature, unless significant correlations between the missing values and the distribution of the missingness are suspected.

In this work we make the MAR assumption, and thus expression (11) applies. In the iQGME framework, the joint likelihood may be further expanded as

$$p(y,\boldsymbol{x}^o|\boldsymbol{\theta}) = \int p(y,\boldsymbol{x}|\boldsymbol{\theta})d\boldsymbol{x}^m = \int_{ty>0} \int p(t|\boldsymbol{x},\boldsymbol{\theta}_2)p(\boldsymbol{x}|\boldsymbol{\theta}_1)d\boldsymbol{x}^m dt. \tag{12}$$

The solution to such a problem with incomplete data $\boldsymbol{x}^m$ is analytical since the distributions of t and $\boldsymbol{x}$ are assumed to be a Gaussian and a Gaussian mixture model, respectively. Naturally, the missing features could be regarded as hidden variables to be inferred and the graphical representation of the iQGME with incomplete data remains the same as in Figure 1, except that the node presenting features are partially observed now. As elaborated below, the important but mild assumption that the features are distributed as a GMM enables us to analytically infer the variational distributions associated with the missing values in a procedure of variational Bayesian inference.

As in many models (Williams et al., 2007), estimating the distribution of the missing values first and learning the classifier at a second step gives the flexibility of selecting the classifier for the second step. However, (12) suggests that the classifier and the data distribution are coupled, provided that partial data are missing and thus have to be integrated out. Therefore, a joint estimation of missing features and classifiers (searching in the space of $(\boldsymbol{\theta_1},\boldsymbol{\theta}_2)$) is more desirable than a two-step process (searching in the space of $\boldsymbol{\theta_1}$ for the distribution of the data, and then in the space of $\boldsymbol{\theta}_2$ for the classifier).

4. Extension to Multi-Task Learning

Assume we have J data sets, with the jth represented as $\mathcal{D}_j = \{(\boldsymbol{x}_{ji}, y_{ji}) : i = 1,\ldots,n_j\}$; our goal is to design a classifier for each data set, with the design of each classifier termed a "task". One may learn separate classifiers for each of the J data sets (single-task learning) by ignoring connections between

the data sets, or a single classifier may be learned based on the union of all data (pooling) by ignoring differences between the data sets. More appropriately, in a hierarchical Bayesian framework J task-dependent classifiers may be learned jointly, with information borrowed via a higher-level prior (multi-task learning). In some previous research all tasks are assumed to be equally related to each other (Yu et al., 2003; Zhang et al., 2006), or related tasks share exactly the same task-dependent classifier (Xue et al., 2007). With multiple local experts, the proposed iQGME model for a particular task is relatively flexible, enabling the borrowing of information across the J tasks (two data sets may share *parts* of the respective classifiers, without requiring sharing of all classifier components).

As discussed in Section 2.2, a DP prior encourages clustering (each cluster corresponds to a local expert). Now considering multiple tasks, a hierarchical Dirichlet process (HDP) (Teh et al., 2006) may be considered to solve the problem of sharing clusters (local experts) across multiple tasks. Assume a random measure G_j is associated with each task j, where each G_j is an independent draw from Dirichlet process $\mathcal{DP}(\alpha G_0)$ with a base measure G_0 drawn from an upper-level Dirichlet process $\mathcal{DP}(\beta H)$, that is,

$$\begin{aligned} G_j &\sim \mathcal{DP}(\alpha G_0), \quad \text{for} \quad j = 1, \ldots, J, \\ G_0 &\sim \mathcal{DP}(\beta H). \end{aligned}$$

As a draw from a Dirichlet process, G_0 is discrete with probability one and has a stick-breaking representation as in (7). With such a base measure, the task-dependent DPs reuse the atoms $\boldsymbol{\theta}_h^*$ defined in G_0, yielding the desired sharing of atoms among tasks.

With the task-dependent iQGME defined in (8), we consider all J tasks jointly:

$$\begin{aligned} (\boldsymbol{x}_{ji}, t_{ji}) &\sim \mathcal{N}_P(\boldsymbol{x}_{ji}|\boldsymbol{\mu}_{ji}, \boldsymbol{\Lambda}_{ji}^{-1}) \mathcal{N}(t_{ji}|\boldsymbol{w}_{ji}^T \boldsymbol{x}_{ji}^b, 1), \\ (\boldsymbol{\mu}_{ji}, \boldsymbol{\Lambda}_{ji}, \boldsymbol{w}_{ji}) &\overset{iid}{\sim} G_j, \\ G_j &\sim \mathcal{DP}(\alpha G_0), \\ G_0 &\sim \mathcal{DP}(\beta H). \end{aligned}$$

In this form of borrowing information, experts with associated means and precision matrices are shared across tasks as distinct atoms. Since means and precision matrices statistically define local regions in feature space, sharing is encouraged locally. We explicitly write the stick-breaking representations for G_j and G_0, with z_{ji} and c_{jh} introduced as the indicators for each data point and each distinct atom of G_j, respectively. By factorizing the base measure H as a product of a normal-Wishart prior for $(\boldsymbol{\mu}_s, \boldsymbol{\Lambda}_s)$ and a normal prior for $\boldsymbol{w}_s$, the hierarchical model of the multi-

task iQGME via the HDP is represented as

$$
\begin{aligned}
&\text{Data Generation:}\\
(t_{ji}|c_{jh}=s,z_{ji}=h) &\sim \mathcal{N}(\boldsymbol{w}_s^T\boldsymbol{x}_{ji}^b,1),\\
(\boldsymbol{x}_{ji}|c_{jh}=s,z_{ji}=h) &\sim \mathcal{N}_P(\boldsymbol{\mu}_s,\boldsymbol{\Lambda}_s^{-1}),\\
&\text{Drawing lower-level indicators:}\\
z_{ji} &\sim \sum_{h=1}^{\infty}\pi_{jh}\delta_h, \quad \text{where} \quad \pi_{jh}=V_{jh}\prod_{l<h}(1-V_{jl}),\\
V_{jh} &\sim Be(1,\alpha),\\
&\text{Drawing upper-level indicators:}\\
c_{jh} &\sim \sum_{s=1}^{\infty}\eta_s\delta_s, \quad \text{where} \quad \eta_s=U_s\prod_{l<s}(1-U_l),\\
U_s &\sim Be(1,\beta),\\
&\text{Drawing parameters from } H:\\
(\boldsymbol{\mu}_s,\boldsymbol{\Lambda}_s) &\sim \mathcal{N}_P(\boldsymbol{\mu}_s|\boldsymbol{m}_0,u_0^{-1}\boldsymbol{\Lambda}_s^{-1})\mathcal{W}(\boldsymbol{\Lambda}_s|\boldsymbol{B}_0,\nu_0),\\
\boldsymbol{w}_s &\sim \mathcal{N}_{P+1}(\boldsymbol{\zeta},[\mathrm{diag}(\boldsymbol{\lambda})]^{-1}).
\end{aligned}
$$

where $j=1,\ldots,J$ and $i=1,\ldots,n_j$ index tasks and data points in each tasks, respectively; $h=1,\ldots,\infty$ and $s=1,\ldots,\infty$ index atoms for task-dependent G_j and the globally shared base G_0, respectively. Hyper-priors are imposed similarly as in the single-task case:

$$
\begin{aligned}
\alpha &\sim Ga(\tau_{10},\tau_{20}),\\
\beta &\sim Ga(\tau_{30},\tau_{40}),\\
(\boldsymbol{\zeta}|\boldsymbol{\lambda}) &\sim \mathcal{N}_{P+1}(\boldsymbol{0},\gamma_0^{-1}[\mathrm{diag}(\boldsymbol{\lambda})]^{-1}),\\
\lambda_p &\sim Ga(a_0,b_0), \quad p=1,\ldots,P+1,
\end{aligned}
$$

The graphical representation of the iQGME for multi-task learning via the HDP is shown in Figure 2.

5. Variational Bayesian Inference

We initially present the inference formalism for single-task learning, and then discuss the (relatively modest) extensions required for the multi-task case.

5.1 Basic Construction

For simplicity we denote the collection of hidden variables and model parameters as Θ and specified hyper-parameters as Ψ. In a Bayesian framework we are interested in $p(\Theta|\mathcal{D},\Psi)$, the joint posterior distribution of the unknowns given observed data and hyper-parameters. From Bayes' rule,

$$p(\Theta|\mathcal{D},\Psi)=\frac{p(\mathcal{D}|\Theta)p(\Theta|\Psi)}{p(\mathcal{D}|\Psi)},$$

where $p(\mathcal{D}|\Psi)=\int p(\mathcal{D}|\Theta)p(\Theta|\Psi)d\Theta$ is the marginal likelihood that often involves multi-dimensional integrals. Since these integrals are nonanalytical in most cases, the computation of the marginal likelihood is the principal challenge in Bayesian inference. These integrals are circumvented if only a

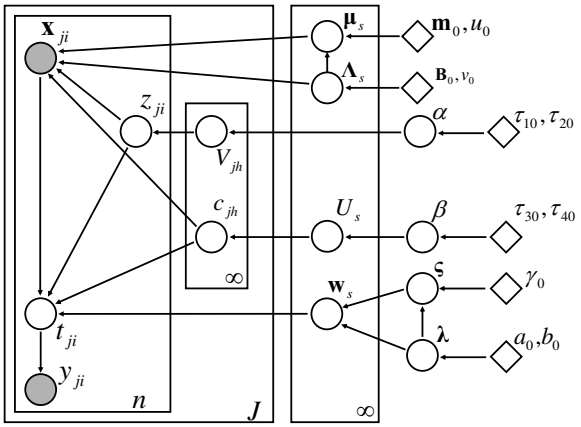

Figure 2: Graphical representation of the iQGME for multi-task leaning via the hierarchical Dirichlet process (HDP). Refer to Figure 1 for additional information.

point estimate $\hat{\Theta}$ is pursued, as in the expectation-maximization algorithm (Dempster et al., 1977). Markov chain Monte Carlo (MCMC) sampling methods (Gelfand et al., 1990; Neal, 1993) provide one class of approximations for the full posterior, based on samples from a Markov chain whose stationary distribution is the posterior of interest. As a Markov chain is guaranteed to converge to its true posterior theoretically as long as the chain is long enough, MCMC samples constitute an unbiased estimation for the posterior. Most previous applications with a Dirichlet process prior (Ishwaran and James, 2001; West et al., 1994), including the related papers we reviewed in Section 1, have been implemented with various MCMC methods. The main concerns of MCMC methods are associated with computational costs for computation of sufficient collection samples, and that diagnosis of convergence is often difficult.

As an efficient alternative, the variational Bayesian (VB) method (Beal, 2003) approximates the true posterior $p(\Theta|\mathcal{D}, \Psi)$ with a variational distribution $q(\Theta)$ with free variational parameters. The problem of computing the posterior is reformulated as an optimization problem of minimizing the Kullback-Leibler (KL) divergence between $q(\Theta)$ and $p(\Theta|\mathcal{D}, \Psi)$, which is equivalent to maximizing a lower bound of log $p(\mathcal{D}|\Psi)$, the log marginal likelihood. This optimization problem can be solved iteratively with two assumptions on $q(\Theta)$: (*i*) $q(\Theta)$ is factorized; (*ii*) the factorized components of $q(\Theta)$ come from the same exponential family as the corresponding priors do. Since the lower bound cannot achieve the true log marginal likelihood in general, the approximation given by the variational Bayesian method is biased. Another issue concerning the VB algorithm is that the solution may be trapped at local optima since the optimization problem is not convex. The main advantages of VB include the ease of convergence diagnosis and computational efficiency. As the VB is solving an optimization problem, the objective function—the lower bound of the log marginal likelihood—is a natural criterion for convergence diagnosis. Therefore, VB is a good alternative to MCMC when conjugacy is achieved and computational efficiency is desired. In recent publications (Blei and Jordan, 2006; Kurihara et al., 2007), discussions on the implementation of the variational Bayesian inference are given for Dirichlet process mixtures.

We implement the variational Bayesian inference throughout this paper, with comparisons made to Gibbs sampling. Since it is desirable to maintain the dependencies among random variables (e.g.,

shown in the graphical models Figure 1) in the variational distribution $q(\Theta)$, one typically only breaks those dependencies that bring difficulty to computation. In the subsequent inference for the iQGME, we retain some dependencies as unbroken. Following Blei and Jordan (2006), we employ stick-breaking representations with a truncation level N as variational distributions to approximate the infinite-dimensional random measures G.

We detail the variational Bayesian inference for the case of incomplete data. The inference for the complete-data case is similar, except that all feature vectors are fully observed and thus the step of learning missing values is skipped. To avoid repetition, a thorough procedure for the complete-data case is not included, with differences from the incomplete-data case indicated.

5.2 Single-task Learning

For single-task iQGME the unknowns are $\Theta = \{\boldsymbol{t}, \boldsymbol{x}^m, \boldsymbol{z}, \boldsymbol{V}, \alpha, \boldsymbol{\mu}, \boldsymbol{\Lambda}, \boldsymbol{W}, \boldsymbol{\zeta}, \boldsymbol{\lambda}\}$, with hyper-parameters $\Psi = \{\boldsymbol{m}_0, u_0, \boldsymbol{B}_0, \nu_0, \tau_{10}, \tau_{20}, \gamma_0, a_0, b_0\}$. We specify the factorized variational distributions as

$$\begin{aligned} & q(\boldsymbol{t}, \boldsymbol{x}^m, \boldsymbol{z}, \boldsymbol{V}, \alpha, \boldsymbol{\mu}, \boldsymbol{\Lambda}, \boldsymbol{W}, \boldsymbol{\zeta}, \boldsymbol{\lambda}) \\ = & \prod_{i=1}^{n} [q_{t_i}(t_i) q_{\boldsymbol{x}_i^{m_i}, z_i}(\boldsymbol{x}_i^{m_i}, z_i)] \prod_{h=1}^{N-1} q_{V_h}(V_h) \prod_{h=1}^{N} [q_{\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h}(\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h) q_{\boldsymbol{w}_h}(\boldsymbol{w}_h)] \prod_{p=1}^{P+1} q_{\zeta_p, \lambda_p}(\zeta_p, \lambda_p) q_\alpha(\alpha) \end{aligned}$$

where

- $q_{t_i}(t_i)$ is a truncated normal distribution,

  $$t_i \sim \mathcal{TN}(\mu_i^t, 1, y_i t_i > 0), \quad i = 1, \ldots, n,$$

  which means the density function of t_i is assumed to be normal with mean μ_i^t and unit variance for those t_i satisfying $y_i t_i > 0$.

- $q_{\boldsymbol{x}_i^{m_i}, z_i}(\boldsymbol{x}_i^{m_i}, z_i) = q_{\boldsymbol{x}_i^{m_i}}(\boldsymbol{x}_i^{m_i} | z_i) q_{z_i}(z_i)$, where $q_{z_i}(z_i)$ is a multinomial distribution with probabilities $\boldsymbol{\rho}_i$, and there are N possible outcomes, $z_i \sim \mathcal{M}_N(1, \rho_{i1}, \ldots, \rho_{iN}), \quad i = 1, \ldots, n$. Given the associated indicators z_i, since features are assumed to be distributed as a multivariate Gaussian, the distributions of missing values $\boldsymbol{x}_i^{m_i}$ are still Gaussian according to conditional properties of multivariate Gaussian distributions:

  $$(\boldsymbol{x}_i^{m_i} | z_i = h) \sim \mathcal{N}_{|m_i|}(\boldsymbol{m}_h^{m_i|o_i}, \boldsymbol{\Sigma}_h^{m_i|o_i}), \quad i = 1, \ldots, n, \quad h = 1, \ldots, N.$$

  We retain the dependency between $\boldsymbol{x}_i^{m_i}$ and z_i in the variational distribution since the inference is still tractable; for complete data, the variation distribution for $(\boldsymbol{x}_i^{m_i} | z_i = h)$ is not necessary.

- $q_{V_h}(V_h)$ is a beta distribution,

  $$V_h \sim Be(v_{h1}, v_{h2}), \quad h = 1, \ldots, N-1.$$

  Recall that we have a truncation level of N, which implies that the mixture proportions $\pi_h(\boldsymbol{V})$ are equal to zero for $h > N$. Therefore, $q_{V_h}(V_h) = \delta_1$ for $h = N$, and $q_{V_h}(V_h) = \delta_0$ for $h > N$. For $h < N$, V_h has a variational Beta posterior.

- $q_{\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h}(\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h)$ is a normal-Wishart distribution,

  $$(\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h) \sim \mathcal{N}_P(\boldsymbol{m}_h, u_h^{-1} \boldsymbol{\Lambda}_h^{-1}) \mathcal{W}(\boldsymbol{B}_h, \nu_h), \quad h = 1, \ldots, N.$$

- $q_{\boldsymbol{w}_h}(\boldsymbol{w}_h)$ is a normal distribution,

$$\boldsymbol{w}_h \sim \mathcal{N}_{P+1}(\boldsymbol{\mu}_h^w, \boldsymbol{\Sigma}_h^w), \quad h = 1, \ldots, N.$$

- $q_{\zeta_p,\lambda_p}(\zeta_p, \lambda_p)$ is a normal-gamma distribution,

$$(\zeta_p, \lambda_p) \sim \mathcal{N}(\phi_p, \gamma^{-1}\lambda_p^{-1}) Ga(a_p, b_p), \quad p = 1, \ldots, P+1.$$

- $q_\alpha(\alpha)$ is a Gamma distribution,

$$\alpha \sim Ga(\tau_1, \tau_2).$$

Given the specifications on the variational distributions, a mean-field variational algorithm (Beal, 2003) is developed for the iQGME model. All update equations and derivations for $q(\boldsymbol{x}_i^{m_i}, z_i)$ are included in the Appendix; similar derivations for other random variables are found elsewhere (Xue et al., 2007; Williams et al., 2007). Each variational parameter is re-estimated iteratively conditioned on the current estimate of the others until the lower bound of the log marginal likelihood converges. Although the algorithm yields a bound for any initialization of the variational parameters, different initializations may lead to different bounds. To alleviate this local-maxima problem, one may perform multiple independent runs with random initializations, and choose the run that produces the highest bound on the marginal likelihood. We will elaborate on our initializations in the experiment section.

For simplicity, we omit the subscripts on the variational distributions and henceforth use q to denote any variational distributions. In the following derivations and update equations, we use generic notation $\langle f \rangle_{q(\cdot)}$ to denote $\mathrm{E}_{q(\cdot)}[f]$, the expectation of a function f with respect to variational distributions $q(\cdot)$. The subscript $q(\cdot)$ is dropped when it shares the same arguments with f.

5.3 Multi-task Learning

For multi-task learning much of the inference is highly related to that of single-task learning, as discussed above; in the following we focus only on differences. In the multi-task learning model, the latent variables are $\boldsymbol{\Theta} = \{\boldsymbol{t}, \boldsymbol{x}^m, \boldsymbol{z}, \boldsymbol{V}, \alpha, \boldsymbol{c}, \boldsymbol{U}, \beta, \boldsymbol{\mu}, \boldsymbol{\Lambda}, \boldsymbol{W}, \boldsymbol{\zeta}, \boldsymbol{\lambda}\}$, and hyper-parameters are $\boldsymbol{\Psi} = \{\boldsymbol{m}_0, u_0, \boldsymbol{B}_0, \nu_0, \tau_{10}, \tau_{20}, \tau_{30}, \tau_{40}, \gamma_0, a_0, b_0\}$. We specify the factorized variational distributions as

$$\begin{aligned} & q(\boldsymbol{t}, \boldsymbol{x}^m, \boldsymbol{z}, \boldsymbol{V}, \alpha, \boldsymbol{c}, \boldsymbol{U}, \beta, \boldsymbol{\mu}, \boldsymbol{\Lambda}, \boldsymbol{W}, \boldsymbol{\zeta}, \boldsymbol{\lambda}) \\ = & \prod_{j=1}^{J} \{ \prod_{i=1}^{n_j} [q(t_{ji}) q(\boldsymbol{x}_{ji}^{m_{ji}}) q(z_{ji})] \prod_{h=1}^{N-1} q(V_{jh}) \prod_{h=1}^{N} q(c_{jh}) \} \prod_{s=1}^{S-1} q(U_s) \\ & \prod_{s=1}^{S} [q(\boldsymbol{\mu}_s, \boldsymbol{\Lambda}_s) q(\boldsymbol{w}_s)] \prod_{p=1}^{P+1} q(\zeta_p, \lambda_p) q(\alpha) q(\beta) \end{aligned}$$

where the variational distributions of $(t_{ji}, V_{jh}, \alpha, \boldsymbol{\mu}_s, \boldsymbol{\Lambda}_s, \boldsymbol{w}_s, \zeta_p, \lambda_p)$ are assumed to be the same as in the single-task learning, while the variational distributions of hidden variables newly introduced for the upper-level Dirichlet process are specified as

- $q(c_{jh})$ for each indicator c_{jh} is a multinomial distribution with probabilities $\boldsymbol{\sigma}_{jh}$,

$$c_{jh} \sim \mathcal{M}_S(1, \sigma_{jh1}, \ldots, \sigma_{jhS}), \quad j = 1, \ldots, J, \quad h = 1, \ldots, N.$$

- $q(U_s)$ for each weight U_s is a Beta distribution,

$$U_s \sim Be(\kappa_{s1}, \kappa_{s2}), \quad s = 1, \ldots, S-1.$$

  Here we have a truncation level of S for the upper-lever DP, which implies that the mixture proportions $\eta_s(\boldsymbol{U})$ are equal to zero for $s > S$. Therefore, $q(U_s) = \delta_1$ for $s = S$, and $q(U_s) = \delta_0$ for $s > S$. For $s < S$, U_s has a variational Beta posterior.

- $q(\beta)$ for the scaling parameter β is a Gamma distribution,

$$\beta \sim Ga(\tau_3, \tau_4).$$

We also note that with a higher-level of hierarchy, the dependency between the missing values $\boldsymbol{x}_{ji}^{m_{ji}}$ and the associated indicator z_{ji} has to be broken so that the inference becomes tractable. The variational distribution of z_{ji} is still assumed to be multinomial distributed, while $\boldsymbol{x}_{ji}^{m_{ji}}$ is assumed to be normally distributed but no longer dependent on z_{ji}. All update equations are included in the Appendix.

5.4 Prediction

For a new observed feature vector $\boldsymbol{x}_\star^{o_\star}$, the prediction on the associated class label $y_\star$ is given by integrating out the missing values.

$$\begin{aligned} P(y_\star = 1|\boldsymbol{x}_\star^{o_\star}, \mathcal{D}) &= \frac{p(y_\star = 1, \boldsymbol{x}_\star^{o_\star}|\mathcal{D})}{p(\boldsymbol{x}_\star^{o_\star}|\mathcal{D})} = \frac{\int p(y_\star = 1, \boldsymbol{x}_\star|\mathcal{D}) d\boldsymbol{x}_\star^{m_\star}}{\int p(\boldsymbol{x}_\star|\mathcal{D}) d\boldsymbol{x}_\star^{m_\star}} \\ = & \frac{\int \sum_{h=1}^N P(z_\star = h|\mathcal{D}) p(x_\star|z_\star = h, \mathcal{D}) P(y_\star = 1|\boldsymbol{x}_\star, z_\star = h, \mathcal{D}) d\boldsymbol{x}_\star^{m_\star}}{\int \sum_{k=1}^N P(z_\star = k|\mathcal{D}) p(x_\star|z_\star = k, \mathcal{D}) d\boldsymbol{x}_\star^{m_\star}}. \end{aligned}$$

We marginalize the hidden variables over their variational distributions to compute the predictive probability of the class label

$$P(y_\star = 1|\boldsymbol{x}_\star^{o_\star}, \mathcal{D}) = \frac{\sum_{h=1}^N \mathrm{E}_V[\pi_h] \int_0^\infty \int \mathrm{E}_{\boldsymbol{\mu}_h \boldsymbol{\Lambda}_h}[\mathcal{N}_P(\boldsymbol{x}_\star|\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h^{-1})] \mathrm{E}_{\boldsymbol{w}_h}\left[\mathcal{N}(t_\star|\boldsymbol{w}_h^T \boldsymbol{x}_\star^b, 1)\right] d\boldsymbol{x}_\star^{m_\star} dt_\star}{\sum_{k=1}^N \mathrm{E}_V[\pi_k] \int \mathrm{E}_{\boldsymbol{\mu}_k \boldsymbol{\Lambda}_k}[\mathcal{N}_P(\boldsymbol{x}_\star|\boldsymbol{\mu}_k, \boldsymbol{\Lambda}_k^{-1})] d\boldsymbol{x}_\star^{m_\star}}$$

where

$$\mathrm{E}_V[\pi_h] = \mathrm{E}_V[V_h \prod_{l<h}(1 - V_l)] = \langle V_h \rangle \prod_{l<h} \langle 1 - V_l \rangle = \left[\frac{v_{h1}}{v_{h1} + v_{h2}}\right]^{\mathbf{1}(h<N)} \prod_{l<h} \left[\frac{v_{l2}}{v_{l1} + v_{l2}}\right]^{\mathbf{1}(h>1)}.$$

The expectation $\mathrm{E}_{\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h}[\mathcal{N}_P(\boldsymbol{x}^\star|\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h^{-1})]$ is a multivariate Student-t distribution (Attias, 2000). However, for the incomplete-data situation, the integral over the missing values is tractable only when the two terms in the integral are both normal. To retain the form of norm distributions, we use the posterior means of $\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h$ and $\boldsymbol{w}_h$ to approximate the variables:

$$\begin{aligned} P(y_\star = 1|\boldsymbol{x}_\star^{o_\star}, \mathcal{D}) \quad \approx \quad & \frac{\sum_{h=1}^N \mathrm{E}_V[\pi_h] \int_0^\infty \int \mathcal{N}_P(\boldsymbol{x}_\star|\boldsymbol{m}_h, (\nu_h \boldsymbol{B}_h)^{-1}) \mathcal{N}(t_\star|(\boldsymbol{\mu}_h^w)^T \boldsymbol{x}_\star^b, 1) d\boldsymbol{x}_\star^{m_\star} dt_\star}{\sum_{k=1}^N \mathrm{E}_V[\pi_k] \int \mathcal{N}_P(\boldsymbol{x}_\star|\boldsymbol{m}_k, (\nu_k \boldsymbol{B}_k)^{-1}) d\boldsymbol{x}_\star^{m_\star}} \\ = \quad & \frac{\sum_{h=1}^N \mathrm{E}_V[\pi_h] \mathcal{N}_{|o_\star|}(\boldsymbol{x}_\star^{o_\star}|\boldsymbol{m}_h^{o_\star}, (\nu_h \boldsymbol{B}_h)^{-1, o_\star o_\star}) \int_0^\infty \mathcal{N}(t_\star|\varphi_{\star h}, g_{\star h}) dt_\star}{\sum_{k=1}^N \mathrm{E}_V[\pi_k] \mathcal{N}_{|o_\star|}(\boldsymbol{x}_\star^{o_\star}|\boldsymbol{m}_k^{o_\star}, (\nu_k \boldsymbol{B}_k)^{-1, o_\star o_\star})} \end{aligned}$$

where

$$\begin{aligned}
\varphi_{\star h} &= [\boldsymbol{m}_h^T, 1]\boldsymbol{\mu}_h^w + \boldsymbol{\Gamma}_{\star h}^T (\boldsymbol{\Delta}_h^{o_\star o_\star})^{-1} (\boldsymbol{x}_\star^{o_\star} - \boldsymbol{m}_h^{o_\star}), \\
g_{\star h} &= 1 + (\bar{\boldsymbol{\mu}}_h^w)^T \boldsymbol{\Delta}_h \bar{\boldsymbol{\mu}}_h^w - \boldsymbol{\Gamma}_{\star h}^T (\boldsymbol{\Delta}_h^{o_\star o_\star})^{-1} \boldsymbol{\Gamma}_{\star h}, \\
\boldsymbol{\Gamma}_{\star h} &= \boldsymbol{\Delta}_h^{o_\star o_\star} (\boldsymbol{\mu}_h^w)^{o_\star} + \boldsymbol{\Delta}_h^{o_\star m_\star} (\boldsymbol{\mu}_h^w)^{m_\star}, \\
\bar{\boldsymbol{\mu}}_h^w &= (\boldsymbol{\mu}_h^w)_{1:P}, \\
\boldsymbol{\Delta}_h &= (\nu_h \boldsymbol{B}_h)^{-1}.
\end{aligned}$$

For complete data the integral of missing features is absent, so we take advantage of the full variational posteriors for prediction.

5.5 Computational Complexity

Given the truncation level (or the number of clusters) N, the data dimensionality P, and the number of data points n, we compare the iQGME to closely related DP regression models (Meeds and Osindero, 2006; Shahbaba and Neal, 2009), in terms of the time and memory complexity. The inference of the iQGME with complete data requires inversion of two $P \times P$ matrices (the covariance matrices for the inputs and the local expert) associated with each cluster. Therefore, the time and memory complexity are $O(2NP^3)$ and $O(2NP^2)$, respectively. With incomplete data, since the missing pattern is unique for each data point, the time and memory complexity increase with number of data points, that is, $O(nNP^3)$ and $O(nNP^2)$, respectively. The mixture of Gaussian process experts (Meeds and Osindero, 2006) requires $O(NP^3 + n^3/N)$ computations for each MCMC iteration if the N experts equally divide the data, and the memory complexity is $O(NP^2 + n^2/N)$. In the model proposed by Shahbaba and Neal (2009), no matrix inversion is needed since the covariates are assumed to be independent. The time and memory complexity are $O(NP)$ and $O(NP)$, respectively.

From the aspect of computational complexity, the model in Meeds and Osindero (2006) is restricted by the increase of both dimensionality and data size; while the model proposed in Shahbaba and Neal (2009) is more efficient. Although the proposed model requires more computations for each MCMC iteration than the latter one, we are able to handle missing values naturally, and much more efficiently compared to the former one. Considering the usual number of iterations required by VB (several dozens) and MCMC (thousands or even tens of thousands), our model is even more efficient.

6. Experimental Results

In all the following experiments the hyper-parameters are set as follows: $a_0 = 0.01$, $b_0 = 0.01$, $\gamma_0 = 0.1$, $\tau_{10} = 0.05$, $\tau_{20} = 0.05$, $\tau_{30} = 0.05$, $\tau_{40} = 0.05$, $u_0 = 0.1$, $\nu_0 = P + 2$, and $\boldsymbol{m}_0$ and $\boldsymbol{B}_0$ are set according to sample mean and sample precision, respectively. These parameters have not been optimized for any particular data set (which are all different in form), and the results are relatively insensitive to "reasonable" settings. The truncation levels for the variational distributions are set to be $N = 20$ and $S = 50$. We have found the results insensitive to the truncation level, for values larger than those considered here.

Because of the local-maxima issue associated with VB, initialization of the inferred VB hyper-parameters is often important. We initialize most variational hyper-parameters using the corresponding prior hyper-parameters, which are data-independent. The precision/covariance matrices

$\boldsymbol{B}_h$ and $\boldsymbol{\Sigma}_h^w$ are simply initialized as identity matrices. However, for several other hyper-parameters, we may obtain information for good start points from the data. Specifically, the variational mean of the soft label μ_i^t is initialized by the associated label y_i. A K-means clustering algorithm is implemented on the feature vectors, and the cluster means and identifications for objects are used to initialize the variational mean of the Gaussian means $\boldsymbol{m}_h$ and the indicator probabilities $\boldsymbol{\rho}_i$, respectively. As an alternative, one may randomly initialize $\boldsymbol{m}_h$ and $\boldsymbol{\rho}_i$ multiple times, and select the solution that produces the highest lower bound on the log marginal likelihood. The two approaches work almost equivalently for low-dimensional problems; however, for problems with moderate to high dimensionality, it could be fairly difficult to get a satisfying initialization by making several random trials.

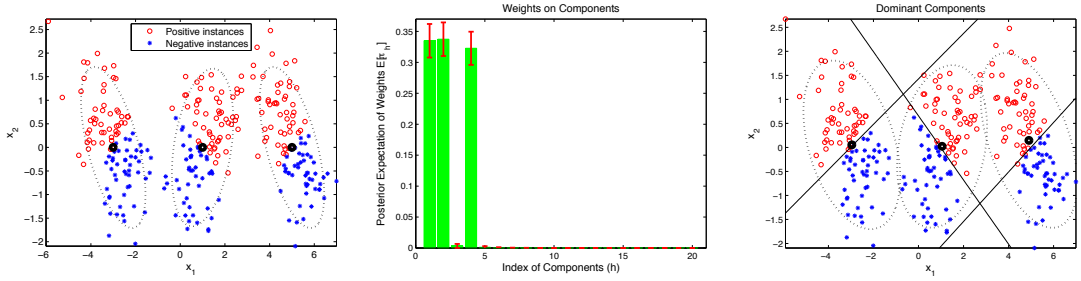
6.1 Synthetic Data

We first demonstrate the proposed iQGME single-task learning model on a synthetic data set, for illustrative purposes. The data are generated according to a GMM model $p(\boldsymbol{x}) = \sum_{k=1}^{3} \pi_k \mathcal{N}_2(\boldsymbol{x}|\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k)$ with the following parameters:

$$\boldsymbol{\pi} = \begin{bmatrix} 1/3 & 1/3 & 1/3 \end{bmatrix}, \quad \boldsymbol{\mu}_1 = \begin{bmatrix} -3 \\ 0 \end{bmatrix}, \quad \boldsymbol{\mu}_2 = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad \boldsymbol{\mu}_3 = \begin{bmatrix} 5 \\ 0 \end{bmatrix}$$

$$\boldsymbol{\Sigma}_1 = \begin{bmatrix} 0.52 & -0.36 \\ -0.36 & 0.73 \end{bmatrix}, \quad \boldsymbol{\Sigma}_2 = \begin{bmatrix} 0.47 & 0.19 \\ 0.19 & 0.7 \end{bmatrix}, \quad \boldsymbol{\Sigma}_3 = \begin{bmatrix} 0.52 & -0.36 \\ -0.36 & 0.73 \end{bmatrix}.$$

The class boundary for each Gaussian component is given by three lines $x_2 = w_k x_1 + b_k$ for $k = 1,2,3$, where $w_1 = 0.75, b_1 = 2.25$, $w_2 = -0.58, b_2 = 0.58$, and $w_3 = 0.75, b_3 = -3.75$. The simulated data are shown in Figure 3(a), where black dots and dashed ellipses represent the true means and covariance matrices of the Gaussian components, respectively.

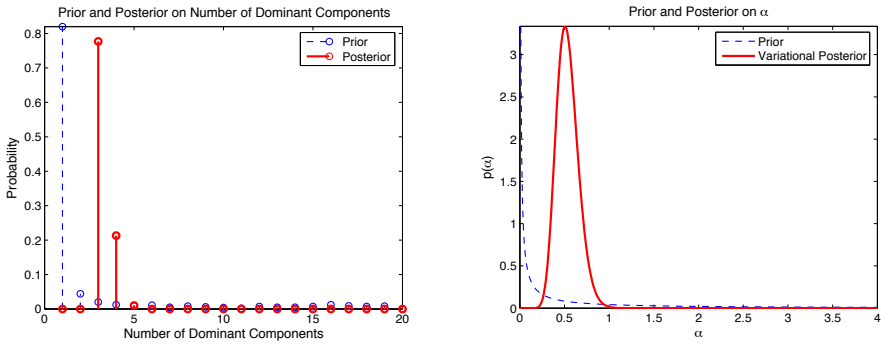


(a) (b) (c)

Figure 3: Synthetic three-Gaussian single-task data with inferred components. (a) Data in feature space with true labels and true Gaussian components indicated; (b) inferred posterior expectation of weights on components, with standard deviations depicted as error bars; (c) ground truth with posterior means of dominant components indicated (the linear classifiers and Gaussian ellipses are inferred from the data).

The inferred mean mixture weights with standard deviations are depicted in Figure 3(b), and it is observed that three dominant mixture components (local "experts") are inferred. The domi-

nant components (those with mean weight larger than 0.005) are characterized by Gaussian means, covariance matrices and local experts, as depicted in Figure 3(c). From Figure 3(c), the nonlinear classification is manifested by using three dominant *local* linear classifiers, with a GMM defining the effective regions stochastically.



(a) (b)

Figure 4: Synthetic three-Gaussian single-task data: (a) prior and posterior beliefs on the number of dominant components; (b) prior and posterior beliefs on α.

An important point is that we are not selecting a "correct" number of mixture components as in most mixture-of-expert models, including the finite QGME model (Liao et al., 2007). Instead, there exists uncertainty on the number of components in our posterior belief. Since this uncertainty is not inferred directly, we obtain samples for the number of dominant components by calculating π_h based on V_h sampled from their probability density functions (prior or variational posterior), and the probability mass functions given by histogram are shown in Figure 4(a). As discussed, the scale parameter α is highly related to the number of clusters, so we depict the prior and the variational posterior on α in Figure 4(b).

The predictions in feature space are presented in Figure 5, where the prediction in sub-figure (a) is given by integrating over the full posteriors of local experts and parameters (means and covariance matrices) of Gaussian components; while the prediction in sub-figure (b) is given by posterior means. We examine these two cases since the analytical integrals over the full posteriors may be unavailable sometimes in practice (for example, for cases with incomplete data as discussed in Section 5). From Figures 5(a) and 5(b), we observe that these two predictions are fairly similar, except that (a) allows more uncertainty on regions with scarce data. The reason for this is that the posteriors are often peaked and thus posterior means are usually representative. As an example, we plot the broad common prior imposed for local experts in Figure 5(c) and the peaked variational posteriors for three dominant experts in Figure 5(d). According to Figure 5, we suggest the usage of full posteriors for prediction whenever integrals are analytical, that is, for experiments with complete data. It also empirically justifies the use of posterior means as an approximation. These results have been computed using VB inference, with MCMC-based results presented below, as a comparison.

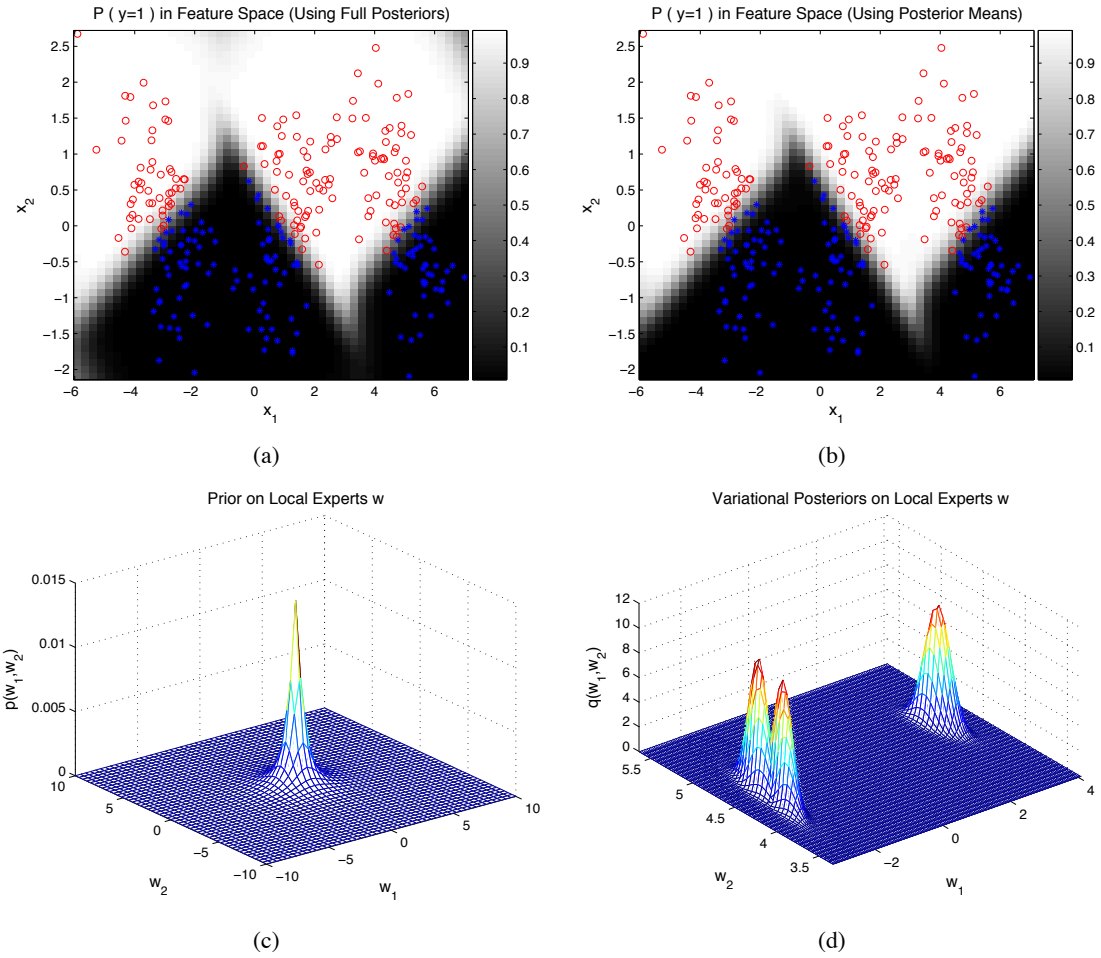


Figure 5: Synthetic three-Gauss single-task data: (a) prediction in feature space using the full posteriors; (b) prediction in feature space using the posterior means; (c) a common broad prior on local experts; (d) variational posteriors on local experts.

6.2 Benchmark Data

To further evaluate the proposed iQGME, we compare it with other models, using benchmark data sets available from the UCI machine learning repository (Newman et al., 1998). Specifically, we consider Wisconsin Diagnostic Breast Cancer (WDBC) and the Johns Hopkins University Ionosphere database (Ionosphere) data sets, which have been studied in the literature (Williams et al., 2007; Liao et al., 2007). These two data sets are summarized in Table 1.

The models we compare to include:

- State-of-the-art classification algorithms: Support Vector Machines (SVM) (Vapnik, 1995) and Relevance Vector Machines (RVM) (Tipping, 2000). We consider both linear models (Linear) and non-linear models with radial basis function (RBF) for both algorithms. For

Data set	Dimension	Number of positive instances	Number of negative instances
Ionosphere	34	126	225
WDBC	30	212	357

Table 1: Details of Ionosphere and WDBC data sets

each data set, the kernel parameter is selected for one training/test/validation separation, and then fixed for all the other experimental settings. The RVM models are implemented with Tipping's Matlab code available at `http://www.miketipping.com/index.php?page=rvm`.

Since those SVM and RVM algorithms are not directly applicable to problems with missing features, we use two methods to impute the missing values before the implementation. One is using the mean of observed values (unconditional mean) for the given feature, referred to as Uncond; the other is using the posterior mean conditional on observed features (conditional mean), referred to as Cond (Schafer and Graham, 2002).

- Classifiers handling missing values: the finite QGME inferred by expectation-maximization (EM) (Liao et al., 2007), referred to as QGME-EM, and a two-stage algorithm (Williams et al., 2007) where the parameters of the GMM for the covariates are estimated first given the observed features, and then a marginalized linear logistic regression (LR) classifier is learned, referred to as LR-Integration. Results are cited from Liao et al. (2007) and Williams et al. (2007), respectively.

In order to simulate the *missing at random* setting, we randomly remove a fraction of feature values according to a uniform distribution, and assume the rest are observed. Any instance with all feature values missing is deleted. After that, we randomly split each data set into training and test subsets, imposing that each subset encompasses at least one instance from each of the classes. Note that the random pattern of missing features and the random partition of training and test subsets are independent of each other. By performing multiple trials we consider the general (average) performance for various data settings. For convenient comparison with Williams et al. (2007) and Liao et al. (2007), the performance of algorithms is evaluated in terms of the area under a receiver operating characteristic (ROC) curve (AUC) (Hanley and McNeil, 1982).

The results on the Ionosphere and WDBC data sets are summarized in Figures 6 and 7, respectively, where we consider 25% and 50% of the feature values missing. Given a portion of missing values, each curve is a function of the fraction of data used in training. For a given size of training data, we perform ten independent trials for the SVM and RVM models and the proposed iQGME.

From both Figures 6 and 7, the proposed iQGME-VB is robust for all the experimental settings, and its overall performance is the best among all algorithms considered. Although the RVM-RBF-Cond and the SVM-RBF-Cond perform well for the Ionosphere data set, especially when the training data is limited, their performance on the WDBC data set is not as good. The kernel methods benefit from the introduction of the RBF kernel for the Ionosphere data set; however, the performance is inferior for the WDBC data set. We also note that the one-step iQGME and the finite QGME outperform the two-step LR-integration. The proposed iQGME consistently performs better than the finite QGME (where, for the latter, in all cases we show results for the best/optimized choice of number of experts K), which reveals the advantage of retaining the uncertainty on the model structure (number of experts) and model parameters. As shown in Figure 7, the advantage of

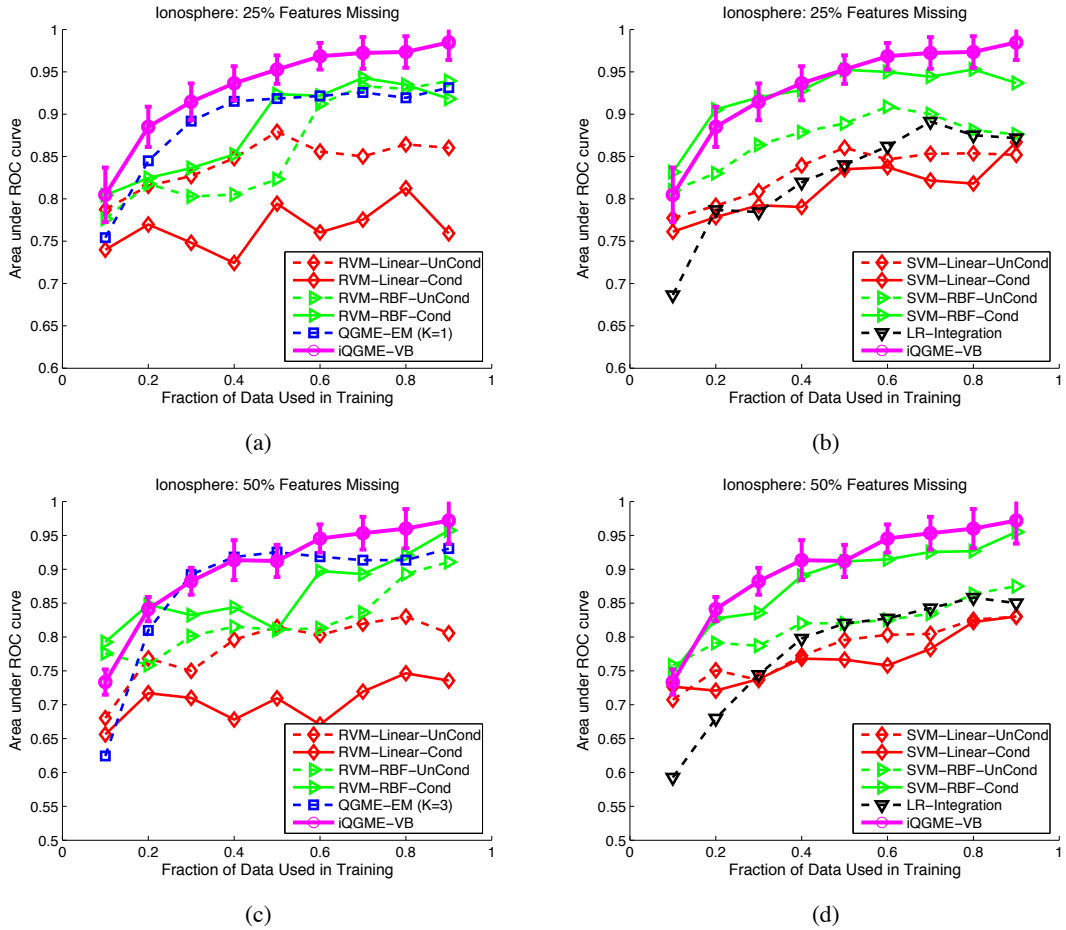

Figure 6: Results on Ionosphere data set for (a)(b) 25%, and (c)(d) 50% of the feature values missing. For legibility, we only report the standard deviation for the proposed iQGME-VB algorithm as error bars, and present the compared algorithms in two figures for each case. The results of the finite QGME solved with an expectation-maximization method are cited from Liao et al. (2007), and those of LR-Integration are cited from Williams et al. (2007). Since the performance of the QGME-EM is affected by the choice of number of experts K, the overall best results among $K = 1, 3, 5, 10, 20$ are cited for comparison in each case (no such selection of K is required for the proposed iQGME-VB algorithm).

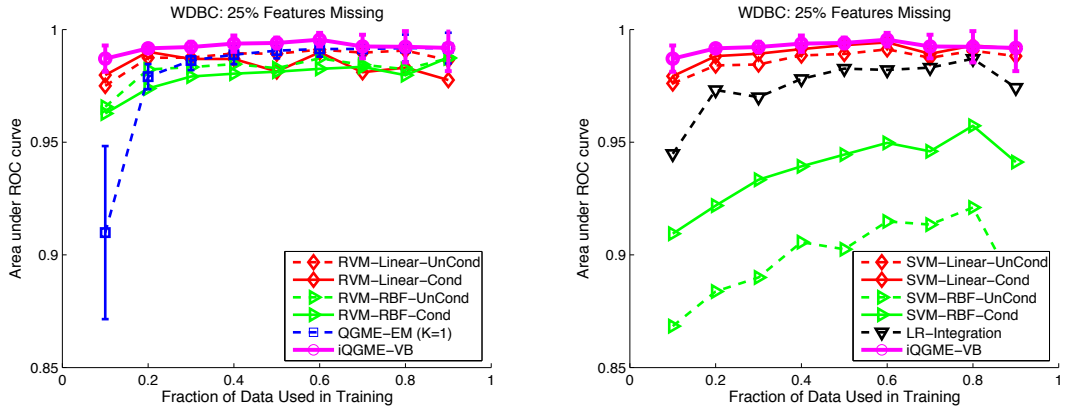
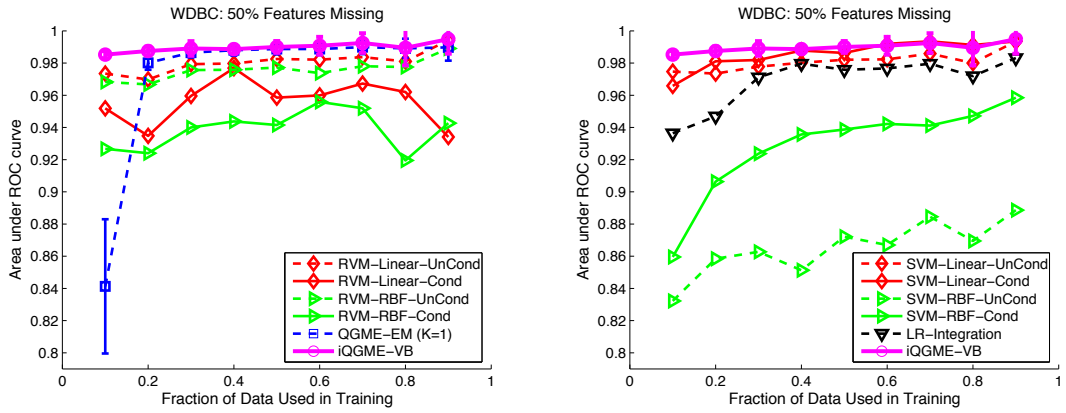
considering the uncertainty on the model parameters is fairly pronounced for the WDBC data set, especially when training examples are relatively scarce and thus the point-estimation EM method suffers from over-fitting issues. A more detailed examination on the model uncertainty is shown in Figures 8 and 9.

In Figure 8, the influence of the preset value for K on the QGME-EM model is examined on the Ionosphere data. We observe that with different fractions of missing values and training samples, the values for K which achieve the best performance may be different; as K goes to a large number (e.g., 20 here), the performance gets worse due to over-fitting. In contrast, we do not need to set the



(a)



(c)

Figure 7: Results on WDBC data set for cases when (a)(b) 25%, and (c)(d) 50% of the feature values are missing. Refer to Figure 6 for additional information.

number of clusters for the proposed iQGME-VB model. As long as the truncation level N is large enough ($N = 20$ for all the experiments), the number of clusters is inferred by the algorithm. We give an example for the posterior on the number of clusters inferred by the proposed iQGME-VB model, and report the statistics for the most probable number of experts given each missing fraction and training fraction in Figure 9, which suggests that the number of clusters may vary significantly even for the trials with the same fraction of feature values missing and the same fraction of samples for training. Therefore, it may be not appropriate to set a fixed value for the number of clusters for all the experimental settings as one has to do for the QGME-EM.

Although our main purpose is classification, one may also be interested in how well the algorithm can estimate the missing values while pursuing the main purpose. In Figure 10, we show the ratio of correctly estimated missing values for the Ionosphere data set with 25% feature values missing, where two criteria are considered: true values are one standard deviation (red circles) or two standard deviations (blue squares) away from the posterior means. This figure suggests that the algorithm estimates most of the missing values in a reasonable range away from the true val-

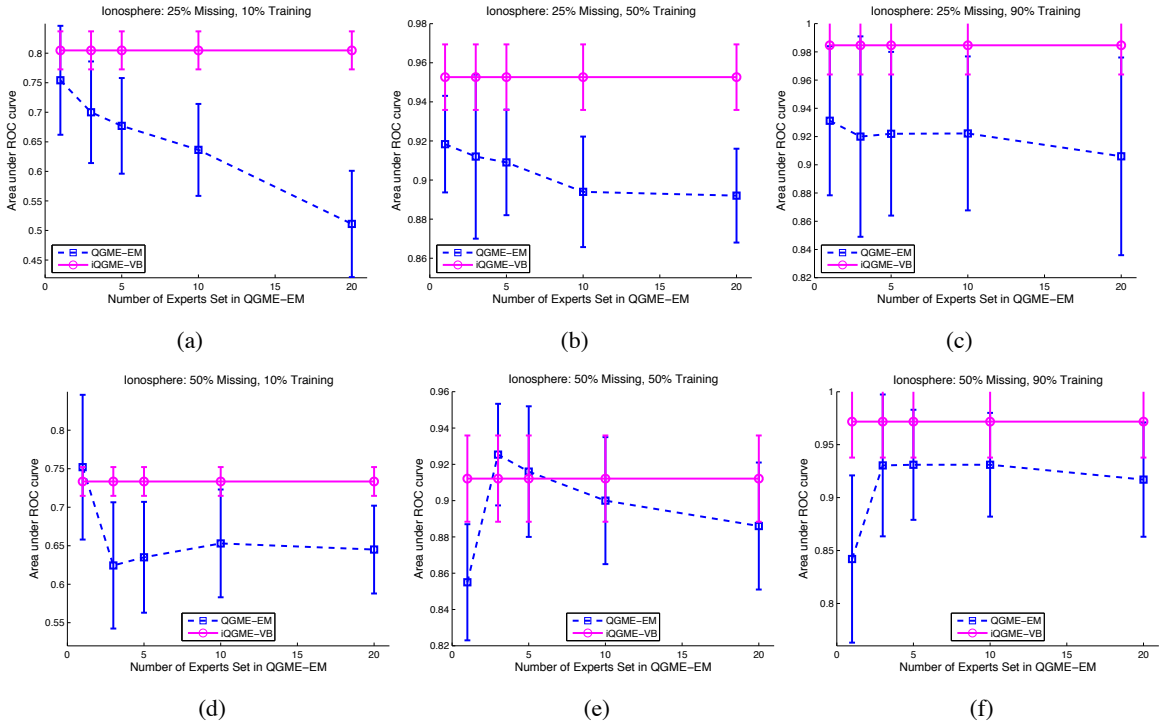


Figure 8: The comparison on the Ionosphere data set between QGME-EM with different preset number of clusters K and the proposed iQGME-VB, when (a)(b)(c) 25%, and (d)(e)(f) 50% of the features are missing. In each row, 10%, 50%, and 90% of samples are used for training, respectively. Results of QGME-EM are cited from Liao et al. (2007).

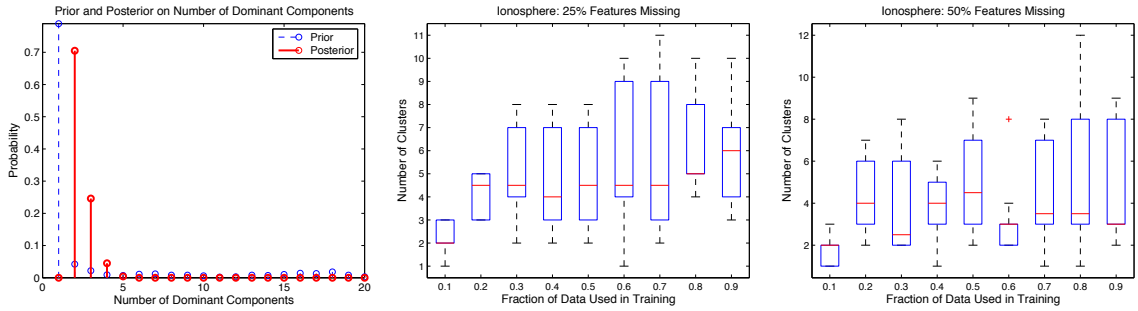
ues when the training size is large enough; even with not so satisfying estimations (as for limited training data), the classification results are still relatively robust as shown in Figure 6.

We have discussed the advantages and disadvantages for the inference with MCMC and VB in Section 5.1. Here we take the Ionosphere data with 25% features missing as an example to compare these two inference techniques, as shown in Figure 11. It can be seen that they achieve similar performance for the particular iQGME model proposed in this paper. The time consumed for each iteration is also comparable, and increases almost linearly with the training size, as discussed in Section 5.5. The VB inference takes a little bit longer per iteration, probably due to the extra computation for the lower bound of the log marginal likelihood, which serves as convergence criterion. Significant differences occur on the number of iterations we have to take. In the experiment, even though we set a very strict threshold (10^{-6}) for the relative change of the lower bound, the VB algorithm converges at about 50 iterations for most cases except when training data are very scarce (10%). For the MCMC inference, we discard the initial samples from the first 1000 iterations (burn-in), and collect the next 500 samples to present the posterior. It is far from enough to claim convergence; however, we consider it a fair comparison for computation as the two methods yield similar results under this setting. Given the fact that the VB algorithm only takes about $1/30$ the CPU time, and VB and MCMC performance are similar, in the following examples we only present results based on VB inference. However, in all the examples below we also performed Gibbs sam-



(a) (b) (c)

Figure 9: Number of clusters for the Ionosphere data set inferred by iQGME-VB. (a) Prior and inferred posterior on the number of clusters for one trial given 10% samples for training, the number of clusters for the case when (b) 25%, and (c) 50% of features are missing. The most probable value of clusters number is used for each trial to generate (b) and (c) (e.g., the most probable value of clusters number is two for the trial shown in (a)). In (b) and (c), the distribution of number of clusters for the ten trials given each missing fraction and training fraction is presented as a box-plot, where the red line represents the median; the bottom and top of the blue box are the 25th and 75th percentile, respectively; the bottom and top black lines are the end of the whiskers, which could be the minimum and maximum, respectively; if some data are beyond 1.5 times of the length of the blue box (interquartile range), they are outliers, indicated by a red '+'.

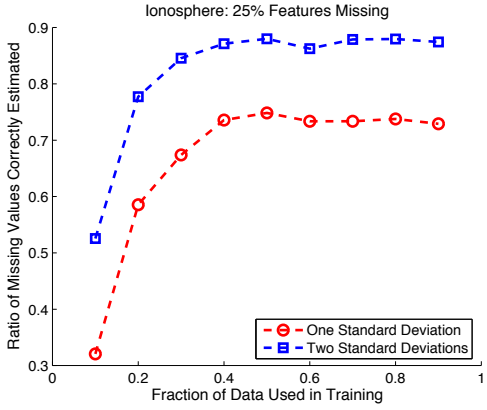


Figure 10: Ratio of missing values whose true values are one standard deviation (red circles) or two standard deviations (blue squares) away from the posterior means for the Ionosphere data set with 25% feature values missing. One trial for each training size is considered.

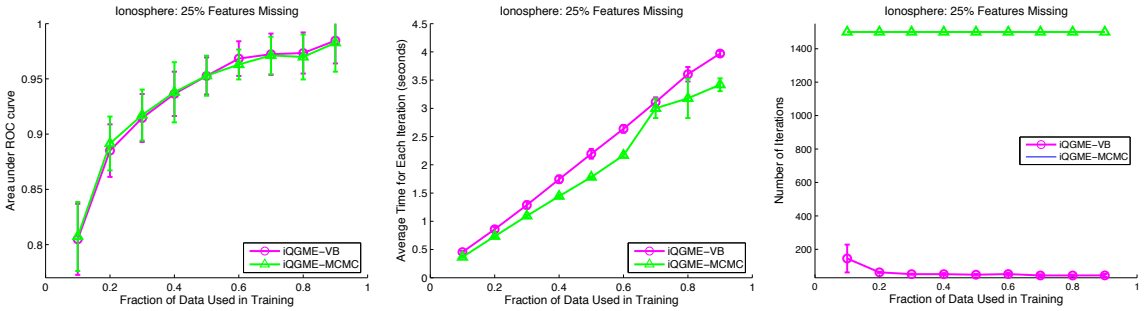
pling, and the relative inference consistency and computational costs relative to VB were found to be as summarized here (i.e., in all cases there was close agreement between the VB and MCMC inferences, and considerable computational acceleration manifested by VB).



(a) (b) (c)

Figure 11: Comparison between VB and MCMC inferred iQGME on the Ionosphere data with 25% features missing in terms of (a) performance, (b) time consumed for each iteration, (c) number of iterations. For the VB inference, we set a threshold (10^{-6}) for the relative change of lower bound in two consecutive iterations as the convergence criterion; for the MCMC inference, we discard the initial samples from the first 1000 iterations (burn-in), and collect the next 500 samples to present the posterior.

6.3 Unexploded Ordnance Data

We now consider an unexploded ordnance (UXO) detection problem (Zhang et al., 2003), where two types of sensors are used to collect data, but one of them may be absent for particular targets. Specifically, one sensor is a magnetometer (MAG) and the other an electromagnetic induction (EMI) sensor; these sensors are deployed separately to interrogate buried targets, and for some targets both sensors are deployed and for others only one sensor is deployed. This is a real sensing problem for which missing data occurs naturally. The data considered were made available to the authors by the US Army (and were collected from a real former bombing range in the US); the data are available to other researchers upon request. The total number of targets are 146, where 79 of them UXO and the rest are non-UXO (i.e., non-explosives). A six-dimensional feature vector is extracted from the raw signals to represent each target, with the first three components corresponding to MAG features and the rest as EMI features (details on feature extraction is provided in Zhang et al., 2003). Figure 12 shows the missing patterns for this data set.

We compare the proposed iQGME-VB algorithm with the SVM, RVM and LR-Integration as detailed in Section 6.2. In order to evaluate the overall performance of classifiers, we randomly partition the training and test subsets, and change the training size. Results are shown in Figure 13, where only performance means are reported for the legibility of the figures. From this figure, the proposed iQGME-VB method is robust for all the experimental settings under both performance criteria.

6.4 Sepsis Classification Data

In Sections 6.2 and 6.3, we have demonstrated the proposed iQGME-VB on data sets with low to moderate dimensionality. A high-dimensional data set with natural missing values is considered in this subsection. These data were made available to the authors from the National Center for Genomic Research in the US, and will be made available upon request. This is another example

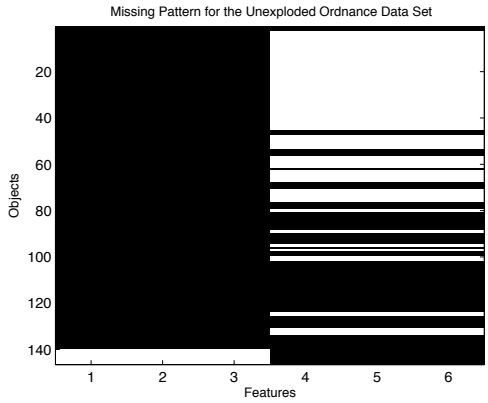


Figure 12: Missing pattern for the unexploded ordnance data set, where black and white indicate observed and missing, respectively.

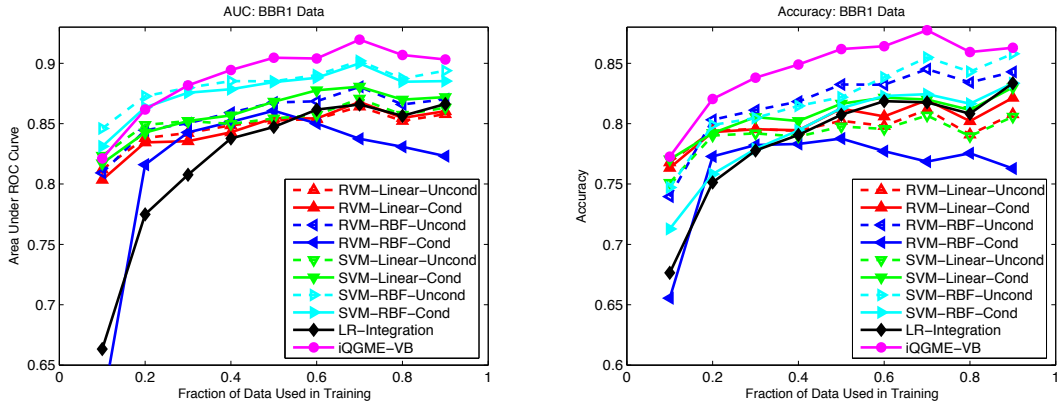


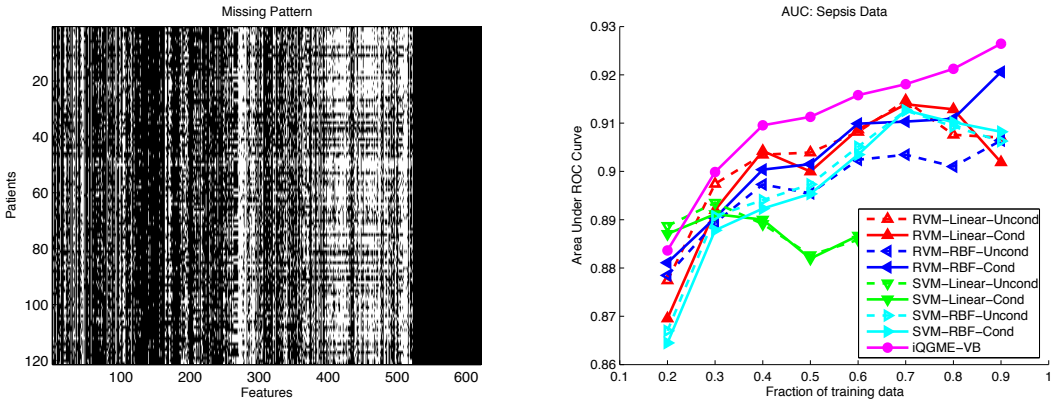
(a) (b)

Figure 13: Mean performance over 100 random training/test partitions for each training fraction on the unexploded ordnance data set, in terms of (a) area under the ROC curve, and (b) classification accuracy.

for which missing data are a natural consequence of the sensing modality. There are 121 patients who are infected by sepsis, with 90 of them surviving (label -1) and 31 of them who die (label 1). For each patient, we have 521 metabolic features and 100 protein features. The purpose is to predict whether a patient infected by sepsis will die given his/her features. The missing pattern of feature values is shown in Figure 14(a), where black indicates observed (this missingness is a natural consequence of the sensing device).

As the data are in a 621-dimensional feature space, with only 121 samples available, we use the MFA-based variant of the iQGME (Section 2.4). To impose the low-rank belief for each cluster, we set $c_0 = d_0 = 1$, and the largest possible dimensionality for clusters is set to be $L = 50$.

We compare to the same algorithms considered in Section 6.3, except the LR-Integration algorithm since it is not capable of handling such a high-dimensional data set. Mean AUC over ten random partitions are reported in Figure 14(b). Here we report the SVM and RVM results on the original data since they are able to classify the data in the original 621-dimensional space after missing values are imputed; we also examined SVM and RVM results on the data in a lower-dimensional latent space, after first performing factor analysis on the data, and these results were very similar to the SVM/RVM results in the original 621-dimensional space. From Figure 14(b), our method provides improvement by handling missing values analytically in the procedure of model inference and performing a dimensionality reduction jointly with local classifiers learning.



(a) (b)

6.5 Multi-Task Learning with Landmine Detection Data

We now consider a multi-task-learning example. In an application of landmine detection (available at `http://www.ee.duke.edu/~lcarin/LandmineData.zip`), data collected from 19 landmine fields are treated as 19 subtasks. Among them, subtasks 1-10 correspond to regions that are relatively highly foliated and subtasks 11-19 correspond to regions that are bare earth or desert. In all subtasks, each target is characterized by a 9-dimensional feature vector $\boldsymbol{x}$ with corresponding binary label y (1 for landmines and -1 for clutter). The number of landmines and clutter in each task is summarized in Figure 15. The feature vectors are extracted from images measured with airborne radar systems. A detailed description of this landmine data set has been presented elsewhere (Xue et al., 2007).

Although our main objective is to simultaneously learn classifiers for multiple tasks with incomplete data, we first demonstrate the proposed iQGME-based multi-task learning (MTL) model on the complete data, comparing it to two multi-task learning algorithms designed for the situation with all the features observed. One is based on task-specific logistic regression (LR) models, with the DP as a hierarchical prior across all the tasks (Xue et al., 2007); the other assumes an underlying

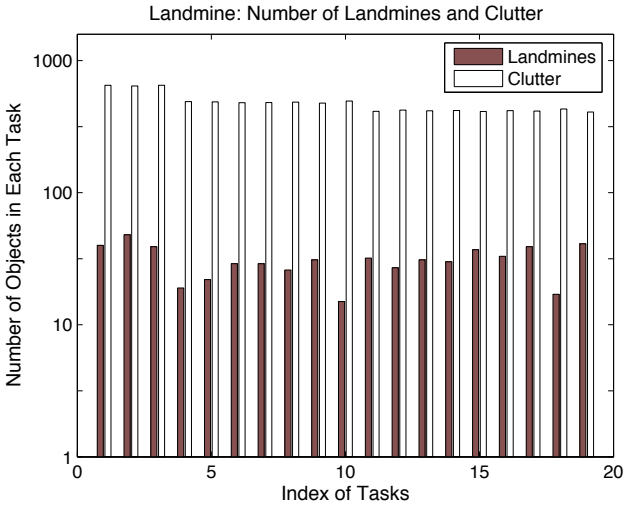

Figure 15: Number of landmines and clutter in each task for the landmine-detection data set (Xue et al., 2007).

structure, which is shared by all the tasks (Ando and Zhang, 2005). For the LR-MTL algorithm, we cite results on complete data from Xue et al. (2007), and implement the authors' Matlab code with default hyper-parameters on the cases with incomplete data. The Matlab implementation for the Structure-MTL algorithm is included in the "Transfer Learning Toolkit for Matlab" available at `http://multitask.cs.berkeley.edu/`. The dimension of the underlying structure is a user-set parameter, and it should be smaller than the feature dimension in the original space. As the dimension of the landmine detection data is 9, we set the hidden dimension as 5. We also tried 6, 7, and 8, and did not observe big differences in performance. Single-task learning (STL) iQGME and LR models are also included for comparison.

Each task is divided into training and test subsets randomly. Since the number of elements in the two classes is highly unbalanced, as shown in Figure 15, we impose that there is at least one instance from each class in each subset. Following Xue et al. (2007), the size of the training subset in each task varies from 20 to 300 in increments of 20, and 100 independent trials are performed for each size of data set. An average AUC (Hanley and McNeil, 1982) over all the 19 tasks is calculated as the performance representation for one trial of a given training size. Results are reported in Figure 16.

The first observation from Figure 16 is that we obtain a significant performance improvement for single-task learning by using the iQGME-VB instead of the linear logistic regression model (Xue et al., 2007). We also notice that the multi-task algorithm based on iQGME-VB further improves the performance when the training data are scarce, and yields comparable overall results as the LR-MTL does. The structure-MTL does not perform well on this data set. We suspect that a hidden structure in such a 9-dimensional space does not necessarily exist. Another possible reason may be that the minimization of empirical risk is sensitive for the cases with highly unbalanced labels, as for this data set.

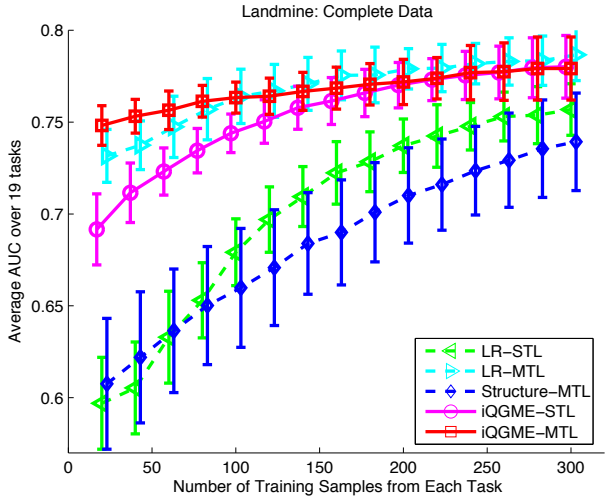

Figure 16: Average AUC over 19 tasks of landmine detection with complete data. Error bars reflect the standard deviation across 100 random partitions of training and test subsets. Results of logistic regression based algorithms are cited from Xue et al. (2007), where LR-MTL and LR-STL respectively correspond to SMTL-2 and STL in Figure 3 of Xue et al. (2007).

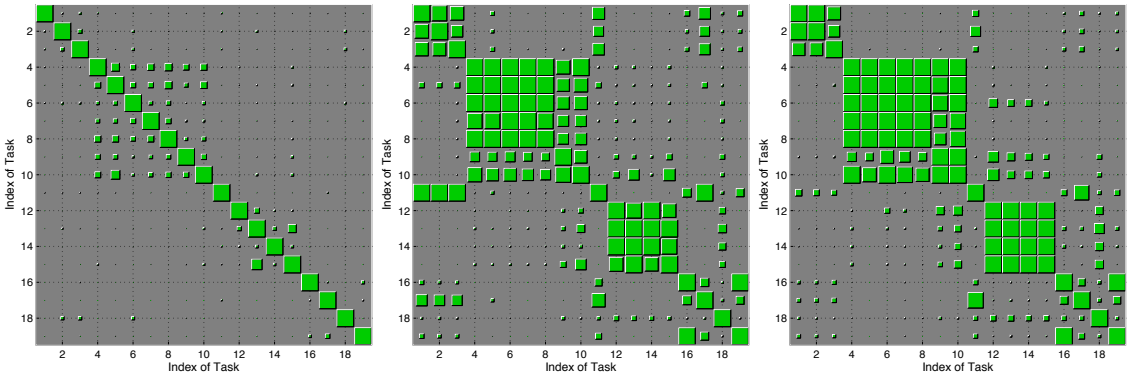
It is also interesting to explore the similarity among tasks. The similarity defined by different algorithms may be different. In Xue et al. (2007), two tasks are defined to be similar if they share the same linear classifier. However, with the joint distribution of covariates and the response, the iQGME-MTL requires both the data distributions and the classification boundaries to be similar if two tasks are deemed to be similar. Another difference is that two tasks could be partially similar since sharing between tasks is encouraged at the cluster-level instead of at the task-level (Xue et al. 2007 employs task-level clustering). We generate the similarity matrices between tasks as follows: In each random trial, there are in total S higher-level items shared among tasks. For each task, we can find the task-specific probability mass function (pmf) over all the higher-level items. Using these pmfs as the characteristics for tasks in the current trial, we calculate the pair-wise Kullback-Leibler (KL) distances and convert them to similarity measures through a minus exponential function. Results of multiple trials are summed over and normalized as shown in Figure 17. It can be seen that the similarity structure among tasks becomes clearer when we have more training data available. As discovered by Xue et al. (2007), we also find two big clusters correspond to two different vegetation conditions of the landmine fields (task 1-10 and task 11-19). Further sub-structures among tasks are also explored by the iQGME-MTL model, which may suggest other unknown difference among the landmine fields.

After yielding competitive results on the landmine-detection data set with complete data, the iQGME-based algorithms are evaluated on incomplete data, which are simulated by randomly removing a portion of feature values for each task as in Section 6.2. We consider three different



(a) (b) (c)

Figure 17: Similarity between tasks in the landmine detection problem with complete data given (a) 20, (b) 100, and (c) 300 training samples from each task. The size of green blocks represent the value of the corresponding matrix element.

portions of missing values: 25%, 50% and 75%. As in the experiments above on benchmark data sets, we perform ten independent random trials for each setting of missing fraction and training size.

To the best of our knowledge, there exists no previous work in the literature on multi-task learning with missing data. As presented in Figure 18, we use the LR-MTL (Xue et al., 2007) and the Structure-MTL (Ando and Zhang, 2005) with missing values imputed as baseline algorithms. Results of the two-step LR with integration (Williams et al., 2007) and the LR-STL with single imputations are also included for comparison. Imputations using both unconditional-means and conditional-means are considered. From Figure 18, iQGME-STL consistently performs best among single-task learning methods and even better than LR-MTL-Uncond when the size of the training set is relatively large. The imputations using conditional-means yields consistently better results for the LR-based models on this data set. The iQGME-MTL outperforms the baselines and all the single-task learning methods overall. Furthermore, the improvement of iQGME-MTL is more pronounced when there are more features missing. These observations underscore the advantage of handling missing data in a principled manner and at the same time learning multiple tasks simultaneously.

The task-similarity matrices for the incomplete-data cases are shown in Figure 19. It can be seen that when a small fraction (e.g., 25%) of the feature values are missing and training data are rich (e.g., 300 samples from each task), the similarity pattern among tasks is similar to what we have seen for the complete-data case. As the fraction of missing values becomes larger, tasks appear more different from each other in terms of the usage of the higher-level items. Considering that the missing pattern for each task is unique, it is probable that tasks look quite different from each other after a large fraction of feature values are missing. However, the fact that tasks tend to use different subsets of higher-level items does not mean it is equivalent to learning them separately (STL), as parameters of the common base measures are inferred based on all the tasks.

6.6 Multi-Task Learning with Handwritten Letters Data

The final example corresponds to multi-task learning of classifiers for handwritten letters, this data set included in the "Transfer Learning Toolkit for Matlab" available at `http://multitask.cs.`

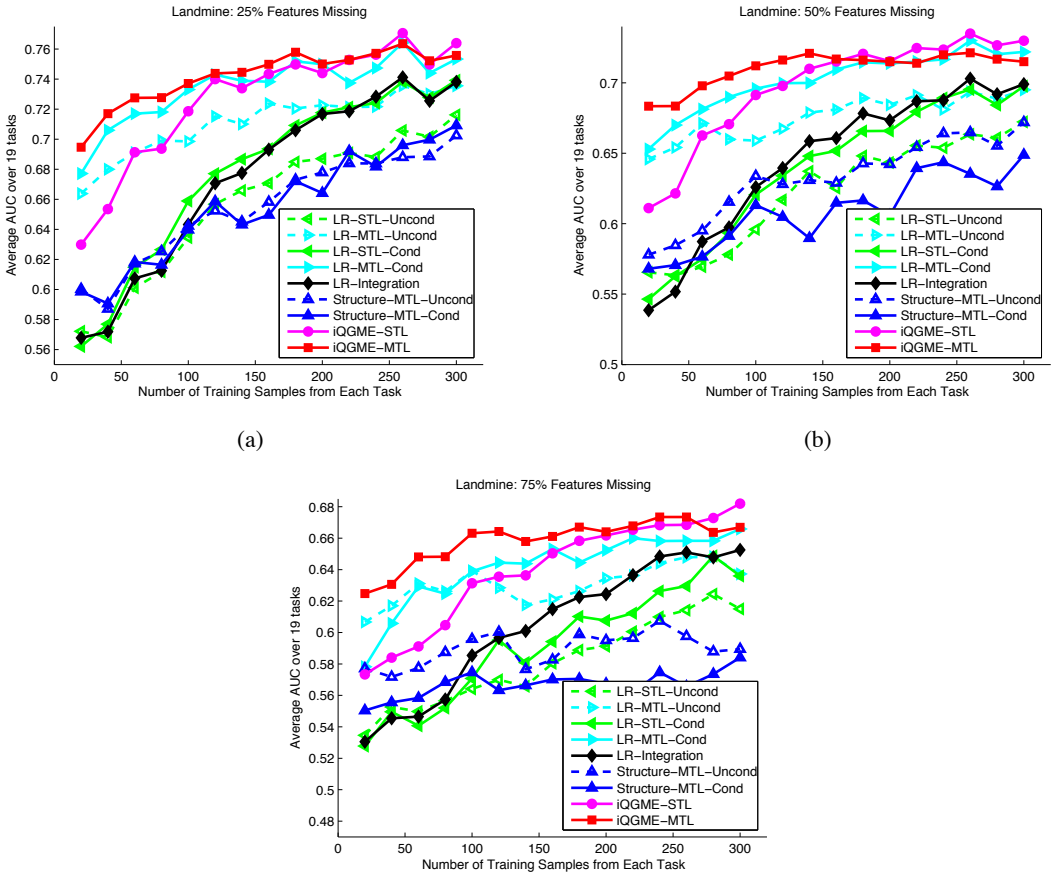


Figure 18: Average AUC over 19 tasks of landmine detection for the cases when (a) 25%, (b) 50%, and (c) 75% of the features are missing. Mean values of performance across 10 random partitions of training and test subsets are reported. Error bars are omitted for legibility.

`berkeley.edu/`. The objective of each task is to distinguish two letters which are easily confused. The number of samples for all the letters considered in the total eight tasks is summarized in Table 2. Each sample is a 16×8 image as shown in Figure 20. We use the 128 pixel values of each sample directly as its feature vector.

Task 1	Task 2	Task 3	Task 4	Task 5	Task 6	Task 7	Task 8
'c': 2107	'g': 2460	'm': 1596	'a': 4016	'i': 4895	'a': 4016	'f': 918	'h': 858
'e': 4928	'y': 1218	'n': 5004	'g': 2460	'j': 188	'o': 3880	't': 2131	'n': 5004

Table 2: Handwritten letters classification data set.

We compare the proposed iQGME-MTL algorithm to the LR-MTL (Xue et al., 2007) and the Structure-MTL (Ando and Zhang, 2005) mentioned in Section 6.5. For the non-parametric Bayesian methods (iQGME-MTL and LR-MTL), we use the same parameter setting as before. The dimension

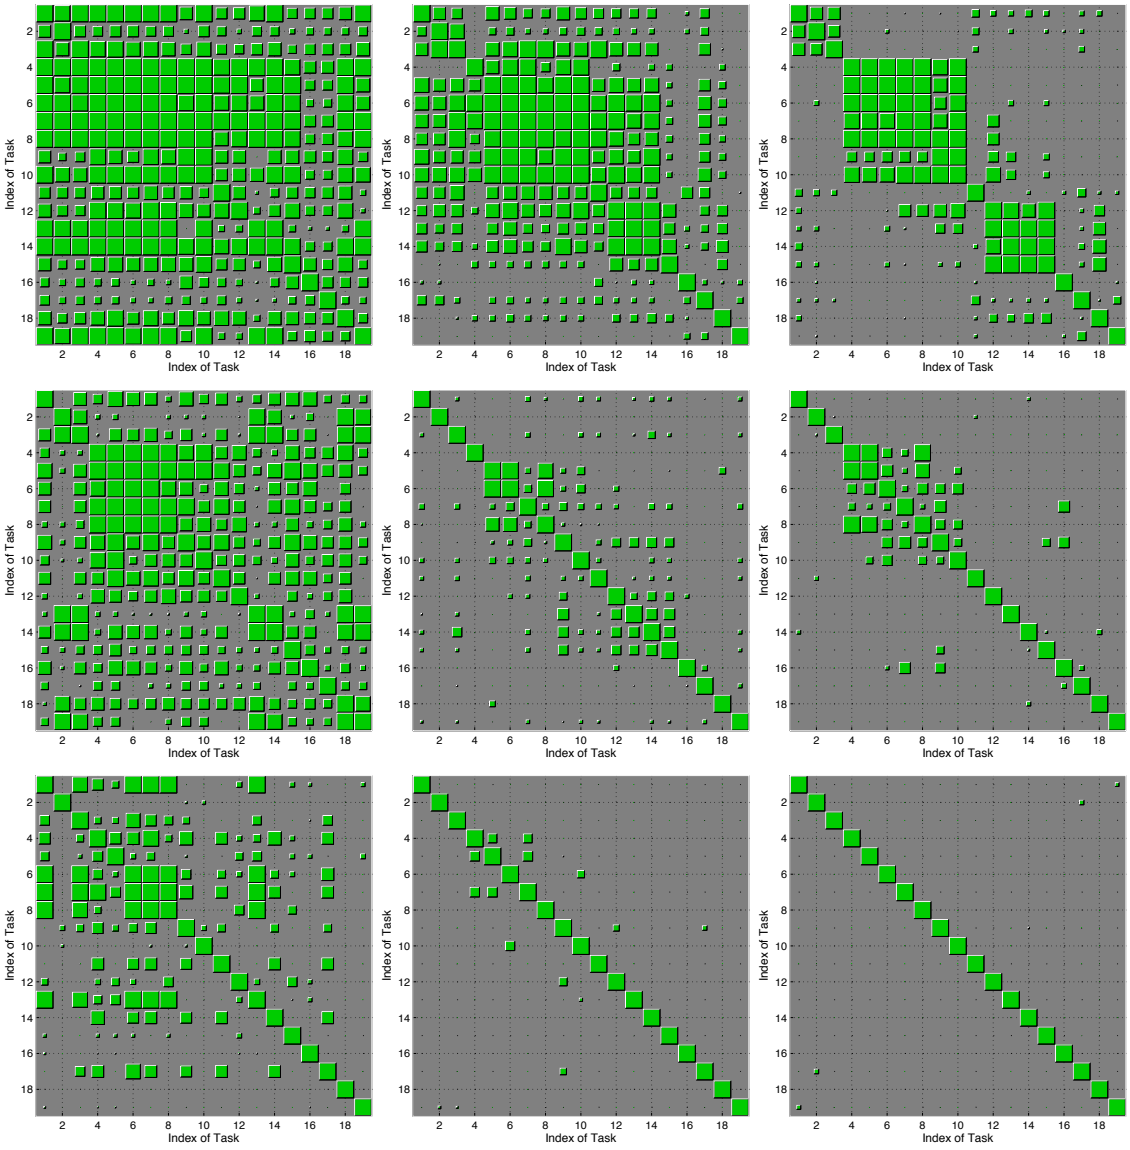

Figure 19: Similarity between tasks in the landmine detection problem with incomplete data. Row 1, 2 and 3 corresponds to the cases with 25%, 50% and 75% features missing, respectively; column 1, 2 and 3 corresponds to the cases with 20, 100 and 300 training samples from each task, respectively.

of the underlying structure for the Structure-MTL is set to be 50 in the results shown in Figure 21. We also tried 10, 20, 40, 60, 80 and 100, and did not observe big difference. From Figure 21, the iQGME-MTL performs significantly better than the baselines on this data set for all the missing fractions and training fractions under consideration. As we expected, the Structure-MTL yields comparable results as the LR-MTL on this data set.

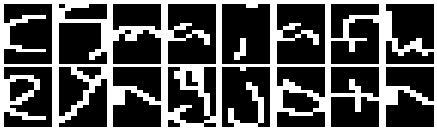

Figure 20: Sample images of the handwritten letters. The two images in each column represents the two classes in the corresponding task described in Table 2.

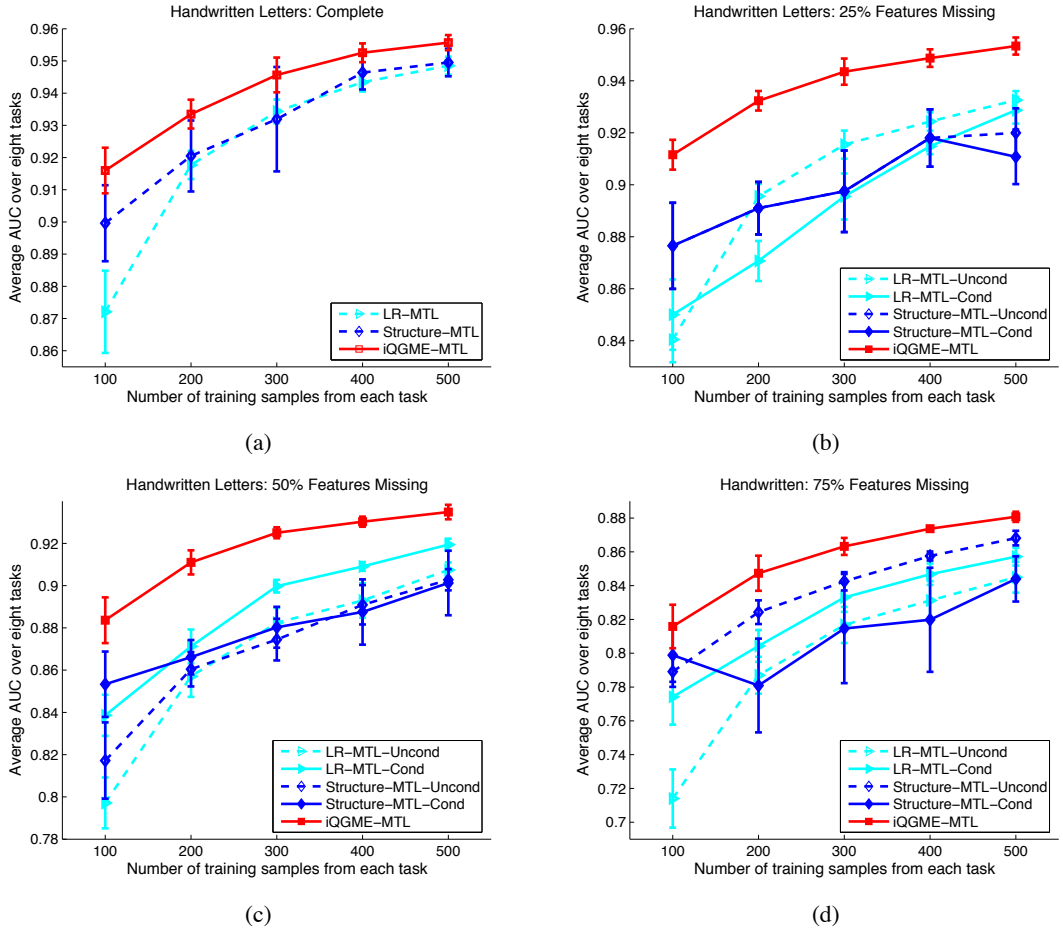

Figure 21: Average AUC over eight tasks of handwriting letters classification for the cases when (a) none, (b) 25%, (c) 50%, and (d) 75% of the features are missing. Mean values of performance with one standard deviation across 10 random partitions of training and test subsets are reported.

7. Conclusion and Future Work

In this paper we have introduced three new concepts, summarized as follows. First, we have employed non-parametric Bayesian techniques to develop a mixture-of-experts algorithm for classifier

design, which employs a set of localized (in feature space) linear classifiers as experts. The Dirichlet process is employed to allow the model to infer automatically the proper number of experts and their characteristics; in fact, since a Bayesian formulation is employed, a full posterior distribution is manifested on the properties of the local experts, including their number. Secondly, the classifier is endowed with the ability to naturally address missing data, without the need for an imputation step. Finally, the whole framework has been placed within the context of a multi-task learning, allowing one to jointly infer classifiers for multiple data sets with missing data. The multi-task-learning component has also been implemented with the general tools associated with the Dirichlet process, with specific implementations manifested via the hierarchical Dirichlet process. Because of the hierarchical form of the model, in terms of a sequence of distributions in the conjugate-exponential family, all inference has been manifested efficiently via variational Bayesian (VB) analysis. The VB results have been compared to those computed via Gibbs sampling; the VB results have been found to be consistent with those inferred via Gibbs sampling, while requiring a small fraction of the computational costs. Results have been presented for single-task and multi-task learning on various data sets with the same hyper-parameters setting (no model-parameter tuning), and encouraging algorithm performance has been demonstrated.

Concerning future research, we note that the use of multi-task learning provides an important class of contextual information, and therefore is particularly useful when one has limited labeled data and when the data are incomplete (missing features). Another form of context that has received significant recent attention is semi-supervised learning (Zhu, 2005). There has been recent work on integrating multi-task learning with semi-supervised learning (Liu et al., 2007). An important new research direction includes extending semi-supervised multi-task learning to realistic problems for which the data are incomplete.

Appendix A.

The update equations of single-task learning with incomplete data are summarized as follows:

1. $q(t_i|\mu_i^t)$

$$\mu_i^t = \sum_{h=1}^{N} \rho_{ih} \langle \boldsymbol{w}_h \rangle^T \hat{\boldsymbol{x}}^b{}_{i,h} \quad \text{where} \quad \hat{\boldsymbol{x}}^b{}_{i,h} = [\boldsymbol{x}_i^{o_i}; \boldsymbol{m}_h^{m_i|o_i}; 1].$$

   The expectation of t_i and t_i^2 may be derived according to properties of truncated normal distributions:

$$\begin{aligned} \langle t_i \rangle &= \mu_i^t + \frac{\phi(-\mu_i^t)}{\mathbf{1}(y_i = 1) - \Phi(-\mu_i^t)}, \\ \langle t_i^2 \rangle &= 1 + (\mu_i^t)^2 + \frac{\mu_i^t \phi(-\mu_i^t)}{\mathbf{1}(y_i = 1) - \Phi(-\mu_i^t)}, \end{aligned}$$

   where $\phi(\cdot)$ and $\Phi(\cdot)$ denote the probability density function and the cumulative density function of the standard normal distribution, respectively.

2. $q(\boldsymbol{x}_i^{m_i}, z_i | \boldsymbol{m}_{ih}^{m_i|o_i}, \boldsymbol{\Sigma}_{ih}^{m_i|o_i}, \rho_{ih})$
   A related derivation for a GMM model with incomplete data could be found in Williams et al. (2007), where no classifier terms appear.

First, we explicitly write the intercept w_h^b , that is, $\boldsymbol{w}_h = [(\boldsymbol{w}_h^x)^T, w_h^b]^T$:

$$\begin{aligned} & q(\boldsymbol{x}_i^{m_i}, z_i = h) \\ \propto\ & \exp\{\langle \ln[p(t_i|z_i = h, \boldsymbol{x}_i, \boldsymbol{W}) p(z_i = h|V) p(\boldsymbol{x}_i|z_i = h, \boldsymbol{\mu}, \boldsymbol{\Lambda})]\rangle_{q(t_i)q(\boldsymbol{w}_h)q(V)q(\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h)}\} \\ \propto\ & A_{ih} \mathcal{N}_P(\boldsymbol{x}_i|\tilde{\boldsymbol{\mu}}_{ih}, \tilde{\boldsymbol{\Sigma}}_{ih}), \end{aligned}$$

where

$$\begin{aligned} \tilde{\boldsymbol{\Sigma}}_{ih} &= [\langle \boldsymbol{w}_h^x (\boldsymbol{w}_h^x)^T \rangle + \nu_h \boldsymbol{B}_h]^{-1} \\ \tilde{\boldsymbol{\mu}}_{ih} &= \tilde{\boldsymbol{\Sigma}}_{ih}[\langle t_i \rangle \langle \boldsymbol{w}_h^x \rangle + \nu_h \boldsymbol{B}_h \boldsymbol{m}_h - \langle \boldsymbol{w}_h^x w_h^b \rangle] \\ A_{ih} &= \exp\{\langle \ln V_h \rangle + \sum_{l<h} \langle \ln(1 - V_l) \rangle + \langle t_i \rangle \langle w_h^b \rangle \\ &\quad + \frac{1}{2}[\langle \ln|\boldsymbol{\Lambda}_h| \rangle + \tilde{\boldsymbol{\mu}}_{ih}^T \tilde{\boldsymbol{\Sigma}}_{ih}^{-1} \tilde{\boldsymbol{\mu}}_{ih} + \ln|\tilde{\boldsymbol{\Sigma}}_{ih}| - \frac{P}{u_h} - \boldsymbol{m}_h^T \nu_h \boldsymbol{B}_h \boldsymbol{m}_h - \langle (w_h^b)^2 \rangle]\}. \end{aligned}$$

Since

$$\begin{bmatrix} \boldsymbol{x}_i^{o_i} \\ \boldsymbol{x}_i^{m_i} \end{bmatrix} \sim \mathcal{N}_P \left(\begin{bmatrix} \tilde{\boldsymbol{\mu}}_{ih}^{o_i} \\ \tilde{\boldsymbol{\mu}}_{ih}^{m_i} \end{bmatrix}, \begin{bmatrix} \tilde{\boldsymbol{\Sigma}}_{ih}^{o_i o_i} & \tilde{\boldsymbol{\Sigma}}_{ih}^{o_i m_i} \\ \tilde{\boldsymbol{\Sigma}}_{ih}^{m_i o_i} & \tilde{\boldsymbol{\Sigma}}_{ih}^{m_i m_i} \end{bmatrix} \right),$$

the conditional distribution of missing features $\boldsymbol{x}_i^{m_i}$ given observable features $\boldsymbol{x}_i^{o_i}$ is also a normal distribution, that is, $\boldsymbol{x}_i^{m_i}|\boldsymbol{x}_i^{o_i} \sim \mathcal{N}_{|m_i|}(\boldsymbol{m}_h^{m_i|o_i}, \boldsymbol{\Sigma}_h^{m_i|o_i})$ with

$$\begin{aligned} \boldsymbol{m}_h^{m_i|o_i} &= \tilde{\boldsymbol{\mu}}_{ih}^{m_i} + \tilde{\boldsymbol{\Sigma}}_{ih}^{m_i o_i} (\tilde{\boldsymbol{\Sigma}}_{ih}^{o_i o_i})^{-1} (\boldsymbol{x}_i^{o_i} - \tilde{\boldsymbol{\mu}}_{ih}^{o_i}), \\ \boldsymbol{\Sigma}_h^{m_i|o_i} &= \tilde{\boldsymbol{\Sigma}}_{ih}^{m_i m_i} - \tilde{\boldsymbol{\Sigma}}_{ih}^{m_i o_i} (\tilde{\boldsymbol{\Sigma}}_{ih}^{o_i o_i})^{-1} \tilde{\boldsymbol{\Sigma}}_{ih}^{o_i m_i}. \end{aligned}$$

Therefore, $q(\boldsymbol{x}_i^{m_i}, z_i = h)$ could be factorized as the product of a factor independent of $\boldsymbol{x}_i^{m_i}$ and the variational posterior of $\boldsymbol{x}_i^{m_i}$, that is,

$$\begin{aligned} q(\boldsymbol{x}_i^{m_i}, z_i = h) &\propto A_{ih} \mathcal{N}_{|o_i|}(\boldsymbol{x}_i^{o_i}|\tilde{\boldsymbol{\mu}}_{ih}^{o_i}, \tilde{\boldsymbol{\Sigma}}_{ih}^{o_i o_i}) \mathcal{N}_{|m_i|}(\boldsymbol{x}_i^{m_i}|\boldsymbol{m}_h^{m_i|o_i}, \boldsymbol{\Sigma}_h^{m_i|o_i}) \\ \rho_{ih} &\propto A_{ih} \mathcal{N}_{|o_i|}(\boldsymbol{x}_i^{o_i}|\tilde{\boldsymbol{\mu}}_{ih}^{o_i}, \tilde{\boldsymbol{\Sigma}}_{ih}^{o_i o_i}) \end{aligned}$$

For complete data, no factorization for the distribution for $\boldsymbol{x}_i^{m_i}$ is necessary:

$$\begin{aligned} \rho_{ih} \propto\ & \exp\{\langle t_i \rangle \langle \boldsymbol{w}_h \rangle^T \boldsymbol{x}_i - \frac{1}{2} \boldsymbol{x}_i^T \langle \boldsymbol{w}_h \boldsymbol{w}_h^T \rangle \boldsymbol{x}_i + \langle \ln V_h \rangle \\ & + \sum_{l<h} \langle \ln(1 - V_l) \rangle + \frac{1}{2} \langle \ln|\boldsymbol{\Lambda}_h| \rangle - \frac{1}{2} \langle (\boldsymbol{x}_i - \boldsymbol{\mu}_h)^T \boldsymbol{\Lambda}_h (\boldsymbol{x}_i - \boldsymbol{\mu}_h) \rangle\} \end{aligned}$$

3. $q(V_h|v_{h1}, v_{h2})$

Similar updating could be found in Blei and Jordan (2006), except that we put a prior belief on α here instead of setting a fixed number.

$$\begin{aligned} & v_{h1} = 1 + \sum_{i=1}^n \rho_{ih}, \quad v_{h2} = \langle \alpha \rangle + \sum_{i=1}^n \sum_{l>h} \rho_{il}; \\ & \langle \ln V_h \rangle = \psi(v_{h1}) - \psi(v_{h1} + v_{h2}), \quad \langle \ln(1 - V_l) \rangle = \psi(v_{l2}) - \psi(v_{l1} + v_{l2}). \end{aligned}$$

4. $q(\boldsymbol{\mu}_h, \boldsymbol{\Lambda}_h | \boldsymbol{m}_h, u_h, \boldsymbol{B}_h, \nu_h)$

   Similar updating could be found in Williams et al. (2007).

$$\nu_h = \nu_0 + N_h, \quad u_h = u_0 + N_h, \quad \boldsymbol{m}_h = \frac{u_0 \boldsymbol{m}_0 + N_h \bar{\boldsymbol{x}}_h}{u_h},$$
$$\boldsymbol{B}_h^{-1} = \boldsymbol{B}_0^{-1} + \sum_{i=1}^{n} \rho_{ih} \hat{\boldsymbol{\Omega}}_{i,h} + N_h \bar{\boldsymbol{S}}_h + \frac{u_0 N_h}{u_h} (\bar{\boldsymbol{x}}_h - \boldsymbol{m}_0)(\bar{\boldsymbol{x}}_h - \boldsymbol{m}_0)^T,$$

   where

$$N_h = \sum_{i=1}^{n} \rho_{ih}, \quad \bar{\boldsymbol{x}}_h = \sum_{i=1}^{n} \rho_{ih} \boldsymbol{x}_i / N_h, \quad \bar{\boldsymbol{S}}_h = \sum_{i=1}^{n} \rho_{ih} (\hat{\boldsymbol{x}}_{i,h} - \bar{\boldsymbol{x}}_h)(\hat{\boldsymbol{x}}_{i,h} - \bar{\boldsymbol{x}}_h)^T / N_h.$$
$$\hat{\boldsymbol{x}}_{i,h} = \begin{bmatrix} \boldsymbol{x}_i^{o_i} \\ \boldsymbol{m}_h^{m_i|o_i} \end{bmatrix}, \quad \hat{\boldsymbol{\Omega}}_{i,h} = \begin{bmatrix} \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{\Sigma}_h^{m_i|o_i} \end{bmatrix}.$$

$$\langle \ln |\boldsymbol{\Lambda}_h| \rangle = \sum_{p=1}^{P} \psi((\nu_h - p + 1)/2) + P \ln 2 + \ln |\boldsymbol{B}_h|,$$

$$\langle (\boldsymbol{x}_i - \boldsymbol{\mu}_h)^T \boldsymbol{\Lambda}_h (\boldsymbol{x}_i - \boldsymbol{\mu}_h) \rangle = (\hat{\boldsymbol{x}}_{i,h} - \boldsymbol{m}_h)^T \nu_h \boldsymbol{B}_h (\hat{\boldsymbol{x}}_{i,h} - \boldsymbol{m}_h) + P/u_h + \mathrm{tr}(\nu_h \boldsymbol{B}_h \hat{\boldsymbol{\Omega}}_{i,h}).$$

5. $q(\boldsymbol{w}_h | \boldsymbol{\mu}_h^w, \boldsymbol{\Sigma}_h^w)$, $\langle \boldsymbol{w}_h \rangle = \boldsymbol{\mu}_h^w$, $\langle \boldsymbol{w}_h \boldsymbol{w}_h^T \rangle = \boldsymbol{\Sigma}_h^w + \boldsymbol{\mu}_h^w (\boldsymbol{\mu}_h^w)^T$.

$$\boldsymbol{\Sigma}_h^w = \left(\sum_{i=1}^{n} \rho_{ih} (\hat{\boldsymbol{\Omega}}_{i,h} + \hat{\boldsymbol{x}^b}_{i,h} \hat{\boldsymbol{x}^b}_{i,h}^T) + \mathrm{diag}(\langle \boldsymbol{\lambda} \rangle) \right)^{-1},$$
$$\boldsymbol{\mu}_h^w = \boldsymbol{\Sigma}_h^w \left(\sum_{i=1}^{n} \rho_{ih} \hat{\boldsymbol{x}^b}_{i,h} \langle t_i \rangle + \mathrm{diag}(\langle \boldsymbol{\lambda} \rangle) \boldsymbol{\phi} \right).$$

6. $q(\zeta_p, \lambda_p | \phi_p, \gamma, a_p, b_p)$, $\langle \lambda_p \rangle = a_p / b_p$.

   Similar updating could be found in Xue et al. (2007).

$$\phi_p = \sum_{h=1}^{N} \langle w_{hp} \rangle / \gamma, \quad \gamma = \gamma_0 + N$$
$$a_p = a_0 + \frac{N}{2}, \quad b_p = b_0 + \frac{1}{2} \sum_{h=1}^{N} \langle w_{hp}^2 \rangle - \frac{1}{2} \gamma \phi_p^2.$$

7. $q(\alpha | \tau_1, \tau_2)$, $\langle \alpha \rangle = \tau_1 / \tau_2$.

   Similar updating could be found in any VB-inferred DP model with a Gamma prior on α (Xue et al., 2007).

$$\tau_1 = N - 1 + \tau_{10}, \quad \tau_2 = \tau_{20} - \sum_{h=1}^{N-1} \langle \ln(1 - V_h) \rangle.$$

The update equations of multi-task learning with incomplete data are summarized as follows:

1. $q(t_{ji}|\mu^t_{ji})$

$$\mu^t_{ji} = \sum_{s=1}^{S} E\sigma_{jis}\langle \boldsymbol{w}_s\rangle^T \hat{\boldsymbol{x}^b}_{ji} \quad \text{where} \quad E\sigma_{jis} = \sum_{h=1}^{N} \rho_{jih}\sigma_{jhs}, \quad \hat{\boldsymbol{x}^b}_{ji} = [\boldsymbol{x}^{o_{ji}}_{ji}; \boldsymbol{m}^{m_{ji}|o_{ji}}_{ji}; 1].$$

2. $q(x^{m_{ji}}_{ji}|\boldsymbol{m}^{m_{ji}|o_{ji}}_{ji}, \boldsymbol{\Sigma}^{m_{ji}|o_{ji}}_{ji})$

$$\begin{aligned} \boldsymbol{m}^{m_{ji}|o_{ji}}_{ji} &= \tilde{\boldsymbol{\mu}}^{m_{ji}}_{ji} + \tilde{\boldsymbol{\Sigma}}^{m_{ji}o_{ji}}_{ji}(\tilde{\boldsymbol{\Sigma}}^{o_{ji}o_{ji}}_{ji})^{-1}(\boldsymbol{x}^{o_{ji}}_{ji} - \tilde{\boldsymbol{\mu}}^{o_{ji}}_{ji}), \\ \boldsymbol{\Sigma}^{m_{ji}|o_{ji}}_{ji} &= \tilde{\boldsymbol{\Sigma}}^{m_{ji}m_{ji}}_{ji} - \tilde{\boldsymbol{\Sigma}}^{m_{ji}o_{ji}}_{ji}(\tilde{\boldsymbol{\Sigma}}^{o_{ji}o_{ji}}_{ji})^{-1}\tilde{\boldsymbol{\Sigma}}^{o_{ji}m_{ji}}_{ji}, \end{aligned}$$

where

$$\begin{aligned} \tilde{\boldsymbol{\Sigma}}_{ji} &= \left(\sum_{s=1}^{S} E\sigma_{jis}(\langle \boldsymbol{w}^x_s(\boldsymbol{w}^x_s)^T\rangle + \nu_s \boldsymbol{B}_s)\right)^{-1}, \\ \tilde{\boldsymbol{\mu}}_{ji} &= \tilde{\boldsymbol{\Sigma}}_{ji}\sum_{s=1}^{S} E\sigma_{jis}(\langle t_{ji}\rangle\langle \boldsymbol{w}^x_s\rangle + \nu_s \boldsymbol{B}_s\boldsymbol{m}_s - \langle \boldsymbol{w}^x_s w^b_s\rangle). \end{aligned}$$

$$\hat{\boldsymbol{x}}_{ji} = \begin{bmatrix} \boldsymbol{x}^{o_{ji}}_{ji} \\ \boldsymbol{m}^{m_{ji}|o_{ji}}_{ji} \end{bmatrix}, \quad \hat{\boldsymbol{\Omega}}_{ji} = \begin{bmatrix} \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{\Sigma}^{m_{ji}|o_{ji}}_{ji} \end{bmatrix}, \quad \langle \boldsymbol{x}_{ji}\boldsymbol{x}^T_{ji}\rangle = \hat{\boldsymbol{x}}_{ji}\hat{\boldsymbol{x}}^T_{ji} + \hat{\boldsymbol{\Omega}}_{ji}.$$

3. $q(z_{ji}|\boldsymbol{\rho}_{ji})$

$$\begin{aligned} & \rho_{jih} = q(z_{ji} = h) \\ \propto\ & \exp\{\sum_{s=1}^{S}\sigma_{jhs}[\langle t_{ji}\rangle\langle \boldsymbol{w}_s\rangle^T \hat{\boldsymbol{x}^b}_{ji} - \frac{1}{2}\mathrm{tr}(\langle \boldsymbol{w}_s\boldsymbol{w}^T_s\rangle\langle \boldsymbol{x}^b_{ji}(\boldsymbol{x}^b_{ji})^T\rangle)] \\ & + \langle \ln V_{jh}\rangle + \sum_{l<h}\langle \ln(1-V_{jl})\rangle \\ & + \frac{1}{2}\sum_{s=1}^{S}\sigma_{jhs}[\langle \ln|\boldsymbol{\Lambda}_s|\rangle - (\hat{\boldsymbol{x}}_{ji} - \boldsymbol{m}_s)^T\nu_s\boldsymbol{B}_s(\hat{\boldsymbol{x}}_{ji} - \boldsymbol{m}_s) - P/u_s - \mathrm{tr}(\nu_s\boldsymbol{B}_s\hat{\boldsymbol{\Omega}}_{ji})]\}. \end{aligned}$$

4. $q(\boldsymbol{V}|\boldsymbol{v})$

$$v_{jh1} = 1 + \sum_{i=1}^{n_j}\rho_{jih}, \qquad v_{jh2} = \langle\alpha\rangle + \sum_{l>h}\sum_{i=1}^{n_j}\rho_{jil}.$$

$$\langle \ln V_{jh}\rangle = \psi(v_{jh1}) - \psi(v_{jh1} + v_{jh2}), \qquad \langle \ln(1-V_{jl})\rangle = \psi(v_{jl2}) - \psi(v_{jl1} + v_{jl2}).$$

5. $q(\alpha|\tau_1,\tau_2)$, $\langle\alpha\rangle = \tau_1/\tau_2$.

$$\tau_1 = J(N-1) + \tau_{10}, \quad \tau_2 = \tau_{20} - \sum_{j=1}^{J}\sum_{h=1}^{N-1}\langle \ln(1-V_{jh})\rangle.$$

6. $q(\boldsymbol{c}|\boldsymbol{\sigma})$

$$\begin{aligned}\sigma_{jhs} \quad \propto \quad & \exp\{\sum_{i=1}^{n_j}\rho_{jih}[\langle t_{ji}\rangle\langle \boldsymbol{w}_s\rangle^T\hat{\boldsymbol{x}^b}_{ji}-\frac{1}{2}\mathrm{tr}(\langle \boldsymbol{w}_s\boldsymbol{w}_s^T\rangle\langle \boldsymbol{x}^b_{ji}(\boldsymbol{x}^b_{ji})^T\rangle)] \\ & +\langle\ln U_s\rangle+\sum_{l<s}\langle\ln(1-U_s)\rangle \\ & +\frac{1}{2}\sum_{i=1}^{n_j}\rho_{jih}[\langle\ln|\boldsymbol{\Lambda}_s|\rangle-(\hat{\boldsymbol{x}}_{ji}-\boldsymbol{m}_s)^T\nu_s\boldsymbol{B}_s(\hat{\boldsymbol{x}}_{ji}-\boldsymbol{m}_s)-P/u_s-\mathrm{tr}(\nu_s\boldsymbol{B}_s\hat{\boldsymbol{\Omega}}_{ji})]\}.\end{aligned}$$

7. $q(U_s|\kappa_{s1},\kappa_{s2})$

$$\kappa_{s1}=1+\sum_{j=1}^{J}\sum_{h=1}^{N}\sigma_{jhs},\quad \kappa_{s2}=\langle\beta\rangle+\sum_{j=1}^{J}\sum_{h=1}^{N}\sum_{l>s}\sigma_{jhl}.$$
$$\langle\ln U_s\rangle=\psi(\kappa_{s1})-\psi(\kappa_{s1}+\kappa_{s2}),\quad \langle\ln(1-U_s)\rangle=\psi(\kappa_{s2})-\psi(\kappa_{s1}+\kappa_{s2}).$$

8. $q(\beta|\tau_3,\tau_4)$, $\langle\beta\rangle=\tau_3/\tau_4$.

$$\tau_3=S-1+\tau_{30},\quad \tau_4=\tau_{40}-\sum_{s=1}^{S-1}\langle\ln(1-U_s)\rangle.$$

9. $q(\boldsymbol{\mu}_s,\boldsymbol{\Lambda}_s|\boldsymbol{m}_s,u_s,\boldsymbol{B}_s,\nu_s)$

$$\nu_s=\nu_0+N_s,\quad u_s=u_0+N_s,\quad \boldsymbol{m}_s=\frac{u_0\boldsymbol{m}_0+N_s\bar{\boldsymbol{x}}_s}{u_s},$$
$$\boldsymbol{B}_s^{-1}=\boldsymbol{B}_0^{-1}+\sum_{j=1}^{J}\sum_{i=1}^{n_j}E\sigma_{jis}\hat{\boldsymbol{\Omega}}_{ji}+N_s\bar{\boldsymbol{S}}_s+\frac{u_0N_s}{u_s}(\bar{\boldsymbol{x}}_s-\boldsymbol{m}_0)(\bar{\boldsymbol{x}}_s-\boldsymbol{m}_0)^T,$$

where $E\sigma_{jis}=\sum_{h=1}^{N}\rho_{jih}\sigma_{jhs}$, and

$$N_s=\sum_{j=1}^{J}\sum_{i=1}^{n_j}E\sigma_{jis},\quad \bar{\boldsymbol{x}}_s=\sum_{j=1}^{J}\sum_{i=1}^{n_j}E\sigma_{jis}\hat{\boldsymbol{x}}_{ji}/N_s,$$
$$\bar{\boldsymbol{S}}_s=\sum_{j=1}^{J}\sum_{i=1}^{n_j}E\sigma_{jis}(\hat{\boldsymbol{x}}_{ji}-\bar{\boldsymbol{x}}_s)(\hat{\boldsymbol{x}}_{ji}-\bar{\boldsymbol{x}}_s)^T/N_s.$$

$$\langle\ln|\boldsymbol{\Lambda}_s|\rangle=\sum_{p=1}^{P}\psi((\nu_s-p+1)/2)+P\ln 2+\ln|\boldsymbol{B}_s|,$$
$$\langle(\boldsymbol{x}_{ji}-\boldsymbol{\mu}_s)^T\boldsymbol{\Lambda}_s(\boldsymbol{x}_{ji}-\boldsymbol{\mu}_s)\rangle=(\hat{\boldsymbol{x}}_{ji}-\boldsymbol{m}_s)^T\nu_s\boldsymbol{B}_s(\hat{\boldsymbol{x}}_{ji}-\boldsymbol{m}_s)+P/u_s+\mathrm{tr}(\nu_s\boldsymbol{B}_s\hat{\boldsymbol{\Omega}}_{ji}).$$

10. $q(\boldsymbol{w}_s|\boldsymbol{\mu}_s^w,\boldsymbol{\Sigma}_s^w)$

$$\begin{aligned}\boldsymbol{\Sigma}_s^w \quad &= \quad \left(\sum_{j=1}^{J}\sum_{i=1}^{n_j}E\sigma_{jis}(\hat{\boldsymbol{x}^b}_{ji}\hat{\boldsymbol{x}^b}^T_{ji}+\hat{\boldsymbol{\Omega}}_{ji})+\mathrm{diag}(\langle\boldsymbol{\lambda}\rangle)\right)^{-1}, \\ \boldsymbol{\mu}_s^w \quad &= \quad \boldsymbol{\Sigma}_s^w\left(\sum_{j=1}^{J}\sum_{i=1}^{n_j}E\sigma_{jis}\hat{\boldsymbol{x}^b}_{ji}\langle t_{ji}\rangle+\mathrm{diag}(\langle\boldsymbol{\lambda}\rangle)\phi\right).\end{aligned}$$

$$\langle\boldsymbol{w}_s\rangle=\boldsymbol{\mu}_s^w,\qquad \langle\boldsymbol{w}_s\boldsymbol{w}_s^T\rangle=\boldsymbol{\Sigma}_s^w+\boldsymbol{\mu}_s^w(\boldsymbol{\mu}_s^w)^T.$$

11. $q(\lambda_p|a_p,b_p)$, $\langle\lambda_p\rangle = a_p/b_p$.

$$\phi_p = \sum_{s=1}^{S}\langle w_{sp}\rangle/\gamma, \quad \gamma = \gamma_0 + S,$$
$$a_p = a_0 + \frac{S}{2}, \quad b_p = b_0 + \frac{1}{2}\sum_{s=1}^{S}\langle W_{sp}^2\rangle - \frac{1}{2}\gamma\phi_p^2.$$

Abstract

The presence of asymmetry in the misclassification costs or class prevalences is a common occurrence in the pattern classification domain. While much interest has been devoted to the study of *cost-sensitive learning* techniques, the relationship between cost-sensitive learning and the specification of the model set in a parametric estimation framework remains somewhat unclear. To that end, we differentiate between the case of the model including the true posterior, and that in which the model is misspecified. In the former case, it is shown that thresholding the maximum likelihood (ML) estimate is an asymptotically optimal solution to the risk minimization problem. On the other hand, under model misspecification, it is demonstrated that thresholded ML is suboptimal and that the risk-minimizing solution varies with the misclassification cost ratio. Moreover, we analytically show that the negative weighted log likelihood (Elkan, 2001) is a tight, convex upper bound of the empirical loss. Coupled with empirical results on several real-world data sets, we argue that weighted ML is the preferred cost-sensitive technique.

Keywords: empirical risk minimization, loss function, cost-sensitive learning, imbalanced data sets

1. Introduction

Pattern classifiers make decisions; when those decisions are wrong, a loss is incurred. Thus, the ultimate goal of a classifier is to minimize the loss. When put into probabilistic terms, the mathematical expectation of the loss is called the *risk*, and is related to the classifier's error rates. In the case of a binary classification this can be written as (Duda et al., 2001):

$$\text{risk} = p(+1)\,c(+1)\,p(\text{error}|+1) + p(-1)\,c(-1)\,p(\text{error}|-1)\,, \tag{1}$$

where $c(+1)$ and $c(-1)$ denote the costs of a false negative and false positive, respectively, $p(+1)$ and $p(-1)$ are the prior probabilities for classes $y=+1$ and $y=-1$, $p(\text{error}|+1)$ is the false

negative rate, and $p(\text{error}|-1)$ is the false positive rate. Notice that the false positive and negative rates are the only terms which depend on the classifier parameters, whereas the misclassification costs and class priors are typically constants of the classification problem (later, we consider the case of example-dependent costs). The class priors are coupled with the costs of misclassification in the expression for expected loss. Thus, the risk minimization problem is uniquely defined by the ratio $\frac{p(+1)c(+1)}{p(-1)c(-1)}$; that is, even though the priors and costs may vary, as long as this ratio stays constant, the optimization problem is unchanged.

The term *cost-sensitive learning* (Elkan, 2001) has been attached to classification environments in which $c(+1) \neq c(-1)$. On the other hand, *classification with imbalanced data sets* (Chawla and Japkowicz, 2004) refers to the case where $p(+1) \neq p(-1)$. The presence of at least one of these asymmetries has been referred to by some as the "nonstandard" case (Lin et al., 2002), even though the situation is rather common in practice. In any case, these two problems may be unified simply by stating that the goal of the classification is to minimize the risk, as opposed to the conventional error rate:

$$\text{error rate} = p(+1)\, p(\text{error}|+1) + p(-1)\, p(\text{error}|-1).$$

A classifier that is designed to minimize the error rate will generally yield a high expected loss when applied to the case $c(+1) \neq c(-1)$, as the error-minimizing classifier will under-emphasize the more costly class. The problem may be exacerbated if the class prevalences are also skewed, and in the extreme case, the algorithm yields a trivial classifier which always selects the common class.

Minimizing risk is synonymous with optimally trading off the false negative and false positive rates. The trade-off between the false positive rate and false negative rate is precisely depicted by receiver operating characteristic (ROC) curves (Provost and Fawcett, 1997; Fawcett, 2004; Egan, 1975). Thus, ROC curves are well-suited to evaluating the expected loss of a classifier across the range of misclassification costs. However, "reading off" the expected loss from an ROC graph is not straightforward, and Drummond and Holte (2000) proposed cost curves as an explicit visualization of a classifier's risk for varying misclassification costs and class priors. Since the ratio $\frac{p(+1)c(+1)}{p(-1)c(-1)}$ is unbounded, the curves instead show the risk as a function of the *probability cost function* (pcf):

$$\text{pcf} = \frac{p(+1)c(+1)}{p(+1)c(+1) + p(-1)c(-1)}.$$

Cost curves facilitate the quantification of the reduction in loss offered by a cost-sensitive learning algorithm.

Several methodologies have been developed in the effort to design risk-minimizing classifiers. The simplest approach is to modify the threshold of an existing, cost-insensitive classifier. If the classifier is based on the log of the ratio of true class posterior probabilities, the threshold should be modified by a value equal to the log of the ratio of misclassification costs (Duda et al., 2001). In practice, the true class-conditional probabilities are unknown. Nevertheless, shifting the threshold by the corresponding amount has become a common heuristic (Elkan, 2001; Lin et al., 2002). Elkan (2001) proposes handling asymmetric misclassification costs by retraining the classifier on a training set in which the proportion of positive and negative examples is matched to the ratio of misclassification costs. Alternatively, if an algorithm may apply weights to the training examples, the negative examples should be weighted by a value corresponding to the asymmetry in misclassification costs. Maloof (2003) points out that although the problems of imbalanced data sets and

varying misclassification costs are separate problems, they may be tackled in very similar ways. He shows empirically that oversampling the less prevalent class (or undersampling the more prevalent class) is a procedure which yields results virtually identical to adjusting the decision threshold.

Domingos (1999) proposes a technique to relabel the training data in such a way that the relabeled data set may be trained using a standard (cost-insensitive) technique to yield a cost-sensitive classifier. The posteriors for the *labeled* examples are estimated via bagging and then used in conjunction with the Bayesian minimum risk criterion to assign new labels to the supervised data. Margineantu (2000) analyzes the approach of Domingos (1999) and suggests ways of improving the class probability estimates of the training data. Dudik and Phillips (2009) address the class imbalance problem by proposing a method which attempts to minimize loss assuming the worst-case class proportions. Masnadi-Shirazi and Vasconcelos (2010) describe a cost-sensitive version of the popular support vector machine.

Some work has been devoted to the case of example-dependent costs (Zadrozny and Elkan, 2001; Zadrozny et al., 2003). Moreover, some authors have advocated for maximizing benefits rather than minimizing costs (Elkan, 2001).

In Guerrero-Curieses et al. (2004), the authors examine loss functions which are minimized by the true class posterior probabilities; moreover, it is pointed out that the corresponding optimization algorithms should focus on training points near the decision boundary.

It is also important to point out that risk minimization is a diverse problem spanning multiple research communities; in particular, significant contributions to the problem have been made in the econometrics literature. To that end, Elliott and Lieli (2007) examine a problem analogous to cost-sensitive learning, namely the determination of a profit maximizing decision scheme by a lender. It is noted therein that to construct the minimum risk decision, the model density need not match the true density; rather, it is only required that the classifier output from the model density falls on the same side of the threshold as the classifier output using the true density. Moreover, the authors use a new loss function, namely an affine transformation of the expected utility (risk), and show an empirical advantage over traditional methods.

While a plethora of cost-sensitive methods has been investigated, it remains unclear under what conditions shifting the threshold of an existing cost-insensitive classifier is an appropriate solution. The distinction between the case of the model family including the true posterior, versus that of "misspecification" (the model does not contain the truth), has large implications on the resulting cost-sensitive learning process.

In the former case, shifting the threshold of the maximum likelihood (ML) solution is an asymptotically optimal solution to the risk minimization problem, and in the following we provide a proof of this important point. This means that when employing an expressive family which contains the true posterior, the cost-sensitive learning problem becomes one of density estimation, and the costs affect only the threshold, not the estimator. This may lead one to use a rich model set leading to complex classifiers. However, the choice to employ a simple classifier brings many advantages: ease of implementation, a lesser number of parameters to estimate, a reduced risk of over-fitting, and consequently simplified regularization procedures. Coupled with the complexity of real-world data sets, misspecified models are frequently encountered in practice. In this case, we demonstrate that thresholded ML is suboptimal, and that the minimum risk solution varies with the ratio of misclassification costs.

The problems with minimizing the true empirical risk, a non-smooth function, are well-known: for zero-one loss, the idea of smoothing out the indicator function appears in Horowitz (1992). In

this paper, we employ a sigmoidal approximation of the empirical risk to yield a novel minimizer of the loss under asymmetric misclassification cost values. Rather than argue for its optimality, this estimator is used as a basis for comparison and to argue for the relative merits of existing cost-sensitive techniques. We show analytically that the negative weighted log likelihood serves as an upper bound to the sigmoidal empirical risk. Based on the convexity of the negative weighted log likelihood and forthcoming numerical results, we will argue that weighted ML is generally the preferred technique.

2. Classification Model

In the following, we adopt a probabilistic model for the classification task: assume that the true posterior probability $p(y|\mathbf{x})$ of class $y \in \{-1,+1\}$ given received feature vector $\mathbf{x} \in \mathbb{R}^D$ is known. Let $c(y,\mathbf{x})$ denote the cost of a misclassification when the true class is y for feature $\mathbf{x}$, minus the cost of a correct prediction. Note that in general, c is feature-dependent, although in many applications, $c(y,\mathbf{x}) = c(y)$. If there is also no cost for a correct decision, then $c(y)$ is simply the cost of a false positive ($y=-1$) or false negative ($y=+1$). The optimal Bayesian decision rule is to predict $\hat{y}=+1$ if (Duda et al., 2001):

$$\frac{p(+1|\mathbf{x})}{p(-1|\mathbf{x})} > c_o(\mathbf{x}),$$

where $c_o(\mathbf{x}) = \frac{c(-1,\mathbf{x})}{c(+1,\mathbf{x})} > 0$. The optimal decision rule may be written as:

$$\hat{y}(\mathbf{x}) = \operatorname{sgn}\left[f(\mathbf{x}) - \ln c_o(\mathbf{x})\right], \tag{2}$$

where $\hat{y}(\mathbf{x})$ is the predicted class given feature vector $\mathbf{x}$, sgn is the signum function $\operatorname{sgn}(x) = \begin{cases} 1 & x>0 \\ -1 & x\leq 0 \end{cases}$, and $f(\mathbf{x})$ is the discriminant function:

$$f(\mathbf{x}) = \ln \frac{p(+1|\mathbf{x})}{p(-1|\mathbf{x})}.$$

It should be noted that the argument of the signum function may be written in log units due to the nonnegativity of the ratio of posteriors and the optimal threshold $c_o(\mathbf{x})$.

In practice, we do not have access to the true class posteriors, but rather estimate their values from available training data. The estimate is denoted by $p(y|\mathbf{x};\theta)$, where $\theta \in \Theta$ is a vector parameterizing the *model* posterior, and Θ is termed the model set. If the true posterior is in the model set, denote the true value of θ by θ^*, such that $p(y|\mathbf{x}) = p(y|\mathbf{x};\theta^*)$. The model discriminant is written as $f(\mathbf{x},\theta) = \ln \frac{p(+1|\mathbf{x};\theta)}{p(-1|\mathbf{x};\theta)}$, and the classifier takes the form:

$$\hat{y}(\mathbf{x},\theta) = \operatorname{sgn}\left[f(\mathbf{x},\theta) - \ln c_o(\mathbf{x})\right]. \tag{3}$$

This paper is concerned with methods of estimating θ to minimize risk, and their relation to the specification of the model set. In order to treat these estimation methods, we briefly outline the risk minimization framework which allows for the subsequent analysis of the various cost-sensitive loss functions.

3. Risk Minimization for Cost-Sensitive Learning

Risk minimization is concerned with choosing a function from a set $\{\hat{y}(\mathbf{x},\theta),\theta\in\Theta\}$ to minimize the resulting *risk functional*

$$R(\theta)=\int\int L(y,\mathbf{x},\theta)\,p(\mathbf{x},y)\,d\mathbf{x}dy,$$

where $L(y,\mathbf{x},\theta)$ quantifies the loss incurred by the classifier $\hat{y}(\mathbf{x},\theta)$ in response to labeled data $(\mathbf{x},y)$. Note that the loss L varies with the feature $\mathbf{x}$. To ease notation throughout the rest of the paper, the dependence of $\hat{y}$ on $\mathbf{x}$ and θ is implied.

The problems of regression, density estimation, and pattern recognition may all be formulated within the context of risk minimization, simply by altering the loss function L, as outlined in Vapnik (1998, 1999). In the case of error-minimizing pattern recognition, the classical zero-one loss function is given by:

$$L(y,\mathbf{x},\theta)=\mathbb{1}(y\neq\hat{y}),$$

where $\mathbb{1}(\Phi)$ is the indicator function which equals one when Φ is true and zero otherwise.

Since we do not have access to the true density $p(\mathbf{x},y)$, the empirical risk minimization (ERM) approach substitutes the empirical density:

$$p_{\text{emp}}(\mathbf{x},y)=\frac{1}{N}\sum_{n=1}^{N}\mathbb{1}(\mathbf{x}=\mathbf{x}_n)\,\mathbb{1}(y=y_n),$$

where $\mathcal{D}=(\mathbf{x}_n,y_n)_{n=1}^{N}$ is a set of N labeled observations which are independent and identically distributed samples drawn from the true joint density $p(\mathbf{x},y)$, leading to the following expression for the *empirical risk*:

$$R_{\text{emp}}(\theta)=\frac{1}{N}\sum_{n=1}^{N}L(y_n,\mathbf{x}_n,\theta). \tag{4}$$

In order to design a cost-sensitive classifier, a loss function modeling the asymmetry in misclassification costs is required. Several alternatives exist. In the following subsections, we describe these loss functions.

3.1 Thresholded Maximum Likelihood

The traditional (cost-insensitive) ML loss function is given by Vapnik (1998):

$$L(y,\mathbf{x},\theta)=-\ln p(y|\mathbf{x};\theta),$$

leading to the following expression for the empirical risk:

$$R^{\text{ml}}_{\text{emp}}(\theta)=-\frac{1}{N}\sum_{n}\ln p(y_n|\mathbf{x}_n;\theta). \tag{5}$$

The minimizer of (5) is the well-known ML estimate (Duda et al., 2001):

$$\begin{aligned}\hat{\theta}_{\mathrm{ML}} &= \arg\max_{\theta\in\Theta} \ln \prod_{n=1}^{N} p\left(y_n|\mathbf{x}_n;\theta\right) \\ &= \arg\max_{\theta\in\Theta} \ln \prod_{n=1}^{N} \frac{1}{1+\frac{p\left(-y_n|\mathbf{x}_n;\theta\right)}{p\left(y_n|\mathbf{x}_n;\theta\right)}} \\ &= \arg\max_{\theta\in\Theta} \sum_{n=1}^{N} \ln\left[\frac{1}{1+e^{-y_n f\left(\mathbf{x}_n,\theta\right)}}\right],\end{aligned}$$

where the second step follows from Bayes' rule. If the model set Θ contains the true parameter θ^*, it follows that in the asymptotic limit, we have $\lim_{N\to\infty}\hat{\theta}_{\mathrm{ML}} = \theta^*$ (Kay, 1993). From (2) and (3), if we have knowledge of θ^*, then a threshold shift of $\ln c_o(\mathbf{x})$ yields the optimal classifier. Assuming continuity of the log likelihood (in θ), we have that $\lim_{N\to\infty}\hat{y}\left(\mathbf{x},\hat{\theta}_{\mathrm{ML}}\right) = \hat{y}\left(\mathbf{x},\theta^*\right)$, and thus the thresholded ML estimate yields the minimum risk decision rule for all cost ratios. Once the ML estimate is available, the cost-sensitive classifier for any cost ratio may be formed by appropriately adjusting the threshold. There is no need to retrain the classifier if the cost ratio changes. In the case of a generalized linear model for $p(y|\mathbf{x},\theta)$, it may easily be shown (McCullagh and Nelder, 1989; Parra et al., 2005) that the risk function is convex, and an iteratively reweighted least squares (IRLS) algorithm locates the optimal linear classifier often within a few iterations.

Unfortunately, in many real-world classification problems, the model set (for example, the set of all hyperplanes) does not contain the true posterior. Notice, for example, that even in the simple case of Gaussian data, the linear discriminant is only optimal in the case of equal covariance matrices; nevertheless, linear classifiers are heavily used. (For a comprehensive treatment of misspecified models in ML, refer to White, 1982.) In such cases, the classifier in the model set which minimizes risk will vary with the pcf. As a result, a shift in threshold of the ML solution will yield a sub-optimal classifier.

3.2 Example: Minimum Risk Hyperplane for Gaussian Data

To illustrate this point, we consider the instructive case of Gaussian densities with unequal covariances and a linear classifier function. The purpose of this exercise is not to argue for a simple Gaussian model or a linear classifier but rather to demonstrate in an analytically tractable case the problem that arises with thresholded ML when the model is misspecified. It is assumed that $c\left(y,\mathbf{x}\right) = c(y)$.

Consider a linear classifier of the form $f\left(\mathbf{x};\theta\right) = \theta^T\mathbf{x} - b$, and assume Gaussian class-conditional densities:

$$p\left(\mathbf{x}|y\right) = \frac{1}{(2\pi)^{D/2}\left|\Sigma_y\right|^{1/2}} e^{-\frac{1}{2}\left(\mathbf{x}-\mu_y\right)^T\Sigma_y^{-1}\left(\mathbf{x}-\mu_y\right)},\ y\in\{-1,+1\}.$$

Note that by the normality of $\mathbf{x}|y$, $\theta^T\mathbf{x}\sim\mathcal{N}\left(\theta^T\mu_y,\theta^T\Sigma_y\theta\right)$. Thus, we have:

$$\begin{aligned}p\left(\text{error}|y\right) &= p\left[y\left(\theta^T\mathbf{x}-b\right)<0\right] \\ &= \frac{1}{2}\left[1+y\cdot\operatorname{erf}\left(\frac{b-\theta^T\mu_y}{\sqrt{2\theta^T\Sigma_y\theta}}\right)\right].\end{aligned} \tag{6}$$

Substituting (6) into (1), the expression for the expected loss takes the form:

$$R(\theta,b) = \frac{c(+1)p(+1)}{2}\left[1+\text{erf}\left(\frac{b-\theta^T\mu_+}{\sqrt{2\theta^T\Sigma_+\theta}}\right)\right] + \frac{c(-1)p(-1)}{2}\text{erfc}\left(\frac{b-\theta^T\mu_-}{\sqrt{2\theta^T\Sigma_-\theta}}\right). \quad (7)$$

The optimal hyperplane is the one which minimizes the risk: $\arg\min_{\theta,b} R(\theta,b)$.

Below, we illustrate an example where the parameters of the data are given by:

$$\mu_+ = \begin{bmatrix} 0.5 & 0 \end{bmatrix}^T,\ \mu_- = \begin{bmatrix} 0 & 0.5 \end{bmatrix}^T,\ \Sigma_+ = \begin{bmatrix} 1 & 0 \\ 0 & 0.5 \end{bmatrix},\ \Sigma_- = \begin{bmatrix} 0.5 & 0 \\ 0 & 1 \end{bmatrix}.$$

In this case of unequal covariance, the optimal ML classification function is not linear but instead a quadric (Duda et al., 2001, Chapter 2).

Figure 1(a) displays the minimum risk quadrics for various values of the pcf, where it is assumed that $p(+1) = p(-1)$. The quadrics are related to each other via a threshold shift. On the other hand, Figure 1(b) depicts the minimum risk planes for the same data, which were computed by minimizing (7) using numerical optimization techniques. It is clear that the direction of the optimal plane is a function of the pcf, and a threshold shift of the minimum error plane is not an optimal solution to the risk minimization problem. Figure 1 (c) displays the threshold-shifted ML solutions for various values of the pcf. The suboptimality of the ML approach is readily apparent by contrasting Figure 1(b) with Figure 1(c). Notice that at the extremes of the pcf, the optimal planes are orthogonal to each other. Meanwhile, the ML plane has unit slope for all pcf. The risks obtained by applying the ML and minimum risk planes to the given data are shown in Figure 1(d). In the figure, we normalize the raw risk of (1) by the "trivial risk", which is defined as the risk achieved by the scheme:

$$\hat{y}_{\text{trivial}} = \text{sgn}\left[p(+1)c(+1) - p(-1)c(-1)\right].$$

We call this the "trivial risk" because the decision rule is feature-independent and is strictly a function of the class priors and misclassification costs. A normalized risk less than 1 indicates that the classification scheme yields a "savings" over the a priori decision rule. The normalization allows us to quantify the "percentage of savings" achieved by employing a "smart" decision rule.

The curves were generated by averaging over 1000 ensembles, where each ensemble consisted of $N = 1000$ training samples. The ML classifier was trained on each ensemble and the resulting risk computed by substituting the solution into (7). The risk margin between the threshold-shifted ML solution and that of the minimum risk plane is what is "available" for cost-sensitive learning algorithms to improve upon. These methods attempt to learn, for each pcf, the minimum risk plane shown in Figure 1(b), to achieve the dashed cost curve in Figure 1(d).

The difference between the threshold-shifted ML and cost-sensitive paradigms may be understood in terms of ROC analysis—Figure 1 (e) depicts the ROC curves for the thresholded ML and minimum risk classifiers. In the ML method, the ROC curve is generated by sweeping the threshold of the base classifier across the real line and computing the corresponding error rates. In the cost-sensitive paradigm, each point on the ROC curve corresponds to a distinct classifier which is computed by minimizing (7) for a specific ratio of misclassification costs, resulting in values for the true and false positive rates. Note that one may also produce a *family* of ROC curves by sweeping the threshold of each of these distinct cost-sensitive classifiers, although this is not shown in the figure.

3.3 Relabeled Examples

One heuristic to cost-sensitive classification is to modify the training labels to achieve a balance in class prevalence. In terms of an ERM loss function, this may be written as:

$$L(y,\mathbf{x},\theta) = -\ln p\left[g(\mathbf{x})|\mathbf{x};\theta\right],$$

where the function $g(\mathbf{x}) : \mathbb{R}^D \rightarrow \{-1,+1\}$, produces a new label for each training sample according to some criterion. Domingos (1999) proposes MetaCost, which reassigns labels according to the

Bayesian minimum risk criterion:

$$g(\mathbf{x}) = \arg \max_{y \in \{-1,+1\}} c(y) \hat{p}(y|\mathbf{x}), \tag{8}$$

where $\hat{p}(y|\mathbf{x})$ is an estimate of the class posterior probability which is obtained using bagging (Breiman, 1996). It is typically the examples near the boundary which are re-labeled. The empirical risk follows as:

$$R^{\text{rel}}_{\text{emp}}(\theta) = -\frac{1}{N} \sum_n \ln p\left[g(\mathbf{x}_n)|\mathbf{x}_n;\theta\right].$$

As the re-labeling of (8) varies with the ratio of misclassification costs, the resulting cost-sensitive classifier is a function of the pcf and thus has the ability to yield the minimum risk estimator. The success of the method hinges on the estimation of the posterior probabilities; in the best case scenario, the re-labeling results in the cost-sensitive boundary approaching the minimum risk boundary. In contrast to the forthcoming methods, MetaCost does not reweight examples, and thus the risk function will not dominated by the examples of a rare but costly class. The technique may be used as a cost-sensitive pre-processing to any classification technique, and not just ML estimation of the posterior. In the case of ML, we maximize the log-likelihood but with the altered labels.

3.4 Weighted Likelihood

A standard approach for developing cost-sensitive classifiers is to weight the training examples according to the "costliness" of misclassifying that example. This procedure may be viewed in terms of an ERM loss function (Elkan, 2001; Zadrozny et al., 2003):

$$L(y,\mathbf{x},\theta) = -c(y,\mathbf{x}) \ln p(y|\mathbf{x};\theta),$$

such that the corresponding empirical risk takes the form:

$$R^{\text{wml}}_{\text{emp}}(\theta) = -\frac{1}{N} \sum_n c(y_n,\mathbf{x}_n) \ln p(y_n|\mathbf{x}_n;\theta). \tag{9}$$

Weighting the log likelihood has previously been studied as a tool to handle misspecification (Shimodaira, 2000). Note that such weighting of examples is equivalent to modifying the proportion of examples in the training set according to the weightings $c(y,\mathbf{x})$. If these weightings change, so does the cost function, and thus the classifier needs to be retrained. In principle, this technique allows the classification to choose the model in Θ which minimizes risk for the specified cost matrix. Moreover, example-weighting may easily be incorporated into the IRLS algorithm, yielding an iterative reweighted *weighted* least-squares scheme (McCullagh and Nelder, 1989) which minimizes (9)—in the appendix, we provide a MATLAB implementation.

Notice that if the misclassification costs are highly asymmetric, the more "costly" examples will be heavily emphasized in the empirical risk function. Furthermore, if there are only a few such examples, the classifier is at an increased risk of overfitting, since the *effective* number of examples is much less than N. This issue plagues any cost-sensitive method which weights the examples based on cost.

3.5 Sigmoidal Empirical Risk

In order to relate the risk of (1) with the empirical risk (4), the appropriate loss function is found to be:

$$L(y,\mathbf{x},\theta) = c(y,\mathbf{x})\mathbb{1}(\hat{y} \neq y).$$

Strict equivalence is achieved in the simplifying case of $c(y,\mathbf{x}) = c(y)\mathbb{1}(\hat{y} \neq y)$ assuming that there is no cost for a correct decision. Generally, the empirical risk follows as:

$$\begin{aligned} R_{\text{emp}}(\theta) &= \text{const.} + \frac{1}{N}\sum_n c(y_n,\mathbf{x}_n)\,\mathbb{1}(\hat{y}_n \neq y_n) \\ &= \text{const.} + \frac{1}{N}\sum_n c(y_n,\mathbf{x}_n)\,u[-y_n f(\mathbf{x}_n,\theta)] \end{aligned} \tag{10}$$

where the constant is a summation across the costs of a correct decision and $u(x)$ is the step function: $u(x) = \begin{cases} 1 & x > 0 \\ 0 & x \leq 0 \end{cases}$. Since our goal is to minimize (1), the optimization of the empirical risk under the direct loss of (10) is of great importance.

Elliott and Lieli (2007) propose to optimize a function closely related to (10) in an econometric context; employing the notation of this paper, the objective function maximized by Elliott and Lieli (2007) is written as:

$$R_{\text{el}}(\theta) = \sum_{n=1}^{N} y_n c(y_n,\mathbf{x}_n)\,\text{sgn}[f(\mathbf{x}_n,\theta) - \ln c_o(\mathbf{x}_n)], \tag{11}$$

and the authors propose simulated annealing to perform the optimization.

Note that both objective functions (10) and (11) are not differentiable due to the non-smoothness of u and sgn at zero, respectively. In the case of (10), we may approximate the step function with a sigmoid :

$$u(x) \approx \frac{1}{1+e^{-x}}. \tag{12}$$

Substituting (12) into (10), we obtain the following expression for the approximate empirical risk:

$$\tilde{R}_{\text{emp}}(\theta) = \frac{1}{N}\sum_n c(y_n,\mathbf{x}_n)\frac{1}{1+e^{y_n f(\mathbf{x}_n,\theta)}}.$$

The classifier θ which minimizes the empirical risk follows as:

$$\hat{\theta} = \arg\min_{\theta} \tilde{R}_{\text{emp}}(\theta). \tag{13}$$

The advantage of this approach is that it closely approximates (up to the ability of the sigmoid to approximate a step) the true empirical risk. On the other hand, the risk function is non-convex, complicating the minimization of (13).

3.6 Relating Sigmoidal Risk to Weighted ML

The need to minimize non-convex functions arises often in practice. A standard trick in optimizing a non-convex function is to optimize a convex upper bound of the original function. In this subsection, we show that the negative weighted log likelihood, a convex function, provides a tight upper bound of the sigmoidal empirical risk.

To see this, note the inequality:

$$z \leq -\ln(1-z), \;\; z \leq 1. \tag{14}$$

Substituting $z = \frac{1}{1+e^{y_n f(\mathbf{x}_n,\theta)}}$ into (14) results in:

$$\frac{1}{1+e^{y_n f(\mathbf{x}_n,\theta)}} \leq -\ln \frac{1}{1+e^{-y_n f(\mathbf{x}_n,\theta)}}.$$

Combining these inequalities over the training examples and assuming strict positivity of the weights $c(y_n, \mathbf{x}_n)$, we obtain:

$$\sum_n c(y_n,\mathbf{x}_n) \frac{1}{1+e^{y_n f(\mathbf{x}_n,\theta)}} \leq -\sum_n c(y_n,\mathbf{x}_n) \ln \frac{1}{1+e^{-y_n f(\mathbf{x}_n,\theta)}}.$$

As a result,

$$\tilde{R}_{\text{emp}}(\theta) \leq R^{\text{wml}}_{\text{emp}}(\theta).$$

This means that minimizing the weighted negative log-likelihood (9) minimizes an upper bound on the empirical risk. As will be shown numerically with upcoming examples, this bound is fairly tight (c.f., Figures 2 and 3). Since the negative weighted log-likelihood is convex, to circumvent the non-convexity of the sigmoidal empirical risk, one option is to employ the weighted likelihood loss function.

4. Experimental Evaluation

To assess the performance of the various cost-sensitive approaches (and its dependence on N), and to support the upper bound relationship of weighted ML to sigmoidal risk, we conducted an empirical evaluation of the various cost-sensitive learning approaches on several data sets. We first consider the case of example-independent and synthetic (i.e., exogenous to the features) costs. Later, we examine a data set where costs are endogenous and depend on the features. We employed a linear model set of the form $f(\mathbf{x},\theta) = \theta^T \mathbf{x} - b$. For all data sets, five-fold cross-validation was employed, and we plot the mean loss over the N examples (each example is used once for validation) along with standard errors of the mean.

The prevalence of the positive class is data-set dependent. The pcf was varied from 0.1 to 0.9 in increments of 0.1. The relationship between the misclassification cost ratio and the pcf is given by:

$$\frac{c(-1)}{c(+1)} = \frac{p(+1)}{p(-1)} \frac{(1-\text{pcf})}{\text{pcf}}.$$

Thus, a pcf of 0.5 corresponds to the case where the ratio of misclassification costs is inversely related to the ratio of class priors [i.e., $c(-1)p(-1) = c(+1)p(+1)$].

The generalization ability of all algorithms benefited from ℓ_2 regularization. Thus, the problem of cost-sensitive learning becomes one of penalized ERM:

$$\hat{\theta} = \arg\min_{\theta} \left\{ R_{\text{emp}}(\theta) + \frac{\lambda}{2} \|\theta\|^2 \right\}. \tag{15}$$

Where computationally feasible, the value of λ was determined using a nested cross-validation loop which tunes λ on the training set; the tuned value is then fed up to the outer cross-validation loop which evaluates performance on the test set.

The implementation of all cost-sensitive learning methods requires solving the optimization problem (15). For the 3 likelihood based methods, the Newton-Raphson IRLS algorithm (McCullagh and Nelder, 1989) was employed to solve the optimization. In order to solve the minimum risk optimization of (13), the Broyden-Fletcher-Goldfarb-Shanno (BFGS) quasi-Newton method (Fletcher, 2000) was employed in conjunction with multiple random restarts: a random starting vector is chosen, the BFGS algorithm is run, and the training risk evaluated. This process is repeated 100 times, and the final solution is selected as the classifier which yields the lowest training risk among the runs.

4.1 Gaussian Data

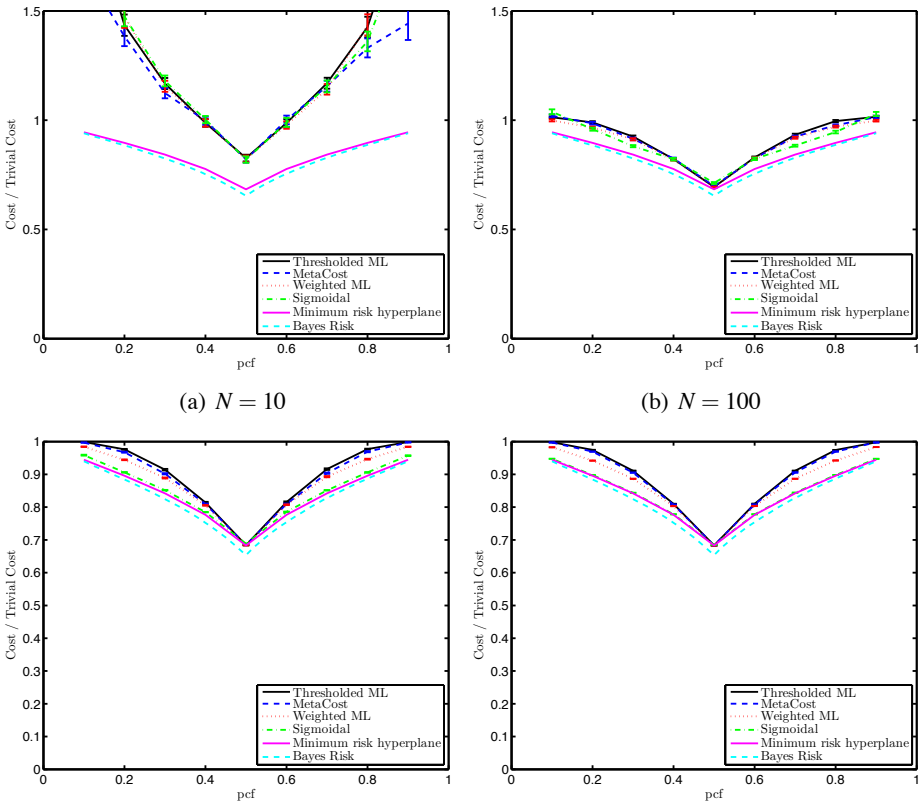
Before delving into real-world data sets, we evaluated the various cost-sensitive approaches on the Gaussian data described in Section 3. This example is instructive as we have a closed-form expression for the minimum attainable value of risk, and thus can evaluate the convergence properties with an increased sample size. Figure 2 depicts the cost curves[1] for various training sizes N. At $N = 10$, there is a substantial loss margin between the minimum risk plane and that which is achieved by the thresholded ML technique. However, it is clear that the cost-sensitive techniques are not able to provide reliable estimates of the minimum risk plane direction with such limited data. As the size of the training set increases, the sigmoidal risk estimator converges to the minimum risk plane. Notice, however, that with such large sample sizes, the thresholded ML technique is relatively adept at yielding risk values comparable to the true minimum. The reason for this is that the examples which are misclassified by thresholded ML and classified correctly by the the other techniques are mostly the low-cost examples (compare Fig. 1(b) with Fig. 1(c), for example). Also shown in all plots is the Bayes risk, which is the risk attained by the minimum risk quadric.

4.2 UCI Data

Next, we evaluate the classifiers on several real-world data sets obtained from the UCI database (Asuncion and Newman, 2007) as well as our previous work on the classification of electroencephalographic (EEG) data in a real-time detection task (Parra et al., 2008).[2] Table 1 summarizes the parameters used in the evaluation of these data sets.

From Figs. 3 (a) and (b), it is once again apparent that given a modest value of N, the benefits provided by cost-sensitive learners over the thresholded ML approach are not substantial. However, in Figs. 3 (c) and (d), one observes a tangible loss reduction of the sigmoidal risk estimator over

1. In addition to the ensemble-averaged risk, we also report standard errors of the mean, which follow as the sample standard deviation of the ensemble-averaged mean, divided by the square root of the number of ensembles.
2. Since only one "ensemble" is available in the experiments with real data, we treat the cost (at test time) of each example as an iid realization of the risk and report standard errors of the mean across examples.



(a) $N = 10$ (b) $N = 100$

(c) $N = 1000$ (d) $N = 10000$

Figure 2: Cost curves for Gaussian data with varying training set sizes. In (d), the thresholded ML and MetaCost curves are nearly equivalent.

Data set	$N(+)$	$N(-)$	D	λ	$p(+1)$

thresholded ML and MetaCost, whose curves overlap. Lastly, Fig. 3 (e) demonstrates the near-optimality of weighted ML and its close approximation of the sigmoidal risk minimizing solution. Note that for this heavily skewed data set, while the total number of examples is $N = 41438$, only 830 of these are positive exemplars. Note also that a skew in class prevalence leads to asymmetry in the resulting cost curves.

4.3 German Banking Data

Finally, we evaluated the risk minimizing classifiers on a publicly available data set collected by a German bank: http://www.stat.uni-muenchen.de/service/datenarchiv/kredit/kredit.html. The data set details the credit history and biographical information of $N = 1000$ past loan applicants, as well

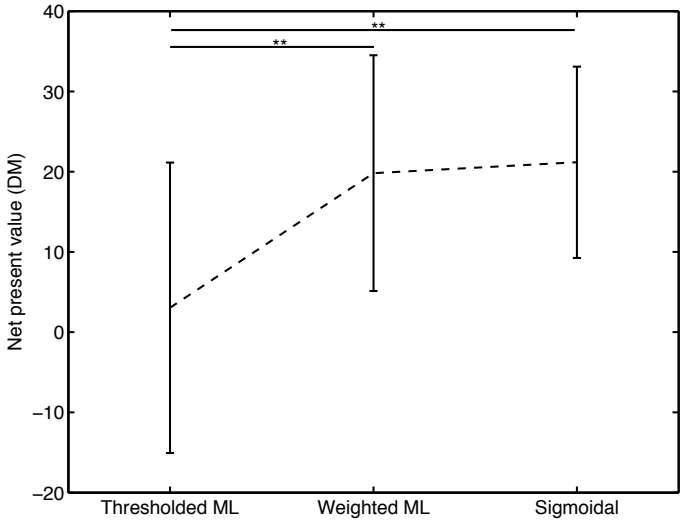

Figure 4: NPV per applicant: means and standard errors. Solid horizontal lines indicate statistical significance at the $p = 0.01$ level.

as whether the loan was repaid. This data set has been used previously to evaluate a novel profit-maximizing decision rule in the econometrics literature (Lieli and White, 2010).

Upon receiving a loan request, the bank decides either to grant the loan at a certain interest rate, or rather to invest the loan amount in a risk-free government bond. In this application, it is easier to work with benefits rather than costs; as such, the net present value (NPV), measured in Deutsche Marks (DM) of extending the loan must be compared with the NPV of rejecting the application, which is zero as outlined in Lieli and White (2010). The NPV of extending the loan depends on whether the loan is repaid, and thus the optimal decision rule takes into account the probability of repayment as well as the potential profit to be made on the loan. Thus, the aim of the evaluation is to predict, from an applicant's credit history and biographical information, the likelihood of the applicant repaying the loan which he/she is seeking.

In the framework described in the earlier sections, we have $c(y,\mathbf{x}) = y \cdot \pi(y,\mathbf{x})$, where $\pi(y,\mathbf{x})$ denotes the NPV associated with predicting $\hat{y} = +1$ when the truth is y (repayment: $y = +1$, default: $y = -1$). Please refer to Lieli and White (2010) for the precise mathematical relationship between the NPV π and the individual features in $\mathbf{x}$. In the evaluation, we used the $D = 5$ dimensional feature set chosen by Lieli and White (2010), as well as their proxies for the interest and risk-free government rates. Note that the "costs" are both example-dependent and endogenous to the problem. We conducted a leave-one-out cross-validation of the thresholded ML, weighted ML, and sigmoidal risk estimators on this $N = 1000$ example data set (MetaCost is not applicable to problems with example-dependent costs).

Figure 4 displays the mean NPV per applicant, along with standard errors. On average, the means obtained by the thresholded ML, weighted ML, and sigmoidal risk estimators are DM 3.0 , DM 19.8 , and DM 21.2 . The standard errors are given by DM 18.1 , DM 14.7, and DM 11.9, respectively (a negative value of NPV indicates an overall loss for the classification scheme). We

performed pairwise sign-tests of statistical significance to determine if performance differs significantly for the classifiers. A statistically significant improvement in NPV is achieved by both WML and sigmoidal risk estimators over the thresholded ML solution ($p < 0.01$). On the other hand, statistical significance cannot be established between WML and sigmoidal risk ($p \approx 0.9$). This empirical finding supports the analytical result of negative weighted log likelihood upper bounding empirical loss.

5. Discussion

It is interesting to point out the process which led to the findings presented in this paper. Initially, we were motivated by the observation that with a misspecified model, the direction of the minimum risk hyperplane is a function of the ratio of misclassification costs and the class priors. Since the ML approach is inherently to shift the minimum error hyperplane, we sought to develop an estimator which, given a ratio of misclassification costs, will find the direction required to minimize risk rather than maximizing likelihood. The expectation was that such an estimator would provide large performance gains over the ML approach. This led us to the development of the sigmoidal empirical risk minimizer. During the algorithm evaluation process, several findings emerged. Firstly, the search for the minimum risk hyperplane is non-trivial: regularization techniques proved to be necessary, particularly in the case of a limited training set. Moreover, both the existing and proposed cost-sensitive learning techniques yield the greatest benefits over thresholded ML when presented with large amounts of training data. When abundant data is available, the sigmoidal risk estimator typically outperforms all other methods, but weighted ML yields quite comparable values.

When the model set includes the true posterior, the threshold-shifted ML approach is optimal. This naturally brings us to the following question: why not employ a rich model set (for example, a multi-layer neural network), estimate its parameters using ML, and then shift the threshold by the log of the misclassification cost ratio? With an infinite amount of training data, we are sure to arrive at the lowest attainable risk. However, there are a few reasons why this procedure may not be desirable: a rich model set consists of many parameters, which in turn requires a large amount of training data to prevent over-fitting. From the so-called *structural risk minimization* principle, it is well-known that a simpler model set yields empirical risks that are closer to the true risk (Vapnik, 1998). Moreover, the optimality of the ML solution is not guaranteed for a finite amount of data. Thus, rates of convergence are key to determining the best approach.

In general, the choice of model complexity hinges upon several factors: the dimensionality of the feature space in relation to the number of available examples, the signal-to-noise ratio, and also the skew in class prevalence. For example, in applications involving a rare and expensive class, the key is to yield accurate decisions for this infrequent class. If the number of such examples is low, then even if the number of overall examples is high, a complex model will generally be undesirable. In other words, the effective sample size is closer to the number of costly examples than the entire sample size N. Consequently, the number of free parameters needs to be limited to prevent overfitting. The design issue in cost-sensitive learning is thus how best to use these few degrees of freedom: whether to "prioritize" correct decisions on the costly training examples, or rather to "spend" the degrees of freedom on achieving the best model fit.

The results with Gaussian data presented above appear to indicate that the sigmoidal risk minimizer tends to the true minimum risk model given enough data. However, the weighted ML estimator provides a tight upper bound on the sigmoidal empirical risk and thus this solution is not far

from optimal. Given that the negative weighted likelihood is convex, weighted ML thus becomes the preferred cost-sensitive technique.

Lastly, as seen in Figure 2, both the opportunity and the challenge in cost-sensitive learning lies in the ability to estimate the minimum risk model with limited data. Thus, the focus going forward should be on sparse (i.e., with few examples relative to the dimensionality of the feature space) inference of the minimum risk classifier.

6. Conclusion

This paper has elucidated the role of the specification of the model set in the problem of learning with asymmetric costs or class prevalences. It was shown that in the case of the model family including the true posterior, thresholding the ML solution is guaranteed to asymptotically minimize risk. In this case, cost-sensitive learning is synonymous with threshold adjustment. On the other hand, with a misspecified model, the risk minimizing solution is a function of the misclassification cost ratios, and thresholding the ML estimate is sub-optimal. A novel estimator based on a sigmoidal estimation of the empirical risk was presented and shown to outperform conventional techniques provided enough data; however, the negative weighted log likelihood was analytically and empirically shown to tightly upper bound the sigmoidal loss. Thus, we advocated for the weighted ML as the preferred cost-sensitive learning technique.

Abstract

This paper introduces a Bayesian algorithm for constructing predictive models from data that are optimized to predict a target variable well for a particular instance. This algorithm learns Markov blanket models, carries out Bayesian model averaging over a set of models to predict a target variable of the instance at hand, and employs an instance-specific heuristic to locate a set of suitable models to average over. We call this method the instance-specific Markov blanket (ISMB) algorithm. The ISMB algorithm was evaluated on 21 UCI data sets using five different performance measures and its performance was compared to that of several commonly used predictive algorithms, including nave Bayes, C4.5 decision tree, logistic regression, neural networks, *k*-Nearest Neighbor, Lazy Bayesian Rules, and AdaBoost. Over all the data sets, the ISMB algorithm performed better on average on all performance measures against all the comparison algorithms.

Keywords: instance-specific, Bayesian network, Markov blanket, Bayesian model averaging

1. Introduction

Prediction is a central problem in machine learning that involves inducing a model from a set of training instances that is then applied to future instances to predict a target variable of interest. Several commonly used predictive algorithms, such as logistic regression, neural networks, decision trees, and Bayesian networks, typically induce a single model from a training set of instances, with the intent of applying it to all future instances. We call such a model a *population-wide model* because it is intended to be applied to an entire population of future instances. A population-wide model is optimized to predict well on average when applied to expected future instances.

Recent research in machine learning has shown that inducing models that are specific to the particular features of a given instance can improve predictive performances (Gottrup et al., 2005). We call such a model an *instance-specific model* since it is constructed specifically for a particular instance (case). The structure and parameters of an instance-specific model are specialized to the particular features of an instance, so that it is optimized to predict especially well for that instance. The goal of inducing an instance-specific model is to obtain optimal prediction for the instance at hand. This is in contrast to the induction of a population-wide model where the goal is to obtain optimal predictive performance on average on all future instances.

There are several possible approaches for learning predictive models that are relevant to a single instance. One approach is to learn a model from a subset of the training data set that consists of instances that are similar in some way to the instance at hand. Another approach is to learn a

model from a subset of variables that are pertinent in some fashion to the instance at hand. A third approach, applicable to model averaging where a set of models is collectively used for prediction, is to identify a set of models that are most relevant to prediction for the instance at hand.

In this paper, we describe a new instance-specific method for learning predictive models that (1) uses Bayesian network models, (2) carries out Bayesian model averaging over a set of models to predict the target variable for the instance at hand, and (3) employs an instance-specific heuristic to identify a set of suitable models to average over. The remainder of this section gives a brief description of each of these characteristics.

Bayesian network (BN) models are probabilistic graphical models that provide a powerful formalism for representation, reasoning and learning under uncertainty (Pearl, 1988; Neapolitan, 2003). These graphical models are also referred to as probabilistic networks, belief networks or Bayesian belief networks. A BN model combines a graphical representation with numerical information to represent a probability distribution over a set of random variables in a domain. The graphical representation constitutes the BN structure, and it explicitly highlights the probabilistic independencies among the domain variables. The complementary numerical information constitutes the BN parameters, which quantify the probabilistic relationships among the variables. The instance-specific method that we describe in this paper uses Markov blanket models, which are a special type of BN models.

Typically, methods that learn predictive models from data, including those that learn BN models, perform model selection. In model selection a single model is selected that summarizes the data well; it is then used to make future predictions. However, given finite data, there is uncertainty in choosing one model to the exclusion of all others, and this can be especially problematic when the selected model is one of several distinct models that all summarize the data more or less equally well. A coherent approach to dealing with the uncertainty in model selection is Bayesian model averaging (BMA) (Hoeting et al., 1999). BMA is the standard Bayesian approach wherein the prediction is obtained from a weighted average of the predictions of a set of models, with more probable models influencing the prediction more than less probable ones. In practical situations, the number of models to be considered is enormous and averaging the predictions over all of them is infeasible. A pragmatic approach is to average over a few good models, termed *selective Bayesian model averaging*, which serves to approximate the prediction obtained from averaging over all models. The instance-specific method that we describe in this paper performs selective BMA over a set of models that have been selected in an instance-specific fashion.

The instance-specific method described here learns both the structure and parameters of BNs automatically from data. The instance-specific characteristic of the method is motivated by the intuition that in constructing predictive models, all the available information should be used including available knowledge of the features of the current instance. Specifically, the instance-specific method uses the features of the current instance to inform the BN learning algorithm to selectively average over models that differ considerably in their predictions for the target variable of the instance at hand. The differing predictions of the selected models are then combined to predict the target variable.

2. Characterization of Instance-Specific Models

Figure 1 illustrates the key difference between population-wide and instance-specific models: the instance-specific model is constructed from data in the training set, as well as, from the features

about the particular instance to which it will be applied. In contrast, the population-wide model is constructed only from data in the training set. Thus, intuitively, the additional information available to the instance-specific method can facilitate the induction of a model that provides better prediction for the instance at hand. In instance-specific modeling, different instances will potentially result in different models, because the instances contain potentially different values for the features.[1] The instance-specific models may differ in the variables included in the model (variable selection), in the interaction among the included variables (encoded in the structure of the model), and in the strength of the interaction (encoded in the parameters of the model). Another approach is to select a subset of the training data that are similar in their feature values to those of the instance at hand and learn the model from the subset. A generalization of this is to weight the instances in the training data set such that those that are more similar to the instance at hand are assigned greater weights than others, and then learn the model from the weighted data set. The following are two illustrative examples where instance-specific methods may perform better than population-wide methods.

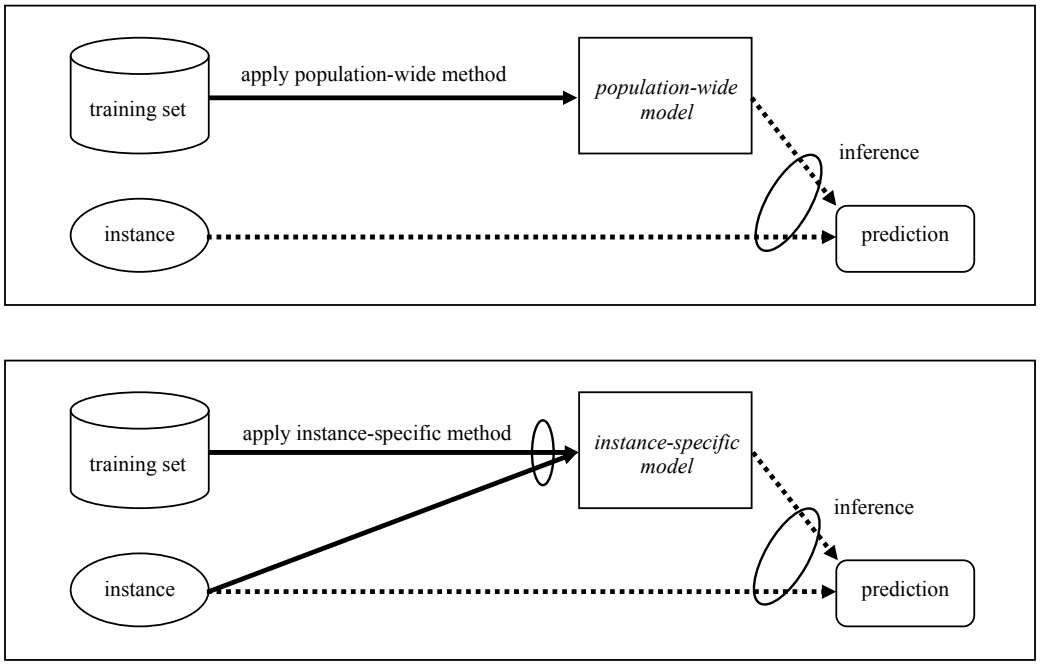

Figure 1: A general characterization of the induction of and inference in population-wide (top panel) and instance-specific (bottom panel) models. In the bottom panel, there is an extra arc from *instance* to *model*, because the structure and parameters of the model are influenced by the features of the instance at hand.

2.1 Variable Selection

Many model induction methods implicitly or explicitly perform variable selection, a process by which a subset of the domain variables is selected for inclusion in the model. For example, logistic

1. A feature is a variable-value pair, that is, a variable that has been assigned a value.

regression is often used with a stepwise variable selection process. An instance-specific version of logistic regression could, for example, select different variables for different instances being predicted, compared to the standard population-wide version that selects a single subset of variables. Consider a simple example where a gene G that has several alleles. Suppose that allele a1 is rare, and it is the only allele that predicts the development of disease D; indeed, it predicts D with high probability. For future instances, the aim is to predict $P(D|G)$. In a population-wide logistic regression model, G may not be included as a predictor (variable) of D, because in the vast majority of instances in the data set $G \neq a1$ and D is absent, and having G as a predictor would just increase the overall noise in predicting D. In contrast, if there is an instance at hand in which $G = a1$, then the training data may contain enough instances to indicate that D is highly likely. In this situation, G would be added as a predictor in an instance-specific model. Thus, for an instance in which $G = a1$, the typical population-wide logistic regression model would predict poorly, but an instance-specific model would predict well.

This idea can be extended to examples with more than one predictor, in which some predictors are characterized by having particular values that are relatively rare but strongly predictive for the outcome. A population-wide model tends to include only those predictors that on average provide the best predictive performance. In contrast, an instance-specific model will potentially include predictors that are highly predictive for the particular instance at hand; such predictors may be different from those included in the population-wide model.

2.2 Decision Theoretic Comparison of Population-Wide and Instance-Specific Models

We first introduce some notation and definitions and then compare population-wide with instance-specific models in decision theoretic terms. Capital letters like X, Z, denote random variables and corresponding lower case letters, x, z, denote specific values assigned to them. A feature is a specification of a variable and its value. Thus, $X = x$ is a feature that specifies that variable X is assigned the value x. Bold upper case letters, such as $\mathbf{X}$, $\mathbf{Z}$, represent sets of variables or random vectors, and their realization is denoted by the corresponding bold lower case letters, $\mathbf{x}$, $\mathbf{z}$. A feature vector is a list of features. Thus, $\mathbf{X} = \mathbf{x}$ is a feature vector that specifies that the variables in $\mathbf{X}$ have the values given by $\mathbf{x}$. In addition, Z denotes the target variable (class variable) being predicted, $\mathbf{X}$ denotes the set of predictor variables, M denotes a model (including both its structure and parameters), D denotes the training data set, $C^i =< \mathbf{X}^i, Z^i >$ denotes a generic training instance in D and $C^t =< \mathbf{X}^t, Z^t >$ denotes a generic test instance that is not in D. A test instance t is one in which the unknown value of the target variable Z^t is to be predicted from the known values of the predictors $\mathbf{X}^t$ and the known values of $< \mathbf{X}^i, Z^i >$ of a set of training instances.

A probabilistic *model* is a family of probability distributions indexed by a set of parameters. *Model selection* refers to the problem of using data to select one model from a set of models under consideration (Wasserman, 2000). The process of selecting a model typically involves model class selection (e.g., logistic regression, BN), variable selection, and parameter estimation. *Model averaging* refers to the process of estimating some quantity (e.g., prediction of the value of a target variable) under each of the models under consideration and obtaining a weighted average of their estimates (Wasserman, 2000).

Model selection can be done using either non-Bayesian or Bayesian approaches. Non-Bayesian methods of model selection include choosing among competing models by maximizing the likelihood, by maximizing a penalized version of the likelihood or by maximizing some measure of

interest (e.g., accuracy) using cross-validation. Use of multiple models to improve performance can also be done using either non-Bayesian or Bayesian approaches. Ensemble techniques such as bagging and boosting are non-Bayesian approaches that combine multiple models to create a new better performing model. In both bagging and boosting, the data are resampled several times, a model is constructed from each sample, and the predictions of the individual models are combined to obtain the final prediction. In the non-Bayesian approach, the heuristics used in model selection and model combination are typically different. In contrast, the Bayesian approach to model selection and model combination both involve computing the posterior probability of each model under consideration. In Bayesian model selection the single model found that has the highest posterior probability is chosen. The Bayesian model combination technique is called model averaging where the combined prediction is the weighted average of the individual predictions of the models with the model posterior probabilities comprising the weights.

When the goal is prediction of future data or future values of the target variable, BMA is preferred, since it suitably incorporates the uncertainty about the identity of the true model. However, sometimes interest is focused on a single model. For example, a single model may be useful for providing insight into the relationships among the domain variables or can be used as a computationally less expensive method for prediction. In such cases, Bayesian model selection maybe preferred to BMA. However, the optimal Bayesian approach is to perform model averaging, and thus, model selection is at best an approximation to model averaging.

Population-wide model selection and instance-specific model selection are characterized in decision theoretic terms as follows. In this paper, all conditional probabilities have a conditioning event K, which represents background knowledge and which we will leave implicit for notational simplicity. Given training data D and a generic test instance $< \mathbf{X}^t, Z^t >$, the *optimal population-wide model* is:

$$\arg\max_{M} \left\{ \sum_{\mathbf{X}^t} U\left[P(Z^t|\mathbf{X}^t,D), P(Z^t|\mathbf{X}^t,M)\right] P(\mathbf{X}^t|D) \right\} \tag{1}$$

where the utility function U gives the utility of approximating the *Bayes optimal estimate* $P(Z^t|\mathbf{X}^t,D)$ with the estimate $P(Z^t|\mathbf{X}^t,M)$ obtained from model M. For a model M, Expression 1 considers all possible instantiations of $\mathbf{X}^t$ and for each instantiation computes the utility of estimating $P(Z^t|\mathbf{X}^t,D)$ with the specific model estimate $P(Z^t|\mathbf{X}^t,M)$, and weights that utility by the posterior probability of that instantiation. The maximization is over the models M in a given model space.

The *Bayes optimal estimate* $P(Z^t|\mathbf{X}^t,D)$ in Expression 1 is obtained by combining the estimates of all models (in a given model space) weighted by their posterior probabilities:

$$P(Z^t|\mathbf{X}^t,D) = \int_M P(Z^t|\mathbf{X}^t,M)P(M|D)dM. \tag{2}$$

The term $P(\mathbf{X}^t|D)$ in Expression 1 is given by:

$$P(\mathbf{X}^t|D) = \int_M P(\mathbf{X}^t|M)P(M|D)dM. \tag{3}$$

The *optimal instance-specific model* for estimating Z^t is the one that maximizes the following:

$$\arg\max_{M} \left\{ U\left[P(Z^t|\mathbf{x}^t,D), P(Z^t|\mathbf{x}^t,M)\right] \right\}, \tag{4}$$

where $\mathbf{x}^t$ are the values of the predictors of the test instance $\mathbf{X}^t$ for which the target variable Z^t is to be predicted. The *Bayes optimal instance-specific prediction* $P(Z^t|\mathbf{X}^t, D)$ is derived using Equation 2, for the special case in which $\mathbf{X}^t = \mathbf{x}^t$, as follows:

$$P(Z^t|\mathbf{x}^t, D) = \int_M P(Z^t|\mathbf{x}^t, M)P(M|D)dM.$$

The difference between the population-wide and the instance-specific model selection can be noted by comparing Expressions 1 and 4. Expression 1 for the population-wide model selects the model that on average will have the greatest utility. Expression 4 for the instance-specific model, however, selects the model that will have the greatest utility for the specific instance $\mathbf{X}^t = \mathbf{x}^t$. For predicting Z^t given instance $\mathbf{X}^t = \mathbf{x}^t$, application of the model selected using Expression 1 can never have an expected utility greater than the application of the model selected using Expression 4. This observation provides support for developing instance-specific models.

Equations 2 and 3 carry out BMA over all models in some specified model space. Expressions 1 and 4 include Equation 2; thus, these expressions for population-wide and instance-specific model selection, respectively, are theoretical ideals. Moreover, Equation 2 is the Bayes optimal prediction of Z^t. Thus, in order to do optimal model selection, the optimal prediction obtained from BMA must already be known.

Model selection, even if performed optimally, ignores the uncertainty inherent in choosing a single model based on limited data. BMA is a normative approach for dealing with the uncertainty in model selection. Such averaging is primarily useful when no single model in the model space under consideration has a dominant posterior probability. However, since the number of models in practically useful model spaces is enormous, *exact BMA*, where the averaging is done over the entire model space, is usually not feasible. That is, it is usually not computationally feasible to solve for the exact solution given by Equation 2. In such cases, *selective BMA* is typically performed, where the averaging is done over a selected subset of models.

BMA has been shown to improve predictive performance, and several examples of significant decrease in prediction errors with the use of BMA are described by Hoeting et al. (1999). However, in other cases BMA has not proved to be better than ensemble techniques. For example, uniform averaging was shown by Cerquides and Mantaras (2005) to have better classification performance than BMA for one dependence estimators. This may be because, as Minka (2002) points out, BMA is better described as a method for 'soft model selection' rather than a technique for model combination.

3. Related Work

There exists a vast literature in machine learning, data mining and pattern recognition that is concerned with the problem of predictive modeling and supervised learning. We briefly describe some of the aspects of the similarity-based methods and instance-specific methods because these methods are most closely relevant to the present paper. Similarity-based methods are characterized by the use of a similarity (or distance) measure necessary for measuring the similarity between instances. Instance-specific methods, on the other hand, learn an explicit model or models from the training instances that are then applied to the test instance. The induction of a model or set of models are influenced by the values of the features of the test instance, and a similarity measure is not used.

3.1 Similarity-Based Methods

These methods are also known as memory-based, case-based, instance-based, or exemplar-based learners. They (1) use a similarity or a distance measure, (2) defer most of the processing until a test instance is encountered, (3) combine the training instances in some fashion to predict the target variable in the test instance, and (4) discard the answer and any intermediate results after the prediction. Typically, no explicit model is induced from the training instances at the time of prediction (Aha, 1998). The similarity measure evaluates the similarity between the test instance and the training instances and selects the appropriate training instances and their relative weights in response to the test instance (Zhang et al., 1997). The selected training instances can be equally weighted or weighted according to their similarity to the test instance. To predict the target variable in the test instance, the values of the target variable in the selected training instances are combined in some simple fashion such as majority vote, simple numerical average or fitted with a polynomial.

The *nearest-neighbor technique* is the canonical similarity-based method. When a test instance is encountered, the training instance that is most similar to the test instance is located and its target value is returned as the prediction (Cover and Hart, 1967). A straight-forward extension to the nearest-neighbor technique is the *k-Nearest Neighbor*(*k*NN) method. For a test instance, this method selects the k most similar training instances and either averages or takes a majority vote of their target values. Another extension is the distance-weighted k-Nearest Neighbor method. This weights the contribution of each of the k most similar training instances according to its similarity to the test instance, assigning greater weights to more similar instances (Dasarathy, 1991). A further extension is locally weighted regression that selects instances similar to the test instance, weights them according to their similarity, and performs regression to predict the target (Atkeson et al., 1997).

One drawback of the similarity-based methods is that they may perform poorly when predictors are redundant, irrelevant or noisy. To make the similarity metrics more robust, variable selection and variable weighting have been employed.

3.2 Instance-Specific Methods

Instance-specific methods are model-based methods that take advantage of the features in the test instance while inducing a model. Such methods are not as reliant on a similarity measure, if they use one at all, as the similarity-based methods.

Friedman et al. (1996) describe one such algorithm called LazyDT that searches for the best CART-like decision tree for a test instance. As implemented by the authors, LazyDT did not perform pruning and processed only nominal variables. The algorithm was compared to ID3 and C4.5 (standard population-wide methods for inducing decision trees), each with and without pruning. When evaluated on 28 data sets from the UCI Machine Learning repository, LazyDT generally out-performed both ID3 and C4.5 without pruning and performed slightly better than C4.5 with pruning.

Ting et al. (1999) developed a framework for inducing rules in a lazy fashion that are tailored to the features of the test instance. Zheng and Webb (2000) describe an implementation of this framework called the Lazy Bayesian Rules (LBR) learner that induces a rule tailored to the features of the test instance that is then used to classify it. A LBR rule consists of (1) a conjunction of the features (variable-value pairs) present in the test instance as the antecedent, and (2) a local naive Bayes classifier as the consequent. The structure of the local naive Bayes classifier consists of

the target variable as the parent of all other variables that do not appear in the antecedent, and the parameters of the classifier are estimated from those training instances that satisfy the antecedent. A greedy step-forward search selects the optimal LBR rule for a test instance to be classified. In particular, each predictor is added to the antecedent of the current best rule and evaluated for whether it reduces the overall error rate on the training set that is estimated by cross-validation. The predictor that most reduces the overall error rate is added to the antecedent and removed from the consequent, and the search continues; if no single predictor move can decrease the current error rate, then the search halts and the current rule is applied to predict the outcome for the test instance. LBR is an example of an instance-specific method that uses feature information available in the test instance to direct the search for a suitable model in the model space.

The performance of LBR was evaluated by Zheng and Webb (2000) on 29 data sets from the UCI Machine Learning repository and compared to that of seven algorithms: a nave Bayes classifier (NB), a decision tree algorithm (C4.5), a Bayesian tree learning algorithm (NBTree) (Kohavi, 1996), a constructive Bayesian classifier that replaces single variables with new variables constructed from Cartesian products of existing nominal variables (BSEJ) (Pazzani, 1998), a selective naive Bayes classifier that deletes irrelevant variables using Backward Sequential Elimination (BSE) (Pazzani, 1995), and LazyDT, which is described above. Based on ten three-fold cross validation trials (for a total of 30 trials), LBR achieved the lowest average error rate across the 29 data sets. The average relative error reduction of LBR over NB, C4.5, NBTree, BSEJ, BSE and LazyDT were 9%, 10%, 2%, 3%, 5% and 16% respectively. LBR performed significantly better than all other algorithms except BSE; compared to BSE its performance was better but not statistically significantly so.

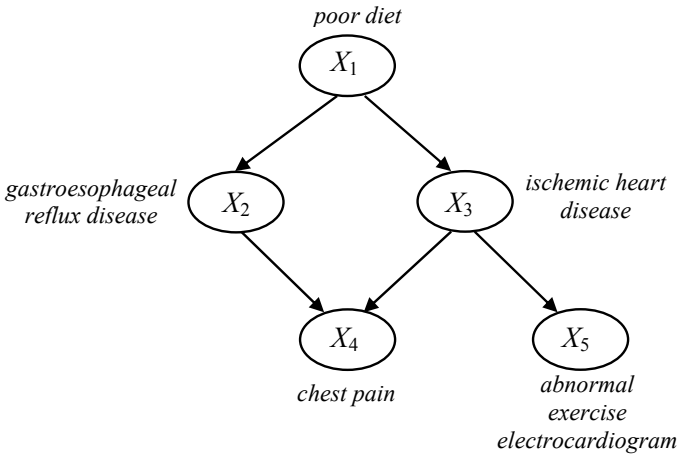
The instance-specific algorithms like LazyDT and LBR have limitations in that they can process only discrete variables, and continuous variables have to be discretized. Also, they are computationally more intensive than many other learning algorithms. However, they have been shown to have better accuracy than several of the population-wide methods.

4. Bayesian Networks

A Bayesian network (BN) is a probabilistic model that combines a graphical representation (the BN structure) with quantitative information (the BN parameterization) to represent a joint probability distribution over a set of random variables (Pearl, 1988; Neapolitan, 2003). More specifically, a BN model M representing the set of random variables $\mathbf{X}$ for some domain consists of a pair G, θ_G. The first component G is a directed acyclic graph (DAG) that contains a node for every variable in $\mathbf{X}$ and an arc between a pair of nodes if the corresponding variables are directly probabilistically dependent. Conversely, the absence of an arc between a pair of nodes denotes probabilistic independence between the corresponding variables. In this paper, the terms variable and node are used interchangeably in the context of random variables being modeled by nodes in a BN. Thus, a variable X_i in the domain of interest is represented by a node labeled X_i in the BN graph. Note that the phrase *BN structure* refers only to the graphical structure G, while the term BN (model) refers to both the structure G and a corresponding set of parameters θ_G.

The terminology of kinship is used to denote various relationships among nodes in a graph. These kinship relations are defined along the direction of the arcs. Predecessors of a node X_i in G, both immediate and remote, are called the *ancestors* of X_i. In particular, the immediate predecessors of X_i are called the *parents* of X_i. The set of parents of X_i in G is denoted by $\mathbf{Pa}(X_i, G)$ or more simply as $\mathbf{Pa}_i$ when the BN structure is obvious from the context. In a similar fashion, successors of

X_i in G, both immediate and remote, are called the *descendants* of X_i, and the immediate successors are called the *children* of X_i. A node X_j is termed a *spouse* of X_i if X_j is a parent of a child of X_i. The set of nodes consisting of a node X_i and its parents is called the *family* of X_i. Figure 2 gives an illustrative example of a simple hypothetical BN, where the top panel shows the graphical component G of the BN. In the figure, the variable *poor diet* is a parent of the variable *ischemic heart disease* as well as a parent of the variable *gastroesophageal reflux disease*. The variable *chest pain* is a child of the variable *lung cancer* as well as a child of the variable *gastroesophageal reflux disease*, and the variables *ischemic heart disease* and *abnormal electrocardiogram* are descendants of the variable *poor diet*.



Node X_1	$P(X_1 = \text{F}) = 0.70$	$P(X_1 = \text{T}) = 0.30$
Node X_2	$P(X_2 = \text{F} \mid X_1 = \text{F}) = 0.97$	$P(X_2 = \text{T} \mid X_1 = \text{F}) = 0.03$
	$P(X_2 = \text{F} \mid X_1 = \text{T}) = 0.96$	$P(X_2 = \text{T} \mid X_1 = \text{T}) = 0.04$
Node X_3	$P(X_3 = \text{F} \mid X_1 = \text{F}) = 0.94$	$P(X_3 = \text{T} \mid X_1 = \text{F}) = 0.06$
	$P(X_3 = \text{F} \mid X_1 = \text{T}) = 0.96$	$P(X_3 = \text{T} \mid X_1 = \text{T}) = 0.08$
Node X_4	$P(X_4 = \text{F} \mid X_2 = \text{F}, X_3 = \text{F}) = 0.90$	$P(X_4 = \text{T} \mid X_2 = \text{F}, X_3 = \text{F}) = 0.10$
	$P(X_4 = \text{F} \mid X_2 = \text{F}, X_3 = \text{T}) = 0.40$	$P(X_4 = \text{T} \mid X_2 = \text{F}, X_3 = \text{T}) = 0.60$
	$P(X_4 = \text{F} \mid X_2 = \text{T}, X_3 = \text{F}) = 0.50$	$P(X_4 = \text{T} \mid X_2 = \text{T}, X_3 = \text{F}) = 0.50$
	$P(X_4 = \text{F} \mid X_2 = \text{T}, X_3 = \text{T}) = 0.25$	$P(X_4 = \text{T} \mid X_2 = \text{T}, X_3 = \text{T}) = 0.75$
Node X_5	$P(X_5 = \text{F} \mid X_3 = \text{F}) = 0.80$	$P(X_5 = \text{T} \mid X_3 = \text{F}) = 0.20$
	$P(X_5 = \text{F} \mid X_3 = \text{T}) = 0.25$	$P(X_5 = \text{T} \mid X_3 = \text{T}) = 0.75$

Figure 2: A simple hypothetical Bayesian network for a medical domain. All the nodes represent binary variables, taking values in the domain T, F where T stands for True and F for False. The graph at the top represents the Bayesian network structure. Associated with each variable (node) is a conditional probability table representing the probability of each variable's value conditioned on its parent set. (Note: these probabilities are for illustration only; they are not intended to reflect frequency of events in any actual patient population.)

The second component θ_G represents the parameterization of the probability distribution over the space of possible instantiations of $\mathbf{X}$ and is a set of local probabilistic models that encode quantitatively the nature of dependence of each variable on its parents. For each node X_i there is a probability distribution (that may be discrete or continuous) defined on that node for each state of its parents. The set of all the probability distributions associated with all the nodes comprises the complete parameterization of the BN. The bottom panel in Figure 2 gives an example of a set of parameters for G. Taken together, the top and bottom panels in Figure 2 provide a fully specified structural and quantitative representation for the BN.

4.1 Markov Blanket

The *Markov blanket* of a variable X_i, denoted by $\mathrm{MB}(X_i)$, defines a set of variables such that conditioned on $\mathrm{MB}(X_i)$ is conditionally independent of all variables given $\mathrm{MB}(X_i)$ for joint probability distributions consistent with BN in which $\mathrm{MB}(X_i)$ appears (Pearl, 1988). The minimal Markov blanket of a node X_i, which is sometimes called its Markov boundary, consists of the parents, children, and children's parents of X_i. In this paper, we refer to the minimal Markov blanket as the Markov blanket (MB). This entails that the variables in $\mathrm{MB}(X_i)$ are sufficient to determine the probability distribution of X_i. Since d-separation is applied to the graphical structure of a BN to identify all conditional independence relations, it can also be applied to identify the MB of a node in a BN. The MB of a node X_i consists of its parents, its children, and its children's parents and is illustrated in Figure 3. The parents and children of X_i are directly connected to it. In addition, the spouses are also included in the MB, because of the phenomenon of explaining away which refers to the observation that when a child node is instantiated its parents in general are statistically dependent. Analogous to BNs, the *MB structure* refers only to the graphical structure while the MB (model) refers to both the structure and a corresponding set of parameters.

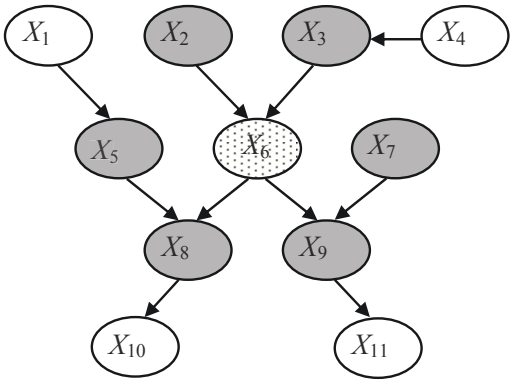


Figure 3: Example of a Markov blanket. The Markov blanket of the node X_6 (shown stippled) comprises the set of parents, children and spouses of the node and is indicated by the shaded nodes. The nodes in the Markov blanket include X_2 and X_3 as parents, X_8 and X_9 as children, and X_5 and X_7 as spouses of X_6. X_1, X_4, X_{10} and X_{11} are not in the Markov blanket of X_6.

The MB of a node is noteworthy because it identifies all the variables that shield the node from the rest of the network. In particular, when interest centers on the distribution of a specific target

node, as is the case in classification, the structure and parameters of only the MB of the target node need be learned.

4.2 Markov Blanket Algorithms

Many approaches for learning general BNs as well as for learning MBs from data have been described in the literature. Here we briefly review algorithms that learn MB classifiers. One of the earliest described MB learning algorithms is the Grow-Shrink (GS) Markov blanket algorithm that orders the variables according to the strength of association with the target and uses conditional independence tests to find a reduced set of variables estimated to be the MB (Margaritis and Thrun, 1999). Madden (2002a,b) described the Markov Blanket Bayesian Classifier (MBBC) algorithm that constructs an approximate MB classifier using a Bayesian score for evaluating the network. The algorithm consists of three steps: the first step identifies a set of direct parents and children of the target, the second step identifies a set of parents of the children, and the third step identifies dependencies among the children. The MBBC was competitive in terms of speed and accuracy relative to Nave Bayes, Tree-Augmented Nave Bayes and general Bayesian networks, when evaluated on a large set of UCI data sets.

Several MB algorithms have been developed in the context of variable selection and learning local causal structures around target variables of interest. Koller and Sahami (1996) showed that the optimal set of variables to predict a target is its MB. They proposed a heuristic entropy-based procedure (commonly referred to as the KS algorithm) that assumes that the target influences the predictor variables and that the variables most strongly associated with the target are in its MB. The KS algorithm was not guaranteed to succeed. Tsamardinos and Aliferis (2003) showed that for faithful distributions, the MB of a target variable is exactly the set of strongly relevant features, and developed the Incremental Association Markov Blanket (IAMB) to identify it. This algorithm has two stages: a growing phase that adds potential predictor variables to the MB and a shrinking phase that removes the false positives that were added in the first phase. Based on the faithfulness assumption, Tsamardinos et al. (2006) later developed the Min-Max Markov Blanket algorithm (MMMB) that first identifies the direct parents and children of the target and then parents of the children using conditional independence tests. A comparison of the efficiency of several MB learning algorithms are provided by Fu and Desmarais (2008). A recent comprehensive overview of MB methods of classification and the local structure learning is provided by Aliferis et al. (2010a,b).

Several methods for averaging over BNs for prediction or classification have been described in the literature, including Dash and Cooper (2002), Dash and Cooper (2004) and Hwang and Zhang (2005). In prior work, we developed a lazy instance-specific algorithm that performs BMA over LBR models (Visweswaran and Cooper, 2004) and showed that it had better classification performance than did model selection. However, to our knowledge, averaging over MBs has not been described in the literature.

5. The Instance-Specific Markov Blanket (ISMB) Algorithm

The goal of the instance-specific Markov blanket (ISMB) algorithm is to predict well a discrete target variable of interest. Relative to some model space, BMA is the optimal method for making predictions in the sense that it achieves the lowest expected error rate in predicting the outcomes of future instances. Such Bayes optimal predictions involve averaging over all models in the model space which is usually computationally intractable. One approach, termed *selective model averag-*

ing, has been to approximate the Bayes optimal prediction by averaging over a subset of the possible models and has been shown to improve predictive performance (Hoeting et al., 1999; Raftery et al., 1997; Madigan and Raftery, 1994). The ISMB algorithm performs selective model averaging and uses a novel heuristic search method to select the models over which averaging is done. The instance-specific characteristic of the algorithm arises from the observation that the search heuristic is sensitive to the features of the particular instance at hand.

The model space employed by the ISMB algorithm is the space of BNs over the domain variables. In particular, the algorithm considers only MBs of the target node, since a MB is sufficient for predicting the target variable. The remainder of this section describes the ISMB algorithm in terms of the (1) model space, (2) scoring functions including parameter and structure priors, and (3) the search procedure for exploring the space of models. The current version of the algorithm handles discrete variables.

5.1 Model Space

As mentioned above, the ISMB algorithm learns MBs of the target variable rather than entire BNs over all the variables. Typically, BN structure learning algorithms that learn from data induce a BN structure over all the variables in the domain. The MB of the target variable can be extracted from the learned BN structure by ignoring those nodes and their relations that are not members of the MB. The ISMB algorithm modifies the typical BN structure learning algorithm to learn only MBs of the target node of interest, by using a set of operators that generate only the MB structures of the target variable.

The ISMB algorithm is a search-and-score method that searches in the space of possible MB structures. Both, the BN structure learning algorithms and the MB structure learning algorithm used by ISMB, search in a space of structures that is exponential in the number of domain variables. Though the number of MB structures grows more slowly than the number of BN structures with the number of domain variables, the number of MB structures is still exponential in the number of variables (Visweswaran and Cooper, 2009). Thus, exhaustive search in this space is infeasible for domains containing more than a few variables and heuristic search is appropriate.

5.2 Instance-Specific Bayesian Model Averaging

The objective of the ISMB algorithm is to derive the posterior distribution $P(Z^t|,\mathbf{x}^t,D)$ for the target variable Z^t in the instance at hand, given the values of the other variables $\mathbf{X}^t = \mathbf{x}^t$ and the training data D. The ideal computation of the posterior distribution $P(Z^t|,\mathbf{x}^t,D)$ by BMA is as follows:

$$P(Z^t|\mathbf{x}^t,D) = \sum_{G \in M} P(Z^t|\mathbf{x}^t,G,D)P(G|D), \tag{5}$$

where the sum is taken over *all* MB structures G in the model space M. The first term on the right hand side, $P(Z^t|\mathbf{x}^t,G,D)$, is the probability $P(Z^t|\mathbf{x}^t)$ computed with a MB that has structure G and parameters $\hat{\theta}_G$ that are given by Equation 6 below. This parameterization of G produces predictions equivalent to those obtained by integrating over all the possible parameterizations for G. The second term, $P(G|D)$, is the posterior probability of the MB structure G given the training data D. In essence, Equation 5 states that a conditional probability of interest $P(Z^t|\mathbf{x}^t)$ is derived by taking a weighted average of that probability over all MB structures, where the weight associated

with a MB structure is the probability of that MB structure given the data. In general, $P(Z^t|\mathbf{x}^t)$ will have different values for the different sets of models over which the averaging is carried out.

5.3 Inference in Markov Blankets

Computing $P(Z^t|\mathbf{x}^t, G, D)$ in Equation 5 involves doing inference in the MB with a specified structure G. First, the parameters of the MB structure G are estimated using Bayesian parameters as given by the following expression (Cooper and Herskovits, 1992; Heckerman, 1999):

$$P(X_i = k|\mathbf{Pa}_i = j) \equiv \hat{\theta}_{ijk} = \frac{\alpha_{ijk} + N_{ijk}}{\alpha_{ij} + N_{ij}} \tag{6}$$

where (1) N_{ijk} is the number of instances in data set D in which $X_i = k$ and the parents of X_i have the state denoted by j, (2) $N_{ij} = \sum_k N_{ijk}$, (3) α_{ijk} is a parameter prior that can be interpreted as belief equivalent to having previously (prior to obtaining D seen α_{ijk} instances in which $X_i = k$ and the parents of X_i have the state denoted by j, and (4) $\alpha_{ij} = \sum_k \alpha_{ijk}$. The $\hat{\theta}_{ijk}$ in Equation 6 represent the expected value of the probabilities that are derived by integrating over all possible parameter values. For the ISMB algorithm we set α_{ijk} to 1 for all i, j, and k, as a simple non-informative parameter prior (Cooper and Herskovits, 1992). Next, the parameterized MB is used to compute the distribution over the target variable Z^t of the instance at hand given the values $\mathbf{x}^t$ of the remaining variables in the MB by applying standard BN inference (Neapolitan, 2003).

5.4 Bayesian Scoring of Markov Blankets

In the Bayesian approach, the scoring function is based on the posterior probability $P(G|D)$ of the BN structure G given data D. This is the second term on the right hand side in Equation 3. The Bayesian approach treats the structure and parameters as uncertain quantities and incorporates prior distributions for both. The specification of the structure prior $P(G)$ assigns prior probabilities for the different MB structures. Application of Bayes rule gives:

$$P(G|D) = \frac{P(D|G)P(G)}{P(D)}. \tag{7}$$

Since the denominator $P(D)$ does not vary with the structure, it simply acts as a normalizing factor that does not distinguish between different structures. Dropping the denominator yields the following Bayesian score:

$$score(G;D) = P(D|G)P(G). \tag{8}$$

The second term on the right in Equation 8 is the prior over structures, while the first term is the marginal likelihood (also know as the integrated likelihood or evidence) which measures the goodness of fit of the given structure to the data. The marginal likelihood is computed as follows:

$$P(D|G) = \int_{\theta_G} P(D|\theta_G, G)P(\theta_G|G)d\theta_G, \tag{9}$$

where $P(D|\theta_G, G)$ is the likelihood of the data given the BN (G, θ_G) and $P(\theta_G|G)$ is the specified prior distribution over the possible parameter values for the network structure G. Intuitively, the marginal likelihood measures the goodness of fit of the structure over all possible values of its parameters. Note that the marginal likelihood is distinct from the maximum likelihood, though both

are computed from the same function: the likelihood of the data given the structure. The maximum likelihood is the maximum value of this function while the marginal likelihood is the integrated (or the average) value of this function with the integration being carried out with respect to the prior $P(\theta_G|G)$.

Equation 9 can be evaluated analytically when the following assumptions hold: (1) the variables are discrete and the data D is a multinomial random sample with no missing values; (2) global parameter independence, that is, the parameters associated with each variable are independent; (3) local parameter independence, that is, the parameters associated with each parent state of a variable are independent; and (4) the parameters' prior distribution is Dirichlet. Under the above assumptions, the closed form for $P(D|G)$ is given by (Cooper and Herskovits, 1992; Heckerman, 1999):

$$P(D|G) = \prod_{i=1}^{n} \prod_{j=1}^{q_i} \frac{\Gamma(\alpha_{ij})}{\Gamma(\alpha_{ij}+N_{ij})} \prod_{k=1}^{r_i} \frac{\Gamma(\alpha_{ijk}+N_{ijk})}{\Gamma(\alpha_{ijk})}, \tag{10}$$

where Γ denotes the Gamma function,n is the number of variables in G, q_i is the number of joint states of the parents of variable X_i that occur in D, r_i is the number of states of X_i that occur in D, and $\alpha_{ij} = \sum_k \alpha_{ijk}$. Also, as previously described, N_{ijk} is the number of instances in the data where node i has value k and the parents of i have the state denoted by j, and $N_{ij} = \sum_k N_{ijk}$.

The Bayesian score in Equation 7 incorporates both structure and parameter priors. The term $P(G)$ represents the structure prior and is the prior probability assigned to the BN structure G. For the ISMB algorithm, a uniform prior belief over all G is assumed which makes the term $P(G)$ a constant. Thus, $P(G|D)$ is equal to $P(D|G)$ up to a proportionality constant and the Bayesian score for $P(G)$ is defined simply as the marginal likelihood as follows:

$$score(G;D) = P(D|G) \propto P(G|D). \tag{11}$$

The parameter priors are incorporated in the marginal likelihood $P(D|G)$ as is obvious from the presence of the alpha terms in Equation 10. For the ISMB algorithm we set α_{ijk} to 1 for all i, j, and k in Equation 10, as a simple non-informative parameter prior, as mentioned in the previous section.

5.5 Selective Bayesian Model Averaging

Since Equation 5 sums over a very large number of MB structures, it is not feasible to compute it exactly. Hence, complete model averaging given by Equation 5 is approximated with selective model averaging, and heuristic search (described in the next section) is used to sample the model space. For a set R of MB structures that have been chosen from the model space by heuristic search, selective model averaging estimates $P(Z^t|\mathbf{x}^t, G)$ as:

$$P(Z^t|\mathbf{x}^t, D) \cong \sum_{G \in R} P(Z^t|\mathbf{x}^t, G, D) \frac{P(G|D)}{\sum_{G' \in R} P(G'|D)}. \tag{12}$$

Substituting Equation 11 into Equation 12, we obtain:

$$P(Z^t|\mathbf{x}^t, D) \cong \sum_{G \in R} P(Z^t|\mathbf{x}^t, G, D) \frac{score(G;D)}{\sum_{G' \in R} score(G';D)}. \tag{13}$$

The ISMB algorithm performs selective model averaging and seeks to locate a good set of models over which averaging is carried out.

5.6 Instance-Specific Search

The ISMB algorithm uses a two-phase search to sample the space of MB structures. The first phase (phase 1) ignores the evidence $\mathbf{x}^t$ from the instance at hand, while searching for MB structures that best fit the training data. The second phase (phase 2) continues to add to the set of MB structures obtained from phase 1, but now searches for MB structures that have the greatest impact on the prediction of Z^t for the instance at hand. We now describe in greater detail the two phases of the search.

Phase 1 uses *greedy hill-climbing search* and accumulates the best model discovered at each iteration of the search into a set R. At each iteration of the search, successor models are generated from the current best model; the best of the successor models is added to R *only if* this model is better than current best model; and the remaining successor models are discarded. Since, no backtracking is performed, phase 1 search terminates in a local maximum.

Phase 2 uses *best-first search* and adds the best model discovered at each iteration of the search to the set R. Unlike greedy hill-climbing search, best-first search holds models that have not been expanded (i.e., whose successors have not be generated) in a *priority queue* Q. At each iteration of the search, successor models are generated from the current best model and added to Q; after an iteration the best model from Q is added to R *even if* this model is not better than the current best model in R. Phase 2 search terminates when a user set criterion is satisfied. Since, the number of successor models that are generated can be quite large, the priority queue Q is limited to a capacity of at most w models. Thus, if Q already contains w models, addition of a new model to it leads to removal of the worst model from it. The queue allows the algorithm to keep in memory up to the best w scoring models found so far, and it facilitates limited backtracking to escape local maxima.

5.7 Search Operators and Scores

The operators used by the ISMB algorithm to traverse the space of MB structures are the same as those used in standard BN structure learning with minor modifications. The standard BN structure learning operators are (1) add an arc between two nodes if one does not exist, (2) delete an existing arc, and (3) reverse an existing arc, with the constraint that an operation is allowed only if it generates a legal BN structure (Neapolitan, 2003). This constraint simply implies that the graph of the generated BN structure be a DAG. A similar constraint is applicable to the generation of MB structures, namely, that an operation is considered valid if it produces a legal MB structure of the target node. This constraint entails that some of the operations be deemed invalid, as illustrated in the following examples. With respect to a MB, the nodes can be categorized into five groups: (1) the target node, (2) parent nodes of the target, (3) child nodes of the target, (4) spousal nodes, which are parents of the children, and (5) other nodes, which are not part of the current MB. Incoming arcs into parents or spouses are not part of the MB structure and, hence operations that add such arcs are deemed invalid. Arcs between nodes not in the MB are not part of the MB structure and, hence operations that add such arcs are also deemed invalid. Figure 4 gives exhaustively the validity of the MB operators. Furthermore, the application of the delete arc or the reverse arc operators may lead to additional removal of arcs to produce a valid MB structure (see Figure 5 for an example).

As described in the previous section, the search for MB structures proceeds in two sequential phases. In phase 1 the candidate MB structures are scored with the Bayesian score (phase 1 score) shown in Equation 11. Since this phase selects the highest scoring MB structure at each iteration, it

X \ Y	T	P	C	S	O
T				✓	✓
P			✓		
C			✓*		
S	✓		✓		
O	✓		✓		

(a) Add arc X → Y

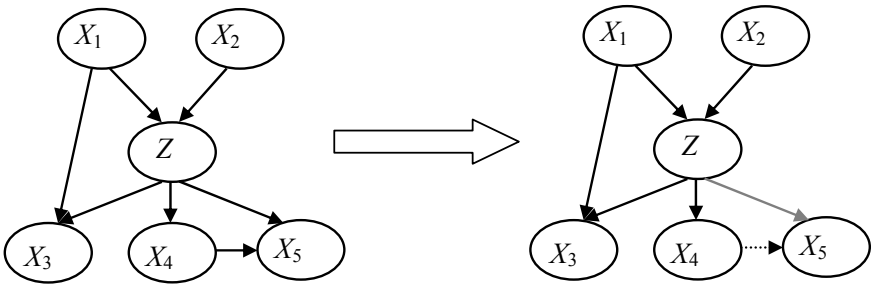
X \ Y	T	P	C	S	O
T			✓		
P	✓		✓		
C			✓		
S			✓		
O					

(b) Delete arc X → Y

X \ Y	T	P	C	S	O
T			✓		
P	✓				
C			✓*		
S					
O					

(c) Reverse arc X → Y

Figure 4: Constraints on the Markov blanket operators. The nodes are categorized into five groups: T = target, P = parent, C = child, S = spouse, and O = other (not in the Markov blanket of T). The cells with check marks indicate valid operations and are the only ones that need to be considered in generating candidate structures. The cells with an asterisk indicate that the operation is valid only if the resulting graph is acyclic.



(a) (b)

Figure 5: An example where the application of an operator leads to additional removal of arcs to produce a valid Markov blanket structure. Deletion of arc $Z \rightarrow X_5$ leads to removal of the arc $X_4 \rightarrow X_5$ since X_5 is no longer a part of the Markov blanket of Z. Reversal of the same arc also leads to removal of the arc $X_4 \rightarrow X_5$ since X_5 is now a parent and is precluded from having incoming arcs. Also, unless $X_4 \rightarrow X_5$ is removed there will be a cycle.

accumulates MB structures with high marginal likelihood. The purpose of this phase is to identify a set of MB structures that are highly probable, given data D.

Phase 2 searches for MB structures that change the current model-averaged estimate of $P(Z^t|\mathbf{x}^t, D)$ the most. The notion here is to find viable competing MB structures for making this posterior probability prediction. When no competitive MB structures can be found, the prediction is assumed to be stable. Phase 2 differs from the phase 1 in two aspects: it uses best-first search and it employs a different scoring function for evaluating candidate MB structures.

At the beginning of the phase 2, R contains MB structures that were generated in phase 1. Successors to the MB structures in R are generated, scored with the phase 2 score (described in detail below) and added to the priority queue Q. At each iteration of the search, the highest scoring MB structure in Q is removed from Q and added to R; all operations leading to legal MB structures are applied to it; the successor structures are scored with the phase 2 score; and the scored structures are added to Q. Phase 2 search terminates when no MB structure in Q has a score higher than some small value ε or when a period of time t has elapsed, where ε and t are user specified parameters.

In phase 2, the model score is computed as follows. Each successor MB structure G^* to be added to Q is scored based on how much it changes the current estimate of $P(Z^t|\mathbf{x}^t,D)$; this is obtained by model averaging over the MB structures in R. More change is better. Specifically, we use the Kullback-Leibler (KL) divergence between the two estimates of $P(Z^t|\mathbf{x}^t,D)$, one estimate computed with and another computed without G^* in the set of models over which the model averaging is carried out. The KL divergence, or relative entropy, is a quantity which measures the difference between two probability distributions (Cover and Joy, 2006). Thus, the phase 2 score for a candidate MB structure G^* is given by:

$$f(R,G^*) = \mathrm{KL}(p||q) \equiv \sum_x p(x) \log \frac{p(x)}{q(x)},$$

where

$$p(x) = \sum_{G \in R} P(Z^t|\mathbf{x}^t,G,D) \frac{P(G|D)}{\sum_{G' \in R} P(G'|D)}$$

and

$$q(x) = \sum_{G \in R \cup G^*} P(Z^t|\mathbf{x}^t,G,D) \frac{P(G|D)}{\sum_{G' \in R \cup G^*} P(G'|D)}.$$

Using Equation 11 the term $P(G|D)$ that appears in $p(x)$ and $q(x)$ can be substituted with the term $score(G;D)$. Using this substitution, the score for G^* is:

$$f(R,G^*) = \mathrm{KL}(p||q) \equiv \sum_x p(x) \log \frac{p(x)}{q(x)}, \tag{14}$$

where

$$p(x) = \sum_{G \in R} P(Z^t|\mathbf{x}^t,G,D) \frac{score(G;D)}{\sum_{G' \in R} score(G';D)}$$

and

$$q(x) = \sum_{G \in R \cup G^*} P(Z^t|\mathbf{x}^t,G,D) \frac{score(G;D)}{\sum_{G' \in R \cup G^*} score(G';D)}.$$

The pseudocode for the two-phase search procedure used by ISMB algorithm is given in Figure 6.

```

        End if
    End do

    Return R
```

Figure 6: Pseudocode for the two-phase search procedure used by the ISMB algorithm. Phase 1 uses greedy hill-climbing search while phase 2 uses best-first search.

5.8 Complexity of the ISMB Algorithm

For one instance, the ISMB algorithm runs in $O(bdmn)$ time and uses $O((w+d)mn)$ space, where m is the number of instances in the training data set D, n is the number of domain variables, d is the

total number of iterations of the search in the two phases 2, b (the branching factor) is the maximum number of successors generated from a MB structure, and w is the capacity of the priority queue Q.

5.8.1 TIME COMPLEXITY

At each iteration of the search, a maximum of b successor MB structures are generated. For d iterations of the search, the number of MB structures generated and scored with the phase 1 score is $O(bd)$. Note that both phases of the search require successor MB structures to be scored with the phase 1 score.

Since the phase 1 score decomposes over the MB nodes, to compute it for a newly generated MB structure only those MB nodes whose parent nodes have changed need be evaluated. The number of MB nodes that need to be evaluated is either one (when the *add* or *remove* operator is applied) or two (when the *reverse* operator is applied). Computing the phase 1 score for a MB node entails estimating the parameters for that node and calculating the marginal likelihood from those parameters. Estimating the parameters requires one pass over D and takes $O(mn)$ time which determines the time complexity of the phase 1 score.

The phase 2 score computes the effect of a candidate MB structure on the model averaged estimate of the distribution of the target variable. This requires doing inference for the target node in a MB that contains all measured variables which takes $O(n)$ since at most n nodes influence the target distribution and hence at most n sets of parameters need be retrieved. Computing both phase 1 and phase 2 scores for a MB structure therefore takes $O(mn)$ time. Thus, the total time required by the ISMB algorithm that runs for d iterations of the search and generates b MB structures at each iteration is $O(bdmn)$. However, the branching factor b is $O(n^2)$ and d is $O(n)$ and hence the overall complexity is $O(mn^4)$. This complexity limits that algorithm's applicability to data sets of small to medium dimensionality with up to several hundred variables.

5.8.2 SPACE COMPLEXITY

The ISMB algorithm searches in the space of MB structures using greedy hill-climbing search for phase 1 and best-first search with a priority queue of capacity w for phase 2. For d iterations of the search, the maximum number of MB structures that is stored is $O(w+d)$. The space required for each MB structure is linear in the number of its parameters.

For a given MB node, the number of parameters (using a conditional probability table) is exponential in the number of its parent nodes. However, the number of distinct parameters cannot be greater than the number of instances m in the training data D; the remaining parameters for a node have a single default value. Thus, the space required for the parameters of a MB node is $O(m)$. In a domain with n variables, a MB structure can have up to n nodes and thus requires space of $O(mn)$. In total, the space required by the ISMB algorithm that runs for d iterations of the search is $O((w+d)mn)$.

6. Evaluation of the ISMB Algorithm

This section describes the evaluation of the ISMB algorithm on a synthetic data set and several data sets from the UCI Machine Learning repository (UCI data sets). We first describe the preprocessing of variables, the evaluation measures and the comparison algorithms.

6.1 Preprocessing

Any instance that had one or more missing values was removed from the data set, as was done by Friedman et al. (1997). Sixteen of the 21 UCI data sets have no missing values and no instances were removed. In the remaining five data sets, removal of missing values resulted in a decrease in the size of the data set of less than 10%. After the removal of instances with missing values, the data sets were evaluated with two stratified applications of 10-fold cross-validation. Hence, each data set was split twice into 10 stratified training and test folds to create a total of 20 training and test folds. All experiments were carried out on the same set of 20 training and test folds. All target variables in all the data sets are discrete. However, some of the predictor variables are continuous. All continuous variables were discretized using the method described by Fayyad and Irani (1993). The discretization thresholds were determined only from the training sets and then applied to both the training and test sets.

6.2 Performance Measures

The performance of the ISMB algorithm was evaluated on two measures of discrimination (i.e., prediction under 0-1 loss) and three probability measures. The discrimination measures used are the misclassification error and the area under the ROC curve (AUC). For multiple classes, we used the method described by Hand and Till (2001) for computing the AUC. The discrimination measures evaluate how well an algorithm differentiates among the various classes (or values of the target variable). The probability measures considered are the logarithmic loss, squared error, and calibration. The closer the measure is to zero the better. For the multiclass case, we computed the logarithmic loss as described by Witten and Frank (2005) and the squared error as described by Yeung et al. (2005). For calibration, we used the CAL score that was developed by Caruana and Alexandru (2004) and is based on reliability diagrams. The probability measures indicate how well probability predictions correspond to reality. For example, consider a subset C of test instances in which target outcome is predicted to be positive with probability p. If a fraction p of C actually has a positive outcome, then such performance will contribute toward the probability measures being low. A brief description of the measures is given in Table 1.

Performance measure	Range	Best score
Misclassification error	$[0, 1]$	0
Area under the ROC curve (AUC)	$[0, 1]$	1
Logarithmic loss	$[0, \infty)$	0
Squared error	$[0, 1]$	0
Calibration score (CAL)	$[0, 1]$	0

Table 1: Brief description of the performance measures used in evaluation of the performance of the algorithms.

6.3 Comparison Algorithms

The performance of the instance-specific algorithms was compared to the following methods: nave Bayes (NB), C4.5 decision tree (DT), logistic regression (LR), neural networks (NN), k-Nearest Neighbor (kNN), Lazy Bayesian Rules (LBR), and AdaBoost (AB). The first four are representative

population-wide methods, the next two are examples of instance-specific methods, and AB is an ensemble method. *k*NN is a similarity-based method. The LBR algorithm induces a rule tailored to the features of the test instance that is then used to classify it, and is an example of a model-based instance-specific method that performs model selection. For all the seven comparison methods, we used the implementations in the Weka software package (version 3.4.3) (Witten and Frank, 2005). We used the default settings provided in Weka for NB, DT, and LR. For NN, we set the number of hidden nodes to $(n+c)/2$ where n is the number of predictor variables and c is the number of classes, the learning rate to 0.3 and the momentum to 0.2 (these are the default settings in Weka) and the number of iterations to 1000 since this setting resulted in slightly better performance than the default setting of 500. For *k*NN, we used the Weka setting that identifies the best value for k (i.e., the number of neighbors) by way of cross validation. For AB, we used Weka's AdaBoostM1 procedure with the decision tree J48 as the base classifier and the number of iterations set to $n/log(m)$, where n is the number of variables and m is the number of instances in the training data set. We did not perform variable selection as a pre-processing step before applying the above classification methods. However, DT, LBR and AB perform variable selection as part of the model learning procedure, while the other the methods do not.

Three versions of the ISMB algorithm were used in the experiments described later in this section, and they are listed in Table 2. The ISMB algorithm performs selective model averaging to estimate the distribution of the target variable of the instance at hand as described in Section 5. The ISMB-MS algorithm is a *model selection* version of the ISMB algorithm. It chooses the MB structure that has the highest posterior probability from those found by the ISMB algorithm in the two-phase search, and uses that single model to estimate the distribution of the target variable of the instance at hand. Comparing the ISMB algorithm to the ISMB-MS algorithm measures the effect of approximating selective model averaging by using model selection. When the training data set is large the performance of the ISMB algorithm and the ISMB-MS algorithm may be similar if a single model with a relatively large posterior probability overwhelms the contributions of the remaining models during model averaging.

Acronym	Algorithm	Phase 1	Phase 2	Prediction
ISMB	Instance-specific Markov blanket	Is non-instance-specific Uses greedy hill-climbing search Uses phase 1 score	Is instance-specific Uses best-first search Uses phase 2 score	By model averaging over models selected in phase 1 and phase 2
ISMB-MS	Instance-specific Markov blanket - Model Selection	Same as ISMB	Same as ISMB	Based on the highest scoring model from models found by ISMB
NISMB	Non-instance-specific Markov blanket	Same as ISMB	Is non-instance-specific Uses best-first search Uses phase 1 score	By model averaging; number of selected models is the same as in ISMB

Table 2: Three versions of the ISMB algorithm.

The NISMB algorithm is the *non-instance-specific* (i.e., population-wide) version of the ISMB algorithm. Phase 1 of the NISMB algorithm is identical to that of the ISMB algorithm. In phase 2, the NISMB algorithm accumulates the same number of MB models as the ISMB algorithm except that the models are identified on the basis of the non-instance-specific phase 1 score. Thus, the NISMB algorithm averages over the same number of models as the ISMB algorithm. Comparing the ISMB algorithm to the NISMB algorithm measures the effect of the instance-specific heuristic on the performance of model averaging.

6.4 Evaluation on a Synthetic Data Set

This section describes the evaluation of the ISMB algorithm on a small synthetic data set. The synthetic domain consists of five binary variables A, B, C, D, Z where Z is a deterministic function of the other variables:

$$Z = A \vee (B \wedge C \wedge D).$$

On such a small data set it is possible to perform model averaging over all models, and this establishes the best possible prediction performance that is attainable using MB models. The training and the test sets used in the experiments are shown in Figure 7. The training set simulates a low occurrence of $A = \mathrm{T}$ (only five out of 69 instances have $A = \mathrm{T}$), and the test set consists of three instances of $A = \mathrm{T}$ which are not present in the training set.

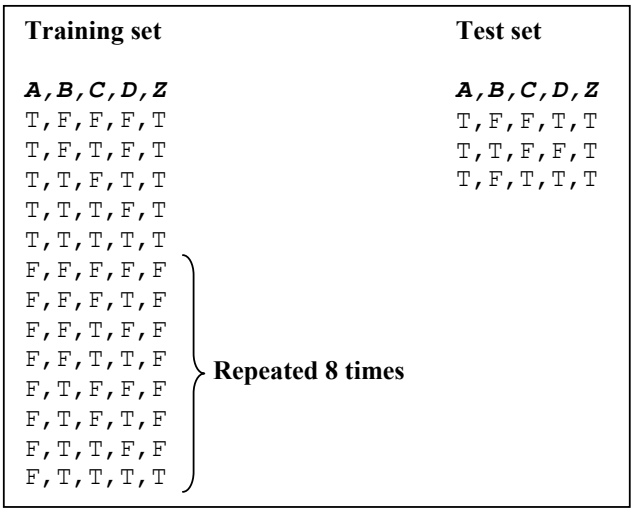

Figure 7: Training and test data sets derived from the deterministic function $Z = A \vee (B \wedge C \wedge D)$. The training set contains a total of 69 instances and the test set a total of three instances as shown; the test instances are not present in the training set. The training set simulates low prevalence of $A = \mathrm{T}$ since only five of the 69 instances have this variable-value combination.

The following algorithms were used in the experiments: (1) a complete model averaged version of the ISMB algorithm where model averaging is carried out over all 3567 possible MB structures, (2) the ISMB algorithm, (3) the ISMB-MS algorithm, and (4) the NISMB algorithm.

The settings used for the ISMB algorithm are as follows:

- Phase 1: As described in Section 5.
- Phase 2: The model score for phase 2 is computed using Equation 14 that is based on KL-divergence. Phase 2 uses best-first search with a priority queue Q whose maximum capacity w was set to 1000. Phase 2 search terminates when no MB structure in Q has a phase 2 score higher than $\varepsilon = 0.001$ for 10 consecutive iterations of the search. The maximum period of running time t for phase 2 was not specified since the algorithm terminated in a reasonable period of time with the specified value for ε.
- The predicted distribution for the target variable Z of the test instance is computed using Equation 13; for each MB structure the parameters are estimated using Equation 6.

The results are given in Table 3. All performance measures except the AUC were computed for the test set of three instances. The AUC could not be computed since all the instances in the test set are from the same class, $Z = \mathrm{T}$. The results from complete model averaging represent the best achievable expected performance that could be achieved by the ISMB algorithm. The ISMB and the NISMB algorithms that average over a subset of all models had poorer performance than complete model averaging but performed better than ISMB-MS. However, the ISMB algorithm improved over the performance of the NISMB algorithm. Though both methods average over the same number of models, the ISMB algorithm uses the instance-specific phase 2 score to choose phase 2 models while the ISMB algorithm uses the non-instance-specific phase 1 score to choose both phase 1 and phase 2 models. The phase 2 models chosen by the ISMB algorithm are potentially different for each test instance in contrast to the NISMB algorithm which selects the same models irrespective of the test instance. These results, while limited in scope, provide support that the instance-specific search for models may be able to choose models that better approximate the distribution of the target variable of the instance at hand.

Performance measure	ISMB complete model averaged	ISMB	ISMB-MS	NISMB
Misclassification error	0.0000	0.0000	0.3333	0.3333
AUC	-	-	-	-
Logarithmic loss	0.0406	0.0505	0.0596	0.0585
Squared error	0.0684	0.0783	0.0902	0.0862
CAL score	0.3720	0.4092	0.4534	0.4284

Table 3: Results obtained from the training and test sets that are given in Figure 7. The AUC could not be computed since the test set instances are all from a single class. Results in the first column are obtained by model averaging over all 3567 MBs.

Figure 8 plots the estimate of $P(Z^t = \mathrm{T}|\mathbf{x}^t, D)$ for each test instance t as it varies with each addition of a model to the set of models being averaged over. A second curve plots the model score as the logarithmic posterior probability of the model given the data; this score measures the relative contribution of the model to the final estimate of $P(Z^t = \mathrm{T}|\mathbf{x}^t, D)$. Each row in the figure contains a pair of plots for a single test instance, the plot on the left is obtained from the ISMB algorithm and

the corresponding plot on the right is obtained from the NISMB algorithm. The plot for the estimate of $P(Z^t = \mathrm{T}|\mathbf{x}^t, D)$ is shown in black while the plot for the model score is shown in gray. In each plot, on going from left to right, the estimate of $P(Z^t = \mathrm{T}|\mathbf{x}^t, D)$ initially fluctuates considerably and then settles to a stable estimate as the number of models providing the estimate increases. In the first two test instances the final estimates of $P(Z^t = \mathrm{T}|\mathbf{x}^t, D)$ obtained from the instance-specific and non-instance-specific model averaging respectively are very close; both the ISMB and the NISMB algorithms predicted the value of Z correctly as T. In the third test instance, the final estimates of $P(Z^t = \mathrm{T}|\mathbf{x}^t, D)$ are quite different; the ISMB algorithm predicted the value of Z correctly as T while the NISMB algorithm predicted the value of Z incorrectly as F.

6.5 Evaluation on UCI Data Sets

We now describe the evaluation of the ISMB algorithm on 21 data sets from the UCI Machine Learning repository (UCI data sets) (Frank and Asuncion, 2010). The selected UCI data sets have between four and 60 predictor variables and a single target variable that has between two and seven classes. The size of the data sets, the number and type of predictor variables, and the number of classes (states) taken by the target variable are given in Table 4 The performance of the ISMB algorithm is compared to that of the ISMB-MS and the NISMB algorithms, and also to that of the seven comparison machine learning methods described in Section 6.3.

6.5.1 EXPERIMENTAL DESIGN

The experimental design is as follows:

- For each data set, a total of 10 machine learning algorithms were run: ISMB, ISMB-MS, NISMB, NB, DT, LR, NN, *k*NN, LBR and AB.
- The data sets used in the experiments are the 21 UCI data sets listed in Table 4.
- Summary statistics were measured using 10-fold stratified cross-validation done twice for a total of 20 training-test pairs. The summary statistics were computed for misclassification error, the AUC, logarithmic loss, squared error and the CAL score.
- The statistical tests performed were (1) significance testing with the Wilcoxon paired-samples signed ranks test, and (2) effect size testing with paired-samples *t* test.

The settings for the ISMB algorithm are the same as those stated in Section 6.4 for the synthetic data evaluation.

6.5.2 RESULTS

Table 5 gives the average number of models selected by the ISMB and the NISMB algorithms in each of the phases for each data set. The average number of models varies from 17.99 for the iris data set (with four predictor variables) to 89.38 for the lymphography data set (with 18 predictor variables).

Tables 6 to 10 report the means of the misclassification error, the AUC, logarithmic loss, squared error and the CAL score respectively for the ISMB algorithm, its variants and the comparison algorithms. In each table, a row represents a data set and a column represents an algorithm. The last

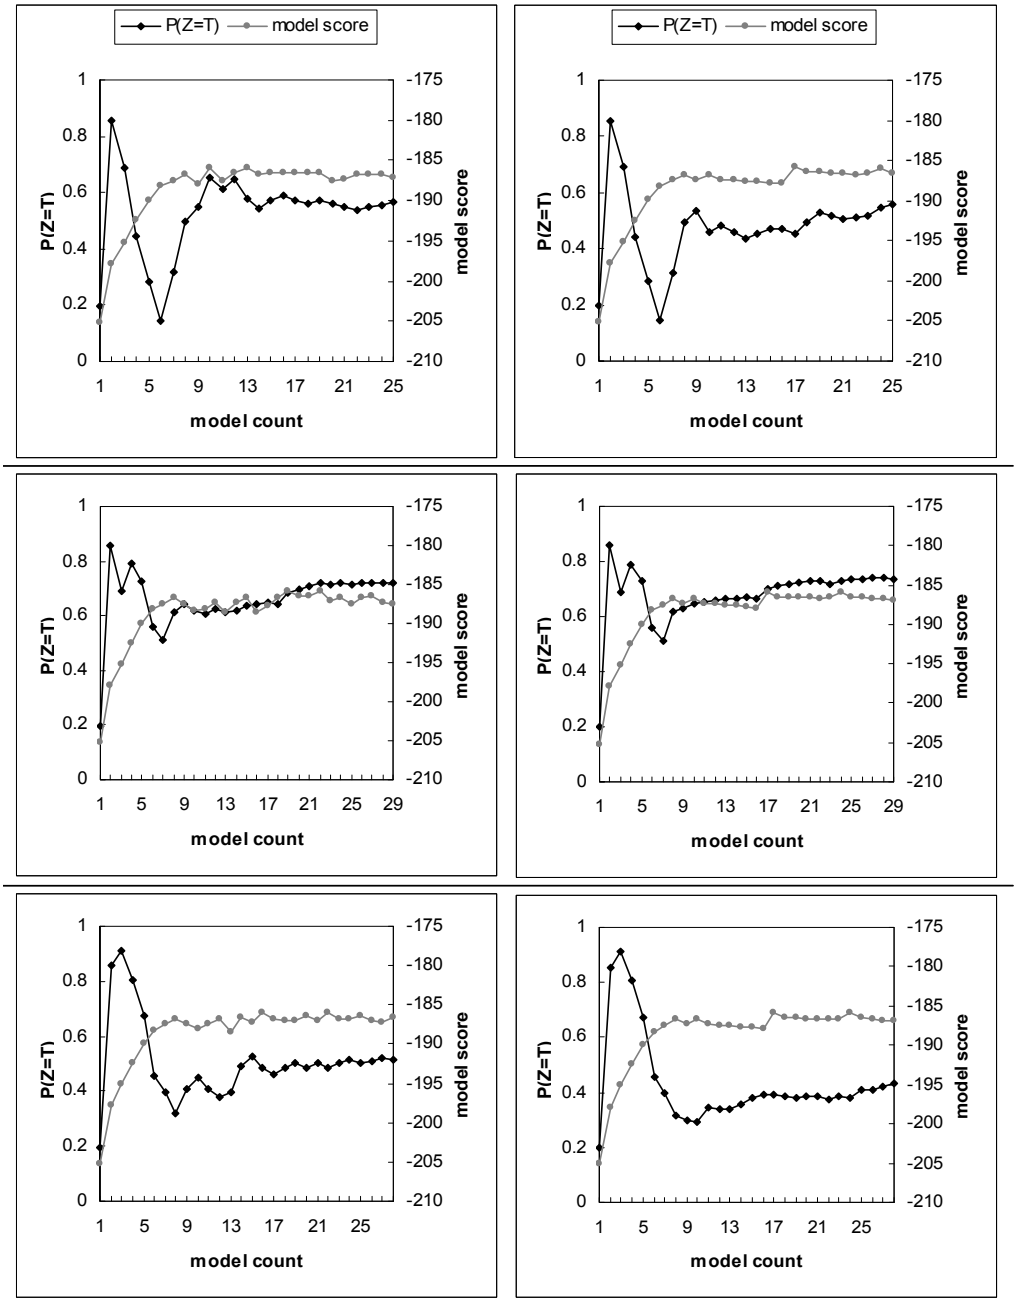

Figure 8: Plots of model averaged estimate of $P(Z^t = \mathrm{T}|\mathbf{x}^t, D)$ that is abbreviated as $P(Z = \mathrm{T})$ and model score obtained by ISMB and NISMB algorithms on the three test cases given in Figure 7. Each row represents a single test case with the plot on the left obtained from the ISMB algorithm and the plot on the right obtained from the NISMB algorithm. The value of the final averaged estimate of $P(Z^t = \mathrm{T}|\mathbf{x}^t, D)$ is the point where the darker curve meets the Y-axis on the right.

Table 4: Description of the 21 UCI data sets used in the experiments. In the column on predictors, the number of continuous (cnt) and discrete (dsc) predictors as well as the total number of predictor variables (excluding the target variable) are given. In the column on instances, the numbers of instances used in the experiments are given; this may be less than the total number of instances in the original UCI data set since instances with missing values were removed.

row in each table gives for each algorithm the overall mean of the specified performance measure across all the data sets. From the tables, it is seen that on all five performance measures, the ISMB algorithm achieved a better overall average score than each of the other algorithms.

Tables 11 and 12 report results from pair-wise comparisons of the performance of the algorithms on all the data sets that are aimed at assessing the statistical significance and the magnitude of the observed differences in the measures. Table 11 reports results from a two-sided Wilcoxon paired-samples signed ranks test, and Table 12 reports results from a two-sided paired-samples t test.

Table 13 reports the running times of the ISMB and the comparison algorithms. The experiments were performed on a server with 8 GB of RAM and two dual core Pentium processors of 3 GHz each that were running the Windows XP operating system. The algorithms were restricted to a single core in all the experiments. Averaged over all the data sets, the ISMB took approximately 2 minutes for a test instance.

We ran additional experiments on the first seven data sets (see Table 4) to analyze the sensitivity of the ISMB algorithm to the parameters w (queue capacity) and ε (change in Phase 2 score). For w, we evaluated values of 100, 200, 400, 800, 1600, 3200 and 6400. The performance on all the evaluation measures peaked at values of 800 or 1600 and beyond 1600 no further improvement was

Table 5: Average number of models in phases 1 and 2 over which averaging is carried out by the ISMB and NISMB algorithms. Both algorithms average over the same number of models in each phase. Both algorithms select the same models in phase 1 but potentially different models in phase 2. The number of models in phases 1 and 2 is the sum of the models selected in the two phases.

seen. For ε, we evaluated values of 1.0, 0.1, 0.01, 0.001, 0.0001 and 0.00001. The performance improved as ε decreased until 0.001 or 0.0001, but did not improve further for smaller values of ε.

The results are encouraging in that they show that the ISMB algorithm never underperformed on any performance measure when compared to the other learning methods including the variants of the ISMB algorithm that do model selection and non-instance-specific model averaging. For misclassification error, logarithmic loss, squared error and the CAL score, the mean difference is always negative which denotes that the ISMB algorithm always has a lower score on these measures. For the AUC, the difference is always positive which means that the ISMB algorithm always has a higher AUC. However, all mean differences are not statistically significant at the 0.05 level as can be seen by the p-values in Tables 11 and 12. The best performance is seen in logarithmic loss where the ISMB algorithm significantly outperforms all other methods, followed by squared error and CAL score where the ISMB algorithm significantly outperforms many of the methods. On misclassification error and the AUC, the ISMB algorithm has smaller performance gains.

Overall, the ISMB algorithm significantly improved on the probabilities of the predictions while maintaining or slightly improving on discrimination over all other algorithms used in the experiments. The non-instance-specific NISMB algorithm had inferior performance on logarithmic loss and squared error but similar performance on the other measures when compared to the ISMB algorithm. Both the ISMB and the NISMB algorithms average over the same number of models and

both select the same models in phase 1 of the search. In phase 2 of the search, while the number of selected models is the same, the two methods identify potentially different models. This provides evidence that the models selected in phase 2 by the ISMB algorithm, using instance-specific search, are able to improve the performance of the ISMB algorithm over the already good performance obtained by the NISMB algorithm. Of note, LBR, which is an instance-specific approach that performs model selection, is tied with ISMB on mean error and comes second after ISMB on AUC, but it performs more poorly on the probabilistic measures.

7. Discussion

This paper described the development and evaluation of a new approach for learning predictive models that are relevant to a single instance. The instance-specific method we developed uses MB models, carries out selective BMA to predict the outcome of interest for the instance at hand, and employs an instance-specific heuristic to locate a set of suitable models to average over. The essence of the instance-specific method lies in the model score used in phase 2 of the search. This score is sensitive to both the posterior probability of the model and the predicted distribution for the outcome variable of the instance at hand. Typically, methods that evaluate models with a score employ a score that is sensitive only to the fit of the model to the training data and not to the prediction of the outcome variable.

Table 7: Mean AUCs of different algorithms based on 10-fold cross-validation done twice. The bottom row gives the average AUCs. Best results are underlined.

The experimental results demonstrate that the ISMB algorithm improves prediction of the target variable on a variety of performance measures when compared to several population-wide predictive algorithms. The greatest improvements occur in logarithmic loss and squared error, followed by good improvement in calibration and smaller improvements in misclassification error and the AUC. BMA had better performance than Bayesian model selection, and within model averaging, instance-specific BMA had better performance than non-instance-specific BMA though the improvement is not as large as that of model averaging over model selection. The improved performance by ISMB may arise from not only the model averaging but also from the variable selection that is performed implicitly by the Markov blanket models. Both these components likely explain the better performance of ISMB over comparison methods such as NB, LR and *k*NN that do not perform variable selection. However, the superiority of ISMB over ISMB-MS suggests that model averaging is an important component in the improved performance of the former. We have also evaluated ISMB on several medical data sets and obtained good results (Visweswaran et al., 2010).

Several situations are possible where the instance-specific method has no advantage over a population-wide method. As one example, in a domain where complete BMA is tractable and model averaging is carried out over all models in the model space, a search heuristic that selects a subset of models such as the one used by the instance-specific method is superfluous. Typically, in real life domains, complete BMA over all models is not tractable due to the enormous number of models in the model space. Thus, the ISMB algorithm is useful for selective model averaging where it identifies a potentially relevant set of models that is predictive of the instance at hand. As another

example, in a domain where features that are relevant are commonly present, selection of relevant variables may not be a problem. In such a situation, the variables selected by a population-wide method are likely to be relevant for predicting any future instance and the instance-specific method that performs model selection will likely select the same set of variables for each new instance.

Improvements in the phase 1 search may make the phase 2 search relatively less contributory to the overall performance. We believe that the greedy hill climbing approach used in phase 1 of ISMB serves as a useful starting point for investigating this algorithm. Nonetheless, such an approach may become trapped in local maxima, leading it to miss finding highly probable MB structures. To explore this issue a number of search strategies that augment local greedy search that have been successfully applied to learning BN structures can be tried, such as best-first search (Neapolitan, 2003), simulated annealing (Heckerman et al., 1995), tabu lists (Friedman et al., 1999), random restarts to escape the numerous local optima (Heckerman et al., 1995), and optimal reinsertion (Moore and Wong, 2003). Algorithms that have been developed specifically for learning MBs such as the Markov Blanket Bayesian Classifier (MBBC) (Madden, 2002a), HITON (Aliferis et al., 2003), the Incremental Association Markov Blanket (IAMB) (Tsamardinos and Aliferis, 2003), and the Min-Max Markov Blanket algorithm (MMMB) (Tsamardinos et al., 2006) are additional candidates for consideration. Investigating the use of such alternative search methods in phase 1 is an interesting open problem.

There are several open questions regarding the behavior of the instance-specific method. Characterizing theoretically the bias of the selective model averaged prediction of the instance-specific

method is an open problem. In contrast, the bias of selective BMA over models that are chosen randomly is low. However, the variance of selective BMA over models that are chosen randomly is likely to be much larger than the variance of selective BMA over models chosen by the instance-specific method which is constrained to prefer models that are good fit to the training data. The results here support that as a practical matter ISMB is attaining a good balance between bias and variance.

The experimental work presented in this paper is a first step in exploring the utility of the instance-specific framework, and several directions of future work are possible. The computation of the phase 2 score (see Equation 14) requires a dissimilarity metric to compare the predictive distributions of the target variable in candidate MB structures. The current implementation of the ISMB algorithm uses KL divergence as the dissimilarity metric. The experimental results indicate that KL divergence optimizes most logarithmic loss and the largest improvement in performance is observed on this measure. Alternative dissimilarity metrics that may optimize other performance measures are worth exploring.

Table 11: Two-sided Wilcoxon paired-samples signed ranks test comparing the performance of ISMB with other algorithms. For each performance measure the number on top is the Z statistic and the number at the bottom is the corresponding p-value. The Z statistic is negative when ISMB has a lower score on a performance measure than the competing algorithm. On all measures, a negative Z statistic indicates better performance by ISMB. Underlined results indicate p-values of 0.05 or smaller.

Table 12: Two-sided paired-samples t test comparing the performance of ISMB with other algorithms. For each performance measure the number on top is the mean difference between ISMB and the indicated algorithm and the number at the bottom is the corresponding p-value. The mean difference is negative when ISMB has a lower score on a performance measure than the competing algorithm. On all measures, a negative mean difference indicates better performance by ISMB. Underlined results indicate p-values of 0.05 or smaller.

Algorithm	Average running time
NB	$<$ 1 second
DT	$<$ 1 second
LR	$<$ 1 second
NN	$<$ 1 second
kNN	$<$ 1 second
LBR	$\approx$ 1 second
AB	$<$ 1 second
ISMB	$\approx$ 2 minutes

Table 13: Approximate running times of the various algorithms. For each algorithm, the time shown is the average running time over all the UCI data sets. For the instance-specific algorithms LBR and ISMB the reported running time is for a single test instance, while for the other algorithms the reported running time is over all test instances.

Abstract

We explore an original strategy for building deep networks, based on stacking layers of *denoising autoencoders* which are trained locally to denoise corrupted versions of their inputs. The resulting algorithm is a straightforward variation on the stacking of ordinary autoencoders. It is however shown on a benchmark of classification problems to yield significantly lower classification error, thus bridging the performance gap with deep belief networks (DBN), and in several cases surpassing it. Higher level representations learnt in this purely unsupervised fashion also help boost the performance of subsequent SVM classifiers. Qualitative experiments show that, contrary to ordinary autoencoders, denoising autoencoders are able to learn Gabor-like edge detectors from natural image patches and larger stroke detectors from digit images. This work clearly establishes the value of using a denoising criterion as a tractable unsupervised objective to guide the learning of useful higher level representations.

Keywords: deep learning, unsupervised feature learning, deep belief networks, autoencoders, denoising

1. Introduction

It has been a long held belief in the field of neural network research that the composition of *several levels of nonlinearity* would be key to efficiently model complex relationships between variables and to achieve better generalization performance on difficult recognition tasks (McClelland et al., 1986; Hinton, 1989; Utgoff and Stracuzzi, 2002). This viewpoint is motivated in part by knowledge

of the layered architecture of regions of the human brain such as the visual cortex, and in part by a body of theoretical arguments in its favor (Håstad, 1986; Håstad and Goldmann, 1991; Bengio and LeCun, 2007; Bengio, 2009). Yet, looking back at the history of multi-layer neural networks, their problematic non-convex optimization has for a long time prevented reaping the expected benefits (Bengio et al., 2007; Bengio, 2009) of going beyond one or two hidden layers.[1] Consequently much of machine learning research has seen progress in shallow architectures allowing for convex optimization, while the difficult problem of learning in deep networks was left dormant.

The recent revival of interest in such *deep architectures* is due to the discovery of novel approaches (Hinton et al., 2006; Hinton and Salakhutdinov, 2006; Bengio et al., 2007; Ranzato et al., 2007; Lee et al., 2008) that proved successful at learning their parameters. Several alternative techniques and refinements have been suggested since the seminal work on deep belief networks (DBN) by Hinton et al. (2006) and Hinton and Salakhutdinov (2006). All appear however to build on the same principle that we may summarize as follows:

- Training a deep network to directly optimize only the supervised objective of interest (for example the log probability of correct classification) by gradient descent, starting from random initialized parameters, does not work very well.

- What works *much* better is to initially use a *local unsupervised criterion* to (pre)train each layer in turn, with the goal of learning to produce a useful *higher-level representation* from the lower-level representation output by the previous layer. From this starting point on, gradient descent on the supervised objective leads to much better solutions in terms of generalization performance.

Deep layered networks trained in this fashion have been shown empirically to avoid getting stuck in the kind of poor solutions one typically reaches with only random initializations. See Erhan et al. (2010) for an in depth empirical study and discussion regarding possible explanations for the phenomenon.

In addition to the supervised criterion relevant to the task, what appears to be key is using an additional *unsupervised criterion* to guide the learning at each layer. In this sense, these techniques bear much in common with the semi-supervised learning approach, except that they are useful even in the scenario where all examples are labeled, exploiting the input part of the data to regularize, thus approaching better minima of generalization error (Erhan et al., 2010).

There is yet no clear understanding of what constitutes "good" representations for initializing deep architectures or what explicit unsupervised criteria may best guide their learning. We know but a few algorithms that work well for this purpose, beginning with restricted Boltzmann machines (RBMs) (Hinton et al., 2006; Hinton and Salakhutdinov, 2006; Lee et al., 2008), and autoencoders (Bengio et al., 2007; Ranzato et al., 2007), but also semi-supervised embedding (Weston et al., 2008) and kernel PCA (Cho and Saul, 2010).

It is worth mentioning here that RBMs (Hinton, 2002; Smolensky, 1986) and basic classical autoencoders are very similar in their functional form, although their interpretation and the procedures used for training them are quite different. More specifically, the deterministic function that maps from input to *mean hidden representation*, detailed below in Section 2.2, is the same for both models. One important difference is that deterministic autoencoders consider that *real valued*

1. There is a notable exception to this in the more specialized convolutional network architecture of LeCun et al. (1989).

mean as their hidden representation whereas stochastic RBMs sample a *binary* hidden representation from that mean. However, after their initial pretraining, the way layers of RBMs are typically used in practice when stacked in a deep neural network is by propagating these real-valued means (Hinton et al., 2006; Hinton and Salakhutdinov, 2006). This is more in line with the deterministic autoencoder interpretation. Note also that reconstruction error of an autoencoder can be seen as an approximation of the log-likelihood gradient in an RBM, in a way that is similar to the approximation made by using the Contrastive Divergence updates for RBMs (Bengio and Delalleau, 2009). It is thus not surprising that initializing a deep network by stacking autoencoders yields almost as good a classification performance as when stacking RBMs (Bengio et al., 2007; Larochelle et al., 2009a). But why is it only *almost* as good? An initial motivation of the research presented here was to find a way to bridge that performance gap.

With the autoencoder paradigm in mind, we began an inquiry into the question of what can shape a good, useful representation. We were looking for unsupervised learning principles likely to lead to the learning of feature detectors that detect important structure in the input patterns.

Section 2 walks the reader along the lines of our reasoning. Starting from the simple intuitive notion of preserving information, we present a generalized formulation of the classical autoencoder, before highlighting its limitations. This leads us in Section 3 to motivate an alternative *denoising* criterion, and derive the *denoising autoencoder* model, for which we also give a possible intuitive geometric interpretation. A closer look at the considered noise types will then allow us to derive a further extension of the base model. Section 4 discusses related preexisting works and approaches. Section 5 presents experiments that qualitatively study the feature detectors learnt by a single-layer denoising autoencoder under various conditions. Section 6 describes experiments with multi-layer architectures obtained by stacking denoising autoencoders and compares their classification performance with other state-of-the-art models. Section 7 is an attempt at turning stacked (denoising) autoencoders into practical generative models, to allow for a qualitative comparison of generated samples with DBNs. Section 8 summarizes our findings and concludes our work.

1.1 Notation

We will be using the following notation throughout the article:

- Random variables are written in upper case, for example, X.
- If X is a random vector, then its j^{th} *component* will be noted X_j.
- Ordinary vectors are written in lowercase bold. For example, a realization of a random vector X may be written $\mathbf{x}$. Vectors are considered column vectors.
- Matrices are written in uppercase bold (e.g., $\mathbf{W}$). $\mathbf{I}$ denotes the identity matrix.
- The transpose of a vector $\mathbf{x}$ or a matrix $\mathbf{W}$ is written $\mathbf{x}^T$ or $\mathbf{W}^T$ (*not* $\mathbf{x}'$ or $\mathbf{W}'$ which may be used to refer to an entirely different vector or matrix).
- We use lower case p and q to denote both probability density functions or probability mass functions according to context.
- Let X and Y two random variables with marginal probability $p(X)$ and $p(Y)$. Their joint probability is written $p(X,Y)$ and the conditional $p(X|Y)$.
- We may use the following common shorthands when unambiguous: $p(\mathbf{x})$ for $p(X=\mathbf{x})$; $p(X|\mathbf{y})$ for $p(X|Y=\mathbf{y})$ (denoting a conditional distribution) and $p(\mathbf{x}|\mathbf{y})$ for $p(X=\mathbf{x}|Y=\mathbf{y})$.

- f, g, h, will be used for ordinary functions.
- Expectation (discrete case, p is probability mass): $\mathbb{E}_{p(X)}[f(X)] = \sum_{\mathbf{x}} p(X = \mathbf{x}) f(\mathbf{x})$.
- Expectation (continuous case, p is probability density): $\mathbb{E}_{p(X)}[f(X)] = \int p(\mathbf{x}) f(\mathbf{x}) \mathrm{d}\mathbf{x}$.
- Entropy or differential entropy: $\mathbb{H}(X) = \mathbb{H}(p) = \mathbb{E}_{p(X)}[-\log p(X)]$.
- Conditional entropy: $\mathbb{H}(X|Y) = \mathbb{E}_{p(X,Y)}[-\log p(X|Y)]$.
- Kullback-Leibler divergence: $\mathbb{D}_{\mathsf{KL}}(p\|q) = \mathbb{E}_{p(X)}[\log \frac{p(X)}{q(X)}]$.
- Cross-entropy: $\mathbb{H}(p\|q) = \mathbb{E}_{p(X)}[-\log q(X)] = \mathbb{H}(p) + \mathbb{D}_{\mathsf{KL}}(p\|q)$.
- Mutual information: $\mathbb{I}(X;Y) = \mathbb{H}(X) - \mathbb{H}(X|Y)$.
- Sigmoid: $s(x) = \frac{1}{1+e^{-x}}$ and $s(\mathbf{x}) = (s(\mathbf{x}_1), \ldots, s(\mathbf{x}_d))^T$.
- Bernoulli distribution with mean μ: $\mathcal{B}(\mu)$. By extension for vector variables: $X \sim \mathcal{B}(\mu)$ means $\forall i, X_i \sim \mathcal{B}(\mu_i)$.

1.2 General setup

We consider the typical supervised learning setup with a training set of n (input, target) pairs $D_n = \{(\mathbf{x}^{(1)}, t^{(1)}) \ldots, (\mathbf{x}^{(n)}, t^{(n)})\}$, that we suppose to be an i.i.d. sample from an **unknown distribution** $q(X,T)$ with corresponding marginals $q(X)$ and $q(T)$. We denote $q^0(X,T)$ and $q^0(X)$ the empirical distributions defined by the samples in D_n. X is a d-dimensional random vector (typically in $\mathbb{R}^d$ or in $[0,1]^d$).

In this work we are primarily concerned with finding a new, higher-level representation Y of X. Y is a d'-dimensional random vector (typically in $\mathbb{R}^{d'}$ or in $[0,1]^{d'}$). If $d' > d$ we will talk of an *over-complete* representation, whereas it will be termed an *under-complete* representation if $d' < d$. Y may be linked to X by a deterministic or stochastic mapping $q(Y|X;\theta)$ parameterized by a vector of parameters θ.

2. What Makes a Good Representation? From Mutual Information to Autoencoders

From the outset we can give an *operational definition* of a "good" representation as one that will eventually be *useful* for addressing tasks of interest, in the sense that it will help the system quickly achieve higher performance on those tasks than if it hadn't first learned to form the representation. Based on the objective measure typically used to assess algorithm performance, this might be phrased as "A good representation is one that will yield a better performing classifier". Final classification performance will indeed typically be used to objectively compare algorithms. However, if a lesson is to be learnt from the recent breakthroughs in deep network training techniques, it is that the error signal from a single narrowly defined classification task should not be the only nor primary criterion used to *guide* the learning of representations. First because it has been shown experimentally that beginning by optimizing an unsupervised criterion, oblivious of the specific classification problem, can actually greatly help in eventually achieving superior performance for that classification problem. Second it can be argued that the capacity of humans to quickly become proficient in new tasks builds on much of what they have learnt *prior* to being faced with that task.

In this section, we begin with the simple notion of retaining information and progress to formally introduce the traditional *autoencoder* paradigm from this more general vantage point.

2.1 Retaining Information about the Input

We are interested in learning a (possibly stochastic) mapping from input X to a novel representation Y. To make this more precise, let us restrict ourselves to parameterized mappings $q(Y|X) = q(Y|X;\theta)$ with parameters θ that we want to learn.

One natural criterion that we may expect any good *representation* to meet, at least to some degree, is to retain a significant amount of information about the *input*. It can be expressed in information-theoretic terms as maximizing the mutual information $\mathbb{I}(X;Y)$ between an input random variable X and its higher level representation Y. This is the *infomax principle* put forward by Linsker (1989).

Mutual information can be decomposed into an entropy and a conditional entropy term in two different ways. A first possible decomposition is $\mathbb{I}(X;Y) = \mathbb{H}(Y) - \mathbb{H}(Y|X)$ which lead Bell and Sejnowski (1995) to their infomax approach to Independent Component Analysis. Here we will start from another decomposition: $\mathbb{I}(X;Y) = \mathbb{H}(X) - \mathbb{H}(X|Y)$. Since observed input X comes from an unknown distribution $q(X)$ on which θ has no influence, this makes $\mathbb{H}(X)$ an unknown constant. Thus the infomax principle reduces to:

$$\begin{aligned}\arg\max_{\theta} \mathbb{I}(X;Y) &= \arg\max_{\theta} -\mathbb{H}(X|Y) \\ &= \arg\max_{\theta} \mathbb{E}_{q(X,Y)}[\log q(X|Y)].\end{aligned}$$

Now for any distribution $p(X|Y)$ we will have

$$\mathbb{E}_{q(X,Y)}[\log p(X|Y)] \leq \underbrace{\mathbb{E}_{q(X,Y)}[\log q(X|Y)]}_{-\mathbb{H}(X|Y)}, \tag{1}$$

as can easily be shown starting from the property that for any two distributions p and q we have $\mathbb{D}_{\mathsf{KL}}(q\|p) \geq 0$, and in particular $\mathbb{D}_{\mathsf{KL}}(q(X|Y=\mathbf{y})\|p(X|Y=\mathbf{y})) \geq 0$.

Let us consider a parametric distribution $p(X|Y;\theta')$, parameterized by θ', and the following optimization:

$$\max_{\theta,\theta'} \mathbb{E}_{q(X,Y;\theta)}[\log p(X|Y;\theta')].$$

From Equation 1, we see that this corresponds to maximizing a lower bound on $-\mathbb{H}(X|Y)$ and thus on the mutual information. We would end up maximizing the *exact* mutual information provided $\exists\theta'$ s.t. $q(X|Y) = p(X|Y;\theta')$.

If, as is done in infomax ICA, we further restrict ourselves to a deterministic mapping from X to Y, that is, representation Y is to be computed by a parameterized function $Y = f_\theta(X)$ or equivalently $q(Y|X;\theta) = \delta(Y - f_\theta(X))$ (where δ denotes Dirac-delta), then this optimization can be written:

$$\max_{\theta,\theta'} \mathbb{E}_{q(X)}[\log p(X|Y = f_\theta(X);\theta')].$$

This again corresponds to maximizing a lower bound on the mutual information.

Since $q(X)$ is unknown, but we have samples from it, the empirical average over the training samples can be used instead as an unbiased estimate (i.e., replacing $\mathbb{E}_{q(X)}$ by $\mathbb{E}_{q^0(X)}$):

$$\max_{\theta,\theta'} \mathbb{E}_{q^0(X)}[\log p(X|Y = f_\theta(X);\theta')]. \tag{2}$$

We will see in the next section that this equation corresponds to the *reconstruction error* criterion used to train *autoencoders*.

2.2 Traditional Autoencoders (AE)

Here we briefly specify the traditional *autoencoder* (AE)[2] framework and its terminology, based on f_θ and $p(X|Y;\theta')$ introduced above.

Encoder: The deterministic mapping f_θ that transforms an input vector $\mathbf{x}$ into hidden representation $\mathbf{y}$ is called the **encoder**. Its typical form is an affine mapping followed by a nonlinearity:

$$f_\theta(\mathbf{x}) = s(\mathbf{W}\mathbf{x}+\mathbf{b}).$$

Its parameter set is $\theta = \{\mathbf{W},\mathbf{b}\}$, where $\mathbf{W}$ is a $d' \times d$ weight matrix and $\mathbf{b}$ is an offset vector of dimensionality d'.

Decoder: The resulting hidden representation $\mathbf{y}$ is then mapped back to a reconstructed d-dimensional vector $\mathbf{z}$ in input space, $\mathbf{z} = g_{\theta'}(\mathbf{y})$. This mapping $g_{\theta'}$ is called the **decoder**. Its typical form is again an affine mapping optionally followed by a squashing non-linearity, that is, either $g_{\theta'}(\mathbf{y}) = \mathbf{W}'\mathbf{y}+\mathbf{b}'$ or

$$g_{\theta'}(\mathbf{y}) = s(\mathbf{W}'\mathbf{y}+\mathbf{b}'), \tag{3}$$

with appropriately sized parameters $\theta' = \{\mathbf{W}',\mathbf{b}'\}$.

In general $\mathbf{z}$ is not to be interpreted as an exact reconstruction of $\mathbf{x}$, but rather in probabilistic terms as the parameters (typically the mean) of a distribution $p(X|Z=\mathbf{z})$ that may generate $\mathbf{x}$ with high probability. We have thus completed the specification of $p(X|Y;\theta')$ from the previous section as $p(X|Y=\mathbf{y}) = p(X|Z=g_{\theta'}(\mathbf{y}))$. This yields an associated reconstruction error to be optimized:

$$L(\mathbf{x},\mathbf{z}) \propto -\log p(\mathbf{x}|\mathbf{z}). \tag{4}$$

Common choices for $p(\mathbf{x}|\mathbf{z})$ and associated loss function $L(\mathbf{x},\mathbf{z})$ include:

- For real-valued $\mathbf{x}$, that is, $\mathbf{x} \in \mathbb{R}^d$: $X|\mathbf{z} \sim \mathcal{N}(\mathbf{z},\sigma^2\mathbf{I})$, that is, $X_j|\mathbf{z} \sim \mathcal{N}(\mathbf{z}_j,\sigma^2)$.
  This yields $L(\mathbf{x},\mathbf{z}) = L_2(\mathbf{x},\mathbf{z}) = C(\sigma^2)\|\mathbf{x}-\mathbf{z}\|^2$ where $C(\sigma^2)$ denotes a constant that depends only on σ^2 and that can be ignored for the optimization. This is the *squared error* objective found in most traditional autoencoders. In this setting, due to the Gaussian interpretation, it is more natural *not* to use a squashing nonlinearity in the decoder.

- For binary $\mathbf{x}$, that is, $\mathbf{x} \in \{0,1\}^d$: $X|\mathbf{z} \sim \mathcal{B}(\mathbf{z})$, that is, $X_j|\mathbf{z} \sim \mathcal{B}(\mathbf{z}_j)$.
  In this case, the decoder needs to produce a $\mathbf{z} \in [0,1]^d$. So a squashing nonlinearity such as a sigmoid s will typically be used in the decoder. This yields $L(\mathbf{x},\mathbf{z}) = L_{\mathbb{H}}(\mathbf{x},\mathbf{z}) = -\sum_j[\mathbf{x}_j\log\mathbf{z}_j + (1-\mathbf{x}_j)\log(1-\mathbf{z}_j)] = \mathbb{H}(\mathcal{B}(\mathbf{x})\|\mathcal{B}(\mathbf{z}))$ which is termed the *cross-entropy loss* because it is seen as the cross-entropy between two independent multivariate Bernoullis, the first with mean $\mathbf{x}$ and the other with mean $\mathbf{z}$. This loss can also be used when $\mathbf{x}$ is not strictly binary but rather $\mathbf{x} \in [0,1]^d$.

2. Note: *AutoEncoders* (AE) are also often called *AutoAssociators* (AA) in the literature. The shorter autoencoder term was preferred in this work, as we believe *encoding* better conveys the idea of producing a novel useful representation. Similarly, what we call Stacked Auto Encoders (SAE) has also been called Stacked AutoAssociators (SAA).

Note that in the general autoencoder framework, we may use other forms of parameterized functions for the encoder or decoder, and other suitable choices of the loss function (corresponding to a different $p(X|z)$). In particular, we investigated the usefulness of a more complex encoding function in Larochelle, Erhan, and Vincent (2009b). For the experiments in the present work however, we will restrict ourselves to the two usual forms detailed above, that is, an **affine+sigmoid encoder** and either **affine decoder with squared error loss** or **affine+sigmoid decoder with cross-entropy loss**. A further constraint that can optionally be imposed, and that further parallels the workings of RBMs, is having *tied weights* between W and W', in effect defining W' as $W' = W^T$.

Autoencoder training consists in minimizing the reconstruction error, that is, carrying the following optimization:

$$\arg\min_{\theta,\theta'} \mathbb{E}_{q^0(X)}[L(X, Z(X))],$$

where we wrote $Z(X)$ to emphasize the fact that Z is a deterministic function of X, since Z is obtained by composition of deterministic encoding and decoding.

Making this explicit and using our definition of loss L from Equation 4 this can be rewritten as:

$$\arg\max_{\theta,\theta'} \mathbb{E}_{q^0(X)}[\log p(X|Z = g_{\theta'}(f_\theta(X)))],$$

or equivalently

$$\arg\max_{\theta,\theta'} \mathbb{E}_{q^0(X)}[\log p(X|Y = f_\theta(X); \theta')].$$

We see that this last line corresponds to Equation 2, that is, the maximization of a lower bound on the mutual information between X and Y.

It can thus be said that **training an autoencoder to minimize reconstruction error amounts to maximizing a lower bound on the mutual information between input X and learnt representation Y**. Intuitively, if a representation allows a good reconstruction of its input, it means that it has retained much of the information that was present in that input.

2.3 Merely Retaining Information is Not Enough

The criterion that representation Y should retain information about input X is not by itself sufficient to yield a useful representation. Indeed mutual information can be trivially maximized by setting $Y = X$. Similarly, an ordinary autoencoder where Y is of the same dimensionality as X (or larger) can achieve perfect reconstruction simply by learning an identity mapping.[3] Without any other constraints, this criterion alone is unlikely to lead to the discovery of a more useful representation than the input.

Thus further constraints need to be applied to attempt to separate useful information (to be retained) from noise (to be discarded). This will naturally translate to non-zero reconstruction error. The traditional approach to autoencoders uses a *bottleneck* to produce an *under-complete* representation where $d' < d$. The resulting lower-dimensional Y can thus be seen as a *lossy compressed representation* of X. When using affine encoder and decoder without any nonlinearity and a squared error loss, the autoencoder essentially performs principal component analysis (PCA) as showed by

3. More precisely, it suffices that $g \circ f$ be the identity to obtain zero reconstruction error. For $d = d'$ if we had a linear encoder and decoder this would be achieved for any invertible matrix $\mathbf{W}$ by setting $\mathbf{W}' = \mathbf{W}^{-1}$. Now there is a sigmoid nonlinearity in the encoder, but it is possible to stay in the linear part of the sigmoid with small enough $\mathbf{W}$.

Baldi and Hornik (1989).[4] When a nonlinearity such as a sigmoid is used in the encoder, things become a little more complicated: obtaining the PCA subspace is a likely possibility (Bourlard and Kamp, 1988) since it is possible to stay in the linear regime of the sigmoid, but arguably not the only one (Japkowicz et al., 2000). Also when using a cross-entropy loss rather than a squared error the optimization objective is no longer the same as that of PCA and will likely learn different features. The use of "tied weights" can also change the solution: forcing encoder and decoder matrices to be symmetric and thus have the same scale can make it harder for the encoder to stay in the linear regime of its nonlinearity without paying a high price in reconstruction error.

Alternatively it is also conceivable to impose on Y different constraints than that of a lower dimensionality. In particular the possibility of using *over-complete* (i.e., higher dimensional than the input) but *sparse* representations has received much attention lately. Interest in sparse representations is inspired in part by evidence that neural activity in the brain seems to be sparse and has burgeoned following the seminal work of Olshausen and Field (1996) on *sparse coding*. Other motivations for sparse representations include the ability to handle effectively variable-size representations (counting only the non-zeros), and the fact that dense compressed representations tend to entangle information (i.e., changing a single aspect of the input yields significant changes in all components of the representation) whereas sparse ones can be expected to be easier to interpret and to use for a subsequent classifier. Various modifications of the traditional autoencoder framework have been proposed in order to learn sparse representations (Ranzato et al., 2007, 2008). These were shown to extract very useful representations, from which it is possible to build top performing deep neural network classifiers. A sparse over-complete representations can be viewed as an alternative "compressed" representation: it has *implicit* straightforward compressibility due to the large number of zeros rather than an explicit lower dimensionality.

3. Using a Denoising Criterion

We have seen that the reconstruction criterion alone is unable to guarantee the extraction of useful features as it can lead to the obvious solution "simply copy the input" or similarly uninteresting ones that trivially maximizes mutual information. One strategy to avoid this phenomenon is to constrain the representation: the traditional bottleneck and the more recent interest on sparse representations both follow this strategy.

Here we propose and explore a very different strategy. Rather than constrain the representation, we change the reconstruction criterion for a both more challenging and more interesting objective: cleaning partially corrupted input, or in short *denoising*. In doing so we modify the implicit definition of a good representation into the following: *"a good representation is one that can be obtained robustly from a corrupted input and that will be useful for recovering the corresponding clean input"*. Two underlying ideas are implicit in this approach:

- First it is expected that a higher level representation should be rather stable and robust under corruptions of the input.
- Second, it is expected that performing the denoising task well requires extracting features that capture useful structure in the input distribution.

4. More specifically it will find the same *subspace* as PCA, but the specific projection directions found will in general not correspond to the actual principal directions and need not be orthonormal.

We emphasize here that our goal is *not* the task of denoising per se. Rather **denoising is advocated and investigated as a *training criterion* for learning to extract useful features** that will constitute better higher level representation. The usefulness of a learnt representation can then be assessed objectively by measuring the accuracy of a classifier that uses it as input.

3.1 The Denoising Autoencoder Algorithm

This approach leads to a very simple variant of the basic autoencoder described above. A *denoising autoencoder (DAE)* is trained to reconstruct a clean "repaired" input from a *corrupted* version of it (the specific types of corruptions we consider will be discussed below). This is done by first corrupting the initial input $\mathbf{x}$ into $\tilde{\mathbf{x}}$ by means of a stochastic mapping $\tilde{\mathbf{x}} \sim q_{\mathcal{D}}(\tilde{\mathbf{x}}|\mathbf{x})$.

Corrupted input $\tilde{\mathbf{x}}$ is then mapped, as with the basic autoencoder, to a hidden representation $\mathbf{y} = f_\theta(\tilde{\mathbf{x}}) = s(\mathbf{W}\tilde{\mathbf{x}} + \mathbf{b})$ from which we reconstruct a $\mathbf{z} = g_{\theta'}(\mathbf{y})$. See Figure 1 for a schematic representation of the procedure. Parameters θ and θ' are trained to minimize the average reconstruction error over a training set, that is, to have $\mathbf{z}$ as close as possible to the *uncorrupted* input $\mathbf{x}$. The key difference is that $\mathbf{z}$ is now a deterministic function of $\tilde{\mathbf{x}}$ rather than $\mathbf{x}$. As previously, the considered reconstruction error is either the cross-entropy loss $L_{\mathbb{H}}(\mathbf{x},\mathbf{z}) = \mathbb{H}(\mathcal{B}(\mathbf{x})\|\mathcal{B}(\mathbf{z}))$, with an affine+sigmoid decoder, or the squared error loss $L_2(\mathbf{x},\mathbf{z}) = \|\mathbf{x}-\mathbf{z}\|^2$, with an affine decoder. Parameters are initialized at random and then optimized by stochastic gradient descent. Note that each time a training example $\mathbf{x}$ is presented, a different corrupted version $\tilde{\mathbf{x}}$ of it is generated according to $q_{\mathcal{D}}(\tilde{\mathbf{x}}|\mathbf{x})$.

Note that denoising autoencoders are still minimizing the same reconstruction loss between a clean X and its reconstruction from Y. So this still amounts to maximizing a lower bound on the mutual information between clean input X and representation Y. The difference is that Y is now obtained by applying deterministic mapping f_θ to a *corrupted* input. It thus forces the learning of a far more clever mapping than the identity: one that extracts features useful for *denoising*.

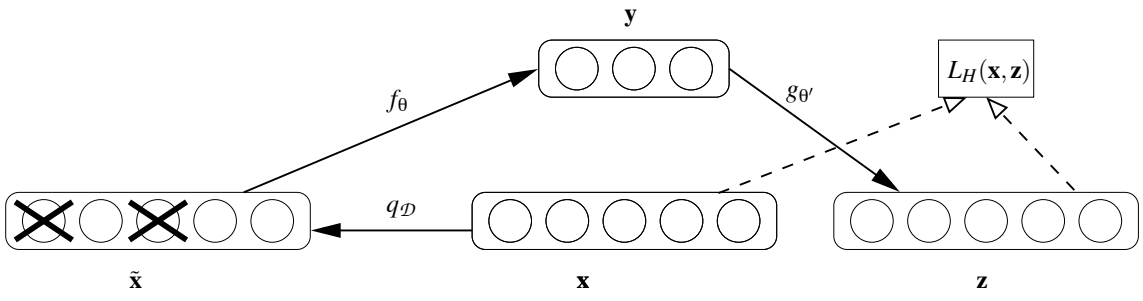

Figure 1: The denoising autoencoder architecture. An example $\mathbf{x}$ is stochastically corrupted (via $q_{\mathcal{D}}$) to $\tilde{\mathbf{x}}$. The autoencoder then maps it to $\mathbf{y}$ (via encoder f_θ) and attempts to reconstruct $\mathbf{x}$ via decoder $g_{\theta'}$, producing reconstruction $\mathbf{z}$. Reconstruction error is measured by loss $L_H(\mathbf{x},\mathbf{z})$.

3.2 Geometric Interpretation

The process of denoising, that is, mapping a corrupted example back to an uncorrupted one, can be given an intuitive geometric interpretation under the so-called *manifold assumption* (Chapelle et al., 2006), which states that natural high dimensional data concentrates close to a non-linear low-dimensional manifold. This is illustrated in Figure 2. During denoising training, we learn a stochastic operator $p(X|\widetilde{X})$ that maps a corrupted $\widetilde{X}$ back to its uncorrupted X, for example, in the case of binary data,

$$X|\widetilde{X} \sim \mathcal{B}(g_{\theta'}(f_\theta(\widetilde{X}))).$$

Corrupted examples are much more likely to be outside and farther from the manifold than the uncorrupted ones. Thus stochastic operator $p(X|\widetilde{X})$ learns a map that tends to go from lower probability points $\widetilde{X}$ to nearby high probability points X, on or near the manifold. Note that when $\widetilde{X}$ is farther from the manifold, $p(X|\widetilde{X})$ should learn to make bigger steps, to reach the manifold. Successful denoising implies that the operator maps even far away points to a small region close to the manifold.

The denoising autoencoder can thus be seen as a way to define and learn a manifold. In particular, if we constrain the dimension of Y to be smaller than the dimension of X, then the intermediate representation $Y = f(X)$ may be interpreted as a coordinate system for points on the manifold. More generally, one can think of $Y = f(X)$ as a representation of X which is well suited to capture the main variations in the data, that is, those along the manifold.

3.3 Types of Corruption Considered

The above principle and technique can potentially be used with any type of corruption process. Also the corruption process is an obvious place where prior knowledge, if available, could be easily incorporated. But in the present study we set to investigate a technique that is generally applicable. In

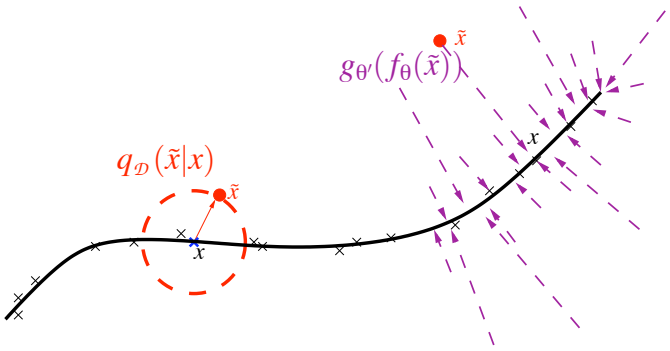

Figure 2: Manifold learning perspective. Suppose training data ($\times$) concentrate near a low-dimensional manifold. Corrupted examples ($\bullet$) obtained by applying corruption process $q_{\mathcal{D}}(\widetilde{X}|X)$ will generally lie farther from the manifold. The model learns with $p(X|\widetilde{X})$ to "project them back" (via autoencoder $g'_\theta(f_\theta(\cdot))$) onto the manifold. Intermediate representation $Y = f_\theta(X)$ may be interpreted as a coordinate system for points X on the manifold.

particular we want it to be usable for learning ever higher level representations by *stacking* denoising autoencoders. Now while prior knowledge on relevant corruption processes may be available in a particular input space (such as images), such prior knowledge will not be available for the space of intermediate-level representations.

We will thus restrict our discussion and experiments to the following simple corruption processes:

- Additive isotropic *Gaussian noise* (GS): $\tilde{\mathbf{x}}|\mathbf{x} \sim \mathcal{N}(\mathbf{x}, \sigma^2 I)$;
- *Masking noise* (MN): a fraction ν of the elements of $\mathbf{x}$ (chosen at random for each example) is forced to 0;
- *Salt-and-pepper noise* (SP): a fraction ν of the elements of $\mathbf{x}$ (chosen at random for each example) is set to their minimum or maximum possible value (typically 0 or 1) according to a fair coin flip.

Additive Gaussian noise is a very common noise model, and is a natural choice for real valued inputs. The *salt-and-pepper noise* will also be considered, as it is a natural choice for input domains which are interpretable as binary or near binary such as black and white images or the representations produced at the hidden layer after a sigmoid squashing function.

Much of our work however, both for its inspiration and in experiments, focuses on *masking noise* which can be viewed as turning off components considered missing or replacing their value by a default value—that is, a common technique for handling missing values. All information about these masked components is thus removed from that particular input pattern, and we can view the denoising autoencoder as trained to *fill-in* these artificially introduced "blanks". Also, numerically, forcing components to zero means that they are totally ignored in the computations of downstream neurons.

We draw the reader's attention to the fact that both salt-and-pepper and masking noise drastically corrupt but a fraction of the elements while leaving the others untouched. Denoising, that is, recovering the values of the corrupted elements, will only be possible thanks to dependencies between dimensions in high dimensional distributions. Denoising training is thus expected to capture these dependencies. The approach probably makes less sense for very low dimensional problems, at least with these types of corruption.

3.4 Extension: Putting an Emphasis on Corrupted Dimensions

Noise types such as *masking noise* and *salt-and-pepper* that erase only a changing subset of the input's components while leaving the others untouched suggest a straightforward extension of the denoising autoencoder criterion. Rather than giving equal weight to the reconstruction of all components of the input, we can put an *emphasis* on the corrupted dimensions. To achieve this we give a different weight α for the reconstruction error on components that were corrupted, and β for those that were left untouched. α and β are considered hyperparameters.

For the squared loss this yields

$$L_{2,\alpha}(\mathbf{x}, \mathbf{z}) = \alpha \left(\sum_{j \in \mathcal{J}(\tilde{\mathbf{x}})} (\mathbf{x}_j - \mathbf{z}_j)^2 \right) + \beta \left(\sum_{j \notin \mathcal{J}(\tilde{\mathbf{x}})} (\mathbf{x}_j - \mathbf{z}_j)^2 \right),$$

where $\mathcal{J}(\tilde{\mathbf{x}})$ denotes the indexes of the components of $\mathbf{x}$ that were corrupted.

And for the cross-entropy loss this yields

$$L_{\mathsf{IH},\alpha}(\mathbf{x},\mathbf{z}) = \alpha\left(-\sum_{j\in\mathcal{J}(\tilde{\mathbf{x}})}[\mathbf{x}_j\log\mathbf{z}_j+(1-\mathbf{x}_j)\log(1-\mathbf{z}_j)]\right) + \beta\left(-\sum_{j\notin\mathcal{J}(\tilde{\mathbf{x}})}[\mathbf{x}_j\log\mathbf{z}_j+(1-\mathbf{x}_j)\log(1-\mathbf{z}_j)]\right).$$

We call this extension *emphasized denoising autoencoder*. A special case that we call *full emphasis* is obtained for $\alpha = 1,\ \beta = 0$ where we only take into account the error on the prediction of corrupted elements.

3.5 Stacking Denoising Autoencoders to Build Deep Architectures

Stacking denoising autoencoders to initialize a deep network works in much the same way as stacking RBMs in deep belief networks (Hinton et al., 2006; Hinton and Salakhutdinov, 2006) or ordinary autoencoders (Bengio et al., 2007; Ranzato et al., 2007; Larochelle et al., 2009a). Let us specify that input corruption is only used for the initial denoising-training of each individual layer, so that it may learn useful feature extractors. Once the mapping f_θ has thus been learnt, it will henceforth be used on *uncorrupted* inputs. In particular no corruption is applied to produce the representation that will serve as clean input for training the next layer. The complete procedure for learning and stacking several layers of denoising autoencoders is shown in Figure 3.

Once a stack of encoders has thus been built, its highest level output representation can be used as input to a stand-alone supervised learning algorithm, for example a Support Vector Machine classifier or a (multi-class) logistic regression. Alternatively, as illustrated in Figure 4, a logistic regression layer can be added on top of the encoders, yielding a *deep neural network* amenable to supervised learning. The parameters of all layers can then be simultaneously *fine-tuned* using a gradient-based procedure such as stochastic gradient descent.

4. Related Approaches in the Literature

In this section, we briefly review and discuss related prior work along three different axes.

4.1 Previous Work on Training Neural Networks for Denoising

The idea of training a multi-layer perceptron using error backpropagation on a denoising task is not new. The approach was first introduced by LeCun (1987) and Gallinari et al. (1987) as an alternative method to learn an *(auto-)associative memory* similar to how Hopfield Networks (Hopfield, 1982) were understood. The networks were trained and tested on binary input patterns, corrupted by flipping a fraction of input bits chosen at random. Both the model and training procedure in this precursory work are very similar to the denoising autoencoder we describe.[5] Our motivation and goal are however quite different. The objective of LeCun (1987) was to study the *capacity* of such a network for memorization tasks, that is, counting how many training patterns it was able to

5. There are a few minor differences; for example, the use of a squared error after sigmoid for binary data, while we tend to use a cross-entropy loss. Also their denoising procedure considers doing several recurrent passes through the autoencoder network, as in a recurrent net.

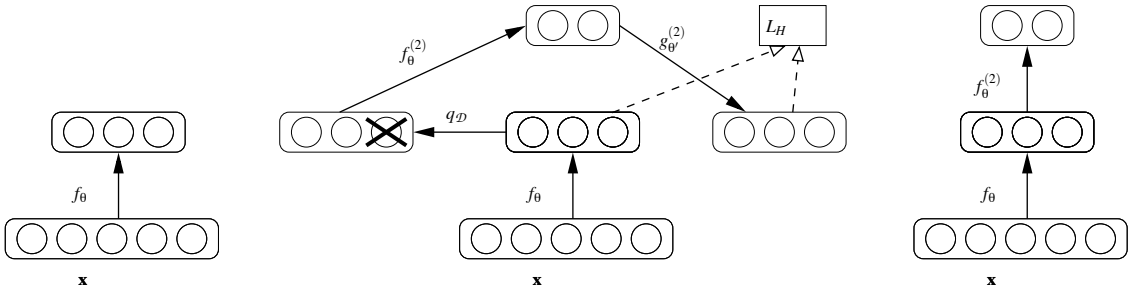

Figure 3: Stacking denoising autoencoders. After training a first level denoising autoencoder (see Figure 1) its learnt encoding function f_θ is used on clean input (left). The resulting representation is used to train a second level denoising autoencoder (middle) to learn a second level encoding function $f_\theta^{(2)}$. From there, the procedure can be repeated (right).

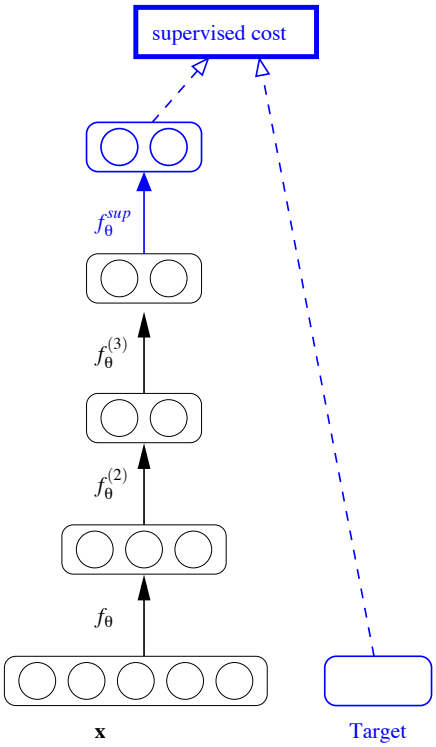

Figure 4: Fine-tuning of a deep network for classification. After training a stack of encoders as explained in the previous figure, an output layer is added on top of the stack. The parameters of the whole system are fine-tuned to minimize the error in predicting the supervised target (e.g., class), by performing gradient descent on a supervised cost.

correctly recall under these conditions. The work also clearly established the usefulness of a non-linear hidden layer for this. By contrast, our work is motivated by the search and understanding of unsupervised pretraining criteria to initialize deep networks. Our primary interest is thus in investigating the ability of the denoising criterion to learn good feature extractors, with which to initialize a deep network by stacking and composing these feature extractors. We focus on analyzing the learnt higher-level representations and their effect on the classification performance of resulting deep networks.

Another insightful work that is very much related to the approach advocated here is the research of Seung (1998), in which a recurrent neural network is trained to complete corrupted input patterns using backpropagation through time. Both the work of Seung (1998) and that of LeCun (1987) and Gallinari et al. (1987) appear to be inspired by Hopfield-type associative memories (Hopfield, 1982) in which learnt patterns are conceived as attractive fixed points of a recurrent network dynamic. Seung (1998) contributes a very interesting analysis in terms of continuous attractors, points out the limitations of regular autoencoding, and advocates the pattern completion task as an alternative to density estimation for unsupervised learning. Again, it differs form our study mainly by its *focus* a) on recurrent networks[6] and b) on the image denoising task per se. The latter justifies their use of prior knowledge of the 2D topology of images, both in the architectural choice of local 2D receptive field connectivity, and in the corruption process that consists in zeroing-out a square image patch at a random position. This occlusion by a 2D patch is a special form of a *structured* masking noise, where the a-priori known 2D topological structure of images is taken into account. In our research we deliberately chose not to use topological prior knowledge in our model nor in our corruption process, so that the *same generic procedure* may be applied to learn higher levels of representation from lower ones, or to other domains for which we have no such topological prior knowledge.

More recently Jain and Seung (2008) presented a very interesting and successful approach for image denoising, that consists in layer-wise building of a deep convolutional neural network. Their algorithm yields comparable or better performance than state-of-the-art Markov Random Field and wavelet methods developed for image denoising. The approach clearly has roots in their earlier work (Seung, 1998) and appears also inspired by more recent research on deep network pretraining, including our own group's (Bengio et al., 2007). But apparently, neither of us was initially aware of the other group's relevant work on denoising (Vincent et al., 2008; Jain and Seung, 2008). Again the focus of Seung (1998) on image denoising per se differs from our own focus on studying deep network pretraining for classification tasks and results in marked differences in the actual algorithms. Specifically, in Jain and Seung (2008) each layer in the stack is trained to reconstruct the original clean image a little better, which makes sense for image denoising. This can be contrasted with our approach, in which upper layers are trained to denoise-and-reconstruct whatever representation they receive from the layer immediately below, rather than to restore the original input image in one operation. This logically follows from our search for a generic feature extraction algorithm for pretraining, where upper level representations will eventually be used for a totally different task such as classification.

6. Note however that a recurrent network can be seen as deep network, with the additional property that all layers share the same weights.

4.2 Training Classifiers with Noisy Inputs

The idea of training a neural network with noisy input (Scalettar and Zee, 1988; von Lehman et al., 1988)—or training with *jitter* as it is sometimes called—has been proposed to enhance generalization performance for supervised learning tasks (Sietsma and Dow, 1991; Holmstrm and Koistinen, 1992; An, 1996). This thread of research is less directly related to autoencoders and denoising than the studies discussed in the previous section. It is nevertheless relevant. After all, denoising amounts to using noisy patterns as input with the clean pattern as a supervised target, albeit a rather high dimensional one. It has been argued that training with noise is equivalent to applying generalized Tikhonov regularization (Bishop, 1995). On the surface, this may seem to suggest that training with noisy inputs has a similar effect to training with an L2 weight decay penalty (i.e., penalizing the sum of squared weights), but this view is incorrect. Tikhonov regularization applied to *linear regression* is indeed equivalent to a L2 weight decay penalty (i.e., ridge regression). But for a non-linear mapping such as a neural network, Tikhonov regularization is no longer so simple (Bishop, 1995). More importantly, in the non-linear case, the equivalence of noisy training with Tikhonov regularization is derived from a Taylor series expansion, and is thus only valid in the limit of very small additive noise. See Grandvalet et al. (1997) for a theoretical study and discussion regarding the limitations of validity for this equivalence. Last but not least, our experimental results in Section 5.1 clearly show qualitatively very different results when using denoising autoencoders (i.e., noisy inputs) than when using regular autoencoders with a L2 weight decay.

Here, we must also mention a well-known technique to improve the generalization performance of a classifier (neural network or other), which consists in augmenting the original training set with additional distorted inputs, either explicitly (Baird, 1990; Poggio and Vetter, 1992) or virtually through a modified algorithm (Simard et al., 1992; Schölkopf et al., 1996). For character images for instance such distortions may include small translations, rotations, scalings and shearings of the image, or even applying a scanner noise model. This technique can thus be seen as training with noisy corrupted inputs, but with a highly structured corruption process based on *much* prior knowledge.[7] As already explained and motivated above, our intent in this work is to develop and investigate a generally applicable technique, that should also be applicable to intermediate higher level representations. Thus we intentionally restrict our study to very simple generic corruption processes that do not incorporate explicit prior knowledge.

We also stress the difference between the approaches we just discussed, that consist in training a neural network by optimizing a *global supervised criterion using noisy input*, and the approach we investigate in the present work, that is, using a *local unsupervised denoising criterion to pretrain each layer of the network* with the goal to learn useful intermediate representations. We shall see in experimental Section 6.4 that the latter applied to a deep network yields better classification performance than the former.

4.3 Pseudo-Likelihood and Dependency Networks

The view of denoising training as "filling in the blanks" that motivated the masking noise and the extension that puts an emphasis on corrupted dimensions presented in Section 3.4, can also be related to the pseudo-likelihood (Besag, 1975) and Dependency Network (Heckerman et al., 2000)

7. Clearly, simple Tikhonov regularization cannot achieve the same as training with such prior knowledge based corruption process. This further illustrates the limitation of the equivalence between training with noise and Tikhonov regularization.

paradigms. Maximizing pseudo-likelihood instead of likelihood implies replacing the likelihood term $p(X)$ by the product of conditionals $\prod_{i=1}^{d} p(X_i|X_{\neg i})$. Here X_i denotes the i^{th} component of input vector variable X and $X_{\neg i}$ denotes all components but the i^{th}. Similarly, in the Dependency Network approach of Heckerman et al. (2000) one learns d conditional distributions, each trained to predict component i given (a subset of) all other components. This is in effect what an *emphasized denoising autoencoder* with a masking noise that masks but one input component ($\nu = \frac{1}{d}$), and a *full emphasis* ($\alpha = 1,\ \beta = 0$), is trained to do. More specifically, for binary variables it will learn to predict $p(X_i = 1|X_{\neg i})$; and when using squared error for real-valued variables it will learn to predict $\mathbb{E}[X_i|X_{\neg i}]$ assuming $X_i|X_{\neg i} \sim \mathcal{N}(\mathbb{E}[X_i|X_{\neg i}], \sigma^2)$. Note that with denoising autoencoders, all d conditional distributions are constrained to *share common parameters*, which define the mapping to and from hidden representation Y. Also when the emphasis is not fully put on the corrupted components ($\beta > 0$) some of the network's capacity will be devoted to encoding/decoding uncorrupted components.

A more important difference can be appreciated by considering the following scenario: What happens if components of the input come in identical pairs? In that case, conditional distribution $p(X_i|X_{\neg i})$ can simply learn to replicate the other component of the pair, thus not capturing any other potentially useful dependency. Now for dependency networks this exact scenario is forbidden by the formal requirement that no input configuration may have zero probability. But a similar problem may occur in practice if the components in a pair are not identical but very highly correlated. By contrast, denoising autoencoders can and will typically be trained with a larger fraction ν of corrupted components, so that reliable prediction of a component cannot rely exclusively on a single other component.

5. Experiments on Single Denoising Autoencoders: Qualitative Evaluation of Learned Feature Detectors

A first series of experiments was carried out using single denoising autoencoders, that is, without any stacking nor supervised fine tuning. The goal was to examine qualitatively the kind of feature detectors learnt by a denoising criterion, for various noise types, and compare these to what ordinary autoencoders yield.

Feature detectors that correspond to the first hidden layer of a network trained on image data are straightforward to visualize. Each hidden neuron $\mathbf{y}_j$ has an associated vector of weights $\mathbf{W}_j$ that it uses to compute a dot product with an input example (before applying its non-linearity). These $\mathbf{W}_j$ vectors, the *filters*, have the same dimensionality as the input, and can thus be displayed as little images showing what aspects of the input each hidden neuron is sensitive to.

5.1 Feature Detectors Learnt from Natural Image Patches

We trained both regular autoencoders and denoising autoencoders on 12×12 patches from whitened natural scene images, made available by Olshausen (Olshausen and Field, 1996).[8] A few of these patches are shown in Figure 5 (left). For these natural image patches, we used a linear decoder and a squared reconstruction cost. Network parameters were trained from a random start,[9] using

8. More specifically randomly positioned 12×12 patches were extracted from the 20×20 patches made available by Olshausen at the following URL: `https://redwood.berkeley.edu/bruno/sparsenet/`.
9. We applied the usual random initialization heuristic in which weights are sampled independently form a uniform in range $[-\frac{1}{\sqrt{\text{fanin}}}, \frac{1}{\sqrt{\text{fanin}}}]$ where fanin in this case is the input dimension.

stochastic gradient descent to perform 500000 weight updates with a fixed learning rate of 0.05. All filters shown were from experiments with tied weights, but untied weights yielded similar results.

Figure 5 displays filters learnt by a regular *under-complete* autoencoder that used a bottleneck of 50 hidden units, as well as those learnt by an *over-complete* autoencoder using 200 hidden units. Filters obtained in the under-complete case look like very local blob detectors. No clear structure is apparent in the filters learnt in the over-complete case.

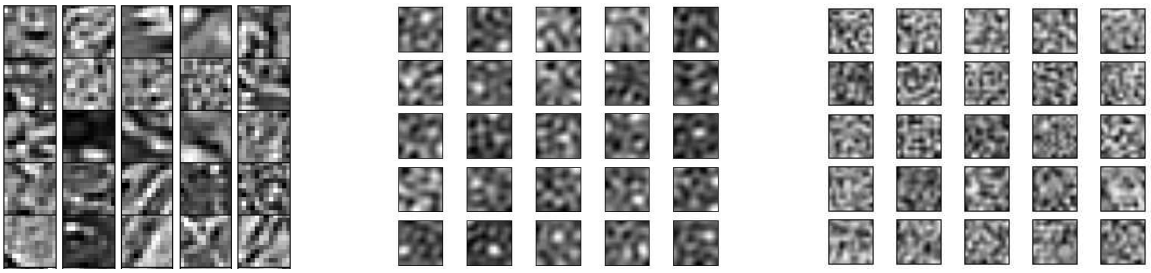

Figure 5: Regular autoencoder trained on natural image patches. *Left:* some of the 12×12 image patches used for training. *Middle:* filters learnt by a regular *under-complete* autoencoder (50 hidden units) using tied weights and L2 reconstruction error. *Right:* filters learnt by a regular *over-complete* autoencoder (200 hidden units). The under-complete autoencoder appears to learn rather uninteresting local blob detectors. Filters obtained in the over-complete case have no recognizable structure, looking entirely random.

We then trained 200 hidden units over-complete noiseless autoencoders regularized with L2 weight decay, as well as 200 hidden units denoising autoencoders with isotropic Gaussian noise (but no weight decay). Resulting filters are shown in Figure 6. Note that a denoising autoencoder with a noise level of 0 is identical to a regular autoencoder. So, naturally, filters learnt by a denoising autoencoder at small noise levels (not shown) look like those obtained with a regular autoencoder previously shown in Figure 5. With a sufficiently large noise level however ($\sigma = 0.5$), the denoising autoencoder learns Gabor-like local oriented edge detectors (see Figure 6). This is similar to what is learnt by sparse coding (Olshausen and Field, 1996, 1997), or ICA (Bell and Sejnowski, 1997) and resembles simple cell receptive fields from the primary visual cortex first studied by Hubel and Wiesel (1959). The L2 regularized autoencoder on the other hand learnt nothing interesting beyond restoring some of the local blob detectors found in the under-complete case. Note that we did try a wide range of values for the regularization hyperparameter,[10] but were never able to get Gabor-like filters. From this experiment, we see clearly that **training with sufficiently large noise yields a qualitatively very different outcome than training with a weight decay regularization**, which confirms experimentally that the two are *not* equivalent for a non-linear autoencoder, as discussed earlier in Section 4.2.

Figure 7 shows some of the results obtained with the other two noise types considered, that is, salt-and-pepper noise, and masking-noise. We experimented with 3 corruption levels ν: $10\%, 25\%, 55\%$. The filters shown were obtained using 100 hidden units, but similar filters were found with 50 or 200 hidden units. Salt-and-pepper noise yielded Gabor-like edge detectors, whereas masking noise

10. Attempted weight decays values were the following: $\lambda \in \{0.0001, 0.0005, 0.001, 0.005, 0.01, 0.05, 0.1, 0.25, 0.5, 1.0\}$.

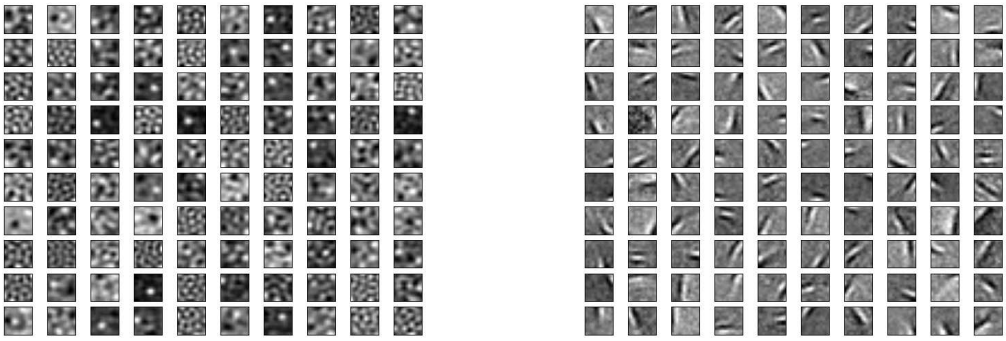

Figure 6: Weight decay vs. Gaussian noise. We show typical filters learnt from natural image patches in the over-complete case (200 hidden units). *Left:* regular autoencoder with weight decay. We tried a wide range of weight-decay values and learning rates: filters never appeared to capture a more interesting structure than what is shown here. Note that some local blob detectors are recovered compared to using no weight decay at all (Figure 5 right). *Right:* a denoising autoencoder with additive Gaussian noise ($\sigma = 0.5$) learns Gabor-like local oriented edge detectors. Clearly the filters learnt are qualitatively very different in the two cases.

yielded a mixture of edge detectors and grating filters. Clearly different corruption types and levels can yield qualitatively different filters. But it is interesting to note that all three noise types we experimented with were able to yield some potentially useful edge detectors.

5.2 Feature Detectors Learnt from Handwritten Digits

We also trained denoising autoencoders on the 28×28 gray-scale images of handwritten digits from the MNIST data set. For this experiment, we used denoising autoencoders with tied weights, cross-entropy reconstruction error, and zero-masking noise. The goal was to better understand the qualitative effect of the noise level. So we trained several denoising autoencoders, all starting from *the same initial random point in weight space*, but *with different noise levels*. Figure 8 shows some of the resulting filters learnt and how they are affected as we increase the level of corruption. With 0% corruption, the majority of the filters appear totally random, with only a few that specialize as little ink blob detectors. With increased noise levels, a much larger proportion of interesting (visibly non random and with a clear structure) feature detectors are learnt. These include local oriented stroke detectors and detectors of digit parts such as loops. It was to be expected that denoising a more corrupted input requires detecting bigger, less local structures: the denoising auto-encoder must rely on longer range statistical dependencies and pool evidence from a larger subset of pixels. Interestingly, filters that start from the same initial random weight vector often look like they "grow" from random, to local blob detector, to slightly bigger structure detectors such as a stroke detector, as we use increased noise levels. By "grow" we mean that the slightly larger structure learnt at a higher noise level often appears related to the smaller structure obtained at lower noise levels, in that they share about the same position and orientation.

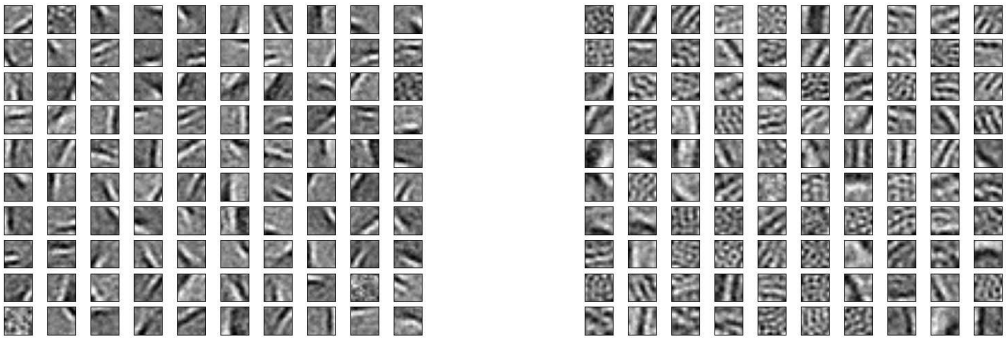

Figure 7: Filters obtained on natural image patches by denoising autoencoders using other noise types. *Left:* with 10% salt-and-pepper noise, we obtain oriented Gabor-like filters. They appear slightly less localized than when using Gaussian noise (contrast with Figure 6 right). *Right:* with 55% zero-masking noise we obtain filters that look like oriented gratings. For the three considered noise types, denoising training appears to learn filters that capture meaningful natural image statistics structure.

6. Experiments on Stacked Denoising Autoencoders

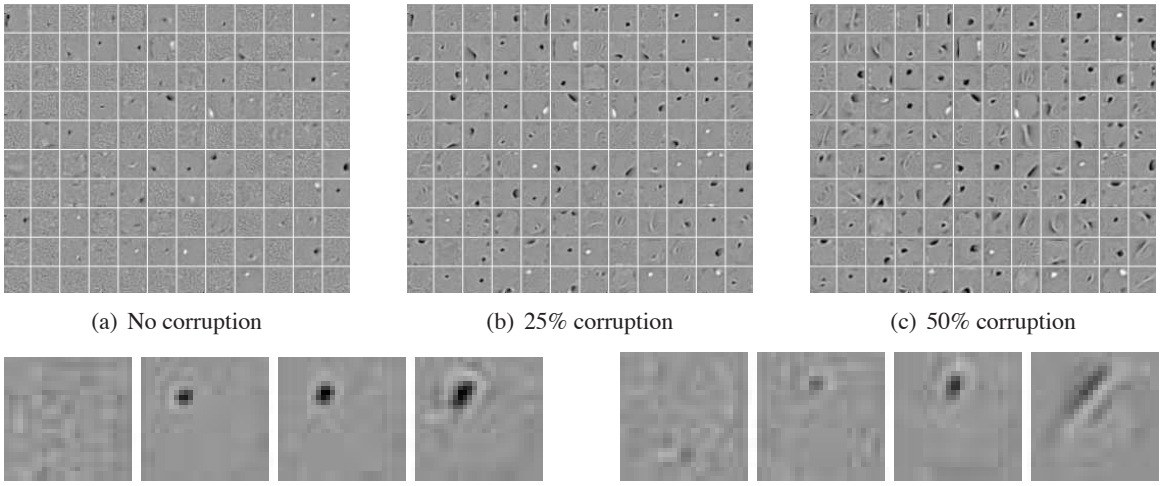
In this section, we evaluate denoising autoencoders as a pretraining strategy for building deep networks, using the stacking procedure that we described in Section 3.5. We shall mainly compare the classification performance of networks pretrained by stacking denoising autoencoders (SDAE), versus stacking regular autoencoders (SAE), versus stacking restricted Boltzmann machines (DBN), on a benchmark of classification problems.

6.1 Considered Classification Problems and Experimental Methodology

We considered 10 classification problems, the details of which are listed in Table 1. They consist of:

- The standard MNIST digit classification problem with 60000 training examples.
- The eight benchmark image classification problems used in Larochelle et al. (2007) which include more challenging variations of the MNIST digit classification problem (all with 10000 training examples), as well as three artificial 28×28 binary image classification tasks.[11] These problems were designed to be particularly challenging to current generic learning algorithms (Larochelle et al., 2007). They are illustrated in Figure 9.
- A variation of the *tzanetakis* audio genre classification data set (Bergstra, 2006) which contains 10000 three-second audio clips, equally distributed among 10 musical genres: blues, classical, country, disco, hiphop, pop, jazz, metal, reggae and rock. Each example in the set

11. The data sets for this benchmark are available at `http://www.iro.umontreal.ca/~lisa/icml2007`.



(a) No corruption (b) 25% corruption (c) 50% corruption

(d) Neuron A (0%, 10%, 20%, 50% corruption) (e) Neuron B (0%, 10%, 20%, 50% corruption)

Figure 8: Filters learnt by denoising autoencoder on MNIST digits, using zero-masking noise. *(a-c)* show some of the filters learnt by denoising autoencoders trained with various corruption levels ν. Filters at the same position in the three images are related only by the fact that the autoencoders were started from the same random initialization point in parameter space. *(d)* and *(e)* zoom in on the filters obtained for two of the neurons. As can be seen, with no noise, many filters remain similarly uninteresting (undistinctive almost uniform random grey patches). As we increase the noise level, denoising training forces the filters to differentiate more, and capture more distinctive features. Higher noise levels tend to induce less local filters, as expected. One can distinguish different kinds of filters, from local blob detectors, to stroke detectors, and character parts detectors at the higher noise levels.

was represented by 592 *Mel Phon Coefficient* (MPC) features. These are a simplified formulation of the *Mel-frequency cepstral coefficients* (MFCCs) that were shown to yield better classification performance (Bergstra, 2006).

All problems except *tzanetakis* had their data split into training set, validation set and test set. We kept the same standard splits that were used in Larochelle et al. (2007). The training set is used for both pretraining and fine tuning of the models. Classification performance on the validation set is used for choosing the best configuration of hyperparameters (model selection). The corresponding classification performance on the test set is then reported together with a 95% confidence interval.

For *tzanetakis* we used a slightly different procedure, since there was no predefined standard split and fewer examples. We used 10-fold cross validation, where each fold consisted of 8000 training examples, 1000 test and 1000 validation examples. For each fold, hyperparameters were chosen based on the performance on the validation set, and the retained model was used for computing the corresponding test error. We report the average test error and standard deviation across the 10 folds.

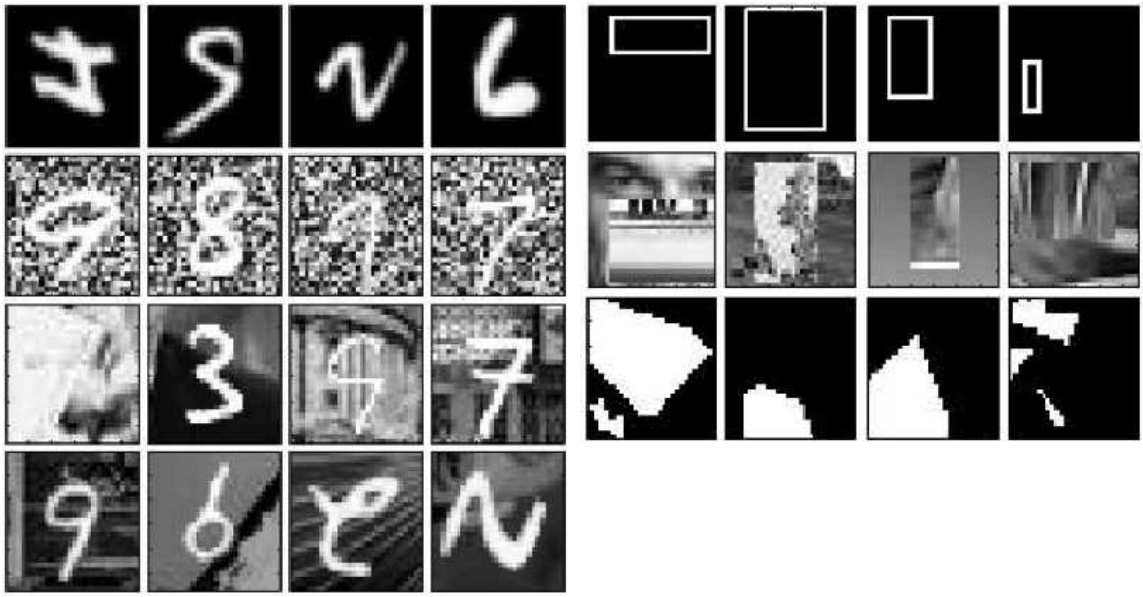
We were thus able to compare the classification performance of deep neural networks using different unsupervised initialization strategies for their parameters:

- MLP random: multilayer perceptron with usual random initialization;
- DBN (deep belief networks) corresponds to stacked RBM pretraining;
- SAE stacked autoencoder pretraining;
- SDAE stacked denoising autoencoder pretraining.

In all cases, the same supervised fine-tuning procedure was then used, that is, simple stochastic gradient descent with early stopping based on validation set performance.

Data Set	**Description**	**input**	m	**Train-Valid-Test**
MNIST	Standard MNIST digit classification problem.	784 gray-scale values scaled to [0,1]	10	50000-10000-10000
basic	Smaller subset of MNIST.		10	10000-2000-50000
rot	MNIST digits with added random rotation.		10	10000-2000-50000
bg-rand	MNIST digits with random noise background.		10	10000-2000-50000
bg-img	MNIST digits with random image background.		10	10000-2000-50000
bg-img-rot	MNIST digits with rotation and image background.		10	10000-2000-50000
rect	Discriminate between tall and wide rectangles (white on black).	784 values $\in\{0,1\}$	2	10000-2000-50000
rect-img	Discriminate between tall and wide rectangular image overlayed on a different background image.	784 values $\in [0,1]$	2	10000-2000-50000
convex	Discriminate between convex and concave shape.	784 values $\in\{0,1\}$	2	6000-2000-50000
tzanetakis	Classify genre of thirty second audio-clip.	592 MPC coefficients, standardized.	10	10-fold cross validation on 10000 training samples.

Table 1: Data sets. Characteristics of the 10 different problems considered. Except for *tzanetakis* whose input is made of 592 MPC features extracted from short audio sequences, all other problems are 28×28 gray-scale image classification tasks (i.e., input dimensionality is $28 \times 28 = 784$). See Larochelle et al. (2007) and Bergstra (2006) for further details on these data sets. The table gives, for each task, its shorthand name, a description of the problem, a description of input preprocessing, the number of classes (m), and the number of examples used for the training, validation and test sets respectively.



(a) *rot*, *bg-rand*, *bg-img*, *bg-img-rot*

(b) *rect*, *rect-img*, *convex*

Figure 9: Samples form the various image classification problems. (a): harder variations on the MNIST digit classification problems. (b): artificial binary classification problems.

On the 28×28 gray-scale image problems, SAE and SDAE used linear+sigmoid decoder layers and were trained using a cross-entropy loss, due to this being a natural choice for this kind of (near) binary images, as well as being functionally closer to RBM pretraining we wanted to compare against.

However for training the *first* layer on the *tzanetakis* problem, that is, for reconstructing *MPC coefficients*, a linear decoder and a squared reconstruction cost were deemed more appropriate (subsequent layers used sigmoid cross entropy as before). Similarly the first layer RBM used in pretraining a DBN on *tzanetakis* was defined with a Gaussian visible layer.

Table 2 lists the hyperparameters that had to be tuned by proper model selection (based on validation set performance). Note that to reduce the choice space, we restricted ourselves to the same number of hidden units, the same noise level, and the same learning rate for *all* hidden layers.

6.2 Empirical Comparison of Deep Network Training Strategies

Table 3 reports the classification performance obtained on all data sets using a 3 hidden layer neural network pretrained with the three different strategies: by stacking denoising autoencoders (SDAE-3), stacking restricted Boltzmann machines (DBN-3), and stacking regular autoencoders (SAE-3). For reference the table also contains the performance obtained by a single hidden-layer DBN-1 and by a Support Vector Machine with a RBF kernel (SVM_{rbf}).[12]

12. SVMs were trained using the libsvm implementation. Their hyperparameters (C and kernel width) were tuned semi-automatically (i.e., by human guided grid-search), searching for the best performer on the validation set.

hyperparameter	description	considered values
nHLay	number of hidden layers	{1,2,3}
nHUnit	number of units per hidden layer (same for all layers)	{1000,2000,3000}
lRate	fixed learning rate for unsupervised pretraining	$\{ 5 \times 10^{-6}, 5 \times 10^{-5}, 5 \times 10^{-4}, 5 \times 10^{-3}, 5 \times 10^{-2}, 10^{-1}\}$
lRateSup	fixed learning rate for supervised fine-tuning	{0.0005,0.005,0.05,0.1,0.15,0.2}
nEpoq	number of pretraining epochs (passages through the whole training set)	{5,10,50,100,125,150,200,300}
ν	corrupting noise level	fraction of corrupted inputs $(0, 0.10, 0.25, 0.40)$ or standard deviation for Gaussian noise $(0, 0.05, 0.10, 0.15, 0.30, 0.50)$

Table 2: List of hyperparameters for deep networks. These hyperparameters are common to all considered deep network training strategies, except for noise level ν which is specific to SDAE (for which we must also choose the kind of corruption). We list the typical values we considered in the majority of our experiments. Best performing configuration on the validation set was always searched for in a semi-automatic fashion, that is, running experiments in parallel on a large computation cluster, but with manual guidance to avoid wasting resources on unnecessary parts of the configuration space. Some experiments meant to study more closely the influence of specific hyperparameters occasionally used a finer search grid for them, as will be specified in the description of these experiments.

In these experiments, SDAE used a zero-masking corruption noise for all problems except for *tzanetakis*, for which a Gaussian noise was deemed more appropriate due to the nature of the input.

We see that SDAE-3 systematically outperforms the baseline SVM, as well as SAE-3 (except for *convex* for which the difference is not statistically significant). This shows clearly that denoising pretraining with a non-zero noise level is a better strategy than pretraining with regular autoencoders. For all but one problem, SDAE-3 is either the best performing algorithm or has its confidence interval overlap with that of the winning algorithm (i.e., difference cannot be considered statistically significant). In most cases, stacking 3 layers of denoising autoencoder seems to be on par or better than stacking 3 layers of RBMs in DBN-3.

In the following subsections, we will be conducting further detailed experiments to shed light on particular aspects of the denoising autoencoder pretraining strategy.

6.3 Influence of Number of Layers, Hidden Units per Layer, and Noise Level

Next we wanted to study more closely the influence of important architectural hyperparameters, namely the number of layers, the number of hidden units per layer, and the noise level. For this finer

Data Set	SVM_{rbf}	DBN-1	SAE-3	DBN-3	SDAE-3 (ν)
MNIST	**1.40**±0.23	**1.21**±0.21	**1.40**±0.23	**1.24**±0.22	**1.28**±0.22 (25%)
basic	**3.03**±0.15	3.94±0.17	3.46±0.16	3.11±0.15	**2.84**±0.15 (10%)
rot	11.11±0.28	14.69±0.31	10.30±0.27	10.30±0.27	**9.53**±0.26 (25%)
bg-rand	14.58±0.31	9.80±0.26	11.28±0.28	**6.73**±0.22	10.30±0.27 (40%)
bg-img	22.61±0.37	**16.15**±0.32	23.00±0.37	**16.31**±0.32	**16.68**±0.33 (25%)
bg-img-rot	55.18±0.44	52.21±0.44	51.93±0.44	47.39±0.44	**43.76**±0.43 (25%)
rect	**2.15**±0.13	4.71±0.19	2.41±0.13	2.60±0.14	**1.99**±0.12 (10%)
rect-img	24.04±0.37	23.69±0.37	24.05±0.37	22.50±0.37	**21.59**±0.36 (25%)
convex	19.13±0.34	19.92±0.35	**18.41**±0.34	**18.63**±0.34	**19.06**±0.34 (10%)
tzanetakis	**14.41**±2.18	18.07±1.31	**16.15**±1.95	18.38±1.64	**16.02**±1.04(0.05)

Table 3: Comparison of stacked denoising autoencoders (SDAE-3) with other models. Test error rate on all considered classification problems is reported together with a 95% confidence interval. Best performer is in bold, as well as those for which confidence intervals overlap. SDAE-3 appears to achieve performance superior or equivalent to the best other model on all problems except *bg-rand*. For SDAE-3, we also indicate the fraction ν of corrupted input components, or in case of *tzanetakis*, the standard deviation of the Gaussian noise, as chosen by proper model selection. Note that SAE-3 is equivalent to SDAE-3 with $\nu = 0\%$.

grained series of experiments, we chose to concentrate on the hardest of the considered problems, that is, the one with the most factors of variation: *bg-img-rot*.

We first examine how the proposed network training strategy behaves as we increase the capacity of the model both in breadth (number of neurons per layer) and in depth (number of hidden layers). Figure 10 shows the evolution of the performance as we increase the number of hidden layers from 1 to 3, for three different network training strategies: without any pretraining (standard MLP), with ordinary autoencoder pretraining (SAE) and with denoising autoencoder pretraining (SDAE). We clearly see a strict ordering: denoising pretraining being better than autoencoder pretraining being better than no pretraining. The advantage appears to increase with the number of layers (note that without pretraining it seems impossible to successfully train a 3 hidden layer network) and with the number of hidden units. This general behavior is a typical illustration of what is gained by pretraining deep networks with a good unsupervised criterion, and appears to be common to several pretraining strategies. We refer the reader to Erhan et al. (2010) for an empirical study and discussion regarding possible explanations for the phenomenon, centered on the observation of *regularization* effects (we exploit the hypothesis that features of X that help to capture $P(X)$ also help to capture $P(Y|X)$) and *optimization* effects (unsupervised pre-training initializes parameters near a better *local minimum* of *generalization* error).

Notice that in tuning the hyperparameters for all classification performances so far reported, we considered only a coarse choice of noise levels ν (namely 0%, 10%, 25%, or 40% of zero-masking corruption for the image classification problems). Clearly it was not necessary to pick the noise level very precisely to obtain good performances. In Figure 11 we examine in more details the influence of the level of corruption ν using a more fine-grained grid for problem *bg-img-rot*. We

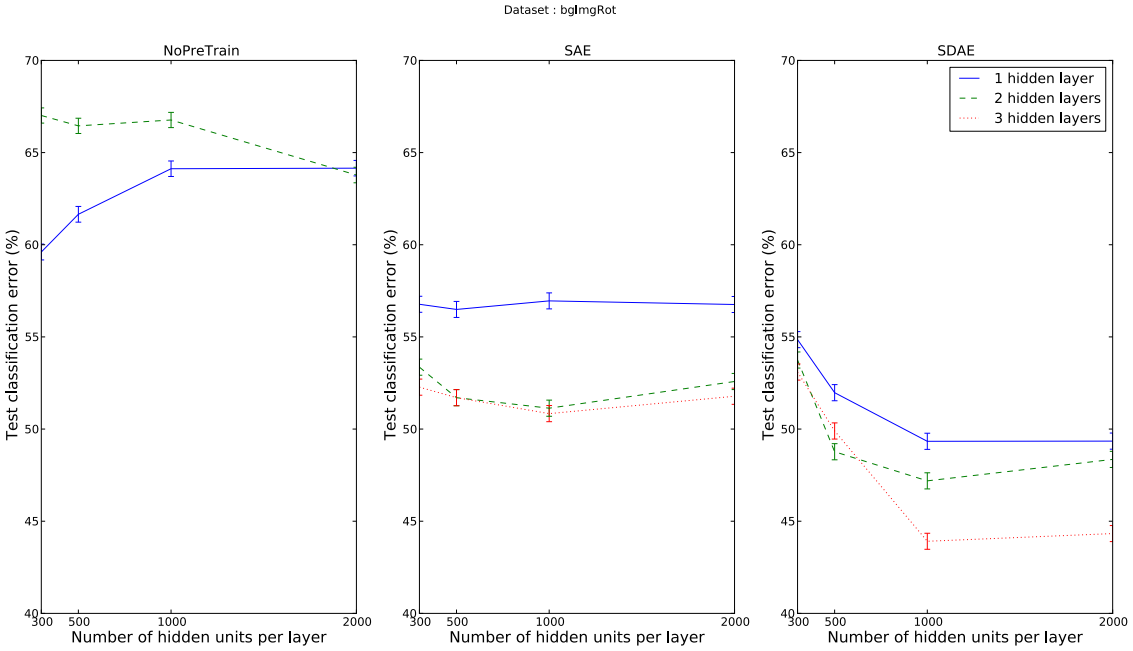


Figure 10: Classification performance on *bg-img-rot* for standard MLP with random initialization (NoPreTrain, left), SAE (middle), and SDAE (right), as we increase the number of hidden layers and the number of neurons per layer. Error bars show 95% confidence intervals. Note that without pretraining the curve for 3 layers is outside the graphic, the classification error being above 89%.

notice that SDAE appears to perform better than SAE (0 noise) for a rather wide range of noise levels, regardless of the number of hidden layers.

The following section reports an experiment that was conducted on three other data sets. The experiment had a different goal and thus used a coarser ν grid, but the resulting curves (see Figure 12) appear to follow a similar pattern to the one seen here (Figure 11).

6.4 Denoising Pretraining vs. Training with Noisy Input

We discussed in Section 4.2 the important distinction between denoising pretraining as it is done in SDAE and simply training with noisy inputs. SDAE uses a denoising criterion to learn good initial feature extractors at each layer that will be used as initialization for a *noiseless* supervised training. This is very different from training with noisy inputs, which amounts to training with a (virtually) expanded data set. This latter approach can in principle be applied to any classifier, such as an SVM[13] or a SAE. Note that in the case of the SAE, since there are two phases (pretraining and fine-tuning), it is possible to use noisy inputs for only the pretraining or for both the pretraining

13. For SAE, input examples can cheaply be corrupted on the fly, but this is not an option with standard SVM algorithms. So for SVM training we first augmented the training set by generating 9 extra variations of each original training example thus yielding a training set 10 times bigger than the original. Alternatively, we could instead have used the

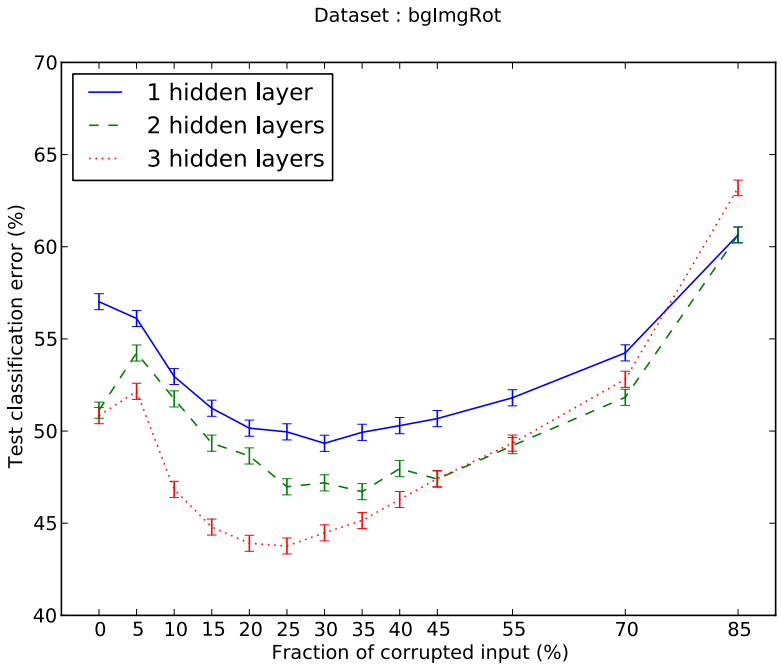

Figure 11: Sensitivity to the level of corruption. The curves report the test error rate for SDAE trained on problem *bg-img-rot* as a function of the fraction ν of corrupted input components (using zero masking noise). Error bars show 95% confidence interval. Note that 0% corruption corresponds to a SAE (regular autoencoder).

and fine-tuning phase. We experimentally compare these different approaches on three data sets in Figure 12. We see that denoising pretraining with SDAE, for a large range of noise levels, yields significantly improved performance, whereas training with noisy inputs sometimes degrades the performance, and sometimes improves it slightly but is clearly less beneficial than SDAE.

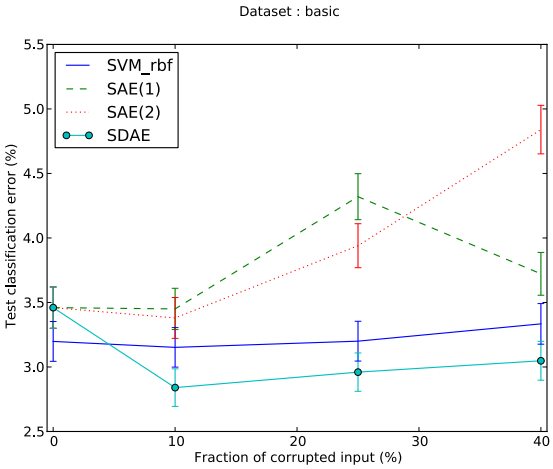
6.5 Variations on the Denoising Autoencoder: Alternate Corruption Types and Emphasizing

In the next series of experiments, we wanted to evaluate quantitatively the effect of using the various corrupting noises described in Section 3.3 as well as the *emphasized denoising autoencoder* variant described in Section 3.4.

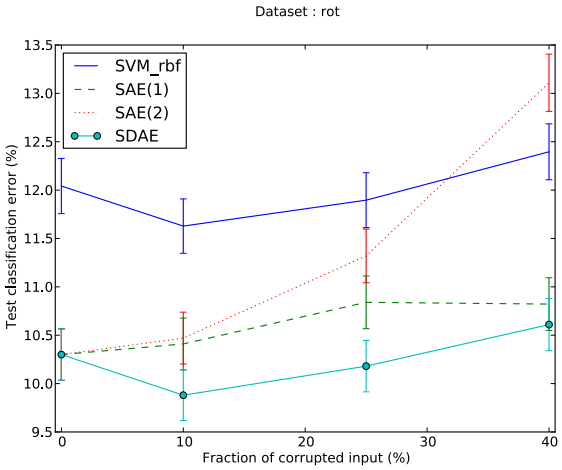
Extensive experiments were carried out on the same 3 problems we used in the previous section. Besides zero-masking noise (MN) we trained 3 hidden layer SDAE using salt-and-pepper noise (SP) and additive Gaussian noise (GS). For MN and SP, we also tried the emphasized variant.[14] For each considered variant, hyperparameters were selected as usual to yield the best performance on the

virtual SV technique (Schölkopf et al., 1996), which may or may not have yielded better performance, but since our main focus here is comparing noisy SAE with SDAE, SVM only serves as a simple baseline.

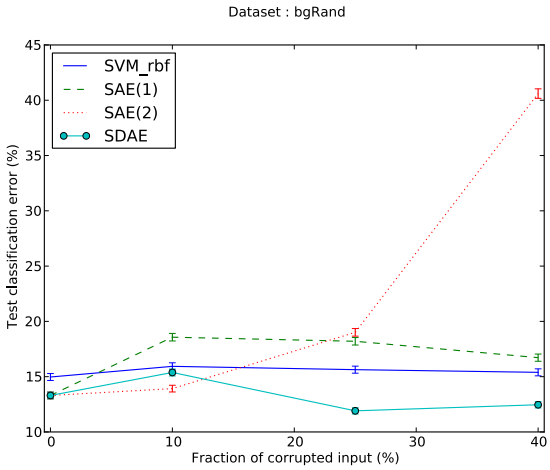
14. As already mentioned previously, since Gaussian noise corrupts every dimension, emphasized denoising does not make sense for this type of corruption.



(a) *basic*



(b) *rot*



(c) *bg-rand*

Figure 12: SDAE vs. training with noisy input. The test error of a **SDAE** with 3 hidden layers is compared to other algorithms trained with noisy inputs: a SVM with RBF kernel (**SVM$_{\text{rbf}}$**), a 3-hidden-layers SAE where noisy inputs were used for pretraining only (**SAE(1)**) and one where noisy inputs were used both for pretraining and supervised fine-tuning (**SAE(2)**). Hidden layers have 1000 neurons each. Zero-masking noise was used. Note that at 0% noise, the three stacked models correspond to an ordinary SAE. Error bars show 95% confidence interval. Denoising pretraining with SDAE appears to always yield significantly better performance, unlike training with noisy inputs.

Model	*basic*	*rot*	*bg-rand*
SVM$_{rbf}$	3.03±0.15	11.11±0.28	14.58±0.31
SAE-3	3.46±0.16	10.30±0.27	11.28±0.28
DBN-3	3.11±0.15	10.30±0.27	**6.73**±0.22
SDAE-3$_{MN}(\nu)$	2.84±0.15(10%)	9.53±0.26(25%)	10.30±0.27(40%)
SDAE-3$_{MN}(\nu)$ **+ emph**	**2.76**±0.14(25%)	10.36±0.27(25%)	9.69±0.26(40%)
SDAE-3$_{SP}(\nu)$	**2.66**±0.14(25%)	9.33±0.25(25%)	10.03±0.26(25%)
SDAE-3$_{SP}(\nu)$ **+ emph**	**2.48**±0.14(25%)	**8.76**±0.29(25%)	8.52±0.24(10%)
SDAE-3$_{GS}(\nu)$	**2.61**±0.14(0.1)	**8.86**±0.28(0.3)	11.73±0.28(0.1)

Table 4: Variations on 3-hidden-layer stacked denoising autoencoders (SDAE-3): alternative noise types and effect of emphasis. Considered noise types are masking noise (MN), salt-and-pepper (SP) and Gaussian noise (GS). Emphasized version considered double emphasis and full emphasis (see main text for detailed explanation). For easy comparison, the table also reproduces previously shown results for SVM_{rbf}, SAE-3, and DBN-3. Test error rate is reported together with a 95% confidence interval. Best performer is in bold, as well as those for which confidence intervals overlap. Corruption level ν (fraction of corrupted input components or Gaussian standard deviation) that was retained by model selection on the validation set is specified in parenthesis. SDAE-3$_{SP}$ with emphasis on reconstruction of corrupted dimension appears to be the best SDAE variant for these data sets, significantly improving performance on *rot* and *bg-rand*.

validation set. These included the number of units per layer (same for all layers), the corruption level ν (fraction of corrupted dimensions for MN and SP, or standard deviation for GS), with the usual considered values (listed previously in Table 2). For the emphasized version, a further hyperparameter was the degree of emphasis. We considered both *double emphasis*, where the weight on the reconstruction of the corrupted components is twice that on the uncorrupted components ($\alpha = 1,\ \beta = 0.5$), and *full emphasis* where all the weight is on reconstructing the corrupted components and none on the uncorrupted dimensions ($\alpha = 1,\ \beta = 0$). Table 4 reports the corresponding classification performance on the held-out test set. For the three considered data sets, an emphasized SDAE with salt-and-pepper noise appears to be the winning SDAE variant. It thus appears that a judicious choice of noise type and added emphasis may often buy us a better performance. However we had hoped, with these variants, to catch up with the performance of DBN-3 on the *bg-rand* problem,[15] but DBN-3 still performs significantly better than the best SDAE variant on this particular problem.

6.6 Are Features Learnt in an Unsupervised Fashion by SDAE Useful for SVMs?

In the following series of experiments, we wanted to verify whether the higher level representations extracted using SDAE could improve the performance of learning algorithms other than a neural network, such as SVMs.

15. As discussed in Larochelle et al. (2007), *bg-rand* is particularly favorable to RBMs because the pixel-wise independent noise perfectly matches what an RBM expects and will naturally not be represented in the hidden units.

To this end, we fed the representations learnt by the purely unsupervised phase of SDAE, at increasing higher levels (first, second and third hidden layer) to both a linear SVM and a Kernel SVM (using a RBF kernel). The hyperparameters of the SVM and its kernel were tuned on the validation set as usual. For computational reasons, we did not re-tune SDAE hyperparameters. Instead, we identified the best performing SDAE-pretrained neural networks with 1000 units per layer, based on their validation performance after fine-tuning from previous experiments, but used their saved weights prior to fine-tuning (i.e., after unsupervised denoising training only).

Results for all considered data sets are reported in Table 5, and Figure 13 highlights performance curves for two of them. Clearly, SVM performance can benefit significantly from using the higher level representation learnt by SDAE.[16] On all problems we see improved performance compared to using the original input (SVM_0). More interestingly, on most problems, SVM performance improves steadily as we use ever higher level representations. While it is not too surprising that linear SVMs can benefit from having the original input processed non-linearly, it is noteworthy that RBF kernel SVMs, which are high-capacity non-linear classifiers, also seem to benefit greatly from the non-linear mapping learned by SDAE.

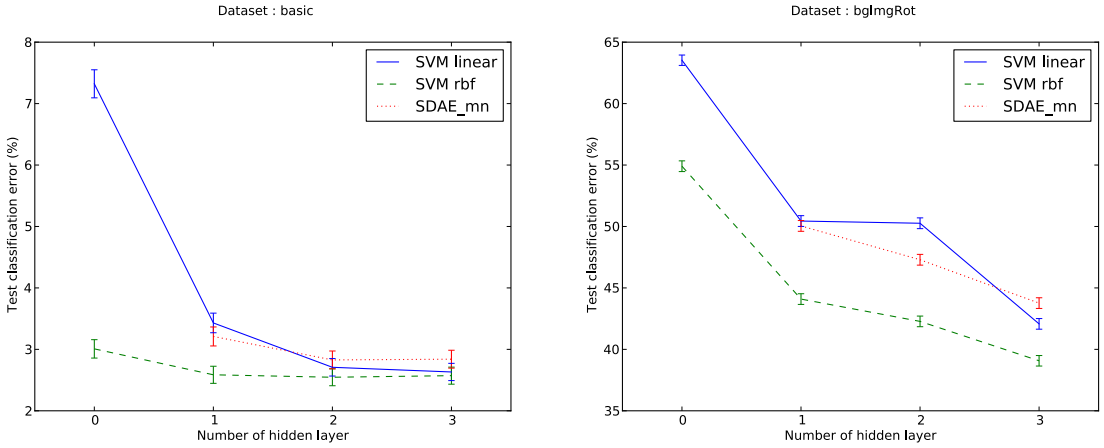


Figure 13: SVM on representations learnt by SDAE. The curves show evolution, on two data sets, of the test performance of linear and RBF kernel SVMs as we train them on higher level representations learnt in the unsupervised phase of SDAE. Performance of SDAE after supervised fine-tuning is also shown as $SDAE_{mn}$ (mn stands for masking noise). Hidden layer 0 corresponds to original input representation.

7. Generating Samples from Stacked Denoising Autoencoder Networks

Besides the classification performance comparisons and qualitative visual inspection of learnt filters, it is also customary in studies of deep generative models such as DBNs, to show samples generated

16. To verify that the learnt representation was responsible for the improved performance, rather than a random non-linear transformation, we also trained SVMs on the representation of the same neural network architecture but using randomly initialized weights: the performance degraded as we used the higher level representations.

Data Set	SVM kernel	SVM_0	SVM_1	SVM_2	SVM_3
MNIST	linear	5.33±0.44	1.49 ±0.24	**1.24**±0.22	**1.2**±0.21

Table 5: SVM performance on higher level representations learnt by SDAE. Performance of both linear SVM, and SVM with RBF kernel is reported, as they are trained on either original input (SVM_0), or on the representation learnt by a SDAE at the level of its first (SVM_1), second (SVM_2), or third (SVM_3) hidden layer. The representations used for the SVMs were those obtained prior to fine-tuning. Test error rate on all considered classification problems is reported together with a 95% confidence interval. Best performer is in bold, as well as those for which confidence intervals overlap. Clearly both linear and kernel SVM performance benefit from using the higher level representations learnt by SDAE. For most problems the performance increases steadily as we use representations from ever higher levels of the architecture.

from the trained models. This can yield another qualitative visual assessment of whether they were able to capture the input distribution well.

7.1 Top-Down Generation of a Visible Sample Given a Top-Layer Representation

Given a top-layer representation, a deep belief network (Hinton et al., 2006) is a directed graphical model, and it is easy to do a top down sampling pass, that is, sampling each layer conditioned on the layer above, to eventually produce a sample in the bottom layer that can be displayed. More precisely, in sigmoid deep belief networks (DBN), the representation at a lower layer X given the

layer above Y is distributed according to a product of independent Bernoullis whose mean is a deterministic function of Y, that is, $X|Y \sim \mathcal{B}(g_{\theta'}(Y))$, where $g_{\theta'}$ has the exact same form as that given in Equation 3 for the *decoder* part of an autoencoder. From a trained SAE or SDAE[17] it is thus possible to generate samples at one layer from the representation of the layer above in the exact same way as in a DBN.

7.2 Bottom-Up Inferring of the Top-Layer Representation Corresponding to a Given Input Pattern

In SAE/SDAE, *given an input representation at the bottom layer*, the corresponding representation in the top layer is computed in a deterministic *bottom-up* pass using encoding functions f_θ. The same procedure is used in DBNs and, in the graphical model perspective, can be viewed as an *approximate inference* of a factorial Bernoulli top-layer distribution given the low level input. This top-layer representation is to be understood as the parameters (the mean) of a factorial Bernoulli distribution for the actual binary units.

7.3 Generating Samples with SAE, SDAE, and DBN Using the Same Procedure

The deep belief network of Hinton et al. (2006) is a fully specified generative model. In particular the joint distribution of its top two layers is defined by an RBM model,[18], that is, an *undirected* graphical model from which one can efficiently sample using alternating Gibbs sampling (Hinton et al., 2006). So to sample from a DBN model, one would first sample from the top-layer RBM using alternating Gibbs sampling. Then, given the thus obtained top-layer representation, perform the single top down sampling pass previously described to produce a visible pattern at the bottom layer.

By contrast, SAE/SDAE training does not attempt to model the distribution of the top-layer representation. So even though—given a top-layer representation—we can use the exact same top down sampling procedure to generate input patterns from a SAE/SDAE as for a DBN, SAE/SDAE cannot by themselves alone be treated as fully specified generative models. They lack a model of the marginal distribution of their top layer.

We can easily fix this by modeling that top-layer distribution non-parametrically by the simple memory-based *empirical distribution* of the encoded top-layer representations of the n training set patterns. A visible sample can then be generated by simply taking the top-layer encoded representation of a randomly picked training set input, and carrying out the top-down sampling procedure explained previously, as illustrated in Figure 14. This same technique can also be used as an alternative sample-generation procedure for DBNs built by stacking RBMs.

If we keep the same fixed input pattern, and hence the same corresponding higher level representation, and perform several top-down samplings, we can thus observe what kind of pattern variations the deep multilayer part of a deep network has learnt to model (or abstract away in extracting the top-layer representation). Figure 15 shows the resulting variability in the regenerated patterns, for models pretrained respectively as SAE, SDAE[19] and DBN on MNIST without any su-

17. SAE and SDAE train such $g_{\theta'}$ to perform reconstruction, that is, predicting the mean value of a layer given the representation in the layer immediately above it.
18. This RBM was trained, using the training set, to model the representations obtained at the layer just below the top one, produced by the bottom-up pass we just described.
19. Both were pretrained with salt-and-pepper noise.

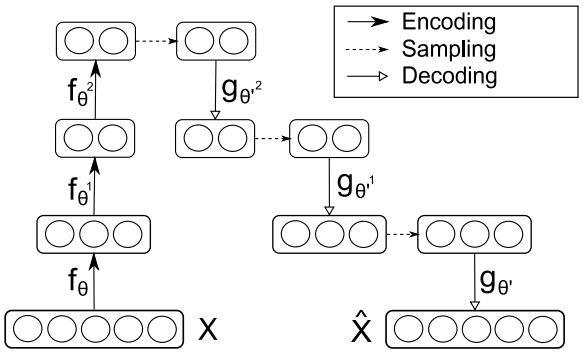

Figure 14: Non-parametric sampling procedure for pretrained networks. A randomly picked input form the original data set is provided as input. Its top level representation is obtained by deterministic bottom-up encoding using functions $f_{\theta^{(k)}}$. A visible pattern is generated given this high level representation, by alternating Bernoulli sampling and deterministic decoding, that is, by successively sampling from $\mathcal{B}(g_{\theta'^{(k)}}(\text{previouslayer}))$. This same procedure can be applied with SAE, SDAE and DBN. It allows to see the quality and variability of patterns one obtains given a high-level representation.

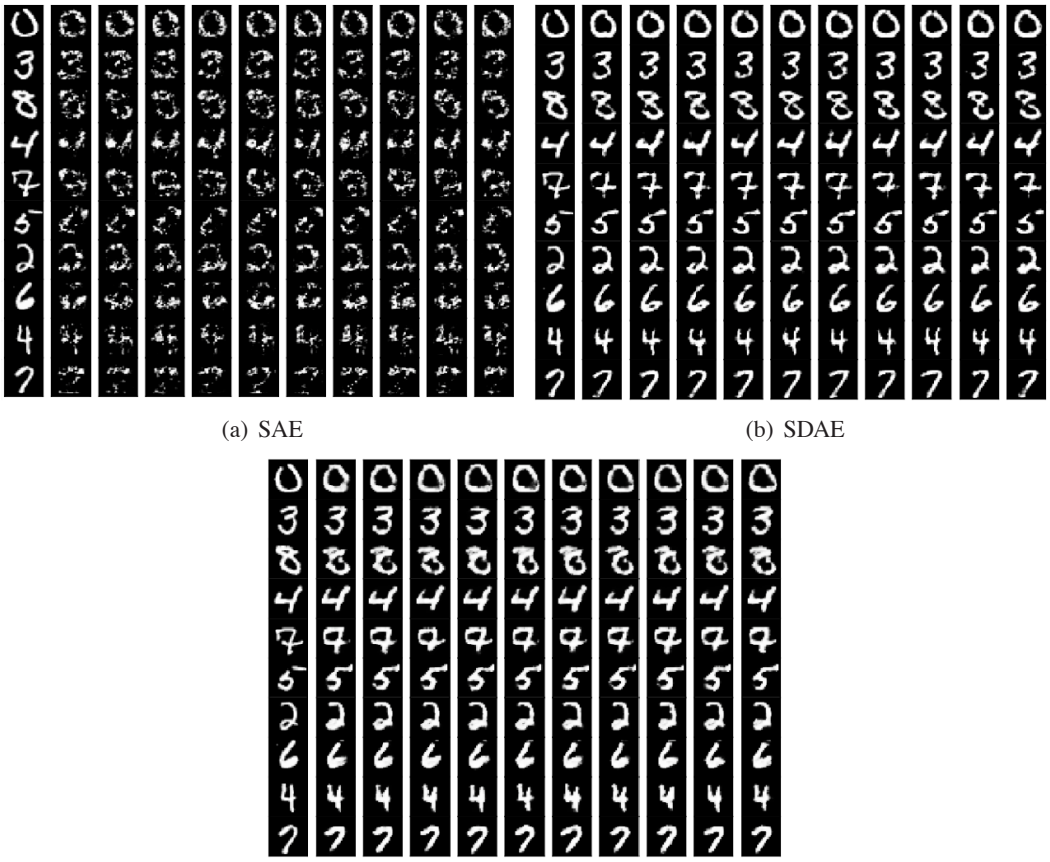
pervised fine-tuning. It appears that SDAE and DBN are able to resynthesize a variety of similarly good quality digits, whereas the SAE trained model regenerates patterns with much visible degradation in quality. This is further evidence of the qualitative difference resulting from optimizing a denoising criterion instead of mere reconstruction criterion. Note how SDAE puts back the missing hole in the loop of the regenerated 6, and sometimes straightens up the upper stroke of the 7, suggesting that it did indeed capture interesting specific characteristics. It appears that, when using this same sample generation procedure, SDAE and DBN yield a similar degree of variability in the regenerated patterns (with DBN patterns looking slightly fatter and SDAE patterns slightly thinner). Neither DBN nor SDAE guarantee that class boundaries will not be crossed,[20] for example DBN closes a loop in a 7 making it look closer to a 9, whereas SDAE sometimes breaks open the loop of an 8 making it look like a 3. But in all cases, and contrary to SAE, the regenerated patterns look like they could be samples from the same unknown input distribution that yielded the training set.

8. Conclusion and Future Work

The present work was inspired by recent successful approaches to training deep networks, specifically by their use of a local unsupervised criterion, and led by the question of what that criterion should be. At the same time we were motivated by a desire to bridge a remaining performance gap between deep belief networks and the stacking of ordinary autoencoders (Bengio et al., 2007; Larochelle et al., 2009a). This led us to address a theoretical shortcoming of traditional autoencoders—namely their inability in principle to learn useful over-complete representations—in a simple yet original way: by changing the objective from one involving mere reconstruction to the more challenging task of *denoising*. The resulting Stacked Denoising Autoencoder algorithm

20. The reader should however keep in mind that this results from unsupervised training only.



(a) SAE (b) SDAE

(c) DBN

Figure 15: Variability of the samples generated with 3-hidden-layer SAE, SDAE and DBN pre-trained models. Each sub-figure is to be read row-wise: the leftmost pattern in each row is a training set pattern. Following the sample generation depicted in Figure 14, it was provided as input to the network and its top-layer representation was computed by deterministic bottom up encoding. Patterns to its right were then generated independently given that top level representation. Clearly, SDAE trained networks, like DBNs, are able to regenerate high quality samples from their high level representation, contrary to SAE. SDAE and DBNs also appear to give rise to a similar level of variability in the bottom-up generated patterns (DBN patterns tending to be somewhat fatter). Note how SDAE puts back the missing hole in the loop of the regenerated 6, and sometimes straightens up the upper stroke of the last 7, suggesting that it did indeed capture meaningful specific characteristics. DBN and SDAE generated patterns can easily pass for samples from the unknown input distribution being modeled, unlike patterns generated by SAE.

for training deep networks, proved indeed able to bridge the performance gap with DBNs, yielding equivalent or better classification performance on all but one of the considered benchmark problems. As a deep network pretraining strategy, stacking of denoising autoencoders yielded in most cases a significant improvement in performance over the stacking of ordinary autoencoders. The representations thus extracted layer by layer, using a purely unsupervised local denoising criterion, appear to make subsequent classification tasks much easier. This is further evidenced by the fact that state-of-the-art shallow classifiers such as kernel SVMs also appear able to greatly benefit from it. Close examination of the feature extractors learnt by denoising autoencoders showed that they were able to zero in on useful structure in the data (such as Gabor-like edge detectors on natural image patches) that regular autoencoders seemed unable to learn.

The algorithm we developed is a straightforward, easy to implement, variation on the well-understood ordinary autoencoders. All that remains to be chosen is the kind and level of corrupting noise. It is likely that a careful choice, possibly guided by prior domain knowledge, may further boost application-specific performance. Nevertheless our experiments showed that high performance can already be achieved using very simple and generic noise types and with little tuning of the noise level. In addition, we were able to show that, contrary to what it may seem on the surface based on popular myths, the denoising training we advocate is *not* equivalent to using a mere weight decay regularization, nor is it the same as direct supervised training with corrupted (jittered) examples.

Beyond the specificities and practical usefulness of the simple algorithm we developed, **our results clearly establish the value of using a *denoising criterion* as an unsupervised objective to guide the learning of useful higher level representations.** This is in our view the most important contribution of our work, as it offers an interesting alternative to more usual (and often intractable) likelihood derived criteria. Indeed, denoising performance can easily be measured and directly optimized. The use of a denoising criterion is very different from the contrastive divergence training of RBMs or the direct enforcing of sparsity in autoencoders. We hope that our very encouraging results will inspire further research in this direction, both theoretical (to better understand the relationship between denoising and representation learning), and practical (to develop better learning algorithms based on this understanding).

There are certainly better ways to use denoising-based training signals in the learning of a deep network than the simple local approach we explored here. In particular, while stacking denoising autoencoders allows us to build a deep network, the denoising autoencoders we used here were shallow. It would thus be interesting to investigate deep denoising autoencoders with several hidden layers, and their ability to form useful representations. The choice and role of the corruption process also deserves further inquiry. If more involved corruption processes than those explored here prove beneficial, it would be most useful if they could be parameterized and learnt directly from the data, rather than having to be hand-engineered based on prior-knowledge.

Abstract

In this paper, we introduce a new family of probability densities called L_p-nested symmetric distributions. The common property, shared by all members of the new class, is the same functional form $\rho(\boldsymbol{x}) = \tilde{\rho}(f(\boldsymbol{x}))$, where f is a nested cascade of L_p-norms $\|\boldsymbol{x}\|_p = (\sum |x_i|^p)^{1/p}$. L_p-nested symmetric distributions thereby are a special case of ν-spherical distributions for which f is only required to be positively homogeneous of degree one. While both, ν-spherical and L_p-nested symmetric distributions, contain many widely used families of probability models such as the Gaussian, spherically and elliptically symmetric distributions, L_p-spherically symmetric distributions, and certain types of independent component analysis (ICA) and independent subspace analysis (ISA) models, ν-spherical distributions are usually computationally intractable. Here we demonstrate that L_p-nested symmetric distributions are still computationally feasible by deriving an analytic expression for its normalization constant, gradients for maximum likelihood estimation, analytic expressions for certain types of marginals, as well as an exact and efficient sampling algorithm. We discuss the tight links of L_p-nested symmetric distributions to well known machine learning methods such as ICA, ISA and mixed norm regularizers, and introduce the nested radial factorization algorithm (NRF), which is a form of non-linear ICA that transforms any linearly mixed, non-factorial L_p-nested symmetric source into statistically independent signals. As a corollary, we also introduce the uniform distribution on the L_p-nested unit sphere.

Keywords: parametric density model, symmetric distribution, ν-spherical distributions, non-linear independent component analysis, independent subspace analysis, robust Bayesian inference, mixed norm density model, uniform distributions on mixed norm spheres, nested radial factorization

1. Introduction

High-dimensional data analysis virtually always starts with the measurement of first and second-order moments that are sufficient to fit a multivariate Gaussian distribution, the maximum entropy distribution under these constraints. Natural data, however, often exhibit significant deviations from a Gaussian distribution. In order to model these higher-order correlations, it is necessary to have more flexible distributions available. Therefore, it is an important challenge to find generalizations of the Gaussian distribution which are more flexible but still computationally and analytically tractable. In particular, density models with an explicit normalization constant are desirable because they make direct model comparison possible by comparing the likelihood of held out test

samples for different models. Additionally, such models often allow for a direct optimization of the likelihood.

One way of imposing structure on probability distributions is to fix the general form of the iso-density contour lines. This approach was taken by Fernandez et al. (1995). They modeled the contour lines by the level sets of a positively homogeneous function of degree one, that is functions ν that fulfill $\nu(a \cdot \boldsymbol{x}) = a \cdot \nu(\boldsymbol{x})$ for $\boldsymbol{x} \in \mathbb{R}^n$ and $a \in \mathbb{R}_0^+$. The resulting class of ν-spherical distributions have the general form $\rho(\boldsymbol{x}) = \tilde{\rho}(\nu(\boldsymbol{x}))$ for an appropriate $\tilde{\rho}$ which causes $\rho(\boldsymbol{x})$ to integrate to one. Since the only access of ρ to $\boldsymbol{x}$ is via ν one can show that, for a fixed ν, those distributions are generated by a univariate radial distribution. In other words, ν-spherically distributed random variables can be represented as a product of two independent random variables: one positive radial variable and another variable which is uniform on the 1-level set of ν. This property makes this class of distributions easy to fit to data since the maximum likelihood procedure can be carried out on the univariate radial distribution instead of the joint density. Unfortunately, deriving the normalization constant for the joint distribution in the general case is intractable because it depends on the surface area of those level sets which can usually not be computed analytically.

Known tractable subclasses of ν-spherical distributions are the Gaussian, elliptically contoured, and L_p-spherical distributions. The Gaussian is a special case of elliptically contoured distributions. After centering and whitening $\boldsymbol{x} := C^{-1/2}(\boldsymbol{s} - E[\boldsymbol{s}])$ a Gaussian distribution is spherically symmetric and the squared L_2-norm $||\boldsymbol{x}||_2^2 = x_1^2 + \cdots + x_n^2$ of the samples follow a χ^2-distribution (that is, the radial distribution is a χ-distribution). Elliptically contoured distributions other than the Gaussian are obtained by using a radial distribution different from the χ-distribution (Kelker, 1970; Fang et al., 1990).

The extension from L_2- to L_p-spherically symmetric distributions is based on replacing the L_2-norm by the L_p-norm

$$\nu(\boldsymbol{x}) = \|\boldsymbol{x}\|_p = \left(\sum_{i=1}^{n} |x_i|^p \right)^{\frac{1}{p}}, \; p > 0$$

in the density definition. That is, the density of L_p-spherically symmetric distributions can always be written in the form $\rho(\boldsymbol{x}) = \tilde{\rho}(||\boldsymbol{x}||_p)$. Those distributions have been studied by Osiewalski and Steel (1993) and Gupta and Song (1997). We will adopt the naming convention of Gupta and Song (1997) and call $\|\boldsymbol{x}\|_p$ an *L_p-norm* even though the triangle inequality only holds for $p \geq 1$. L_p-spherically symmetric distributions with $p \neq 2$ are no longer invariant with respect to rotations (transformations from $SO(n)$). Instead, they are only invariant under permutations of the coordinate axes. In some cases, it may not be too restrictive to assume permutation or even rotational symmetry for the data. In other cases, such symmetry assumptions might not be justified and cause the model to miss important regularities.

Here, we present a generalization of the class of L_p-spherically symmetric distributions within the class of ν-spherical distributions that makes weaker assumptions about the symmetries in the data but still is analytically tractable. Instead of using a single L_p-norm to define the contour of the density, we use a nested cascade of L_p-norms where an L_p-norm is computed over groups of L_p-norms over groups of L_p-norms ..., each of which having a possibly different p. Due to this nested structure we call this new class of distributions *L_p-nested symmetric distributions*. The nested combination of L_p-norms preserves positive homogeneity but does not require permutation invariance anymore. While L_p-nested symmetric distributions are still invariant under reflections of the coordinate axes, permutation symmetry only holds within the subspaces of the L_p-norms at the bottom of

the cascade. As demonstrated in Sinz et al. (2009b), one possible application domain of L_p-nested symmetric distributions is natural image patches. In the current paper, we would like to present a formal treatment of this class of distributions. Readers interested in the application of these distributions to natural images should refer to Sinz et al. (2009b).

We demonstrate below that the construction of the nested L_p-norm cascade still bears enough structure to compute the Jacobian of polar-like coordinates similar to those of Song and Gupta (1997), and Gupta and Song (1997). With this Jacobian at hand it is possible to compute the univariate radial distribution for an arbitrary L_p-nested symmetric density and to define the uniform distribution on the L_p-nested unit sphere $\mathbb{L}_\nu = \{\boldsymbol{x} \in \mathbb{R}^n | \nu(\boldsymbol{x}) = 1\}$. Furthermore, we compute the surface area of the L_p-nested unit sphere and, therefore, the general normalization constant for L_p-nested symmetric distributions. By deriving these general relations for the class of L_p-nested symmetric distributions we have determined a new class of tractable ν-spherical distributions which is so far the only one containing the Gaussian, elliptically contoured, and L_p-spherical distributions as special cases.

L_p-spherically symmetric distributions have been used in various contexts in statistics and machine learning. Many results carry over to L_p-nested symmetric distributions which allow a wider application range. Osiewalski and Steel (1993) showed that the posterior on the location of a L_p-spherically symmetric distributions together with an improper Jeffrey's prior on the scale does not depend on the particular type of L_p-spherically symmetric distribution used. Below, we show that this results carries over to L_p-nested symmetric distributions. This means that we can robustly determine the location parameter by Bayesian inference for a very large class of distributions.

A large class of machine learning algorithms can be written as an optimization problem on the sum of a regularizer and a loss function. For certain regularizers and loss functions, like the sparse L_1 regularizer and the mean squared loss, the optimization problem can be seen as the maximum a posteriori (MAP) estimate of a stochastic model in which the prior and the likelihood are the negative exponentiated regularizer and loss terms. Since $\rho(\boldsymbol{x}) \propto \exp(-||\boldsymbol{x}||_p^p)$ is an L_p-spherically symmetric model, regularizers which can be written in terms of a norm have a tight link to L_p-spherically symmetric distributions. In an analogous way, L_p-nested symmetric distributions exhibit a tight link to mixed-norm regularizers which have recently gained increasing interest in the machine learning community (see, e.g., Zhao et al., 2008; Yuan and Lin, 2006; Kowalski et al., 2008). L_p-nested symmetric distributions can be used for a Bayesian treatment of mixed-norm regularized algorithms. Furthermore, they can be used to understand the prior assumptions made by such regularizers. Below we discuss an implicit dependence assumption between the regularized variables that follows from the theory of L_p-nested symmetric distributions.

Finally, the only factorial L_p-spherically symmetric distribution (Sinz et al., 2009a), the p-generalized Normal distribution, has been used as an ICA model in which the marginals follow an exponential power distribution. This class of ICA is particularly suited for natural signals like images and sounds (Lee and Lewicki, 2000; Zhang et al., 2004; Lewicki, 2002). Interestingly, L_p-spherically symmetric distributions other than the p-generalized Normal give rise to a non-linear ICA algorithm called radial Gaussianization for $p = 2$ (Lyu and Simoncelli, 2009) or radial factorization for arbitrary p (Sinz and Bethge, 2009). As discussed below, L_p-nested symmetric distributions are a natural extension of the linear L_p-spherically symmetric ICA algorithm to ISA, and give rise to a more general non-linear ICA algorithm in the spirit of radial factorization.

The remaining part of the paper is structured as follows: in Section 2 we define polar-like coordinates for L_p-nested symmetrically distributed random variables and present an analytical expression

for the determinant of the Jacobian for this coordinate transformation. Using this expression, we define the uniform distribution on the L_p-nested unit sphere and the class of L_p-nested symmetric distributions for an arbitrary L_p-nested function in Section 3. In Section 4 we derive an analytical form of L_p-nested symmetric distributions when marginalizing out lower levels of the L_p-nested cascade and demonstrate that marginals of L_p-nested symmetric distributions are not necessarily L_p-nested symmetric. Additionally, we demonstrate that the only factorial L_p-nested symmetric distribution is necessarily L_p-spherically symmetric and discuss the implications of this result for mixed norm regularizers. In Section 5 we propose an algorithm for fitting arbitrary L_p-nested symmetric models. We derive a sampling scheme for arbitrary L_p-nested symmetric distributions in Section 6. In Section 7 we generalize a result by Osiewalski and Steel (1993) on robust Bayesian inference on the location parameter to L_p-nested symmetric distributions. In Section 8 we discuss the relationship of L_p-nested symmetric distributions to ICA and ISA, and their possible role as priors on hidden variables in over-complete linear models. Finally, we derive a non-linear ICA algorithm for linearly mixed non-factorial L_p-nested symmetric sources in Section 9 which we call nested radial factorization (NRF).

2. L_p-nested Functions, Coordinate Transformation and Jacobian

Consider the function

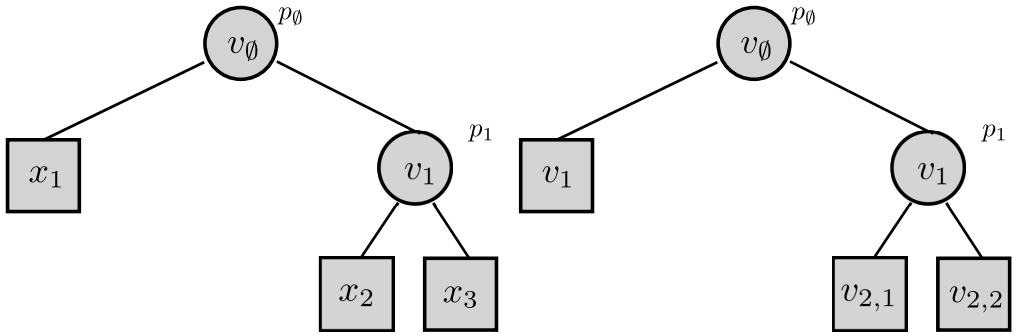
$$f(\boldsymbol{x}) = \left(|x_1|^{p_\emptyset} + \left(|x_2|^{p_1} + |x_3|^{p_1} \right)^{\frac{p_\emptyset}{p_1}} \right)^{\frac{1}{p_\emptyset}} \tag{1}$$

with $p_\emptyset, p_1 \in \mathbb{R}^+$. This function is obviously a cascade of two L_p-norms and is thus positively homogeneous of degree one. Figure 1(a) shows this function visualized as a tree. Naturally, any tree like the ones in Figure 1 corresponds to a function of the kind of Equation (1). In general, the n leaves of the tree correspond to the n coefficients of the vector $\boldsymbol{x} \in \mathbb{R}^n$ and each inner node computes the L_p-norm of its children using its specific p. We call the class of functions which is generated in this way *L_p-nested* and the corresponding distributions, which are symmetric or invariant with respect to it, *L_p-nested symmetric distributions*.

L_p-nested functions are much more flexible in creating different shapes of level sets than single L_p-norms. Those level sets become the iso-density contours in the family of L_p-nested symmetric distributions. Figure 2 shows a variety of contours generated by the simplest non-trivial L_p-nested function shown in Equation (1). The shapes show the unit spheres for all possible combinations of $p_\emptyset, p_1 \in \{0.5, 1, 2, 10\}$. On the diagonal, $p_\emptyset$ and p_1 are equal and therefore constitute L_p-norms. The corresponding distributions are members of the L_p-spherically symmetric class.

To make general statements about general L_p-nested functions, we introduce a notation that is suitable for the tree structure of L_p-nested functions. As we will heavily use that notation in the remainder of the paper, we would like to emphasize the importance of the following paragraphs. We will illustrate the notation with an example below. Additionally, Figure 1 and Table 1 can be used for reference.

We use multi-indices to denote the different nodes of the tree corresponding to an L_p-nested function f. The function $f = f_\emptyset$ itself computes the value $v_\emptyset$ at the root node (see Figure 1). Those values are denoted by variables v. The functions corresponding to its children are denoted by $f_1, ..., f_{\ell_\emptyset}$, that is, $f(\cdot) = f_\emptyset(\cdot) = \|(f_1(\cdot), ..., f_{\ell_\emptyset}(\cdot))\|_{p_\emptyset}$. We always use the letter "ℓ" indexed by the node's multi-index to denote the total number of direct children of that node. The functions of



(a) Equation (1) as tree. (b) Equation (1) as tree in multi-index notation.

Figure 1: Equation (1) visualized as a tree with two different naming conventions. Figure (a) shows the tree where the nodes are labeled with the coefficients of $\boldsymbol{x} \in \mathbb{R}^n$. Figure (b) shows the same tree in multi-index notation where the multi-index of a node describes the path from the root node to that node in the tree. The leaves $v_1, v_{2,1}$ and $v_{2,2}$ still correspond to x_1, x_2 and x_3, respectively, but have been renamed to the multi-index notation used in this article.

$f(\cdot) = f_\emptyset(\cdot)$	L_p-nested function
$I = i_1, ..., i_m$	Multi-index denoting a node in the tree: The single indices describe the path from the root node to the respective node I.
$\boldsymbol{x}_I$	All entries in $\boldsymbol{x}$ that correspond to the leaves in the subtree under the node I
$\boldsymbol{x}_{\widehat{I}}$	All entries in $\boldsymbol{x}$ that are not leaves in the subtree under the node I
$f_I(\cdot)$	L_p-nested function corresponding to the subtree under the node I
$v_\emptyset$	Function value at the root node
v_I	Function value at an arbitrary node with multi-index I
ℓ_I	The number of direct children of a node I
n_I	The number of leaves in the subtree under the node I
$\boldsymbol{v}_{I,1:\ell_I}$	Vector with the function values at the direct children of a node I

Table 1: Summary of the notation used for L_p-nested functions in this article.

the children of the i^{th} child of the root node are denoted by $f_{i,1}, ..., f_{i,\ell_i}$ and so on. In this manner, an index is added for denoting the children of a particular node in the tree and each multi-index denotes the path to the respective node in the tree. For the sake of compact notation, we use upper case letters to denote a single multi-index $I = i_1, ..., i_\ell$. The range of the single indices and the length of the multi-index should be clear from the context. A concatenation I, k of a multi-index I with a single index k corresponds to adding k to the index tuple, that is, $I, k = i_1, ..., i_m, k$. We use the

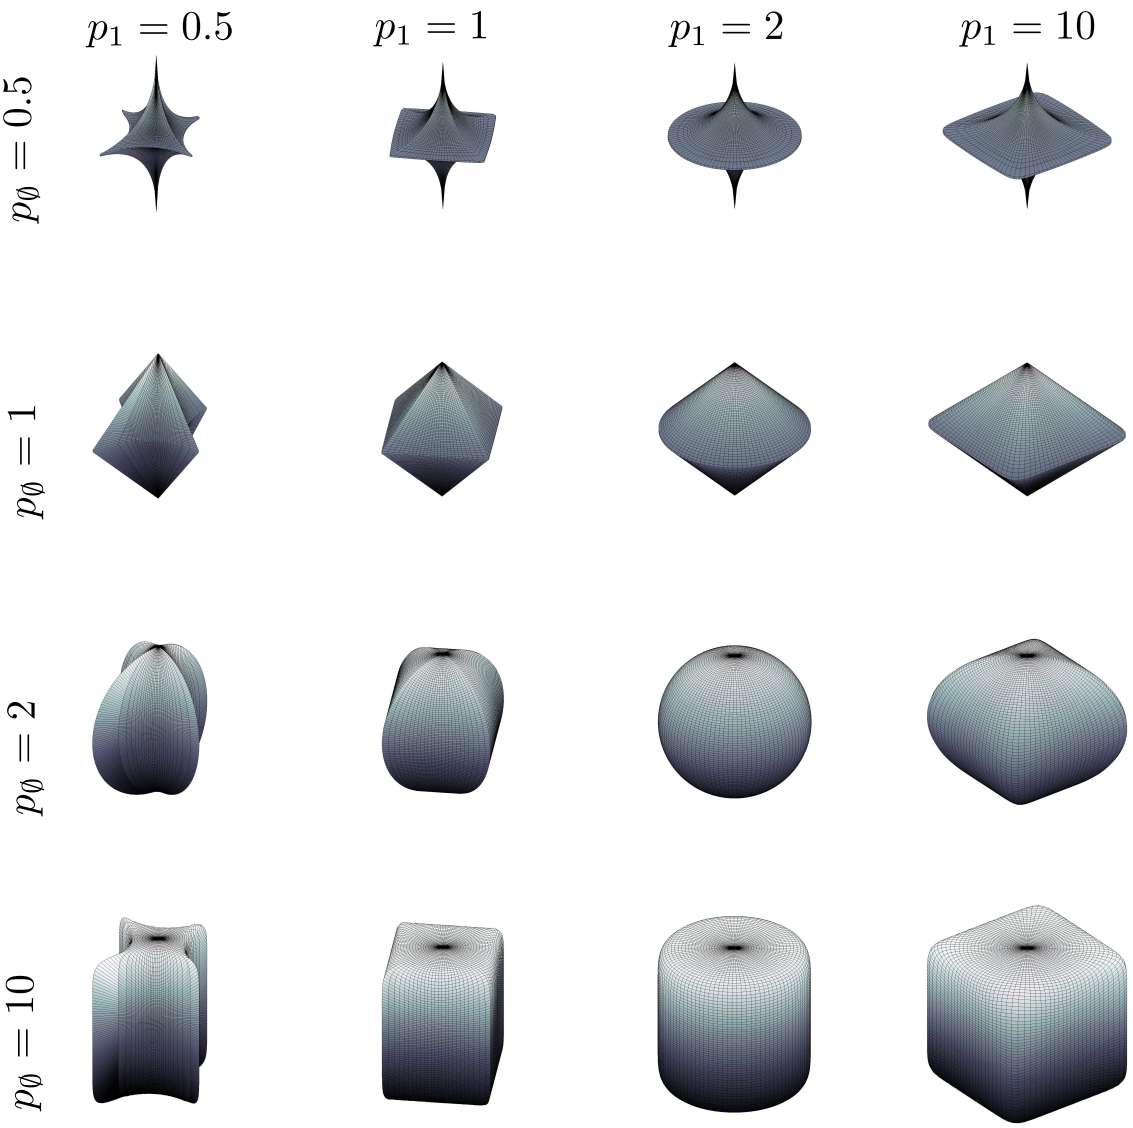


Figure 2: Variety of contours created by the L_p-nested function of Equation (1) for all combinations of $p_\emptyset, p_1 \in \{0.5, 1, 2, 10\}$.

convention that $I, \emptyset = I$. Those coefficients of the vector $\boldsymbol{x}$ that correspond to leaves of the subtree under a node with the index I are denoted by $\boldsymbol{x}_I$. The complement of those coefficients, that is, the ones that are not in the subtree under the node I, are denoted by $\boldsymbol{x}_{\hat{I}}$. The number of leaves in a subtree under a node I is denoted by n_I. If I denotes a leaf then $n_I = 1$.

The L_p-nested function associated with the subtree under a node I is denoted by

$$f_I(\boldsymbol{x}_I) = ||(f_{I,1}(\boldsymbol{x}_{I,1}), ..., f_{I,\ell_I}(\boldsymbol{x}_{I,\ell_I}))^\top||_{p_I}.$$

Just like for the root node, we use the variable v_I to denote the function value $v_I = f_I(\boldsymbol{x}_I)$ of a subtree I. A vector with the function values of the children of I is denoted with bold font $\boldsymbol{v}_{I,1:\ell_I}$ where the colon indicates that we mean the vector of the function values of the ℓ_I children of node I:

$$\begin{aligned} f_I(\boldsymbol{x}_I) &= ||(f_{I,1}(\boldsymbol{x}_{I,1}),...,f_{I,\ell_I}(\boldsymbol{x}_{I,\ell_I}))^\top||_{p_I} \\ &= ||(v_{I,1},...,v_{I,\ell_I})^\top||_{p_I} = ||\boldsymbol{v}_{I,1:\ell_I}||_{p_I}. \end{aligned}$$

Note that we can assign an arbitrary p to leaf nodes since ps for single variables always cancel. For that reason we can choose an arbitrary p for convenience and fix its value to $p = 1$. Figure 1(b) shows the multi-index notation for our example of Equation (1).

To illustrate the notation: Let $I = i_1,...,i_d$ be the multi-index of a node in the tree. $i_1,...,i_d$ describes the path to that node, that is, the respective node is the i_d^{th} child of the i_{d-1}^{th} child of the i_{d-2}^{th} child of the ... of the i_1^{th} child of the root node. Assume that the leaves in the subtree below the node I cover the vector entries $x_2,...,x_{10}$. Then $\boldsymbol{x}_I = (x_2,...,x_{10})$, $\boldsymbol{x}_{\widehat{I}} = (x_1,x_{11},x_{12},...)$, and $n_I = 9$. Assume that node I has $\ell_I = 2$ children. Those would be denoted by $I,1$ and $I,2$. The function realized by node I would be denoted by f_I and only acts on $\boldsymbol{x}_I$. The value of the function would be $f_I(\boldsymbol{x}_I) = v_I$ and the vector containing the values of the children of I would be $\boldsymbol{v}_{I,1:2} = (v_{I,1},v_{I,2})^\top = (f_{I,1}(\boldsymbol{x}_{I,1}),f_{I,2}(\boldsymbol{x}_{I,2}))^\top$.

We now introduce a coordinate representation specially tailored to L_p-nested symmetrically distributed variables: One of the most important consequences of the positive homogeneity of f is that it can be used to "normalize" vectors and, by that property, create a polar like coordinate representation of a vector $\boldsymbol{x}$. Such polar-like coordinates generalize the coordinate representation for L_p-norms by Gupta and Song (1997).

Definition 1 (Polar-like Coordinates) *We define the following polar-like coordinates for a vector* $\boldsymbol{x} \in \mathbb{R}^n$*:*

$$\begin{aligned} u_i &= \frac{x_i}{f(\boldsymbol{x})} \text{ for } i = 1,...,n-1, \\ r &= f(\boldsymbol{x}). \end{aligned}$$

The inverse coordinate transformation is given by

$$\begin{aligned} x_i &= r u_i \text{ for } i = 1,...,n-1, \\ x_n &= r \Delta_n u_n \end{aligned}$$

where $\Delta_n = \operatorname{sgn} x_n$ *and* $u_n = \frac{|x_n|}{f(\boldsymbol{x})}$.

Note that u_n is not part of the coordinate representation since normalization with $1/f(\boldsymbol{x})$ decreases the degrees of freedom $\boldsymbol{u}$ by one, that is, u_n can always be computed from all other u_i by solving $f(\boldsymbol{u}) = f(\boldsymbol{x}/f(\boldsymbol{x})) = 1$ for u_n. We use the term u_n only for notational simplicity. With a slight abuse of notation, we will use $\boldsymbol{u}$ to denote the normalized vector $\boldsymbol{x}/f(\boldsymbol{x})$ or only its first $n-1$ components. The exact meaning should always be clear from the context.

The definition of the coordinates is exactly the same as the one by Gupta and Song (1997) with the only difference that the L_p-norm is replaced by an L_p-nested function. Just as in the case of L_p-spherical coordinates, it will turn out that the determinant of the Jacobian of the coordinate

transformation does not depend on the value of Δ_n and can be computed analytically. The determinant is essential for deriving the uniform distribution on the unit L_p-nested sphere $\mathbb{L}_f$, that is, the 1-level set of f. Apart from that, it can be used to compute the radial distribution for a given L_p-nested symmetric distribution. We start by stating the general form of the determinant in terms of the partial derivatives $\frac{\partial u_n}{\partial u_k}$, u_k and r. Afterwards we demonstrate that those partial derivatives have a special form and that most of them cancel in Laplace's expansion of the determinant.

Lemma 2 (Determinant of the Jacobian) *Let r and $\boldsymbol{u}$ be defined as in Definition 1. The general form of the determinant of the Jacobian $\mathcal{J} = \left(\frac{\partial x_i}{\partial y_j}\right)_{ij}$ of the inverse coordinate transformation for $y_1 = r$ and $y_i = u_{i-1}$ for $i = 2,\ldots,n$, is given by*

$$|\det \mathcal{J}| = r^{n-1}\left(-\sum_{k=1}^{n-1}\frac{\partial u_n}{\partial u_k}\cdot u_k + u_n\right). \tag{2}$$

Proof The proof can be found in the Appendix A. ■

The problematic parts in Equation (2) are the terms $\frac{\partial u_n}{\partial u_k}$, which obviously involve extensive usage of the chain rule. Fortunately, most of them cancel when inserting them back into Equation (2), leaving a comparably simple formula. The remaining part of this section is devoted to computing those terms and demonstrating how they vanish in the formula for the determinant. Before we state the general case we would like to demonstrate the basic mechanism through a simple example. We urge the reader to follow this example as it illustrates all important ideas about the coordinate transformation and its Jacobian.

Example 1 *Consider an L_p-nested function very similar to our introductory example of Equation (1):*

$$f(\boldsymbol{x}) = \left(\left(|x_1|^{p_1} + |x_2|^{p_1}\right)^{\frac{p_\emptyset}{p_1}} + |x_3|^{p_\emptyset}\right)^{\frac{1}{p_\emptyset}}.$$

Setting $\boldsymbol{u} = \frac{\boldsymbol{x}}{f(\boldsymbol{x})}$ and solving for u_3 yields

$$f(\boldsymbol{u}) = 1 \Leftrightarrow\ u_3 = \left(1 - \left(|u_1|^{p_1} + |u_2|^{p_1}\right)^{\frac{p_\emptyset}{p_1}}\right)^{\frac{1}{p_\emptyset}}. \tag{3}$$

We would like to emphasize again, that u_3 is actually not part of the coordinate representation and only used for notational simplicity. By construction, u_3 is always positive. This is no restriction since Lemma 2 shows that the determinant of the Jacobian does not depend on its sign. However, when computing the volume and the surface area of the L_p-nested unit sphere, it will become important since it introduces a factor of 2 to account for the fact that u_3 (or u_n in general) can in principle also attain negative values.

Now, consider

$$G_2(\boldsymbol{u}_{\widehat{2}}) = g_2(\boldsymbol{u}_{\widehat{2}})^{1-p_\emptyset} = \left(1 - \left(|u_1|^{p_1} + |u_2|^{p_1}\right)^{\frac{p_\emptyset}{p_1}}\right)^{\frac{1-p_\emptyset}{p_\emptyset}},$$
$$F_1(\boldsymbol{u}_1) = f_1(\boldsymbol{u}_1)^{p_\emptyset - p_1} = \left(|u_1|^{p_1} + |u_2|^{p_1}\right)^{\frac{p_\emptyset - p_1}{p_1}},$$

where the subindices of $\boldsymbol{u}$, f, g, G *and* F *have to be read as multi-indices. The function* g_I *computes the value of the node* I *from all other leaves that are not part of the subtree under* I *by fixing the value of the root node to one.*

$G_2(\boldsymbol{u}_{\widehat{2}})$ *and* $F_1(\boldsymbol{u}_1)$ *are terms that arise from applying the chain rule when computing the partial derivatives* $\frac{\partial u_3}{\partial u_k}$. *Taking those partial derivatives can be thought of as peeling off layer by layer of Equation* (3) *via the chain rule. By doing so, we "move" on a path between* u_3 *and* u_k. *Each application of the chain rule corresponds to one step up or down in the tree. First, we move upwards in the tree, starting from* u_3. *This produces the G-terms. In this example, there is only one step upwards, but in general, there can be several, depending on the depth of* u_n *in the tree. Each step up will produce one G-term. At some point, we will move downwards in the tree to reach* u_k. *This will produce the F-terms. While there are as many G-terms as upward steps, there is one term less when moving downwards. Therefore, in this example, there is one term* $G_2(\boldsymbol{u}_{\widehat{2}})$ *which originates from using the chain rule upwards in the tree and one term* $F_1(\boldsymbol{u}_1)$ *from using it downwards. The indices correspond to the multi-indices of the respective nodes.*

Computing the derivative yields

$$\frac{\partial u_3}{\partial u_k} = -G_2(\boldsymbol{u}_{\widehat{2}})F_1(\boldsymbol{u}_1)\Delta_k|u_k|^{p_1-1}.$$

By inserting the results in Equation (2) we obtain

$$\begin{aligned}
\frac{1}{r^2}|\mathcal{J}| &= \sum_{k=1}^{2} G_2(\boldsymbol{u}_{\widehat{2}})F_1(\boldsymbol{u}_1)|u_k|^{p_1} + u_3 \\
&= G_2(\boldsymbol{u}_{\widehat{2}})\left(F_1(\boldsymbol{u}_1)\sum_{k=1}^{2}|u_k|^{p_1} + 1 - F_1(\boldsymbol{u}_1)F_1(\boldsymbol{u}_1)^{-1}\left(|u_1|^{p_1}+|u_2|^{p_1}\right)^{\frac{p_\emptyset}{p_1}}\right) \\
&= G_2(\boldsymbol{u}_{\widehat{2}})\left(F_1(\boldsymbol{u}_1)\sum_{k=1}^{2}|u_k|^{p_1} + 1 - F_1(\boldsymbol{u}_1)\sum_{k=1}^{2}|u_k|^{p_1}\right) \\
&= G_2(\boldsymbol{u}_{\widehat{2}}).
\end{aligned}$$

The example suggests that the terms from using the chain rule downwards in the tree cancel while the terms from using the chain rule upwards remain. The following proposition states that this is true in general.

Proposition 3 (Determinant of the Jacobian) *Let* $\mathcal{L}$ *be the set of multi-indices of the path from the leaf* u_n *to the root node (excluding the root node) and let the terms* $G_{I,\ell_I}(\boldsymbol{u}_{\widehat{I,\ell_I}})$ *recursively be defined as*

$$G_{I,\ell_I}(\boldsymbol{u}_{\widehat{I,\ell_I}}) = g_{I,\ell_I}(\boldsymbol{u}_{\widehat{I,\ell_I}})^{p_{I,\ell_I}-p_I} = \left(g_I(\boldsymbol{u}_{\widehat{I}})^{p_I} - \sum_{j=1}^{\ell-1} f_{I,j}(\boldsymbol{u}_{I,j})^{p_I}\right)^{\frac{p_{I,\ell_I}-p_I}{p_I}}$$

where each of the functions g_{I,ℓ_I} *computes the value of the* ℓ^{th} *child of a node* I *as a function of its neighbors* $(I,1)$, ..., (I,ℓ_I-1) *and its parent* I *while fixing the value of the root node to one. This is equivalent to computing the value of the node* I *from all coefficients* $\boldsymbol{u}_{\widehat{I}}$ *that are not leaves in the subtree under* I. *Then, the determinant of the Jacobian for an* L_p*-nested function is given by*

$$|\det \mathcal{J}| = r^{n-1}\prod_{L\in\mathcal{L}} G_L(\boldsymbol{u}_{\widehat{L}}).$$

Proof The proof can be found in the Appendix A. ■

Let us illustrate the determinant with two examples:

Example 2 *Consider a normal L_p-norm*

$$f(\boldsymbol{x}) = \left(\sum_{i=1}^{n} |x_i|^p \right)^{\frac{1}{p}}$$

which is obviously also an L_p-nested function. Resolving the equation for the last coordinate of the normalized vector $\boldsymbol{u}$ yields $g_n(\boldsymbol{u}_{\widehat{n}}) = u_n = \left(1 - \sum_{i=1}^{n-1} |u_i|^p\right)^{\frac{1}{p}}$. Thus, the term $G_n(\boldsymbol{u}_{\widehat{n}})$ is given by $\left(1 - \sum_{i=1}^{n-1} |u_i|^p\right)^{\frac{1-p}{p}}$ which yields a determinant of $|\det \mathcal{J}| = r^{n-1} \left(1 - \sum_{i=1}^{n-1} |u_i|^p\right)^{\frac{1-p}{p}}$. This is exactly the one derived by Gupta and Song (1997).

Example 3 *Consider the introductory example*

$$f(\boldsymbol{x}) = \left(|x_1|^{p_\emptyset} + (|x_2|^{p_1} + |x_3|^{p_1})^{\frac{p_\emptyset}{p_1}} \right)^{\frac{1}{p_\emptyset}}.$$

Normalizing and resolving for the last coordinate yields

$$u_3 = \left((1 - |u_1|^{p_\emptyset})^{\frac{p_1}{p_\emptyset}} - |u_2|^{p_1} \right)^{\frac{1}{p_1}}$$

and the terms $G_2(\boldsymbol{u}_{\widehat{2}})$ and $G_{2,2}(\boldsymbol{u}_{\widehat{2,2}})$ of the determinant $|\det \mathcal{J}| = r^2 G_2(\boldsymbol{u}_{\widehat{2}}) G_{2,2}(\boldsymbol{u}_{\widehat{2,2}})$ are given by

$$G_2(\boldsymbol{u}_{\widehat{2}}) = (1 - |u_1|^{p_\emptyset})^{\frac{p_1 - p_\emptyset}{p_\emptyset}},$$
$$G_{2,2}(\boldsymbol{u}_{\widehat{2,2}}) = \left((1 - |u_1|^{p_\emptyset})^{\frac{p_1}{p_\emptyset}} - |u_2|^{p_1} \right)^{\frac{1-p_1}{p_1}}.$$

Note the difference to Example 1 where x_3 was at depth one in the tree while x_3 is at depth two in the current case. For that reason, the determinant of the Jacobian in Example 1 involved only one G-term while it has two G-terms here.

3. L_p-Nested Symmetric and L_p-Nested Uniform Distribution

In this section, we define the L_p-nested symmetric and the L_p-nested uniform distribution and derive their partition functions. In particular, we derive the surface area of an arbitrary L_p-nested unit sphere $\mathbb{L}_f = \{\boldsymbol{x} \in \mathbb{R}^n \mid f(\boldsymbol{x}) = 1\}$ corresponding to an L_p-nested function f. By Equation (5) of Fernandez et al. (1995) every ν-spherical and hence any L_p-nested symmetric density has the form

$$\rho(\boldsymbol{x}) = \frac{\phi(f(\boldsymbol{x}))}{f(\boldsymbol{x})^{n-1} \mathcal{S}_f(1)}, \tag{4}$$

where $\mathcal{S}_f$ is the surface area of $\mathbb{L}_f$ and ϕ is a density on $\mathbb{R}^+$. Thus, we need to compute the surface area of an arbitrary L_p-nested unit sphere to obtain the partition function of Equation (4).

Proposition 4 (Volume and Surface of the L_p-nested Sphere) *Let f be an L_p-nested function and let I be the set of all multi-indices denoting the inner nodes of the tree structure associated with f. The volume $\mathcal{V}_f(R)$ and the surface $\mathcal{S}_f(R)$ of the L_p-nested sphere with radius R are given by*

$$\mathcal{V}_f(R) = \frac{R^n 2^n}{n} \prod_{I \in \mathcal{I}} \left(\frac{1}{p_I^{\ell_I - 1}} \prod_{k=1}^{\ell_I - 1} B\left[\frac{\sum_{i=1}^{k} n_{I,k}}{p_I}, \frac{n_{I,k+1}}{p_I} \right] \right) \tag{5}$$

$$= \frac{R^n 2^n}{n} \prod_{I \in \mathcal{I}} \frac{\prod_{k=1}^{\ell_I} \Gamma\left[\frac{n_{I,k}}{p_I}\right]}{p_I^{\ell_I - 1} \Gamma\left[\frac{n_I}{p_I}\right]}, \tag{6}$$

$$\mathcal{S}_f(R) = R^{n-1} 2^n \prod_{I \in \mathcal{I}} \left(\frac{1}{p_I^{\ell_I - 1}} \prod_{k=1}^{\ell_I - 1} B\left[\frac{\sum_{i=1}^{k} n_{I,k}}{p_I}, \frac{n_{I,k+1}}{p_I} \right] \right) \tag{7}$$

$$= R^{n-1} 2^n \prod_{I \in \mathcal{I}} \frac{\prod_{k=1}^{\ell_I} \Gamma\left[\frac{n_{I,k}}{p_I}\right]}{p_I^{\ell_I - 1} \Gamma\left[\frac{n_I}{p_I}\right]} \tag{8}$$

where $B[a,b] = \frac{\Gamma[a]\Gamma[b]}{\Gamma[a+b]}$ denotes the β-function.

Proof The proof can be found in the Appendix B. ■

Inserting the surface area in Equation 4, we obtain the general form of an L_p-nested symmetric distribution for any given radial density ϕ.

Corollary 5 (L_p-nested Symmetric Distribution) *Let f be an L_p-nested function and ϕ a density on $\mathbb{R}^+$. The corresponding L_p-nested symmetric distribution is given by*

$$\rho(\boldsymbol{x}) = \frac{\phi(f(\boldsymbol{x}))}{f(\boldsymbol{x})^{n-1} \mathcal{S}_f(1)}$$

$$= \frac{\phi(f(\boldsymbol{x}))}{2^n f(\boldsymbol{x})^{n-1}} \prod_{I \in \mathcal{I}} \left(p_I^{\ell_I - 1} \prod_{k=1}^{\ell_I - 1} B\left[\frac{\sum_{i=1}^{k} n_{I,k}}{p_I}, \frac{n_{I,k+1}}{p_I} \right]^{-1} \right). \tag{9}$$

The results of Fernandez et al. (1995) imply that for any ν-spherically symmetric distribution, the radial part is independent of the directional part, that is, r is independent of $\boldsymbol{u}$. The distribution of $\boldsymbol{u}$ is entirely determined by the choice of ν, or by the L_p-nested function f in our case. The distribution of r is determined by the radial density ϕ. Together, an L_p-nested symmetric distribution is determined by both, the L_p-nested function f and the choice of ϕ. From Equation (9), we can see that its density function must be the inverse of the surface area of $\mathbb{L}_f$ times the radial density when transforming (4) into the coordinates of Definition 1 and separating r and $\boldsymbol{u}$ (the factor $f(\boldsymbol{x})^{n-1} = r$ cancels due to the determinant of the Jacobian). For that reason we call the distribution of $\boldsymbol{u}$ *uniform on the L_p-sphere* $\mathbb{L}_f$ in analogy to Song and Gupta (1997). Next, we state its form in terms of the coordinates $\boldsymbol{u}$.

Proposition 6 (L_p-nested Uniform Distribution) *Let f be an L_p-nested function. Let $\mathcal{L}$ be the set of multi-indices on the path from the root node to the leaf corresponding to x_n. The uniform*

distribution on the L_p-nested unit sphere, that is, the set $\mathbb{L}_f = \{\boldsymbol{x} \in \mathbb{R}^n | f(\boldsymbol{x}) = 1\}$ is given by the following density over $u_1, ..., u_{n-1}$

$$\rho(u_1, , ..., u_{n-1}) = \frac{\prod_{L \in \mathcal{L}} G_L(\boldsymbol{u}_{\widehat{L}})}{2^{n-1}} \prod_{I \in \mathcal{I}} \left(p_I^{\ell_I - 1} \prod_{k=1}^{\ell_I - 1} B\left[\frac{\sum_{i=1}^{k} n_{I,k}}{p_I}, \frac{n_{I,k+1}}{p_I} \right]^{-1} \right).$$

Proof Since the L_p-nested sphere is a measurable and compact set, the density of the uniform distribution is simply one over the surface area of the L_p-nested unit sphere. The surface $\mathcal{S}_f(1)$ is given by Proposition 4. Transforming $\frac{1}{\mathcal{S}_f(1)}$ into the coordinates of Definition 1 introduces the determinant of the Jacobian from Proposition 3 and an additional factor of 2 since the $(u_1, ..., u_{n-1}) \in \mathbb{R}^{n-1}$ have to account for both half-shells of the L_p-nested unit sphere, that is, to account for the fact that u_n could have been be positive or negative. This yields the expression above. ■

Example 4 *Let us again demonstrate the proposition at the special case where f is an L_p-norm $f(\boldsymbol{x}) = ||\boldsymbol{x}||_p = (\sum_{i=1}^{n} |x_i|^p)^{\frac{1}{p}}$. Using Proposition 4, the surface area is given by*

$$\mathcal{S}_{||\cdot||_p} = 2^n \frac{1}{p_\emptyset^{\ell_\emptyset - 1}} \prod_{k=1}^{\ell_\emptyset - 1} B\left[\frac{\sum_{i=1}^{k} n_k}{p_\emptyset}, \frac{n_{k+1}}{p_\emptyset} \right] = \frac{2^n \Gamma^n \left[\frac{1}{p}\right]}{p^{n-1} \Gamma\left[\frac{n}{p}\right]}.$$

The factor $G_n(\boldsymbol{u}_{\widehat{n}})$ is given by $\left(1 - \sum_{i=1}^{n-1} |u_i|^p\right)^{\frac{1-p}{p}}$ (see the L_p-norm example before), which, after including the factor 2, yields the uniform distribution on the L_p-sphere as defined in Song and Gupta (1997)

$$p(\boldsymbol{u}) = \frac{p^{n-1} \Gamma\left[\frac{n}{p}\right]}{2^{n-1} \Gamma^n \left[\frac{1}{p}\right]} \left(1 - \sum_{i=1}^{n-1} |u_i|^p\right)^{\frac{1-p}{p}}.$$

Example 5 *As a second illustrative example, we consider the uniform density on the L_p-nested unit ball, that is, the set $\{\boldsymbol{x} \in \mathbb{R}^n | f(\boldsymbol{x}) \leq 1\}$, and derive its radial distribution ϕ. The density of the uniform distribution on the unit L_p-nested ball does not depend on $\boldsymbol{x}$ and is given by $\rho(\boldsymbol{x}) = 1/\mathcal{V}_f(1)$. Transforming the density into the polar-like coordinates with the determinant from Proposition 3 yields*

$$\frac{1}{\mathcal{V}_f(1)} = \frac{n r^{n-1} \prod_{L \in \mathcal{L}} G_L(\boldsymbol{u}_{\widehat{L}})}{2^{n-1}} \prod_{I \in \mathcal{I}} \left(p_I^{\ell_I - 1} \prod_{k=1}^{\ell_I - 1} B\left[\frac{\sum_{i=1}^{k} n_{I,k}}{p_I}, \frac{n_{I,k+1}}{p_I} \right]^{-1} \right).$$

After separating out the uniform distribution on the L_p-nested unit sphere, we obtain the radial distribution

$$\phi(r) = n r^{n-1} \text{ for } 0 < r \leq 1$$

which is a β-distribution with parameters n and 1.

The radial distribution from the preceeding example is of great importance for our sampling scheme derived in Section 6. The idea behind it is the following: First, a sample from a "simple" L_p-nested symmetric distribution is drawn. Since the radial and the uniform component on the L_p-nested unit sphere are statistically independent, we can get a sample from the uniform distribution on the L_p-nested unit sphere by simply normalizing the sample from the simple distribution. Afterwards we can multiply it with a radius drawn from the radial distribution of the L_p-nested symmetric distribution that we actually want to sample from. The role of the simple distribution will be played by the uniform distribution within the L_p-nested unit ball. Sampling from it is basically done by applying the steps in Proposition 4's proof backwards. We lay out the sampling scheme in more detail in Section 6.

4. Marginals

In this section we discuss two types of marginals: First, we demonstrate that, in contrast to L_p-spherically symmetric distributions, marginals of L_p-nested symmetric distributions are not necessarily L_p-nested symmetric again. The second type of marginals we discuss are obtained by collapsing all leaves of a subtree into the value of the subtree's root node. For that case we derive an analytical expression and show that the values of the root node's children follow a special kind of Dirichlet distribution.

Gupta and Song (1997) show that marginals of L_p-spherically symmetric distributions are again L_p-spherically symmetric. This does not hold, however, for L_p-nested symmetric distributions. This can be shown by a simple counterexample. Consider the L_p-nested function

$$f(\boldsymbol{x}) = \left((|x_1|^{p_1} + |x_2|^{p_1})^{\frac{p_\emptyset}{p_1}} + |x_3|^{p_\emptyset} \right)^{\frac{1}{p_\emptyset}}.$$

The uniform distribution inside the L_p-nested ball corresponding to f is given by

$$\rho(\boldsymbol{x}) = \frac{n p_1 p_\emptyset \Gamma\left[\frac{2}{p_1}\right] \Gamma\left[\frac{3}{p_\emptyset}\right]}{2^3 \Gamma^2\left[\frac{1}{p_1}\right] \Gamma\left[\frac{2}{p_0}\right] \Gamma\left[\frac{1}{p_0}\right]}.$$

The marginal $\rho(x_1, x_3)$ is given by

$$\rho(x_1, x_3) = \frac{n p_1 p_\emptyset \Gamma\left[\frac{2}{p_1}\right] \Gamma\left[\frac{3}{p_\emptyset}\right]}{2^3 \Gamma^2\left[\frac{1}{p_1}\right] \Gamma\left[\frac{2}{p_0}\right] \Gamma\left[\frac{1}{p_0}\right]} \left((1 - |x_3|^{p_\emptyset})^{\frac{p_1}{p_\emptyset}} - |x_1|^{p_1} \right)^{\frac{1}{p_1}}.$$

This marginal is not L_p-spherically symmetric. Since any L_p-nested symmetric distribution in two dimensions must be L_p-spherically symmetric, it cannot be L_p-nested symmetric as well. Figure 3 shows a scatter plot of the marginal distribution. Besides the fact that the marginals are not contained in the family of L_p-nested symmetric distributions, it is also hard to derive a general form for them. This is not surprising given that the general form of marginals for L_p-spherically symmetric distributions involves an integral that cannot be solved analytically in general and is therefore not very useful in practice (Gupta and Song, 1997). For that reason we cannot expect marginals of L_p-nested symmetric distributions to have a simple form.

In contrast to single marginals, it is possible to specify the joint distribution of leaves and inner nodes of an L_p-nested tree if all descendants of their inner nodes in question have been integrated

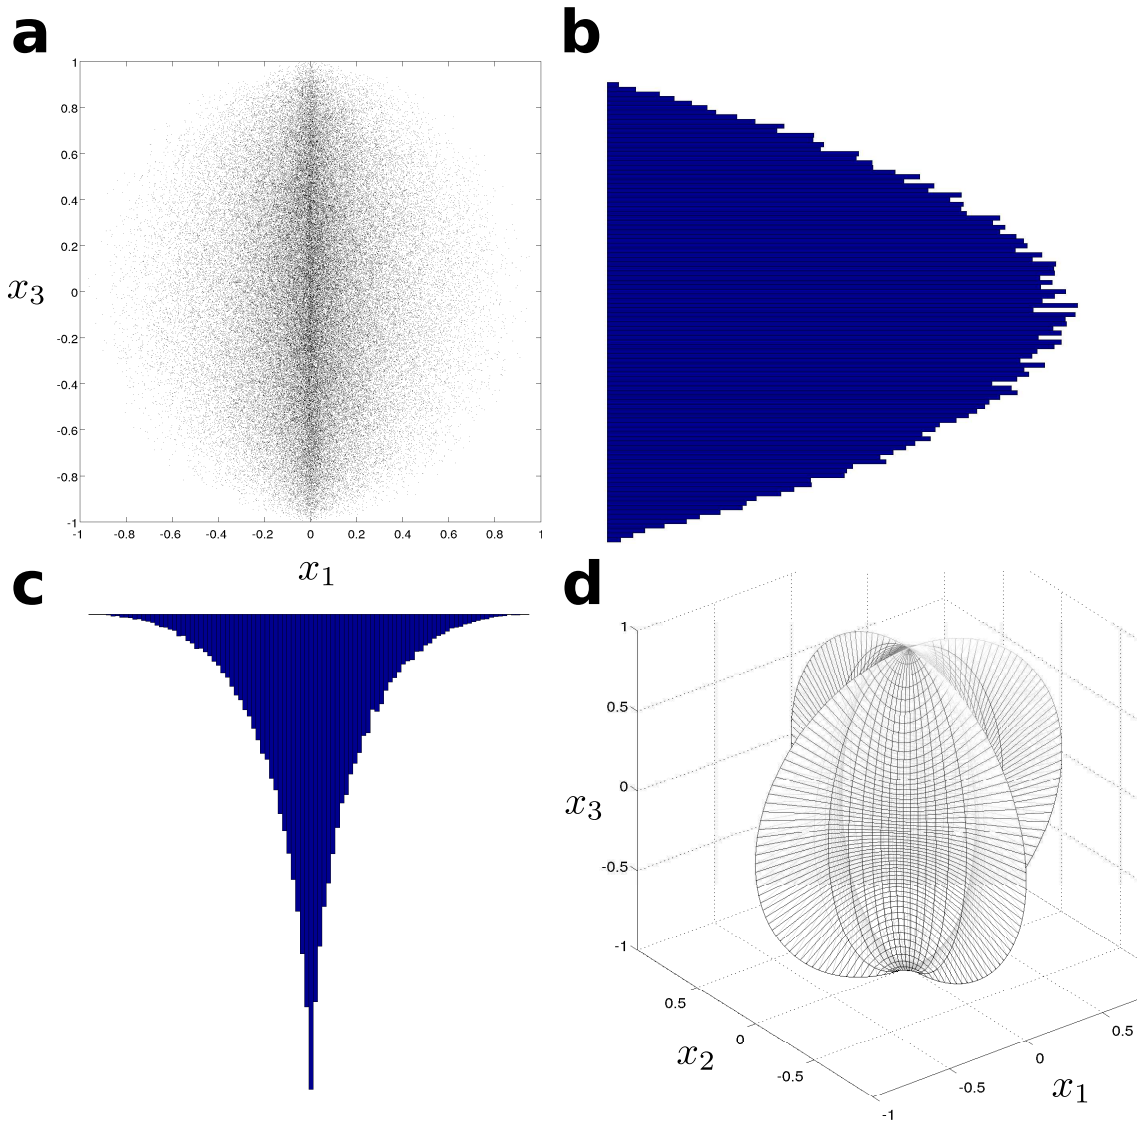

Figure 3: Marginals of L_p-nested symmetric distributions are not necessarily L_p-nested symmetric: Figure (**a**) shows a scatter plot of the (x_1, x_2)-marginal of the counterexample in the text with $p_\emptyset = 2$ and $p_1 = \frac{1}{2}$. Figure (**d**) displays the corresponding L_p-nested sphere. (**b-c**) show the univariate marginals for the scatter plot. Since any two-dimensional L_p-nested symmetric distribution must be L_p-spherically symmetric, the marginals should be identical. This is clearly not the case. Thus, (**a**) is not L_p-nested symmetric.

out. For the simple function above (the same that has been used in Example 1), the joint distribution of x_3 and $v_1 = \|(x_1, x_2)^\top\|_{p_1}$ would be an example of such a marginal. Since marginalization affects

the L_p-nested tree vertically, we call this type of marginals *layer marginals*. In the following, we present their general form.

From the form of a general L_p-nested function and the corresponding symmetric distribution, one might think that the layer marginals are L_p-nested symmetric again. However, this is not the case since the distribution over the L_p-nested unit sphere would deviate from the uniform distribution in most cases if the distribution of its children were L_p-spherically symmetric.

Proposition 7 *Let f be an L_p-nested function. Suppose we integrate out complete subtrees from the tree associated with f, that is, we transform subtrees into radial times uniform variables and integrate out the latter. Let $\mathcal{J}$ be the set of multi-indices of those nodes that have become new leaves, that is, whose subtrees have been removed, and let n_J be the number of leaves (in the original tree) in the subtree under the node J. Let $\boldsymbol{x}_{\widehat{\mathcal{J}}} \in \mathbb{R}^m$ denote those coefficients of $\boldsymbol{x}$ that are still part of that smaller tree and let $\boldsymbol{v}_{\mathcal{J}}$ denote the vector of inner nodes that became new leaves. The joint distribution of $\boldsymbol{x}_{\widehat{\mathcal{J}}}$ and $\boldsymbol{v}_{\mathcal{J}}$ is given by*

$$\rho(\boldsymbol{x}_{\widehat{\mathcal{J}}}, \boldsymbol{v}_{\mathcal{J}}) = \frac{\phi(f(\boldsymbol{x}_{\widehat{\mathcal{J}}}, \boldsymbol{v}_{\mathcal{J}}))}{S_f(f(\boldsymbol{x}_{\widehat{\mathcal{J}}}, \boldsymbol{v}_{\mathcal{J}}))} \prod_{J \in \mathcal{J}} v_J^{n_J - 1}. \tag{10}$$

Proof The proof can be found in the Appendix C. ■

Equation (10) has an interesting special case when considering the joint distribution of the root node's children.

Corollary 8 *The children of the root node $\boldsymbol{v}_{1:\ell_\emptyset} = (v_1, ..., v_{\ell_\emptyset})^\top$ follow the distribution*

$$\rho(\boldsymbol{v}_{1:\ell_\emptyset}) = \frac{p_\emptyset^{\ell_\emptyset - 1} \Gamma\left[\frac{n}{p_\emptyset}\right]}{f(v_1, ..., v_{\ell_\emptyset})^{n-1} 2^m \prod_{k=1}^{\ell_\emptyset} \Gamma\left[\frac{n_k}{p_\emptyset}\right]} \phi\left(f(v_1, ..., v_{\ell_\emptyset})\right) \prod_{i=1}^{\ell_\emptyset} v_i^{n_i - 1}$$

where $m \leq \ell_\emptyset$ is the number of leaves directly attached to the root node. In particular, $\boldsymbol{v}_{1:\ell_\emptyset}$ can be written as the product RU, where R is the L_p-nested radius and the single $|U_i|^{p_\emptyset}$ are Dirichlet distributed, that is, $(|U_1|^{p_\emptyset}, ..., |U_{\ell_\emptyset}|^{p_\emptyset}) \sim Dir\left[\frac{n_1}{p_\emptyset}, ..., \frac{n_{\ell_\emptyset}}{p_\emptyset}\right]$.

Proof The joint distribution is simply the application of Proposition (7). Note that $f(v_1, ..., v_{\ell_\emptyset}) = ||\boldsymbol{v}_{1:\ell_\emptyset}||_{p_\emptyset}$. Applying the pointwise transformation $s_i = |u_i|^{p_\emptyset}$ yields

$$(|U_1|^{p_\emptyset}, ..., |U_{\ell_\emptyset - 1}|^{p_\emptyset}) \sim \text{Dir}\left[\frac{n_1}{p_\emptyset}, ..., \frac{n_{\ell_\emptyset}}{p_\emptyset}\right].$$

■

The Corollary shows that the values $f_I(\boldsymbol{x}_I)$ at inner nodes I, in particular the ones directly below the root node, deviate considerably from L_p-spherical symmetry. If they were L_p-spherically symmetric, the $|U_i|^p$ should follow a Dirichlet distribution with parameters $\alpha_i = \frac{1}{p}$ as has been already shown by Song and Gupta (1997). The Corollary is a generalization of their result.

We can use the Corollary to prove an interesting fact about L_p-nested symmetric distributions: The only factorial L_p-nested symmetric distribution must be L_p-spherically symmetric.

Proposition 9 *Let $\boldsymbol{x}$ be L_p-nested symmetric distributed with independent marginals. Then $\boldsymbol{x}$ is L_p-spherically symmetric distributed. In particular, $\boldsymbol{x}$ follows a p-generalized Normal distribution.*

Proof The proof can be found in the Appendix D. ■

One immediate implication of Proposition 9 is that there is no factorial probability model corresponding to mixed norm regularizers which have the form $\sum_{i=1}^{k} \|\boldsymbol{x}_{I_k}\|_p^q$ where the index sets I_k form a partition of the dimensions $1,...,n$ (see, e.g., Zhao et al., 2008; Yuan and Lin, 2006; Kowalski et al., 2008). Many machine learning algorithms are equivalent to minimizing the sum of a regularizer $R(\boldsymbol{w})$ and a loss function $L(\boldsymbol{w},\boldsymbol{x}_1,...,\boldsymbol{x}_m)$ over the coefficient vector $\boldsymbol{w}$. If the $\exp(-R(\boldsymbol{w}))$ and $\exp(-L(\boldsymbol{w},\boldsymbol{x}_1,...,\boldsymbol{x}_m))$ correspond to normalizeable density models, the minimizing solution of the objective function can be seen as the maximum a posteriori (MAP) estimate of the posterior $p(\boldsymbol{w}|\boldsymbol{x}_1,...,\boldsymbol{x}_m) \propto p(\boldsymbol{w}) \cdot p(\boldsymbol{x}_1,...,\boldsymbol{x}_m|\boldsymbol{w}) = \exp(-R(\boldsymbol{w})) \cdot \exp(-L(\boldsymbol{w},\boldsymbol{x}_1,...,\boldsymbol{x}_m))$. In that sense, the regularizer naturally corresponds to the prior and the loss function corresponds to the likelihood. Very often, regularizers are specified as a norm over the coefficient vector $\boldsymbol{w}$ which in turn correspond to certain priors. For example, in Ridge regression (Hoerl, 1962) the coefficients are regularized via $\|\boldsymbol{w}\|_2^2$ which corresponds to a factorial zero mean Gaussian prior on $\boldsymbol{w}$. The L_1-norm $\|\boldsymbol{w}\|_1$ in the LASSO estimator (Tibshirani, 1996), again, is equivalent to a factorial Laplacian prior on $\boldsymbol{w}$. Like in these two examples, regularizers often correspond to a *factorial* prior.

Mixed norm regularizers naturally correspond to L_p-nested symmetric distributions. Proposition 9 shows that there is no factorial prior that corresponds to such a regularizer. In particular, it implies that the prior cannot be factorial between groups and coefficients at the same time. This means that those regularizers implicitly assume statistical dependencies between the coefficient variables. Interestingly, for $q = 1$ and $p = 2$ the intuition behind these regularizers is exactly that whole groups I_k get switched on at once, but the groups are sparse. The Proposition shows that this might not only be due to sparseness but also due to statistical dependencies between the coefficients within one group. The L_p-nested symmetric distribution which implements independence between groups will be further discussed below as a generalization of the p-generalized Normal (see Section 8). Note that the marginals can be independent if the regularizer is of the form $\sum_{i=1}^{k} \|\boldsymbol{x}_{I_k}\|_p^p$. However, in this case $p = q$ and the L_p-nested function collapses to a simple L_p-norm which means that the regularizer is not mixed norm.

5. Maximum Likelihood Estimation of L_p-Nested Symmetric Distributions

In this section, we describe procedures for maximum likelihood fitting of L_p-nested symmetric distributions on data. We provide a toolbox online for fitting L_p-spherically symmetric and L_p-nested symmetric distributions to data. The toolbox can be downloaded at `http://www.kyb.tuebingen.mpg.de/bethge/code/`.

Depending on which parameters are to be estimated, the complexity of fitting an L_p-nested symmetric distribution varies. We start with the simplest case and later continue with more complex ones. Throughout this subsection, we assume that the model has the form $p(\boldsymbol{x}) = \rho(W\boldsymbol{x}) \cdot |\det W| = \frac{\phi(W\boldsymbol{x})}{f(W\boldsymbol{x})^{n-1} S_f(1)} \cdot |\det W|$ where $W \in \mathbb{R}^{n \times n}$ is a complete whitening matrix. This means that given any whitening matrix W_0, the freedom in fitting W is to estimate an orthonormal matrix $Q \in SO(n)$ such that $W = QW_0$. This is analogous to the case of elliptically contoured distributions where the

distributions can be endowed with 2nd-order correlations via W. In the following, we ignore the determinant of W since data points can always be rescaled such that $\det W = 1$.

The simplest case is to fit the parameters of the radial distribution when the tree structure, the values of the p_I, and W are fixed. Due to the special form of L_p-nested symmetric distributions (4), it then suffices to carry out maximum likelihood estimation on the radial component only, which renders maximum likelihood estimation efficient and robust. This is because the only remaining parameters are the parameters $\boldsymbol{\vartheta}$ of the radial distribution and, therefore,

$$\begin{aligned}\operatorname{argmax}_{\boldsymbol{\vartheta}} \log \rho(W\boldsymbol{x}|\boldsymbol{\vartheta}) &= \operatorname{argmax}_{\boldsymbol{\vartheta}} \left(-\log \mathcal{S}_f(f(W\boldsymbol{x})) + \log \phi(f(W\boldsymbol{x})|\boldsymbol{\vartheta})\right) \\ &= \operatorname{argmax}_{\boldsymbol{\vartheta}} \log \phi(f(W\boldsymbol{x})|\boldsymbol{\vartheta}).\end{aligned}$$

In a slightly more complex case, when only the tree structure and W are fixed, the values of the p_I, $I \in \mathcal{I}$ and $\boldsymbol{\vartheta}$ can be jointly estimated via gradient ascent on the log-likelihood. The gradient for a single data point $\boldsymbol{x}$ with respect to the vector $\boldsymbol{p}$ that holds all p_I for all $I \in \mathcal{I}$ is given by

$$\nabla_{\boldsymbol{p}} \log \rho(W\boldsymbol{x}) = \frac{d}{dr} \log \phi(f(W\boldsymbol{x})) \cdot \nabla_{\boldsymbol{p}} f(W\boldsymbol{x}) - \frac{(n-1)}{f(W\boldsymbol{x})} \nabla_{\boldsymbol{p}} f(W\boldsymbol{x}) - \nabla_{\boldsymbol{p}} \log \mathcal{S}_f(1).$$

For i.i.d. data points $\boldsymbol{x}_i$ the joint gradient is given by the sum over the gradients for the single data points. Each of them involves the gradient of f as well as the gradient of the log-surface area of $\mathbb{L}_f$ with respect to $\boldsymbol{p}$, which can be computed via the recursive equations

$$\frac{\partial}{\partial p_J} v_I = \begin{cases} 0 & \text{if } I \text{ is not a prefix of } J \\ v_I^{1-p_I} v_{I,k}^{p_I - 1} \cdot \frac{\partial}{\partial p_J} v_{I,k} & \text{if } I \text{ is a prefix of } J \\ \frac{v_J}{p_J} \left(v_J^{-p_J} \sum_{k=1}^{\ell_J} v_{J,k}^{p_J} \cdot \log v_{J,k} - \log v_J \right) & \text{if } J = I \end{cases}$$

and

$$\begin{aligned}\frac{\partial}{\partial p_J} \log \mathcal{S}_f(1) = &- \frac{\ell_J - 1}{p_J} + \sum_{k=1}^{\ell_J - 1} \Psi\left[\frac{\sum_{i=1}^{k+1} n_{J,k}}{p_J}\right] \frac{\sum_{i=1}^{k+1} n_{J,k}}{p_J^2} \\ &- \sum_{k=1}^{\ell_J - 1} \Psi\left[\frac{\sum_{i=1}^{k} n_{J,k}}{p_J}\right] \frac{\sum_{i=1}^{k} n_{J,k}}{p_J^2} - \sum_{k=1}^{\ell_J - 1} \Psi\left[\frac{n_{J,k+1}}{p_J}\right] \frac{n_{J,k+1}}{p_J^2},\end{aligned}$$

where $\Psi[t] = \frac{d}{dt} \log \Gamma[t]$ denotes the digamma function. When performing the gradient ascent, one needs to set $\mathbf{0}$ as a lower bound for $\boldsymbol{p}$. Note that, in general, this optimization might be a highly non-convex problem.

On the next level of complexity, only the tree structure is fixed, and W can be estimated along with the other parameters by joint optimization of the log-likelihood with respect to $\boldsymbol{p}$, $\boldsymbol{\vartheta}$ and W. Certainly, this optimization problem is also not convex in general. Usually, it is numerically more robust to whiten the data first with some whitening matrix W_0 and perform a gradient ascent on the special orthogonal group $SO(n)$ with respect to Q for optimizing $W = QW_0$. Given the gradient $\nabla_W \log \rho(W\boldsymbol{x})$ of the log-likelihood, the optimization can be carried out by performing line searches along geodesics as proposed by Edelman et al. (1999) (see also Absil et al. (2007)) or by projecting $\nabla_W \log \rho(W\boldsymbol{x})$ on the tangent space $T_W SO(n))$ and performing a line search along $SO(n)$ in that direction as proposed by Manton (2002).

The general form of the gradient to be used in such an optimization scheme can be defined as

$$\begin{aligned}&\nabla_W \log \rho(W\boldsymbol{x})\\ =&\nabla_W \left(-(n-1)\cdot \log f(W\boldsymbol{x}) + \log \phi(f(W\boldsymbol{x}))\right)\\ =&-\frac{(n-1)}{f(W\boldsymbol{x})}\cdot \nabla_{\boldsymbol{y}} f(W\boldsymbol{x})\cdot \boldsymbol{x}^\top + \frac{d\log\phi(r)}{dr}(f(W\boldsymbol{x}))\cdot \nabla_{\boldsymbol{y}} f(W\boldsymbol{x})\cdot \boldsymbol{x}^\top,\end{aligned}$$

where the derivatives of f with respect to $\boldsymbol{y}$ are defined by recursive equations

$$\frac{\partial}{\partial y_i} v_I = \begin{cases} 0 & \text{if } i \notin I \\ \operatorname{sgn} y_i & \text{if } v_{I,k} = |y_i| \\ v_I^{1-p_I}\cdot v_{I,k}^{p_I-1}\cdot \frac{\partial}{\partial y_i} v_{I,k} & \text{for } i \in I, k. \end{cases}$$

Note, that f might not be differentiable at $\boldsymbol{y} = 0$. However, we can always define a sub-derivative at zero, which is zero for $p_I \neq 1$ and $[-1,1]$ for $p_I = 1$. Again, the gradient for i.i.d. data points $\boldsymbol{x}_i$ is given by the sum over the single gradients.

Finally, the question arises whether it is possible to estimate the tree structure from data as well. A simple heuristic would be to start with a very large tree, for example, a full binary tree, and to prune out inner nodes for which the parents and the children have sufficiently similar values for their p_I. The intuition behind this is that if they were exactly equal, they would cancel in the L_p-nested function. This heuristic is certainly sub-optimal. Firstly, the optimization will be time consuming since there can be about as many p_I as there are leaves in the L_p-nested tree (a full binary tree on n dimensions will have $n-1$ inner nodes) and due to the repeated optimization after the pruning steps. Secondly, the heuristic does not cover all possible trees on n leaves. For example, if two leaves are separated by the root node in the original full binary tree, there is no way to prune out inner nodes such that the path between those two nodes will not contain the root node anymore.

The computational complexity for the estimation of all other parameters despite the tree structure is difficult to assess in general because they depend, for example, on the particular radial distribution used. While the maximum likelihood estimation of a simple log-Normal distribution only involves the computation of a mean and a variance which are in $O(m)$ for m data points, a mixture of log-Normal distributions already requires an EM algorithm which is computationally more expensive. Additionally, the time it takes to optimize the likelihood depends on the starting point as well as the convergence rate, and we neither have results about the convergence rate nor is it possible to make problem independent statements about a good initialization of the parameters. For this reason we state only the computational complexity of single steps involved in the optimization.

Computation of the gradient $\nabla_{\boldsymbol{p}} \log \rho(W\boldsymbol{x})$ involves the derivative of the radial distribution, the computation of the gradients $\nabla_{\boldsymbol{p}} f(W\boldsymbol{x})$ and $\nabla_{\boldsymbol{p}} \mathcal{S}_f(1)$. Assuming that the derivative of the radial distribution can be computed in $O(1)$ for each single data point, the costly steps are the other two gradients. Computing $\nabla_{\boldsymbol{p}} f(W\boldsymbol{x})$ basically involves visiting each node of the tree once and performing a constant number of operations for the local derivatives. Since every inner node in an L_p-nested tree must have at least two children, the worst case would be a full binary tree which has $2n-1$ nodes and leaves. Therefore, the gradient can be computed in $O(nm)$ for m data points. For similar reasons, $f(W\boldsymbol{x})$, $\nabla_{\boldsymbol{p}} \log \mathcal{S}_f(1)$, and the evaluation of the likelihood can also be computed in $O(nm)$. This means that each step in the optimization of $\boldsymbol{p}$ can be done $O(nm)$ plus the computational costs for the line search in the gradient ascent. When optimizing for $W = QW_0$ as well, the computational

costs per step increase to $O(n^3 + n^2 m)$ since m data points have to be multiplied with W at each iteration (requiring $O(n^2 m)$ steps), and the line search involves projecting Q back onto $SO(n)$ which requires an inverse matrix square root or a similar computation in $O(n^3)$.

For comparison, each step of fast ICA (Hyvärinen and O., 1997) for a complete demixing matrix takes $O(n^2 m)$ when using hierarchical orthogonalization and $O(n^2 m + n^3)$ for symmetric orthogonalization. The same applies to fitting an ISA model (Hyvärinen and Hoyer, 2000; Hyvärinen and Köster, 2006, 2007). A Gaussian Scale Mixture (GSM) model does not need to estimate another orthogonal rotation Q because it belongs to the class of spherically symmetric distributions and is, therefore, invariant under transformations from $SO(n)$ (Wainwright and Simoncelli, 2000). Therefore, fitting a GSM corresponds to estimating the parameters of the scale distribution which is $O(nm)$ in the best case but might be costlier depending on the choice of the scale distribution.

6. Sampling from L_p-Nested Symmetric Distributions

In this section, we derive a sampling scheme for arbitrary L_p-nested symmetric distributions which can for example be used for solving integrals when using L_p-nested symmetric distributions for Bayesian learning. Exact sampling from an arbitrary L_p-nested symmetric distribution is in fact straightforward due to the following observation: Since the radial and the uniform component are independent, normalizing a sample from any L_p-nested symmetric distribution to f-length one yields samples from the uniform distribution on the L_p-nested unit sphere. By multiplying those uniform samples with new samples from another radial distribution, one obtains samples from another L_p-nested symmetric distribution. Therefore, for each L_p-nested function f, a single L_p-nested symmetric distribution which can be easily sampled from is enough. Sampling from all other L_p-nested symmetric distributions with respect to f is then straightforward due to the method we just described. Gupta and Song (1997) sample from the p-generalized Normal distribution since it has independent marginals which makes sampling straightforward. Due to Proposition 9, no such factorial L_p-nested symmetric distribution exists. Therefore, a sampling scheme like that for L_p-spherically symmetric distributions is not applicable. Instead we choose to sample from the uniform distribution inside the L_p-nested unit ball for which we already computed the radial distribution in Example 5. The distribution has the form $\rho(\boldsymbol{x}) = \frac{1}{\mathcal{V}_f(1)}$. In order to sample from that distribution, we will first only consider the uniform distribution in the positive quadrant of the unit L_p-nested ball which has the form $\rho(\boldsymbol{x}) = \frac{2^n}{\mathcal{V}_f(1)}$. Samples from the uniform distributions inside the whole ball can be obtained by multiplying each coordinate of a sample with independent samples from the uniform distribution over $\{-1, 1\}$.

The idea of the sampling scheme for the uniform distribution inside the L_p-nested unit ball is based on the computation of the volume of the L_p-nested unit ball in Proposition 4. The basic mechanism underlying the sampling scheme below is to apply the steps of the proof backwards, which is based on the following idea: The volume of the L_p-unit ball can be computed by computing its volume on the positive quadrant only and multiplying the result with 2^n afterwards. The key is now to not transform the whole integral into radial and uniform coordinates at once, but successively upwards in the tree. We will demonstrate this through a brief example which also should make the sampling scheme below more intuitive. Consider the L_p-nested function

$$f(\boldsymbol{x}) = \left(|x_1|^{p_\emptyset} + \left(|x_2|^{p_1} + |x_3|^{p_1} \right)^{\frac{p_\emptyset}{p_1}} \right)^{\frac{1}{p_\emptyset}}.$$

To solve the integral

$$\int_{\{\boldsymbol{x}: f(\boldsymbol{x}) \leq 1 \,\&\, \boldsymbol{x} \in \mathbb{R}_+^n\}} d\boldsymbol{x},$$

we first transform x_2 and x_3 into radial and uniform coordinates only. According to Proposition 3 the determinant of the mapping $(x_2, x_3) \mapsto (v_1, \tilde{u}) = (\|\boldsymbol{x}_{2:3}\|_{p_1}, \boldsymbol{x}_{2:3} / \|\boldsymbol{x}_{2:3}\|_{p_1})$ is given by $v_1 (1 - \tilde{u}^{p_1})^{\frac{1-p_1}{p_1}}$. Therefore the integral transforms into

$$\int_{\{\boldsymbol{x}: f(\boldsymbol{x}) \leq 1 \,\&\, \boldsymbol{x} \in \mathbb{R}_+^n\}} d\boldsymbol{x} = \int_{\{v_1, x_1 : f(x_1, v_1) \leq 1 \,\&\, x_1, v_1 \in \mathbb{R}_+\}} \int \int v_1 (1 - \tilde{u}^{p_1})^{\frac{1-p_1}{p_1}} dx_1 dv_1 d\tilde{u}.$$

Now we can separate the integrals over x_1 and v_1, and the integral over $\tilde{u}$, since the boundary of the outer integral does only depend on v_1 and not on $\tilde{u}$:

$$\int_{\{\boldsymbol{x}: f(\boldsymbol{x}) \leq 1 \,\&\, \boldsymbol{x} \in \mathbb{R}_+^n\}} d\boldsymbol{x} = \int (1 - \tilde{u}^{p_1})^{\frac{1-p_1}{p_1}} d\tilde{u} \cdot \int_{\{v_1, x_1 : f(x_1, v_1) \leq 1 \,\&\, x_1, v_1 \in \mathbb{R}_+\}} \int v_1 dx_1 dv_1.$$

The value of the first integral is known explicitly since the integrand equals the uniform distribution on the $\|\cdot\|_{p_1}$-unit sphere. Therefore, the value of the integral must be its normalization constant which we can get using Proposition 4:

$$\int (1 - \tilde{u}^{p_1})^{\frac{1-p_1}{p_1}} d\tilde{u} = \frac{\Gamma\left[\frac{1}{p_1}\right]^2 \cdot p_1}{\Gamma\left[\frac{2}{p_1}\right]}.$$

An alternative way to arrive at this result is to use the transformation $s = \tilde{u}^{p_1}$ and to notice that the integrand is a Dirichlet distribution with parameters $\alpha_i = \frac{1}{p_1}$. The normalization constant of the Dirichlet distribution and the constants from the determinant of the Jacobian of the transformation yield the same result.

To compute the remaining integral, the same method can be applied again yielding the volume of the L_p-nested unit ball. The important part for the sampling scheme, however, is not the volume itself but the fact that the intermediate results in this integration process equal certain distributions. As shown in Example 5 the radial distribution of the uniform distribution on the unit ball is $\beta[n, 1]$, and as just indicated by the example above, the intermediate results can be seen as transformed variables from a Dirichlet distribution. This fact holds true even for more complex L_p-nested unit balls although the parameters of the Dirichlet distribution can be slightly different. Reversing the steps leads us to the following sampling scheme. First, we sample from the β-distribution which gives us the radius $v_\emptyset$ on the root node. Then we sample from the appropriate Dirichlet distribution and exponentiate the samples by $\frac{1}{p_\emptyset}$ which transforms them into the analogs of the variable u from above. Scaling the result with the sample $v_\emptyset$ yields the values of the root node's children, that is, the analogs of x_1 and v_1. Those are the new radii for the levels below them where we simply repeat this procedure with the appropriate Dirichlet distributions and exponents. The single steps are summarized in Algorithm 1.

The computational complexity of the sampling scheme is $O(n)$. Since the sampling procedure is like expanding the tree node by node starting with the root, the number of inner nodes and leaves is the total number of samples that have to be drawn from Dirichlet distributions. Every node in an L_p-nested tree must at least have two children. Therefore, the maximal number of inner nodes and leaves is $2n - 1$ for a full binary tree. Since sampling from a Dirichlet distribution is also in $O(n)$, the total computational complexity for one sample is in $O(n)$.

Algorithm 1 Exact sampling algorithm for L_p-nested symmetric distributions

Input: The radial distribution ϕ of an L_p-nested symmetric distribution ρ for the L_p-nested function f.
Output: Sample $\boldsymbol{x}$ from ρ.
Algorithm

1. Sample $v_\emptyset$ from a beta distribution $\beta[n,1]$.
2. For each inner node I of the tree associated with f, sample the auxiliary variable $\boldsymbol{s}_I$ from a Dirichlet distribution $\mathrm{Dir}\left[\frac{n_{I,1}}{p_I},...,\frac{n_{I,\ell_I}}{p_I}\right]$ where $n_{I,k}$ are the number of leaves in the subtree under node I,k. Obtain coordinates on the L_p-nested sphere within the positive orthant by $\boldsymbol{s}_I \mapsto \boldsymbol{s}_I^{\frac{1}{p_I}} = \tilde{\boldsymbol{u}}_I$ (the exponentiation is taken component-wise).
3. Transform these samples to Cartesian coordinates by $v_I \cdot \tilde{\boldsymbol{u}}_I = \boldsymbol{v}_{I,1:\ell_I}$ for each inner node, starting from the root node and descending to lower layers. The components of $\boldsymbol{v}_{I,1:\ell_I}$ constitute the radii for the layer direct below them. If $I = \emptyset$, the radius had been sampled in step 1.
4. Once the two previous steps have been repeated until no inner node is left, we have a sample $\boldsymbol{x}$ from the uniform distribution in the positive quadrant. Normalize $\boldsymbol{x}$ to get a uniform sample from the sphere $\boldsymbol{u} = \frac{\boldsymbol{x}}{f(\boldsymbol{x})}$.
5. Sample a new radius $\tilde{v}_\emptyset$ from the radial distribution of the target radial distribution ϕ and obtain the sample via $\tilde{\boldsymbol{x}} = \tilde{v}_\emptyset \cdot \boldsymbol{u}$.
6. Multiply each entry x_i of $\tilde{\boldsymbol{x}}$ by an independent sample z_i from the uniform distribution over $\{-1,1\}$.

7. Robust Bayesian Inference of the Location

For L_p-spherically symmetric distributions with a location and a scale parameter

$$p(\boldsymbol{x}|\boldsymbol{\mu},\tau) = \tau^n \rho(\|\tau(\boldsymbol{x}-\boldsymbol{\mu})\|_p),$$

Osiewalski and Steel (1993) derived the posterior in closed form using a prior $p(\boldsymbol{\mu},\tau) = p(\mu)\cdot c\cdot\tau^{-1}$, and showed that $p(\boldsymbol{x},\boldsymbol{\mu})$ does not depend on the radial distribution ϕ, that is, the particular type of L_p-spherically symmetric distributions used for a fixed p. The prior on τ corresponds to an improper Jeffrey's prior which is used to represent lack of prior knowledge on the scale. The main implication of their result is that Bayesian inference of the location $\boldsymbol{\mu}$ under that prior on the scale does not depend on the particular type of L_p-spherically symmetric distribution used for inference. This means that under the assumption of an L_p-spherically symmetric distributed variable, for a fixed p, one has to know the exact form of the distribution in order to compute the location parameter.

It is straightforward to generalize their result to L_p-nested symmetric distributions and, hence, making it applicable to a larger class of distributions. Note that when using any L_p-nested symmetric distribution, introducing a scale and a location via the transformation $\boldsymbol{x} \mapsto \tau(\boldsymbol{x}-\boldsymbol{\mu})$ introduces a factor of τ^n in front of the distribution.

Proposition 10 *For fixed values $p_\emptyset, p_1, \ldots$ and two independent priors $p(\boldsymbol{\mu},\tau) = p(\boldsymbol{\mu}) \cdot c\tau^{-1}$ of the location μ and the scale τ where the prior on τ is an improper Jeffrey's prior, the joint distribution $p(\boldsymbol{x},\boldsymbol{\mu})$ is given by*

$$p(\boldsymbol{x},\boldsymbol{\mu}) = f(\boldsymbol{x}-\boldsymbol{\mu})^{-n} \cdot c \cdot \frac{1}{Z} \cdot p(\boldsymbol{\mu}),$$

where Z denotes the normalization constant of the L_p-nested uniform distribution.

Proof Given any L_p-nested symmetric distribution $\rho(f(\boldsymbol{x}))$, the transformation into the polar-like coordinates yields the following relation

$$1 = \int \rho(f(\boldsymbol{x}))d\boldsymbol{x} = \int\int \prod_{L\in\mathcal{L}} G_L(\boldsymbol{u}_{\widehat{L}}) r^{n-1}\rho(r)drd\boldsymbol{u} = \int \prod_{L\in\mathcal{L}} G_L(\boldsymbol{u}_{\widehat{L}})d\boldsymbol{u} \cdot \int r^{n-1}\rho(r)dr.$$

Since $\prod_{L\in\mathcal{L}} G_L(\boldsymbol{u}_{\widehat{L}})$ is the unnormalized uniform distribution on the L_p-nested unit sphere, the integral must equal the normalization constant which we denote with Z for brevity (see Proposition 6 for an explicit expression). This implies that ρ has to fulfill

$$\frac{1}{Z} = \int r^{n-1}\rho(r)dr.$$

Writing down the joint distribution of $\boldsymbol{x},\boldsymbol{\mu}$ and τ, and using the substitution $s = \tau f(\boldsymbol{x}-\boldsymbol{\mu})$ we obtain

$$\begin{aligned} p(\boldsymbol{x},\boldsymbol{\mu}) &= \int \tau^n \rho(f(\tau(\boldsymbol{x}-\boldsymbol{\mu}))) \cdot c\tau^{-1} \cdot p(\boldsymbol{\mu})d\tau \\ &= \int s^{n-1}\rho(s) \cdot c \cdot p(\boldsymbol{\mu}) f(\boldsymbol{x}-\boldsymbol{\mu})^{-n} ds \\ &= f(\boldsymbol{x}-\boldsymbol{\mu})^{-n} \cdot c \cdot \frac{1}{Z} \cdot p(\boldsymbol{\mu}). \end{aligned}$$

■

Note that this result could easily be extended to ν-spherical distributions. However, in this case the normalization constant Z cannot be computed for most cases and, therefore, the posterior would not be known explicitly.

8. Relations to ICA, ISA and Over-Complete Linear Models

In this section, we explain the relations among L_p-spherically symmetric, L_p-nested symmetric, ICA and ISA models. For a general overview see Figure 4.

The density model underlying ICA models the joint distribution of the signal $\boldsymbol{x}$ as a linear superposition of statistically independent hidden sources $A\boldsymbol{y} = \boldsymbol{x}$ or $\boldsymbol{y} = W\boldsymbol{x}$. If the marginals of the hidden sources belong to the exponential power family, we obtain the p-generalized Normal which is a subset of the L_p-spherically symmetric class. The p-generalized Normal distribution $p(\boldsymbol{y}) \propto \exp(-\tau\|\boldsymbol{y}\|_p^p)$ is a density model that is often used in ICA algorithms for kurtotic natural signals like images and sound by optimizing a demixing matrix W w.r.t. to the model $p(\boldsymbol{y}) \propto \exp(-\tau\|W\boldsymbol{x}\|_p^p)$ (Lee and Lewicki, 2000; Zhang et al., 2004; Lewicki, 2002). It can be

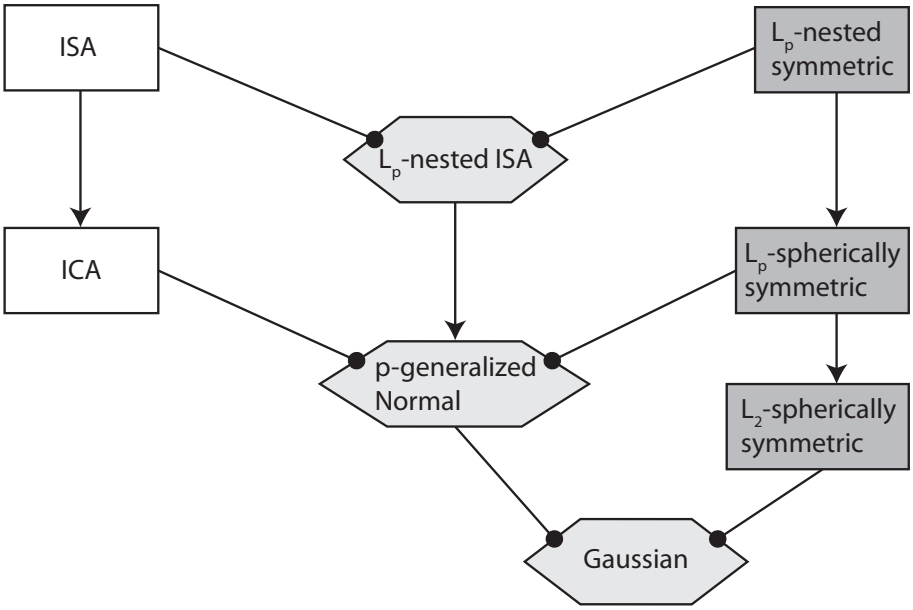

Figure 4: Relations between the different classes of distributions: Arrows indicate that the child class is a specialization (subset) of the parent class. Polygon-shaped classes are intersections of those parent classes which are connected via edges with round arrow-heads. For one-dimensional subspaces ISA is a superclass of ICA. All classes belonging to ISA are colored white or light gray. L_p-nested symmetric distributions are a superclass of L_p-spherically symmetric distributions. All L_p-nested symmetric models are colored dark or light gray. L_p-nested ISA models live in the intersection of L_p-nested symmetric distributions and ISA models. Those L_p-nested ISA models that are L_p-spherically symmetric are also ICA models: This is the class of p-generalized Normal distributions. If p is fixed to two, one obtains the L_2-spherically symmetric distributions. The only class of distributions in the intersection between spherically symmetric distributions and ICA models is the Gaussian.

shown that the p-generalized Normal is the only factorial model in the class of L_p-spherically symmetric models (Sinz et al., 2009a), and, by Proposition 9, also the only factorial L_p-nested symmetric distribution.

An important generalization of ICA is the independent subspace analysis (ISA) proposed by Hyvärinen and Hoyer (2000) and by Hyvärinen and Köster (2007) who used L_p-spherically symmetric distributions to model the single subspaces, that is, each ρ_k below was L_p-spherically symmetric. Like in ICA, ISA models the hidden sources of the signal as a product of multivariate distributions:

$$\rho(\boldsymbol{y}) = \prod_{k=1}^{K} \rho_k(\boldsymbol{y}_{I_k}).$$

Here, $\boldsymbol{y} = W\boldsymbol{x}$ and I_k are index sets selecting the different subspaces from the responses of W to $\boldsymbol{x}$. The collection of index sets I_k forms a partition of $1,\ldots,n$. ICA is a special case of ISA in which

$I_k = \{k\}$ such that all subspaces are one-dimensional. For the ISA models used by Hyvärinen et al. the distribution on the subspaces was chosen to be either spherically or L_p-spherically symmetric.

In its general form, ISA is not a generalization of L_p-spherically symmetric distributions. The most general ISA model for the transformed data $\boldsymbol{y} = W\boldsymbol{x}$ does not assume a certain type of distribution on the single subspace like in Hyvärinen and Köster (2007). While one could say for any non-factorial distribution that a factorial product over subspaces is a generalization, this is certainly a trivial step. Only in this particular sense is the particular ISA model by Hyvärinen and Köster (2007) a generalization of L_p-spherically symmetric distributions.

In contrast to ISA, L_p-nested symmetric distributions generally do not make an independence assumption on the "subspaces". In fact, for most of the models the subspaces will be dependent (see also our diagram in Figure 4). Therefore, not every ISA model is automatically L_p-nested symmetric and vice versa. In fact, in Sinz et al. (2009b) we have demonstrated for natural images that the dependencies *between* subspaces is stronger than the dependencies *within* subspaces on natural image patches. This is in stark contrast to the assumptions underlying ISA.

Note also that the product of L_p-spherically symmetric distributions used by Hyvärinen and Köster (2007) is not an L_p-nested function (Equation (6) in Hyvärinen and Köster, 2007) since the single a_j can be different and, therefore, the overall function is not positively homogeneous in general.

ICA and ISA have been used to infer features from natural signals, in particular from natural images. However, as mentioned by several authors (Zetzsche et al., 1993; Simoncelli, 1997; Wainwright and Simoncelli, 2000) and demonstrated quantitatively by Bethge (2006) and Eichhorn et al. (2009), the assumptions underlying linear ICA are not well matched by the statistics of the pixel intensities of natural images. A reliable parametric way to assess how well the independence assumption is met by a signal at hand is to fit a more general class of distributions that contains factorial as well as non-factorial distributions which both can equally well reproduce the marginals. By comparing the likelihood on held out test data between the best fitting non-factorial and the best-fitting factorial case, one can assess how well the sources can be described by a factorial distribution. For natural images, for example, one can use an arbitrary L_p-spherically symmetric distribution $\rho(\|W\boldsymbol{x}\|_p)$, fit it to the whitened data and compare its likelihood on held out test data to the one of the p-generalized Normal distribution (Sinz and Bethge, 2009). Since any choice of radial distribution ϕ determines a particular L_p-spherically symmetric distribution, the idea is to explore the space between factorial and non-factorial models by using a very flexible density ϕ on the radius. Note that having an explicit expression of the normalization constant allows for particularly reliable model comparisons via the likelihood. For many graphical models, for instance, such an explicit and computable expression is often not available.

The same type of dependency-analysis can be carried out for ISA using L_p-nested symmetric distributions (Sinz et al., 2009b). Figure 5 shows the L_p-nested tree corresponding to an ISA with four subspaces. In general, for such trees, each inner node—except the root node—corresponds to a single subspace. When using the radial distribution

$$\phi_\emptyset(v_\emptyset) = \frac{p_\emptyset v_\emptyset^{n-1}}{\Gamma\left[\frac{n}{p_\emptyset}\right] s^{\frac{n}{p_\emptyset}}} \exp\left(-\frac{v_\emptyset^{p_\emptyset}}{s}\right), \tag{11}$$

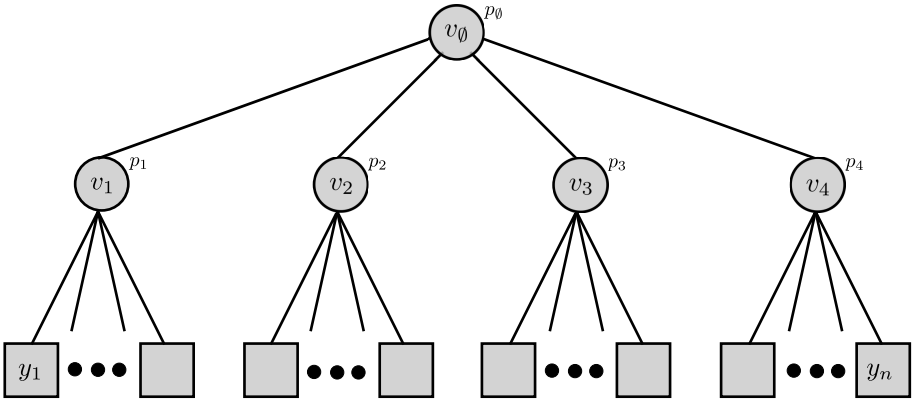

Figure 5: Tree corresponding to an L_p-nested ISA model.

the subspaces $v_1, ..., v_{\ell_\emptyset}$ become independent and one obtains an ISA model of the form

$$\begin{aligned}
\rho(\boldsymbol{y}) &= \frac{1}{Z}\exp\left(-\frac{f(\boldsymbol{y})^{p_\emptyset}}{s}\right) \\
&= \frac{1}{Z}\exp\left(-\frac{\sum_{k=1}^{\ell_\emptyset}\|\boldsymbol{y}_{I_k}\|_{p_k}}{s}\right) \\
&= \frac{p_\emptyset^{\ell_\emptyset}}{s^{\frac{n}{p_\emptyset}}\prod_{i=1}^{\ell_\emptyset}\Gamma\left[\frac{n_i}{p_\emptyset}\right]}\exp\left(-\frac{\sum_{k=1}^{\ell_\emptyset}\|\boldsymbol{y}_{I_k}\|_{p_k}}{s}\right)\prod_{k=1}^{\ell_\emptyset}\frac{p_k^{\ell_k-1}\Gamma\left[\frac{n_k}{p_k}\right]}{2^{n_k}\Gamma^{n_k}\left[\frac{1}{p_I}\right]},
\end{aligned}$$

which has L_p-spherically symmetric distributions on each subspace. Note that this radial distribution is equivalent to a Gamma distribution whose variables have been raised to the power of $\frac{1}{p_\emptyset}$. In the following we will denote distributions of this type with $\gamma_p(u,s)$, where u and s are the shape and scale parameter of the Gamma distribution, respectively. The particular γ_p distribution that results in independent subspaces has arbitrary scale but shape parameter $u = \frac{n}{p_\emptyset}$. When using any other radial distribution, the different subspaces do not factorize, and the distribution is also not an ISA model. In that sense L_p-nested symmetric distributions are a generalization of ISA. Note, however, that not every ISA model is also L_p-nested symmetric since not every product of arbitrary distributions on the subspaces, even if they are L_p-spherically symmetric, must also be L_p-nested.

It is natural to ask, whether L_p-nested symmetric distributions can serve as a prior distribution $p(\boldsymbol{y}|\boldsymbol{\vartheta})$ over hidden factors in over-complete linear models of the form

$$p(\boldsymbol{x}|W,\sigma,\boldsymbol{\vartheta}) = \int p(\boldsymbol{x}|W\boldsymbol{y},\sigma)p(\boldsymbol{y}|\boldsymbol{\vartheta})d\boldsymbol{y},$$

where $p(\boldsymbol{x}|W\boldsymbol{y})$ represents the likelihood of the observed data point $\boldsymbol{x}$ given the hidden factors $\boldsymbol{y}$ and the over-complete matrix W. For example, $p(\boldsymbol{x}|W\boldsymbol{y},\sigma) = \mathcal{N}(W\boldsymbol{y},\sigma\cdot I)$ could be a Gaussian like in Olshausen and Field (1996). Unfortunately, such a model would suffer from the same problems as all over-complete linear models: While sampling from the prior is straightforward sampling from the posterior $p(\boldsymbol{y}|\boldsymbol{x},W,\boldsymbol{\vartheta},\sigma)$ is difficult because a whole subspace of $\boldsymbol{y}$ leads to the same $\boldsymbol{x}$.

Since parameter estimation either involves solving the high-dimensional integral $p(\boldsymbol{x}|W,\sigma,\boldsymbol{\vartheta}) = \int p(\boldsymbol{x}|W\boldsymbol{y},\sigma)p(\boldsymbol{y}|\boldsymbol{\vartheta})d\boldsymbol{y}$ or sampling from the posterior, learning is computationally demanding in such models. Various methods have been proposed to learn W, ranging from sampling the posterior only at its maximum (Olshausen and Field, 1996), approximating the posterior with a Gaussian via the Laplace approximation (Lewicki and Olshausen, 1999) or using Expectation Propagation (Seeger, 2008). In particular, all of the above studies either do not fit hyper-parameters $\boldsymbol{\vartheta}$ for the prior (Olshausen and Field, 1996; Lewicki and Olshausen, 1999) or rely on the factorial structure of it (Seeger, 2008). Since L_p-nested symmetric distributions do not provide such a factorial prior, Expectation Propagation is not directly applicable. An approximation like in Lewicki and Olshausen (1999) might be possible, but additionally estimating the parameters $\boldsymbol{\vartheta}$ of the L_p-nested symmetric distribution adds another level of complexity in the estimation procedure. Exploring such over-complete linear models with a non-factorial prior may be an interesting direction to investigate, but it will need a significant amount of additional numerical and algorithmical work to find an efficient and robust estimation procedure.

9. Nested Radial Factorization with L_p-Nested Symmetric Distributions

L_p-nested symmetric distribution also give rise to a non-linear ICA algorithm for linearly mixed non-factorial L_p-nested hidden sources $\boldsymbol{y}$. The idea is similar to the radial factorization algorithms proposed by Lyu and Simoncelli (2009) and Sinz and Bethge (2009). For this reason, we call it *nested radial factorization (NRF)*. For a one layer L_p-nested tree, NRF is equivalent to radial factorization as described in Sinz and Bethge (2009). If additionally p is set to $p = 2$, one obtains the radial Gaussianization by Lyu and Simoncelli (2009). Therefore, NRF is a generalization of radial Factorization. It has been demonstrated that radial factorization algorithms outperform linear ICA on natural image patches (Lyu and Simoncelli, 2009; Sinz and Bethge, 2009). Since L_p-nested symmetric distributions are slightly better in likelihood on natural image patches (Sinz et al., 2009b) and since the difference in the average log-likelihood directly corresponds to the reduction in dependencies between the single variables (Sinz and Bethge, 2009), NRF will slightly outperform radial factorization on natural images. For other types of data the performance will depend on how well the hidden sources can be modeled by a linear superposition of—possibly non-independent—L_p-nested symmetrically distributed sources. Here we state the algorithm as a possible application of L_p-nested symmetric distributions for unsupervised learning.

The idea is based on the observation that the choice of the radial distribution ϕ already determines the type of L_p-nested symmetric distribution. This also means that by changing the radial distribution by remapping the data, the distribution could possibly be turned in a factorial one. Radial factorization algorithms fit an L_p-spherically symmetric distribution with a very flexible radial distribution to the data and map this radial distribution ϕ_s (s for source) into the one of a p-generalized Normal distribution by the mapping

$$\boldsymbol{y} \mapsto \frac{(\mathcal{F}_{\perp\!\!\perp}^{-1} \circ \mathcal{F}_s)(\|\boldsymbol{y}\|_p)}{\|\boldsymbol{y}\|_p} \cdot \boldsymbol{y}, \tag{12}$$

where $\mathcal{F}_{\perp\!\!\perp}$ and $\mathcal{F}_s$ are the cumulative distribution functions of the two radial distributions involved. The mapping basically normalizes the demixed source $\boldsymbol{y}$ and rescales it with a new radius that has the correct distribution.

Exactly the same method cannot work for L_p-nested symmetric distributions since Proposition 9 states that there is no factorial distribution into which we could map the data by merely changing the radial distribution. Instead we have to remap the data in an iterative fashion beginning with changing the radial distribution at the root node into the radial distribution of the L_p-nested ISA shown in Equation (11). Once the nodes are independent, we repeat this procedure for each of the child nodes independently, then for their child nodes and so on, until only leaves are left. The rescaling of the radii is a non-linear mapping since the transform in Equation (12) is non-linear. Therefore, NRF is a non-linear ICA algorithm.

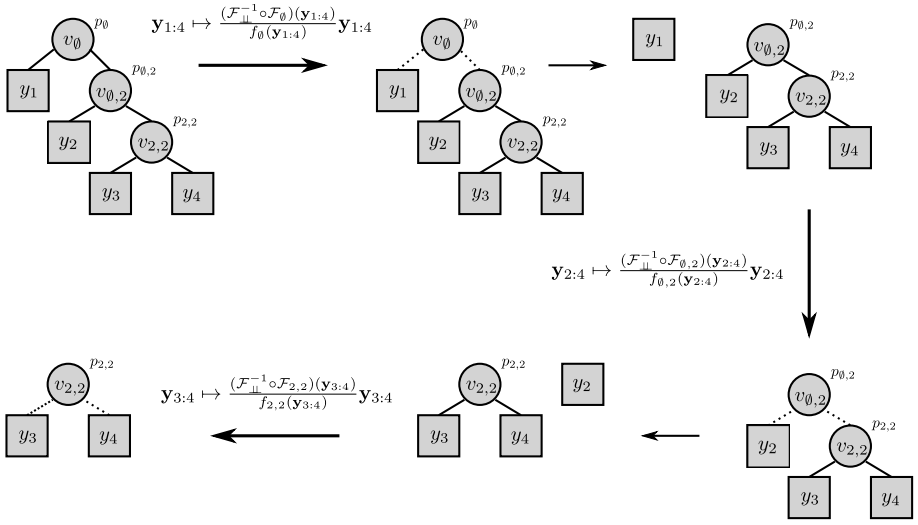

Figure 6: L_p-nested non-linear ICA for the tree of Example 6: For an arbitrary L_p-nested symmetric distribution, using Equation (12), the radial distribution can be remapped such that the children of the root node become independent. This is indicated in the plot via dotted lines. Once the data have been rescaled with that mapping, the children of root node can be separated. The remaining subtrees are again L_p-nested symmetric and have a particular radial distribution that can be remapped into the same one that makes their root nodes' children independent. This procedure is repeated until only leaves are left.

We demonstrate this with a simple example.

Example 6 *Consider the function*

$$f(\mathbf{y}) = \left(|y_1|^{p_\emptyset} + \left(|y_2|^{p_{\emptyset,2}} + \left(|y_3|^{p_{2,2}} + |y_4|^{p_{2,2}} \right)^{\frac{p_{\emptyset,2}}{p_{2,2}}} \right)^{\frac{p_\emptyset}{p_{\emptyset,2}}} \right)^{\frac{1}{p_\emptyset}}$$

for $\mathbf{y} = W\boldsymbol{x}$ where W has been estimated by fitting an L_p-nested symmetric distribution with a flexible radial distribution to $W\boldsymbol{x}$ as described in Section 5. Assume that the data has already been transformed once with the mapping of Equation (12)*. This means that the current radial distribution*

is given by (11) where we chose $s = 1$ for convenience. This yields a distribution of the form

$$\rho(\mathbf{y}) = \frac{p_\emptyset}{\Gamma\left[\frac{n}{p_\emptyset}\right]} \exp\left(-|y_1|^{p_\emptyset} - \left(|y_2|^{p_{\emptyset,2}} + \left(|y_3|^{p_{2,2}} + |y_4|^{p_{2,2}}\right)^{\frac{p_{\emptyset,2}}{p_{2,2}}}\right)^{\frac{p_\emptyset}{p_{\emptyset,2}}}\right)$$
$$\times \frac{1}{2^n} \prod_{I \in I} p_I^{\ell_I - 1} \frac{\Gamma\left[\frac{n_I}{p_I}\right]}{\prod_{k=1}^{\ell_I} \Gamma\left[\frac{n_{I,k}}{p_I}\right]}.$$

Now we can separate the distribution of y_1 from the distribution over $y_2, ..., y_4$. The distribution of y_1 is a p-generalized Normal

$$p(y_1) = \frac{p_\emptyset}{2\Gamma\left[\frac{1}{p_\emptyset}\right]} \exp\left(-|y_1|^{p_\emptyset}\right).$$

Thus the distribution of $y_2, ..., y_4$ is given by

$$\rho(y_2, ..., y_4) = \frac{p_\emptyset}{\Gamma\left[\frac{n_{\emptyset,2}}{p_\emptyset}\right]} \exp\left(-\left(|y_2|^{p_{\emptyset,2}} + \left(|y_3|^{p_{2,2}} + |y_4|^{p_{2,2}}\right)^{\frac{p_{\emptyset,2}}{p_{2,2}}}\right)^{\frac{p_\emptyset}{p_{\emptyset,2}}}\right)$$
$$\times \frac{1}{2^{n-1}} \prod_{I \in I \setminus \emptyset} p_I^{\ell_I - 1} \frac{\Gamma\left[\frac{n_I}{p_I}\right]}{\prod_{k=1}^{\ell_I} \Gamma\left[\frac{n_{I,k}}{p_I}\right]}.$$

By using Equation (9) we can identify the new radial distribution to be

$$\phi(v_{\emptyset,2}) = \frac{p_\emptyset v_{\emptyset,2}^{n-2}}{\Gamma\left[\frac{n_{\emptyset,2}}{p_\emptyset}\right]} \exp\left(-v_{\emptyset,2}^{p_\emptyset}\right).$$

Replacing this distribution by the one for the p-generalized Normal (for data we would use the mapping in Equation (12)), we obtain

$$\rho(y_2, ..., y_4) = \frac{p_{\emptyset,2}}{\Gamma\left[\frac{n_{\emptyset,2}}{p_{\emptyset,2}}\right]} \exp\left(-|y_2|^{p_{\emptyset,2}} - \left(|y_3|^{p_{2,2}} + |y_4|^{p_{2,2}}\right)^{\frac{p_{\emptyset,2}}{p_{2,2}}}\right)$$
$$\times \frac{1}{2^{n-1}} \prod_{I \in I \setminus \emptyset} p_I^{\ell_I - 1} \frac{\Gamma\left[\frac{n_I}{p_I}\right]}{\prod_{k=1}^{\ell_I} \Gamma\left[\frac{n_{I,k}}{p_I}\right]}.$$

Now, we can separate out the distribution of y_2 which is again p-generalized Normal. This leaves us with the distribution for y_3 and y_4

$$\rho(y_3, y_4) = \frac{p_{\emptyset,2}}{\Gamma\left[\frac{n_{2,2}}{p_{\emptyset,2}}\right]} \exp\left(-\left(|y_3|^{p_{2,2}} + |y_4|^{p_{2,2}}\right)^{\frac{p_{\emptyset,2}}{p_{2,2}}}\right) \frac{1}{2^{n-2}} \prod_{I \in I \setminus \{\emptyset,(\emptyset,2)\}} p_I^{\ell_I - 1} \frac{\Gamma\left[\frac{n_I}{p_I}\right]}{\prod_{k=1}^{\ell_I} \Gamma\left[\frac{n_{I,k}}{p_I}\right]}.$$

For this distribution we can repeat the same procedure which will also yield p-generalized Normal distributions for y_3 and y_4.

Algorithm 2 Recursion NRF($\boldsymbol{y}, f, \phi_s$)

Input: Data point $\boldsymbol{y}$, L_p-nested function f, current radial distribution ϕ_s,
Output: Non-linearly transformed data point $\boldsymbol{y}$
Algorithm

1. Set the target radial distribution to be $\phi_{\perp\!\!\!\perp} \leftarrow \gamma_p \left(\frac{n_\emptyset}{p_\emptyset}, \frac{\Gamma\left[\frac{1}{p_\emptyset}\right]^{\frac{p_\emptyset}{2}}}{\Gamma\left[\frac{3}{p_\emptyset}\right]^{\frac{p_\emptyset}{2}}} \right)$
2. Set $\boldsymbol{y} \leftarrow \frac{\mathcal{F}_{\perp\!\!\!\perp}^{-1}(\mathcal{F}_s(f(\boldsymbol{y})))}{f(\boldsymbol{y})} \cdot \boldsymbol{y}$ where $\mathcal{F}$ denotes the cumulative distribution function of the respective ϕ.
3. For all children i of the root node that are not leaves:
   (a) Set $\phi_s \leftarrow \gamma_p \left(\frac{n_{\emptyset,i}}{p_\emptyset}, \frac{\Gamma\left[\frac{1}{p_\emptyset}\right]^{\frac{p_\emptyset}{2}}}{\Gamma\left[\frac{3}{p_\emptyset}\right]^{\frac{p_\emptyset}{2}}} \right)$
   (b) Set $\boldsymbol{y}_{\emptyset,i} \leftarrow \text{NRF}(\boldsymbol{y}_{\emptyset,i}, f_{\emptyset,i}, \phi_s)$. Note that in the recursion $\emptyset, i$ will become the new $\emptyset$.
4. Return $\boldsymbol{y}$

This non-linear procedure naturally carries over to arbitrary L_p-nested trees and distributions, thus yielding a general non-linear ICA algorithm for linearly mixed non-factorial L_p-nested symmetric sources. For generalizing Example 6, note the particular form of the radial distributions involved. As already noted above, the distribution (11) on the root node's values that makes its children statistically independent is that of a Gamma distributed variable with shape parameter $\frac{n_\emptyset}{p_\emptyset}$ and scale parameter s which has been raised to the power of $\frac{1}{p_\emptyset}$. In Section 8 we denoted this class of distributions with $\gamma_p[u,s]$, where u and s are the shape and the scale parameter, respectively. Interestingly, the radial distributions of the root node's children are also γ_p except that the shape parameter is $\frac{n_{\emptyset,i}}{p_\emptyset}$. The goal of the radial remapping of the children's values is hence just changing the shape parameter from $\frac{n_{\emptyset,i}}{p_\emptyset}$ to $\frac{n_{\emptyset,i}}{p_{\emptyset,i}}$. Of course, it is also possible to change the scale parameter of the single distributions during the radial remappings. This will not affect the statistical independence of the resulting variables. In the general algorithm, that we describe now, we choose s such that the transformed data is white.

The algorithm starts with fitting a general L_p-nested model of the form $\rho(W\boldsymbol{x})$ as described in Section 5. Once this is done, the linear demixing matrix W is fixed and the hidden non-factorial sources are recovered via $\boldsymbol{y} = W\boldsymbol{x}$. Afterwards, the sources $\boldsymbol{y}$ are non-linearly made independent by calling the recursion specified in Algorithm 2 with the parameters $W\boldsymbol{x}$, f and ϕ, where ϕ is the radial distribution of the estimated model.

The computational complexity for transforming a single data point is $O(n^2)$ because of the matrix multiplication $W\boldsymbol{x}$. In the non-linear transformation, each single data dimension is not rescaled more that n times which means that the rescaling is certainly also in $O(n^2)$.

An important aspect of NRF is that it yields a probabilistic model for the transformed data. This model is simply a product of n independent exponential power marginals. Since the radial remappings do not change the likelihood, the likelihood of the non-linearly separated data is the

same as the likelihood of the data under L_p-nested symmetric distribution that was fitted to it in the first place. However, in some cases, one might like to fit a different distribution to the outcome of Algorithm 2. In that case the determinant of the transformation is necessary to determine the likelihood of the input data—and not the transformed one—under the model. The following lemma provides the determinant of the Jacobian for the non-linear rescaling.

Lemma 11 (Determinant of the Jacobian) *Let $\boldsymbol{z} = NRF(W\boldsymbol{x}, f, \phi_s)$ as described above. Let $\boldsymbol{t}_I$ denote the values of $W\boldsymbol{x}$ below the inner node I which have been transformed with Algorithm 2 up to node I. Let $g_I(r) = (\mathcal{F}_{\phi_{\perp\!\!\!\perp}} \circ \mathcal{F}_{\phi_s})(r)$ denote the radial transform at node I in Algorithm 2. Furthermore, let $\mathcal{I}$ denote the set of all inner nodes, excluding the leaves. Then, the determinant of the Jacobian $\left(\frac{\partial z_i}{\partial x_j}\right)_{ij}$ is given by*

$$\left|\det \frac{\partial z_i}{\partial x_j}\right| = |\det W| \cdot \prod_{I \in \mathcal{I}} \left| \frac{g_I(f_I(\boldsymbol{t}_I))^{n_I - 1}}{f_I(\boldsymbol{t}_I)^{n_I - 1}} \cdot \frac{\phi_s(f_I(\boldsymbol{t}_I))}{\phi_{\perp\!\!\!\perp}(g_I(f_I(\boldsymbol{t}_I)))} \right|$$

Proof The proof can be found in the Appendix E. ■

10. Conclusion

In this article we presented a formal treatment of the first tractable subclass of ν-spherical distributions which generalizes the important family of L_p-spherically symmetric distributions. We derived an analytical expression for the normalization constant, introduced a coordinate system particularly tailored to L_p-nested functions, and computed the determinant of the Jacobian for the corresponding coordinate transformation. Using these results, we introduced the uniform distribution on the L_p-nested unit sphere and the general form of an L_p-nested symmetric distribution for arbitrary L_p-nested functions and radial distributions. We also derived an expression for the joint distribution of inner nodes of an L_p-nested tree and derived a sampling scheme for an arbitrary L_p-nested symmetric distribution.

L_p-nested symmetric distributions naturally provide the class of probability distributions corresponding to mixed norm priors, allowing full Bayesian inference in the corresponding probabilistic models. We showed that a robustness result for Bayesian inference of the location parameter known for L_p-spherically symmetric distributions carries over to the L_p-nested symmetric class. We discussed the relationship of L_p-nested symmetric distributions to indepedent component (ICA) and independent subspace Analysis (ISA), as well as its applicability as a prior distribution in overcomplete linear models. Finally, we showed how L_p-nested symmetric distributions can be used to construct a non-linear ICA algorithm called nested radial factorization (NRF).

The application of L_p-nested symmetric distribution has been presented in a previous conference paper (Sinz et al., 2009b). Code for training this class of distribution is provided online under `http://www.kyb.tuebingen.mpg.de/bethge/code/`.

Acknowledgments

We would like to thank Eero Simoncelli for bringing up the problem whether the class of L_p-spherical distributions can be generalized to L_p-nested symmetric distributions. Furthermore, we

want to thank Sebastian Gerwinn, Suvrit Sra, Reshad Hosseini, Lucas Theis, Holly Gerhard, and Sina Tootoonian for fruitful discussions and feedback on the manuscript. Finally, we would like to thank the anonymous reviewers for their comments that helped to improve the manuscript.

This work is supported by the German Ministry of Education, Science, Research and Technology through the Bernstein prize to MB (BMBF; FKZ: 01GQ0601), a scholarship to FS by the German National Academic Foundation, and the Max Planck Society.

Appendix A. Determinant of the Jacobian

Proof [Lemma 2] The proof is very similar to the one in Song and Gupta (1997). To derive Equation (2) one needs to expand the Jacobian of the inverse coordinate transformation with respect to the last column using the Laplace's expansion of the determinant. The term Δ_n can be factored out of the determinant and cancels due to the absolute value around it. Therefore, the determinant of the coordinate transformation does not depend on Δ_n.

The partial derivatives of the inverse coordinate transformation are given by:

$$\begin{aligned}
\frac{\partial}{\partial u_k} x_i &= \delta_{ik} r \text{ for } 1 \leq i,k \leq n-1 \\
\frac{\partial}{\partial u_k} x_n &= \Delta_n r \frac{\partial u_n}{\partial u_k} \text{ for } 1 \leq k \leq n-1 \\
\frac{\partial}{\partial r} x_i &= u_i \text{ for } 1 \leq i \leq n-1 \\
\frac{\partial}{\partial r} x_n &= \Delta_n u_n.
\end{aligned}$$

Therefore, the structure of the Jacobian is given by

$$\mathcal{J} = \begin{pmatrix} r & \dots & 0 & u_1 \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \dots & r & u_{n-1} \\ \Delta_n r \frac{\partial u_n}{\partial u_1} & \dots & \Delta_n r \frac{\partial u_n}{\partial u_{n-1}} & \Delta_n u_n \end{pmatrix}.$$

Since we are only interested in the absolute value of the determinant and since $\Delta_n \in \{-1, 1\}$, we can factor out Δ_n and drop it. Furthermore, we can factor out r from the first $n-1$ columns which yields

$$|\det \mathcal{J}| = r^{n-1} \left| \det \begin{pmatrix} 1 & \dots & 0 & u_1 \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \dots & 1 & u_{n-1} \\ \frac{\partial u_n}{\partial u_1} & \dots & \frac{\partial u_n}{\partial u_{n-1}} & u_n \end{pmatrix} \right|.$$

Now we can use the Laplace's expansion of the determinant with respect to the last column. For that purpose, let $\mathcal{J}_i$ denote the matrix which is obtained by deleting the last column and the ith row

from $\mathcal{J}$. This matrix has the following structure

$$\mathcal{J}_i = \begin{pmatrix} 1 & & & 0 & & & \\ & \ddots & & 0 & & & \\ & & 1 & 0 & & & \\ & & & \vdots & 1 & & \\ & & & 0 & & \ddots & \\ & & & 0 & & & 1 \\ \frac{\partial u_n}{\partial u_1} & & & \frac{\partial u_n}{\partial u_i} & & & \frac{\partial u_n}{\partial u_{n-1}} \end{pmatrix}.$$

We can transform $\mathcal{J}_i$ into a lower triangular matrix by moving the column with all zeros and $\frac{\partial u_n}{\partial u_i}$ bottom entry to the rightmost column of $\mathcal{J}_i$. Each swapping of two columns introduces a factor of -1. In the end, we can compute the value of $\det \mathcal{J}_i$ by simply taking the product of the diagonal entries and obtain $\det \mathcal{J}_i = (-1)^{n-1-i} \frac{\partial u_n}{\partial u_i}$. This yields

$$\begin{aligned} |\det \mathcal{J}| &= r^{n-1} \left(\sum_{k=1}^{n} (-1)^{n+k} u_k \det \mathcal{J}_k \right) \\ &= r^{n-1} \left(\sum_{k=1}^{n-1} (-1)^{n+k} u_k \det \mathcal{J}_k + (-1)^{2n} \frac{\partial x_n}{\partial r} \right) \\ &= r^{n-1} \left(\sum_{k=1}^{n-1} (-1)^{n+k} u_k (-1)^{n-1-k} \frac{\partial u_n}{\partial u_k} + u_n \right) \\ &= r^{n-1} \left(-\sum_{k=1}^{n-1} u_k \frac{\partial u_n}{\partial u_k} + u_n \right). \end{aligned}$$

■

Before proving Proposition 3 stating that the determinant only depends on the terms $G_I(\boldsymbol{u}_{\widehat{I}})$ produced by the chain rule when used upwards in the tree, let us quickly outline the essential mechanism when taking the chain rule for $\frac{\partial u_n}{\partial u_q}$: Consider the tree corresponding to f. By definition u_n is the rightmost leaf of the tree. Let L, ℓ_L be the multi-index of u_n. As in the example, the chain rule starts at the leaf u_n and ascends in the tree until it reaches the lowest node whose subtree contains both, u_n and u_q. At this point, it starts descending the tree until it reaches the leaf u_q. Depending on whether the chain rule ascends or descends, two different forms of derivatives occur: while ascending, the chain rule produces $G_I(\boldsymbol{u}_{\widehat{I}})$-terms like the one in the example above. At descending, it produces $F_I(\boldsymbol{u}_I)$-terms. The general definitions of the $G_I(\boldsymbol{u}_{\widehat{I}})$- and $F_I(\boldsymbol{u}_I)$-terms are given by the recursive formulae

$$G_{I,\ell_I}(\boldsymbol{u}_{\widehat{I,\ell_I}}) = g_{I,\ell_I}(\boldsymbol{u}_{\widehat{I,\ell_I}})^{p_{I,\ell_I}-p_I} = \left(g_I(\boldsymbol{u}_{\widehat{I}})^{p_I} - \sum_{j=1}^{\ell_I-1} f_{I,j}(\boldsymbol{u}_{I,j})^{p_I} \right)^{\frac{p_{I,\ell_I}-p_I}{p_I}}$$

and

$$F_{I,i_r}(\boldsymbol{u}_{I,i_r}) = f_{I,i_r}(\boldsymbol{u}_{I,i_r})^{p_I - p_{I,i_r}} = \left(\sum_{k=1}^{\ell_{I,i_r}} f_{I,i_r,k}(\boldsymbol{u}_{I,i_r,k})^{p_{I,i_r}} \right)^{\frac{p_I - p_{I,i_r}}{p_{I,i_r}}}.$$

The next two lemmata are required for the proof of Proposition 3. We use the somewhat sloppy notation $k \in I, i_r$ if the variable u_k is a leaf in the subtree below I, i_r. The same notation is used for $\widehat{I}$.

Lemma 12 *Let $I = i_1, ..., i_{r-1}$ and I, i_r be any node of the tree associated with an L_p-nested function f. Then the following recursions hold for the derivatives of $g_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}})^{p_{I,i_r}}$ and $f_{I,i_r}^{p_I}(\boldsymbol{u}_{I,i_r})$ w.r.t u_q: If u_q is not in the subtree under the node I, i_r, that is, $k \notin I, i_r$, then*

$$\frac{\partial}{\partial u_q} f_{I,i_r}(\boldsymbol{u}_{I,i_r})^{p_I} = 0$$

and

$$\frac{\partial}{\partial u_q} g_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}})^{p_{I,i_r}} = \frac{p_{I,i_r}}{p_I} G_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}}) \cdot \begin{cases} \frac{\partial}{\partial u_q} g_I(\boldsymbol{u}_{\widehat{I}})^{p_I} & \text{if } q \in I \\ -\frac{\partial}{\partial u_q} f_{I,j}(\boldsymbol{u}_{I,j})^{p_I} & \text{if } q \in I, j \end{cases}$$

for $q \in I, j$ and $q \notin I, k$ for $k \neq j$. Otherwise

$$\frac{\partial}{\partial u_q} g_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}})^{p_{I,i_r}} = 0 \text{ and } \frac{\partial}{\partial u_q} f_{I,i_r}(\boldsymbol{u}_{I,i_r})^{p_I} = \frac{p_I}{p_{I,i_r}} F_{I,i_r}(\boldsymbol{u}_{I,i_r}) \frac{\partial}{\partial u_q} f_{I,i_r,s}(\boldsymbol{u}_{I,i_r,s})^{p_{I,i_r}}$$

for $q \in I, i_r, s$ and $q \notin I, i_r, k$ for $k \neq s$.

Proof Both of the first equations are obvious, since only those nodes have a non-zero derivative for which the subtree actually depends on u_q. The second equations can be seen by direct computation

$$\begin{aligned}
\frac{\partial}{\partial u_q} g_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}})^{p_{I,i_r}} &= p_{I,i_r} g_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}})^{p_{I,i_r}-1} \frac{\partial}{\partial u_q} G_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}}) \\
&= p_{I,i_r} g_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}})^{p_{I,i_r}-1} \frac{\partial}{\partial u_q} \left(g_I(\boldsymbol{u}_{\widehat{I}})^{p_I} - \sum_{j=1}^{\ell_I - 1} f_{I,j}(\boldsymbol{u}_{I,j})^{p_I} \right)^{\frac{1}{p_I}} \\
&= \frac{p_{I,i_r}}{p_I} g_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}})^{p_{I,i_r}-1} g_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}})^{1-p_I} \frac{\partial}{\partial u_q} \left(g_I(\boldsymbol{u}_{\widehat{I}})^{p_I} - \sum_{j=1}^{\ell_I - 1} f_{I,j}(\boldsymbol{u}_{I,j})^{p_I} \right) \\
&= \frac{p_{I,i_r}}{p_I} G_{I,i_r}(\boldsymbol{u}_{\widehat{I,i_r}}) \cdot \begin{cases} \frac{\partial}{\partial u_q} g_I(\boldsymbol{u}_{\widehat{I}})^{p_I} & \text{if } q \in I \\ -\frac{\partial}{\partial u_q} f_{I,j}(\boldsymbol{u}_{I,j})^{p_I} & \text{if } q \in I, j \end{cases}
\end{aligned}$$

Similarly

$$\begin{aligned}
\frac{\partial}{\partial u_q} f_{I,i_r}(\boldsymbol{u}_{I,i_r})^{p_I} &= p_I f_{I,i_r}(\boldsymbol{u}_{I,i_r})^{p_I-1} \frac{\partial}{\partial u_q} f_{I,i_r}(\boldsymbol{u}_{I,i_r}) \\
&= p_I f_{I,i_r}(\boldsymbol{u}_{I,i_r})^{p_I-1} \frac{\partial}{\partial u_q} \left(\sum_{k=1}^{\ell_{I,i_r}} f_{I,i_r,k}(\boldsymbol{u}_{I,i_r,k})^{p_{I,i_r}} \right)^{\frac{1}{p_{I,i_r}}} \\
&= \frac{p_I}{p_{I,i_r}} f_{I,i_r}(\boldsymbol{u}_{I,i_r})^{p_I-1} f_{I,i_r}(\boldsymbol{u}_{I,i_r})^{1-p_{I,i_r}} \frac{\partial}{\partial u_q} f_{I,i_r,s}(\boldsymbol{u}_{I,i_r,s})^{p_{I,i_r}} \\
&= \frac{p_I}{p_{I,i_r}} F_{I,i_r}(\boldsymbol{u}_{I,i_r}) \frac{\partial}{\partial u_q} f_{I,i_r,s}(\boldsymbol{u}_{I,i_r,s})^{p_{I,i_r}}
\end{aligned}$$

for $k \in I, i_r, s$. ■

The next lemma states the form of the whole derivative $\frac{\partial u_n}{\partial u_q}$ in terms of the $G_I(\boldsymbol{u}_{\widehat{I}})$- and $F_I(\boldsymbol{u}_I)$-terms.

Lemma 13 *Let $|u_q| = v_{\ell_1,\ldots,\ell_m,i_1,\ldots,i_t}$, $|u_n| = v_{\ell_1,\ldots,\ell_d}$ with $m < d$. The derivative of u_n w.r.t. u_q is given by*

$$\begin{aligned}
\frac{\partial}{\partial u_q} u_n = &-G_{\ell_1,\ldots,\ell_d}(\boldsymbol{u}_{\widehat{\ell_1,\ldots,\ell_d}}) \cdot \ldots \cdot G_{\ell_1,\ldots,\ell_{m+1}}(\boldsymbol{u}_{\ell_1,\ldots,\widehat{\ell_{m+1}}}) \\
&\times F_{\ell_1,\ldots,\ell_m,i_1}(\boldsymbol{u}_{\ell_1,\ldots,\ell_m,i_1}) \cdot F_{\ell_1,\ldots,\ell_m,i_1,\ldots,i_{t-1}}(\boldsymbol{u}_{\ell_1,\ldots,\ell_m,i_1,\ldots,i_{t-1}}) \cdot \Delta_q |u_q|^{p_{\ell_1,\ldots,\ell_m,i_1,\ldots,i_{t-1}}-1}
\end{aligned}$$

with $\Delta_q = \operatorname{sgn} u_q$ and $|u_q|^p = (\Delta_q u_q)^p$. In particular

$$\begin{aligned}
u_q \frac{\partial}{\partial u_q} u_n = &-G_{\ell_1,\ldots,\ell_d}(\boldsymbol{u}_{\widehat{\ell_1,\ldots,\ell_d}}) \cdot \ldots \cdot G_{\ell_1,\ldots,\ell_{m+1}}(\boldsymbol{u}_{\ell_1,\ldots,\widehat{\ell_{m+1}}}) \\
&\times F_{\ell_1,\ldots,\ell_m,i_1}(\boldsymbol{u}_1) \cdot F_{\ell_1,\ldots,\ell_m,i_1,\ldots,i_{t-1}}(\boldsymbol{u}_{\ell_1,\ldots,\ell_m,i_1}) \cdot |u_q|^{p_{\ell_1,\ldots,\ell_m,i_1,\ldots,i_{t-1}}}.
\end{aligned}$$

Proof Successive application of Lemma (12). ■

Proof [Proposition 3] Before we begin with the proof, note that $F_I(\boldsymbol{u}_I)$ and $G_I(\boldsymbol{u}_{\widehat{I}})$ fulfill following equalities

$$\begin{aligned}
G_{I,i_m}(\boldsymbol{u}_{\widehat{I,i_m}})^{-1} g_{I,i_m}(\boldsymbol{u}_{\widehat{I,i_m}})^{p_{I,i_m}} &= g_{I,i_m}(\boldsymbol{u}_{\widehat{I,i_m}})^{p_I} \\
&= g_I(\boldsymbol{u}_{\widehat{I}})^{p_I} - \sum_{k=1}^{\ell_I-1} F_{I,k}(\boldsymbol{u}_{I,k}) f_{I,k}(\boldsymbol{u}_{I,k})^{p_{I,k}} \qquad (13)
\end{aligned}$$

and

$$f_{I,i_m}(\boldsymbol{u}_{I,i_m})^{p_{I,i_m}} = \sum_{k=1}^{\ell_{I,i_m}} F_{I,i_m,k}(\boldsymbol{u}_{I,i_m,k}) f_{I,i_m,k}(\boldsymbol{u}_{I,i_m,k})^{p_{I,i_m,k}}. \qquad (14)$$

Now let $L = \ell_1,\ldots,\ell_{d-1}$ be the multi-index of the parent of u_n. We compute $\frac{1}{r^{n-1}}|\det \mathcal{J}|$ and obtain the result by solving for $|\det \mathcal{J}|$. As shown in Lemma (2) $\frac{1}{r^{n-1}}|\det \mathcal{J}|$ has the form

$$\frac{1}{r^{n-1}}|\det \mathcal{J}| = -\sum_{k=1}^{n-1} \frac{\partial u_n}{\partial u_k} \cdot u_k + u_n.$$

By definition $u_n = g_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}}) = g_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{p_{L,\ell_d}}$. Now, assume that $u_m, ..., u_{n-1}$ are children of L, that is, $u_k = v_{L,I,i_t}$ for some $I, i_t = i_1, ..., i_t$ and $m \leq k < n$. Remember, that by Lemma (13) the terms $u_q \frac{\partial}{\partial u_q} u_n$ for $m \leq q < n$ have the form

$$u_q \frac{\partial}{\partial u_q} u_n = - G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}}) \cdot F_{L,i_1}(\boldsymbol{u}_{L,i_1}) \cdot ... \cdot F_{L,I}(\boldsymbol{u}_{L,I}) \cdot |u_q|^{p_{\ell_1,...,\ell_{d-1},i_1,...,i_{t-1}}}.$$

Using Equation (13), we can expand the determinant as follows

$$\begin{aligned}
&- \sum_{k=1}^{n-1} \frac{\partial u_n}{\partial u_k} \cdot u_k + g_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{p_{L,\ell_d}} \\
= &- \sum_{k=1}^{m-1} \frac{\partial u_n}{\partial u_k} \cdot u_k - \sum_{k=m}^{n-1} \frac{\partial u_n}{\partial u_k} \cdot u_k + g_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{p_{L,\ell_d}} \\
= &- \sum_{k=1}^{m-1} \frac{\partial u_n}{\partial u_k} \cdot u_k \\
&+ G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}}) \left(- \sum_{k=m}^{n-1} G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{-1} \frac{\partial u_n}{\partial u_k} \cdot u_k + G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{-1} g_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{p_{L,\ell_d}} \right) \\
= &- \sum_{k=1}^{m-1} \frac{\partial u_n}{\partial u_k} \cdot u_k \\
&+ G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}}) \left(- \sum_{k=m}^{n-1} G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{-1} \frac{\partial u_n}{\partial u_k} \cdot u_k + g_L(\boldsymbol{u}_{\widehat{L}})^{p_L} - \sum_{k=1}^{\ell_d - 1} F_{L,k}(\boldsymbol{u}_{L,k}) f_{L,k}(\boldsymbol{u}_{L,k})^{p_{L,k}} \right).
\end{aligned}$$

Note that all terms $G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{-1} \frac{\partial u_n}{\partial u_k} \cdot u_k$ for $m \leq k < n$ now have the form

$$G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{-1} u_k \frac{\partial}{\partial u_k} u_n = -F_{L,i_1}(\boldsymbol{u}_{L,i_1}) \cdot ... \cdot F_{L,I}(\boldsymbol{u}_{L,I}) \cdot |u_q|^{p_{\ell_1,...,\ell_{d-1},i_1,...,i_{t-1}}}$$

since we constructed them to be neighbors of u_n. However, with Equation (14), we can further expand the sum $\sum_{k=1}^{\ell_d - 1} F_{L,k}(\boldsymbol{u}_{L,k}) f_{L,k}(\boldsymbol{u}_{L,k})^{p_{L,k}}$ down to the leaves $u_m, ..., u_{n-1}$. When doing so we end up with the same factors $F_{L,i_1}(\boldsymbol{u}_{L,i_1}) \cdot ... \cdot F_{L,I}(\boldsymbol{u}_{L,I}) \cdot |u_q|^{p_{\ell_1,...,\ell_{d-1},i_1,...,i_{t-1}}}$ as in the derivatives $G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{-1} u_q \frac{\partial}{\partial u_q} u_n$. This means exactly that

$$- \sum_{k=m}^{n-1} G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{-1} \frac{\partial u_n}{\partial u_k} \cdot u_k = \sum_{k=1}^{\ell_d - 1} F_{L,k}(\boldsymbol{u}_{L,k}) f_{L,k}(\boldsymbol{u}_{L,k})^{p_{L,k}}$$

and, therefore,

$$
\begin{aligned}
&-\sum_{k=1}^{m-1}\frac{\partial u_n}{\partial u_k}\cdot u_k \\
&+G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})\left(-\sum_{k=m}^{n-1}G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})^{-1}\frac{\partial u_n}{\partial u_k}\cdot u_k+g_L(\boldsymbol{u}_{\widehat{L}})^{p_L}-\sum_{k=1}^{\ell_d-1}F_{L,k}(\boldsymbol{u}_{L,k})f_{L,k}(\boldsymbol{u}_{L,k})^{p_{L,k}}\right)\\
=&-\sum_{k=1}^{m-1}\frac{\partial u_n}{\partial u_k}\cdot u_k \\
&+G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})\left(\sum_{k=1}^{\ell_d-1}F_{L,k}(\boldsymbol{u}_{L,k})f_{L,k}(\boldsymbol{u}_{L,k})^{p_{L,k}}+g_L(\boldsymbol{u}_{\widehat{L}})^{p_L}-\sum_{k=1}^{\ell_d-1}F_{L,k}(\boldsymbol{u}_{L,k})f_{L,k}(\boldsymbol{u}_{L,k})^{p_{L,k}}\right)\\
=&-\sum_{k=1}^{m-1}\frac{\partial u_n}{\partial u_k}\cdot u_k+G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})g_L(\boldsymbol{u}_{\widehat{L}})^{p_L}.
\end{aligned}
$$

By factoring out $G_{L,\ell_d}(\boldsymbol{u}_{\widehat{L,\ell_d}})$ from the equation, the terms $\frac{\partial u_n}{\partial u_k}\cdot u_k$ loose the G_{L,ℓ_d} in front and we get basically the same equation as before, only that the new leaf (the new "u_n") is $g_L(\boldsymbol{u}_{\widehat{L}})^{p_L}$ and we got rid of all the children of L. By repeating that procedure up to the root node, we successively factor out all $G_{L'}(\boldsymbol{u}_{\widehat{L'}})$ for $L'\in\mathcal{L}$ until all terms of the sum vanish and we are only left with $v_\emptyset=1$. Therefore, the determinant is

$$
\frac{1}{r^{n-1}}|\det \mathcal{J}|=\prod_{L\in\mathcal{L}}G_L(\boldsymbol{u}_{\widehat{L}})
$$

which completes the proof. ■

Appendix B. Volume and Surface of the L_p-Nested Unit Sphere

Proof [Proposition 4] We obtain the volume by computing the integral $\int_{f(\boldsymbol{x})\le R}d\boldsymbol{x}$. Differentiation with respect to R yields the surface area. For symmetry reasons we can compute the volume only on the positive quadrant $\mathbb{R}^n_+$ and multiply the result with 2^n later to obtain the full volume and surface area. The strategy for computing the volume is as follows. We start with inner nodes I that are parents of leaves only. The value v_I of such a node is simply the L_{p_I} norm of its children. Therefore, we can convert the integral over the children of I with the transformation of Gupta and Song (1997). This maps the leaves $\boldsymbol{v}_{I,1:\ell_I}$ into v_I and "angular" variables $\tilde{\boldsymbol{u}}$. Since integral borders of the original integral depend only on the value of v_I and not on $\tilde{\boldsymbol{u}}$, we can separate the variables $\tilde{\boldsymbol{u}}$ from the radial variables v_I and integrate the variables $\tilde{\boldsymbol{u}}$ separately. The integration over $\tilde{\boldsymbol{u}}$ yields a certain factor, while the variable v_I effectively becomes a new leaf.

Now suppose I is the parent of leaves only. Without loss of generality let the ℓ_I leaves correspond to the last ℓ_I coefficients of $\boldsymbol{x}$. Let $\boldsymbol{x} \in \mathbb{R}^n_+$. Carrying out the first transformation and integration yields

$$\begin{aligned}\int_{f(\boldsymbol{x})\leq R} d\boldsymbol{x} &= \int_{f(\boldsymbol{x}_{1:n-\ell_I}, v_I)\leq R} \int_{\tilde{\boldsymbol{u}}\in\mathcal{V}_+^{\ell_I-1}} v_I^{\ell_I-1} \left(1-\sum_{i=1}^{\ell_I-1}\tilde{u}_i^{p_I}\right)^{\frac{1-p_I}{p_I}} dv_I d\tilde{\boldsymbol{u}} d\boldsymbol{x}_{1:n-\ell_I} \\ &= \int_{f(\boldsymbol{x}_{1:n-\ell_I}, v_I)\leq R} v_I^{n_I-1} dv_I d\boldsymbol{x}_{1:n-\ell_I} \times \int_{\tilde{\boldsymbol{u}}\in\mathcal{V}_+^{\ell_I-1}} \left(1-\sum_{i=1}^{\ell_I-1}\tilde{u}_i^{p_I}\right)^{\frac{n_{I,\ell_I}-p_I}{p_I}} d\tilde{\boldsymbol{u}}.\end{aligned}$$

where $\mathcal{V}_+$ denotes the intersection of the positive quadrant and the L_{p_I}-norm unit ball. For solving the second integral we make the pointwise transformation $s_i = \tilde{u}_i^{p_I}$ and obtain

$$\begin{aligned}\int_{\tilde{\boldsymbol{u}}\in\mathcal{V}_+^{\ell_I-1}} \left(1-\sum_{i=1}^{\ell_I-1}\tilde{u}_i^{p_I}\right)^{\frac{n_{I,\ell_I}-p_I}{p_I}} d\tilde{\boldsymbol{u}} &= \frac{1}{p_I^{\ell_I-1}} \int_{\sum s_i\leq 1} \left(1-\sum_{i=1}^{\ell_I-1} s_i\right)^{\frac{n_{I,\ell_I}}{p_I}-1} \prod_{i=1}^{\ell_I-1} s_i^{\frac{1}{p_I}-1} d\boldsymbol{s}_{\ell_I-1} \\ &= \frac{1}{p_I^{\ell_I-1}} \prod_{k=1}^{\ell_I-1} B\left[\frac{\sum_{i=1}^k n_{I,k}}{p_I}, \frac{n_{I,k+1}}{p_I}\right] \\ &= \frac{1}{p_I^{\ell_I-1}} \prod_{k=1}^{\ell_I-1} B\left[\frac{k}{p_I}, \frac{1}{p_I}\right]\end{aligned}$$

by using the fact that the transformed integral has the form of an unnormalized Dirichlet distribution and, therefore, the value of the integral must equal its normalization constant.

Now, we solve the integral

$$\int_{f(\boldsymbol{x}_{1:n-\ell_I}, v_I)\leq R} v_I^{n_I-1} dv_I d\boldsymbol{x}_{1:n-\ell_I}. \tag{15}$$

We carry this out in exactly the same manner as we solved the previous integral. We need only to make sure that we only contract nodes that have only leaves as children (remember that radii of contracted nodes become leaves) and we need to find a formula describing how the factors $v_I^{n_I-1}$ propagate through the tree.

For the latter, we first state the formula and then prove it via induction. For notational convenience let $\mathcal{J}$ denote the set of multi-indices corresponding to the contracted leaves, $\boldsymbol{x}_{\hat{\mathcal{J}}}$ the remaining coefficients of $\boldsymbol{x}$ and $\boldsymbol{v}_{\mathcal{J}}$ the vector of leaves resulting from contraction. The integral which is left to solve after integrating over all $\tilde{\boldsymbol{u}}$ is given by (remember that n_J denotes real leaves, that is, the ones corresponding to coefficients of $\boldsymbol{x}$):

$$\int_{f(\boldsymbol{x}_{\hat{\mathcal{J}}}, \boldsymbol{v}_{\mathcal{J}})\leq R} \prod_{J\in\mathcal{J}} v_J^{n_J-1} d\boldsymbol{v}_{\mathcal{J}} d\boldsymbol{x}_{\hat{\mathcal{J}}}.$$

We already proved the first induction step by computing Equation (15). For computing the general induction step suppose I is an inner node whose children are leaves or contracted leaves. Let $\mathcal{J}'$ be the set of contracted leaves under I and $\mathcal{K} = \mathcal{J}\backslash\mathcal{J}'$. Transforming the children of I into radial

coordinates by Gupta and Song (1997) yields

$$\begin{aligned}
\int_{f(\boldsymbol{x}_{\widehat{\mathcal{J}}},\boldsymbol{v}_{\mathcal{J}})\le R}\prod_{J\in\mathcal{J}} v_J^{n_J-1}d\boldsymbol{v}_{\mathcal{J}}d\boldsymbol{x}_{\widehat{\mathcal{J}}} &= \int_{f(\boldsymbol{x}_{\widehat{\mathcal{J}}},\boldsymbol{v}_{\mathcal{J}})\le R}\left(\prod_{K\in\mathcal{K}} v_K^{n_K-1}\right)\cdot\left(\prod_{J'\in\mathcal{J}'} v_{J'}^{n_{J'}-1}\right)d\boldsymbol{v}_{\mathcal{J}}d\boldsymbol{x}_{\widehat{\mathcal{J}}}\\
&= \int_{f(\boldsymbol{x}_{\widehat{\mathcal{K}}},\boldsymbol{v}_{\mathcal{K}},v_I)\le R}\int_{\tilde{\boldsymbol{u}}_{\ell_I-1}\in\mathcal{V}_+^{\ell_I-1}}\left(\left(1-\sum_{i=1}^{\ell_I-1}\tilde{u}_i^{p_I}\right)^{\frac{1-p_I}{p_I}} v_I^{\ell_I-1}\right)\cdot\left(\prod_{K\in\mathcal{K}} v_K^{n_K-1}\right)\\
&\times\left(\left(v_I\left(1-\sum_{i=1}^{\ell_I-1}\tilde{u}_i^{p_I}\right)^{\frac{1}{p_I}}\right)^{n_{\ell_I}-1}\prod_{k=1}^{\ell_I-1}(v_I\tilde{u}_k)^{n_k-1}\right)d\boldsymbol{x}_{\widehat{\mathcal{K}}}d\boldsymbol{v}_{\mathcal{K}}dv_Id\tilde{\boldsymbol{u}}_{\ell_I-1}\\
&= \int_{f(\boldsymbol{x}_{\widehat{\mathcal{K}}},\boldsymbol{v}_{\mathcal{K}},v_I)\le R}\int_{\tilde{\boldsymbol{u}}_{\ell_I-1}\in\mathcal{V}_+^{\ell_I-1}}\left(\prod_{K\in\mathcal{K}} v_K^{n_K-1}\right)\\
&\times\left(v_I^{\ell_I-1+\sum_{i=1}^{\ell_I}(n_i-1)}\left(1-\sum_{i=1}^{\ell_I-1}\tilde{u}_i^{p_I}\right)^{\frac{n_{\ell_I}-p_I}{p_I}}\prod_{k=1}^{\ell_I-1}\tilde{u}_k^{n_k-1}\right)d\boldsymbol{x}_{\widehat{\mathcal{K}}}d\boldsymbol{v}_{\mathcal{K}}dv_Id\tilde{\boldsymbol{u}}_{\ell_I-1}\\
&= \int_{f(\boldsymbol{x}_{\widehat{\mathcal{K}}},\boldsymbol{v}_{\mathcal{K}},v_I)\le R}\left(\prod_{K\in\mathcal{K}} v_K^{n_K-1}\right)v_I^{n_I-1}d\boldsymbol{x}_{\widehat{\mathcal{K}}}d\boldsymbol{v}_{\mathcal{K}}dv_I\\
&\times\int_{\tilde{\boldsymbol{u}}_{\ell_I-1}\in\mathcal{V}_+^{\ell_I-1}}\left(1-\sum_{i=1}^{\ell_I-1}\tilde{u}_i^{p_I}\right)^{\frac{n_{\ell_I}-p_I}{p_I}}\prod_{k=1}^{\ell_I-1}\tilde{u}_k^{n_k-1}d\tilde{\boldsymbol{u}}_{\ell_I-1}.
\end{aligned}$$

Again, by transforming it into a Dirichlet distribution, the latter integral has the solution

$$\int_{\tilde{\boldsymbol{u}}_{\ell_I-1}\in\mathcal{V}_+^{\ell_I-1}}\left(1-\sum_{i=1}^{\ell_I-1}\tilde{u}_i^{p_I}\right)^{\frac{n_{\ell_I}-p_I}{p_I}}\prod_{k=1}^{\ell_I-1}\tilde{u}_k^{n_k-1}d\tilde{\boldsymbol{u}}_{\ell_I-1}=\prod_{k=1}^{\ell_I-1}B\left[\frac{\sum_{i=1}^{k}n_{I,k}}{p_I},\frac{n_{I,k+1}}{p_I}\right]$$

while the remaining former integral has the form

$$\int_{f(\boldsymbol{x}_{\widehat{\mathcal{K}}},\boldsymbol{v}_{\mathcal{K}},v_I)\le R}\left(\prod_{K\in\mathcal{K}} v_K^{n_K-1}\right)v_I^{n_I-1}d\boldsymbol{x}_{\widehat{\mathcal{K}}}d\boldsymbol{v}_{\mathcal{K}}dv_I=\int_{f(\boldsymbol{x}_{\widehat{\mathcal{J}}},\boldsymbol{v}_{\mathcal{J}})\le R}\prod_{J\in\mathcal{J}} v_J^{n_J-1}d\boldsymbol{v}_{\mathcal{J}}d\boldsymbol{x}_{\widehat{\mathcal{J}}}$$

as claimed.

By carrying out the integration up to the root node, the remaining integral becomes

$$\int_{v_\emptyset\le R} v_\emptyset^{n-1}dv_\emptyset=\int_0^R v_\emptyset^{n-1}dv_\emptyset=\frac{R^n}{n}.$$

Collecting the factors from integration over the $\tilde{\boldsymbol{u}}$ proves the Equations (5) and (7). Using $B[a,b]=\frac{\Gamma[a]\Gamma[b]}{\Gamma[a+b]}$ yields Equations (6) and (8). ■

Appendix C. Layer Marginals

Proof [Proposition 7]

$$\begin{aligned}\rho(\boldsymbol{x}) &= \frac{\phi(f(\boldsymbol{x}))}{\mathcal{S}_f(f(\boldsymbol{x}))} \\ &= \frac{\phi(f(\boldsymbol{x}_{1:n-\ell_I}, v_I, \tilde{\boldsymbol{u}}_{\ell_I-1}, \Delta_n))}{\mathcal{S}_f(f(\boldsymbol{x}))} \cdot v_I^{\ell_I-1} \left(1 - \sum_{i=1}^{\ell_I-1} |\tilde{u}_i|^{p_I}\right)^{\frac{1-p_I}{p_I}}\end{aligned}$$

where $\Delta_n = \operatorname{sign}(x_n)$. Note that f is invariant to the actual value of Δ_n. However, when integrating it out, it yields a factor of 2. Integrating out $\tilde{\boldsymbol{u}}_{\ell_I-1}$ and Δ_n now yields

$$\begin{aligned}\rho(\boldsymbol{x}_{1:n-\ell_I}, v_I) &= \frac{\phi(f(\boldsymbol{x}_{1:n-\ell_I}, v_I))}{\mathcal{S}_f(f(\boldsymbol{x}))} \cdot v_I^{\ell_I-1} \frac{2^{\ell_I}\Gamma^{\ell_I}\left[\frac{1}{p_I}\right]}{p_I^{\ell_I-1}\Gamma\left[\frac{\ell_I}{p_I}\right]} \\ &= \frac{\phi(f(\boldsymbol{x}_{1:n-\ell_I}, v_I))}{\mathcal{S}_f(f(\boldsymbol{x}_{1:n-\ell_I}, v_I))} \cdot v_I^{\ell_I-1}\end{aligned}$$

Now, we can go on and integrate out more subtrees. For that purpose, let $\boldsymbol{x}_{\hat{\mathcal{J}}}$ denote the remaining coefficients of $\boldsymbol{x}$, $\boldsymbol{v}_{\mathcal{J}}$ the vector of leaves resulting from the kind of contraction just shown for v_I, and $\mathcal{J}$ the set of multi-indices corresponding to the "new leaves", that is, node v_I after contraction. We obtain the following equation

$$\rho(\boldsymbol{x}_{\hat{\mathcal{J}}}, \boldsymbol{v}_{\mathcal{J}}) = \frac{\phi(f(\boldsymbol{x}_{\hat{\mathcal{J}}}, \boldsymbol{v}_{\mathcal{J}}))}{S_f(f(\boldsymbol{x}_{\hat{\mathcal{J}}}, \boldsymbol{v}_{\mathcal{J}}))} \prod_{J \in \mathcal{J}} v_J^{n_J-1}.$$

where n_J denotes the number of leaves in the subtree under the node J. The calculations for the proof are basically the same as the one for proposition (4). ■

Appendix D. Factorial L_p-Nested Distributions

Proof [Proposition 9] Since the single x_i are independent, $f_1(\boldsymbol{x}_1), ..., f_{\ell_\emptyset}(\boldsymbol{x}_{\ell_\emptyset})$ and, therefore, $v_1, ..., v_{\ell_\emptyset}$ must be independent as well ($\boldsymbol{x}_i$ are the elements of $\boldsymbol{x}$ in the subtree below the ith child of the root node). Using Corollary 8 we can write the density of $v_1, ..., v_{\ell_\emptyset}$ as (the function name g is unrelated to the usage of the function g above)

$$\rho(\boldsymbol{v}_{1:\ell_\emptyset}) = \prod_{i=1}^{\ell_\emptyset} h_i(v_i) = g(\|\boldsymbol{v}_{1:\ell_\emptyset}\|_{p_\emptyset}) \prod_{i=1}^{\ell_\emptyset} v_i^{n_i-1}$$

with

$$g(\|\boldsymbol{v}_{1:\ell_\emptyset}\|_{p_\emptyset}) = \frac{p_\emptyset^{\ell_\emptyset-1}\Gamma\left[\frac{n}{p_\emptyset}\right]}{\|\boldsymbol{v}_{1:\ell_\emptyset}\|_{p_\emptyset}^{n-1} 2^m \prod_{k=1}^{\ell_\emptyset} \Gamma\left[\frac{n_k}{p_\emptyset}\right]} \phi(\|\boldsymbol{v}_{1:\ell_\emptyset}\|_{p_\emptyset})$$

Since the integral over g is finite, it follows from Sinz et al. (2009a) that g has the form $g(\|\boldsymbol{v}_{1:\ell_\emptyset}\|_{p_\emptyset}) = \exp(a_\emptyset\|\boldsymbol{v}_{1:\ell_\emptyset}\|_{p_\emptyset}^{p_\emptyset} + b_\emptyset)$ for appropriate constants $a_\emptyset$ and $b_\emptyset$. Therefore, the marginals have the form

$$h_i(v_i) = \exp(a_\emptyset v_i^{p_\emptyset} + c_\emptyset) v_i^{n_i-1}. \tag{16}$$

On the other hand, the particular form of g implies that the radial density has the form $\phi(f(\boldsymbol{x})) \propto f(\boldsymbol{x})^{(n-1)} \exp(a_\emptyset f(\boldsymbol{x})^{p_\emptyset} + b_\emptyset)^{p_\emptyset}$. In particular, this implies that the root node's children $f_i(\boldsymbol{x}_i)$ $(i = 1,...,\ell_\emptyset)$ are independent and L_p-nested symmetric again. With the same argument as above, it follows that their children $\boldsymbol{v}_{i,1:\ell_i}$ follow the distribution $\rho(v_{i,1},...,v_{i,\ell_i}) = \exp(a_i\|\boldsymbol{v}_{i,1:\ell_i}\|_{p_i}^{p_i} + b_i)\prod_{j=1}^{\ell_i} v_{i,j}^{n_{i,j}-1}$. Transforming that distribution to L_p-spherically symmetric polar coordinates $v_i = \|\boldsymbol{v}_{i,1:\ell_i}\|_{p_i}$ and $\tilde{\boldsymbol{u}} = \boldsymbol{v}_{i,1:\ell_i-1}/\|\boldsymbol{v}_{i,1:\ell_i}\|_{p_i}$ as in Gupta and Song (1997), we obtain the form

$$\begin{aligned}
\rho(v_i, \tilde{\boldsymbol{u}}) &= \exp(a_i v_i^{p_i} + b_i) v_i^{\ell_i-1} \left(1 - \sum_{j=1}^{\ell_i-1} |\tilde{u}_j|^{p_i}\right)^{\frac{1-p_i}{p_i}} \left(v_i \left(1 - \sum_{j=1}^{\ell_i-1} |\tilde{u}_j|^{p_i}\right)^{\frac{1}{p_i}}\right)^{n_{i,\ell_i}-1} \prod_{j=1}^{\ell_i-1} (\tilde{u}_j v_i)^{n_{i,j}-1} \\
&= \exp(a_i v_i^{p_i} + b_i) v_i^{n_i-1} \left(1 - \sum_{j=1}^{\ell_i-1} |\tilde{u}_j|^{p_i}\right)^{\frac{n_{i,\ell_i}-p_i}{p_i}} \prod_{j=1}^{\ell_i-1} \tilde{u}_j^{n_{i,j}-1},
\end{aligned}$$

where the second equation follows the same calculations as in the proof of Proposition 4. After integrating out $\tilde{\boldsymbol{u}}$, assuming that the x_i are statistically independent, we obtain the density of v_i which is equal to (16) if and only if $p_i = p_\emptyset$. However, if $p_\emptyset$ and p_i are equal, the hierarchy of the L_p-nested function shrinks by one layer since p_i and $p_\emptyset$ cancel themselves. Repeated application of the above argument collapses the complete L_p-nested tree until one effectively obtains an L_p-spherical function. Since the only factorial L_p-spherically symmetric distribution is the p-generalized Normal (Sinz et al., 2009a) the claim follows. ■

Appendix E. Determinant of the Jacobian for NRF

Proof [Lemma 11] The proof is a generalization of the proof of Lyu and Simoncelli (2009). Due to the chain rule the Jacobian of the entire transformation is the multiplication of the Jacobians for each single step, that is, the rescaling of a subset of the dimensions for one single inner node. The Jacobian for the other dimensions is simply the identity matrix. Therefore, the determinant of the Jacobian for each single step is the determinant for the radial transformation on the respective dimensions. We show how to compute the determinant for a single step.

Assume that we reached a particular node I in Algorithm 2. The leaves, which have been rescaled by the preceding steps, are called $\boldsymbol{t}_I$. Let $\boldsymbol{\xi}_I = \frac{g_I(f_I(\boldsymbol{t}_I))}{f_I(\boldsymbol{t}_I))} \cdot \boldsymbol{t}_I$ with $g_I(r) = (\mathcal{F}_{\perp\!\!\!\perp}^{-1} \circ \mathcal{F}_s)(r)$. The general form of a single Jacobian is

$$\frac{\partial \boldsymbol{\xi}_I}{\partial \boldsymbol{t}_I} = \boldsymbol{t}_I \cdot \frac{\partial}{\partial \boldsymbol{t}_I}\left(\frac{g_I(f_I(\boldsymbol{t}_I))}{f_I(\boldsymbol{t}_I)}\right) + \frac{g_I(f_I(\boldsymbol{t}_I))}{f_I(\boldsymbol{t}_I)} I_{n_I},$$

where

$$\frac{\partial}{\partial \boldsymbol{t}_I}\left(\frac{g_I(f_I(\boldsymbol{t}_I))}{f_I(\boldsymbol{t}_I)}\right) = \left(\frac{g_I'(f_I(\boldsymbol{t}_I))}{f_I(\boldsymbol{t}_I)} - \frac{g_I(f_I(\boldsymbol{t}_I))}{f_I(\boldsymbol{t}_I)^2}\right) \frac{\partial}{\partial \boldsymbol{t}_I} f_I(\boldsymbol{t}_I).$$

Let y_i be a leave in the subtree under I and let $I, J_1, ..., J_k$ be the path of inner nodes from I to y_i, then

$$\frac{\partial}{\partial y_i} f_I(\boldsymbol{t}_I) = v_I^{1-p_I} v_{J_1}^{p_I - p_{J_1}} \cdot \ldots \cdot v_k^{p_{J_{k-1}} - p_{J_k}} |y_i|^{p_{J_k}-1} \cdot \operatorname{sgn} y_i.$$

If we denote $r = f_I(\boldsymbol{t}_I)$ and $\zeta_i = v_{J_1}^{p_I - p_{J_1}} \cdot \ldots \cdot v_k^{p_{J_{k-1}} - p_{J_k}} |y_i|^{p_{J_k}-1} \cdot \operatorname{sgn} y_i$ for the respective J_k, we obtain

$$\det\left(\boldsymbol{t}_I \cdot \frac{\partial}{\partial \boldsymbol{t}_I}\left(\frac{g_I(f_I(\boldsymbol{t}_I))}{f_I(\boldsymbol{t}_I)}\right) + \frac{g_I(f_I(\boldsymbol{t}_I))}{f_I(\boldsymbol{t}_I)} I_{n_I}\right) = \det\left(\left(g_I'(r) - \frac{g_I(r)}{r}\right) r^{-p_I} \boldsymbol{t}_I \cdot \boldsymbol{\zeta}^\top + \frac{g_I(r)}{r} I_{n_I}\right).$$

Now we can use Sylvester's determinant formula $\det(I_n + b\boldsymbol{t}_I\boldsymbol{\zeta}^\top) = \det(1 + b\boldsymbol{t}_I^\top\boldsymbol{\zeta}) = 1 + b\boldsymbol{t}_I^\top\boldsymbol{\zeta}$ or equivalently

$$\begin{aligned}
\det(aI_n + b\boldsymbol{t}_I\boldsymbol{\zeta}^\top) &= \det\left(a \cdot \left(I_n + \frac{b}{a}\boldsymbol{t}_I\boldsymbol{\zeta}^\top\right)\right) \\
&= a^n \det\left(I_n + \frac{b}{a}\boldsymbol{t}_I\boldsymbol{\zeta}^\top\right) \\
&= a^{n-1}(a + b\boldsymbol{t}_I^\top\boldsymbol{\zeta}),
\end{aligned}$$

as well as $\boldsymbol{t}_I^\top\boldsymbol{\zeta} = f_I(\boldsymbol{t}_I)^{p_I} = r^{p_I}$ to see that

$$\begin{aligned}
\det\left(\left(g_I'(r) - \frac{g_I(r)}{r}\right) r^{-p_I}\boldsymbol{t}_I \cdot \boldsymbol{\zeta}^\top + \frac{g_I(r)}{r} I_n\right) &= \frac{g_I(r)^{n-1}}{r^{n-1}} \det\left(\left(g_I'(r) - \frac{g_I(r)}{r}\right) r^{-p_I}\boldsymbol{t}_I^\top \cdot \boldsymbol{\zeta} + \frac{g_I(r)}{r}\right) \\
&= \frac{g_I(r)^{n-1}}{r^{n-1}} \det\left(g_I'(r) - \frac{g_I(r)}{r} + \frac{g_I(r)}{r}\right) \\
&= \frac{g_I(r)^{n-1}}{r^{n-1}} \frac{d}{dr} g_I(r).
\end{aligned}$$

$\frac{d}{dr} g_I(r)$ is readily computed via $\frac{d}{dr} g_I(r) = \frac{d}{dr}(\mathcal{F}_{\perp\perp}^{-1} \circ \mathcal{F}_s)(r) = \frac{\phi_s(r)}{\phi_{\perp\perp}(g_I(r))}$.

Multiplying the single determinants along with $\det W$ for the final step of the chain rule completes the proof. ■

Abstract

The topic of the paper is computer testing of (probabilistic) *conditional independence* (CI) implications by an algebraic method of structural imsets. The basic idea is to transform (sets of) CI statements into certain integral vectors and to verify by a computer the corresponding algebraic relation between the vectors, called the *independence implication*. We interpret the previous methods for computer testing of this implication from the point of view of polyhedral geometry. However, the main contribution of the paper is a new method, based on *linear programming* (LP). The new method overcomes the limitation of former methods to the number of involved variables. We recall/describe the theoretical basis for all four methods involved in our computational experiments, whose aim was to compare the efficiency of the algorithms. The experiments show that the LP method is clearly the fastest one. As an example of possible application of such algorithms we show that testing inclusion of Bayesian network structures or whether a CI statement is encoded in an acyclic directed graph can be done by the algebraic method.

Keywords: conditional independence inference, linear programming approach

1. Introduction

First, we explain the motivation and mention some previous work. Then we describe the aim and structure of the paper.

1.1 Motivation

Conditional independence (CI) is a highly important concept in statistics and artificial intelligence. Properties of probabilistic CI provide theoretical justification for the method of local computation

∗. Also at the University of Auckland, New Zealand.

(Cowel et al., 1999) which is at the core of probabilistic expert systems (Jensen, 2001), successfully applied in numerous areas. The importance of CI is given by its interpretation in terms of *relevance among symptoms* or variables in consideration (Pearl, 1988); that's why it is crucial in probabilistic reasoning. Traditional methods for describing (statistical models of) CI structures use graphs whose nodes correspond to variables in consideration; it leads to popular *graphical models* (Lauritzen, 1996).

Formal properties of probabilistic CI and the attempts to describe probabilistic *CI inference* in terms of mathematical logic have been traditional research topics since the late 1970's. Basic properties of CI, now known as the *semi-graphoid properties*, were accentuated in statistics by Dawid (1979). Pearl (1988) interpreted those properties, formulated in the form of simple implications between CI statements, as axioms for the relevance relation. Moreover, Pearl proposed to view graphs as "inference engines" devised for efficient representing and manipulating relevance relationships. His idea (see Pearl, 1988, page 14) was to use an *input list of CI statements* to construct a graph and then, by using a special graphical separation criterion, to read from the graph additional CI statements, implied by the input list through the axioms. The goal of such inference procedures is to enable one to determine, at any state of knowledge, what information is relevant to the task at hand and what can be ignored.

Pearl's intention led him to a conjecture that CI inference for discrete probabilistic distributions can be characterized by the semi-graphoid properties. The conjecture was refuted in Studený (1989); actually, it has been shown later that there is no finite system of properties of semi-graphoid type characterizing (discrete probabilistic) CI inference (Studený, 1992). Thus, the question of computer testing of CI inference became a topic of research interest.

In Studený (2005), the method of *structural imsets* has been proposed as a non-graphical algebraic device for describing probabilistic CI structures; its advantage over graphical approaches is that it allows one to describe any discrete probabilistic CI structure. The idea is to use, instead of graphs, certain special integral vectors (of high dimension), called *imsets*, as tools for describing CI structures and implementing the "inference engine" for CI implication. This is because the corresponding algebraic relation between structural imsets, called *independence implication*, gives a sufficient condition for (probabilistic) CI inference. The topic of this paper is computer testing of this implication. The intended use is

- computer testing of implications between CI statements, and
- checking equivalence of structural imsets by an algebraic method.

Another (indirect) source of motivation for this paper is learning *Bayesian network* (BN) structures by score and search methods (Neapolitan, 2004). The point is that every BN structure can be described uniquely by a simple algebraic representative, called the *standard imset*. It was shown in Studený (2005, Chapter 8) that every reasonable scoring function (for learning BN structures) can be viewed as an affine function of the standard imset. This observation opens the way to the application of efficient *linear programming* (LP) methods in this area (Studený, Vomlel, and Hemmecke, 2010). Nevertheless, if a graphical model of CI structure is described by an imset, a natural question arises: is there any criterion, a counterpart of the graphical separation criterion, which allows one to read from this algebraic representative all CI statements encoded in it? This question again leads to the task of (computer) testing independence implication.

1.2 Some Former Algorithms

Given structural imsets u and v (over a set of variables N), the intuitive meaning of the implication $u \rightharpoonup v$ ($\equiv$ u independence implies v) is that the CI structure induced by u contains the CI structure induced by v. In Studený (2005, § 6.2) two algebraic characterizations of the relation $u \rightharpoonup v$ were given. They established the theoretical basis for the first-generation algorithms for computer testing of $u \rightharpoonup v$. The limitation of these algorithms is that to implement them fully one needs some additional information obtainable as the result of computations, which were performed only for $|N| \leq 5$ (Studený, Bouckaert, and Kočka, 2000).

The theoretical aspects of their implementation were analyzed in Studený (2004), while their practical implementations were described in detail in Bouckaert and Studený (2007). Basically, there are two algorithms, which can be interpreted as mutually complementary procedures. One of them, based on so-called "direct" characterization of $u \rightharpoonup v$ (see Studený, 2005, § 6.2.1), is suitable to confirm the implication; that's why it was called the *verification algorithm* in Bouckaert and Studený (2007). The other algorithm, based on so-called "skeletal" characterization of $u \rightharpoonup v$ (see Studený, 2005, § 6.2.2), fits to disproving the implication; that's why it was named the *falsification algorithm*.

The main idea of Bouckaert and Studený (2007) was to combine both algorithms to get a more effective tool. Owing to the computations from Studený et al. (2000), the implemented versions of both these algorithms are guaranteed to give a decisive answer to any independence implication problem for $|N| \leq 5$. Nevertheless, the combined version has also been implemented for $|N| = 6$, although without a guaranteed response to each implication problem. Recently, the first-generation algorithms from Bouckaert and Studený (2007) have been applied (in a modified form) in connection with the lattice-theoretic approach to CI inference (Niepert, van Gucht, and Gyssens, 2008).

1.3 Aim of the Paper

In this paper, we bring a new view on the problem of testing CI inference. First, we interpret the previous methods from the point of view of polyhedral geometry. Second, this geometric interpretation and the *linear programming approach* lead to new methods and, consequently, to the second-generation algorithms for testing CI inference, which appear to be more efficient than the first-generation algorithms.

More specifically, the geometric view has recently helped to solve an open problem that was very closely related to the topic of CI inference (see Studený, 2005, Question 7). It was the question whether every structural imset is a *combinatorial imset*, that is, whether it can be written as the sum of elementary imsets (= imsets corresponding to elementary CI statements). The question has been answered negatively in Hemmecke et al. (2008), where an example of a structural imset over 5 variables was found that is not combinatorial.

This fact naturally leads to a more advanced question motivated by the topic of CI inference: what is the so-called *Hilbert basis* of the cone generated by standard imsets (cf., Studený, 2005, Theme 10). A recent achievement is that the Hilbert basis for $|N| = 5$ has been found as a result of computations by Bruns et al. (2010). This makes it possible to design two modifications of the verification algorithm for 5 variables. In fact, the CI inference problem is transformed to testing whether a given imset is combinatorial, respectively structural.

Another important idea brought by this paper is that every testing $u \rightharpoonup v$ task can be re-formulated as a special LP problem. Note that the LP approach was mentioned as a potential method for testing

this implication already in Studený (2004, § 5). However, in the present paper, we re-formulate this implication problem in a different way. The LP approach has the following advantages:

- it allows one to go far beyond the limit of 5 variables,
- the second-generation algorithms are much faster than the first-generation ones,
- the re-formulation makes it possible to apply highly effective software packages developed to solve LP problems.

The goal of this paper is to describe the idea of the new approach, the corresponding algorithms and the experiments, whose aim was to compare the new algorithms (with the old ones).

Moreover, to give an example of the possible use of the algorithms we prove a result related to learning Bayesian networks. We characterize the inclusion of BN structures in terms of their algebraic representatives, standard imsets. Given acyclic directed graphs G and H over N, we show that the BN structure induced by H is contained in the one induced by G iff the difference $u_G - u_H$ of their standard imsets is a combinatorial imset, which happens iff it is a structural imset. Thus, testing the inclusion can be transformed to testing combinatorial imsets (or structural ones). A consequence of this observation is an elegant algebraic procedure for reading CI statements represented in a standard imset u_G, a kind of counterpart of the graphical separation criterion. Since the standard imset u_G is quite simple we have reasons to conjecture that our procedure can be implemented with polynomial complexity with respect to $|N|$.

1.4 Structure of the Paper

Section 2 is devoted to the terminology for CI inference using structural imsets, while basic concepts from polyhedral geometry are recalled in Section 3. In Section 4, the methods we are using are explained and, in Section 5, the experiments we performed are described. In Conclusions we discuss the perspectives and formulate some open problems. Appendices contain some proofs, a table of types of the Hilbert basis elements for 5 variables, an illustrative example and a comment on possible interpretation of the LP method.

2. Concepts Concerning CI Inference

The symbol N will be used to denote a non-empty finite set of *variables* in consideration. Given disjoint sets of variables $A, B \subseteq N$, the juxtaposition AB will denote their union.

2.1 Conditional Independence

Let P be a discrete probability distribution over N specified by its density $p : \mathsf{X}_N \to [0,1]$, where $\mathsf{X}_N \equiv \prod_{i \in N} \mathsf{X}_i$ is the joint sample space, a product of non-empty finite individual sample spaces. Given $A \subseteq N$ and $x \in \mathsf{X}_N$, let x_A denote the respective marginal configuration of x and p_A the marginal density of p; by convention $p_\emptyset(-) = 1$. Given pairwise disjoint $A, B, C \subseteq N$, we say that A is *conditionally independent of B given C* with respect to P if

$$\forall x \in \mathsf{X}_N \quad p_{A \cup B \cup C}(x_{A \cup B \cup C}) \cdot p_C(x_C) = p_{A \cup C}(x_{A \cup C}) \cdot p_{B \cup C}(x_{B \cup C}) \,.$$

We write $A \perp\!\!\!\perp B\,|\,C\,[P]$ then and call it a *CI statement* with respect to P; if P is not material we just use the symbol $A \perp\!\!\!\perp B\,|\,C$. The *CI structure* induced by P consists of all CI statements valid with respect to P.

Now, let L be a set of CI statements, called an *input list*, and t a CI statement outside L. We say L *probabilistically implies* t if, for every discrete probability distribution P, whenever all statements in L are valid with respect to P then t is valid with respect to P, too. Classic examples of valid probabilistic CI implications are the *semi-graphoid properties* (Pearl, 1988):

Symmetry	$A \perp\!\!\!\perp B\,\|\,C$	$\Longrightarrow$	$B \perp\!\!\!\perp A\,\|\,C$,
Decomposition	$A \perp\!\!\!\perp BD\,\|\,C$	$\Longrightarrow$	$A \perp\!\!\!\perp D\,\|\,C$,
Weak union	$A \perp\!\!\!\perp BD\,\|\,C$	$\Longrightarrow$	$A \perp\!\!\!\perp B\,\|\,DC$,
Contraction	$A \perp\!\!\!\perp B\,\|\,DC$ & $A \perp\!\!\!\perp D\,\|\,C$	$\Longrightarrow$	$A \perp\!\!\!\perp BD\,\|\,C$.

A CI statement $A \perp\!\!\!\perp B\,|\,C$ is called *elementary* if both A and B are singletons and it is called *trivial* if either $A = \emptyset$ or $B = \emptyset$. Since trivial statements are always valid, it follows from the semi-graphoid properties that, for any discrete probability distribution P, the CI structure induced by P is uniquely determined by the list of elementary CI statements valid with respect to P.

2.2 Imsets

An *imset* over N is an integer-valued function on the power set of N, denoted by $\mathcal{P}(N)$ in the rest of the paper.[1] It can be viewed as a vector whose components, indexed by subsets of N, are integers. An easy example is the *zero imset*, denoted by 0; another simple example is the identifier δ_A of a subset $A \subseteq N$:

$$\delta_A(S) = \begin{cases} 1 & \text{if } S = A, \\ 0 & \text{if } S \subseteq N,\ S \neq A. \end{cases}$$

An imset associated with a CI statement $A \perp\!\!\!\perp B\,|\,C$ is then the combination

$$u_{\langle A,B|C\rangle} \equiv \delta_{ABC} + \delta_C - \delta_{AC} - \delta_{BC}\,.$$

The class of *elementary imsets* (over N), denoted by $\mathcal{E}(N)$, consists of imsets associated with elementary CI statements (over N).

A *combinatorial imset* is an imset u that can directly be decomposed into elementary imsets, that is,

$$u = \sum_{w \in \mathcal{E}(N)} k_w \cdot w \qquad \text{for some } k_w \in \mathbb{Z}_+\,.$$

We denote the class of combinatorial imsets over N by $\mathcal{C}(N)$.

An imset u over N will be called *structural* if there exists $n \in \mathbb{N}$ such that the multiple $n \cdot u$ is a combinatorial imset, that is,

$$n \cdot u = \sum_{w \in \mathcal{E}(N)} k_w \cdot w \quad \text{for some } n \in \mathbb{N},\ k_w \in \mathbb{Z}_+\,.$$

In other words, a structural imset is an imset which is a combination of elementary ones with non-negative rational coefficients. The class of structural imsets over N will be denoted by $\mathcal{S}(N)$; this

1. The word **imset** is an abbreviation for **i**nteger-valued **m**ulti**set**.

class of imsets is intended to describe CI structures. Clearly, $\mathcal{E}(N) \subseteq \mathcal{C}(N) \subseteq \mathcal{S}(N)$. One has $\mathcal{C}(N) = \mathcal{S}(N)$ for $|N| \leq 4$ (Studený, 1991), but $\mathcal{S}(N) \neq \mathcal{C}(N)$ for $|N| = 5$ (Hemmecke et al., 2008).

However, one can show (see Studený, 2005, Lemma 6.3) that there exists a smallest $n_* \in \mathbb{N}$, depending on $|N|$, such that $u \in \mathcal{S}(N) \Leftrightarrow n_* \cdot u \in \mathcal{C}(N)$ for every imset u over N. One has $n_* = 1$ for $|N| \leq 4$ (Studený, 1991) and one of the news brought by this paper is that $n_* = 2$ for $|N| = 5$ (see Proposition 6 in Appendix B). An open question is what is the exact value of n_* for every $|N|$ (cf., Studený, 2005, Theme 11).

2.3 Independence Implication

Let u, v be structural imsets over N. We say that u *independence implies* v and write $u \rightharpoonup v$ if there exists $k \in \mathbb{N}$ such that $k \cdot u - v$ is a structural imset:

$$u \rightharpoonup v \quad \text{iff} \quad \exists k \in \mathbb{N} \quad k \cdot u - v \in \mathcal{S}(N)\,. \tag{1}$$

Now, given $u \in \mathcal{S}(N)$ the corresponding CI structure $\mathcal{M}(u)$ consists of all CI statements $A \perp\!\!\!\perp B\,|\,C$ such that $u \rightharpoonup u_{\langle A,B|C\rangle}$. The importance of structural imsets follows from the fact that, for every discrete probability distribution P over N, there exists $u \in \mathcal{S}(N)$ such that the CI structure induced by P coincides with $\mathcal{M}(u)$ (use Studený, 2005, Theorem 5.2).

An equivalent characterization of independence implication is as follows. A real set function $m : \mathcal{P}(N) \to \mathbb{R}$ is called *supermodular* iff

$$m(C \cup D) + m(C \cap D) \geq m(C) + m(D) \qquad \text{for every } C, D \subseteq N.$$

Such a function can be viewed as a real vector whose components are indexed by subsets of N. The *scalar product* of m and an imset u over N is then

$$\langle m, u \rangle \equiv \sum_{S \subseteq N} m(S) \cdot u(S)\,.$$

The dual definition of independence implication is this (see Studený, 2005, Lemma 6.2): one has $u \rightharpoonup v$ iff, for every supermodular function m over N,

$$\langle m, u \rangle = 0 \quad \Longrightarrow \quad \langle m, v \rangle = 0\,. \tag{2}$$

The independence implication can be viewed as a sufficient condition for probabilistic CI implication. More specifically, given an input list L of CI statements, let us "translate" every statement s in L into the associated imset u_s and introduce a combinatorial imset $u_L \equiv \sum_{s \in L} u_s$. Then one has:

Proposition 1 Let L be an input list of CI statements and t another CI statement over N. If $u_L \rightharpoonup u_t$ then L probabilistically implies t.

The proof, based on observations from Studený (2005), is given in Appendix A. Note that the above-mentioned condition is a sufficient condition for the probabilistic CI implication, but not a necessary one. On the other hand, the analysis in the case of four variables suggests that it is quite good approximation of probabilistic implication. For $|N| = 4$, one has 22108 (formal) CI structures induced by structural imsets, while the actual number of (discrete) probabilistic CI structures is 18478 (Šimeček, 2007), and there are only about 20 types of probabilistic CI implications that are not derivable through Proposition 1.

The reader may be interested in whether there exists a limit for the factor k in (1). If we assume that the "input" u is a combinatorial imset and the "output" v an elementary one then such a limit exists. One can show (cf., Studený, 2005, Lemma 6.4) that the least $k_* \in \mathbb{N}$ exists such that

$$u \rightharpoonup v \quad \text{iff} \quad k_* \cdot u - v \in \mathcal{S}(N)\,.$$

It depends on $|N|$: $k_* = 1$ for $|N| \leq 4$ and $k_* = 7$ for $|N| = 5$ (Studený et al., 2000). It is an open question what is the exact value of k_* for $|N| \geq 6$ (cf., Studený, 2005, Theme 12).

2.4 Bayesian Network Translation

Bayesian networks (Pearl, 1988; Neapolitan, 2004) can be interpreted as graphical models of CI structures assigned to acyclic directed graphs. More specifically, given an acyclic directed graph G having N as the set of its nodes, the corresponding graphical separation criterion (for the definition see Lauritzen, 1996, § 3.2.2) defines the collection $I(G)$ of CI restrictions given by G. The corresponding statistical model then consists of probability distributions on X_N that are *Markovian with respect to* G, that is, satisfy those CI restrictions. Given two acyclic directed graphs G and H over N, we say they are *independence equivalent* if $I(G) = I(H)$; it essentially means they define the same statistical model.

Given an acyclic directed graph G over N, the *standard imset* for G, denoted by u_G, is given by the formula

$$u_G = \delta_N - \delta_\emptyset + \sum_{i \in N} \{\, \delta_{\mathrm{pa}_G(i)} - \delta_{\{i\} \cup \mathrm{pa}_G(i)} \,\}, \tag{3}$$

where $\mathrm{pa}_G(i) \equiv \{j \in N;\, j \to i \ \text{ in } G\}$ denotes the set of *parents* of a node i in G. Lemma 7.1 in Studený (2005) says that u_G is always a combinatorial imset and $\mathcal{M}(u_G) = I(G)$. Thus, the graphical separation criterion applied to G can be replaced by an algebraic criterion applied to u_G. Moreover, Corollary 7.1 in Studený (2005) adds that $u_G = u_H$ iff G and H are independence equivalent. That means, the standard imset is a unique representative of the equivalence class of graphs.

Note that u_G need not be the only combinatorial imset defining $I(G)$; it is the simplest such imset, a kind of "standard" representative. Using standard imsets we can easily characterize the inclusion for Bayesian networks:

Proposition 2 Let G and H be acyclic directed graphs over N. Then $I(H) \subseteq I(G)$ if and only if $u_G - u_H \in \mathcal{C}(N)$, which is also equivalent to $u_G - u_H \in \mathcal{S}(N)$.

Proof The equivalence $I(H) \subseteq I(G) \Leftrightarrow u_G - u_H \in \mathcal{C}(N)$ is proved in (Studený, 2005, Lemma 8.6). Clearly, $u_G - u_H \in \mathcal{C}(N)$ implies $u_G - u_H \in \mathcal{S}(N)$. Conversely, if $u_G - u_H \in \mathcal{S}(N)$ then, by (1), $u_G \rightharpoonup u_H$ and it makes no problem to show $\mathcal{M}(u_H) \subseteq \mathcal{M}(u_G)$. This means $I(H) \subseteq I(G)$. ■

We have some reasons to conjecture that testing whether a difference of two standard imsets is a combinatorial imset can be done with polynomial complexity in $|N|$; see Conclusions for the discussion. Moreover, let us emphasize that as far as we are aware of, there is no direct graphical characterization of independence inclusion; in our view, it is quite difficult task to describe this in graphical terms. Note that indirect transformational graphical description of independence inclusion by Chickering (2002) does not provide an algorithm for testing the inclusion for a given pair of

acyclic directed graphs G and H. Of course, a different situation is with testing independence equivalence, in which case a simple graphical characterization and algorithms are available.

Proposition 2 has the following consequence, which allows one to replace the graphical separation criterion by testing whether an imset is combinatorial.

Corollary 3 Given an acyclic directed graph G over N, the class $I(G)$ coincides with the collection of CI statements $A \perp\!\!\!\perp B \,|\, C$ such that $u_G - u_{\langle A,B|C\rangle} \in \mathcal{C}(N)$, respectively $u_G - u_{\langle A,B|C\rangle} \in \mathcal{S}(N)$.

Proof It is enough to construct, for every CI statements $A \perp\!\!\!\perp B \,|\, C$, an acyclic directed graph H such that $u_{\langle A,B|C\rangle} = u_H$. To this end, consider a total order of nodes in N in which C is followed A, B and $N \setminus ABC$, direct edges of the complete undirected graph over N according to this order and remove the arrows between A and B. ■

Of course, as mentioned above, there are elegant graphical separation criteria for testing whether a CI statement is represented in an acyclic directed graph. There are no doubts that these criteria can be implemented with polynomial complexity in $|N|$ (see Geiger, Verma, and Pearl, 1989) and that they are also appropriate for human users. However, our method proposed in Corollary 3 may appear to be suitable for computer testing, in particular in the situation when the Bayesian network structure is internally represented in a computer by the standard imset, as suggested in Studený, Vomlel, and Hemmecke (2010).

3. Basic Concepts from Polyhedral Geometry

Here we recall some well-known concepts and facts from the theory of convex polyhedra. Proofs can be found in textbooks on linear programming, for example Schrijver (1986).

Vectors are regarded as column vectors. Given two vectors $\mathbf{x}, \mathbf{y}$, their scalar product will be denoted either by $\langle \mathbf{x}, \mathbf{y} \rangle$ or, using matrix multiplication notation, by $\mathbf{x}^\intercal \mathbf{y}$, where $\mathbf{x}^\intercal$ is the transpose of $\mathbf{x}$. The inequality $\mathbf{x} \leq \mathbf{y}$ is meant in all components, and $\mathsf{0}$, respectively $\mathsf{1}$, is a vector all whose components are zeros, respectively ones.

3.1 Polyhedra, Polyhedral Cones and Farkas' Lemma

Systems of linear inequalities appear in many areas of mathematics. Let $\mathbf{A}$ be a $d \times n$-matrix and $\mathbf{b}$ a d-vector. The set of all solutions in $\mathbb{R}^n$ to the linear system $\mathbf{A}\mathbf{x} \leq \mathbf{b}$ is called a *polyhedron*. If the defining matrix $\mathbf{A}$ and the right-hand side vector $\mathbf{b}$ are rational, the polyhedron is said to be *rational*. Polyhedra defined via homogeneous inequalities $\mathbf{A}\mathbf{x} \leq \mathsf{0}$ are called *polyhedral cones*.

A non-trivial fundamental result in polyhedral geometry states that every polyhedral cone C can equivalently be introduced as the *conical hull* $\mathrm{cone}(\mathsf{V})$ of finitely many points $\mathsf{V} \subseteq \mathbb{R}^n$, that is, the set of all finite conical combinations $\sum_t \lambda_t \cdot \mathbf{v}_t$ (with $\lambda_t \geq 0$ for all t) of elements $\mathbf{v}_t \in \mathsf{V}$ (see Schrijver, 1986, Corollary 7.1a). If the polyhedral cone is *rational* then it is the conical hull of finitely many *rational* points. A classic algorithmic task is to change between the *inner description* $\mathsf{C} = \mathrm{cone}(\mathsf{V})$ and the *outer description* $\mathsf{C} = \{\mathbf{x} \in \mathbb{R}^n; \mathbf{A}\mathbf{x} \leq \mathsf{0}\}$, and back. Standard software packages that allow one to switch between both descriptions are for example 4TI2 (4ti2 team, 2008), CDD (Fukuda, 2008), or CONVEX (Franz, 2009).

In our studies below, it will be important to decide whether a given polyhedron P is empty or not. Clearly, a certificate for $\mathsf{P} = \{\mathbf{x} \in \mathbb{R}^n; \mathbf{A}\mathbf{x} \leq \mathbf{b}\} \neq \emptyset$ is any $\mathbf{v} \in \mathsf{P}$. Given $\mathbf{v} \in \mathbb{R}^n$, we can easily

check whether $\mathbf{A}\mathbf{v} \leq \mathbf{b}$ and thus, $\mathbf{v} \in \mathsf{P}$. However, is there also a simple certificate for the case that $\mathsf{P} = \emptyset$? Indeed, there is such a certificate (see Schrijver, 1986, Corollary 7.1e):

Lemma 4 (Farkas' lemma) *The system $\boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}$ is solvable iff every $\boldsymbol{u} \in \mathbb{R}^d$ with $\boldsymbol{A}^\intercal \boldsymbol{u} = 0$, $\boldsymbol{u} \geq 0$ satisfies $\boldsymbol{u}^\intercal \boldsymbol{b} \geq 0$.*

Thus, any $\mathbf{u} \in \mathbb{R}^d$ satisfying $\mathbf{A}^\intercal \mathbf{u} = 0$, $\mathbf{u} \geq 0$ and $\mathbf{u}^\intercal \mathbf{b} < 0$ gives a certificate that P is empty. Indeed, given $\mathbf{x} \in \mathsf{P}$, write $0 = 0^\intercal \mathbf{x} = (\mathbf{A}^\intercal \mathbf{u})^\intercal \mathbf{x} = (\mathbf{u}^\intercal \mathbf{A})\mathbf{x} = \mathbf{u}^\intercal (\mathbf{A}\mathbf{x}) \leq \mathbf{u}^\intercal \mathbf{b} < 0$ to get a contradiction.

To decide using a computer whether $\mathsf{P} \neq \emptyset$ or not, we can make use of well-developed tools from the theory of linear programming (see below, Section 3.4).

3.2 Dimension and Faces of a Polyhedron

The *dimension* $\dim(\mathsf{P})$ of a polyhedron $\mathsf{P} \subseteq \mathbb{R}^n$ is the dimension of its *affine hull* $\mathrm{aff}(\mathsf{P})$, which is the set of all finite affine combinations $\sum_t \lambda_t \cdot \mathbf{v}_t$ (with $\lambda_t \in \mathbb{R}$ for all t and $\sum_t \lambda_t = 1$) of elements $\mathbf{v}_t \in \mathsf{P}$. By convention, the dimension of the empty set is -1. A polyhedron is *full-dimensional* if $\dim(\mathsf{P}) = n$.

Given $\mathbf{v} \in \mathbb{R}^n$ and $\alpha \in \mathbb{R}$, we call the inequality $\langle \mathbf{v}, \mathbf{x} \rangle \leq \alpha$ *valid* for a polyhedron $\mathsf{P} \subseteq \mathbb{R}^n$ if it is satisfied for every $\mathbf{x} \in \mathsf{P}$. If the inequality $\langle \mathbf{v}, \mathbf{x} \rangle \leq \alpha$ is valid for the polyhedron P, we call the set $\mathsf{F} = \mathsf{P} \cap \{\mathbf{x} \in \mathbb{R}^n; \langle \mathbf{v}, \mathbf{x} \rangle = \alpha\}$ a *face* of P.

The sets $\emptyset$ and P are always faces of a polyhedron P, defined by the valid inequalities $\langle 0, \mathbf{x} \rangle \leq 1$ and $\langle 0, \mathbf{x} \rangle \leq 0$, respectively. Every polyhedron P has only finitely many faces and all of them are polyhedra, too (see Schrijver, 1986, § 8.3). They can be classified by their dimension. Faces of dimension 0 are points in $\mathbb{R}^n$, called *vertices*. Faces of dimension 1 are called *edges*: these are either line-segments, half-lines or lines. Faces of dimension $\dim(\mathsf{P}) - 1$ are called *facets*.

If a polyhedron is full-dimensional then facet-defining inequalities establish a unique (up to positive scalar factors) inclusion-minimal inequality system defining P (for details see Schrijver, 1986, § 8.4). Since every (proper) face F of P is the intersection of facets containing it, facets implicitly determine all faces.

A polyhedron $\mathsf{P} = \{\mathbf{x}; \mathbf{A}\mathbf{x} \leq \mathbf{b}\}$ is *pointed* if the only vector $\mathbf{y}$ with $\mathbf{A}\mathbf{y} = 0$ is the zero vector $\mathbf{y} = 0$ (see Schrijver, 1986, § 8.2). A non-empty pointed polyhedron has at least one vertex. A pointed polyhedral cone C has just one vertex 0, its edges are half-lines, called *extreme rays*. Non-zero representatives of the extreme rays of C then provide its inclusion-minimal inner description (Schrijver, 1986, § 8.8).

3.3 Hilbert Basis

A *lattice point* (in $\mathbb{R}^n$) is an integral vector $\mathbf{x} \in \mathbb{Z}^n$, that is, a vector whose components are integers. If C is a pointed rational polyhedral cone then each of its extreme rays contains a non-zero lattice point; this lattice point is unique if it is *normalized*, that is, if its components have no common integer divisor. Then one can show that every lattice point in C is a linear combination of these unique representatives (of extreme rays) with non-negative rational coefficients (Studený, 1993, Lemma 10). However, in general, not every lattice point in C can be obtained as such a combination of those representatives with non-negative *integral* coefficients. Therefore, the following concept is important.

By a *Hilbert basis* of a rational polyhedral cone C (see Schrijver, 1986, § 16.4) is meant a finite set $\mathsf{H} \subseteq \mathsf{C}$ of lattice points such that every lattice point in C is a non-negative integer linear combination of elements in H. A relevant result in polyhedral geometry (Schrijver, 1986, Theorem 16.4) says that every rational polyhedral cone possesses a Hilbert basis. If the cone is in addition pointed, there is a unique inclusion-minimal Hilbert basis. Clearly, any Hilbert basis of C has to include the above mentioned normalized representatives of extreme rays of C.

Again, it is a challenging algorithmic task to compute the minimal integral Hilbert basis of a given (pointed) rational polyhedral cone. However, there are a few software packages that allow to do so in some simpler cases, for example 4TI2 (4ti2 team, 2008) or NORMALIZ (Bruns, Ichim, and Söger, 2009).

3.4 LP Problems and the Simplex Method

A *linear programming* (LP) problem is the task to maximize/minimize a linear function $\mathbf{x} \mapsto \langle \mathbf{c}, \mathbf{x} \rangle$, where $\mathbf{c} \in \mathbb{R}^n$, over a polyhedron $\mathsf{P} = \{\mathbf{x} \in \mathbb{R}^n;\, \mathbf{A}\mathbf{x} \leq \mathbf{b}\}$. A classic tool to deal with this problem is the *simplex method*. Nevertheless, it is not the aim to describe here the details of this method; they can be found in textbooks on linear programming; for example Schrijver (1986, Chapter 11).

We just recall its main features to explain the geometric interpretation. The plain version of the simplex method (see Schrijver, 1986, § 11.1) assumes one has a vertex of (a pointed polyhedron) P as a starting iteration. The basic idea is to move from vertex to vertex along the edges of P until an optimal vertex is reached or an edge is found on which the linear function is unbounded. Each particular variant of the simplex method uses a special *pivoting operation* to choose the next iteration, which should have a better value of the linear objective function than the previous one.

However, it may be the case that one is not sure whether the polyhedron P is non-empty. Then the simplex method has two phases. In Phase I, one finds at least one $\mathbf{x} \in \mathsf{P}$, called a *feasible vertex solution*, provided that it exists, or one concludes that $\mathsf{P} = \emptyset$ otherwise. If a feasible solution is available, Phase II consists of finding an optimal solution as mentioned above. A standard trick to deal with Phase I is to re-formulate it as an auxiliary LP problem, in which a feasible vertex solution is known.

For example, consider the task to optimize a linear function over a special polyhedron of the form $\mathsf{Q} = \{\mathbf{x} \in \mathbb{R}^n;\, \mathbf{A}\mathbf{x} = \mathbf{b}, \mathbf{x} \geq \mathsf{0}\}$, where $\mathbf{A} \in \mathbb{R}^{d \times n}$ and $\mathbf{b} \in \mathbb{R}^d$, which task is, in fact, equivalent to the general case (see Schrijver, 1986, § 7.4). Moreover, one can assume without loss of generality $\mathbf{b} \geq \mathsf{0}$ here.[2] Then the auxiliary LP problem is as follows:

$$\min \{\, \langle \mathsf{1}, \mathbf{z} \rangle;\ (\mathbf{x}, \mathbf{z}) \in \mathbb{R}^{n+d},\ \mathbf{A}\mathbf{x} + \mathbf{z} = \mathbf{b},\ \mathbf{x} \geq \mathsf{0},\ \mathbf{z} \geq \mathsf{0} \,\}. \tag{4}$$

This LP problem has the vector $(\mathsf{0}, \mathbf{b})$ as a feasible vertex solution[3] and it has the property that its optimal value $\langle \mathsf{1}, \mathbf{z} \rangle$ is 0 iff $(\mathbf{x}, \mathbf{z}) = (\mathbf{x}, \mathsf{0})$ and $\mathbf{x} \in \mathsf{Q}$. Thus, testing whether the polyhedron Q is non-empty can be done in this way.

4. Methods

In this section, we describe a few methods that can be used to test CI inference. The task is as follows. An input list L of *elementary* CI statements and another elementary CI statement t over

2. Indeed, if the i-th component of $\mathbf{b}$ is negative, one can replace the i-th row of $\mathbf{A}$ and the i-th component of $\mathbf{b}$ with their multiples by -1.

3. Actually, $(\mathsf{0}, \mathbf{b})$ is a vertex of the region, defined by valid inequality $\langle \mathsf{1}, \mathbf{x} \rangle \geq 0$.

N are given and the goal is to decide whether $u_L \rightharpoonup u_t$ (cf., Proposition 1). We are going to give a computational comparison of these methods for $|N| = 5$ in Section 5.1 to see which of them is the fastest.

4.1 Method 1: using Skeletal Characterization

This is the first ever implemented method for testing independence implication (Studený et al., 2000, § 7.4). The motivation source for this method was the dual definition (2) of independence implication in terms of supermodular functions (see Section 2.3). The point is that, in (2), written in contrapositive form as [4]

$$\langle m, v\rangle > 0 \quad \Longrightarrow \quad \langle m, u\rangle > 0\,,$$

one can limit oneself to ℓ-standardized supermodular functions $m : \mathcal{P}(N) \to \mathbb{R}$, that is, to those that satisfy $m(S) = 0$ if $|S| \leq 1$. This is a pointed rational polyhedral cone. The class of normalized integral representatives of its extreme rays was called the *ℓ-skeleton* in Studený (2005) and denoted by $\mathcal{K}^{\diamond}_{\ell}(N)$.

The *skeletal characterization* of the implication $u \rightharpoonup v$, for $u, v \in \mathcal{S}(N)$, is as follows:

$$\forall\, m \in \mathcal{K}^{\diamond}_{\ell}(N) \qquad \langle m, v\rangle > 0 \quad \Longrightarrow \quad \langle m, u\rangle > 0 \tag{5}$$

(see Studený, 2005, Lemma 6.2). The ℓ-skeleton was computed for $|N| = 5$ (Studený et al., 2000): it consists of 117978 imsets, which break into 1319 permutational types.

Thus, the corresponding algorithm consists in checking whether each of the implications in (5) is valid or not. To disprove the implication $u \rightharpoonup v$ it is enough to find at least one $m \in \mathcal{K}^{\diamond}_{\ell}(N)$ violating (5); to confirm it one has to check that all of them are valid. By ordering the elements of the ℓ-skeleton such that those $m \in \mathcal{K}^{\diamond}_{\ell}(N)$ which are more likely to cause violation are tried earlier one can speed up the disproval (but not the confirmation). This suggested to sort elements of $\mathcal{K}^{\diamond}_{\ell}(N)$ on the basis of zeros in $\{\langle m, w\rangle\,;\; w \in \mathcal{E}(N)\}$ (for details see Bouckaert and Studený, 2007, § 3.1).

Example 1 *To illustrate the method consider a trivial example with $N = \{a, b, c\}$: take the input $L = \{\, a \perp\!\!\!\perp b \,|\, c\,,\; a \perp\!\!\!\perp c \,|\, \emptyset\,\}$ and $t : a \perp\!\!\!\perp b \,|\, \emptyset$. We already know by semi-graphoid properties that L probabilistically implies t (see Section 2.1). However, the aim of this example is to get this conclusion through Proposition 1 (see Section 2.3) using the skeletal characterization. We have*

$$u_L = u_{\langle a,b|c\rangle} + u_{\langle a,c|\emptyset\rangle} = \delta_{abc} - \delta_{bc} - \delta_a + \delta_\emptyset \quad \textit{and} \quad u_t = u_{\langle a,b|\emptyset\rangle} = \delta_{ab} - \delta_a - \delta_b + \delta_\emptyset\,.$$

In the case of 3 variables, the ℓ-skeleton has 5 elements, listed in rows of Table 1. The columns in the table correspond to structural imsets u_t and u_L, the items are corresponding scalar products. The condition (5) evidently holds for $v = u_t$ and $u = u_L$. Thus, $u_L \rightharpoonup u_t$.

The interpretation of the method from the point of view of polyhedral geometry is as follows. The independence implication can equivalently be defined in terms of (inclusion of) facets of the cone $\mathcal{R}(N) \equiv \mathrm{cone}\,(\mathcal{E}(N))$, the cone spanned by elementary imsets. Let F_u denote the face of $\mathcal{R}(N)$ generated by $u \in \mathcal{S}(N) \subseteq \mathcal{R}(N)$, that is, the least face of $\mathcal{R}(N)$ containing u ($\equiv$ the intersection of all faces of $\mathcal{R}(N)$ containing u). Then, for $u, v \in \mathcal{S}(N)$, one has $u \rightharpoonup v$ iff the face F_u contains v, which means, $F_v \subseteq F_u$ (see Studený, 2005, Remark 6.2).

4. Note that $\langle m, u\rangle \geq 0$ for any m supermodular and $u \in \mathcal{S}(N)$ (see Studený, 2005, Proposition 5.1).

	$u_t = \delta_{ab} - \delta_a - \delta_b + \delta_\emptyset$	$u_L = \delta_{abc} - \delta_{bc} - \delta_a + \delta_\emptyset$
$m_1 = \delta_{abc}$	0	1
$m_2 = \delta_{abc} + \delta_{ab}$	1	1
$m_3 = \delta_{abc} + \delta_{ac}$	0	1
$m_4 = \delta_{abc} + \delta_{bc}$	0	0
$m_5 = 2 \cdot \delta_{abc} + \delta_{ab} + \delta_{ac} + \delta_{bc}$	1	1

Table 1: Scalar products with elements of $\mathcal{K}^\diamond_\ell(N)$ for $N = \{a,b,c\}$.

The method is based on the computation of all facets of the cone $\mathcal{R}(N)$. These facets correspond to the extreme rays of the (dual) cone of ℓ-standardized supermodular functions. Thus, basically, one is checking whether every facet containing F_u also contains F_v. The problem with this approach is that it can hardly be extended beyond five variables because computing these facets seems to be computationally infeasible for $|N| \geq 6$.

4.2 Method 2: Racing Algorithms

The idea of the paper (Bouckaert and Studený, 2007) was to combine two algorithms for testing the independence implication $u \rightharpoonup v$. One of them, called the *verification algorithm*, was based on (1) and appeared to be suitable to confirm the implication provided it holds. However, it may spend a long time before it gives a response if the implication does not hold. The other algorithm, called the *falsification algorithm* and based on (2), was designed to disprove the implication if it does not hold. However, it is not able to confirm $u \rightharpoonup v$ provided it holds.

The combined procedure starts with two threads, the verification one and the falsification one. Once one thread finds its proof, it stops the other and returns its outcome. This approach makes it possible to go beyond 5 variables, but may not give a decisive response (in reasonable time) to some complex implication problems. On the other hand, empirical evidence from Bouckaert and Studený (2007) suggests that this method is, on average, faster than the method described in Section 4.1.

4.2.1 VERIFICATION: DECOMPOSING INTO ELEMENTARY IMSETS

Consider a combinatorial imset $u \in \mathcal{C}(N)$, an elementary imset $v \in \mathcal{E}(N)$ and the task to decide whether $u \rightharpoonup v$. That is, by (1), testing whether $k \cdot u - v$ is a structural imset for some $k \in \mathbb{N}$. Observe that (1) is equivalent to

$$\exists l \in \mathbb{N} \qquad l \cdot u - v \in \mathcal{C}(N)\,. \tag{6}$$

Indeed, $\mathcal{C}(N) \subseteq \mathcal{S}(N)$ gives (6)$\Rightarrow$(1). Now, (1) implies that $n \cdot (k \cdot u - v)$ is a combinatorial imset for some $k, n \in \mathbb{N}$ (see Section 2.2). As $(n-1) \cdot v \in \mathcal{C}(N)$, it gives $(n \cdot k) \cdot u - v \in \mathcal{C}(N)$. Moreover, it follows from concluding remarks in Sections 2.2 and 2.3 that $n_* \cdot k_*$ is an upper limit for l in (6). In general, we do not know what is the least such upper limit for l. Even in case $|N| = 5$, we only know it is a number between 7 (see Studený et al., 2000) and $14 = 2 \cdot 7 = n_* \cdot k_*$.

The characterization (6) allows one to transform testing independence implication to the task to decide whether a given candidate imset $y = l \cdot u - v$ is combinatorial. A combinatorial imset y may have many decompositions $y = \sum_{w \in \mathcal{E}(N)} k_w \cdot w$, $k_w \in \mathbb{Z}_+$ into elementary imsets. However, the number $\sum_{w \in \mathcal{E}(N)} k_w$ of summands, called the *degree* of y, is the same for any such decomposition (see Studený, 2005, § 4.2.2). Because there is a simple formula for the degree of the candidate imset

y, the search space, the tree of potential decompositions, is known. This space could be big, but it can be limited by introducing additional sanity checks, which allow one to cut off some blind alleys in the tree. Moreover, the search can be guided by suitable heuristics and this can speed up the resulting algorithm (for details see Bouckaert and Studený, 2007, § 3.2).

The decomposition itself is quite fast, but what can slow down the whole procedure is the factor l from (6), depending on a particular pair u, v. The point is that the degree of a candidate imset $y = l \cdot u - v$ grows (linearly) with l; consequently, the size of the corresponding tree of possible decompositions grows exponentially with l. Typically, if $u \rightharpoonup v$ holds then one often finds a decomposition of y with $l = 1$. However, for $|N| = 5$, there are a few cases when the decomposition of y exists for $1 < l \leq 7$ and not for $l - 1$ (for examples see Studený et al., 2000, § 4.3). In these cases and also when $u \rightharpoonup v$ does not hold one has to search through a huge space, which makes the method infeasible for efficient disproving implications.

Example 2 *Consider $N = \{a, b, c, d\}$, the input list*

$$L = \{\, a \perp\!\!\!\perp b \,|\, c\,,\ a \perp\!\!\!\perp c \,|\, d\,,\ a \perp\!\!\!\perp d \,|\, b\,,\ b \perp\!\!\!\perp c \,|\, ad \,\}\,, \tag{7}$$

and another CI statement $t : a \perp\!\!\!\perp c \,|\, b$. We are going to show $u_L \rightharpoonup u_t$ by the decomposition method. Actually, we show that (6) holds with $l = 1$. More specifically, we have

$$\begin{aligned} u_L &= u_{\langle a,b|c\rangle} + u_{\langle a,c|d\rangle} + u_{\langle a,d|b\rangle} + u_{\langle b,c|ad\rangle} \\ &= \delta_{abcd} + \delta_{abc} - \delta_{ab} - \delta_{ac} - \delta_{bc} - \delta_{bd} - \delta_{cd} + \delta_b + \delta_c + \delta_d\,, \end{aligned}$$

and, as $u_t = \delta_{abc} - \delta_{ab} - \delta_{bc} + \delta_b$, we know that

$$y \equiv 1 \cdot u_L - u_t = \delta_{abcd} - \delta_{ac} - \delta_{bd} - \delta_{cd} + \delta_c + \delta_d\,.$$

The task is to test whether y is a combinatorial imset. If this is the case then the degree of y must be 3, which means we search for a decomposition into elementary imsets with 3 summands. Clearly, at least one summand v has to satisfy $v(abcd) > 0$. There are 6 elementary imsets over $\{a, b, c, d\}$ with this property and two of them are excluded by sanity checks. For example, for $v' = u_{\langle c,d|ab\rangle}$ and $y' = y - v'$ one has $-1 = \sum_{\{c,d\} \subseteq T} y'(T) < 0$, which is impossible for a combinatorial imset in place of y'. However, if we subtract $\tilde{v} = u_{\langle a,b|cd\rangle}$ then

$$\tilde{y} = y - \tilde{v} = \delta_{acd} + \delta_{bcd} - \delta_{ac} - \delta_{bd} - 2 \cdot \delta_{cd} + \delta_c + \delta_d$$

is a good direction. Again, at least one of two summands v in the searched decomposition of $\tilde{y}$ must satisfy $v(acd) > 0$ and the choice $v = u_{\langle a,d|c\rangle}$ leads to the final decomposition

$$y = u_{\langle a,b|cd\rangle} + u_{\langle a,d|c\rangle} + u_{\langle b,c|d\rangle}\,.$$

Thus, the implication $u_L \rightharpoonup u_t$ has been confirmed by the decomposition method.

To explain the geometric interpretation (of the method) note that the cone $\mathcal{R}(N) = \mathrm{cone}\,(\mathcal{E}(N))$ is slightly special. The lattice points in this cone are just structural imsets.[5] Moreover, there exists

5. As mentioned in Section 3.3, lattice points in $\mathcal{R}(N)$ are just non-negative rational combinations of elementary imsets $\mathcal{E}(N)$, that is, structural imsets (see Section 2.2).

a hyperplane in $\mathbb{R}^{\mathcal{P}(N)}$ which intersects all extreme rays of $\mathcal{R}(N)$ just in its normalized integral representatives $\mathcal{E}(N)$ and these are the only lattice points in the intersection of this hyperplane with $\mathcal{R}(N)$. In particular, every structural imset belongs to one of parallel hyperplanes (to this basic one) and its "degree" says how far it is from the origin (= zero imset). Now, the condition (1) means that at least one multiple of u (by $k \in \mathbb{N}$) has the property that it remains a lattice point within the cone $\mathcal{R}(N)$ even if v is subtracted. The condition (6) is a minor modification of (1): it requires a multiple of u minus v is a sum of elementary imsets (with possible repetition). The algorithm, therefore, looks for the decomposition and the degree (of the candidate imset y) serves as the measure of its complexity.

4.2.2 FALSIFICATION: RANDOMLY GENERATING SUPERMODULAR FUNCTIONS

Falsification is based on the characterization (2). To disprove the implication $u \rightharpoonup v$ it is enough to find a supermodular function $m : \mathcal{P}(N) \to \mathbb{R}$ such that $\langle m, u \rangle = 0$ and $\langle m, v \rangle > 0$. Actually, one can limit oneself to ℓ-standardized integer-valued supermodular functions, that is, *supermodular imsets*. These imsets have a special form which allows one to generate them randomly. The idea is

- to randomly generate a collection of subsets of N,
- to assign them randomly selected positive integer values (and the zero values to remaining sets), and
- to modify the resulting function to make it a supermodular imset.

The details of this procedure can be found in Bouckaert and Studený (2007, § 3.3). The procedure allows one to disprove (= falsify) the implication $u \rightharpoonup v$ even for $|N| \geq 6$, but it is clearly not able to confirm it provided it holds. Therefore, it has to be combined with a verification procedure.

Example 3 *Consider $N = \{a,b,c,d\}$ and the same input list (7) as in Example 2, but a different CI statement $t : b \perp\!\!\!\perp c \,|\, a$ to be derived. If our random procedure generates the supermodular imset*

$$m = 2 \cdot \delta_{abcd} + \delta_{abc} + \delta_{abd} + \delta_{acd} + 2 \cdot \delta_{bcd} + \delta_{bc} + \delta_{bd} + \delta_{cd} \,,$$

then one can observe that $\langle m, u_L \rangle = 0$ while $\langle m, u_{\langle b,c|a \rangle} \rangle = 1$. In particular, by (2), the respective implication is not valid: $\neg(u_L \rightharpoonup u_{\langle b,c|a \rangle})$.

The geometric interpretation of the algorithm is similar to the interpretation of the method from Section 4.1. Supermodular functions correspond to faces of the cone $\mathcal{R}(N)$. Thus, the procedure consists in random generating faces of $\mathcal{R}(N)$ and the aim to find a face of $\mathcal{R}(N)$ which contains u but not v.

4.3 Method 3: Decomposition via Hilbert Basis

An alternative to testing whether an imset is combinatorial is testing whether it is structural. Since structural imsets coincide with the lattice points in the cone $\mathcal{R}(N) \equiv \text{cone}\,(\mathcal{E}(N))$, each of them can be written as a sum (with possible repetition) of the elements of the Hilbert basis $\mathcal{H}(N)$ of the cone $\mathcal{R}(N)$ (see Section 3.3). For $|N| \leq 4$ one has $\mathcal{H}(N) = \mathcal{E}(N)$ (Studený, 1991); however, the results from Hemmecke et al. (2008) imply that the set of elementary imsets does not constitute a Hilbert basis of $\mathcal{R}(N)$ for $|N| \geq 5$.

Computation of the Hilbert basis is a very hard task. Recently, the Hilbert basis of $\mathcal{R}(N)$ for $|N| = 5$ has been obtained as a result of sophisticated computations (Bruns et al., 2010). In Appendix B we provide a list of its representatives. Altogether, the obtained Hilbert basis of $\mathcal{R}(N)$ has 1300 elements, falling into 35 (permutation equivalence) types.

Thus, having the Hilbert basis of $\mathcal{R}(N)$ at hand, one can test the independence implication $u \rightharpoonup v$ for $u, v \in \mathcal{S}(N)$ through (1): the task is to find out whether there exists a decomposition of $y \equiv k \cdot u - v$ into Hilbert basis elements for some $k \in \mathbb{N}$. This is analogous to the decomposition approach from Section 4.2.1, where the set of elementary imsets $\mathcal{E}(N)$ was used instead of $\mathcal{H}(N)$.

Thus, the interpretation of this new method is the same, the difference is that we have now a wider class of leaves of the (potential) decomposition tree. On the other hand, the advantage of the Hilbert basis decomposition for $|N| = 5$ should be that, in some complex cases, a much simpler decomposition of y may exist that involves also the elements of $\mathcal{H}(N) \setminus \mathcal{E}(N)$ (simpler = with a less number of summands). We are also sure that the upper limit for the constant k is only $k_* = 7$. In particular, the depth of the tree of potential decompositions should be smaller, while the tree itself is expected to be wider.

4.4 Method 4: Linear Programming

The basic idea is to re-formulate (the definition of) independence implication in terms of the (pointed rational polyhedral) cone $\mathcal{R}(N) \equiv \mathrm{cone}(\mathcal{E}(N))$ spanned by elementary imsets. More specifically, given $u, v \in \mathcal{S}(N)$, the condition (1) can be expressed in this way:

$$u \rightharpoonup v \quad \text{iff} \quad \exists k \in [0, \infty) \quad k \cdot u - v \in \mathcal{R}(N)\,. \tag{8}$$

Indeed, since $\mathcal{S}(N) \subseteq \mathcal{R}(N)$ the implication (1)⇒(8) is evident. Conversely, provided (8) holds with k, it holds with any $k' \geq k$ because $\mathcal{R}(N)$ is a cone and $(k' - k) \cdot u \in \mathcal{R}(N)$. Therefore, there exists $k' \in \mathbb{N}$ with $k' \cdot u - v \in \mathcal{R}(N)$. As $k' \cdot u - v$ is an imset, it belongs to $\mathcal{S}(N)$, and (1) holds.

The geometric interpretation of the condition (8) is clear. It means that the ray (= half-line) with the origin in $-v$ and the direction given by u intersects the cone $\mathcal{R}(N)$. The point is that testing whether this happens can be viewed as an LP problem:

Lemma 5 Given $u, v \in \mathcal{S}(N)$ one has $u \rightharpoonup v$ iff the system of equalities

$$\sum_{w \in \mathcal{E}(N)} \lambda_w \cdot w(S) - k \cdot u(S) = -v(S) \qquad \text{for any } S \subseteq N\,, \tag{9}$$

has a non-negative solution in λ_w, $w \in \mathcal{E}(N)$ and k.

Proof The cone $\mathcal{R}(N)$ consists of conic combinations of representatives of its extreme rays, that is, of elementary imsets. Thus, (8) can be re-written as the requirement for the existence of $k \geq 0$ and $\lambda_w \geq 0$ with $k \cdot u - v = \sum_{w \in \mathcal{E}(N)} \lambda_w \cdot w$. This imset equality, specified for any $S \subseteq N$, yields (9). ■

Non-negative solutions to (9) form a polyhedron of the type $\mathsf{Q} = \{\mathbf{x}; \mathbf{A}\mathbf{x} = \mathbf{b}, \mathbf{x} \geq \mathsf{0}\}$, $\mathbf{A} \in \mathbb{R}^{d \times n}$, $\mathbf{b} \in \mathbb{R}^d$. Indeed, the rows of $\mathbf{A}$ correspond to subsets of N, while the columns to elementary imsets and the factor k. Thus, $d = |\mathcal{P}(N)| = 2^{|N|}$ and $n = |\mathcal{E}(N)| + 1 = \binom{|N|}{2} \cdot 2^{|N|-2} + 1$. As explained in Section 3.4, testing whether Q is non-empty is equivalent to solving the auxiliary LP problem (4) in

$(n+d)$-dimensional space. An illustrative example of the application of this LP method in the case $|N| = 3$ is given in Appendix C.

The advantage of this approach is that it is not limited to a particular number of variables as the previous ones. To get an impression of the implication problem complexity at hand, let us have a look at Table 2. Clearly, these (comparably small) linear programs should be solvable quickly in practice. We give computational evidence to this claim in Section 5.2. Another comment is that this LP method can be interpreted as a kind of decomposition procedure (analogous to the one from Section 4.2.1); see Appendix D for an explanation.

$\|N\|$	3	4	5	6	7	8	9	10
$n+d$	15	41	113	305	801	2049	5121	12545

Table 2: The dimensions of LP problems to be solved in order to decide $u \rightharpoonup v$.

Let us finally note that there are alternative ways to re-formulate testing of $u \rightharpoonup v$ as an LP problem. For example, consider the cone of ℓ-standardized supermodular functions. We know the outer description of this (pointed) cone:

$$\mathcal{K}_\ell(N) = \{m \in \mathbb{R}^{\mathcal{P}(N)};\ m(S) = 0 \text{ for } |S| \leq 1,\ \langle m, w\rangle \geq 0 \text{ for } w \in \mathcal{E}(N)\}.$$

Since, in (2), one can limit oneself to ℓ-standardized supermodular functions, $u \rightharpoonup v$ is equivalent to the requirement

$$\sup\{\langle m, v\rangle;\ m \in \mathcal{K}_\ell(N),\ \langle m, u\rangle = 0\} = 0. \tag{10}$$

This is an LP problem with a feasible region.[6] Thus, Phase II of the simplex method can be applied to solve it. Note that (10), mentioned in Studený (2004, § 5), can be viewed, after appropriate modifications, as the dual LP problem to (9) in the sense of the LP theory; however, we omit the details in this paper.

5. Experiments

In this section, we describe the results of our computational experiments. We performed two separate bunches of experiments. One of them was done in New Zealand and the aim was to compare various methods in case $|N| = 5$ (see Section 5.1).

As the result was that the LP method performs best in case $|N| = 5$, the aim of the other group of experiments (see Section 5.2), done in Germany, was to test the LP approach in case $|N| > 5$. These latter experiments were based on the commercial optimization software CPLEX (IBM Ilog team, 2009).

5.1 Comparison for Five Variables

Empirical evaluation of the methods can give insight in the practical behavior of the various methods. First, we considered the case of five variables, so that we can compare the new methods with techniques based on skeletal representations (see Section 4.1). The experimental set up from Bouckaert and Studený (2007) was used for the five-variable tests. In short, a thousand random input lists

6. Indeed, $m \equiv 0$ is a feasible solution to (10).

containing 3, up to 11 elementary CI statements were generated and, for each elementary CI statement outside the input list, it was verified whether it was implicated or not. So, the thousand 3-input cases result in verification of a thousand times the total number of elementary CI statements (80 for 5 variables) minus the 3 statements already given in the input list, that is, $1000 \times (80-3) = 77000$ inference problems. Table 3 lists the numbers of inference problems in its last column.

The algorithms considered were:

- Skeletal algorithm and sorted skeletal algorithm (see Section 4.1).
- Racing algorithms (see Section 4.2). There are situations where both the verification and the falsification algorithm perform poor, resulting in unacceptable running times. These outliers distort the typical behavior of the algorithm, so we put a cap on total calculation time and report the number of problems where a solution is not found within this deadline as the number of unresolved cases in Table 3.
- *Hilbert basis* (HB) decomposition algorithm (see Section 4.3). Initial experimentation showed that the HB approach is very good at verifying the implication. However, when a CI statement is not implied, it takes a long time to traverse the search space. So, the average time for the HB approach is expected to be very poor. Again, we capped the allowed time for the algorithm to run and when no solution was found within that time the problem was as marked unresolved.
- The observation that the HB algorithm performs well for implication but poor on falsification immediately gives rise to another algorithm where the HB decomposition algorithm and falsification algorithm are raced against each other. This algorithm is called the *Hilbert racer*. Like the racer algorithm, this algorithm was time constrained.
- Now we have two algorithms that appear to perform well for verification, it is natural to combine them with the falsifier and thus get a three horse race. This algorithm is called the *triple racer*, and it is time constrained as well.
- The last algorithm under consideration is the LP method described in Section 4.4.

Input size	Hilbert capped		Hilbert racer		racer		triple racer		Total
3	5127	(6.7%)	0	(0%)	0	(0%)	0	(0%)	77000
4	10098	(13.3%)	0	(0%)	0	(0%)	0	(0%)	76000

Table 3: Numbers of inference problems that were not resolved due to time-outs.

All algorithms were implemented in Java, run under Sun Java 1.6.0_12 in server mode on a Intel dual Core 3.00GHz CPU with 2GB memory, though memory is not an issue for any of the algorithms.

5.1.1 RESULTS AND DISCUSSION

Table 3 shows the number of unresolved cases when time was capped at 1 second per problem. Only the algorithms that did not resolve all problems are shown there. The numbers in brackets are percentages, the last column the total number of problems for a particular input size.

Given the total number of problems (around 70 thousand per input size) this restricted calculation took around 20 hours per input size. Clearly, the HB decomposition method when capped leaves a large proportion of implication problems unresolved, up to a quarter for the larger input sizes.

Combining the HB algorithm with the falsification algorithm reduces the number of unresolved problems to less than a third of a percent. Comparing the Hilbert racer with the original racer algorithm shows that more problems are resolved in the time available, so the HB decomposition algorithm appears to perform better at resolving problems. Finally, the triple racer, which combines both algorithms, performs in between the two algorithms in terms of number of unresolved problems. At first sight, one would expect the triple racer to perform at least as good as the Hilbert racer, however, since the test was run on a dual core processor instead of a machine with at least three cores, the various algorithms were too busy battling for processor access and lost time to make the deadline.

	User time

Table 4: Total computer times for the experiments in seconds.

Table 4 shows total computer time to resolve all problems for a given input size. This is a rough indication of the average computation time per implication problem, given that the number of problems per input size changes slightly (less than 10%) from the smallest 3-input problems to the largest 11-input problems. The user time is time the processor spent on the problem, while elapsed

time is actual clock time. Since the racing algorithms are multi-threaded, having multiple jobs run in parallel, elapsed time can be less than user time. For the single threaded algorithms, user time is approximately equal to elapsed time.

Comparing the unsorted and sorted skeleton approaches, it shows that ordering the skeletons can result in considerable time savings.

The HB decomposition algorithm is outperformed, clearly due to its bad performance in falsifications. There is a relatively large gap between user and elapsed time for the HB algorithm, which is due to the way the time-out is implemented. This causes the central processing unit to be idle for some of the time in some cases. Note the high correlation between user time and number of unresolved problems in Table 3. This indicates that the HB decomposition algorithm finds a resolution for a large number of problems very quickly, but performs very poor on a large number of others.

The racer algorithm performs very well on the smaller input sizes, but looses out on the larger ones. The Hilbert racer performs even better on the smaller problems, but again looses out on the larger input sizes. The triple racer is the best performer on the larger problems. However, taking in account the number of unresolved problems, the Hilbert racer is winning out, so it is to be expected that a slightly longer time-out period will bring the performance of the triple racer on the same level as the Hilbert racer.

The most remarkable result is the performance of the LP algorithm. Unlike all the other algorithms, it does not suffer from performance degradation with increasing input sizes. Furthermore, the calculation times are just a fraction of the times for the other algorithms. Considering that this is a straightforward Java implementation of the algorithm where only limited effort went in optimizing the code, its performance compared to the other algorithms is overwhelmingly better.

5.2 Experiments for Higher Number of Variables

To perform the experiments for $|N| > 5$, the only chance is to use the LP method presented in Section 4.4. The experiments were analogously defined as in Section 5.1. If L is an input list of elementary CI statements, then one single experiment comprises the testing of $|\mathcal{E}(N)|$ many independence implications $u_L \rightharpoonup u$ for all $u \in \mathcal{E}(N)$.[7] For $|N| = 4,5,6$ we have considered input lists L containing 3 up to 11 different elementary CI statements over N and performed 1000 such experiments for each combination of $|N|$ and $|L|$. Thus, we made 9000 experiments in total for $|N| = 4,5,6$. For $|N| = 7,8,9,10$ we only considered 1000 experiments with L containing 3 elementary CI statements.

The number of LP problems to be tested within a single experiment and the dimension of these problems depends on the number $|\mathcal{E}(N)| = \binom{|N|}{2} \cdot 2^{|N|-2}$ of elementary imsets and on the number $2^{|N|}$ of subsets of N (compare with Table 2 in Section 4.4). The running times are averaged over all 9000 experiments for $|N| = 4,5,6$ and over all 1000 experiments for $|N| = 7,8,9,10$, respectively. The running times include the set up of the LP method and the actual LP computation. The tests are done using the commercial optimization software CPLEX 9.100 (IBM Ilog team, 2009) on a Sun Fire V890 Ultra Sparc IV processor.

Table 5 illustrates the growth of the running times of the computations for $|N| = 4$ up to $|N| = 10$. Therein, we relate the running times with the growth of $|N|$ and the amount $|\mathcal{E}(N)|$ of LP problems to be tested for each experiment.

7. Contrary to Section 5.1, we involved "unnecessary" testing $u_L \rightharpoonup u_t$ for $t \in L$ in the experiments.

$\|N\|$	4	5	6	7	8	9	10
LPs/experiment	24	80	240	672	1792	4608	11520
time/experiment	4 ms	18 ms	115 ms	658 ms	5037 ms	150.38s	3862.10s

Table 5: The growth of computation times for $|N| = 4$ to $|N| = 10$.

5.2.1 RESULTS AND DISCUSSION

Table 5 illustrates a natural increase in the time needed for one experiment as $|N|$ increases. This is clear as both more LP problems have to be solved and they are of higher dimensions. For small values of $|N|$ the increase in time occurs mainly because of the LP set up, not because of the computation itself. For higher $|N|$ this proportion changes. But in spite of that, even for $|N| = 7$ all 1000 experiments together could be done within minutes. For $|N| = 10$ it took more than one month to perform all 1000 experiments; however, it took only about an hour for each single experiment. More specifically, on average, only about one third of a second was enough to test $u_L \rightharpoonup u_t$ for $|N| = 10$.

Just looking at the increase of the dimensions of the LP problems, it is reasonable to assume that one can test independence implication for up to $|N| = 15$ by directly plugging the corresponding LP problem into CPLEX. However, testing all $|\mathcal{E}(N)|$ inference problems for one experiment would be too expensive. Recall that one experiment already required about one hour of computation time for $|N| = 10$. To go even beyond $|N| = 15$ for testing $u_L \rightharpoonup u_t$, one can still exploit the known structure of the matrix $\mathbf{A}$ of the LP problem and employ column generation techniques in order to solve these much bigger LP problems to optimality. Of course, this approach has to be coded and tested for bigger $|N|$ to determine its efficiency.

6. Conclusions

Our computational experiments confirmed that the LP approach both overcomes the barriers of previous methods set by the number of variables in consideration and, moreover, it is also much faster. The new method also has the perspective to go even beyond the present limits, provided special LP techniques are used.

For small CI inference problems, involving a limited number of variables, one can enter data manually through web interfaces (based on LP method) available at

`http://www.cs.waikato.ac.nz/~remco/ci/.`

For bigger inference problems, in which the input is expected in the form of a file, one can use efficient commercial LP software instead.

We showed that the potential application of computer testing of CI inference is in the area of Bayesian networks (see Section 2.4). More specifically, by Proposition 2 (and Corollary 3), testing independence inclusion (and reading CI restrictions from an acyclic directed graph) can be transformed to the task whether a difference of two standard imsets is a combinatorial imset. Since, by (3), every standard imset has at most $2 \cdot |N|$ non-zero values, and, also, its degree is at most $|N| - 1$, we have good reasons to believe that the decomposition algorithm from Section 4.2.1 can be implemented with polynomial complexity in this special case. Actually, a relevant result (Studený and Vomlel, 2011, Lemma 3) implies that if the difference of two standard imsets is a combinatorial imset then it is a plain sum of elementary imsets (= a combination with coefficients $+1$). Thus, we

dare to conjecture that testing whether a difference of two standard imsets is a combinatorial imset can be done with polynomial complexity in $|N|$ using the procedure from Section 4.2.1.

After finishing this paper, we learned about a conference paper by Niepert (2009), which also comes with the idea of application of the LP approach to probabilistic CI inference. The reader may be interested in what is the relation of both approaches. The LP problem in Niepert (2009, Proposition 4.9) is, in fact, equivalent to our task (9) with fixed factor $k = 1$, if one uses a suitable one-to-one linear transformation to involved imsets u, v and w. This transformation has a nice property that the transformed LP problem $\tilde{\mathbf{A}}\mathbf{x} = \tilde{\mathbf{b}}, \mathbf{x} \geq \mathbf{0}$ has 0-1 matrix $\tilde{\mathbf{A}}$ and $\tilde{\mathbf{b}} \geq \mathbf{0}$. However, since the transformation is linear and one-to-one, it is essentially the same LP problem. Our approach is more general because it allows one to consider the multiplicative factor $k \geq 0$ in (9), which results in a wider class of derivable CI implications (cf., Section 4.2.1). We hope that the algorithms presented in our paper will find their application, perhaps in the research on stable CI statements (Niepert, van Gucht, and Gyssens, 2010).

The results presented in the paper lead to further open theoretical problems. The most difficult one is probably to find out what is the exact value of the constant n_* from Section 2.2 for $|N| > 5$, as it seems to be related to finding the Hilbert basis $\mathcal{H}(N)$, which is a hard task. Another group of open questions concerns the verification of the implication $u \rightharpoonup v$ for $u \in \mathcal{C}(N)$ and $v \in \mathcal{E}(N)$. We would like to know the minimal bounds for the factors in (1), (6) and (8). Perhaps computing these bounds can be formulated as a mixed (integer) LP problem. Finally, there are general questions of complexity, like whether it is NP hard to decide CI implications with respect to the input size.

Acknowledgments

The research of Milan Studený has been supported by the grants GAČR n. 201/08/0539 and MŠMT n. 1M0572. We thank the reviewers for their comments, which helped to improve the readability of the paper.

Appendix A. Proof of Proposition 1

Recall that L is an input list of CI statements over N and t another CI statement over N. The basic tool for our arguments is the *multiinformation function* $m_P : \mathcal{P}(N) \to \mathbb{R}$ ascribed to any discrete probability distribution P over N (for technical details see Studený, 2005, § 2.3.4). Corollary 2.2 in Studený (2005) says that m_P is always a supermodular function and, for every CI statement $s \equiv A \perp\!\!\!\perp B\,|\,C$ over N, one has

$$\langle m_P, u_s \rangle = 0 \quad \text{iff} \quad A \perp\!\!\!\perp B\,|\,C\,[P]\,. \tag{11}$$

Now, assuming $u_L \rightharpoonup u_t$, the equivalent characterization (2) of the independence implication implies that, for every discrete probability distribution P over N,

$$\text{whenever } \langle m_P, u_L \rangle = 0 \quad \text{then} \quad \langle m_P, u_t \rangle = 0\,. \tag{12}$$

Assuming P is a distribution such that every s in L is valid with respect to P, one has $\langle m_P, u_s \rangle = 0$ by (11), and, hence, by the linearity of the scalar product, $\langle m_P, u_L \rangle = \sum_{s \in L} \langle m_P, u_s \rangle = 0$. This implies, by (12), $\langle m_P, u_t \rangle = 0$, which means, by (11), that t is a valid CI statement with respect to P.

Appendix B. Hilbert Basis for Five Variables

As said in Section 4.3, the Hilbert basis $\mathcal{H}(N)$ for $|N| = 5$ falls into 35 types. Nevertheless, there is a further symmetry within it. Consider a bijective *reflection* map $\iota : \mathcal{P}(N) \to \mathcal{P}(N)$, given by $\iota(A) = N \setminus A$ for $A \subseteq N$. Observe that elementary imsets are closed under (the composition with) reflection. Thus, the cone $\mathcal{R}(N)$ and its Hilbert basis $\mathcal{H}(N)$ are closed under the reflection, too. In particular, some of 35 permutation equivalence classes are reflections of others. If the reflection is taken into consideration, the number of resulting equivalence classes in $\mathcal{H}(N)$ is lower, namely 21. Their representatives are given in Table 6.

Table 6: The 21 columns correspond to representatives of equivalence classes of $\mathcal{H}(N)$.

The consequence of finding $\mathcal{H}(N)$ for $|N| = 5$ in Bruns et al. (2010) is as follows:

Proposition 6 For $|N| = 5$, the least factor $n_* \in \mathbb{N}$ such that, for any imset u over N, it holds $u \in \mathcal{S}(N) \Leftrightarrow n_* \cdot u \in \mathcal{C}(N)$, is $n_* = 2$.

Proof Using a computer, we checked that every element $v \in \mathcal{H}(N)$ for $|N| = 5$ has the property that $2 \cdot v$ is a combinatorial imset. Now, given $u \in \mathcal{S}(N)$, consider its Hilbert basis decomposition $u = \sum_{v \in \mathcal{H}(N)} k_v \cdot v$, $k_v \in \mathbb{Z}_+$ and write $2 \cdot u = \sum_{v \in \mathcal{H}(N)} k_v \cdot (2 \cdot v)$, where each summand $2 \cdot v$ is known to be a combinatorial imset. In particular, $2 \cdot u \in \mathcal{C}(N)$. ■

Appendix C. Example of the Application of the LP Method

The aim of this text is to illustrate the LP method from Section 4.4 by an example. We assume that the reader is familiar with the details of the tableau form of the simplex method (see, for example, Schrijver, 1986, § 11.2). Consider the same situation as in Example 1:

$$N = \{a,b,c\}, \quad L = \{\, a \perp\!\!\!\perp b \,|\, c\,,\ a \perp\!\!\!\perp c \,|\, \emptyset\,\}, \ \text{ and } \ t : a \perp\!\!\!\perp b \,|\, \emptyset\,,$$

which leads to the task to verify/disprove $u \rightharpoonup v$ for

$$u = u_L = \delta_{abc} - \delta_{bc} - \delta_a + \delta_\emptyset \ \text{ and } \ v = u_t = \delta_{ab} - \delta_a - \delta_b + \delta_\emptyset\,.$$

By Lemma 5, this is equivalent to solving the system of equations (9). In this case, it means searching for a non-negative solution $\mathbf{x} \geq \mathtt{0}$ of $\mathbf{A}\mathbf{x} = \mathbf{b}$, where $\mathbf{A}$ is 8×7-matrix and $\mathbf{b}$ a column 8-vector specified as follows:

A	$\lambda_{\langle a,b\mid c\rangle}$	$\lambda_{\langle a,c\mid b\rangle}$	$\lambda_{\langle b,c\mid a\rangle}$	$\lambda_{\langle a,b\mid\emptyset\rangle}$	$\lambda_{\langle a,c\mid\emptyset\rangle}$	$\lambda_{\langle b,c\mid\emptyset\rangle}$	k	**b**
$\emptyset$	0	0	0	+1	+1	+1	−1	−1
a	0	0	+1	−1	−1	0	+1	+1
b	0	+1	0	−1	0	−1	0	+1
c	+1	0	0	0	−1	−1	0	0
ab	0	−1	−1	+1	0	0	0	−1
ac	−1	0	−1	0	+1	0	0	0
bc	−1	−1	0	0	0	+1	+1	0
abc	+1	+1	+1	0	0	0	−1	0

Here, the first 6 columns of $\mathbf{A}$ are elementary imsets, the 7-th column is $-u$, while $\mathbf{b}$ encodes $-v$. Moreover, the columns of $\mathbf{A}$ are named by the respective (searched) non-negative coefficients, while the rows are named by corresponding subsets of N. To get the standard case $\mathbf{b} \geq \mathtt{0}$ we modify it by multiplying by (-1) the rows of $\mathbf{A}$ and components of $\mathbf{b}$ corresponding $\emptyset$ and ab. The modified system is $\mathbf{A}'\mathbf{x} = \mathbf{b}'$, where one has:

$\mathbf{A}'$	$\lambda_{\langle a,b\mid c\rangle}$	$\lambda_{\langle a,c\mid b\rangle}$	$\lambda_{\langle b,c\mid a\rangle}$	$\lambda_{\langle a,b\mid\emptyset\rangle}$	$\lambda_{\langle a,c\mid\emptyset\rangle}$	$\lambda_{\langle b,c\mid\emptyset\rangle}$	k	$\mathbf{b}'$
$\emptyset$	0	0	0	−1	−1	−1	+1	+1
a	0	0	+1	−1	−1	0	+1	+1
b	0	+1	0	−1	0	−1	0	+1
c	+1	0	0	0	−1	−1	0	0
ab	0	+1	+1	−1	0	0	0	+1
ac	−1	0	−1	0	+1	0	0	0
bc	−1	−1	0	0	0	+1	+1	0
abc	+1	+1	+1	0	0	0	−1	0

We are going to solve the auxiliary LP problem (4) (see Section 3.4), to which purpose we create a tableau with additional identity submatrix and cost vector.

	$\lambda_{\langle a,b\mid c\rangle}$	$\lambda_{\langle a,c\mid b\rangle}$	$\lambda_{\langle b,c\mid a\rangle}$	$\lambda_{\langle a,b\mid\emptyset\rangle}$	$\lambda_{\langle a,c\mid\emptyset\rangle}$	$\lambda_{\langle b,c\mid\emptyset\rangle}$	k	$\emptyset$	a	b	c	ab	ac	bc	abc	
cost	0	0	0	0	0	0	0	+1	+1	+1	+1	+1	+1	+1	+1	0
$\emptyset$	0	0	0	−1	−1	−1	+1	+1	0	0	0	0	0	0	0	+1
a	0	0	+1	−1	−1	0	+1	0	+1	0	0	0	0	0	0	+1
b	0	+1	0	−1	0	−1	0	0	0	+1	0	0	0	0	0	+1
c	+1	0	0	0	−1	−1	0	0	0	0	+1	0	0	0	0	0
ab	0	+1	+1	−1	0	0	0	0	0	0	0	+1	0	0	0	+1
ac	−1	0	−1	0	+1	0	0	0	0	0	0	0	+1	0	0	0
bc	−1	−1	0	0	0	+1	+1	0	0	0	0	0	0	+1	0	0
abc	+1	+1	+1	0	0	0	−1	0	0	0	0	0	0	0	+1	0

The next step is to "recompute" the cost vector to get zeros above the identity submatrix. In our case it means subtracting the sum of 8 rows that correspond to sets from the previous version of the cost vector. In the additional row, bullets indicate the current basis and the corresponding (starting) vertex is given by the coefficients indicated.

	$\lambda_{\langle a,b\|c\rangle}$	$\lambda_{\langle a,c\|b\rangle}$	$\lambda_{\langle b,c\|a\rangle}$	$\lambda_{\langle a,b\|\emptyset\rangle}$	$\lambda_{\langle a,c\|\emptyset\rangle}$	$\lambda_{\langle b,c\|\emptyset\rangle}$	k	$\emptyset$	a	b	c	ab	ac	bc	abc	
cost	0	−2	−2	+4	+2	+2	−2	0	0	0	0	0	0	0	0	−4
$\emptyset$	0	0	0	−1	−1	−1	+1	+1	0	0	0	0	0	0	0	+1
a	0	0	+1	−1	−1	0	+1	0	+1	0	0	0	0	0	0	+1
b	0	+1	0	−1	0	−1	0	0	0	+1	0	0	0	0	0	+1
c	+1	0	0	0	−1	−1	0	0	0	0	+1	0	0	0	0	0
ab	0	+1	+1	−1	0	0	0	0	0	0	0	+1	0	0	0	+1
ac	−1	0	−1	0	+1	0	0	0	0	0	0	0	+1	0	0	0
bc	−1	−1	0	0	0	+1	+1	0	0	0	0	0	0	+1	0	0
abc	+1	+1	+1	0	0	0	−1	0	0	0	0	0	0	0	+1	0
								•	•	•	•	•	•	•	•	
vert								1	1	1	0	1	0	0	0	

Now, the proper algorithm can start. The strategy for the choice of the pivoting position from Schrijver (1986, § 11.2) leads to pivoting on $abc \times \lambda_{\langle a,c|b\rangle}$-cell, which results in the following tableau:

	$\lambda_{\langle a,b\|c\rangle}$	$\lambda_{\langle a,c\|b\rangle}$	$\lambda_{\langle b,c\|a\rangle}$	$\lambda_{\langle a,b\|\emptyset\rangle}$	$\lambda_{\langle a,c\|\emptyset\rangle}$	$\lambda_{\langle b,c\|\emptyset\rangle}$	k	$\emptyset$	a	b	c	ab	ac	bc	abc	
cost	+2	0	0	+4	+2	+2	−4	0	0	0	0	0	0	0	+2	−4
$\emptyset$	0	0	0	−1	−1	−1	+1	+1	0	0	0	0	0	0	0	+1
a	0	0	+1	−1	−1	0	+1	0	+1	0	0	0	0	0	0	+1
b	−1	0	−1	−1	0	−1	+1	0	0	+1	0	0	0	0	−1	+1
c	+1	0	0	0	−1	−1	0	0	0	0	+1	0	0	0	0	0
ab	−1	0	0	−1	0	0	+1	0	0	0	0	+1	0	0	−1	+1
ac	−1	0	−1	0	+1	0	0	0	0	0	0	0	+1	0	0	0
bc	0	0	+1	0	0	+1	0	0	0	0	0	0	0	+1	+1	0
abc	+1	+1	+1	0	0	0	−1	0	0	0	0	0	0	0	+1	0
		•						•	•	•	•	•	•	•		
vert		0						1	1	1	0	1	0	0		

The vertex and the value of the cost function in it remain unchanged, just the vertex is expresses using another basis. The same procedure now leads to the choice of another pivoting cell: the column corresponds to k and the row to $\emptyset$.

	$\lambda_{\langle a,b\|c\rangle}$	$\lambda_{\langle a,c\|b\rangle}$	$\lambda_{\langle b,c\|a\rangle}$	$\lambda_{\langle a,b\|\emptyset\rangle}$	$\lambda_{\langle a,c\|\emptyset\rangle}$	$\lambda_{\langle b,c\|\emptyset\rangle}$	k	$\emptyset$	a	b	c	ab	ac	bc	abc	
cost	+2	0	0	0	−2	−2	0	+4	0	0	0	0	0	0	+2	0
$\emptyset$	0	0	0	−1	−1	−1	+1	+1	0	0	0	0	0	0	0	+1
a	0	0	+1	0	0	+1	0	−1	+1	0	0	0	0	0	0	0
b	−1	0	−1	0	+1	0	0	−1	0	+1	0	0	0	0	−1	0
c	+1	0	0	0	−1	−1	0	0	0	0	+1	0	0	0	0	0
ab	−1	0	0	0	+1	+1	0	−1	0	0	0	+1	0	0	−1	0
ac	−1	0	−1	0	+1	0	0	0	0	0	0	0	+1	0	0	0
bc	0	0	+1	0	0	+1	0	0	0	0	0	0	0	+1	+1	0
abc	+1	+1	+1	−1	−1	−1	0	+1	0	0	0	0	0	0	+1	+1
		•					•		•	•	•	•	•	•		
vert		1					1		0	0	0	0	0	0		

Now, we observe the decrease in the value of the cost function: the corresponding vertex is given by $k = 1$, $\lambda_{\langle a,c|b\rangle} = 1$ and remaining coefficients vanishing. The value of the cost function is already 0, a further terminating iteration (= pivoting on $b \times \lambda_{\langle a,c|\emptyset\rangle}$-cell) does not change the vertex and, hence, the value of the cost function in it. Thus, we have successfully found a non-negative solution to (9). In particular, we confirmed $u_L \rightharpoonup u_t$ by the LP method.

Appendix D. Decomposition Interpretation of the LP Method

In spite of the different formulations, the procedure from Section 4.2.1 and the LP approach from Section 4.4 have common points. Given $u \in \mathcal{C}(N)$ and $v \in \mathcal{E}(N)$, both methods try to find a decomposition of $k \cdot u - v$ into elementary imsets. A formal difference is that k and the searched coefficients are integers in Section 4.2.1 but reals in Section 4.4. We try now to explain the analogy to the reader familiar with the details of the simplex method.

To see the analogy let us assume that k is a fixed natural number, as in Section 4.2.1. For example, let k be the upper limit for the factor l in (6). This ensures that $k \cdot u - v \in \mathcal{C}(N)$ iff $u \rightharpoonup v$. Put $b(S) = k \cdot u(S) - v(S)$ for $S \subseteq N$ and search for a non-negative solution in λ_w, $w \in \mathcal{E}(N)$ to the system

$$\sum_{w \in \mathcal{E}(N)} \lambda_w \cdot w(S) = b(S) \qquad \text{for any } S \subseteq N.$$

The set of such solutions is a polyhedron $\hat{\mathsf{Q}} = \{\mathbf{x} \in \mathbb{R}^n; \mathbf{A}\mathbf{x} = \mathbf{b}, \mathbf{x} \geq \mathtt{0}\}$, with $\mathbf{A} \in \mathbb{R}^{d \times n}$ and $\mathbf{b} \in \mathbb{R}^d$. Here, the rows of $\mathbf{A}$ correspond to subsets of N ($d = |\mathcal{P}(N)|$), the columns to elementary imsets ($n = |\mathcal{E}(N)|$) and $\mathbf{b}$ has $b(S)$, $S \subseteq N$ as components. The only difference from the situation in Section 4.4 is that we have one column less.

As mentioned in Section 3.4, $\mathbf{b}$ (and $\mathbf{A}$) can be modified so that it has non-negative integers as components and entries in $\mathbf{A}$ remain in $\{-1, 0, 1\}$. The simplex method takes $(\mathtt{0}, \mathbf{b}) \equiv (\mathbf{x}_0, \mathbf{z}_0)$ as its starting iteration and generates a sequence $(\mathbf{x}_0, \mathbf{z}_0), \ldots, (\mathbf{x}_m, \mathbf{z}_m)$, $m \geq 0$ of points in the feasible region of (4). The final iteration $(\mathbf{x}_m, \mathbf{z}_m)$ then minimizes the function $(\mathbf{x}, \mathbf{z}) \mapsto \langle \mathtt{1}, \mathbf{z} \rangle$ over that region. As explained in Section 3.4, $\hat{\mathsf{Q}} \neq \emptyset$ iff $\mathbf{z}_m = \mathtt{0}$.

Now, the move from $(\mathtt{0}, \mathbf{b}) \equiv (\mathbf{x}_0, \mathbf{z}_0)$ to $(\mathbf{x}_1, \mathbf{z}_1)$ means the following. One finds $w \in \mathcal{E}(N)$, corresponding to a (column) component x_w, and a set $S' \subseteq N$, corresponding to a component $z_{S'}$, such that $b(S') - \lambda_w \cdot w(S') = 0$ with $\lambda_w \geq 0$. The components of $\mathbf{z}_1$ are then $b(S) - \lambda_w \cdot w(S)$ for $S \subseteq N$. Since $\mathbf{b} = \mathbf{z}_0$ has integral components, $\lambda_w \in \mathbb{Z}^+$. In other words, the first step of the simplex method, the move from $\mathbf{z}_0$ to $\mathbf{z}_1$, means subtracting a non-negative integral multiple of an elementary imset w from $\mathbf{b} = \mathbf{z}_0$ so that the result remains a non-negative vector.

Although further steps already cannot be interpreted as elementary imset subtraction, the following still holds. If $\hat{\mathsf{Q}} \neq \emptyset$, the simplex method finds iteratively the decomposition of $\mathbf{b}$ into elementary imsets with non-negative coefficients. Moreover, in every iteration, one set (= a component of $\mathbf{z}$) is "vanished". This is analogous to the procedure from Section 4.2.1, the difference is that the heuristic for finding the next set S' to be "vanished" is given by the pivoting operation.

Abstract

This paper presents a statistical model for expressing preferences through rankings, when the number of alternatives (items to rank) is large. A human ranker will then typically rank only the most preferred items, and may not even examine the whole set of items, or know how many they are. Similarly, a user presented with the ranked output of a search engine, will only consider the highest ranked items. We model such situations by introducing a stagewise ranking model that operates with finite ordered lists called top-t orderings over an infinite space of items. We give algorithms to estimate this model from data, and demonstrate that it has sufficient statistics, being thus an exponential family model with continuous and discrete parameters. We describe its conjugate prior and other statistical properties. Then, we extend the estimation problem to multimodal data by introducing an *Exponential-Blurring-Mean-Shift* nonparametric clustering algorithm. The experiments highlight the properties of our model and demonstrate that infinite models over permutations can be simple, elegant and practical.

Keywords: permutations, partial orderings, Mallows model, distance based ranking model, exponential family, non-parametric clustering, branch-and-bound

1. Introduction

The stagewise ranking model of Fligner and Verducci (1986), also known as *generalized Mallows (GM)*, has been recognized as particularly appropriate for modeling the human process of ranking. This model assigns a permutation π over n items a probability that decays exponentially with its distance to a *central permutation* σ. Here we study this class of models in the limit $n \to \infty$, with the assumption that out of the infinitely many items ordered, one only observes those occupying the first t ranks.

Ordering an infinite number of items is common in retrieval tasks: search engines, programs that match a face, or a fingerprint, or a biological sequence against a database, all output the first t items in a ordering over virtually infinitely many objects. We shall call this output a *top-t* ordering. Unlike machines, people can only reliably rank a small number of items. The GM model has been successfully used to model human ranking decisions. We can view the difference between the standard GM model and the *Infinite GM model* that we introduce here as the difference between an election where each voter returns an ordering of a small number of preselected candidates (nominees) and a "grassroots" election process, where everyone can nominate and order their own favourites from a virtually unlimited population. For instance, the difference between "Order the following issues by how much you care about them" vs. "List in order the issues that you care most about" illustrates

the difference between the standard and the Infinite GM models. By these examples, we argue that the Infinite GM corresponds to realistic scenarios. An even more realistic scenario, that we will not tackle for now, is one where a voter (ranker) does not have access to the whole population of items (e.g., a search engine only orders a subset of the web, or a reviewer only evaluates a subset of the submissions to a conference).

After defining the infinite GM model, we show that it has sufficient statistics and give algorithms for estimating its parameters from data in the Maximum Likelihood (ML) framework. To be noted that our model will have an infinite number of parameters, of which only a finite number will be constrained by the data from any finite sample.

Then, we consider the non-parametric clustering of top-t ranking data. Non-parametric clustering is motivated by the fact that in many real applications the number of clusters is not known and outliers are possible. Outliers are known to throw off estimation in an exponential model, unless the tails are very heavy. We introduce an adapted version of the well known Gaussian Blurring Mean-Shift algorithm (Carreira-Perpiñán, 2006) (GBMS) that we call exponential blurring Mean Shift (EBMS).

2. The Infinite Generalized Mallows Model

In this section, we give definitions of key terms used in the article and introduce the *Infinite Generalized Mallows* (IGM) model.

2.1 Permutations, Infinite Permutations and top-t Orderings

A permutation σ is a function from a set of *items* $\{i_1, i_2, \ldots i_n\}$ to the set of *ranks* $1:n$. W.l.o.g. the set of items can be considered to be the set $1:n$. Therefore $\sigma(i)$ denotes the *rank* of item i and $\sigma^{-1}(j)$ denotes the item at rank j in σ.

There are many other ways to represent permutations, of which we will use three, the *ranked list*, the *matrix* and the *inversion table* representation; all three will be defined shortly.

In this paper, we consider permutations over a countable set of items, assumed for convenience to be the the set of positive natural numbers $\mathbb{P} = \{1, 2, \ldots, i \ldots\}$. It is easy to see that the notations $\sigma(i), \sigma^{-1}(j)$ extend immediately to countable items. This will be the case with the other definitions; hence, from now on, we will always consider that the set of items is $\mathbb{P}$.

Any permutation σ can be represented by the (infinite) *ranked list* $(\sigma^{-1}(1)|\sigma^{-1}(2)|\ldots|\sigma^{-1}(j)|\ldots)$. For example, let $\sigma = (2|3|1|5|6|4|\ldots|3n-1|3n|3n-2|\ldots)$. Then $\sigma(1) = 3$ means that item 1 has rank 3 in this permutation; $\sigma(2) = 1$ means that item 2 has rank 1, etc. Conversely, $\sigma^{-1}(1) = 2$ and $\sigma^{-1}(3j) = 3j-2$ mean that the first in the list representation of σ is item 2, and that at rank $3j$ is to be found item $3j-2$, respectively. Often we will call the list representation of a permutation an *ordering*.

A top-t ordering π is the prefix $(\pi^{-1}(1)|\pi^{-1}(2)|\ldots|\pi^{-1}(t))$ of some infinite ordering. For instance, the top-3 ordering of the above σ is $(2|3|1)$.

A top-t ordering can be seen as defining a set consisting of those infinite orderings which start with the prefix π. If we denote by $\mathcal{S}_{\mathbb{P}}$ the set of all permutations over $\mathbb{P}$ and by $\mathcal{S}_{\mathbb{P}-t} = \{\sigma \in \mathcal{S}_{\mathbb{P}} \,|\, \sigma(i) = i, \text{for} \, i = 1:t\}$ the subgroup of all permutations that leave the top-t ranks unchanged, then a top-t ordering π corresponds to a unique element of the right coset $\mathcal{S}_{\mathbb{P}}/\mathcal{S}_{\mathbb{P}-t}$.

We will use Greek letters like π and σ for both full permutations and for top-t orderings to keep the notation light. But we will distinguish almost always between "central permutations"

ideal infinite objects denoted by σ, and observed orderings, denoted by π, which by virtue of being observed, are always top-t , that is, truncated. Hence, unless otherwise stated, π will denote a top-t ordering, while σ will denote an infinite permutation.

2.2 The Permutation Matrix Representation and the Inversion Table

Now we introduce the two other ways use to represent permutations and top-t orderings.

For any σ, the *permutation matrix* Σ corresponding to σ has $\Sigma_{ij} = 1$ iff $\sigma(i) = j$ and $\Sigma_{ij} = 0$ otherwise. If σ is an infinite permutation, Σ will be an infinite matrix with exactly one 1 in every row and column. For two permutations σ, σ' over $\mathbb{P}$, the matrix product $\Sigma\Sigma'$ corresponds to the function composition $\sigma' \circ \sigma$.

The matrix Π of a top-t ordering π is a truncation of some infinite permutation matrix Σ. It has t columns, each with a single 1 in $\pi^{-1}(j)$, for $j = 1:t$.

For example, if $\sigma = (2|3|1|7|4|\ldots)$ and $\pi = (2|3|1)$ is its top-3 ordering, then

$$\Sigma = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 & \ldots \\ 1 & 0 & 0 & 0 & 0 & \ldots \\ 0 & 1 & 0 & 0 & 0 & \ldots \\ 0 & 0 & 0 & 0 & 1 & \ldots \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \end{bmatrix} \quad \text{and} \quad \Pi = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ \ldots & \ldots & \ldots \end{bmatrix}. \tag{1}$$

For a permutation σ and a top-t ordering π, the matrix $\Sigma^T\Pi$ corresponds to the list of ranks in σ of the items in π. In this context, one can consider σ as a one-to-one relabeling of the set $\mathbb{P}$.

The *inversion table* of a permutation σ, with respect to the identity permutation id is an infinite sequence of non-negative integers $(s_1, s_2, \ldots)$ which are best defined algorithmically and recursively. We consider the ranked list $(1|2|3|\ldots)$. In it, we find $\sigma^{-1}(1)$ the first item of σ, and count how many positions past the head of the list it lies. This is s_1, and it always equals $\sigma^{-1}(1) - 1$. Then we delete the entry $\sigma^{-1}(1)$ from the list, and look up $\sigma^{-1}(2)$; s_2 is the number of positions past the head of this list where we find $\sigma^{-1}(2)$. We then delete $\sigma^{-1}(2)$ as well and proceed to find $\sigma^{-1}(3)$, which will give us s_3, etc. By induction, it follows that an infinite permutation can be represented uniquely by the list $(s_1, s_2, \ldots)$. Hence $s_j \in \{0, 1, 2, \ldots\}$, and, denoting by $1_{[p]}$ the function which is 1 if the predicate p is true and is 0 otherwise, we have

$$s_j(\sigma) \;=\; \sigma^{-1}(j) - 1 - \sum_{j'<j} 1_{[\sigma^{-1}(j') < \sigma^{-1}(j)]}.$$

It is also easy to see that, if π is a top-t ordering, it can be uniquely represented by an inversion table of the form $(s_1, \ldots s_t)$. If π is the top-t ordering of an infinite permutation σ, then the inversion table of π is the t-prefix of the inversion table of σ. This property makes the inversion table particularly convenient for our purposes.

For example, if $\sigma = (2|3|1|7|4|\ldots)$ and $\pi = (2|3|1)$, then $s_1(\sigma) = s_1(\pi) = 1$, $s_2(\sigma) = s_2(\pi) = 1$, $s_3(\sigma) = s_3(\pi) = 0$, $s_4(\sigma) = 3$, $s_5(\sigma) = 0$, etc.

The inversion table has a particularly simple interpretation in the matrix representation of σ or π: s_1 equals the number of zeros preceding 1 in column 1; we delete the row containing this 1, then count the number of zeros in column 2 preceding the 1 to obtain s_2; we delete the row containing this 1, then go to column 3 to count the zeros preceding the 1 in column 3 in order to obtain s_3, and so on. The reader can verify that $s_{1:3}(\pi) = (1, 1, 0)$ from the matrix Π in Equation (1) above.

Another property of the inversion table is that it can be defined with respect to any infinite permutation σ_0, by letting the ordered list corresponding to σ_0 replace the list $(1|2|3|\ldots)$ in the above definition of the inversion table as follows:

$$s_j(\sigma|\sigma_0) \;=\; \sigma_0(\sigma^{-1}(j)) - 1 - \sum_{j'<j} 1_{[\sigma_0(\sigma^{-1}(j'))<\sigma_0(\sigma^{-1}(j))]}. \tag{2}$$

In other words, $1+s_j$ is the rank of $\sigma^{-1}(j)$ in $\sigma_0\big|_{\mathbb{P}\setminus\{\sigma^{-1}(1),\ldots\sigma^{-1}(j-1)\}}$.

In matrix representation, $s_1(\sigma|\sigma_0)$ is the number of 0's preceding the 1 in the first column of $\Sigma_0^T\Sigma$; after we delete the row containing this 1, $s_2(\sigma|\sigma_0)$ is the number of 0's preceding the 1 in the second column, and so on. For a top-t ordering π, this operation is done on the matrix $\Sigma_0^T\Pi$.

For example, for $\pi = (3|2|1)$ and $\sigma_0 = (3|4|2|1|\ldots)$ the matrix representation is

$$\Sigma_0^T\Pi \;=\; \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ \ldots & \ldots & \ldots \end{bmatrix},$$

and $s_1(\pi|\sigma_0) = 0$, $s_2(\pi|\sigma_0) = 1$, $s_3(\pi|\sigma_0) = 1$.

If σ_0 is given, π is completely determined by the inversion table $s_{1:t}(\pi|\sigma)$. Equation (2) can be interpreted as a recursive algorithm to construct π from σ, which we briefly describe here. We imagine σ to be an ordered list of available items. From it, we choose the first rank in π by skipping the first s_1 ranks in σ and picking $\pi^{-1}(1) = \sigma^{-1}(s_1+1)$. Once $\pi^{-1}(1)$ is picked, this item is deleted from the ordering σ. From this new list of available items, the second rank in π is picked by skipping the first s_2 ranks, and chosing the item in the (s_2+1)-th rank. This item is also deleted, and one proceeds to choose $\pi^{-1}(3), \pi^{-1}(4), \ldots \pi^{-1}(t)$, etc. in a similar manner. This reconstruction algorithm proves that the representation $(s_{1:t})$ uniquely determines π. It is also easy to see that if π is a prefix of σ, that is, if $\pi^{-1}(j) = \sigma^{-1}(j)$ for $j = 1:t$, then $s_1 = s_2 = \ldots = s_t = 0$.

For an example we now show how to reconstruct $\pi = (3|2|1)$ using $\sigma = (3|4|2|1|\ldots)$. Recall that the inversion table of π is given by $s_1(\pi|\sigma) = 0$, $s_2(\pi|\sigma) = 1$, $s_3(\pi|\sigma) = 1$.

Stage	π	σ	Comments
Initial	$()$	$(3\|4\|2\|1\|\ldots)$	
$j=1$	(3)	$(\not{3}\|4\|2\|1\|\ldots)$	Skip $s_1=0$ ranks from σ, then assign the current item to $\pi^{-1}(1)$
$j=2$	$(3\|2)$	$(\not{3}\|4\|\not{2}\|1\|\ldots)$	Skip $s_2=1$ ranks from σ, then assign the current item to $\pi^{-1}(2)$
$j=3$	$(3\|2\|1)$	$(\not{3}\|4\|\not{2}\|\not{1}\|\ldots)$	Skip $s_3=1$ ranks from σ, then assign the current item to $\pi^{-1}(3)$

The definition of the inversion table s is identical to the first equation of Section 3 from Fligner and Verducci (1986). A reciprocal definition of the inversion table is used by Meilă et al. (2007) and Stanley (1997) and is typically denoted by $(V_1, V_2, \ldots)$. The "V" form of the inversion table is closely related to the inversion table we use here. We discuss this relationship in Section 7.

2.3 Kendall Type Divergences

For finite permutations of n items π and σ,

$$d_K(\pi,\sigma) \;=\; \sum_{j=1}^{n-1} s_j(\pi|\sigma) \;=\; \sum_{j=1}^{n-1} s_j(\sigma|\pi)$$

denotes the *Kendall distance* (Mallows, 1957) (or *inversion distance*) which is a metric. In the above, the index j runs only to $n-1$ because for a finite permutation, $s_n \equiv 0$. The Kendall distance represents the number of adjacent transpositions needed to turn π into σ. An extension of the Kendall distance which has been found very useful for modeling purposes was introduced by Fligner and Verducci (1986). It is

$$d_\theta(\pi,\sigma) \;=\; \sum_{j=1}^{n-1} \theta_j s_j(\pi|\sigma),$$

with $\theta = (\theta_1, \ldots \theta_{n-1})$ a vector of real parameters, typically non-negative. Note that d_θ is in general not symmetric, nor does it always satisfy the triangle inequality.

For the case of countable items, we introduce the divergence

$$d_\theta(\pi,\sigma) \;=\; \sum_{j=1}^{t} \theta_j s_j(\pi|\sigma), \tag{3}$$

where π is a top-t ordering, σ is a permutation in $\mathcal{S}_\mathbb{P}$, and $\theta = (\theta_{1:t})$ a vector of *strictly positive* parameters.[1]

When θ_j are all equal $d_\theta(\pi,\sigma)$ is proportional to the Kendall distance between σ and the set of orderings compatible with π and counts the number of inversions needed to make σ compatible with π. In general, this "distance" between a top-t ordering and an infinite ordering is a *set distance*.[2]

2.4 A Probability Model over top-t Rankings of Infinite Permutations

Now we are ready to introduce the *Infinite Generalized Mallows* (IGM) model. We start with the observation that as any top-t ordering can be represented uniquely by a sequence of t natural numbers, defining a distribution over the former is equivalent to defining a distribution over the latter, which is a more intuitive task. In keeping with the GM paradigm of Fligner and Verducci (1986), each s_j is sampled independently from a discrete exponential with parameter $\theta_j > 0$.

$$P(s_j) \;=\; \frac{1}{\psi(\theta_j)} e^{-\theta_j s_j}, \qquad s_j = 0, 1, 2, \ldots. \tag{4}$$

The normalization constant ψ is

$$\psi(\theta_j) = \sum_{k=0}^{\infty} e^{-\theta_j k} = \frac{1}{1-e^{-\theta_j}}, \tag{5}$$

and the expectation of s_j is $E[s_j|\theta_j] = \frac{e^{-\theta_j}}{1-e^{-\theta_j}} = \frac{1}{e^{\theta_j}-1}$ the well known expectation of the discrete geometric distribution. Now we fix a permutation σ. Since any π is uniquely defined by σ and the inversion table $s_{1:t}(\pi|\sigma)$, Equations (4) and (5) define a distribution over top-t orderings, by $P_{\theta,\sigma}(\pi) = \prod_{j=1}^{t} P(s_j(\pi|\sigma))$. This is equivalent to

$$P_{\theta,\sigma}(\pi) \;=\; e^{-\sum_{j=1}^{t}[\theta_j s_j(\pi|\sigma) + \ln\psi(\theta_j)]}. \tag{6}$$

1. Definition 3 can be easily extended to a pair $\sigma, \sigma' \in \mathcal{S}_\mathbb{P}$, but in this case the divergence will often take infinite values.
2. A set distance, often called "distance" between two sets, is the minimum distance between elements in different sets, that is, $\delta(A,B) = \min_{x\in A, y\in B} \delta(x,y)$ for a metric or divergence δ. The set distance is not a metric, as it can easily be shown by counterexample.

The above $P_{\theta,\sigma}(\pi)$ has a t-dimensional real parameter θ and an infinite-dimensional discrete parameter σ. The normalization constant $\prod_{j=1}^{t}\psi(\theta_j)$ ensures that

$$\sum_{\pi\in\text{top-}t\text{ orderings of }\mathbb{P}} P_{\theta,\sigma}(\pi) \;=\; 1.$$

In contrast with the finite GM, the parameters θ_j must be strictly positive for the probability distribution to exist. The most probable π for any given t has $s_1(\pi|\sigma) = \ldots = s_t(\pi|\sigma) = 0$. This is the top-$t$ prefix of σ.

The permutation σ is called the *central permutation* of $P_{\theta,\sigma}$. The parameters θ control the spread around the mode σ. Larger θ_j correspond to more concentrated distributions. These facts are direct extensions of statements about the GM model from Fligner and Verducci (1986) and therefore the detailed proofs are omitted.

What is different about the IGM model definition w.r.t its finite counterpart is that the parameter σ is now an infinite sequence instead of a finite one. Another difference is the added condition that $\theta_j > 0$ which ensures that $\psi(\theta_j)$ is finite. This condition is not necessary in the finite case, which leads to the non-identifiability[3] of the parameter σ.

If $\theta_1 = \theta_2 = \ldots = \theta$ the IGM model is called a *single parameter* IGM model. In this case Equation (6) simplifies to

$$P_{\theta,\sigma}(\pi) \;=\; e^{-\theta\sum_{j=1}^{t} s_j(\pi|\sigma) - t\ln\psi(\theta)}.$$

2.5 The IGM Model is a Marginal Distribution

Any top-t ordering π stands for a set of infinite sequences starting with $s_{1:t}(\pi|\sigma)$. Therefore, $P_{\theta,\sigma}(\pi)$ can be viewed as the marginal of $s_{1:t}$ in the infinite product space defined by the distribution

$$P_{\theta,\sigma}(s) \;=\; e^{-\sum_{j=1}^{\infty}[\theta_j s_j + \ln\psi(\theta_j)]} \qquad s \in \mathbb{N}\times\mathbb{N}\times\ldots.$$

Because every infinite sequence s uniquely determines an infinite permutation, the distribution (6) also represents the probability of the π element of the right coset $\mathcal{S}_{\mathbb{P}}/\mathcal{S}_{\mathbb{P}-t}$, that is, the set of infinite permutations that have $(\pi^{-1}(1)|\pi^{-1}(2)|\ldots|\pi^{-1}(t))$ as a prefix. This fact was noted by Fligner and Verducci (1986) in the context of finite number of items. Thus, the IGM model (6) is the infinite counter part of the GM model.

Note also that the expected value of s_j is the mean of the geometric distribution $E[s_j] = \frac{1}{e^{\theta_j}-1} \equiv \xi_j$. Thus, the mean value parametrization of the IGM can be easily derived (proof omitted):

$$P_{\xi,\sigma}(\pi) \;=\; \prod_{j=1}^{t} \frac{\xi_j^{s_j(\pi|\sigma)}}{(\xi_j+1)^{s_j(\pi|\sigma)+1}}. \tag{7}$$

It is clear by now that the IGM $P_{\theta,\sigma}$ is an exponential family model over the sample space $(s_1, s_2, \ldots)$ (note that here σ plays no role). It is also evidently an exponential family model in θ over complete or top-t permutations. The next section will demonstrate that, less evidently, the IGM is in fact in the exponential family with respect to the discrete parameter σ as well.

3. The non-identifiability of the GM model is however not a severe problem for estimation, and can be removed by imposing $\theta_j \geq 0$ (Meilă et al., 2007).

3. Estimating the Model From Data

We are given a set of N top-t orderings $\mathcal{S}_N$. Each $\pi \in \mathcal{S}_N$ can have a different length t_π; all π are sampled independently from a $P_{\theta,\sigma}$ with unknown parameters. We propose to estimate θ, σ from this data in the ML paradigm. We will start by rewriting the log-likelihood of the model, in a way that will uncover a set of sufficient statistics. Then we will show how to estimate the model based on the sufficient statistics.

3.1 Sufficient Statistics

For any square (infinite) matrix $A \in \mathbb{R}^{\mathbb{P}\times\mathbb{P}}$, denote by $L(A) = \sum_{i>j} A_{ij}$ the sum of the elements below the diagonal of A. Let $L_\sigma(A) = L(\Sigma^T A \Sigma)$, and let $\mathbf{1}$ be a vector of all 1's. For any π, let t_π be its length and denote $t_{max} = \max_{\mathcal{S}_N} t_\pi$, $T = \sum_{\mathcal{S}_N} t_\pi$, and by n the number of distinct items observed in the data. As we shall see, t_{max} is the dimension of the concentration parameter θ, n is the order of the estimated central permutation σ, and T counts the total number of items in the data, playing a role akin to the sample size.

Proposition 1 *Let $\{N_j, q_j, Q_j\}_{j\geq 0}$ represent the following statistics: N_j is the number of $\pi \in \mathcal{S}_N$ that have length $t_\pi \geq j$ (in other words, that contain rank j); q_j is the vector $[q_{i,j}]_{i\in\mathbb{P}}$, with $q_{i,j}$ being the number of times i is observed in rank j in the data $\mathcal{S}_N$, $Q_j = [Q_{ii',j}]_{i',i\in\mathbb{P}}$ is a matrix whose element $Q_{ii',j}$ counts how many times $\pi(i) = j$ and $\pi(i') < j$. Then,*

$$\ln P_{\theta,\sigma}(\mathcal{S}_N) \;=\; -\sum_{j\geq 1} [\theta_j L_\sigma(R_j) + N_j \ln \psi(\theta_j)] \quad \text{with } R_j \;=\; q_j \mathbf{1}^T - Q_j, \tag{8}$$

To prove this result, we first introduce an alternative expression for the inversion table $s_j(\pi|\sigma)$. Let the data set $\mathcal{S}_N$ consist of a single permutation π and define $q_j(\pi), Q_j(\pi)$ and $R_j(\pi)$ similar to q_j, Q_j, R_j above. Then we have

Proposition 2

$$s_j(\pi|\sigma) \;=\; L_\sigma(q_j(\pi)\mathbf{1}^T - Q_j(\pi)). \tag{9}$$

Proof Let Q_0 be the infinite matrix that has 1 above the main diagonal and 0 elsewhere, $(Q_0)_{ij} = 1$ iff $j > i$ and let $\Pi_{:j}$ denote the j-th column of Π. It is then obvious that $L(A) = \text{trace}\,(Q_0 A)$ for any A.

By definition, s_j represents the number of 0's preceding 1 in column j, minus all the 1's in the submatrix $(\Sigma^T\Pi)_{1:\sigma(\pi^{-1}(j))-1,1:j-1}$. In other words,

$$\begin{aligned}
s_j(\pi|\sigma) &= \sum_{l\geq 1} (Q_0 \Sigma^T \Pi_{:j})_l (\mathbf{1} - \Sigma^T\Pi_{:1} - \Sigma^T\Pi_{:2} - \ldots \Sigma^T \Pi_{:j-1})_l, \\
&= (\mathbf{1} - \sum_{j'<j} \Sigma^T \Pi_{:j'})^T Q_0 \Sigma^T \Pi_{:j}, \\
&= \mathbf{1}^T Q_0 \Sigma^T \Pi_{:j} - \sum_{j'<j} \Pi_{:j'}^T \Sigma Q_0 \Sigma^T \Pi_{:j}, \\
&= \text{trace}\, Q_0 \Sigma^T \Pi_{:j} \mathbf{1}^T - \sum_{j'<j} \text{trace}\, \Pi_{:j} \Pi_{:j'}^T \Sigma Q_0 \Sigma^T, \\
&= \text{trace}\, Q_0 \Sigma^T [\Pi_{:j}\mathbf{1}^T - \sum_{j'<j} \Pi_{:j}\Pi_{:j'}^T \Sigma], \\
&= L(\Sigma^T [\Pi_{:j}\mathbf{1}^T - \sum_{j'<j} \Pi_{:j}\Pi_{:j'}^T]\Sigma) \;=\; L_\sigma(\Pi_{:j}\mathbf{1}^T - \sum_{j'<j} \Pi_{:j}\Pi_{:j'}^T).
\end{aligned}$$

We use the fact that multiplying left by Q_0 counts the zeros preceding 1 in a column in the first equality, traceAB = traceBA in the fourth and fifth equations, and the identity $\mathbf{1}^T\Sigma = \mathbf{1}^T$ in the last equation. We now note that $\Pi_{:j} = q_j(\pi)$ and $\sum_{j'<j}\Pi_{:j}\Pi_{:j'}^T = Q_j(\pi)$ and the result follows. □

Proof of Proposition 1. The log-likelihood of $\mathcal{S}_N$ is given by

$$\begin{aligned}\ln P_{\theta,\sigma}(\mathcal{S}_N) &= -\sum_{\pi\in\mathcal{S}_N}\left[\sum_{j=1}^{t}\pi\theta_j s_j(\pi|\sigma)+\ln\psi(\theta_j)\right],\\ &= -\sum_{j\geq 1}\left[\theta_j\sum_{\pi\in\mathcal{S}_N}s_j(\pi|\sigma)+N_j\ln\psi(\theta_j)\right].\end{aligned}$$

Because L_σ is a linear operator, the sum over $\pi\in\mathcal{S}_N$ equals

$$L_\sigma[(\sum_{\pi\in\mathcal{S}_N}q_j(\pi))\mathbf{1}^T-\sum_{\pi\in\mathcal{S}_N}Q_j(\pi))].$$

It is easy to verify now that the first sum represents q_j and the second one represents Q_j.
□

The sufficient statistics for the single parameter IGM model are described by the following corollary.

Corollary 3 *Denote*

$$q=\sum_j q_j,\quad Q=\sum_j Q_j,\quad R\ =\ q\mathbf{1}^T-Q. \tag{10}$$

If $\theta_1=\theta_2=\ldots=\theta$ *then the log-likelihood of the data* $\mathcal{S}_N$ *can be written as*

$$\ln P_{\theta,\sigma}(\mathcal{S}_N)\ =\ -\theta L_\sigma(R)-T\ln\psi(\theta). \tag{11}$$

Note that q_i, $Q_{ii'}$ represent respectively the number of times item i is observed in the data and the number of times item i' precedes i in the data.

Proposition 1 and Corollary 3 show that the infinite model $P_{\theta,\sigma}$ has *sufficient statistics*. The result is obtained without any assumptions on the lengths of the observed permutations. The data $\pi\in\mathcal{S}_N$ can have different lengths t_π, t_π may be unbounded, and may even be infinite.

As the parameters θ,σ of the model are infinite, the sufficient statistics R_j (or R) are infinite matrices. However, for any practically observed data set, t_{max} will be finite and the total number of items observed will be finite. Thus, N_j, R_j will be 0 for any $j > t_{max}$ and $R=\sum_{j\in\mathbb{P}}R_j$ will have non-zero entries only for the items observed in some $\pi\in\mathcal{S}_N$. Moreover, with a suitable relabeling of the observed items, one can reduce R_j to a matrix of dimension n, the number of distinct observed items. The rest of the rows and columns of R_j will be 0 and can be discarded. So in what follows we will assume that R_j and the other sufficient statistics have dimension n.

3.2 ML Estimation: The Case of a Single θ

We now go on to estimate θ and σ starting with the case of equal θ_j, that is, $\theta_1=\theta_2=\ldots=\theta$. In this case, Equation (11) shows that the estimation of θ and σ decouple. For any fixed σ, Equation (11) attains its maximum over θ at

$$\theta=\ln(1+T/L_\sigma(R)). \tag{12}$$

In contrast to the above explicit formula, for the finite GM, the likelihood has no analytic solution for θ (Fligner and Verducci, 1986). The estimated value of θ increases when $L_\sigma(R)$ decreases. This has an intuitive interpretation. The lower triangle of $\Sigma^T R \Sigma$ counts the "out of order" events w.r.t. the chosen model σ. Thus, $L_\sigma(R)$ can be seen as a residual, which is normalized by the "sample size" T. Equation (12) can be re-written as $L_\sigma(R)/T = 1/(e^\theta - 1) \equiv \xi$. In other words, the mean value parameter ξ equals the average residual. This recovers a well-known fact about exponential family models. In particular, if the residual is small, that is $L_\sigma(R)$ has low counts, we conclude that the distribution is concentrated, hence has a high θ.

Estimating σ^{ML} amounts to minimizing $L_\sigma(R)$ w.r.t σ, independently of the value of θ. The optimal σ according to Corollary 3 is the permutation that minimizes the lower triangular part of $\Sigma^T R \Sigma$. To find it we exploit an idea first introduced in Meilă et al. (2007). This idea is to search for $\sigma = (i_1|i_2|i_3|\ldots)$ in a stepwise fashion, starting from the top item i_1 and continuing down.

Assuming for a moment that $\sigma = (i_1|i_2|i_3|\ldots)$ is known, the cost to be minimized $L_\sigma(R)$ can be decomposed columnwise as

$$L_\sigma(R) \;=\; \sum_{l \neq i_1} R_{l i_1} + \sum_{l \neq i_1, i_2} R_{l i_2} + \sum_{l \neq i_1, i_2, i_3} R_{l i_3} + \ldots,$$

where the number of non-trivial terms is one less than the dimension of R. It is on this decomposition that the search algorithm is based. Reading the above algorithmically, we can compute $L_\sigma(R)$, for any given σ by the following steps

1. zero out the diagonal of R
2. sum over column i_1 of the resulting matrix
3. remove row and column i_1
4. repeat recursively from step 2 for $i_2, i_3, \ldots$.

If now σ is not known, the above steps 2, 3 become the components of a search algorithm, which works by trying every i_1 in turn, saving the partial sums, then continuing down for a promising i_1 value to try all i_2's that could follow it, etc. This type of search is represented by a *search tree*, whose nodes are candidate prefixes for σ.

The search tree has $n!$ nodes, one for each possible ordering of the observed items. Finding the lowest cost path through the tree is equivalent to minimizing $L_\sigma(R)$. *Branch-and-bound (BB)* (Pearl, 1984) algorithms are methods to explore the tree nodes in a way that guarantees that the optimum is found, even though the algorithm may not visit all the nodes in the tree. The number of nodes explored in the search for σ^{ML} depends on the individual sufficient statistics matrix R. It was shown by Meilă et al. (2007) that in the worst case, the number of nodes searched can be a significant fraction of $n!$ and as such intractable for all but small n. However, if the data distribution is concentrated around a mode, then the search becomes tractable. The more concentrated the data, the more effective the search.

We call the BB algorithm for estimating σ the SIGMA*, by analogy with the name A^* under which such algorithms are sometimes known. The algorithm is outlined in Figure 1. In this figure, A is an *admissible heuristic*; Pearl (1984) explains their role. By default, one can use $A \equiv 0$. A higher bound than 0 will accelerate the search; some of the admissible heuristics of Mandhani and Meilă (2009) can be used for this purpose.

In addition to this slow but exact algorithm, various heuristic search techniques can be used to explore the search tree of the problem. Two of them which showed good performance for the

standard GM model and which transfer immediately to the infinite model are the greedy search (GREEDYR) and the the SORTR heuristic of Fligner and Verducci (1988), both described in Figure 2. The SORTR computes the costs of the first step of BB, then outputs the permutation σ that sorts these costs in increasing order. The algorithm as proposed by Fligner and Verducci (1988) also performs limited search around this σ. For simplicity, this was not included in the pseudocode, but can be implemented easily.

The GREEDYR replaces BB with greedy search on the same sufficient statistics matrix. This algorithm was used by Cohen et al. (1999), where a factor of 2 approximation bound w.r.t. the cost was also shown to hold.

A third heuristic is related to the special case $t = 1$, when each π contains only 1 element. This is the situation of, for example, a search engine returning just the best match to a query. For $t = 1$, as Q is 0, the optimal ordering is the one minimizing $L_\sigma(q\mathbf{1}^T) = [0\ 1\ \ldots n-1]\Sigma^T q$. This is obviously the ordering that sorts the items in descending order of their frequency q.

In conclusion, to estimate the parameters from data in a single parameter case, one first computes the sufficient statistics, then a prefix of σ is estimated by exact or heuristic methods, and finally, with the obtained ordering of the observed items, one can compute the estimate of θ.

3.3 ML Estimation: The Case of General θ

Maximizing the likelihood of the data $\mathcal{S}_N$ is equivalent, by Proposition 1, with minimizing

$$J(\theta,\sigma) \;=\; \sum_j [\theta_j L_\sigma(R_j) + N_j \ln\psi(\theta_j)] \;=\; L_\sigma(\underbrace{\sum_j \theta_j R_j}_{R_\theta}) + \text{function of } \theta. \tag{13}$$

This estimation equation does not decouple w.r.t θ and σ. Minimization is however possible, due to the following two observations. First, for any fixed set of θ_j values, minimization w.r.t σ is possible by the algorithms described in the previous section. Second, for fixed σ, the optimal θ_j parameters can be found analytically by

$$\theta_j = \ln(1 + N_j / L_\sigma(R_j)). \tag{14}$$

The two observations immediately suggest an alternating minimization approach to obtaining θ^{ML}, σ^{ML}. The algorithm is given in Figure 3. For the optimization w.r.t σ exact minimization can be replaced with any algorithm that decreases the r.h.s of (13). As both steps increase the likelihood, the algorithm will stop in a finite number of steps at a local optimum.[4]

3.4 Identifiability and Consistency Results

One remarkable property of the IGM, which is easily noted by examining the likelihood in (8) or (11), is that the data will only constrain a finite number of parameters of the model. The log-likelihood (8) depends only on the parameters $\theta_{1:t_{max}}$. Maximizing likelihood will determine $\theta_{1:t_{max}}$ leaving the other θ_j parameters undetermined.

4. The reader may have noted that $P_{\theta,\sigma}$ is an exponential family model. For exponential family models with *continuous* parameters over a convex set, the likelihood is log-concave and an iteration like the one presented here would end at the global optimum. For our model, however, the parameter σ is discrete; moreover, the set of σ's forms the vertices of a convex polytope. One can show theoretically and practically that optimizing $L_\sigma(R)$ can have multiple optima and hence one cannot expect to always find a global maximum for the likelihood. However, we suspect that under the conditions that make optimization tractable, that is, a concentrated data distribution, existence of a global optimum may be proved.

Algorithm SIGMA*

Input matrix $R \in \mathbb{R}^{n\times n}$ of sufficient statistics

Initialize

$S = \{\bar{\sigma}_\emptyset\}$, $\bar{\sigma}_\emptyset$ =the empty ordering, $j = 0$, $C(\bar{\sigma}_\emptyset) = B(\bar{\sigma}_\emptyset) = 0$

Do

remove $\bar{\sigma} \in \underset{\bar{\sigma}\in S}{\operatorname{argmin}} B(\bar{\sigma})$ from S

if length$(\bar{\sigma}) = n$ *(Return)*

Output $\bar{\sigma}$, $B(\bar{\sigma}) = C(\bar{\sigma})$ and **Stop**.

else *(Expand* $\bar{\sigma}$*)*

for $i_{j+1} \in \{1:n\} \setminus \bar{\sigma}$

1. create node $\bar{\sigma}' = (i_1|\ldots,|i_j|i_{j+1})$
2. $v_{j+1}(\bar{\sigma}') = \sum_{l\in\{1:n\}\setminus\bar{\sigma}'} R_{li_{j+1}}$
3. calculate $C(\bar{\sigma}') = C(\bar{\sigma}) + v_{j+1}$, calculate $A(\bar{\sigma}')$
4. $B(\bar{\sigma}') = C(\bar{\sigma}') + A(\bar{\sigma}')$
5. store node $(\bar{\sigma}', j+1, C(\bar{\sigma}'), B(\bar{\sigma}'))$ in S

Figure 1: Algorithm SIGMA* outline. S is the set of nodes to be expanded; $\bar{\sigma} = (i_1|\ldots,|i_j)$ designates a top-j ordering, that is, a node in the tree at level j. The cost of the path $\bar{\sigma}$ is given by $C(\bar{\sigma}) = \sum_{j'=1}^{j}\sum_{l\notin\{i_{1:j'}\}} R_{li_l}$, and $A(\bar{\sigma})$ is a lower bound on the cost to go from $\bar{\sigma}$, possibly 0. The total estimated cost of node $\bar{\sigma}$ is $B(\bar{\sigma}) = C(\bar{\sigma}) + A(\bar{\sigma})$, which is used to predict which is the most promising path through the tree. In an implementation, node $\bar{\sigma}$ stores: $\bar{\sigma} = (i_1|\ldots,|i_j)$, $j = |\bar{\sigma}|$, $C(\bar{\sigma})$, $B(\bar{\sigma})$.

Let n be the number of distinct items observed in the data. From σ, we can estimate at most its restriction to the items observed, that is, the restriction of σ to the set $\bigcup_{\pi\in\mathcal{S}_N}\{\pi^{-1}(1),\pi^{-1}(2),\ldots,\pi^{-1}(t_\pi)\}$. The next proposition shows that the ML estimate will always be a permutation which puts the observed items before any unobserved items.

Proposition 4 *Let $\mathcal{S}_N$ be a sample of top-t orderings, and let σ be a permutation over $\mathbb{P}$ that ranks at least one unobserved item i_0 before an item observed in $\mathcal{S}_N$. Then there exists another permutation $\tilde{\sigma}$ which ranks all observed items before any unobserved items, so that for any parameter vector $(\theta_{1:t})$, $P_{\theta,\sigma}(\mathcal{S}_N) < P_{\theta,\tilde{\sigma}}(\mathcal{S}_N)$.*

Proof For an item i_0 not observed in the data, $q_{i_0,j}, Q_{i_0 i,j}$ and $R_{i_0 i,j}$ are 0, for any $j = 1:t$ and any observed item i. Hence row i_0 in any R_j is zero. Also note that if we switch among each other items that were not observed, there is no effect in the likelihood. Hence, w.l.o.g we assume that i_0 has rank j_0 in σ and is followed by an item i which is observed.

Algorithm SORTR

Input matrix $R \in \mathbb{R}^{n\times n}$ of sufficient statistics with 0 diagonal

1. compute the column sums of R, $r_l = \sum_k R_{kl}$, $l = 1:n$
2. sort r_l, $l = 1:n$ in increasing order

Output σ the sorting permutation

Algorithm GREEDYR

Input matrix $R \in \mathbb{R}^{n\times n}$ of sufficient statistics with 0 diagonal

1. set $V = 1:n$ the set of unused items
2. Repeat for $j = 1:n-1$
   (a) compute $r_l = \sum_{k\in V} R_{kl}$, $l \in V$ the column sums of a submatrix of R
   (b) let $l^* = \text{argmin}_{l\in V} r_l$
   (c) set $\sigma^{-1}(j) = l^*, V \leftarrow V \setminus \{l^*\}$
3. set $\sigma^{-1}(n)$ to the last remaining item in V

Output σ

Figure 2: Heuristic algorithms to estimate a central permutation: SORTR and GREEDYR. The elements R_{ii} are never part of any s_j, hence to simplify the code we assume they are set to 0.

Algorithm ESTIMATESIGMATHETA

Input Sufficient statistics R_j, N_j, $j = 1:t_{max}$
Initial parameter values $\theta_{1:t_{max}} > 0$

Iterate until convergence:

1. Calculate $R_\theta = \sum_j \theta_j R_j$
2. Find the ordering $\sigma = \text{argmin}_\sigma L_\sigma(R_\theta)$ (exactly by SIGMA* or by heuristics)
3. Estimate $\theta_j = \ln(1 + N_j / L_\sigma(R_j))$

Output σ, $\theta_{1:t_{max}}$

Figure 3: Algorithm ESTIMATESIGMATHETA.

The idea of the proof is to show that if we switch items i_0 and i the lower triangle of any R_j will not increase, and for at least one R_j it will strictly decrease.

For this, we examine row i of some R_j. We have $Q_{ii_0,j} = 0$ and $Q_{ii_0,j} = q_{i,j}$. Since i is observed then for at least one j we have $R_{ii_0,j} > 0$. Denote by σ' the permutation which is equal to σ except for switching i and i_0. The effect of switching i and i_0 on R_j is to switch elements $R_{ii_0,j}$ and $R_{i_0i,j}$. Since the latter is always 0 and the former is greater or equal to 0, it follows that $L_{\sigma'}(R_j) \leq L_\sigma(R_j)$ for any j, and that the inequality is strict for at least one j. By examining the likelihood expression in Equation (8), we can see that for any positive parameters $\theta_{1:j}$ we have $\ln P_{\theta,\sigma}(\mathcal{S}_N) < \ln P_{\theta,\sigma'}(\mathcal{S}_N)$.

By successive switches like the one described here, we can move all observed items before the unobserved items in a finite number of steps. Let the resulting permutation be $\tilde{\sigma}$. In this process, the likelihood will be strictly increasing at each step, therefore the likelihood of $\tilde{\sigma}$ will be higher than that of σ. □.

In other words σ^{ML} is a permutation of the observed items, followed by the unobserved items in any order. Hence the ordering of the unobserved items is completely non-identifiable (naturally so). But not even the restriction of σ to the observed items is always completely determined. This can be seen by the following example. Assume the data consists of the the two top-t orderings $(a|b|c)$, $(a|b|d)$. Then $(a|b|c|d)$ and $(a|b|d|c)$ are both ML estimates for σ; hence, it would be more accurate to say that the ML estimate of σ is the *partial ordering* $(a|b|\{c,d\})$. The reason σ^{ML} is not unique over a,b,c,d in this example is that the data has no information about the relative ranking c,d, neither directly by observing c,d together in the same π, nor indirectly, via a third item. This situation is likely to occur for the rarely observed items, situated near the ends of the observed π's. Thus this kind of inderterminacy will affect predominantly the last ranks of σ^{ML}. Another kind of indeterminacy can occur when the data is ambiguous w.r.t the ranking of two items c,d, that is, when $R_{cd} = R_{dc} > 0$. This situation can occur at any rank, and will occur more often for values of the θ_j parameters near 0. However, observing more data mitigates this problem. Also, since more observations typically increase the counts more for the first items in σ, this type of indeterminacy is also more likely to occur for the later ranks of σ^{ML}.

Thus, in general, there is a finite set of permutations of the observed items which have equal likelihood. We expect that these permutations will agree more on their first ranks and less in the last ranks. The exact ML estimation algorithm SIGMA* described here will return one of these permutations.

We now discuss the convergence of the parameter estimates to their true values. The IGM model has t real parameters θ_j, $j = 1:t$ and a discrete and infinite dimensional parameter, the central permutation σ. We give partial results on the consistency of the ML estimators, under the assumption that the true model is an IGM model and that t the length of the observed permutations is fixed or bounded.

Before we present the results, we need to make some changes in notation. In this section we will denote by $\hat{q}, \hat{R}$, etc the statistics obtained from a sample, normalized by the sample size N. We use q, R, etc for the asymptotic, population based expectation of a statistic under the true model $P_{\mathrm{id},\theta}$ (single parameter or multiple parameters as will be the case). For instance $\hat{q}_{i,j} = \sum_{\pi \in \mathcal{S}_N} q_{i,j}(\pi)/N$ represents the frequency of i appearing in position j in the sample, while $q_{i,j}$ is the probability of this event under $P_{\mathrm{id},\theta}$. For simplicity of notation, the dependence of N is omitted.

We will show that under weak conditions, the statistics of the type q, Q, R converge to their expectations, which in turn will entail convergence of the estimates based on them. The proofs are in Appendix A.1.

Proposition 5 *Let σ be any infinite permutation. If the true model is $P_{\mathrm{id},\theta}$ (multiple parameters) and t is fixed, then $\lim_{N\to\infty} L_\sigma(\hat{R}_j) = L_\sigma(R_j)$ for any $j = 1:t$.*

Since we can assume w.l.o.g. that the central permutation of the true model is the identity permutation, this proposition implies that for any IGM, with single or multiple parameters, and for any σ, the statistics $L_\sigma(\hat{R}_j)$ are consistent when t is constant.

Proposition 6 *If the true model is $P_{\mathrm{id},\theta}$ (multiple or single parameter) and t is fixed, then for any infinite permutation σ, denote by $\hat{\theta}_j(\sigma)$ (or $\hat{\theta}(\sigma)$) the ML estimate of θ_j (or θ) given that the estimate of the central permutation is σ. Then for $j = 1:t$*

$$\begin{aligned} \lim_{N\to\infty} \hat{\theta}_j(\sigma) &= \theta_j(\sigma), \\ \lim_{N\to\infty} \hat{\theta}(\sigma) &= \theta(\sigma), \end{aligned}$$

where the limits should be taken in the sense of convergence in probability.

Proposition 7 *Assume that the true model is $P_{\mathrm{id},\theta}$, t is fixed, and $\theta_j \geq \theta_{j+1}$ for $j = 1:t-1$. Let $\sigma \neq \mathrm{id}$ be an infinite permutation. Then, $P[L_{\mathrm{id}}(\hat{R}_j) < L_\sigma(\hat{R}_j)] \to 1$. Consequently, $P[L_{\mathrm{id}}(\hat{R}) < L_\sigma(\hat{R})] \to 1$.*

The consequences of these results are as follows. Assume the true model has a single parameter, and we are estimating a single parameter IGM model. Then, the likelihood of an infinite permutation σ is given by $\hat{R} = \sum_{j=1}^{t} \hat{R}_j$. By Proposition 7, for any σ other than the true one, the likelihood will be lower than the likelihood of the true permutation, except in a vanishingly small set of cases. This result is weaker than ideal, since ideally we would like to prove that the likelihood of the true σ is higher than that of all other permutations simultaneously. We intend to pursue this topic, but to leave the derivation of stronger and results for a further publication.

Proposition 6 shows that, if the correct σ is known, then the θ_j parameters, or alternatively the single θ parameter, are consistent.

In the multiple parameter IGM case, for any fixed θ, the likelihood of σ is given by $\hat{R} = \sum_{j=1}^{t} \theta_j \hat{R}_j$. Hence, by Proposition 7, in this case too, for any given σ different from the true central permutation, the likelihood of σ will be lower than the likelihood of the true model permutation.

The reader will note that these results can be easily extended to the case of bounded t.

4. Non-parametric Clustering

The above estimation algorithms can be thought of as finding a *consensus ordering* for the observed data. When the data have multiple modes, the natural extension to optimizing consensus is clustering, that is, finding the groups of the population that exhibit consensus.

Having defined a distance and a method for estimating ML parameters gives one access to a large number of the existing clustering paradigms originally defined for Euclidean data. For instance, the extensions of the K-means and EM algorithms to infinite orderings is immediate, and so are extensions to other distance-based clustering methods. Here we will present only one clustering method, a the *Exponential Blurring Mean-Shift (EBMS)*, but which illustrates well the issues of clustering in the space of top-t orderings. The EBMS is a nonparametric clustering method.

Algorithm EBMS

Input Top-t orderings $\mathcal{S}_N = \{\pi_i\}_{i=1:N}$, with length t_i; optionally, a scale parameter θ

1. For $\pi_i \in \mathcal{S}_N$ compute q_i, Q_i, R_i the sufficient statistics of a single data point.

2. Reduce data set by counting only the distinct permutations to obtain reduced $\tilde{\mathcal{S}}_N$ and counts $N_i \geq 1$ for each ordering $\pi_i \in \tilde{\mathcal{S}}_N$.

3. For $\pi_i, \pi_j \in \tilde{\mathcal{S}}_N$ calculate Kendall distance $d_{ij} = d_K(\pi_i, \pi_j)$.

4. (Optional, if θ not given in input) Set θ by solving the equation

$$E_\theta[d(\tilde{\mathcal{S}}_N)] = \frac{t_\pi e^{-\theta}}{1-e^{-\theta}} - \sum_{j=1}^{t_\pi} \frac{j e^{-\theta}}{1-e^{-j\theta}}$$

   where we set $E_\theta[d(\tilde{\mathcal{S}}_N)]$ to be the average of pairwise distances in step 3.

5. For $\pi_i \in \tilde{\mathcal{S}}_N$ *(Compute weights and shift)*

   (a) For $\pi_j \in \tilde{\mathcal{S}}_N$: set $\alpha_{ij} = \frac{\exp(-\theta d_{ij})}{\sum_{j'=1}^{n} \exp(-\theta d_{ij'})}$
   (b) Calculate $\bar{R}_i = \sum_{\pi_j \in \tilde{\mathcal{S}}_N} N_j \alpha_{ij} R_j$
   (c) Estimate σ_i the "central" permutation that optimizes $\bar{R}_i$ (exactly or by heuristics)
   (d) Set $\pi_i \leftarrow \sigma_i(1 : t_\pi)$

6. Go to step 2, until no π_i changes.

Output $\tilde{\mathcal{S}}_N$

Figure 4: The EBMS algorithm.

Nonparametric clustering is motivated by the fact that in many real applications the number of clusters is unknown and outliers exist. We consider an adapted version of the well known blurring mean-shift algorithm for ranked data (Fukunaga and Hostetler, 1975; Cheng, 1995; Carreira-Perpiñán, 2006). We choose the exponential kernel with bandwidth $\frac{1}{\theta} > 0$: $K_\theta(\pi, \sigma) = \frac{e^{-\theta d(\pi,\sigma)}}{\psi(\theta)}$. Under the Kendall distance $d_K(\pi, \sigma)$ the kernel has the same form as the one parameter Mallows' model. The kernel estimator of π_i is given by

$$\hat{r}(\pi_i) = \sum_{j=1}^{n} \frac{K_\theta(\pi_i, \pi_j)}{\sum_{k=1}^{n} K_\theta(\pi_i, \pi_k)} \pi_j = \sum_{j=1}^{n} \frac{e^{-\theta d_K(\pi_i, \pi_j)}}{\sum_{k=1}^{n} e^{-\theta d_K(\pi_i, \pi_k)}} \pi_j,$$

which does not depend on the normalizing constant $\psi(\theta)$ in Mallows' model.

The EBMS algorithm is summarized in Figure 4. It shift the "points" (i.e., top-t orderings) to new locations obtained by a locally weighted combination of all the data. Thus, every π is

"attracted" towards its closest neighbors; as the shifting is iterated the data collapse into one or more clusters. The algorithm has a *scale parameter* θ. The scale influences the size of the local neighborhood of a top-t ordering, and thereby controls the granularity of the final clustering: for small θ values (large neighborhoods), points will coalesce more and few large clusters will form; for large θ's the orderings will cluster into small clusters and singletons. In the EBMS algorithm, we estimate the scale parameter θ at each iteration by solving the equation in step (d).

Practical experience shows that blurring mean-shift merges the points into compact clusters in a few iterations and then these clusters do not change but simply approach each other until they eventually merge into a single point (Carreira-Perpiñán, 2006). Therefore, to obtain a meaningful clustering, a proper stopping criterion should be proposed in advance. For ranked data, this is not the case: since at each iteration step we round the local estimator into the nearest permutation, the algorithm will stop in a finite number of steps, when no ordering moves from its current position. Moreover, because ranked data is in a discrete set, we can also perform an accelerating process. As soon as two or more orderings become identical, we replace this *cluster* with a single ordering with a weight proportional to the cluster's number of members. The total number of iterations remains the same as for the original exponential blurring mean-shift but each iteration uses a data set with fewer elements and is thus faster.

In the algorithm one evaluates distances between top-t orderings. There are several ways in which to turn $d_K(\pi,\sigma)$ into a $d(\pi_1,\pi_2)$, where both terms are top-t orderings, containing different sets of items. Critchlow (1985) studied them, and here we adopt for $d(\pi_1,\pi_2)$ what is called the set distance, that is, the distance between the sets of infinite orderings compatible with π_1 respectively π_2.

We chose this formulation rather than others because this distance equals 0 when $\pi_1 = \pi_2$, and this is good, one could even argue necessary, for clustering. In addition, it can be calculated by a relatively simple formula, inspired by Critchlow (1985). Let

A	the set intersection of orderings π_1,π_2	t_1,t_2	lengths of π_1,π_2
B	$\pi_1 \setminus A$, the items in π_1 not in π_2	$n_{A,B,C}$	the number of items in A, B, C
C	$\pi_2 \setminus A$, the items in π_2 not in π_1	k_j	the index in π_1 of the j-th item not in A
		l_j	the index in π_2 of the j-th item not in A

Then

$$d(\pi_1,\pi_2) \;=\; d_K((\pi_1)_{|A},(\pi_2)_{|A}) + n_B n_C + n_B t_1 - \sum_{j=1}^{n_B} k_j - \frac{n_B(n_B-1)}{2} + n_C t_2 - \sum_{j=1}^{n_C} l_j - \frac{n_C(n_C-1)}{2}. \tag{15}$$

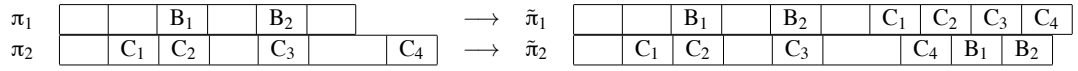

Figure 5: An example of obtaining two partial orderings $\tilde{\pi}_1,\tilde{\pi}_2$ compatible respectively with π_1,π_2 that achieve the set distance. Empty spaces represent the common items, while B and C symbols mark the items in B, respectively C. The distance $d(\pi_1,\pi_2)$ is the Kendall distance between $\tilde{\pi}_1$ and $\tilde{\pi}_2$.

The intuitive interpretation of this distance is given in Figure 5. We extend π_1 and π_2 to two longer orderings $\tilde{\pi}_1, \tilde{\pi}_2$, so that: (i) $\tilde{\pi}_1, \tilde{\pi}_2$ have identical sets of items, (ii) $\tilde{\pi}_1$ is the closest ordering to π_2 which is compatible with π_1, and (iii) reciprocally, $\tilde{\pi}_2$ is the closest ordering to π_1 which is compatible with π_2. We obtain $\tilde{\pi}_1$ by taking all items in π_2 but not in π_1 and appending them at the end of π_1 while preserving their relative order. A similar operation gives us $\tilde{\pi}_2$. Then, $d(\pi_1,\pi_2) = d_K(\tilde{\pi}_1,\tilde{\pi}_2)$, and Equation (15) expresses this value.

5. The Conjugate Prior

The existence of sufficient statistics implies the existence of a conjugate prior (DeGroot, 1975) for the parameters of model (6). Here we introduce the general form of this prior and show that computing with the conjugate prior (or posterior), is significantly harder than computing with the likelihood (6).

We shall assume for simplicity that all top-t rankings have the same t. Consequently, our parameter space consists of the real positive vector $\theta_{1:t}$ and the discrete infinite parameter Σ.

We define the prior parameters as a set of "fictitious sufficient statistics", by analogy with the sufficient statistics for model (6). For this we first make a few straightforward observations about the sufficient statistics q_j, Q_j, $j = 1:t$ as follows:

$$\begin{aligned} Q_1 &\equiv 0, \\ Q_{ii',j} &\geq 0 \quad \text{for all } i,i',j, \\ \sum_i q_{i,j} &= N_j \quad \text{for all } j, \\ Q_j\mathbf{1} &= (j-1)q_j \quad \text{for all } j>1. \end{aligned}$$

Therefore

$$R_j = q_j\mathbf{1}^T - Q_j = \begin{cases} Q_j\left(\frac{1}{j-1}\mathbf{1}\mathbf{1}^T - I\right) & \text{for } j>1 \\ q_1\mathbf{1}^T & \text{for } j=1 \end{cases}.$$

Now we let ν denote the *prior strength*, representing the equivalent sample size, and λ_1, Λ_j, $j = 2:t$ be the prior parameters corresponding to the sufficient statistics q_1, $Q_{2:t}$, normalized as follows.

Proposition 8 *Let $\nu > 0$, λ_1 be a vector and Λ_j, $j = 2:t$ denote a set of possibly infinite matrices satisfying*

$$\begin{aligned} \lambda_1 &\geq 0, \\ \Lambda_{ii',j} &\geq 0 \quad \text{for all } i,i',j, \\ \Lambda_j\mathbf{1} &= (j-1)\lambda_j \quad \text{for all } j>1 \quad \text{(by definition)}, \\ \mathbf{1}^T\lambda_j &= 1 \quad \text{for all } j. \end{aligned}$$

Denote $\mathbf{\Lambda} = \{\nu, \lambda_1, \Lambda_{2:t}\}$ and

$$R_j^0 = \begin{cases} \Lambda_j\left(\frac{1}{j-1}\mathbf{1}\mathbf{1}^T - I\right) & \text{for } j>1 \\ \lambda_1\mathbf{1}^T & \text{for } j=1 \end{cases}.$$

Define the distribution

$$P_{\mathbf{\Lambda}}(\sigma,\theta) \propto e^{-\nu\sum_{j=1}^t[\theta_j L(\Sigma^T R_j^0\Sigma)+\ln\psi(\theta_j)]}, \tag{16}$$

which is a conjugate prior for the model $P_{\theta,\sigma}(\pi)$ defined in (6).

Proof Given observed permutations $\pi_{1:N}$ with sufficient statistics R_j, $j = 1:t$, the posterior distribution of (σ, θ) is updated by

$$\begin{aligned} P(\theta, \sigma \,|\, \mathbf{\Lambda}, \pi_{1:N}) &\propto e^{-\sum_{j=1}^{t}[(\nu L_\sigma(R_j^0)+L_\sigma(R_j))\theta_j+(N+\nu)\ln\psi(\theta_j)]}, \\ &= e^{-(N+\nu)\sum_{j=1}^{t}[\theta_j L_\sigma\left(\frac{\nu R_j^0+R_j}{N+\nu}\right)+\ln\psi(\theta_j)]}. \end{aligned}$$

If the hyperparameters $\nu, \lambda_1, \Lambda_{2:t}$ satisfy the conditions of the proposition, then the new hyperparameters $\mathbf{\Lambda}' = \{\nu+N, (\nu\lambda_1+q_1)/(\nu+N), (\nu\Lambda_j+Q_j)/(\nu+N), j = 2:t\}$ satisfy the same conditions. □.

The conjugate prior is defined in (16) only up to a normalization constant.[5] As it will be shown below, this normalization constant is not always computable in closed form. Another aspect of conjugacy is that one prefers the conjugate hyperparameters to represent expectations of the sufficient statistics under some $P_{\theta,\sigma}$. The conditions in Proposition 8 are necessary, but not sufficient to ensure this fact.

To simplify the notations, we write

$$S_j^* \;=\; L_\sigma(\nu R_j^0 + R_j). \tag{17}$$

This notation reflects the fact that S_j^* is the counterpart in the posterior of the s_j in the distribution $P_{\theta,\sigma}(\pi)$. If $N = 0$, then $S_j^* = \nu L_\sigma(R_j^0)$. The value of S_j^* depends on σ and the hyperparameters, but does not depend on θ. The following result shows that for any fixed S_j^*, the posterior can be integrated over θ_j in closed form.

Proposition 9 *Let $P_{\mathbf{\Lambda}}(\sigma, \theta)$ be defined as in (16) and S_j^* be defined by (17). Then,*

$$P_{\mathbf{\Lambda}}(\theta_j \,|\, \sigma) \;=\; Beta_{S_j^*, \nu+1}(e^{-\theta_j}),$$

where $Beta_{\alpha,\beta}$ denotes the Beta distribution.

Proof sketch Replacing $\psi(\theta_j)$ with its value (5) yields

$$P_{\mathbf{\Lambda}}(\theta_j \,|\, \sigma) \;\propto\; e^{-S_j^*\theta_j}(1-e^{-\theta_j})^\nu,$$

from which the desired result follows by a change of variable. □

As a consequence, we have that

$$P_{\mathbf{\Lambda}}(\sigma) \;\propto\; \prod_{j=1}^{t} Beta(S_j^*(\sigma), 1+\nu). \tag{18}$$

In the above, the notation $Beta(x, y)$ is used to denote the special function Beta defined as $Beta(x, y) = \frac{\Gamma(x)\Gamma(y)}{\Gamma(x+y)}$.

We have shown thus that closed form integration over the continuous parameters θ_j is possible. The summation over the discrete parameters poses much harder problems. We list them here.

5. The general form of a conjugate prior may include factors in σ and θ which do not depend on Λ. For simplicity of the exposition, we do not consider such a form here.

A first unsolved question is the range of the variables S^*_j. While the s_j variables in the infinite GM model are always integers ranging from 0 to infinity, the S^*_j variables can have non-integer values if ν or Λ_j are non-integer. The latter is almost always the case, since under the conditions of Proposition 8, Λ_j is not integer unless all its elements are 0 or 1. Second, Λ_j must have an infinite number of non-null entries, which may create problems for its numerical representation. And finally, there can be dependencies between S^*_j values for different j's. Hence, the factored expression (18) *should not be interpreted* as implying the independence of the S^*_j's.

We illustrate these points by a simple example. Assume that the conjugate prior hyperparameters are equivalent to the fictitious sample $\{\pi_1 = (1|2|3|\ldots), \pi_2 = (2|1|3|\ldots)\}$. Then,

$$\nu = 2,\ \lambda_1 = \begin{bmatrix} 0.5 \\ 0.5 \\ 0 \end{bmatrix}\ \Lambda_2 = \begin{bmatrix} - & 0.5 & 0 \\ 0.5 & - & 0 \\ 0 & 0 & - \end{bmatrix},\ \Lambda_3 = \begin{bmatrix} - & 0 & 0 \\ 0 & - & 0 \\ 1 & 1 & - \end{bmatrix},$$

$$R^0_1 = \begin{bmatrix} - & 0.5 & 0.5 \\ 0.5 & - & 0.5 \\ 0 & 0 & - \end{bmatrix},\ R^0_2 = \begin{bmatrix} - & 0 & 0.5 \\ 0 & - & 0.5 \\ 0 & 0 & - \end{bmatrix},\ R^0_3 = \begin{bmatrix} - & 0 & 0 \\ 0 & - & 0 \\ 0 & 0 & - \end{bmatrix}.$$

For this example, there are two central rankings $\sigma_1 = (1|2|3|\ldots)$ and $\sigma_2 = (2|1|3|\ldots)$ which have the same $S^*_{1:3} = (1,0,0)$, but no σ with $S^*_j \equiv 0$. Assume now that we are given just $R^0_{1:3}$, $\nu = 2$ and $S^*_1(\sigma) = 1$ for some σ. Because $S^*_1 + 2$ is the sum of ranks of ${\pi^{-1}}_{1,2}(1)$ in σ, we can easily infer that the first two items in σ must be either $(1|2)$ or $(2|1)$ since any other σ will have $S^*_1 \neq 1$. But, for either of these possibilities, the computation of $S^*_2(\sigma)$ from R^0_2 gives $S^*_2(\sigma) = 0$. Hence, knowing S^*_1 informs about S^*_2 (in fact determines it completely), showing that S^*_1, S^*_2 are not independent.

Due to the above difficulties, computing the normalization constant of the posterior is an open problem. However, under some restrictive conditions, we are able to compute the normalization constant of the posterior in closed form.

Proposition 10 *If ν and $\Lambda_{1:t}$ are all integer, the S^*_j variables are independent, and the range of values of S^*_j is $\mathbb{P}$ then*

$$P(S^*_j = k) \ = \ (N+\nu)Beta(k+1, N+1+\nu),$$

and consequently

$$P_{\Lambda,\nu}(\theta_{1:t}, S^*_{1:t}) \ = \ (N+\nu)^t e^{-\sum_{j=1}^t [\theta_j S^*_j + (N+\nu)\ln\psi(\theta_j)]}.$$

The proof is given in Appendix A.1.

Now we examine the case of a single parameter IGM. The conjugate prior is given by $\nu > 0$ and a single matrix R^0 corresponding to the normalized sufficient statistics matrix R,

$$P_{\nu,R^0}(\theta,\sigma) \ \propto \ e^{-\theta L(\Sigma^T \nu R^0 \Sigma) + t\nu \ln\psi(\theta)}, \tag{19}$$

The posterior is

$$P_{\nu,R^0}(\theta,\sigma\,|\,\pi_{1:N}) \ \propto \ e^{-L(\theta\Sigma^T(\nu R^0 + R)\Sigma) + t(\nu+N)\ln\psi(\theta)]}.$$

Denote for simplicity $N' = N+\nu$, $R' = (R+\nu R^0)/(N+\nu)$, $S^*(\sigma) = L_\sigma(N'R')$. Then, the parameter θ again follows a Beta distribution given σ,

$$P_{N',R'}(\theta\,|\,\sigma) \ \propto \ Beta_{S^*;tN'+1}(e^{-\theta}).$$

After integrating θ out, we obtain

$$P_{N',R'}(\sigma) \;\propto\; Beta(S^*(\sigma), tN'+1).$$

Finally, let us note that that the priors in (16) and (19) are both informative with respect to σ. By replacing the term $L_\sigma(R_j^0)$ (respectively $L_\sigma(R^0)$) with some $r_j > 0$ (respectively $r > 0$) one can obtain a prior that is independent of σ, hence uninformative. However, this prior is improper.

6. Experiments

In this section, we conduct experiments on single θ estimation, general θ estimation, real data sets, and clustering.

6.1 Estimation Experiments, Single θ

In these experiments we generated data from an infinite GM model with constant $\theta_j = \ln 2, \ln 4$ and estimated the central permutation and the parameter θ. To illustrate the influence of t, t_π was constant over each data set. The results are summarized in Table 1.

Note that while θ appears to converge, the distance $d_K(\sigma^{ML}, \sigma)$ remains approximately the same. This is due to the fact that, as either N or t increase, n, the number of items to be ranked, increases. Thus the distance d_K will be computed between ever longer permutations. The least frequent items will have less support from the data and will be those misranked. We have confirmed this by computing the distance between the true σ and our estimate, restricted to the first t ranks. This was always 0, with the exception of $n = 200, \theta = 0.69, t = 2$ when it averaged 0.04 (2 cases in 50 runs) (A more detailed analysis of the ordering errors will be presented in the next subsection.)

Even so the table shows that most ordering errors are no larger than 1. We also note that the sufficient statistic R is an unbiased estimate of the expected R. Hence, for any fixed length $\tilde{t}$ of σ^{ML}, the σ estimated from R should converge to the true σ (see also Fligner and Verducci, 1988). The θ^{ML} based on the true σ is also unbiased and asymptotically normal.

6.2 Estimation Experiments, General θ

We now generated data from an Infinite GM model with $\theta_1 = \ln 2$ or $\ln 4$ and $\theta_j = 2^{-(j-1)/2}\theta_1$ for $j > 1$. As before, t_π was fixed in each experiment at the values 2, 4, 8. We first look at the results for $t = 8$ in more detail. As the estimation algorithm has local optima, we initialized the θ parameters multiple times. The initial values were (i) the constant value 0.1 (chosen to be smaller than the correct values of all θ_j), (ii) the constant values 1 and respectively 2 depending whether $\theta_1 = \ln 2$ or $\theta_1 = \ln 4$ and (iii) the true θ parameters. The case (ii) ensured that the initial point is higher than all correct values for all the estimated θ_j.

Figure 6 shows the estimated values of θ_j for different sample sizes N ranging in $\{200, 500, 1000, 2000\}$. By comparing the respective (i) and (ii) panels, one sees that the final result was insensitive to the initial values and always close to the true θ_j. The results were also identical to the results for the initialization (iii), and this was true for all the experiments we performed. Therefore, in the subsequent plots, we only display results for one initialization, (i).

Qualitatively, the results are similar to those for single θ, with the main difference stemming from the fact that, with decreasing θ_j values, the sampling distribution of the data is spread more, especially w.r.t the lower ranks.

Estimates of θ (mean stdev)									
θ	**N**	200		500		1000		2000	
		mean	std	mean	std	mean	std	mean	std
0.69	$t=2$	0.68	0.04	0.68	0.03	0.68	0.03	0.68	0.024
	$t=4$	0.67	0.03	0.69	0.02	0.69	0.01	0.69	0.01
	$t=8$	0.68	0.02	0.69	0.01	0.69	0.01	0.69	0.007

Table 1: Results of estimation experiments, single parameter IGM. Top: mean and standard deviation of θ^{ML} for two values of the true θ and for different t values and sample sizes N. Middle: the proportion of cases when the ordering error, that is, the number inversions w.r.t the true σ^{-1} was 0, respectively 1. Bottom: number of observed items n (mean and standard deviation). Each estimation was replicated 25 or more times.

This figure allows us to observe the "asymmetry" of the error in θ^{ML}. The estimates seem to biased towards larger values, especially for higher j and less data. There is a theoretical reason for this. Recall that by Equation (12) θ is a decreasing function of $L_\sigma(R)$. If the true σ is not optimal for the given R, due to sample variance, then θ^{ML} will tend to overestimate θ. Hence θ^{ML} is a *biased* estimate of θ. If however, due to imperfect optimization, the estimated σ^{ML} is not optimal and has higher cost than σ, then θ^{ML} will err towards underestimation. In Figures 6 and 7 the bias is always positive, indicating that the minimization over σ is done well (even though it is not guaranteed to reach optimality).

Now we consider the recovery of the central permutation σ. From our previous remarks, we expect to see more ordering errors in the bottom ranks of σ^{ML}, where the distribution is less concentrated (smaller θ_j) and there is less data available. To visualize these effects easier, it is interesting to look at rankings with small t. When t is small, 2, 4 or 8, the total number of items to be ranked (Figure 8) is several times larger than t for our experiments. Thus the estimation algorithm has to put together an ordering over this many items, when only groups of $t = 2, 4, \ldots$ were observed together. As an additional confounding effect, the top elements will be oversampled, so the information about the lower ranks will have to be inferred indirectly by pooling the information from the whole data set. This is what the algorithm is doing, and Figure 9 shows how well it succeeds in that.

The figure displays the ordering error between σ^{ML} and the true σ for each rank, which is measured by $s_j(\sigma^{ML}|\sigma)$. Recall that the total number of inversions between σ^{ML} and σ is the sum of all s_j; similarly, the total number of errors in σ^{ML} up to rank r is given by $\sum_{j=1}^{r} s_j(\sigma^{ML}|\sigma)$. All plots illustrate the same general tendency of the s_j values to increase *slowly* with j. The increase is slower when there are more observations per rank, that is when N and t are larger, and when the θ_j are larger (thus the data distribution is more concentrated).

6.3 Experiments on Real Data Sets, With General θ, Tied Parameters

The next experiment was conducted with the data collected by Cohen et al. (1999). The data consists of a list of 157 universities, the queries, and a set of 21 search engines, the "experts". Each search engine outputs a list of up to $t_{max} = 30$ URL's when queried with the name of the university. The data set provides also a "target" output for each query, which is the university's home page.

Hence, we have 147 estimation problems (10 universities with no data), with sample size $N \leq 21$ (as some experts return empty lists) and with variable length data ranging from $t = 1$ to $t = 30$. Figure 10 gives a summary view of number of samples for each rank N_j, $j = 1 : t$, the number of distinct items n and the cumulative number of ranks observed (i.e., $T = \sum_{j \leq 30} N_j$). These values suggest that estimating a fully parameterized model with distinct $\theta_{1:30}$ may lead to overfitting and therefore we estimate several parameterizations, all having the form $\Theta_r = (\theta_1, \theta_2, \ldots \theta_{r-1}, \theta_r, \theta_r, \ldots \theta_r)$. In other words, ranks $1 : r-1$ have distinct parameters, while the following ranks share parameter θ_r. We call $\theta_{1:r-1}$ the *free* parameters and θ_r the *tied* parameter. For $r = 1$ we have the single parameter model, and for $r = t_{max} = 30$ we have the fully parameterized model.

Estimating a model with r parameters is done by a simple modification of the ESTIMATESIGMATHETA algorithm which is left to the reader.

The estimation algorithm was started from the fixed value $\theta_j = 0.1$ for all runs. The number of iterations to convergence range between 10 and 50, with typical value 18. The running time was around per model estimated.

In Figure 11 we give a synopsis of the values of the θ parameters under different models. The single parameter models yields θ values in the range [0.007, 0.104] with the 10%, 50% and 90% quantiles being respectively 0.009, 0.018,and 0.032. The parameters θ are on average decreasing in all models, with the free parameters higher than the tied parameters for the remaining ranks. This is true on average only, while for individual samples some of the free parameters may be smaller than the tied parameter.

Notice also that for the models with fewer parameters the values of the free parameters tend to be higher than the corresponding values in models with more parameters. Compare for instance the values of θ_1 in the two-parameter model with θ_1 in the 30 parameter model.

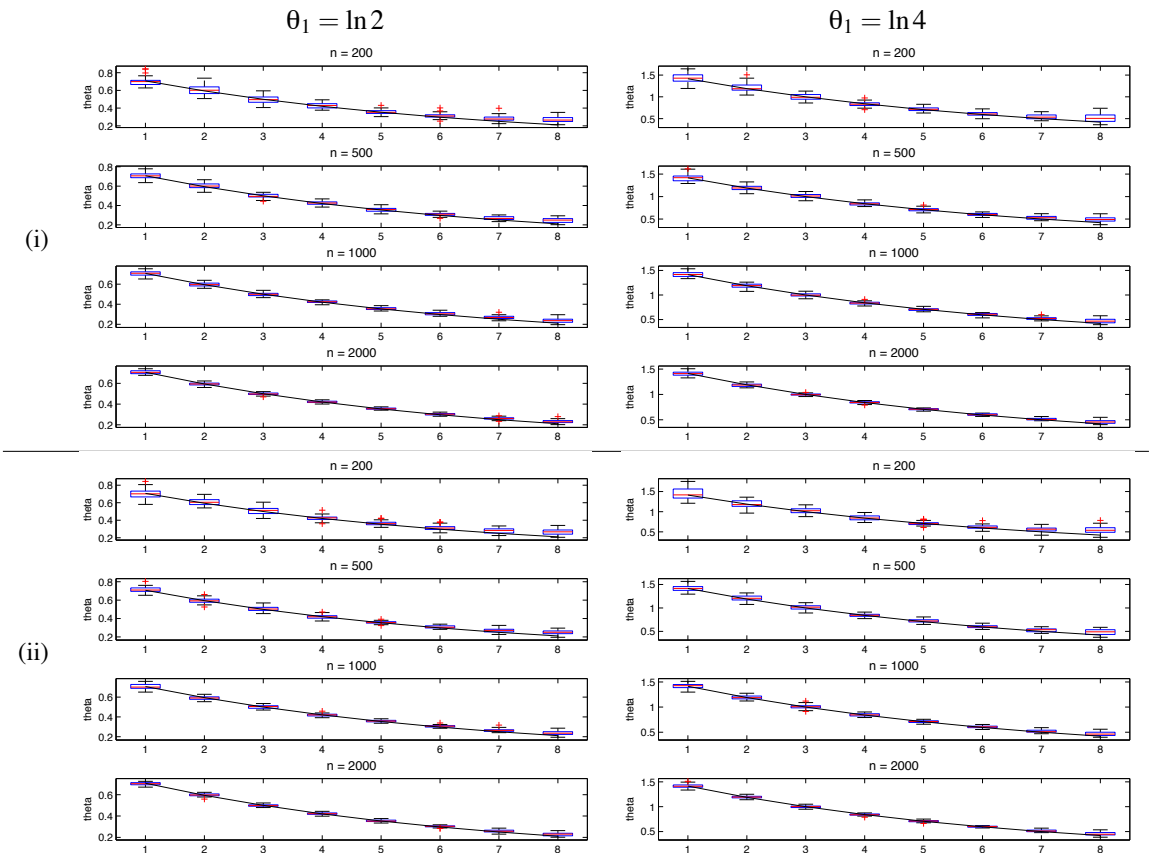

Figure 6: Estimation of the parameters $\theta_{1:t}$ for $t = 8$, different sample sizes $N = 200, 500, 1000, 2000$, different true parameters θ, and different initializations: (i) $\theta_j \leftarrow 0.1$, (ii) $\theta_j \leftarrow 1$ or 2. For each experimental condition, the corresponding graph displays box plots of the obtained estimates of θ_j, $j = 1:8$ for 50 random samples, with the j on the horizontal axis. The continuous line crossing the box plots marks the true values of the parameters $\theta_{1:8}$ (exponential decay starting from the given θ_1).

For each query and each model size, we computed the rank of the true university home page, that is, the *target*, under the estimated central permutation σ^{ML}. Assuming the search engines are reasonably good, this rank is an indirect indicator of the goodness of a model. In addition, for each query, we selected one model by BIC and calculated the target ranks for these models. Table 2 gives the mean and median of the target rank for each model, as well as for the BIC selection. The rank is assigned to $t_{max} + 1 = 31$ if the target is not among the items returned by the search engines.

It is evident that while BIC's performance is better than selecting a one-parameter model, it is not optimal w.r.t the ranking of the target home page.

We used a modified form of the BIC criterion, that takes into account that the continuous parameters are not all estimated from the same sample size. We have derived[6] the following formula

6. The derivation is omitted, being outside the scope of this paper.

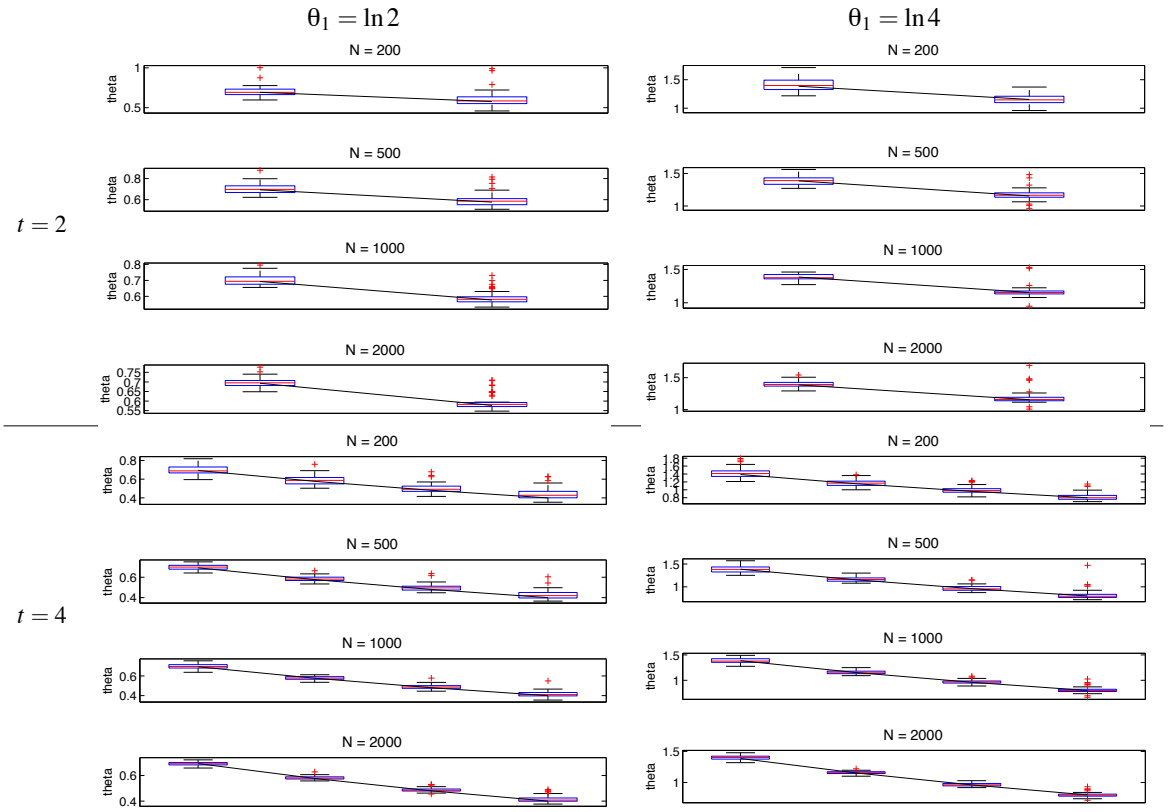

Figure 7: Same as Figure 6 for $t = 2$ and $t = 4$ and a single initial point $\theta_j \equiv 0.1$.

for BIC:

$$BIC(r) \;=\; \ln P_{\sigma,\theta}(\mathcal{S}_N) - \frac{1}{2}\sum_{j=1}^{r} \ln N'_j \tag{20}$$

where $N'_j = N_j$ for $j < r$ and $N'_r = \sum_{j'=r}^{t} N_j$. This expression approximates the marginal distribution of the model w.r.t the continuous parameter. The discrete parameter σ is not marginalized out. This parameter has always the same dimension, dictated by the observed data, and independent of r. In any finite data situation, the parameter will be finite. Therefore we can see the model selection problem as a model selection over r and a very large but finite set of discrete σ's. Maximizing the BIC in (20) is equivalent with maximizing the BIC over this much larger set of models, if one assumes that the ML estimation procedure attains a global optimum.

Next, we tested the ESTIMATESIGMATHETA algorithm on the Jester data of Goldberg et al. (2001).[7] This data set represents a set of 100 jokes, which were scored by approximately 25,000 people. From the numerical scores, we obtained a partial ordering over the jokes rated by each individual. Mao and Lebanon (2008) also analyzed this data set and found that it was multimodal. To obtain data sets closer to unimodality, we picked a person at random (this is person 945 in the data) and extracted the N nearest neighbors of this ranking, for $N = 200$ and $N = 12,000$. The smaller data set was expected to be more concentrated than the larger data set.

7. Available at `http://goldberg.berkeley.edu`.

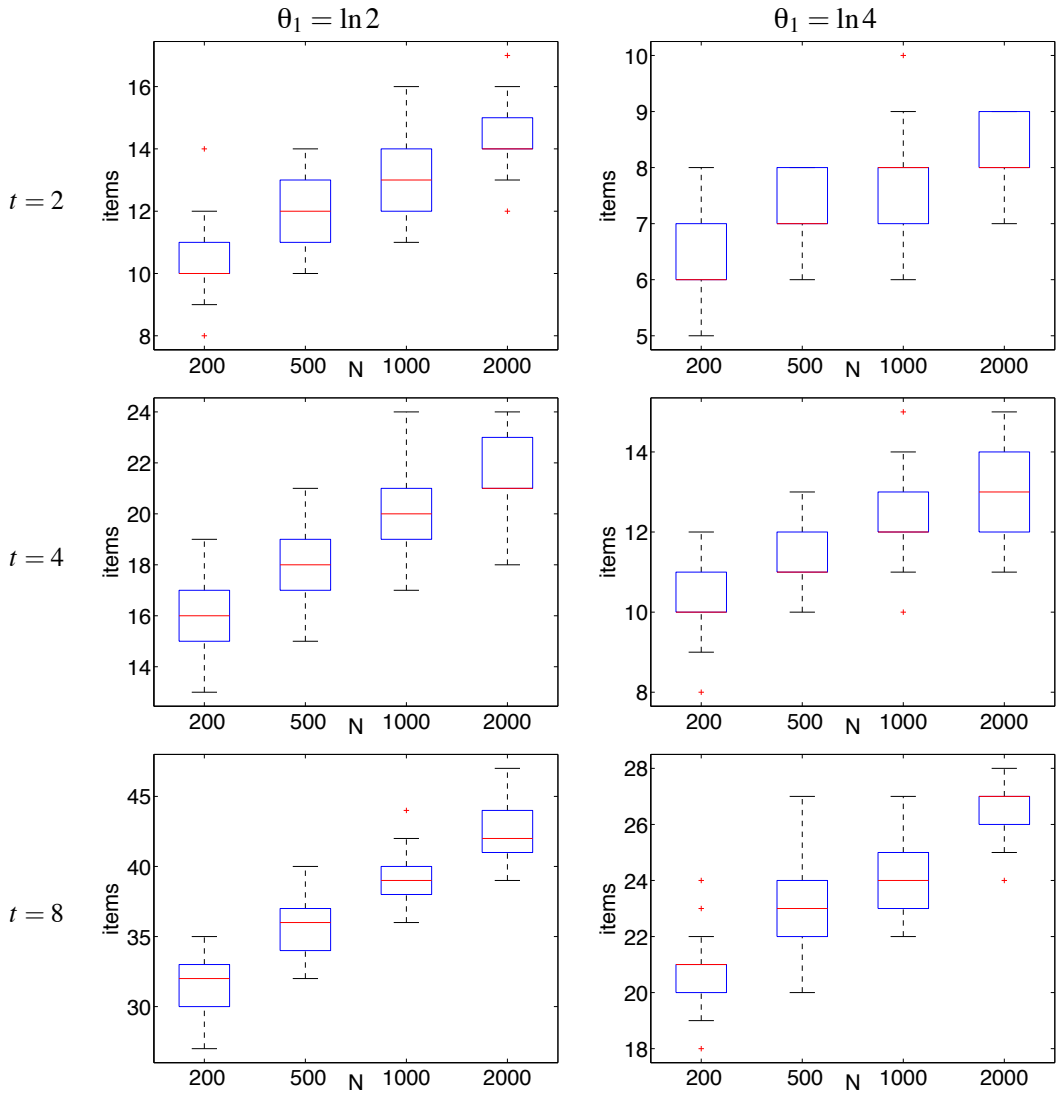

Figure 8: Number of items observed for $N = 200, 500, 1000, 2000$, different parameters θ and $t = 2, 4, 8$. Each box plot represents the distribution of the number of items over 50 random samples.

We ran the ESTIMATESIGMATHETA on this data set with different values of r. The log-likelihoods obtained on the training set and the BIC values are shown in Figure 12.

As expected, the likelihood is highest or nearly so for the model with maximum number of free parameters (for $N = 12,000$ the likelihood is not monotonic due to imperfect optimization over σ). However, the BIC is not monotonic. For the large N case, where the data is dispersed, it chooses a model with $r = 76$ parameters. The estimated θ_j values range in $[0.05, 0.07]$ for $j = 1 : 30$ (nearly all ranks that have $N_j = 12000$) but become higher, up to 0.2 for the ranks that have smaller N_j's. For the smaller and more concentrated data set, BIC has equal values for three different models: the

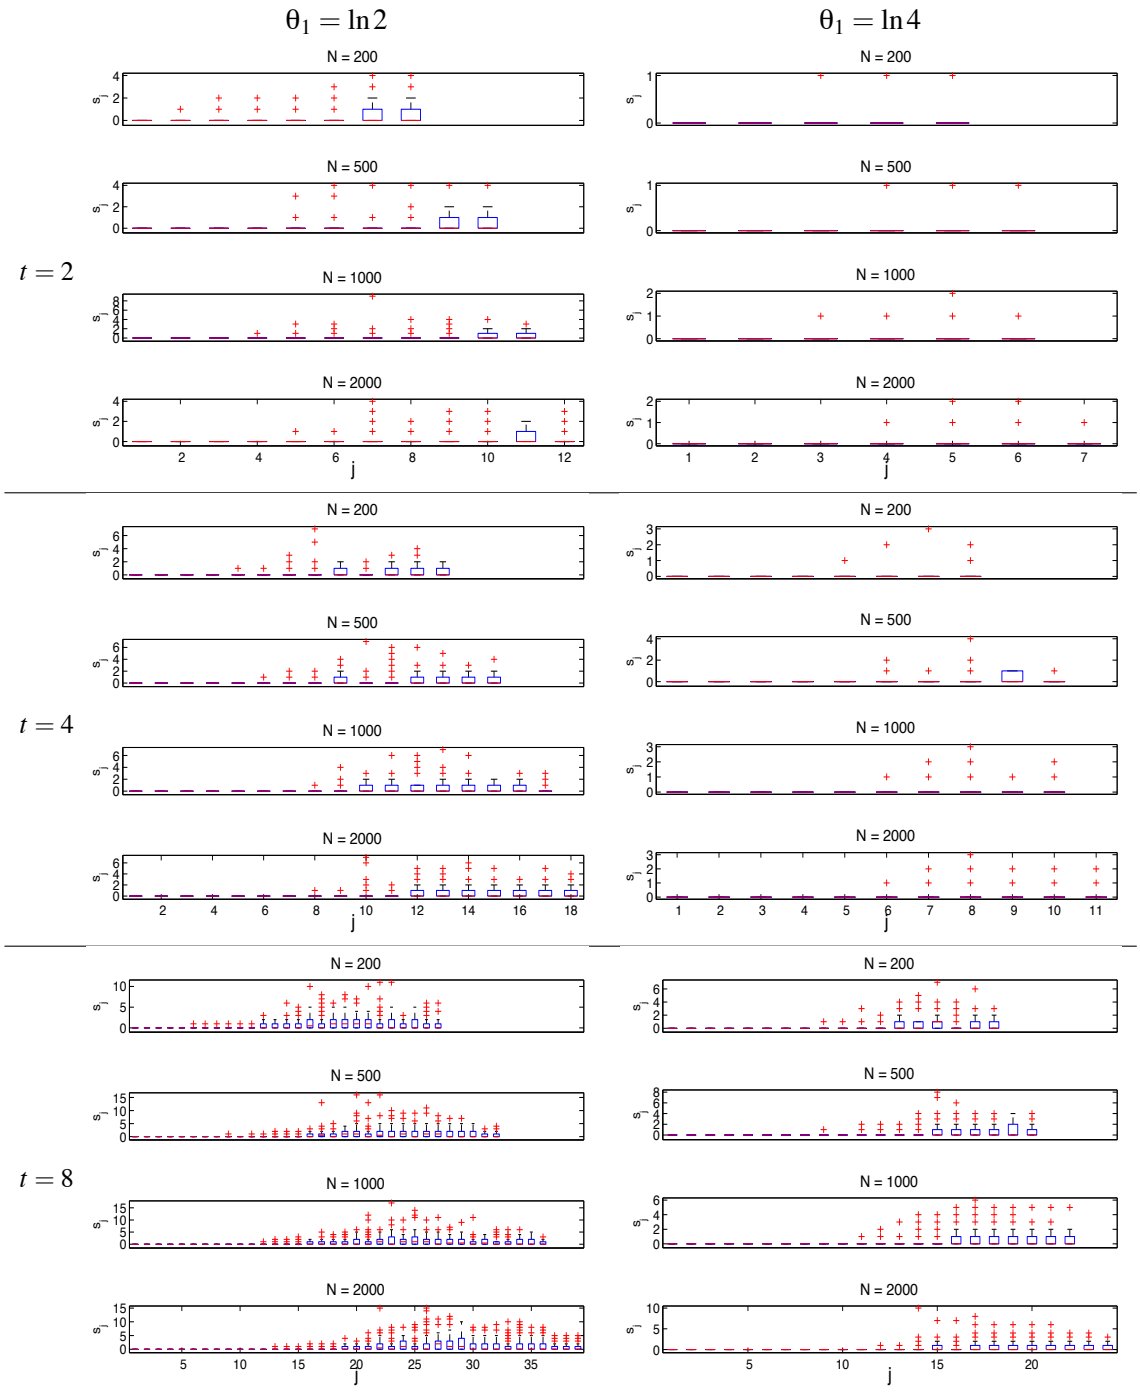

Figure 9: Ordering errors for $N = 200, 500, 1000, 2000$, different parameters θ_j , and $t = 2, 4, 8$. The error for a rank j is given by $s_j(\sigma^{ML}|\sigma^{true})$. Each box plot represents the distribution of s_j over 50 random samples.

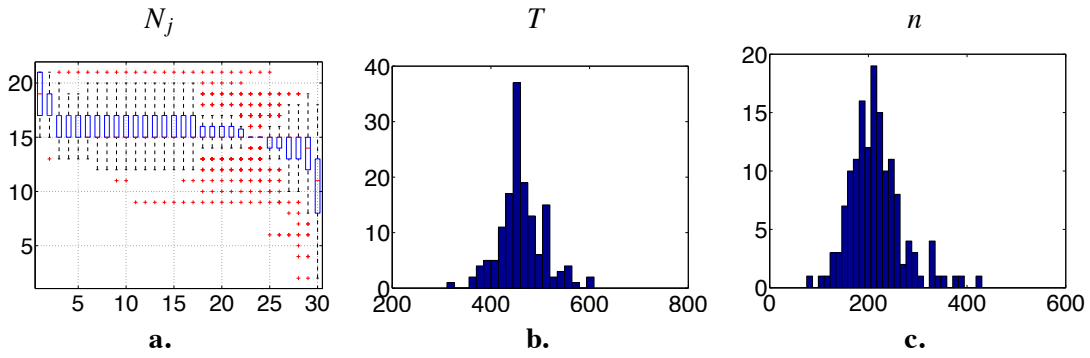

Figure 10: Summaries of the universities data: boxplots of the number of samples per rank, (a), histogram of total items observed T (b), histogram of the number n of distinct items observed (c), over all 147 queries.

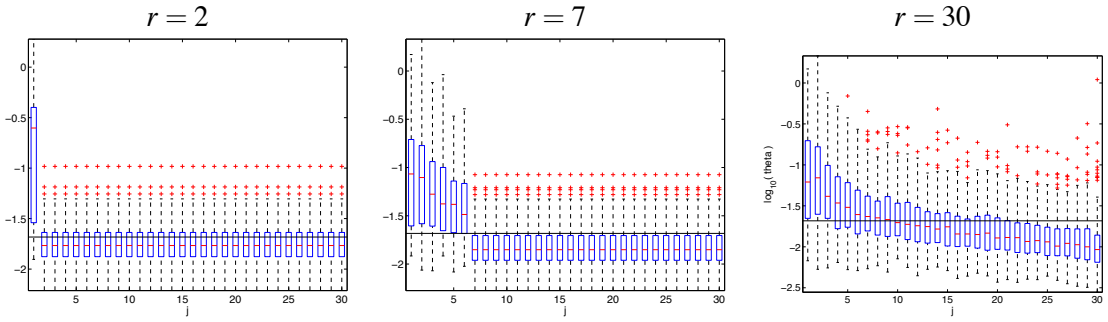

Figure 11: Boxplots of the Θ estimates over all queries for model with 2, 7, and 30 parameters. The vertical axis of the scale is *logarithmic, base 10*, that is, 0 corresponds to $\theta_j = 1$ and -2 to $\theta_j = 0.01$. For clarity, the distribution of the tied parameter (which is always the last parameter) is replicated for $j = r : t_{max}$. The horizontal line marks the mean value of θ in the single parameter model.

Model size	1	2	3	4	5	6	7	8	9	10	30	BIC
Mean rank (good)	5.3	5.7	4.2	4.2	**4.1**	**4.1**	4.4	4.5	5.0	5.2	5.1	5.5
Median rank (good)	3	3	**1.5**	2	2	2	2	2	2	3	3	3
Mean rank (all)	16.5	16.1	**15.4**	15.5	15.5	15.6	15.8	15.7	15.9	16.0	16.0	17.5
Median rank (all)	13	15	11	11	12	**9**	10	10	11	11	11	18

Table 2: Mean and median of the rank of the target web page under each model, and under the BIC selected model. These statistics are computed once over all 147 universities and once over a subset of 41 universities where the target is always ranked in the first 30; the subset is labeled as "good".

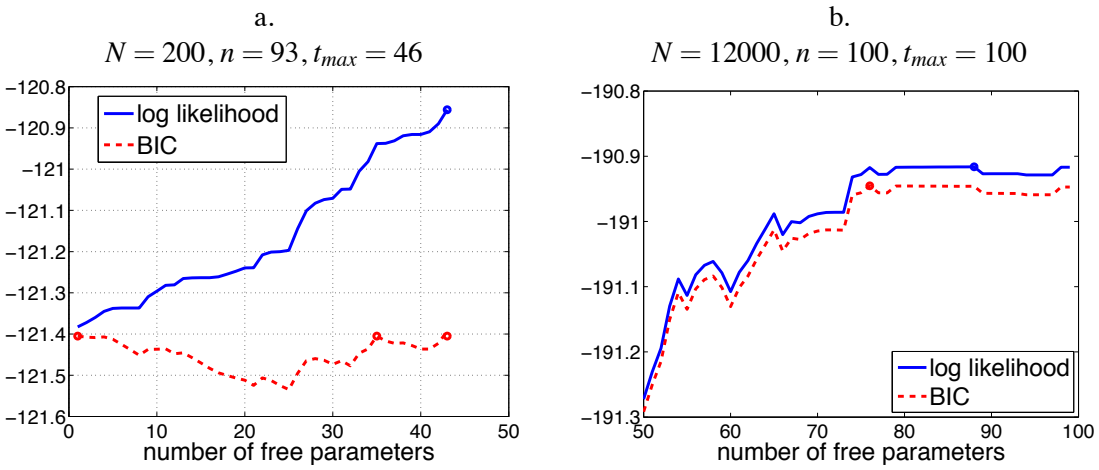

Figure 12: Log likelihood and BIC values per data point on two subsamples from the Jester data set. The circles mark the maxima of the log-likelihood, respectively BIC.

single parameter model, the full parameter model, and an intermediate model with $r = 36$. This is not so suprising as it may appear, since $N_j = N$ for $j \geq 36$, and the estimated θ_j values in this range are all very close to 0.1. Thus, the three models will effectively differ only in the way they model ranks $37 : 43$.

This finding suggests that the single parameter (infinite) Mallows model is a good model locally, in the space of the `jester` data. The large N experiment indicates otherwise, which agrees both with our common sense assumption that this data is multimodal, and with the finding of Mao and Lebanon (2008). In Mao and Lebanon (2008) a non-parametric Mallows model was used (more about this model in Section 7.3); our experiment supports their use of a single parameter model.

6.4 Clustering Experiments

The first experiment was with artificial data. We generated sample orderings with 3 clusters of 150 rankings each. Each cluster k was sampled from an Infinite GM model with a single spread parameters θ_k, with θ_1, θ_2, θ_3 equal to 1.5, 1.0, 0.7 respectively. The cluster centers are random permutations of infinitely many objects. In addition, each data set contains 50 outliers. In each data set all data had the same length t. We experimented with $t_\pi = 4, 6, 8$.

We ran the Exponential Blurring Mean-Shift, K-means, and EM Model-based clustering algorithms 10 times on samples from this distribution. For EBMS, the scale parameter was estimated based on the average of pairwise distances. In step 5c of the algorithm, the new ranking can be much longer than the original partial ranking. As seen above, the last ranks are subject to noise and overfitting. Therefore we truncated the new ranking to the length of number of observed items.

For the K-means and model-based algorithms, we experiment with different numbers of clusters, and report the best classification error with respect to the true clustering. This puts these two

algorithms at an advantage w.r.t EBMS, but as Table 3 shows, even so the nonparametric algorithm achieves the best performance.

Note that the error rate in Table 3 is computed including the outliers, that is, we compared a true clustering with 53 clusters (3 clusters and 50 singletons) to the clustering obtained when the algorithm converged.

For EM and K-means the number of clusters associated with the lowest classification errors was between 3 and 5. From the table we see that the K-means and model based approach identified three primary clusters correctly. K-means did not have the ability of identifying the outliers, so it just assigned each outlier into one of those primary clusters. The model-based approach assigned outliers into primary clusters too, but it also gave more uncertainty on the outliers (the probabilities of outliers belonging to their assigned cluster were relatively smaller than data from primary clusters).

The running time per data set of EBMS was under a minute, and the number of iterations to convergence followed the pattern typical of mean-shift algorithms and was never larger than 10.

Next, we examine data on college course preferences in the Republic of Ireland. Each prospective student applies by ranking up to 10 degree course in order of preference. Extensive details of the college applications system are available at `http://www.cao.ie`.

The data used in our analysis was previously studied by Gormley and Murphy (2006). They found that the geographical positions of the institution had a significant influence on choice of courses which complicated the interpretation of the vocational callings. Our analysis focuses on the subset of students who applied to Trinity College Dublin (TR) and University College Dublin (DN), both located in the capital of Ireland. These two universities offered $n = 228$ degree courses. There were 1095 female and 862 male applicants who only put TR and DN courses in their top-5 preferences. The EBMS algorithm is applied to top-5 rankings for the female and male applicants separately.

Table 4 shows these clustering results. For the female applicants the first cluster mostly consists of Art, Law and Business courses. Since the largest cluster contains about three quarters of the data, we run the EBMS clustering again for the applicants within this cluster and find four major subgroups in term of vocational callings: Law, Business, Drama, and English. The clustering results for male applicants show 5 clusters, plus a singleton. We run EBMS again for the largest cluster, and find three major sub-groups in term of vocational callings: Finance, Law, and History. As Gormley and Murphy (2006) discovered in their experiments, for the subset of Dublin applicants, there are differences between the clustering of females and males in the central permutations, but similarities too. The main similarity is that the grouping is vocational. Each group contains courses in both universities, with no strong preference for one versus the other. Second, a large proportion of both genders opt for business, economics and law disciplines. For the females, the Arts courses are also highly favored. As Gormley and Murphy (2006) explains, the Arts course is a broad liberal arts

Top-t rankings	EBMS	K-means	EM
$t = 4$	0.0030 (0.0001)	0.1014 (0.0038)	0.1008 (0.0025)
$t = 6$	0.0014 (0.0001)	0.0986 (0.0010)	0.1000 (0.0000)
$t = 8$	0.0002 (0.0001)	0.0972 (0.0010)	0.1000 (0.0000)

Table 3: Classification Errors: mean and standard deviation of 10 random samples.

course which can be followed with many different specializations later on. Hence, its high ranking in several clusters is an indication that female candidates want to leave more options open later. In general, the central rankings of each cluster are very clearly separating the pool of candidates into various profiles.

7. Discussion and Related Work

In this section, we discuss the relation between IGM and GM, other related models and algorithms, and draw the brief conclusion.

7.1 Relation to the GM Model

It is useful to compare the various aspects of the IGM presented here with the respective aspects of the standard GM. We do so now, highlighting also which of them were already published and which are new.

- s **representation.** This was introduced by Fligner and Verducci (1986) for the GM model. For finite number of items n, j ranges in $1:n-1$ and s_j in $0:n-j+1$.

- **marginal distributions, $P_{\theta,\sigma}$, over top-t orderings.** It is also introduced by Fligner and Verducci (1986). The main difference with the IGM model is in the normalization constant, which has the expression

$$\prod_{j=1}^{t}\psi_j(\theta_j) \quad \text{with} \quad \psi_j(\theta_j) = \frac{1-e^{-(n-j+1)\theta_j}}{1-e^{-\theta_j}}. \tag{21}$$

  Also, for the GM model, the underlying space $\mathcal{S}_n$ is finite, while for the IGM, $\mathcal{S}_{\mathbb{P}}$ is uncountable.

- **sufficient statistics as in Proposition 1.** Proposition 1 represents a new result for the GM as well. The only difference is in the replacement of $\psi(\theta_j)$ with $\psi_j(\theta_j)$ from (21) in (8). The

nearest previous result is that of Meilă et al. (2007) which establishes sufficient statistics for the GM model over complete permutations.

If we have a single parameter GM model and complete permutations, then it is easy to see that $\sum_j Q_j$ represents the sufficient statistics for σ alone. In computer science estimating σ in this context is called the *consensus ranking* problem, or the *minimum feedback arc set* problem. In this case, by setting $t = n$ for all permutations, the sufficient statistics defined in (8) reduce to the previously known $\sum_j Q_j$. Thus, our main contribution in this respect is to prove that not knowing θ, and not observing complete permutations still results in an exponential family model with sufficient statistics.

- θ **estimation.** In the GM case, this is a convex unidimensional optimization solved numerically (Fligner and Verducci, 1986; Meilă et al., 2007).

- σ **estimation by** SIGMA* The SIGMA* and ESTIMATESIGMATHETA algorithms can be used for the GM model as well, with the estimation of θ performed numerically. The closed form Equation (12) can serve as a very good initial point for the iterative optimization algorithm. Note that while the heuristics SORTR and GREEDYR are simple, they could not have been applied before to the GM model over top-t orderings because it was not known that this model has sufficient statistics for σ.

- **conjugate prior** Fligner and Verducci (1990) introduced an informative prior for θ, which had a single "sufficient statistics" parameter. They used it with a uniform prior over σ, noting that this prior cannot be normalized or integrated analytically. The informative conjugate prior for θ and σ introduced in Section 5 applies also to the standard GM. Again, the main formal change is replacing $\psi(\theta_j)$ by $\psi_j(\theta_j)$. With this change, we lose the elegant closed form integration over θ proved in Proposition 9. The GM conjugate prior will not be in general integrable in closed form over θ. The uninformative prior for the IGM becomes of course a proper prior in the GM case. If we set all the r_j parameters to the same value, we obtain exactly the same prior as Fligner and Verducci (1990).

  Often a non-informative prior is used as a regularizer for the ML estimator, turning it into a *Maximum A-Posteriori (MAP)* estimator. This is possible for the IGM and GM too. All one needs to do is to replace, in the inputs to the estimation algorithms, the data sufficient statistics with the posterior sufficient statistics.

- EBMS **clustering** The algorithm adapts seamlessly to finite number of items.

7.2 Other Models and Algorithms for Finite Permutations

This work acknowledges its roots in the work of Fligner and Verducci (1986) on stagewise ordering models and in the recent paper Meilă et al. (2007). The latter shows for the first time that GM models have sufficient statistics, and describes an exact but non-polynomial algorithm to find the central permutation. While similarities exist between the algorithm of Meilă et al. (2007) and the SIGMA* algorithm presented here, we stress that our representation (based on the inversion table $(s_j)_{j=1:t}$) is *different* from the representation (denoted V_j) in Meilă et al. (2007).

In fact, the two representations could be called reciprocal, as for any given complete permutation π, finite or infinite, $s_j(\pi|\mathrm{id}) = V_j(\pi^{-1}|\mathrm{id})$. This difference is trivial if complete permutations are

observed, but not for missing data. In particular, the distribution of V_j for top-t orderings does not seem to have sufficient statistics for $j > 2$ even in the case of finite permutations. The s_j representation has another advantage that V_j has not: for any finite data set, a parameter s_j is either completely determined or completely undetermined the data, whereas in the reciprocal V_j representation *all* V_j are weakly constrained by data.

While both our SIGMA* and the algorithm of Meilă et al. (2007) perform branch-and-bound search on a matrix of sufficient statistics, the sufficient statistics in this paper are derived by an entirely different method, and cannot be obtained by naively replacing the sufficient statistics of Meilă et al. (2007).

It may be noted that the cost $L_\sigma(R)$ bears a striking similarity to the cost function used by Quadrianto et al. (2010) in the context of matching by the method of kernelized sorting. The latter cost function can be expressed as $\operatorname{trace} K\Sigma^T L\Sigma$, to be minimized over Σ. The authors show that this problem is quadratic in the matrix Σ when K, L are symmetric, positive definite matrices and use a quadratic relaxation algorithm to optimize it efficiently. The cost $L_\sigma(R)$ can be rewritten as $\operatorname{trace} Q_0\Sigma^T R\Sigma$ where Q_0 is the upper triangular matrix defined in the proof of Proposition 2. The main difference between our cost function and the one of Quadrianto et al. (2010) is the fact that ours involves the non-symmetric matrices Q_0, R and is not a quadratic problem in Σ.

An interesting application of the GM model to multimodal data is Lebanon and Lafferty (2003), where the σ's play the role of the data, so the parameter estimation is done entirely differently. In an early work Critchlow (1985) examines several classes of (Haussdorf) distances for partial orderings. Murphy and Martin (2003) cluster ranking data by the EM algorithm and in Gormley and Murphy (2005, 2006) the EM is used for the purpose of analyzing Irish voting patterns and college applications. The base model used by the latter papers is is not the Mallows model but the Plackett-Luce model (Plackett, 1975; Luce, 1959). The estimation of this model from data is much more difficult and, as Gormley and Murphy (2005) show, can be only done approximately. Busse et al. (2007) use the s_j representation in the context of EM clustering of partial orderings, without however recognizing the existence of sufficient statistics.

A greedy algorithm for consensus ordering with partially observed data is introduced in Cohen et al. (1999). Meilă et al. (2007) show that their cost function optimized is closely related to the log-likelihood of the Mallows' model, using a modified form of the Q matrix defined in (10). This algorithm, like GREEDYR, does not estimate a θ parameter. Cohen et al. (1999) introduce a computational improvement based on interpreting a value $Q_{ii'} > 0.5$ as an arc from i to i'. They note that it is sufficient to search for the optimal permutation in each *strongly connected component* of the resulting directed graph, which can sometimes greatly reduce the dimension of the search space.

If a permutation π is not complete, Cohen et al. (1999) replaces the unobserved $Q_{ii'}(\pi)$ with the value 0.5. This ad-hoc procedure allows the GREEDYR to run on top-t rankings, but it is not statistically correct, since the optimized cost will not be a likelihood. If we use the correct matrix of sufficient statistics R, then the reduction procedure based on strongly connected components does not apply any more.

7.3 Other Models and Algorithms For Infinite Permutations

All the above works deal with permutations on finite sets. In fairness to Cohen et al. (1999) we remark that their work, although non-rigorous with respect to incomplete permutations, is motivated

by the same problem as ours, that is, dealing with a very large set of items, of which only some are ranked by the "voters".

The paper of Thoma (1964) studies the space of infinite permutations which differ from the identity in a finite number of positions. In the vocabulary of the present paper, these would be the infinite permutations at finite distance d_K from σ. In a single parameter infinite GM, these infinite permutations are the only ones which have non-zero probability. While from a probabilistic perspective the two views are equivalent, from a practical perspective they are not. We prefer to consider in our sample space all possibile orderings, including those with vanishing probability. It is the latter who are more representative of real experiments. For instance, in the university web sites ranking experiment, our model assumed that there is a "true" central permutation from which the observations were generated as random perturbations. This is already an idealization. But we also have the liberty to assume that the observations are very long orderings which are close to the central permutation only in their highest ranks, and which can diverge arbitrarily far from it in the latter ranks. We consider this a more faithful scenario than assuming in addition that the observation must be identical to the central permutation (and hence to each other!) on all but a finite number of ranks.

Recently Mao and Lebanon (2008) introduced a kernel density estimator and estimation algorithm, that elegantly allows partial orderings of a large variety of *types* to be modeled together. The kernel is the single parameter Mallows' model, with θ as kernel width. One of the interesting contributions of this paper is an algorithm for averaging the $d(\tilde{\pi}_1, \tilde{\pi}_2)$ over all (infinite) permutations $\tilde{\pi}_1, \tilde{\pi}_2$ compatible with given partial orderings π_1, π_2. The relation with EBMS is evident. It is also evident that within EBMS one could incorporate the average distance as calculated by Mao and Lebanon (2008) instead of the current set distance, with everything else staying the same. Since the average distance is always larger than the set (minimum) distance for top-t permutations, and in particular it is not 0, the optimal kernel width θ will have different values.

7.4 Conclusion

We have introduced a natural extension of stagewise ordering to the the case of infinitely many items. The new probabilistic model preserves the elegant properties of its finite counterpart: it has sufficient statistics, an exact estimation algorithm (albeit intractable in the worst case) and tractable heuristics that work well when the data come from a unimodal distribution. Sampling, distance computations, clustering extend to this class of models in a natural way.

We have paid particular attention to non-parametric clustering by mean-shift blurring, showing by experiments that the algorithm is practical and effective. This illustrates our view of the utility of the IGM model. The IGM, an exponential model with a simple, intuitive distribution, should be seen as a building block for more complex distributions, as needed by the data at hand. For instance, the extension to finite mixtures (that is, parametric clustering and multimodal distributions) is immediate. It is also an open problem to extend the kernel density estimator of Mao and Lebanon (2008) to infinite models and GM models with multiple parameters.

We are not aware of any statistical work on estimating parametric models over infinite orderings. There are also no previous results on sufficient statistics for finite partial orderings, so the present paper can be said be first in this respect as well.

One important advantage of having a model with multiple parameters, with n finite or infinite, is that each rank can be modeled by a separate parameter θ_j (the standard GM/IGM) or one can

tie the parameters of different ranks (the way we did in Section 6). This way, one can use larger θ_j values to penalize the errors in the first ranks more, and smaller θ_j values for the lower ranks, where presumably more noise in the orderings is permissible. This property of the model fits well with human perception of "distance" between orderings, or with the noise we may expect in human generated data.

Tying the parameters for the lower ranks is also important for reducing variance. If the observed data have different lengths t, then necessarily $N_j \geq N_{j'}$ for $j' > j$. In other words, for larger j's we may have less data available to estimate θ_j. Tying the parameters has the benefic effect of smoothing the θ_j values, as it was shown in all the experiments with real data. Another way to smooth the parameters is to use an uninformative prior as a regularizer. This way, too, each θ_j can be regularized separately by the hyperparameter r_j. This hyperparameter has a clear meaning—it is the expectation of s_j in the fictitious sample; therefore, a user can easily tune the strength of the prior using Equation (7) with r_j in place of ξ_j. This equation will give for any r_j a value θ_j^0 towards which the θ_j value will be shrunk. Shrinkage via the conjugate prior can be done for the finite GM as well, except that the relation (7) will be implicit instead of closed form.

Beyond its mathematical elegance and simplicity of use, we believe that an infinite model has practical importance as well. In many instances the number of items to rank is very large. Search engines come immediately to mind, understood as algorithms for retrieval by inexact matching from a large database. Under this umbrella fall not only the well-known web search engines, but also the various specialized algorithms for finding matches in biological data bases, like Sequest (Eng et al., 1994) and Blast (Altschul et al., 1990). These algorithms output ranked lists, from which the human user interprets only the top t entries. The data base, that is, the set of items, is usually not fixed; typically it is growing as more proteins, genes, web pages are discovered. It is natural under this scenario to assume that n is potentially infinite. As we have shown, this does not make working with the data more difficult, and occasionally makes it faster.

Acknowledgments

Thanks to Jon Wellner for bringing up the question of infinite permutations. This work was partially supported by NSF awards IIS-0313339 and IIS-0535100. A preliminary version of the IGM model was published as Meilă and Bao (2008).

Appendix A. Proofs

We give the proofs for the asymptotic results in the following subsection.

A.1 Proofs for the Asymptotic Results

Proof of Proposition 5 We start with the observation that under $P_{\mathrm{id},\theta}$ any observed top-t ranking π is a function of the variables $s_{1:t}$ who are independently distributed according to discrete exponential laws. For each s_j the empirical CDF converges to the true CDF and, as we know, this entails the fact that for any function f over $\mathbb{N}$, the sample expectation of f converges to the true expectation of f; see for example, van der Vaart (1998). This also holds for the joint distribution of $s_{1:t}$ and functions of $s_{1:t}$. In other words, the sample expectation of any function $f(\pi)$ is consistent, when π ranges over all top-t permutations.

Now consider $L_\sigma(R_j)$ for a fixed σ. By definition, $L_\sigma(R_j(\pi)) = s_j(\pi|\sigma)$ and $L_\sigma(\hat{R}_j)$ is the sample expectation of $s_j(\pi|\sigma)$. According to the definition of $s_j(\pi|\sigma)$ in (2), this is a function of $\pi^{-1}(1),\ldots\pi^{-1}(j)$ and the fixed σ. It follows by the argument above that $L_\sigma(\hat{R}_j)$ converges to $L_\sigma(R_j)$ for any j and any σ.

Note that for $\sigma = \mathrm{id}$ the argument is simpler, since $L(R_j) = s_j$. □

We now refer to a property of the Mallows model introduced by Fligner and Verducci (1988). An IGM $P_{\sigma,\theta}$ has *complete consensus* if for any two items i, i' with $i \prec_\sigma i$, we have that $P[i \prec_\pi i'] > P[i' \prec_\pi i]$. The following result is a modified form of Theorem 2 of Fligner and Verducci (1988) that applies to truncated infinite permutations.

Proposition 11 (Complete consensus) *The IGM model $P_{\sigma,\theta}$ with*

$$\theta_j \geq \theta_{j+1}, \tag{22}$$

has complete consensus. Moreover, condition (22) entails that for any fixed t, any $j = 1:t$, and any items i, i' with $\sigma(i) < \sigma(i')$

$$R_{ii',j} \;<\; R_{i'i,j}.$$

Proof Fix i, i' as above. Let π be a (complete) permutation where $i \prec_\pi i'$. Let us denote by π' the permutation obtained by transposing i and i' in π; denote $\pi(i) = k$, $\pi(i') = k'$, $k' > k$.

We want to show that under the condition of the proposition, $P_{\sigma,\theta}(\pi) \geq P_{\sigma,\theta}(\pi')$. We first observe that

$$s_j(\pi') = \begin{cases} s_j(\pi) & \text{for} \quad j < k \,\text{or}\, j > k' \\ s_j(\pi) + i' - i - r & \text{for} \quad j = k \,\text{and}\, r = |\{x \,|\, i < \sigma(x) < i', \pi(x) < k\}| \\ s_j(\pi) \,\text{or}\, s_j(\pi) + 1 & \text{for} \quad k < j < k' \\ s_j(\pi) - r' & \text{for} \quad j = k' \,\text{and}\, r' = |\{x \,|\, i < \sigma(x) < i', \pi(x) > k'\}| \end{cases}.$$

Note also that $r + r' \leq i' - i - 1$ or, in other words, $i' - i - r > r'$. Now, we look at the likelihood ratio $P_{\sigma,\theta}(\pi)/P_{\sigma,\theta}(\pi')$:

$$\begin{aligned} \ln[P_{\sigma,\theta}(\pi)/P_{\sigma,\theta}(\pi')] &= \sum_{j=k}^{k'} \theta_j [s_j(\pi') - s_j(\pi)], \\ &\geq \theta_k [s_k(\pi') - s_k(\pi)] + \theta_{k'} [s_{k'}(\pi') - s_{k'}(\pi)], \\ &= \theta_k (i' - i - r) - \theta_{k'} r', \\ &\geq \theta_k r' - \theta_{k'} r' \;=\; (\theta_k - \theta_{k'}) r' \;\geq\; 0. \end{aligned}$$

It follows that $P_{\sigma,\theta}(\pi) \geq P_{\sigma,\theta}(\pi')$. Moreover, if $\pi(i) = j, \pi(i') = j+1$ for some j then this inequality is strict. Now let $A = \{\pi \,|\, i \prec_\pi i'\}$ be the set of all permutations π as defined above; its complement B equals $\{\pi' \,|\, i' \prec_{\pi'} i\}$. It is immediate that from the above that $P_{\sigma,\theta}(A) = P_{\sigma,\theta}(i \prec i') > P_{\sigma,\theta}(B) = P_{\sigma,\theta}(i' \prec i)$, which proves the first claim of the proposition.

For the second claim, fix i, i' with $\sigma(i) < \sigma(i')$, a rank j and another rank $j' > j$. Take π such that $\pi(i) = j$ and $\pi(i') = j'$, and let π' be the permutation obtained by transposing i and i' in π. Then obviously $P_{\sigma,\theta}(\pi) > P_{\sigma,\theta}(\pi')$. $R_{ii',j}$, by definition, is the total probability of permutations of the form π with $j' = j+1, j+2, \ldots$, while $R_{i'i,j}$ is the total probability of permutations of the form π'. Therefore, $R_{ii',j} > R_{i'i,j}$. □

Proof of Proposition 5 From Proposition 11 it follows that if the true central permutation is the identity, then $L_{\mathrm{id}}(R_j) < L_\sigma(R_j)$ for any $\sigma \neq \mathrm{id}$. Let $\varepsilon = L_\sigma(R_j) - L_{\mathrm{id}}(R_j) > 0$. Then, because of the consistency of $L_\sigma(R_j)$ for any σ, it follows that $P_{\mathrm{id},\theta}[L_{\mathrm{id}}(\hat{R}_j) - L_\sigma(\hat{R}_j) > L_{\mathrm{id}}(R_j) - L_\sigma(R_j) + \varepsilon = 0] \to 0$. □

Proof of Proposition 6 This proof follows from the consistency of $L_\sigma(R_j)$. Since the ML estimate of θ_j is a continuous function of $L_\sigma(R_j)$ it will be consistent as well. Similarly, for the single parameter IGM, the ML estimate of θ is a continuous function of $(L_\sigma(R_j),\, j = 1:t)$, and therefore it is consistent as well. □

Proof of Proposition 10 Given the observed rankings $\{\pi_{1:N}\}$ and the hyperparameters ν, $\Lambda_{1:t}$ the marginal distribution of the central permutation σ can be expressed in terms of S_j^*:

$$P(S_j^* = k) \;\propto Beta(k+1, N+1+\nu) \;=\; \frac{\Gamma(k+1)\Gamma(N+1+\nu)}{\Gamma(k+N+2+\nu)} \;=\; f(k),$$

$$\frac{f(k+1)}{f(k)} \;=\; \frac{\Gamma(k+2)\Gamma(N+1+\nu)}{\Gamma(k+N+3+\nu)} \div \frac{\Gamma(k+1)\Gamma(N+1+\nu)}{\Gamma(k+N+2+\nu)} \;=\; \frac{k+1}{N+k+2+\nu},$$

$$f(k) \;=\; \frac{k!}{(N+2+\nu)\cdots(N+1+\nu+k)} \times f(0) \;=\; \frac{k!}{(N+1+\nu)\cdots(N+1+\nu+k)}.$$

We prove in Lemma 12 that $\sum_{k=0}^{\infty} f(k) = \frac{1}{(N+\nu)}$. Therefore, the normalization constant of $P(S_j^*)$ is $1/(N+\nu)$ and the conclusion of the Proposition follows. □

Lemma 12 $\sum_{k=0}^{\infty} \frac{k!}{(N+\nu+1)\cdots(N+\nu+1+k)} = \frac{1}{(N+\nu)}$.

Proof of Lemma 12 We write the general term of the series as a difference

$$\begin{aligned}
\frac{1}{N+\nu} - \frac{1}{(N+\nu+1)} &= \frac{1!}{(N+\nu)(N+\nu+1)}, \\
\frac{1!}{(N+\nu)(N+\nu+1)} - \frac{1!}{(N+\nu+1)(N+\nu+2)} &= \frac{2!}{(N+\nu)(N+\nu+1)(N+\nu+2)}, \\
&\vdots
\end{aligned}$$

Through mathematical induction we can prove that

$$\sum_{k=0}^{K} \frac{k!}{(N+\nu+1)\cdots(N+\nu+1+k)} + \frac{(K+1)!}{(N+\nu)(N+\nu+1)\cdots(N+K+\nu+1)} = \frac{1}{(N+\nu)}.$$

Moreover, for fixed N, ν,

$$\begin{aligned}
\frac{(K+1)!}{(N+\nu)(N+\nu+1)\cdots(N+K+\nu+1)} &= \frac{(K+1)!(N+\nu-1)!}{(N+K+\nu+1)!}, \\
&= \frac{(N+\nu-1)!}{(K+2)(K+3)\cdots(N+K+\nu+1)}, \\
&= O(k^{-(N+\nu)}).
\end{aligned}$$

From this the desired result follows. □

Abstract

We consider the estimation of regression coefficients in a high-dimensional linear model. For regression coefficients in ℓ_r balls, we provide lower bounds for the minimax ℓ_q risk and minimax quantiles of the ℓ_q loss for all design matrices. Under an ℓ_0 sparsity condition on a target coefficient vector, we sharpen and unify existing oracle inequalities for the Lasso and Dantzig selector. We derive oracle inequalities for target coefficient vectors with many small elements and smaller threshold levels than the universal threshold. These oracle inequalities provide sufficient conditions on the design matrix for the rate minimaxity of the Lasso and Dantzig selector for the ℓ_q risk and loss in ℓ_r balls, $0 \le r \le 1 \le q \le \infty$. By allowing $q = \infty$, our risk bounds imply the variable selection consistency of threshold Lasso and Dantzig selectors.

Keywords: variable selection, estimation, oracle inequality, minimax, linear regression, penalized least squares, linear programming

1. Introduction

As modern information technologies relentlessly generate voluminous and complex data, penalized high-dimensional regression methods have been a focus of intense research activities in machine learning and statistics in recent years. In many statistical and engineering applications, the number p of design variables (features, covariates) can be larger or even of larger order than the sample size n, but the number of important variables may still be smaller than the sample size. In such cases, one seeks a parsimonious model that fits the data well. In linear regression, a popular approach for achieving this goal is to impose a suitable penalty on the empirical loss.

This paper considers the estimation of a sparse vector of regression coefficients in a linear model. Specifically, we are interested in the rate minimaxity of the Lasso and Dantzig selector under the ℓ_q loss for the estimation of regression coefficients in ℓ_r balls. This requires lower bounds of the minimax ℓ_q risk and minimax quantiles of the ℓ_q loss over all estimators as well as matching upper bounds for the Lasso and Dantzig selector.

Let $y \in \mathbb{R}^n$ be a response vector and $X = (x_1, \ldots, x_p) \in \mathbb{R}^{n \times p}$ be a design matrix. The Lasso (Tibshirani, 1996) is the ℓ_1-penalized estimator

$$\widehat{\beta}^{(L)}(\lambda) = \arg\min_b \left\{ \|y - Xb\|^2/(2n) + \lambda \|b\|_1 \right\} \tag{1}$$

for the regression coefficients. In the signal processing literature, the Lasso is known as basis pursuit (Chen and Donoho, 1994). The Lasso has the interpretation as boosting (Freund and Schapire, 1996; Friedman, Hastie, and Tibshirani, 2000) and is computationally feasible for high-dimensional data (Osborne, Presnell, and Turlach, 2000a,b; Efron, Hastie, Johnstone, and Tibshirani, 2004). More recently, Candes and Tao (2007) proposed an ℓ_1-minimization method called the Dantzig selector,

$$\widehat{\beta}^{(D)}(\lambda) = \arg\min_b \left\{ \|b\|_1 : |x_j'(y - Xb)/n| \le \lambda, \forall j \right\}. \tag{2}$$

A focus of recent studies of high-dimensional linear regression has been on the performance of the Lasso and Dantzig selector for the estimation of the regression coefficients. Candes and Tao (2007) derived an elegant probabilistic upper bound for the ℓ_2 loss of the Dantzig selector under a condition on the number of nonzero coefficients and a uniform uncertainty principle on the Gram matrix. Efron, Hastie, and Tibshirani (2007) questioned whether a similar performance bound holds for the Lasso estimator as well. Upper bounds for the ℓ_q loss of the Lasso estimator has being studied by Bunea, Tsybakov, and Wegkamp (2007) and van de Geer (2008) for $q = 1$, Zhang and Huang (2008) for $q \in [1,2]$, Meinshausen and Yu (2009) for $q = 2$, Bickel, Ritov, and Tsybakov (2009) for $q \in [1,2]$ with a parallel analysis of the Dantzig selector, and Zhang (2009b) for $q \ge 1$. Under different sets of regularity conditions on the Gram matrix and the sparsity of regression coefficients $\beta \in \mathbb{R}^p$, these results provide error bounds of the form $\|\widehat{\beta} - \beta\|_q \le O(k^{1/q}\lambda)$, where k is the number of nonzero entries of a target vector of regression coefficients or an intrinsic dimensionality of the sparse estimation problem. For $N(0, \sigma^2)$ errors and standardized designs with $\|x_j\| = \sqrt{n}$, these studies require a universal penalty level $\lambda_{univ} = \sigma\sqrt{(2/n)\log p}$ or greater for the Dantzig selector and a penalty level λ greater by a constant factor than λ_{univ} for the Lasso. Different sets of regularity conditions lead to different forms of constant factors in the error bounds so that the existing error bounds are typically not directly comparable mathematically.

This paper contributes to high-dimensional regression in several ways. We provide lower bounds for the minimax ℓ_q risk in ℓ_r balls and the minimax quantiles of the ℓ_q loss for all designs X. We derive sufficient conditions on X for the Lasso and Dantzig selector to attain the rate of the minimax ℓ_q risk and the minimax quantiles of the ℓ_q loss. We provide oracle inequalities for the ℓ_q loss of the Lasso and Dantzig selector which sharpen, unify and extend the existing results and allow the penalty level λ to be of smaller order than the universal penalty level.

The rest of the paper is organized as follows. In Section 2, we describe lower bounds for the minimax risk and loss in ℓ_r balls. In Section 3, we provide oracle inequalities for the Lasso and Dantzig selector under the ℓ_0 sparsity of regression coefficients. We compare these oracle inequalities with existing ones and describe their implications in variable selection and rate minimaxity in ℓ_0 balls. In Section 4, we provide more general oracle inequalities to allow many small regression coefficients and penalty levels of smaller order than $\sigma\sqrt{(2/n)\log p}$. These oracle inequalities are used to establish the rate minimaxity for the ℓ_q loss in ℓ_r balls. In Section 5, we make a few remarks. An appendix contains all proofs.

We use the following notation throughout the paper. For vectors $v = (v_1, \ldots, v_p)'$, $\|v\|_0 = \#\{j : v_j \neq 0\}$ and $\|v\|_q = (\sum_j |v_j|^q)^{1/q}$ is the ℓ_q norm with the special $\|v\| = \|v\|_2$ and the usual extension to $q = \infty$. Functions are applied to vectors in individual components, $f(v) = (f(v_1), \ldots, f(v_p))'$. For matrices M and $0 \leq a, b \leq \infty$, $\|M\|_{a,b} = \max\{\|Mv\|_b : \|v\|_a = 1\}$ is the operator norm from ℓ_a to ℓ_b. For subsets A and B of $\{1, \ldots, p\}$, $X_A = (x_j, j \in A)$, $\Sigma_{A,B} = X_A' X_B / n$, $\Sigma_{A,*} = X_A' X / n$, $\Sigma_A = \Sigma_{A,A}$, and P_A is the projection from $\mathbb{R}^n$ to the linear span of $\{x_j : j \in A\}$. For real x, $x_+ = \max(x, 0)$, $1/x_+ = \infty$ for $x \leq 0$, and $\lceil x \rceil$ is the largest integer upper bound of x. For real numbers a_n and b_n, $a_n \approx b_n$ means $a_n = (1 + o(1))b_n$, $a_n \lessapprox b_n$ means $a_n \leq (1 + o(1))b_n$, and $a_n \lesssim b_n$ means $a_n = O(b_n)$. For simplicity, the dependence of estimators on the penalty level λ is suppressed unless otherwise stated.

2. Lower Bounds for the Estimation Risk and Loss

Consider the linear model

$$y = X\beta + \varepsilon = \sum_{j=1}^{p} \beta_j x_j + \varepsilon. \tag{3}$$

Throughout the sequel, $P_{\beta,X}$ is the probability measure given $\{\beta, X\}$ under which $\varepsilon \sim N(0, \sigma^2 I_n)$. For simplicity, we also assume $\|x_j\|^2 = n$ whenever $P_{\beta,X}$ is referred to. Define

$$\Theta_{r,R} = \{v \in \mathbb{R}^p : \|v\|_r \leq R\},\ r > 0, \quad \Theta_{0,k} = \{v \in \mathbb{R}^p : \|v\|_0 \leq k\}, \tag{4}$$

as the ℓ_r and ℓ_0 balls respectively. Let $\sigma_n = \sigma/\sqrt{n}$ and

$$\lambda_{univ} = \sigma_n \sqrt{2 \log p},\ \lambda_{mm} = \sigma_n \left\{ 2 \log \left(\frac{\sigma_n^r p}{R^r} \right) \right\}^{1/2},\ \lambda_{mm} = \sigma_n \sqrt{2 \log(p/k)}, \tag{5}$$

be respectively the universal (univ) penalty level (Donoho and Johnstone, 1994) and the minimax (mm) penalty levels for the ℓ_r and ℓ_0 balls. The dependence of λ_{mm} on $\{r, R\}$ or $\{0, k\}$ is suppressed since λ_{mm} is always used in association with a specific ball in (4).

Donoho and Johnstone (1994) proved that for $0 < r < q$ and based on a p-vector $\widetilde{y} \sim N(\beta, \sigma_n^2 I_p)$, the minimax ℓ_q risk in the ℓ_r ball $\Theta_{r,R}$ is approximately

$$\inf_{\delta} \sup_{\beta \in \Theta_{r,R}} E_{\beta,X} \left\| \delta(\widetilde{y}) - \beta \right\|_q^q = (1 + o(1)) R^r \lambda_{mm}^{q-r}$$

and is achieved within an infinitesimal fraction by threshold estimators at the threshold level λ_{mm}, provided that $\lambda_{mm}/\sigma_n \to \infty$ and $R^r/\lambda_{mm}^r \to \infty$. Here the infimum is taken over all Borel mappings δ of proper dimensions. The following theorem extends their result to the estimation of regression coefficients under $P_{\beta,X}$. For any class of vectors $\Theta \subset \mathbb{R}^p$, the minimax ℓ_q risk is $\mathscr{R}_q(\Theta; X) = \inf_\delta \sup_{\beta \in \Theta} E_{\beta,X} \|\delta(X, y) - \beta\|_q^q$.

Theorem 1 *Let $\Theta_{r,R}$ and $\Theta_{0,k}$ be as in (4) and λ_{mm} as in (5) with $R > 0$ and $q \geq r > 0$. Suppose $R^r/\lambda_{mm}^r \to \infty$, $k \to \infty$ and $\lambda_{mm}/\sigma_n \to \infty$. Then,*

$$\frac{\mathscr{R}_q(\Theta_{r,R}; X)}{R^r \lambda_{mm}^{q-r}} \geq (1 + o(1)), \quad \frac{\mathscr{R}_q(\Theta_{0,k}; X)}{k \lambda_{mm}^q} \geq (1 + o(1)). \tag{6}$$

Moreover, for either $\Theta = \Theta_{r,R}$ with $k = R^r/\lambda_{mm}^r$ or $\Theta = \Theta_{0,k}$,

$$\inf_X \inf_\delta \sup_{\beta \in \Theta} P_{\beta,X} \left\{ \|\delta(X, y) - \beta\|_q^q \geq (1 - \varepsilon) k \lambda_{mm}^q \right\} \geq \frac{\varepsilon + o(1)}{3^q},\ 0 < \varepsilon < 1. \tag{7}$$

Remark 2 *The value k in (7) can be viewed as an intrinsic lower bound for the number of parameters to be estimated for the minimaxity under the ℓ_q loss. By (5), $\lambda_{mm} \le \lambda_{univ}$ iff $R \ge \sigma_n$ for $r > 0$. For $\lambda_{univ} \asymp \lambda_{mm}$ and respectively for $r = 0$ and $0 < r \le 1$, Corollary 4 in Section 3.1 and Theorem 17 in Section 4.2 provide conditions on X for the Lasso and Dantzig selector to match the rate of the minimax lower bound $k\lambda_{mm}^q$ in (7). For $\lambda_{mm} \ll \lambda_{univ}$, Theorem 19 in Section 4.2 gives the rate minimaxity of the Lasso.*

During the revision of this paper, we became aware of the technical report of Raskutti, Wainwright, and Yu (2009). The lower bounds in Theorem 1 are identical for all design matrices X and thus are sharp only up to a constant factor under certain conditions on X. For example, the minimax risk in a parameter class $\Theta \ni 0$ is no smaller than the radius of the null set $\Theta \cap \{b : Xb = 0\}$. This and some other aspect of the design matrix have been used to derive sharper lower bounds in Raskutti, Wainwright, and Yu (2009). In our technical report (Ye and Zhang, 2009) and in Zhang (2009a), Theorem 1 only covers the case $r > 0$.

3. Oracle Inequalities under ℓ_0 Sparsity and Variable Selection

We discuss in three subsections oracle inequalities for the ℓ_q loss, related work, and variable selection. We focus on coefficient vectors with a relatively small number of nonzero entries here. The more complicated ℓ_r-sparse case will be considered in Section 4.

3.1 Oracle Inequalities and Rate Minimaxity under ℓ_0 Sparsity

For $\xi \ge 0$ and $J \subset \{1, \ldots, p\}$, define cone invertibility factors (CIF)

$$CIF_{q,\ell}(\xi, J) = \inf\Big\{ \frac{|J|^{1/q}\|\Sigma u\|_\infty}{\|u_A\|_q} : u \in \mathscr{C}(\xi, J), |A \setminus J| \le \ell \Big\} \tag{8}$$

with cones $\mathscr{C}(\xi, J) = \{u : \|u_{J^c}\|_1 \le \xi \|u_J\|_1 \ne 0\}$. Note that $CIF_{q,\ell}(\xi, J) = CIF_{q,p-|J|}(\xi, J)$ for $\ell \ge p - |J|$ and since the infimum is attained when u_A takes the ℓ largest elements of u outside J, $CIF_{q,\ell}(\xi, J)$ is decreasing in ℓ. Similarly, define sign-restricted cone invertibility factors (SCIF)

$$SCIF_{q,\ell}(\xi, J) = \inf\Big\{ \frac{|J|^{1/q}\|\Sigma u\|_\infty}{\|u_A\|_q} : u \in \mathscr{C}_-(\xi, J), |A \setminus J| \le \ell \Big\}. \tag{9}$$

with sign-restricted cones $\mathscr{C}_-(\xi, J) = \{u \in \mathscr{C}(\xi, J) : u_j \Sigma_{j,*} u \le 0 \ \forall j \notin J\}$. We first present oracle inequalities in terms of the (sign-restricted) CIF.

Theorem 3 *Let $\widehat{\beta}^{(D)}$ and $\widehat{\beta}^{(L)}$ be the Lasso and Dantzig selector in (1) and (2), $1 \le q \le \infty$, $\beta^* \in \mathbb{R}^p$, $J = \{j : \beta_j^* \ne 0\}$ and $z_\infty^* = \|X'(y - X\beta^*)/n\|_\infty$.*
(i) Let $CIF_{q,\ell}(1, J)$ and $SCIF_{q,\ell}(\xi, J)$ be as in (8) and (9). In the event $z_\infty^* \le \lambda$,

$$\|\widehat{\beta}^{(D)} - \beta^*\|_q \le \frac{|J|^{1/q}(\lambda + z_\infty^*)}{CIF_{q,p}(1, J)} \le \frac{2|J|^{1/q}\lambda}{CIF_{q,p}(1, J)}, \tag{10}$$

and in the event $z_\infty^* \le \lambda(\xi - 1)/(\xi + 1)$

$$\|\widehat{\beta}^{(L)} - \beta^*\|_q \le \frac{|J|^{1/q}(\lambda + z_\infty^*)}{SCIF_{q,p}(\xi, J)} \le \frac{\{2\xi/(\xi + 1)\}|J|^{1/q}\lambda}{SCIF_{q,p}(\xi, J)}. \tag{11}$$

(ii) For $\lambda = \sigma\sqrt{(2/n)\log(p/\varepsilon)}$ *and* $\lambda = \sigma\sqrt{(2/n)\log(p/\varepsilon)}(\xi+1)/(\xi-1)$ *respectively, (10) and (11) hold with* $\beta^* = \beta$ *and at least probability* $1-\varepsilon/\sqrt{\pi\log(p/\varepsilon)}$ *under* $P_{\beta,X}$.

Theorem 3 immediately provides a sufficient condition on the design X for the rate minimaxity of the Lasso and Dantzig selector in the quantiles of the ℓ_q loss in ℓ_0 balls, in the sense of (7) of Theorem 1. We state this result as the following corollary. Define

$$CIF_q^*(\xi,k) = \inf\Big\{k^{1/q}\|\Sigma u\|_\infty/\|u\|_q : 0 < \|u\|_1 \le (1+\xi)\max_{|J|=k}\|u_J\|_1\Big\}. \tag{12}$$

Corollary 4 *Suppose* $k\wedge(p/k)\to\infty$ *for certain* $(p,k) = (p_n,k_n)$.
(i) Suppose $M_{q,k}^{(D)} = 2\sqrt{\log p}/\{\sqrt{\log(p/k)}CIF_q^*(1,k)\} \le M_* < \infty$. *Then, the Dantzig selector* $\widehat\beta = \widehat\beta^{(D)}$ *with* $\lambda = \lambda_{univ}$ *in (5) is rate minimax in the sense of*

$$\sup_{\beta\in\Theta_{0,k}} P_{\beta,X}\big\{\|\widehat\beta-\beta\|_q \ge M_* k^{1/q}\lambda_{mm}\big\} \to 0. \tag{13}$$

(ii) Suppose $M_{q,k,\xi}^{(L)} = \max_{|J|\le k} 2\{\xi/(\xi-1)\}\sqrt{\log p}/\{\sqrt{\log(p/k)}SCIF_{q,p}(\xi,J)\} \le M_* < \infty$. *Then, (13) holds for the Lasso* $\widehat\beta = \widehat\beta^{(L)}$ *with* $\lambda = \lambda_{univ}(\xi+1)/(\xi-1)$.

The proof of Theorem 3 is simple since the (sign-restricted) CIF are exactly what we need. Let $h^{(D)} = \beta^{(D)}(\lambda)-\beta^*$, $h^{(L)} = \beta^{(L)}(\lambda)-\beta^*$ and $h = h^{(D)}$ or $h^{(L)}$ throughout the sequel. It follows from the feasibility of β^* for the constraint in (2) and the Karush-Kuhn-Tucker conditions for the Lasso (1) respectively that for $z_\infty^* \le \lambda$,

$$h^{(D)} \in \mathscr{C}(1,J),\ v'\Sigma h^{(L)} \le (z_\infty^*+\lambda)\|v_J\|_1 + (z_\infty^*-\lambda)\|v_{J^c}\|_1, \tag{14}$$

for all vectors v satisfying $\mathrm{sgn}(v_{J^c}) = \mathrm{sgn}(h^{(L)}_{J^c})$. With $v = h^{(L)}$ or $v_J = 0$ in (14), it follows that $h^{(L)} \in \mathscr{C}_-(\xi,J)$ for $\xi \ge (\lambda+z_\infty^*)/(\lambda-z_\infty^*)$. Theorem 3 then follows from

$$\|\Sigma h\|_\infty \le z_\infty^* + \lambda. \tag{15}$$

The lower bounds for the (sign-restricted) CIF in the following proposition facilitate more explicit results and connections to existing approaches. For given $\{J,\ell\}$ define

$$\phi_{q,\ell}(u,A,r,w,B;\xi,J) = 1 - \xi|J|^{1-1/q}(a_r/\ell)^{1-1/r}\|\Sigma_{B,A}w_A\|_{r/(r-1)} \tag{16}$$

in the following domain: $u\in\mathscr{C}(\xi,J)$, $A = \arg\max_{|B\setminus J|\le\ell}\|u_B\|_1$ (determined by u up to ties), $r\ge 1$, $w_A'\Sigma_A u_A = \|u_A\|_q$, $B\cap A = \emptyset$, $|B| = \lceil \ell/a_r\rceil$ and $a_r = (1-1/r)/r^{1/(r-1)}$.

Proposition 5 *Let* $\{\xi,q,r\}\subset[1,\infty]$, $1\le s\le q$ *and* $0<\ell\le p-|J|$. *Then,*

$$\max\Big\{\frac{CIF_{q,\ell}(\xi,J)}{CIF_{s,p}(\xi,J)}, \frac{SCIF_{q,\ell}(\xi,J)}{SCIF_{s,p}(\xi,J)}\Big\} \le C_{s,q}(\xi,|J|/\ell), \tag{17}$$

where $C_{s,q}(\xi,t) = (1+\xi)^{(1/s-1/q)/(1-1/q)}\{1+\xi^q(a_q t)^{q-1}\}^{(1-1/s)/(q-1)}$;

$$CIF_{q,\ell}(\xi,J) = \inf_{u\in\mathscr{C}(\xi,J)}\inf_{|A\setminus J|=\ell}\sup_{v\ne0}\frac{|J|^{1/q}v'\Sigma u}{\|v\|_1\|u_A\|_q} \ge \phi_{q,\ell}^*(\xi,J), \tag{18}$$

where $\phi^*_{q,\ell}(\xi,J) = \min_{u,A}\max_{r,w}\min_B \phi_{q,\ell}(u,A,r,w,B;\xi,J)|J|^{1/q}/\|w_A\|_1$*; and*

$$SCIF_{q,\ell}(\xi,J) \geq \inf_{u\in\mathscr{C}_-(\xi,J)}\inf_{|A\setminus J|=\ell}\sup_{v\in\mathscr{Q}(u,J)}\frac{|J|^{1/q}v'\Sigma u}{\|v_J\|_1\|u_A\|_q} \geq \phi^{**}_{q,\ell}(\xi,J), \tag{19}$$

where $\phi^{**}_{q,\ell}(\xi,J) = \min_{u,A}\max_{r,w}\min_B \phi_{q,\ell}(u,A,r,w,B;\xi,J)|J|^{1/q}/\|w_J\|_1$ *with* $\mathscr{Q}(u,J) = \{v : sgn(v_{J^c}) = sgn(u_{J^c})\}$ *and vectors* $u \in \mathscr{C}_-(\xi,J)$ *and* $w \in \mathscr{Q}(u,J)$.

Remark 6 *Taking* $w = u\|u_A\|/(u_A'\Sigma_A u_A)$ *in (16) for the* ℓ_2 *loss, we find*

$$\begin{aligned}\widetilde{\phi}^*_{2,\ell}(\xi,J) &= \min_{u,A}\max_r\min_B\big\{u_A'\Sigma_A u_A - \xi|J|^{1/2}(a_r/\ell)^{1-1/r}\|\Sigma_{B,A}u_A\|_{r/(r-1)}\big\},\\ &\leq \min\big\{\phi^{**}_{2,\ell}(\xi,J), \{(1+\ell/|J|)^{1/2}\wedge(1+\xi)\}\phi^*_{2,\ell}(\xi,J)\big\}\end{aligned} \tag{20}$$

with $\|u_A\| = 1$ *and* $\{A,r,B\}$ *in (16), due to* $\|u_A\|_1 \leq \{(1+\ell/|J|)^{1/2}\wedge(1+\xi)\}|J|^{1/2}$ *and* $\|w_J\|_1 \leq |J|^{1/2}/(u_A'\Sigma_A u_A)$*. However, for* $q > 2$*,* $w \propto u$ *in (16) does not lead to a right normalization since* $\|u_A\|/|A|^{1/2}$ *does not control* $\|u_A\|_q/|A|^{1/q}$*. For general* $q \in [1,\infty]$*,* $\|\Sigma_A w_A\|_{q/(q-1)} = w_A'\Sigma_A u_A/\|u_A\|_q = 1$ *gives a properly length normalized lower bound:*

$$\phi^*_{q,\ell}(\xi,J) \geq \min_{A,B}\big\{1-\xi|J|^{1-1/q}(a_r/\ell)^{1-1/r}\|\Sigma_A^{-1}\Sigma_{A,B}\|_{r,q}\big\}|J|^{1/q}/\|\Sigma_A^{-1}\|_{\infty,q}. \tag{21}$$

For $(|A|,|B|,\|u\|,\|v\|_r) = (\lceil a\rceil,\lceil b\rceil,1,1)$ with $A\cap B = \emptyset$, define

$$\delta_a^{\pm} = \max_{A,u}\Big\{\pm\Big(\|\Sigma_A u\| - 1\Big)\Big\},\ \delta_a = \delta_a^+\vee\delta_a^-,\ \theta^{(r)}_{a,b} = \max_{A,B,u,v} v'\Sigma_{A,B}u. \tag{22}$$

Oracle inequalities for the ℓ_q loss, $1\leq q\leq 2$, have been given in terms of the quantities in (22). The quantities $1\pm\delta_a^{\pm}$ give the maximum and minimum sparse eigenvalues of the Gram matrix Σ up to dimension $\lceil a\rceil$. For $\|u_A\| = 1$, we have $u_A'\Sigma_A u_A \geq 1-\delta^-_{|A|}$, $\|\Sigma_{B,A}u_A\|_{r/(r-1)} \leq \theta^{(r)}_{|B|,|A|}$ and $\|\Sigma_{B,A}u_A\|^2 \leq (1+\delta^+_{|B|})u_A'\Sigma_A u_A$. Thus, Theorem 3, (17) with $C_{q,2}(\xi,k/\ell) = (1+\xi)^{2/q-1}\{1+\xi^2 k/(4\ell)\}^{1-1/q}$, and (20) with $r\in\{2,\infty\}$ yield the following corollary.

Corollary 7 *Let* $\|\beta^*\|_0 = |J| = k$ *and* $1\leq q\leq 2$*. Then, for* $z^*_\infty = \|X'(y-X\beta^*)/n\|_\infty \leq \lambda$*,*

$$\|\widehat{\beta}^{(D)}(\lambda)-\beta^*\|_q \leq \frac{2|J|^{1/q}\lambda}{CIF_{q,p}(1,J)} \leq \frac{2^{2/q}(1+k/(4\ell))^{1-1/q}(2\wedge\sqrt{1+\ell/k})k^{1/q}\lambda}{(1-\delta^-_{k+\ell})_+\{1-\min(\widetilde{F}_1,\widetilde{F}_2,\widetilde{F}_3)\}_+}, \tag{23}$$

where $1\leq\ell\leq p-k$*,* $\widetilde{F}_1 = (k^{1/2}/\ell)\theta^{(\infty)}_{\ell,k+\ell}/(1-\delta^-_{k+\ell})_+$*,* $\widetilde{F}_2 = \sqrt{k/(4\ell)}\,\theta^{(2)}_{4\ell,k+\ell}/(1-\delta^-_{k+\ell})_+$ *and* $\widetilde{F}_3 = \{(k/(4\ell))(1+\delta^+_{4\ell})/(1-\delta^-_{k+\ell})_+\}^{1/2}$*. Moreover, for* $z^*_\infty \leq \lambda(\xi-1)/(\xi+1)$*,*

$$\|\widehat{\beta}^{(L)}(\lambda)-\beta^*\|_q \leq \frac{\{2\xi/(\xi+1)\}|J|^{1/q}\lambda}{SCIF_{q,p}(\xi,J)} \leq \frac{(1+\xi)^{2/q-2}(1+\xi^2 k/(4\ell))^{1-1/q}2\xi k^{1/q}\lambda}{(1-\delta^-_{k+\ell})_+\{1-\xi\min(\widetilde{F}_1,\widetilde{F}_2,\widetilde{F}_3)\}_+}. \tag{24}$$

3.2 Related Work

Here we discuss the connections between the results in Section 3.1 and related work. We show that the (sign-restricted) CIF-based oracle inequalities in Theorem 3 and Corollary 7 sharpen, unify and extend existing performance bounds and offer a clear explanation of the differences among existing analyses.

The CIF and SCIF in (8) and (9) are related to the restricted eigenvalues (RE)

$$RE_{q,\ell}(\xi,J) = \inf\Big\{ \frac{|J|^{1/q}\|Xu\|}{|nJ|^{1/2}\|u_A\|_q} : u \in \mathscr{C}(\xi,J), |A \setminus J| \le \ell \Big\}, \tag{25}$$

since they all conveniently provide factors required in proofs of the same type of oracle inequalities. The quantity (25) includes as special cases the ℓ_2 version $RE_{2,p}(\xi,J)$ of Bickel, Ritov, and Tsybakov (2009) and Koltchinskii (2009) and the constant factor $RE_{1,0}(3,J)$ for the compatibility condition of van de Geer (2007). van de Geer and Bühlmann (2009) called $RE_{1,0}(\xi,J)$ the restricted ℓ_1-eigenvalue.

Both types of quantities in (8), (9) and (25) involve minimum ratios of seminorms over cones. The main differences between them are the quantities used to bound the estimation error and the sign-restriction for $SCIF_{q,\ell}(\xi,J)$. Let $\{h^{(L)}, h^{(D)}, h\}$ be as in (14) and (15). While the RE in (25) uses the prediction regret $h'\Sigma h$ to bound the estimation error h, the (sign-restricted) CIF in (8) and (9) uses the ℓ_∞ norm of the gradient to bound the estimation error via (15). The use of the gradient bound in (8) and (9) provides sharper oracle inequalities by allowing the flexibility with the choice of v in (18) and (19).

For the ℓ_2 loss of the Dantzig selector, the oracle inequality of Bickel, Ritov, and Tsybakov (2009) and Theorem 3 can be compared as follows: for $z^* \le \lambda$

$$\|h^{(D)}\| \le \frac{2|J|^{1/2}\lambda}{CIF_{2,p}(1,J)} \le \frac{4|J|^{1/2}\lambda}{RE_{1,0}(1,J)RE_{2,p}(1,J)} \le \frac{4(1+\sqrt{|J|/\ell})|J|^{1/2}\lambda}{RE^2_{2,\ell}(1,J)}. \tag{26}$$

The right-hand side of (26) is the upper bound in (7.6) of Theorem 7.1 of Bickel, Ritov, and Tsybakov (2009). An application of the upper bound of van de Geer and Bühlmann (2009) on $\|h^{(D)}_J\|_1$ in a modification of the proof of Bickel, Ritov, and Tsybakov (2009) yields the intermediate upper bound. Theorem 3 provides the sharpest upper bound in (26). The second inequality in (26) follows from (18) with $\{\ell, v\} = \{p-|J|, u\}$. The third inequality in (26) follows from $RE_{1,0}(\xi,J) \ge RE_{2,\ell}(\xi,J)$ as in van de Geer and Bühlmann (2009) and $(1+\xi|J|/\ell)^{1/2}RE_{2,p}(\xi,J) \ge RE_{2,\ell}(\xi,J)$ by the shifting inequality in Candes and Tao (2007). The shifting inequality of Cai, Wang, and Xu (2010) can be used to reduce the factor $(1+\sqrt{|J|/\ell})$ to $\sqrt{1+|J|/(4\ell)}$ in (26), but (26) still holds. Similarly, for $z^* \le \lambda/2$,

$$\|h^{(L)}\| \le \frac{(3/2)|J|^{1/2}\lambda}{SCIF_{2,p}(3,J)} \le \frac{(3/2)|J|^{1/2}\lambda}{RE_{1,0}(3,J)RE_{2,p}(3,J)} \le \frac{4(1+3\sqrt{|J|/\ell})|J|^{1/2}\lambda}{RE^2_{2,\ell}(3,J)}, \tag{27}$$

with (7.10) of Theorem 7.2 of Bickel, Ritov, and Tsybakov (2009) on the right-hand side. The differences of the upper bounds in (26) and (27) could be nontrivial since van de Geer and Bühlmann (2009) showed by example the possibility of $RE_{2,0}(\xi,J)/RE_{1,0}(\xi,J) \to 0$.

A significant difference between the (sign-restricted) CIF- and RE- based oracle inequalities is their relationships to the oracle inequalities of Candes and Tao (2007) and Zhang (2009b). While

Theorem 3 is sharper than these inequalities, the RE-based oracle inequalities seem not to have this property.

The flexibility with the choice of v in (18) and (19) is a significant advantage for (8) and (9). The square of the potentially small $(\|\Sigma_A^{1/2}u_A\| - \|\Sigma_{A^c}^{1/2}u_{A^c}\|)_+$ has been used to bound $u'\Sigma u = \|Xu\|^2/n$ from below in the proofs of RE-based oracle inequalities. This is not needed in Candes and Tao (2007) and Zhang (2009b) since their arguments correspond to using vectors v with $v_{A^c} = 0$ in (18) and (19). For example, (23) with $\widetilde{F}_3$ is at least by a factor $\{1 - \min(\widetilde{F}_1, \widetilde{F}_2, \widetilde{F}_3)\}_+$ sharper than inserting Lemma 4.1 (ii) into (7.6) in Bickel, Ritov, and Tsybakov (2009), even after an application of sharper shifting inequalities to their Lemma 4.1 (ii). For $q > 2$, the ratio in (18) is not properly length normalized with $v = u$, as discussed in Remark 6. Thus, direct extensions of (25) with $u'\Sigma u$ in the numerator may not yield performance bounds of the right order.

Corollary 7 sharpens the oracle inequality of Candes and Tao (2007). The upper bound (23) with $\widetilde{F}_1$ is of the sharpest form among the three for large ℓ due to the factor $1/\ell$, compared with $\sqrt{1/(4\ell)}$ for $\widetilde{F}_2$ and $\widetilde{F}_3$. For $\ell = k/4$ and $q = 2$, (23) with $\widetilde{F}_2$ yields

$$z^* \le \lambda \;\Rightarrow\; \|\widehat{\beta}^{(D)}(\lambda) - \beta^*\| \le \frac{2\sqrt{k}\lambda}{CIF_{2,p}(1,J)} \le \frac{\sqrt{10k}\lambda}{(1 - \delta^-_{1.25k} - \theta^{(2)}_{k,1.25k})_+}, \tag{28}$$

a slightly sharper version of Cai, Wang, and Xu (2010) improvement of Candes and Tao (2007) result due to $\delta^-_{1.25k} \le \delta_{1.25k}$. Similarly, (24) with $\xi = \sqrt{2}$ and $\ell = k/2$ yields

$$z^* \le \lambda \;\Rightarrow\; \|\widehat{\beta}^{(L)}\big((1+\sqrt{2})^2\lambda\big) - \beta^*\| \le \frac{(1+\sqrt{2})\sqrt{8k}\lambda}{SCIF_{2,p}(\sqrt{2},J)} \le \frac{(1+\sqrt{2})4\sqrt{k}\lambda}{(1 - \delta^-_{1.5k} - \theta^{(2)}_{2k,1.5k})_+}. \tag{29}$$

The right-hand sides of (28) and (29) are directly comparable with the Candes and Tao (2007) inequality $\|\widehat{\beta}^{(D)}(\lambda) - \beta^*\| \le 4\sqrt{k}\lambda/(1 - \delta_{2k} - \theta^{(2)}_{k,2k})_+$ in the same event.

Another option is to apply (17), (18) and (21) with $(r,s) = (\infty, q)$ to (10), resulting in

$$\|\widehat{\beta}^{(D)}(\lambda) - \beta^*\|_q \le \frac{2|J|^{1/q}\lambda}{CIF_{q,p}(1,J)} \le \max_{A,B} \frac{2\lambda\|\Sigma_A^{-1}\|_{\infty,q}(1 + (a_q k/\ell)^{q-1})^{1/q}}{\{1 - (k^{1-1/q}/\ell)\|\Sigma_A^{-1}\Sigma_{A,B}\|_{\infty,q}\}_+} \tag{30}$$

for all $1 \le q \le \infty$ in the event $z^*_\infty \le \lambda$, where $k = |J|$ and A and B are as in (16). Inequality (30) and the combination of (11) and (19) with $w_A \propto \mathrm{sgn}(u_A)|u_A|^{q-1}$ are related to the results of Zhang (2009b). For $\|\beta^*\|_0 = k$, his oracle inequality for the Lasso can be written as

$$\big\|\widehat{\beta}^{(L)}(\lambda/t^*) - \beta^*\big\|_q \le \frac{32(1+F^*)G^*}{\widetilde{C}(1-F^*)_+^2} \quad \text{for } z^*_\infty \le \lambda,\ 1 \le q \le \infty,\ \ell \ge k, \tag{31}$$

with $F^* = \max_{A,B,w}(k^{1-1/q}\|\Sigma_{B,A}w_A\|_1/\ell)$, $G^* = \widetilde{C}\lambda(k+\ell)^{1/q}\max_{A,w}\|w_A\|_{q/(q-1)}$ for $w \propto \Sigma_A^{-1}\mathrm{sgn}(u_A)|u_A|^{q-1}$, $G^* = \widetilde{C}\lambda k^{1/q}\max_{A,w}\|w_A\|_{q/(q-1)}$ for $w_A \propto \mathrm{sgn}(u_A)|u_A|^{q-1}$, $\widetilde{C} = (1 + 1/t^*)$ and $t^* = (1-F^*)/\{4(1+F^*)\}$, where $w_A'\Sigma_A u_A = \|u_A\|_q = 1$ and $\{A, B, u_A\}$ are as in (16). It turns out that the combination of (11) and (19) with the same choice of w and $(r, a_r) = (\infty, 1)$ is at least by a factor of $5/12$ sharper than (31), even with the suboptimal $a_q = 1$. For small k/ℓ, Zhang (2009b) pointed out the smaller order $k^{1/q}\lambda$ of G^* for $w_A \propto \mathrm{sgn}(u_A)|u_A|^{q-1}$ as an advantage of the Lasso, compared with the order $(k+\ell)^{1/q}\lambda$. The cost of this advantage is the square of $(1-F^*)_+$ in the

denominator of (31), compared with (23) and (30) for the Dantzig selector. Moreover, the error bound in (23) for the Dantzig selector is also of the order $k^{1/q}\lambda$ for $q \le 2$ with much smaller constant factors, and the difference between $k^{1/q}$ and $(k+\ell)^{1/q}$ diminishes for large q as in Theorem 8. Thus, the advantage of the Lasso in this aspect has some limitations.

We have proved that Theorem 3 sharpens and unifies a number of existing oracle inequalities for the Lasso and Dantzig estimators, so that they can all be viewed as (possibly more explicit) upper bounds for the right-hand sides of (10) and (11). The choice $r = \infty$ in (16), and consequently in (18), (19), (20) and (21), typically gives oracle inequalities of the sharpest form involving the dimension-normalized $\|\cdot\|_{\infty,q}$ norm as in (30), compared with the typical $\|\cdot\|_{q,q}$ norm in the literature. Oracle inequalities for $\beta^*_{J^c} \ne 0$ are given in Section 4. Although (10) and (11) are of the same format, the Dantzig selector requires smaller λ and smaller $\xi = 1$. This theoretical advantage of the Dantzig selector for $z^*_\infty \le \lambda$ reverses if $\|\widehat{\beta}^{(D)}(\lambda)\|_1 \le \|\beta^*\|_1$ is replaced by $\|\widehat{\beta}^{(D)}(\lambda)\|_1 \le \|\widehat{\beta}^{(L)}(\lambda)\|_1$ for $z^*_\infty > \lambda$.

3.3 Vaiable Selection

Variable selection is fundamental for the interpretation of models with hign-dimensional data. Meinshausen and Bühlmann (2006), Tropp (2006), Zhao and Yu (2006), and Wainwright (2009) proved that the Lasso is variable selection consistent under a strong irrepresentable condition and some other regularity conditions on X and β. Candes and Plan (2009) proved the selection consistency of the Lasso under random permutation and sign-change of regression coefficients and a mild condition on the maximum absolute correlation among design vectors. Consistent variable selection in linear regression can be achieved with a concave penalty (Fan and Li, 2001; Zhang, 2010) or adaptive Lasso (Zou, 2006; Huang, Ma, and Zhang, 2008), without requiring the strong irrepresentable condition.

The ℓ_∞ error bounds in Theorem 3 (i) and their more explicit versions, for example, (30) with $q = \infty$, naturally lead to variable selection by thresholding the Lasso or Dantzig selector. We focus on the Dantzig selector here although parallel results can be obtained for the Lasso in the same way. Zhang (2009b) studied the selection consistency of thresholding the Lasso through his upper bounds for $\|\widehat{\beta}^{(L)} - \beta^*\|_\infty$. Lounici (2008) considered thresholding either the Lasso or the Dantzig selector under the stronger condition $\max_{j\ne k}|(\Sigma)_{jk}| \le 1/\{\alpha(1+2\xi)|J|\}$ with $\alpha > 1$, $(\Sigma)_{jj} = 1$, $\xi = 3$ for the Lasso, and $\xi = 1$ for the Dantzig selector.

Candes and Tao (2007) considered the Gauss-Dantzig selector

$$\widehat{\beta}^{(GD)} = \arg\min_b \Big\{ \|y - Xb\| : |\widehat{\beta}_j| \le \lambda' \Rightarrow b_j = 0, \forall j, \widehat{\beta} = \widehat{\beta}^{(D)}(\lambda) \Big\}. \tag{32}$$

For threshold functions $t(x;\lambda)$ satisfying $\{x : t(x;\lambda) = 0\} = \{x : |x| \le \lambda\}$ and $xt(x;\lambda) \ge 0$, define the threshold Dantzig selector as

$$\widehat{\beta}^{(TD)} = t\big(\widehat{\beta}^{(D)}(\lambda);\lambda'\big). \tag{33}$$

This includes the hard $t(x;\lambda) = xI\{|x| > \lambda\}$ and the soft $t(x;\lambda) = \mathrm{sgn}(x)(|x| - \lambda)_+$. Define

$$\widehat{\beta}^{(oracle)} = \arg\min_b \Big\{ \|y - Xb\| : \beta_j = 0 \Rightarrow b_j = 0, \forall j \Big\}.$$

Theorem 8 *Suppose (3) holds with $J = \{j : \beta_j \neq 0\}$. Let $\widehat{\beta}^{(GD)}$ and $\widehat{\beta}^{(TD)}$ be as in (32) and (33) respectively with the universal penalty level $\lambda = \lambda_{univ} = \sigma\sqrt{(2/n)\log p}$ and a threshold level λ' satisfying $2\lambda_{univ}/CIF_{\infty,p}(1,J) \leq \lambda' < \min_{\beta_j \neq 0} |\beta_j|/2$. Then,*

$$P_{\beta,X}\Big\{ sgn(\widehat{\beta}^{(TD)}) \neq sgn(\beta) \text{ or } \widehat{\beta}^{(GD)} \neq \widehat{\beta}^{(oracle)} \Big\} \leq 1/\sqrt{\pi \log p} \to 0. \tag{34}$$

Remark 9 *If we use (21) in Theorem 8, $(|J|/\ell)\max_{A,B} \|\Sigma_A^{-1}\Sigma_{A,B}\|_{\infty,\infty} < 1$ becomes a basic condition for (34). Meanwhile, the strong irrepresentable condition for the selection consistency of the Lasso without post-thresholding is $\|\Sigma_{J^c,J}\Sigma_J^{-1}\|_{\infty,\infty} < 1$. Compared with Lounici (2008), we improve the factor $1+2\xi$ to $1+\xi$ via*

$$CIF_{\infty,p}(\xi,J) \geq \min_{j\in J}(\Sigma)_{jj} - (|J|-1+\xi|J|)\max_{j\neq k}|(\Sigma)_{jk}|.$$

4. Upper Bounds for the ℓ_q Loss in ℓ_r Balls

We divide this section into two subsections. The first subsection provides non-probabilistic oracle inequalities: conditions on the data (X,y) and a target coefficient vector β^* for upper bounds of $\|\widehat{\beta} - \beta^*\|_q$ for the Lasso and Dantzig selector. The second subsection provides sufficient condition on the design X for the rate minimaxity for the ℓ_q loss in ℓ_r balls under $P_{\beta,X}$.

4.1 Oracle Inequalities

The oracle inequalities here differ from Theorem 3 (i) by allowing target vectors with many small entries and smaller penalty levels.

Our first theorem deals with the usual $\lambda \geq z_\infty^*$ and allows targets β^* with small $\|\beta^*_{J^c}\|_1$ for a certain set $J \subset \{1,\ldots,p\}$. The effect of the elements of β^* in J^c is controlled by

$$M_q(\lambda,\rho) = \sup\Big\{ \|u\|_q : \|\Sigma u\|_\infty \leq \lambda, \|u\|_1 \leq \rho \Big\}. \tag{35}$$

Theorem 10 *Let β^* be a target vector, $q \in [1,\infty]$, $J \subset \{1,\ldots,p\}$ and $\rho_J = \|\beta^*_{J^c}\|_1$. Then,*

$$\|\widehat{\beta}^{(D)} - \beta^*\|_q \leq \max\Big\{ \frac{2|J|^{1/q}\lambda}{CIF_{q,p}(\xi,J)}, 2M_q\Big(\lambda, \frac{\xi+1}{\xi-1}\rho_J\Big)\Big\}, \ \forall \xi > 1, \tag{36}$$

in the event $z_\infty^* = \|X'(y - X\beta^*)/n\|_\infty \leq \lambda$. Moreover, for $z_\infty^* \leq \lambda(\xi_0-1)/(\xi_0+1)$,

$$\|\widehat{\beta}^{(L)} - \beta^*\|_q \leq \max\Big\{ \frac{\xi_1|J|^{1/q}\lambda}{CIF_{q,p}(\xi,J)}, M_q\big(\xi_1\lambda, \xi_2\rho_J\big)\Big\}, \ \forall \xi > \xi_0, \tag{37}$$

where $CIF_{q,\ell}(\xi,J)$ is as in (8), $\xi_1 = 2\xi_0/(\xi_0+1)$ and $\xi_2 = (1+\xi_0)(1+\xi)/(\xi-\xi_0)$.

Remark 11 *The first component of (36) and (37) can be viewed as the cost of estimating the large components β^* in J without knowing J, and the second component the cost of having potentially many small elements of β^* in J^c. Since $M_q(\lambda,\rho) \leq \rho$ for $q \geq 1$, $\beta^*_{J^c}$ does not contribute to the order of the error bounds in (36) and (37) when $\rho_J \lesssim |J|^{1/q}\lambda/CIF_{q,p}(\xi,J)$. In Proposition 15 below, we provide conditions for $M_q(\lambda,\rho) \lesssim \lambda(\rho/\lambda)^{1/q}$, as if $\Sigma = I$.*

Our next theorem deals with smaller penalty levels satisfying $z^*_{2,d} \le \lambda < z^*_\infty$, where

$$z^*_{q,d} = \max_{|A|=d} z^*_{q,A},\ z^*_{q,A} = \|X'_A(y - X\beta^*)/n\|_q/|A|^{1/q}, \quad z^*_\infty = z^*_{\infty,1}. \tag{38}$$

Since $z^*_{q,d}$ is the length normalized ℓ_q norm of the d largest absolute values of the elements of $z = X'(y - X\beta^*)/n$, $z^*_{q,d}$ is increasing in q and decreasing in d, and $z^*_{q,d} \le z^*_\infty$. Let

$$\mathscr{C}_{relax}(\xi, J, d) = \Big\{ u : \|u_{J^c}\|_1 \le \xi d^{1/2} \max_{|A|=d, A\supseteq J} \|u_A\| \Big\} \tag{39}$$

as a relaxed cone, and define the corresponding relaxed CIF as

$$CIF_{q,relax}(\xi, J, d) = \inf_{u\in\mathscr{C}_{relax}(\xi,J,d)} \Big\{ \frac{d^{1/q}\|\Sigma_{A,*}u\|}{d^{1/2}\|u\|_q} : A = \operatorname*{arg\,max}_{|B|=d, B\supseteq J} \|u_B\| \Big\}. \tag{40}$$

The following quantity plays the role of (35) for relaxed cones:

$$M_{q,relax}(\lambda, \rho, J, d) = \sup_{\|u\|_1\le\rho} \Big\{ \|u\|_q : \|\Sigma_{A,*}u\| \le d^{1/2}\lambda, A = \operatorname*{arg\,max}_{|B|=d, B\supseteq J} \|u_B\| \Big\}. \tag{41}$$

Since $\|u_J\|_1 \le |A|^{1/2}\|u_A\|$ for $A \supseteq J$, the relaxed cone (39) is larger than the cone in (8). Moreover, since $\|\Sigma_{A,*}u\|/|A|^{1/2} \le \|\Sigma u\|_\infty$,

$$CIF_{q,relax}(\xi, J, d) \le (d/|J|)^{1/q} CIF_{q,p}(\xi, J),\ M_{q,relax}(\lambda, \rho, J, d) \ge M_q(\lambda, \rho).$$

Theorem 12 *Let β^* be a target vector, $q \in [1,\infty]$, $J \subset \{1,\dots,p\}$ with $(4|J|/3) \vee 1 \le d \le p$, $\rho_J = \|\beta^*_{J^c}\|_1$ and $z^*_{2,d}$ be as in (38). Then, for $z^*_{2,d} \le \lambda(\xi_0 - 1)/(\xi_0 + 1)$,*

$$\|\widehat{\beta}^{(L)} - \beta^*\|_q \le \max\Big\{ \frac{\xi_1 d^{1/q}\lambda}{CIF_{q,relax}(\xi, J, d)}, M_{q,relax}\Big(\xi_1\lambda, \xi_2\rho_J, J, d\Big) \Big\}, \tag{42}$$

where $\xi_1 = 2\xi_0/(\xi_0+1)$ and $\xi_2 = (\xi_0+1)(\xi+1)/(\xi-\xi_0)$.

Remark 13 *By (22) and (38), $(z^*_{2,d})^2/\{\sigma^2(1+\delta^+_d)\}$ is no greater than the maximum of $\binom{p}{d}$ χ^2_d variables under $P_{\beta^*,X}$ in (3), so that for certain $\lambda \asymp \sigma\{(1+\delta^+_d)(2/n)\log(p/d)\}^{1/2}$, $z^*_{2,d} \le \lambda(\xi_0 - 1)/(\xi_0+1)$ with large probability. Thus, for $|J| = k \asymp d$ and $\log(p/d) \ll \log p$, Theorem 12 allows $\lambda \ll \lambda_{univ} = \sigma\{(2/n)\log p\}^{1/2}$. Zhang (2010) derived similar oracle inequalities for the Lasso, MC+, and other concave penalized least squares estimators at the same λ under the sparse Riesz condition $|J| \le d/\{(1+\delta^+_d)/(1-\delta^-_d) + 1/2\}$.*

Remark 14 *Since $\|u_A\|/d^{1/2}$ does not control $\|u_A\|_q/d^{1/q}$ for $q > 2$ and large $|A| = d$, the relaxed constant factors in (40) and (41) are not properly normalized for $q > 2$ and $\Sigma = I$. Thus, Theorem 12 is most useful when $1 \le q \le 2$, although it is valid for all $1 \le q \le \infty$.*

We use the following quantities to bound the constant factors in Theorems 10 and 12:

$$\begin{aligned} \eta_{q,d} &= \max_{|A|=d} \|\Sigma_A^{-1}\|_{\infty,q}/d^{1/q},\ \eta^*_{q,d} = \max_A \|\Sigma_A^{-1}\|_{q,q}, \\ \kappa_{q,d,\ell} &= \max_{|A|=d} \min_{r\ge1} \max_{|B|=\ell} \ell^{1-1/q}(a_r/\ell)^{1-1/r}\|\Sigma_A^{-1}\Sigma_{A,B}\|_{r,q}. \end{aligned} \tag{43}$$

Proposition 15 *Let $CIF_{q,relax}(\xi,J,\ell)$, $M_q(\lambda,\rho)$ and $M_{q,relax}(\lambda,\rho,J,\ell)$ be as in (40), (35) and (41) respectively. Let $\{\eta_{q,d},\eta^*_{q,d},\kappa_{q,d,\ell}\}$ be as in (43) and $a_q=(1-1/q)/q^{1/(q-1)}$. Then,*

$$M_q(\lambda,\rho)\le \eta_{q,k}k^{1/q}\lambda+(\kappa^q_{q,k,k}+a_q^{q-1})^{1/q}k^{1/q-1}\rho,\ \forall\, k\ge 1, 1\le q\le\infty, \tag{44}$$

$$M_{q,relax}(\lambda,\rho,J,d)\le \eta^*_{2,d}d^{1/q}\lambda+\{(d/\ell)^{1-q/2}\kappa^q_{2,d,\ell}+a_q^{q-1}\}^{1/q}\ell^{1/q-1}\rho,\ 1\le q\le 2, \tag{45}$$

with $\ell=d-|J|$, and with $C_{q,2}(\xi,t)$ and $\widetilde{\phi}^*_{2,\ell}(\xi,J)$ as in (17) and (20),

$$CIF_{q,p}(\xi,J)\ge CIF_{q,relax}(\xi,J,\ell)\ge \frac{(d/|J|)^{1/q-1/2}\widetilde{\phi}^*_{2,\ell}(\xi\sqrt{d/|J|},J)}{C_{q,2}\big(\xi(d/|J|)^{1/2},|J|^2/(d\ell)\big)}. \tag{46}$$

Remark 16 *Suppose that the quantities in (43) are bounded whenever invoked. For $\rho/\lambda\asymp k\asymp\ell$, (44) and (45) give the rate $M_q(\lambda,\rho)\lesssim\rho(\lambda/\rho)^{1-1/q}$ and $M_{q,relax}(\lambda,\rho,J,d)\lesssim\rho(\lambda/\rho)^{1-1/q}$, the same as the simplest case $\Sigma=I$. Since (46) is of the form (20), Corollary 7 can be automatically extended under the setting of Theorem 12.*

4.2 Rate ℓ_q Minimax Estimation in ℓ_r Balls

We present sufficient conditions for the rate minimaxity of the Lasso and Dantzig selector in ℓ_r balls in (4) in the sense of (6) and (7). Let λ_{univ} and λ_{mm} be as in (5). We first consider the ℓ_q risk.

Theorem 17 *Let $q\ge 1\ge r>0$. Suppose $(\log p)/n=O(1)$ and $R^r/\lambda^r_{mm}\asymp d\le n\wedge p$ for some integer $d\to\infty$ satisfying $(\log d)/\log p\le c_0<1$. Let $0<\alpha_0<1$ and $\widehat{\beta}$ be either the Lasso or Dantzig selector with $\lambda=\lambda_{univ}/\alpha_0$. Suppose $p^{1-(\alpha_1/\alpha_0)^2}(n^q/d+d^{q/r-1})\le 1$ and $p^{1-(\alpha/\alpha_0)^2}d^{q/r-q}\le 1$ for certain $\{\alpha,\alpha_1\}\subset(\alpha_0,1)$. For the Dantzig selector, let $\xi>1$, $\xi^*=1$ for $r=1$ and $\xi^*=(\xi+1)/(\xi-1)$ for $r<1$. For the Lasso, let $\xi>(1+\alpha)/(1-\alpha)$ $\xi^*=1/(1-\alpha_1)$ for $r=1$ and $\xi^*=(\xi+1)/\{\xi-1-\alpha(\xi+1)\}$ for $r<1$. Then,*

$$\frac{\sup_{\beta\in\Theta_{r,R}}E_{\beta,X}\|\widehat{\beta}-\beta\|_q^q}{R^r\lambda_{mm}^{q-r}}\lessapprox\Big[\max\Big\{\frac{C_1I\{r<1\}}{CIF_q^*(\xi,d)},C_1M_q\Big(\frac{1}{d^{1/q}},\frac{\xi^*C_2}{d^{1/q-1}}\Big)\Big\}\Big]^q, \tag{47}$$

where $C_1=2(d\lambda^r_{mm}/R^r)^{1/q}/(\alpha_0\sqrt{1-c_0})$, $C_2=\alpha_0\sqrt{1-c_0}R/(d^{1/r}\lambda_{mm})$, $CIF_q^*(\xi,d)$ is as in (12) and $M_q(\lambda,\rho)$ is as in (35). Consequently, if either $\eta_{q,d}+\kappa_{q,d,d}=O(1)$ with the $\{\eta_{q,d},\kappa_{q,d,d}\}$ in (43) or $M_q(d^{-1/q},d^{1-1/q})+I\{r<1\}/CIF_q^*(\xi,d)=O(1)$, then

$$\sup_{\|\beta\|_r\le R}E_{\beta,X}\|\widehat{\beta}-\beta\|_q^q\lesssim\inf_{\delta}\sup_{\|\beta\|_r\le R}E_{\beta,X}\|\delta(X,y)-\beta\|_q^q. \tag{48}$$

Remark 18 *For $q=2$, $\eta_{q,k}+\kappa_{q,k,k}=O(1)$ for some $k\asymp d$ if the sparse Riesz condition holds Zhang and Huang (2008), that is, $1/(1-\delta_d^-)+\delta_d^+=O(1)$ for the $\delta_d^\pm$ in (22). For $p\gg n$, random matrix theory can be applied to validate such conditions up to $d\asymp n/\log(p/n)$.*

Theorem 17 differs from existing results by directly comparing the ℓ_q risk of estimators with the minimax risk, instead of finding upper bounds for the ℓ_q loss. It is based on the oracle inequality for $\lambda>\lambda_{univ}$ in Theorem 10. However, in practice, a penalty level $\lambda<\lambda_{univ}$ is often empirically the best choice. As we mentioned in Remark 2, $\lambda_{mm}<\lambda_{univ}$ iff $R>\sigma/\sqrt{n}$. For $\lambda_{mm}/\lambda_{univ}=o(1)$,

oracle inequalities requiring penalty levels $\lambda \geq \lambda_{univ}$ do not match the order of the minimax lower bounds in Theorem 1. For example, when $p = n\log n$ and $d \asymp R^r/\lambda_{mm}^r \asymp n/\log\log n$, $\lambda_{mm}/\lambda_{univ} \to 0$ as $n \to \infty$ and the regularity conditions on X may still hold. Theorem 19 below closes this gap by providing the rate minimaxity of the Lasso in the quantiles of the ℓ_q loss with $\lambda \asymp \lambda_{mm} = o(\lambda_{univ})$. Define

$$CIF^*_{q,relax}(\xi,k,d) = \inf_{|A|=d}\Big\{\frac{d^{1/q}\|\Sigma_{A,*}u\|}{d^{1/2}\|u\|_q} : \min_{|A\setminus J|=d-k}\|u_{J^c}\|_1 < \xi d^{1/2}\|u_A\|\Big\}, \tag{49}$$

$$M^*_{q,relax}(\lambda,\rho,k,d) = \sup_{|A|=d}\Big\{\|u\|_q : \|\Sigma_{A,*}u\| \leq d^{1/2}\lambda, \min_{|A\setminus J|=d-k}\|u_{J^c}\|_1 \leq \rho\Big\}. \tag{50}$$

Theorem 19 *Let* $\lambda = \min\big(\lambda_{univ}, (1+\varepsilon_0)(1+\delta_d^+)^{1/2}\lambda_{mm}\big)/\alpha$ *with* $0 < \varepsilon_0 \leq \alpha < 1$ *and* $\{\lambda_{mm}, \lambda_{univ}, \delta_d^+\}$ *in (5) and (22). Let* $0 < r \leq 1 \leq q \leq 2$. *Suppose* $n \wedge p \geq d \asymp R^r/\lambda_{mm}^r \to \infty$, $\delta_d^+ = O(1)$ *and* $\lambda_{mm}n^{1/2}/\sigma \to \infty$. *Suppose that for certain* $k+\ell = d$ *with* $k \asymp \ell$,

$$\max\Big\{1/CIF^*_{q,relax}(\xi,k,d), M^*_{q,relax}(d^{-1/2}, d^{1/2}, k, d)\Big\} = O(1).$$

Then, the Lasso is rate minimax in ℓ_r *balls in the sense that for all* $\varepsilon > 0$,

$$\begin{aligned} &\inf\Big[t : \sup_{\|\beta\|_r \leq R} P_{\beta,X}\Big\{\|\widehat{\beta}^{(L)} - \beta\|_q^q \geq t^q R^r \lambda_{mm}^{q-r}\Big\} \leq \varepsilon\Big] \\ \lesssim\ &\inf\Big[t : \inf_{\delta}\sup_{\|\beta\|_r \leq R} P_{\beta,X}\Big\{\|\delta(X,y) - \beta\|_q^q \geq t^q R^r \lambda_{mm}^{q-r}\Big\} \leq \varepsilon\Big] < \infty. \end{aligned} \tag{51}$$

In particular, (51) holds if $1/(1-\delta_d^-) + \delta_d^+ = O(1)$ *as in Remark 18.*

The quantities (8), (12), (35), (40), (41), (49) and (50) are best understood by comparisons with functions of (22) and (43) via Propositions 5 and 15. These quantities also facilitate comparisons between our and existing upper bounds on the loss as in the derivation of Corollary 7. In such comparisons, the Hölder inequality and (22) give

$$\eta_{q,d} \leq \eta^*_{q,d},\ \ \kappa_{q,d,\ell} \leq \kappa^*_{q,d,\ell},\ \ \eta^*_{2,d} = 1/(1-\delta_d^-),\ \ \kappa^*_{2,d,\ell} \leq \theta_{d,\ell}\eta^*_{2,d},$$

where $\kappa^*_{q,d,\ell} = a_q^{1-1/q}\max_{A,B}\|\Sigma_A^{-1}\Sigma_{A,B}\|_{q,q}$ with $|A| = d$, $|B| = \ell$ and $A \cap B = \emptyset$.

5. Discussion

Although this paper focuses on the estimation of regression coefficients, the estimation of $X\beta^*$ (prediction) is an important problem (Greenshtein and Rotiv, 2004). Similar to the proof of (11), (9), (14) and (15) imply

$$\|X\widehat{\beta}^{(L)} - X\beta^*\|^2/n + 2\lambda\|(\widehat{\beta} - \beta^*)_J\|_1/(\xi+1) \leq \frac{\{2\xi/(\xi+1)\}|J|\lambda^2}{SCIF_{1,0}(\xi,J)} \tag{52}$$

in the event $z^*_\infty = \|X'(y - X\beta^*)/n\|_\infty \leq \lambda(\xi-1)/(\xi+1)$. Since $SCIF_{1,0}(\xi,J) \geq RE_{1,0}(\xi,J)$, (52) implies Lemma 2.1 of van de Geer and Bühlmann (2009) for $(z^*_\infty, \xi) = (0,1)$.

As we have explained in Section 3.2, the use of $\|\Sigma u\|_\infty$ in the numerator of (8) and (9) seems necessary to ensure the dominance of Theorem 3 over the oracle inequalities of the type (30). However, if we make the numerator quadratic in u, Corollary 7 still holds up to a constant factor with the following weak CIF:

$$CIF^w_{q,\ell}(\xi,J) = \inf_{u\in\mathscr{C}(\xi,J)} \frac{|J|^{1/q}u'_A\Sigma_{A,*}u}{\|u_J\|_1\|u_A\|_q},\ SCIF^w_{q,\ell}(\xi,J) = \inf_{u\in\mathscr{C}_-(\xi,J)} \frac{|J|^{1/q}u'_A\Sigma_{A,*}u}{\|u_J\|_1\|u_A\|_q}, \tag{53}$$

where $A = \arg\max_{|A\setminus J|\le\ell}\|u_A\|$. For example, (26), (27) and (28) are still consequences of Theorem 3 when (53) is used instead of (8) and (9).

Since the oracle inequalities in this paper apply directly to data points (X,y) and target vectors β^*, the normality assumption on the error in (3) is not crucial for the upper bounds for the estimation risk and loss (not even the condition $E_{\beta,X}y = X\beta$). For example, for the estimation of a target β^* with $X\beta^* \approx Ey$, the upper bounds in Theorem 19 are valid for $\|\widehat{\beta}^{(L)} - \beta^*\|_q^q$ with large probability under P and $\sigma = \sigma_1 + \sigma_2$, provided that

$$\begin{cases} E\exp(v'X'(y-Ey)) \le \exp(-n\sigma_1^2 v'\Sigma v/2), \\ \max_{|A|=\ell}\|P_A(Ey - X\beta^*)\| \le \sigma_2\sqrt{2\ell\log(p/\ell)}. \end{cases}$$

For design matrices X with iid sub-Gaussian rows, our results can be extended to β in ℓ_r balls with $1 < r \le 2$ due to $\sigma_2 \le O(\|\beta_{J^c}\|)$ for $\beta^*_J = \beta_J$ and $\beta^*_{J^c} = 0$.

The proofs in this paper do not completely deal with the most difficult case of $q > 2$ and $\lambda_{mm} = o(\lambda_{univ})$. For example, an extension of Theorem 12 to $q > 2$ seems to require sharp upper bounds for $z^*_{q,d}$ in (38).

For $\lambda < \lambda_{univ}$, the proof of Theorem 12 can be extended to the Dantzig selector with the feasibility of β^* replaced by the feasibility of $\widehat{\beta}^{(L)}$. This would yield slightly worse error bounds than those in Theorem 12. However, if we modify the Dantzig selector as

$$\widetilde{\beta} = \arg\min_b \left\{\|b\|_1 : \max_{|A|=d}\|X'_A(y-Xb)\| \le \sqrt{d}\lambda\right\}, \tag{54}$$

the feasibility of β^* would be guaranteed in the event $z^*_{2,d} \le \lambda$ even for $\lambda = o(\lambda_{univ})$ as in Theorems 12 and 19. This will provide sharper error bounds for the smaller λ and $q \le 2$. We omit this modification since the computational issues with (54) is not clear for $d > 1$.

Appendix A. Proofs

We provide all the proofs here. Lemms are stated and proved as needed.

Proof of Theorem 1. Let $\Theta = \Theta_{r,R}$ and $k = R^r/\lambda_{mm}^r$ for $r > 0$ and $\Theta = \Theta_{0,k}$ for $r = 0$. By (5), $\lambda_{mm}/\sigma_n = \sqrt{2\log(p/k) - r\log(\lambda_{mm}/\sigma_n)}$ for $r > 0$. Since $\lambda_{mm}/\sigma_n \to \infty$,

$$\lambda_{mm} = (1+o(1))\sigma_n\sqrt{2\log(p/k)},\ \min(k,p/k) \to \infty, \quad \forall\, r \geq 0. \tag{55}$$

Let $P_{\mu,w}$ be a (prior) probability distribution under which (z_j, β_j) are iid vectors with

$$z_j|\beta_j \sim N(\beta_j, \sigma_n^2),\ P_{\mu,w}\{\beta_j = \mu\} = w = 1 - P_{\mu,w}\{\beta_j = 0\},$$

where $\mu = \lambda_{mm}(1-\varepsilon)$ and $w = (1-\varepsilon)k/p$. Since $\widetilde{z}_j = x_j'(y - \sum_{i\neq j}\beta_i x_i)/n$ is sufficient for β_j given $(X, y, \beta_i, i \neq j)$ and $\widetilde{z}_j|\beta \sim z_j|\beta$, the minimum Bayes risk is bounded by

$$\begin{aligned}
\inf_{\widehat{\beta}} E_{\mu,w}E_{\beta,X}\|\widehat{\beta} - \beta\|_q^q &\geq E_{\mu,w}\sum_{j=1}^p \min_t E_{\beta,X}\Big[|t-\beta_j|^q\Big|X,y\Big] \\
&\geq E_{\mu,w}\sum_{j=1}^p \min_t E_{\beta,X}\Big[|t-\beta_j|^q\Big|X,y,\beta_i,i\neq j\Big] \\
&= E_{\mu,w}\sum_{j=1}^p \min_t E_{\beta,X}\Big[|t-\beta_j|^q\Big|z_j\Big] \\
&= (1+o(1))k\lambda_{mm}^q
\end{aligned} \tag{56}$$

as $k \wedge (p/k) \to \infty$ and then $\varepsilon \to 0$. The last step above is by Donoho and Johnstone (1994).

Let $N = \#\{j : \beta_j \neq 0\}$. Under $P_{\mu,w}$, $\|\beta\|_r^r = N\mu^r$ and $\|\beta\|_q^q = N\mu^q$, so that

$$\beta \in \Theta \ \Leftrightarrow\ N \leq k/(1-\varepsilon)^r \ \Rightarrow\ \|\beta\|_q^q \leq k\lambda_{mm}^q,\ \forall\, r \geq 0, \tag{57}$$

due to $R^r/\mu^r = k/(1-\varepsilon)^r$ and $\{k/(1-\varepsilon)^r\}\mu^p/\lambda_{mm}^p = k(1-\varepsilon)^{q-r} \leq k$ for $r > 0$. Let

$$\delta^* = \arg\min_\delta E_{\mu,w}E_{\beta,X}\big[\|\delta(X,y) - \beta\|_q^q\big|X,y,\beta\in\Theta\big].$$

Since the conditional Bayes risk of δ^* is no greater than the minimax risk in Θ,

$$\begin{aligned}
& (1+o(1))k\lambda_{mm}^q \\
\leq\ & E_{\mu,w}E_{\beta,X}\big[\|\delta^*-\beta\|_q^q\big|\beta\in\Theta\big] + E_{\mu,w}E_{\beta,X}\|\delta^*-\beta\|_q^q I\{\beta\notin\Theta\} \\
\leq\ & \mathscr{R}(\Theta;X) + 2^{(q-1)_+}E_{\mu,w}E_{\beta,X}\big(\|\delta^*\|_q^q + \|\beta\|_q^q\big)I\{\beta\notin\Theta\}.
\end{aligned} \tag{58}$$

Since $E_{\mu,w}E_{\beta,X}[\|\delta^*-\beta\|_q^q|X,y,\beta\in\Theta] \leq E_{\mu,w}[\|\beta\|_q^q|X,y,\beta\in\Theta] \leq k\lambda_{mm}^q$ by (57), $\|\delta^*\|_q^q \leq 2^{(q-1)_+}k\lambda_{mm}^q$ a.s. Thus, since $N \sim \text{Binomial}(p,w)$ with $pw = (1-\varepsilon)k \to \infty$,

$$\begin{aligned}
& E_{\mu,w}E_{\beta,X}\big(\|\delta^*\|_q^q + \|\beta\|_q^q\big)I\{\beta\notin\Theta\} \\
\leq\ & 2^{(q-1)_+}k\lambda_{mm}^q P_{\mu,w}\{N > wp/(1-\varepsilon)\} + \mu^q E_{\mu,w}NI\{N > wp/(1-\varepsilon)\} \\
=\ & o(1)k\lambda_{mm}^q
\end{aligned} \tag{59}$$

by (57). The combination of (58) and (59) gives (6).

Now consider the loss $L(\delta,\beta) = I\{\|\delta-\beta\|_q > ck^{1/q}\lambda_{mm}\}$ in (7). Define

$$\widehat{\beta} = \delta(X,y)I\Big\{\|\delta(X,y)\|_q \leq (1+c)k^{1/q}\lambda_{mm}\Big\}.$$

By (57), $\beta \in \Theta$ implies $\|\beta\|_q^q \le k\lambda_{mm}^q$ and

$$\begin{aligned}\|\widehat{\beta}-\beta\|_q^q &\le c^q k\lambda_{mm}^q I\Big\{\|\delta-\beta\|_q \le ck^{1/q}\lambda_{mm}\Big\} \\ &\quad +\Big(\|\beta\|_q+(1+c)k^{1/q}\lambda_{mm}\Big)^q I\Big\{\|\delta-\beta\|_q > ck^{1/q}\lambda_{mm}\Big\}.\end{aligned}$$

Since $\|\beta\|_q^q = N\mu^q \le N\lambda_{mm}^q$, it follows that

$$\begin{aligned}E_{\mu,w}E_{\beta,X}\|\widehat{\beta}-\beta\|_q^q &\le c^q k\lambda_{mm}^q + (2+c)^q k\lambda_{mm}^q \max_{\beta\in\Theta} E_{\beta,X}L(\delta(X,y),\beta) \\ &\quad +2^{q-1}\lambda_{mm}^q E_{\mu,w}\Big(N+(1+c)^q k\Big)I\{\beta\notin\Theta\}. \qquad (60)\end{aligned}$$

Since $E_{\mu,w}\Big(N+(1+c)^q k\Big)I\{\beta\notin\Theta\} = o(1)k$ by (57), (56) and (60) yield

$$\sup_{\beta\in\Theta} E_{\beta,X}L(\delta(X,y),\beta) \ge \frac{1-c^q+o(1)}{(2+c)^q}.$$

Since the $o(1)$ is uniform in the choice of $\delta(X,y)$, we find

$$\inf_{\delta}\sup_{\beta\in\Theta} P_{\beta,X}\Big\{\|\delta(X,y)-\beta\|_q^q > (1-\varepsilon)k\lambda_{mm}^q\Big\} \ge \frac{\varepsilon+o(1)}{3^q},\ \forall 0<\varepsilon<1.$$

This gives (7) and completes the proof. ■

Proof of Theorem 3. Part (i) follows from (14) and (15) as briefly explained in the paragraph below the statement of the theorem. For the Dantzig selector, $z^* \le \lambda$ implies (15) and the feasibility of β^* for the ℓ_∞ constraint in (2), and the feasibility of β^* implies (14). For the Lasso estimator, (14) and (15) follow from the Karush-Kuhn-Tucker conditions

$$\|x_j(y-X\widehat{\beta})/n\|_\infty \le \lambda, \quad \widehat{\beta}_j \ne 0 \ \Rightarrow\ x_j(y-X\widehat{\beta})/n = \mathrm{sgn}(\widehat{\beta}_j)\lambda.$$

Part (ii) follows from $P_{\beta,X}\{z_\infty^* > t\sigma/\sqrt{n}\} \le 2pP\{N(0,1)>t\}$. ■

In this paper and those cited in Section 3.2, tails of ℓ_q norms or inner products are bounded by shifting inequalities (Candes and Tao, 2007, Lemma 3.1). The following lemma combines and extends the sharp shifting inequalities of Cai, Wang, and Xu (2010) for $q=2$ and Ye and Zhang (2009) for $w'h$ with $q=\infty$.

Lemma 20 *Let $1 \le q \le \infty$ and $a_q = (1-1/q)/q^{1/(q-1)}$ with $a_\infty = 1$. Let $h \in \mathbb{R}^p$, $J \subset \{1,\ldots,p\}$ and A be the union of J and the indices of the ℓ largest $|h_j|$ with $j \notin J$, $1 \le \ell \le p-|J|$. Then, $\|h_{A^c}\|_q \le (a_q/\ell)^{1-1/q}\|h_{J^c}\|_1$. Moreover, for any vector $w \in \mathbb{R}^p$,*

$$\sum_{j\notin A} w_j h_j \le \|h_{J^c}\|_1\Big(\frac{a}{\ell}\vee\frac{a_q}{\ell}\Big)^{1-1/q}\max\Big\{\|w_B\|_{q/(q-1)} : B\cap A=\emptyset, |B|\le\lceil\ell/a\rceil\Big\}. \qquad (61)$$

Proof. We first prove that for all decreasing functions $h(t)\ge 0$,

$$\sum_{m=0}^{\infty}\Big(\int_{\ell+m\ell/a}^{\ell+(m+1)\ell/a} h^q(t)dt\Big)^{1/q} \le \max\big\{1,(a_q/a)^{1-1/q}\big\}\frac{a^{1-1/q}}{\ell^{1-1/q}}\int_0^\infty h(t)dt. \qquad (62)$$

With $x = at/\ell - m$ and possibly different $h \downarrow 0$, the above inequality is a consequence of

$$\max\Big\{\int_a^{1+a} h^q(x)dx : \int_0^1 h(x)dx = 1\Big\} \le \max\big\{1, (a_q/a)^{q-1}\big\} \tag{63}$$

It suffices to consider $0 < a \le a_q$. Since $\int_a^{1+a} h^q(x)dx$ is convex in h, it suffices to consider $h(x) = v + (u-v)I\{x \le w\}$ for certain $u \ge 1 \ge v$ and $a \le w \le 1$. Since $\int_0^1 h(x)dx = 1$, $v = (1-uw)/(1-w)$. Thus, for fixed w, $\int_a^{1+a} h^q(x)dx$ is convex in u, and its maximum is attained at the extreme points $u \in \{1, 1/w\}$. For $u = 1/w$, we have $v = 0$ and $\int_a^{1+a} h^q(x)dx = u^{q-1} - au^q$, so that the optimal u satisfies $au = (q-1)/q$, resulting in the maximum $\{(q-1)/(qa)\}^{q-1}/q = (a_q/a)^{q-1}$. This yields (63) since $\int_a^{1+a} h^q(x)dx = 1$ at the other extreme $u = 1$. Thus, $\|h_{A^c}\|_q \le (a_q/\ell)^{1-1/q}\|h_{J^c}\|_1$ by (62), and (61) follows with an application of the Hölder inequality to $\int_{\ell+m\ell/a}^{\ell+(m+1)\ell/a} w(t)h(t)dt$. ■

Proof of Proposition 5. Let $k = |J|$. Since $\|u_{A^c}\|_q \le (a_q/\ell)^{1-1/q}\|u_{J^c}\|_1$ by Lemma 20 and $\|u_{J^c}\|_1 \le \xi\|u_J\|_1 \le \xi k^{1-1/q}\|u_A\|_q$, $\|u\|_q \le C_{q,q}(\xi, k/\ell)\|u_A\|_q$. By the Hölder inequality $\|u\|_s \le \|u\|_1^{(1/s-1/q)/(1-1/q)}\|u\|_q^{(1-1/s)/(1-1/q)} = \|u\|_1^{1/s_1}\|u\|_q^{1-1/s_1}$ with $s_1 = (1-1/q)/(1/s-1/q) \ge s$. Since $\|u\|_1 \le (1+\xi)\|u_J\|_1 \le (1+\xi)k^{1-1/q}\|u_A\|_q$,

$$\|u\|_s k^{1/q-1/s}/\|u_A\|_q \le (1+\xi)^{1/s_1} C_{q,q}^{1-1/s_1}(\xi, k/\ell) = C_{s,q}(\xi, k/\ell).$$

This gives (17). Since $v'_{J^c}\Sigma_{J^c,*}u \le 0$ for $u \in \mathscr{C}_-(\xi, J)$ and $v \in \mathscr{Q}(u, J)$, the first parts of (18) and (19) follow from (8) and (9). For $h = u$ and the choice of A in Lemma 20, an application of (61) with $w = (v'_A\Sigma_{A,*})'$ yields

$$\begin{aligned} v'_A\Sigma_{A,*}u &= v'_A\Sigma_A u_A + v'_A\Sigma_{A,A^c}u_{A^c} \\ &\ge v'_A\Sigma_A u_A - \max_B \|\Sigma_{B,A}v_A\|_{r/(r-1)}(a_r/\ell)^{1-1/r}\|u_{J^c}\|_1. \end{aligned} \tag{64}$$

Since $\|u_{J^c}\|_1 \le \xi\|u_J\|_1 \le \xi k^{1-1/q}\|u_A\|_q$, (64) and (16) imply

$$\begin{aligned} \frac{v'_A\Sigma_{A,*}u}{\|v_A\|_1\|u_A\|_q/k^{1/q}} &\ge \frac{v'_A\Sigma_A u_A - \xi\|u_A\|_q k^{1-1/q}(a_r/\ell)^{1-1/r}\max_B\|\Sigma_{B,A}v_A\|_{r/(r-1)}}{\|v_A\|_1\|u_A\|_q/k^{1/q}} \\ &= \phi_{q,\ell}(u, A, r, w, B; \xi, J)k^{1/q}/\|w_A\|_1 \end{aligned}$$

with $w = v\|u_A\|_q/(v'_A\Sigma_A u_A)$. This gives the second parts of (18) and (19). ■

Proof of Theorem 8. This theorem is a direct consequence of (10) with $q = \infty$, since $\|\widehat{\beta} - \beta\|_\infty \le \lambda' < \min_{\beta_j \ne 0}|\beta_j|/2$ guarantees $\{j : |\widehat{\beta}_j| > \lambda'\} = \{j : \beta_j \ne 0\}$. ■

Proof of Theorem 10. Let $h = \widehat{\beta} - \beta^*$ for either estimator. As in (14) and (15),

$$\|\Sigma h\|_\infty \le \xi_1\lambda,\ \|h_{J^c}\|_1 \le \xi_0\|h_J\|_1 + (\xi_0+1)\rho_J, \tag{65}$$

in the given events, with $\{\xi_0, \xi_1\} = (1, 2)$ for the Dantzig selector and the $\{\xi_0, \xi_1\}$ in (37) for the Lasso. It follows from Theorem 3 that (36) and (37) hold for $\|h_{J^c}\|_1 \le \xi\|h_J\|_1$, or equivalently $h \in \mathscr{C}(\xi, J)$. By (65), it remains to consider

$$\xi\|h_J\|_1 \le \|h_{J^c}\|_1 \le \xi_0\|h_J\|_1 + (\xi_0+1)\rho_J.$$

Since $\xi > \xi_0$, $\|h_J\|_1 \le (\xi_0+1)\rho_J/(\xi-\xi_0)$ in this case, so that $\|h\|_1 \le (1+\xi_0)\|h_J\|_1 + (\xi_0+1)\rho_J \le \rho_J(1+\xi_0)(1+\xi)/(\xi-\xi_0) = \xi_2\rho_J$. Thus, (35) gives $\|h\|_q \le M_q(\xi_1\lambda, \xi_2\rho_J)$. ■

Proof of Theorem 12. Let $h = \widehat{\beta}^{(L)} - \beta^*$, $z = X'(y - X\beta^*)/n$, $k = |J|$, $\ell = d - k$, and $A = \arg\max_{|B|=d, B\supset J} \|h_B\|$ as in (40). Since $k \le 3d/4$, $4\ell \ge d$. Lemma 20 with $\{w, q, a_q\} = \{z, 2, 1/4\}$ yields $h'_{A^c} z_{A^c} \le \|h_{J^c}\|_1 z^*_{2,4\ell} \le \|h_{J^c}\|_1 z^*_{2,d}$, so that

$$\begin{aligned} \|Xh\|^2/n &= h'_A z_A + h'_{A^c} z_{A^c} - h'X'(y - X\widehat{\beta}^{(L)})/n \\ &\le \sqrt{d}\|h_A\| z^*_{2,d} + \|h_{J^c}\|_1 z^*_{2,d} - \lambda\|\widehat{\beta}^{(L)}\|_1 + \lambda\|\beta^*\|_1. \end{aligned}$$

Since $-\lambda\|\widehat{\beta}^{(L)}\|_1 + \lambda\|\beta^*\|_1 \le -\lambda\|h_{J^c}\|_1 + \lambda\|h_J\|_1 + 2\lambda\rho_J$ and $\|h_J\|_1 \le \sqrt{3d/4}\|h_A\|$,

$$\|Xh\|^2/n + (\lambda - z^*_{2,d})\|h_{J^c}\|_1 \le (\lambda + z^*_{2,d})\sqrt{d}\|h_A\| + 2\lambda\rho_J.$$

Since $\Sigma_{A,*}h = z_A - X'_A(y - X\widehat{\beta}^{(L)})/n$, $\|\Sigma_{A,*}h\| \le (z^*_{2,d} + \lambda)\sqrt{d}$. Thus, as in (65),

$$\|\Sigma_{A,*}h\| \le \xi_1\sqrt{d}\lambda,\ \|h_{J^c}\|_1 \le \xi_0\sqrt{d}\|h_A\| + (\xi_0 + 1)\rho_J. \tag{66}$$

For $\|h_{J^c}\|_1 \le \xi\sqrt{d}\|h_A\|$, (42) follows from

$$d^{1/2-1/q}\|h\|_q CIF_{q,relax}(\xi, J, d) \le \|\Sigma_{A,*}h\| \le \xi_1\sqrt{d}\lambda.$$

For $\xi\sqrt{d}\|h_A\| \le \|h_{J^c}\|_1$, the second inequality of (66) gives $\sqrt{d}\|h_A\| \le (\xi_0 + 1)\rho_J/(\xi - \xi_0)$ and then $\|h\|_1 \le (1 + \xi_0)(\sqrt{d}\|h_A\| + \rho_J) \le \xi_2\rho_J$. Thus, $\|h\|_q \le M_{q,relax}(\xi_1\lambda, \xi_2\rho_J, J, d)$ by (41), in view of the first inequality of (66). ■

Proof of Proposition 15. Let A be the index set of the k largest u_j and w satisfy $\|\Sigma_A w_A\|_{q/(q-1)} = w'_A\Sigma_A u_A/\|u_A\|_q = 1$. By Lemma 20, $w'_A\Sigma_{A,A^c}u_{A^c} \le \kappa_{q,k,k}k^{1/q-1}\rho$, so that $\|u_A\|_q = w'_A\Sigma_A u_A \le \|w_A\|_1\|\Sigma u\|_\infty + \kappa_{q,k,k}k^{1/q-1}\rho \le \eta_{q,k}k^{1/q}\lambda + \kappa_{q,k,k}k^{1/q-1}\rho$. This and $\|u\|_q \le (\|u_A\|_q^q + (a_q/k)^{q-1}\rho^q)^{1/q}$ from Lemma 20 yields (44).

Let A be as in (41) and $w_A = \Sigma_A^{-1}u_A/\|u_A\|$. For $\|\Sigma_{A,*}u\| \le \sqrt{d}\lambda$ and $\|u\|_1 \le \rho$, $\|u_A\| = w'_A\Sigma_A u_A \le \|w_A\|d^{1/2}\lambda + w_A\Sigma_{A,A^c}u_{A^c} \le \eta^*_{2,d}d^{1/2}\lambda + \kappa_{2,d,\ell}\ell^{-1/2}\rho$, so that (45) follows from $\|u\|_q^q \le (d^{1/q-1/2}\|u_A\|)^q + (a_q/\ell)^{q-1}\rho^q$.

Let u and A be as in (40) and $k = |J|$. Similar to the proof of Proposition 5, we have $\|u\|^2 \le \{1 + \xi^2 k/(4\ell)\}\|u_A\|^2$ and $\|u\|_1 \le \sqrt{k}\|u_A\| + \|u_{J^c}\|_1 \le (1 + \xi\sqrt{d/k})k^{1/2}\|u_A\|$. Thus, for $1 \le q \le 2$, $\|u\|_q \le \|u\|_1^{2/q-1}\|u\|^{2-2/q} \le C_{q,2}(\xi(d/k)^{1/2}, k^2/(d\ell))k^{1/q-1/2}\|u_A\|$. Since $\|u_{J^c}\|_1 \le \xi d^{1/2}\|u_A\|$ and (64) holds for $v = u$, $u'_A\Sigma_{A,*}u \ge \phi_{2,\ell}(u, A, r, w, B; \xi', J)/\|w_A\|$ for $\|u_A\| = 1$, where $\xi' = \xi\sqrt{d/k}$ and $w = u/(u'_A\Sigma_A u_A)$. Thus, (20) gives (46). ■

The proof of Theorem 17 requires the following lemma.

Lemma 21 *Let $\widehat{\beta}$ be either the Dantzig or the Lasso estimator at penalty level λ. Suppose $\|\beta\|_r \le R$ with $0 < r \vee 1 \le q$. For any event Ω_0 with $t_* = \sqrt{2\log(1/P_{\beta,X}(\Omega_0))} \ge 1$,*

$$E_{\beta,X}\|\widehat{\beta} - \beta\|_q^q I_{\Omega_0} \le 2^{q-1}P_{\beta,X}(\Omega_0)\Big\{\frac{\Gamma(2q+1)}{(t_*^2 n\lambda/\sigma^2)^q} + \Big(\frac{(t_* + \sqrt{n})^2}{n\lambda/\sigma^2} + 2p^{(1-1/r)_+}R\Big)^q\Big\}. \tag{67}$$

In particular, if $(\log p)/n + \sigma^2/(n\lambda^2) + R^r/(n\lambda^r) + \lambda^r/R^r = O(1)$, then

$$E_{\beta,X}\|\widehat{\beta} - \beta\|_q^q I_{\Omega_0} = o(1)R^r\lambda^{q-r}, \tag{68}$$

provided that $P_{\beta,X}(\Omega_0)(\lambda^r/R^r)\{(\sigma/\lambda)^{2q} + p^{q(1-1/r)_+}(R/\lambda)^q\} = o(1)$.

Remark 22 *Since the unit sphere $S^{n-1} \subset \mathbb{R}^n$ is covered by $(2/\varepsilon+1)^n$ ε-balls for all $\varepsilon > 0$, a certain ε ball contains at least m unit vectors $x_j/\|x_j\|$ for $\varepsilon = (\log(p/m))/(2n)$. It follows that the set of design vectors x_j contains some highly correlated clusters when $(\log p)/n \geq 2$. Thus, the condition $(\log p)/n = O(1)$ is natural for the estimation of β.*

Proof. Let $\widehat{\beta}$ be the Lasso estimator. Since $\widehat{\beta}$ minimizes the penalized loss, $\lambda\|\widehat{\beta}\|_1 \leq \|\varepsilon\|^2/(2n) + \lambda\|\beta\|_1$, so that

$$\|\widehat{\beta}\|_1 + \|\beta\|_1 \leq \frac{\|\varepsilon\|^2}{2n\lambda} + 2\|\beta\|_1 \leq \frac{(\|\varepsilon\|/\sigma - t_* - \sqrt{n})_+^2}{n\lambda/\sigma^2} + \frac{(t_* + \sqrt{n})^2}{n\lambda/\sigma^2} + 2p^{(1-1/r)_+}R.$$

Since $\|\varepsilon/\sigma\|$ is a Lipschitz(1) function of $\varepsilon/\sigma \sim N(0, I_n)$ and $E_{\beta,X}\|\varepsilon\|/\sigma \leq \sqrt{n}$, the Gaussian isoperimetric theorem gives $P_{\beta,X}\{\|\varepsilon\|/\sigma - \sqrt{n} > t\} \leq e^{-t^2/2}$, so that

$$\begin{aligned} E_{\beta,X}(\|\varepsilon\|/\sigma - t_* - \sqrt{n})_+^{2q} &\leq \int_0^\infty P_{\beta,X}\{\|\varepsilon\|/\sigma - t_* - \sqrt{n} > t\} dt^{2q} \\ &\leq \int_0^\infty e^{-t_*^2/2 - t_* t} dt^{2q} = P_{\beta,X}(\Omega_0)\Gamma(2q+1)/t_*^{2q}. \end{aligned}$$

The above inequalities yield (67) due to $\|\widehat{\beta} - \beta\|_q^q \leq (\|\widehat{\beta}\|_1 + \|\beta\|_1)^q$ for $q \geq 1$.

It follows from (67) that

$$\begin{aligned} & E_{\beta,X}\|\widehat{\beta} - \beta\|_q^q I_{\Omega_0}/\{R^r\lambda^{q-r}\} \\ = \;& O(\lambda^r/R^r)P_{\beta,X}(\Omega_0)\Big\{O(1) + (t_*^2/n+1)^q(\sigma/\lambda)^{2q} + p^{q(1-1/r)_+}R^q/\lambda^q\Big\}. \end{aligned}$$

Since the right-hand side is of no greater order than $P_{\beta,X}(\Omega_0)\{(t_*^2+n)^q + p^q n^{q/r}\} = o(1)$ for $t_*^2/(n \vee \log p) \to \infty$, it suffices to consider the case $t_*^2/n = O(1)$. Hence, (68) holds under the specified conditions. The same conclusions hold for the Dantzig selector, since $\|\widehat{\beta}^{(D)}\|_1 \leq \|\widehat{\beta}^{(L)}\|_1$. ■

Proof of Theorem 17. We first bound $\lambda_{univ}/\lambda_{mm}$ and the expected loss for large $z_\infty^* = \|X'\varepsilon/n\|_\infty$. Let $\sigma_n = \sigma/\sqrt{n}$. Since $R^r/\lambda_{mm}^r \asymp d$, (5) and (55) give

$$2\sigma_n^2 \log(p/d) \approx \lambda_{mm}^2. \tag{69}$$

Since $(\log d)/\log p \leq c_0$, $(1-c_0)\lambda_{univ}^2 = (1-c_0)2\sigma_n^2 \log p \leq 2\sigma_n^2 \log(p/d) \approx \lambda_{mm}^2$ and

$$C_1 \approx C_1^* = 2(\lambda/\lambda_{mm})(d\lambda_{mm}^r/R^r)^{1/q},\ C_2 \approx C_2^* = R/(\lambda d^{1/r}).$$

Let $\Omega_0 = \{z_\infty^*/\lambda > \alpha_1\}$. Since z_∞^* is the maximum of p variables from $N(0, \sigma_n^2)$, $P_{\beta,X}\{\Omega_0\} \ll p\exp(-n(\alpha_1\lambda)^2/(2\sigma^2)) \leq p^{1-(\alpha_1/\alpha_0)^2}$ for large n. Thus, due to $\lambda^2/\sigma_n^2 \asymp \log p$ and $n \geq d \asymp R^r/\lambda_{mm}^r \asymp R^r/\lambda^r \to \infty$, we have

$$P_{\beta,X}(\Omega_0)(\lambda^r/R^r)\{(\sigma/\lambda)^{2q} + (R/\lambda)^q\} = o(1)p^{1-(\alpha_1/\alpha_0)^2}(n^q/d + d^{q/r-1}) = o(1).$$

Since $0 < r \leq 1$, Lemma 21 gives $E_{\beta,X}\|h\|_q^q I\{z_\infty^*/\lambda > \alpha_1\} = o(R^r\lambda_{mm}^{q-r})$, where $h = \widehat{\beta} - \beta$.

Next we prove $E_{\beta,X}\|h\|_q^q I\{z_\infty^*/\lambda \leq \alpha_1\} = O(R^r\lambda_{mm}^{q-r})$. Consider $z_\infty^* \leq \alpha_1\lambda$. By (65) with $J = \emptyset$, $\|h\|_q \leq 2M_q(\lambda, \xi'\|\beta\|_1)$ with $\xi' = \xi^*$ for $r = 1$. Since $M_q(\lambda, \rho) = cM_q(\lambda/c, \rho/c)$,

$$\|h\|_q/(R^{r/q}\lambda_{mm}^{1-r/q}) \leq C_1^* M_q(d^{-1/q}, \xi_2' C_2^* d^{1/r-1/q}).$$

This gives (47) for $r = 1$ and $E_{\beta,X}\|h\|_q^q I\{\alpha\lambda < z_\infty^* \le \alpha_1\lambda\} = o(p^{1-(\alpha/\alpha_0)^2} d^{q(1/r-1)}) = o(1)$ for $r < 1$. Let $J = \arg\max_{|A|=d} \|\beta_A\|_1$. For $\beta \in \Theta_{r,R}$, $\|\beta_{J^c}\|_\infty \le (R^r/d)^{1/r}$, so that $\rho_J/(\lambda d) \le (R^r/d)^{(1-r)/r} R^r/(\lambda d) = C_2^*$. Thus, in the event $z_\infty^* \le \alpha\lambda$, Theorem 10 gives

$$\|h\|_q/(R^{r/q}\lambda_{mm}^{1-r/q}) \le \max\left\{C_1^*/CIF_q^*(\xi,d), C_1^* M_q(d^{-1/q}, \xi^* C_2^* d^{1-1/q})\right\},\ r < 1.$$

It remains to prove (48) under $\eta_{q,d} + \kappa_{q,d,d} = O(1)$. In fact, by (44) it suffices to prove $1/CIF_q^*(\xi,k) = O(1)$ for any $k + \ell = d$ with $k \asymp d$. This follows from (21), since $CIF_{q,p}(\xi,|J|) \gtrsim \{1 - \xi(k/\ell)^{1-1/q}\kappa_{q,d,d}\}/\eta_{q,d} > 0$ uniformly for $|J| = k$ and small k/ℓ. ■

The proof of Theorem 19 requires the following simpler version of Lemma 2 in Zhang (2010).

Lemma 23 *Let $\widetilde{p}_\ell$ be the positive number satisfying $2\log\widetilde{p}_\ell - 1 - \log(2\log\widetilde{p}_\ell) = (2/\ell)\log\binom{p}{\ell}$. Suppose $\varepsilon \sim N(\mathbf{0}, \sigma^2 I_n)$ under probability P. Then,*

$$P\Big\{\max_{|A|=\ell} \|P_A\varepsilon\| \ge \sigma\sqrt{2\ell\log\widetilde{p}_\ell}\Big\} \le \frac{1}{2\sqrt{\log\widetilde{p}_\ell}} \le \frac{1}{\sqrt{2}},$$

where $P_A = X_A(X_A'X_A)^{-1}X_A'$ is the projection to the linear span of $\{x_j, j \in A\}$.

Proof of Theorem 19. Let $\gamma_d = (1+\delta_d^+)^{1/2}$ There are two cases. We omit the proof in the case of $\lambda = \lambda_{univ}/\alpha$ since it is identical to the second half of the proof of Theorem 17. It remains to consider the case $\lambda < \lambda_{univ}/\alpha$, that is, $(1+\varepsilon_0)\gamma_d\lambda_{mm} < \lambda_{univ}$.

For $|A| = d$, $\|X_A'\varepsilon/n\| \le \gamma_d\|P_A\varepsilon\|/\sqrt{n}$, so that by (38) and Lemma 23

$$P_{\beta,X}\Big\{z_{2,d}^* \le \gamma_d\sigma\sqrt{(2/n)\log\widetilde{p}_d}\Big\} \ge 1 - 1/(2\sqrt{\log\widetilde{p}_d}) \to 1.$$

Since $R^r/\lambda_{mm}^r \asymp d$ and $\lambda_{mm}n^{1/2}/\sigma \to \infty$, $\lambda_{mm} = (1+o(1))\sigma\sqrt{(2/n)\log(p/d)}$ by (69). By Stirling, $\log\binom{p}{d} = (1+o(1))d\log(p/d)$ for $p/d \to \infty$, so that $\lambda_{mm} = (1+o(1))\sigma\sqrt{(2/n)\log\widetilde{p}_d}$. Thus, $\gamma_d\sigma\sqrt{(2/n)\log\widetilde{p}_d} \le \alpha\lambda$ and $P_{\beta,X}\{z_{2,d}^* \le \alpha\lambda\} \to 1$.

Consider the event $z_{2,d}^* \le \alpha\lambda$. Since $\xi > (1+\alpha)/(1-\alpha)$, Theorem 12 asserts that for $J = \arg\max_{|A|=k}\|\beta_A\|_1$ and certain constants $\{\xi_1, \xi_2\}$,

$$\|h\|_q \le \max\Big\{\frac{\xi_1 d^{1/q}\lambda}{CIF_{q,relax}(\xi,J,d)}, M_{q,relax}\Big(\xi_1\lambda, \xi_2\rho_J, J, d\Big)\Big\}.$$

The rest of the proof is similar to the proof of Theorem 17 and omitted. ■

Abstract

We propose a class of Bayesian networks appropriate for structured prediction problems where the Bayesian network's model structure is a function of the predicted output structure. These incremental sigmoid belief networks (ISBNs) make decoding possible because inference with partial output structures does not require summing over the unboundedly many compatible model structures, due to their directed edges and incrementally specified model structure. ISBNs are specifically targeted at challenging structured prediction problems such as natural language parsing, where learning the domain's complex statistical dependencies benefits from large numbers of latent variables. While exact inference in ISBNs with large numbers of latent variables is not tractable, we propose two efficient approximations. First, we demonstrate that a previous neural network parsing model can be viewed as a coarse mean-field approximation to inference with ISBNs. We then derive a more accurate but still tractable variational approximation, which proves effective in artificial experiments. We compare the effectiveness of these models on a benchmark natural language parsing task, where they achieve accuracy competitive with the state-of-the-art. The model which is a closer approximation to an ISBN has better parsing accuracy, suggesting that ISBNs are an appropriate abstract model of natural language grammar learning.

Keywords: Bayesian networks, dynamic Bayesian networks, grammar learning, natural language parsing, neural networks

1. Introduction

In recent years, there has been increasing interest in structured prediction problems, that is, classification problems with a large (or infinite) structured set of output categories. The set of output categories are structured in the sense that useful generalisations exist across categories, as usually reflected in a structured representation of the individual categories. For example, the output categories might be represented as arbitrarily long sequences of labels, reflecting generalisations across categories which share similar sets of sub-sequences. Often, given an input, the structure of the possible output categories can be uniquely determined by the structure of the input. For example in sequence labelling tasks, all possible output categories are label sequences of the same length as the input sequence to be labelled. In this article, we investigate structured classification problems

where this is not true; the structure of the possible output categories is not uniquely determined by the input to be classified. The most common type of such problems is when the input is a sequence and the output is a more complex structure, such as a tree. In reference to this case, we will refer to problems where the output structure is not uniquely determined by the input as "parsing problems". Such problems frequently arise in natural language processing (e.g., prediction of a phrase structure tree given a sentence), biology (e.g., protein structure prediction), chemistry, or image processing. We will focus on the first of these examples, natural language parsing. The literature on such problems clearly indicates that good accuracy cannot be achieved without models which capture the generalisations which are only reflected in the output structure. For example, in English sentences, if a noun is parsed as the subject of a verb, then these words must be compatible in their singular/plural markings, independent of whether they are near each other in the input sentence.

In addition to limiting the scope of this article to parsing problems, we focus on tasks where the training data specifies the output structure, but the labelling of this structure is not fully annotated. While the unannotated labelling may not be evaluated in the task, by assuming incomplete labelling we allow our models to capture generalisation which are not directly reflected in the labelled output structure given for training. For example, the training data for natural language parsing problems is generally assumed to be a tree, but assuming that all generalisations can be expressed in terms of one-level fragments of the tree leads to poor empirical performance. However, much better performance can be achieved with such a model by extending the labelling to include features of the structural context (Charniak, 2000). Because we want to learn the necessary additional labelling, we need to solve a limited form of grammar induction.

Graphical models provide the formal mechanisms needed to learn and reason about incomplete labelling, using latent variables. They also provide the formal mechanisms needed to specify the statistical dependencies implied by the structure of a single output category. However, these mechanisms are not sufficient to specify a complete probability model for a parsing problem, because we need to specify the statistical dependencies for the complete space of possible output categories. As we will discuss in Section 3, even graphical models for unbounded sequence labelling, such as dynamic Bayesian networks, are in general not adequate for this task, because they are limited to finite-state models.

There are well established methods for specifying probabilistic models of parsing problems, based on grammar formalisms, such as probabilistic context-free grammars (PCFGs). The grammar formalism defines how the complete space of possible pairs of an input sequence with an output structure can be specified as a set of sequences of decisions about the input-output pair. Each possible sequence of decisions, called a derivation, specifies a single input-output pair (e.g., phrase structure tree or protein structure). The probability model is then defined in terms of probabilities for each decision. In its most general form, these decision probabilities are conditioned on anything from the unbounded history of previous decisions:

$$P(T) = P(D^1, ..., D^m) = \prod_t P(D^t | D^1, \ldots, D^{t-1}), \tag{1}$$

where T is the input-output structure and $D^1, \ldots, D^m$ is its equivalent sequence of decisions.

In PCFGs, the context-free assumption means that only a bounded amount of the history $D^1, \ldots, D^{t-1}$ is relevant to the probability for decision D^t. The context-free assumption only allows statistical dependencies within each bounded one-level subtree of the output tree, so two such subtrees can only interact through the bounded choice of label for the node they share, if any. Because the context-free assumption is defined in terms of the output structure, not in terms of the

input sequence, which decisions in the history are relevant depends on the output structure specified by the derivation. In graphical models, such a specification of which decisions are statistically dependent on which other decisions is called the "model structure". Thus PCFGs, like other grammar formalisms, are examples of models where the model structure is a function of the output structure, not just of the input sequence. This is the fundamental distinction between models of parsing problems and models of sequence labelling problems, and it will be central to our discussions in this article.

The most common approach to building probability models for parsing problems is to use PCFGs without any latent variables (e.g., Charniak, 2000; Collins, 1999; Durbin et al., 1998), but this approach relies on hand-built sets of features to represent the unbounded decision histories in (1). Latent probabilistic context-free grammars (LPCFGs) (Matsuzaki et al., 2005) extend the node labels of PCFGs with latent annotations, but previous proposals have successfully induced only a small number of latent annotations.

An alternative proposal to extending the labelling of parse trees is to use the hidden units of a neural network (Henderson, 2003). In the model of Henderson (2003), vectors of hidden unit values decorate the positions t in the derivation sequence, and are used to encode features of the unbounded derivation history $D^1, \ldots, D^{t-1}$. As with LPCFGs, the pattern of interdependencies between layers of hidden units is a function of the output structure, making it appropriate for parsing problems. But unlike LPCFGs, the pattern of interdependencies is not required to respect the context-free assumption. This model achieved state-of-the-art results, but there is no clear probabilistic semantics for the induced hidden representations.

In this article, we propose a class of graphical models which we call incremental sigmoid belief networks (ISBNs), which are closely related to the neural network of Henderson (2003), but which have a clear probabilistic semantics for all their variables. ISBNs are a kind of sigmoid belief network (Neal, 1992), but are dynamic models and have an incrementally specified set of statistical dependencies. Each position in the decision sequence has a vector of latent state variables, which are statistically dependent on variables from previous positions via a pattern of edges determined by the previous decisions. This incrementally specified model structure allows ISBNs to capture the generalisations which are only reflected in the output structure, such as the tendency towards correlations which are local in the output structure, which motivates the context-free assumption of PCFGs.

Allowing the model structure to depend on the output structure means that the complete model structure is not known until the complete output derivation is known. In general, this can complicate decoding (i.e., parsing) because computing probabilities for sub-derivations requires marginalising out the unknown portion of the model structure, which in the worst case could require summing over an unbounded number of possible model structures. The properties of ISBNs avoid this problem because the probability of a derivation prefix is always independent of the unknown portion of the model structure, as discussed in Section 3.

Despite this simplification, exact inference (i.e., computing probabilities) is not in general tractable in ISBNs, because they allow large vectors of latent variables in a heavily interconnected directed model. We demonstrate the practical applicability of ISBN models by providing efficient approximate inference methods. We consider two forms of approximation for ISBNs, a feed-forward neural network approximation (NN) and a form of mean field approximation (Saul and Jordan, 1999). In Section 5, we first show that the neural network model in Henderson (2003) can be viewed as a coarse approximation to inference with ISBNs. We then propose an incremental

mean field method (IMF), which provides an improved approximation but remains tractable. Both these approximations give us valid probability models.

In Section 7, we present two empirical evaluations. In the first experiment, we trained both of the approximation models on artificial data generated from random ISBNs. The NN model achieves a 60% average relative error reduction over a baseline model and the IMF model achieves a further 27% average relative error reduction over the NN model. These results demonstrate that the distribution of output structures specified by an ISBN can be approximated, that these approximations can be learnt from data, and that the IMF approximation is indeed better than the NN approximation. In the second experiment, we apply both of the approximation models to phrase structure parsing with data from the Wall Street Journal Penn Treebank (Marcus et al., 1993). The IMF model achieves statistically significant error reduction of about 8% over the NN model. Results of the IMF model are non-significantly worse (less than 1% relative error increase) than the results of one of the best known history-based models of parsing (Charniak, 2000). We argue that this correlation between better approximation and better accuracy suggests that ISBNs are a good abstract model for structured prediction.

Section 8 discusses related work not covered in the rest of this article. It focuses particularly on previous work on LPCFGs.

2. Inference with Sigmoid Belief Networks

Before defining ISBNs, we provide background on sigmoid belief networks. A sigmoid belief network (SBN) (Neal, 1992) is a type of Bayesian network. Bayesian networks are directed acyclic graphs where the nodes are variables and the edges specify statistical dependencies between variables. SBNs have binary variables which have conditional probability distributions (CPDs) of the form:

$$P(S_i = 1|Par(S_i)) = \sigma(\sum_{S_j \in Par(S_i)} J_{ij} S_j), \tag{2}$$

where $Par(S_i)$ is the set of variables with edges directed to S_i, σ denotes the logistic sigmoid function $\sigma(x) = 1/(1+e^{-x})$, and J_{ij} is the weight for the edge from variable S_j to variable S_i.[1] SBNs are similar to feed-forward neural networks, but unlike neural networks, SBNs have a precise probabilistic semantics of their hidden variables. In ISBNs we consider a generalised version of SBNs where we allow variables with any range of discrete values. The normalised exponential function is used to define the CPDs at these nodes:

$$P(S_i = k|Par(S_i)) = \frac{\exp(\sum_{S_j \in Par(S_i)} W^i_{kj} S_j)}{\sum_{k'} \exp(\sum_{S_j \in Par(S_i)} W^i_{k'j} S_j)}, \tag{3}$$

where W^i is the weight matrix for the variable S_i.

Exact inference with all but very small SBNs is not tractable. Initially sampling methods were used (Neal, 1992), but they are also not feasible for large networks, especially for the dynamic models of the type described in Section 4. Variational methods have also been proposed for approximating SBNs (Saul et al., 1996; Saul and Jordan, 1999). The main idea of variational methods (Jordan

1. For convenience, where possible, we will not explicitly include bias terms in expressions, assuming that every latent variable in the model has an auxiliary parent variable set to 1.

et al., 1999) is, roughly, to construct a tractable approximate model with a number of free parameters. The free parameters are set so that the resulting approximate model is as close as possible to the original model for a given inference problem.

The simplest example of a variational method is the mean field method, originally introduced in statistical mechanics and later applied to neural networks in Hinton et al. (1995). Let us denote the set of visible variables in the model by V and latent (hidden) variables by $H = h_1, \ldots, h_l$. The mean field method uses a fully factorised distribution $Q(H|V) = \prod_i Q_i(h_i|V)$ as the approximate model, where each Q_i is the distribution of an individual latent variable. The independence between the variables h_i in this approximate distribution Q does not imply independence of the free parameters which define the Q_i. These parameters are set to minimise the Kullback-Leibler divergence between the approximate distribution $Q(H|V)$ and the true distribution $P(H|V)$ or, equivalently, to maximise:

$$L_V = \sum_H Q(H|V) \ln \frac{P(H,V)}{Q(H|V)}. \tag{4}$$

The expression L_V is a lower bound on the log-likelihood $\ln P(V)$. It is used in the mean field theory (Saul and Jordan, 1999) as an approximation of the log-likelihood. However, in our case of dynamic graphical models, as explained later, we have to use a different approach which allows us to construct an incremental structured prediction method without needing to introduce the additional parameters proposed in Saul and Jordan (1999), as we will discuss in Section 5.3.

3. Incrementally Specifying Model Structure

We want to extend SBNs to make them appropriate for modelling parsing problems. As discussed in the introduction, this requires being able to model arbitrarily long decision sequences $D^1, ..., D^m$, and being able to specify the pattern of edges (the model structure) as a function of the chosen output structure. In this section, we define how incremental sigmoid belief networks specify such model structures.

To extend SBNs for processing arbitrarily long sequences, such as the derivation decision sequence $D^1, ..., D^m$, we use dynamic models. This gives us a form of dynamic Bayesian network (DBN). To handle unboundedly long sequences, DBNs specify a Bayesian network template which gets instantiated for each position in the sequence, thereby constructing a Bayesian network which is as large as the sequence is long. This constructed Bayesian network is illustrated in the rightmost graph of Figure 1, where the repeated two-box pattern is the template, and the left-to-right order is the derivation order. This template instantiation defines a new set of variables for each position in the sequence, but the set of edges and parameters for these variables are the same as in other positions. The edges which connect variables instantiated for different positions must be directed forward in the sequence, thereby allowing a temporal interpretation of the sequence. DBNs based on sigmoid belief networks were considered in Sallans (2002) in the context of reinforcement learning. Normally, DBNs only allow edges between adjacent (or a bounded window of) positions, which imposes a Markov assumption on statistical dependencies in the Bayesian network.

The problem with only allowing edges between variables instantiated at positions which are adjacent (or local) in the decision sequence is that this does not allow the model structure to adequately reflect the correlations found in parsing problems. In particular, in many domains, correlations tend to be local in the output structure, even when they are not local in the derivation sequence for that structure. To capture these correlations in the statistical dependencies learnt by the model, we want

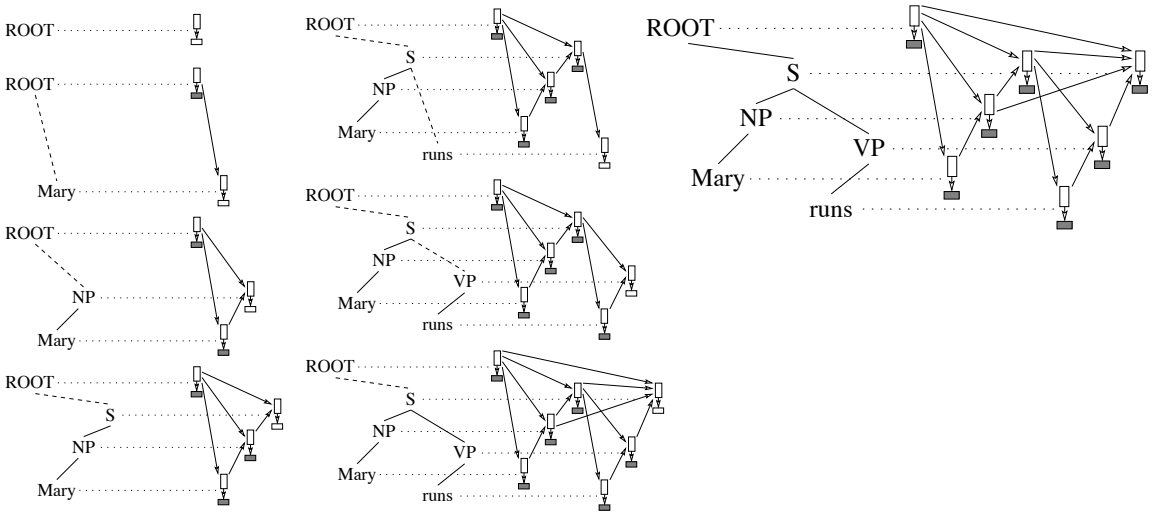

Figure 1: Illustration of the predictive LR derivation of an output structure and its associated incremental specification of an ISBN model structure (ordered top-to-bottom, left-to-right). Dotted lines indicate the top of the parser's stack at each derivation decision in the model structure.

the edges of the model to reflect locality in the output structure. This requires specifying edges based on the actual outputs in the decision sequence $D^1, ..., D^m$, not just based on adjacency in this sequence.

We constrain this edge specification so that a decision $D^{t'}$ can only effect the placement of edges whose destination variable is at a position $t > t'$ after the decision $D^{t'}$. This gives us a form of switching model (Murphy, 2002), where each decision switches the model structure used for the remaining decisions. We allow the incoming edges for a given position to be any discrete function of the sequence of decisions which precede that position. For this reason, we call our model an "incremental" model, not just a dynamic model; the structure of the Bayesian network is determined incrementally as the decision sequence proceeds. This incremental specification of the model structure is illustrated in Figure 1 (the directed graphs), along with the partial output structures incrementally specified by the derivation (the trees). In Figure 1, dotted lines associate a position's instantiated template with the node in the output structure which is on top of the parser's stack when making that position's decision. Note that the incoming edges for a position's instantiated template reflect edges between the associated nodes in the partial output structure.

Any discrete function can be used to map the preceding sequence of decisions to a set of incoming edges for a given decision. In general, we can characterise this function in terms of an automaton which reads derivations and deterministically outputs model structures. For every derivation prefix $D^1, ..., D^{t-1}$, the automaton outputs a set of labelled positions in the derivation prefix. For each labelled position $(t-c, r)$ in this set, label r determines which variables instantiated at that position are linked to which variables instantiated at the current position t, and with which parameters.[2] For

2. In all our models to date, we have respected the additional constraint that there is at most one labelled position in the set for each label r, so the size of the set is bounded. We do not impose this constraint here because the model is still well defined without it, but we do not have empirical evidence about the effect of removing it.

example, the ISBN illustrated in Figure 1 uses a push-down automaton to compute which output structure nodes are currently important (e.g., the top and next-to-top nodes on the automaton's stack) and specifies conditional dependencies between the current decision and previous decisions where these nodes were on the top of the stack. By using a push-down automaton, this model is able to express non-Markovian (e.g., context-free) regularities in the derivation sequences.

Previous applications of switching models to DBNs (e.g., Murphy, 2002) have allowed statistical dependencies to be a function of the output, but only of the output from the immediately preceding position in the sequence, and therefore have only allowed switching between a bounded number of alternatives. Because the number of switched alternatives is bounded, the whole set of alternatives can be expressed as a single bounded model, whose CPDs incorporate the discrete switching. Thus, switching does not allow us to specify any models which could not be specified with a complicated DBN, so switching DBNs also impose some form of Markov assumption. In terms of the automata discussed above, this means that switching DBNs can be expressed using finite-state automata, so would only be appropriate for problems with a regular-language structure to their output categories. This limitation does not give us sufficient power to express the kinds of output-conditioned statistical dependencies we need for parsing problems in general. Therefore, it is crucial to distinguish between standard dynamic models and our incremental models.

Incremental sigmoid belief networks allow the model structure to depend on the output structure without overly complicating the inference of the desired conditional probabilities $P(D^t|D^1,\ldots,D^{t-1})$. Computing this probability requires marginalising out the unknown model structure for the portion of the Bayesian network which follows position t. In general, this could require explicitly summing over multiple possible model structures, or in the worst case summing over the unbounded number of possible model structures. ISBNs avoid summing over any of these possible model structures because in ISBNs $P(D^t|D^1,\ldots,D^{t-1})$ is independent of all model structure which follows position t. This can be proved by considering two properties of ISBNs. At position t in the sequence, the only edges whose placement are not uniquely determined by $D^1,\ldots,D^{t-1}$ have their destinations after t. Also, none of the variables after t are visible (i.e., have their values specified in $D^1,\ldots,D^{t-1}$). Therefore none of the edges whose placement is not yet known can have any impact on the inference of $P(D^t|D^1,\ldots,D^{t-1})$, as follows directly from well known properties of Bayesian networks. This property implies that each individual Bayesian network depicted in Figure 1 can be used to compute the conditional probability of its next derivation decision, and it will give the same answer as if the same conditional probability were computed in the final Bayesian network at the end of the derivation, or indeed in any such valid continuation.

The use of directed edges to avoid the need to sum over unknown model structures can also be seen in Hidden Markov Models (HMMs). Given a sequence prefix, we can use an HMM to infer the probability of the following element of the sequence. This distribution is not dependent on the total length of the sequence, which would be needed to draw the complete HMM model for the sequence. Note that this property does not hold for undirected graphical models, such as Conditional Random Fields (Lafferty et al., 2001). Rohanimanesh et al. (2009) investigate inference in undirected models with edges that are a function of the output structure, but the solutions are approximate and computationally expensive.

The incremental specification of model structure can also be seen in LPCFGs. Given a top-down left-to-right derivation of a phrase structure tree, the dependencies between LPCFG derivation decisions have the same structure as the phrase structure tree, but with LPCFG rules (one-level subtrees) labelling each node of this derivation tree. The number of branches at a node in the

derivation tree is determined by the rule which is chosen to label that node, thereby incrementally specifying the complete derivation tree. If we expressed an LPCFG as a graphical model, the model structures would have the same general form as the derivation trees, so the model structure would also be incrementally specified. Also, the edges in this graphical model would need to be directed, because LPCFG rule probabilities are locally normalised. Therefore LPCFG can also be thought of as Bayesian networks with incrementally specified model structure. The differences between ISBNs and LPCFG will be discussed in the next section and Section 8.

As illustrated by the above examples, the argument for the incremental specification of model structure can be applied to any Bayesian network architecture, not just sigmoid belief networks. We focus on ISBNs because, as shown in Section 5, they are closely related to the empirically successful neural network models of Henderson (2003). This previous work has shown that the combination of logistic sigmoid hidden units and having a model structure which reflect locality in the output structure results in a powerful form of feature induction. The edges from hidden units to hidden units allow information to propagate beyond the notion of immediate structural locality defined in the model, but the logistic sigmoid ensures a bias against propagating information through long chains of hidden units, thereby providing a soft but domain-appropriate bias to feature induction.

4. The Probabilistic Model of Structured Prediction

In this section we complete the definition of incremental sigmoid belief networks for grammar learning. We only consider joint probability models, since they are generally simpler and, unlike history-based conditional models, do not suffer from the label bias problem (Bottou, 1991). Also, in many complex predication tasks, such as phrase structure parsing, many of the most accurate models make use of a joint model, either in reranking or model combinations (e.g., Charniak and Johnson, 2005; Henderson, 2004).

We use a history-based probability model, as in Equation (1), but instead of treating each D^t as an atomic decision, it will be convenient below to further split it into a sequence of elementary decisions $D^t = d^t_1, \ldots, d^t_n$:

$$P(D^t | D^1, \ldots, D^{t-1}) = \prod_k P(d^t_k | h(t,k)),$$

where $h(t,k)$ denotes the decision history $D^1, \ldots, D^{t-1}, d^t_1, \ldots, d^t_{k-1}$. For example, a decision to create a new node in a labelled output structure can be divided into two elementary decisions: deciding to create a node and deciding which label to assign to it.

An example of the kind of graphical model we propose is illustrated in Figure 2. It is organised into vectors of variables: latent state variable vectors $S^{t'} = s^{t'}_1, \ldots, s^{t'}_n$, representing an intermediate state at position t', and decision variable vectors $D^{t'}$, representing a decision at position t', where $t' \leq t$. Variables whose value are given at the current decision (t,k) are shaded in Figure 2; latent and current decision variables are left unshaded.

As illustrated by the edges in Figure 2, the probability of each state variable s^t_i depends on all the variables in a finite set of relevant previous state and decision vectors, but there are no direct dependencies between the different variables in a single state vector. As discussed in Section 3, this set of previous state and decision vectors is determined by an automaton which runs over the derivation history $D^1, \ldots, D^{t-1}$ and outputs a set of labelled positions in the history which are connected to the current position t. For each pair $(t-c, r)$ in this set, r represents a relation between

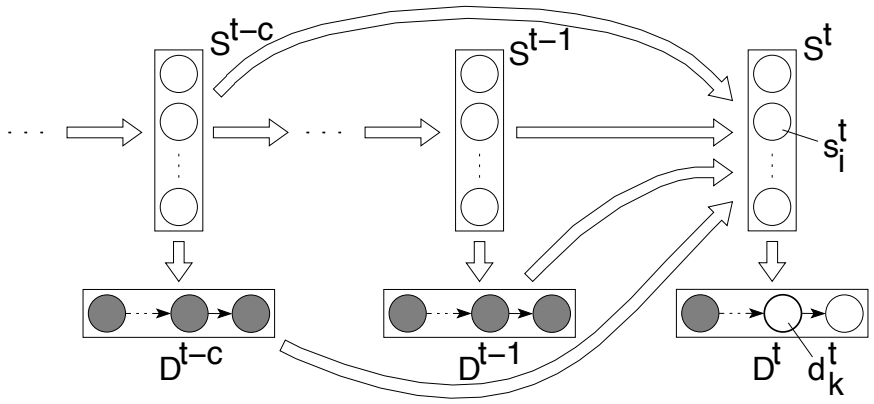

Figure 2: ISBN for estimating $P(d_k^t|h(t,k))$.

position t and the position $t-c$ in the history. We denote by $r(t-c,t)$ the predicate which returns true if the position $t-c$ with the relation label r is included in the set for t, and false otherwise. In general this automaton is allowed to perform arbitrary computations, as specified by the model designer. For example, it could select the most recent state where the same output structure node was on the top of the automaton's stack, and a decision variable representing that node's label. Each such selected relation r has its own distinct weight matrix for the resulting edges in the graph, but the same weight matrix is used at each position where the relation is relevant (see Section 7.2 for examples of relation types we use in our experiments).

We can write the dependency of a latent variable s_i^t on previous latent variable vectors and a decision history as:

$$P(s_i^t = 1|S^1,\ldots,S^{t-1},h(t,1)) = \sigma\left(\sum_{r,t':r(t',t)}\sum_j J_{ij}^r s_j^{t'} + \sum_k B_{id_k^{t'}}^{rk}\right), \tag{5}$$

where J^r is the latent-to-latent weight matrix for relation r and B^{rk} is the decision-to-latent weight matrix for relation r and elementary decision k. If there is no previous step $t' < t$ which is in relation r to the time step t, that is, $r(t',t)$ is false for all t', then the corresponding relation r is skipped in the summation. For each relation r, the weight J_{ij}^r determines the influence of the jth variable in the related previous latent vector $S^{t'}$ on the distribution of the ith variable of the considered latent vector S^t. Similarly, $B_{id_k^{t'}}^{rk}$ defines the influence of the past decision $d_k^{t'}$ on the distribution of the considered latent vector variable s_i^t.

In the previous paragraph we defined the conditional distribution of the latent vector variables. Now we describe the distribution of the decision vector $D^t = d_1^t,\ldots d_n^t$. As indicated in Figure 2, the probability of each elementary decision d_k^t depends both on the current latent vector S^t and on the previously chosen elementary action d_{k-1}^t from D^t. This probability distribution has the normalised exponential form:

$$P(d_k^t = d|S^t,d_{k-1}^t) = \frac{\Phi_{h(t,k)}(d)\exp(\sum_j W_{dj}s_j^t)}{\sum_{d'}\Phi_{h(t,k)}(d')\exp(\sum_j W_{d'j}s_j^t)}, \tag{6}$$

where $\Phi_{h(t,k)}$ is the indicator function of the set of elementary decisions that can possibly follow the last decision in the history $h(t,k)$, and the W_{dj} are the weights of the edges from the state variables. Φ is essentially switching the output space of the elementary inference problems $P(d_k^t = d|S^t, d_{k-1}^t)$ on the basis of the previous decision d_{k-1}^t. For example, in a generative history-based model of natural language parsing, if decision d_1^t was to create a new node in the tree, then the next possible set of decisions defined by $\Phi_{h(t,2)}$ will correspond to choosing a node label, whereas if decision d_1^t was to generate a new word then $\Phi_{h(t,2)}$ will select decisions corresponding to choosing this word.

Given this design for using ISBNs to model derivations, we can compare such ISBN models to LPCFG models. As we showed in the previous section, LPCFGs can also be thought of as Bayesian networks with incrementally specified model structure. One difference between LPCFGs and ISBNs is that LPCFGs add latent annotations to the symbols of a grammar, while ISBNs add latent annotations to the states of an automaton. However, this distinction is blurred by the use of grammar transforms in LPCFG models, and the many equivalences between grammars and automata. But certainly, the automata of ISBNs are much less constrained than the context-free grammars of LPCFGs. Another distinction between LPCFGs and ISBNs is that LPCFGs use latent annotations to split symbols into multiple atomic symbols, while ISBNs add vectors of latent variables to the existing symbol variables. The structure of the similarities between vectors is much richer than the structure of similarities between split atomic symbols, which gives ISBNs a more structured latent variable space than LPCFGs. This makes learning easier for ISBNs, allowing the induction of more informative latent annotations. Both these distinctions will be discussed further in Section 8.

5. Approximating Inference in ISBNs

Exact inference with ISBNs is straightforward, but not tractable. It involves a summation over all possible variable values for all the latent variable vectors. The presence of fully connected latent variable vectors does not allow us to use efficient belief propagation methods. Even in the case of dynamic SBNs (i.e., Markovian models), the large size of each individual latent vector would not allow us to perform the marginalisation exactly. This makes it clear that we need to develop methods for approximating the inference problems required for structured prediction. Standard Gibbs sampling (Geman and Geman, 1984) is also expensive because of the huge space of variables and the need to resample after making each new decision in the sequence. It might be possible to develop efficient approximations to Gibbs sampling or apply more complex versions of Markov Chain Monte-Carlo techniques, but sampling methods are generally not as fast as variational methods. In order to develop sufficiently fast approximations, we have investigated variational methods.

This section is structured as follows. We start by describing the application of the standard mean field approximation to ISBNs and discuss its limitations. Then we propose an approach to overcome these limitations, and two approximation methods. First we show that the neural network computation used in Henderson (2003) can be viewed as a mean field approximation with the added constraint that computations be strictly incremental. Then we relax this constraint to build more accurate but still tractable mean field approximation.

5.1 Applicability of Mean Field Approximations

In this section we derive the most straightforward way to apply mean field methods to ISBN. Then we explain why this approach is not feasible for structured prediction problems of the scale of natural language parsing.

The standard use of the mean field theory for SBNs (Saul et al., 1996; Saul and Jordan, 1999) is to approximate probabilities using the value of the lower bound L_V from expression (4) in Section 2. To obtain a tighter bound, as we explained above, L_V is maximised by choosing the optimal distribution Q. To approximate $P(d_k^t|h(t,k))$ using the value of L_V, we have to include the current decision d_k^t in the set of visible variables, along with the visible variables specified in $h(t,k)$. Then to estimate the conditional probability $P(d_k^t|h(t,k))$, we need to normalise over the set of all possible value of d_k^t. Thus we need to compute a separate estimate $\max_Q L_V^{t,k}(d)$ for each possible value of $d_k^t = d$:

$$\max_Q L_V^{t,k}(d) = \max_Q \sum_H Q(H^t|h(t,k),d_k^t = d) \ln \frac{P(H^t,h(t,k),d_k^t = d)}{Q(H^t|h(t,k),d_k^t = d)},$$

where $H^t = \{S^1,\ldots,S^t\}$. Then $P(d_k^t = d|h(t,k))$ can be approximated as the normalised exponential of $L_V^{t,k}(d)$ values:

$$\hat{P}(d_k^t = d|h(t,k)) = \frac{\exp(\max_Q L_V^{t,k}(d))}{\sum_{d'} \exp(\max_Q L_V^{t,k}(d'))}. \tag{7}$$

It is not feasible to find the optimal distribution Q for SBNs, and mean field methods (Saul et al., 1996; Saul and Jordan, 1999) use an additional approximation to estimate $\max_Q L_V^{t,k}(d)$. Even with this approximation, the maximum can be found only by using an iterative search procedure. This means that decoding estimator (7) requires performing this numerical procedure for every possible value of the next decision. Unfortunately, in general this is not feasible, in particular with labelled output structures where the number of possible alternative decisions d_k^t can be large. For our generative model of natural language parsing, decisions include word predictions, and there can be a very large number of possible next words. Even if we choose not to recompute mean field parameters for all the preceding states $S^{t'}, t' < t$, but only for the current state S^t (as proposed below), tractability still remains a problem.[3]

In our modifications of the mean field method, we propose to consider the next decision d_k^t as a hidden variable. Then the assumption of full factorisability of $Q(H^t,d_k^t|h(t,k))$ is stronger than in the standard mean field theory because the approximate distribution Q is no longer conditioned on the next decision d_k^t. The approximate fully factorisable distribution $Q(H|V)$ can be written as:

$$Q(H|V) = q_k^t(d_k^t) \prod_{t'i} \left(\mu_i^{t'}\right)^{s_i^{t'}} \left(1-\mu_i^{t'}\right)^{1-s_i^{t'}}.$$

where $\mu_i^{t'}$ is the free parameter which determines the distribution of state variable i at position t', namely its mean, and $q_k^t(d_k^t)$ is the free parameter which determines the distribution over decisions d_k^t. Importantly, we use $q_k^t(d)$ to estimate the conditional probability of the next decision:

$$P(d_k^t = d|h(t,k)) \approx q_k^t(d),$$

3. We conducted preliminary experiments with natural language parsing on very small data sets and even in this setup the method appeared to be very slow and, surprisingly, not as accurate as the modification considered further in this section.

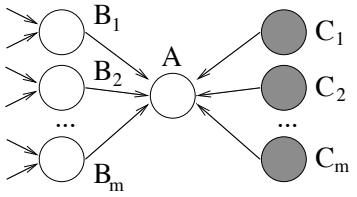

Figure 3: A graphical model fragment where variable A is a sink.

and the total structure probability is therefore computed as the product of decision probabilities corresponding to its derivation:

$$P(T) = P(D^1, \ldots, D^m) \approx \prod_{t,k} q_k^t(d_k^t). \tag{8}$$

5.2 A Feed-Forward Approximation

In this section we will describe the sense in which neural network computation can be regarded as a mean field approximation under an additional constraint of strictly feed-forward computation. We will call this approximation the feed-forward approximation. As in the mean field approximation, each of the latent variables in the feed-forward approximation is independently distributed. But unlike the general case of mean field approximation, in the feed-forward approximation we only allow the parameters of every distribution $Q(s_i^{t'}|h(t,k))$ and $Q(d_k^t|h(t,k))$ to depend on the approximate distributions of their parents, thus requiring that any information about the distribution of its descendants is not taken into account. This additional constraint increases the potential for a large KL divergence with the true model, but it significantly simplifies the computations.

We start with a simple proposition for general graphical models. Under the feed-forward assumption, computation of the mean field distribution of a node in an ISBN is equivalent to computation of a distribution of a variable corresponding to a sink in the graph of the model, that is, a node which does not have any outgoing edges. For example, node A is a sink in Figure 3. The following proposition characterises the mean field distribution of a sink.

Proposition 1 *The optimal mean field distribution of a sink A depends on the mean field distribution $Q(B)$ of its hidden parents $B = (B_1, \ldots, B_m)$ as*

$$Q(A = a) \propto \exp(E_Q \log P(A = a|B,C)),$$

where Q is the mean field distribution of hidden variables, P is the model distribution, C are visible parents of the node A and E_Q denotes the expectation under the mean field distribution $Q(B)$.

This proposition is straightforward to prove by maximising the variational bound L_V (4) with respect to the distribution $Q(A)$. Now we can use the fact that SBNs have log-linear CPD. By substituting their CPD given in expression (2) for P in the lemma statement, we obtain:

$$Q(S_i = 1) = \sigma(\sum_{S_j \in Par(S_i)} J_{ij}\mu_j),$$

which exactly replicates computation of a feed-forward neural network with the logistic sigmoid activation function. Similarly, we can show that for variables with soft-max CPD, as defined in (3), their mean field distribution will be the log-linear function of their parents' means. Therefore minimising KL divergence under the constraint of feed-forward computation is equivalent to using log-linear functions to compute distributions of random variables given means of their parents.

Now let us return to the derivation of the feed-forward approximation of ISBNs. As we just derived, under the feed-forward assumption, means of the latent vector $S^{t'}$ are given by

$$\mu_i^{t'} = \sigma(\eta_i^{t'}),$$

where $\eta_i^{t'}$ is the weighted sum of the parent variables' means:

$$\eta_i^{t'} = \sum_{r,t'':r(t'',t')} \sum_j J_{ij}^r \mu_j^{t''} + \sum_k B_{id_k^{t''}}^{rk}, \tag{9}$$

as follows from the definition of the corresponding CPD (5).

The same argument applies to decision variables; the approximate distribution of the next decision $q_k^t(d)$ is given by

$$q_k^t(d) = \frac{\Phi_{h(t,k)}(d) \exp(\sum_j W_{dj} \mu_j^t)}{\sum_{d'} \Phi_{h(t,k)}(d') \exp(\sum_j W_{d'j} \mu_j^t)}. \tag{10}$$

The resulting estimate of the probability of the entire structure is given by (8).

This approximation method replicates exactly the computation of the feed-forward neural network model of Henderson (2003), where the above means $\mu_i^{t'}$ are equivalent to the neural network hidden unit activations. Thus, that neural network probability model can be regarded as a simple approximation to the ISBN graphical model.

In addition to the drawbacks shared by any mean field approximation method, this feed-forward approximation cannot capture bottom-up reasoning. By bottom-up reasoning, we mean the effect of descendants in a graphical model on distributions of their ancestors. For mean field approximations to ISBNs, it implies the need to update the latent vector means $\mu_i^{t'}$ after observing a decision d_k^t, for $t' \leq t$. The use of edges directly from decision variables to subsequent latent vectors is designed to mitigate this limitation, but such edges cannot in general accurately approximate bottom-up reasoning. The next section discusses how bottom-up reasoning can be incorporated in the approximate model.

5.3 Incremental Mean Field Approximation

In this section we relax the feed-forward assumption to incorporate bottom-up reasoning into the approximate model. Again as in the feed-forward approximation, we are interested in finding the distribution Q which maximises the quantity L_V in expression (4). The decision distribution $q_k^t(d_k^t)$ maximises L_V when it has the same dependence on the latent vector means μ_j^t as in the feed-forward approximation, namely expression (10). However, as we mentioned above, the feed-forward computation does not allow us to compute the optimal values of state means $\mu_i^{t'}$.

Optimally, after each new decision d_k^t, we should recompute all the means $\mu_i^{t'}$ for all the latent vectors $S^{t'}$, $t' \leq t$. However, this would make the method intractable for tasks with long decision sequences. Instead, after making each decision d_k^t and adding it to the set of visible variables

V, we recompute only the means of the current latent vector S^t. This approach also speeds up computation because, unlike in the standard mean field theory, there is no need to introduce an additional variational parameter for each hidden layer variable s_i^t.

The denominator of the normalised exponential function in (6) does not allow us to compute L_V exactly. Instead, we approximate the expectation of its logarithm by substituting S_j^t with their means:[4]

$$E_Q \ln \sum_d \Phi_{h(t,k)}(d) \exp(\sum_j W_{dj} S_j^t) \approx \ln \sum_d \Phi_{h(t,k)}(d) \exp(\sum_j W_{dj} \mu_j^t),$$

where the expectation is taken over the latent vector S^t distributed according to the approximate distribution Q. Unfortunately, even with this assumption there is no analytic way to maximise the approximation of L_V with respect to the means μ_i^t, so we need to use numerical methods. We can rewrite the expression (4) as follows, substituting the true $P(H,V)$ defined by the graphical model and the approximate distribution $Q(H|V)$, omitting parts independent of the means μ_i^t:

$$\begin{aligned} L_V^{t,k} = & \sum_i -\mu_i^t \ln \mu_i^t - (1-\mu_i^t) \ln \left(1-\mu_i^t\right) + \mu_i^t \eta_i^t \\ & + \sum_{k'<k} \sum_j W_{d_{k'}^t j} \mu_j^t - \ln \left(\sum_d \Phi_{h(t,k')}(d) \exp(\sum_j W_{dj} \mu_j^t) \right), \end{aligned} \tag{11}$$

here, η_i^t is computed from the previous relevant state means and decisions as in (9). This expression is concave with respect to the parameters μ_i^t, so the global maximum can be found. In the appendix, where we derive the learning algorithm, we show that the Hessian of this expression can be viewed as the negated sum of a positive diagonal matrix and some covariance matrices, thus implying the concavity of expression (11). We use coordinatewise ascent, where each μ_i^t is selected by a line search (Press et al., 1996) while keeping other $\mu_{i'}^t$ fixed.

Though we avoided re-computation of means of the previous states, estimation of the complex decision probability $P(D^t|h(t,k))$ will be expensive if the decision D^t is decomposed in a large number of elementary decisions. As an example, consider a situation in dependency parsing, where after deciding to create a link, the parser might need to decide on the type of the link and, then, predict the part of speech type of the word and, finally, predict the word itself. The main reason for this complexity is the presence of the summation over k' in expression (11), which results in expensive computations during the search for an optimal value of μ_i^t. This computation can be simplified by using the means of S^t computed during the estimation of $P(d_{k-1}^t|h(t,k-1))$ as priors for the computation of the same means during the estimation of $P(d_k^t|h(t,k))$. If we denote the means computed at an elementary step (t,k) as $\mu_i^{t,k}$, then for $k=1$, minimisation of $L_V^{t,k}$ can be performed analytically, by setting

$$\mu_i^{t,1} = \sigma(\eta_i^t). \tag{12}$$

4. In initial research, we considered the introduction of additional variational parameters associated with every possible value of the decision variable in a way similar to Saul and Jordan (1999), but this did not improve the prediction accuracy of the model, and considerably increased the computational time.

For $k > 1$, expression (11) can be rewritten as:

$$\begin{aligned} L_V^{t,k} = & \sum_i -\mu_i^{t,k} \ln \mu_i^{t,k} - (1-\mu_i^{t,k}) \ln \left(1-\mu_i^{t,k}\right) \\ & + \mu_i^{t,k} \left(\ln \mu_i^{t,k-1} - \ln(1-\mu_i^{t,k-1})\right) + W_{d^t_{k-1} i} \mu_i^{t,k} \\ & - \ln \left(\sum_d \Phi_{h(t,k-1)}(d) \exp\left(\sum_j W_{dj} \mu_j^{t,k}\right) \right). \end{aligned} \tag{13}$$

Note that maximisation of this expression is done also after computing the last decision K_t for the state t. The resulting means μ^{t,K_t+1} are then used in the computation of $\eta_i^{t'}$ for the relevant future states t', that is, such t' that $r(t,t')$ holds for some r:

$$\eta_i^{t'} = \sum_{r,t:r(t,t')} \sum_j J^r_{ij} \mu_j^{t,K_t+1} + \sum_k B^{rk}_{id^t_k}, \tag{14}$$

Concavity of expression (13) follows from concavity of (11), as their functional forms are different by only a linear term and the presence of summation over the elementary decisions. See the appendix where we will show that the Hessian of $L_v^{t,k}$ is negative semidefinite, confirming this statement.

6. Learning and Decoding

We train the models described in Sections 5.2 and 5.3 to maximise the fit of the approximate models to the data. We use gradient descent, and a maximum likelihood objective function. In order to compute the derivatives with respect to the model parameters, the error should be propagated back through the structure of the graphical model. For the feed-forward approximation, computation of the derivatives is straightforward, as in neural networks (Rumelhart et al., 1986). But for the mean field approximation, this requires computation of the derivatives of the means μ_i^t with respect to the other parameters in expression (13). The use of a numerical search in the mean field approximation makes the analytical computation of these derivatives impossible, so a different method needs to be used to compute their values. The appendix considers the challenges arising when using maximum likelihood estimation with the incremental mean field algorithm and introduces a modification of the error backpropagation algorithm for this model. For both approximations, their respective backpropagation algorithms have computational complexity linear in the length of a derivation.

The standard mean field approach considered in Saul and Jordan (1999) maximised L_V (4) during learning, because L_V was used as an approximation of the log-likelihood of the training data. L_V is actually the sum of the log-likelihood and the negated KL divergence between the approximate distribution $Q(H|V)$ and the SBN distribution $P(H|V)$. Thus, maximising L_V will at the same time direct the SBN distribution toward configurations which have a lower approximation error. It is important to distinguish this regularisation of the approximate distribution from the Gaussian priors on the SBN parameters, which can be achieved by simple weight decay. We believe that these two regularisations should be complementary. However, in our version of the mean field method the approximate distributions of hidden decision variables q_k^t are used to compute the data likelihood (8) and, thus, maximising this target function will not automatically imply KL divergence minimisation. Application of an additional regularisation term corresponding to minimisation of the KL divergence might be beneficial for our approach, and it could be a subject of further research.

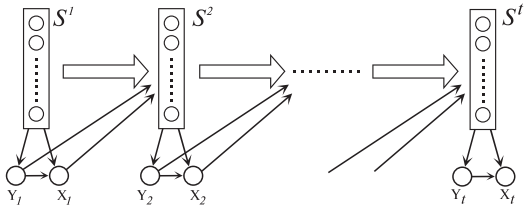

Figure 4: Dynamic SBN used in artificial experiments.

In our current experiments, we used standard weight decay, which regularises the SBN distribution with a Gaussian prior over weights.

ISBNs define a probability model which does not make any a-priori assumptions of independence between any decision variables. As we discussed in Section 3, the use of relations based on the partial output structure makes it possible to take into account statistical interdependencies between decisions closely related in the output structure, but separated by arbitrarily many positions in the input structure. In general, this property leads to the complexity of complete search being exponential in the number of derivation decisions. Fortunately, for many problems, such as natural language parsing, efficient heuristic search methods are possible.

7. Experiments

The goal of the evaluation is to demonstrate that ISBNs are an appropriate model for grammar learning. Also, we would like to show that learning the mean field approximation derived in Section 5.3 (IMF method) results in a sufficiently accurate model, and that this model is more accurate than the feed-forward neural network approximation (NN method) of Henderson (2003) considered in Section 5.2. First, we start with an artificial experiment where the training and testing data is known to have been generated by a SBN, and compare models based on each of the approximation methods. Second, we apply the models to a real problem, parsing of natural language, where we compare our approximations with state-of-the-art models.

7.1 Artificial Experiment

In order to have an upper bound for our artificial experiments, we do not consider incremental models, but instead use a dynamic sigmoid belief network, a first order Markovian model, and consider a sequence labelling task. This simplification allowed us to use Gibbs sampling from a *true* model as an upper bound of accuracy. The following generative story corresponds to the random dynamic SBNs:

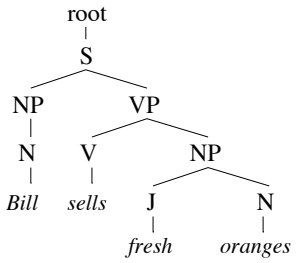

Figure 5: An example phrase structure tree.

Draw initial state vector S^1 from a distribution of initial states $P(S^1)$.
t = 0.
Do
t = t + 1,
draw a label Y^t from the distribution $P(Y^t|S^t)$ as in (6),
draw an input element X^t from the distribution $P(X^t|Y^t,S^t)$,
draw the next latent state vector S^{t+1} from $P(S^{t+1}|S^t,X^t,Y^t)$,
while $Y^t \neq 0$ and $t < t_{max}$.

A graphical representation of this dynamic model is shown in Figure 4. Different weight matrices were used in the computation of $P(X^t|Y^t,S^t)$ for each value of the label Y^t. It is easy to see that this model is a special case of the ISBN graphical model, namely Figure 2 with non-Markovian dependencies removed. The state vector length was set to 5, the number of possible labels to 6, the number of distinct input elements to 8, the maximal length of each sequence t_{max} to 100. We performed 10 experiments.[5] For each of the experiments, we trained both IMF and NN approximations on a training set of 20,000 elements, and tested them on another 10,000 elements. Weight-decay and learning rate were reduced through the course of the experiments whenever accuracy on the development set went down. Beam search with a beam of 10 was used during testing. The IMF methods achieved average error reduction of 27% with respect to the NN method, where accuracy of the Gibbs sampler was used as an upper bound (average accuracies of 80.5%, 81.0%, and 82.3% for the NN, IMF, and sampler, respectively).

The IMF approximation performed better than the NN approximation on 9 experiments out of 10 (statistically significant in 8 cases).[6] These results suggest that the IMF method leads to a much more accurate model than the NN method when the true distribution is defined by a dynamic SBN. In addition, the average relative error reduction of even the NN approximation over the unigram model exceeded 60% (the unigram model accuracy was 77.4% on average), which suggests that both approximations are sufficiently accurate and learnable.

7.2 Natural Language Parsing

We compare our two approximations on the natural language phrase structure parsing task. The output structure is defined as a labelled tree, which specifies the hierarchical decomposition of a

5. We preselected these 10 models to avoid random dynamic SBNs with trivial distributions. We excluded SBNs for which unigram model accuracy was within 3% of the Gibbs sampler accuracy, and where accuracy of the Gibbs sampler did not exceed 70%. All these constants were selected before conducting the experiments.
6. In all our experiments we used the permutation test (Diaconis and Efron, 1983) to measure significance and considered a result significant if p-value is below 5%.

sentence into phrases. An example of such a tree is presented on Figure 5, where the tree specifies that the adjective (J) *fresh* and the noun (N) *oranges* form a noun phrase (NP) *"fresh oranges"*, which, when combined with the verb (V) *sells*, forms the verb phrase (VP) *"sells fresh oranges"*. The hypothesis we wish to test here is that the more accurate approximation of ISBNs will result in a more accurate model of parsing. If this is true, then it suggests that ISBNs are a good abstract model for problems similar to natural language parsing, namely parsing problems which benefit from latent variable induction.

We replicated the same definition of derivation and the same pattern of interconnection between states as described in Henderson (2003). For the sake of completeness we will provide a brief description of the structure of the model here, though more details can be found in Henderson (2003).

The model uses a modification of the predictive LR order (Soisalon-Soininen and Ukkonen, 1979), illustrated in Figure 6. In this ordering, a parser decides to introduce a node into the parse tree after the entire subtree rooted at the node's first child has been fully constructed. Then the subtrees rooted at the remaining children of the node are constructed in their left-to-right order. The state of the parser is defined by the current stack of nodes, the queue of remaining input words and the partial structure specified so far. The parser starts with an artificial *root* element in the stack and terminates when it reaches a configuration with an empty queue and with the artificial root element on the top of the stack. The algorithm uses 3 main types of decisions:

1. The decision $\mathbf{Shift}_w$ shifts the word w from the queue to the stack.
2. The decision $\mathbf{Project}_Y$ replaces the current top of the stack X with a new node Y, and specifies that Y is the parent of X in the output structure.
3. The decision **Attach** removes the current top of the stack X and specifies that element Y under the top of the stack is the parent of X.

Though these three types of decisions are sufficient to parse any constituent tree, Henderson (2003) extends the parsing strategy to include a specific treatment of a particular configuration in the parse tree, *Chomsky adjunction*, using a version of the Attach decision called **Modify**.

As was defined in expression (5), the probability of each state variable s_j^t in the ISBN depends on all the latent variables and previous relevant decisions in a subset of previous relevant positions t' : $r(t',t)$. In this ISBN model for phrase structure parsing, we use the same pattern of interconnections between variables as in the neural network of Henderson (2003), where there are different relations

$r(t',t)$ for selecting previous decision variables $D^{t'}$ and for selecting previous latent variables $S^{t'}$. Namely, the following four types of relations for selecting the previous positions $t' : r(t',t)$ for latent variables $S^{t'}$ are used:

1. *Stack Context*: the last previous position with the same element on top of the stack as at current position t.
2. *Sub-Top of Stack*: the last previous position where the node under the current top of the stack was on top of the stack.
3. *Left Child of Top of Stack*: the last previous position where the leftmost child of the current stack top was on top of the stack.
4. *Right Child of Top of Stack*: the last previous position where the rightmost child of the current stack top was on top of the stack.

These relations were motivated by linguistic considerations and many of them have also been found useful in other parsing models (Johnson, 1998; Roark and Johnson, 1999). Also, this set of relations ensures that the immediately preceding state is always included somewhere in the set of connected states. This requirement ensures that information, at least theoretically, can pass between any two states in the decision sequence, thereby avoiding any hard independence assumptions. Also note that each relation only selects at most one position (the most recent one of that kind). This ensures that the number of such connections to a latent vector remains bounded at four, so it should generalise well across larger, more complex constituency structures.

For selecting the previous positions $t' : r(t',t)$ for decision variables $D^{t'}$, the following relations are use:

1. *Previous*: the previous position $t-1$.
2. *Top*: the position at which the current top of the stack was shifted (if it is a terminal) or introduced (if non-terminal).
3. *Last Shift*: the position at which the last terminal was shifted.
4. *Left Terminal of Top of Stack*: the position when the leftmost terminal dominated by the current stack top was shifted.

This set includes the previous decision (*Previous*), which is important if the model does not do backward reasoning, as in the feed-forward approximation. The remaining relations pick out important labels, part-of-speech tags, and words in the context.

We used the Penn Treebank Wall Street Journal corpus to perform the empirical evaluation of the considered approaches. It is expensive to train the IMF approximation on the whole WSJ corpus, so instead we both trained and tested the model only on sentences of length at most 15, as in Taskar et al. (2004); Turian et al. (2006); Finkel et al. (2008). The standard split of the corpus into training (9,753 sentences, 104,187 words), validation (321 sentences, 3,381 words), and testing (603 sentences, 6,145 words) was performed.

As in Henderson (2003) and Turian and Melamed (2006) we used a publicly available tagger (Ratnaparkhi, 1996) to provide the part-of-speech tag for each word in the sentence. For each tag, there is an unknown-word vocabulary item which is used for all those words which are not sufficiently frequent with that tag to be included individually in the vocabulary. We only included a specific tag-word pair in the vocabulary if it occurred at least 20 time in the training set, which (with tag-unknown-word pairs) led to the very small vocabulary of 567 tag-word pairs.

Table 1: Percentage labelled constituent recall (R), precision (P), combination of both (F_1) on the testing set.

For decoding, we use best-first search with the search space pruned in two different ways. First, only a fixed number of the most probable partial derivations are pursued after each word shift operation. Secondly, the branching factor at each decision is limited. In the experiments presented in this chapter, we used the post-shift beam width of 10 and the branching factor of 5. Increasing the beam size and the branching factor beyond these values did not significantly effect parsing accuracy. For both of the models, the state vector length of 40 was used. All the parameters for both the NN and IMF models were tuned on the validation set. A single best model of each type was then applied to the final testing set.

Table 1 lists the results of the NN approximation and the IMF approximation,[7] along with results of different generative and discriminative parsing methods evaluated in the same experimental setup (Bikel, 2004; Taskar et al., 2004; Turian et al., 2006; Charniak, 2000; Finkel et al., 2008).[8] The IMF model improves over the baseline NN approximation, with a relative error reduction in F-measure exceeding 8%. This improvement is statistically significant.

The IMF model achieves results which do not appear to be significantly different from the results of the best model in the list (Charniak, 2000). Although no longer one of the most accurate parsing models on the standard WSJ parsing benchmark (including sentences of all lengths), the (Charniak, 2000) parser achieves competitive results (89.5% F-measure) and is still considered a viable approach, so the results reported here confirm the viability of our models. It should also be noted that previous results for the NN approximation to ISBNs on the standard WSJ benchmark (Henderson, 2003, 2004) achieved accuracies which are still competitive with the state of the art (89.1% F-measure for Henderson, 2003 and 90.1% F-measure for Henderson, 2004). For comparison, the LPCFG model of Petrov et al. (2006) achieve 89.7% F-measure on the standard WSJ benchmark.

We do not report the results on our data set of the LPCFG model of Petrov et al. (2006), probably the most relevant previous work on grammar learning (see the extended discussion in Section 8), as it would require tuning of their split-merge EM algorithm to achieve optimal results on the smaller

7. Approximate training times on a standard desktop PC for the IMF and NN approximations were 140 and 3 hours, respectively, and parsing times were 3 and 0.05 seconds per token, respectively. Parsing with the IMF method could be made more efficient, for example by not requiring the numerical approximations to reach convergence.

8. The results for the models of Bikel (2004) and Charniak (2000) trained and tested on sentences of length at most 15 were originally reported by Turian and Melamed (2005).

data set. However, we note that the CRF-based model of Finkel et al. (2008) (the reported 'feature-based' version) and the LPCFG achieves very close results when trained and tested on the sentences of length under 100 (Finkel et al., 2008) and, therefore, would be expected to demonstrate similar results in our setting. Note also that the LPCFG decoding algorithm uses a form of Bayes risk minimisation to optimise for the specific scoring function, whereas our model, as most parsing methods in the literature, output the highest scoring tree (maximum a-posteriori decoding). In fact, approximate Bayes risk minimisation can be used with our model and in our previous experiments resulted in approximately 0.5% boost in performance (Titov and Henderson, 2006). We chose not to use it here, as the maximum a-posteriori decoding is simpler, more widely accepted and, unlike Bayes risk minimisation, is expected to result in self-consistent trees.

These experimental results suggest that ISBNs are an appropriate model for structured prediction. Even approximations such as those tested here, with a very strong factorisability assumption, allow us to build quite accurate parsing models. We believe this provides strong justification for work on more accurate approximations of ISBNs.

8. Additional Related Work

Whereas graphical models are standard models for sequence processing, there has not been much previous work on graphical models for the prediction of structures more complex than sequences. Sigmoid belief networks were used originally for character recognition tasks, but later a Markovian dynamic extension of this model was applied to the reinforcement learning task (Sallans, 2002). However, their graphical model, approximation method, and learning method differ substantially from those of this paper.

When they were originally proposed, latent variable models for natural language parsing were not particularly successful, demonstrating results significantly below the state-of-the-art models (Kurihara and Sato, 2004; Matsuzaki et al., 2005; Savova and Peshkin, 2005; Riezler et al., 2002) or they were used in combination with already state-of-the-art models (Koo and Collins, 2005) and demonstrated a moderate improvement. More recently several methods (Petrov et al., 2006; Petrov and Klein, 2007; Liang et al., 2007), framed as grammar refinement approaches, demonstrated results similar to the best results achieved by generative models. All these approaches considered extensions of a classic PCFG model, which augment non-terminals of the grammar with latent variables (Latent-annotated PCFGs, LPCFGs). Even though marginalisation can be performed efficiently by using dynamic programming, decoding under this model is NP-hard (Matsuzaki et al., 2005; Sima'an, 1992). Instead, approximate parsing algorithms were considered.

The main reason for the improved performance of the more recent LPCFG methods is that they address the problem that with LPCFGs it is difficult to discover the appropriate latent variable augmentations for non-terminals. Early LPCFG models which used straight-forward implementations of expectation maximisation algorithms did not achieve state-of-the-art results (Matsuzaki et al., 2005; Prescher, 2005). To solve this problem the split-and-merge approach was considered in Petrov et al. (2006); Petrov and Klein (2007) and Dirichlet Process priors in Liang et al. (2007). The model of Petrov and Klein (2007) achieved the best reported result for a single model parser (90.1% F-measure). Even with the more sophisticated learning methods, in all of the work on LPCFGs the number of latent annotations which are successfully learnt is small, compared to the 40-dimensional vectors used in our experiments with ISBNs.

One important difference between LPCFGs and ISBNs is that in LPCFGs the latent annotations are used to expand the set of atomic labels used in a PCFG, whereas ISBNs directly reason with a vector of latent features. This use of a vector space instead of atomic labels provides ISBNs with a much larger label space with a much richer structure of similarity between labels, based on shared features. This highly structured label space allows standard gradient descent techniques to work well even with large numbers of latent features. In contrast, learning for LPCFGs has required the specialised methods discussed above and has succeeded in searching a much more limited space of latent annotations. These specialised methods impose a hierarchical structure of similarity on the atomic labels of LPCFGs, based on recursive binary augmentations of labels ("splits"), but this hierarchical structure is much less rich that the similarity structure of a vector space.

Another important difference with LPCFGs is that ISBN models do not place strong restrictions on the structure of statistical dependencies between latent variables, such as the context-free restriction of LPCFGs. This makes ISBNs easily applicable to a much wider set of problems. For example, ISBNs have been applied to the dependency parsing problem (Titov and Henderson, 2007) and to joint dependency parsing and semantic role labelling (Henderson et al., 2008; Gesmundo et al., 2009), where in both cases they achieved state-of-the-art results. The application of LPCFG models to even dependency parsing has required sophisticated grammar transformations (Musillo and Merlo, 2008), to which the split-and-merge training approach has not yet been successfully adapted.

The experiments reported in Henderson et al. (2008) also suggest that the latent annotations of syntactic states are not only useful for syntactic parsing itself but also can be helpful for other tasks. In these experiments, semantic role labelling performance rose by about 3.5% when latent annotations for syntactic decision were provided, thereby indicating that the latent annotation of syntactic parsing states helps semantic role labelling.

9. Conclusions

This paper proposes a new class of graphical models for structured prediction problems, incremental sigmoid belief networks, and has applied it to natural language grammar learning. ISBNs allow the structure of the graphical model to be dependent on the output structure. This allows the model to directly express regularities that are local in the output structure but not local in the input structure, making ISBNs appropriate for parsing problems. This ability supports the induction of latent variables which augment the grammatical structures annotated in the training data, thereby solving a limited form of grammar induction. Exact inference with ISBNs is not tractable, but we derive two tractable approximations. First, it is shown that the feed-forward neural network of Henderson (2003) can be considered as a simple approximation to ISBNs. Second, a more accurate but still tractable approximation based on mean field theory is proposed.

Both approximation models are empirically evaluated. First, artificial experiments were performed, where both approximations significantly outperformed a baseline. The mean field method achieved average relative error reduction of about 27% over the neural network approximation, demonstrating that it is a more accurate approximation. Second, both approximations were applied to the natural language parsing task, where the mean field method demonstrated significantly better results. These results are non-significantly different from the results of another history-based probabilistic model of parsing (Charniak, 2000) which is competitive with the state-of-the-art for single-model parsers. The fact that a more accurate approximation leads to a more accurate parser

suggests that the ISBNs proposed here are a good abstract model for grammar learning. This empirical result motivates further research into more accurate approximations of ISBNs.

Acknowledgments

We would like to acknowledge support for this work from the Swiss NSF scholarship PBGE22-119276 and from the European Commission (EC) funded CLASSiC project (project number 216594 funded under EC FP7, Call 1), and the partial support of the Excellence Cluster on Multimodal Computing and Interaction (MMCI) at Saarland University. We would also like to thank Paola Merlo for extensive discussions and Mark Johnson for his helpful comments on this work.

Appendix A.

This appendix presents details of computing gradients for the incremental mean field approximation. We perform maximum likelihood estimation of the ISBN parameters, using the estimator of the structure probability defined in expression (8). We focus on the incremental mean field approximation introduced in Section 5.3. As we have shown there, estimates of the conditional distribution $q_k^t(d) \approx P(d_k^t = d|h(t,k))$ are dependent on the means $\mu^{t,k}$ computed at the elementary step (t,k) in the same way as the estimates $q_k^t(d)$ in the feed-forward approximation depend on the means μ^t in expression (10), that is,

$$q_k^t(d) = \frac{\Phi_{h(t,k)}(d)\exp(\sum_j W_{dj}\mu_j^{t,k})}{\sum_{d'}\Phi_{h(t,k)}(d')\exp(\sum_j W_{d'j}\mu_j^{t,k})}. \tag{15}$$

We use the gradient descent algorithm, so the goal of this section is to describe how to compute derivatives of the log-likelihood

$$\hat{L}(T) = \sum_{t,k}\sum_j W_{d_k^t j}\mu_j^{t,k} - \log\left(\sum_{d'}\Phi_{h(t,k)}(d')\exp(\sum_j W_{d'j}\mu_j^{t,k})\right)$$

with respect to all the model parameters. The derivatives of $\hat{L}(T)$ with respect to model parameters can be expressed as

$$\frac{d\hat{L}(T)}{dx} = \sum_{d,j}\frac{\partial\hat{L}(T)}{\partial W_{dj}}\frac{dW_{dj}}{dx} + \sum_{t,k,i}\frac{\partial\hat{L}(T)}{\partial\mu_i^{t,k}}\frac{d\mu_i^{t,k}}{dx}, \tag{16}$$

where x is any model parameter, that is, entries of the weight matrices J, B and W. All the terms except for $\frac{d\mu_i^{t,k}}{dx}$ are trivial to compute:

$$\frac{\partial\hat{L}(T)}{\partial W_{dj}} = \sum_{t,k}\mu_j^{t,k}\left(\delta_{d_k^t d} - q_k^t(d)\right), \tag{17}$$

$$\frac{\partial\hat{L}(T)}{\partial\mu_i^{t,k}} = (1-\delta_{k,K_t+1})\left(W_{d_k^t i} - \sum_d q_k^t(d)W_{di}\right),$$

where δ_{ij} is the Kronecker delta. Computation of the total derivatives $\frac{d\mu_i^{t,k}}{dx}$ is less straightforward. The main challenge is that dependence of $\mu_j^{t,k}$ for $k > 1$ on other model parameters cannot be expressed analytically, as we found values of $\mu_j^{t,k}$ by performing numerical maximisation of the expression $L_V^{t,k}$ (13). In the next several paragraphs we will consider only the case of $k > 1$, but later we will return to the simpler case of $k = 1$, where the computation of derivatives is equivalent to the backpropagation algorithm in standard feed-forward neural networks.

Note that the gradient of the log-likelihood can be easily computed in the standard mean field methods for SBNs (Saul and Jordan, 1999; Saul et al., 1996), even though they also use numeric strategies to find optimal means. There means are selected so as to maximise the variational upper bound L_V (4), which is used as the log-likelihood $\hat{L} = L_V$ in their approach. In static SBNs it is feasible to perform complete maximisation of the entire $\hat{L}$, which involves multiple backward-forward passes through the structure of the graphical model. This leads to all the derivatives $\frac{d\hat{L}}{d\mu_i}$ being equal to zero. Therefore, no error backpropagation is needed in their case. All the derivatives $\frac{d\hat{L}}{dx}$ can be computed using variational parameters associated with the nodes corresponding to the parameter x. E.g. if x is a weight of an edge then only variational parameters associated with the variables at its ends are needed to compute the derivative. Unfortunately, learning with the incremental mean field approximation proposed in this paper is somewhat more complex.

In order to compute derivatives $\frac{d\mu_i^{t,k}}{dx}$ we assume that maximisation of $L_V^{t,k}$ is done until convergence, then the partial derivatives of $L_V^{t,k}$ with respect to $\mu_i^{t,k}$ are equal to zero. This gives us a system of linear equations, which describes interdependencies between the current means $\mu^{t,k}$, the previous means $\mu^{t,k-1}$ and the weights W:

$$F_i^{t,k} = \frac{\partial L_V^{t,k}}{\partial \mu_i^{t,k}} = \ln(1-\mu_i^{t,k}) - \ln\mu_i^{t,k} - \ln(1-\mu_i^{t,k-1}) + \ln\mu_i^{t,k-1} + W_{d_{k-1}^t i} - \sum_d \hat{q}_{k-1}^t(d) W_{di} = 0,$$

for $1 < i \leq n$, where $\hat{q}_{k-1}^t$ is the distribution over decisions computed in the same way as q_{k-1}^t (15), but using means $\mu_i^{t,k}$ instead of $\mu_i^{t,k-1}$:

$$\hat{q}_{k-1}^t(d) = \frac{\Phi_{h(t,k-1)}(d) \exp(\sum_j W_{dj} \mu_j^{t,k})}{\sum_{d'} \Phi_{h(t,k-1)}(d') \exp(\sum_j W_{d'j} \mu_j^{t,k})}.$$

This system of equations permits the use of implicit differentiation to compute the derivatives $\frac{\partial \mu_i^{t,k}}{\partial z}$, where z can be a weight matrix component W_{dj} or a previous mean $\mu_j^{t,k-1}$ involved in expression (13). It is important to distinguish z from x, used above, because x can be an arbitrary model parameter not necessary involved in the expression $L_V^{t,k}$ but affecting the current means $\mu_i^{t,k}$ through $\mu_j^{t,k-1}$. Equally important to distinguish partial derivatives $\frac{\partial \mu_i^{t,k}}{\partial z}$ from the total derivatives $\frac{d\mu_i^t}{dz}$, because the dependency of $\mu_i^{t,k}$ on parameter z can be both direct, through maximisation of $L_V^{t,k}$, but also indirect through previous maximisation steps (t',k'), where $L_V^{t',k'}$ was dependent on z. The relation between the total and partial derivatives can be expressed as

$$\frac{d\mu_i^{t,k}}{dz} = \frac{\partial \mu_i^{t,k}}{\partial z} + \sum_j \frac{\partial \mu_i^{t,k}}{\partial \mu_j^{t,k-1}} \frac{d\mu_j^{t,k-1}}{dz},$$

meaning that indirect dependencies of $\mu_i^{t,k}$ ($k > 1$) on parameters z are coming through previous means $\mu_j^{t,k-1}$. We apply the implicit differentiation theorem and obtain the vector of partial derivatives with respect to a parameter z $D_z\mu^t = \{\frac{\partial \mu_1^t}{\partial z}, \ldots, \frac{\partial \mu_n^t}{\partial z}\}$ as

$$D_z\mu^t = -\left(D_{\mu^t}F^{t,k}\right)^{-1} D_z F^{t,k}, \tag{18}$$

where $D_{\mu^t}F^{t,k}$ and $D_z F^{t,k}$ are Jacobians:

$$D_{\mu^t}F^{t,k} = \begin{pmatrix} \frac{\partial F_1^{t,k}}{\partial \mu_1^t} & \cdots & \frac{\partial F_1^{t,k}}{\partial \mu_n^t} \\ \cdots & \cdots & \cdots \\ \frac{\partial F_n^{t,k}}{\partial \mu_1^t} & \cdots & \frac{\partial F_n^{t,k}}{\partial \mu_n^t} \end{pmatrix}, \quad D_z F^{t,k} = \begin{pmatrix} \frac{\partial F_1^{t,k}}{\partial z} \\ \cdots \\ \frac{\partial F_n^{t,k}}{\partial z} \end{pmatrix}.$$

Now we derive the Jacobians $D_{\mu^t}F^{t,k}$ and $D_z F^{t,k}$ for different types of parameters z. The matrix $D_{\mu^t}F^{t,k}$ consists of the components

$$\begin{aligned} \frac{\partial F_i^{t,k}}{\partial \mu_j^{t,k}} = &- \frac{\delta_{ij}}{\mu_j^{t,k}(1-\mu_j^{t,k})} - \sum_d \hat{q}_{k-1}^t(d) W_{di} W_{dj} \\ &+ \left(\sum_d \hat{q}_{k-1}^t(d) W_{di}\right)\left(\sum_d \hat{q}_{k-1}^t(d) W_{dj}\right), \end{aligned} \tag{19}$$

where δ_{ij} is the Kronecker delta. If we consider $W_{\cdot i}$ as a random variable accepting values W_{di} under distribution $\hat{q}_{k-1}^t$, we can rewrite the Jacobian $D_{\mu^t}F^{t,k}$ as the negated sum of a positive diagonal matrix and the covariance matrix $\Sigma_{\hat{q}_{k-1}^t}(W)$. Therefore the matrix $D_{\mu^t}F^{t,k}$ is negative semidefinite.

Note that this matrix is the Hessian for the expression $L_V^{t,k}$ (13), which implies concavity of $L_V^{t,k}$ stated previously without proof. Similarly, the Hessian for (11) is only different by including output weight covariances for all the previous elementary decision, not only for the last one, and therefore expression (11) is also concave.

To conclude with the computation of $\frac{\partial \mu_i^{t,k}}{\partial z}$, we compute $D_{\mu^{t,k-1}}F^{t,k}$ and $D_W F^{t,k}$:

$$\frac{\partial F_i^{t,k}}{\partial \mu_j^{t,k-1}} = \frac{\delta_{ij}}{\mu_j^{t,k-1}(1-\mu_j^{t,k-1})}, \tag{20}$$

$$\frac{\partial F_i^{t,k}}{\partial W_{dj}} = \delta_{ij}\delta_{dd_k^t} - \hat{q}_{k-1}^t(d)\left(\delta_{ij} + (W_{di} - \sum_{d'} \hat{q}_{k-1}^t(d') W_{d'i})\mu_j^{t,k}\right). \tag{21}$$

Now the partial derivatives $\frac{\partial \mu_i^{t,k}}{\partial W_{dj}}$ and $\frac{\partial \mu_i^{t,k}}{\partial \mu_i^{t,k-1}}$ can be computed by substituting expressions (19)-(21) into (18).

For $k = 1, \mu_i^{t,1}$ was shown to be equal to the sigmoid function of the weighted sum of the parents means as defined in (12) and (14). Therefore, we can compute the partial derivatives of $\mu_i^{t,1}$ with respect to other means and parameters involved in (12) and (14):

$$\frac{\partial \mu_i^{t,1}}{\partial \mu_j^{t',K_{t'}+1}} = \sigma'(\eta_i^t) \sum_{r:r(t',t)} J_{ij}^r,$$

$$\frac{\partial \mu_i^{t,1}}{\partial J_{jl}^r} = \delta_{ij}\sigma'(\eta_i^t) \sum_{t':r(t',t)} \mu_l^{t',K_{t'}+1},$$

$$\frac{\partial \mu_i^{t,1}}{\partial B_{jd}^{rk}} = \delta_{ij}\sigma'(\eta_i^t) \sum_{t':r(t',t)} \delta_{dd_k^{t'}}.$$

where $\sigma'(\eta_i^t) = \sigma(\eta_i^t)\,(1-\sigma(\eta_i^t))$.

In order to compute $\frac{d\mu_i^{t,k}}{dx}$ in (16), derivatives with respect to previous means $\frac{\partial \mu_i^{t,k}}{\partial \mu_i^{t,k-1}}$ are used to propagate the error in a similar way to the neural network backpropagation algorithm (Rumelhart et al., 1986). We denote the total derivative of the approximate log-likelihood with respect to the means of the latent variables as $\varepsilon_i^{t,k} = \frac{d\hat{L}(T)}{d\mu_i^{t,k}}$. The incrementality of the mean field algorithm guarantees that latent vectors of means $\mu^{t,k}$ are computed from the means of the previous elementary steps. Therefore, values $\varepsilon_i^{t,k}$ can be computed in the opposite order, propagating the information back through the structure. Namely, the recursive formulae would be:

$$\varepsilon_i^{t,k} = \frac{\partial \log q_k^t}{\partial \mu_i^{t,k}} + \sum_j \varepsilon_j^{t,k+1} \frac{\partial \mu_j^{t,k+1}}{\partial \mu_i^{t,k}}, \;\; k \le K_t \;,$$

$$\varepsilon_i^{t,K^t+1} = \sum_{r,t':r(t,t')} \sum_j \varepsilon_j^{t',1} \sigma'(\eta_j^{t'}) J_{ji}^r.$$

After computing values ε for all the elementary steps (t,k), we can evaluate the derivatives of the model parameters. We start with the output distribution parameters W_{di}:

$$\frac{d\hat{L}(T)}{dW_{di}} = \frac{\partial \hat{L}(T)}{\partial W_{di}} + \sum_{t,k} \sum_j \varepsilon^{t,k} \frac{\partial \mu_j^{t,k}}{\partial W_{di}}.$$

The first term here is evaluated as defined in (17), the term $\frac{\partial \mu_j^{t,k}}{\partial W_{di}}$ is computed as explained above.

Finally, the total derivatives of the log-likelihood with respect to the parameters J_{ij}^t and B_{id}^{rk} are found as follows

$$\frac{d\hat{L}(T)}{dJ_{ij}^r} = \sum_t \mu_j^t \sum_{t':r(t,t')} \varepsilon_i^{t',1} \sigma'(\eta_i^{t'}),$$

$$\frac{d\hat{L}(T)}{dB_{id}^{rk}} = \sum_t \delta_{d_k^t d} \sum_{t':r(t,t')} \varepsilon_i^{t',1} \sigma'(\eta_i^{t'}).$$

Abstract

In regular statistical models, the leave-one-out cross-validation is asymptotically equivalent to the Akaike information criterion. However, since many learning machines are singular statistical models, the asymptotic behavior of the cross-validation remains unknown. In previous studies, we established the singular learning theory and proposed a widely applicable information criterion, the expectation value of which is asymptotically equal to the average Bayes generalization loss. In the present paper, we theoretically compare the Bayes cross-validation loss and the widely applicable information criterion and prove two theorems. First, the Bayes cross-validation loss is asymptotically equivalent to the widely applicable information criterion as a random variable. Therefore, model selection and hyperparameter optimization using these two values are asymptotically equivalent. Second, the sum of the Bayes generalization error and the Bayes cross-validation error is asymptotically equal to $2\lambda/n$, where λ is the real log canonical threshold and n is the number of training samples. Therefore the relation between the cross-validation error and the generalization error is determined by the algebraic geometrical structure of a learning machine. We also clarify that the deviance information criteria are different from the Bayes cross-validation and the widely applicable information criterion.

Keywords: cross-validation, information criterion, singular learning machine, birational invariant

1. Introduction

A statistical model or a learning machine is said to be regular if the map taking parameters to probability distributions is one-to-one and if its Fisher information matrix is positive definite. If a model is not regular, then it is said to be singular. Many learning machines, such as artificial neural networks (Watanabe, 2001b), normal mixtures (Yamazaki and Watanabe, 2003), reduced rank regressions (Aoyagi and Watanabe, 2005), Bayes networks (Rusakov and Geiger, 2005; Zwiernik, 2010), mixtures of probability distributions (Lin, 2010), Boltzmann machines (Aoyagi, 2010), and hidden Markov models (Yamazaki and Watanabe, 2005), are not regular but singular (Watanabe, 2007). If a statistical model or a learning machine contains a hierarchical structure, hidden variables, or a grammatical rule, then the model is generally singular. Therefore, singular learning theory is necessary in modern information science.

The statistical properties of singular models have remained unknown until recently, because analyzing a singular likelihood function had been difficult (Hartigan, 1985; Watanabe, 1995). In singular statistical models, the maximum likelihood estimator does not satisfy asymptotic normality.

Consequently, AIC is not equal to the average generalization error (Hagiwara, 2002), and the Bayes information criterion (BIC) is not equal to the Bayes marginal likelihood (Watanabe, 2001a), even asymptotically. In singular models, the maximum likelihood estimator often diverges, or even if it does not diverge, makes the generalization error very large. Therefore, the maximum likelihood method is not appropriate for singular models. On the other hand, Bayes estimation was proven to make the generalization error smaller if the statistical model contains singularities. Therefore, in the present paper, we investigate methods for estimating the Bayes generalization error.

Recently, new statistical learning theory, based on methods from algebraic geometry, has been established (Watanabe, 2001a; Drton et al., 2009; Watanabe, 2009, 2010a,c; Lin, 2010). In singular learning theory, a log likelihood function can be made into a common standard form, even if it contains singularities, by using the resolution theorem in algebraic geometry. As a result, the asymptotic behavior of the posterior distribution is clarified, and the concepts of BIC and AIC can be generalized onto singular statistical models. The asymptotic Bayes marginal likelihood was proven to be determined by the real log canonical threshold (Watanabe, 2001a), and the average Bayes generalization error was proven to be estimable by the widely applicable information criterion (Watanabe, 2009, 2010a,c).

Cross-validation is an alternative method for estimating the generalization error (Mosier, 1951; Stone, 1977; Geisser, 1975). By definition, the average of the cross-validation is equal to the average generalization error in both regular and singular models. In regular statistical models, the leave-one-out cross-validation is asymptotically equivalent to AIC (Akaike, 1974) in the maximum likelihood method (Stone, 1977; Linhart, 1986; Browne, 2000). However, the asymptotic behavior of the cross-validation in singular models has not been clarified.

In the present paper, in singular statistical models, we theoretically compare the Bayes cross-validation, the widely applicable information criterion, and the Bayes generalization error and prove two theorems. First, we show that the Bayes cross-validation loss is asymptotically equivalent to the widely applicable information criterion as a random variable. Second, we also show that the sum of the Bayes cross-validation error and the Bayes generalization error is asymptotically equal to $2\lambda/n$, where λ is the real log canonical threshold and n is the number of training samples. It is important that neither λ or n is a random variable. Since the real log canonical threshold is a birational invariant of the statistical model, the relationship between the Bayes cross-validation and the Bayes generalization error is determined by the algebraic geometrical structure of the statistical model.

The remainder of the present paper is organized as follows. In Section 2, we introduce the framework of Bayes learning and explain singular learning theory. In Section 3, the Bayes cross-validation is defined. In Section 4, the main theorems are proven. In Section 5, we discuss the results of the present paper, and the differences among the cross-validation, the widely applicable information criterion, and the deviance information criterion are investigated theoretically and experimentally. Finally, in Section 6, we summarize the primary conclusions of the present paper.

2. Bayes Learning Theory

In this section, we summarize Bayes learning theory for singular learning machines. The results presented in this section are well known and are the fundamental basis of the present paper. Table 1 lists variables, names, and equation numbers in the present paper.

Variable	Name	Equation number
$\mathbb{E}_w[\ ]$	posterior average	Equation (1)
$\mathbb{E}_w^{(i)}[\ ]$	posterior average without X_i	Equation (16)
$L(w)$	log loss function	Equation (8)
L_0	minimum loss	Equation (9)
L_n	empirical loss	Equation (10)
$B_gL(n)$	Bayes generalization loss	Equation (3)
$B_tL(n)$	Bayes training loss	Equation (4)
$G_tL(n)$	Gibbs training loss	Equation (7)
$C_vL(n)$	cross-validation loss	Equation (17)
$B_g(n)$	Bayes generalization error	Equation (11)
$B_t(n)$	Bayes training error	Equation (12)
$C_v(n)$	cross-validation error	Equation (28)
$V(n)$	functional variance	Equation (5)
$Y_k(n)$	kth functional cumulant	Equation (18)
WAIC(n)	WAIC	Equation (6)
λ	real log canonical threshold	Equation (29)
ν	singular fluctuation	Equation (30)

Table 1: Variables, Names, and Equation Numbers

2.1 Framework of Bayes Learning

First, we explain the framework of Bayes learning.

Let $q(x)$ be a probability density function on the N dimensional real Euclidean space $\mathbb{R}^N$. The training samples and the testing sample are denoted by random variables $X_1, X_2, ..., X_n$ and X, respectively, which are independently subject to the same probability distribution as $q(x)dx$. The probability distribution $q(x)dx$ is sometimes called the true distribution.

A statistical model or a learning machine is defined as a probability density function $p(x|w)$ of $x \in \mathbb{R}^N$ for a given parameter $w \in W \subset \mathbb{R}^d$, where W is the set of all parameters. In Bayes estimation, we prepare a probability density function $\varphi(w)$ on W. Although $\varphi(w)$ is referred to as a prior distribution, in general, $\varphi(w)$ does not necessary represent an *a priori* knowledge of the parameter.

For a given function $f(w)$ on W, the expectation value of $f(w)$ with respect to the posterior distribution is defined as

$$\mathbb{E}_w[f(w)] = \frac{\displaystyle\int f(w) \prod_{i=1}^{n} p(X_i|w)^{\beta}\, \varphi(w) dw}{\displaystyle\int \prod_{i=1}^{n} p(X_i|w)^{\beta}\, \varphi(w) dw}, \tag{1}$$

where $0 < \beta < \infty$ is the inverse temperature. The case in which $\beta = 1$ is most important because this case corresponds to strict Bayes estimation. The Bayes predictive distribution is defined as

$$p^*(x) \equiv \mathbb{E}_w[p(x|w)]. \tag{2}$$

In Bayes learning theory, the following random variables are important. The Bayes generalization loss $B_gL(n)$ and the Bayes training loss $B_tL(n)$ are defined, respectively, as

$$B_gL(n) = -\mathbb{E}_X[\log p^*(X)], \tag{3}$$

$$B_tL(n) = -\frac{1}{n}\sum_{i=1}^{n}\log p^*(X_i), \tag{4}$$

where $\mathbb{E}_X[\ ]$ gives the expectation value over X. The *functional variance* is defined as

$$V(n) = \sum_{i=1}^{n}\Big\{\mathbb{E}_w[(\log p(X_i|w))^2] - \mathbb{E}_w[\log p(X_i|w)]^2\Big\}, \tag{5}$$

which shows the fluctuation of the posterior distribution. In previous papers (Watanabe, 2009, 2010a,b), we defined the widely applicable information criterion

$$\mathrm{WAIC}(n) \equiv B_tL(n) + \frac{\beta}{n}V(n), \tag{6}$$

and proved that

$$\mathbb{E}[B_gL(n)] = \mathbb{E}[\mathrm{WAIC}(n)] + o(\frac{1}{n}),$$

holds for both regular and singular statistical models, where $\mathbb{E}[\ ]$ gives the expectation value over the sets of training samples.

Remark 1 *Although the case in which* $\beta = 1$ *is most important, general cases in which* $0 < \beta < \infty$ *are also important for four reasons. First, from a theoretical viewpoint, several mathematical relations can be obtained using the derivative of* β*. For example, using the Bayes free energy or the Bayes stochastic complexity,*

$$\mathcal{F}(\beta) = -\log\int\prod_{i=1}^{n}p(X_i|w)^{\beta}\varphi(w)dw,$$

the Gibbs training loss

$$G_tL(n) = -\mathbb{E}_w\Big[\frac{1}{n}\sum_{i=1}^{n}\log p(X_i|w)\Big] \tag{7}$$

can be written as

$$G_tL(n) = \frac{\partial\mathcal{F}}{\partial\beta}.$$

Such relations are useful in investigating Bayes learning theory. We use $\partial^2\mathcal{F}/\partial\beta^2$ *to investigate the deviance information criteria in Section 5. Second, the maximum likelihood method formally corresponds to* $\beta = \infty$*. The maximum likelihood method is defined as*

$$p^*(x) = p(x|\hat{w}),$$

instead of Equation (2), where $\hat{w}$ is the maximum likelihood estimator. Its generalization loss is also defined in the same manner as Equation (3). In regular statistical models, the asymptotic Bayes generalization error does not depend on $0 < \beta \leq \infty$, whereas in singular models it strongly depends on β. Therefore, the general case is useful for investigating the difference between the maximum likelihood and Bayes methods. Third, from an experimental viewpoint, in order to approximate the posterior distribution, the Markov chain Monte Carlo method is often applied by controlling β. In particular, the identity

$$\mathcal{F}(1) = \int_0^1 \frac{\partial F}{\partial \beta}\, d\beta$$

is used in the calculation of the Bayes marginal likelihood. The theoretical results for general β are useful for monitoring the effect of controlling β (Nagata and Watanabe, 2008). Finally, in the regression problem, β can be understood as the variance of the unknown additional noise (Watanabe, 2010c) and so may be optimized as the hyperparameter. For these reasons, in the present paper, we theoretically investigate the cases for general β.

2.2 Notation

In the following, we explain the notation used in the present study.

The log loss function $L(w)$ and the entropy S of the true distribution are defined, respectively, as

$$\begin{aligned} L(w) &= -\mathbb{E}_X[\log p(X|w)], \\ S &= -\mathbb{E}_X[\log q(X)]. \end{aligned} \tag{8}$$

Then, $L(w) = S + D(q||p_w)$, where $D(q||p_w)$ is the Kullback-Leibler distance defined as

$$D(q||p_w) = \int q(x) \log \frac{q(x)}{p(x|w)} dx.$$

Then, $D(q||p_w) \geq 0$, hence $L(w) \geq S$. Moreover, $L(w) = S$ if and only if $p(x|w) = q(x)$.

In the present paper, we assume that there exists a parameter $w_0 \in W$ that minimizes $L(w)$,

$$L(w_0) = \min_{w \in W} L(w).$$

Note that such w_0 is not unique in general because the map $w \mapsto p(x|w)$ is, in general, not a one-to-one map in singular learning machines. In addition, we assume that, for an arbitrary w that satisfies $L(w) = L(w_0)$, $p(x|w)$ is the same probability density function. Let $p_0(x)$ be such a unique probability density function. In general, the set

$$W_0 = \{w \in W; p(x|w) = p_0(x)\}$$

is not a set of a single element but rather an analytic or algebraic set with singularities. Here, a set in $\mathbb{R}^d$ is said to be an analytic or algebraic set if and only if the set is equal to the set of all zero points of an analytic or algebraic function, respectively. For simple notations, the minimum log loss L_0 and the empirical log loss L_n are defined, respectively, as

$$L_0 = -\mathbb{E}_X[\log p_0(X)], \tag{9}$$

$$L_n = -\frac{1}{n}\sum_{i=1}^{n} \log p_0(X_i). \tag{10}$$

Then, by definition, $L_0 = \mathbb{E}[L_n]$. Using these values, Bayes generalization error $B_g(n)$ and Bayes training error $B_t(n)$ are defined, respectively, as

$$B_g(n) = B_g L(n) - L_0, \tag{11}$$
$$B_t(n) = B_t L(n) - L_n. \tag{12}$$

Let us define a log density ratio function as:

$$f(x,w) = \log \frac{p_0(x)}{p(x|w)},$$

which is equivalent to

$$p(x|w) = p_0(x)\exp(-f(x,w)).$$

Then, it immediately follows that

$$\begin{aligned} B_g(n) &= -\mathbb{E}_X[\log \mathbb{E}_w[\exp(-f(X,w))]], \\ B_t(n) &= -\frac{1}{n}\sum_{i=1}^{n} \log \mathbb{E}_w[\exp(-f(X_i,w))], \\ V(n) &= \sum_{i=1}^{n} \Big\{ \mathbb{E}_w[f(X_i,w)^2] - \mathbb{E}_w[f(X_i,w)]^2 \Big\}. \end{aligned}$$

Therefore, the problem of statistical learning is characterized by the function $f(x,w)$.

Definition 2 *(1) If $q(x) = p_0(x)$, then $q(x)$ is said to be realizable by $p(x|w)$. Otherwise, $q(x)$ is said to be unrealizable.*
(2) If the set W_0 consists of a single point w_0 and if the Hessian matrix $\nabla\nabla L(w_0)$ is strictly positive definite, then $q(x)$ is said to be regular for $p(x|w)$. Otherwise, $q(x)$ is said to be singular for $p(x|w)$.

Bayes learning theory was investigated for a realizable and regular case (Schwarz, 1978; Levin et al., 1990; Amari, 1993). The WAIC was found for a realizable and singular case (Watanabe, 2001a, 2009, 2010a) and for an unrealizable and regular case (Watanabe, 2010b). In addition, WAIC was generalized for an unrealizable and singular case (Watanabe, 2010d).

2.3 Singular Learning Theory

We summarize singular learning theory. In the present paper, we assume the followings.

2.3.1 ASSUMPTIONS

(1) The set of parameters W is a compact set in $\mathbb{R}^d$, the open kernel[1] of which is not the empty set. The boundary of W is defined by several analytic functions,

$$W = \{w \in \mathbb{R}^d; \pi_1(w) \geq 0, \pi_2(w) \geq 0, ..., \pi_k(w) \geq 0\}.$$

1. The open kernel of a set A is the largest open set that is contained in A.

(2) The prior distribution satisfies $\varphi(w) = \varphi_1(w)\varphi_2(w)$, where $\varphi_1(w) \geq 0$ is an analytic function and $\varphi_2(w) > 0$ is a C^∞-class function.
(3) Let $s \geq 8$ and let

$$L^s(q) = \{f(x); \|f\| \equiv \Big(\int |f(x)|^s q(x) dx \Big)^{1/s} < \infty \}$$

be a Banach space. The map $W \ni w \mapsto f(x,w)$ is an $L^s(q)$ valued analytic function.
(4) A nonnegative function $K(w)$ is defined as

$$K(w) = \mathbb{E}_X[f(X,w)].$$

The set W_ε is defined as

$$W_\varepsilon = \{w \in W \ ; \ K(w) \leq \varepsilon\}.$$

It is assumed that there exist constants $\varepsilon, c > 0$ such that

$$(\forall w \in W_\varepsilon) \quad \mathbb{E}_X[f(X,w)] \geq c\, \mathbb{E}_X[f(X,w)^2]. \tag{13}$$

Remark 3 *In ordinary learning problems, if the true distribution is regular for or realizable by a learning machine, then assumptions (1), (2), (3) and (4) are satisfied, and the results of the present paper hold. If the true distribution is singular for and unrealizable by a learning machine, then assumption (4) is satisfied in some cases but not in other cases. If the assumption (4) is not satisfied, then the Bayes generalization and training errors may have asymptotic behaviors other than those described in Lemma 1 (Watanabe, 2010d).*

The investigation of cross-validation in singular learning machines requires singular learning theory. In previous papers, we obtained the following lemma.

Lemma 1 *Assume that assumptions (1), (2), (3), and (4) are satisfied. Then, the followings hold.*
(1) Three random variables $nB_g(n)$, $nB_t(n)$, and $V(n)$ converge in law, when n tends to infinity. In addition, the expectation values of these variables converge.
(2) For $k = 1,2,3,4$, we define

$$M_k(n) \equiv \sup_{|\alpha| \leq 1+\beta} \mathbb{E}\Big[\frac{1}{n} \sum_{i=1}^{n} \frac{\mathbb{E}_w[|f(X_i,w)|^k \exp(\alpha f(X_i,w))]}{\mathbb{E}_w[\exp(\alpha f(X_i,w))]} \Big],$$

where $\mathbb{E}[\ ]$ gives the average over all sets of training samples. Then,

$$\mathrm{limsup}_{n\to\infty} \Big(n^{k/2}\, M_k(n) \Big) < \infty. \tag{14}$$

(3) The expectation value of the Bayes generalization loss is asymptotically equal to the widely applicable information criterion,

$$\mathbb{E}[B_g L(n)] = \mathbb{E}[WAIC(n)] + o(\frac{1}{n}). \tag{15}$$

Proof For the case in which $q(x)$ is realizable by and singular for $p(x|w)$, this lemma was proven in Watanabe (2010a) and Watanabe (2009). In fact, the proof of Lemma 1 (1) is given in Theorem 1 of Watanabe (2010a). Also Lemma 1 (2) can be proven in the same manner as Equation (32) in Watanabe (2010a) or Equation (6.59) in Watanabe (2009). The proof of Lemma 1 (3) is given in Theorem 2 and the discussion of Watanabe (2010a). For the case in which $q(x)$ is regular for and unrealizable by $p(x|w)$, this lemma was proven in Watanabe (2010b). For the case in which $q(x)$ is singular for and unrealizable by $p(x|w)$, these results can be generalized under the condition that Equation (13) is satisfied (Watanabe, 2010d). ■

3. Bayes Cross-Validation

In this section, we introduce the cross-validation in Bayes learning.

The expectation value $\mathbb{E}_w^{(i)}[\ \ ]$ using the posterior distribution leaving out X_i is defined as

$$\mathbb{E}_w^{(i)}[\ \ ] = \frac{\int (\ \ ) \prod_{j\neq i}^{n} p(X_j|w)^{\beta}\, \varphi(w) dw}{\int \prod_{j\neq i}^{n} p(X_j|w)^{\beta}\, \varphi(w) dw}, \tag{16}$$

where $\prod_{j\neq i}^{n}$ shows the product for $j = 1,2,3,..,n$, which does not include $j = i$. The predictive distribution leaving out X_i is defined as

$$p^{(i)}(x) = \mathbb{E}_w^{(i)}[p(x|w)].$$

The log loss of $p^{(i)}(x)$ when X_i is used as a testing sample is

$$-\log p^{(i)}(X_i) = -\log \mathbb{E}_w^{(i)}[p(X_i|w)].$$

Thus, the log loss of the Bayes cross-validation is defined as the empirical average of them,

$$C_v L(n) = -\frac{1}{n}\sum_{i=1}^{n} \log \mathbb{E}_w^{(i)}[p(X_i|w)]. \tag{17}$$

The random variable $C_v L(n)$ is referred to as the *cross-validation loss*. Since $X_1, X_2, ..., X_n$ are independent training samples, it immediately follows that

$$\mathbb{E}[C_v L(n)] = \mathbb{E}[B_g L(n-1)].$$

Although the two random variables $C_v L(n)$ and $B_g L(n-1)$ are different,

$$C_v L(n) \neq B_g L(n-1),$$

their expectation values coincide with each other by the definition. Using Equation (15), it follows that

$$\mathbb{E}[C_v L(n)] = \mathbb{E}[\mathrm{WAIC}(n-1)] + o(\frac{1}{n}).$$

Therefore, three expectation values $\mathbb{E}[C_v L(n)]$, $\mathbb{E}[B_g L(n-1)]$, and $\mathbb{E}[\mathrm{WAIC}(n-1)]$ are asymptotically equal to each other. The primary goal of the present paper is to clarify the asymptotic behaviors of three random variables, $C_v L(n)$, $B_g L(n)$, and $\mathrm{WAIC}(n)$, when n is sufficiently large.

Remark 4 *In practical applications, the Bayes generalization loss $B_g L(n)$ indicates the accuracy of Bayes estimation. However, in order to calculate $B_g L(n)$, we need the expectation value over the testing sample taken from the unknown true distribution, hence we cannot directly obtain $B_g L(n)$ in practical applications. On the other hand, both the cross-validation loss $C_v L(n)$ and the widely applicable information criterion $WAIC(n)$ can be calculated using only training samples. Therefore, the cross-validation loss and the widely applicable information criterion can be used for model selection and hyperparameter optimization. This is the reason why comparison of these random variables is an important problem in statistical learning theory.*

4. Main Results

In this section, the main results of the present paper are explained. First, we define functional cumulants and describe their asymptotic properties. Second, we prove that both the cross-validation loss and the widely applicable information criterion can be represented by the functional cumulants. Finally, we prove that the cross-validation loss and the widely applicable information criterion are related to the birational invariants.

4.1 Functional Cumulants

Definition 5 *The generating function $F(\alpha)$ of functional cumulants is defined as*

$$F(\alpha) = \frac{1}{n}\sum_{i=1}^{n} \log \mathbb{E}_w[p(X_i|w)^\alpha].$$

The kth order functional cumulant $Y_k(n)$ $(k = 1,2,3,4)$ is defined as

$$Y_k(n) = \frac{d^k F}{d\alpha^k}(0). \tag{18}$$

Then, by definition,

$$\begin{aligned} F(0) &= 0, \\ F(1) &= -B_t L(n), \\ Y_1(n) &= -G_t L(n), \\ Y_2(n) &= V(n)/n. \end{aligned}$$

For simple notation, we use

$$\ell_k(X_i) = \mathbb{E}_w[(\log p(X_i|w))^k] \quad (k = 1,2,3,4).$$

Lemma 2 *Then, the following equations hold:*

$$Y_1(n) = \frac{1}{n}\sum_{i=1}^{n} \ell_1(X_i), \tag{19}$$

$$Y_2(n) = \frac{1}{n}\sum_{i=1}^{n}\Big\{\ell_2(X_i) - \ell_1(X_i)^2\Big\}, \tag{20}$$

$$Y_3(n) = \frac{1}{n}\sum_{i=1}^{n}\Big\{\ell_3(X_i) - 3\ell_2(X_i)\ell_1(X_i) + 2\ell_1(X_i)^3\Big\}, \tag{21}$$

$$Y_4(n) = \frac{1}{n}\sum_{i=1}^{n}\Big\{\ell_4(X_i) - 4\ell_3(X_i)\ell_1(X_i) - 3\ell_2(X_i)^2 + 12\ell_2(X_i)\ell_1(X_i)^2 - 6\ell_1(X_i)^4\Big\}. \tag{22}$$

Moreover,

$$Y_k(n) = O_p(\frac{1}{n^{k/2}}) \quad (k = 2,3,4).$$

In other words,

$$\mathrm{limsup}_{n\to\infty}\mathbb{E}[n^{k/2}\,|Y_k(n)|] < \infty \quad (k = 2,3,4). \tag{23}$$

Proof First, we prove Equations (19) through (22). Let us define

$$g_i(\alpha) = \mathbb{E}_w[p(X_i|w)^\alpha].$$

Then, $g_i(0) = 1$,

$$g_i^{(k)}(0) \equiv \frac{d^k g_i}{d\alpha^k}(0) = \ell_k(X_i) \quad (k = 1,2,3,4),$$

and

$$F(\alpha) = \frac{1}{n}\sum_{i=1}^{n}\log g_i(\alpha).$$

For arbitrary natural number k,

$$\Big(\frac{g_i(\alpha)^{(k)}}{g_i(\alpha)}\Big)' = \frac{g_i(\alpha)^{(k+1)}}{g_i(\alpha)} - \Big(\frac{g_i(\alpha)^{(k)}}{g_i(\alpha)}\Big)\Big(\frac{g_i(\alpha)'}{g_i(\alpha)}\Big).$$

By applying this relation recursively, Equations (19), (20), (21), and (22) are derived. Let us prove Equation (23). The random variables $Y_k(n)$ $(k = 2,3,4)$ are invariant under the transform,

$$\log p(X_i|w) \mapsto \log p(X_i|w) + c(X_i), \tag{24}$$

for arbitrary $c(X_i)$. In fact, by replacing $p(X_i|w)$ by $p(X_i|w)e^{C(X_i)}$, we define

$$\hat{F}(\alpha) = \frac{1}{n}\sum_{i=1}^{n}\log\mathbb{E}_w[p(X_i|w)^\alpha\, e^{\alpha c(X_i)}].$$

Then, the difference between $F(\alpha)$ and $\hat{F}(\alpha)$ is a linear function of α, which vanishes by higher-order differentiation. In particular, by selecting $c(X_i) = -\log p_0(X_i)$, we can show that $Y_k(n)$ $(k = 2,3,4)$ are invariant by the following replacement,

$$\log p(X_i|w) \mapsto f(X_i, w).$$

In other words, $Y_k(n)$ $(n=2,3,4)$ are invarianrt by the replacement,

$$\ell_k(X_i) \mapsto \mathbb{E}_w[f(X_i,w)^k].$$

Using the Cauchy-Schwarz inequality, for $1 \leq k' \leq k$,

$$\mathbb{E}_w[|f(X_i,w)|^{k'}]^{1/k'} \leq \mathbb{E}_w[|f(X_i,w)|^k]^{1/k}.$$

Therefore, for $k=2,3,4$,

$$\mathbb{E}[|Y_k(n)|] \leq \mathbb{E}\Big[\frac{C_k}{n}\sum_{i=1}^n \mathbb{E}_w[|f(X_i,w)|^k]\Big] \leq C_k M_k(n),$$

where $C_2=2, C_3=6, C_4=26$. Then, using Equation (14), we obtain Equation (23). ■

Remark 6 *Using Equation (24) with* $c(X_i) = -\mathbb{E}_w[\log p(X_i|w)]$ *and the normalized function defined as*

$$\ell_k^*(X_i) = \mathbb{E}_w[(\log p(X_i|w) - c(X_i))^k],$$

it follows that

$$\begin{aligned} Y_2(n) &= \frac{1}{n}\sum_{i=1}^n \ell_2^*(X_i), \\ Y_3(n) &= \frac{1}{n}\sum_{i=1}^n \ell_3^*(X_i), \\ Y_4(n) &= \frac{1}{n}\sum_{i=1}^n \Big\{\ell_4^*(X_i) - 3\ell_2^*(X_i)^2\Big\}. \end{aligned}$$

These formulas may be useful in practical applications.

4.2 Bayes Cross-validation and Widely Applicable Information Criterion

We show the asymptotic equivalence of the cross-validation loss $C_v L(n)$ and the widely applicable information criterion $\mathrm{WAIC}(n)$.

Theorem 1 *For arbitrary* $0 < \beta < \infty$, *the cross-validation loss* $C_v L(n)$ *and the widely applicable information criterion* $\mathrm{WAIC}(n)$ *are given, respectively, as*

$$\begin{aligned} C_v L(n) &= -Y_1(n) + \Big(\frac{2\beta-1}{2}\Big)Y_2(n) \\ &\quad -\Big(\frac{3\beta^2-3\beta+1}{6}\Big)Y_3(n) + O_p(\frac{1}{n^2}), \\ \mathrm{WAIC}(n) &= -Y_1(n) + \Big(\frac{2\beta-1}{2}\Big)Y_2(n) \\ &\quad -\frac{1}{6}Y_3(n) + O_p(\frac{1}{n^2}). \end{aligned}$$

Proof First, we consider $C_v L(n)$. From the definitions of $\mathbb{E}_w[\ ]$ and $\mathbb{E}_w^{(i)}[\ ]$, we have

$$\mathbb{E}_w^{(i)}[(\ \ )] = \frac{\mathbb{E}_w[(\ \ )p(X_i|w)^{-\beta}\ ]}{\mathbb{E}_w[p(X_i|w)^{-\beta}\ ]}. \tag{25}$$

Therefore, by the definition of the cross-validation loss, Equation (17),

$$C_v L(n) = -\frac{1}{n}\sum_{i=1}^{n} \log \frac{\mathbb{E}_w[\ p(X_i|w)^{1-\beta}\ ]}{\mathbb{E}_w[\ p(X_i|w)^{-\beta}\ ]}.$$

Using the generating function of functional cumulants $F(\alpha)$,

$$C_v L(n) = F(-\beta) - F(1-\beta). \tag{26}$$

Then, using Lemma 1 (2) for each $k = 2,3,4$, and $|\alpha| < 1+\beta$,

$$\begin{aligned}
\mathbb{E}[|F^{(k)}(\alpha)|] &\leq \mathbb{E}\Big[\frac{C_k}{n}\sum_{i=1}^{n}\frac{\mathbb{E}_w[|f(X_i,w)|^k \exp(\alpha f(X_i,w))]}{\mathbb{E}_w[\exp(\alpha f(X_i,w))]}\Big] \\
&\leq C_k M_k(n),
\end{aligned}$$

where $C_2 = 2, C_3 = 6, C_4 = 26$. Therefore,

$$|F^{(k)}(\alpha)| = O_p(\frac{1}{n^{k/2}}). \tag{27}$$

By Taylor expansion of $F(\alpha)$ among $\alpha = 0$, there exist β^*, β^{**} ($|\beta^*|, |\beta^{**}| < 1+\beta$) such that

$$\begin{aligned}
F(-\beta) &= F(0) - \beta F'(0) + \frac{\beta^2}{2}F''(0) \\
&\quad -\frac{\beta^3}{6}F^{(3)}(0) + \frac{\beta^4}{24}F^{(4)}(\beta^*), \\
F(1-\beta) &= F(0) + (1-\beta)F'(0) + \frac{(1-\beta)^2}{2}F''(0) \\
&\quad +\frac{(1-\beta)^3}{6}F^{(3)}(0) + \frac{(1-\beta)^4}{24}F^{(4)}(\beta^{**}).
\end{aligned}$$

Using $F(0) = 0$ and Equations (26) and (27), it follows that

$$\begin{aligned}
C_v L(n) &= -F'(0) + \frac{2\beta-1}{2}F''(0) \\
&\quad -\frac{3\beta^2 - 3\beta + 1}{6}F^{(3)}(0) + O_p(\frac{1}{n^2}).
\end{aligned}$$

Thus, we have proven the first half of the theorem. For the latter half, by the definitions of $\mathrm{WAIC}(n)$, Bayes training loss, and the functional variance, we have

$$\begin{aligned}
\mathrm{WAIC}(n) &= B_t L(n) + (\beta/n)V(n), \\
B_t L(n) &= -F(1), \\
V(n) &= nF''(0).
\end{aligned}$$

Therefore,

$$\mathrm{WAIC}(n) = -F(1) + \beta F''(0).$$

By Taylor expansion of $F(1)$, we obtain

$$\mathrm{WAIC}(n) = -F'(0) + \frac{2\beta - 1}{2} F''(0) - \frac{1}{6} F^{(3)}(0) + O_p(\frac{1}{n^2}),$$

which completes the proof. ■

From the above theorem, we obtain the following corollary.

Corollary 1 *For arbitrary $0 < \beta < \infty$, the cross-validation loss $C_v L(n)$ and the widely applicable information criterion* $\mathrm{WAIC}(n)$ *satisfy*

$$C_v L(n) = \mathrm{WAIC}(n) + O_p(\frac{1}{n^{3/2}}).$$

In particular, for $\beta = 1$,

$$C_v L(n) = \mathrm{WAIC}(n) + O_p(\frac{1}{n^2}).$$

More precisely, the difference between the cross-validation loss and the widely applicable information criterion is given by

$$C_v L(n) - \mathrm{WAIC}(n) \cong \Big(\frac{\beta - \beta^2}{2}\Big) Y_3(n).$$

If $\beta = 1$,

$$C_v L(n) - \mathrm{WAIC}(n) \cong \frac{1}{12} Y_4(n).$$

4.3 Generalization Error and Cross-validation Error

In the previous subsection, we have shown that the cross-validation loss is asymptotically equivalent to the widely applicable information criterion. In this section, let us compare the Bayes generalization error $B_g(n)$ given in Equation (11) and the cross-validation error $C_v(n)$, which is defined as

$$C_v(n) = C_v L(n) - L_n. \tag{28}$$

We need mathematical concepts, the real log canonical threshold, and the singular fluctuation.

Definition 7 *The zeta function $\zeta(z)$ $(Re(z) > 0)$ of statistical learning is defined as*

$$\zeta(z) = \int K(w)^z \varphi(w) dw,$$

where

$$K(w) = \mathbb{E}_X[f(X,w)]$$

is a nonnegative analytic function. Here, $\zeta(z)$ can be analytically continued to the unique meromorphic function on the entire complex plane $\mathbb{C}$. All poles of $\zeta(z)$ are real, negative, and rational numbers. The maximum pole is denoted as

$$(-\lambda) = \textit{ maximum pole of } \zeta(z). \tag{29}$$

Then, the positive rational number λ is referred to as the real log canonical threshold. The singular fluctuation is defined as

$$\nu = \nu(\beta) = \lim_{n\to\infty} \frac{\beta}{2}\mathbb{E}[V(n)]. \tag{30}$$

Note that the real log canonical threshold does not depend on β, whereas the singular fluctuation is a function of β.

Both the real log canonical threshold and the singular fluctuation are birational invariants. In other words, they are determined by the algebraic geometrical structure of the statistical model. The following lemma was proven in a previous study (Watanabe, 2010a,b,d).

Lemma 3 *The following convergences hold:*

$$\lim_{n\to\infty} n\mathbb{E}[B_g(n)] = \frac{\lambda-\nu}{\beta} + \nu, \tag{31}$$

$$\lim_{n\to\infty} n\mathbb{E}[B_t(n)] = \frac{\lambda-\nu}{\beta} - \nu, \tag{32}$$

Moreover, convergence in probability

$$n(B_g(n) + B_t(n)) + V(n) \to \frac{2\lambda}{\beta} \tag{33}$$

holds.

Proof For the case in which $q(x)$ is realizable by and singular for $p(x|w)$, Equations (31) and (32) were proven by in Corollary 3 in Watanabe (2010a). The equation (33) was given in Corollary 2 in Watanabe (2010a). For the case in which $q(x)$ is regular for $p(x|w)$, these results were proved in Watanabe (2010b). For the case in which $q(x)$ is singular for and unrealizable by $p(x|w)$ they were generalized in Watanabe (2010d). ■

4.3.1 EXAMPLES

If $q(x)$ is regular for and realizable by $p(x|w)$, then $\lambda = \nu = d/2$, where d is the dimension of the parameter space. If $q(x)$ is regular for and unrealizable by $p(x|w)$, then λ and ν are given by Watanabe (2010b). If $q(x)$ is singular for and realizable by $p(x|w)$, then λ for several models are obtained by resolution of singularities (Aoyagi and Watanabe, 2005; Rusakov and Geiger, 2005; Yamazaki and Watanabe, 2003; Lin, 2010; Zwiernik, 2010). If $q(x)$ is singular for and unrealizable by $p(x|w)$, then λ and ν remain unknown constants.

We have the following theorem.

Theorem 2 *The following equation holds:*

$$\lim_{n\to\infty} n\mathbb{E}[C_v(n)] = \frac{\lambda-\nu}{\beta}+\nu,$$

The sum of the Bayes generalization error and the cross-validation error satisfies

$$B_g(n)+C_v(n) = (\beta-1)\frac{V(n)}{n}+\frac{2\lambda}{\beta n}+o_p(\frac{1}{n}).$$

In particular, if $\beta = 1$,

$$B_g(n)+C_v(n) = \frac{2\lambda}{n}+o_p(\frac{1}{n}).$$

Proof By Equation (31),

$$\mathbb{E}[B_g(n-1)] = \Big(\frac{\lambda-\nu}{\beta}+\nu\Big)\frac{1}{n}+o(\frac{1}{n}).$$

Since $\mathbb{E}[C_v(n)] = \mathbb{E}[B_g(n-1)]$,

$$\begin{aligned}\lim_{n\to\infty} n\mathbb{E}[C_v(n)] &= \lim_{n\to\infty} n\mathbb{E}[B_g(n-1)]\\ &= \frac{\lambda-\nu}{\beta}+\nu.\end{aligned}$$

From Equation (33) and Corollary 1,

$$B_t(n) = C_v(n)-\frac{\beta}{n}V(n)+O_p(\frac{1}{n^{3/2}}),$$

and it follows that

$$(B_g(n)+C_v(n)) = (\beta-1)\frac{V(n)}{n}+\frac{2\lambda}{\beta n}+o_p(\frac{1}{n}),$$

which proves the Theorem. ■

This theorem indicates that both the cross-validation error and the Bayes generalization error are determined by the algebraic geometrical structure of the statistical model, which is extracted as the real log canonical threshold. From this theorem, in the strict Bayes case $\beta = 1$, we have

$$\begin{aligned}\mathbb{E}[B_g(n)] &= \frac{\lambda}{n}+o(\frac{1}{n}),\\ \mathbb{E}[C_v(n)] &= \frac{\lambda}{n}+o(\frac{1}{n}),\end{aligned}$$

and

$$B_g(n)+C_v(n) = \frac{2\lambda}{n}+o_p(\frac{1}{n}). \tag{34}$$

Therefore, the smaller cross-validation error $C_v(n)$ is equivalent to the larger Bayes generalization error $B_g(n)$. Note that a regular statistical model is a special example of singular models, hence both Theorems 1 and 2 also hold in regular statistical models. In Watanabe (2009), it was proven that the random variable $nB_g(n)$ converges to a random variable in law. Thus, $nC_v(n)$ converges to a random variable in law. The asymptotic probability distribution of $nB_g(n)$ can be represented using a Gaussian process, which is defined on the set of true parameters, but is not equal to the χ^2 distribution in general.

Remark 8 *The relation given by Equation (34) indicates that, if $\beta = 1$, the variances of $B_g(n)$ and $C_v(n)$ are equal. If the average value $2\nu = \mathbb{E}[V(n)]$ is known, then $B_t(n) + 2\nu/n$ can be used instead of $C_v(n)$, because both average values are asymptotically equal to the Bayes generalization error. The variance of $B_t(n) + 2\nu/n$ is smaller than that of $C_v(n)$ if and only if the variance of $B_t(n)$ is smaller than that of $B_g(n)$. If a true distribution is regular for and realizable by the statistical model, then the variance of $B_t(n)$ is asymptotically equal to that of $B_g(n)$. However, in other cases, the variance of $B_t(n)$ may be smaller or larger than that of $B_g(n)$.*

5. Discussion

Let us now discuss the results of the present paper.

5.1 From Regular to Singular

First, we summarize the regular and singular learning theories.

In regular statistical models, the generalization loss of the maximum likelihood method is asymptotically equal to that of the Bayes estimation. In both the maximum likelihood and Bayes methods, the cross-validation losses have the same asymptotic behaviors. The leave-one-out cross-validation is asymptotically equivalent to the AIC, in both the maximum likelihood and Bayes methods.

On the other hand, in singular learning machines, the generalization loss of the maximum likelihood method is larger than the Bayes generalization loss. Since the generalization loss of the maximum likelihood method is determined by the maximum value of the Gaussian process, the maximum likelihood method is not appropriate in singular models (Watanabe, 2009). In Bayes estimation, we derived the asymptotic expansion of the generalization loss and proved that the average of the widely applicable information criterion is asymptotically equal to the Bayes generalization loss (Watanabe, 2010a). In the present paper, we clarified that the leave-one-out cross-validation in Bayes estimation is asymptotically equivalent to WAIC.

It was proven (Watanabe, 2001a) that the Bayes marginal likelihood of a singular model is different from BIC of a regular model. In the future, we intend to compare the cross-validation and Bayes marginal likelihood in model selection and hyperparameter optimization in singular statistical models.

5.2 Cross- validation and Importance Sampling

Second, let us investigate the cross-validation and the importance sampling cross-validation from a practical viewpoint.

In Theorem 1, we theoretically proved that the leave-one-out cross-validation is asymptotically equivalent to the widely applicable information criterion. In practical applications, we often approx-

imate the posterior distribution using the Markov Chain Monte Carlo or other numerical methods. If the posterior distribution is precisely realized, then the two theorems of the present paper hold. However, if the posterior distribution was not precisely approximated, then the cross-validation might not be equivalent to the widely applicable information criterion.

In Bayes estimation, there are two different methods by which the leave-one-out cross-validation is numerically approximated. In the former method, CV_1 is obtained by realizing all posterior distributions $\mathbb{E}_w^{(i)}[\ ]$ leaving out X_i for $i = 1, 2, 3, ..., n$, and the empirical average

$$CV_1 = -\frac{1}{n}\sum_{i=1}^{n} \log \mathbb{E}_w^{(i)}[p(X_i|w)]$$

is then calculated. In this method, we must realize n different posterior distributions, which requires heavy computational costs.

In the latter method, the posterior distribution leaving out X_i is estimated using the posterior average $\mathbb{E}_w[\ ]$, in the same manner as Equation (25),

$$\mathbb{E}_w^{(i)}[p(X_i|w)] \cong \frac{\mathbb{E}_w[p(X_i|w)\ p(X_i|w)^{-\beta}\ ]}{\mathbb{E}_w[p(X_i|w)^{-\beta}\ ]}.$$

This method is referred to as the importance sampling leave-one-out cross-validation (Gelfand et al., 1992), in which only one posterior distribution is needed and the leave-one-out cross-validation is approximated by CV_2,

$$CV_2 \cong -\frac{1}{n}\sum_{i=1}^{n} \log \frac{\mathbb{E}_w[p(X_i|w)\ p(X_i|w)^{-\beta}\ ]}{\mathbb{E}_w[p(X_i|w)^{-\beta}\ ]}.$$

If the posterior distribution is completely realized, then CV_1 and CV_2 coincide with each other and are asymptotically equivalent to the widely applicable information criterion. However, if the posterior distribution is not sufficiently approximated, then the values CV_1, CV_2, and $\mathrm{WAIC}(n)$ might be different.

The average values using the posterior distribution may sometimes have infinite variances (Peruggia, 1997) if the set of parameters is not compact. Moreover, in singular learning machines, the set of true parameters is not a single point but rather an analytic set, hence we must restrict the parameter space to be compact for well-defined average values. Therefore, we adopted the assumptions in Section 2.3 that the parameter space is compact and the log likelihood function has the appropriate properties. Under these conditions, the observables studied in the present paper have finite variances.

5.3 Comparison with the Deviance Information Criteria

Third, let us compare the deviance information criterion (DIC) (Spiegelhalter et al., 2002) to the Bayes cross-validation and WAIC, because DIC is sometimes used in Bayesian model evaluation. In order to estimate the Bayesian generalization error, DIC is written by

$$DIC_1 = B_t L(n) + \frac{2}{n}\sum_{i=1}^{n} \Big\{ -E_w[\log p(X_i|w)] + \log p(X_i|E_w[w]) \Big\},$$

where the second term of the right-hand side corresponds to the "effective number of parameters" of DIC divided by the number of parameters. Under the condition that the log likelihood ratio function

in the posterior distribution is subject to the χ^2 distribution, a modified DIC was proposed (Gelman et al., 2004) as

$$DIC_2 = B_t L(n) + \frac{2}{n}\Big[E_w[\Big\{\sum_{i=1}^{n}\log p(X_i|w)\Big\}^2] - E_w[\sum_{i=1}^{n}\log p(X_i|w)]^2\Big],$$

the variance of which was investigated previously (Raftery, 2007). Note that DIC_2 is different from WAIC. In a singular learning machine, since the set of optimal parameters is an analytic set, the correlation between different true parameters does not vanish, even asymptotically.

We first derive the theoretical properties of DIC. If the true distribution is regular for the statistical model, then the set of the optimal parameter is a single point w_0. Thus, the difference of $E_w[w]$ and the maximum *a posteriori* estimator is asymptotically smaller than $1/\sqrt{n}$. Therefore, based on the results in Watanabe (2010b), if $\beta = 1$,

$$\mathbb{E}[DIC_1] = L_0 + (3\lambda - 2\nu(1))\frac{1}{n} + o(\frac{1}{n}).$$

If the true distribution is realizable by or regular for the statistical model and if $\beta = 1$, then the asymptotic behavior of DIC_2 is given by

$$\mathbb{E}[DIC_2] = L_0 + (3\lambda - 2\nu(1) + 2\nu'(1))\frac{1}{n} + o(\frac{1}{n}), \tag{35}$$

where $\nu'(1) = (d\nu/d\beta)(1)$. Equation (35) is derived from the relations (Watanabe, 2009, 2010a,b,d),

$$\begin{aligned} DIC_2 &= B_t L(n) - 2\frac{\partial}{\partial\beta}G_t L(n), \\ \mathbb{E}[G_t L(n)] &= L_0 + \Big(\frac{\lambda}{\beta} - \nu(\beta)\Big)\frac{1}{n} + o(\frac{1}{n}), \end{aligned}$$

where $G_t L(n)$ is given by Equation (7).

Next, let us consider the DIC for each case. If the true distribution is regular for and realizable by the statistical model and if $\beta = 1$, then $\lambda = \nu = d/2, \nu'(1) = 0$, where d is the number of parameters. Thus, their averages are asymptotically equal to the Bayes generalization error,

$$\begin{aligned} \mathbb{E}[DIC_1] &= L_0 + \frac{d}{2n} + o(\frac{1}{n}), \\ \mathbb{E}[DIC_2] &= L_0 + \frac{d}{2n} + o(\frac{1}{n}). \end{aligned}$$

In this case, the averages of DIC_1, DIC_2, CV_1, CV_2, and WAIC have the same asymptotic behavior.

If the true distribution is regular for and unrealizable by the statistical model and if $\beta = 1$, then $\lambda = d/2$, $\nu = (1/2)\mathrm{tr}(IJ^{-1})$, and $\nu'(1) = 0$ (Watanabe, 2010b), where I is the Fisher information matrix at w_0, and J is the Hessian matrix of $L(w)$ at $w = w_0$. Thus, we have

$$\begin{aligned} \mathbb{E}[DIC_1] &= L_0 + \Big(\frac{3d}{2} - \mathrm{tr}(IJ^{-1})\Big)\frac{1}{n} + o(\frac{1}{n}), \\ \mathbb{E}[DIC_2] &= L_0 + \Big(\frac{3d}{2} - \mathrm{tr}(IJ^{-1})\Big)\frac{1}{n} + o(\frac{1}{n}). \end{aligned}$$

In this case, as shown in Lemma 3, the Bayes generalization error is given by $L_0 + d/(2n)$ asymptotically, and so the averages of the deviance information criteria are not equal to the average of the Bayes generalization error.

If the true distribution is singular for and realizable by the statistical model and if $\beta = 1$, then

$$\begin{aligned} \mathbb{E}[DIC_1] &= C + o(1), \\ \mathbb{E}[DIC_2] &= L_0 + (3\lambda - 2\nu(1) + 2\nu'(1))\frac{1}{n} + o(\frac{1}{n}), \end{aligned} \tag{36}$$

where C ($C \neq L_0$) is, in general, a constant. Equation (36) is obtained because the set of true parameters in a singular model is not a single point, but rather an analytic set, so that, in general, the average $E_w[w]$ is not contained in the neighborhood of the set of the true parameters. Hence the averages of the deviance information criteria are not equal to those of the Bayes generalization error.

The averages of the cross-validation loss and WAIC have the same asymptotic behavior as that of the Bayes generalization error, even if the true distribution is unrealizable by or singular for the statistical model. Therefore, the deviance information criteria are different from the cross-validation and WAIC, if the true distribution is singular for or unrealizable by the statistical model.

5.4 Experiment

In this section, we describe an experiment. The purpose of the present paper is to clarify the theoretical properties of the cross-validation and the widely applicable information criterion. An experiment was conducted in order to illustrate the main theorems.

Let $x, y \in \mathbb{R}^3$. We considered a statistical model defined as

$$p(x,y|w) = \frac{s(x)}{(2\pi\sigma^2)^{3/2}} \exp(-\frac{\|y - R_H(x,w)\|^2}{2\sigma^2}),$$

where $\sigma = 0.1$ and $s(x)$ is $\mathcal{N}(0, 2^2 I)$. Here, $\mathcal{N}(m,A)$ exhibits a normal distribution with the average vector m and the covariance matrix A, and I is the identity matrix. Note that the distribution $s(x)$ was not estimated. We used a three-layered neural network,

$$R_H(x,w) = \sum_{h=1}^{H} a_h \tanh(b_h \cdot x),$$

where the parameter was

$$w = \{(a_h \in \mathbb{R}^3, b_h \in \mathbb{R}^3)\ ;\ h = 1,2,...,H\} \in \mathbb{R}^{6H}.$$

In the experiment, a learning machine with $H = 3$ was used and the true distribution was set with $H = 1$. The parameter that gives the distribution is denoted as w_0, which denotes the parameters of both models $H = 1, 3$. Then, $R_H(x,w_0) = R_{H_0}(x,w_0)$. Under this condition, the set of true parameters

$$\{w \in W; p(x|w) = p(x|w_0)\}$$

is not a single point but an analytic set with singularities, resulting that the regularity condition is not satisfied. In this case, the log density ratio function is equivalent to

$$f(x,y,w) = \frac{1}{2\sigma^2}\Big\{\|y - R_H(x,w)\|^2 - \|y - R_H(x,w_0)\|^2\Big\}.$$

In this model, although the Bayes generalization error is not equal to the average square error

$$\mathrm{SE}(n) = \frac{1}{2\sigma^2}\mathbb{E}\mathbb{E}_X\Big[\parallel R_H(X,w_0) - \mathbb{E}_w[R_H(X,w)] \parallel^2\Big],$$

asymptotically $\mathrm{SE}(n)$ and $B_g(n)$ are equal to each other (Watanabe, 2009).

The prior distribution $\varphi(w)$ was set as $\mathcal{N}(0, 10^2 I)$. Although this prior does not have compact support mathematically, it can be understood in the experiment that the support of $\varphi(w)$ is essentially contained in a sufficiently large compact set.

In the experiment, the number of training samples was fixed as $n = 200$. One hundred sets of 200 training samples each were obtained independently. For each training set, the strict Bayes posterior distribution $\beta = 1$ was approximated by the Markov chain Monte Carlo (MCMC) method. The Metropolis method, in which each random trial was taken from $\mathcal{N}(0, (0.005)^2 I)$, was applied, and the average exchanging ratio was obtained as approximately 0.35. After 100,000 iterations of Metropolis random sampling, 200 parameters were obtained in every 100 sampling steps. For a fixed training set, by changing the initial values and the random seeds of the software, the same MCMC sampling procedures were performed 10 times independently, which was done for the purpose of minimizing the effect of the local minima. Finally, for each training set, we obtained $200 \times 10 = 2,000$ parameters, which were used to approximate the posterior distribution.

Table 2 shows the experimental results. We observed the Bayes generalization error $BG = B_g(n)$, the Bayes training error $BT = B_t(n)$, importance sampling leave-one-out cross-validation $CV = CV_2 - L_n$, the widely applicable information criterion $\mathrm{WAIC} = \mathrm{WAIC}(n) - L_n$, two deviance information criteria, namely, $DIC1 = DIC_1 - L_n$ and $DIC2 = DIC_2 - L_n$, and the sum $BG + CV = B_g(n) + C_v(n)$. The values AVR and STD in Table 2 show the average and standard deviation of one hundred sets of training data, respectively. The original cross-validation CV_1 was not observed because the associated computational cost was too high.

The experimental results reveal that the average and standard deviation of BG were approximately the same as those of CV and WAIC, which indicates that Theorem 1 holds. The real log canonical threshold, the singular fluctuation, and its derivative of this case were estimated as

$$\begin{aligned} \lambda &\approx 5.6, \\ \nu(1) &\approx 7.9, \\ \nu'(1) &\approx 3.6. \end{aligned}$$

Note that, if the true distribution is regular for and realizable by the statistical model, $\lambda = \nu(1) = d/2 = 9$ and $\nu'(1) = 0$. The averages of the two deviance information criteria were not equal to that of the Bayes generalization error. The standard deviation of $BG + CV$ was smaller than the standard deviations of BG and CV, which is in agreement with Theorem 2.

Note that the standard deviation of BT was larger than those of CV and WAIC, which indicates that, even if the average value $\mathbb{E}[C_v(n) - B_t(n)] = 2\nu/n$ is known and an alternative cross-validation, such as the AIC,

$$CV_3 = B_t L(n) + 2\nu/n,$$

is used, then the variance of $CV_3 - L_n$ was larger than the variances of $C_v L(n) - L_n$ and $\mathrm{WAIC}(n) - L_n$.

	BG	*BT*	*CV*	WAIC	*DIC*1	*DIC*2	*BG*+*CV*
AVR	0.0264	-0.0511	0.0298	0.0278	-35.1077	0.0415	0.0562
STD	0.0120	0.0165	0.0137	0.0134	19.1350	0.0235	0.0071

Table 2: Average and standard deviation

	BG	*BT*	*CV*	WAIC	*DIC*1	*DIC*2	*BG*+*CV*
BG	1.000	-0.854	-0.854	-0.873	0.031	-0.327	0.043
BT		1.000	0.717	0.736	0.066	0.203	-0.060
CV			1.000	0.996	-0.087	0.340	0.481
WA				1.000	-0.085	0.341	0.443
*DIC*1					1.000	-0.069	-0.115
*DIC*2						1.000	0.102

Table 3: Correlation matrix

Table 3 shows the correlation matrix for several values. The correlation between *CV* and WAIC was 0.996, which indicates that Theorem 1 holds. The correlation between *BG* and *CV* was -0.854, and that between *BG* and WAIC was -0.873, which corresponds to Theorem 2.

The accuracy of numerical approximation of the posterior distribution depends on the statistical model, the true distribution, the prior distribution, the Markov chain Monte Carlo method, and the experimental fluctuation. In the future, we intend to develop a method by which to design experiments. The theorems proven in the present paper may be useful in such research.

5.5 Birational Invariant

Finally, we investigate the statistical problem from an algebraic geometrical viewpoint.

In Bayes estimation, we can introduce an analytic function of the parameter space $g : U \to W$,

$$w = g(u).$$

Let $|g'(u)|$ be its Jacobian determinant. Note that the inverse function g^{-1} is not needed if g satisfies the condition that $\{u \in U; |g'(u)| = 0\}$ is a measure zero set in U. Such a function g is referred to as a birational transform. It is important that, by the transform,

$$\begin{aligned} p(x|w) &\mapsto p(x|g(u)), \\ \varphi(w) &\mapsto \varphi(g(u))|g'(u)|, \end{aligned}$$

the Bayes estimation on W is equivalent to that on U. A constant defined for a set of statistical models and a prior is said to be a birational invariant if it is invariant under such a transform $w = g(u)$.

The real log canonical threshold λ is a birational invariant (Atiyah, 1970; Hiroanaka, 1964; Kashiwara, 1976; Kollór et al., 1998; Mustata, 2002; Watanabe, 2009) that represents the algebraic geometrical relation between the set of parameters W and the set of the optimal parameters W_0. Although the singular fluctuation is also a birational invariant, its properties remain unknown. In the present paper, we proved in Theorem 1 that

$$\mathbb{E}[B_g L(n)] = \mathbb{E}[C_v L(n)] + o(1/n). \tag{37}$$

On the other hand, in Theorem 2, we proved that

$$B_g(n) + C_v(n) = \frac{2\lambda}{n} + o_p(1/n). \tag{38}$$

In model selection or hyperparameter optimization, Equation (37) shows that minimization of the cross-validation makes the generalization loss smaller on average. However, Equation (38) shows that minimization of the cross-validation does not ensure minimum generalization loss. The widely applicable information criterion has the same property as the cross-validation. The constant λ appears to exhibit a bound, which can be attained by statistical estimation for a given pair of a statistical model and a prior distribution. Hence, clarification of the algebraic geometrical structure in statistical estimation is an important problem in statistical learning theory.

6. Conclusion

In the present paper, we have shown theoretically that the leave-one-out cross-validation in Bayes estimation is asymptotically equal to the widely applicable information criterion and that the sum of the cross-validation error and the generalization error is equal to twice the real log canonical threshold divided by the number of training samples. In addition, we clarified that cross-validation and the widely applicable information criterion are different from the deviance information criteria. This result indicates that, even in singular statistical models, the cross-validation is asymptotically equivalent to the information criterion, and that the asymptotic properties of these models are determined by the algebraic geometrical structure of a statistical model.

Abstract

We derive PAC-Bayesian generalization bounds for supervised and unsupervised learning models based on clustering, such as co-clustering, matrix tri-factorization, graphical models, graph clustering, and pairwise clustering.[1] We begin with the analysis of co-clustering, which is a widely used approach to the analysis of data matrices. We distinguish among two tasks in matrix data analysis: discriminative prediction of the missing entries in data matrices and estimation of the joint probability distribution of row and column variables in co-occurrence matrices. We derive PAC-Bayesian generalization bounds for the expected out-of-sample performance of co-clustering-based solutions for these two tasks. The analysis yields regularization terms that were absent in the previous formulations of co-clustering. The bounds suggest that the expected performance of co-clustering is governed by a trade-off between its empirical performance and the mutual information preserved by the cluster variables on row and column IDs. We derive an iterative projection algorithm for finding a local optimum of this trade-off for discriminative prediction tasks. This algorithm achieved state-of-the-art performance in the MovieLens collaborative filtering task. Our co-clustering model can also be seen as matrix tri-factorization and the results provide generalization bounds, regularization terms, and new algorithms for this form of matrix factorization.

The analysis of co-clustering is extended to tree-shaped graphical models, which can be used to analyze high dimensional tensors. According to the bounds, the generalization abilities of tree-shaped graphical models depend on a trade-off between their empirical data fit and the mutual information that is propagated up the tree levels.

We also formulate weighted graph clustering as a prediction problem: given a subset of edge weights we analyze the ability of graph clustering to predict the remaining edge weights. The analysis of co-clustering easily extends to this problem and suggests that graph clustering should optimize the trade-off between empirical data fit and the mutual information that clusters preserve on graph nodes.

Keywords: matrix tri-factorization, graphical models, graph clustering, pairwise clustering, combinatorial priors, density estimation

1. Introduction

Structure learning and, in particular, clustering is an important and long-standing problem in science. In many situations it has to be performed based on a limited data sample and with no or limited supervision. A natural question that arises in this context is to what extent the inferred structure is a reflection of a "true" structure underlying the data or a mere artifact of the learning model and/or statistical fluctuation of the finite sample. But is there a "true structure" in the first place? Consider the following example: assume we have a bag of blocks which we can cluster by multiple parameters, such as shape, color, material they are made of, and so on. All these possibilities are equally plausible and asking whether a clustering of blocks by shape is better or worse than a clustering of blocks by color makes no sense. But the absence of an objective comparison criterion for outputs of two structure learning algorithms poses a serious obstacle for their evaluation and the advancement of unsupervised learning in general.

We argue that one does not learn structure for its own sake, but rather to facilitate solving some higher level task. By evaluating the contribution of structure learning to the solution of the higher level task it is possible to derive an objective comparison of the utility of different structures in the context of this specific task. Returning to the bag of blocks example, if we know that after clustering the blocks we will have to pack them into a box, then the clustering of blocks by shape is much more useful than the clustering of blocks by color, since packing is indifferent to color. We can further measure the amount of time that different clusterings saved us in the packing task and thereby obtain an objective numerical evaluation of the utility of clustering of blocks by different parameters in this context. Moreover, by repeating the experiment several times (or by some more intelligent analysis) it is possible to provide generalization guarantees on how much time this or other clustering algorithm is expected to save us in the packing task in the future.

Since in any non-trivial data many structures coexist simultaneously, "blind" unsupervised learning without specification of its potential application is doomed to failure in the general case. This is because the potential application (or range of applications) can make any property or element of the structure either decisive or completely irrelevant for the task, and hence render it useful or useless for identification by unsupervised learning. The need to consider unsupervised learning within the context of its subsequent application has been pointed out by many researchers, especially those concerned with practical applications of these methods (Guyon et al., 2009). In the present paper we reformulate traditional unsupervised learning problems as prediction problems and then adapt well-developed tools from supervised learning to provide generalization bounds on their expected out-of-sample performance. We start with the problem of co-clustering, but then show that our approach to problem formulation is applicable to and can be analyzed in a much broader range of applications.

Co-clustering is a widely used method for analysis of data in matrix form by simultaneous clustering of rows and columns of the matrix (Banerjee et al., 2007). Here we focus solely on co-clustering solutions that result in a grid form partition of the data matrix. This form of co-clustering is also known as partitional co-clustering (Banerjee et al., 2007), checkerboard bi-clustering (Cheng and Church, 2000; Kluger et al., 2003), grid clustering (Devroye et al., 1996; Seldin and Tishby, 2008, 2009), and box clustering. Note that some authors use the terms co-clustering and bi-clustering to refer to a simultaneous grouping of rows and columns that does not result in a grid-form partition of the whole data matrix (Hartigan, 1972; Madeira and Oliveira, 2004), but these forms of partitions are not discussed in this work. Note as well that this paper considers soft as-

signments of rows and columns to their clusters, while using two-level generative models such as those discussed in Dhillon et al. (2003) and Banerjee et al. (2007) for hard assignments. Recently, Bayesian approaches to co-clustering have been suggested, for example see Shan and Banerjee (2008), Salakhutdinov and Mnih (2008), Shafiei and Milios (2006), Wang et al. (2009) and Lashkari and Golland (2009), which consider mixed memberships by introducing an additional level to the generative process. However, three-level generative models require approximate inference methods such as variational inference or Markov Chain Monte Carlo, whereas the two-level model for discriminative prediction discussed here can be learned by iterative projections. The analysis presented here is not limited to two-dimensional data matrices, but holds for higher dimensional tensors as well. A three-level Bayesian approach to clustered tensor factorization was recently presented by Sutskever et al. (2009).

In the past decade co-clustering has successfully been applied in multiple domains, including clustering of documents and words in text mining (Slonim and Tishby, 2000; El-Yaniv and Souroujon, 2001; Dhillon et al., 2003; Takamura and Matsumoto, 2003), genes and experimental conditions in bioinformatics (Cheng and Church, 2000; Cho et al., 2004; Kluger et al., 2003; Cho and Dhillon, 2008), tokens and contexts in natural language processing (Freitag, 2004; Rohwer and Freitag, 2004; Li and Abe, 1998), viewers and movies in recommender systems (George and Merugu, 2005; Seldin et al., 2007; Salakhutdinov and Mnih, 2008; Seldin, 2009), etc. In Seldin et al. (2007) and Seldin and Tishby (2009) it was pointed out that there are actually two different classes of problems that are solved with co-clustering that correspond to two different high-level tasks and should be analyzed separately. The first class of problems are discriminative prediction tasks, one typical representative of which is collaborative filtering (Herlocker et al., 2004). In collaborative filtering, the analyst is given a matrix of viewers by movies with ratings, for example, on a five-star scale, attributed by the viewers to the movies. The matrix is usually sparse, as most viewers have not seen all the movies. In this problem the task is usually to predict the missing entries. We assume that there is some unknown probability distribution $p(x_1, x_2, y)$ over the triplets of viewer x_1, movie x_2, and rating y. The goal is to build a discriminative predictor $q(y|x_1, x_2)$ that given a pair of viewer x_1 and movie x_2 will predict the expected rating y. A natural form of evaluation of such predictors, no matter whether they are based on co-clustering or not, is to evaluate the expected loss $\mathbb{E}_{p(x_1,x_2,y)}\mathbb{E}_{q(y'|x_1,x_2)}l(Y,Y')$, where $l(y,y')$ is an externally provided loss function for predicting y' instead of y. In Section 3 we provide this analysis for co-clustering-based predictors. The analysis can be used not only to construct co-clustering solutions to this problem, but also to conduct a theoretical comparison of the co-clustering-based approach to this problem with other possible approaches.

The second class of problems, which are solved using co-clustering, are problems of estimation of a joint probability distribution in co-occurrence data analysis. A typical example of this kind of problem is the analysis of word-document co-occurrence matrices in text mining (Slonim and Tishby, 2000; El-Yaniv and Souroujon, 2001; Dhillon et al., 2003). Word-document co-occurrence matrices are matrices of words by documents where the number of times each word occurred in each document is counted in the corresponding entries. If normalized, such a matrix can be regarded as an empirical joint probability distribution of words and documents. To illustrate the difference between co-occurrence data and the data considered in discriminative prediction tasks, we point out that the ratings in the collaborative filtering example are functions of viewer and movie ID pairs and they do not depend on other viewers or movies. By contrast, in co-occurrence data the joint probability (or the number of co-occurrence events) is normalized by the size of the corpus and thus depends on

the whole subset of words and documents considered (or the size of the corpus if no normalization is applied).

Although many researchers have analyzed co-occurrence data by clustering similar words and similar documents (Slonim and Tishby, 2000; El-Yaniv and Souroujon, 2001; Dhillon et al., 2003; Takamura and Matsumoto, 2003), or by using topic models (Steyvers and Griffiths, 2006; Blei and Lafferty, 2009) and other approaches, no clear learning task in this problem has been defined and it remains difficult to compare different approaches or perform model order selection. In Seldin and Tishby (2009) one possible way of defining a high-level task for this problem was suggested. It was assumed that the observed co-occurrence matrix was drawn from an unknown joint probability distribution $p(x_1, x_2)$ of words x_1 and documents x_2. The suggested task was an estimation of this joint probability distribution based on the observed sample. In such a formulation, the quality of an estimator $q(x_1, x_2)$ for $p(x_1, x_2)$ can be measured by $-\mathbb{E}_{p(x_1,x_2)} \ln q(X_1, X_2)$, where the choice of the logarithmic loss is natural in the context of density estimation. In particular, it corresponds to the expected code length of an encoder that uses $q(x_1, x_2)$ to encode samples generated by $p(x_1, x_2)$ (Cover and Thomas, 1991). In Section 3 we provide an analysis of this quantity for co-clustering-based density estimators. Similar to the case with co-clustering-based discriminative predictors, the analysis serves to perform model order selection in this problem. It further enables a theoretical comparison of the co-clustering-based approach to this problem with other possible approaches.

For the purpose of analysis and derivation of generalization bounds for the above two problems we found it convenient to apply the PAC-Bayesian framework (McAllester, 1998, 1999), which is reviewed in Section 2. Similar to the Probably Approximately Correct (PAC) learning model (Valiant, 1984), PAC-Bayesian bounds pose no assumptions or restrictions on the distribution that generates the data (apart from the usual assumption that the data are independent and identically distributed (i.i.d.) and that the train and test distributions are the same). However, unlike the usual PAC bounds, where the whole hypothesis space is characterized by its Vapnik-Chervonenkis (VC) dimension (Vapnik and Chervonenkis, 1968, 1971), PAC-Bayesian bounds apply a non-uniform treatment of the hypotheses by introducing a prior distribution over the hypothesis space. For example, within the class of decision trees a preference for shallow trees can be given by assigning a higher prior. If a good prior over the hypothesis space can be designed, the tightness of the bounds can be improved considerably. As shown in the literature, PAC-Bayesian analysis is able to provide practically useful bounds that in some cases are only 10%-20% away from the test error (Langford, 2005; Seldin and Tishby, 2008; Seldin, 2009; Germain et al., 2009).

Originally, PAC-Bayesian bounds were derived for classification tasks. They have been applied in the analysis of decision trees (Mansour and McAllester, 2000), Support Vector Machines (SVMs) (Langford and Shawe-Taylor, 2002; McAllester, 2003; Langford, 2005; Ambroladze et al., 2007; Crammer et al., 2009; Germain et al., 2009), transductive learning (Derbeko et al., 2004), structured prediction (Bartlett et al., 2005; McAllester, 2007), and other supervised learning models. In Seldin and Tishby (2009) we introduced PAC-Bayesian analysis to discrete density estimation. Recently, Higgs and Shawe-Taylor (2010) applied PAC-Bayesian analysis to continuous density estimation. In Section 3 we present the PAC-Bayesian analysis of discriminative prediction and density estimation with co-clustering. According to the derived bounds, the generalization performance of co-clustering-based models depends on a trade-off between their empirical performance and the mutual information that the clusters preserve on the observed parameters (row and column IDs). The mutual information term introduces model regularization that was absent in the previous formulations of co-clustering (Dhillon et al., 2003; Banerjee et al., 2007). We further suggest

algorithms for optimization of the trade-off in Section 4. In Section 5, we achieve state-of-the-art performance in the prediction of missing ratings in the MovieLens collaborative filtering data set by optimization of the trade-off.

The co-clustering models analyzed here are tightly related to matrix tri-factorization—a 3-factor decomposition of a matrix of the form $A \approx Q_1^T F Q_2$ (Banerjee et al., 2007; Ding et al., 2006; Yoo and Choi, 2009a,b) and to Tucker decomposition of higher dimensional tensors (Kim and Choi, 2007). This relation is discussed in Section 6. We point out that similar to co-clustering itself there are at least two different forms of matrix tri-factorization; one that corresponds to discriminative prediction tasks, such as collaborative filtering, and the other which is more appropriate for co-occurrence data analysis. In the first case A can be arbitrary, whereas in the second case the input matrix A is a joint probability distribution matrix (its entries are non-negative and sum up to one). At the technical level, in discriminative prediction tasks Q_1 and Q_2 are right stochastic matrices (their rows sum up to one) and F is arbitrary, whereas in co-occurrence data analysis Q_1 and Q_2 are left stochastic matrices (their columns sum up to one) and F is a joint probability distribution matrix (in the cluster product space). Our analysis provides generalization bounds, regularization terms, and new algorithms for both forms of matrix tri-factorization.

Co-clustering can also be regarded as a simple graphical model. In Section 7 we suggest how to extend our analysis to more general tree-shaped graphical models. Such graphical models can be useful to treat the curse of dimensionality in the analysis of high dimensional tensors. This also provides a new perspective on learning graphical models: instead of learning a graphical model that fits the training data, the approach suggests optimizing the model's ability to predict new observations. In Sections 3 and 7 it is demonstrated that PAC-Bayesian bounds are able to take advantage of the factor form of graphical models and provide bounds that depend on the sizes of the cliques of graphical models and the amount of mutual information that is propagated up the tree levels.

In Section 8 we extend our approach to the formulation of unsupervised learning problems as prediction problems to graph clustering and pairwise clustering (the latter is equivalent to clustering of a weighted graph, where edge weights correspond to pairwise distances). We formulate weighted graph clustering as a prediction problem: given a sample of edge weights we analyze the ability of graph clustering to predict the remaining edge weights. We adapt the PAC-Bayesian analysis of co-clustering to derive a PAC-Bayesian generalization bound for graph clustering. The bound shows that graph clustering should optimize a trade-off between empirical data fit and the mutual information that clusters preserve on the graph nodes. A similar trade-off derived from information-theoretic considerations has been shown to produce state-of-the-art results in practice (Slonim et al., 2005; Yom-Tov and Slonim, 2009). This paper supports the empirical evidence by providing a better theoretical foundation, suggesting formal generalization guarantees, and offering a more accurate way to deal with finite sample issues.

2. PAC-Bayesian Generalization Bounds

This section is devoted to PAC-Bayesian generalization bounds, which are the main tool used for the analysis of our learning models in the subsequent sections. We review the well-known PAC-Bayesian bound for classification and present a slight variation of a less well-known PAC-Bayesian bound for discrete density estimation. The PAC-Bayesian generalization bounds pioneered by McAllester (1998, 1999) provide guarantees on generalization abilities of randomized predictors (formally defined below in Section 2.1) within the classical PAC learning model (Valiant, 1984)

and build upon preceding works on PAC analysis of Bayesian learning models (Shawe-Taylor et al., 1998; Shawe-Taylor and Williamson, 1997). The classical PAC learning model evaluates learning algorithms by their ability to predict new events generated by the same probability distribution as the one that was used to train the algorithm. No restrictions on the data generating probability distribution are imposed except the assumption that the samples are i.i.d. The PAC-Bayesian framework should be distinguished from Bayesian learning, which assumes that the data were generated by hypotheses from the hypothesis class and applies Bayes' rule for inference. Bayesian learning does not provide guarantees on the expected error of the Bayes' inference rule and in some situations can lead to overfitting (Kearns et al., 1997).

The classical PAC bounds are derived by covering the error space of a hypothesis class. For example, the most familiar PAC bounds are based on the VC-dimension of a hypothesis class, which is a logarithm of the maximal number of points that can be jointly classified in any possible way by functions from the hypothesis class (Vapnik and Chervonenkis, 1968, 1971; Vapnik, 1998; Devroye et al., 1996). More recent bounds involve Rademacher and Gaussian complexities (Koltchinskii, 2001; Bartlett et al., 2001; Bartlett and Mendelson, 2001; Boucheron et al., 2005). However, in all the above approaches the whole hypothesis class is characterized by a single number: its VC-dimension or Rademacher complexity, which means that all the incorporating hypotheses are treated identically and there is no way to differentiate them and give preference to "simpler" ones. For example, if the hypothesis class consists of straight lines and parabolas, its VC-dimension is equal to the VC-dimension of a hypothesis class consisting of parabolas only and there is no direct way to give preference to straight lines within the combined hypothesis class. PAC-Bayesian bounds are derived by covering the hypothesis space and they enable non-uniform treatment of the hypotheses. In the PAC-Bayesian approach each hypothesis is characterized by its own complexity defined by its prior. This refined approach provides several important benefits, which include: (1) the ability to give explicit preference to certain hypotheses (e.g, in the example above we can assign a higher prior to straight lines); (2) a gradient within the hypothesis space, which can be used in algorithms for bound minimization; (3) considerably tighter bounds, which are meaningful in a practical sense: in some applications the discrepancy between the bound value and the test error is only 10%-20% (Langford, 2005; Seldin and Tishby, 2008; Seldin, 2009; Germain et al., 2009). There is one more distinction between the usual PAC analysis and the PAC-Bayesian bounds that extend the scope of applicability of the latter. Classical PAC analysis aims at bounding the discrepancy between the expected performance of the hypothesis with the best empirical performance and the best hypothesis within the hypothesis class. Such types of bounds require a uniform bound on the discrepancies between empirical and expected performances for all the hypotheses within a hypothesis class. The uniform bound exists if and only if the hypothesis class has a finite VC-dimension. PAC-Bayesian bounds bound the expected performance of a given hypothesis, but do not attempt to bound its gap to the performance of the best hypothesis within the hypothesis class. This fact makes it possible to apply PAC-Bayesian bounds even in situations where the VC-dimension of a hypothesis class is infinite, for example, decision trees of unlimited depth or separating hyperplanes in infinite-dimensional spaces. This does not disprove the fundamental theorem of PAC learning theory, which states that learning is possible if and only if the VC-dimension of a hypothesis class is finite, but rather extends the notion of learnability. Instead of a regret-based definition of learnability, by which the ability to learn is the ability to achieve, up to a small epsilon, the best possible solution within a hypothesis class, the PAC-Bayesian approach defines learnability as the ability to bound the

expected performance of the obtained solution. Then it is a question for the user to decide whether the guaranteed expected performance is sufficient for his or her needs.

Since the strength of PAC-Bayesian analysis lies in its ability to provide a non-uniform treatment of the hypotheses within a hypothesis class, its advantage over traditional PAC analysis is best seen in the analysis of heterogeneous hypothesis classes (or, in other words, when the hypotheses constituting a hypothesis class are not symmetric). Some hypothesis classes exhibit a "natural heterogeneity"; for example, we can partition the class of decision trees into subclasses according to tree depth. A higher prior can then be assigned to shallow trees to provide them with preference over deep trees. For example, a prior $\mathcal{P}(t) = 2^{-(d(t)+1)}2^{-2^{d(t)}}$, where $d(t)$ is the depth of a tree t would be a legal prior over the space of full binary decision trees of unlimited depth ($2^{-(d(t)+1)}$ is a prior over tree depth and $2^{-2^{d(t)}}$ is a prior over trees of a given depth). Note that it is possible to assign a higher prior to *all* shallow trees simultaneously because there are fewer shallow trees than deep trees. Hence, the above prior exploits knowledge about the structure of the hypothesis space, but makes no assumptions about the data. As we will see below, the bounds depend on $-\ln \mathcal{P}(t) = \ln(2)[(d(t)+1) + 2^{d(t)}]$; thus the value of the logarithm of the first part of the prior $(d(t)+1)$, which accounts for the tree depth, is negligible compared to the value of the logarithm of the second half of the prior $(2^{d(t)})$, which counts the number of symmetric trees given the depth. Given a strong prior knowledge on the problem domain, which breaks the symmetry between trees of a given depth, it is possible to give preference (a higher prior) to certain deep trees; however it is impossible to give a higher prior to all deep trees simultaneously, because there are too many of them. Thus, a choice of a different prior over tree depth and even precise prior knowledge of the tree depth can only negligibly improve the bound.

For some hypothesis spaces which seem homogeneous at a first glance it may still be possible to identify non-trivial asymmetries and define a corresponding structural prior. The best example comes from the analysis of SVMs, where the class of all possible separating hyperplanes in $\mathbb{R}^d$ is partitioned into subclasses according to the size of the margin and a higher prior is given to the hyperplanes with large margins (Langford and Shawe-Taylor, 2002; McAllester, 2003; Langford, 2005). In structure learning the hypothesis class usually exhibits a natural heterogeneity since the hypotheses (structures) can be differentiated by their complexity. Hence, PAC-Bayesian analysis has great potential in the analysis of structure learning which is only partially explored in this work. PAC-Bayesian bounds are further distinguished by their explicit dependence on model parameters, which makes their optimization easy.

Following the pioneering work of McAllester (1998, 1999), the PAC-Bayesian bounds were tightened and simplified by Seeger (2002, 2003). Some further improvements were suggested in Maurer (2004), Audibert and Bousquet (2007) and Blanchard and Fleuret (2007). This section draws on the easier-to-read expositions by Maurer (2004) and Banerjee (2006). In order to present the bounds for classification and density estimation, we need to define the notion of randomized predictors, which is done next. We then present the PAC-Bayesian theorems and their proofs.

2.1 Randomized Predictors

Let $\mathcal{H}$ be a hypothesis class and let $\mathcal{Q}(h)$ be a distribution over $\mathcal{H}$ (if $\mathcal{H}$ is infinite then $\mathcal{Q}(h)$ is a probability density). A *randomized predictor* associated with $\mathcal{Q}$, and with a small abuse of notation denoted by $\mathcal{Q}$, is defined in the following way: For each sample x a hypothesis $h \in \mathcal{H}$ is drawn according to $\mathcal{Q}(h)$, and then applied to make a prediction on x. In the classification context, $\mathcal{Q}$

is termed a *randomized classifier* (Langford, 2005). However, since this work extends the PAC-Bayesian framework beyond the classification scenario by using the same randomization technique, we use the term "randomized predictor". In this more general context $h(x)$ is a general function of x, not necessarily a classifier.

In the context of classification, let $S = \{(x_1, y_1), .., (x_N, y_N)\}$ be an i.i.d. sample of size N of instances and their labels drawn according to unknown distribution $p(x, y)$ and let $l(y, y')$ be a given loss function for predicting y' instead of y. Let $h(x)$ be the label of x predicted by hypothesis h. For each $h \in \mathcal{H}$ we denote by $\hat{L}(h) = \frac{1}{N}\sum_i l(y_i, h(x_i))$ the empirical loss of the hypothesis h on S and by $L(h) = \mathbb{E}_{p(x,y)} l(Y, h(X))$ the expected loss of h with respect to the true, unknown distribution that generates the data. We further extend the definitions of the empirical and expected losses for randomized predictors in the following way:

$$\hat{L}(\mathcal{Q}) = \mathbb{E}_{\mathcal{Q}(h)}\hat{L}(h) \qquad \text{and} \qquad L(\mathcal{Q}) = \mathbb{E}_{\mathcal{Q}(h)}L(h).$$

For two distributions q and p over domain $\mathcal{X}$ we define

$$KL(q\|p) = \mathbb{E}_q \ln \frac{q(x)}{p(x)}$$

to be the Kullback-Leibler (KL) divergence between q and p (Cover and Thomas, 1991). As well, we define

$$kl(\hat{L}(\mathcal{Q})\|L(\mathcal{Q})) = \hat{L}(\mathcal{Q}) \ln \frac{\hat{L}(\mathcal{Q})}{L(\mathcal{Q})} + (1 - \hat{L}(\mathcal{Q})) \ln \frac{1 - \hat{L}(\mathcal{Q})}{1 - L(\mathcal{Q})}$$

as the KL-divergence between two Bernoulli distributions with biases $\hat{L}(\mathcal{Q})$ and $L(\mathcal{Q})$. Now we are ready to state the PAC-Bayesian theorems.

2.2 PAC-Bayesian Theorems

Theorem 1 (PAC-Bayesian bound for classification) *For a hypothesis class $\mathcal{H}$, a prior distribution $\mathcal{P}$ over $\mathcal{H}$ and a zero-one loss function l, with probability greater than $1 - \delta$ over drawing a sample of size N, for all randomized classifiers $\mathcal{Q}$ simultaneously*:

$$kl(\hat{L}(\mathcal{Q})\|L(\mathcal{Q})) \leq \frac{KL(\mathcal{Q}\|\mathcal{P}) + \ln(N+1) - \ln\delta}{N}. \tag{1}$$

Theorem 2 (PAC-Bayesian bound for discrete density estimation) *Let $\mathcal{X}$ be the sample space (possibly infinite) and let $p(x)$ be an unknown distribution over $x \in \mathcal{X}$. Let $\mathcal{H}$ be a hypothesis class, such that each member $h \in \mathcal{H}$ is a function from $\mathcal{X}$ to a finite set $\mathcal{Z}$ with cardinality $|\mathcal{Z}|$. Let $p_h(z) = P_{X\sim p(x)}\{h(X) = z\}$ be the distribution over $\mathcal{Z}$ induced by $p(x)$ and h. Let $\mathcal{P}$ be a prior distribution over $\mathcal{H}$. Let $\mathcal{Q}$ be an arbitrary distribution over $\mathcal{H}$ and $p_{\mathcal{Q}}(z) = \mathbb{E}_{\mathcal{Q}(h)} p_h(z)$ a distribution over $\mathcal{Z}$ induced by $p(x)$ and $\mathcal{Q}$. Let S be an i.i.d. sample of size N generated according to $p(x)$ and let $\hat{p}(x)$ be the empirical distribution over $\mathcal{X}$ corresponding to S. Let $\hat{p}_h(z) = P_{X\sim\hat{p}(x)}\{h(X) = z\}$ be the empirical distribution over $\mathcal{Z}$ corresponding to h and S. Let $\hat{p}_{\mathcal{Q}}(z) = \mathbb{E}_{\mathcal{Q}(h)}\hat{p}_h(z)$. Then with probability greater than $1 - \delta$ for all possible $\mathcal{Q}$ simultaneously*:

$$KL(\hat{p}_{\mathcal{Q}}(z)\|p_{\mathcal{Q}}(z)) \leq \frac{KL(\mathcal{Q}\|\mathcal{P}) + (|\mathcal{Z}| - 1)\ln(N+1) - \ln\delta}{N}. \tag{2}$$

Remarks:

1. This form of Theorem 1 first appeared in Seeger (2002). A slightly different version of Theorem 2 first appeared in Seeger (2003) and independently in Seldin and Tishby (2009), where it found the first non-trivial application.

2. The PAC-Bayesian bound for classification (1) is a direct consequence of the PAC-Bayesian bound for density estimation (2). To see this, let Z be the error variable. Then each hypothesis $h \in \mathcal{H}$ is a function from the sample space (in this case the samples are pairs $\langle X, Y \rangle$) to the error variable Z and $|\mathcal{Z}| = 2$. Furthermore, $\hat{L}(h) = \hat{p}_h(Z = 1)$ and $L(h) = p_h(Z = 1)$, hence $kl(\hat{L}(\mathcal{Q}) \| L(\mathcal{Q})) = KL(\hat{p}_{\mathcal{Q}}(z) \| p_{\mathcal{Q}}(z))$. Substituting this into (2) yields (1).

3. Maurer (2004) showed that due to convexity of the KL-divergence, inequality (1) is valid for all loss functions bounded in the [0,1] interval, and not only for the zero-one loss. He also proved that due to tighter concentration of empirical means of binary variables, for $N \geq 8$ bound (1) can be further tightened:

$$kl(\hat{L}(\mathcal{Q}) \| L(\mathcal{Q})) \leq \frac{KL(\mathcal{Q} \| \mathcal{P}) + \frac{1}{2} \ln(4N) - \ln \delta}{N} \tag{3}$$

   and that this is the tightest result that can be proved using the techniques which are also used in this paper.

4. Although there is no analytical expression for the inverse of the kl-divergence, $L(\mathcal{Q})$ can be bounded numerically:

$$\begin{aligned} L(\mathcal{Q}) &\leq kl^{-1}\left(\hat{L}(\mathcal{Q}), \frac{KL(\mathcal{Q} \| \mathcal{P}) + \frac{1}{2} \ln(4N) - \ln \delta}{N}\right) \\ &= \max\left\{v : kl(\hat{L}(\mathcal{Q}) \| v) \leq \frac{KL(\mathcal{Q} \| \mathcal{P}) + \frac{1}{2} \ln(4N) - \ln \delta}{N}\right\}. \end{aligned} \tag{4}$$

   Since $kl(\hat{L}(\mathcal{Q}) \| v)$ is convex in v, (4) is easy to compute.

5. The proof of Theorem 2 presented below reveals a close relation between the PAC-Bayesian theorems and the method of types in information theory (Cover and Thomas, 1991). The trade-off between $\hat{L}(\mathcal{Q})$ and $KL(\mathcal{Q} \| \mathcal{P})$ in the PAC-Bayesian bounds also has a tight relation to the maximum entropy principle in learning and statistical mechanics (Jaynes, 1957; Dudík et al., 2007; Catoni, 2007; Shawe-Taylor and Hardoon, 2009). The relations between the PAC-Bayesian bounds, information theory, and statistical mechanics are further discussed in Catoni (2007).

The proof of Theorem 2 presented below is based on two auxiliary results which have value in their own right and therefore are presented in dedicated subsections. The first auxiliary result applies the method of types to bound the expectation of the exponent of the divergence between empirical and expected distributions over $\mathcal{Z}$ for a single hypothesis: $\mathbb{E}_S e^{N \cdot KL(\hat{p}_h(z) \| p_h(z))}$. The second auxiliary result relates the divergence $\mathbb{E}_{\mathcal{Q}(h)} KL(\hat{p}_h(z) \| p_h(z))$ for all $\mathcal{Q}$ to a single (prior) reference measure $\mathcal{P}$. This relation is actually the cornerstone of the PAC-Bayesian analysis. Finally, in Section 2.5 a quantity depending on the prior measure $\mathcal{P}$ is treated using the first auxiliary result to obtain the final bound in Equation (2).

2.3 The Law of Large Numbers

In this subsection we analyze the rate of convergence of empirical distributions over finite domains to their true values. The following result is based on the method of types in information theory (Cover and Thomas, 1991).

Theorem 3 *Let $S = \{X_1, .., X_N\}$ be i.i.d. distributed by $p(x)$. Denote by $\hat{p}(x)$ the empirical distribution over $\mathcal{X}$ corresponding to S and by $|\mathcal{X}|$ the cardinality of $\mathcal{X}$. Then*:

$$\mathbb{E}_S e^{N \cdot KL(\hat{p}(x) \| p(x))} \leq (N+1)^{|\mathcal{X}|-1}. \tag{5}$$

Proof Enumerate the possible values of $\mathcal{X}$ by $1, .., |\mathcal{X}|$ and let n_i count the number of occurrences of value i. Let p_i denote the probability of value i and $\hat{p}_i = \frac{n_i}{N}$ be its empirical counterpart. Let $H(\hat{p}) = -\sum_i \hat{p}_i \ln \hat{p}_i$ be the empirical entropy. Then:

$$\begin{aligned}
\mathbb{E}_S e^{NKL(\hat{p}\|p)} &= \sum_{\substack{n_1,..,n_{|\mathcal{X}|}: \\ \sum_i n_i = N}} \binom{N}{n_1, .., n_{|\mathcal{X}|}} \cdot \prod_{i=1}^{|\mathcal{X}|} p_i^{N\hat{p}_i} \cdot e^{NKL(\hat{p}\|p)} \\
&\leq \sum_{\substack{n_1,..,n_{|\mathcal{X}|}: \\ \sum_i n_i = N}} e^{NH(\hat{p})} \cdot e^{N \sum_i \hat{p}_i \ln p_i} \cdot e^{NKL(\hat{p}\|p)} \qquad (6) \\
&= \sum_{\substack{n_1,..,n_{|\mathcal{X}|}: \\ \sum_i n_i = N}} 1 = \binom{N+|\mathcal{X}|-1}{|\mathcal{X}|-1} \leq (N+1)^{|\mathcal{X}|-1}. \qquad (7)
\end{aligned}$$

In (6) we used the $\binom{N}{n_1,..,n_{|\mathcal{X}|}} \leq e^{NH(\hat{p})}$ bound on the multinomial coefficient, which counts the number of sequences with a fixed cardinality profile (unnormalized type) $n_1, .., n_{|\mathcal{X}|}$ (Cover and Thomas, 1991). In the second equality in (7) the number of ways to choose n_i-s equals the number of ways we can place $|\mathcal{X}|-1$ ones in a sequence of $N+|\mathcal{X}|-1$ ones and zeros, where ones symbolize a partition of zeros ("balls") into $|\mathcal{X}|$ bins. ■

2.4 Change of Measure Inequality

The simultaneous treatment of all possible distributions (measures) $\mathcal{Q}$ over $\mathcal{H}$ is done by relating them all to a single reference (prior) measure $\mathcal{P}$. We call this relation a *change of measure inequality*. This inequality was formulated as a standalone result in Banerjee (2006), although it originates much earlier. Banerjee (2006) terms it a *compression lemma*; however we find the term "change of measure inequality" more appropriate to its nature and usage. The inequality is a simple consequence of Jensen's inequality.

Lemma 4 (Change of Measure Inequality) *For any measurable function $\phi(h)$ on $\mathcal{H}$ and any distributions $\mathcal{P}$ and $\mathcal{Q}$ on $\mathcal{H}$, we have:*

$$\mathbb{E}_{\mathcal{Q}(h)} \phi(h) \leq KL(\mathcal{Q}\|\mathcal{P}) + \ln \mathbb{E}_{\mathcal{P}(h)} e^{\phi(h)}. \tag{8}$$

Proof For any measurable function $\phi(h)$, we have:

$$\begin{aligned}
\mathbb{E}_{\mathcal{Q}(h)}\phi(h) &= \mathbb{E}_{\mathcal{Q}(h)} \ln \left(\frac{\mathcal{Q}(h)}{\mathcal{P}(h)} \cdot e^{\phi(h)} \cdot \frac{\mathcal{P}(h)}{\mathcal{Q}(h)} \right) \\
&= KL(\mathcal{Q}\|\mathcal{P}) + \mathbb{E}_{\mathcal{Q}(h)} \ln \left(e^{\phi(h)} \cdot \frac{\mathcal{P}(h)}{\mathcal{Q}(h)} \right) \\
&\leq KL(\mathcal{Q}\|\mathcal{P}) + \ln \mathbb{E}_{\mathcal{Q}(h)} \left(e^{\phi(h)} \cdot \frac{\mathcal{P}(h)}{\mathcal{Q}(h)} \right) \qquad (9) \\
&= KL(\mathcal{Q}\|\mathcal{P}) + \ln \mathbb{E}_{\mathcal{P}(h)} e^{\phi(h)},
\end{aligned}$$

where (9) is by Jensen's inequality. ■

2.5 Proof of the PAC-Bayesian Generalization Bound for Density Estimation

We apply the results of the previous two subsections to prove the PAC-Bayesian generalization bound for density estimation.

Proof of Theorem 2 Let $\phi(h, S, p) = NKL(\hat{p}_h(z)\|p_h(z))$. Then:

$$\begin{aligned}
NKL(\hat{p}_{\mathcal{Q}}(z)\|p_{\mathcal{Q}}(z)) &= NKL(\mathbb{E}_{\mathcal{Q}(h)}\hat{p}_h(z)\|\mathbb{E}_{\mathcal{Q}(h)}p_h(z)) \\
&\leq \mathbb{E}_{\mathcal{Q}(h)} NKL(\hat{p}_h(z)\|p_h(z)) \qquad (10) \\
&\leq KL(\mathcal{Q}\|\mathcal{P}) + \ln \mathbb{E}_{\mathcal{P}(h)} e^{NKL(\hat{p}_h(z)\|p_h(z))}, \qquad (11)
\end{aligned}$$

where (10) is by the convexity of the KL-divergence (Cover and Thomas, 1991) and (11) is by the change of measure inequality. To obtain (2) it is left to bound $\mathbb{E}_{\mathcal{P}(h)} e^{NKL(\hat{p}_h(z)\|p_h(z))}$. This is a random quantity depending on the sample S since $\hat{p}_h(z)$ for each h depends on the sample. By Markov's inequality we know that with probability at least $1-\delta$ over the sample $\mathbb{E}_{\mathcal{P}(h)} e^{NKL(\hat{p}_h(z)\|p_h(z))} \leq \frac{1}{\delta}\mathbb{E}_S \left[\mathbb{E}_{\mathcal{P}(h)} e^{NKL(\hat{p}_h(z)\|p_h(z))} \right]$. In order to obtain a bound on $\mathbb{E}_S \left[\mathbb{E}_{\mathcal{P}(h)} e^{NKL(\hat{p}_h(z)\|p_h(z))} \right]$ we note that it is possible to exchange $\mathbb{E}_S$ with $\mathbb{E}_{\mathcal{P}(h)}$ since S and h are independent:

$$\mathbb{E}_S \left[\mathbb{E}_{\mathcal{P}(h)} e^{NKL(\hat{p}_h(z)\|p_h(z))} \right] = \mathbb{E}_{\mathcal{P}(h)} \left[\mathbb{E}_S e^{NKL(\hat{p}_h(z)\|p_h(z))} \right] \leq (N+1)^{|\mathcal{Z}|-1}. \qquad (12)$$

The last inequality in (12) is justified by the fact that $\mathbb{E}_S e^{NKL(\hat{p}_h(z)\|p_h(z))} \leq (N+1)^{|\mathcal{Z}|-1}$ for each h individually according to (5). By Markov's inequality we conclude that with probability of at least $1-\delta$ over S:

$$\mathbb{E}_{\mathcal{P}(h)} e^{NKL(\hat{p}_h(z)\|p_h(z))} \leq \frac{(N+1)^{|\mathcal{Z}|-1}}{\delta}.$$

Substituting this into (11) and normalizing by N yields (2). ■

2.6 Addendum to the Law of Large Numbers

Note in passing that it is straightforward to recover theorem 12.2.1 in Cover and Thomas (1991) from Theorem 3 (even with a slight improvement). This theorem is used later in the estimation of marginal distributions.

Theorem 5 (12.2.1 in Cover and Thomas, 1991) *Under the notations of Theorem 3 with probability greater than* $1-\delta$:

$$KL(\hat{p}(x)\|p(x)) \leq \frac{(|\mathcal{X}|-1)\ln(N+1)-\ln\delta}{N}.$$

Proof Immediate from application of Markov's inequality to (5). ■

2.7 Construction of a Density Estimator

Although we have bounded $KL(\hat{p}_{\mathcal{Q}}(z)\|p_{\mathcal{Q}}(z))$ in Theorem 2, $\hat{p}_{\mathcal{Q}}(z)$ still cannot be used as a density estimator for $p_{\mathcal{Q}}(z)$, because it is not bounded from zero. In order to bound the logarithmic loss $-\mathbb{E}_{p_{\mathcal{Q}}(z)}\ln\hat{p}_{\mathcal{Q}}(z)$, which corresponds, for example, to the expected code length of encoder $\hat{p}_{\mathcal{Q}}$ when samples are generated by $p_{\mathcal{Q}}$, we have to smooth $\hat{p}_{\mathcal{Q}}$. We denote a smoothed version of $\hat{p}_{\mathcal{Q}}$ by $\tilde{p}_{\mathcal{Q}}$ and define it as:

$$\tilde{p}_h(z) = \frac{\hat{p}_h(z)+\gamma}{1+\gamma|\mathcal{Z}|}, \tag{13}$$
$$\tilde{p}_{\mathcal{Q}}(z) = \mathbb{E}_{\mathcal{Q}(h)}\tilde{p}_h(z) = \frac{\hat{p}_{\mathcal{Q}}(z)+\gamma}{1+\gamma|\mathcal{Z}|}.$$

In the following theorem we show that if $KL(\hat{p}_{\mathcal{Q}}(z)\|p_{\mathcal{Q}}(z)) \leq \varepsilon(\mathcal{Q})$ and $\gamma(\mathcal{Q}) = \frac{\sqrt{\varepsilon(\mathcal{Q})/2}}{|\mathcal{Z}|}$, then $-\mathbb{E}_{p_{\mathcal{Q}}(z)}\ln\tilde{p}_{\mathcal{Q}}(z)$ is roughly within $\pm\sqrt{\varepsilon(\mathcal{Q})/2}\ln|\mathcal{Z}|$ range around $H(\hat{p}_{\mathcal{Q}}(z))$. The bound on $KL(\hat{p}_{\mathcal{Q}}(z)\|p_{\mathcal{Q}}(z))$ is naturally obtained by Theorem 2. Thus, the performance of the density estimator $\tilde{p}_{\mathcal{Q}}$ is optimized by distribution $\mathcal{Q}$ that minimizes the trade-off between $H(\hat{p}_{\mathcal{Q}}(z))$ and $\frac{1}{N}KL(\mathcal{Q}\|\mathcal{P})$.

Note that for a uniform distribution $u(z) = \frac{1}{|\mathcal{Z}|}$ the value of $-\mathbb{E}_{p(z)}\ln u(z) = \ln|\mathcal{Z}|$. Thus, the theorem below is interesting when $\sqrt{\varepsilon(\mathcal{Q})/2}$ is significantly smaller than 1. For technical reasons in the proofs of the following section, the upper bound in the next theorem is stated for $-\mathbb{E}_{p_{\mathcal{Q}}(z)}\ln\tilde{p}_{\mathcal{Q}}(z)$ and for $-\mathbb{E}_{\mathcal{Q}(h)}\mathbb{E}_{p_h(z)}\ln\tilde{p}_h(z)$. We also denote $\varepsilon = \varepsilon(\mathcal{Q})$ for brevity.

Theorem 6 *Let Z be a random variable distributed according to $p_{\mathcal{Q}}(z)$ and assume that $KL(\hat{p}_{\mathcal{Q}}(z)\|p_{\mathcal{Q}}(z)) \leq \varepsilon$. Then $-\mathbb{E}_{p_{\mathcal{Q}}(z)}\ln\tilde{p}_{\mathcal{Q}}(z)$ is minimized by $\gamma = \frac{\sqrt{\varepsilon/2}}{|\mathcal{Z}|}$. For this value of γ the following inequalities hold:*

$$-\mathbb{E}_{\mathcal{Q}(h)}\mathbb{E}_{p_h(z)}\ln\tilde{p}_h(z) \leq H(\hat{p}_{\mathcal{Q}}(z)) + \sqrt{\varepsilon/2}\ln|\mathcal{Z}| + \phi(\varepsilon), \tag{14}$$
$$-\mathbb{E}_{p_{\mathcal{Q}}(z)}\ln\tilde{p}_{\mathcal{Q}}(z) \leq H(\hat{p}_{\mathcal{Q}}(z)) + \sqrt{\varepsilon/2}\ln|\mathcal{Z}| + \phi(\varepsilon), \tag{15}$$
$$-\mathbb{E}_{p_{\mathcal{Q}}(z)}\ln\tilde{p}_{\mathcal{Q}}(z) \geq H(\hat{p}_{\mathcal{Q}}(z)) - \sqrt{\varepsilon/2}\ln|\mathcal{Z}| - \psi(\varepsilon), \tag{16}$$

where:

$$\psi(\varepsilon) = \sqrt{\varepsilon/2}\ln\frac{1+\sqrt{\varepsilon/2}}{\sqrt{\varepsilon/2}} \;\; \textit{and} \;\; \phi(\varepsilon) = \psi(\varepsilon) + \ln(1+\sqrt{\varepsilon/2}).$$

The proof is provided in appendix A. Note that both $\phi(\varepsilon)$ and $\psi(\varepsilon)$ converge to zero approximately as $-\sqrt{\varepsilon/2}\ln\sqrt{\varepsilon/2}$ and for $\sqrt{\varepsilon/2} < \frac{1}{|\mathcal{Z}|}$ they are in fact dominant over the $\sqrt{\varepsilon/2}\ln|\mathcal{Z}|$ term. Nevertheless, the main message is still that in order to minimize $-\mathbb{E}_{p_{\mathcal{Q}}(z)}\ln\tilde{p}_{\mathcal{Q}}(z)$ the trade-off between $H(\hat{p}_{\mathcal{Q}}(z))$ and $KL(\hat{p}_{\mathcal{Q}}(z)\|p_{\mathcal{Q}}(z))$ should be minimized. This message is explored in more details in Section 3.4.

Remark: As an aside we consider the case of direct density estimation. Assume we are given a set of N i.i.d. observations $x_1,..,x_N$ generated according to an unknown distribution $p(x)$ over a finite domain $\mathcal{X}$. We want to construct an estimate $\tilde{p}(x)$ for $p(x)$ based on the empirical frequencies $\hat{p}(x)$, such that the expectation $-\mathbb{E}_{p(x)}\ln\tilde{p}(x)$ is minimized. This problem, known as "histogram smoothing", has received significant attention in statistics and information theory (Gilbert, 1971; Cover, 1972; Krichevskiy, 1998; Paninski, 2004). Uniform smoothing of the form

$$\tilde{p}(x) = \frac{\hat{p}(x)+\gamma}{1+\gamma|\mathcal{X}|},$$

such as the one applied in (13) is known as the Dirichlet-Bayes or "add-constant" estimator. Theorem 6 provides the optimal value of γ

$$\gamma = \frac{1}{|\mathcal{X}|}\sqrt{\varepsilon/2} = \frac{1}{|\mathcal{X}|}\sqrt{\frac{(|\mathcal{X}|-1)\ln(N+1)-\ln\delta}{2N}}$$

for which with probability greater than $1-\delta$ over the sample

$$H(\hat{p}(x)) - \sqrt{\varepsilon/2}\ln|\mathcal{X}| - \psi(\varepsilon) \le -\mathbb{E}_{p(x)}\ln\tilde{p}(x) \le H(\hat{p}(x)) + \sqrt{\varepsilon/2}\ln|\mathcal{X}| + \phi(\varepsilon),$$

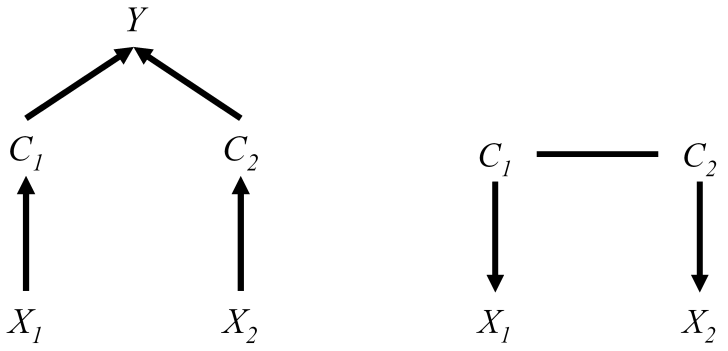
where $\varepsilon = \frac{(|\mathcal{X}|-1)\ln(N+1)-\ln\delta}{N}$ is obtained from Theorem 5. By Theorem 6 the optimal smoothing γ decreases as the sample size N increases. A more detailed comparison of this result with preceding work is beyond the scope of this paper and will be presented elsewhere. Note that in the more general case considered in Theorem 6, where the distribution $p_{\mathcal{Q}}(z)$ depends on $\mathcal{Q}$ the smoothing parameter γ also depends on $\mathcal{Q}$.

3. PAC-Bayesian Analysis of Co-clustering

In the introduction we defined two high-level goals, which can be solved via co-clustering. The first is discriminative prediction of the matrix entries, as in the collaborative filtering example. The second is estimation of the joint probability distribution in co-occurrence data analysis. We further defined the notion of generalization for each of the two problems. In this section we derive PAC-Bayesian generalization bounds for the two settings. We begin with the co-clustering approach to discriminative prediction, which is slightly easier in terms of presentation. Then we consider the discrete density estimation problem.

3.1 PAC-Bayesian Analysis of Discriminative Prediction with Grid Clustering

Let $\mathcal{X}_1 \times .. \times \mathcal{X}_d \times \mathcal{Y}$ be a $(d+1)$-dimensional product space. We assume that each $\mathcal{X}_i$ is categorical and its cardinality, denoted by $|\mathcal{X}_i| = n_i$, is fixed and known. We also assume that $\mathcal{Y}$ is finite with cardinality $|\mathcal{Y}|$ and that a bounded loss function $l(y,y')$ for predicting y' instead of y is given. As an example, consider collaborative filtering. In collaborative filtering $d=2$, $\mathcal{X}_1$ is the space of the



(a) Graphical Model for Discriminative Prediction

(b) Graphical Model for Density Estimation

Figure 1: Illustration of graphical models corresponding to discriminative prediction (17) and density estimation (26). The illustrations are for $d = 2$.

viewers, n_1 is the number of viewers, $\mathcal{X}_2$ is the space of the movies, n_2 is the number of movies, and $\mathcal{Y}$ is the space of the ratings (e.g., on a five-star scale). The loss $l(y, y')$ can be, for example, the absolute loss $l(y, y') = |y - y'|$ or the quadratic loss $l(y, y') = (y - y')^2$. There is no natural metric either on the space of viewers or on the space of movies; thus both $\mathcal{X}_1$ and $\mathcal{X}_2$ are categorical.

We assume an existence of an unknown probability distribution $p(x_1, .., x_d, y)$ over the $\mathcal{X}_1 \times .. \times \mathcal{X}_d \times \mathcal{Y}$ product space. We further assume that we are given an i.i.d. sample of size N generated according to $p(x_1, .., x_d, y)$. We use $\hat{p}(x_1, .., x_d, y)$ to denote the empirical frequencies of $(d+1)$-tuples $\langle x_1, .., x_d, y \rangle$ in the sample. We consider the following form of discriminative predictors:

$$q(y|x_1, .., x_d) = \sum_{c_1,..,c_d} q(y|c_1, .., c_d) \prod_{i=1}^{d} q(c_i|x_i). \tag{17}$$

The hidden variables $C_1, .., C_d$ represent a clustering of the observed variables $X_1, .., X_d$. The hidden variable C_i accepts values in $\{1, .., m_i\}$, where $m_i = |C_i|$ denotes the number of clusters used along dimension i. The conditional probability distribution $q(c_i|x_i)$ represents the probability of mapping (assigning) x_i to cluster c_i. The conditional probability $q(y|c_1, .., c_d)$ represents the probability of assigning label y to cell $\langle c_1, .., c_d \rangle$ in the cluster product space. The prediction model (17) corresponds to the graphical model in Figure 1.a. Note that this is a two-level randomized prediction model. The free parameters of the model are the conditional distributions $\{q(c_i|x_i)\}_{i=1}^{d}$ and $q(y|c_1, .., c_d)$. We denote these collectively by $\mathcal{Q} = \left\{ \{q(c_i|x_i)\}_{i=1}^{d}, q(y|c_1, .., c_d) \right\}$. In the next subsection we show that (17) corresponds to a randomized prediction strategy. We further denote:

$$L(\mathcal{Q}) = \mathbb{E}_{p(x_1,..,x_d,y)} \mathbb{E}_{q(y'|x_1,..,x_d)} l(Y, Y')$$

and

$$\hat{L}(\mathcal{Q}) = \mathbb{E}_{\hat{p}(x_1,..,x_d,y)} \mathbb{E}_{q(y'|x_1,..,x_d)} l(Y, Y'),$$

where $q(y|x_1, .., x_d)$ is defined by (17). We define

$$\bar{I}(X_i; C_i) = \frac{1}{n_i} \sum_{x_i, c_i} q(c_i|x_i) \ln \frac{q(c_i|x_i)}{\bar{q}(c_i)},$$

where $x_i \in \mathcal{X}_i$ are the possible values of X_i, $c_i \in \{1,..,m_i\}$ are the possible values of C_i, and

$$\bar{q}(c_i) = \frac{1}{n_i} \sum_{x_i} q(c_i|x_i)$$

is the marginal distribution over C_i corresponding to $q(c_i|x_i)$ and a *uniform* distribution $u(x_i) = \frac{1}{n_i}$ over $\mathcal{X}_i$. Thus, $\bar{I}(X_i;C_i)$ is the mutual information corresponding to the joint distribution $\bar{q}(x_i,c_i) = \frac{1}{n_i} q(c_i|x_i)$ defined by $q(c_i|x_i)$ and the uniform distribution over $\mathcal{X}_i$.

With the above definitions we can state the following generalization bound for discriminative prediction with co-clustering.

Theorem 7 *For any probability measure $p(x_1,..,x_d,y)$ over $\mathcal{X}_1 \times .. \times \mathcal{X}_d \times \mathcal{Y}$ and for any loss function l bounded by 1, with probability of at least $1-\delta$ over a selection of an i.i.d. sample S of size N according to p, for all randomized classifiers $\mathcal{Q} = \left\{\{q(c_i|x_i)\}_{i=1}^d, q(y|c_1,..,c_d)\right\}$:*

$$kl(\hat{L}(\mathcal{Q}) \| L(\mathcal{Q})) \leq \frac{\sum_{i=1}^d \left(n_i \bar{I}(X_i;C_i) + m_i \ln n_i\right) + M \ln|\mathcal{Y}| + \frac{1}{2}\ln(4N) - \ln\delta}{N}, \qquad (18)$$

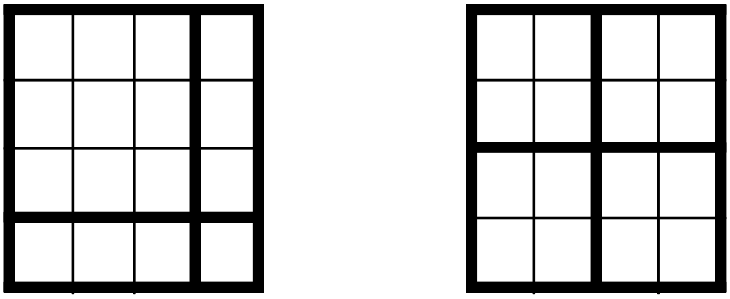
where M is the number of partition cells:

$$M = \prod_{i=1}^d m_i.$$

Remarks: Of course, any bounded loss can be normalized to the [0,1] interval. Note that given a prediction strategy $\mathcal{Q} = \left\{\{q(c_i|x_i)\}_{i=1}^d, q(y|c_1,..,c_d)\right\}$ both $\hat{L}(\mathcal{Q})$ and $\bar{I}(X_i;C_i)$ are computable exactly. $L(\mathcal{Q})$ can be bounded by numerical inversion of kl, as shown in Equation (4). To minimize $L(\mathcal{Q})$ both $\hat{L}(\mathcal{Q})$ and $\bar{I}(X_i;C_i)$ should be minimized.

Discussion: There are two extreme solutions to the collaborative filtering task that provide good intuitions on the co-clustering approach to this problem. If we assign all of the data to a single large cluster, we can evaluate the empirical mean/median/most frequent rating of that cluster fairly well. In this situation the empirical loss $\hat{L}(\mathcal{Q})$ is expected to be large, because we approximate all the entries with the global average, but its distance to the true loss $L(\mathcal{Q})$ is expected to be small. If we take the other extreme and assign each row and each column to a separate cluster, $\hat{L}(\mathcal{Q})$ can be zero given that we can approximate every entry with its own value, but its distance to the true loss $L(\mathcal{Q})$ is expected to be large because each cluster has too little data to make a statistically reliable estimation. Thus, the goal is to optimize the trade-off between the locality of the predictions and their statistical reliability.

This trade-off is explicitly exhibited in bound (18): if we assign all x_i-es to a single cluster, then $\bar{I}(X_i;C_i) = 0$ and therefore $L(\mathcal{Q})$ is close to $\hat{L}(\mathcal{Q})$. And if we assign each x_i to a separate cluster, then $\bar{I}(X_i;C_i)$ is large, specifically in this case $\bar{I}(X_i;C_i) = \ln n_i$, and $L(\mathcal{Q})$ is far from $\hat{L}(\mathcal{Q})$. But there are even finer observations we can draw from the bound. Bear in mind that $n_i \bar{I}(X_i;C_i)$ is linear in n_i, whereas $m_i \ln n_i$ is logarithmic in n_i. Thus, at least when m_i is small compared to n_i (which is a reasonable assumption when we cluster the values of $\mathcal{X}_i$) the leading term in (18) is $n_i \bar{I}(X_i;C_i)$. This term penalizes the *effective* complexity of a partition, rather than the raw number of clusters used. For example, the unbalanced partition of a 4×4 matrix into 2×2 clusters in Figure 2.a is simpler than the balanced partition into the same number of clusters in Figure 2.b. The reason,



(a) Unbalanced Partition (b) Balanced Partition

Figure 2: Illustration of (a) an unbalanced and (b) a balanced partition of a 4×4 matrix into 2×2 clusters. Note that there are 4 possible ways to group 4 objects into 2 unbalanced clusters and $\binom{4}{2} = 6$ possible ways to group 4 objects into 2 balanced clusters. Thus, the subspace of the unbalanced partitions is smaller than the subspace of the balanced partitions and the unbalanced partitions are simpler (it is easier to describe an unbalanced partition than a balanced one).

which will become clearer after we have defined the prior over the space of partitions in Section 3.3, is that there are fewer unbalanced partitions than balanced ones. Therefore, the subspace of unbalanced partitions is smaller than the subspace of balanced partitions and it is easier to describe an unbalanced partition than a balanced one. Intuitively, the partition in Figure 2.a does not fully use the 2×2 clusters that it could use, and should therefore be penalized less. On a practical level, the bound makes it possible to operate at the optimization step with more clusters than are actually required and to penalize the final solution according to a de facto measure of cluster use. This claim is supported by our experiments. To summarize this point, the bound (18) suggests a trade-off between the empirical performance and the effective complexity of a partition.

Finally, consider the $M \ln |\mathcal{Y}|$ term in the bound. M is the number of partition cells (in a hard partition) and $M \ln |\mathcal{Y}|$ corresponds to the size of the $\langle C_1, .., C_d, Y \rangle$ clique in the moral graph corresponding to the graph in Figure 1.a. The number of sample points N should be comparable to the number of partition cells, so it is natural for this term to appear in the bound. This term grows exponentially with the number of dimensions d; thus we can apply the bound for low-dimensional problems like collaborative filtering, but when the number of dimensions grows a different approach is required. We suggest one possible way to handle high dimensional problems in Section 7.

Proof of Theorem 7 The proof is a direct application of the PAC-Bayesian bound for classification in Theorem 1 (or, more precisely, its refinement in (3)). In order to apply the theorem, we have to define a hypothesis space $\mathcal{H}$, a prior over hypothesis space $\mathcal{P}$, a posterior over hypothesis space $\mathcal{Q}$, and calculate the KL-divergence $KL(\mathcal{Q}\|\mathcal{P})$. We define the hypothesis space in the next subsection and design a prior over it in Section 3.3. Substitution of the calculation of $KL(\mathcal{Q}\|\mathcal{P})$ in Lemma 9 into Theorem 1 completes the proof. ■

3.2 Grid Clustering Hypothesis Space

We define the hypothesis space $\mathcal{H}$ to be the space of hard grid partitions of the product space $\mathcal{X}_1 \times .. \times \mathcal{X}_d$ (as illustrated in Figure 2) augmented with label assignments to the partition cells. (In Section 3.4 we use grid partitions without labels on the partition cells; thus the discussion in this and the following subsection is kept general enough to hold in both cases.) In a hard grid partition each value $x_i \in \mathcal{X}_i$ is mapped deterministically to a single cluster $c_i \in \{1, .., m_i\}$. To operate on $\mathcal{H}$ we use the following notations:

- Let $\bar{m} = (m_1, .., m_d)$ be a vector counting the number of clusters along each dimension.
- We use $\mathcal{H}|_i$ to denote the space of partitions of $\mathcal{X}_i$. In other words, $\mathcal{H}|_i$ is a projection of $\mathcal{H}$ onto dimension i.
- Let $\mathcal{H}_{\bar{m}}$ denote the subspace of partitions of $\mathcal{X}_1 \times .. \times \mathcal{X}_d$ in which the number of clusters used along each dimension matches $\bar{m}$. Obviously, for distinct $\bar{m}$-s, $\mathcal{H}_{\bar{m}}$-s are disjoint.
- We use $\mathcal{H}|_{(y|\bar{m})}$ or simply $\mathcal{H}|_{y|\bar{m}}$ to denote the space of possible assignments of labels to $\mathcal{H}_{\bar{m}}$. Then we can write $\mathcal{H} = \bigcup_{\bar{m}} \left(\mathcal{H}_{\bar{m}} \times \mathcal{H}|_{y|\bar{m}} \right)$.
- For each $h \in \mathcal{H}$ we write $h = h|_1 \times .. \times h|_d \times h|_{y|\bar{m}}$, where $h|_i$ denotes the partition induced by h along dimension i and $h|_{y|\bar{m}}$ denotes the assignment of labels to partition cells of h. In the discussion of density estimation with grid clustering in Section 3.4, h is just $h = h|_1 \times .. \times h|_d$, without the labels assignment.

We show that $\mathcal{Q} = \left\{ \{q(c_i|x_i)\}_{i=1}^d, q(y|c_1, .., c_d) \right\}$ is a distribution over $\mathcal{H}$ and (17) corresponds to a randomized prediction strategy. More precisely, $\mathcal{Q}$ is a distribution over $\mathcal{H}_{\bar{m}} \times \mathcal{H}|_{y|\bar{m}}$, where $\bar{m}$ matches the cardinalities of C_i-s in the definitions of $\left\{ \{q(c_i|x_i)\}_{i=1}^d, q(y|c_1, .., c_d) \right\}$. In order to draw a hypothesis $h \in \mathcal{H}$ according to $\mathcal{Q}$ we draw a cluster c_i for each $x_i \in \mathcal{X}_i$ according to $q(c_i|x_i)$ and then draw a label for each partition cell according to $q(y|c_1, .., c_d)$. For example, we map each viewer to a cluster of viewers, map each movie to a cluster of movies, and assign ratings to the product space of viewer clusters by movie clusters. Then, in order to assign a label to a sample $\langle x_1, .., x_d \rangle$ we simply check which partition cell it has fallen into and return the corresponding label. Recall that in order to assign a label to another sample point, we have to draw a new hypothesis from $\mathcal{H}$.

Note that in (17) we actually skip the step of assigning a cluster for each $x_i \in \mathcal{X}_i$ and a label for each partition cell (in fact, the whole step of drawing a hypothesis) and assign a label to a given point $\langle x_1, .., x_d \rangle$ directly. Nevertheless, (17) corresponds to the randomized prediction process described above. This makes it possible to apply the PAC-Bayesian analysis.

3.3 Combinatorial Priors in PAC-Bayesian Bounds

In this section we design a combinatorial prior over the grid clustering hypothesis space and calculate the KL-divergence $KL(\mathcal{Q}\|\mathcal{P})$ between the posterior defined earlier and the prior. An interesting point about this result is that combinatorial priors result in mutual information terms in the calculations of the KL-divergence. This can be contrasted with the L_2-norm and L_1-norm terms resulting from Gaussian and Laplacian priors respectively in the analysis of SVMs (Langford, 2005). Another

important point to mention is that the posterior $\mathcal{Q}$ returns a named partition of $\mathcal{X}_i$-s (the conditional distribution $q(c_i|x_i)$ specifies the "name" c_i of the cluster that x_i is mapped to). However, the hypothesis space $\mathcal{H}$ and the prior $\mathcal{P}$ defined below operate with unnamed partitions: they only depend on the structure of a partition (the sizes of the clusters), but do not depend on the names assigned to the clusters. In this manner we account for all possible permutations of cluster names, which are irrelevant for the solution.

The statements in the next two lemmas are given in two versions, one for $\mathcal{H}$ augmented with labels, which is used in the proofs of Theorem 7, and the other for $\mathcal{H}_{\bar{m}}$ without the labels, which is used later for the proofs on density estimation with grid clustering.

Lemma 8 *It is possible to define a prior $\mathcal{P}$ over $\mathcal{H}_{\bar{m}}$ that satisfies*:

$$\mathcal{P}(h) \geq \frac{1}{\exp\left[\sum_{i=1}^{d}\left(n_i H(hist(h|_i)) + (m_i - 1)\ln n_i\right)\right]}, \tag{19}$$

where $hist(h|_i) = \{|c_{i1}|, .., |c_{im_i}|\}$ denotes the cardinality profile (histogram) of cluster sizes along dimension i of a partition corresponding to h and $H(hist(h|_i)) = -\sum_{j=1}^{m_i} \frac{|c_{ij}|}{n_i} \ln \frac{|c_{ij}|}{n_i}$ is the entropy of the (normalized) cardinality profile (note that $\sum_{j=1}^{m_i} |c_{ij}| = n_i$).

It is further possible to define a prior $\mathcal{P}$ over $\mathcal{H} = \bigcup_{\bar{m}} \left(\mathcal{H}_{\bar{m}} \times \mathcal{H}|_{y|\bar{m}}\right)$ that satisfies:

$$\mathcal{P}(h) \geq \frac{1}{\exp\left[\sum_{i=1}^{d}\left(n_i H(hist(h|_i)) + m_i \ln n_i\right) + M \ln |\mathcal{Y}|\right]}. \tag{20}$$

Remark: The prior $\mathcal{P}$ over $\mathcal{H}$ that is defined explicitly in the proof of the lemma exploits structural asymmetries between more and less balanced grid partitions, as shown in Figure 2, without making assumptions on the data generating process. Note that the leading terms in the prior are $n_i H(hist(h|_i))$ that count the number of possible ways to assign x_i-s to c_i-s, which are invariant under permutation of x_i-s within each $\mathcal{X}_i$ (see the proof for details). Thus, it is impossible to design a significantly better prior without "strong" prior knowledge on the data generating process that can break the permutation symmetry of x_i-s. "Weak" prior knowledge on the number of clusters m_i along each dimension and even on their sizes can only introduce an improvement that is logarithmic in n_i-s to the bounds. The PAC-Bayesian analysis enables us to operate with all possible grid partitions, while paying a very low (logarithmic) price for this generality.

We note that recently Lever et al. (2010) suggested an elegant technique for defining priors based on the true data distribution, which is, of course, a "strong" prior knowledge. For example, using the true marginal distributions $p(x_i)$ over $\mathcal{X}_i$-s in the definition of the prior would break the permutation symmetry of x_i-s. Since the true data distribution is independent of the sample, such priors are perfectly valid, although uncomputable. Lever et. al. show that, at least in some situations, the KL-divergence $KL(\mathcal{Q}\|\mathcal{P})$ can nevertheless be bounded, which is sufficient for application of the PAC-Bayesian bounds. The possibility of application of distribution-dependent priors in co-clustering will be explored in future work.

Lemma 9 *For the prior defined in* (19) *and posterior $\mathcal{Q} = \{q(c_i|x_i)\}_{i=1}^{d}$:*

$$KL(\mathcal{Q}\|\mathcal{P}) \leq \sum_{i=1}^{d}\left(n_i \bar{I}(X_i; C_i) + (m_i - 1)\ln n_i\right). \tag{21}$$

For the prior defined in (20) *and posterior* $\mathcal{Q} = \Big\{\{q(c_i|x_i)\}_{i=1}^d, q(y|c_1,..,c_d)\Big\}$:

$$KL(\mathcal{Q}\|\mathcal{P}) \leq \sum_{i=1}^{d}\Big(n_i\bar{I}(X_i;C_i) + m_i \ln n_i\Big) + M\ln|\mathcal{Y}|. \tag{22}$$

3.3.1 PROOFS

Proof of Lemma 8 To define the prior $\mathcal{P}$ over $\mathcal{H}_{\bar{m}}$ we count the hypotheses in $\mathcal{H}_{\bar{m}}$. There are $\binom{n_i-1}{m_i-1} \leq n_i^{m_i-1}$ possibilities to choose a cluster cardinality profile along a dimension i. (This is because each of the m_i clusters has a size of at least one. To define a cardinality profile we are free to distribute the "excess mass" of $n_i - m_i$ among the m_i clusters. The number of possible distributions equals the number of possibilities to place $m_i - 1$ ones in a sequence of $(n_i - m_i) + (m_i - 1) = n_i - 1$ ones and zeros.) For a fixed cardinality profile $hist(h|_i)$ there are $\binom{n_i}{|c_{i1}|,..,|c_{im_i}|} \leq e^{n_i H(hist(h|_i))}$ possibilities to assign x_i-s to the clusters. Putting the combinatorial calculations together we can define a distribution $\mathcal{P}$ over $\mathcal{H}_{\bar{m}}$ that satisfies (19).

To prove (20) we further define a uniform prior over $\mathcal{H}|_{y|\bar{m}}$. Note that there are $|\mathcal{Y}|^M$ possibilities to assign labels to the partition cells in $\mathcal{H}_{\bar{m}}$. Finally, we define a uniform prior over the choice of $\bar{m}$. There are n_i possibilities to chose the value of m_i (we can assign all x_i-s to a single cluster, assign each x_i to a separate cluster, and all the possibilities in between). Combining this with the combinatorial calculations performed for (19) yields (20). ■

Proof of Lemma 9 We first handle bound (21). We use the decomposition $KL(\mathcal{Q}\|\mathcal{P}) = -\mathbb{E}_{\mathcal{Q}}\ln\mathcal{P}(h) - H(\mathcal{Q})$ and bound $-\mathbb{E}_{\mathcal{Q}}\ln\mathcal{P}(h)$ and $H(\mathcal{Q})$ separately. We further decompose $\mathcal{P}(h) = \mathcal{P}(h|_1)\cdot..\cdot\mathcal{P}(h|_d)$ and $\mathcal{Q}(h)$ in a similar manner. Then $-\mathbb{E}_{\mathcal{Q}}\ln\mathcal{P}(h) = -\sum_i \mathbb{E}_Q \ln\mathcal{P}(h|_i)$ and $H(\mathcal{Q}) = \sum_i H(\mathcal{Q}(h|_i))$. Therefore, we can treat each dimension separately.

By Lemma 8:

$$-\mathbb{E}_{\mathcal{Q}}\ln\mathcal{P}(h|_i) \leq (m_i - 1)\ln n_i + n_i\mathbb{E}_{\mathcal{Q}}H(hist(h|_i)). \tag{23}$$

Hence, in order to bound $-\mathbb{E}_{\mathcal{Q}}\ln\mathcal{P}(h|_i)$ we have to bound the expected entropy of cluster cardinality profiles of the hypotheses generated by $\mathcal{Q}$. Recall that $\mathcal{Q}$ draws a cluster C_i for each $x_i \in \mathcal{X}_i$ according to $q(c_i|x_i)$ and that this process results in marginal distribution $\bar{q}(c_i) = \frac{1}{n_i}\sum_{x_i} q(c_i|x_i)$ over the normalized cluster sizes (this is where the uniform distribution over $\mathcal{X}_i$ comes in). To bound $\mathbb{E}_{\mathcal{Q}}H(hist(h|_i))$ we use the result on negative bias of empirical entropy estimates cited below, see Paninski (2003) for a proof.

Theorem 10 (Paninski, 2003) *Let $X_1,..,X_N$ be i.i.d. distributed by $p(x)$ and let $\hat{p}(x)$ be their empirical distribution. Then:*

$$\mathbb{E}_p H(\hat{p}) = H(p) - \mathbb{E}_p KL(\hat{p}\|p) \leq H(p). \tag{24}$$

By (24) $\mathbb{E}_{\mathcal{Q}}H(hist(h|_i)) \leq H(\bar{q}(c_i))$. Substituting this into (23) yields:

$$-\mathbb{E}_{\mathcal{Q}}\ln\mathcal{P}(h|_i) \leq n_i H(\bar{q}(c_i)) + (m_i - 1)\ln n_i. \tag{25}$$

Now we turn to bound $-H(\mathcal{Q}(h|_i)) = \mathbb{E}_{\mathcal{Q}}\ln\mathcal{Q}(h|_i)$. To do so we bound $\ln\mathcal{Q}(h|_i)$ from above. The bound follows from the fact that if we draw n_i values of C_i according to $q(c_i|x_i)$ the probability

of the resulting type is bounded from above by $e^{-n_i \bar{H}(C_i|X_i)}$, where $\bar{H}(C_i|X_i) = -\frac{1}{n_i}\sum_{x_i,c_i} q(c_i|x_i)\ln q(c_i|x_i)$ (see Cover and Thomas, 1991, Theorem 12.1.2). Thus, $\mathbb{E}_{\mathcal{Q}} \ln \mathcal{Q}(h|_i) \leq -n_i \bar{H}(C_i|X_i)$, which together with (25) and the identity $\bar{I}(X_i;C_i) = H(\bar{q}(c_i)) - \bar{H}(C_i|X_i)$ completes the proof of (21).

To prove (22) we recall that $\mathcal{Q}$ is defined for a fixed $\bar{m}$. Hence, $-\mathbb{E}_{\mathcal{Q}} \ln \mathcal{P}(h|_{y|\bar{m}}) = M \ln |\mathcal{Y}|$ and $-H(\mathcal{Q}(h|_{y|\bar{m}})) \leq 0$. Finally, since the prior $\mathcal{P}(\bar{m})$ over the selection of $\bar{m}$ is uniform we have $-\mathbb{E}_{\mathcal{Q}} \ln \mathcal{P}(\bar{m}) = \sum_{i=1}^{d} \ln n_i$ and $H(\mathcal{Q}(\bar{m})) = 0$, which is added to (21) by the additivity of $KL(\mathcal{Q}\|\mathcal{P})$ completing the proof. ■

3.4 PAC-Bayesian Analysis of Density Estimation with Grid Clustering

In this subsection we derive a generalization bound for density estimation with grid clustering. This time we have no labels and the goal is to find a good estimator for an unknown joint probability distribution $p(x_1,..,x_d)$ over a d-dimensional product space $\mathcal{X}_1 \times .. \times \mathcal{X}_d$ based on a sample of size N from p. As an illustrative example, think of estimating a joint probability distribution of words and documents (X_1 and X_2) from their co-occurrence matrix. The goodness of an estimator q for p is measured by $-\mathbb{E}_{p(x_1,..,x_d)} \ln q(X_1,..,X_d)$.

By Theorem 5, to obtain a meaningful bound for a direct estimation of $p(x_1,..,x_d)$ from $\hat{p}(x_1,..,x_d)$ we need N to be exponential in n_i-s, since the cardinality of the random variable $\langle X_1,..,X_d\rangle$ is $\prod_i n_i$. To reduce this dependency to be linear in $\sum_i n_i$ we restrict the estimator $q(X_1,..,X_d)$ to be of the factor form:

$$q(x_1,..,x_d) = \sum_{c_1,..,c_d} q(c_1,..,c_d) \prod_{i=1}^{d} q(x_i|c_i) \tag{26}$$

$$= \sum_{c_1,..,c_d} q(c_1,..,c_d) \prod_{i=1}^{d} \frac{q(x_i)}{q(c_i)} q(c_i|x_i). \tag{27}$$

We emphasize that the above decomposition assumption is only on the estimator q and not on the generating distribution p. A graphical model corresponding to Equation (26) is given in Figure 1.b. Similar to the model for discriminative prediction, this is also a two-level randomized prediction model.

We select the hypothesis space $\mathcal{H}$ to be the space of hard partitions of the product space $\mathcal{X}_1 \times .. \times \mathcal{X}_d$, as before; however, this time there are no labels to the partition cells. The general message of the following two theorems is that the empirical distribution over the coarse partition space $C_1 \times .. \times C_d$ converges to the true one faster than the empirical distribution over $\mathcal{X}_1 \times .. \times \mathcal{X}_d$ converges to its true counterpart. We also show that (27) can be used to extrapolate the distribution over cluster space back to $\mathcal{X}_1 \times .. \times \mathcal{X}_d$ space and obtain better generalization guarantees. Next we state this more formally.

As seen in the previous subsection, a distribution $\mathcal{Q} = \{q(c_i|x_i)\}_{i=1}^{d}$ is a distribution over $\mathcal{H}_{\bar{m}}$. To obtain a hypothesis $h \in \mathcal{H}_{\bar{m}}$ we draw a cluster for each $x_i \in \mathcal{X}_i$ according to $q(c_i|x_i)$. The way we have written (27) enables us to view it as a randomized prediction process: we draw a hypothesis h according to $\mathcal{Q}$ and then predict the probability of $\langle x_1,..,x_d\rangle$ as $q(c_1^h(x_1),..,c_d^h(x_d)) \prod_i \frac{q(x_i)}{q(c_i^h(x_i))}$, where $c_i^h(x_i) = h(x_i)$ is the partition cell that x_i fell within h. Although (27) skips the process of

drawing the complete partition h and returns the probability of $\langle x_1,..,x_d\rangle$ directly, the described randomized prediction process matches the predictions by (27) and thus enables its analysis with PAC-Bayesian bounds.

Let $h \in \mathcal{H}$ be a hard partition of $\mathcal{X}_1 \times .. \times \mathcal{X}_d$ and let $h(x_i)$ denote the cluster to which x_i is mapped in h. We define the distribution over the partition cells $\langle c_1,..,c_d\rangle$ induced by p and h:

$$p_h(c_1,..,c_d) = \sum_{\substack{x_1,..,x_d:\\ \forall i \;\; h(x_i)=c_i}} p(x_1,..,x_d),$$
$$p_h(c_i) = \sum_{x_i:h(x_i)=c_i} p(x_i).$$

We further define the distribution over partition cells induced by the empirical distribution $\hat{p}(x_1,..,x_d)$ corresponding to the sample and h by substitution of $\hat{p}$ instead of p in the above definitions:

$$\hat{p}_h(c_1,..,c_d) = \sum_{\substack{x_1,..,x_d:\\ \forall i \;\; h(x_i)=c_i}} \hat{p}(x_1,..,x_d),$$
$$\hat{p}_h(c_i) = \sum_{x_i:h(x_i)=c_i} \hat{p}(x_i).$$

We also define the distribution over partition cells induced by $\mathcal{Q}$ and p and its empirical counterpart:

$$p_{\mathcal{Q}}(c_1,..,c_d) = \sum_h \mathcal{Q}(h) p_h(c_1,..,c_d) = \sum_{x_1,..,x_d} p(x_1,..,x_d) \prod_{i=1}^d q(c_i|x_i),$$
$$p_{\mathcal{Q}}(c_i) = \sum_h \mathcal{Q}(h) p_h(c_i) = \sum_{x_i} p(x_i) q(c_i|x_i),$$

$$\hat{p}_{\mathcal{Q}}(c_1,..,c_d) = \sum_h \mathcal{Q}(h) \hat{p}_h(c_1,..,c_d) = \sum_{x_1,..,x_d} \hat{p}(x_1,..,x_d) \prod_{i=1}^d q(c_i|x_i),$$
$$\hat{p}_{\mathcal{Q}}(c_i) = \sum_h \mathcal{Q}(h) \hat{p}_h(c_i) = \sum_{x_i} \hat{p}(x_i) q(c_i|x_i).$$

We extrapolate $p_h, p_{\mathcal{Q}}, \hat{p}_h$ and $\hat{p}_{\mathcal{Q}}$ to the whole space $\mathcal{X}_1 \times .. \times \mathcal{X}_d$ using (27):

$$p_h(x_1,..,x_d) = p_h(c_1^h(x_1),..,c_d^h(x_d)) \prod_{i=1}^d \frac{p(x_i)}{p_h(c_i^h(x_i))},$$

$$p_{\mathcal{Q}}(x_1,..,x_d) = \sum_{c_1,..,c_d} p_{\mathcal{Q}}(c_1,..,c_d) \prod_{i=1}^d \frac{p(x_i)}{p_{\mathcal{Q}}(c_i)} q(c_i|x_i),$$

$$\hat{p}_h(x_1,..,x_d) = \hat{p}_h(c_1^h(x_1),..,c_d^h(x_d)) \prod_{i=1}^d \frac{\hat{p}(x_i)}{\hat{p}_h(c_i^h(x_i))},$$

$$\hat{p}_{\mathcal{Q}}(x_1,..,x_d) = \sum_{c_1,..,c_d} \hat{p}_{\mathcal{Q}}(c_1,..,c_d) \prod_{i=1}^d \frac{\hat{p}(x_i)}{\hat{p}_{\mathcal{Q}}(c_i)} q(c_i|x_i).$$

Note that $p_{\mathcal{Q}}(x_1,..,x_d)$ is a distribution over $\mathcal{X}_1 \times .. \times \mathcal{X}_d$, which has the form (27) and is the closest to the true distribution $p(x_1,..,x_d)$ under the constraint that $\{q(c_i|x_i)\}_{i=1}^d$ are fixed. Further, note

that since we have no access to $p(x_1,..,x_d)$ we do not know $p_{\mathcal{Q}}(x_1,..,x_d)$. In the next theorem we provide rates of convergence of the distributions $\hat{p}_{\mathcal{Q}}(x_1,..,x_d)$, $\hat{p}_{\mathcal{Q}}(c_1,..,c_d)$, and $\hat{p}_{\mathcal{Q}}(x_i)$ based on the sample to their counterparts corresponding to the true distribution $p(x_1,..,x_d)$.

Theorem 11 *For any probability measure p over $\mathcal{X}_1 \times .. \times \mathcal{X}_d$ and an i.i.d. sample S of size N according to p, with probability of at least $1-\delta$ for all grid clusterings $\mathcal{Q} = \{q(c_i|x_i)\}_{i=1}^d$ the following holds simultaneously*:

$$KL(\hat{p}_{\mathcal{Q}}(c_1,..,c_d)\|p_{\mathcal{Q}}(c_1,..,c_d)) \leq \frac{\sum_{i=1}^d n_i \bar{I}(X_i;C_i) + K_1}{N} \tag{28}$$

and for all i

$$KL(\hat{p}(x_i)\|p(x_i)) \leq \frac{(n_i-1)\ln(N+1) + \ln\frac{d+1}{\delta}}{N}, \tag{29}$$

where

$$K_1 = \sum_{i=1}^d m_i \ln n_i + (M-1)\ln(N+1) + \ln\frac{d+1}{\delta}. \tag{30}$$

As well, with probability greater than $1-\delta$:

$$KL(\hat{p}_{\mathcal{Q}}(x_1,..,x_d)\|p_{\mathcal{Q}}(x_1,..,x_d)) \leq \frac{\sum_{i=1}^d n_i \bar{I}(X_i;C_i) + K_2}{N}, \tag{31}$$

where

$$K_2 = \sum_{i=1}^d m_i \ln n_i + \left[M + \sum_{i=1}^d n_i - d - 1\right]\ln(N+1) - \ln\delta.$$

Before we discuss and prove the theorem we point out that although $\hat{p}_{\mathcal{Q}}(x_1,..,x_d)$ converges to $p_{\mathcal{Q}}(x_1,..,x_d)$ it still cannot be used to minimize $-\mathbb{E}_{p(x_1,..,x_d)}\ln\hat{p}_{\mathcal{Q}}(X_1,..,X_d)$, because it is not bounded from zero. Also, we cannot construct a density estimator by smoothing $\hat{p}_{\mathcal{Q}}(x_1,..,x_d)$ directly using Theorem 6, because the cardinality of the random variable $\langle X_1,..,X_d\rangle$ is $\prod_i n_i$ and this term will enter into the bounds. To circumvent this we take advantage of the factor form of $p_{\mathcal{Q}}$ and use the bounds (28) and (29). We define an estimator $\tilde{p}_{\mathcal{Q}}$, which is a smoothed version of $\hat{p}_{\mathcal{Q}}$ in the following way:

$$\begin{aligned}
\tilde{p}_h(c_1,..,c_d) &= \frac{\hat{p}_h(c_1,..,c_d)+\gamma}{1+\gamma M},\\
\tilde{p}(x_i) &= \frac{\hat{p}(x_i)+\gamma_i}{1+\gamma_i n_i},\\
\tilde{p}_h(c_i) &= \sum_{x_i:h(x_i)=c_i} \tilde{p}(x_i),\\
\tilde{p}_h(x_1,..,x_d) &= \tilde{p}_h(c_1^h(x_1),..,c_d^h(x_d)) \prod_{i=1}^d \frac{\tilde{p}(x_i)}{\tilde{p}_h(c_i^h(x_i))}.
\end{aligned} \tag{32}$$

And for a distribution $\mathcal{Q}$ over $\mathcal{H}$:

$$\tilde{p}_{\mathcal{Q}}(c_1,..,c_d) = \frac{\hat{p}_{\mathcal{Q}}(c_1,..,c_d)+\gamma}{1+\gamma M}, \tag{33}$$

$$\tilde{p}_{\mathcal{Q}}(c_i) = \sum_{x_i}\tilde{p}(x_i)q(c_i|x_i) = \frac{\hat{p}_{\mathcal{Q}}(c_i)+\gamma_i\bar{q}(c_i)n_i}{1+\gamma_i n_i}, \tag{34}$$

$$\begin{aligned}\tilde{p}_{\mathcal{Q}}(x_1,..,x_d) &= \sum_h \mathcal{Q}(h)\tilde{p}_h(x_1,..,x_d)\\ &= \sum_{c_1,..,c_d}\tilde{p}_{\mathcal{Q}}(c_1,..,c_d)\prod_{i=1}^{d}\frac{\tilde{p}(x_i)}{\tilde{p}_{\mathcal{Q}}(c_i)}q(c_i|x_i).\end{aligned} \tag{35}$$

In the following theorem we provide a bound on $-\mathbb{E}_{p(x_1,..,x_d)}\ln\tilde{p}_{\mathcal{Q}}(X_1,..,X_d)$. Note that we take the expectation with respect to the true, unknown distribution p that may have an arbitrary form (i.e., p is not restricted to be of the factor form (26)).

Theorem 12 *For the density estimator $\tilde{p}_{\mathcal{Q}}(x_1,..,x_d)$ defined by equations* (32), (33), (34), *and* (35), *$-\mathbb{E}_{p(x_1,..,x_d)}\tilde{p}_{\mathcal{Q}}(X_1,..,X_d)$ attains its minimum at $\gamma(\mathcal{Q}) = \frac{\sqrt{\varepsilon(\mathcal{Q})/2}}{M}$ and $\gamma_i = \frac{\sqrt{\varepsilon_i/2}}{n_i}$, where $\varepsilon(\mathcal{Q})$ is defined by the right-hand side of* (28) *and ε_i-s are defined by the right-hand side of* (29). *At this optimal level of smoothing, with probability greater than $1-\delta$ for all $\mathcal{Q} = \{q(c_i|x_i)\}_{i=1}^d$ simultaneously*:

$$-\mathbb{E}_{p(x_1,..,x_d)}\ln\tilde{p}_{\mathcal{Q}}(X_1,..,X_d) \le -I(\hat{p}_{\mathcal{Q}}(c_1,..,c_d)) + \ln(M)\sqrt{\frac{\sum_{i=1}^d n_i\bar{I}(X_i;C_i)+K_1}{2N}} + K_3, \tag{36}$$

where $I(\hat{p}_{\mathcal{Q}}(c_1,..,c_d)) = \left[\sum_{i=1}^d H(\hat{p}_{\mathcal{Q}}(c_i))\right] - H(\hat{p}_{\mathcal{Q}}(c_1,..,c_d))$ is the multi-information between $C_1,..,C_d$ with respect to $\hat{p}_{\mathcal{Q}}(c_1,..,c_d)$, K_1 is defined by (30),

$$K_3 = \phi(\varepsilon(\mathcal{Q})) + \left[\sum_{i=1}^d H(\hat{p}(x_i)) + 2\sqrt{\varepsilon_i/2}\ln n_i + \phi(\varepsilon_i) + \psi(\varepsilon_i)\right],$$

and the functions ϕ and ψ are defined in Theorem 6.

Discussion: We discuss Theorem 12 first. We point out that $\tilde{p}_{\mathcal{Q}}(x_1,..,x_d)$ is directly related to $\hat{p}_{\mathcal{Q}}(x_1,..,x_d)$ and that $\hat{p}_{\mathcal{Q}}(x_1,..,x_d)$ is determined by the empirical frequencies $\hat{p}(x_1,..,x_d)$ of the sample and our choice of $\mathcal{Q} = \{q(c_i|x_i)\}_{i=1}^d$. There are only two quantities in the bound (36) that depend on the choice of $\mathcal{Q}$: $-I(\hat{p}_{\mathcal{Q}}(c_1,..,c_d))$ and $\sum_i \frac{n_i}{N}\bar{I}(X_i;C_i)$ [note that the latter also appears in $\phi(\varepsilon(\mathcal{Q})$ in K_3]. Thus, Theorem 12 suggests that a good estimator $\tilde{p}_{\mathcal{Q}}(x_1,..,x_d)$ of $p(x_1,..,x_d)$ should optimize the trade-off between $-I(\hat{p}_{\mathcal{Q}}(c_1,..,c_d))$ and $\sum_i \frac{n_i}{N}\bar{I}(X_i;C_i)$. Similar to Theorem 7, the latter term corresponds to the mutual information that the hidden cluster variables preserve on the observed variables. Larger values of $\bar{I}(X_i;C_i)$ correspond to partitions of $\mathcal{X}_1,..,\mathcal{X}_d$, which are more complex. The first term, $-I(\hat{p}_{\mathcal{Q}}(c_1,..,c_d))$, corresponds to the amount of structural information on C_i-s extracted by the partition. More precisely, we need to look at the value of $\sum_i H(\hat{p}(x_i)) - I(\hat{p}_{\mathcal{Q}}(c_1,..,c_d))$, where $\sum_i H(\hat{p}(x_i))$ is a part of K_3 and roughly corresponds to the performance we can achieve by approximating $p(x_1,..,x_d)$ with a product of empirical marginals $\prod_i \hat{p}(x_i)$. Thus, $-I(\hat{p}_{\mathcal{Q}}(c_1,..,c_d))$ is the added value of the partition in estimating $p(x_1,..,x_d)$ and since $\sum_i H(\hat{p}(x_i)) \ge I(\hat{p}_{\mathcal{Q}}(c_1,..,c_d))$ the bound (36) is always positive.

The value of $I(\hat{p}_{\mathcal{Q}}(c_1,..,c_d))$ increases monotonically with the increase of the partition complexity $\mathcal{Q}$ (we can see this by the information processing inequality, Cover and Thomas, 1991). Thus, the trade-off in (36) is analogous to the trade-off in (18): the partition $\mathcal{Q}$ should balance its utility function $-I(\hat{p}_{\mathcal{Q}}(c_1,..,c_d))$ and the statistical reliability of the estimate of the utility function, which is related to $\sum_i \frac{n_i}{N} \bar{I}(X_i;C_i)$. This trade-off suggests a modification to the original objective of co-clustering in Dhillon et al. (2003), which is maximization of $I(C_1;C_2)$ alone (Dhillon et al., 2003 discuss the case of two-dimensional matrices). The trade-off in (36) can be applied to model order selection.

Now we make a few comments concerning Theorem 11. An interesting point about this theorem is that the cardinality of the random variable $\langle X_1,..,X_d \rangle$ is $\prod_i n_i$. Thus, a direct application of Theorem 2 to bound $KL(\hat{p}_{\mathcal{Q}}(x_1,..,x_d)\|p_{\mathcal{Q}}(x_1,..,x_d))$ would introduce this term into the bound. However, by using the factor form (27) of $\hat{p}_{\mathcal{Q}}(x_1,..,x_d)$ and $p_{\mathcal{Q}}(x_1,..,x_d)$ we are able to reduce this dependency to $(M+\sum_i n_i - d - 1)$. This result reveals the great potential of applying PAC-Bayesian analysis to more complex graphical models, which we explore further in Section 7.

3.4.1 PROOFS

We conclude this section by presenting the proofs of Theorems 11 and 12.

Proof of Theorem 11 The proof is based on PAC-Bayesian theorem on density estimation (Theorem 2). To apply the theorem we need to define a prior $\mathcal{P}$ over $\mathcal{H}$ and then calculate $KL(\mathcal{Q}\|\mathcal{P})$. We note that for a fixed $\mathcal{Q}$ the cardinalities of the clusters $\bar{m}$ are fixed. There are $\prod_i n_i$ disjoint subspaces $\mathcal{H}_{\bar{m}}$ in $\mathcal{H}$. We handle each $\mathcal{H}_{\bar{m}}$ independently and then combine the results to obtain Theorem 11.

By Theorem 2 and Lemma 9, for the prior $\mathcal{P}$ over $\mathcal{H}_{\bar{m}}$ defined in Lemma 8, with probability greater than $1-\frac{\delta}{(d+1)\prod_i n_i}$ we obtain (28) for each $\mathcal{H}_{\bar{m}}$. In addition, by Theorem 5 with probability greater than $1-\frac{\delta}{d+1}$ inequality (29) holds for each X_i. By a union bound over the $\prod_i n_i$ subspaces of $\mathcal{H}$ and the d variables X_i we obtain that (28) and (29) hold simultaneously for all $\mathcal{Q}$ and X_i with probability greater than $1-\delta$.

To prove (31), fix some hard partition h and let $c_i^h = h(x_i)$. Then:

$$
\begin{aligned}
&KL(\hat{p}_h(x_1,..,x_d)\|p_h(x_1,..,x_d)) \\
&\quad = KL(\hat{p}_h(x_1,..,x_d,c_1^h(x_1),..,c_d^h(x_d))\|p_h(x_1,..,x_d,c_1^h(x_1),..,c_d^h(x_d))) \\
&\quad = KL(\hat{p}_h(c_1,..,c_d)\|p_h(c_1,..,c_d)) \\
&\qquad + KL(\hat{p}_h(x_1,..,x_d|c_1^h(x_1),..,c_d^h(x_d))\|p_h(x_1,..,x_d|c_1^h(x_1),..,c_d^h(x_d))) \\
&\quad = KL(\hat{p}_h(c_1,..,c_d)\|p_h(c_1,..,c_d)) + \sum_{i=1}^{d} KL(\hat{p}_h(x_i|c_i^h(x_i))\|p_h(x_i|c_i^h(x_i))) \\
&\quad = KL(\hat{p}_h(c_1,..,c_d)\|p_h(c_1,..,c_d)) + \sum_{i=1}^{d} KL(\hat{p}(x_i)\|p(x_i)) - \sum_{i=1}^{d} KL(\hat{p}_h(c_i)\|p_h(c_i)) \\
&\quad \leq KL(\hat{p}_h(c_1,..,c_d)\|p_h(c_1,..,c_d)) + \sum_{i=1}^{d} KL(\hat{p}(x_i)\|p(x_i)).
\end{aligned}
$$

And:

$$\begin{aligned}\mathbb{E}_S e^{NKL(\hat{p}_h(x_1,..,x_d)\|p_h(x_1,..,x_d))} &\leq \left(\mathbb{E}_S e^{NKL(\hat{p}_h(c_1,..,c_d)\|p_h(c_1,..,c_d))}\right)\prod_{i=1}^{d}\mathbb{E}_S e^{NKL(\hat{p}(x_i)\|p(x_i))}\\ &\leq (N+1)^{M+\sum_{i=1}^{d}n_i-(d+1)},\end{aligned}$$

where the last inequality is by Theorem 3. From here we follow the lines of the proof of Theorem 2. Namely:

$$\begin{aligned}\mathbb{E}_S\left[\mathbb{E}_{\mathcal{P}(h)}e^{NKL(\hat{p}_h(x_1,..,x_d)\|p_h(x_1,..,x_d))}\right] &= \mathbb{E}_{\mathcal{P}(h)}\left[\mathbb{E}_S e^{NKL(\hat{p}_h(x_1,..,x_d)\|p_h(x_1,..,x_d))}\right]\\ &\leq (N+1)^{M+\sum_{i=1}^{d}n_i-(d+1)}.\end{aligned}$$

Thus, by Markov's inequality $\mathbb{E}_{\mathcal{P}(h)}e^{NKL(\hat{p}_h(x_1,..,x_d)\|p_h(x_1,..,x_d))} \leq \frac{1}{\delta}(N+1)^{M+\sum_i n_i-(d+1)}$ with probability of at least $1-\delta$ and (31) follows by the change of measure inequality (8) and convexity of the KL-divergence, when the prior $\mathcal{P}$ over $\mathcal{H}$ defined in Lemma 8 is selected (this time we give a weight of $(\prod_i n_i)^{-1}$ to each $\mathcal{H}_{\bar{m}}$ and obtain a prior over the whole $\mathcal{H}$). The calculation of $KL(\mathcal{Q}\|\mathcal{P})$ for this prior is provided in Lemma 9. ■

Proof of Theorem 12

$$\begin{aligned}-\mathbb{E}_{p(x_1,..,x_d)}\ln\tilde{p}_{\mathcal{Q}}(X_1,..,X_d) &= -\mathbb{E}_{p(x_1,..,x_d)}\ln\mathbb{E}_{\mathcal{Q}(h)}\tilde{p}_h(X_1,..,X_d)\\ &\leq -\mathbb{E}_{\mathcal{Q}(h)}\mathbb{E}_{p(x_1,..,x_d)}\ln\tilde{p}_h(X_1,..,X_d)\\ &= -\mathbb{E}_{\mathcal{Q}(h)}\mathbb{E}_{p(x_1,..,x_d)}\ln\tilde{p}_h(C_1^h(X_1),..,C_d^h(X_d))\prod_i\frac{\tilde{p}(X_i)}{\tilde{p}_h(C_i^h(X_i))}\\ &= -\mathbb{E}_{\mathcal{Q}(h)}\left[\mathbb{E}_{p_h(c_1,..,c_d)}\ln\tilde{p}_h(C_1,..,C_d)\right]-\sum_i\mathbb{E}_{p(x_i)}\ln\tilde{p}(X_i)+\sum_i\mathbb{E}_{\mathcal{Q}(h)}\mathbb{E}_{p_h(c_i)}\ln\tilde{p}_h(C_i)\\ &\leq -\mathbb{E}_{\mathcal{Q}(h)}\left[\mathbb{E}_{p_h(c_1,..,c_d)}\ln\tilde{p}_h(C_1,..,C_d)\right]-\sum_i\mathbb{E}_{p(x_i)}\ln\tilde{p}(X_i)+\sum_i\mathbb{E}_{p_{\mathcal{Q}}(c_i)}\ln\tilde{p}_{\mathcal{Q}}(C_i)\end{aligned}$$

At this point we use (14) to bound the first and the second term and the lower bound (16) to bound the last term and obtain (36). ■

4. Algorithms

In the previous section we presented generalization bounds for discriminative prediction and density estimation with co-clustering. The bounds presented in Theorems 7 and 12 hold for any prediction rule $\mathcal{Q}$ based on grid clustering of the parameter space $\mathcal{X}_1 \times .. \times \mathcal{X}_d$. In Seldin (2009) it is shown that for $d = 1$ the global minimum of bound (18) can be found efficiently. However, for $d \geq 2$ it can be exponentially hard to find the global minimum of both (18) and (36). Further, although we show in the applications section that bound (18) is remarkably tight, its tightness can still be insufficient for practical purposes. In this section we suggest how to replace the bounds with parameterized trade-offs that can be further fine-tuned, for example, via cross-validation, to improve the usability

in practice. The substitution of the bounds with parametrized trade-offs does not compromise on the rigor of the analysis: first, the bounds hold simultaneously for all the solutions found by minimization of the parameterized trade-offs and, second, the parameter of the trade-offs can also be tuned by substituting the result of trade-off minimization back into the corresponding bound, thus providing an estimate on a local minima of the bound.

4.1 Minimization of the PAC-Bayesian Bound for Discriminative Prediction with Grid Clustering

We start with minimization of the PAC-Bayesian bound for discriminative prediction based on grid clustering (18) suggested in Theorem 7. We rewrite the bound in a slightly different way in order to separate terms which are independent of the conditional distributions in $\mathcal{Q}$:

$$kl(\hat{L}(\mathcal{Q})\|L(\mathcal{Q})) \leq \frac{\sum_{i=1}^{d} n_i \bar{I}(X_i;C_i) + K}{N}, \tag{37}$$

where

$$K = \sum_{i=1}^{d} m_i \ln n_i + M \ln |\mathcal{Y}| + \frac{1}{2}\ln(4N) - \ln \delta. \tag{38}$$

Note that K depends on the number of clusters m_i used along each dimension, but not on a specific form of a grid partition. Once the number of clusters used along each dimension has been selected, K is constant.

The minimization problem corresponding to (37) can be stated as follows:

$$\min_{\mathcal{Q}} \; L \quad s.t. \quad kl(\hat{L}(\mathcal{Q})\|L) = \frac{\sum_{i=1}^{d} n_i \bar{I}(X_i;C_i) + K}{N}. \tag{39}$$

It is generally possible to find a local minimum of the minimization problem (39) directly using alternating projection methods - see, for example, Germain et al. (2009) for such an approach to solving a similar minimization problem for linear classifiers. We take a slightly different approach that further enables us to compensate for the imperfection of the bounds. Since K is constant, $L(\mathcal{Q})$ depends on a parameterized trade-off between $\hat{L}(\mathcal{Q})$ and $\sum_{i=1}^{d} n_i \bar{I}(X_i;C_i)$, which can be written as follows:

$$\mathcal{F}(\mathcal{Q},\beta) = \beta N \hat{L}(\mathcal{Q}) + \sum_{i=1}^{d} n_i \bar{I}(X_i;C_i), \tag{40}$$

where β is the trade-off parameter. The corresponding minimization problem is:

$$\mathcal{F}_{min}(\beta) = \min_{\mathcal{Q}} \beta N \hat{L}(\mathcal{Q}) + \sum_{i=1}^{d} n_i \bar{I}(X_i;C_i). \tag{41}$$

In general, every value of β yields a different solution to the minimization problem (41). The optimum of (39) (which is computationally hard to find) corresponds to some specific value of β. Hence, by scanning the possible values of β, minimizing (41), and substituting the resulting $\hat{L}(\mathcal{Q})$ and $\bar{I}(X_i;C_i)$ back into (18) it is virtually possible to find the optimum of (39) (only virtually, because finding the global optimum of (41) is computationally hard as well). However, the trade-off (40) provides an additional degree of freedom. In cases where the bound (18) is not sufficiently

tight for practical applications it is possible to tune the trade-off by determining the desired value of β via cross-validation instead of back-substitution into the bound.

The minimization problem (41) is closely related to the rate distortion trade-off in information theory (Cover and Thomas, 1991). To find a local minimum of $\mathcal{F}(\mathcal{Q},\beta)$ we adopt an EM-like alternating projection procedure, very similar to the Blahut-Arimoto algorithm for minimization of the rate distortion function (Arimoto, 1972; Blahut, 1972; Cover and Thomas, 1991). We note that for $d \geq 2$ the alternating projections involve more than two convex sets and hence only a local minimum can be achieved. (For $d = 1$ the procedure achieves the global minimum.) For the sake of simplicity of the notations we restrict ourselves to the case of $d = 2$, but it is straightforward to extend the algorithm to higher dimensions.

The Lagrangian corresponding to the minimization problem (41) is:

$$\mathcal{L}(\mathcal{Q},\beta) = \beta N \hat{L}(\mathcal{Q}) + \sum_{i=1}^{2} n_i \bar{I}(X_i;C_i) + \sum_{i=1}^{2} \sum_{x_i \in \mathcal{X}_i} \nu(x_i) \sum_{c_i} q(c_i|x_i) + \sum_{c_1,c_2} \nu(c_1,c_2) \sum_{y} q(y|c_1,c_2),$$

where ν-s are Lagrange multipliers corresponding to normalization constraints on $\{q(c_i|x_i)\}_{i=1}^{2}$ and $q(y|c_1,c_2)$. In order to minimize $\mathcal{L}(\mathcal{Q},\beta)$ we write $\hat{L}(\mathcal{Q})$ explicitly:

$$\begin{aligned}
\hat{L}(\mathcal{Q}) &= \sum_{x_1,x_2,y} \hat{p}(x_1,x_2,y) \sum_{y'} q(y'|x_1,x_2) l(y,y') \\
&= \sum_{x_1,x_2,y} \hat{p}(x_1,x_2,y) \sum_{y',c_1,c_2} q(y'|c_1,c_2) q(c_1|x_1) q(c_2|x_2) l(y,y') \\
&= \sum_{y,y'} l(y,y') \sum_{c_1,c_2} q(y'|c_1,c_2) \sum_{x_1,x_2} q(c_1|x_1) \hat{p}(x_1,x_2,y) q(c_2|x_2).
\end{aligned}$$

We further derive $\hat{L}(\mathcal{Q})$ with respect to $q(c_1|x_1)$. The derivative with respect to $q(c_2|x_2)$ is similar.

$$\frac{\partial \hat{L}(\mathcal{Q})}{\partial q(c_1|x_1)} = \sum_{y,y'} l(y,y') \sum_{x_2,c_2} q(y'|c_1,c_2) \hat{p}(x_1,x_2,y) q(c_2|x_2). \tag{42}$$

Recall that $\bar{I}(X_i;C_i) = \frac{1}{n_i} \sum_{x_i,c_i} q(c_i|x_i) \ln \frac{q(c_i|x_i)}{\bar{q}(c_i)}$ and $\bar{q}(c_i) = \frac{1}{n_i} \sum_{x_i} q(c_i|x_i)$. Hence the derivative of $n_i \bar{I}(X_i;C_i)$ is:

$$\frac{\partial n_i \bar{I}(X_i;C_i)}{\partial q(c_i|x_i)} = \ln \frac{q(c_i|x_i)}{\bar{q}(c_i)}.$$

Derivatives of the remaining terms in $\mathcal{L}(\mathcal{Q},\beta)$ provide normalization for the corresponding variables. Thus, by taking the derivative of $\mathcal{L}(\mathcal{Q},\beta)$ with respect to $q(c_i|x_i)$, equating it to zero and reorganizing the terms we obtain a set of self-consistent equations that can be iterated until conver-

gence:

$$\bar{q}_t(c_i) = \frac{1}{n_i}\sum_{x_i} q_t(c_i|x_i),$$
$$q_{t+1}(c_i|x_i) = \frac{\bar{q}_t(c_i)}{Z_{t+1}(x_i)} e^{-\beta N \frac{\partial \hat{L}(\mathcal{Q}_t)}{\partial q(c_i|x_i)}},$$
$$Z_{t+1}(x_i) = \sum_{c_i} q_{t+1}(c_i|x_i),$$
$$y^*_{t+1}(c_1,c_2) = \arg\min_{y'} \sum_{y} l(y,y') \sum_{x_1,x_2} q_{t+1}(c_1|x_1)\hat{p}(x_1,x_2,y)q_{t+1}(c_2|x_2), \tag{43}$$
$$q_{t+1}(y|c_1,c_2) = \delta[y, y^*_{t+1}(c_1,c_2)], \tag{44}$$

where $\delta[\cdot,\cdot]$ is the Kronecker delta function, $\frac{\partial \hat{L}(\mathcal{Q})}{\partial q(c_i|x_i)}$ is given by (42), and the subindex t denotes the iteration number. Equations (43) and (44) correspond to minimization of $\hat{L}(\mathcal{Q})$ with respect to $q(y|c_1,c_2)$ and generally depend on the loss function. For the zero-one loss, $y^*(c_1,c_2)$ is the most frequent value of y appearing in the $\langle c_1,c_2\rangle$ partition cell; for the absolute loss it is the median value; for the quadratic loss it is the average value. We summarize the algorithm in the Algorithm 1 box.[2] We note that for the quadratic loss the loss minimizer $y^*(c_1,c_2)$, which is the average value in this case, can fall out of the finite space of labels $\mathcal{Y}$. However, the algorithm can still be applied and a bound can be obtained by post-process quantization, see appendix B for details.

Algorithm 1 Algorithm for minimization of $\mathcal{F}(\mathcal{Q},\beta) = \beta N \hat{L}(\mathcal{Q}) + \sum_{i=1}^{2} n_i \bar{I}(X_i;C_i)$ by alternating projections.

Input: $\hat{p}(x_1,x_2,y), N, n_1, n_2, m_1, m_2, l(y,y'), |\mathcal{Y}|, \beta$.
Initialize: $q_0(c_i|x_i)$ and $q_0(y|c_1,c_2)$ randomly.
$t \leftarrow 0$
$\bar{q}_t(c_i) \leftarrow \frac{1}{n_i}\sum_{x_i} q_t(c_i|x_i)$
repeat
  for $i = 1,2$ **do**
    $q_{t+1}(c_i|x_i) \leftarrow \bar{q}_t(c_i) e^{-\beta N \frac{\partial \hat{L}(\mathcal{Q}_t)}{\partial q(c_i|x_i)}}$
    $Z_{t+1}(x_i) \leftarrow \sum_{c_i} q_{t+1}(c_i|x_i)$
    $q_{t+1}(c_i|x_i) \leftarrow \frac{q_{t+1}(c_i|x_i)}{Z_{t+1}(x_i)}$
    $\bar{q}_{t+1}(c_i) \leftarrow \frac{1}{n_i}\sum_{x_i} q_{t+1}(c_i|x_i)$
    $y^*_{t+1}(c_1,c_2) \leftarrow \arg\min_{y'} \sum_{y} l(y,y') \sum_{x_1,x_2} q_{t+1}(c_1|x_1)\hat{p}(x_1,x_2,y)q_{t+1}(c_2|x_2)$
    $q_{t+1}(y|c_1,c_2) \leftarrow \delta[y, y^*_{t+1}(c_1,c_2)]$
    $t \leftarrow t+1$
  end for
until convergence
return $\{q_t(c_i|x_i)\}_{i=1}^2, q_t(y|c_1,c_2)$ from the last iteration.

2. Matlab implementation of the algorithm is available at `http://www.kyb.mpg.de/~seldin`.

4.2 Minimization of the PAC-Bayesian Bound for Density Estimation

Similar to the PAC-Bayesian bound for discriminative prediction, the PAC-Bayesian bound for density estimation (36) depends on the trade-off:

$$\mathcal{G}(\mathcal{Q},\beta) = -\beta N I(\hat{p}_{\mathcal{Q}}(c_1,c_2)) + \sum_{i=1}^{2} n_i \bar{I}(X_i;C_i).$$

All other terms in (36) do not depend on the specific form of grid partition $\mathcal{Q}$. (As in the previous subsection we restrict ourselves to $d=2$.) Unfortunately, $-I(\hat{p}_{\mathcal{Q}}(c_1,c_2))$ is concave in $q(c_i|x_i)$-s, whereas $\bar{I}(X_i;C_i)$ is convex in $q(c_i|x_i)$. Therefore, alternating projection methods are hard to apply. Instead, $\mathcal{G}(\mathcal{Q},\beta)$ can be minimized (with respect to $\mathcal{Q}$) using sequential minimization (Slonim et al., 2002; Dhillon et al., 2003). The essence of the sequential minimization method is that we start with some random assignment $q(c_i|x_i)$ and then iteratively take x_i-s out of their clusters and reassign them to new clusters, so that $\mathcal{G}(\mathcal{Q},\beta)$ is minimized. This approach leads to a hard partition of the data (i.e., each x_i is deterministically assigned to a single c_i). The algorithm is given in Algorithm 2 box.

Algorithm 2 Algorithm for sequential minimization of $\mathcal{G}(\mathcal{Q},\beta) = -\beta N I(\hat{p}_{\mathcal{Q}}(c_1,c_2)) + \sum_{i=1}^{2} n_i \bar{I}(X_i;C_i)$.

Input: $\hat{p}(x_1,x_2), N, n_1, n_2, m_1, m_2, \beta$.
Initialize: $q_0(c_i|x_i)$ randomly.
repeat
  for all $x_1 \in \mathcal{X}_1$ and all $x_2 \in \mathcal{X}_2$ according to some random order over $\mathcal{X}_1$ and $\mathcal{X}_2$ **do**
    for $i = 1,2$ **do**
      Select $x_i \in \mathcal{X}_i$ according to the order selected above.
      Compute $\mathcal{G}(\mathcal{Q},\beta)$ for each possible assignment of x_i to $c_i \in \{1,..,m_i\}$
      Reassign x_i to c_i such that $\mathcal{G}(\mathcal{Q},\beta)$ is minimized.
      Update $\hat{p}_{\mathcal{Q}}(c_1,c_2) \leftarrow \sum_{x_1,x_2} q(c_1|x_1)\hat{p}(x_1,x_2)q(c_2|x_2)$.
    end for
  end for
until no reassignments further minimize $\mathcal{G}(\mathcal{Q},\beta)$.
return $\{q(c_i|x_i)\}_{i=1}^{2}$ from the last iteration.

5. Applications

In this section we illustrate an application of the PAC-Bayesian bound for discriminative prediction based on co-clustering (18) and Algorithm 1 for minimization of the corresponding trade-off (40) on the problem of collaborative filtering. The problem of collaborative filtering was discussed in the previous sections. The goal of collaborative filtering is to complete the missing entries in a viewers-by-movies ratings matrix. This problem attracted a great deal of attention recently thanks to the Netflix challenge.[3] Since our goal here is mainly to illustrate our approach to co-clustering via the PAC-Bayesian bounds rather than to solve the large-scale challenge we concentrate on a

3. See `http://www.netflixprize.com/rules`.

much smaller MovieLens 100K data set.[4] The data set consists of 100,000 ratings on a five-star scale for 1,682 movies by 943 users. We take the five non-overlapping splits of the data set into 80% training and 20% test subsets provided at the MovieLens website. We stress that the training data are extremely sparse - only 5% of the training matrix entries are populated, whereas 95% of the values are missing.

To measure the accuracy of our algorithm we use the mean absolute error (MAE) measure, which is commonly used for evaluation on this data set (Herlocker et al., 2004). Let $\check{p}(x_1, x_2, y)$ be the distribution over $\langle X_1, X_2, Y \rangle$ in the test set. The mean absolute error is defined as:

$$MAE = \sum_{x_1, x_2, y} \check{p}(x_1, x_2, y) \sum_{y'} q(y'|x_1, x_2)|y - y'|.$$

In previous work the best MAE reported for this data set was 0.73 (Herlocker et al., 2004). It is worth recalling that the ratings are on a five-star scale, thus a MAE of 0.73 means that, on average, the predicted rating is 0.73 stars (less than one star) far from the observed rating. The maximal possible error is 4 (which occurs if we predict one star instead of five or vice versa), which determines the scale on which all the results should be judged.

In Seldin et al. (2007) we improved the MAE on this data set to 0.72 by using a Minimum Description Length (MDL, Grünwald, 2007) formulation of co-clustering. In the MDL formulation the co-clustering solutions are evaluated by the total description length, which includes the length of the description of assignments of x_i-s to c_i-s together with the length of the description of the ratings given the assignments. For fixed numbers of clusters (m_i-s) used along each dimension, the MDL solution corresponds to optimization of the trade-off (40) with logarithmic loss $\hat{L}(\mathcal{Q}) = \hat{I}(Y; C_1, C_2)$ and $\beta = 1$ (where $\hat{I}(Y; C_1, C_2)$ is the empirical mutual information between the clusters and the label). In the MDL formulation of co-clustering developed in Seldin et al. (2007) only hard (deterministic) assignments of x_i-s to c_i-s were considered. The best performance of 0.72 was achieved at $m_1 = 13$ and $m_2 = 6$ with below 1% sensitivity to small changes in m_1 and m_2 both in the description length and in the prediction accuracy. The deviation in prediction accuracy between the five splits of the MovieLens data set was below 0.01.

In the present work we implemented Algorithm 1 for minimization of $\mathcal{F}(\mathcal{Q}, \beta)$ as a function of $\mathcal{Q}$ and applied it to the MovieLens data set. There are four major differences between Algorithm 1 and the MDL algorithm suggested in Seldin et al. (2007) that should be highlighted:

- Algorithm 1 directly optimizes a given loss function (MAE in the case of MovieLens) rather than the description length, which is only indirectly related to the loss function.

- Algorithm 1 considers soft assignments of x_i-s to c_i-s.

- Algorithm 1 is an iterative projection algorithm rather than the sequential optimization algorithm suggested in Seldin et al. (2007). Note that this point is neither positive nor negative, since sequential optimization algorithms are very powerful and especially in hard cases can outperform iterative projection methods. The advantage of iterative projection methods is in their mathematical elegance, faster convergence (although in the hard cases it may be fast convergence to trivial, but strong attractors), and the ability to handle soft assignments.

(a) Bound (18). (b) Test Loss (zoom into subfigure a.).

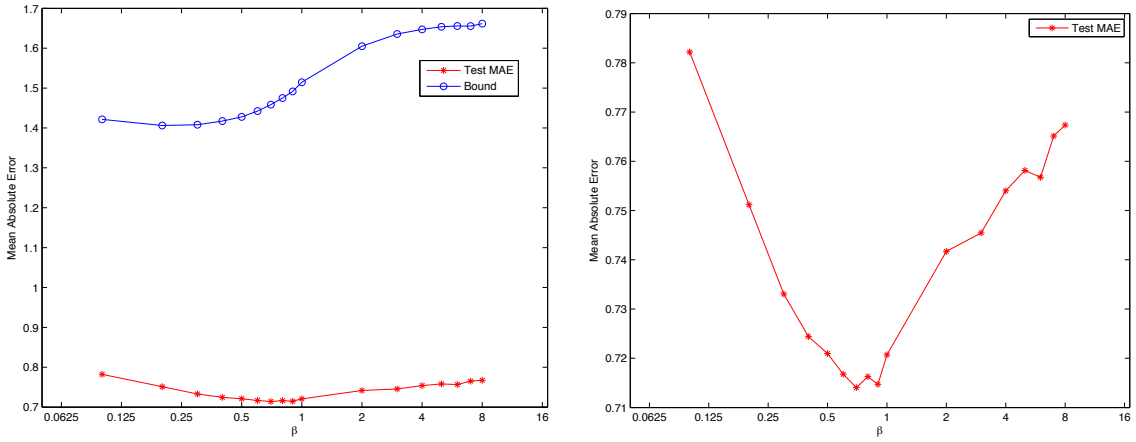
Figure 3: Co-clustering of the MovieLens data set into 13x6 clusters. Figure (a) shows the value of bound (18) together with the MAE on the test set as a function of β. Figure (b) zooms into MAE on the test set. The values of β are on a log scale. See text for further details.

- Algorithm 1 considers arbitrary values of β. (However, the algorithm in Seldin et al. (2007) can be easily extended to handle arbitrary values of β.) As we will show below, the value of $\beta = 1$ dictated by the MDL formulation is not always optimal and MDL solutions can overfit the data. This observation was already made previously in a context of other learning problems by Kearns et al. (1997).

We conducted three experiments with Algorithm 1. In all three experiments we fixed the numbers of clusters m_1 and m_2 used along both dimensions and analyzed the MAE on the test set and the value of bound (18) as a function of β. In each experiment, for each of the five splits of the data set into training and test sets mentioned earlier, and for each value of β we applied 10 random initializations of the algorithm. The solution $\mathcal{Q}$ corresponding to the best value of $\mathcal{F}(\mathcal{Q}, \beta)$ per each data split and per each value of β was then selected. We further calculated the average of the results over the data set splits to produce the graphs of the bound values and test MAE as functions of β.

In the first experiment we verified that we are able to reproduce the results achieved previously in Seldin et al. (2007). We set $m_1 = 13$ and $m_2 = 6$, as the best values obtained in Seldin et al. (2007) and applied Algorithm 1. The results are presented in Figure 3. We make the following conclusions from this experiment:

- The performance of Algorithm 1 is comparable to the performance achieved in Seldin et al. (2007) with sequential optimization.
- The optimal performance is achieved at β close to one, which corresponds to the MDL functional optimized in Seldin et al. (2007).
- The values of the bound are meaningful (recall that the maximal possible loss is 4; thus the bound value of ~ 1.25 is informative).
- The bound is 25%-75% far from the test error.



(a) Bound (18). (b) Test Loss (zoom into subfigure a.).

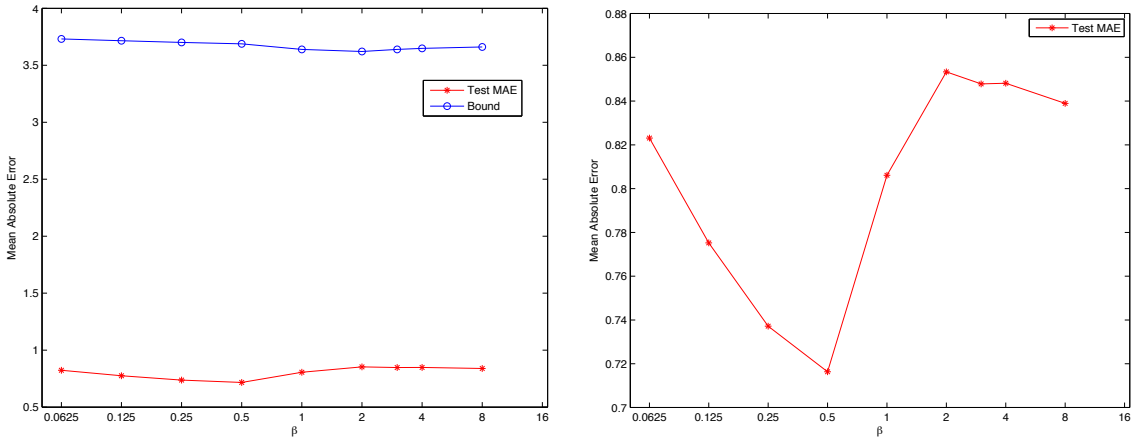
Figure 4: Co-clustering of the MovieLens data set into 50x50 clusters. Figure (a) shows the value of bound (18) together with the MAE on the test set as a function of β. Figure (b) zooms into MAE on the test set. The values of β are on a log scale. See text for further details.

- The bound does not follow the shape of the test loss. According to the bound in this task it is best to assign all the data to one big cluster. This is explained by the fact that this is a hard problem and the improvement in the empirical loss $\hat{L}(\mathcal{Q})$ achieved by co-clustering is relatively small. For the best co-clustering solution found $\hat{L}(\mathcal{Q}) \approx 0.67$, whereas if we assign all the data to one big cluster $\hat{L}(\mathcal{Q}) \approx 0.89$. Thus, the improvement in $\hat{L}(\mathcal{Q})$ achieved by the clustering is only about 30% while the tightness of the bound is 25%-75%. This is clearly insufficient to apply the bound as the main guideline for model order selection. However, it is possible to set the value of β in the trade-off $\mathcal{F}(\mathcal{Q}, \beta)$ via cross-validation and obtain remarkably good results. It should be pointed out that the trade-off $\mathcal{F}(\mathcal{Q}, \beta)$ was derived from the bound, thus even though the analysis is not perfectly tight it produced a useful practical result.

- Note that in the setting of this experiment the small values of m_1 and m_2 provide "natural regularization"; thus there is no significant decrease in performance when we increase β beyond 1. This will change in the following experiments.

The power of bound (18) and the trade-off $\mathcal{F}(\mathcal{Q}, \beta)$ derived from the bound is that it penalizes the effective complexity of the solution rather than the gross number of clusters used. The practical implication of this property is that we can initialize the optimization algorithm with more clusters than are actually required to solve a problem, and the algorithm will automatically adjust the extent to which it uses said available clusters. This property is verified in the following two experiments. In the first experiment we initialized Algorithm 1 with $m_1 = m_2 = 50$ clusters along each dimension. The result of optimization of $\mathcal{F}(\mathcal{Q}, \beta)$ as a function of β is presented in Figure 4. We make the following observations based on this experiment:

- The best performance (the 0.72 test MAE) achieved in the previous setting with $m_1 = 13$ and $m_2 = 6$ is achieved in the new setting with $m_1 = m_2 = 50$ as well. This supports the ability



(a) Bound (18). (b) Test Loss (zoom into subfigure a.).

Figure 5: Co-clustering of the MovieLens data set into 283x283 clusters. Figure (a) shows the value of bound (18) together with the MAE on the test set as a function of β. Figure (b) zooms into MAE on the test set. The values of β are on a log scale. See text for further details.

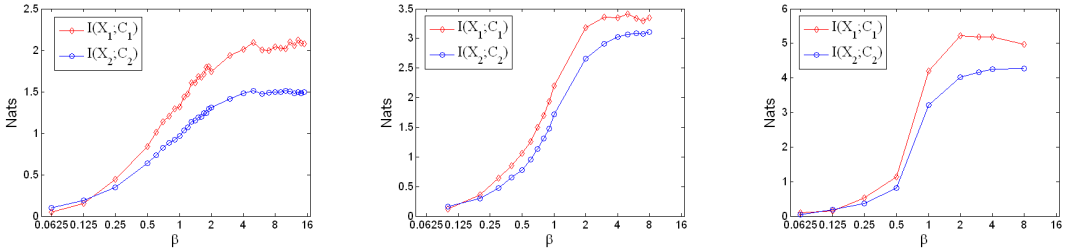
of the algorithm to operate with more clusters than are actually required by the problem and to adjust the complexity of the solution automatically.

- Note that the optimal value of β in this setting is below 1. In particular, this implies that the MDL formulation, which corresponds to $\beta = 1$ would overfit in this case. The role of the regularization parameter β is also more evidently expressed here compared to the preceding experiment.

- The values of the bound, although less tight than in the previous case, are still meaningful. The shape of the bound becomes closer to the shape of the test loss, although in light of the preceding experiment we would not attribute importance to it, and would still prefer to set the value of β via cross-validation.

In our last experiment we went to the extreme case of taking $m_1 = m_2 = 283 = \sqrt{N}$. Note that the size of the cluster space $M = m_1 m_2$ in this case is $80,089$ and is equal to the size of the training set, $N = 80,000$. The implication is that extensive use of all available clusters can result in a situation where each partition cell contains an order of a single observation, which is clearly insufficient for statistically reliable predictions. Thus, in this experiment the number of clusters provides no regularization at all and the only parameter responsible for regularization of the model is the trade-off parameter β. The result of the experiment is presented in Figure 5. We highlight the following points regarding this experiment:

- The best performance (the 0.72 test MAE) is achieved in this experiment as well. This further stresses the ability to have full control over regularization of the model via parameter β of the trade-off $\mathcal{F}(\mathcal{Q}, \beta)$.



(a) 13x6 clusters (b) 50x50 clusters (c) 283x283 clusters

Figure 6: The values of $\bar{I}(X_i;C_i)$ in the minimized $\mathcal{F}(\mathcal{Q},\beta)$ corresponding to Figures 3, 4, 5. We show the values of $\bar{I}(X_i;C_i)$ that were obtained after minimization of $\mathcal{F}(\mathcal{Q},\beta)$ by $\mathcal{Q}$ when clustering the MovieLens data set into 13x6, 50x50, and 283x283 clusters.

- The role of the regularization parameter β is further increased in this experiment compared to the previous two. The optimal value of β here is clearly below 1 (the optimal $\beta \approx 0.5$), suggesting that the MDL solution would be overfitting.

- The value of the bound still remains meaningful, although it is already quite far from the test error. The shape of the bound does not seem to provide useful information and the value of β should be set via cross-validation.

In Figure 6 we show how the mutual information $\bar{I}(X_1;C_1)$ and $\bar{I}(X_2;C_2)$ changed in the three experiments as we optimized $\mathcal{F}(\mathcal{Q},\beta)$ by $\mathcal{Q}$ for increasing values of β. An important observation to be made from these graphs (by relating them to Figures 3, 4, and 5) is that in all three experiments the best prediction performance was achieved at roughly the same values of the mutual information $\bar{I}(X_1;C_1)$ and $\bar{I}(X_2;C_2)$. For clustering into 13x6 clusters prediction performance of MAE equal to 0.72 and slightly lower was achieved at β values starting from 0.7 and larger, when $\bar{I}(X_1;C_1)$ was in the range between 1.1 and 2.1 and $\bar{I}(X_2;C_2)$ was in the range between 0.8 and 1.5; for clustering into 50x50 clusters prediction performance of 0.72 and slightly lower was achieved for β values in the range between 0.5 and 1.0, when $\bar{I}(X_1;C_1)$ was in the range between 1.1 and 2.2 and $\bar{I}(X_2;C_2)$ was in the range between 0.8 and 1.7; and for clustering into 283x283 clusters the optimal prediction performance of slightly below 0.72 was achieved for $\beta = 0.5$ and at this value of β we had $\bar{I}(X_1;C_1) = 1.1$ and $\bar{I}(X_2;C_2) = 0.8$. We see that although the three experiments were initialized with different numbers of clusters m_1 and m_2, the optimal prediction performance was achieved at roughly the same *effective complexity* of the solution (measured by $\bar{I}(X_i;C_i)$-s) and that the trade-off parameter β took care of regularization of the model.

6. Probabilistic Matrix Tri-Factorization

For $d = 2$ the discriminative prediction and density estimation models considered in this paper can be seen as two forms of matrix tri-factorization and for higher dimensions $d > 2$ as Tucker decompositions. In this section we discuss this relation in more detail, starting from the discriminative prediction problem.

6.1 Probabilistic Matrix Tri-Factorization for Discriminative Prediction

For $d = 2$ Equation (17) accepts the form:

$$q(y|x_1, x_2) = \sum_{c_1,c_2} q(c_1|x_1)q(y|c_1, c_2)q(c_2|x_2).$$

If $q(y|c_1, c_2)$ is restricted to be a delta distribution then it can be replaced by a function $f(c_1, c_2)$. This means that instead of drawing y in the cluster product space according to a distribution $q(y|c_1, c_2)$ it is predicted deterministically by $f(c_1, c_2)$. Note that the assignment of x_i-s to c_i-s remains stochastic. The restriction of deterministic $q(y|c_1, c_2)$ does not limit the model significantly, since for many loss functions, such as zero-one, absolute, or quadratic losses the optimal prediction rule is deterministic in the cluster product space in any case. At the same time the bounds derived previously are still valid, since they are valid for any distribution $q(y|c_1, c_2)$ and in particular for the delta distribution. The restricted model accepts the form:

$$f(x_1, x_2) = \sum_{c_1,c_2} q(c_1|x_1)f(c_1, c_2)q(c_2|x_2),$$

which can be written as a matrix product:

$$A = Q_1^T F Q_2, \tag{45}$$

where

$$Q_i = [q(c_i|x_i)] \qquad (i = 1, 2)$$

are $m_i \times n_i$ *left* stochastic matrices[5] mapping x_i-s to their clusters c_i-s, and

$$F = [f(c_1, c_2)]$$

is an $m_1 \times m_2$ matrix describing what happens in the cluster product space.

Given a data matrix A (probably sparse) and a trade-off parameter β Algorithm 1 provides a locally optimal approximation of A in the form of (45) regularized by the mutual information preserved in Q_1 and Q_2. Note that Algorithm 1 naturally handles the missing entries in A. The product $Q_1^T F Q_2$ can then be used to complete the missing entries.

Matrix factorization of the form (45) was already considered in Banerjee et al. (2007) without regularization. However, in Banerjee et al. (2007) the matrices Q_1 and Q_2 are restricted to deterministic assignments of x_i-s to c_i-s (the entries of Q_1 and Q_2 are in $\{0, 1\}$), whereas in the factorization proposed here Q_1 and Q_2 are stochastic matrices and F is arbitrary. Matrix tri-factorization considered in Ding et al. (2006); Yoo and Choi (2009a) is more closely related to matrix tri-factorization for density estimation discussed in the next subsection. We note that the recent Bayesian approaches to matrix factorization (Shan and Banerjee, 2008; Salakhutdinov and Mnih, 2008) are three-level stochastic models and unlike the two-level stochastic model in (45) cannot be written as a simple product of matrices. The following list of positive properties of probabilistic matrix tri-factorization suggested here further distinguishes it from other forms of matrix factorization, including singular value decomposition (SVD) (Strang, 2009; Golub and Loan, 1996), non-negative matrix factorization (Lee and Seung, 1999, 2001), low-rank matrix factorization (Srebro et al., 2005a), and maximum margin matrix factorization (Srebro et al., 2005b; Srebro, 2004), that satisfy only parts of the list:

5. A *left* stochastic matrix is a matrix of non-negative real numbers with each column summing up to 1. In a *right* stochastic matrix each row sums up to 1.

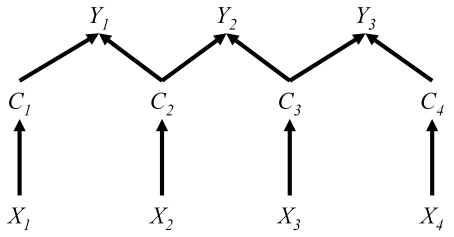


Figure 7: A graphical model for simultaneous tri-factorization of multiple matrices (equations (46)-(48)). The mapping of X_i to C_i is modeled by a corresponding matrix Q_i and labels Y_i correspond to prediction tasks in the respective matrices A_i.

- It has a clear probabilistic interpretation.
- It naturally handles missing values.
- The factorized matrix A can be arbitrary (not necessarily positive or positive definite).
- Overfitting can be controlled via the regularization parameter β.
- The generalization bound derived for co-clustering applies to this form of matrix factorization.
- It is a two-level stochastic model of the data.
- The model can be optimized by iterative projections.
- The model achieves state-of-the-art results in prediction of missing matrix entries.

We leave a wider practical comparison of the different matrix factorization methods as a subject for future work.

A promising direction for future research suggested in Seldin (2009) and independently in Yoo and Choi (2009b) is to apply matrix tri-factorization in tasks, where multiple related data sets are considered. For example, let A_1 be a matrix of viewers-by-viewers properties, A_2 be a collaborative filtering matrix, and A_3 be a matrix of movies-by-movies properties. We can look for simultaneous tri-factorizations, such that:

$$A_1 \approx Q_1^T F_1 Q_2 \tag{46}$$

$$A_2 \approx Q_2^T F_2 Q_3 \tag{47}$$

$$A_3 \approx Q_3^T F_3 Q_4. \tag{48}$$

In other words, the clustering of viewers into clusters of viewers is shared between factorizations of A_1 and A_2 and the clustering of movies into clusters of movies is shared between factorizations of A_2 and A_3. An unregularized form of simultaneous tri-factorization for collaborative filtering was already explored in Yoo and Choi (2009b). Problems of a similar form are also frequent in bioinformatics, when multiple experiments with partial relations are considered. For example, Alter et al. (2003) applied generalized SVD (GSVD) to compare yeast and human cell-cycle gene expression data sets. In their experiment it is natural to create separate systems of clusters for yeast and human

genes, but a common system of clusters for the cell-cycle time points. As already pointed out, probabilistic matrix tri-factorization suggested here has several advantages over SVD (and consequently over GSVD). Hence, it would be interesting to apply it to this type of problem.

6.2 Probabilistic Matrix Tri-Factorization for Density Estimation

The model for discrete density estimation based on co-clustering in Equation (26) can also be written as matrix tri-factorization (for $d = 2$):

$$A = R_1^T G R_2, \tag{49}$$

where

$$R_i = [q(x_i|c_i)] = \left[\frac{q(x_i)}{q(c_i)} q(c_i|x_i)\right] \qquad (i = 1, 2)$$

are $m_i \times n_i$ *right* stochastic matrices of probabilities of generating x_i-s given c_i-s and

$$G = [q(c_1, c_2)]$$

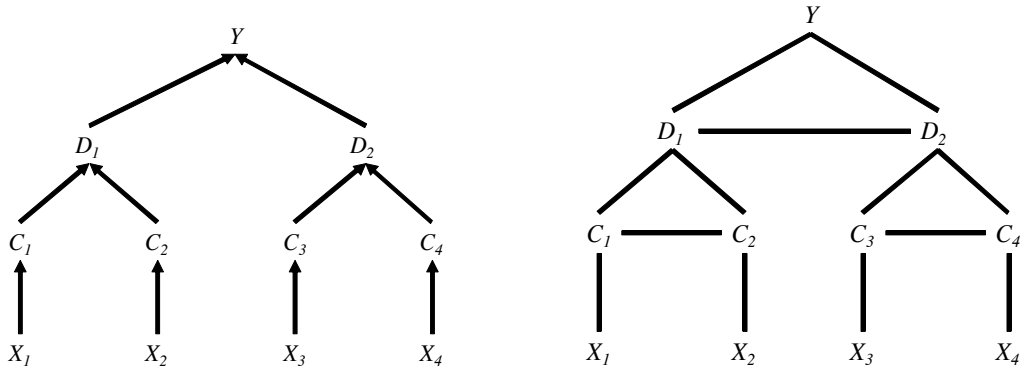
is an $m_1 \times m_2$ matrix of joint probability distribution of c_1 and c_2. As already mentioned, this model is appropriate for co-occurrence data analysis, such as word-document co-occurrence matrices. An unregularized form of such decomposition was already considered in Ding et al. (2006) and Yoo and Choi (2009a). Here, A is assumed to be a joint probability matrix (i.e., the entries of A are non-negative and sum up to 1). In practice A is an empirical joint probability distribution matrix and factorization (49) regularized by the mutual informations $\bar{I}(X_i; C_i)$ can be used to regularize the estimation of the joint probability distribution. Algorithm 2 can be used to find a local optimum of such factorization given the regularization parameter β. The generalization bound developed in Theorem 12 holds for this factorization. We remind the reader that Algorithm 2 operates with deterministic assignments of x_i-s to clusters c_i-s. Although the resulting reverse conditional distribution $q(x_i|c_i)$ is not deterministic, the algorithm does not explore all possible solutions to this problem. Developing an algorithm for finding a local optimum of the regularized decomposition with mixed memberships of x_i-s is a challenging direction for future research.

7. PAC-Bayesian Analysis of Graphical Models

The analysis of co-clustering presented in Section 3 holds for any dimension d. However, the dependence of the bounds (18), (31), and (36) on d is exponential because of the $M = \prod_i m_i$ term that they involve. This term is reasonably small when the number of dimensions is small (two or three), as in the example of co-clustering. However, as the number of dimensions grows, this term grows exponentially. Thus, high dimensional tasks require a different treatment. Some improvements are also possible if we consider discriminative prediction based on a single parameter X (i.e., in the case of $d = 1$), but the one-dimensional case is beyond the scope of this paper and we refer the interested reader to (Seldin and Tishby, 2008; Seldin, 2009) for further details. In this section we suggest a hierarchical approach to handle high-dimensional problems. We then show that this approach can also be applied to generalization analysis of graphical models.

7.1 Hierarchical Approach to High Dimensional Problems ($d > 2$)

One possible way to handle high dimensional problems is to use hierarchical partitions, as shown in Figures 8 and 9. For example, the discriminative prediction rule corresponding to the model in



(a) Discriminative Prediction Model (b) Moralization of (a)

Figure 8: Illustration of (a) a graphical model for discriminative prediction and (b) its moralized counterpart. The illustration is for $d = 4$.

Figure 8.a is:

$$q(y|x_1,..,x_4) = \sum_{d_1,d_2} q(y|d_1,d_2) \sum_{c_1,..,c_4} \prod_{i=1}^{2} q(d_i|c_{2i-1},c_{2i}) \prod_{j=1}^{4} q(c_j|x_j). \tag{50}$$

And the corresponding randomized prediction strategy is $\mathcal{Q} = \{\{q(c_i|x_i)\}_{i=1}^4, \{q(d_i|c_{2i-1},c_{2i})\}_{i=1}^2, q(y|d_1,d_2)\}$. In this case the hypothesis space is the space of all hard partitions of x_i-s to c_i-s and of the pairs $\langle c_{2i-1},c_{2i}\rangle$ to d_i-s. By repeating the analysis in Theorem 7 we obtain that with probability greater than $1-\delta$:

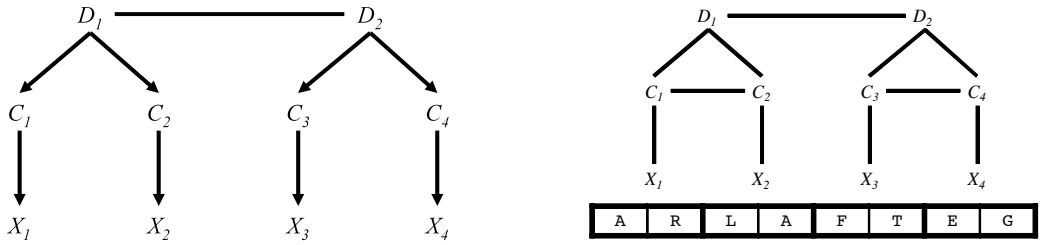
$$kl(\hat{L}(\mathcal{Q})\|L(\mathcal{Q})) \leq \frac{B_1 + B_2 + |D_1||D_2|\ln|\mathcal{Y}| + \frac{1}{2}\ln(4N) - \ln\delta}{N}, \tag{51}$$

where

$$B_1 = \sum_{i=1}^{4} \left(n_i \bar{I}(X_i;C_i) + m_i \ln n_i \right),$$
$$B_2 = \sum_{i=1}^{2} \left((m_{2i-1}m_{2i}) \bar{I}(D_i;C_{2i-1},C_{2i}) + |D_i| \ln(m_{2i-1}m_{2i}) \right).$$

Observe that the $M\ln|\mathcal{Y}|$ term in (18), which corresponds to the clique $\langle C_1,C_2,C_3,C_4,Y\rangle$, is replaced in (51) with terms which correspond to much smaller cliques $\langle C_1,C_2,D_1\rangle$, $\langle C_3,C_4,D_2\rangle$, and $\langle D_1,D_2,Y\rangle$. This factorization makes it possible to control the complexity of the partition and the tightness of the bound. In a similar way it is possible to derive factorized analogs to bounds (31) and (36) that apply to density estimation hierarchies as in Figure 9.

We provide an illustration of a possible application of the models in Figure 9. Imagine that we intend to analyze protein sequences. Protein sequences are sequences over the alphabet of 20 amino acids. Subsequences of length 8 can reach $20^8 = 256 \cdot 10^8$ instances. Instead of studying this space directly, which would require an order of $256 \cdot 10^8$ samples, we can associate each X_i



(a) Density Estimation Model (b) Moralization and Application of (a)

Figure 9: Illustration of (a) a directed model for density estimation and (b) its moralization and application to sequence modeling. The sequence in subfigure (b) is an imaginary subsequence of length 8 of a protein sequence. Each X_i corresponds to a pair of amino acids in the subsequence.

with a pair of amino acids - see Figure 9. The subspace of pairs of amino acids is only $20^2 = 400$ instances and local interactions between adjacent pairs of amino acids can easily be studied. We can cluster the pairs of amino acids into, say, 20 clusters C. Interactions between adjacent pairs of C-s in such a construction correspond to interactions between quadruples of amino acids. The subspace of quadruples is $20^4 = 16 \cdot 10^4$ instances. However, the reduced subspace of pairs of C_i-s is only $20^2 = 400$ instances. Thus, we have doubled the range of interactions, but remained at the same level of complexity. We can further cluster pairs of C_i-s (which correspond to quadruples of amino acids) into D_i-s and study the space of 8-tuples of amino acids while remaining at the same level of complexity.

The above approach shares the same basic principle already discussed in the collaborative filtering task: by clustering together similar pairs (and then quadruples) of amino acids we increase the statistical reliability of the observations, but reduce the resolution at which we process the data. Bound (51) suggests how the trade-off between model resolution and statistical reliability can be optimized.

7.2 PAC-Bayesian Analysis of Graphical Models

The result in the previous subsection suggests a new approach to learning graphical models by providing a way to evaluate the expected performance of a graphical model on new data. Thus, instead of constructing a graphical model that fits the observed data it serves to construct a model with good generalization properties. The analysis used to derive bound (51) can be applied to any directed graphical model in the form of a tree (as in Figures 8.a, 9.a) or its moralized counterpart (as in Figures 8.b, 9.b). The analysis shows that the generalization power of these graphical models is determined by a trade-off between empirical performance and the amount of mutual information that is propagated up the tree. It is important to note that the PAC-Bayesian bound is able to take advantage of the factor form of distribution (50) and that bound (51) depends on the sizes of the tree cliques, but not on the size of the parameter space $\mathcal{X}_1 \times .. \times \mathcal{X}_d$. Further, a prior can be added over all possible directed graphs under consideration to obtain a PAC-Bayesian bound that will hold for all of them simultaneously. Development of efficient algorithms for optimization of the tree structure and extension of the results to more general graphical models are key directions for future research.

8. PAC-Bayesian Analysis of Graph Clustering and Pairwise Clustering

In this section we show that our approach to predictive formulation of unsupervised learning problems and their subsequent PAC-Bayesian analysis can also be applied to weighted graph clustering (and, consequently, to pairwise clustering, which can be regarded as clustering of a graph with edge weights corresponding to pairwise distances). Graph clustering is an important tool in data analysis with a wide variety of applications including social networks analysis, bioinformatics, image processing, and many more. As a result, a multitude of different approaches to graph clustering were developed. Examples include graph cut methods (Shi and Malik, 2000), spectral clustering (Ng et al., 2001), information-theoretic approaches (Slonim et al., 2005), to name just a few. Comparing the different approaches is usually a painful task, mainly because the goal of each of these clustering methods is formulated in terms of the solution: most clustering methods start by defining some objective functional and then minimize it. But, for a given problem, how can we choose whether to apply a graph cut method, spectral clustering, or an information-theoretic approach?

Here we formulate weighted graph clustering as a prediction problem.[6] Given a subset of edge weights we analyze the ability of graph clustering to predict the remaining edge weights. The rationale behind this formulation is that if a model (not necessarily cluster-based) is able to predict with high precision all edge weights of a graph given a small subset of edge weights then it is a good model of the graph. The advantage of this formulation of graph modeling is that it is independent of the specific way chosen to model the graph and can be used to compare any two solutions, either by comparison of generalization bounds or by cross-validation. The generalization bounds or cross-validation also address the finite-sample nature of the graph clustering problem and provide a clear criterion for model order selection. For very large data sets, where computational constraints can prevent considering all edges of a graph, as for example in Yom-Tov and Slonim (2009), the generalization bounds can be used to resolve the trade-off between computational workload and precision of graph modeling.

Below we provide a PAC-Bayesian analysis of graph clustering in the case, where independent sampling of edge weights is possible. For example, in the analysis of flow graphs, such as loads on links in traffic or communication networks, we can repeatedly sample one or more non-adjacent edge weights at a time (non-adjacent edges have no common vertices). In the analysis of snapshot graphs, for example image segmentation, the dependencies between adjacent edge weight samples should be taken into account, but this is again beyond the scope of this paper.

8.1 PAC-Bayesian Analysis of Graph Clustering

Assume that $\mathcal{X}$ is a space of $|\mathcal{X}|$ nodes and denote by $w_{x_1x_2}$ the weight of an edge connecting nodes x_1 and x_2.[7] We assume that the weights $w_{x_1x_2}$ are generated according to an unknown probability distribution $p(w|x_1,x_2)$. We further assume that the space of nodes $\mathcal{X}$ is known and we are given a sample of size N of edge weights, generated according to $p(x_1,x_2,w)$. The goal is to build a regression function $q(w|x_1,x_2)$ that will minimize the expected prediction error of the edge weights $\mathbb{E}_{p(x_1,x_2,w)}\mathbb{E}_{q(w'|x_1,x_2)}l(W,W')$ for some externally given loss function $l(w,w')$. Note that this formulation does not assume any specific form of $q(w|x_1,x_2)$ and enables comparison of all possible approaches to this problem.

6. Unweighted graphs can be modeled by setting the weight of present edges as 1 and absent edges as 0.

7. All the results can be straightforwardly extended to hyper-graphs.

Here we analyze generalization abilities of $q(w|x_1,x_2)$ based on clustering:

$$q(w|x_1,x_2)=\sum_{c_1,c_2} q(w|c_1,c_2)q(c_1|x_1)q(c_2|x_2). \tag{52}$$

One can immediately see the relation between (52) and the co-clustering model for discriminative prediction (17). The only difference is that in (52) the nodes x_1,x_2 belong to the same space of nodes $\mathcal{X}$ and the conditional distribution $q(c|x)$ is shared for the mapping of endpoints of an edge. Let $\hat{p}(x_1,x_2,w)$ be the empirical distribution over edge weights. The empirical loss of prediction strategy $\mathcal{Q}=\{q(c|x),q(w|c_1,c_2)\}$ corresponding to (52) can then be written as:

$$\hat{L}(\mathcal{Q})=\mathbb{E}_{\hat{p}(x_1,x_2,w)}\mathbb{E}_{q(w'|x_1,x_2)}l(W,W').$$

The following generalization bound for graph clustering can be proved by a minor adaptation of the proof of Theorem 7.

Theorem 13 *For any probability measure $p(x_1,x_2,w)$ over the space of nodes and edge weights $\mathcal{X}\times\mathcal{X}\times\mathcal{W}$ and for any loss function l bounded by 1, with probability of at least $1-\delta$ over a selection of an i.i.d. sample S of size N according to p, for all graph clustering models defined by $\mathcal{Q}=\{q(c|x),q(w|c_1,c_2)\}$:*

$$kl(\hat{L}(\mathcal{Q})\|L(\mathcal{Q}))\leq\frac{n\bar{I}(X;C)+m\ln n+m^2\ln|\mathcal{W}|+\frac{1}{2}\ln(4N)-\ln\delta}{N}, \tag{53}$$

where $m=|C|$, $n=|\mathcal{X}|$, and $|\mathcal{W}|$ is the number of distinct edge weights.

Continuous edge weights can be handled by post-process quantization, as shown in appendix B.

As in the case of co-clustering, in practice we can replace (53) with a trade-off:

$$\mathcal{J}(\mathcal{Q},\beta)=\beta N\hat{L}(\mathcal{Q})+n\bar{I}(X;C) \tag{54}$$

and tune β either by substituting $\hat{L}(\mathcal{Q})$ and $\bar{I}(X;C)$ resulting from the solution of (54) back into the bound or via cross-validation.

If the distribution $q(w|c_1,c_2)$ is restricted to be a delta distribution Equation (52) can be rewritten as:

$$f(x_1,x_2)=\sum_{c_1,c_2} q(c_1|x_1)f(c_1,c_2)q(c_2|x_2)$$

and the corresponding matrix form is:

$$A\approx Q^TFQ,$$

where $Q=[q(c|x)]$, $F=[f(c_1,c_2)]$, and A is an input matrix (probably sparse) providing a sample of graph edge weights. This form of symmetric matrix tri-factorization is briefly mentioned in Ding et al. (2006). Let $\mathbb{I}$ be an indicator matrix for the entries present in A. For quadratic loss the empirical approximation error $\hat{L}(\mathcal{Q})$ can be written as:

$$\hat{L}(\mathcal{Q})=\frac{1}{N}\|\mathbb{I}\circ(A-Q^TFQ)\|_2^2, \tag{55}$$

where $\circ$ denotes entrywise product of two matrices. From (55) it is easy to see that $\hat{L}(\mathcal{Q})$ is not convex in Q (unlike in the case of co-clustering, where the dependence on Q_i-s was quadratic,

here the power of Q is 4). Hence, although alternating projections similar to those in Algorithm 1 can be applied to $\mathcal{J}(\mathcal{Q},\beta)$ they are not guaranteed to converge to a local minimum. Nevertheless, according to some preliminary experiments they can achieve reasonably good solutions and bound (53) provides reasonably tight guarantees on the expected approximation quality (Seldin, 2010). Alternatively, trade-off $\mathcal{J}(\mathcal{Q},\beta)$ can be optimized by sequential minimization. Unlike alternating projections, sequential minimization (similar to the one in Algorithm 2) is guaranteed to converge to a local minimum, but can operate with deterministic assignments of graph nodes x_i-s to the clusters c_i-s only. A convergent algorithm that will be able to explore stochastic assignments still awaits to be developed.

8.2 Related Work on Pairwise Clustering

The regularization of pairwise clustering by mutual information $\bar{I}(X;C)$ was already applied in practice by Slonim et al. (2005). They maximized a parameterized trade-off $\beta\langle s\rangle - \bar{I}(X;C)$, where $\langle s\rangle = \sum_c \bar{q}(c) \sum_{x_1,x_2} q(x_1|c)q(x_2|c)w_{x_1x_2}$ measured average pairwise similarities within a cluster.[8] Their algorithm demonstrated superior results in cluster coherence compared to 18 other clustering methods. The regularization by mutual information was motivated by information-theoretic considerations inspired by the rate distortion theory (Cover and Thomas, 1991). Namely, the authors drew a parallel between $\langle s\rangle$ and distortion and $\bar{I}(X;C)$ and compression rate of a clustering algorithm. Further, Yom-Tov and Slonim (2009) showed that the algorithm can be run in parallel mode, where each parallel worker operates with a subset of pairwise relations at each iteration rather than all of them. Such a mode of operation was motivated by inability to consider all pairwise relations in very large data sets due to computational constraints. Yom-Tov and Slonim (2009) reported only minor empirical degradation in clustering quality, but no formal analysis or guarantees were suggested. The results presented here can help to analyze such problems and help to address the trade-off between computational workload and approximation quality in analysis of very large graphs.

9. Related Work on Clustering

The idea of considering clustering in the context of a higher level task was inspired by the Information Bottleneck (IB) principle (Tishby et al., 1999; Slonim, 2002; Slonim et al., 2006). The IB principle considers the problem of extracting information from a random variable X that is relevant for prediction of a random variable Y. The relevance variable Y defines the high-level task. For example, X might be a speech signal and the task might be identification of the speaker or transcription of the signal. The extraction of relevant information from X is done by means of clustering of $\mathcal{X}$ into clusters $\tilde{\mathcal{X}}$ that preserve the information on $\mathcal{Y}$ (Tishby et al., 1999). Clearly, each relevance variable $\mathcal{Y}$ corresponds to a different partition (clustering) of $\mathcal{X}$. The IB principle was further extended to graphical models in Slonim et al. (2006).

The idea to consider clustering as a proxy to solution of a prediction task was further developed in Krupka and Tishby (2005, 2008) and Krupka (2008). Krupka and Tishby analyze a scenario wherein each object has multiple properties, but only a fraction of the properties is observed. Consider the following illustration: assume we are presented with multiple fruits and we observe their parameters, such as size, color, and weight. We can cluster the fruits by their observed parameters

8. The loss $L(\mathcal{Q})$ is slightly more general than $\langle s\rangle$ since it also considers edges between the clusters. Although, this generality breaks the convexity of $\hat{L}(\mathcal{Q})$ in (55).

in order to facilitate prediction of unobserved parameters, such as taste and toxicity. This approach enables one to conduct a formal analysis and derive generalization bounds for prediction rules based on clustering.

In recent years extensive attempts have been made to address the question of model order selection in clustering through evaluation of its stability (Lange et al., 2004; von Luxburg and Ben-David, 2005; Ben-David et al., 2006; Shamir and Tishby, 2009; Ben-David and von Luxburg, 2008). This perspective suggests that for two random samples generated by the same source, clustering of the samples should be similar (and hence stable). Otherwise the obtained clustering is unreliable. Although it has been proven that in a large sample regime stability can be used for model order selection (Shamir and Tishby, 2009), no upper bounds on the minimal sample size required for stability estimates to hold can be proved. Moreover, in certain cases stability indices based on arbitrarily large samples can be misleading (Ben-David and von Luxburg, 2008). Since in any practical application the amount of data available is limited, currently existing stability indices cannot be used for reliable model order selection and it is not clear whether the stability indices can be used to compare solutions based on different optimization objectives.

Gaussian ring example. We use the following example from Seldin (2009) to illustrate that generalization and stability criteria for evaluation of clustering are not equivalent. Assume points in $\mathbb{R}^2$ are generated according to the following process. First, we select a center μ of a Gaussian according to a uniform distribution on a unit circle in $\mathbb{R}^2$. Then we generate a point $x \sim \mathcal{N}(\mu, \sigma^2 I)$ according to a Gaussian distribution centered at μ with a covariance matrix $\sigma^2 I$ for a fixed σ (I is a 2 by 2 identity matrix). Given a sample generated according to the above process we can apply a mixture of Gaussians clustering in order to learn the generating distribution. Note that:

1. Due to the circular symmetry in the generating process and model redundancy, the solution will always be unstable (the centers of Gaussians in the mixture of Gaussians model can move arbitrarily along the unit circle and their variance in the direction tangential to the circle is loosely constrained).

2. By increasing the sample size and the number of Gaussians in the mixture of Gaussians model the true density of the points can be approximated arbitrarily well.

Hence, models with good generalization properties are not necessarily stable. This point should be kept in mind when using generalization as an evaluation criterion in clustering.

10. Discussion and Future Work

This paper underlines the importance of external evaluation of unsupervised learning, such as clustering or more general structure learning, based on the context of its potential application. Such a form of evaluation is important for delivery of better structure learning algorithms as well as for better understanding of their outcome. We argue that structure learning does not occur for its own sake, but rather in order to facilitate a solution of some higher level goal. In any non-trivial data many structures co-exist simultaneously and it is a matter of the subsequent usage of the outcome of the learning algorithm to determine which of the structure elements are valuable and which are not. Therefore, unsupervised learning cannot be analyzed in isolation from its potential application. In our opinion, one of the main obstacles in theoretical advancement of unsupervised learning is an absence of a good mathematical definition of the context of its application. The analysis of co-clustering presented here is a first step toward context-based analysis of more complex models.

The work presented here started with an attempt to improve our understanding of clustering. We note that clustering is tightly related to the object naming process in human language. In a sense, a cluster is an entity that can be assigned a name. By clustering objects we ignore their irrelevant properties and concentrate on the relevant ones. And of course, this division can change according to our needs. For example, we can divide animals into birds and mammals or into flying and notatorial or into domestic and wild. Whereas the classification into birds and mammals or flying and notatorial may be considered intrinsic, the classification into domestic and wild is definitely application-oriented. In order to design successful clustering and categorization algorithms it is important to understand the basic principles behind this process. It is not a-priori clear that, if we restrict ourselves to pure prediction tasks, clustering the underlying sample space helps. As shown in Seldin and Tishby (2008); Seldin (2009), in classification by a single parameter there is no need to cluster the parameter space, but rather simple smoothing performs better. In classification in higher dimensional spaces, kernel-based methods can be superior to clustering-based approaches. However, we know that as humans we communicate by using a clustered representation of the world rather than by kernel matrices. Thus, there should be advantages for such form of communication. Identification, understanding, and analysis of these advantages is an important future direction for the design of better clustering and higher structure learning algorithms.

Acknowledgments

We are very grateful to the anonymous reviewers for their valuable comments that helped us to improve this manuscript significantly. We would also like to thank Ohad Shamir, Joachim M. Buhmann, and Suvrit Sra for helpful discussions. This work was supported in part by the Israel Science Foundation Bikura grant 942/09 and the NATO SfP BESAFE CBM.MD.SFPP-982480 grant.

Appendix A. Proof of Theorem 6

Proof of Theorem 6 First we prove inequality (14):

$$\begin{aligned}
-\mathbb{E}_{\mathcal{Q}(h)}\mathbb{E}_{p_h(z)}\ln\tilde{p}_h(Z) &= \mathbb{E}_{\mathcal{Q}(h)}\mathbb{E}_{[\hat{p}_h(z)-p_h(z)]}\ln\tilde{p}_h(Z) - \mathbb{E}_{\mathcal{Q}(h)}\mathbb{E}_{\hat{p}_h(z)}\ln\tilde{p}_h(Z) \\
&= \mathbb{E}_{\mathcal{Q}(h)}\mathbb{E}_{[\hat{p}_h(z)-p_h(z)]}\ln\frac{\hat{p}_h(Z)+\gamma}{1+\gamma|\mathcal{Z}|} - \mathbb{E}_{\mathcal{Q}(h)}\mathbb{E}_{\hat{p}_h(z)}\ln\frac{\hat{p}_h(Z)+\gamma}{1+\gamma|\mathcal{Z}|} \\
&\leq -\frac{1}{2}\|\hat{p}_{\mathcal{Q}}(z)-p_{\mathcal{Q}}(z)\|_1\ln\frac{\gamma}{1+\gamma|\mathcal{Z}|} + \mathbb{E}_{\mathcal{Q}(h)}H(\hat{p}_h(z)) + \ln(1+\gamma|\mathcal{Z}|) \\
&\leq H(\hat{p}_{\mathcal{Q}}(z)) - \sqrt{\varepsilon/2}\ln\frac{\gamma}{1+\gamma|\mathcal{Z}|} + \ln(1+\gamma|\mathcal{Z}|). \qquad (56)
\end{aligned}$$

The last inequality is justified by the concavity of the entropy function H and the KL-divergence bound on the L_1 norm (Cover and Thomas, 1991):

$$\|\hat{p}_{\mathcal{Q}}(z)-p_{\mathcal{Q}}(z)\|_1 \leq \sqrt{2KL(\hat{p}_{\mathcal{Q}}(z)\|p_{\mathcal{Q}}(z))} \leq \sqrt{2\varepsilon}.$$

By differentiation (56) is minimized by $\gamma = \frac{\sqrt{\varepsilon/2}}{|\mathcal{Z}|}$. By substitution of this value of γ into (56) we obtain (14). Inequality (15) is justified by (14) and the concavity of the $\ln$ function. Finally, we

prove the lower bound (16):

$$\begin{aligned}-\mathbb{E}_{p_{\mathcal{Q}}(z)} \ln \tilde{p}_{\mathcal{Q}}(Z) &= \mathbb{E}_{[\hat{p}_{\mathcal{Q}}(z)-p_{\mathcal{Q}}(z)]} \ln \tilde{p}_{\mathcal{Q}}(Z) - \mathbb{E}_{\hat{p}_{\mathcal{Q}}(z)} \ln \tilde{p}_{\mathcal{Q}}(Z) \\ &\geq -\frac{1}{2}\|\hat{p}_{\mathcal{Q}}(z) - p_{\mathcal{Q}}(z)\|_1 \ln \frac{1+\gamma|\mathcal{Z}|}{\gamma} + H(\hat{p}_{\mathcal{Q}}(z)) \\ &\geq H(\hat{p}_{\mathcal{Q}}(z)) - \sqrt{\varepsilon/2} \ln \frac{|\mathcal{Z}|(1+\sqrt{\varepsilon/2})}{\sqrt{\varepsilon/2}}.\end{aligned}$$

■

Appendix B. Treatment of Continuous Label Spaces $\mathcal{Y}$ via Quantization

In Theorems 7 and 13 it was assumed that the label space $\mathcal{Y}$ (or the edge weight space $\mathcal{W}$) is finite. However, for quadratic loss the minimization of $\mathcal{F}(\mathcal{Q}, \beta)$ by Algorithm 1 can return a solution that falls out of this finite space. Furthermore, the input space $\mathcal{Y}$ itself does not have to be finite (e.g., gene expression levels in bioinformatics can be given on a continuous scale). Here we show that the bound can be easily generalized to handle this case via quantization of $\mathcal{Y}$. The analysis can be seen as post-processing and does not require modifications of the trade-off $\mathcal{F}(\mathcal{Q}, \beta)$ and of Algorithm 1, since the algorithm does not assume finiteness of $\mathcal{Y}$.

Assume that $\mathcal{Y}$ is limited in [0,1] interval and apply uniform quantization of $\mathcal{Y}$ at intervals Δ, then $|\mathcal{Y}_\Delta| = \frac{1}{\Delta}$ ($\mathcal{Y}_\Delta$ is the quantized copy of $\mathcal{Y}$ and we assume that the quantization starts at $\frac{1}{2}\Delta$ and ends at $1 - \frac{1}{2}\Delta$). By rounding the continuous values of y obtained by Algorithm 1 toward the closest quantization both the empirical and the expected loss are increased by at most $2\Delta + \Delta^2$ (in the case of quadratic loss). This is because quantization can shift the true y and the prediction y' by at most $\frac{1}{2}\Delta$ and then $l(y - \frac{1}{2}\Delta, y' + \frac{1}{2}\Delta) = (y - y' - \Delta)^2 = (y - y')^2 - 2(y - y')\Delta + \Delta^2 \leq l(y, y') + 2\Delta + \Delta^2$, where the last inequality follows from the assumption that $\mathcal{Y}$ is limited in [0,1]. Hence, we have

$$L(\mathcal{Q}) \leq kl^{-1}\left(\hat{L}(\mathcal{Q}) + 2\Delta + \Delta^2, \frac{\sum_{i=1}^{d} n_i \bar{I}(X_i; C_i) + K}{N}\right) + 2\Delta + \Delta^2,$$

where K, defined previously in (38), becomes:

$$K = \sum_{i=1}^{d} m_i \ln n_i - M \ln \Delta + \frac{1}{2}\ln(4N) - \ln \delta.$$

As a rule of thumb one can choose $\Delta = kM/N$ for $k \approx 5$, so that the contribution of Δ to the two operands of the inverse KL-divergence is approximately equivalent. In general this correction for quantization has no significant influence on the bound (Seldin, 2010).

Abstract

Learning dynamic Bayesian network structures provides a principled mechanism for identifying conditional dependencies in time-series data. An important assumption of traditional DBN structure learning is that the data are generated by a stationary process, an assumption that is not true in many important settings. In this paper, we introduce a new class of graphical model called a non-stationary dynamic Bayesian network, in which the conditional dependence structure of the underlying data-generation process is permitted to change over time. Non-stationary dynamic Bayesian networks represent a new framework for studying problems in which the structure of a network is evolving over time. Some examples of evolving networks are transcriptional regulatory networks during an organism's development, neural pathways during learning, and traffic patterns during the day. We define the non-stationary DBN model, present an MCMC sampling algorithm for learning the structure of the model from time-series data under different assumptions, and demonstrate the effectiveness of the algorithm on both simulated and biological data.

Keywords: Bayesian networks, graphical models, model selection, structure learning, Monte Carlo methods

1. Introduction

A principled mechanism for identifying conditional dependencies in time-series data is provided through structure learning of dynamic Bayesian networks. An important requirement of this learning is that the time-series data is generated by a distribution that does not change with time—it is stationary. The assumption of stationarity is adequate in many situations since certain aspects of data acquisition or generation can be easily controlled and repeated. However, other interesting and important circumstances exist where that assumption does not hold and potential non-stationarity cannot be ignored.

The inspiration for this model of "networks evolving over time" comes primarily from neurobiology. Dynamic Bayesian networks have been used to identify networks of neural information flow that operate in the brains of songbirds (Smith et al., 2006). When a juvenile male songbird is born, he cannot sing any songs; however, as he ages, he learns songs from other birds singing around him. As the songbird learns from its environment, the networks of neural information flow slowly adapt to make the processing of sensory information more efficient. The analysis carried out by Smith et al. (2006) was limited by the fact that the researchers were forced to learn networks on subsets of the data since DBN structure learning algorithms assume stationarity of the data. Therefore, a learn-

ing algorithm based upon dynamic Bayesian networks that relaxes the data stationarity assumption would be ideally suited to this problem.

As another example, structure learning of DBNs has been used widely in reconstructing transcriptional regulatory networks from gene expression data (Friedman et al., 2000; Hartemink et al., 2001). But during development, these regulatory networks are evolving over time, with certain conditional dependencies between gene products being created as the organism develops, and others being destroyed. As yet another example, one can use a DBN to model traffic flow patterns. The roads upon which traffic passes do not change on a daily basis, but the dynamic utilization of those roads changes daily during morning rush, lunch, evening rush, and weekends.

If one collects time-series data describing the levels of gene products in the case of transcriptional regulation, traffic density in the case of traffic flow, or neural activity in the case of neural information flow, and attempts to learn a DBN describing the conditional dependencies in the time-series, one could be seriously misled if the data-generation process is non-stationary.

Here, we introduce a new class of graphical model called a non-stationary dynamic Bayesian network (nsDBN), in which the conditional dependence structure of the underlying data-generation process is permitted to change over time. In the remainder of the paper, we introduce and define the nsDBN framework, present a simple but elegant algorithm for efficiently learning the structure of an nsDBN from time-series data under a variety of different assumptions, and demonstrate the effectiveness of these algorithms on both simulated and experimental data.

1.1 Related Work

Representing relationships or statistical dependencies between variables in the form of a network is a popular technique in many communities, from economics to computational biology to sociology. Recently, researchers have been interested in elucidating the temporal evolution of genetic regulatory networks (Arbeitman et al., 2002; Luscombe et al., 2004) and neural information flow networks (Smith et al., 2006), but were forced to perform their analysis on subsets of the data since their structure learning algorithms assumed stationarity of the data. Additionally, some economics techniques require prior specification of a graphical model (for a particular data set) and assume it is stationary (Carvalho and West, 2007) when the data set may actually be highly non-stationary (Xuan and Murphy, 2007). Therefore, the identification of non-stationary behavior in graphical models is of significant interest and importance to many communities.

We divide models of evolving statistical dependencies into those that model changing structures and those that model changing parameters, and describe examples of both in this section. Additionally, we briefly explain how our approach compares and some of the advantages it provides over other methods.

1.1.1 STRUCTURAL NON-STATIONARITY

Approaches that learn structural non-stationarities are those that explicitly model the presence of statistical dependencies between variables and allow them to appear and disappear over time (e.g., they define directed or undirected networks whose edges change over time).

In recent work modeling the temporal progression of networks from the social networks community (Hanneke and Xing, 2006), the $p*$ or exponential random graph model (ERGM) (Wasserman and Pattison, 1996) was generalized to the temporal ERGM (tERGM) model, where a structural evolutionary process is modeled with a set of features between adjacent network structures (Han-

neke and Xing, 2006). The tERGM model was further extended to the hidden tERGM (htERGM) to handle situations where the networks are latent (unobserved) variables that generate observed time-series data (Guo et al., 2006, 2007).

While the transition model of an htERGM allows for nearly unlimited generality in characterizing how the network structure changes with time, it is restricted to functions of temporally adjacent network structures. Therefore, an evolutionary process that differs between early observations and later observations may not be effectively captured by a single transition model. Also, the emission model defined in Guo et al. (2007) must be estimated *a priori* and only captures pairwise correlations between variables; more complicated relationships between multiple variables that change over time may be missed altogether. Finally, Guo and colleagues focus on identifying undirected edges. Although it is possible to adapt the ERGM model for directed graphs, it becomes more difficult to define the parameters of the tERGM and the emission model assuming directed edges.

In the continuous domain, some research has focused on learning the structure of a time-varying undirected Gaussian graphical model (Talih and Hengartner, 2005). These authors use a reversible-jump MCMC approach to estimate the time-varying variance structure of the data. They explicitly model the network's edges as non-zeroes in the precision matrix. While this model allows for fast, efficient sampling, it only does so by defining several restrictions to the model space. First, the structural evolutionary process is piecewise-stationary and restricted to single edge changes. Rapid and significant structural changes would be approximated by a slowly changing network structure, resulting in an inaccurate portrayal of the true evolutionary behavior of the data-generating process. Additionally, the total number of segments or epochs in the piecewise stationary process is assumed known *a priori*, thereby limiting application of the method in situations where the number of epochs is not known. Finally, this approach only identifies undirected edges (correlations), while time-series data should allow one to identify directed edges (conditional dependencies).

A similar algorithm—also based on undirected Gaussian graphical models—has been developed to segment multivariate time-series data (Xuan and Murphy, 2007). This approach iterates between a convex optimization for determining the graph structure and a dynamic programming algorithm for calculating the segmentation. This results in some notable advantages over Talih and Hengartner (2005): it has no single edge change restriction and the number of segments is calculated *a posteriori*. The main restriction, however, is that the graph structure must be decomposable. Additionally, because this method models structure as non-zeroes in the precision matrix, it only identifies undirected edges. Finally, the networks (precision matrices) in each segment are assumed independent, preventing the sharing of parameters and data between segments.

Another recently proposed model for identifying evolving networks is the temporally smoothed l_1-regularized logistic regression (TESLA) method, described by Kolar et al. (2010) and Ahmed and Xing (2009). This approach involves learning a discrete binary Markov random field with sparse, varying parameters. A useful advantage of this model is that can be reparameterized to account for either smoothly varying or abrupt sudden changes to the network structure. Additionally, it scales well to thousands of nodes. However, it is undirected, requires binary data, and only captures pairwise relationships between variables. The binary input and pairwise relationship requirements may be relaxed, but the likelihood function would have to be significantly modified to incorporate cliques; the resulting optimization problem might become intractable.

1.1.2 PARAMETER NON-STATIONARITY

Approaches that learn parameter non-stationarities are those that explicitly model the evolution of parameters over time. Here we only focus on a few that can be represented as networks with temporally changing parameters.

Switching state-space models (SSMs) represent a piecewise-stationary extension of linear dynamic systems (Ghahramani and Hinton, 2000). In an SSM, a sequence of observations is modeled as a function of several independent hidden variables which is itself controlled by a switch variable. The hidden variables as well as the switch variable all have Markovian dynamics. While this approach is similar to ours in that it describes the evolution of a piecewise-stationary process, it does have some notable differences. Our model has no hidden variables, only observed variables. Critically, our variables are not assumed to be independent; rather, their dependencies are unknown and must be estimated *a posteriori*. Additionally, the piecewise-stationary process in our approach does not follow Markovian dynamics, like the switch variable in an SSM.

A more closely related model is the recently published non-homogeneous Bayesian network (Grzegorczyk et al., 2008). In this model, the conditional distributions of the variables are assumed to follow a mixture of Gaussians. Each observation is allocated to a single mixture component where the parameters and number of the mixture components are determined *a posteriori* using an allocation sampler. Unfortunately, an allocation sampler does not allow data to be shared across different mixture components since they are assumed independent. However, this model seems to do a good job of capturing the non-stationary behavior of parameters in a Gaussian Bayesian network, assuming that the underlying structure is inferred correctly.

1.1.3 OUR APPROACH

Although we provide more detail in Section 3, for the purpose of comparison, we define our approach as the identification of a discrete Bayesian network that evolves according to a piecewise-stationary process where edges are gained and lost over time. Building on the Bayesian network model allows us to identify directed networks and results in efficient learning (under certain assumptions). Additionally, when the conditional probability distributions of the Bayesian network are multinomial, we can identify linear, non-linear, and combinatorial interactions between variables. Finally, the piecewise-stationary assumption (and additional constraints on how and when edge changes occur) allows our method to scale to large data sets with many variables and provides a natural parameterization for placing priors on the structural evolution process.

Our method falls into the category of models that identify non-stationarities in structure, not parameters. In the rest of this paper, we define non-stationarities as times at which conditional dependencies between variables are gained or lost (i.e., edges are gained or lost). We have chosen to focus on structural non-stationarity for several reasons. First, we are not as interested in making predictions about future data (such as might be the case with spam prediction) as we are in the analysis of collected data to identify non-stationary statistical relationships between variables in multivariate time-series. Additionally, the problems we analyze in this paper are highly multimodal in the posterior over structures and likely to be even more varied in the posterior over parameters. By assuming conjugate parameter priors, we address both problems by averaging out all possible parameters and only examining the posterior over structures.

However, we recognize that the parameters of the conditional distributions may also change with time. Some changes to the parameters of the conditional distributions may effectively result in

a structural change, while other changes may be dramatic, yet not alter the structure. Ultimately, a trade-off must be made between simplifying model assumptions resulting in greater statistical power versus a completely general framework requiring approximation schemes. Under our modeling assumptions, we can identify non-stationarities in the parameters of the conditional distributions that are significant enough to result in structural changes; we assume other changes are small enough to not alter edges in the predicted structure.

2. Brief Review of Structure Learning of Bayesian Networks

Bayesian networks are directed acyclic graphical models that represent conditional dependencies between variables as edges. They define a simple decomposition of the complete joint distribution—a variable x_i is conditionally independent of its non-descendants given its parents. Therefore, the joint distribution of every variable x_i can be rewritten as $P(x_1,\ldots,x_n) = \prod_i P(x_i|\pi_i)$, where π_i are the parents of x_i. Bayesian networks may be learned on time-series data, but the semantics are slightly different, leading to the dynamic Bayesian network (DBN) model. DBNs enable cyclic dependencies between variables to be modeled across time. DBNs are a special case of Bayesian networks, with modeling assumptions regarding how far back in time one variable can depend on another (minimum and maximum lag), and constraints placed on edges so that they do not go backwards in time. For notational simplicity, we assume hereafter that the minimum and maximum lag are both 1.

The task of inferring the structure (i.e., the set of conditional dependencies) of a Bayesian network is typically expressed using Bayes' rule, where the posterior probability of a given network structure G (i.e., the set of conditional dependencies) after having observed data D is given by

$$P(G|D) = \frac{P(D|G)P(G)}{P(D)}.$$

Since $P(D)$ is the same for all structures, we see that $P(G|D) \propto P(D|G)P(G)$. The prior over networks $P(G)$ can be used to incorporate prior knowledge about the existence of specific edges (Bernard and Hartemink, 2005) or the overall topology of the network (e.g., sparse); often, prior knowledge is not available and $P(\Theta)$ is assumed uniform. The marginal likelihood $P(D|G)$ is further defined in terms of the parameters Θ_i of the conditional probability distributions (CPDs) between a variable and its parents $P(x_i|\pi_i,\Theta_i)$. The entire set of parameters Θ_i for all variables is simply Θ.

$$P(D|G) = \int P(D|\Theta,G)P(\Theta|G)\mathrm{d}\Theta. \tag{1}$$

One might be interested in inferring the values of Θ given a particular network, but we will be focusing on learning the network itself, or the set of conditional dependencies. In computer science, this task is often referred to as structure learning; in statistics, it is often called model selection. More detailed reviews of structure learning of Bayesian networks can be found in Buntine (1996), Chrisman (1998), Krause (1998), and Murphy (2001).

For the remainder of this section, we review the most common approaches to inferring dynamic Bayesian networks, thereby setting the stage for what changes we will need to make in the following section to handle inference in the non-stationary setting. For brevity, we will focus on dynamic Bayesian networks with discrete variables, though the ideas could also be applied to networks of continuous variables. Details specific to structure learning of Bayesian networks with continuous variables can be found in Hofmann and Tresp (1995) and Margaritis (2005).

2.1 Evaluating the Marginal Likelihood $P(D|G)$

Evaluation of the marginal likelihood in Equation (1) can be performed either approximately or exactly. The marginal likelihood can be approximated with the Akaike information criterion (AIC), the Bayesian information criterion (BIC) (Friedman et al., 1998), or the minimum description length (MDL) (Lam and Bacchus, 1994; Suzuki, 1996) metric. Each of these metrics suggests how model complexity should be penalized. For example, the AIC metric penalizes free parameters less strongly than the BIC metric; therefore, a Bayesian network learned using the AIC metric would be likely be more dense than a Bayesian network learned using the BIC metric.

Alternatively, if a conjugate prior is placed on Θ which is then marginalized out, the value of $P(D|G)$ can be computed exactly. Assuming that Θ parameterizes multinomially distributed conditional probability distributions, one can place a conjugate Dirichlet prior on the parameters Θ and then marginalize them out to obtain the Bayesian-Dirichlet (BD) metric. The BD metric can be further modified so that all of the networks that represent the same set of conditional independence relationships have the same probability; this is called the Bayesian-Dirichlet equivalent (BDe) metric (Heckerman et al., 1995). By using a Dirichlet prior and marginalizing over all values of Θ, the BD and BDe metrics inherently penalize more complex models, so a prior on the network $P(G)$ may not always be necessary. The primary advantage of the BD family of metrics is that the evaluation of $P(D|G)$ is exact and can be computed in closed form. However, if the assumption that the parameters of CPDs are multinomially distributed is incorrect, these metrics might not find the true network of conditional dependencies.

Since we will be modifying it later in this paper, we show the closed-form expression for the BDe metric below:

$$P(D|G) = \prod_{i=1}^{n} \prod_{j=1}^{q_i} \frac{\Gamma(\alpha_{ij})}{\Gamma(\alpha_{ij}+N_{ij})} \prod_{k=1}^{r_i} \frac{\Gamma(\alpha_{ijk}+N_{ijk})}{\Gamma(\alpha_{ijk})} \tag{2}$$

where q_i is the number of configurations of the parent set π_i, r_i is the number of discrete states of variable x_i, N_{ijk} is the number of times x_i took on the value k given the parent configuration j, $N_{ij} = \sum_{k=1}^{r_i} N_{ijk}$, and α_{ij} and α_{ijk} are Dirichlet hyper-parameters on various entries in Θ. If α_{ijk} is set to $\alpha/(q_i r_i)$ (essentially a uniform Dirichlet prior), we get a special case of the BDe metric: the uniform BDe metric (BDeu), whose parameter priors are all controlled by a single hyperparameter α.

2.2 Deciding Between Search or Sampling Strategies

Once a form of the marginal likelihood $P(D|G)$ is defined and a method for evaluating it is chosen, one must decide whether the objective is to identify the best network or to capture the uncertainty over the space of all posterior networks. Search methods may be used to find the best network or set of networks (i.e., a mode in the space of all networks), while sampling methods may be used to estimate posterior quantities from the space of all networks.

Search methods may be exact or heuristic, but exact search for Bayesian networks is computationally infeasible for more than about 30 variables because the number of possible networks is super-exponential in the number of variables. In fact, identifying the highest scoring Bayesian network has been shown to be NP-Hard (Chickering et al., 1994). If the maximum number of parents for any variable is limited to some constant p_{max}, the total number of valid networks becomes exponential in the number of variables; however, finding the best network is still NP-Hard (for $p_{max} \geq 2$). Therefore, heuristic searches are often employed, including greedy hill-climbing,

simulated annealing (Heckerman et al., 1995), the K2 algorithm (Chickering et al., 1995), genetic algorithms (Larrañaga et al., 1996), and even ant colony optimization (de Campos et al., 2002). Most heuristic searches perform well in a variety of settings, with greedy hill-climbing and simulated annealing being the most commonly used techniques.

A different approach from search is the use of sampling techniques (Madigan et al., 1995; Giudici et al., 1999; Tarantola, 2004). If the best network is all that is desired, heuristic searches will typically find it more quickly than sampling techniques. However, sampling methods allow the probability or importance of individual edges to be evaluated over all possible networks. In settings where many modes are expected, sampling techniques will more accurately capture posterior probabilities regarding various properties of the network. The primary disadvantage of sampling methods in comparison to search methods is that they often take longer before accurate results become available.

A common sampling technique often used in this setting is the Metropolis-Hastings algorithm, which is a Markov chain Monte Carlo (MCMC) method. The M-H acceptance probability for moving from state x to state x' is shown below, where each *state* is a DBN.

$$\alpha(x,x') = \min\left\{1, \frac{p(D|x')}{p(D|x)} \times \frac{p(x' \to x)}{p(x \to x')}\right\} = \min\left\{1, \underbrace{\frac{p(D|x')}{p(D|x)}}_{\textit{likelihood ratio}} \times \underbrace{\frac{\sum_{M'} p(M')p(x|x',M')}{\sum_{M} p(M)p(x'|x,M)}}_{\textit{proposal ratio}}\right\} \quad (3)$$

where M is the move type that allows for a transition from state x to x' and M' is the reverse move type for a transition from state x' back to state x. While multiple moves may result in a transition from state x to state x' (and vice versa), typically there is only a single move for each transition. In such a case, the sums over M and M' each only include one term, and the proposal ratio can be split into two terms: one is the ratio of the proposal probabilities for move types and the other is the ratio of selecting a particular state given the current state and the move type. The choice of scoring metric determines the likelihoods, and $p(M')$ and $p(M)$ are often chosen *a priori* to be equivalent or simple to calculate.

2.3 Determining the Move Set

Once a search or sampling strategy has been selected, one must determine how to move through the space of all networks. A *move set* defines a set of local traversal operators for moving from a particular state (i.e., a network) to nearby states. The set of states that can be reached from the current one is often called the *local neighborhood* of that state. The values of $p(x'|x,M)$ and $p(x|x',M)$ in the proposal ratio are defined by the move set.

Ideally, the move set includes changes that allow posterior modes to be frequently visited. For example, it is reasonable to assume that networks that differ by a single edge will have similar likelihoods. A well-designed move set results in fast convergence since less time is spent in the low probability regions of the state space. For example, with traditional Bayesian networks, Madigan et al. (1995) proposed that the move set be: *add an edge* and *delete an edge*. However, it was later shown by Giudici and Castelo (2003) that the convergence rate could be increased with the addition of another move to the move set: *reverse an edge*.

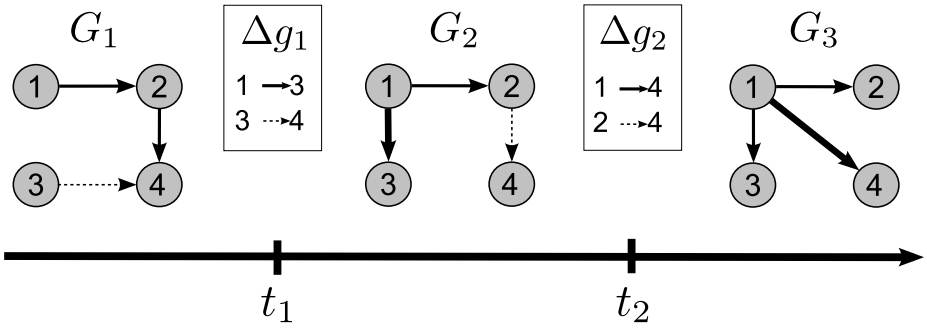

Figure 1: An example nsDBN with labeled components (namely, transition times t_1 and t_2 and edge change sets Δg_1 and Δg_2). Edges that are gained from the previous epoch are shown as thicker lines and edges that will be lost in the next epoch are shown as dashed lines. Note that the network at each epoch is actually a DBN drawn in compact form, where each edge represents a statistical dependence between a node at time t and its parent at the previous time $t-1$.

3. Learning Non-Stationary Dynamic Bayesian Networks

While DBNs are excellent models for describing dependencies between time-series random variables, they cannot represent or reason about how these dependencies might change over time. In contrast, our nsDBN model is capable of characterizing dependencies between temporally observed variables, as well as reasoning about whether and how those dependencies change. Because DBNs are well studied and well understood, we have chosen to introduce the details of our nsDBN model by building upon the existing DBN model. Therefore, we use this section to detail how the structure learning procedure for DBNs needs to be modified and extended to account for non-stationarity when learning a non-stationary DBN.

Assume that we observe the state of n random variables at N discrete times. Call this multivariate time-series data D, and further assume that it is generated according to a non-stationary process, which is unknown. The process is non-stationary in the sense that the network of conditional dependencies prevailing at any given time is itself changing over time. We call the initial (dynamic) network of conditional dependencies G_1 and subsequent networks are called $G_2, G_3, \ldots, G_m$. We define Δg_i to be the set of edges that change (either added or deleted) between G_i and G_{i+1}. The number of edge changes specified in Δg_i is s_i. We define the *transition time* t_i to be the time at which G_i is replaced by G_{i+1} in the data-generation process. We call the period of time between consecutive transition times—during which a single network of conditional dependencies is operative—an *epoch*. So we say that G_1 prevails during the first epoch, G_2 prevails during the second epoch, and so forth. We will refer to the entire series of prevailing networks as the *structure* of the nsDBN. Figure 1 shows an example nsDBN with the components labeled.

3.1 Updating the Marginal Likelihood and Incorporating Priors

Since we wish to estimate a set of networks instead of one network we must derive a new expression for the marginal likelihood. Consider the simplest case where $m = 2$ and the transition time t_1 at which the structure of the nsDBN evolves from network G_1 to network G_2 is known. We would like

to find the networks G_1 and G_2 that have the highest probability given the observed time-series data D and prior. Thus, we want to find the networks that maximize the expression below:

$$P(G_1, G_2|D, t_1) = \frac{P(D|G_1, G_2, t_1)P(G_1, G_2|t_1)}{P(D|t_1)} \propto P(D|G_1, G_2, t_1)P(G_1, G_2|t_1).$$

To maximize the marginal likelihood $P(D|G_1, G_2, t_1)$ in the above expression, one approach might be to estimate a different network for each epoch. Unfortunately, if the number of observations in each epoch is small, accurate reconstruction of the correct structure may be difficult or impossible (Friedman and Yakhini, 1996; Smith et al., 2003). Additionally, learning each network separately might lead to predictions that are vastly different during each epoch. If prior knowledge about the problem dictates that the networks will not vary dramatically across adjacent epochs, information about the networks learned in adjacent epochs can be leveraged to increase the accuracy of the network learned in the current epoch.

Expanding the simple formulation to multiple epochs, assume there exist m different epochs with transition times $T = \{t_1, \ldots, t_{m-1}\}$. The network G_{i+1} prevailing in epoch $i+1$ differs from network G_i prevailing in epoch i by a set of edge changes we call Δg_i. We would like to determine the sequence of networks $G_1, \ldots, G_m$ that maximize the posterior given below:

$$P(G_1, \ldots, G_m|D, T) \propto P(D|G_1, \ldots, G_m, T)P(G_1, \ldots, G_m|T). \tag{4}$$

Since each network differs from the previous one by a set of edge changes, we can rewrite the prior and obtain the expression below:

$$P(G_1, \ldots, G_m|T) = P(G_1, \Delta g_1, \ldots, \Delta g_{m-1}|T).$$

By writing the objective function this way, we rephrase the problem as finding the initial network and $m-1$ sets of edge changes that best describe the data. Unfortunately, the search space for finding the best structure is still super-exponential (in n) for the initial network and the task of identifying the other networks is exponential (in both m and n). However, using this formulation, it is easy to place some constraints on the search space to reduce the number of valid structures. If we specify that the maximum number of parents for any variable is p_{max} and, through priors, require that the maximum number of edge changes for any Δg_i is s_{max}, the search space for finding the best structure becomes exponential (in n) for the initial network and exponential (in m and s_{max}) for the other networks.

We assume the prior over networks can be further split into components describing the initial network and subsequent edge changes, shown below:

$$P(G_1, \Delta g_1, \ldots, \Delta g_{m-1}|T) = P(G_1)P(\Delta g_1, \ldots, \Delta g_{m-1}|T).$$

leading to the final form of the posterior

$$P(G_1, \Delta g_1, \ldots, \Delta g_{m-1}|D, T) \propto P(D|G_1, \Delta g_1, \ldots, \Delta g_{m-1}, T)P(G_1)P(\Delta g_1, \ldots, \Delta g_{m-1}|T). \tag{5}$$

As in the stationary setting, if prior knowledge about particular edges or overall topology is available, an informative prior can be placed on $P(G_1)$. In the context of the simulations and experiments in this paper, we had no prior knowledge about the network; thus, we assumed a uniform prior on $P(G_1)$. We do, however, place some prior assumptions on the ways in which edges change in the

structure. First, we assume that the networks evolve smoothly over time. To encode this prior knowledge, we place a truncated geometric prior with parameter $p = 1 - e^{-\lambda_s}$ on the number of changes (s_i) in each edge change set (Δg_i), with the distribution truncated for $s_i > s_{max}$. For the problems we explore, the truncation has no noticeable effect since s_{max} is chosen to be large. The updated posterior for the structure is given below:

$$\begin{aligned} P(G_1, \Delta g_1, \ldots, \Delta g_{m-1} | D, T) &\propto P(D|G_1, \ldots, G_m, T) \prod_i \frac{\left(1 - e^{-\lambda_s}\right)\left(e^{-\lambda_s}\right)^{s_i}}{1 - \left(e^{-\lambda_s}\right)^{s_{max}+1}} \\ &\propto P(D|G_1, \ldots, G_m, T) \prod_i \left(e^{-\lambda_s}\right)^{s_i} \\ &\propto P(D|G_1, \ldots, G_m, T) e^{-\lambda_s s}, \end{aligned}$$

where $s = \sum_i s_i$. Therefore, a (truncated) geometric prior on each s_i is essentially equivalent to a (truncated) geometric prior on the sufficient statistic s, the total number of edge changes.

When the transition times are *a priori* unknown, we would like to estimate them. The posterior in this setting becomes

$$\begin{aligned} P(G_1, \Delta g_1, \ldots, \Delta g_{m-1}, T | D) &\propto P(D|G_1, \ldots, G_m, T) P(G_1, \Delta g_1, \ldots, \Delta g_{m-1}, T) \\ &= P(D|G_1, \ldots, G_m, T) P(G_1) P(\Delta g_1, \ldots, \Delta g_{m-1}, T) \\ &= P(D|G_1, \ldots, G_m, T) P(G_1) P(\Delta g_1, \ldots, \Delta g_{m-1}) P(T). \end{aligned}$$

We assume that the joint prior over the evolutionary behavior of the network and the locations of transition times can be decomposed into two independent components. We continue to use the previous geometric prior with parameter $p = 1 - e^{-\lambda_s}$ on the total number of edge changes. Any choice for $P(T)$ can be made, but for the purposes of this paper, we have no prior knowledge about the transition times; therefore, we assume a uniform prior on T so that all settings of transition times are equally likely for a given value of m.

Finally, when neither the transition times nor the number of epochs are known *a priori*, both the number and times of transitions must be estimated *a posteriori*. If prior knowledge dictates that the networks evolve slowly over time (i.e., a transition does not occur at every observation), we can include this knowledge by placing a non-uniform prior on m, for example a (truncated) geometric prior with parameter $p = 1 - e^{\lambda_m}$ on the number of epochs m, with the distribution truncated for $m > N$. A geometric prior on the number of epochs is equivalent to a geometric prior on epoch lengths (see Appendix A).

The form of the geometric prior was chosen for convenience since under a log transformation, the likelihood (and prior) calculations reduce to: $\log(\text{likelihood}) - \lambda_s s - \lambda_m m$. In general, large values of λ_m encode the strong prior belief that the structure changes slowly (i.e., few epochs exist) and large values of λ_s encode the strong prior belief that the structure changes smoothly (i.e., few edge changes exist).

Fortunately, the likelihood component of the posterior does not change whether we know the transition times *a priori* or not. Therefore, any uncertainty about the transition times can be incorporated into the evaluation of the prior, leaving the evaluation of the likelihood unchanged.

3.2 Evaluating the New Marginal Likelihood

Now that a new likelihood has been defined, we must decide on which method to use for evaluation and how to modify it to account for multiple structures. Any of the previously mentioned metrics

can be modified to account for non-stationarity, but we chose to extend the BDe metric because it is exact and because edges are the only representation of conditional dependencies that are left after the parameters have been marginalized away. This provides a useful paradigm for non-stationarity that is both simple to define and easy to analyze.

The BDe metric needs to be modified when learning an nsDBN because in Equation (2), N_{ij} and N_{ijk} are calculated for a particular parent set over the entire data set D. However, in an nsDBN, a node may have multiple parent sets operative at different times. The calculation for N_{ij} and N_{ijk} must therefore be modified to specify the *intervals* during which each parent set is operative. Note that an interval may include several epochs. An epoch is defined between adjacent transition times while an interval is defined as the union of consecutive epochs during which a particular parent set is operative (which may include all epochs).

For each node i, the parent set π_i in the BDe metric is replaced by a set of parent sets π_{ih}, where h indexes the interval I_h during which parent set π_{ih} is operative for node i. Letting p_i be the number of such intervals and q_{ih} be the number of configurations of π_{ih} results in the expression below:

$$P(D|G_1,\ldots,G_m,T) \propto \prod_{i=1}^{n}\prod_{h=1}^{p_i}\prod_{j=1}^{q_{ih}} \frac{\Gamma(\alpha_{ij}(I_h))}{\Gamma(\alpha_{ij}(I_h)+N_{ij}(I_h))}\prod_{k=1}^{r_i}\frac{\Gamma(\alpha_{ijk}(I_h)+N_{ijk}(I_h))}{\Gamma(\alpha_{ijk}(I_h))}$$

where the counts N_{ijk} and pseudocounts α_{ijk} have been modified to apply only to the data in each interval I_h. The modified BDe metric will be referred to as nsBDe. Given that $|I_h| = t_{h+1} - t_h$, we set $\alpha_{ijk}(I_h) = (\alpha_{ijk}|I_h|)/N$ (e.g., proportional to the length of the interval during which that particular parent set is operative). If α_{ijk} is set everywhere to $\alpha/(q_i r_i)$ as in the BDeu metric, then we generalize the BDeu metric to nsBDeu, and the parameter priors are again all controlled by a single hyperparameter α.

The derivation of the BDe metric requires seven assumptions: multinomial sample, parameter independence, likelihood modularity, parameter modularity, Dirichlet distribution for parameters, complete data, likelihood equivalence, and structure possibility (Heckerman et al., 1995). To extend the BDe metric to account for non-stationary behavior, we must extend only the parameter independence assumption.

Parameter independence is split into local parameter independence and global parameter independence. Letting G represent an individual network, global parameter independence is represented as $p(\Theta_G|G) = \prod_{i=1}^{n} p(\Theta_i|G)$. In other words, the conditional probabilities can be decomposed by variable. Local parameter independence is represented as $p(\Theta_i|G) = \prod_{j=1}^{q_i} p(\Theta_{ij}|G)$; the conditional probabilities for each variable are decomposable by parent configuration.

For nsDBNs, we also need to assume parameter independence across intervals. Parameter independence is thus split into three assumptions. The updated parameter independence assumptions are defined below, where $\mathbb{G}$ represents an nsDBN structure, or set of networks.

Global parameter independence: The conditional probabilities are decomposable by variable:

$$p(\Theta_{\mathbb{G}}|\mathbb{G}) = \prod_{i=1}^{n} p(\Theta_i|\mathbb{G}).$$

Interval parameter independence: The conditional probabilities for each variable are decomposable by interval:

$$p(\Theta_i|\mathbb{G}) = \prod_{h=1}^{p_i} p(\Theta_{ih}|\mathbb{G}).$$

Local parameter independence: The conditional probabilities for each variable for each interval are decomposable by parent configuration:

$$p(\Theta_{ih}|\mathbb{G}) = \prod_{j=1}^{q_{ih}} p(\Theta_{ihj}|\mathbb{G}).$$

3.3 Using a Sampling Strategy and Choosing a New Move Set

We decide to take a sampling approach rather than using heuristic search because the posterior over structures includes many modes. In particular, when the transition times are not known *a priori*, the posterior is highly multimodal because structures with slightly different transition times likely have similar posterior probabilities. Additionally, sampling offers the further benefit of allowing us to evaluate interesting posterior quantities, such as when are the most likely times at which transitions occur—a question that would be difficult to answer in the context of heuristic search.

Because the number of possible nsDBN structures is so large (significantly greater than the number of possible DBNs), we must be careful about what is included in the move set. To provide quick convergence, we want to ensure that every move in the move set efficiently jumps between posterior modes. Therefore, the majority of the next section is devoted to describing effective move sets under different levels of uncertainty.

4. Settings

Each of the following subsections demonstrates a method for calculating an nsDBN under a variety of *settings* that differ in terms of the level of uncertainty about the number and times of transitions. The different settings will be abbreviated according to the type of uncertainty: whether the *number* of transitions is *known* (KN) or *unknown* (UN) and whether the transition *times* themselves are *known* (KT) or *unknown* (UT). Figure 2 shows plate diagrams relating the DBN model to the three different settings of the nsDBN model, described in the following subsections.

4.1 Known Number and Known Times of Transitions (KNKT)

In the KNKT setting, we know all of the transition times *a priori*; therefore, we only need to identify the most likely initial network G_1 and sets of edge changes $\Delta g_1, \ldots, \Delta g_{m-1}$. Thus, we wish to maximize Equation (5).

To create a move set that results in an effectively mixing chain, we consider which types of local moves result in jumps between posterior modes. As mentioned earlier, networks that differ by a single edge will probably have similar likelihoods. Therefore, the move set includes a single edge addition or deletion to G_1. Each of these moves results in the structural difference of a single edge over all observations. One can also consider adding or deleting an edge in a particular Δg_i; this results in the structural difference of a single edge for all observations after t_i. Finally, we consider moving an edge from one Δg_i to another, which results in the structural difference of a single edge for all observations between t_i and t_j. These moves are listed as M_1–M_5 in Table 1, along with the various proposal probabilities defined in the Metropolis-Hastings acceptance ratio shown in Equation (3).

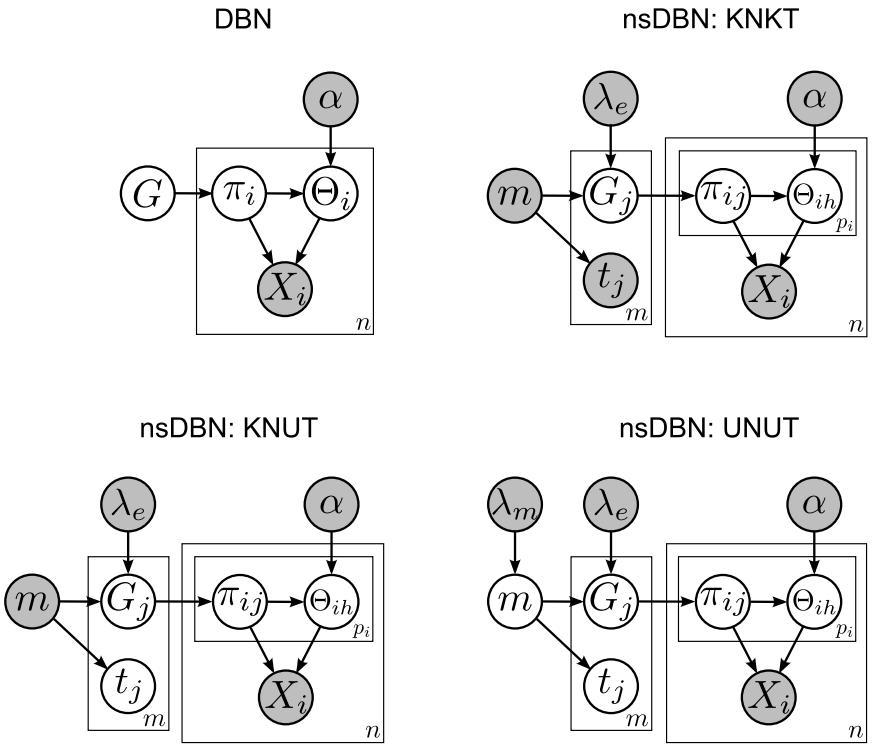

Figure 2: Plate diagrams relating DBNs to nsDBNs under each setting. Gray circles represent quantities that are known *a priori* while white circles represent those that are unknown. Non-stationary DBNs may have multiple networks (m, indexed by j) and multiple different parent sets for each variable (p_i for variable i, indexed by h). In the KNKT setting, the transition times t_j are known *a priori*, but they must be estimated in the two other settings. In the KNUT setting, the number of epochs m is still known, but the transition times themselves are not. Finally, in the UNUT setting, even the number of epochs is unknown; instead a truncated geometric prior is placed on m.

4.2 Known Number But Unknown Times of Transitions (KNUT)

Knowing in advance the times at which all the transitions occur, as was assumed in the previous subsection, is often unrealistic. To relax this assumption, we now assume that while m is known, the set T is not given *a priori* but must also be estimated. Thus, rather than maximizing Equation (5), we maximize the expression below:

$$P(G_1, \Delta g_1, \ldots, \Delta g_{m-1}, T|D).$$

Structures with the same edge sets but slightly different transition times will probably have similar likelihoods. Therefore, we can add a new move that proposes a local shift to one of the transition times: let d be some small positive integer and let the new time t_i' be drawn from a discrete uniform distribution $t_i' \sim DU(t_i - d, t_i + d)$ with the constraint that $t_{i-1} < t_i' < t_{i+1}$. Initially, we set the $m-1$ transition times so that the epochs are roughly equal in length. This placement allows the transition times ample room to locally shift without "bumping" into each other too early in the sampling

procedure. The complete move set for this setting includes all of the moves described previously as well as this new *local shift move*, listed as M_6 in Table 1.

As with the last setting, the number of epochs does not change; therefore, only the prior on the number of edge changes s is used.

4.3 Unknown Number and Unknown Times of Transitions (UNUT)

In the most general UNUT setting, both the transition times T and the number of transitions are unknown and must be estimated. While this is the most interesting setting, it is also the most difficult. Since the move set from the KNUT setting provides a solution to this problem when m is known, a simple approach would be to try various values of m and then determine which value of m seems optimal. However, this approach is theoretically unsatisfying and would be incredibly slow. Instead, we will further augment the move set to allow the number of transitions to change. Since both the number of edge changes s and the number of epochs m are allowed to vary, we need to incorporate both priors mentioned in Section 3.1 when evaluating the posterior.

To allow the number of epochs m to change during sampling, we introduce *merge* and *split* operations to the move set. For the merge operation, two adjacent edge sets (Δg_i and Δg_{i+1}) are combined to create a new edge set. The transition time of the new edge set is selected to be the mean of the previous locations weighted by the size of each edge set: $t_i' = (s_i t_i + s_{i+1} t_{i+1})/(s_i + s_{i+1})$. For the split operation, an edge set Δg_i is randomly chosen and randomly partitioned into two new edge sets $\Delta g_i'$ and $\Delta g_{i+1}'$ with all subsequent edge sets re-indexed appropriately. Each new transition time is selected as described above. The move set is completed with the inclusion of the *add transition time* and *delete transition time* operations. These moves are similar to the split and merge operations except they also increase or decrease s, the total number of edge changes in the structure. The four additional moves are listed as M_7–M_{10} in Table 1.

4.4 MCMC Sampler Implementation Details

In practice, the sampler is designed so that the proposal ratio $\frac{p(M')}{p(M)} \frac{p(x|x',M')}{p(x'|x,M)}$ is exactly 1 for most moves. For example, if either move M_1 or move M_2 is randomly selected, the sampling procedure is as follows: random variables x_i and x_j are selected, if the edge $x_i \to x_j$ exists in G_1, it is deleted, otherwise it is added (subject to the maximum of p_{max} parents constraint). We know that the maximal number of edges in G_1 is np_{max} (due to the maximum parent constraint) and we let E_1 be the current number of edges in G_1. If we are making move M_1, the probability that we select a legal edge to add is $P_a = \frac{np_{max}-E_1}{np_{max}}$. The probability of making the reverse move (from x' back to x) is $P_d = \frac{E_1+1}{np_{max}}$. The resulting proposal ratio is thus:

$$\frac{P_d}{P_a} \frac{p(x|x',M_2')}{p(x'|x,M_1)} = \frac{E_1+1}{np_{max}-E_1} \frac{np_{max}-E_1}{E_1+1} = 1.$$

A similar approach can be applied to the other moves.

This paradigm also handles boundary cases: if G_1 is complete, then $P(M_1) = 0$; if G_1 is empty, then $P(M_2) = 0$; if $s_i = s_{max} \forall i$, then $P(M_3) = 0$; if $s_i = 1 \forall i$, then $P(M_4) = 0$; etc.

The relative proposal probabilities between different moves are designed so that all pairs of complementary moves (a move and its reverse move) are equally likely. Under the KNKT setting, $P_a + P_d = P_{ae} + P_{de} = 2P_{me}$. Under the KNUT setting, $P_a + P_d = P_{ae} + P_{de} = 2P_{me} = 2P_{st}$. Finally, under the UNUT setting, $P_a + P_d = P_{ae} + P_{de} = 2P_{me} = 2P_{st} = P_m + P_s = P_{ag} + P_{dg}$.

Move type M	Proposal probability	$\frac{p(M')}{p(M)}$	$\frac{p(x\|x',M')}{p(x'\|x,M)}$	
(M_1) add edge to G_1	P_a	$\frac{P_d}{P_a}$	$\frac{(E_1+1)^{-1}}{(np_{max}-E_1)^{-1}} = \frac{np_{max}-E_1}{E_1+1}$	KNKT, KNUT, UNUT
(M_2) delete edge from G_1	P_d	$\frac{P_a}{P_d}$	$\frac{(np_{max}-E_1+1)^{-1}}{E_1^{-1}} = \frac{E_1}{np_{max}-E_1+1}$	KNKT, KNUT, UNUT
(M_3) add edge to Δg_i	P_{ae}	$\frac{P_{de}}{P_{ae}}$	$\frac{m^{-1}(S_i+1)^{-1}}{m^{-1}(S_{max}-S_i)^{-1}} = \frac{S_{max}-S_i}{S_i+1}$	KNKT, KNUT, UNUT
(M_4) delete edge from Δg_i	P_{de}	$\frac{P_{ae}}{P_{de}}$	$\frac{m^{-1}(S_{max}-S_i+1)^{-1}}{m^{-1}S_i^{-1}} = \frac{S_i}{S_{max}-S_i+1}$	KNKT, KNUT, UNUT
(M_5) move edge from Δg_i to Δg_j	P_{me}	1	$\frac{(m-1)^{-1}(\sum_i S_i)^{-1}}{(m-1)^{-1}(\sum_i S_i)^{-1}} = 1$	KNKT, KNUT, UNUT
(M_6) locally shift t_i	P_{st}	1	$\frac{(2d+1)^{-1}}{(2d+1)^{-1}} = 1$	KNUT, UNUT
(M_7) merge Δg_i and Δg_{i+1}	P_m	$\frac{P_s}{P_m}$	$\frac{(m-1)\mathbb{1}^1 2(S_i+S_{i+1})^{-1}\binom{S_i+S_{i+1}}{S_i}^{-1}}{(m-1)^{-1}} = \frac{2}{(S_i+S_{i+1})\binom{S_i+S_{i+1}}{S_i}}$	KNUT, UNUT
(M_8) split Δg_i	P_s	$\frac{P_m}{P_s}$	$\frac{(m-1)^{-1}}{(m-1)^{-1}(S_i/2)^{-1}\binom{S_i}{x}^{-1}} = (S_i/2)\binom{S_i}{x}$	KNUT, UNUT
(M_9) create new Δg_i	P_{ag}	$\frac{P_{dg}}{P_{ag}}$	$\frac{(m+1)^{-1}}{(N-m)^{-1}n^{-2}} = \frac{(N-m)n^2}{m+1}$	UNUT
(M_{10}) delete Δg_i	P_{dg}	$\frac{P_{ag}}{P_{dg}}$	$\frac{(N-m-1)^{-1}n^{-2}}{m^{-1}} = \frac{m}{(N-m-1)n^2}$	UNUT

Table 1: The move sets under different settings. E_1 is the total number of edges in G_1, p_{max} is the maximum parent set size, s_{max} is the maximum number of edge changes allowed in a single transition time, and s_i is the number of edge changes in the set Δg_i. The proposal ratio is the product of the last two columns. The KNKT setting uses moves M_1–M_5, KNUT uses moves M_1–M_6, and UNUT uses moves M_1–M_{10}, in each case with the proposal probabilities appropriately normalized to add to 1.

5. Results on Simulated and Real Data Sets

Here we examine both the speed and accuracy of our sampling algorithm under all three settings and on both simulated and real data sets. We want to solve real-world problems, but accurate ground truths are often not available to assess performance; therefore, we must rely on simulation studies to provide representative performance estimates for the real problems of interest.

We have studied the performance characteristics of our algorithm in simulation studies that vary by several orders of magnitude in number of observations, number of variables, number of epochs, and network density. In each case, we perform simulations with multiple data sets multiple times with multiple chains to help ensure our results are robust to simulation artifacts. For brevity, we only present a few simulation results here; the broader set of experiments we have conducted yield similar results.

All experiments were run on a 3.6GHz dual-core Intel Xeon machine with 4 GB of RAM.

5.1 Small Simulated Data Set

To evaluate the effectiveness of our method, we first apply it to a small, simulated data set. The first experiment is on a simulated ten node network with 1020 observations and six single-edge changes between seven epochs, where the length of each epoch varies between 20 and 400 observations. The

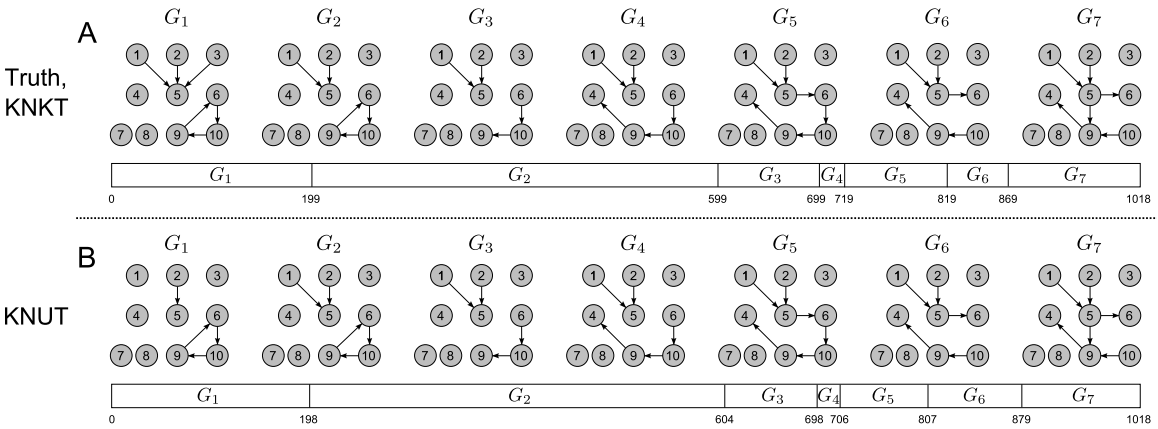

Figure 3: nsDBN structure learning with known numbers of transitions. *A*: True non-stationary data-generation process. The structure evolves gradually from the network at the left labeled G_1 to the network at the right labeled G_7. The epochs in which the various networks are active are shown in the horizontal bars, roughly to scale. The horizontal bars represent the segmentation of the 1020 observations, with the transition times labeled below. When these times are known to the algorithm (the KNKT setting), the recovered nsDBN structure is exactly the true structure. *B*: When the times of the transitions are not known (the KNUT setting), the algorithm learns the model-averaged nsDBN structure shown (selecting edges that occur in greater than fifty percent of the sampled structures). The learned networks and most likely transition times are highly accurate (only missing two edges in G_1 and all predicted transition times close to the truth).

true structure is shown in Figure 3A. We chose a small network with features biologically relevant to genetic regulatory networks: a feedback loop, a variable with at least three parents, a pathway of length six, and the inclusion of observed variables that do not even participate in the network.

5.1.1 KNKT SETTING

In this simple setting, the sampler rapidly converges to the correct solution. We generate a data set using the structure in Figure 3A, and run our sampler for 100,000 iterations, with the first 25,000 samples thrown out for burn-in.

To obtain a consensus (model averaged) structure prediction, an edge is considered present at a particular time if the posterior probability of the edge is greater than 0.5. The value of λ_m has no effect in this setting, and the value of λ_s is varied between 0.1 and 50. The predicted structure is exactly identical to the true structure shown in Figure 3A for a broad range of values, $0.5 \leq \lambda_s \leq 10$, indicating robust and accurate learning.

5.1.2 KNUT SETTING

In this setting, transition times are unknown and must be estimated *a posteriori*. The prior on m remains unused, and for the prior on s, the value of λ_s is again varied between 0.1 and 50.

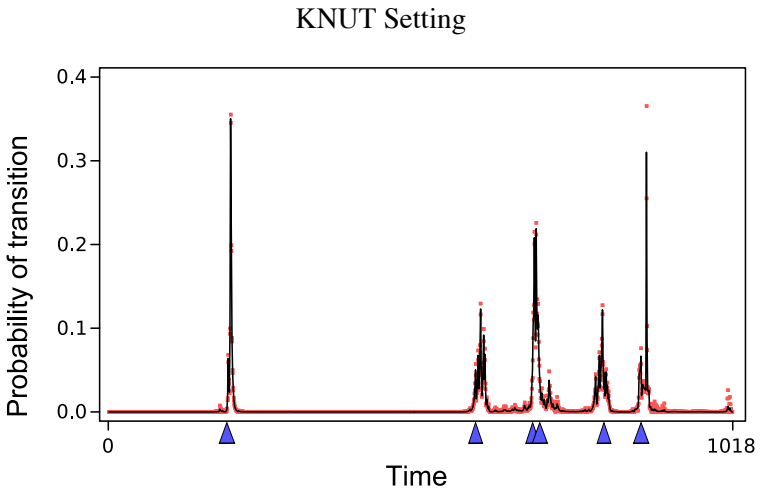

Figure 4: Posterior probability of transition times when learning an nsDBN in the KNUT setting. The blue triangles on the baseline represent the true transition times and the red dots represent one standard deviation from the mean probability, which is drawn as a black line. The variance estimates were obtained using multiple chains. The highly probable transition times correspond closely with the true transition times.

Again, we generate a data set using the structure from Figure 3A and run the sampler for 200,000 iterations, with the first 50,000 samples thrown out for burn-in. More samples are collected in the KNUT setting because we expect that convergence will be slower given the larger space of nsDBNs to explore.

The predicted consensus structure is shown in Figure 3B for $\lambda_s = 5$; this choice of λ_s provides the most accurate predictions. The estimated structure and transition times are very close to the truth. All edges are correct, with the exception of two missing edges in G_1, and the predicted transition times are all within 10 of the true transition times. We can also examine the posterior probabilities of transition times over all sampled structures. This is shown in Figure 4. The blue triangles on the baseline represent the true transition times, and spikes represent transition times that frequently occurred in the sampled structures. While the highest probability regions do occur near the true transition times, some uncertainty exists about the exact locations of t_3 and t_4 since the fourth epoch is exceedingly short.

To obtain more accurate measures of the posterior quantities of interest (such as the locations of transition times), we generate samples from multiple chains; we use 25 in the KNUT setting. Combining the samples from several chains allows us to estimate both the probability of a transition occurring at a certain time and the variance of that estimate. The red dots in Figure 4 represent one standard deviation above and below the estimated mean probability of a transition occurring at a particular time. We discovered that the speed of convergence under the KNKT and KNUT settings were very similar for a given m. This unexpected result implies that the posterior over transition times is rather smooth; therefore, the mixing rate is not greatly affected when sampling transition times.

5.1.3 UNUT SETTING

Finally, we consider the UNUT setting where the number and times of transitions are both unknown. We examine the accuracy of our method in this setting using several values of λ_s and λ_m. We use the range $1 \leq \lambda_s \leq 5$ because we know from the previous settings that the most accurate solutions were obtained using a prior within this range; the range $1 \leq \lambda_m \leq 50$ is selected to provide a wide range of estimates for the prior on m since we have no previous knowledge of what it should be.

Again, we generate a data set using the structure from Figure 3A and run the sampler for 300,000 iterations, with the first 75,000 samples thrown out for burn-in. We collect samples from 25 chains in this setting.

Figure 5 shows the posterior probabilities of transition times for various settings of λ_s and λ_m. As expected, when λ_m increases, the number of peaks decreases. Essentially, when λ_m is large, only the few transition times that *best* characterize the non-stationary behavior of the data will be identified. On the other hand, when λ_m is very small, noises within the data begin to be identified as transition times, leading to poor estimates of transition times.

We can also examine the posterior on the number of epochs, as shown in Figure 6. The largest peak can be used to provide an estimate of m. A smaller λ_m results in more predicted epochs and less confidence about the most probable value of m.

Finally, since we know what the true structure is, we can obtain a precision-recall curve for each value of λ_s and λ_m. The precision-recall curves are shown at the top of Figure 7. To calculate these values, we obtained individual precision and recall estimates for each network at each observation and averaged them over all observations. Therefore, the reported precision and recall values can be viewed as the average precision and average recall over all observations.

One way to identify the best parameter settings for λ_s and λ_m is to examine the best F1-measure (the harmonic mean of the precision and recall) for each. The table in Figure 7 shows the best F1-measures and reveals $\lambda_s = 5$ and $\lambda_m = 1$ as best for this data, although nearly all choices achieve an F1-measure above 0.9.

5.2 Larger Simulated Data Set

To evaluate the scalability of our technique in the most difficult UNUT setting, we also simulate data from a 100 variable network with an average of 50 edges over five epochs spanning 4800 observations, with one to three edges changing between each epoch. We generate 10 different data sets from the model and acquire 25 chains from each data set. For each chain, we take 800,000 samples, with the first 200,000 samples thrown out for burn-in.

The posterior probabilities of transition times and the number of epochs (corresponding to Figures 5 and 6) for one of the simulated data sets are shown in Figure 8. The significantly sharper prediction for the posterior probabilities of transitions occurring at specific times is most likely due to having more observations and, thus, more confident estimates. The number of epochs with the highest posterior probability is five for all choices of priors, which is exactly the true number of epochs for this data set.

Additionally, the precision-recall curves and F1-measures are shown in Figure 9, revealing the $\lambda_s = 1$ and $\lambda_m = 5$ assignments to be best for this data, although all choices achieve excellent results.

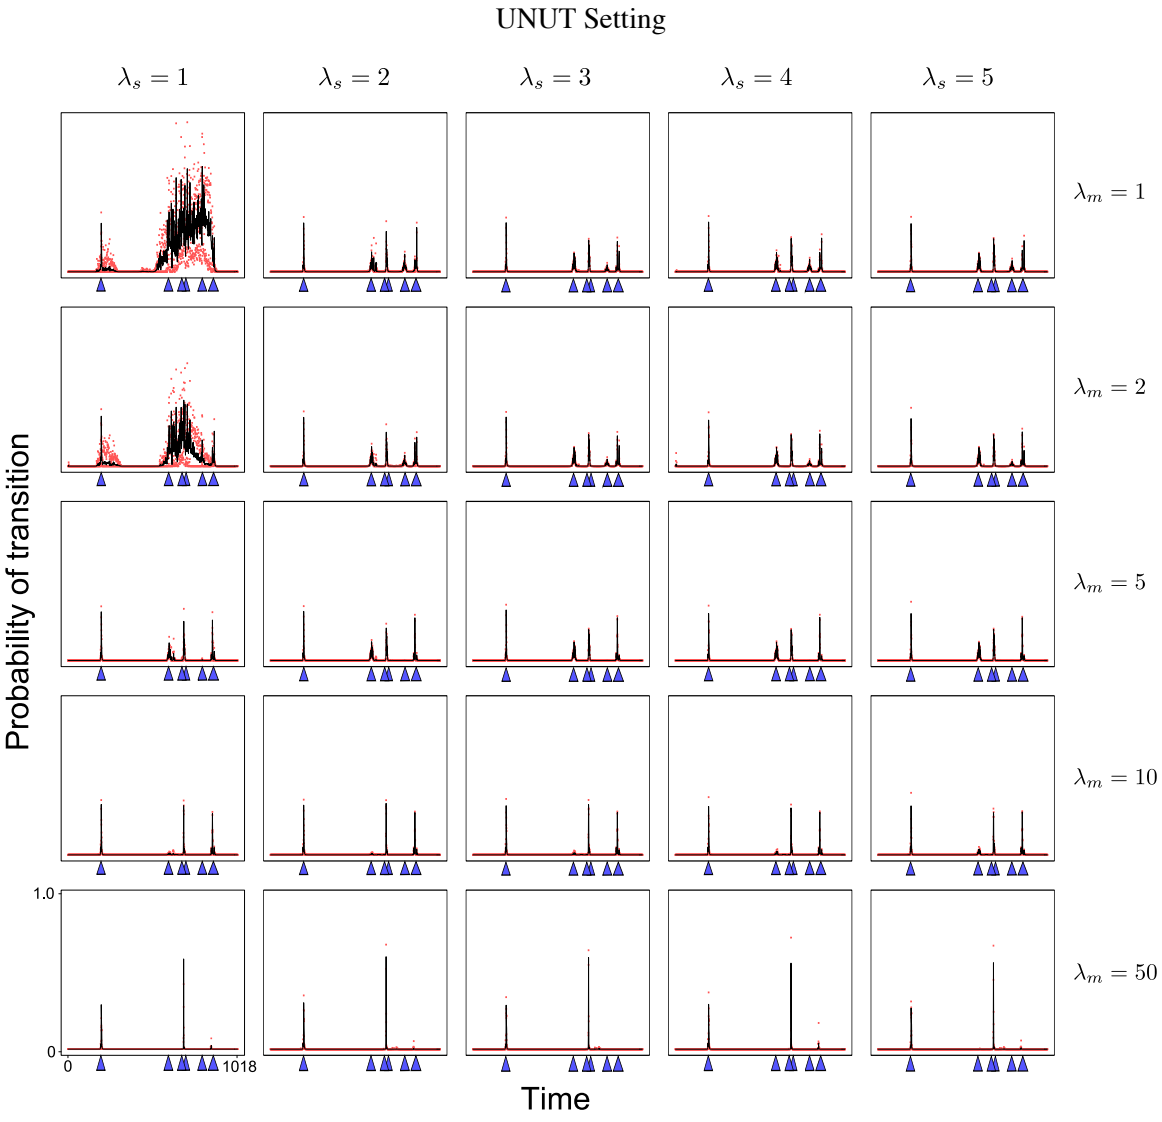

Figure 5: The posterior probabilities of transition times from the sampled structures in the UNUT setting for various values of λ_s and λ_m. As in Figure 4, the blue triangles on the baseline represent the true transition times and the red dots represent one standard deviation from the mean probability obtained from several runs, which is drawn as a black line. Only the (λ_s, λ_m) values of $(1,1)$ and $(1,2)$ seem to result in poor estimates of the true transition times.

5.3 *Drosophila* Muscle Development Gene Regulatory Networks

Having achieved excellent results even in the hardest UNUT setting across ten different data sets generated from two different simulated networks—one with 10 variables and the other with 100—we are confident enough in the usefulness of our model to analyze some real data.

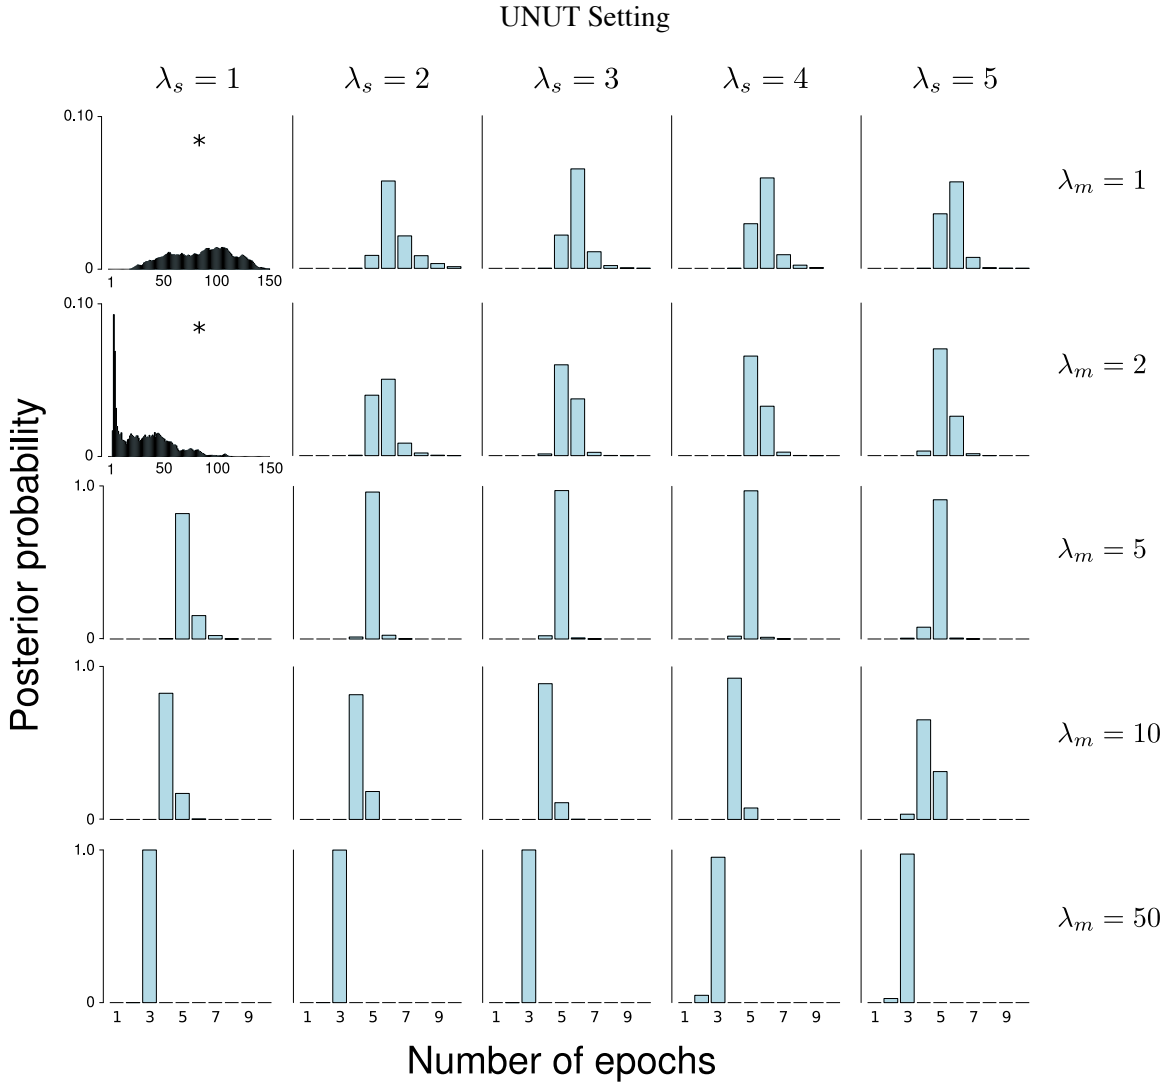

Figure 6: The posterior probabilities of the number of epochs for various values of λ_s and λ_m. The x-axes range from 1 to 10 and the y-axes from 0 to 1 for all of the plots except those marked with a star. The starred plots show predictions with significantly more epochs than the truth. The posterior estimates on the number of epochs *m* are closest to the true value of 7 when λ_m is 1 or 2.

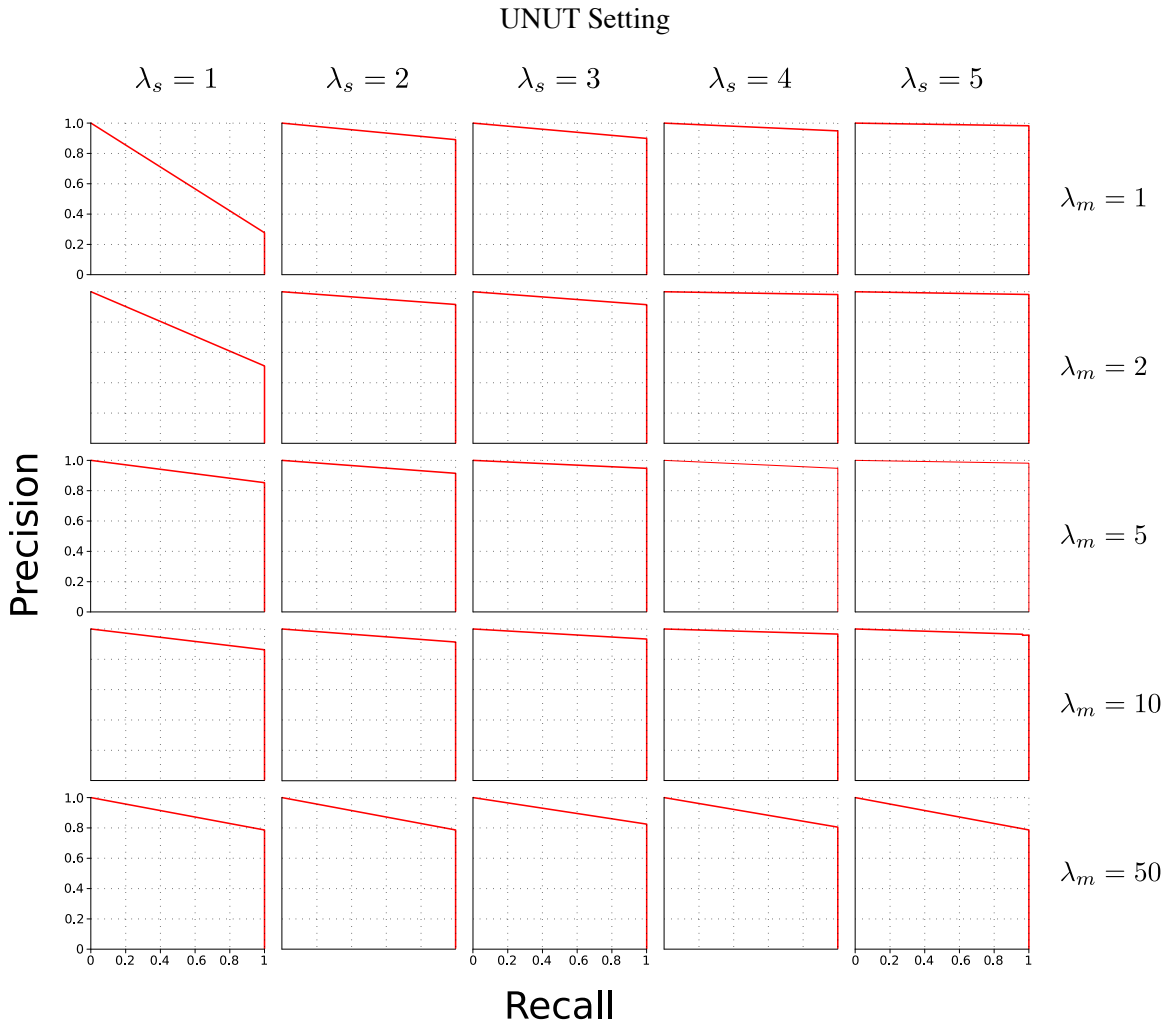
In this subsection, we apply our method to identify non-stationary networks using *Drosophila* development gene expression data from Arbeitman et al. (2002). This data contains expression measurements of 4028 *Drosophila* genes over 66 time steps throughout development and growth during the embryonic, larval, pupal, and adult stages of life. Zhao et al. (2006) focused on 19 genes involved in muscle development and learned a single network over all 66 time steps with this data. Using the same data, Guo et al. (2007) learned a time-varying undirected network over a subset of



λ_s

1	2	3	4	5	
0.4341	0.9423	0.9469	0.9738	**0.9912**	1

λ_m

Figure 7: *Top*: Precision-recall curves for various values of λ_s and λ_m under the UNUT setting. The most accurate estimates for the structure of the nsDBN arise when $\lambda_s = 5$ and $\lambda_m = 1$. *Bottom*: Corresponding F1-measures for the precision-recall curves. F1-measures over 0.9 are shaded; darker shades indicate values closer to 1, and the highest value is shown in bold.

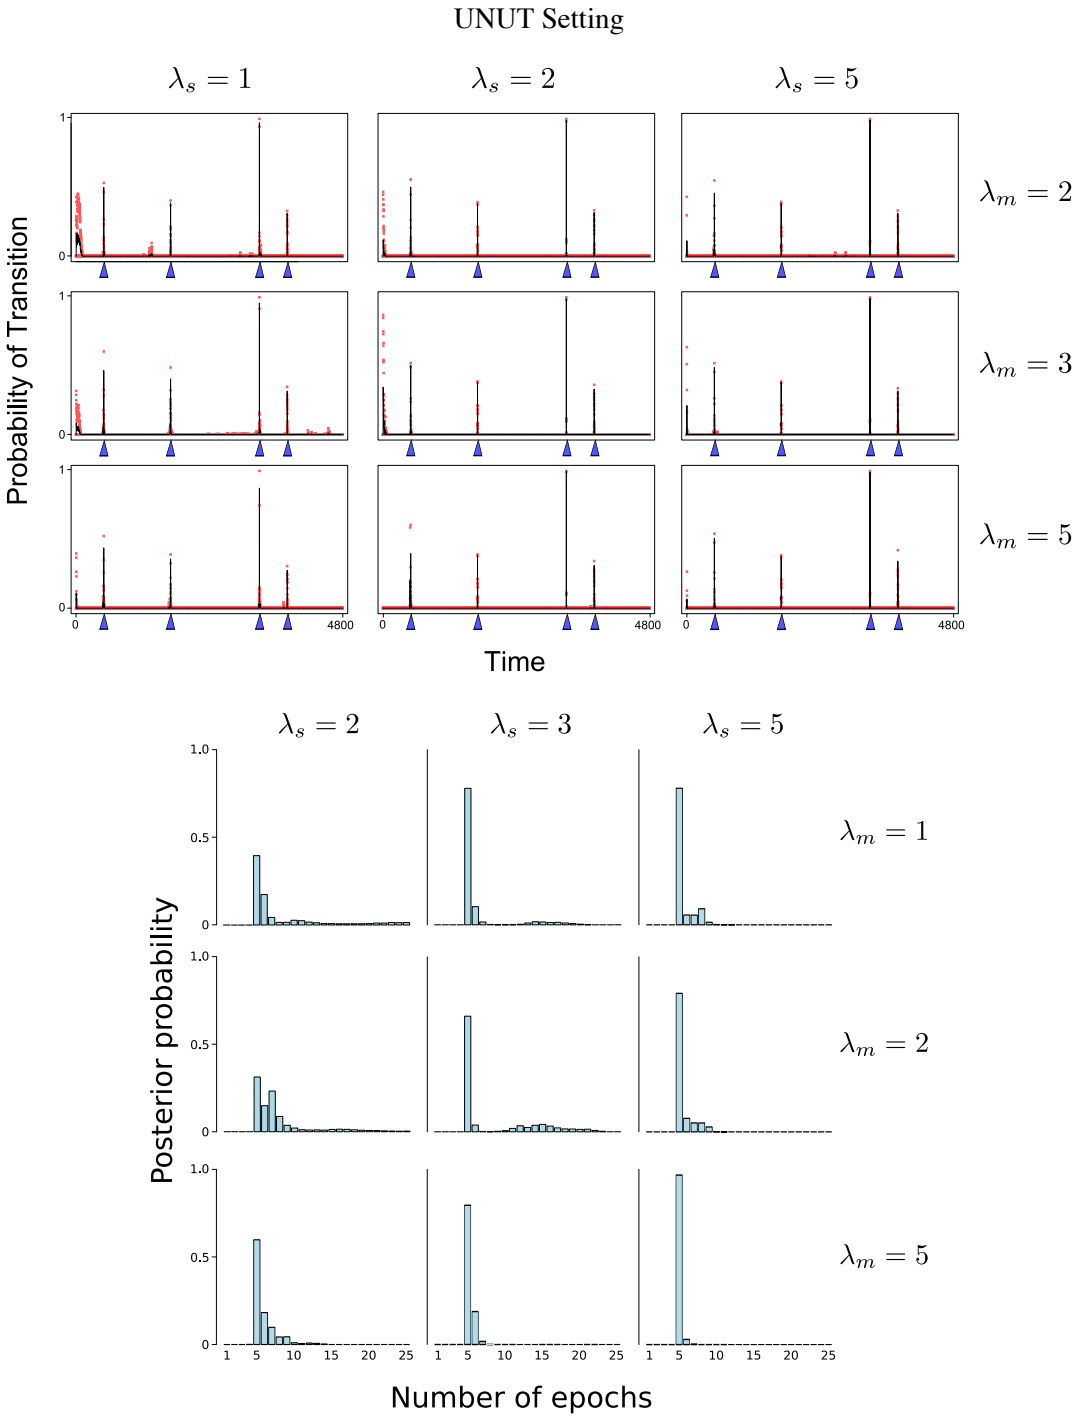

Figure 8: The posterior probabilities of transition times and number of epochs from one of the larger (100 variables, 5 epochs, and 4800 observations) simulated data sets under the UNUT setting for various values of λ_s and λ_m. The axes are the same for all plots. *Top*: The blue triangles on the baseline represent the true transition times and the red dots represent one standard deviation from the mean probability obtained from several runs, which is drawn as a black line.

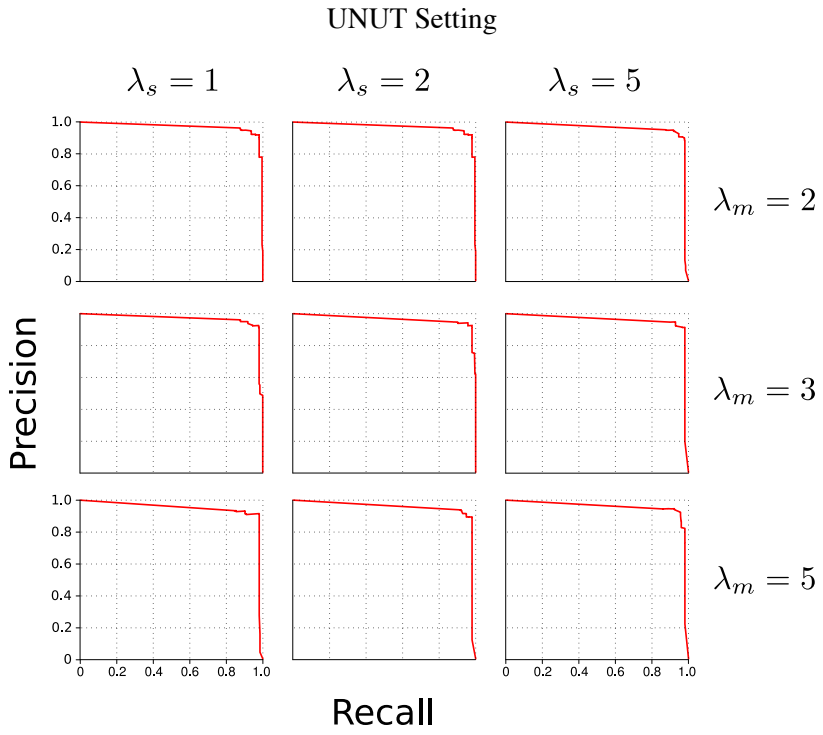

λ_m \ λ_s	1	3	5
1	0.9489	0.9510	0.9468
2	0.9377	0.9521	0.9356
5	**0.9531**	0.9459	0.9398

Figure 9: *Top*: Precision-recall curves for several values of λ_s and λ_m under the larger 100 variable simulation. *Bottom*: Corresponding F1-measures for the precision-recall curves. F1-measures over 0.9 are shaded; the highest value is shown in bold.

11 of the 19 genes identified by Zhao et al. (2006). To facilitate comparison with as many existing methods as possible, we apply our method to the data describing the expression of the same 11 genes, preprocessing the data in the same way as described by Zhao et al. (2006). Unfortunately, no other techniques predict non-stationary directed networks, so our comparisons are made against the stationary directed network predicted by Zhao et al. (2006) and the non-stationary undirected network predicted by Guo et al. (2007).

We collect 50,000 samples and throw out the first 10,000 for burn-in; we then repeat this process for 25 chains. We need fewer samples in this problem compared to previous data sets because there are relatively few variables and observations.

Figure 10 shows how our predicted structure compares to those reported by Zhao et al. (2006) and Guo et al. (2007). The nsDBN in Figure 10C was learned using the KNKT setting with transition times defined at the borders between the embryonic, larval, pupal, and adult stages.

While all three predictions share many edges, certain similarities between our prediction and one or both of the other two predictions are of special interest. In all three predictions, a cluster seems to form around *myo61f*, *msp-300*, *up*, *mhc*, *prm*, and *mlc1*. All of these genes except *up* are in the myosin family, which contains genes involved in muscle contraction. Within the directed predictions, *msp-300* primarily serves as a hub gene that regulates the other myosin family genes. It is interesting to note that the undirected method predicts connections between *mlc1*, *prm*, and *mhc* while neither directed method makes these predictions. Since *msp-300* seems to serve as a regulator to these genes, the method of Guo et al. (2007) may be unable to distinguish between direct and indirect interactions, due to its undirected nature and reliance on correlations.

Two interesting temporal similarities arise when comparing our predictions to those from Guo et al. (2007). First, an interaction between *eve* and *actn* arise at the beginning of the pupal stage in both methods. Second, the connection between *msp-300* and *up* is lost in the adult network. Note that the loss of this edge actually characterizes the progression to the adult stage from the pupal stage in our prediction, while the method from Guo et al. (2007) combines the two stages. The estimation of a combined pupal/adult stage may simply be due to predicting the loss of the edge between *msp-300* and *up* earlier in development than our method.

Despite the similarities, some notable differences exist between our prediction and the other two predictions. First, we predict interactions from *myo61f* to both *prm* and *up*, neither of which is predicted in the other methods, suggesting a greater role for *myo61f* during muscle development. Also, we do not predict any interactions with *twi*. During muscle development in *Drosophila*, *twi* acts as a regulator of *mef2* which in turn regulates some myosin family genes, including *mlc1* and *mhc* (Sandmann et al., 2006; Elgar et al., 2008); our prediction of no connection to *twi* mirrors this biological behavior. Finally, we note that in our predicted structure, *actn* never connects as a regulator (parent) to any other genes, unlike in the network predicted by Zhao et al. (2006). Since *actn* (actinin) only binds actin, we do not expect it to regulate other muscle development genes, even indirectly.

If we transition to the UNUT setting, we can also examine the posterior probabilities of transition times and epochs. These plots are shown in Figure 11A and 11B, respectively. The transition times with high posterior probabilities correspond well to the embryonic→larval and the larval→pupal transitions, but a posterior peak occurs well before the supposed time of the pupal→adult transition; this reveals that the gene expression program governing the transition to adult morphology is active well before the fly emerges from the pupa, as would clearly be expected. Also, we see that the most probable number of epochs is three to four, mirroring closely the total number of developmental stages.

5.4 Simulated Data Set Similar to the *Drosophila* Data Set

To evaluate the accuracy of a recovered nsDBN on a problem of exactly the same size as the predicted *Drosophila* muscle development network, we simulate a non-stationary time-series with the same number of nodes and a similar level of connectivity as the *Drosophila* data set. We generate data from an nsDBN with 66 observations and transition times at 30, 40, and 58 to mirror the number of observations in embryonic, larval, pupal, and adult stages of the experimental fly data. Since

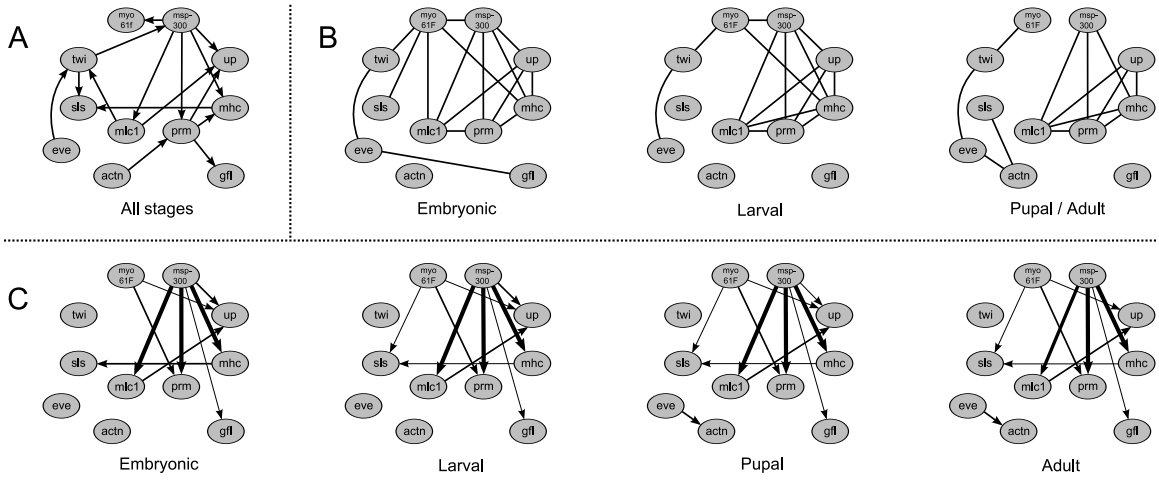

Figure 10: Comparison of computationally predicted *Drosophila* muscle development networks. *A*: The directed network reported by Zhao et al. (2006). *B*: The undirected networks reported by Guo et al. (2007). *C*: The nsDBN structure learned under the KNKT setting with $\lambda_s = 2$. Only the edges that occurred in greater than 50 percent of the samples are shown, with thicker edges representing connections that occurred more frequently.

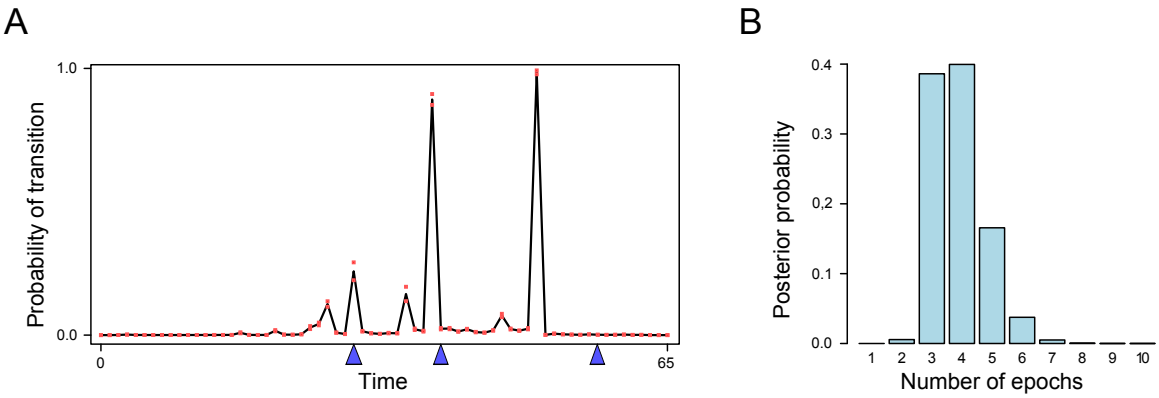

Figure 11: Learning nsDBN structure in the UNUT setting using the *Drosophila* muscle development data. *A*: Posterior probabilities of transition times using $\lambda_m = \lambda_s = 2$. The blue triangles on the baseline represent the borders of embryonic, larval, pupal, and adult stages. *B*: Posterior probability of the number of epochs. The high weight for 3 and 4 epochs closely matches the true number of developmental stages.

it is difficult to estimate the amount of noise in the experimental data, we also simulate noise at various signal-to-noise ratios, from 4:1 down to 1:1. Finally, since many biological processes have more variables than observations, we examine the effect of increasing the number of experimental replicates as a possible means to overcome this challenge.

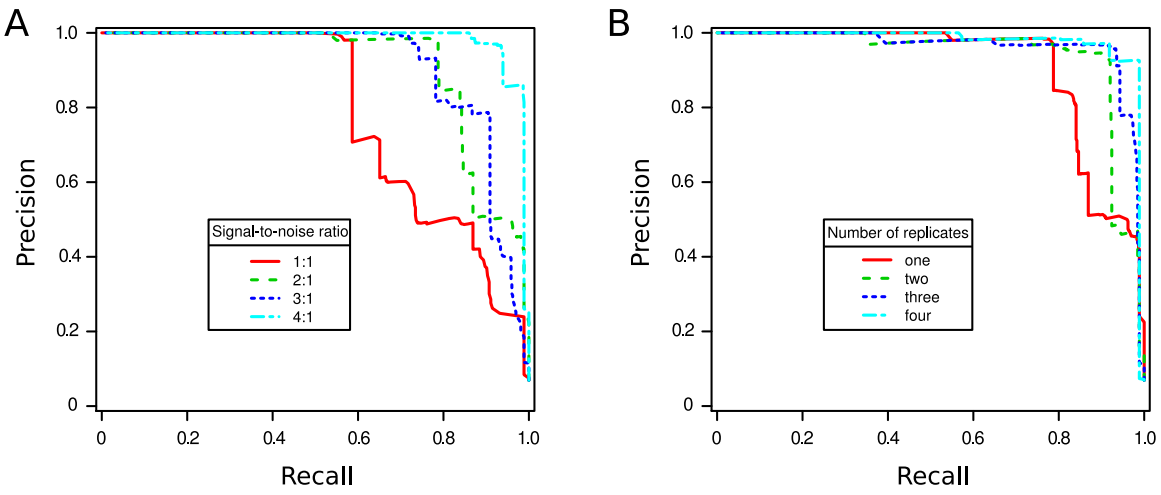

Figure 12: An nsDBN was learned on simulated data that mimicked the number of nodes, connectivity, and transition behavior of the experimental fly data. This allowed us to estimate the accuracy of learned nsDBNs on a problem of this size. *A*: Precision-recall curves for increasing values of the signal to noise ratio in the data (using one replicate). *B*: Precision recall curves for an increasing number of experimental replicates (using an SNR of 2:1). A greater signal to noise ratio and a greater number of experimental replicates both result in better performance, as expected.

As discussed earlier, to obtain posterior estimates of quantities of interest, such as the number of epochs or transition times, we generate many samples from several chains; averaging over chains provides a more efficient exploration of the sample space. To incorporate replicates into the posterior calculations, we generate samples from multiple chains (25) for each set of replicates. Since the underlying data generation process is the same for each replicate, we simply average over all the chains. The results of these simulations are summarized in Figure 12.

As expected, as the signal-to-noise ratio of the data increases, the greater the accuracy in the learned nsDBNs as reflected in the F1-measures: 1:1 is 0.734, 2:1 is 0.850, 3:1 is 0.875, and 4:1 is 0.950. Additionally, increasing the number of replicates also increases prediction accuracy: one is 0.869, two is 0.924, three is 0.945, and four is 0.956. This demonstrates the importance of multiple replicates for biological data with many variables but few observations.

This simulation study allows us to explore how much a relatively small data set and noise affect the predictions from our algorithm on a problem of similar size as the *Drosophila* muscle development network. From the results in Figure 12, we see that learning an nsDBN on a problem of the same scale as the *Drosophila* data set results in accurate network reconstruction, even in the presence of substantial noise. Therefore, we can surmise that any inaccuracies in our predicted *Drosophila* muscle development network would not arise due to the use of a dataset of that size, but might arise from an exceptionally high level of noise in the data (or inappropriate modeling assumptions).

5.5 Neural Information Flow Networks in Songbirds

Our goal is to learn neural information flow networks in the songbird brain. Such networks represent the transmission of information between different regions of the brain. Like roads, the anatomical connectivity of a brain indicates potential pathways along which information can travel. Like traffic, neural information flow networks represent the dynamic utilization of these pathways. By identifying the neural information flow networks in songbirds during auditory stimuli, we hope to understand how sounds are stored and processed in the brain.

In this experiment, eight electrodes were placed into the vocal nuclei of six female zebra finches. Voltage changes were recorded from populations of neurons while the birds were provided with four different two-second auditory stimuli, each presented twenty times. The resulting voltages were post-processed with an RMS transformation and binned to 5 ms; this interval was chosen because it takes 5–10 ms for a neural signal to propagate through one synaptic connection (Kimpo et al., 2003). We analyze data recorded from electrodes for two seconds pre-stimulus, two seconds during stimulus, and two seconds post-stimulus. We learn an nsDBN for two of the birds over six seconds for two different stimuli using all repetitions; this data set contains 8 variables and nearly 25,000 observations for each bird and each stimulus.

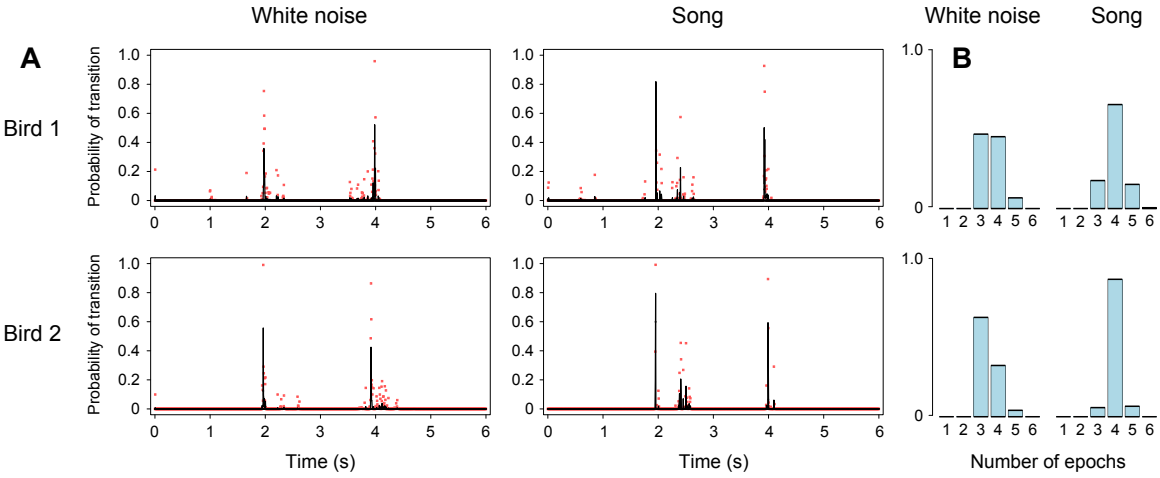

Figure 13: Posterior results of learning nsDBNs under the UNUT setting for two birds presented with two different stimuli (white noise and song). *A*: Posterior transition time probabilities. Transitions are consistently predicted near the stimulus onset (2 seconds) and offset (4 seconds). *B*: Posterior estimates of the number of epochs. The estimated number of epochs is three or four, with strong support for the value four when the bird is presented with a song.

The posterior transition time probabilities and the posterior number of epochs for two birds presented with two different stimuli under the UNUT setting ($\lambda_s = \lambda_m = 2$) can be seen in Figure 13. Note how the estimated transition times correspond closely with the times of the stimulus onset and offset and how the posterior estimate of the number of epochs is around three or four; taken together, these statistics imply that different networks predominate in the pre-stimulus, during stimulus, and post-stimulus time periods.

The posterior estimates consistently differ when the bird is listening to white noise versus song. When listening to a song, an additional transition is predicted 300–400 ms after the onset of a song but not after the onset of white noise. This implies that the bird further analyzes a sound after recognizing it (e.g., hearing a known song), but performs no further analysis when it does not recognize a sound (e.g., hearing white noise).

Previous analysis of this data assumed that any changes in the neural information flow network of a songbird listening to sound occurred only at sound onset and offset (Smith et al., 2006). Only by appropriately modeling the neural information flow networks as nsDBNs are we able to learn that this assumption is not accurate.

Further analysis and investigation of this data is left to future work.

5.6 Performance and Scalability

Due to the use of efficient data structures in the sampler implementation, the computational time needed to update the likelihood is essentially the same for all moves. Therefore, the runtimes of the algorithm under the KNKT, KNUT, and UNUT settings do not differ for a given number of samples. Nevertheless, one typically wants more samples in settings with increased uncertainty to ensure proper convergence.

For the small ten variable simulated data set, the sample collection process for each chain takes about 10 seconds per 100,000 samples, which translates to 10 seconds for the KNKT setting, 20 seconds for the KNUT setting, and 30 seconds for the UNUT setting. Fortunately, all runs can easily be executed in parallel. Sample collection for the *Drosophila* data set and the similarly sized simulated data set takes only a few seconds for each chain under all settings.

For the larger 100 variable simulated data set, sample collection takes about 2 minutes per 100,000 samples. The increased runtime is primarily due to the larger number of variables, so defining the neighborhood for each move takes more time. Due to intelligent caching schemes, the number of observations affects runtime in only a sublinear fashion (provided that enough memory is available).

Surprisingly, one of the largest contributors to running time is the actual recording of the MCMC samples. For example, each sample in the larger simulated data set can be represented by a 10,000 by 4,800 binary matrix of indicators for individual edges at every point in time. A full recording of each sample is therefore very time consuming: just recording each sample in the larger simulated data set leads to an increased runtime of about 50 minutes per 100,000 samples. We can alleviate this problem in several ways. First, because only a small number of those 48 million values actually change between samples, each sample can be represented and output in a compressed fashion; however, the same amount of processing still must occur after the sample collection completes. A better option is to only record the posterior quantities of interest. For example, recording just the transition times and number of epochs adds only a few seconds to the runtime on the larger simulated data set.

6. Discussion

Non-stationary dynamic Bayesian networks provide a useful framework for learning Bayesian networks when the generating processes are non-stationary. Using the move sets described in this paper, nsDBN learning is efficient even for networks of 100 variables, is generalizable to situations of varying uncertainty (KNKT, KNUT, and UNUT), and is robust (i.e., not very sensitive) to the

choice of hyper-parameters over a large range of values. Additionally, by using a sampling-based approach, our method allows us to assess a confidence for each predicted edge—an advantage that neither Zhao et al. (2006) nor Guo et al. (2007) share.

We have demonstrated the feasibility of learning an nsDBN in all three settings using simulated data sets of various numbers of transition times, observations, variables, epochs, and connection densities. Additionally, we have identified nsDBNs in the KNKT and UNUT settings using biological gene expression data. The *Drosophila* muscle development network we predict is consistent with the predictions from other techniques and conforms to many known biological interactions from the literature. The predicted transition times and number of epochs also correspond to the known times of large developmental changes. Although each connection on the predicted *Drosophila* muscle development network is difficult to verify, simulated experiments of a similar scale demonstrate highly accurate predictions, even with moderately noisy data and one replicate.

While we focus on certain aspects of the model in this paper, many of our decisions are choices rather than restrictions. For example, we present results using a Markov lag of one, but any Markov lag could be used. Additionally, we use the BDe score metric, but any score metric or conditional independence test can be used instead; however, any score metric which does not integrate over the non-structural parameters would require an augmented sampling procedure. The assumption of discrete data is not necessary; our method easily extends to continuous data, provided that an appropriate scoring metric (like BG) is adapted.

A discrete view of time is necessary to our approach, but many continuous-time data sets can be transformed into discrete-time ones without significant loss of information. The use of directed graphs is also necessary, and desired, but undirected estimates can be obtained through moralization of directed estimates. Although we choose simple priors to learn smoothly evolving networks, nearly any priors would be easy to incorporate; in particular, incorporating expert knowledge about the problem domain would be an ideal method for defining priors.

For problems of more than a few variables, the use of MCMC sampling is essential since EM techniques would not converge in any reasonable time frame given such a large sample space. One of our key discoveries for increasing convergence is the reformulation of the problem from learning multiple networks to learning a network and changes to that network. This parameterization provides an intuitive means for defining evolving networks and allows us to define move sets with good convergence properties. Our particular choices of the move sets are not the only possible ones, but we have taken extra care to ensure that they work well on the types of problems we examine in this paper.

The proposed sampling algorithm scales well to problems with hundreds of variables and thousands of observations, but we are not certain how well it will scale to problems that are orders of magnitude larger. When obtaining sample runs takes days instead of minutes or hours, it may become desirable to obtain faster estimates, even if they are approximate. Variational methods are one alternative to MCMC sampling approaches, often obtaining faster estimates at the cost of decreased accuracy (Beal and Ghahramani, 2006). For the scale of problems in this paper, the run times and convergence rates of our MCMC sampling algorithm were good enough that we did not have to resort to variational approximations. However, if we wish to explore much larger data sets in the future, we may need to develop a variational algorithm to obtain results in a reasonable time frame.

Non-stationary DBNs offer all of the advantages of DBNs (identifying directed, potentially non-linear interactions between variables in multivariate time-series) and are additionally able to identify non-stationarities in the interactions between variables. The sampling algorithm presented

here allows one to estimate the strength of individual edges as well as posterior distributions of and quantities of interest. In future work, we hope to analyze data from other fields that have traditionally used DBNs and instead use nsDBNs to identify and model previously unknown or uncharacterized non-stationary behavior.

Another direction that could be explored in the future is nsDBN learning with latent variables. Following an EM approach like in Friedman (1997) would be the first step, but one would also need to consider how to connect hidden variables across epochs and how to incorporate different numbers of hidden variables at different epochs. Learning non-stationary networks with latent variables seems to present a vexing challenge in the general case, but might be feasible in simple cases when enough data is available.

Acknowledgments

Sloan Fellowship, and a grant from NIH in Collaborative Research in Computational Neuroscience (R01-DC007996-01).

Appendix A.

While we decided to place a (truncated) geometric prior on the number of epochs m, other priors may be considered. Talih and Hengartner (2005) chose to model epoch lengths as i.i.d. geometric random variables. Here, we prove that a geometrically distributed prior on epoch lengths is equivalent to a geometrically distributed prior on the number of epochs.

Letting l_i be the length of epoch i and N be the total number of observations, we can write a geometrically distributed prior on epoch lengths as:

$$\begin{aligned}\prod_{i=1}^{m}(1-p)^{l_i-1}p &= p^m\prod_{i=1}^{m}(1-p)^{l_i-1} \\ &= p^m(1-p)^{\sum_{i=1}^{m}l_i-1} \\ &= p^m(1-p)^{N-m} \\ &= \left(\frac{p}{1-p}\right)^m(1-p)^N.\end{aligned}$$

Since N is the same for every nsDBN, we see that the geometrically distributed prior is simply a function of the number of epochs m. Compare this to a geometrically distributed prior on the number of epochs, shown below:

$$\begin{aligned}(1-q)^{m-1}q &= (1-q)^m\frac{q}{1-q} \\ &= A(1-q)^m.\end{aligned}$$

where A is a constant that is the same for all nsDBNs. Therefore, a geometrically distributed prior on epoch lengths with success probability $p=\frac{1-q}{2-q}<1/2$ is equivalent to a geometrically distributed prior on the number of epochs with success probability q. In this paper, we assume that q takes the form $q=1-\mathrm{e}^{-\lambda}$, allowing for a more intuitive control of the prior by simply changing λ.
